Aqueous nonelectrolyte solutions. Part XVI. Formula of deuterium sulfide D-hydrate and its dissociation thermodynamic functions

Colin W. Clarke and David N. Glew

Abstract: A method has been devised to approximate both the hydrate formula number *n* and the standard thermodynamic functions for hydrate dissociation from the temperature change of the hydrate former fugacity along a univariant three-phase (hl_1g) equilibrium line. Thermodynamic equations are derived, their validity discussed, and an iterative method for their solution is described. The univariant (hl_1g) equilibrium dissociation of deuterium sulfide D-hydrate ($D_2S{\cdot}nD_2O$ phase h) into gaseous deuterium sulfide (g) and liquid deuterium oxide (l_1) has been treated to give approximate formulae and dissociation constants at 58 temperatures from 2.798 to 30.666°C. Dissociation equilibrium constants $Kp(h{\rightarrow}l_1g)$ have been represented as a function of temperature by a four-parameter equation which yields both values and standard errors (*i*) for $\Delta H^{ot}(h{\rightarrow}l_1g)$ and $\Delta Cp^{ot}(h{\rightarrow}l_1g)$ the standard enthalpy and heat capacity changes for D-hydrate dissociation and (*ii*) for $n = r$ the approximate formula number of the D-hydrate at each experimental temperature. The formula $D_2S{\cdot}6.115D_2O$ with standard error $0.018D_2O$ is found for deuterium sulfide D-hydrate at lower quadruple point $Q(hs_1l_1g)$ 3.392°C; an approximate formula $D_2S{\cdot}5.840D_2O$ with SE $0.019D_2O$ is found at upper quadruple point $Q(hs_1l_2g)$ 30.770°C.

Key words: clathrate D-hydrate of deuterium sulfide, deuterium sulfide D-hydrate, formula of deuterium sulfide D-hydrate, thermodynamics of clathrate hydrate dissociation, dissociation equilibrium constant of deuterium sulfide D-hydrate, standard enthalpy, and heat capacity changes for dissociation of deuterium sulfide D-hydrate.

Résumé : En faisant appel à la variation en fonction de la fugacité du produit formant un hydrate en fonction de la température le long d'une ligne d'équilibre à trois phases (hl_1g) univariables, on a développé une méthode permettant déterminer de façon approximative la nombre, *n*, d'hydrates dans une formule ainsi que les fonctions thermodynamiques associées à la dissociation de cet hydrate. On en a déduit les équations thermodynamiques, on discute de leur validité et on décrit une méthode itérative pour leur solution. On a traité la dissociation en équilibre univariable (hl_1g) entre l'hydrate-D du sulfure de deutérium ($D_2S{\cdot}nD_2O$, phase h) et le sulfure de deutérium gazeux (g) et l'oxyde de deutérium liquide (l_1) pour en tirer les valeurs approximatives des formules ainsi que des constantes de dissociation à 58 températures entre 2,798 et 30,666°C. Les constantes d'équilibre de dissociation, $Kp(h{\rightarrow}l_1g)$, en fonction de la température peuvent être représentées à l'aide d'une équation à quatre paramètres qui permet d'en extraire, pour chaque température expérimentale, les valeurs ainsi que les erreurs standards (*i*) pour $\Delta H^{ot}(h{\rightarrow}l_1g)$ et $\Delta Cp^{ot}(h{\rightarrow}l_1g)$, les changements d'enthalpie et de capacité calorifique standards accompagnant la dissociation de l'hydrate-D ainsi que (*ii*) la valeur approximative du nombre de formule pour $n = r$. Pour le point quadruple inférieur à 3,392°C, $Q(hs_1l_1g)$, de l'hydrate-D du sulfure de deutérium, on a trouvé une formule $D_2S{\cdot}6{,}115D_2O$ avec une erreur standard de $0{,}018D_2O$ alors que pour le point quadruple supérieur à 30,770°C, $Q(hl_1l_2g)$, on a trouvé une formule $D_2S{\cdot}5{,}840D_2O$ avec une erreur standard de $0{,}019D_2O$.

Mots clés : clathrate, hydrate-D du sulfure de deutérium, formule, thermodynamique, constante de dissociation, enthalpie standard, changement de capacité calorifique.

[Traduit par la Rédaction]

Introduction

As part of our continuing study (1–4) of the thermodynamic properties of aqueous nonelectrolyte solutions and of their clathrate hydrate solid solutions, it became of interest in 1963 to compare the thermodynamic properties of nonelectrolyte solutions in deuterium oxide with their clathrate D-hydrate solid solutions. At that time the properties of aqueous hydrogen sulfide solutions (5, 6) and of the hydrogen sulfide gas hydrate (7–11) were well known, but the properties of deuterium sulfide solutions in deuterium oxide and of the deuterium sulfide D-hydrate had not been reported in the literature.

The volumetric properties of deuterium sulfide and its solubility in deuterium oxide were reported earlier (12, 13). Additional equilibrium measurements on the two-component

Accepted October 14, 1999.

deuterium oxide (c_1) – deuterium sulfide (c_2) system up to 33.003°C were reported recently (14). In that work proper representation of the deuterium sulfide D-hydrate dissociation pressure $P(hl_1g)$ between 2.798 and 30.666°C required a seven-parameter equation, which requirement was primarily responsible for our development (15) of a general method for evaluation of thermodynamic functions from equilibrium constants.

In this report we develop a classical thermodynamic treatment for the dissociation with temperature of a deuterium sulfide D-hydrate of variable composition along its univariant (hl_1g) three-phase equilibrium line. It is shown that when the D-hydrate formula number n is known at the temperature of the lower quadruple point $Q(hs_1l_1g)$, approximate values of $n = r$ at higher temperatures may be estimated with good accuracy and small error up to the upper quadruple point $Q(hl_1l_2g)$.

In this work we evaluate further the (hl_1g) measurements, recently reported in Tables 2 and 5 of ref. 14: the results are presented in Tables 1 and 2. Regression equations are evaluated using the method of weighted least squares, and a predicted estimate is qualified with standard error, written SE.

Derivation of the thermodynamic equations

Dissociation equilibrium of deuterium sulfide D-hydrate into deuterium sulfide gas and deuterium oxide liquid

Consider the three-phase (hl_1g) equilibrium of solid deuterium sulfide D-hydrate (h) with gaseous deuterium sulfide (g) and liquid deuterium oxide (l_1) formally represented by the equation

[1] $D_2S{\cdot}nD_2O\ (h) \leftrightarrows D_2S\ (g) + nD_2O\ (l_1)$

$G_2^h\ nG_1^h \qquad G_2^g \qquad nG_1^{l1}$

$a_2^h\ a_1^h \qquad f_2 \qquad a_1^{l1}$

which defines the transfer of 1 mol (gram molar mass) of deuterium sulfide from the D-hydrate into the gas phase, with equilibrium molar Gibbs' energies G_2^h, nG_1^h, G_2^g, and nG_1^{l1}, equilibrium activities a_2^h, a_1^h, f_2, and a_1^{l1}, and dissociation equilibrium constant defined by

[2] $Kp(h{\rightarrow}l_1g) = f_2{\cdot}(1/a_2^h){\cdot}\ (a_1^{l1}/a_1^h)^n$

where the formula number n varies with temperature. The molar Gibbs' energies and activities are defined in eqs. [3]–[6]:

[3] $G_2^h = G_2^{oh} + RT \ln a_2^h = G_2^{oh}$

[4] $G_1^h = G_1^{oh} + RT \ln a_1^h = G_1^{oh} + [P(hl_1g) - 0.10](V^h/46)$

[5] $G_2^g = G_2^{og} + RT \ln f_2$

[6a] $G_1^{l1} = G_1^{ol1} + RT \ln a_1^{l1}$

[6b] $G_1^{l1} = G_1^{ol1} + RT \ln x_1^{l1} + [P(hl_1g) - 0.10]V_1^{l1}$

G_2^{oh} is the standard molar Gibbs' energy of deuterium sulfide encaged within the D-hydrate lattice at 0.10 MPa pressure with activity a_2^h defined as unity. The effect of pressure on G_2^h for the encaged hydrate-former is included within V^h in eq. [4]. G_1^{oh} and G_1^{ol1} are the standard molar Gibbs' energies of deuterium oxide in the D-hydrate lattice and in pure l_1 at 0.10 MPa pressure. G_2^{og} is the standard molar Gibbs' energy of gaseous deuterium sulfide at 1.0 MPa fugacity.

The deuterium sulfide D-hydrate molar volume V^h for a unit cell containing $46/n$ mol D_2S and 46 mol D_2O is taken to be invariant 1.0458 dm^3, assuming the same cubic Structure I lattice and 1.202 nm spacing reported for hydrogen sulfide hydrate (11, 16). The molar volume of the deuterium sulfide encaged within the D-hydrate lattice is already included within the unit-cell volume. The molar volume V_1^{l1} of our deuterium oxide sample (17) at 0.10 MPa is evaluated from the work of Kell (18).

For dissociation reaction [1] at equilibrium, at constant T and total pressure $P(hl_1g)$, the molar Gibbs' energy change, denoted $\Delta G(h{\rightarrow}l_1g)$, is zero and is given by

[7] $\Delta G(h{\rightarrow}l_1g) = 0 = G_2^g + nG_1^{l1} - G_2^h - nG_1^h$

Substitution of eqs.[3]–[6] into eq.[7] yields the basic relations

[8] $-\Delta G°(h{\rightarrow}l_1g) = -(G_2^{og} + nG_1^{ol1} - G_2^{oh} - nG_1^{oh})$

[8a] $= RT \ln Kp(h{\rightarrow}l_1g)$

[8b] $= RT \ln f_2 + nRT \ln a_1^{l1} - nRT \ln a_1^h$

[8c] $= RT \ln f_2 + nRT \ln x_1^{l1} + n[P(hl_1g) - 0.10][V_1^{l1} - (V^h/46)]$

connecting $\Delta G°(h{\rightarrow}l_1g)$, the standard molar Gibbs' energy change for reaction [1], with the dissociation equilibrium constant, the equilibrium phase activities and the volumetric properties of the phases. Rearrangement of eq. [8] and division by RT gives

[9] $\ln Kp(h{\rightarrow}l_1g) = \ln f_2 + n \ln x_1^{l1} + n[P(hl_1g) - 0.10][V_1^{l1} - (V^h/46)]/RT$

which defines $\ln Kp(h{\rightarrow}l_1g)$, the equilibrium constant for D-hydrate dissociation at temperature T K, in terms of the deuterium sulfide fugacity f_2 with corrections (*i*) for the deuterium oxide mole fraction of phase l_1 and (*ii*) for the effect of pressure on the phases h and l_1. To evaluate these corrections n must be known.

Dissociation equilibrium of deuterium sulfide D-hydrate into deuterium sulfide gas and D-ice

Consider the three-phase (hs_1g) equilibrium formally represented by

[10] $D_2S{\cdot}nD_2O\ (h) \leftrightarrows D_2S\ (g) + nD_2O\ (s_1)$

$G_2^h\ nG_1^h \qquad G_2^g \qquad nG_1^{s1}$

$a_2^h\ a_1^h \qquad f_2 \qquad a_1^{s1}$

at constant T and total pressure $P(hs_1g)$ for dissociation of deuterium sulfide D-hydrate into deuterium sulfide gas (g) and solid D-ice (s_1). Using a treatment similar to that following eq. [1], we define the dissociation equilibrium constant

[11] $Kp(h{\rightarrow}s_1g) = f_2{\cdot}(1/a_2^h){\cdot}(a_1^{s1}/a_1^h)^n$

[a]Upper quadruple point.

[b]Lower quadruple point.

for the transfer of 1 mol of deuterium sulfide from the D-hydrate into the gas phase together with the collapse of the D-hydrate lattice nD$_2$O (h) to form nD$_2$O (s$_1$) of D-ice. The equilibrium molar Gibbs' energy of D-ice is defined by

$$[12]\quad G_1^{s1} = G_1^{os1} + RT \ln a_1^{s1} = G_1^{os1} + [P(hs_1g) - 0.10]V_1^{s1}$$

in which a_1^{s1} is its equilibrium activity, V_1^{s1} its molar volume, and G_1^{os1} its standard molar Gibbs' energy at 0.10 MPa pressure.

Similarly following eq. [8], we obtain

$$[13]\quad -\Delta G°(h\rightarrow s_1g) = -(G_2^{og} + nG_1^{os1} - G_2^{oh} - nG_1^{oh})$$

$$[13a]\quad = RT \ln Kp(h\rightarrow s_1g)$$

$$[13b]\quad = RT \ln f_2 + nRT \ln a_1^{s1} - nRT \ln a_1^{h}$$

$$[13c]\quad = RT \ln f_2 + n[P(hs_1g) - 0.l0][V_l^{s1} - (V^h/46)]$$

connecting $\Delta G°(h\rightarrow s_1g)$, the standard change of molar Gibbs' energy for reaction [10], with the dissociation equilibrium constant, the equilibrium phase activities and the volumetric properties of the phases. Rearrangement of eq. [13] and division by RT gives

$$[14]\quad \ln Kp(h\rightarrow s_1g) = \ln f_2 + n[P(hs_1g) - 0.10][V_1^{s1} - (V^h/46)]/RT$$

which defines ln $Kp(h\rightarrow s_1g)$, the equilibrium constant for D-hydrate dissociation at temperature T K into D-ice, in terms of the deuterium sulfide fugacity f_2 with corrections for the effect of pressure on the solid phases h and s$_1$. To evaluate these corrections n must be known.

Results and discussion

Standard enthalpy change for dissociation of deuterium sulfide D-hydrate into deuterium sulfide gas and D-ice

Because we have no measurements for the temperature dependence of $P(hs_1g)$ for the deuterium sulfide D-hydrate equilibrium with D-ice, a method has been devised to evaluate the missing data as a small perturbation on the equilibrium $P(hs_1g)$ measurements for hydrogen sulfide hydrate with ice by Scheffer and Meyer (9).

Six experimental studies of the (hs_1g) equilibrium, namely, (*i*) hydrogen sulfide hydrate with ice from –26 to –l°C (9), (*ii*) bromochlorodifluoromethane hydrate with ice from –20 to –0.3°C (2), (*iii*) two cyclopropane hydrates with ice from –36 to –9°C and from –15 to –l°C (19), and (*iv*) two cyclopropane D-hydrates with D-ice from –63 to –10°C and from –30 to 0°C (20), all show that the derived standard dissociation enthalpy changes, $\Delta H^{ot}(h\rightarrow s_1g)$, are sensibly temperature invariant, with the standard heat capacity changes $\Delta Cp^{ot}(h\rightarrow s_1g)$ equal to zero within experimental error. This zero standard heat capacity change value is assumed for the similar equilibrium of deuterium sulfide D-hydrate with D-ice.

Comparison of the cyclopropane hydrates (19) with their D-hydrates (20) shows that values for the standard dissociation enthalpy change $\Delta H^{ot}(h\rightarrow s_1g)$ are slightly larger for the D-hydrates: for the Structure I D-hydrate the difference is 1.0% with SE 0.5%, for Structure II the difference is 0.2% with SE 1.2%, relative to the hydrates.

The measurements of hydrogen sulfide hydrate with ice (9) down to –21°C have been reevaluated using eq. [14] with n = 6.1, the hydrogen sulfide fugacity f_2 from the Redlich–Kwong equation of state (12, 13, 21, 22), and the molar volumes of hydrate (11, 16) and of ice V_1^{s1} (23). The standard dissociation enthalpy change $\Delta H^{ot}(h\rightarrow s_1g)$ is found to be 25 416 with SE 52 J/mol of hydrogen sulfide, with $\Delta Cp^{ot}(h\rightarrow s_1g)$ insignificantly different from zero. This value of the standard enthalpy change is slightly less than the 25 500 J/mol found by Scheffer and Meyer (9) using partial pressures.

The environmental similarity of aqueous solutes in water at low temperature with hydrate formers within their hydrate water polyhedra has been discussed in ref. 3, where in Table III of that work, similar values have been shown for the enthalpy change $\Delta H_2°(l_1\rightarrow g)$ for solute escape from aqueous solution and for $\Delta H°(h\rightarrow s_1g)$ for hydrate-former solute escape from clathrate hydrate solid solutions. Using that model (3), the enthalpy difference between dissociation of D$_2$S D-hydrate to D-ice and dissociation of H$_2$S hydrate to ice is taken as equal to the molar enthalpy difference for D$_2$S evolution from deuterium oxide solution minus that for H$_2$S

© 2000 NRC Canada

evolution from aqueous solution. Using the solubilities (13), the difference of molar enthalpies for D_2S and H_2S evolution from their solutions is 310 with SE 92 J/mol at the freezing points 3.82 and 0.0°C, respectively, and is 326 with SE 96 J/mol at the quadruple points 3.392 and –0.4°C.

The standard enthalpy difference of $\Delta H^{oq}(h \rightarrow s_1g)$ for the Structure I cyclopropane D-hydrate to D-ice minus that for the Structure I cyclopropane hydrate to ice at their quadruple points (19, 20) is 310 with SE 150 J/mol, in good agreement with the two enthalpy differences from the solubilities.

The mean of the three enthalpy differences, 315 with SE 94 J/mol, is added to the standard enthalpy change for hydrogen sulfide hydrate dissociation to ice, 25 416 with SE 52 J/mol, to give the standard enthalpy change for dissociation of deuterium sulfide D-hydrate to D-ice $\Delta H^{oq}(h \rightarrow s_1g)$, 25 732 with SE 108 J/mol, at 3.392°C.

Formula of deuterium sulfide D-hydrate at lower quadruple point $Q(hs_1l_1g)$

The formula of deuterium sulfide D-hydrate is evaluated by the method of Scheffer and Meyer (9) who first derived the thermochemical identity eq. [15] for n

$$[15] \quad \Delta H^{oq}(\, h \rightarrow l_1g) - \Delta H^{oq}\,(h \rightarrow s_1g) = n\, \Delta H^{oq}(s_1 \rightarrow l_1)$$

which is exact at the quadruple point $Q(hs_1l_1g)$, with the equilibrium standard enthalpy changes denoted by superscript q. Substitution into eq. [15], of 64 031 with SE 28 J/mol D_2S for ΔH^{oq} $(h \rightarrow l_1g)$, of 25 732 with SE 108 J/mol D_2S for $\Delta H^{oq}(h \rightarrow s_1g)$, and of 6263 with SE 13 J/mol D_2O for $\Delta H^{oq}(s_1 \rightarrow l_1)$ evaluated from Long and Kemp (24), yields n = 6.115 with SE 0.018 for the deuterium sulfide D-hydrate formula at 3.392°C.

Using this method, which they had developed for the purpose, Scheffer and Meyer (9) determined n = 6.06 for the formula of hydrogen sulfide hydrate at the quadruple point –0.4°C: later reevaluation (10) of the same data (9), using only the four most accurate (hl_1g) measurements, confirmed n = 6.06 with error 0.13.

The formula $D_2S{\cdot}6.115D_2O$ of deuterium sulfide D-hydrate at its quadruple point $Q(hs_1l_1g)$ is significantly larger by three standard errors than the $H_2S{\cdot}6.06H_2O$ found for hydrogen sulfide hydrate at its quadruple point (9, 10). Our formula is well within the error range $H_2S{\cdot}6.19H_2O$ and $H_2S{\cdot}5.93H_2O$ indicated for the hydrate by Korvezee and Scheffer (10).

Formula of deuterium sulfide D-hydrate at temperatures different from the lower quadruple point

We now extend eq. [15], valid at $Q(hs_1l_1g)$, for more general use at temperature t°C to evaluate an approximate formula number, defined as r, using the thermochemical identity [16]

$$[16] \quad \Delta H^{ot}(h \rightarrow l_1g) - \Delta H^{ot}(h \rightarrow s_1g) = r\, \Delta H^{ot}(s_1 \rightarrow l_1)$$

in which superscript t in eq. [16] has replaced q in eq. [15]. Values of $\Delta H^{ot}(h \rightarrow s_1g)$ and ΔH^{ot} $(s_1 \rightarrow l_1)$ at temperature t are equal to their values at the quadruple point plus the integral of their heat capacities from the quadruple point.

The first term in eq. [16] is from measurements of this work. Assumption 1 is that the second term $\Delta H^{ot}(h \rightarrow s_1g)$ is temperature invariant (2, 9, 19, 20) and is 25 732 with SE 108 J/mol D_2S, the same as $\Delta H^{oq}(h \rightarrow s_1g)$ in eq. [15]. Assumption 2 is that the final term in eq. [16] is the standard molar enthalpy change for fusion of D-ice D_2O (s_1) into liquid D_2O (l_1) at t°C. This can be evaluated using the Taylor's series expansion

$$\begin{aligned}[17] \quad \Delta H^{ot}(s_1 \rightarrow l_1) &= \Delta H^{oo}(s_1 \rightarrow l_1) \\ &+ \Delta Cp^{oo}(s_1 \rightarrow l_1){\cdot}(t - 3.82) \\ &+ d\Delta Cp^{oo}(s_1 \rightarrow l_1)/dt{\cdot}(1/2){\cdot}(t - 3.82)^2 \\ &+ d^2\Delta Cp^{oo}(s_1 \rightarrow l_1)/dt^2{\cdot}(1/6){\cdot}(t - 3.82)^3\end{aligned}$$

about the normal freezing point 3.82°C, with $\Delta H^{oo}(s_1 \rightarrow l_1)$ = 6280 J/mol (24). The standard molar heat capacity change and its temperature derivatives for fusion are evaluated at 3.82°C using (*i*) the heat capacities of D-ice between –74 and –2.6°C by Long and Kemp (24) and (*ii*) the tabulated heat capacities of liquid deuterium oxide between 20 and 100°C (25).

Method for evaluation of formula number r and dissociation equilibrium constant of deuterium sulfide D-hydrate

The phase rule requires that the equilibrium deuterium oxide – deuterium sulfide, two-component, three-phase, (hl_1g) system is univariant and that the intensive properties of each of the equilibrium phases are continuous functions of temperature along the (hl_1g) equilibrium line. In particular, the equilibrium hydrate composition and its component D_2O/D_2S mole ratio n are continuous functions of temperature only.

A method is now presented to evaluate the approximate formula number r for the D-hydrate $D_2S{\cdot}rD_2O$ and its dissociation equilibrium constant $Kp(h \rightarrow l_1g)$ at each experimental temperature on the univariant (hl_1g) equilibrium line, from 2.798°C just below the lower quadruple point $Q(hs_1l_1g)$ up to 30.666°C just below the upper quadruple point $Q(hl_1l_2g)$.

The convergence of the method to a stable solution depends on the temperature continuity of the intensive properties of the three equilibrium phases, in particular, that the approximate hydrate formula number r is a continuous function of temperature. Initially we assume that $n = r = 6.0$ in eq. [9] for all measurements, giving a first approximation for the logarithm of the equilibrium constant, abbreviated to ln Kp(lst). The ln Kp(lst) values are fitted as a proper function of temperature (15) by the method of weighted least squares (26) to yield the best thermodynamic equation of the form

$$[18] \quad \ln Kp(h \rightarrow l_1g) = b0 + b1{\cdot}u1 + b2{\cdot}u2 + b3{\cdot}u3$$

which is mathematically equivalent to

$$[18a] \quad \ln Kp(h \rightarrow l_1g) = A + B/T + C \ln T + DT$$

and contains the maximum number of significant parameters. These measurements require three temperature variables ($u1$, $u2$, $u3$) with $x = (T - 298.16)/298.15$, and define (15) the four thermodynamic function parameters ($b0$, $b1$, $b2$, $b3$) and their errors at 298.15 K. Derived from ($b1$, $b2$, $b3$) of eq. [18], the first approximation standard enthalpy changes $\Delta H^{ot}(h \rightarrow l_1g)$, abbreviated to ΔH(1st), for each

© 2000 NRC Canada

measurement at its temperature t are substituted into eq. [16], to give a first approximation formula number r(lst).

The values of r(1st) are substituted for n in eq. [9] for each measurement to provide a second approximation for the logarithm of the equilibrium constant ln Kp(2nd); the ln Kp(2nd) values are refitted by eq. [18], thence to obtain second approximation ΔH(2nd) values; these are substituted for $\Delta H^{ot}(h \rightarrow l_1g)$ in eq. [16] to give r(2nd) values which are recycled for n in eq. [9], and so on. Iterations for 35 cycles give converged values of Kp(h→l_1g) and r which are presented in Tables 1 and 2.

Equilibrium constant for dissociation of deuterium sulfide D-hydrate

Table 1 lists 58 determinations between 30.666 and 2.798°C of the equilibrium constant, $Kp(h \rightarrow l_1g)$ MPa, for dissociation of deuterium sulfide D-hydrate to deuterium sulfide gas and liquid deuterium oxide according to eq. [1] with $n = r$. Quadruple point temperatures are noted. The first row presents estimates extrapolated at 30.770°C, $Q(hl_1l_2g)$. Standard thermodynamic function changes refer to dissociation of one mole of $D_2S \cdot rD_2O$ (h) at 0.10 MPa pressure to form one mole of D_2S (g) at 1.0 MPa fugacity together with r mole of pure D_2O (l_1) at 0.10 MPa pressure.

The second column of Table 1 denotes the pressure gauge used (14), data marked 500, 200, and 16 used the 500, 200, and 16 psi (1 psi = 6.895 kPa) gauges, respectively. The third column gives the square root of the weights used to combine data from the various pressure gauges into a properly weighted least-squares regression of the logarithm of $Kp(h \rightarrow l_1g)$ as a function of temperature.

The fourth column lists $Kp(h \rightarrow l_1g)$ observed, the fifth gives $Kp(h \rightarrow l_1g)$ calculated from the converged best eq. [18]. The percentage differences between observed and calculated equilibrium constants, shown in the sixth column, give an overall SE of 0. 020% for a single determination of unit weight with 54 degrees of freedom. The seventh column shows the percentage error on the equilibrium constant estimated from the weighted regression model eq. [18].

Weights used in this work are derived from those used earlier for the representation of ln $P(hl_1g)$ as a function of temperature (14). However, here more measurements are assigned lower weights to reduce possible bias and to enable smoother transitions between the measurement ranges of the three pressure gauges. The 14 measurements at low pressure using the 16 psi gauge are by far the most accurate and these are assigned unit weight. In the region of overlap of the 16 psi gauge by the 200 psi gauge, the low weights, $w^{1/2} = 0.04$, are assigned to the low-pressure measurements using the 200 psi gauge in order to reduce possible bias of the regression equation by these less accurate measurements. At higher pressures the 13 measurements using the 200 psi gauge are assigned weights, $w^{1/2} = 0.5$, the same as in ref. 14. In the region of overlap of the 200 psi gauge by the 500 psi gauge, lower weights are assigned to the conflicting measurements using the 500 psi gauge. At high pressures the 10 measurements using the 500 psi gauge are assigned weights, $w^{1/2} = 0.4$, the same as in ref. 14. The five measurements using the 500 psi gauge with the lower weights, $w^{1/2} = 0.088$, 0.115, 0.192, 0.169, and 0.195 all showed differences of $Kp(h \rightarrow l_1g)$ of greater than five standard errors: the weights assigned are the inverse of the differences in standard errors, namely the inverse of the differences of 11.4, 8.7, 5.2, 5.9, and 5.1 standard errors, respectively.

The 14 residuals from measurements using the 16 psi gauge indicate a SE of 0.025%, the 13 residuals with weight, $w^{1/2} = 0.5$, from the 200 psi gauge indicate a SE of 0.036%, and the 10 residuals with weight, $w^{1/2} = 0.4$, from the 500 psi gauge indicate a SE of 0.054%. Comparison of these SE estimates for $Kp(h \rightarrow l_1g)$ with the gauge accuracies for pressure measurement (12) shows that (*i*) the data at low pressure are properly represented with SE 0.025% and a 0.020% accuracy of 16 psi gauge calibration, (*ii*) the data at intermediate pressure with SE 0.036% are comparable with the 0.030% accuracy of 200 psi gauge calibration, and (*iii*) the high-pressure data with SE 0.054% are about twice as variable as the 0.030% accuracy of 500 psi gauge calibration. These SE estimates from the four-parameter model are approximately double those indicated by the seven-parameter model for the D-hydrate pressures in ref. 14.

The four parameters of the converged eq. [18] with their (SE) are $b0 = -0.0662\ 35$ (0.000 11), $b1 = 27.1578$ (0.0070), $b2 = 20.0170$ (0.60), $b3 = 23.4281$ (9.0). We note that the deuterium sulfide D-hydrate equilibrium constants properly define three enthalpy parameters $b1–b3$ at 25°C, that these parameters are all positive with no alternation of sign, and that the value of the least significant parameter $b3$ could arise by pure chance at a probability level of about 1.3%.

By contrast, eq. [18] with four parameters is totally inadequate to represent the weighted ln $P(hl_1g)$ measurements as an accurate function of temperature, where the lack of fit indicates an eight-times enhanced SE of 0.16% for a point of unit weight, compared with SE 0.020% for the similarly weighted ln $Kp(h \rightarrow l_1g)$.

Approximate formula number r for deuterium sulfide D-hydrate

Table 2 presents estimates and SEs for the standard enthalpy change $\Delta H^{ot}(h \rightarrow l_1g)$, the standard heat capacity change $\Delta Cp^{ot}(h \rightarrow l_1g)$, and the approximate formula number $n = r$ for dissociation of deuterium sulfide D-hydrate according to eq. [1]. We note that the results listed in Tables 1 and 2 are biased estimates, except for those given at the lower quadruple point $Q(hs_1l_1g)$ 3.392°C, where eq. [16] is exact and the estimates of $Kp(h \rightarrow l_1g)$, $\Delta H^{oq}(h \rightarrow l_1g)$, $\Delta Cp^{oq}(h \rightarrow l_1g)$, and of $n = r$ are true and unbiased.

Bias 1 arises from assumption 1, because it is assumed in eq. [16] that $\Delta H^{ot}(h \rightarrow s_1g)$ is temperature-invariant with $\Delta Cp^{ot}(h \rightarrow s_1g) = 0$ over the extrapolated temperature range 2.798 to 30.666°C, where it is possible that the standard heat capacity change may have a small negative value. This bias is assessed using the datum $\Delta Cp^{ot}(h \rightarrow s_1g) = -8.0$ with SE 24 J mol^{-1}deg^{-1}, found but not significant for hydrogen sulfide hydrate with ice (9). Evaluation at 30.666°C, using eq. [16] with $\Delta H^{oq}(h \rightarrow s_1g) = 25\,732$ J/mol and a constant $\Delta Cp^{ot}(h \rightarrow s_1g) = -8.0$ J mol^{-1}deg^{-1}, gives $r = 5.863$ with SE 0.040: a result in good agreement with, and not significantly different from, the 5.840 with SE 0.019 listed in Table 2.

Bias 2 arises from assumption 2, because it is assumed in eq. [16] that $\Delta H^{ot}(s_1 \rightarrow l_1)$ is given by the Taylor's series eq. [17] over the extrapolated temperature range 2.798 – 30.666°C. Classical error theory (26) shows that the SE on

© 2000 NRC Canada

r at 30.666°C, due to errors on the Taylor's series parameters of eq. [17], is less than 0.0005 and is not significant.

The SE's on the standard enthalpy changes for *r* at 30.666°C are, 51 J/mol on $\Delta H^{ot}(h \rightarrow l_1 g)$, 108 J/mol on $\Delta H^{oq}(h \rightarrow s_1 g)$, and 15 J/mol on $\Delta H^{ot}(s_1 \rightarrow l_1)$, showing that the major contribution to the SE on *r* is always the SE on the estimate of $\Delta H^{oq}(h \rightarrow s_1 g)$.

In Table 2 it is shown that the value of *r* decreases monotonously with increasing temperature and asymptotically approaches its theoretical lower limit of 5.75, for a Structure I hydrate (11, 16), at a temperature above the quadruple point $Q(hl_1l_2g)$ at 30.770°C.

This means a continuous increase with temperature in the number of D_2S hydrate-former molecules per unit cell of $46D_2O$, from 7.510 with SE 0.022 at 2.798°C to about 7.875 with SE 0.025 at 30.666°C, asymptotically trending towards an upper limit of 8.0 (11, 16) above 30.770°C.

This proves that an increased fraction of cavities must be occupied by D_2S molecules in order to stabilize the solid D-hydrate lattice against collapse at higher temperatures. Although these numbers may be slightly biased, the overall effect of increasing temperature remains unchanged.

Dissociation of deuterium sulfide D-hydrate at 30.770°C, the quadruple point $Q(hl_1l_2g)$, occurs with 1.54% of empty and 98.46% of occupied cavities with SE 0.32% at the saturation activity of liquid D_2S (l_2). This fits in well with the work on hydrogen sulfide hydrate by Scheffer (8), who showed that hydrostatic pressure increased the temperature for hydrogen sulfide hydrate stability above $Q(hl_1l_2g)$ along the (hl_1l_2) three-phase line, where presumably empty cavities within the hydrate lattice were progressively being filled with additional H_2S at the higher pressures and temperatures.

We attempt to justify the use of the temperature invariant $\Delta H^{oq}(h \rightarrow s_1 g) = 25\,732$ J/mol for the hypothetical $\Delta H^{ot}(h \rightarrow s_1 g)$ above the quadruple point $Q(hs_1l_1g)$ at high temperatures where D-ice (s_1) is metastable with D-water (l_1). The major problem is resolved if it is justifiable to extrapolate the experimental heat capacities of D-ice between –74 and +3.82°C (24) using eq. [17] to provide valid heat capacities for metastable D-ice between 3.82 and 30.770°C. Applying classical error theory (26) to the D-ice measurements (24) shows that the SE on the standard enthalpy of D-ice at 30.666°C is 2.3 J/mol larger than the SE at 3.82°C. This error for extrapolation to 30.666°C is negligible compared with the SE of 0.2% or 13 J/mol, given by the authors (24), on the standard enthalpy for fusion of D-ice at 3.82°C. Thus, the use of eq. [17] is proven valid up to 30.666°C.

A minor problem is justification of extrapolation of $\Delta H^{oq}(h \rightarrow s_1 g)$, derived from measurements between –21 and 3.392°C (9, 14), to higher temperatures above the quadruple point $Q(hs_1l_1g)$. The low temperature measurements (9) show that $\Delta Cp^{ot}(h \rightarrow s_1 g)$ is zero within experimental error, with a non significant value of –8.0 with SE 24 J $mol^{-1}deg^{-1}$. It thus appears reasonable to assume that $\Delta Cp^{ot}(h \rightarrow s_1 g)$ is not significantly different from zero at higher temperatures, so that $\Delta H^{ot}(h \rightarrow s_1 g)$ is temperature invariant and is equal to $\Delta H^{oq}(h \rightarrow s_1 g)$. This means that up to 30.666°C the standard molar heat capacity of deuterium sulfide D-hydrate $D_2S \cdot rD_2O$ (h) is not significantly different from the standard molar heat capacity of deuterium sulfide gas plus the standard molar heat capacity of *r* moles of D-ice. This approximation seems reasonable in the absence of heat capacity data for deuterium sulfide D-hydrate.

Let us now assess internal evidence from the present measurements in an attempt to justify the use of a temperature invariant $\Delta H^{ot}(h \rightarrow s_1 g)$ between 2.798 and 30.666°C. Within the temperature range between 2.798 and 30.666°C, respectively, between 93.74% (7.510/8 = 1/1.0652) and 98.46% (7.877/8 = 1/1.0156), of the D-hydrate cavities are occupied by deuterium sulfide: over such a relatively small range of D-hydrate composition, $\Delta H^{ot}(h \rightarrow s_1 g)$, the standard enthalpy change for evaporation of one mole of D_2S hydrate-former from 1.0652 to 1.0156 mol of lattice cavities with the D-hydrate lattice forming D-ice may be expected to vary little. This is because the predominant enthalpy change arises from the evaporation of one mole of condensed deuterium sulfide from within the D-hydrate to form one mole of gaseous deuterium sulfide, and the associated minor enthalpy change arises from the assumed nearly athermal transformation of 6.125 to 5.840 mol of D_2O from solid D-hydrate into solid D-ice. At low temperatures below the quadruple point $Q(hs_1l_1g)$ down to –21°C (9), where the transformation of solid hydrate to solid ice probably involves more than 6.115 mol of H_2O, the derived value of $\Delta H^{ot}(h \rightarrow s_1 g)$ is invariant with temperature and $\Delta Cp^{ot}(h \rightarrow s_1 g)$ is zero within experimental error. Since the extrapolation of $\Delta H^{ot}(h \rightarrow s_1 g)$ above the quadruple point to higher temperatures involves transformation of fewer than 6.115 mol of D_2O solid D-hydrate to form solid D-ice, it appears that the value of $\Delta Cp^{ot}(h \rightarrow s_1 g)$ may be numerically even smaller and nearer to zero, and that $\Delta H^{ot}(h \rightarrow s_1 g)$ remains sensibly invariant with temperature.

The reason that the approximation of eq. [16] appears to work so well at higher temperatures probably depends on the real equality of the standard heat capacity of the D-hydrate $D_2S \cdot rD_2O$ to the sum of the standard heat capacities of one mole of D_2S gas and of *r* moles of D-ice, making $\Delta Cp^{ot}(h \rightarrow s_1 g)$ very near to zero at high temperatures, just as found experimentally (2, 9, 19, 20) at low temperatures. Apparently, large standard heat capacity changes and large biases of *r* away from the true *n* do not occur, even at our highest observed temperature 30.666°C.

In conclusion, the results for deuterium sulfide D-hydrate appear to provide a subsequent justification for the use of eqs. [16] and [17] with their assumptions at all temperatures along the (hl_1g) equilibrium line, to give estimates which are exact for $r = n$ at the lower quadruple point $Q(hs_1l_1g)$, and which are apparently a good approximation at higher temperatures up to the upper quadruple point $Q(hl_1l_2g)$.

Synthesis and X-ray structures of amidinate, oxoamidate, and thioamidate complexes of boron

Pierre Blais, Tristram Chivers, Andrew Downard, and Masood Parvez

Abstract: The reactions of $PhBCl_2$ with Li[CE(N^{t}Bu)(^{n}Bu)] or Li[CS(N^{t}Bu)(NH^{t}Bu)] (1:1 molar ratio) in toluene at 23°C produced the heterocycles Ph(Cl)B(μ-N^{t}Bu)(μ-E)C(^{n}Bu) (**1a**, E = N^{t}Bu; **1b**, E = O; **1c**, E = S) or Ph(Cl)B(μ-N^{t}Bu)(μ-S)C(NH^{t}Bu) (**2**), which were characterized by ^{1}H, ^{11}B and ^{13}C NMR and by mass spectra. X-ray structural determinations revealed that **1a**, **1c** and **2** contain four-membered rings. In **2** the thioamidate ligand adopts an *N*,*S* bonding mode. Crystal data: **1a**, monoclinic, space group $P2_1$, a = 8.816(3), b = 11.311(2), c = 10.168(3) Å, β = 98.86(3)°, V = 1001.7(5) Å^3, Z = 2, R = 0.042, and R_w = 0.020; **1c**, monoclinic, space group $P2_1/n$, a = 7.617(2), b = 11.200(1), c = 19.568(2), β = 90.74(2)°, V = 1669.1(5) Å^3, Z = 4, R = 0.046, and R_w = 0.059; **2**, monoclinic, space group $P2_1/a$, a = 11.357(2), b = 12.289(2), c = 12.620(3) Å, β = 95.43(2)°, V = 1753.4(5) Å^3, Z = 4, R = 0.043, and R_w = 0.027.

Key words: boron, amidinate, oxoamidate, thioamidate, X-ray structures.

Résumé : Les réactions entre le $PhBCl_2$ et Li[(CE(N^{t}Bu)(^{n}Bu)] ou Li[CS(N^{t}Bu)(NH^{t}Bu)] (rapport molaire de 1:1), dans le toluène, à 23°C, conduisent à la formation d'hétérocycles Ph(Cl)B(μ-N^{t}Bu)(μ-E)C(^{n}Bu) (**1a**, E = N^{t}Bu; **1b**, E = O; **1c**, E = S) ou Ph(Cl)B(μ-N^{t}Bu)(μ-S)C(NH^{t}Bu) (**2**) que l'on a caractérisés par RMN du ^{1}H, ^{11}B et ^{13}C ainsi que par spectrométrie de masse. La diffraction des rayons appliquée aux produits **1a**, **1c** et **2** révèle qu'ils comportent des cycles à quatre chaînons. Dans le produit **2**, le ligand thioamidate adopte un mode de liaison *N*,*S*. Les données cristallographiques: **1a**, monoclinique, groupe d'espace $P2_1$, a = 8,816(3), b = 11,311(2) et c = 10,168(3)Å, β = 98,86(3)°, V = 1001,7(5)Å^3, Z = 2, R = 0,042 et R_w = 0,020; **1c**, monoclinique, groupe d'espace $P2_1/n$, a = 7,617(2), b = 11,200(1) et c = 19,568(2)Å, β = 90,74(2)°, V = 1669,1(5)Å^3, Z = 4, R = 0,046 et R_w = 0,059 et **2**, monoclinique, groupe d'espace $P2_1/a$, a = 11,357(2), b = 12,289(2) et c = 12,620(3) Å, β = 95,43(2)°, V = 1753,4(5) Å^3, Z = 4, R = 0,043 et R_w = 0,027.

Mots clés : bore, amidinate, oxoamidate, thiamidate, structures, diffraction des rayons X.

[Traduit par la Rédaction]

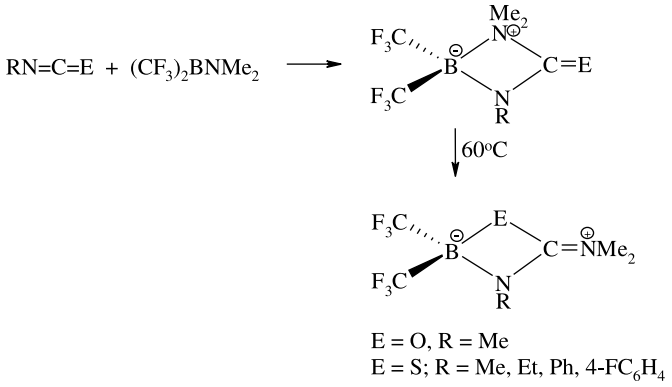
Introduction

There is an extensive literature of heterocyclic compounds involving boron–nitrogen (B-N) linkages (1). Four-membered rings are uncommon in comparison with larger ring sizes, but such systems are well established for three-coordinate boron when another heteroatom, e.g., Si(2), P(2–4), Te(5, 6), is incorporated into the ring.

Carbon-containing four-membered B-N heterocycles are relatively rare. Paetzold et al. (7) prepared the three-coordinate boron system $C_6F_5B(\mu\text{-}N^tBu)_2CPh_2$ by the [2+2] cycloaddition of $C_6F_5B \triangleq N^tBu$ and ^{t}BuN = CPh_2. A similar approach employing iso(thio)cyanates was used by Ansorge et al. (8) to create related four-coordinate boron systems. An interesting feature of the latter is the thermally induced isomerization of the *N*,*N*′-chelated complex to the unsymmetrical (*N*,*E*-chelation) isomer (Scheme 1). This process occurs more readily for E = S than for E = O and it is prevented by bulky *R* groups, e.g., ^{t}Bu (8).

An alternative route to $\overline{BNCN}$ heterocycles involves the reaction of BX_3 (X = Cl, Br) with Li[$CPh(NSiMe_3)_2$] which produces $X_2BCPh(NSiMe_3)_2$ (9). Although there have been extensive studies of amidinate complexes of the heavier Group 13 elements (Al, Ga, In, Tl) in recent years (10–18), investigations of boron derivatives are limited to this single report. The chloride was obtained as a yellow oil and the bromide gave yellow crystals, but no structural information was obtained (9).

Here we describe the synthesis and characterization of the series of $\overline{BNCE}$ (E = N, O, S) heterocycles **1a**–**c** by the route shown in eq. [1]. The preparation and X-ray structures of the hexameric reagents {Li[CE(N^{t}Bu)(^{n}Bu)]}$_6$ (E = O, S) were published very recently (19). Although a few transition-metal complexes of oxoamidate and thioamidate anions [RC(E)(NR′)]$^-$ have been reported (E = O (20), S (21)), none of them were generated from these anions by metathetical reactions. Furthermore, heterocycles **1b** and **1c** are, to our knowledge, the first examples of *p*-block element complexes



Accepted October 26, 1999.

2

Experimental

The reagents *t*BuNCE (E = N*t*Bu, O, S), Li*n*Bu (2.5 M in hexane), *t*BuNH$_2$, and PhBCl$_2$ were all obtained from Aldrich and used as received. The reagents Li[CE(N*t*Bu)*n*Bu] were prepared by the addition of Li*n*Bu to an equimolar amount of *t*BuNCE (E = N*t*Bu, O, S) in toluene at 23°C (19, 22). LiNH*t*Bu was made by the reaction of dry *t*BuNH$_2$ with Li*n*Bu. All solvents were dried with appropriate drying agents and distilled. Deuterated solvents were degassed immediately before use. All reactions and manipulations of moisture and air-sensitive products were carried out using a glove box and Schlenk techniques under an atmosphere of high purity, dried argon.

^{1}H NMR spectra were recorded on a Bruker ACE200 spectrometer and the chemical shifts are reported relative to Me_4Si in C_6D_6. ^{11}B and ^{13}C NMR spectra were recorded on a Bruker AMX300 spectrometer and the chemical shifts are reported relative to $BF_3{\cdot}OEt_2$ in C_6D_6 and TMS in C_6D_6, respectively. Elemental analyses were provided by the Analytical Services Laboratory, Department of Chemistry, University of Calgary. IR spectra were obtained as Nujol mulls on a Mattson 4030 FTIR spectrophotometer. Mass spectra (EI, 70eV) were measured on a Kratos MS80RFA instrument.

Preparation of Ph(Cl)B(μ-N*t*Bu)$_2$C*n*Bu (1a)

A solution of PhBCl$_2$ (0.925 g, 5.82 mmol) in toluene (5 mL) was added dropwise via a stainless steel cannula to a solution of Li[C(N*t*Bu)$_2$*n*Bu] (1.267 g, 5.29 mmol) in toluene (10 mL) at 23°C. The mixture was stirred for 2 h to give a white precipitate and a pale yellow solution. Lithium chloride was removed by filtration and removal of solvent yielded a viscous yellow oil, which was washed with diethyl ether (2 × 5 mL) to give pale yellow crystals of **1a** (1.46 g, 4.36 mmol, 82%); mp 76–79°C. ^{1}H NMR (in C_6D_6, 25°C, δ): 8.1–7.2 (m, 5H, C_6H_5), 2.14 (m, 2H, CH_2), 1.60 (m, 2H, CH_2), 1.17 (s, 18H, $C(CH_3)_3$), 1.11 (m, 2H, CH_2), 0.73 (t, 3H, CH_3). ^{13}C NMR (in C_6D_6, 25°C, δ): 176.3 (s, $C(N^tBu)_2{}^nBu$), 134.0–128.2 (m, C_6H_5B-), 54.1 (s, -$C(CH_3)_3$), 31.6 (s, -$C(CH_3)_3$), 49.3 (s, $CH_2CH_2CH_2CH_3$), 30.4 (s, $CH_2CH_2CH_2CH_3$), 24.4 (s, $CH_2CH_2CH_2CH_3$), 6.4 (s, -$CH_2CH_2CH_2CH_3$). ^{11}B NMR (in C_6D_6, 25°C, δ): 6.8 (s). EIMS: *m/z* 334 (M^+, $C_{19}H_{32}N_2{}^{11}B^{35}Cl$; good agreement between calculated and observed isotopic distribution). Anal. calcd. for $C_{19}H_{32}N_2BCl$: C 68.16, H 9.65, N 8.37; found: C 67.76, H 9.97, N 8.45.

Preparation of Ph(Cl)B(μ-N*t*Bu)(μ-O)C*n*Bu (1b)

A solution of PhBCl$_2$ (0.889 g, 5.60 mmol) in toluene (5 mL) was added dropwise to a solution of Li[CO(N*t*Bu)*n*Bu] (0.885 g, 5.42 mmol) in toluene (10 mL) at 23°C. Observations and work-up procedure were similar to those described for **1a**. The crude product was washed with cold (–80°C) hexane (5 mL) (6 × 5 mL) to give **1b** as a yellow solid (1.03 g, 3.69 mmol, 68%); mp 111–112°C. ^{1}H NMR (in C_6D_6, 25°C, δ): 8.3–7.2 (m, 5H, C_6H_5), 1.93 (m, 2H, CH_2), 1.42 (m, 2H, CH_2), 1.14 (m, 2H, CH_2), 0.98 (s, 9H, $C(CH_3)_3$), 0.70 (t, 3H, CH_3). ^{13}C NMR (in C_6D_6, 25°C, δ): 184.2 (s, $CO(N^tBu)^nBu$), 136–127 (m, C_6H_5B-), 54.1 (s, -$C(CH_3)_3$), 29.9 (s, -$C(CH_3)_3$), 31.0 (s, -$CH_2CH_2CH_2CH_3$), 27.1 (s, -$CH_2CH_2CH_2CH_3$), 23.1 (s, -$CH_2CH_2CH_2CH_3$), and 14.5 (s, -$CH_2CH_2CH_2CH_3$). ^{11}B NMR (in C_6D_6, 25°C, δ): 11.6 (s). FAB–MS: *m/z* 280 [(M+H)$^+$]. Anal. calcd. for $C_{15}H_{23}NOBCl$: C 64.56, H 8.33, N 5.02; found: C 63.91, H 8.41, N 4.67.

Preparation of Ph(Cl)B(μ-N*t*Bu)(μ-S)C*n*Bu (1c)

A solution of PhBCl$_2$ (0.997 g, 6.28 mmol) in hexane (5 mL) was added dropwise to a solution of Li[CS(N*t*Bu)*n*Bu] (0.880 g, 4.91 mmol) in hexane (10 mL) at 23°C. Observations and work-up procedure were similar to those described for **1a**. The crude product was washed with diethyl ether (2 × 3 mL) to give **1c** as a yellow powder (0.455 g, 1.54 mmol, 31%); mp 67–69°C. ^{1}H NMR (in C_6D_6, 25°C, δ): 8.4–7.0 (m, 5H, C_6H_5), 2.23 (m, 2H, CH_2), 1.40 (m, 2H, CH_2), 1.11 (m, 2H, CH_2), 1.07 (s, 9H, $C(CH_3)_3$), 0.71 (t, 3H, CH_3). ^{13}C NMR (in C_6D_6, 25°C, δ): 203.7 (s, $CS(N^tBu)^nBu$), 136–128 (m, C_6H_5B-), 60.5 (s, -$C(CH_3)_3$), 29.5 (s, -$C(CH_3)_3$) and ($CH_2CH_2CH_2CH_3$), 37.0 (s, -$CH_2CH_2CH_2CH_3$), 22.8 (s, -$CH_2CH_2CH_2CH_3$), and 14.2 (s, -$CH_2CH_2CH_2CH_3$). ^{11}B NMR (in C_6D_6, 25°C, δ): 6.5 (s). EIMS: *m/z* 295 (M^+). Anal. calcd. for $C_{15}H_{23}NSBCl$: C 60.92, H 7.86, N 4.74; found: C 61.82, H 8.49, N 4.55.

Preparation of Ph(Cl)B(μ-N*t*Bu)(μ-S)CN(H)*t*Bu (2)

A solution of *tert*-butyl isothiocyanate (1.94 g, 16.8 mmol) in toluene (10 mL) was added dropwise to a slurry of LiNH*t*Bu (2.68 g, 33.9 mmol) in toluene (15 mL) at 20°C. The reaction mixture was stirred for 18 h. Solvent and

X-ray analysis

Crystal data for **1a, 1c**, and **2** are summarized in Table 1.[2]

1a

A colourless, prismatic crystal (0.45 × 0.40 × 0.55 mm) was obtained from a mixture of pentane and diethyl ether (1:1) at 23°C. It was coated with epoxy and mounted on a glass fibre. Accurate cell dimensions and a crystal orientation matrix were obtained on a Rigaku AFC6S diffractometer by a least-squares fit of the setting angles of 25 reflections in the range 18.39° < 2θ < 23.96°. Intensity data were collected by the ω/2θ method using a scan speed of 4.0° min^{-1}, scan width (1.31 + 0.34 tan θ)°, and monochromatic MoK$_\alpha$ radiation in the range 4.0° < 2θ < 55.1°.

The intensities of 2443 unique reflections were measured of which 1346 had $I > 3\sigma(I)$. Data were corrected for Lorentz-polarization and absorption effects. The structure was solved by direct methods (23) and expanded using Fourier techniques (24). The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included but not refined. Scattering factors were those of Cromer and Waber (25) and allowance was made for anomalous dispersion (26). All calculations were performed using teXsan.[3]

1c

A colourless, prismatic crystal (0.50 × 0.48 × 0.45 mm) was obtained from pentane–Et_2O at –14°C. Data collection, structure solution and refinement procedures were similar to those described for **1a** except for the use of a different direct methods program (27). Range of data collected 4.0° < 2θ < 55.1°, scan speed 8.0° min^{-1}, scan width (1.57 + 0.34 tan θ)°, 4063 unique reflections of which 2431 had $I > 3\sigma(I)$.

2

A colourless, prismatic crystal (0.50 × 0.35 × 0.30 mm) was obtained from diethyl ether at –18°C. Data collection, structure solution and refinement procedures were similar to those described for **1c**. Range of data collected 4.0° < 2θ < 51.0°, scan speed 8.0° min^{-1}, scan width (1.63 + 0.34 tan θ)°, 4241 unique reflections of which 2330 had $I > 3\sigma(I)$.

Results and discussion

Compounds **1a–c** were obtained as moisture-sensitive pale yellow solids by the metathetical reaction illustrated in eq. [1]. They were characterized by elemental analyses and

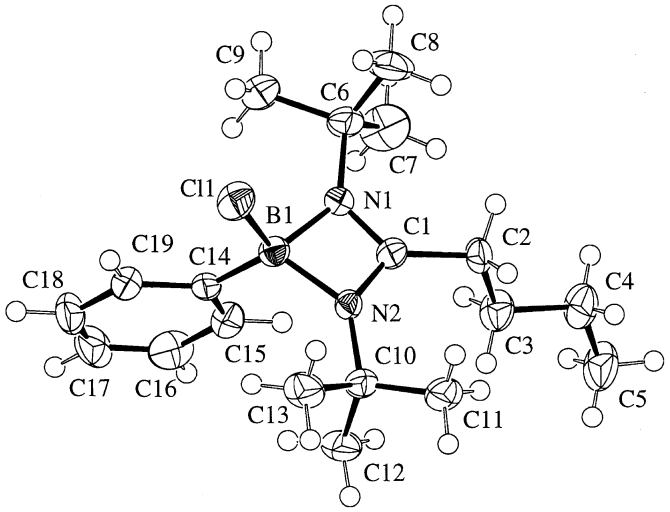
Fig. 1. ORTEP drawing of PhB(Cl)(μ-N^{t}Bu)$_2$C^{n}Bu (**1a**).



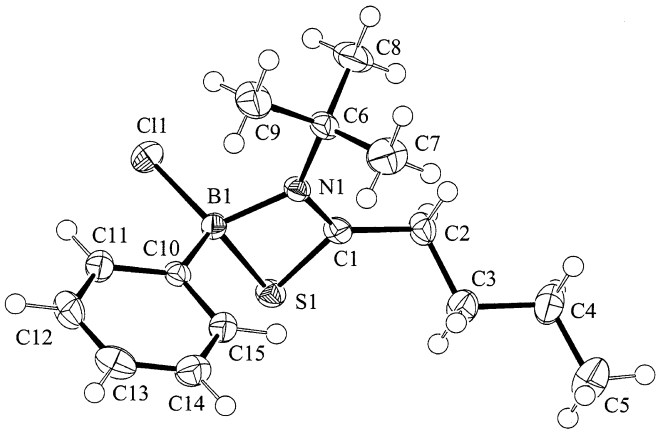


Fig. 2. ORTEP drawing of PhB(Cl)(μ-N^{t}Bu)(μ-S)C^{n}Bu (**1c**).

by ^{1}H, ^{13}C, and ^{11}B NMR spectra. The ^{11}B NMR chemical shifts are in the range δ 6–12 ppm consistent with tetracoordinate boron (28). The highest molecular ions observed in the EI and FAB mass spectra indicate monomeric structures in the solid state. We note, however, that four-coordinate boron compounds involving the [Me$_2$P(S)NR]$^-$ ligand, cf. [RC(S)N^{t}Bu]$^-$, exist in solution as an equilibrium mixture of monomers and dimers (29).

The related complex **2** was obtained unexpectedly, and in low yield, from the reaction of PhBCl$_2$ with Li$_2$[CS(N^{t}Bu)$_2$]. A major by-product of this reaction is (PhBS)$_3$ (30),[4] which accounts for the low yield of **2**.[5] Surprisingly, we were unable to obtain **2** from the reaction of PhBCl$_2$ with Li[CS(NH^{t}Bu)(N^{t}Bu)] (prepared from the reaction of ^{t}BuNCS with LiNH^{t}Bu in a 1:1 molar ratio). The ^{1}H and ^{13}C NMR spectra of **2** both show the presence of inequivalent N^{t}Bu environments and the ^{1}H NMR spectrum also exhibits a broad singlet at δ 5.2 attributable to the N*H* group. The ^{11}B NMR chemical shift for **2** is 6.5 ppm consistent with tetracoordinate boron.

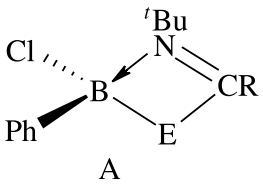
N(1)-C(1)-N$_{exo}$	—	—	128.8 (3)
E[b]-C(1)-N$_{exo}$	—	—	127.4 (2)

[a] C$_{Ar}$ = *ipso* carbon of C$_6$H$_5$ group.
[b] **1a**, E = N(2); **1c**, E = S; **2**, E = S.
[c] N$_{exo}$ = exocyclic N atom.



The monomeric, four-membered ring structures of **1a**, **1c**, and **2** were confirmed by X-ray crystallography (see Figs. 1–3). Numerous attempts to obtain crystals of **1b** suitable for X-ray crystallography were unsuccessful. Pertinent metrical parameters for these heterocyclic systems are compared in Table 2. All three ring systems are essentially planar with torsion angles (BNCE) of –1.9(4)°, 1.2(3)°, and –3.9(2)° for

[4] In one experiment a small amount of the five-membered ring (PhB)$_2$S$_3$ was isolated and identified by X-ray crystallography. This structure has been reported previously in a review (31).
[5] The metathetical reactions of Li$_2$[CSN^{t}Bu]$_2$ with other organometallic halides also produce the corresponding sulfides. For example, (Cp$_2$ZrS)$_2$ (32) and (Me$_2$SnS)$_3$ (33) were obtained from the reactions with Cp$_2$ZrCl$_2$ and Me$_2$SnCl$_2$, respectively, and identified by comparison of spectroscopic data with those reported in the literature (P. Blais and T. Chivers, unpublished results).

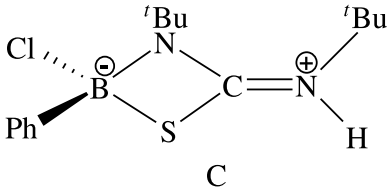
1a, **1c,** and **2**, respectively. The anionic ligand in **2** is chelated to boron in an *N*,*S* rather than *N*,*N*′ bonding mode consistent with the previous observations of Ansorge et al. (8) for related ligands in four-coordinate boron complexes.



The C—N bond distances (1.321(6) and 1.341(6) Å) in the amidinate **1a** are almost equal, approximately intermediate between C—N double-bond and C—N(sp^2) single-bond values. The sums of the bond angles at the three-coordinate N and C centres are ca. 360° (as is the case for the other two heterocycles **1c** and **2**). These structural features indicate delocalized bonding in the NCN unit with approximately equal contributions from the two canonical forms **A** and **B** (E = N^{t}Bu). Consistently, the B—N bond lengths are also approximately equal (1.590(6) and 1.567(6) Å) and fall within the range of 1.55–1.61 Å found for B—N bonds involving four-coordinate boron linked to three-coordinate nitrogen (34). Interestingly, the endocyclic and exocyclic C—N bond lengths in **2** are identical at 1.323(3) Å. The shortness of the exocyclic bond suggests a significant contribution from the resonance form **C** to the overall structure (cf. Scheme 1 (8)).

A

B

C

The C—S bond lengths in **1c** and **2** are equal at 1.74 Å, which is close to the typical single-bond distance for sp^2-carbon atoms attached to two-coordinate sulfur (34). This observation and the relatively short (1.302(4) Å) C—N bond distance suggest that resonance form **A** (E = S) is a much more important contributor than **B** to the structure of **1c**. The B—S bond lengths in **1c** and **2** (2.032(4) and 2.008(3) Å, respectively) are somewhat longer than the mean single-bond value of 1.90 Å for four-coordinate boron attached to two-coordinate sulfur (34). This may reflect the relatively weak affinity of the hard Lewis acid boron for a soft Lewis base donor, sulfur, compared to nitrogen, a hard Lewis base centre.

The endocyclic bond angles at boron and carbon fall within the narrow ranges of 81.6(3)–84.9(2)° and 101.6(4)–105.0(3)°, respectively. However, there are substantial differences in the other two endocyclic bond angles for the S-containing rings **1c** and **2** compared to the corresponding values for **1a** as a result of the ability of two-coordinate sulfur to accommodate relatively small bond angles. Thus the endocyclic bond angles are ca. 71° at sulfur and ca. 100° at nitrogen in **1c** and **2**, cf. 88–89° at the N atoms in **1a**.

Conclusions

The first *p*-block element complexes of oxo- and thioamidate anions have been prepared by metathetical reactions using the novel reagents Li[CE(N^{t}Bu)(^{n}Bu)] (E = O, S). By analogy with the extensive chemistry of amidinates it is likely that this approach can be applied to the synthesis of a wide range of main group element and transition metal complexes of these hetero-bidentate ligands.

A kinetic modeling study of ethylene pyrolysis

John M. Roscoe, Alain R. Bossard, and Margaret H. Back

Abstract: A kinetic model is presented for the pyrolysis of ethylene at pressures ranging from 0.8 to 27 kPa and temperatures from 774 to 1023 K. The model is based on experimental measurements of C_2H_2, C_2H_6, C_3H_6, 1-C_4H_8, and 1,3-C_4H_6. In this temperature range the reaction is initiated by the disproportionation of C_2H_4 and the observed products result from reactions of the C_2H_3 and C_2H_5 radicals produced in this process. The C_2H_2 and 1,3-C_4H_6 result from reactions of C_2H_3 while C_2H_6, C_3H_6, and 1-C_4H_8 result from reactions of C_2H_5. C_2H_2 is produced exclusively by the decomposition of the C_2H_3 radical. This process is in its falloff region throughout the range of experimental conditions examined and the yield of C_2H_2 provides a measure of the degree of falloff. The production of 1,3-C_4H_6 is controlled by the reaction $C_4H_7 \rightarrow C_4H_6 + H$. The rate constants for this reaction were independent of pressure and are given as a function of temperature by $k = 2.2 \times 10^{13} \exp(-19.6 \times 10^3/T)$. Production of C_2H_6 is controlled by the reaction $C_2H_5 + C_2H_4 \rightarrow C_2H_6 + C_2H_3$. The rate constant for this reaction is given as a function of temperature by $k = 5.83 \times 10^{11} \exp(-14.6 \times 10^3/T)$. C_3H_6 is produced by decomposition of 2-C_4H_9 and is controlled kinetically by the isomerization reaction 1-$C_4H_9 \rightarrow$ 2-C_4H_9. The temperature dependence of the rate constants obtained for this reaction leads to a preexponential factor of approximately 3×10^{16} and an activation energy of approximately 200 kJ mol^{-1}. The yield of 1-C_4H_8 is controlled by 1-$C_4H_9 \rightarrow$ 1-C_4H_8 + H. The rate constants for this reaction were independent of pressure and are given as a function of temperature by $k = 2.97 \times 10^{12} \exp(-17.1 \times 10^3/T)$.

Key words: kinetic modeling, ethylene pyrolysis.

Résumé : On présente un modèle cinétique pour la pyrolyse de l'éthylène à des pressions allant de 0,8 à 27 kPa et à des températures allant de 774 à 1023 K. Le modèle est basé sur des mesures expérimentales de C_2H_2, C_2H_6, C_3H_6, but-1-ène et buta-1,3-diène. Dans cette plage de températures, la réaction est initiée par la dismutation du C_2H_4 et les produits observés résultent de réactions de radicaux C_2H_3 et C_2H_5 produit au cours de ce processus. La formation de C_2H_2 et le buta-1,3-diène résulte de réactions du C_2H_3 alors que la formation de C_2H_6, C_3H_6 et de but-1-ène résulte de réactions de C_2H_5. Le C_2H_2 ne se forme que par décomposition du radical C_2H_3; ce processus se retrouve dans la région de ralentissement dans toutes les conditions expérimentales étudiées et le rendement en C_2H_2 est une mesure du ralentissement. La production de buta-1,3-diène est contrôlée par la réaction $C_4H_7 \rightarrow C_4H_6 + H$. Les constantes de vitesse de cette réaction sont indépendantes de la pression et elle peuvent être exprimées comme une fonction de la température par l'équation $k = 2{,}2 \times 10^{13} \exp(-19{,}6 \times 10^3/T)$. La production de C_2H_6 est contrôlée par la réaction $C_2H_5 + C_2H_4 \rightarrow C_2H_6 + C_2H_3$. Les constantes de vitesse de cette réaction sont indépendantes de la pression et elle peuvent être exprimées comme une fonction de la température par l'équation $k = 5{,}83 \times 10^{11} \exp(-14{,}6 \times 10^3/T)$. La formation de C_3H_6 résulte de la décomposition du but-2-ène et, d'un point de vue cinétique, elle est contrôlée par la réaction d'isomérisation 1-$C_4H_9 \rightarrow$ 1-C_4H_8. La relation entre la température et les constantes de vitesse de cette réaction conduisent à un facteur préexponentiel d'environ 3 × 1016, une énergie d'activation d'environ 200 kJ mol^{-1}. Le rendement en but-1-ène est contrôlé par la réaction 1-$C_4H_9 \rightarrow$ 1-C_4H_8 + H. Les constantes de vitesse de cette réaction sont indépendantes de la pression et elles peuvent être exprimées en fonction de la température par l'équation $k = 2{,}97 \times 10^{12} \exp(-17{,}1 \times 10^3/T)$.

Mots clés : modélisation cinétique, pyrolyse de l'éthylène.

[Traduit par la Rédaction]

Introduction

The thermal reactions of hydrocarbons are important in combustion chemistry and petroleum processing. An understanding of the thermal decomposition of ethylene, the prototypical olefin, is essential for understanding the high temperature chemistry of other olefins. While the chemistry of saturated radicals such as C_2H_5 is reasonably well understood, a central issue in understanding the pyrolysis of olefins is elucidation of the chemistry of unsaturated radicals such as C_2H_3. These play a critical role at a much earlier stage in the thermal decomposition of olefins than in the corresponding reactions of saturated hydrocarbons. Indeed, it is the lack of well established kinetic parameters for the reactions of these unsaturated radicals that has prevented as comprehensive a description of olefin pyrolysis as has been developed for the thermal chemistry of saturated hydrocarbons.

The pyrolysis of olefins has been reviewed (1) and two limiting conditions are found for C_2H_4. At the high tempera-

tures characteristic of shock tube experiments, a comprehensive model has been developed (2) in which the reaction is initiated by decomposition of C_2H_4 via two channels: production of C_2H_2 + H_2 and production of C_2H_3 + H. Below about 1000 K, these reactions become very slow and the decomposition of C_2H_4 is initiated by its disproportionation to C_2H_5 and C_2H_3. This reaction has been extensively studied experimentally at temperatures between about 750 and 1000 K (3–13) and a kinetic model for the very early stages of the pyrolysis at about 900 K has been reported (14). The work which we present here extends that model to somewhat larger C_2H_4 conversions and to conditions which span a wide range of temperatures. This permits evaluation of the way in which the roles of key reactions in the process change with temperature and pressure over a significant range of these parameters and permits evaluation of Arrhenius parameters for those reactions that control the yields of the measured products.

Experimental

The kinetic modeling is based on the experiments of Bossard and Back (13) which provide an internally consistent data set for C_2H_2, C_2H_6, C_3H_6, C_4H_6, and 1-C_4H_8 at temperatures from 774 to 1023 K and pressures of 0.8 to 27 kPa. The experiments were performed in a static reaction vessel with chemical analysis by gas chromatography. The details of the methods used are given in the original publication (13). This provides experimental data obtained by methods which differ significantly from those upon which our earlier model was based (14) as well as giving data over a wide temperature range. It also includes results for the yield of C_2H_2 which was not measured in the experiments used for development of the earlier model. Knowledge of the C_2H_2 yield permits evaluation of the importance of decomposition of C_2H_3, information that is important in properly modeling other reactions of this radical which ultimately control the yields of 1,3-C_4H_6.

Kinetic modeling was done on a personal computer with a computer program which we have used in other work (14). It uses the DIFSUB integrator (15) to avoid stiffness instability and includes provision for first order sensitivity analysis. Rate constants were provided in the modified Arrhenius form

$$[1] \qquad k = AT^n \exp(-E_a/RT)$$

with the kinetic parameters A, n and E_a obtained from a variety of reviews and compilations (16–22). To the extent possible, data from reference (21) were used to improve internal consistency. When more recent direct experimental measurements of kinetic parameters were available and seemed to represent an improvement in accuracy, the more recent results were used. When the rate constant for a reaction was potentially subject to pressure falloff, this was evaluated using the Troe formalism (23) with the relations

$$[2] \qquad k = k_\infty \frac{P_r}{(1+P_r)} F, \qquad \text{where } P_r = \frac{k_0}{k_\infty}\frac{P}{RT}$$

Here, k_0 and k_∞ are the low pressure and high pressure limiting rate constants, respectively. The broadening factor F is given by

$$[3a] \qquad \log F = \frac{\log F_{cent}}{1+\left(\frac{\log P_r - 0.12}{0.85 - 0.67\log F_{cent}}\right)^2}, \qquad \text{when } P_r > 1$$

$$[3b] \qquad \log F = \frac{\log F_{cent}}{1+\left(\frac{\log P_r - 0.12}{0.65 - 1.87\log F_{cent}}\right)^2}, \qquad \text{when } P_r > 1$$

The value of the parameter F_{cent} varies with temperature and is specific to each reaction. The parameters needed in eqs. [2] and [3] were obtained from the same literature sources as the kinetic parameters where available.

Adjustment of the initial values of the rate constants for the reactions in the model was guided by sensitivity analysis and by the reported estimates of uncertainty of the kinetic parameters obtained from the literature. The number of reactions for which rate constants could be adjusted was limited by the number of reaction products for which measured yields were available. Rate constants were adjusted manually until the curves represented by the calculated composition appeared visually to represent the median trend of the experimental data points. The number of experimental measurements of composition as a function of time was generally insufficient to warrant the use of a statistical method such as least squares in assessing goodness of fit. In most cases, the sensitivity of the system to the rate constant being manually adjusted was sufficient to show a significant variation in the visual fit with a change of at most about 10% in the rate constant being fitted. The adjusted rate constants were finally constrained to fit eq. [1] except for those cases in which they had a clear dependence on pressure. The number of pressures for which data were available was too small to permit a quantitative analysis of the pressure falloff for those reactions having pressure sensitive rate constants.

Results and discussion

The full model consisted of 100 reactions, 96 of which corresponded to those evaluated in developing our earlier model (14). As in that work, many of these reactions had very small rates and negligibly small sensitivity coefficients for the reaction products for which experimental data were available. Such reactions were removed from the model if their removal did not appreciably alter the quality of the fit to the experimental data, provided they had not been shown to be important in our earlier model. This latter constraint is necessary because the earlier model was based on analytical data for H_2 and CH_4, two products for which information was not available in the experiments of Bossard and Back but which were used here.

The reduced model was larger than the reduced model presented in our earlier work and is given in Table 1. It consists of a total of 58 reactions, 27 of which are supplementary to those in the earlier model. Of these, 11 make an appreciable contribution to the measured products only at the higher temperatures examined. The quality of fit to the data provided by the model is indicated for three of the experimental data sets in Fig. 1. The kinetic parameters identi-

[a]The values of the kinetic parameters given in the table are those used in the model calculations. They are not intended to imply a level of accuracy or precision in the numerical values.

[b]Reactions not included in the model of ref. 14.

[c]Reactions not included in the model of ref. 14 and only appreciable at high temperatures.

[d]The rate parameters are for the high pressure limit. The rate constants for these reactions were corrected for falloff.

fied in Table 1 as resulting from this work were obtained by fitting the rate constants for reactions having high, selective sensitivities to specific products so as to obtain optimal agreement with the experimental yields. The quality of fit obtained in such cases was well within the experimental uncertainty of the analytical data. However, the rate constants obtained in this way showed the normal experimental scatter about an Arrhenius plot. The kinetic parameters used in Table 1 result from these Arrhenius fits and the lack of exact agreement with the experimental data in Fig. 1 is a result of this scatter about the Arrhenius fits. While some of the Arrhenius plots appear curved, as will be seen later, the use of a nonlinear modified Arrhenius fit as defined in eq. [1] was not justified either by the number of experimental conditions or by the scatter of the kinetic data.

As in most attempts to infer detailed mechanisms for pyrolysis, some reactions must be evaluated for which experimental measurements of the relevant kinetic parameters are not available. We now outline how the parameters, which are indicated in Table 1 as estimates, were obtained.

The kinetic parameters for the reaction

[11] $C_4H_7 + C_2H_4 \rightarrow 1\text{-}C_4H_8 + C_2H_3$

were assumed to be similar to those for the corresponding reaction of C_2H_5.

[9] $C_2H_5 + C_2H_4 \rightarrow C_2H_6 + C_2H_3$

The measured product yields are not sensitive to variations of a factor of ±10 in the rate constant for reaction [11].

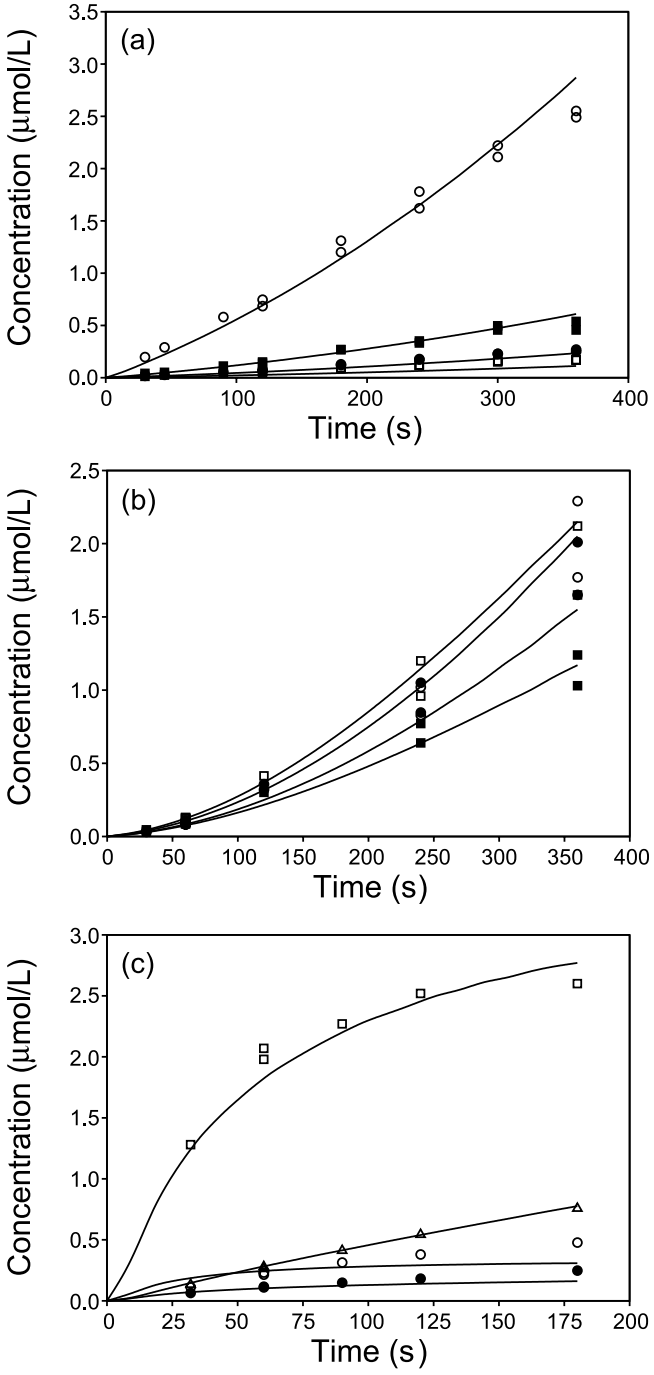
Weissman and Benson (40) estimate a preexponential factor of 2×10^8 L mol^{-1} s^{-1} and an activation energy lower limit of 8 kJ mol^{-1} for the reaction

[17] $C_2H_3 + C_2H_4 \rightarrow C_4H_7$

In our earlier model (14), we fixed the kinetic parameters for the subsequent reaction

[–23] $C_4H_7 \rightarrow C_4H_6 + H$

at the values given by Weissman and Benson (40) and adjusted the rate constant for reaction [17] to provide agreement with the measured yield of C_4H_6. We noted then that this decision was somewhat arbitrary since adjustment of the rate constant for either reaction [17] or [–23] would have served to fit the C_4H_6 yield. Reaction [17] was chosen as the one for which less was known about the kinetic parameters. Since our experiments were all made at temperatures within a few degrees of 900 K, we were unable to calculate an activation energy or preexponential factor. However, with an activation energy of 30 kJ mol^{-1}, typical of many radical additions to C_2H_4, our results suggested that the preexponential factor for reaction [17] would be 2.7×10^7 L mol^{-1} s^{-1}.



It was initially intended to fit the C_4H_6 yields in the current work by adjusting k_{17} at each temperature to determine whether the unexpectedly small rate constant for reaction [17] at 900 K was due to an unusually small preexponential factor or an unexpectedly large activation energy. It became clear that the overall magnitudes of the yields of most of the products could not be made large enough with reasonable values of the other rate constants unless the preexponential factor of reaction [17] was approximately 2×10^8 L mol^{-1} s^{-1} with our estimated activation energy of 30 kJ mol^{-1}. The yield of C_4H_6 could then be fitted satisfactorily at the lower temperatures by adjusting the value of k_{-23}. Above approximately 925 K, the general magnitudes of the predicted yields of the other products tended to be low unless the preexponential factor of reaction [17] was increased to approximately 5×10^8. This does not necessarily indicate that the preexponential factor suggested by Weissman and Benson is too small but may well indicate that our estimate of the activation energy is too large. However, the sensitivity of the system to the value of the rate constant for reaction [17] is not sufficient over the range of conditions for which data are available to permit unambiguous evaluation of the preexponential factor and activation energy of this reaction.

No information could be found in the literature for the reaction

[20] $C_4H_7 + C_2H_4 \rightarrow 6\text{-}C_6H_{11}$

© 2000 NRC Canada

Fig. 1. (*a*) Yields of reaction products in ethylene pyrolysis at 26.7 kPa and 774 K. The lines represent calculations using the model. The data points represent the experimental yields as follows: ○, C_3H_6; ■, 1-C_4H_8; ●, C_2H_6; □, C_4H_6. (*b*) Yields of reaction products in ethylene pyrolysis at 6.7 kPa and 853 K. The lines represent calculations using the model. The data points represent the experimental yields as follows: ○, C_3H_6; ■, 1-C_4H_8; ●, C_2H_6; □, C_4H_6. (*c*) Yields of reaction products in ethylene pyrolysis at 0.83 kPa and 974 K. The lines represent calculations using the model. The data points represent the experimental yields as follows: ○, C_3H_6; □, C_4H_6; ●, C_2H_6; △, C_2H_2.

We estimate its Arrhenius parameters to be similar to those for reaction [17]. This reaction only has a significant effect on the yield of C_4H_6 and its effect is significantly less sensitive than that of reaction [–23]. Its effect is more pronounced at low temperatures than at the higher ones.

The model contains three decomposition reactions of cyclic radicals.

[31] $c\text{-}C_6H_{11} \rightarrow c\text{-}C_6H_{10} + H$

[34] $c\text{-}C_5H_9 \rightarrow c\text{-}C_5H_8 + H$

[36] $c\text{-}C_6H_9 \rightarrow c\text{-}C_6H_8 + H$

Kinetic parameters for these reactions are scarce and varied. We used a preexponential factor of 2×10^{13} s^{-1} and an activation energy of 160 kJ mol^{-1} for all three reactions on the assumption that these would be similar to reactions [–21] or [28]. The calculations are not sensitive to the values of these rate constants.

Reaction [–24] has a modest effect on C_4H_6 and virtually no effect on any other

[–24] $C_6H_9 \rightarrow C_4H_6 + C_2H_3$

measured product. While there are no values available in the literature for its kinetic parameters, it is likely to be similar to reactions [–20] and [32]. On that basis, we estimate a preexponential factor of approximately 10^{13} s^{-1} with an activation energy of about 120 kJ mol^{-1}.

Reactions [40], [42], [43], [–43], [44], [45], and [–45] have very small effects on

[40] $3\text{-}C_6H_{13} \rightarrow 2\text{-}C_6H_{13}$

[42] $2\text{-}C_5H_{11} \rightarrow 3\text{-}C_5H_{11}$

[43] $6\text{-}C_6H_{11} \rightarrow c\text{-}C_6H_{11}$

[–43] $c\text{-}C_6H_{11} \rightarrow 6\text{-}C_6H_{11}$

[44] $2\text{-}C_6H_{13} \rightarrow 3\text{-}C_6H_{13}$

[45] $C_6H_9 \rightarrow c\text{-}C_6H_9$

[–45] $c\text{-}C_6H_9 \rightarrow C_6H_9$

the calculated yields of the measured products. The kinetic parameters for reactions [40], [42], and [44] were assumed to be the same as those for the other isomerization reactions of radicals with the same empirical formula. The kinetic parameters for reactions [43] and [45] were assumed to be the same as those for reaction [41], while those for reactions [–43] and [–45] were assumed to be similar to those for cleavage of an aliphatic C—C bond.

We now describe in some detail the selection of reactions whose rate constants were adjusted in fitting the model calculations to the experimental product yields. The yield of a product invariably showed a sensitive dependence on the rate constants of several reactions and this sensitivity frequently varied with temperature, pressure and reaction time. In the discussion which follows, the sensitivity of the model calculations to the rate constants of individual reactions is used to justify the selection of the reactions whose rate constants were adjusted. The results obtained by fitting these kinetic

1.63	1023	6.0×10^{5}
0.83	1023	6.0×10^{5}

parameters to obtain agreement with experiment are then presented.

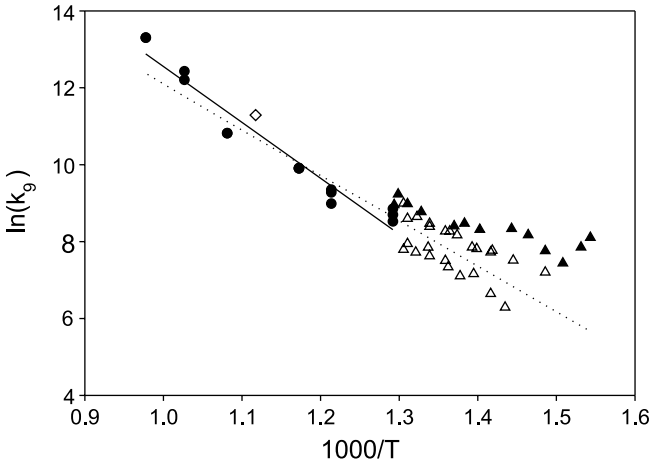
The initiation step,

[4] $2C_2H_4 \rightarrow C_2H_3 + C_2H_5$

has received extensive study and the agreement among the experiments reported in the literature is good. These results are summarized in reference (22) and a linear Arrhenius fit to the collected data was used to obtain the kinetic parameters for this reaction quoted in Table 1. It seemed preferable to use this composite representation of the kinetic data in the literature rather than singling out a specific piece of work because of the good agreement among the experimental measurements made in several laboratories. While the selection of kinetic parameters for the initiation step is clearly a key decision in establishing the kinetic model, this reaction did not have a selective effect on any reaction product. Indeed, many other reactions in the model showed a much more sensitive and selective effect on the calculated yields of the measured products.

The reactions

[18] $H + C_2H_4 \rightarrow C_2H_5$



[–18] $C_2H_5 \rightarrow C_2H_4 + H$

[27] $C_2H_3 \rightarrow C_2H_2 + H$

were in their falloff region over the entire range of reaction conditions. Falloff corrections were calculated for reactions [18] and [–18] using the relation for F_{cent} given by Larson et al. (41) and microscopic reversibility. Examination of the calculated rates of reactions [18] and [–18] indicated that the reaction was virtually equilibrated. While the yields of many reaction products are sensitive to the choice of rate constant of either reaction [18] or [–18] individually, the calculated yields were not sensitive to the falloff calculation as long as the values of k_{18} and k_{-18} were consistent with the established thermochemistry of the C_2H_5 radical.

Initial estimates of the falloff corrections for the C_2H_3 radical were made using the relation for F_{cent} reported for reaction [27] by Knyazev and Slagle (34) with N_2 as the bath gas. The calculated yields were insensitive to the reverse of reaction [27] and it is therefore not included in the reduced model presented in Table 1. Below 925 K, none of the product yields were sensitive to the value of k_{27} while at this temperature and above, only the yield of C_2H_2 showed a consistently large and selective sensitivity to this rate constant. The yield of C_2H_2 could then be used to refine the estimate of the falloff correction for reaction [27] at the higher temperatures to give rate constants with a falloff correction appropriate to a bath gas of C_2H_4 rather than N_2. At the lower temperatures, where yields of C_2H_2 were not available, the falloff correction was calculated for N_2. This was felt to be sufficiently accurate since the calculated yields of the other products were very insensitive to the value of k_{27} at these temperatures. Unfortunately, the limited number of temperatures and pressures for which data were available prevents analysis of the falloff corrected values of k_{27} to obtain useful values of F_{cent} for C_2H_4 as a bath gas.

Fig. 2. Temperature dependence of k_9. ●, this work; ▲, ref. 43; ◇, ref. 9; △, ref. 42: Rate constants were measured by a relative method. The upper set of points use $C_2H_5 + C_3H_8 \rightarrow C_2H_6 + C_3H_7$ as the reference reaction. The rate constants are calculated using kinetic parameters for the reference reaction taken from reference 18. The total reference rate constant is taken as the sum of the rate constants for the two channels giving respectively 1-C_3H_7 and 2-C_3H_7. The lower set of points are based on C_2H_5 + iso-$C_4H_{10} \rightarrow C_2H_6 + C_4H_9$ as the reference reaction with kinetic parameters as in ref. 42. ·····, ref. 18.

The calculated yields of C_2H_6 showed consistently high sensitivity to the reaction

[9] $C_2H_5 + C_2H_4 \rightarrow C_2H_6 + C_2H_3$

None of the other product yields showed high sensitivity to this reaction. At the higher temperatures, reactions [18] and [–18] had an increasingly sensitive effect on the yield of C_2H_6 but the values of the rate constants for these reactions and their dependence on pressure were fixed as indicated earlier. Moreover, reactions [18] and [–18] have a sensitive effect on several products. This makes them unsuitable for use in fitting the yields of specific reaction products because the choice of product to use for fitting is ambiguous.

The yields of C_2H_6 could be exactly fitted over the entire range of reaction conditions by adjusting only the rate constant of reaction [9]. The values obtained are given in

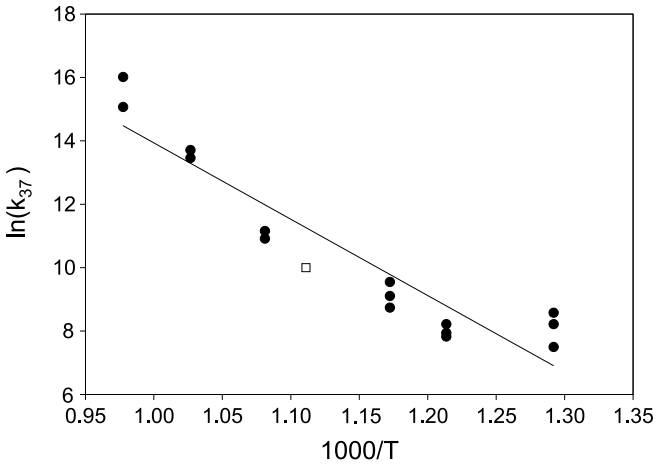
0.83	974	9.0×10^5
1.63	1023	3.5×10^6
0.83	1023	9.0×10^6

Table 2 and Fig. 2. Also shown in the figure are results taken from the literature. Our fitted values fall close to the recommendation of Tsang and Hampson (18) and, at the lower temperature, merge with the high temperature results of Ahonkhai et al. (42) and Zhang and Back (43). A single value at 900 K by MacKenzie et al. (9) falls within our combined uncertainties. A linear Arrhenius fit to our data leads to a preexponential factor of 5.83×10^{11} L mol^{-1} s^{-1} and an activation energy of 121 kJ mol^{-1} for this reaction.

The reaction product C_3H_6 arises from decomposition of the 2-C_4H_9 radical. However, its yield is kinetically limited by the isomerization of the 1-C_4H_9 radical. The reactions leading from the initiation reaction to C_3H_6 are therefore

[15] $C_2H_5 + C_2H_4 \rightarrow$ 1-C_4H_9



[37] 1-$C_4H_9 \rightarrow$ 2-C_4H_9

[25] 2-$C_4H_9 \rightarrow C_3H_6 + CH_3$

At all temperatures, the rate of reaction [25] is equal to that of reaction [37] and the sensitivity coefficient of reaction [25] is zero. The yield of C_3H_6 can be made to agree with the experimental value without appreciably altering the yields of the other measured products by adjusting the rate constant of reaction [37]. As the temperature increases, the number of reactions influencing the formation of C_3H_6 increases. However, the rate of reaction [25] is always equal to that of reaction [37] so adjustment of the rate constant for this reaction properly reflects the kinetic control of the C_3H_6 yield over the entire range of reaction conditions. The sensitivity coefficient for reaction [37] remains large throughout. Most of the additional reactions that increase in sensitivity consist of nearly equilibrated pairs of forward and reverse processes; therefore, their net sensitivity is determined by the difference between the forward and reverse sensitivity coefficients and is quite small. The effect of these reactions is therefore more a reflection of the relevant thermochemistry than of kinetic control.

The rate constants obtained as outlined above are listed in Table 3. While the rate constants obtained at temperatures below 853 K seem to show a systematic decrease with decreasing pressure, this may be an artefact resulting from the small number of pressures examined. The average deviation from the mean at the lowest two temperatures is of the same magnitude as that at the higher temperatures. The limited precision of these rate constants and the limited number of pressures used prevents any systematic examination of a pressure dependence for k_{37}. These rate constants are plotted in Arrhenius form in Fig. 3. Also shown in that plot is a single point obtained by MacKenzie et al. at 900 K (11) which fits very well into our results. The data lead to a preexponential factor of approximately 3×10^{16} and an activation energy of approximately 200 kJ mol^{-1}. However, within the scatter of the data, the activation energy could be uncertain by as much as ±30 kJ mol^{-1} with a consequent extrapolation uncertainty of as much as two orders of magnitude in the preexponential factor. The large activation energy is, however, consistent with the widely held view that isomerization of small free radicals is a slow process with a large activation energy.

Fig. 3. Temperature dependence of k_{37}. ●, this work; □, ref. 11.

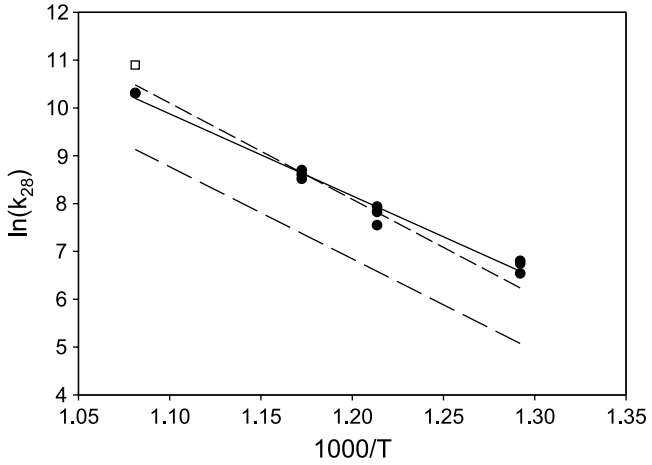
The yield of 1-C_4H_8 is controlled by

[28] 1-$C_4H_9 \rightarrow$ 1-C_4H_8 + H

The only other reactions which have significant sensitivities for 1-C_4H_8 at the lower temperatures are

[15] $C_2H_5 + C_2H_4 \rightarrow$ 1-C_4H_9

[46] $2C_2H_5 \rightarrow C_4H_{10}$



Reaction [15] is nearly equilibrated so its effect is governed by thermochemistry rather than kinetics and the rate constant for reaction [46] is sufficiently well established and insensitive to temperature that adjustment of its value would not be appropriate for fitting the experimental yields of 1-C_4H_8. The sensitivity coefficient for reaction [28] was consistently the largest of any reaction throughout the entire set of reaction conditions and the rate constant for that reaction was adjusted to bring the yields of 1-C_4H_8 calculated with the model into agreement with experiment. As the temperature increases, a substantial number of additional reactions begin to have a significant effect on the yield of 1-C_4H_8. The net effect is a decrease in the relative yield of 1-C_4H_8 and above 925 K the amounts formed were too small to measure

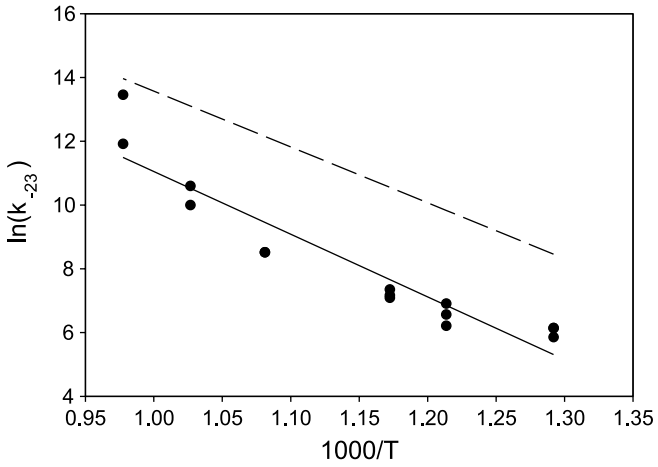
experimentally. The reaction that has the dominant effect on this reduction in C_4H_8 yield is

[5] 1-$C_4H_8 \rightarrow CH_3 + C_3H_5$



The sensitivity to this reaction is quite small at the lower temperatures. However, it has a sufficiently sensitive effect at the higher temperatures that inaccuracy in the value of k_5 could have an appreciable effect on the accuracy of the adjusted values of k_{28}. The other additional reactions which intervene at the higher temperatures are generally nearly equilibrated and their effect is largely due to thermochemical control rather than kinetic control.

The rate constants for reaction [28] obtained with the model are listed in Table 4 and plotted in Arrhenius form in Fig. 4. Also plotted in that figure are an Arrhenius fit to the experimental measurements by Lin and Back (44) and a single point measured at 900 K by MacKenzie et al. (11) as well as a line representing an estimate by Dean (24) of the Arrhenius parameters for this reaction. Our rate constants are in good agreement with the experimental results and roughly a factor of three above Dean's estimate. There is no apparent dependence of the rate constants on pressure within the precision of the data over the range of experimental conditions examined. An Arrhenius fit to our data leads to a

Table 5. Rate constants for $C_4H_7 \rightarrow C_4H_6$ + H.

preexponential factor of 2.97×10^{12} s^{-1} and an activation energy of 142 kJ mol^{-1} for reaction [28]. This analysis is restricted to temperatures at and below 925 K because of the lack of measured yields of 1-C_4H_8 at the higher temperatures.

Butadiene is formed in the following sequence of reactions.

[17] $C_2H_3 + C_2H_4 \rightarrow C_4H_7$

[–23] $C_4H_7 \rightarrow C_4H_6 + H$

Neither reaction has well established kinetic parameters and the thermochemistry of the C_2H_3 radical is not as accurately known as that of C_2H_5 which played a significant role in determining the yields of C_2H_6, C_3H_6, and 1-C_4H_8. Reaction [17] plays a role in the production of several of the measured reaction products and this role varies with temperature. The rationale for estimating the rate constants for reactions [17] and [–17] was presented earlier. At the lower temperatures, the yield of C_4H_6 is not sensitive to the values of k_{17} and k_{-17} while at the higher temperatures the sensitiv-

© 2000 NRC Canada

ity to both reactions increases, with the positive sensitivity to k_{17} being significantly compensated by the negative sensitivity to k_{-17}. At the lower temperatures, the sensitivity to reaction [–23] dominates, therefore adjustment of k_{-23} provides a sensitive and selective means of fitting the calculated yield of C_4H_6 to the experimental yield. However, the sensitivity of this adjustment decreases with increasing temperature and is dependent to some degree on the estimates of kinetic parameters for reactions [17] and [–17]. For these reasons, the rate constants used for reaction [–23] in fitting the calculated yields of C_4H_6 to the experimental data are perhaps best regarded as estimates which may depend significantly on other parameters related to the reactions of C_2H_3 and C_4H_7.

The values of k_{-23} which provided agreement with the measured yields of C_4H_6 are presented in Table 5 and Fig. 5. Also shown in the figure is a line calculated from the Arrhenius parameters for reaction [–23] estimated by Weissman and Benson (40). Our results are approximately a factor of seven lower than their estimate with about the same activation energy. Our scatter is fairly large at the highest temperatures, possibly reflecting a problem resulting from the increased complexity of the dependence of the C_4H_6 yield on other reactions in the model. The uncertainty in the values of the kinetic parameters for some of the other reactions of C_2H_3 and C_4H_7 will almost certainly have a bearing on this behaviour. However, with these reservations in mind, our rate constants lead to an activation energy of 160 kJ mol^{-1} and a preexponential factor of 2.2×10^{13} s^{-1}, both of which are consistent with results for other hydrogen atom elimination reactions of hydrocarbon free radicals.

The model presented here provides a relatively concise description of the pyrolysis of ethylene at temperatures from about 750 to 1000 K. The rate constants obtained by fitting the yields calculated with the model to those measured experimentally give acceptable to good fits to Arrhenius plots. The parameters obtained from these plots are in excellent agreement with work in the literature where such comparisons are possible. The temperature dependence for the isomerization of the 1-C_4H_9 radical has been assessed for the first time. The results are in excellent agreement with a single published value of the rate constant at 900 K and lead to an expected large activation energy for the reaction. The isomerization appears to be in its falloff region at the lower temperatures at which it was examined. An estimate of the temperature dependence for the decomposition of the C_4H_7 radical to butadiene has been made which is in reasonable agreement with an estimate in the literature based on thermochemistry and group additivity. Work is needed to better define the thermochemistry of the C_2H_3 radical and the kinetics of its reactions in the presence of ethylene so that some of the uncertainties, particularly relative to the description of the yields of C_4H_6, can be resolved.

Acknowledgements

The experimental work upon which the model is based was supported by funding from the Department of Energy, Mines and Resources Canada. General support for the modelling was provided by an operating grant from the Natural Sciences and Engineering Research Council Canada.

Structure of 8-[4′-(3″-nitrobenzamido)benzamido]naphthalene-1,3,6-trisulfonate (NF-033), and molecular basis of its cellular toxicity

Arthur Camerman, Donald Mastropaolo, Peter Nickel, Andrew Hempel, and Norman Camerman

Abstract: The title compound is one of a large number of compounds related to the drug suramin which have been found to have anti-HIV properties. However, its toxicity to uninfected cells is high. We crystallized the compound, determined its structure, and investigated the molecular basis for its high toxicity. The crystals are monoclinic, *C*2/*c*, a = 28.614(1), b = 10.031(0), c = 24.051(1) Å, β = 98.36(2)°, Z = 8, convergence at R = 0.066 for 4264 reflections with $I > 2\sigma(I)$. The oxygen atoms of one of the sulfonate groups are disordered, as are several water molecules. Stereochemical comparisons with a segment of B-DNA have yielded a plausible explanation for the molecule's toxicity.

Key words: crystal structure, cellular toxicity, stereochemistry, NF-033.

Résumé : Le composé mentionné dans le titre est l'un de plusieurs composés apparentés à la suramine qui présente des propriétés anti-HIV. Toutefois, sa toxicité par rapport aux cellules qui ne sont pas infectées est élevée. On a cristallisé ce composé, on en a déterminé la structure et essayé de déterminer les bases moléculaires de sa toxicité élevée. Les cristaux sont monocliniques, groupe d'espace *C*2/*c*, avec a = 28,614(1), b = 10,031(0) et c = 24,051(1) Å, β = 98,36(2)°, Z = 8 et R = 0,066 pour 4264 réflexions avec $I > 2\sigma(I)$. Les atomes d'oxygène de l'un des groupes sulfonates sont désordonnés et c'est aussi le cas pour plusieurs molécules d'eau. Les comparaisons stéréochimiques avec un segment d'ADN-B ont permis de fournir une explication plausible pour la toxicité de la molécule.

Mots clés : structure cristalline, toxicité cellulaire, stéréochimie, NF-033.

Introduction

Suramin is a well-known antiprotozoal agent. Interest with respect to use in AIDS occurred because it had been reported (1) that suramin was a potent competitive inhibitor of the reverse transcriptase of a number of animal retroviruses. *In vitro* effectivity of suramin against HIV-1 virus in clinical doses was demonstrated (2) and short term clinical trials showed virustatic activity *in vivo* (3, 4). In the course of clinical trials for treatment of AIDS, suramin exhibited activity against both HIV-associated lymphoma and cutaneous Kaposi sarcoma (5), generating interest in the compound as a potential anticancer drug. Subsequently, clinical trials have shown suramin to have benefit in the treatment of a number of types of cancers, including some which are refractory to other treatments (6–11). A serious drawback to all suramin uses, however, is the drug's toxicity, which can be potentially life-threatening at the levels at which it is used for clinical chemotherapy. Suramin is thought to inhibit retroviruses by binding to the template/primer binding site of viral reverse transcriptase (RT) (1, 12); its toxicity results from similar binding to cellular DNA polymerases and other DNA-binding enzymes (12–14).

In an attempt to create more effective drugs, a large number of suramin derivatives have been synthesized and tested for their ability to inhibit HIV-1 RT, and for their toxicity to uninfected cells (15). The title compound, designated NF-033, had an anti-RT ID_{50} comparable to suramin, but was tenfold more toxic; indeed its toxicity in uninfected cells was the highest of all the analogues tested. We undertook crystallization and structure elucidation of NF-033 in order to investigate the stereochemical bases for its high toxicity.

Experimental

The structure was initially determined from room-temperature X-ray diffraction data. Because of some disorder, the data were recollected at low temperature, but the

disorder remained. We report the results of the low temperature experiment.

Crystals were obtained by vapor diffusion of dioxane into an aqueous solution of NF-033. Data were collected at 96 K using a Nonius Kappa CCD diffractometer with rotating anode, MoK$_\alpha$ radiation and Nonius Kappa CCD software. The unit cell parameters were determined by a least-squares fit of the angular settings of all collected reflections. Processing was carried out using Denzo-SMN package (16). A total of 6912 unique reflections were measured and used in the structure analysis and refinement. The structure was solved and refined by SHELX97.[2] All non-hydrogen atoms, except for the water molecules and disordered oxygen atoms at S(3), were found from the best solution E-map. Refinement was by full-matrix least squares. Subsequently eight water molecules, six with partial occupancies, and six oxygen atoms of the disordered SO_3 group, also with partial occupancies, were found from a difference map. Hydrogen atoms positions were calculated geometrically and during the refinement were riding on parent atoms. No hydrogen atoms were fitted to water molecule oxygens. Crystal data and other pertinent information are presented in Table 1.[3]

Fig. 1. Labeled drawing of the molecular structure of the sodium salt of NF-033. Water molecules have been omitted for clarity.

Dispersion corrections and absorption coefficients were taken from International Tables for Crystallography (17), tables 6.1.1.4, 4.2.6.8, and 4.2.4.2 respectively. The final *R* factor converged at *R* = 0.066 for 4264 observed reflections with $I > 2\sigma(I)$, and *R* = 0.108 for all 6912 unique reflections. Atom coordinates and equivalent isotropic thermal parameters are shown in Table 2.

Results and discussion

Crystal and molecular structures

The asymmetric unit of the crystal consists of one molecule of NF-033, three sodium ions, and eight water molecules of which six have partial occupancies. The structure of NF-033 is shown in Fig. 1. The molecule consists of a naphthalene ring system and two phenyl rings, each linked by amide bonds, and overall the molecule is basically planar. The root mean square deviation of the atoms in the best plane passing through the three ring systems is 0.13 Å, and the maximum atomic deviation of the ring atoms from this plane is 0.28 Å (C(13)). The nitro group oxygen atoms are also coplanar with the phenyl ring; this is a consequence of the molecular packing, and to some degree π-electrons delocalization. The two amide groupings are also planar, and remarkably coplanar with each other. They are, however, not coplanar with the ring systems; calculation of all ring-amide torsion angles showed the terminal phenyl ring to be tilted about 33° to the amide, the middle phenyl ring to be tilted about 25.5° to each amide,

[a] U_{eq} = 1/3 (trace of the orthogonalized U_{ij} matrix).

and the naphthyl system to be tilted about 37.5° to the amide. These molecular features are shown in Fig. 2.

The 3-sulfonate group is disordered, with each oxygen atom occupying two positions at approximate ratios of 65:35. Bond lengths and angles in the rest of the molecule have normal values; the C—N distances of 1.354 and 1.362 Å reflect the delocalized character of the amide bonds. The negative charge at each SO_3 group is delocalized over the oxygen atoms. There is one intramolecular hydrogen bond in the structure, N(8)-H(8)···O(1A), with N···O distance of 2.75 Å and N-H···O angle of 152°. The other amide nitrogen is a donor in an intermolecular hydrogen bond, N(15)-H(15)···O(1C), with N···O distance of 2.81 Å and N-H···O angle of 150°.

Two sodium cations occupy general positions while the third occupies two special crystallographic positions with 0.5 occupancy in each. Each sodium ion is coordinated with six sulfonate, water and nitro group oxygen atoms, at distances ranging from 2.29–2.62 Å. Two water molecules (W1 and W2) are fully present in the crystal, while the other six have partial occupancies ranging from 0.25 to 0.76. Water oxygens O(W1)–O(W4) interact with sodium ions; the other water molecules do not appear to form intermolecular interactions.

Molecules of NF-033 are held together in dimers by two intermolecular hydrogen bonds and by extensive aromatic ring stacking involving nitrophenyl–naphthyl, phenyl–phenyl, and amide–amide π-electron interactions (Fig. 3). Parallel sets of dimers are stacked in infinite sheet structures, parallel to the (**a**, **b**) plane, held together within sheets by similar π-electron interactions. The sulfonic acid groups extend above and below the sheets; the spaces between sheets are occupied by the sodium ions and water molecules, which connect sheets through interactions with the sulfonates.

Molecular basis of toxicity

If the toxicity to uninfected cells of these types of compounds arises from binding to DNA-binding enzymes, it is likely the compounds bear stereochemical resemblance to DNA, although any such resemblance is not immediately obvious from the chemical structures. In order to reveal stereochemical similarities we have performed molecular superposition studies of NF-033 with segments of the sugar-phosphate backbone of a single strand of B-DNA.[4] The re-

[4] NF-033 was overlapped on a 3-nucleotide segment of a single strand of B-DNA by superposing the central C-C-N atoms of NF-033 with the B-DNA center O-P-O phosphate. In addition, to bring the ends of the molecules into the same plane, a naphthalene sulfonate S atom was superposed with a terminal DNA phosphorus atom. Two rotations were made to the NF-033 crystal structure conformation, both were 180° about C—C single bonds, thus leaving NF-033 planarity and conformational energy unchanged. These rotations brought an NF-033 carbonyl O and the terminal nitro group into approximation with a DNA phosphate oxygen and terminal phosphate group respectively.

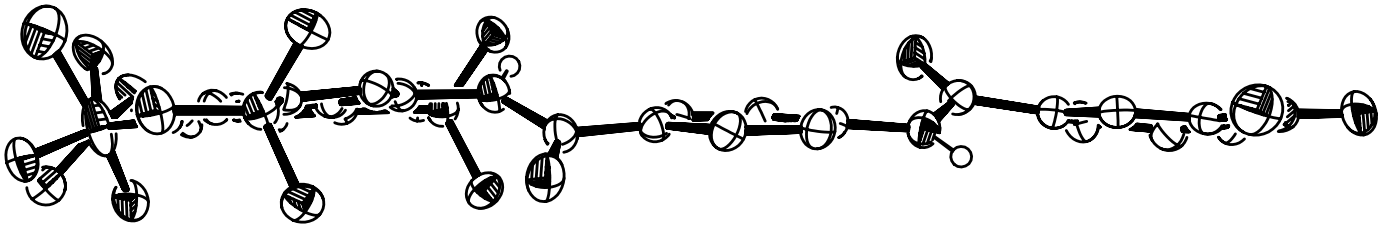

Fig. 3. Stereoscopic view of arrangement of NF-033 molecules as dimers.

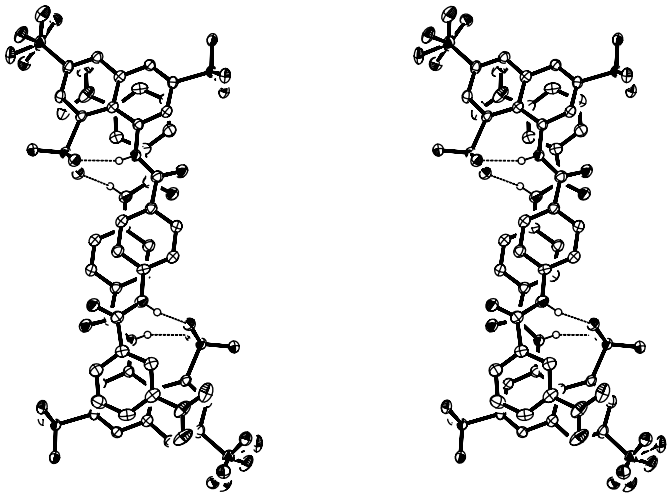

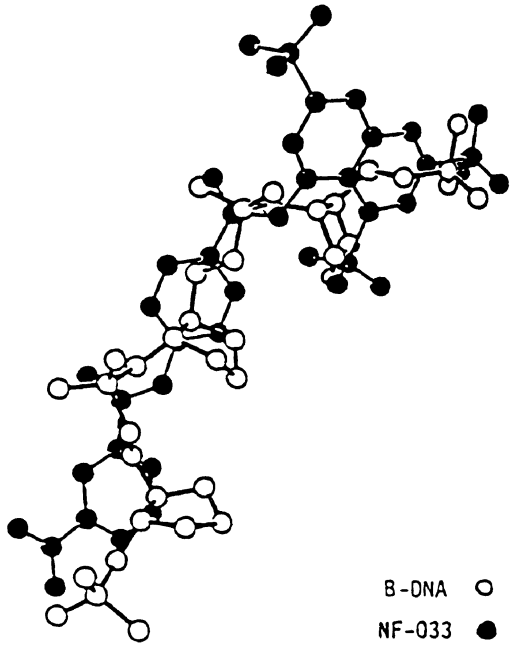

Fig. 4. Molecular superposition of NF-033 and a segment of the sugar-phosphate backbone of a single strand of B-DNA.

sults are shown in Fig. 4. Inspection of the figure reveals that NF-033's planar conformation fits the B-DNA helical conformation very well. Firstly, the molecular length of NF-033 is almost identical to the length of a three nucleotide segment of B-DNA. Secondly, there are close positionings of a number of chemically similar groups in the two molecules: the 3-sulfonate group with a DNA phosphate, a 1-sulfonate oxygen atom with a sugar hydroxyl oxygen, amide carbonyl oxygens with phosphate oxygens, and the NF-033 nitro group with a DNA phosphate. Additionally, the two phenyl groups in NF-033 are in the same neighborhoods as sugar rings in DNA. The molecular fits could possibly be additionally optimized by more extensive fitting procedures which allow for molecular flexibilities, but the fit is sufficient at this level to provide a plausible explanation of the molecular basis for NF-033 toxicity to uninfected cells, because the stereochemical similarities suggest how the molecule could interact with DNA polymerase and other DNA-binding enzymes. The results also indicate approaches to reducing toxicity in these molecules, by altering features which superpose with stereochemically similar groups in DNA.

New abietane diterpenoids from the cones of *Larix kaempferi*

Hironori Ohtsu, Reiko Tanaka, Yasuko In, Shunyo Matsunaga, Harukuni Tokuda, and Hoyoku Nishino

Abstract: A new podocarpane diterpene, 7α,15-dihydroxypodocarp-8(14)-en-13-one (**1**) and eight new abietane diterpenes, abiet-8(14)-en-7α,13β,15,18-tetraol (**2**), 7α,13β,15-trihydroxyabiet-8(14)-en-18-oic acid (**3**), 13β,18-dihydroxyabiet-8(14)-en-7-one (**4**), 13β,15,18-trihydroxyabiet-8(14)-en-7-one (**5**), 7-oxo-13β-methoxyabiet-8(14)-en-18-oic acid (**7**), abiet-8(14)-en-7α,12α,13β,18-tetraol (**8**), 7α,12α,13β-trihydroxyabiet-8(14)-en-18-oic acid (**9**), and abiet-8(14)-en-7α,12α,13β,15,18-pentaol (**10**) were isolated from the $CHCl_3$ extract of the cones of *Larix kaempferi*. Their structures were determined on the basis of chemical and spectral evidence. The inhibitory effects of compounds **1–4** and **7–9** on Epstein–Barr virus early antigen (EBV–EA) activation induced by the tumor promoter, 12-*O*-tetradecanoylphorbol-13-acetate (TPA), were examined for a primary screening for anti-tumor promotors.

Key words: *Larix kaempferi*, Pinaceae, cones, abietane, EBV–EA.

Résumé : L'extraction au $CHCl_3$ de cônes de *Larix kaempferi* a permis d'isoler un nouveau diterpène de la série du podocarpane, le 7α,15-dihydroxypodocarp-8(14)-én-13-one (**1**) ainsi que huit nouveaux diterpènes de la série de l'abiétane, abiét-8(14)-ène-7α,13,β,15,18-tétraol (**2**), acide 7α,13β,15-trihydroxyabiét-8(14)-énoïque (**3**), 13β,18-dihydroxyabiét-8(14)-én-7-one (**4**), acide 13β,15,18-trihydroxyabiét-8(14)-én-7-one (**5**) 7-oxo-13β-méthoxyabiét08(14)-én-18-oïque (**7**), abiét-8(14)-ène-7α,12α,13β,18-tétraol (**8**), acide 7α,12α,13β-trihydroxyabiét-8(14)-én-18-oïque (**9**) et abiét-8(14)-ène-7α,12α,13β,15,18-pentaol (**10**). On a déterminé les structures en se basant sur des données chimiques et spectroscopiques. À titre d'évaluation primaire comme promoteurs d'effets antitumoraux, on a examiné les effets inhibiteurs des composés **1–4** et **7–9** sur l'activation de l'antigène primaire du virus d'Epstein–Barr (« EBV–EA ») induite par le promoteur tumoral, le 13-acétate de 12-*O*-tétradécanoylphorbol (« TPA »).

Mots clés : *Larix kaempferi*, Pinaceae, cônes, abiétane, « EBV–EA ».

[Traduit par la Rédaction]

Introduction

We have focused our attention on the biologically active constituents of the leaves, cones, and bark of coniferous trees which have been treated as wastes in the forestry industry. During the investigation of the chemical constituents of Pinaceae plants, we had reported that the leaves and bark of *Larix kaempferi* contained three new abietane-type diterpenes (1) and new cycloartane and lanostane-type triterpenes (2). Furthermore, we recently reported the isolation and structural elucidation of five new abietane-type diterpenes from the $CHCl_3$ extract of the cones of this tree (3, 4). Further fractionation of the extract led to the isolation of a new podocarpane diterpene (**1**) and eight new highly oxygenated abietane diterpenes (**2–5** and **7–10**), together with a known compound, 7-oxo-13β-hydroxyabiet-8(14)-en-18-oic acid (**6**).

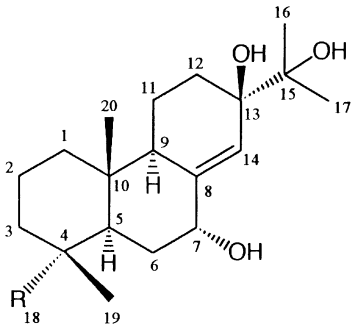
This paper deals with the structural elucidation of these new compounds. The inhibitory effects of compounds **1–4** and **7–9** on Epstein–Barr virus early antigen (EBV–EA) activation induced by the tumor promoter, 12-*O*-tetradecanoylphorbol-13-acetate (TPA), were examined for a primary screening for anti-tumor-promotors.

Results and discussion



The preliminary silica gel column chromatography of the $CHCl_3$ extract of *L. kaempferi* had been reported previously (3). Rechromatography of EtOAc–MeOH (10:1) eluate (11.34 g) on silica gel, reversed-phase silica gel (ODS), and HPLC (ODS) furnished nine new diterpenes **1–5** and **7–10** as well as a known abietane (**6**). The known compound **6** was identified as 7-oxo-13β-hydroxyabiet-8(14)-en-18-oic acid by a comparison with literature data (5).

Compound **1** was assigned the molecular formula $C_{17}H_{26}O_3$ by HREIMS. The UV and IR spectra showed the presence of a hydroxyl group (ν_{max} 3375 cm^{-1}), an α,β-unsaturated ketone (λ_{max} 237 nm; ν_{max} 1684 cm^{-1}), and a trisubstituted double bond (ν_{max} 837 cm^{-1}). The ^1H and ^{13}C NMR spectra of **1** (Tables 1 and 2) revealed signals for two tertiary methyl groups, six methylene groups, two methine groups, two sp^3 quaternary carbons, an oxygenated methylene (δ_H 2.93 and 3.51 (each 1H, d, J = 11.0 Hz) ppm; δ_C

9 R^1 = COOH, R^2 = H

10 $R^1 = CH_2OH$, R^2 = OH

70.2 (t) ppm), an oxygenated methine (δ_H 4.36 (1H, t, J = 3.0 Hz) ppm; δ_C 71.4 (d) ppm), and an α,β-unsaturated ketone (δ_H 5.94 (1H, d, J = 2.0 Hz) ppm; δ_C 127.5 (d), 164.1 (s), and 201.1 (s) ppm). Compound **1** was deduced to have one primary and one secondary hydroxyl group because treatment of **1** with Ac_2O-pyridine afforded a diacetate (**1a**). The planar structure of **1** was determined by a combination of ^1H–^1H COSY, HMQC and HMBC spectra (Fig. 1), which proved that **1** had a podocarpane skeleton bearing a primary hydroxyl group at C-4, a secondary hydroxyl group at C-7, and an α,β-unsaturated ketone at C-8(14)-13 positions. The relative stereochemistry of **1** was determined by NOESY experiment. In the NOESY spectrum, significant NOEs were observed for: (*i*) H-16 with H-17, (*ii*) H-7 with H-6α and H-6β, and (*iii*) a hydroxymethyl signal with H-3α and H-5α. Thus, the primary hydroxyl group was located at C-15, and the C-7 hydroxyl group had α-configuration. The absolute structure of **1** was determined by the CD exciton chirality method (6). As illustrated in Scheme 1, after protection of the primary hydroxyl group of **1** with a *t*-butyldimethylsilyl group, compound **1** was derived to *p*-chlorobenzoate (**1c**) (Scheme 1). The CD spectrum of **1c** (Fig. 2) showed a negative Cotton effect curve at 245 nm (Δε –20.4) and 223 nm (Δε +15.7). Therefore, the absolute configuration of C-7 of **1** was proved to be *R*, and the absolute stereostructure was as formulated in **1**.

HREIMS analysis of compound **2** revealed the molecular formula to be $C_{20}H_{34}O_4$. Its IR spectrum showed strong absorption for hydroxyl groups (ν_{max} 3340 cm^{-1}) and a trisubstituted double bond (ν_{max} 840 cm^{-1}). The ^1H and ^{13}C NMR spectra (Tables 1 and 2) suggested the presence of two tertiary methyl groups, a hydroxyisopropyl group (δ_H 1.18 and 1.23 (each 3H, s) ppm; δ_C 24.7 (q), 24.8 (q) and 76.0 (s) ppm), six methylene groups, two methine groups, two sp^3 quaternary carbons, a trisubstituted double bond, a primary hydroxyl group, a secondary hydroxyl group, and an oxygenated sp^3 quaternary carbon (δ_C 74.3 (s) ppm). Acetylation of **2** in usual manner gave a diacetate (**2a**). The molecular formula of compound **3** was assigned as $C_{20}H_{32}O_5$ by HREIMS and DEPT data. The IR spectrum suggested the presence of a carboxyl group (ν_{max} 3668–2869, 1697 cm^{-1}), and this was supported by esterification of **3** with diazomethane to afford a methyl ester (**3a**). The ^1H and ^{13}C NMR data of **3** closely resembled those of **2** except for the presence of a carboxyl group instead of a primary hydroxyl group in **2**. The relative structures of **2** and **3** were determined by analyzing their ^1H–^1H COSY, HMQC and HMBC spectra (Fig. 3), and the X-ray crystallographic analysis of **3** (Fig. 4). Then, the relative structures of **2** and **3** were proved to be abiet-8(14)-en-7α,13β,15,18-tetraol and 7α,13β,15-trihydroxyabiet-8(14)-en-18-oic acid, respectively. The absolute structures of **2** and **3** were determined by the following

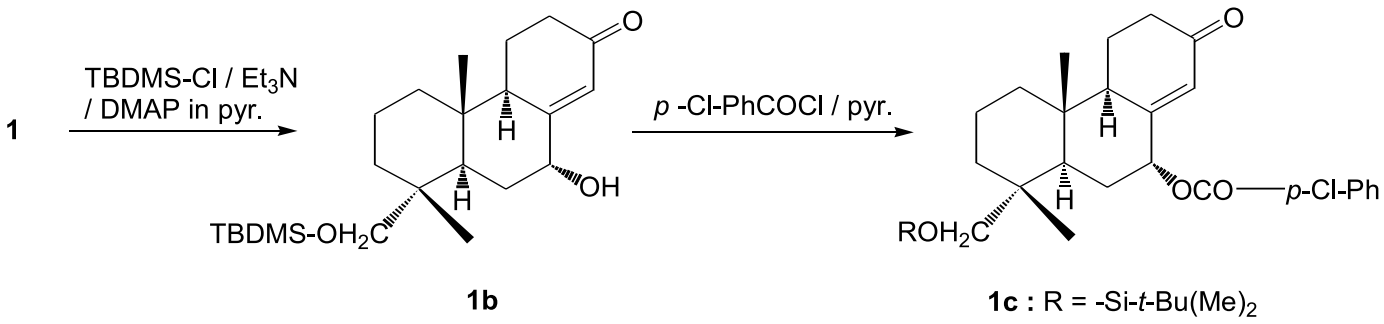
[a]Compounds **1**, **4**, and **5** were measured in $CDCl_3$, and **2** and **3** were measured in CD_3OD. δ in ppm; *J* (in parentheses) in Hz; assignments from ^{1}H–^{1}H COSY, HMQC, HMBC, and NOESY data.

chemical reactions: reduction of **3a** with $LiAlH_4$ gave compound **2**, followed by oxidation with $NaIO_4$ in CH_2Cl_2-H_2O to afford compound **1**. This chemical correlation indicated that the absolute structures of **2** and **3** were as formulated (Scheme 2).

Compound **4** was assigned the molecular formula $C_{20}H_{32}O_3$ by HREIMS. The UV and IR spectra showed the presence of hydroxyl groups (ν_{max} 3410 cm^{-1}), an α,β-unsaturated ketone (λ_{max} 245 nm; ν_{max} 1676 cm^{-1}), and a trisubstituted double bond (ν_{max} 1611 and 840 cm^{-1}). Signals were observed for two tertiary methyl groups, an isopropyl group, six methylenes, two methines, two quaternary carbons, a primary hydroxyl group (δ_H 3.11 and 3.37 (each 1H, d, *J* = 11.0 Hz) ppm; δ_C 70.8 (t) ppm), a tertiary hydroxyl group (δ_C 71.8 (s) ppm), and an α,β-unsaturated ketone (δ_C 200.4 (s) ppm) in the ^{1}H and ^{13}C NMR spectra (Tables 1 and 2). These spectral data were similar to those of a known compound, 7-oxo-13β-hydroxyabiet-8(14)-en-18-oic acid (**6**), except for the presence of a primary hydroxyl group instead of a carboxyl group of **6**. The HMBC data of **4** are listed in Table 1. From these spectral data, the structure of **4** was proved to be 13β,18-dihydroxyabiet-8(14)-en-7-one, the C-18 hydroxyl analog of **6**.



Compound **5** has the molecular formula $C_{20}H_{32}O_4$ by HREIMS and DEPT data. The ^{1}H and ^{13}C NMR data of **5** (Tables 1 and 2) closely resembled those of **4**, although two tertiary methyl signals of a hydroxyisopropyl group (δ_H 1.15 and 1.24 (each 3H, s) ppm; δ_C 23.9 and 24.7 (each q), 74.7 (s) ppm) were observed in **5** instead of an isopropyl group of **4**. These spectral data indicated that **5** should be a 15-hydroxyl derivative of **4**. This structure was supported by the HMBC spectrum of **5**. Therefore, the structure of **5** was proved to be 13β,15,18-trihydroxyabiet-8(14)-en-7-one.

Compound **7** was assigned the molecular formula $C_{21}H_{32}O_4$ by HREIMS. The IR, ^{1}H, and ^{13}C NMR spectra of **7** (Tables 2 and 3) were very similar to those of **6**, except that a tertiary methoxyl signal (δ_H 3.12 (3H, s) ppm; δ_C 75.5 (s) ppm) was observed in **7** instead of a tertiary hydroxyl group at C-13 in **6**. The EIMS spectrum of **7** showed a fragment ion peak at *m/z* 316.2009 corresponding to the loss of MeOH from the molecular ion. The linkage position for the methoxyl group was established as C-13 by HMBC correlation for the methoxyl proton to C-13, and the configuration of the methoxyl group was determined to be β because the methoxyl proton showed NOEs with H-11β and H-12β in the NOESY experiment. Therefore, the structure of **7** was proved to be 7-oxo-13β-methoxyabiet-8(14)-en-18-oic acid.

Compounds **8** and **9** have the molecular formula $C_{20}H_{34}O_4$ and $C_{20}H_{32}O_5$, respectively, based on the HREIMS and DEPT data. Acetylation of **8** with Ac_2O-pyridine gave a triacetate (**8a**), while **9** gave a methyl ester (**9a**) on treatment with diazomethane. The ^{1}H and ^{13}C NMR data (Tables 2 and 3) of **8** and **9** were similar, except for the presence of signals for a primary hydroxyl group (δ_H 2.99 and 3.37 (each d, *J* =

11.5 Hz) ppm; δ_C 71.9 (t) ppm) in **8**, and a carboxyl group (δ_C 184.5 (s) ppm) in **9**. The signals observed in common in their NMR spectra were as follows: two tertiary methyl groups, an isopropyl group, five methylene groups, two methine groups, two sp^3 quaternary carbons, two secondary hydroxyl group, a tertiary hydroxyl group, and a trisubstituted double bond. Comparison of these signal patterns with those of **2** and **3** showed that compounds **8** and **9** also contained 7α,13β-dihydroxyabiet-8(14)-en systems in their molecules. The secondary hydroxyl groups of **8** and **9** which appeared at δ_H 3.82 ppm were attributable to C-12 positions because these signals showed cross-correlations with C-9, C-11 and C-13 in the HMBC spectra. Configuration of the C-12 hydroxyl groups were determined to be α, based on the significant NOEs for H-12 with H-11α and H-11β in the NOESY experiments of **8** and **9** (Fig. 5). Therefore, the relative structures of **8** and **9** were elucidated as abiet-8(14)-en-7α,12α,13β,18-tetraol and 7α,12α,13β-trihydroxyabiet-8(14)-en-18-oic acid, respectively. The absolute structures of **8** and **9** were determined by CD spectra. Compounds **8** and **9a** were treated with benzoyl chloride in pyridine to give corresponding

[a]Compounds **1**, **4**, **5**, and **7** were measured in $CDCl_3$, and **2**, **3**, and **8–10** were measured in CD_3OD. Assignments from DEPT, HMQC, and HMBC data.

Fig. 3. ^1H–^1H COSY (——) and HMBC (→) correlations for **2** and **3**.

2 : R = CH_2OH
3 : R = COOH

Fig. 4. ORTEP drawing of **3**.

tribenzoate (**8b**) and dibenzoate (**9b**), respectively (Scheme 3). The CD spectra of **8b** and **9b** (Fig. 6) showed the negative Cotton effects at 231 nm ($\Delta\varepsilon$ –22.7 and –15.7) which were in agreement with the wavelength of the allyl benzoate (7). Therefore, the absolute configurations of C-7 in **8b** and **9b** were proved to be *R*, and the absolute structures of **8** and **9** were established as depicted.

Compound **10**, the most polar substance in this series, was assigned the molecular formula $C_{20}H_{34}O_5$ by HREIMS and DEPT data. The ^1H and ^{13}C NMR spectra of **10** (Tables 2 and 3) were very similar to those of **2** and **8**. An oxygenated methylene signal at δ_H 3.00 and 3.38 ppm closely matched the H-18 signals of **2** and **8**, a signal at δ_H 4.23 ppm closely matched the H-7β signal of **2**, and a signal of δ_H 4.02 ppm matched the H-12β signal of **8**. Two tertiary methyl signals at 1.28 and 1.34 ppm were assigned to methyl signals of a hydroxyisopropyl group at C-13. Therefore **10** had hydroxyls at C-7α, C-12α, C-13β, C-15 and C-18, and the structure of **10** was proved to be abiet-8(14)-en-7α,12α,13β,15,18-pentaol.

Compounds **1–5** and **7–10** are new natural products and they all bear the abiet-8(14)-ene skeleton as a common structural unit. Among these compounds, the tetraols (**2** and **8**) and the pentaol (**10**), highly oxygenated abietanes having hydroxyls at C-7, C-12, C-13 C-15 and C-18 positions, are rare in nature.

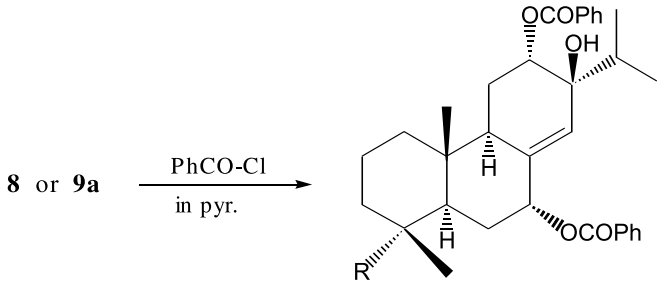
9 : R = COOH

Fig. 6. CD spectra of **8b** (– – –) and **9b** (——) in EtOH.

The inhibitory effects of **1–4** and **7–9** on EBV–EA activation induced by TPA were examined for a primary screening of anti-tumor-promoting activities and the results are shown in Table 4. All these compounds preserved the high viability of Raji cells, and showed moderate inhibitory effects on EBV–EA activation. Among them, compound **7** exhibited the most significant inhibitory effects on the activation (100% inhibition of activation at 1000 mol ratio/TPA, and more than 50% inhibition at 500 mol ratio/TPA), and was found to be more effective than that of β-carotene, a vitamin A precursor that has been intensively studied in cancer prevention using animal models (8).



Experimental section

General experimental procedures

Melting points were determined on a Yanagimoto micro-melting-point apparatus and are uncorrected. Optical rota-

tions were measured using a Jasco DIP-1000 digital polarimeter. UV spectra were recorded on a Hitachi 150-20 spectrophotometer and IR spectra were recorded using a Perkin-Elmer 1720X FT-IR spectrophotometer. CD spectra were recorded on a Jasco J-500A spectrometer. ^1H and ^{13}C NMR spectra were obtained on a Varian XL-300 and INOVA 500 spectrometer with standard pulse sequences operating at 300 and 500 MHz, and 74.5 and 125 MHz, respectively. EIMS and HREIMS were recorded on a Hitachi 4000H double focusing mass spectrometer (70 eV). Column chromatography was carried out over silica gel (70–230, and 230–400 mesh, Merck). Preparative HPLC was carried out using a TOSOH-system equipped with a CCPM-prep pump, a SC-8020 system controller, and a TSK-gel ODS-80Ts (21.5 × 300 mm). Fractions obtained from column chromatography were monitored by TLC (silica gel 60 F_{254}). Preparative TLC was carried out on Merck silica gel 60 F_{254} plates (20 × 20 cm, 0.5 mm in thickness).

Extraction and isolation

Fresh cones of *L. kaempferi* (1.45 kg), collected in July 1995, were cut off and treated with $CHCl_3$ (4 L × 5). The resulting $CHCl_3$ extract (123 g) was subjected to silica gel column chromatography (1). The EtOAc-MeOH (10:1) eluate (11.34 g), the most polar fraction in the preliminary silica gel column, was further subjected to silica gel column chromatography with EtOAc and EtOAc–MeOH (10:1 → 5:1) to yield EtOAc eluate (6.13 g) and EtOAc–MeOH (10:1) eluate (3.18 g). The EtOAc eluate was subjected to reversed-phase silica gel (ODS) column chromatography with MeOH–H_2O (75:25) and HPLC (ODS) with MeCN–H_2O (70:30) to give **1** (33 mg), **4** (25 mg), **5** (5 mg), **6** (106 mg), and **7** (18 mg). The EtOAc–MeOH (10:1) eluate was subjected to Sephadex LH-20 column chromatography with $CHCl_3$–MeOH (1:1) and ODS column chromatography with MeOH–H_2O (60:40) to yield **2** (25 mg), **3** (48 mg), **8** (6 mg), **9** (6 mg), and **10** (4 mg). Compound **6** was identified as 7-oxo-13β-hydroxyabiet-8(14)-en-18-oic acid by a comparison of its physical and spectral data with those reported in the literature (3).

*7α,15-Dihydroxypodocarp-8(14)-en-13-one (**1**):* Colorless needles, mp 153–154°C (*n*-hex-EtOAc); $[\alpha]_D^{23}$ –61.0°(*c* 0.44, EtOH); CD (*c* 7.81 × 10^{-5} M, EtOH) (Δε): 375 (0), 323 (–2.33), 260 (0) nm; UV (EtOH) λ_{max} (log ε): 237 (3.96) nm; IR (film) ν_{max}: 3375 (OH), 1684 (C=C-C=O), 1649, 1042, 837 (>C=CH-) cm^{-1}; ^1H and ^{13}C NMR: Tables 1 and 2; EIMS *m/z* (rel. int.): 278 $[M]^+$ (17), 260 (16), 151 (82), 123 (100), 81 (46), 67 (35); HREIMS *m/z*: 278.1882 $[M]^+$ (calcd. for $C_{17}H_{26}O_3$: 278.1880).

[a]Values represent relative percentages to the positive control value. TPA (32 pmol, 20 ng) = 100%. Values in parentheses are viability percentages of Raji cells.

*Acetylation of **1***

A mixture of compound **1** (5 mg) and Ac_2O (0.5 mL) in pyridine (0.5 mL) was kept at room temperature overnight. Evaporation of the solvent under reduced pressure gave a residue (6 mg), which was purified by preparative TLC (*n*-hex-EtOAc = 3:1) to furnish a diacetate (**1a**), 4.5 mg, as colorless oil, $C_{21}H_{30}O_5$; $[\alpha]_D^{23}$ –21.5°(*c* 0.28, EtOH); IR ν_{max} (film): 1735, 1732, 1237 (OAc), 1685 (>C=O), 835 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 0.87 (3H, s, H-17), 0.89 (3H, s, H-16), 2.04 and 2.08 (each 3H, s, -OCOMe × 2), 3.61 and 3.92 (each 1H, d, *J* = 11.0 Hz, H-15), 5.49 (1H, t, *J* = 3.0 Hz, H-7 β), 6.08 (1H, d, *J* = 2.0 Hz, H-14) ppm; ^{13}C NMR ($CDCl_3$) δ: 15.9 (q, C-17), 17.7 (q, C-16), 17.9 (t, C-2), 20.4 (t, C-11), 20.9 and 21.4 (each q, -OCO*Me* × 2), 27.6 (t, C-6), 35.6 (t, C-3), 36.4 (s, C-4). 36.6 (t, C-12), 38.5 (t, C-1), 39.0 (s, C-10), 41.6 (d, C-5), 47.9 (d, C-9), 72.0 (t, C-15), 73.0 (d, C-7), 130.0 (d, C-14), 157.6 (s, C-8), 169.5 and 170.8 (each s, -O*C*OMe × 2), 199.9 (s, C-13) ppm; EIMS *m/z* (rel. int.): 362 $[M]^+$ (4), 320 (17), 302 (100), 260 (17), 242 (79), 229 (83), 121 (41), 43 (88).

Preparation of p-*chlorobenzoate (**1c**)*

A mixture of **1** (12 mg), Et_3N (10 μL), DMAP (3 mg), and TBDMS-Cl (10 mg) in dry CH_2Cl_2 (2 mL) was stirred for 48 h at room temperature. The reaction mixture was diluted with Et_2O and washed successively with aqueous $NaHCO_3$ and saturated brine solution, and dried with Na_2SO_4. The organic layer was concentrated under reduced pressure to give a residue (13 mg). Purification of the residue by preparative TLC (*n*-hex-EtOAc = 3:1) afforded a TBDMS ether of **1** (**1b**), 6 mg and **1**, 5 mg. **1b**: colorless oil, $C_{23}H_{40}O_3Si$; EIMS *m/z* (rel. int.): 392 $[M]^+$ (1), 376 (1), 349 (3), 335 (48), 305 (25), 243 (55), 148 (63), 105 (27), 75 (100). A solution of **1b** (4.8 mg) and *p*-chlorobenzoyl chloride (20 μL) in pyridine was stirred at room temperature for 24 h. After evaporation of the solvent under reduced pressure, the resulting product was purified by preparative TLC (*n*-hex-EtOAc = 3:1) to yield a *p*-chlorobenzoate (**1c**), 3.6 mg, as colorless oil, $C_{30}H_{43}O_4SiCl$; $[\alpha]_D^{23}$ –66.9°(*c* 0.28, $CHCl_3$); CD (*c* 8.40 × 10^{-5} M, EtOH) (Δε): 380 (0),

*Acetylation of **2***

A solution of **2** (6 mg) and Ac_2O (0.2 mL) in pyridine (0.2 mL) was kept at room temperature overnight. Work-up as usual afforded a residue (9 mg), which was purified by preparative TLC (*n*-hex-EtOAc = 1:2) to give a diacetate (**2a**), 5.2 mg, as colorless oil, $C_{24}H_{38}O_6$; $[\alpha]_D^{23}$ +26.5°(*c* 0.36, $CHCl_3$); IR (film) ν_{max}: 3473 (OH), 2929, 1738, 1733, 1245 (OAc), 839 (>C=CH-) cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 0.82 (3H, s, H-20), 0.88 (3H, s, H-19), 1.98 and 2.07 (each 3H, s, -OCOMe × 2), 3.60 and 3.90 (each 1H, d, *J* = 11.5 Hz, H-18), 5.36 (1H, t, *J* = 3.0 Hz, H-7β), 6.11 (1H, br s, H-14) ppm; ^{13}C NMR ($CDCl_3$) δ: 14.7 (q, C-20), 17.5 (t, C-11), 17.7 (q, C-19), 18.0 (t, C-2), 21.0 and 21.5 (each q, -OCO*Me* × 2), 24.2 and 24.3 (each q, C-16 and C-17), 27.5 (t, C-6), 29.3 (t, C-12), 35.8 (t, C-3), 36.3 (s, C-4), 37.6 (s, C-10), 38.5 (t, C-1), 41.8 (d, C-5), 47.7 (d, C-9), 72.3 (t, C-18), 73.6 (s, C-13), 74.6 (s, C-15), 74.7 (d, C-7), 131.2 (d, C-14), 140.3 (s, C-8), 169.9 and 170.9 (each q, -O*C*OMe × 2) ppm; EIMS *m/z* (rel. int.): 386 $[M - 2H_2O]^+$ (0.4), 363 (2), 344 (12), 326 (13), 304 (100), 244 (23), 229 (14).

*$NaIO_4$ oxidation of **2***

$NaIO_4$ (6 mg) was added to a solution of **2** (6 mg) in CH_2Cl_2–H_2O (3:1, 4 mL) and the mixture was stirred at room temperature for 24 h. After separation of the organic layer, the aqueous layer was extracted with CH_2Cl_2. The combined CH_2Cl_2 solution was dried with Na_2SO_4, and then concentrated. The resulting residue was purified by preparative TLC ($CHCl_3$–MeOH = 20:1) to afford a 13-keto derivative (4.2 mg), which was identical with compound **1**.

*7α,13β,15-Trihydroxyabiet-8(14)-en-18-oic acid (**3**)*: Colorless plates, $C_{20}H_{32}O_5$, mp 215–216°C (MeOH-H_2O); $[\alpha]_D^{23}$ –8.6° (*c* 0.64, EtOH); IR (film) ν_{max}: 3668–2869, 1697 (COOH), 3392 (OH), 841 (>C=CH-) cm^{-1}; ^{1}H and ^{13}C NMR: Tables 1 and 2; EIMS *m/z* (rel. int.): 316 $[M - 2H_2O]^+$ (100), 298 $[M - 3H_2O]^+$ (43), 276 (62), 270 (37), 237 (22), 183 (11), 150 (38), 110 (15); HREIMS *m/z*: 316.2027 $[M - 2H_2O]^+$ (calcd. for $C_{20}H_{28}O_3$: 316.2037).

*Methyl ester of compound **3** (**3a**)*

A solution of diazomethane in ether was added to a solution of **3** (15 mg) in ether (2 mL), and the mixture was allowed to stand over night. The removal of the solvent gave a residue (17 mg), which was purified by preparative TLC to give a methyl ester of **3** (**3a**), 14 mg, colorless oil, $C_{21}H_{34}O_5$; $[\alpha]_D^{23}$ –19.7° (*c* 0.27, $CHCl_3$); IR (film) ν_{max}: 3411 (OH), 1724, 1256 (COOMe), 1654, 831 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 0.80 (3H, s, H-20), 1.17 (3H, s, H-19), 1.21 and 1.24 (each 3H, s, H-16 and H-17), 3.68 (3H, s, -COO*Me*), 4.21 (1H, t, *J* = 3.0 Hz, H-7β), 6.02 (1H, br s, H-14) ppm; ^{13}C NMR ($CDCl_3$) δ: 15.1 (q, C-20), 17.7 (q, C-19), 18.0 (t, C-11), 18.7 (t, C-2), 25.1 (q × 2, C-16 and C-17), 32.4 (t, C-6), 37.6 (t, C-3), 38.3 (s, C-10), 38.8 (t, C-1), 42.4 (d, C-5), 47.7 (d, C-9), 47.6 (s, C-4), 52.8 (q, -COO*Me*), 73.2 (d, C-7), 74.5 (s, C-13), 75.3 (s, C-15), 129.0 (d, C-14), 146.0 (s, C-8), 179.6 (s, C-18) ppm; EIMS *m/z* (rel. int.): 348 $[M - H_2O]^+$ (1), 330 (9), 290 (100), 247 (67), 230 (27), 181 (4), 123 (9), 110 (15).

*X-ray crystallographic analysis of **3***

Single crystals of **3** crystallized from MeOH–H_2O were $C_{20}H_{32}O_5$, Mr = 352.47, orthorhombic, space group $P2_12_12_1$, with unit cell dimensions *a* = 10.955(2), *b* = 24.122(3), *c* = 6.959(3) Å, *V* = 1839.1(9) $Å^3$, *Z* = 4, $D_{(calc)}$ = 1.273 g cm^{-1}. All unique reflections with 48.81° < 2θ < 49.93° were collected on a Rigaku AFC-5 diffractometer using graphite-monochromated Cu Kα radiation and employing ω–2θ scan mode. In 1831 collected reflections, 1681 reflections ($I > 2\sigma(I)$) were judged as observed and used for the structural determination and refinement. The structure was solved by direct methods and refined by full-matrix least-squares method with anisotropic thermal parameters using the SHELXL-97 programs.[2] The positions of H atoms were obtained from a difference Fourier map and were included in the final refinement. The residual factors were *R* = 0.040 and R_w = 0.135 for 1681 reflections. All calculation were performed using the teXsan.[3] List of atomic coordinates, thermal parameters, bond lengths and angles, the torsion angles, and the calculated and observed structure factors have been deposited.[4]

*$LiAlH_4$ reduction of **3***

A mixture of **3** (10 mg) and $LiAlH_4$ (17 mg) in dry THF (6 mL) was stirred at 40°C for 18 h. After deactivation of an excess of $LiAlH_4$ with H_2O, the reaction mixture was extracted with EtOAc. The EtOAc layer was washed successively with H_2O and saturated brine solution, and dried with Na_2SO_4. Evaporation of the solvent gave a residue (16 mg), which was purified by preparative TLC ($CHCl_3$–MeOH = 20:1) to afford the corresponding alcohol (5.5 mg) identical in all respects with compound **2**.

*13β,18-Dihydroxyabiet-8(14)-en-7-one (**4**)*: Colorless oil; $[\alpha]_D^{23}$ +8.9° (*c* 0.64, $CHCl_3$); UV(EtOH) λ_{max} (log ε): 245

colorless oil, $C_{21}H_{34}O_5$; IR (film) ν_{max}: 3450 (OH), 1733, 1237 (COOMe), 840 (>C=CH-) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 0.78 (3H, s, H-20), 0.99 and 1.01 (each, 3H, d, J = 7.0 Hz, H-16 and H-17), 1.20 (3H, s, H-19), 3.69 (3H, s, -COOMe), 3.88 (1H, br s, H-12β), 4.20 (1H, br s, H-7β), 5.80 (1H, br s, H-14) ppm.

*Treatment of **9a** with benzoyl chloride*

Using the same procedure for compound **8**, a solution of compound **9a** (1.8 mg) in pyridine (0.5 mL) was treated with benzoyl chloride (20 μL) and purified by preparative TLC (*n*-hex-EtOAc = 1:1) to afford the corresponding dibenzoate (**9b**), 1.7 mg, colorless oil, $C_{35}H_{42}O_7$; CD (c 6.17 × 10^{-5} M, EtOH) (Δε): 285 (0), 231 (–15.72), 210 (–2.46) nm; ^1H NMR ($CDCl_3$) δ: 0.86 and 1.04 (each 3H, d, J = 7.0 Hz, H-16 and H-17), 0.90 (3H, s, H-20), 1.22 (3H, s, H-19), 5.31 (1H, br s, H-12β), 5.65 (1H, br s, H-7β), 6.21 (1H, br s, H-14), 6.99 – 8.08 (10H, -COO-Ph × 2) ppm.

Abiet-8(14)-en-7α,12α,13β,15,18-pentaol (**10**): Colorless powder, $C_{20}H_{34}O_5$; mp >300°C (MeOH–H_2O); $[\alpha]_D^{23}$ –23.0° (c 0.20, $CHCl_3$–MeOH = 1:1); IR (film) ν_{max}: 3340 (OH), 1632, 840 (>C=CH-) cm^{-1}; ^1H and ^{13}C NMR: Tables 2 and 3; EIMS *m/z* (rel. int.): 336 $[M - H_2O]^+$ (3), 318 (6), 300 (6), 278 (100), 260 (15), 229 (50), 123 (51), 109 (56), 81 (20), 59 (32); HREIMS *m/z*: 336.2304 $[M - H_2O]^+$ (calcd. for $C_{20}H_{32}O_4$: 336.2299).

Biological activities

The inhibition of EBV–EA activation was assayed using Raji cells (virus-nonproducer), the EBV genome-carrying human lymphoblastoid cells, that were cultivated in 10% FBS RPMI 1640 medium solution (Nacarai Tesque). The indicator cells (Raji) (1 × 10^6/mL) were incubated at 37°C for 48 h in 1 mL of the medium containing *n*-butyric acid (4 mM, inducer), 32 pmol of TPA (20 ng/mL; in DMSO), and a known amount of test compound in DMSO. Smears were made from the cell suspension. The activated cells were stained by high titer EBV–EA-positive sera from nasopharyngeal carcinoma (NPC) patients and were detected by a conventional indirect immunofluorescence technique. In each assay, at least 500 cells were counted and the experiments were repeated three times. The average EA induction was compared with that of positive control experiments with *n*-butyric acid plus TPA in which EA induction was ordinarily around 30%. The viability of cells was assayed by the Trypan Blue staining method reported previously (9).

Acknowledgments

The authors are grateful to Mr. Katsuhiko Minoura and Mrs. Mihoyo Fujitake of this University for NMR and MS measurements.

On chirality measures and chirality properties

Noham Weinberg and Kurt Mislow

Abstract: It is shown that chiral zeroes are integral to all pseudoscalar functions, and that these functions, and thus the chirality properties that are described by them, are therefore normally unsuitable as chirality measures. The multidimensional nature of chirality properties is explored. Chirality measures for nonrigid objects and stochastic systems are discussed. It is shown that if the chirality of a nonrigid object is described as a time average of the chirality measures of its instant configurations, this time average is nonzero not only for chiral but also for achiral molecules. This paradox can be resolved if chirality measures are properly applied to nonrigid objects.

Key words: chirality, chiral zeroes, chirality measures, chirality properties.

Résumé : On démontre que les zéro chiraux font partie intégrale de toutes les fonctions pseudoscalaires et que ces fonctions, et en conséquence les propriétés de chiralité qu'elles décrivent, ne sont donc normalement pas des mesures adéquates de la chiralité. On a exploré la nature multidimensionnelle des propriétés de chiralité. On discute des mesures de chiralité pour les objets non rigides et les systèmes stochastiques. Si la chiralité d'un objet non rigide est décrite par une moyenne en fonction du temps de configurations instantanées, on démontre que cette moyenne en fonction du temps n'est pas égale à zéro non seulement pour les molécules chirales, mais aussi pour les molécules achirales. On peut résoudre ce paradoxe si les mesures de chiralité sont appliquées correctement aux objets non rigides.

Mots clés : chiralité, zéro chiraux, mesures de chiralité, propriétés de chiralité.

Introduction

More than a century ago, Guye (1) introduced a set of continuous functions designed to correlate a pseudoscalar property, i.e., optical rotation, with the structure of a chiral molecule. In effect, this was the first attempt to quantify chirality. Since then a number of other schemes have been suggested (see references in (2), as well as subsequent works (3)). Some of these approaches employ pseudoscalar functions that change sign under space inversion and thus would appear to lend themselves to the left–right classification of chiral objects. It has long been recognized, however, that left–right classifications are vitiated when such pseudoscalar functions as chirality polynomials assume a value of zero for chiral objects, the "chiral zero" (4). In the following two sections we show that chiral zeroes are integral to *all* pseudoscalar functions and that chirality properties therefore cannot normally be used as chirality measures. In the last section we analyze a paradoxical situation that arises when a chirality measure defined for a rigid object, such as a geometrical figure, is applied to a nonrigid one, such as a vibrating molecule, and define a chirality measure that is suitable for nonrigid objects and stochastic systems.

Chirality measures

An object X (no matter whether physical or geometrical) is chiral if and only if it is not superposable on its mirror image $\overline{X}$ ($X \neq \overline{X}$) by a combination of rotations and translations. A chirality measure $\chi(X)$ is a real-valued function defined on a set Ω of objects X. It ranks the members of Ω in degrees of their chirality. The set Ω can be either discrete or continuous. We assume that Ω is a continuous set, any two elements of which can be connected by a continuous deformation.

The following would seem to be a set of natural requirements for a chirality measure $\chi(X)$:

1. Any two close objects, X_1 and X_2, are expected to have close degrees of chirality. Therefore,

[1] $\chi(X)$ is a continuous function on Ω

2. If X is superposable upon its mirror image $\overline{X}$ ($X \neq \overline{X}$), i.e. if it is achiral, then its degree of chirality is zero. That is,

[2] $X = \overline{X} \Rightarrow \chi(X) = 0$

3. Any two enantiomorphs, X and $\overline{X}$, are chiral to the same degree. That is,

[3*a*] $\chi(\overline{X}) = \chi(X)$ (scalar χ)

or

[3*b*] $\chi(\overline{X}) = -\chi(X)$ (pseudoscalar χ)

Of the two types of real-valued functions, scalar and pseudoscalar, that satisfy conditions [1]–[3], the latter might appear to have certain advantages as a chirality measure. First, condition [2] follows directly from [3*b*]. Second, the opposite signs assigned to the degrees of chiralities of

 © 2000 NRC Canada

enantiomorphs can be seen as a natural basis for a left–right classification of chiral objects. And, third, pseudoscalar functions [3*b*] are expected to have a direct connection to experimentally observed pseudoscalar properties, such as optical rotation.

There is, however, one more important constraint that has to be applied to $\chi(X)$: in order to properly measure chirality, this function is allowed to assume a value of zero only for achiral objects. That is,

[4] $\chi(X) = 0 \Rightarrow X = \overline{X}$

Combining [2] and [4], it follows that a proper chirality measure $\chi(X)$ equals zero *if and only if X* is achiral. That is,

[5] $\chi(X) = 0 \Leftrightarrow X = \overline{X}$

Accordingly, chiral zeroes, i.e., situations where $\chi(X) = 0$ for $X \neq \overline{X}$, are excluded.

Let us now return to the perceived advantages of pseudoscalar $\chi(X)$. It has been demonstrated (5) that, with rare exceptions of low-dimensional sets, a chiral object can be chirally connected to its enantiomorph, i.e., there always exists a path (a parametrized curve) $\Lambda \subset \Omega$ linking $X = X_0$ to $\overline{X} = X_1$ such that all $X_\lambda \in \Lambda$, $\lambda \in [0,1]$ are chiral. Along this path Λ, a pseudoscalar $\chi(X)$ can be considered as a real-valued continuous function defined on segment [0,1]. It changes its sign on this segment and therefore has to take a zero value somewhere within Λ, i.e., at some chiral X_λ. Thus $\chi(X)$ possesses chiral zeroes. It follows that, as a rule, *continuous pseudoscalar functions cannot be used as chirality measures in three and higher dimensions*. This conclusion renders questionable current and past attempts to formulate "chirality measures" on the basis of pseudoscalar functions.

An important exception obtains when a set of objects is split by its achiral subset into two disjoint subsets of chiral objects, such that any path connecting enantiomorphs must pass through the achiral boundary. Examples of such sets are the set of triangles of variable shape in two dimensions (6), the set of helices of variable pitch (7), and Ruch's models of class *a* (4). In such rare cases, a pseudoscalar $\chi(X)$ changes its sign only at the achiral boundary and is therefore suitable as a chirality measure.

Chirality properties

Optical rotation was the first recognized manifestation of chirality. Under identical conditions, enantiomers rotate the plane of polarization to the same degree but in opposite directions. The angle of rotation is therefore a pseudoscalar property. The situation is similar with respect to circular dichroism: ellipticity is a pseudoscalar property. Indeed, *all* manifestations of chirality are described by pseudoscalars. But, as stated in the previous section, pseudoscalar functions cannot normally be used as chirality measures. It follows that, as a rule, *chirality properties are unsuited as chirality measures*.

In this connection, we need to point out a key distinction between a chirality measure and a chirality property. The former is a mathematical construct that measures how far an object is from being achiral; even though this measure depends on a particular defining scheme, it is always associated with an isolated object and is independent of any external object or field. The latter, on the other hand, is an observable property that manifests itself through the difference in the interactions of a chiral object X and its enantiomorph $\overline{X}$ with a reference chiral object or field H, or, alternatively, through the difference in the interactions of X with enantiomorphs H and $\overline{H}$.

Let $P(X \circ H)$ represent a *scalar* property of a chiral complex $X \circ H$ or the result of the interaction of X with a chiral object or field H. Then an observed chirality property $\pi_H(X)$ can be expressed as a difference, either as

[6*a*] $\pi_H(X) = P(X \circ H) - P(\overline{X} \circ H)$

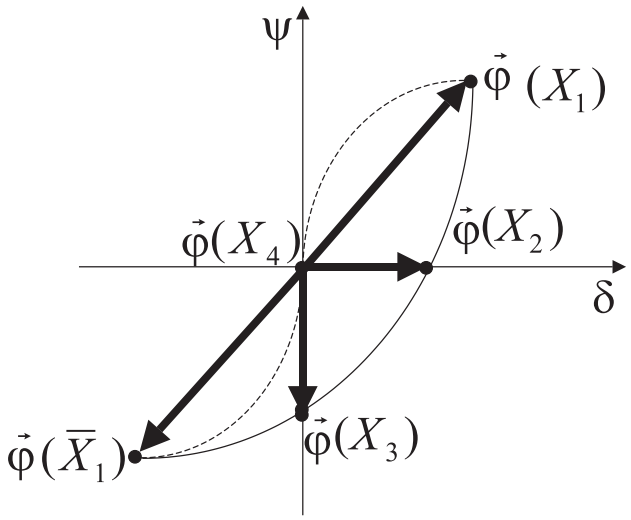
or as

[6*b*] $\pi_H(X) = P(X \circ H) - P(X \circ \overline{H})$

It follows from eq. [6*a*] that $\pi_H(X)$ is a pseudoscalar property. That is,

[7] $\pi_H(\overline{X}) = -\pi_H(X)$

Equations [6*a*] and [6*b*] are equivalent because $\overline{X} \circ H$ and $X \circ \overline{H}$ are enantiomorphous. Their different appearance only reflects the difference in the operations used to determine $\pi_H(X)$. For example, $\pi_H(X)$ in [6*a*] might represent the difference in retention times for enantiomers X and $\overline{X}$ on a chiral column H, while in [6*b*] it might represent the angle of rotation of plane-polarized light due to its interaction with X, found as a difference in phases of left and right circularly polarized waves, H and $\overline{H}$. The equivalence of definitions [6*a*] and [6*b*] implies that for each observable chiral property there should be two equivalent ways of experimental determination. For instance, the difference in retention times mentioned above can be equivalently found by chromatography of the same compound X through two enantiomeric columns, H and $\overline{H}$, and the angle of rotation can be found as a difference of phases of a left (or right) circularly polarized wave H as a result of its interaction with enantiomers X and $\overline{X}$.



Depending on the conditions of measurement (temperature, wavelength, etc.) an object and its enantiomorph may have a scalar property of the same magnitude. That is, $P(X \circ H)$ and $P(\overline{X} \circ H)$ can be *accidentally* equal even for a chiral X. Thus, the fact that $\pi_H(X)$ equals zero does not necessarily mean that X is achiral. Chiral zeroes are therefore expected to occur for chirality properties.

This does not mean, however, that pseudoscalar properties fail to characterize a chiral object as chiral. The reason is that there are a virtually limitless number of such properties associated with a given object, and its observed chirality is therefore expressed as an infinite-dimensional pseudovector. This pseudovector remains nonzero if one, or even several, of its components vanish. Only for a truly achiral object is it the case that *all* of its individual pseudoscalar properties are zero, and hence that the whole chirality pseudovector is zero.

This statement may be illustrated by the example of optical rotation. Rotation angle δ and ellipticity ψ are known to be frequency-dependent, and at some frequencies become zero. They are related to the refractive index and absorption coefficient, the real and imaginary parts of the same complex quantity (8), and are therefore not independent. As a result, whenever δ takes on a value of zero in an isolated

© 2000 NRC Canada

Fig. 1. A chiral (solid line) and an achiral (dashed line) path connect enantiomorphs X_1 and $\overline{X}_1$. Pseudovector $\vec{\varphi}(X)$ (eq. [8*b*]) never turns zero on the chiral path even though one of its components turns zero for chiral objects: δ for X_3 and ψ for X_2. For an achiral object X_4, both δ and ψ are zero and $\vec{\varphi}(X) = 0$.

transition, the absolute value of ψ is near or at its maximum (the Cotton effect) (9). Thus, a complex pseudoscalar

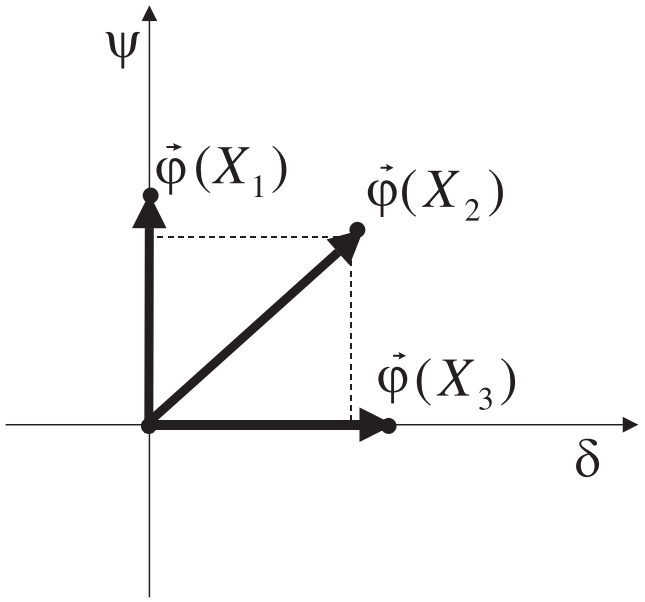
[8*a*] $\varphi = \delta + i\psi$

or, equivalently, a two-dimensional pseudovector

[8*b*] $\vec{\varphi} = \begin{pmatrix} \delta \\ \psi \end{pmatrix}$

does not become zero for chiral molecules, but is identically zero for achiral molecules.

Similarly, if the entire function $\delta(\nu)$ that represents rotation angles for the whole range of frequencies ν is used, rather than a single value of δ taken at a particular frequency, the problem of chiral zeroes is also avoided since $\delta(\nu)$ is identically zero only for achiral molecules.



The above discussion suggests that a pseudovector $\vec{\chi}(X)$ can be continuously transformed into $\vec{\chi}(\overline{X}) = -\vec{\chi}(X)$ without passing through zero (Fig. 1), and that the problem of chiral zeroes can thus be avoided even though eq. [3*b*] is obeyed. It has to be added, however, that although a pseudovector $\vec{\chi}(X)$ can differentiate chiral objects from achiral ones, it cannot be directly used to compare their degrees of chirality because relations "greater than" or "less than" are not naturally defined for any two vectors (10). In other words, if chirality is described by $\vec{\chi}(X)$, it becomes impossible in many cases to say which of two objects is more chiral. To restore a linear ordering, one needs to use scalar quantities associated with pseudovectors, such as Euclidean norms

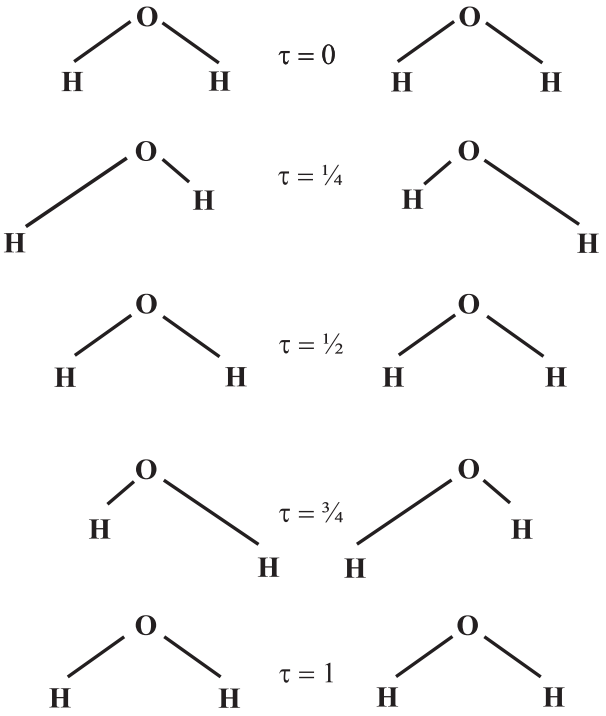
[9*a*] $\left\|\vec{\varphi}\right\| = \sqrt{\delta^2 + \psi^2}$

or

[9*b*] $\left\|\delta\right\| = \sqrt{\int_{\nu_{\min}}^{\nu_{\max}} [\delta(\nu)]^2 \, d\nu}$

Fig. 2. Chirality properties of three chiral objects, X_1, X_2, and X_3, are characterized by pseudovectors $\vec{\varphi}(X_1)$, $\vec{\varphi}(X_2)$, and $\vec{\varphi}(X_3)$, respectively. Optical rotation angle δ identifies X_3 as the most chiral object but fails to detect the chirality of X_1. Similarly, ellipticity ψ selects X_1 as the most chiral object but fails to detect the chirality of X_3. When δ and ψ are combined, however, and the norm $\left\|\vec{\varphi}\right\|$ (eq. [9*a*]) is used, all three objects are identified as chiral and X_2 is found to be the most chiral of the three.

Norms [9*a*] and [9*b*] are "well-behaved" scalar functions that obey conditions [1], [3*a*], and [5], and thus qualify as chirality measures.



These considerations may be illustrated with the reference to Fig. 2. Three chiral objects, X_1, X_2, and X_3, are characterized by the pseudovector $\vec{\varphi}$ (eq. [8*b*]). If δ were to be chosen as the sole measure of chirality, the ranking would be $X_3 > X_2 > X_1$, with X_1 being "achiral" (zero optical rotation). Similarly, ψ as the sole measure of chirality would produce a different ranking, $X_1 > X_2 > X_3$, with X_3 now being "achiral" (zero ellipticity). Both rankings are clearly unacceptable, not only because they are mutually inconsistent but also because of the chiral zeroes. If, however, we use norm $\left\|\vec{\varphi}\right\|$ (eq. [9*a*]), for example, then this problem can be overcome because chiral zeroes no longer exist and the contributions of different chirality properties are integrated into a single chirality measure.

Chirality measures for nonrigid objects and stochastic systems

If a molecule such as methane is considered in a state of vibrational motion, most of its instantaneous configurations are chiral (7). Each such configuration is as probable as its enantiomorph, and the contributions from different configurations to the net observed chirality property will therefore cancel out on average. For this reason, no chirality properties are observed for such molecules. At the same time, however, in accordance with our earlier discussion, a chirality measure is a sign-preserving function on a set of instant configurations, and the contributions from different configurations therefore *cannot* cancel each other. Hence, if the

© 2000 NRC Canada

Fig. 3. An array of instant configurations **X** of a vibrating water molecule and its mirror-image array $\overline{\mathbf{X}}$.

chirality of a nonrigid object, such as a vibrating molecule, is described in terms of the time average of the chirality measures of its instant rigid configurations, *this time average is nonzero not only for a chiral but, paradoxically, even for any achiral molecule*.

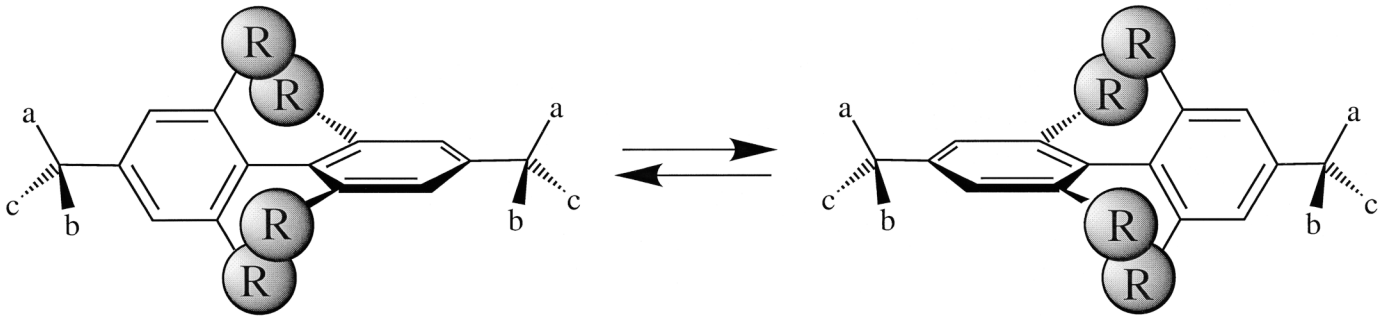
This paradox can be avoided, however, if a chirality measure is defined for a nonrigid object as a whole rather than for its instant configurations.

We consider a nonrigid object **X** as a parametrized set of its instant rigid configurations X_τ:

$$\mathbf{X} = \{X_\tau;\ \tau \in T\}$$

Correspondingly, its enantiomorph $\overline{\mathbf{X}}$ can be represented as a set of the enantiomorphs $\overline{X}_\tau$of rigid configurations X_τ. That is,

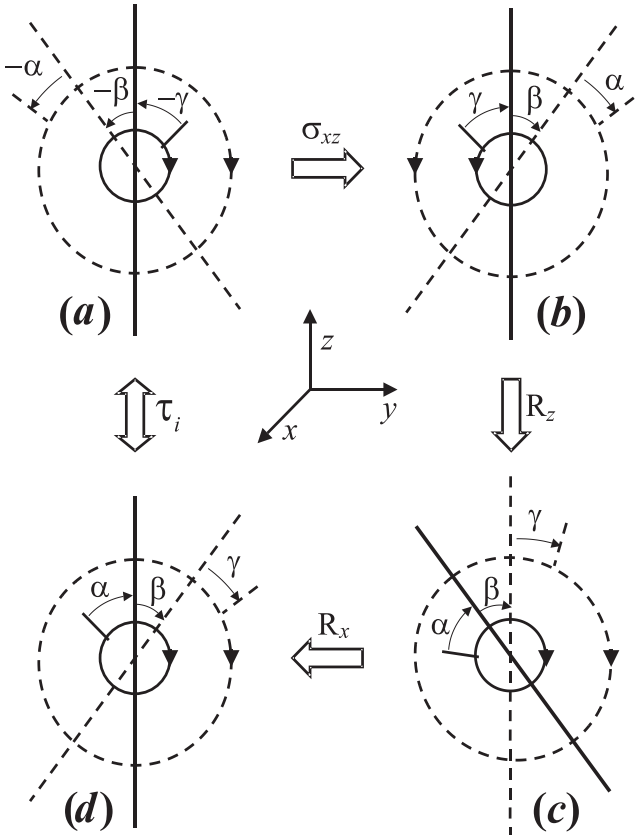
$$\overline{\mathbf{X}} = \{\overline{X}_\tau; \tau \in T\}$$



A congruency-based chirality measure χ (2b) is then defined for **X** as a minimum distance between **X** and $\overline{\mathbf{X}}$, for example as

$$[10] \qquad \chi(\mathbf{X}) = \frac{\int_{\tau\in T} \min_{\tau'\in T} \{dist(X_\tau, \overline{X}_{\tau'})\}\, d\tau}{\int_{\tau\in T} d\tau}$$

If **X** and $\overline{\mathbf{X}}$ differ only by a permutation of their elements, by virtue of [10] they are achiral. The following two examples serve as illustrations. Consider a vibrating water molecule in two-dimensional space (Fig. 3). Almost all instant configurations X_τ (except X_0, $X_{1/2}$, and X_1) are chiral in 2D. The entire array **X**, however, is achiral because $X_\tau = \overline{X}_{1-\tau}$ (e.g., $X_{1/4} = \overline{X}_{3/4}$, $X_{3/4} = \overline{X}_{1/4}$). Another example is a compound of the type 4-[(*R*)-*sec*-butyl]-4′-[(*S*)-*sec*-butyl]-2,2′,6,6′-tetramethylbiphenyl (Fig. 4) which consists entirely of chiral conformations (11). Instant configurations X_τ of this molecule are characterized by triples $\tau = (\tau_1, \tau_2, \tau_3)$, where τ_1 and τ_3 are torsion angles for phenyl-Cabc bonds and τ_2 is the torsion angle for the central phenyl-phenyl bond. Torsion angles τ_1, τ_2, and τ_3 can be changed to $-\tau_1$, $-\tau_2$, and $-\tau_3$ by internal rotations around the respective bonds. Although τ_2 cannot assume a value of zero (the two phenyl rings cannot become coplanar due to the presence of the bulky substituents R) it is nevertheless possible to transform τ_2 into $180^o - \tau_2$, which, by virtue of the symmetry of the rings and their R substituents, is equivalent to $-\tau_2$. As shown in Fig. 5, for any conformation X_τ of **X** with torsion parameter $\tau = (\alpha, \beta, \gamma)$ there exists another conformation of **X**, $X_{\tau'}$ with $\tau' = (-\gamma, -\beta, -\alpha)$, such that $X_\tau = \overline{X}_{\tau'}$. Therefore, in accordance with [10], $\chi(\mathbf{X}) = 0$, i.e. the discussed molecule is achiral even though it does not have a single achiral conformation.



A similar approach applies to nonrigid stochastic systems, such as ensembles of molecules. The simplest example of this kind is a system that contains a statistically significant number *N* of monoatomic molecules (12), e.g., a mole of helium gas in a cubic box. Such a system can be described by its dynamic trajectory **X** in a 3*N*-dimensional configuration space. Practically every instant configuration, X_τ, acquired by the system at time τ, is bound to be chiral because random achiral arrangements of a large number of particles are highly improbable. The enantiomorphous configurations $\overline{X}_{\tau'}$ also belong to the configuration space but do not necessarily belong to the trajectory **X**. In accordance with the ergodic

Fig. 4. Schematic drawing of two enantiomorphous conformations of a biphenyl with bulky substituents (e.g., R = CH_3) in the 2,2′,6,6′ positions and enantiomorphous -Cabc groups (e.g., -$CH(CH_3)C_2H_5$) in the 4,4′ positions.

Fig. 5. Schematic side-view projection of conformations belonging to the molecular system of Fig. 4. Straight lines represent the edges of phenyl rings (substituents R are not shown); oriented circles represent -Cabc groups (the arrows point in the directions a → b → c). Solid lines represent parts of the molecule that are closer to the viewer; dashed lines represent the more distant ones. Conformations $X_{\tau'}$ (*a*) and X_{τ} (*d*) are interconverted by internal rotations τ_i. Conformation $X_{\tau'}$ (*a*) is converted to $\overline{X}_{\tau'}$ (*b*) by reflection σ_{xz} in the *xz* plane. A different view (*c*) of $\overline{X}_{\tau'}$ is obtained by a rigid 180° rotation R_z about the *z* axis. Conversion of $\overline{X}_{\tau'}$ (*c*) to X_{τ} (*d*) is achieved by rigid rotation R_x about the *x* axis by an angle β.

hypothesis (13), however, the trajectory **X** thoroughly covers the entire conformation space so that every point of the space that represents a structure with the same energy is infinitesimally closely approached by the trajectory. That is, for any configuration X_{τ} of **X** there always exists an infinitesimally close configuration $\overline{X}_{\tau'}$ of $\overline{\mathbf{X}}$. Thus, it follows from [10] that $\chi(\mathbf{X}) = 0$, i.e., that the system is achiral even though almost all of its instantaneous configurations are chiral.

A 2D deuterium NMR study of molecular reorientation in $(CH_3)_3E^+X^-$ onium salts

Andrew M. Wachner, Kenneth R. Jeffrey, and Glenn H. Penner

Abstract: Two dimensional deuterium NMR measurements are reported for three different onium salts $(CH_3)_3SeNO_3$-d_3, $(CH_3)_3TeI$-d_3, and $(CH_3)_3SI$-d_9. In these molecular solids with the general structure $(CH_3)_3E^+X^-$, three methyl groups are attached to the E atom. There is the possibility of reorientation of the methyls about their C_3 axes and reorientation of the whole tri-methyl group about the C_3' axis. From an analysis of the 2D NMR exchange spectra the angle between the E—C bonds and the rotation axis for trimethyl reorientation were determined. Exchange rates and spin lattice relaxation times are given for several temperatures, to show how the mixing times for the experiments were selected. The data presented for $(CH_3)_3TeI$-d_3, demonstrate that 2D techniques are sensitive to motions on a time scale an order of magnitude slower than that accessible using 1D line shape techniques.

Key words: deuterium NMR, molecular motion, onium salts, two dimensional spectra.

Résumé : On a effectué des mesures bidimensionnelles de RMN du deutérium pour trois sels onium différents, $(CH_3)_3SeNO_3$-d_3, $(CH_3)_3TeI$-d_3 et $(CH_3)_3SI$-d_9. Dans ces trois solides moléculaires comportant la structure générale $(CH_3)_3E^+X^-$, les trois groupes méthyles sont attachés à l'atome E. Il existe une possibilité de réorientation des groupes méthyles autour de leurs axes C_3 et de réorientation de l'ensemble du groupe triméthyle autour de l'axe C_3'. Sur la base d'une analyse du spectre d'échange RMN-2D, on a pu déterminer l'angle entre les liaisons E—C et l'axe de rotation pour la réorientation du triméthyle. On rapporte les vitesses d'échange et les temps de relaxation spin-réseau à plusieurs températures et ces données permettent de comprendre comment les temps de mélanges des expériences ont été choisis. Les données rapportées pour le $(CH_3)_3TeI$-d_3 démontrent que les techniques 2D sont sensibles aux mouvements sur une échelle de temps d'un ordre de grandeur inférieur à celle disponible à l'aide des techniques de formes de bandes en 1D.

Mots clés : RMN du deutérium, mouvement moléculaire, sels onium, spectres bidimensionnels.

[Traduit par la Rédaction]

Introduction

Two dimensional (2D) deuterium NMR has been used extensively to determine the nature of the molecular reorientation that is taking place in crystalline and amorphous solids (1–3). In the case of large finite angle jump reorientation, it has been shown that 2D deuterium NMR exchange spectra provide a model-independent method of measuring the angle of reorientation in many materials (4).

In previous work reported on the molecular dynamics of the onium salts (5) it was demonstrated, using one dimensional line shape analysis of spectra over a large temperature range and fitting to appropriate model simulations, that it was possible to determine certain bond angles and rates of reorientation. The present work is intended to confirm the results of the previous 1D study, using the model independent methods of Spiess (3), and to extend the results into the region of slower exchange rates not available to 1D line shape analysis techniques.

Deuterium is an ideal probe nucleus for the study of molecular dynamics because it can be treated as an isolated spin. The reason being that the strength of the quadrupolar interaction is 100–250 kHz while the strength of the dipolar interaction between spins is 1–2 kHz and as a result can be neglected. For the case of methyl groups, it is reasonable to assume that the electric field gradient at the deuterium site is axially symmetric along the C—D bond. The resonance frequency of the deuteron at the site of an axially symmetric electric field gradient is shifted as a result of the quadrupolar interaction by an amount

$$[1] \qquad \omega = \pm \frac{3}{8}\frac{e^2qQ}{\hbar}(3\cos^2\beta - 1)$$

where β is the angle between the carbon deuterium bond and the magnetic field axis and $e^2qQ/\hbar$ is the quadrupolar coupling. Because the angular dependence of the resonance frequency provides a direct measure of the orientation of a carbon deuterium bond, changes in the resonance frequency can be used to probe the reorientation that is taking place in a sample. Any change in the orientation of the bond vector will result in a change in the resonance frequency.

Fig. 1. Stimulated Echo pulse sequence. To measure the sin–sin correlation select $P_1 = 90_y$, $P_2 = 45_{-x}$, $P_3 = 45_x$, $P_4 = 90_x$, and to measure the cos–cos correlation function select $P_1 = 90_y$, $P_2 = 90_{-y}$, $P_3 = 90_y$, $P_4 = 90_x$.

The 2D exchange experiment (2) provides a method of directly measuring the sin–sin and cos–cos two time single particle correlation functions given in eqs. [2] and [3].

$$[2] \qquad f_{cc}(t_1, t_m, t_2) \propto \langle \cos(\omega_1 t_1) \cos(\omega_2 t_2) \rangle$$

$$[3] \qquad f_{ss}(t_1, t_m, t_2) \propto \langle \sin(\omega_1 t_1) \sin(\omega_2 t_2) \rangle$$

where the angular brackets represent an ensemble average over the powder sample. Double Fourier transforming these functions leads to a 2D spectrum which can be analyzed to determine the nature of the reorientation that is taking place in the system. The appropriate 4 pulse sequence is shown in Fig. 1. The quadrupolar frequency ω_1 measured during the evolution time (t_1) is compared with the frequency ω_2 observed in the detection time (t_2) using the cos–cos and sin–sin correlation functions. Molecular reorientation during the mixing time (t_m) results in a loss of correlation and the creation of off-diagonal peaks in the 2D spectrum. To eliminate double quantum coherences and spectrometer imperfections the CYCLOPS (2) phase variations must be used with the above 2D exchange sequence. The pulse sequence shown in Fig. 1 is subject to a few constraints when used to measure 2D exchange spectra. The rate of exchange taking place in the system must be in the range (10^3–10^{-1} s^{-1}), to satisfy the requirements that no exchange takes place during the evolution time (t_1) and detection time (t_2) which is on the order of 1 ms. Sufficient exchange must take place during the mixing time (t_m) before the signal decays due to spin-lattice relaxation.

Using the method of Schmidt et al. (2) the above two correlation functions can be appropriately Fourier transformed and combined to produce a pure absorption mode spectrum. In the case of large finite angle jump reorientation, the spectra will contain two ellipses (3). By measuring the major and minor axis of these ellipses the jump angle can be determined from eq. [4],

$$[4] \qquad \alpha = \tan^{-1}\left(\frac{B}{A}\right)$$

where B is the minor axis, A is the major axis of the ellipse and α is the jump angle.

Experimental

All of the measurements were performed on a home built spectrometer using a Bruker (6.8 T) superconducting magnet with a deuterium resonance frequency of 44 MHz. Data accumulation was performed on a Nicolet Instruments 2090 III A digital oscilloscope that was interfaced with a 486 personal computer. Temperature control was maintained by regulating the flow of cold nitrogen gas over the sample and the current in a heater wrapped on a copper container surrounding the sample. The electronic feed back loop was able to maintain a stability of ±0.2°C over the duration of an experiment.

Samples of $(CH_3)_3SeI$-d_3, $(CH_3)_3TeI$-d_3, and $(CH_3)_3SI$-d_9 were prepared by reacting deuterated methyl iodide with $(CH_3)_2Se$, $(CH_3)_2Te$, and $(CH_3)_2S$ using the method outlined in the original paper (5). $(CH_3)_3SeNO_3$-d_3 was prepared by ion exchanging $(CH_3)_3SeI$-d_3.

Before a 2D spectra can be measured it is necessary to choose the appropriate temperature and the mixing time. One method to determine these quantities is to measure the sin–sin correlation function (f_{ss}) at several temperatures with several mixing times. These data can then be fit with eq. [5] to determine the exchange rate and the spin-lattice relaxation time (1).

$$[5] \qquad f_{ss}(t_1, t_2) = \frac{1}{n}\left\{tr\left[\sin(\omega_Q t_1)\right]\cdot tr\left[\sin(\omega_Q t_2)\right] - \left[1\cdot\sin(\omega_Q t_1)\cdot\left(\frac{\Pi}{\Omega}\cdot\sin(\omega_Q t_2)\right)\cdot 1\right] \exp(-n\Omega t_m)\right\}\exp\left(\frac{-t_m}{T_1}\right)$$

where ω_Q is a matrix with diagonal elements equal to the resonance frequency at the ith site. Π is an exchange matrix where each element Π_{ij} is the transition rate on going from site j to site i with the general condition that

$$\Pi_{ij} = \sum_j \Pi_{ij}, (i \neq j)$$

Equation [5] was also used to simulate the 2D spectra shown in the next section.

Results and discussion

The three salts that were analyzed in this study are $(CH_3)_3SeNO_3$-d_3, $(CH_3)_3TeI$-d_3, and $(CH_3)_3SI$-d_9. There is the possibility of both methyl group (CH_3) reorientation and rotation of the trimethyl $(CH_3)_3$ as previously discussed (5). The methyl group motion has a lower activation energy and occurs at lower temperatures. The 2D experiments reported in this paper explore the motion of the $E(CH_3)_3$ group in these compounds. The trimethyl group reorientation is shown in Fig. 2 and the relationship between the jump angle (α) and the angle (θ) between the E—CD_3 bond and the C_3' rotation axis, is given in eq. [5].

$$[5] \qquad \frac{\sqrt{3}}{2}\sin(\theta) = \sin\left(\frac{\alpha}{2}\right)$$

***Trimethylselenonium nitrate*-d_3:**

To determine the mixing time for the 2D spectra the sin–sin correlation function was measured as a function of the mixing time for 4 temperatures (0, –10, –20, and –30°C). A sample plot of this data at –30°C is shown in Fig. 3. The results of fitting with eq. [4] are summarized in Table 1. In

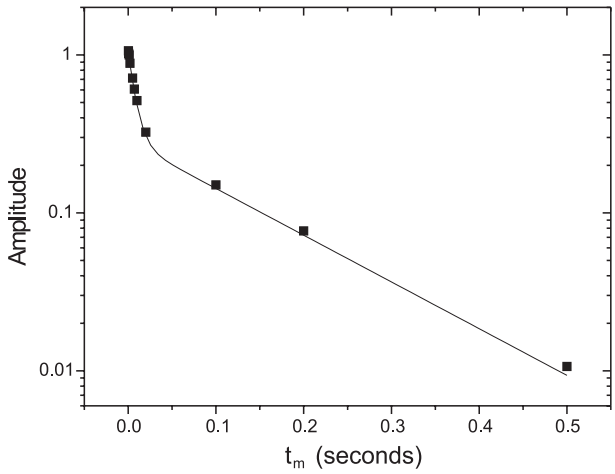

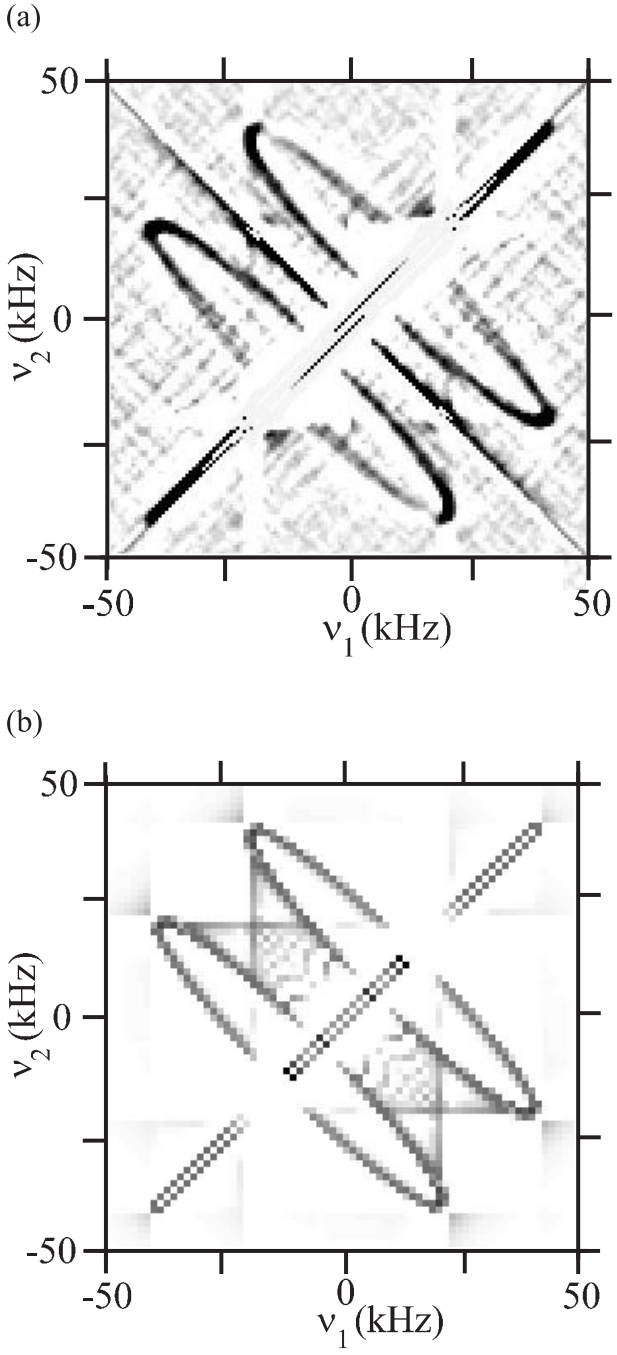

Fig. 3 the initial rapid decay is due to exchange while the longer decay is due to T_{1Q}.

To ensure that there is little exchange during the times t_1 and t_2 but appreciable reorientation during the mixing time (t_m) the 2D exchange experiment was performed at –30°C with a mixing time of 20 ms and 256 t_1 and t_2 values. A repetition rate of 0.5 s was used and 512 scans for each t_1 were collected to enhance the signal to noise ratio. The experimental and simulated spectra are shown in Figs. 4*a* and 4*b*. The spectra show that the elliptical ridge pattern has been well resolved, however the anti-diagonal has not been completely eliminated which indicates that there are some slight inconsistencies between the sin–sin spectrum and the cos–cos spectrum. These arise because of small differences in T_1 and T_{1Q} and a slight imbalance in the intensities of the two correlation functions. From the experimental 2D spectrum the reorientation angle (α) was determined to be 98.5 ± 0.5 degrees. This value is in good agreement with previous studies (5, 6) as shown in Table 2.

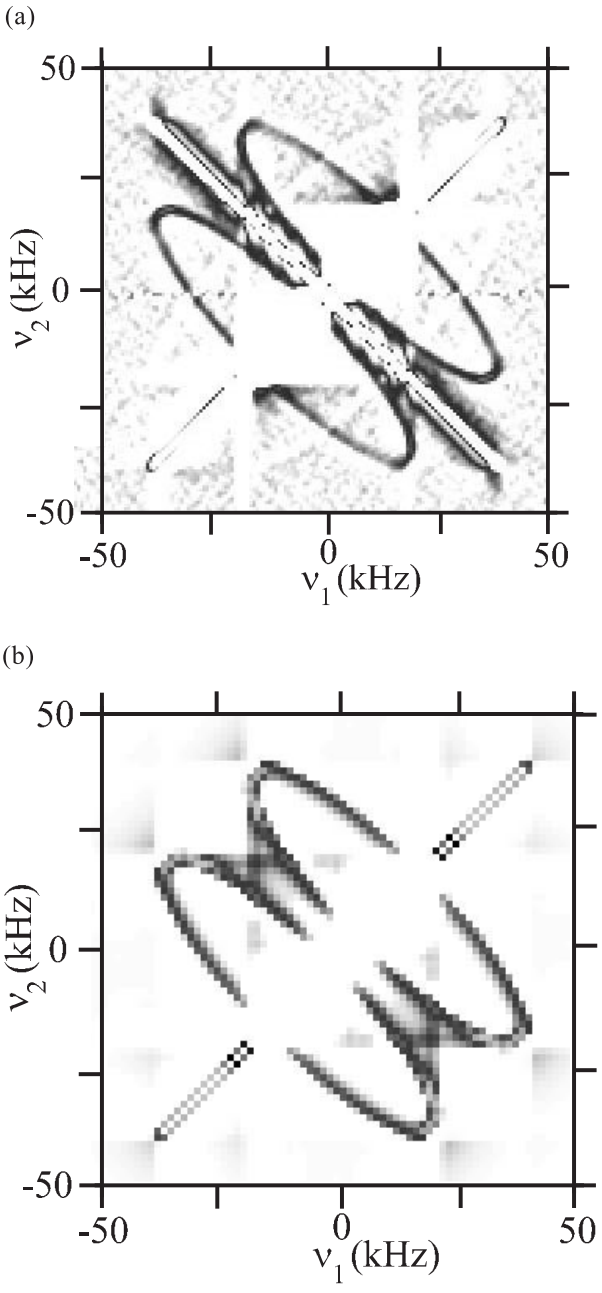
–50	920	4.4

***Trimethylsulfonium iodide*-d_9:**

To determine the appropriate mixing time to use to obtain the 2D exchange spectrum for $(CH_3)_3SI$-d_9 the sin–sin correlation function was measured as a function of the mixing time for four temperatures. This data is given in Table 3. As the temperature decreases the exchange rate and the T_{1Q} value decrease as expected. At –50°C it is difficult to fit the two components of the decay since the two rates have similar values. However, the 2D exchange experiment was performed at –50°C so that the condition of no exchange during the detection and evolution times could be satisfied. Because T_{1Q} was so short a mixing time of 3 ms was selected, to permit exchange to occur during the mixing time and to limit the effects of T_{1Q} relaxation during the mixing time.



The 2D spectrum was obtained using 256 t_1 values and a repetition rate of 0.1 s. The final 2D spectrum is shown in Fig. 5*a* and the corresponding simulation is shown in Fig. 5*b*. From the experimental spectrum the jump angle (α) was determined to be 103.7 ± 0.5 degrees which is again in good agreement with earlier NMR (5) and X-ray work (7) as summarized in Table 2.

***Trimethyltelleronium iodide*-d_3:**

To determine the appropriate mixing time for $(CH_3)_3TeI$-d_3 the sin–sin correlation function was measured as a function of t_m at three temperatures. This data is summarized in Table 4. At the lower temperatures, 20°C and 50°C, only one component is present, this indicates that the exchange rate is very slow and cannot be distinguished from the spin alignment relaxation T_{1Q}. However at 75°C the two components in the decay are very distinct and the exchange rate is on the order of 100 s^{-1} which is ideal for the 2D exchange measurement. However the T_{1Q} value is quite long at 1.1s, which meant that the acquisition of the 2D data set was very time consuming.

The 2D spectrum was obtained using 128 t_1 values, a mixing time of 50 ms, a repetition rate of 5.3 s, and 256 scans were accumulated to improve the signal to noise ratio. The final spectrum is shown in Fig. 6*a*, along with a simulation in Fig. 6*b*. The spectrum shows that the ellipses have been resolved even though there is a significant amount of noise. This noise is largely thermal noise in the probe that is increased at high temperatures. From this spectrum the jump angle (α) was measured to be 95.6 ± 0.7 degree; this value is in good agreement with previous X-ray data (8) as shown in Table 2.

Fig. 5. $(CH_3)_3SI$ 2D exchange spectra at –50°C, (*a*) experimental, (*b*) simulation.

It should be noted that for each of the three onium salts studied the unit cell in the crystalline solid contains more that one formula unit (6–8). The crystal symmetry however demands that the molecular conformation is that same for

Fig. 6. $(CH_3)_3TeI$ 2D exchange spectra at 75°C, (*a*) experimental, (*b*) simulation.

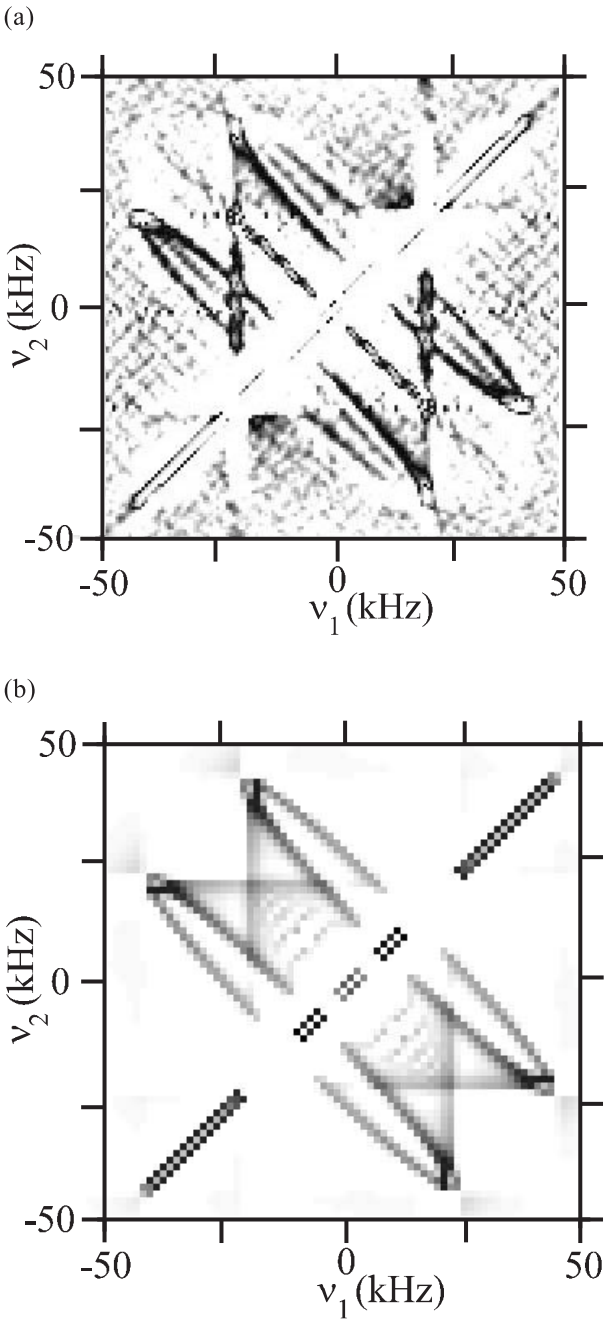

Table 4. Fitted parameters for $(CH_3)_3TeI$.

Temperature (°C)	Exchange rate (s^{-1})	T_{1Q} (s)
20	—	0.95
50	—	0.84
75	106	1.11

each formula unit. It is found that there are two crystallographically inequivalent carbon atoms in each $(CH_3)_3M^+$ ion but the bond lengths and C-M-C angles are nearly equally and the symmetry of the ion is nearly 3*m*. As a result the angles measured by NMR are averages over the two values obtained from X-ray diffraction.

Conclusions

It has been shown in this work that 2D exchange spectra provide a model independent method of determining the jump angle in several $(CH_3)_3E^+X^-$ odium salts. The jump angles obtained are in good agreement with previous studies. For the case of $(CH_3)_3TeI$-d_3 it was possible to determine the jump angle (α) using 2D exchange techniques where 1D line shape analysis methods failed because 2D spectral techniques are sensitive to motion on a slower time scale than 1D line shape techniques. Previously (5) it had not been possible to increase the temperature to the point where line shape changes in the 1D spectra could be observed and as a result model fitting was not possible.

Pyrolysis gas chromatography – mass spectrometry of humic substances extracted from Canadian lake sediments

Helen A. Joly, Hongbo Li, and Nelson Belzile

Abstract: Humic substances (HS) were extracted with the aid of 0.1 M $Na_4P_2O_7$ and 0.5 M NaOH solutions from the sediments of four lakes located in the Sudbury area in Ontario, Canada, namely, Tilton, Clearwater, Silver and Ramsey Lake. The humic acid (HA) and fulvic acid (FA) extracts, purified and characterized using classical methods i.e., elemental analysis, FTIR spectroscopy, and CPMAS ^{13}C NMR (see N. Belzile, H.A. Joly, and H. Li. (1997)), were submitted to pyrolysis – gas chromatography – mass spectrometry (Py–GC–MS). The pyrolysates of the HA and FA extracts were found to be complex mixtures of at least 200 compounds. Results based on statistical analysis of the abundances of pyrolysis products (of known origin) revealed trends similar to those obtained from the classical bulk characterization techniques. The Py–GC–MS technique supported the observation, obtained from classical methods, that the chemical composition of HA extracts varied less significantly among the four lake sediments than for the FA extracts. The abundances of lignin and carbohydrate pyrolysates showed the highest variation among the FA extracts. Pyrolysis products originating from lignin, carbohydrates, proteins, and fatty acids were identified.

Key words: humic substances, humic acid, fulvic acid, pyrolysis, pyrolysis – gas chromatography – mass spectrometry, lake sediments.

Résumé : On a extrait des substances humiques (SH) à l'aide de solutions de $Na_4P_2O_7$ 0,1 M et de NaOH 0,5 M, à partir des sédiments de quatre lacs situés dans la région de Sudbury, en Ontario, Canada, à savoir, des lacs Tilton, Clearwater, Silver et Ramsey. Les acides humiques (AH) et fulviques (AF) isolés ont été purifiés et caractérisés à l'aide de méthodes classiques, comme l'analyse élémentaire, la spectroscopie IR à TF, et la RMN du ^{13}C à l'angle magique (« CPMAS ») (voir: N. Belzile, H.A. Joly et H. Li. (1997)) avant d'être soumis à une pyrolyse couplée à de la chromatographie gazeuse et à de la spectrométrie de masse (Py–CG–SM). On a trouvé que les pyrolysats des AH et AF extraits sont des mélanges complexes formés d'au moins 200 composés. Des résultats qui reposent sur une analyse statistique des abondances des produits de pyrolyse (d'origine connue) mettent en évidence des tendances semblables à celles obtenues à partir de techniques de caractérisation classique de la masse. Les résultats obtenus à l'aide de la technique de la Py–CG–SM sont en accord avec ceux obtenus à l'aide de méthodes classiques, selon lesquels la variation dans la composition chimique des AH extraits est moins importante que celle observée avec les AF. Les variations dans les abondances de la lignine et des hydrates de carbone dans les pyrolysats sont maximales avec les AF extraits. On a identifié les produits de pyrolyse qui tirent leur origine de la lignine, des hydrates de carbone, des protéines et des acides gras.

Mots clés : substances humiques, acide humique, acide fulvique, pyrolyse, pyrolyse – chromatographie gazeuse – spectrométrie de masse, sédiments de lacs.

[Traduit par la Rédaction]

1. Introduction

Organic matter (OM) in lake sediments is made up of a complex mixture of lipids, carbohydrates, proteins, and other biomaterials originating from the tissues of living benthic micro-organisms and the detritus of organisms formerly living in the lake and its watershed. In spite of the application of many analytical and spectroscopic methods, knowledge of their complex nature and composition is still limited. The methods most frequently used to characterize humic fractions, namely elemental analysis, visible, IR and NMR spectroscopy indicate the nature and origin of these compounds. More specifically, the atomic ratios H:C, O:C, and N:C, determined from elemental data, are indicators of the degree of aromaticity, carbohydrate content, and protein content, respectively. A comparison of these ratios to those reported for humic fractions from different origins is used to identify differences as well as to monitor the structural changes of humates in soils (1).

Characterization of humic substances (HS) by visible spectroscopy requires that the optical densities (E) of dilute aqueous solutions of HA and FA be recorded at 465 and

665 nm. The ratio of the optical density measured at two different wavelengths, E_4:E_6, has been shown to vary for humic materials of different soil types (2, 3). Furthermore, the E_4:E_6 ratio is thought to reflect (4): (*i*) the total carbon content of the HS, (*ii*) the number of aromatic residues versus the number of aliphatic residues, and (*iii*) the molecular weight of the HS, IR, and NMR spectroscopic studies of HS have also provided useful information concerning the types of functional groups present in the material. It has been shown that a comparison of the peak areas of the signals found in the aromatic and aliphatic regions of the ^{13}C NMR spectra of HS is indicative of the degree of aromaticity versus aliphaticity of the HS (5–8).

Another useful approach for obtaining information on the structure of HS involves degrading the macromolecular substance using an oxidative or reductive process (9–11) or a pyrolytic technique. The degradation products are recovered and identified with the aid of a suitable method, for example mass spectrometry. The degradation products give information concerning the residues originally present in the HS. In fact, the aromatic building blocks which make up the HS as well as some of the alkanes, fatty acids, and aliphatic chains have been identified by the degradation technique (12). Thermal degradation or pyrolysis has proven to be very useful in the identification of the substructures of macromolecules, especially HS (13–18). Of the various pyrolysis approaches known, pyrolysis – gas chromatography – mass spectrometry (Py–GC–MS) seems to be the most reliable as products can be separated by GC and identified by MS (15). It is also an advantageous technique with respect to the other degradation methods because: (*i*) the pyrolyser is a relatively inexpensive tool which can be easily coupled to a GC–MS, (*ii*) it can be applied to a large variety of samples, and (*iii*) little or no sample manipulation is required prior to analysis.

Pyrolysis is by no means an ideal technique for investigating the structural features of HS because the interpretation of the pyrograms can at times be difficult. Besides the fact that HS produce hundreds of degradation products, there is an added complication in that certain pyrolysis products undergo secondary reactions. Identification of the residues present in the original HS macromolecular structure requires an understanding of their behaviour under pyrolytic conditions. However time consuming the data analysis may be, it does provide a means of identifying the residues which make up the HS, information which the above mentioned conventional analytical techniques have not as of yet provided. Finally, the task of data analysis is facilitated as more pyrolysis studies of HS become available.

In an earlier study (12, 19), we used elemental analysis, visible spectroscopy (E_4:E_6 ratio), FTIR, and solid-state ^{13}C CPMAS NMR to study the composition and the chemical nature of HA and FA isolated from the sediment of four Sudbury Lakes. The results suggested that the HS extracted from the different lake sediments have similar chemical composition and structure suggesting that the factors influencing the formation and preservation of HS were similar in the lakes tested. The HS of lake sediments were found to contain a greater proportion of HA than FA. The higher H:C and O:C ratios found for FA extracts than for HA extracts suggested that the FA contained more carbohydrate and carboxylic functionalities. This was confirmed by the ^{13}C NMR spectra of the FA and HA extracts. Analysis of the NMR spectra also showed that the lake sediment FA and HA were highly aliphatic in nature. The FTIR spectra indicated, as did the NMR data, the presence of aromatic, aliphatic, O–alkyl, and carboxylic functionalities. However, no apparent structural differences were found between the FA and HA extracted from the lake sediments using the FTIR technique.

In the present study, the same HS extracted from the sediment of the four Sudbury lakes with the aid of 0.1 M $Na_4P_2O_7$ and 0.5 M NaOH were characterized using Py–GC–MS. A statistical analysis was applied to the abundances of the pyrolysis products to determine the significance of the pyrolytic trends observed for the different sediment samples. The pyrolytic results were compared to those obtained by the classical methods mentioned above.

Methodology

Sampling and extraction

A detailed description of the sampling sites, sample collection and the sequential extraction of organic matter is presented elsewhere (19). Sediment samples were collected from four different lakes located in the Sudbury Region (46° 25′ N, 81° 00′ W) namely, Tilton, Clearwater, Silver, and Ramsey. The four lakes chosen in this area differ in pH, levels of metal contamination, surrounding vegetation, and in the amount of dissolved organic matter in the water (19). Three sampling points were selected for each lake and surficial sediments were collected using a sediment grab. The sediments obtained from the three points were mixed to give one sample and air-dried at room temperature for seven days. The sediments were next ground and sieved through a 2 mm sieve. The dried sediment samples were treated with organic solvents to remove organic material trapped in the complicated macromolecular matrix. More specifically, 25.0 g of the sediment sample were placed in a Whatman extraction thimble, fitted into a Soxhlet extraction apparatus, and extracted with 300 mL of spectrograde solvent for 48 h. Two different solvents (*n*-hexane followed by chloroform) were used in the extraction process.

Although there are a number of classification schemes (20) for natural organic matter, the HS in this study have been defined with respect to their solubility in alkali and acid. More specifically, humic acid (HA) is defined as the fraction of the HS that is soluble in dilute alkali but is coagulated by acidification of the alkaline extract (below pH 2); fulvic acid (FA) is the fraction that remains in solution when the alkaline extract is acidified, that is, the fraction that is soluble in both dilute alkali and dilute acid. Humin is the fraction of the HS that cannot be extracted from the soil by dilute acid or base. The HA and FA were isolated from the residual sediment using the method introduced by Schnitzer and Schuppli (21, 22) for soil samples. The sediment was first shaken with a 0.1 M $Na_4P_2O_7$ solution, under a nitrogen atmosphere, for a period of 24 h. The solution was centrifuged (10 400 G) and filtered using a 0.45 μm Millipore membrane. The filtrate contained a mixture of FA and HA. Acidification of the filtrate with 6 N HCl resulted in the precipitation of the HA which was subsequently collected with

the aid of vacuum filtration and further purified. The pH of the supernatant was adjusted to 8 with 5 N NaOH and the resulting solution dialyzed using dialysis tubing with a molecular weight cutoff of 3500 amu. The FA was recovered from the solution with the aid of a freeze dryer.

Next the residue resulting from $Na_4P_2O_7$ extraction was treated with a 0.5 M NaOH solution for a 24 h period. The FA and HA were recovered as described above for the $Na_4P_2O_7$ extract. The extraction process afforded two HA and two FA samples for each of the sediment samples studied, i.e., HA–$Na_4P_2O_7$, HA–NaOH, FA–$Na_4P_2O_7$, and FA–NaOH respectively.

Characterization

HA and FA extracts were characterized by classical techniques such as elemental analysis, visible (E_4:E_6) and infrared (FTIR) spectroscopy, and CPMAS ^{13}C-NMR (12, 19). The experimental details have been published elsewhere (19).

Pyrolysis – gas chromatography – mass spectrometry (Py–GC–MS)

The HA and FA fractions were also analyzed with the aid of a CDS Pyroprobe 1000 heated coil filament coupled to a Varian Saturn II gas chromatograph – ion trap mass spectrometer. Samples (450–900 µg) were pyrolyzed in quartz tubes (placed in the platinum coil of the pyroprobe) at 700°C for 10 s for FA and 20 s for HA. The pyrolysis unit – GC interface was maintained at 200°C. The pyrolyzed samples were swept into a gas chromatograph equipped with (*i*) a 1077 Split–Splitless capillary injector which was operated in split mode with a split ratio of ca. 75:1 and at a temperature of 250°C, and (*ii*) a Supelco SPB-5 bonded phase capillary column (30 m × 0.32 mm i.d., 0.25 µm film thickness). The column oven was programmed from an initial temperature of 50°C (isothermal, 2 min) to a final temperature of 250°C at a rate of 5°C per minute. The final hold period was 5 min. Ultrapure helium was used as the carrier gas with a column head pressure of 85 kPa. The GC–MS mass transfer line was set at 260°C. The mass spectrometer was operated at 70 eV in the electron impact mode with a manifold temperature of 220°C. Mass spectral scans ranging from *m/z* 450 to *m/z* 40 were recorded at a scan rate of 0.5 s/scan.

Identification was achieved by comparing the mass spectra of the pyrolysis products with standard mass spectra in the computer library (NIST), by comparing the GC–MS data with literature data (16), and (or) comparison with authentic standard compounds. The relative amount of the pyrolysis products ($\%P_i$) was calculated by dividing the areas counts obtained from electronic integration of individual peaks (AC_i) by the sum of the area counts of all the peaks in the chromatogram (ΣAC_i), eq. [1].

$$[1] \qquad \%P_i = (AC_i / \Sigma AC_i) \times 100$$

Results and discussion

The elemental ratios, H:C, N:C, and O:C, the E_4:E_6 ratios and CPMAS ^{13}C NMR spectroscopic data of the HA and FA extracts isolated from the sediment of four Sudbury area lakes, namely Tilton, Clearwater, Silver, and Ramsey Lake were the subject of an earlier report (19). The results are summarized in Table 1 for the purpose of comparison with the Py–GC–MS results presented below.

A Py–GC–MS analysis of the HA and FA samples isolated from the lake sediments was carried out according to

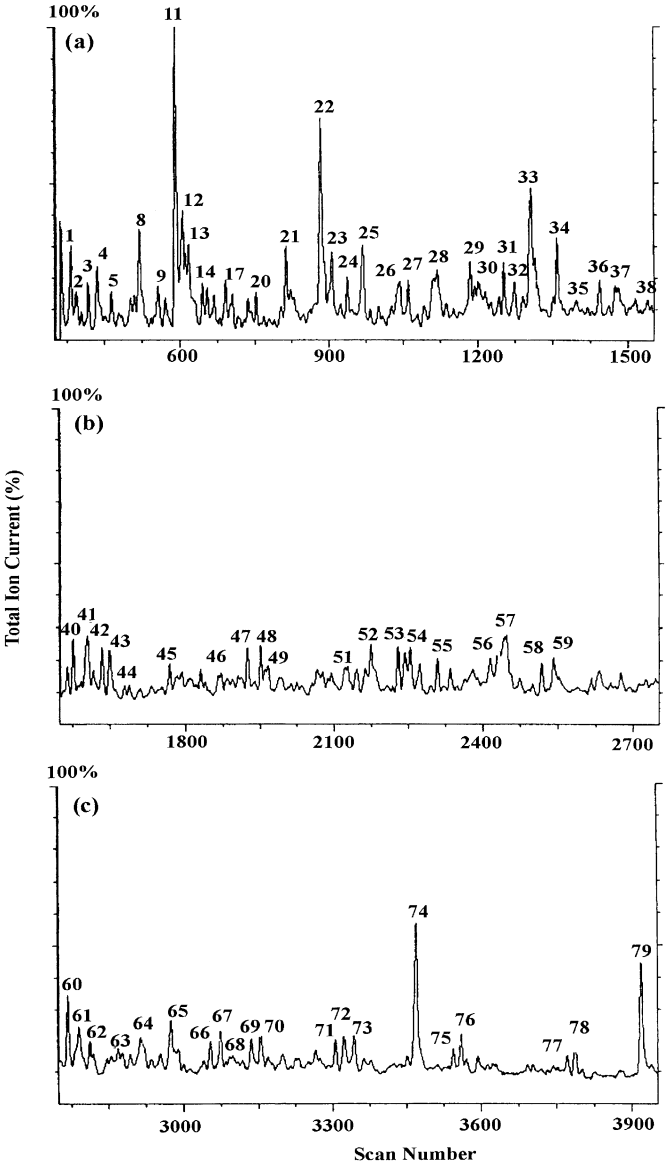
Fig. 1. The Total Ion Current (TIC) pyrogram (displayed in three windows, i.e., a, b, and c) of HA extracted from Ramsey Lake sediment with 0.1 M $Na_4P_4O_7$. Peak numbers correspond to those in Table 2.



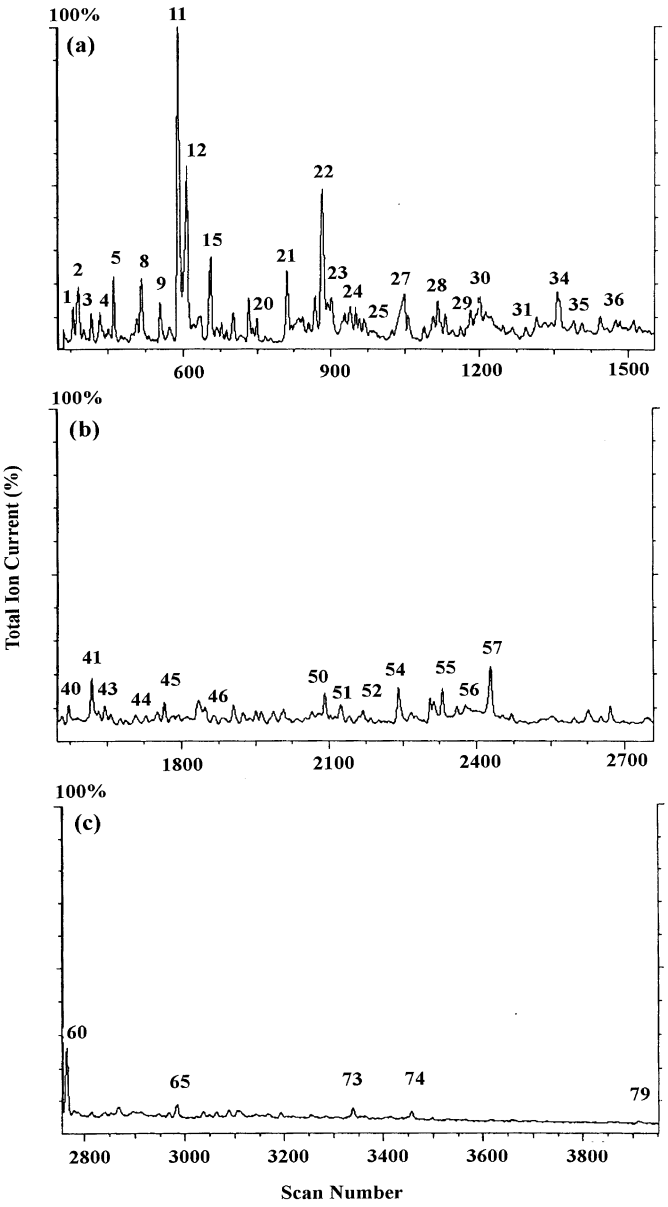


Fig. 2. The Total Ion Current (TIC) pyrogram (displayed in three windows, i.e., a, b, and c) of FA extracted from Ramsey Lake sediment with 0.1 M $Na_4P_4O_7$. Peak numbers correspond to those in Table 2.

the method provided by Chiavari et al. (16). The pyrolytic technique causes the thermal degradation of the FA and HA producing molecules of molecular mass range which are detectable by GC–MS. Representative total ion current (TIC) pyrograms of HA and FA extracted from the sediment of Ramsey Lake are given in Fig. 1 and 2. The same pyrolysis products were obtained whether the HS were extracted by NaOH or $Na_4P_2O_7$. However, the relative amounts of the products change and these changes will be discussed below.

Identification of the pyrolysis products

The pyrolysis products provide a fingerprint which aids in characterizing the original sample. An examination of the pyrograms (Fig. 1 and 2) indicates that there were more than 250 pyrolysis products in the pyrolysate of HA and approximately 200 products in the pyrolysate of FA. The complexity of the pyrograms is consistent with the fact that humic materials are complex heterogeneous macromolecular substances. The peaks corresponding to the main pyrolysis products were identified by comparing the GC and MS data to Py–GC–MS results published by Chiavari et al. (16). This could be done because the experimental set up was identical to that used by Chiavari and co-workers (16).

In order to facilitate identification of the products, authentic samples of phenol and indole were analyzed using the same GC–MS configuration as that used to study the pyroly-

© 2000 NRC Canada

sis products. The scan numbers (*SN*) obtained for the standards were compared to those reported for phenol and indole by Chiavari et al. (16). A correction was applied to the scan numbers in order to standardize the two studies, eq. [2]:

$$[2] \quad SN_{corr} = (SN_{phenol})_{exp} + (SN_r - SN_{phenol}) \times \frac{(SN_{indole})_{exp} - (SN_{phenol})_{exp}}{SN_{indole} - SN_{phenol}}$$

where $(SN_{indole})_{exp}$ and $(SN_{phenol})_{exp}$ are the scan numbers determined for indole and phenol in this study, SN_{indole} and SN_{phenol} are the scan number determined by Chiavari et al. (16) and SN_r is the scan number of a pyrolysis product in the pyrogram published by Chiavari et al. (16). Eq. [2] was used to predict the retention time of the reported pyrolysis products (16) under our experimental conditions (SN_{corr}). Twenty seven of the ninety-nine compounds were identified by comparing our data to the corrected scan numbers. For instance, 2-methylphenol, a pyrolysis product reported by Chiavari et al. (16) was found to have a scan number (SN_r) of 544. By using eq. [2] a SN_{corr} of 819 was calculated for 2-methylphenol. The product labelled **21** in Fig. 2 has a scan number of 811, very close to SN_{corr} for 2-methylphenol. The mass spectral data for the compound eluting at 811 is consistent with that of 2-methylphenol. The scan number, retention time, relative molecular weight, and the proposed origin of the products identified in the pyrolysates of the HA and FA samples have been listed in Table 2. Only peaks with an intensity ≥0.5% of the mixture were considered in the analysis. There are a number of products found in the pyrolysis of the sediment HS which were not observed in the soil humic acid pyrolysis. Their assignment was based on the comparison of the mass spectral data with spectra found in the NIST reference library and other published collections of Py–GC–MS data (23–25). The proposed identity of the pyrolysis products for the HA and or FA is found in column 6 of Table 2. In the cases where positive identification could not be made, the *m/z* of the main mass spectral fragments and their relative intensities to the base peak are presented.

Classification of the pyrolysis products according to their origin: Protein (P), Carbohydrate (C), Lignin (L), or Fatty acid (F)

In theory, the pyrolysis products can provide information on the structure of the HS. However, in practice this task is difficult because pyrolysis compounds can be products of secondary reactions. In addition, certain pyrolysis products are characteristic of many different types of biomaterials and of little use in identifying biological precursors. The interpretation of pyrolysis data is therefore complicated. Before the data can be used to elucidate the structure of HS, one must acquire a better understanding of the behaviour of the organic compounds likely to be present in HS under pyrolytic conditions.

Generally, the pyrolysis products obtained from HS can be classified according to their origin, i.e., protein (P), carbohydrate or structural polysaccharides (C), lignin (L), or fatty acids (F). Chiavari and Galletti (26) have identified the main pyrolysis products generated by 19 α-amino acids using Py–GC–MS. For instance, tryptophan produces indole, 3-methylindole, 3-ethylindole, and 2,3-dimethylindole on pyrolysis, while asparagine produces maleimide and succinimide. It follows that the alkylindoles and maleimide identified in the pyrolysis of the sediment HA and FA samples originate from proteinaceous material containing tryptophan and asparagine. The pyrolysis of proteins also yields N-containing heterocyclic compounds, alkylbenzonitriles, and some aromatic compounds such as benzene, toluene, styrene, phenol, etc. Polysaccharides are also incorporated into the macromolecular structure of HS. The pyrolysis of plant and soil polysaccharides produces a complex mixture of volatile, relatively low molecular weight compounds as well as anhydrosugars (27). Aldehydes and ketones of varying chain lengths, furans, and pyranones are also thought to originate from the pyrolysis of carbohydrate or structural polysaccharides. The pyrolysate of lignin contains primary pyrolysis products derived from the *p*-coumaryl, coniferyl, and (or) syringyl alcohol units depending on the type of lignin. These include phenol, 2-methoxyphenol, and 2,6-dimethoxyphenol. In addition, the thermal modification of functional groups of the basic phenolic units leads to a number of secondary products which can be attributed to lignin. Fatty acids (which are thought to be evaporation products) are known to produce alkylbenzenes and naphthalenes upon pyrolysis (27). The alkanes and alkenes may result from the decarboxylation of fatty acid moieties. Support for this interpretation comes from a study carried out by Saiz-Jimenez (28) where the protection of carboxylic groups by a methylation procedure greatly reduced the quantity of alkanes and alkenes observed in the pyrogram.

As many of the products observed in the pyrolysis of the HA and FA samples as possible were classified according to their origin (Table 2, column 9). This exercise again points to the complexity of characterizing the HS. There are many compounds which could originate from several sources. For instance, the alkanes can either come from the decarboxylation of fatty acids or are a product of evaporation. In other words, alkanes, synthesized by microorganisms can be trapped in the macromolecular matrix and released upon heating the HS. It should be noted that even though the FA and HA samples were previously treated with organic solvents to remove organic matter that was not covalently bound to the macromolecular structure small amounts could still have been trapped. Evidence for this comes from the detection of fatty acids in pyrolysates despite the fact that the HS were first treated with organic solvents (28).

In the pyrolysates of the HA and FA, 22 fragments were ascribed to lignin, 13 were labelled as protein markers, 8 originate from carbohydrate fragments and, finally, 4 peaks were identified as fatty acids. These results suggest that a variety of heterogeneous materials including lignins, proteins, polysaccharides, and fatty acids are components of the humic and fulvic acid molecules. In the case of the HA samples (Table 4, vide infra) approximately 12% of the pyrolysable organic matter is thought to originate from protein, 20% from lignin, 8% from carbohydrates, 6% from fatty acids. A similar analysis for the FA pyrolysate (Table 5, vide infra) shows that 19% of the matter originated from protein, 21% from lignin, 11% from carbohydrates and 0% from fatty acids. In a soil sample from an experimental

farm in Carpi (16), using the exact same experimental method, the relative amounts of protein, lignin, carbohydrate and fatty acid markers were 10%, 40%, 4.3%, and 0.5%, respectively.

Considering that only 50–70% of the pyrolysis products could be identified, any comparison and interpretation remain difficult. However, it is evident from this simple analysis that the carbohydrate content of the HA and FA extracted from lake sediment is considerably lower than that found for soils. The differences observed in the composition of lake sediment humics relative to those from soils might be partially due to the different circulation behaviour of aquagenic versus pedogenic organic matter in lakes. In addition, the FA appears to have a greater amount of products originating from proteinaceous material. This tendency was also observed in the N:C ratios for FA extracted by NaOH. Material which is high in nitrogen reflects a higher concentration of nonvascular aquatic plants (29). The presence of lignin derivatives can be related to terrestrial plants which are expected to contribute significantly to the pool of HS in small lakes surrounded by vegetation. A predominant proportion of phytoplanktonic material (30) would have been indicated by much higher percentages of protein (~50%) and carbohydrates (~30%).

Reproductibility of the Pyrolysis Data

Before making a quantitative comparison of the relative amounts of the pyrolysis products from the different lake sediments, the reproducibility of the relative amounts of the pyrolysis products was tested. This was done by pyrolyzing three samples of the same HA extracted with the aid of NaOH from Tilton Lake sediments. The relative amounts of 52 of the 94 compounds were determined for each of the 3 pyrolysis experiments by comparing the peak areas (eq. [1], vide infra). The average amount of each product generated in the pyrolysis and the standard deviation were calculated (Table 3). The average amounts of the pyrolysis products used to test the reproducibility range from 0.1 to 3.7%. As expected the largest errors occur for the compounds present in low concentration (≤0.5%). However, on average, standard deviations of about 13% were found for peaks larger than 0.5% of the total peak area. Therefore the reproducibility

© 2000 NRC Canada

was acceptable, considering the heterogeneity of the sample and the fact that often several compounds elute at virtually the same retention time.

FA and HA extracted from lake sediments

The FA and HA composition can first be compared in a qualitative fashion. Caution must always be exercised when comparing pyrograms because of their complexity. Often the peaks detected in the pyrograms represent a complex mixture of compounds with similar retention times. As a result, the mass spectrum is often a composite of two or three compounds making it difficult to interpret. We have been able to identify *94* major products in the pyrolysate of HA while *58* have been identified in the case of FA.

All of the products generated in the pyrolysis of the FA samples were detected in the TIC pyrograms of the HA samples, with the exception of the compounds eluting at a scan number of 939, 949, 958, 1621, and 2090. These products include α-methylbenzyl cyanide, an unknown compound, methylbenzofuran, 1,3-benzofurandione, and 1*H*-isoindol-1,3–2(*H*)-dione.

The pyrolysis of HA produced a number of products not detected in the pyrolysis of FA. Over half, i.e., 24 of the additional products generated in the pyrolysis of the HA samples were alkanes, alkenes, and alkylbenzenes. Hydroxybenzonitrile, hydroxybenzeneacetonitrile, methoxybenzenediol, furanmethanol, 4-ethyl-2-methoxyphenol, 3′,5′-dimethoxy-4′-hydroxyacetophenone, 4-hydroxy-3,5-dimethoxybenzoic acid, tetradecanoic acid, pentadecanoic acid, and eight unidentified compounds were also exclusively formed in the pyrolysis of the HA samples.

It should be noted that the major pyrolysis fragments of HA and FA were the same with the only difference being their relative proportion, Tables 4 and 5. Kuckuk et al. (18) observed a similar phenomenon in his study of HS extracted from peat and groundwater (Hannover, Germany).

The relative proportions of a number of products resulting from the pyrolysis of HA extracted from the four lake sediment samples by NaOH and $Na_4P_2O_7$ are given in Table 4. The average values of the pyrolysis products for the four lake sediments range from 0.2% for 4-hydroxy-3,5-dimethoxybenzoic acid to approximately 5% for 4-methylphenol in both the NaOH–extracted and $Na_4P_2O_7$–extracted HA. As was indicated above, the relative error associated with the reproducibility of the pyrolysis experiment is on average usually less than 13% for compounds which produce peaks larger than 0.5% of the total peak area. In comparing the relative amounts of each pyrolysis product for the respective lake sediments some small variations are apparent. For example, in the case of HA–NaOH, phenol, 2-methoxyphenol, 2-methoxy-4-methylphenol, 2-methoxy-4-vinylphenol, 4-hydroxy-3-methoxybenzoic acid, 1-(3,5-dimethoxy-4-hydroxyphenyl)-2-propanone, 4-hydroxy-3,5-dimethoxybenzoic acid, and hexadecanoic acid have relative deviations which are larger than 30%.

A chi-square goodness-of-fit test (31) was applied to the data to determine if there was a statistical difference in the composition of the pyrolysates of the different lake sediments. In the case of the HA–NaOH for the various lake sediments, the analysis showed that the pyrolysis products were formed in the same relative amounts at the 95% confidence level. The greatest variation in concentration was observed for phenol, 4-methylphenol, 2-methoxyphenol, 2-methoxy-4-methylphenol, 2-methoxy-4-vinylphenol, 4-hydroxy-3-methoxybenzoic acid, 1-(3,5-dimethoxy-4-hydroxyphenyl)-2-propanone, 4-hydroxy-3,5-dimethoxybenzoic acid, and hexadecanoic acid. Similarly, when the chi-square test was applied to the HA–$Na_4P_2O_7$ data, the concentration of only a few of the products formed during the pyrolysis varied significantly. These include 2,3-dihydromethylfuran-2-one, 4-methylphenol, benzenediol, 4-hydroxy-3-methoxybenzoic acid, and 4-hydroxy-3,5-dimethoxybenzoic acid. When the combined HA–NaOH and HA–$Na_4P_2O_7$ data were subjected to the chi-square goodness-of-fit test, the pyrolysis products were produced in the same relative amounts at the 95% confidence level. The statistical analysis confirmed that the variation in the composition of the HA collected from the different Sudbury area lakes (based on the pyrolysis data) is slight and that the material extracted using NaOH and $Na_4P_2O_7$ is virtually the same.

A similar conclusion can be reached when comparing the H:C, N:C, and O:C ratios determined for the HA extracted by $Na_4P_2O_7$ and NaOH (Table 1). The elemental ratios differ anywhere from 4–13%, with the largest deviations being observed for H:C and O:C ratios of HA extracted by $Na_4P_2O_7$. The changes detected in the H:C and O:C ratios suggest that there are small differences in the carbohydrate and aromatic composition of the HA. Finally, the major HA pyrolysis fragments in the lake sediments appear to be alkylbenzene (~2%), methyl-2-furaldehyde (~3%), phenol (~3.9%), maleimide (~2.8%), and 4-methylphenol (~5.2%).

The relative proportions of several of the pyrolysis products generated by the FA extracted from the four lake sediments using NaOH and $Na_4P_2O_7$ are presented in Table 5. The average values of the pyrolysis products ranged from 0.1% for 1-(3,5-dimethoxy-4-hydroxyphenyl)-2-propanone to 8% for 2-methylphenol in the FA-NaOH samples and from 0.1% for methylindole to 11% for phenol in the FA–$Na_4P_2O_7$ samples. The main FA pyrolysis products were 2,3-dihydro-methylfuran-2-one (~3.1%), methyl-2-furaldehyde (~4.2%), phenol(~8.6%), maleimide (5.5%), and 4-methylphenol (~7.6%).

The relative proportions of many of the pyrolysis products for the respective FA samples were clearly different which is supported by a chi-square goodness-of-fit test on the data. In fact, 2,3-dihydromethylfuran-2-one, phenol, maleimide, and allylbenzene could be rejected at a 90% confidence level. Large variations were observed for 2-methylphenol, 4-methylphenol, benzyl cyanide, dimethylphenol, 4-vinylphenol, and 1-(4-hydroxy-3-methoxyphenyl)-2-propanone in the case of the FA–NaOH and 2-furaldehyde, alkylpyridine, methyl-2-furaldehyde, 4-methylphenol, 2-methoxy-4-methylphenol, benzenediol, 3-methoxyphenol, 1*H*-indole, and 2,3-dihydro-3-methylindole in the case of FA–$Na_4P_2O_7$. Application of the chi-square test to the combined FA–NaOH and FA–$Na_4P_2O_7$ data suggests there is a difference in the material that was extracted using NaOH and $Na_4P_2O_7$. For example, the average percentage of phenol found in the NaOH extracts (6.1%) was lower than that of phenol found in the $Na_4P_2O_7$ extracts (11.2%). The probability that the relative amount of phenol formed is the same for the NaOH and

© 2000 NRC Canada

$Na_4P_2O_7$ extracts is 1%. In fact, the FA samples extracted with $Na_4P_2O_7$ produce more phenol upon pyrolysis in each case.

The FA samples differed from the HA samples in that their composition was variable. Moreover, the FA composition was dependent on the extractant used. The sediments were collected from lakes with different pH values, i.e., 4.0 (Silver Lake), 4.8 (Clearwater Lake), 5.6 (Tilton Lake), and 7.5 (Ramsey Lake). The carboxylic acid and phenolic hydroxyl groups of FA causes it to be relatively hydrophilic (24). Therefore, its solubility in water is expected to be higher than that of HA. The solubility of organic matter in the lake water was found to be dependent on pH. In fact, the dissolved organic matter increased as the pH of the lake increased (Table 1 in ref. 19). Presumably the soluble organic matter was primarily FA. This could explain why a significant variation in the relative amounts of the FA pyrolysis products was observed for samples taken from the different lakes.

A close examination of the data presented in Table 1 (vide supra) shows that the variation in N:C ratio determined for FA samples extracted from lake sediment was greater than that observed for the HA (cf. 9.3% vs. 5%). In other words, the protein content (which is related to the N:C ratio) was found to be more variable in the FA samples. Similar information can be obtained from the Py–GC–MS data in that the variation of the relative proportion of six of the eight pyrolysates generated by the proteinaceous material in FA found in the different lake sediments is greater than can be accounted for statistically. For the HA samples, the greatest variability in composition occurred for pyrolysis products originating from lignin.

The O:C ratio, as one might expect, is sensitive to carbohydrate content. The variation in the O:C ratio for FA extracted by $Na_4P_2O_7$ from the different lake sediments is four times greater than that observed for FA extracted with NaOH (0.36 vs. 0.08). Similarly, in regards to the Py–GC–MS data, large variations in the relative proportion of 3 of the 4 carbohydrate pyrolysates were detected for the FA–$Na_4P_2O_7$ material whereas only 1 carbohydrate pyrolysate deviated significantly from the norm in the FA–NaOH material indicating the greater variability of the carbohydrate content of the FA–$Na_4P_2O_7$ material. However, it must be taken into account that in the pyrolysis experiment, O-rich polysaccharides are converted to low molecular weight volatile products which elute before being analyzed which causes the carbohydrate content of the HS to be underestimated by pyrolysis.

The variation in the H:C ratios for FA extracted by $Na_4P_2O_7$ and NaOH, were found to be 10% and 5% respectively. The H:C ratios are thought to reflect the degree of aromaticity of the HS. Low H:C ratios are interpreted as meaning that the HS are highly aromatic in character. There are a few pyrolysis fragments originating from lignin, e.g., 2-methylphenol, 1-(4-hydroxy-3-methylphenyl)-2-propanone, 2-methoxy-4-methylphenol, and 3-methoxyphenol, which change significantly as a function of the FA sample. This change in composition of the lignin pyrolysis products could be related to the change in the H:C ratios observed for the FA samples. One again must exercise caution in using pyrolysis data to comment on aromatic:aliphatic ratios because of their sensitivity to pyrolysis temperatures (32).

Finally, from the cross polarization magic-angle spinning (CPMAS) ^{13}C NMR data we concluded that the most intense peak in the HA spectra was found at around 35 ppm, corresponding to the aliphatic C region. This is consistent with the pyrolysis data for the HA extracts in that the majority of the pyrolysates contain aliphatic carbons. In fact, approximately 20–22% of the pyrolysates were found to be long chain alkanes, alkenes, and fatty acids. For the FA extracts long chain hydrocarbons only represented 1% of the pyrolysates. This is in agreement with our finding that the most intense signal in the CPMAS ^{13}C NMR spectra occurs at 176 ppm (the carboxylic C region) rather than at 31 ppm as was observed in the HA spectra. An examination of the remaining pyrolysates (aromatic hydrocarbons, N-containing compounds, furans, phenols, guaiacols, syringols, etc.) is also consistent with finding peaks in the O–alkyl, aromatic, carboxyl, and carbonyl spectral regions.

Conclusions

In this study, organic matter was extracted from the sediment of four Sudbury area lakes, with 0.1 M $Na_4P_2O_7$, and 0.5 M NaOH solutions. The different fractions including FA and HA were characterized by Py–GC–MS. Several pyrolysis and evaporation products were identified in the pyrolysates of the HA (94) and FA (58) samples. The HS extracted from the different lake sediments gave similar pyrolysis products. One notable difference being the large number of alkanes, alkenes, and alkylbenzenes generated by the HA samples. The relative amounts of the pyrolysis products varied slightly between the HA samples whereas variation in the relative amounts of the FA pyrolysis products was significant according to a chi-square goodness-of-fit test. The pyrolysis products were related to the N:C ratios. Therefore it was interpolated that the protein content of the HA samples was similar in all four sediment samples while the FA protein composition differed for the lakes studied. The detection of pyrolysis products originating from lignin and carbohydrates indicates they are present in the humic macromolecular structure and reflects the contribution of terrestrial plants to the pool of natural HS.

Infrared titration of aqueous NaOH by aqueous HCl

Jean-Joseph Max and Camille Chapados

Abstract: The titration of NaOH by HCl is achieved through infrared spectral measurement of the various mixtures. Factor Analysis (FA) is used to separate the spectra. Four principal spectra were necessary to perform the analysis: pure water, 2.09 M HCl, 2.23 M NaOH, and 2.60 M NaCl solvated water. Each of the 18 experimental spectra obtained was determined to be a linear combination of these principal spectra. The composition of the solutions retrieved from the IR analysis is identical to what was determined by the mass balance. The mean activity coefficient of HCl was calculated using the concentration of HCl obtained by IR and the activity obtained by pH measurements. It was found that the mean activity coefficient increased by a factor greater than 2 in the presence of 1 M NaCl. Because the water molecules associated to the ionic pair H^+/Cl^-, as observed by IR, are unmodified by the presence of the salt, such an increase cannot be attributed to a modification of the strong association of the water molecules to the pair of ions.

Key words: infrared spectroscopy; ATR; liquid; acidic solutions; alkaline solutions; aqueous solutions; factor analysis; principal spectra; HCl-, NaOH-, NaCl-solvated water; activity coefficient; IR titration.

Résumé : Le titrage d'une solution aqueuse de NaOH a été réalisé en mesurant le spectre infrarouge de différents mélanges et en utilisant l'analyse par facteurs. Quatre espèces principales ont été nécessaires pour réaliser cette analyse: l'eau pure, et des solutions de HCl (2.09 M), de NaOH (2.23 M) et de NaCl (2.60 M). Nous avons trouvé que chacun des 18 spectres expérimentaux obtenus est une combinaison linéaire des spectres de ces espèces principales. La composition de chacun des 18 mélanges obtenue par l'analyse par facteurs est la même que celle déterminée par la balance de masse. Le coefficient moyen d'activité du HCl a été calculé à partir des concentrations en HCl résultant des mesures infrarouge et des activités obtenues par mesure de pH. Les résultats ont montré que le coefficient moyen d'activité du HCl est multiplié par un facteur plus grand que 2 lorsque du NaCl (1 M) est ajouté à la solution. Puisque l'association de molécules d'eau avec la paire ionique H^+/Cl^-, telle qu'observée par infrarouge, n'est pas modifiée par la présence du sel, on en conclut que cet accroissement du coefficient d'activité de l'acide chlorhydrique ne peut être imputé à une modification de l'interaction forte des ions avec les molécules d'eau.

Mots clés : spectroscopie infrarouge; liquide; solutions acides; solutions alcalines; solutions aqueuses; analyse par facteurs; spectre principal; HCl-, NaOH- et NaCl-solvatés par de l'eau; coefficient d'activité; titrage IR.

Introduction

In previous papers (1, 2) (hereafter referred to as **I** and **II**) we studied aqueous solutions of NaCl and KCl using infrared (IR) spectroscopy and showed that in order to represent the species in 0 to 300 g/L solutions, only two principal spectra were necessary: that of pure water and that of a 300 g/L aqueous solution of salt. In **I,** we mentioned that liquid water and saline solutions are made of numerous species composed of clusters that may contain from 3 to 8, or even more, molecules of water. As the salt concentration of the solution is increased, the species are modified as two entities, forming what we call two types of species of water. This indicates that within the entire solubility range of the salts, saline solutions are composed of two types of species of water: pure water and NaCl- or KCl-solvated water. The two types of species of water are defined by the two eigenspectra, which indicates that the molecules within one type of species behave in the same manner. We use the term "eigenspectra" as an extension of the definition of Malinowski and Howery (3) to refer to principal spectra even when these spectra are not orthogonal.

Transmission spectra of aqueous solutions are difficult to obtain in the mid-IR region because in the 3–μm infrared region, the high absorptivity of water necessitates thin films. In contrast, ATR spectra of aqueous solutions do not require thin films and are easy to obtain. In **II** we compared the ATR spectra of KCl aqueous solutions to the real and imaginary refractive index spectra obtained by the Kramers–Krönig relation and reflection equations, and found that as long as the proper material is used for the ATR crystal and that the concentration of water is not drastically decreased compared to pure water, then the IR-ATR measurements as they appear directly reflect the chemistry of the sample.

In **I** it was established that it is possible to use only two eigenspectra to accurately subtract the water bands in the spectra of NaCl aqueous solution. Sodium monochloroacetate that was dissolved in the saline solution was used to test the procedure. After carefully subtracting the water spectra, a clean spectrum of the solute was retrieved, with no correction required to obtain a flat baseline. Spectral subtraction of water and baseline correction are difficulties encountered when working with IR spectra of aqueous solutions of biological (4) and other materials because the water spectrum does not remain constant but is influenced by the ions present, even though these ions do not absorb (5). Several complicated methods have been proposed to solve these problems (6–11). However, the method proposed in **I** is simple and requires no artifact to make the proper correction in order to obtain a flat baseline. This method has been tried successfully with several salts (1, 12), acids and bases (13–15).

A third paper (12) (**III**) confirmed the previous results by giving the equations that allow the interpolation and extrapolation of spectra of aqueous saline solutions. Given a spectrum of an aqueous solution obtained at one salt concentration, it is possible to calculate that spectrum at any other concentration. This development was necessary since binary salts dissolved in water are ionized and therefore do not absorb in the m-IR frequency range. The Beer-Lambert Law can therefore not be used directly. However, these samples were mixtures of two substances, one of which does not absorb but strongly influences the second. Applying factor analysis (FA) to aqueous salt solutions led to the following conclusions: (*i*) two types of species of water are present in the solutions; (*ii*) each spectrum is a linear combination of the spectra of the two types of species of water (pure water and salt solvated water); (*iii*) the intensity (in AU) of aqueous salt solutions is the sum of two intensities, each of which is proportional to the concentration of the respective type of species of water.

The development in **III** gave the relations as functions of the concentration of the non-absorbing species. By this scheme we calculated the virtual spectrum of "pure" KCl-solvated water. The latter is outside the solubility range of the salt but is present in the solution at concentrations lower than saturation. The "pure" KCl-solvated water contained no ordinary water, being composed of the two close-bound ions (cation and anion) and a mean of 5 molecules of water forming a cluster: $K^+(H_2O)_5Cl^-$. Using the data in **I** we also determined in **III** that NaCl in water behaves in the same manner, forming a cluster also containing a mean of 5 molecules of water: $Na^+(H_2O)_5Cl^-$. For other ions, the number of water molecules associated to them may be different than that obtained for KCl and NaCl (unpublished results).

The IR spectra of aqueous HCl and aqueous NaOH solutions at several concentrations were studied in **IV** (13). We found that each solution could be explained as a combination of two eigenspectra: pure water and HCl-solvated water, and pure water and NaOH-solvated water, respectively. Malic acid dissolved in acidic water and in basic water was used to illustrate the procedure. In both cases, two eigenspectra multiplied by the proper multiplying factors (MFs) (see Section 2.1) enabled the subtraction of the water spectra to produce the spectrum of malic acid in one case, and of sodium malate in the other. Both spectra were free of identifiable water bands. This result indicated that, for these solutions at least, it is possible to use the inter- and extrapolation procedure described in **III** to obtain the spectrum at a given concentration.

The object of the present study is to test the knowledge gained in **I**, **II**, **III**, and **IV** by performing a quantitative IR titration of NaOH by HCl, knowing that all the ions involved are either non-absorbing or very weakly-absorbing. Furthermore, these ions are in solution in a strong absorber: water. As the titration proceeds, the solvent that contains an increasing amount of NaCl, is successively basic, neutral, and acidic. The spectra obtained in the 14 to 0 pH range will be separated by FA to obtain the MFs in order to relate the concentration of the species to the values determined by the mass balance.

IR titration of aqueous glycine and of aqueous butyloxypropylaminodiacetic (BOPA) have previously been reported (14, 15). Good results have been obtained in both cases. In both cases, contrary to the one presented here, strong IR absorption bands of the solute varied with pH and served as good internal indicators of the ionic situation of the solution. The eigenspectra are constant throughout the pH range and indicates that the only types of species defined by these spectra are present in the solution. No intermediate species resulting from some interactions between the species are formed because the residues obtained are null for all the spectra. The situation is similar in the NaOH–HCl titration. For the latter, the situation is less evident because these species are not visible or only barely visible in IR but their interactions with water are observed.

For this base–acid titration where salt is formed one question comes to mind: what influence has salt on the measurements because it has been reported that the acidity and the ionic activity of aqueous solutions is greatly modified by the presence of salts (16, 17)? It has also been reported that the IR spectrum of aqueous HCl is greatly modified by the presence of binary salts (5). Electrolytes in an aqueous solution have been reported to influence the hydrolysis rate of esters (18). One of the aims of the present study is to examine the relationship between the IR spectroscopic characteristics of HCl-solvated water and the mean activity coefficient of HCl. The knowledge gained by the IR titration of NaOH by HCl may give some new insight into this age-old process and could determine the exact ionic composition of the solution as the titration proceeds.

2. Theoretical considerations

2.1. Factor analysis (FA)

The basic principles of FA applied to chemical analysis and the mathematical formulation of FA can be found in the book of Malinowski and Howery (3). The method of subtracting water bands from the spectrum of an aqueous solution is given in **I** for a binary salt and in **IV** for an acid and a base. It consisted of defining four eigenspectra: pure water and NaCl, HCl, and NaOH aqueous solutions. These four spectra are genuine but are not orthogonal spectra. The NaCl, HCl, and NaOH aqueous solutions contain an unknown amount of water organized as in pure water with the rest being organized as solvated water (**III**). S_e^p is the spec-

© 2000 NRC Canada

trum of pure water, $S_a^{M_a}$, $S_b^{M_b}$, and $S_c^{M_c}$ are the spectra of NaCl, HCl, and NaOH at the concentrations M_a, M_b, and M_c, respectively. With these four eigenspectra, FA was used on a series of 18 IR spectra (S_j) obtained in saline, acidic, and alkaline solutions. The MFs retrieved by FA are related to the concentration of the corresponding type of water in the sample. The MFs of each eigenspectrum in S_j are determined when the sum of the eigenspectra multiplied by their respective MF is compared to the experimental spectrum. The MFs are adjusted until a satisfactory fit is obtained. With the four eigenspectra $S_a^{M_a}$, $S_b^{M_b}$, $S_c^{M_c}$, S_e^P, the MFs obtained for the spectrum S_j are denoted $y_{aj}^{M_a}$, $y_{bj}^{M_b}$, $y_{cj}^{M_c}$, $y_{ej}^{M_aM_bM_c}$. The solutions used to obtain the three eigenspectra ($S_a^{M_a}$, $S_b^{M_b}$, $S_c^{M_c}$) contained some water organized as in "pure water." As a result, the MFs of pure water depend on the concentrations of the solutions used for the eigenspectra of the three other species and must be written: $y_{ej}^{M_aM_bM_c}$.

2.2. Calculation of Sample Composition from MFs

The composition of the sample is calculated from the MF values obtained by FA. The concentration of the three species **a**, **b** and **c** present in the solution are obtained by multiplying the MF value by the concentration of the solution used for the corresponding eigenspectrum. The solvent content of the samples is obtained by multiplying the amount of solvent in each of the four solutions used for the eigenspectra by its respective MF in the sample and calculating the sum of the four values obtained.

3. Experimental

3.1. Chemicals and Solutions

Deionized water was used to prepare the aqueous solutions. Sodium hydroxide (Fisher Scientific, purity 97%), and concentrated hydrochloric acid (Fisher Scientific, 38.0% w/w, density 1.19 g/mL, 12.40 M) were used to prepare the solutions of NaOH–, HCl–, and the NaOH–HCl mixtures. In order to produce the best spectra possible, high concentrations of titrant were used so as to avoid diluted solutions.

A stock solution of 1.12 M NaOH was prepared by weighing 11.2 ± 0.1 g of NaOH pellets in an empty 250 mL volumetric flask and completing the volume with water. The weight of the resulting solution was 260.1 ± 0.1g. The mixtures of NaOH and HCl were prepared by weighing an amount of aqueous 12.40 M HCl in empty 10 mL volumetric flasks. The volume of each sample was then completed to 10 mL with the stock solution of NaOH. The mass and pH of the samples were measured. The composition of each sample calculated from the mass balance is listed in Table 1.

The eigenspectra of NaOH, HCl, and NaCl used for FA were defined using the solutions obtained by weighing 0.8901, 2.0041, and 1.5189 g (± 0.0001 g), respectively in 10 mL volumetric flasks. Each sample was completed to 10 mL with water and the mass measured, giving: 10.8466, 10.2938, and 10.9484 g (± 0.0001 g), respectively. All samples produced homogeneous solutions.

For the pure solutions of NaOH and HCl in the 0 to 40 g/L range, we used the spectra reported in **IV**, whose pH had been measured using the method described below.

3.2. pH measurements

The pH was measured at room temperature (26.5 ± 0.3°C) with a pH meter (Omega model PHH-253) equipped with a combination electrode (Analytical Sensors, Inc., model PH10107B-03-B). Prior to any series of measurements a two-point calibration was carried out at pH = 2.00 and 7.00, or 7.00 and 10.00.

3.3. IR measurements

The IR measurements were obtained using a Model 510P Nicolet FT-IR spectrometer with a TGS detector. Two KBr windows isolate the measurement chamber from the outside. The samples were contained in a "Circle Cell" (SpectraTech, Inc.) equipped with a ZnSe crystal rod in an ATR configuration (making 11 internal reflections, the incident beam is at an angle of 45° with respect to the rod's axis). The spectral range of the ZnSe rod in the spectrophotometer is situated between 4800 and 650 cm^{-1}. The spectra were taken under a flow of nitrogen to ensure a low residue of CO_2 and water vapors in the spectrometer. For each spectrum, an accumulation of 100 scans with a resolution of 4 cm^{-1} was obtained. All measurements were taken at 26.5°C ± 0.3°C. The cell was carefully washed and dried before each measurement. Model 510P is a single-beam spectrometer and a background with the empty cell was taken before measuring each sample.

Due to the variation of the penetration depth with the wavelength, the use of an ATR configuration causes some modifications in the spectra compared to the transmission configuration. The depth of penetration is dependent on the wavelength, the angle of incidence, and the ratio of the refractive indices of the crystal to the sample (19). Nevertheless, for a sample with a constant refractive index (as a function of wavelength), the ratio of the depths of penetration for two given wavelengths is independent of both refractive indices and angle of incidence and depends only on the two wavelengths. From one spectrum to the other, the only possible variation may occur in the refractive index of the sample. The refractive index of aqueous KCl varies from 1.332 to 1.367 for concentrations 0 to 300 g/L (20). This minor variation will influence the IR ATR measurements but very little and has thus been disregarded in the present study. Since we deal only with ATR spectra, comparing them on a wavelength to wavelength basis, no major difficulty was encountered and no correction relative to this configuration was deemed necessary.

In **II** we demonstrated that the ATR spectrum of aqueous solutions and the spectrum recovered by the use of reflectance calculation and the Kramers-Krönig Relation ($k(\tilde{\nu})$ spectrum) are very similar. Their differences in shape are minor and only found at the top of the absorption band of the different components. The Anomalous Dispersion Effects neither mask nor create transformations in the ATR spectra of water when a binary salt is added. The Anomalous Dispersion Effects follow the pattern set by the transformation of the spectral characteristics of water when a salt is added. Since the modifications of the experimental ATR spectrum and the $k(\tilde{\nu})$ spectrum are proportional (**II**), it is not necessary to separate the optical effects of the ATR spectra beforehand to observe the sample's chemical modifications.

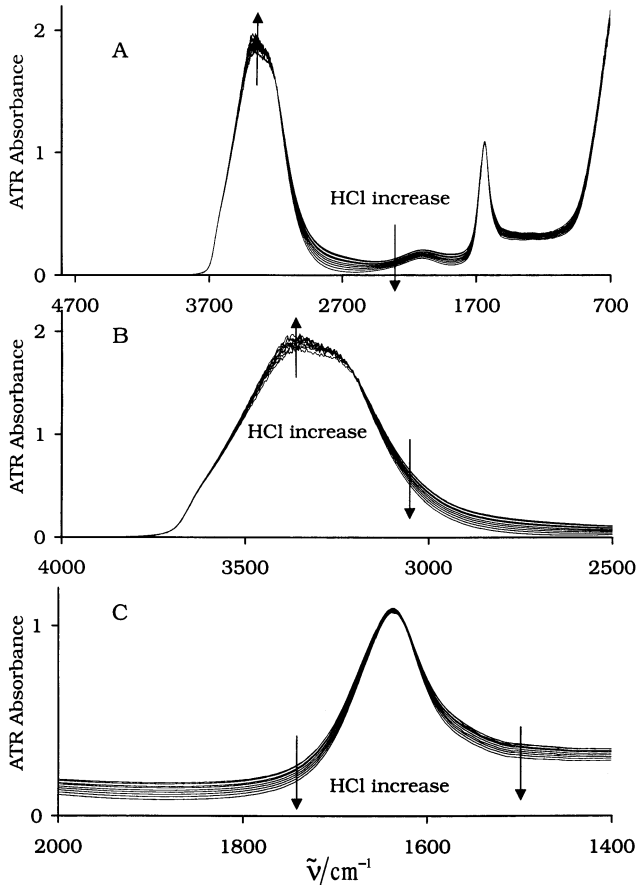
The IR measurements consisted in obtaining the ATR background intensity: R_0, and the ATR sample intensity: R. The R/R_0 ratio produced intensity I for the spectral range being studied. Thereafter, data points (I ($\tilde{\nu}$) vs. $\tilde{\nu}$ (in cm^{-1})) were transferred to a Microsoft Excel spreadsheet program on a personal computer where the numerical treatments were performed. Intensities I were then transformed into log(1/I) that we designated as ATR Absorbance. No baseline correction was made.

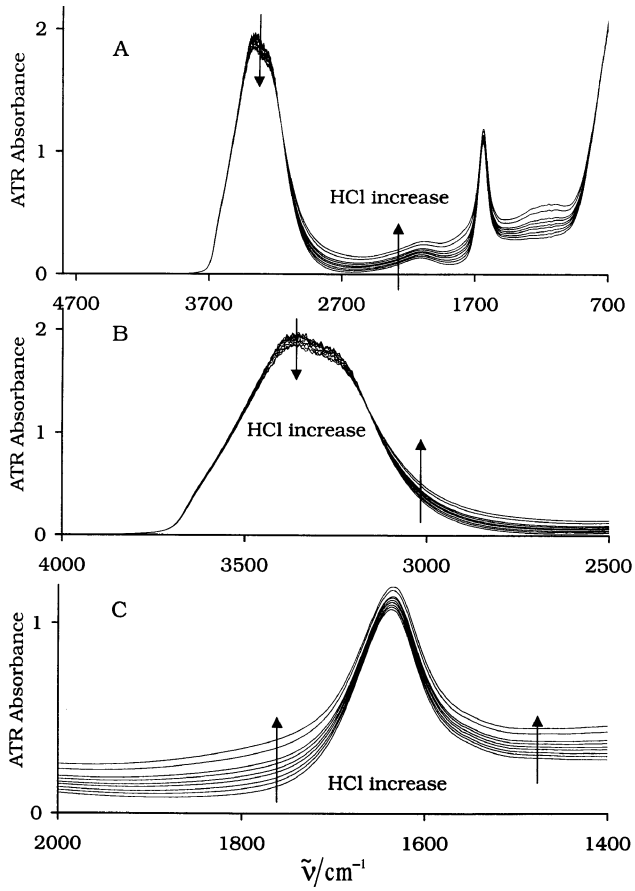
3.4. Factor analysis



FA was applied to the series of spectra of aqueous NaOH and aqueous HCl. This was achieved using the eigenspectra and multiplying each by its MF. The MFs varied in order to obtain the fit that would best minimize the difference between the experimental and calculated spectra. The latter were obtained by adding the eigenspectra multiplied by their MFs. The minimization was monitored by using the least square fit procedure. The absorbance of water in the 3500–3100 cm^{-1} region and below 750 cm^{-1} was near saturation, resulting in a noisy signal in these frequency ranges. Consequently, these regions were eliminated in the least square fit procedure. Each mixture obtained by titration in the –0.3 to 14 pH range was composed of three components and as a result, three eigenspectra were sufficient to perform the analysis in each region.

4. Results and discussion

4.1. Spectra of 18 mixtures of NaOH and HCl



The spectra of the 18 samples reported in Table 1 are presented without modification in Figs. 1 and 2. To avoid confusion, the spectra of the alkaline solutions are given in Fig. 1 and the spectra of the acidic solutions are given in Fig. 2. Figures 1A and 2A show the spectra from 4800 to 700 cm^{-1}. Figures 1B and 2B show a blowup of the OH stretch region. In the latter, we observed that the central region of the band is not much displaced by the added HCl

Fig. 1. (A) IR-ATR spectra of the 9 mixtures of NaOH and HCl at pH higher than 7; (B) Expanded view of the OH stretching region; C) Expanded view of the OH deformation region.

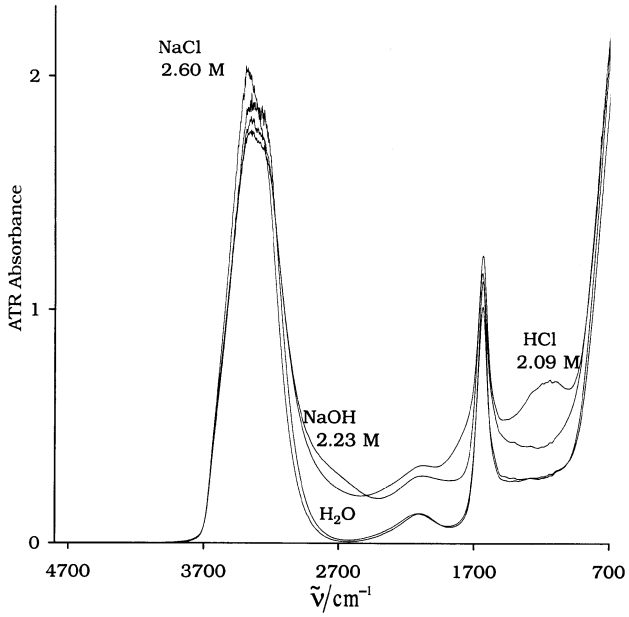

Fig. 2. (A) IR-ATR spectra of the 9 mixtures of NaOH and HCl at pH lower than 7; (B) Expanded view of the OH stretching region; C) Expanded view of the OH deformation region.

titrant, whereas the lower frequency far wing region is modified. Figures 1C and 2C display a blowup of the ν_2 water region. Within the resolution of 4 cm^{-1}, the ν_2 band center is not modified, although the far wing regions (high and low) are. As the pH decreases from 14 to 7, the intensity of the far wings decreases (Fig. 1C). Further decreasing the pH from 7 to –0.3, the intensity of the far wings increases (Fig. 2C). These modifications are in agreement with our previous studies. In **IV**, an increase in the HCl or NaOH content in pure water in turn increased the intensity of the far wings, as indicated by an apparent upward shift of the baseline. These modifications also confirm the results presented in **I,** where an increase in the NaCl content in pure water did not modify the apparent baseline. At the beginning of the titration of NaOH by HCl (pH = 13.89), an absorption is present in the far wings (the apparent baseline is high). Adding HCl neutralizes part of the samples' NaOH and therefore diminishes the NaOH content, which in turn lowers the far wings. When neutralization is reached, the sample is made of water and salt, both leading to low intensity far wings. Adding more HCl increases the sample's HCl content, therefore increasing the far wings.

The four eigenspectra used to deal with the base (NaOH) – acid (HCl) titration are provided in Fig. 3: pure water; 2.60 M NaCl; 2.09 M HCl; and 2.23 M NaOH. These spectra are uncorrected. All the spectra show large structureless

Fig. 3. The four eigenspectra: pure water; 2.60 M NaCl; 2.23 M NaOH; and 2.09 M HCl.

bands appearing in the same regions. Although the spectra are distinctly different, they display similar features in the strong absorption bands. This explains the difficulty of dealing with aqueous solutions.

4.2. MFs retrieved by FA for the IR titration of NaOH by HCl

Figure 4A illustrates the density of the samples as a function of the mass of the added 12.40 M HCl. The titration is divided into two regions. The first region is related to the mixtures of water, NaOH, and NaCl. The second region is related to the mixtures of water, NaCl, and HCl. In each region, within experimental error, the density is linear with the added titrant. It is easily demonstrated that this linearity stems from the linearity of the density of aqueous solutions in each of the three components, as a function of the respective concentration (in the 0–120 g/L range) (20). Consequently, as indicated in **III**, the equations of normalization, interpolation, and extrapolation can be used.

Figure 4B gives the MFs retrieved by factor analysis. The results were obtained by minimizing the intensity of the residues in the least square fit procedure. An example of the procedure can be found in Fig. 5A, where the situation at 0.7325 g of 12.40 M HCl was used for the exercise. The three species present are: pure, NaOH-, and NaCl-solvated water. The eigenspectra of these species (Fig. 3) are multiplied by the MFs given in Fig. 4B. The sum of the spectra is subtracted from the corresponding experimental spectrum given in Fig. 1. The residue observed at the bottom of Fig. 5A is a straight line at the 0.00 AU level. The residues, obtained for the 18 mixtures prepared for the titration, are illustrated in Fig. 5B. Except for the 3 μm region, the maximum and mean absolute absorbance of the residues were below 0.01 and 0.002, respectively. The minute residues obtained for all the samples indicate that FA procedure is adequate and that the results obtained are reliable.

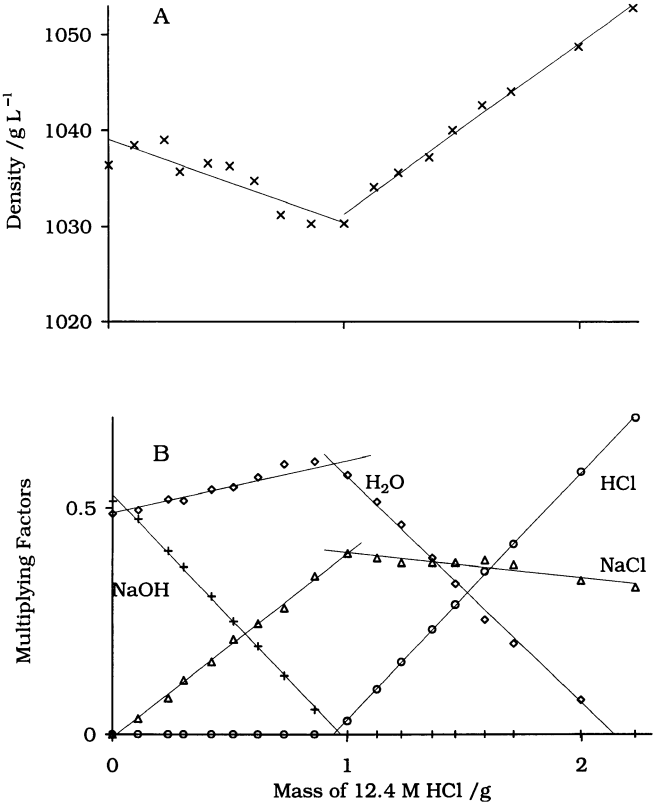
Fig. 4. (A) Density (×) of the mixture of NaOH and HCl as a function of titrant; B) MFs retrieved for the solutions using the eigenspectra of Fig. 3: HCl (O) ; NaCl (Δ), NaOH (+), and pure water (◇).



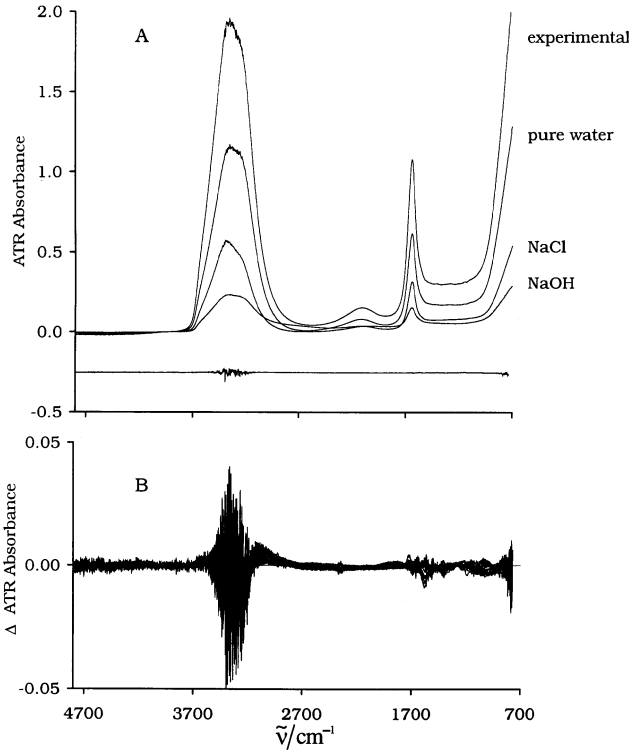


Figure 4B documents the results of the IR determination of the different species during the titration of NaOH by HCl. At the beginning of the titration, HCl reacted with NaOH to form H_2O and NaCl and therefore the MF of free NaOH decreased while the MF of NaCl increased. The two curves are linear functions of the amount of added titrant. No free HCl remained in the solution whose MF was zero. Once all NaOH was neutralized, the MF of free NaOH fell to zero while the MF of free HCl increased linearly when this substance was added to the solution. Since the samples were made with a constant volume, as the amount of titrant increased, the volume of the stock solution of NaOH in the sample decreased. Consequently, after neutralization of NaOH, the MF of NaCl slightly decreased (Fig. 4B).

4.3. Spectral differences between NaCl-, NaOH-, and HCl-solvated waters

The eigenspectra of pure water and solvated waters given in Fig. 3 are different. They were necessary and sufficient to perform FA on the series of samples throughout titration. This indicates that the four types of species of water defined by their respective eigenspectra are independent, that is: the interactions between the three types of species of water present at any time after the neutralization reaction are very weak. For example, after some titrant HCl has been added to the titrate NaOH, but before reaching the isoelectric point, aqueous NaOH, aqueous NaCl, and pure water are present in the solution at equilibrium. The NaCl-, NaOH-solvated waters, and pure water are the only water present in the solution. They are independent from each other (at the first order) because their eigenspectra, obtained with the pure solutions, are the only spectra used to recompose the spectra of the solution (Fig. 5A). If there were some interactions between the types of species of water, then the residue would not be at the zero level and this would indicate that one or more new species would be present in the solution. These new species would have genuine spectra different than the ones given in Fig. 3A. We have observed no such spectra. On other systems such intermediate spectra indicative of new species have been observed (unpublished results).

Fig. 5. (A) Example of FA decomposition of the sample at pH = 13.40. The top trace is the experimental spectrum. The three middle traces are the eigenspectra of water, 2.23 M NaOH, and 2.60 M NaCl multiplied by their respective MFs (Fig. 4B). The residue (shifted by –0.25 AU) is the difference between the top spectrum and the sum of the three others. (B) Residues of the 18 spectra of the NaOH–HCl mixtures. (Note the expanded intensity scale).

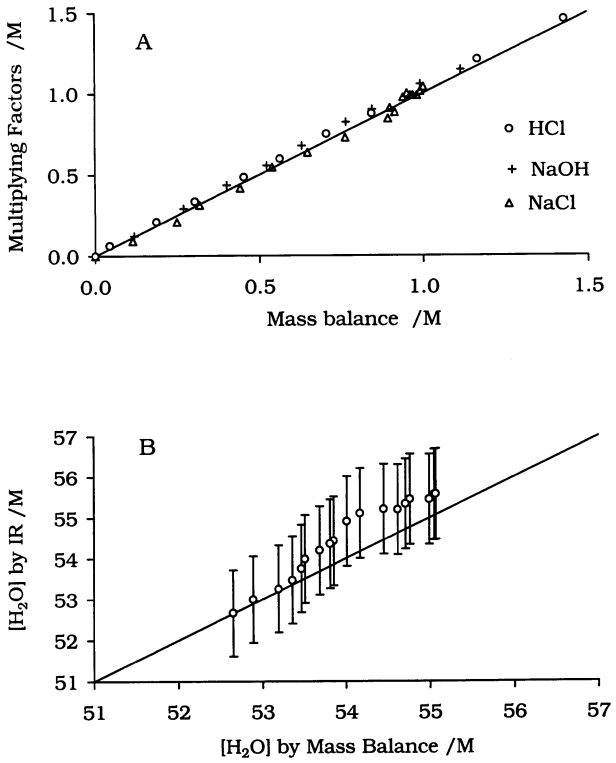
Schlöberg and Zundel reported that the spectra of 1M and 5 M HCl are modified by the presence of salts (5). They related the modifications of the water spectrum in the presence of ions to the action of a strong local electric field on the highly polarizable OH bonds. The results obtained by the present study of the IR titration of NaOH by HCl indicate that the spectral modifications observed are not caused by any modification in the spectrum of aqueous HCl, but represent the sum of the aqueous HCl and aqueous NaCl spectra in the low pH region and the sum of aqueous NaOH and of aqueous NaCl spectra in the high pH region.

The spectra given in Fig. 3 and the FA for the IR titration of NaOH by HCl (Fig. 4B) establish that the spectrum of aqueous NaCl cannot be represented by a combination of the

© 2000 NRC Canada

spectra of aqueous NaOH and aqueous HCl. Furthermore, the spectral characteristics of the NaCl-solvated water cannot be retrieved using the spectrum of NaOH-solvated water, nor with the spectrum of HCl-solvated water. This indicates that the solvation of NaCl by water does not produce isolated solvated ions, namely solvated Na^+ and solvated Cl^- in water. This confirms the results set forth in **III** where it was found that the pair Na^+/Cl^- formed a strong cluster with a mean of 5 molecules of water: Na^+-$(H_2O)_5$-Cl^-. We observed that the spectra for NaCl-, NaOH- and HCl-solvated waters are unchanged in the presence of the other types of species of water. This indicates that the organization Na^+-$(H_2O)_5$-Cl^- is not modified by the presence of HCl and that the structure of HCl–solvated water is unchanged when NaCl is present. Consequently, each pair of ions Na^+/Cl^-, Na^+/OH^-, and H_3O^+/Cl^- is associated to an amount of solvated water molecules and within each cluster the interactions of the ions with the water molecules are strong, while the interactions are weak between clusters. Strong interactions of the molecules imply modification of the intramolecular vibrations and result in significant spectral displacements.

4.4. Correlation between IR and mass balance results



To make the correlation between the composition of NaCl, NaOH and HCl present in the sample calculated from the mass balance and that retrieved from the IR measurements, the MFs of Fig. 4B were taken and transformed into concentrations (Section 2.2). For instance, take the sample that originally contained 0.7325 g of 12.40 M HCl to which the NaOH solution was added. The MFs of this situation taken from Fig. 4B are: 0.280, 0.130, and 0.000 for NaCl, NaOH, and HCl, respectively. The concentrations of the original eigenspectra being 2.599, 2.225, and 2.086, then the concentrations of NaCl, NaOH, and HCl are 0.728, 0.289, and 0.000, respectively. The latter are the ordinates of the three points in Fig. 6A. From Table 1, the abscissas of these points are: 0.764, 0.268, and 0.000 (in mol/L), respectively. Similarly, the calculations are made for all the samples. The results given in Fig. 6A indicate that all the points are near the solid line, which is the theoretical slope for a perfect one to one correlation.

Figure 6B illustrates the correlation plot of the amount of water in the titration derived from the balance of mass and that retrieved from the IR analysis. Once again, all the points are in agreement with the theoretical slope. This indicates that FA is a reliable method of retrieving the right concentrations of NaOH, NaCl, HCl, and water in an aqueous solution from the IR spectra.

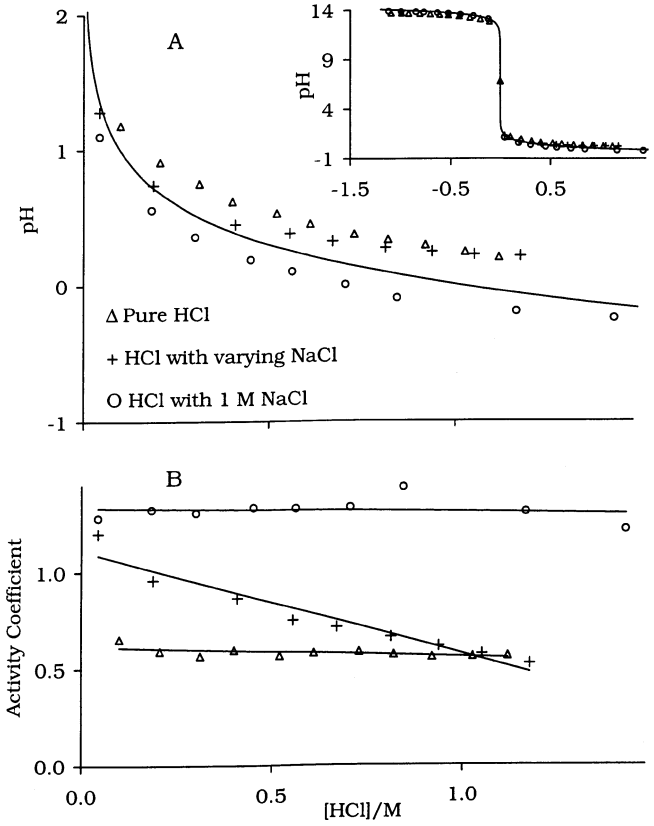
4.5. IR titration of NaOH by HCl

The concentration of the stock solution of NaOH can be obtained with the MFs provided in Fig. 4B. First, the complete neutralization of NaOH by HCl is obtained at the intercept of the two straight lines defined by the MFs of NaOH and HCl: 0.96 g of 12.4 M HCl. The amount of HCl added is determined by multiplying the mass by its concentration ([HCl] = 12.4 mol/L) and dividing the result by its density (d = 1.19 kg/L). The volume of the stock solution corresponding to this situation is then obtained by subtracting the volume of titrant (x/d) from the total volume (V). Finally, the concentration of the stock solution of NaOH is:

Fig. 6. Correlation plot between the concentrations obtained from the mass balance (Table 1) and that retrieved from the IR measurements. (A) for: HCl (O), NaOH (+), and NaCl (Δ); (B) H_2O with 2% error bars.

$$[1] \qquad [\mathrm{NaOH}] = \frac{\frac{x\,[\mathrm{HCl}]}{d}}{V - \frac{x}{d}} = \frac{[\mathrm{HCl}]}{\frac{Vd}{x} - 1}$$

Using the values [HCl] = (12.4 ± 0.1) M, d = (1190 ± 4) g/L, x = (0.96 ± 0.01) g, and V = (0.01000 ± 0.00005) L in eq. [1] we obtain a value of (1.09 ± 0.03) M for the concentration of NaOH. The concentration calculated directly from the mass of NaOH pellets is (1.086 ± 0.010) M. The result above indicates that IR titration produced the true concentration of NaOH with accuracy.



4.6. Rapid determination of NaOH, HCl, and NaCl concentrations in a solution by IR

The above titration was performed to establish that the three types of species of water simultaneously present in a solution are independent of each other. The present study shows that it is possible to obtain the accurate concentration of NaOH, NaCl, and HCl in water using a single IR spectrum. Therefore, a single spectrum of a given solution is sufficient to determine its ionic content.

The root mean square of the residue obtained in this series was 0.002 AU (Fig. 5B), to be compared to the absorbance level of HCl 2.09 M and NaOH 2.23 M near 2650 cm^{-1} (0.218 and 0.272, respectively, see Fig. 3). We can thus predict that for concentrations exceeding 10^{-2} M it is possible,

Fig. 7. (A) Plot of pH as a function of [HCl] in the samples in mol/L: pure (Δ), from titration of NaOH by HCl (O), and from titration of HCl by NaOH (+). The insert shows the full scale titration curve. The full lines are theoretical results for HCl with mean activity coefficient equal to unity. (B) Plot of the mean activity coefficient of HCl as a function of [HCl] calculated by eq. [2]. (Same symbols as in A). Full lines are linear fits in each case.

using IR, to obtain the titration of NaOH and HCl with an accuracy comparable to that of a volumetric titration. This method can be used to determine the concentration of NaOH and HCl in high-concentration solutions where it is often difficult to obtain these values rapidly. The lower limit of the determination depends on the IR apparatus used. This IR method can be automated to provide real time measurements. It would therefore be possible to monitor the variations of the concentrations of HCl, NaOH and NaCl in water in real time during a reaction involving either species, even in the presence of the other substances.

4.7. The activity coefficient and the IR spectrum of HCl

The activity and the specific conductivity of HCl have been reported to be greatly influenced by the presence of salt (5, 16, 17, 21, 22). The IR titration of NaOH by HCl presented here allows us to discuss the relation between the mean activity coefficient of aqueous HCl and its IR spectrum.

Estimating the activity of HCl or its acidity is no easy task (21, 22). Schwabe studied the relation between the acidity, activity, and pH according to conventional measurement techniques and the various sizes of different ionic species in water for several binary acids mixed with neutral salts (21). The purpose, in our study, is to determine whether or not there is a relation between the activity of HCl in water and the IR spectrum of aqueous HCl when a neutral salt is added (from 0 to 1 M NaCl). To this end, we used pH values obtained from a pH-meter.

Measurement by a pH-meter gives a representation of the activity of H^+ in the solution: pH ≈ paH = –log a_{H+} (21, 23). The mean activity coefficient of HCl (γ_{H^+/Cl^-}) is obtained through the usual relation:

$$[2] \qquad \gamma_{H^+/Cl^-} = \frac{a_{H^+}}{[H^+]} = \frac{10^{-pH}}{[H^+]}$$

The activity coefficients were retrieved from the pH measurements and the concentrations obtained from the IR measurements. In Fig. 7A, pH is a function of the concentrations of HCl retrieved by IR: neutralization of NaOH by HCl (O); neutralization of HCl by NaOH (+); and pure HCl (Δ). The values of the latter came from **IV**. The full line represents the theoretical curve for HCl where the mean activity coefficient is equal to unity. Figure 7A shows that the pH is lowered by adding a neutral salt (the salt comes from the neutralization of NaOH by HCl), passing from the values of pure HCl (Δ) to the values of HCl with NaCl (O). When HCl is neutralized by NaOH, the salt concentration varies and the mean activity coefficient varies with the concentration of the salt (Fig. 7A, +). The difference between the latter curve and that of pure HCl (Fig. 7A, Δ) is explained by the variation of the activity coefficient of HCl (21).

The results obtained by eq. [2] from the experimental values are illustrated in Fig. 7B in the 0.05 to 1.4 mol/L range where the mean activity coefficient of aqueous HCl is given as a function of HCl concentration. In the absence of NaCl (Δ data from **IV**), the mean activity coefficient of HCl is approximately constant at 0.6 from 0.1 M to 1.2 M HCl. In the presence of 1 M NaCl (○), the HCl mean activity coefficient is approximately 1.3. The mean activity coefficient of HCl is significantly increased when 1 M NaCl is present in the solution. Furthermore, when the concentration of salt increased in the HCl solution, the mean activity coefficient in the latter increased (+). This behavior and the range of value obtained are in agreement with that observed 30 years ago by Schwabe (21). The discussion about the exact value of the mean activity coefficient of HCl, its acidity (pwH, Hammet function, and other functions) (21, 22) is beyond the scope of this study.

The IR titration (Section 4.5) indicated that the spectra of NaCl-, NaOH-, and HCl-solvated waters were independent one from the other. Therefore the spectrum of HCl-solvated water is unchanged when NaCl-solvated water is present. From this we conclude that the structure of HCl-solvated water is stable and unchanged in the presence of NaCl-solvated water. Consequently, the variation of the mean activity coefficient of HCl is not related to a modification of the structure of the HCl-solvated water. This is true in the first order. Second order effects were not observed in the present study. Therefore, the activity of HCl in water is not related to its direct solvation by water. It could possibly de-

© 2000 NRC Canada

pend on the dynamics of the solvation. This effect is beyond the scope of the present study.

5. Conclusion

The species formed following the solvation of HCl, NaOH, and NaCl in water are stable in the concentration range 0 to 2 M for NaOH and HCl and 0 to 5.1 M for NaCl (higher concentrations have not been studied here). The spectra of water, NaOH-solvated water, NaCl-solvated water, and HCl-solvated water are all different and remain unchanged in the presence of the other species. The method of using four eigenspectra for the analysis of the IR spectra of mixtures of water, NaOH, HCl, and NaCl is accurate and gives the right composition of the samples. This is achieved even when the ionic species (H^+, Cl^-, Na^+, HO^-) dissolved in a strong absorber (H_2O) are either non-absorbing or very weakly-absorbing. Therefore, it is possible to titrate NaOH by HCl using their IR spectra even in the presence of NaCl. The four eigenspectra of water previously defined are necessary to this end. The result is a good first order approximation. IR spectra are well suited for measuring high concentrations of acids, bases, salts and their mixtures (14, 15, 24, 25). Furthermore, the IR spectrum, which is a non-destructive technique, can give precisely the ionization ratio which is difficult to obtain by means of usual techniques (22).

The addition of NaCl does not modify the structure of HCl-solvated water nor that of NaOH-solvated water. From the IR point of view, the ions of each of these three pairs are not solvated separately or independently of their respective counter ion. The mean activity coefficient of HCl is not related to its direct solvation by water. It possibly depends on the dynamics of the ionic solvation process which is a phenomenon that has not been studied here.

Photoyellowing of peroxide-bleached lignin-rich pulps: a photochemical study on stilbene–hydroquinone chromophores issued from β-5 units of lignin during refining and (or) bleaching

Brigitte Ruffin and Alain Castellan

Abstract: The contribution of stilbene–parahydroquinone structures, formed from β-5 units during refining and bleaching, in photoreversion of peroxide-bleached high-yield pulps, was studied using 4′-benzyloxy-2,5-dihydroxy-3,3′-dimethoxystilbene (**I**), as a model compound. The various photoproducts formed during irradiation of **I** in solution or adsorbed on cellulose paper were identified. Isomerization of the stilbene double bond and oxidation of the hydroquinone into quinone were observed in solution, whereas in the solid state only the formation of the quinone was found to operate. Our attempts to detect and quantify stilbene–hydroquinones forming from β-5 units created on peroxide bleached mechanical pulp were not met with success.

Key words: lignin, stilbene, hydroquinone, lignin model compound, pulp, photoyellowing.

Résumé : La contribution des structures stilbène–parahydroquinone, formées à partir des unités β-5 durant le raffinage et le blanchiment de la pâte, au photojaunissement des pâtes mécaniques blanchies au peroxyde d'hydrogène a été étudiée à l'aide du 4′-benzyloxy-2,5-dihydroxy-3,3′-diméthoxystilbène (**I**). Les photoproduits formés sous irradiation de **I** en solution ou adsorbé sur papier de cellulose ont été identifiés. L'isomérisation de la double liaison stilbène ainsi que l'oxydation de l'hydroquinone en quinone ont été observées en solution, tandis qu'en phase solide, seule la formation de la quinone est notée. La détection et le dosage des unités stilbène-hydroquinone dans la pâte mécanique blanchie ne se sont pas révélés concluants.

Mots clés : lignine, stilbène, hydroquinone, composé modèle de la lignine, pâte, photojaunissement.

Introduction

High-yield pulps are obtained by mechanical refining of wood. This treatment causes some chemical modifications in the pulp and new chemical structures are formed. For example, phenylcoumaran (1, 2) and β-1 units (3) are turned into stilbenes by mechanochemistry, β-O-4 entities are converted into parahydroxybenzaldehyde (4), and coniferyl alcohols create α, β-unsaturated groups (5). Also acidic treatment generates stilbenes and phenylcoumarones (6) very sensitive to UV light (7, 8).

When lignin-rich pulps are bleached, new chromophores very sensitive to UV light are created. For example by the action of alkaline H_2O_2 bleaching solution, β-1 diol units are turned into stilbenes (9), α-carbonyl phenols were converted into hydroquinones (Dakin reaction) (10). In the same way, coniferaldehydes are transformed into methoxyhydroquinones (11). All these chromophores, hydroquinones in particular, were considered to have a key role in the photoyellowing of bleached mechanical pulps because hydroquinones, non-colored compounds, are easily oxidized into quinones (12), (very colored species). Lee and Sumimoto (13) suggested that parahydrobenzoquinone derivatives including a stilbene or biphenyl or diphenyl ether conjugated structures were the major chromophores responsible of the color reversion of pulps.

In a recent study (14), we performed a semi-quantitative evaluation, in peroxide-bleached high-yield pulps, of *p*-stilbene phenols formed from β-1 units and demonstrated that they are not the main contributors of the rapid photoyellowing of these pulps. The present article describes a similar approach on the photochemical behavior of chromophores including both parahydroquinone and stilbene entities. In that respect, the photochemical behavior of model **I** (Fig. 1) before and after catalytic hydrogenation and (or) acetylation was established and also a tentative evaluation of the content of this type of structure in peroxide-bleached softwood mechanical pulps was carried out.

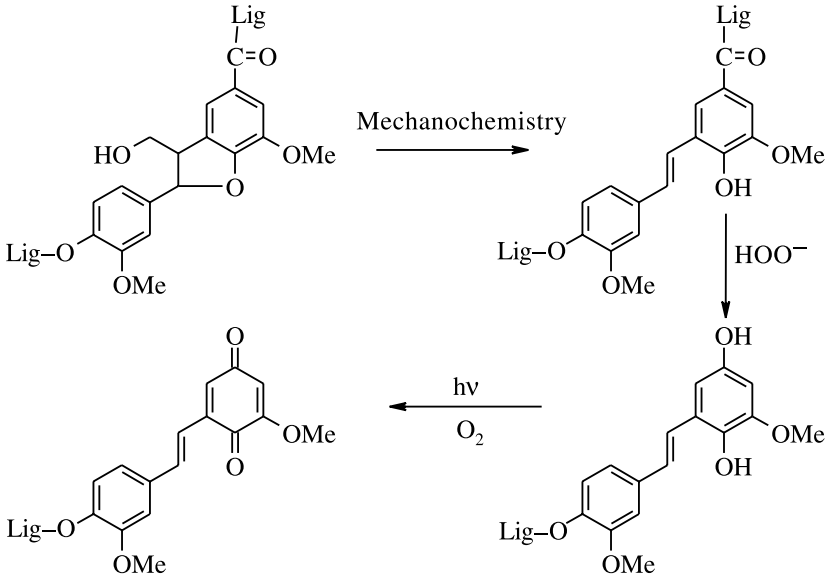
200 (^{1}H, ^{13}C) spectrometer (reference Me_4Si, solvent $CDCl_3$). The IR and UV absorption spectra were respectively performed on a Perkin–Elmer Paragon 1000 PC and an Hitachi U-3300 spectrometers. Mass spectra were obtained using a VG Micromass Autospec Q instrument.

The chemicals were obtained from Aldrich and were used without further purification. The synthesized compounds were purified by column chromatography on silica gel 60 (70–200 mesh) using the appropriate eluents. The solid products were crystallized after chromatography.

2. Syntheses



2.1 Stilbene derivatives

4′-benzyloxy-2,5-dihydroxy-3,3′-dimethoxystilbene (I)

*4′-benzyloxy-5-formyl-2-hydroxy-3,3′-dimethoxystilbene (**3**)*: Compounds **1** and **2** were prepared from vanillin by conventional methods respectively described in ref. 15 and 16. A *n*-butyl lithium solution in *n*-hexane (conc = 2.5 mol L^{-1}, 16 mmol) was added to a suspension of the phosphonium salt **2** (4.2 g, 8.0 mmol) in anhydrous THF (50 mL) under N_2 atmosphere and the mixture was stirred for 30 min at 0°C. The resulting red solution was treated with a solution of aldehyde **1** (1.6 g, 8.0 mmol) in anhydrous THF (40 mL). After being stirred for 3 h at room temperature, the THF was removed under vacuum, the residue was dissolved in CH_2Cl_2 and treated with hydrochloric acid (10%). The aqueous layer was extracted with CH_2Cl_2 (3 × 50 mL). The combined organic layers were washed with water, dried over $MgSO_4$, filtered, and concentrated. The residue was purified by chromatography on silica gel (eluent: CH_2Cl_2–EP) affording the expected *E* stilbene **3** as white crystals (1.15 g, yield 37%, mp 133°C). IR (KBr) ν : 950, 1010, 1080, 1140, 1260, 1520, 1600, 1690, 3400 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ: 3.96 (s, 3H, OCH_3), 3.99 (s, 3H, OCH_3), 5.19 (s, 2H, OCH_2), 6.50 (s, 1H, OH), 6.88 (d, 1H, J = 8.24, $H_{5'}$), 7.04 (dd, 1H, J = 1.83 and 8.24, $H_{6'}$), 7.13 (d,1H, J = 1.83, $H_{2'}$), 7.2–7.5 (m, 8H, ArH), 7.71 (d, 1H, J = 1.52 H_4 or H_6), 9.88 (s, 1H, CHO) ppm. ^{13}C NMR ($CDCl_3$) δ: 56.1 (OCH_3), 56.4 (OCH_3), 71.0

Scheme 1. Formation of stilbenes via mechanochemistry and then quinones by photooxidation (**1**, **2**).

(OCH_2), 106.9 (CH ar.), 109,6 (CH ar.), 113.9 (CH ar.), 114.6 (CH ar.), 119.7 (CH ar.), 120.1 (=CH), 124.1 (C ar.), 127.3 (CH Bn), 127.9 (CH Bn), 128.6 (CH Bn), 129.2 (C ar.), 130.6 (=CH), 130.8 (C ar.), 134.2 (C Bn), 147.3 (C ar.), 148.3 (C ar.), 148.6 (C ar.), 149.8 (C ar.), 191.2 (CHO) ppm.

*4′-benzyloxy-2,5-dihydroxy-3,3′-dimethoxystilbene (**I**)*: A solution of compound **3** (600 mg, 1.4 mmol) in THF–water (30mL and 8 mL) under nitrogen atmosphere was treated with sodium carbonate (126 mg, 1.4 mmol) and oxygen peroxide (240 µL, 2.3 mmol). After being stirred at room temperature for 3 h, the reaction mixture was reacted with 1 mL of acetic acid. The aqueous layer was extracted with CH_2Cl_2 (3 × 30 mL). The combined organic layers were washed with water, dried over $MgSO_4$, filtered, and concentrated. The residue was purified by crystallization (CH_2Cl_2–EP) affording the expected *E* stilbene **I** as white crystals (360 mg, yield 62%, mp 150°C). UV λ_{max} (MeOH)/nm : 320 (ε/L mol^{-1} cm^{-1} 19 600). IR (KBr) ν : 960, 1000, 1080, 1130, 1260, 1510, 1600, 3400 cm^{-1}. ^1H NMR ($CDCl_3$) δ: 3.87 (s, 3H, OCH_3), 3.94 (s, 3H, OCH_3), 4.46 (s, 1H, OH), 5.14 (s, 2H, OCH_2), 5.55 (s, 1H, OH) 6.36 (d, 1H, H_4, *J* = 2.75 Hz), 6.60 (d, 1H, H_6, *J* = 2.75 Hz), 6.85 (d, 1H, $H_{5'}$, *J* = 8.22 Hz), 6.98 (dd, 1H, $H_{6'}$, *J* = 2.15 and 8.22 Hz), 7.00 (d, 1H, H_α or $H_{\alpha'}$, *J* = 16.45 Hz), 7.11 (d, 1H, $H_{2'}$, *J* = 2.15 Hz), 7.24 (d, 1H, H_α or $H_{\alpha'}$, *J* = 16.45 Hz), 7.25–7.6 (m, 5H, ArH) ppm. ^{13}C NMR ($CDCl_3$) δ: 56.1 (OCH_3), 56.2 (OCH_3), 71.0 (OCH_2), 98.7 (CH ar.), 103.4 (CH ar.), 109.5 (CH ar.), 114.0 (CH ar.), 120.0 (CH ar.), 120.8 (=CH), 123.8 (C ar.), 127.3 (CH Bn), 127.9 (CH Bn), 128.6 (CH Bn), 129.3 (=CH), 137.1 (C Bn), 137.6 (C ar.), 147.3 (C ar.), 148.0 (C ar.), 148.7 (C ar.), 149.8 (C ar.) ppm. MS (EI) *m/z* (%): 378 ($M^{+\cdot}$, 65), 287 (100), 255 (14), 227 (14), 91 (48). HPLC–MS (solvent acetonitrile, negative mode) *m/z*: 377 $(M - H)^-$.

*2,5-diacetoxy-4′-benzyloxy-3,3′-dimethoxystilbene (**III**)*: Compound **I** (200 mg, 0.43 mmol) in dichloromethane (40 mL) was refluxed under nitrogen in presence of acetic anhydride (1.2 mL, 1.2 mmol), triethylamine (0.17 mL, 1.2 mmol), and 4-dimethylaminopyridine (DMAP, 5 mg) for 4 h. The reacting mixture was treated with hydrochloric acid (10%) and extracted with dichloromethane. The organic layer was washed with water to neutrality, dried over magnesium sulfate and evaporated under reduced pressure. The reacting mixture, separated by chromatography (eluent: CH_2Cl_2–Et_2O, 95:5), followed by crystallization in ethanol afforded the expected *E* stilbene **III** as white crystals (204 mg, yield 93%, mp 158°C). IR (KBr) ν : 1030, 1080, 1140, 1180, 1210, 1270, 1510, 1590, 1760 cm^{-1}. UV λ_{max} (MeOH)/nm : 320 (ε/L mol^{-1} cm^{-1} 29 000). ^1H NMR ($CDCl_3$) δ: 2.31 (s, 3H, CH_3), 2.36 (s, 3H, CH_3), 3.81 (s, 3H, OCH_3), 3.93 (s, 3H, OCH_3), 5.18 (s, 2H, OCH_2), 6.66 (d, 1H, H_4, *J* = 2.75 Hz), 6.87 (d, 1H, $H_{2'}$, *J* = 8.24 Hz), 6.91 (d, H_α, *J* = 15.26 Hz), 6.96–7.05 (m, 3H, H_6, $H_{6'}$, and $H_{5'}$), 7.40 (d, $H_{\alpha'}$, *J* = 15.26 Hz), 7.3–7.5 (m, 5H, ArH) ppm. ^{13}C NMR ($CDCl_3$) δ: 20.5 (CH_3), 21.2 (CH_3), 56.1 (OCH_3), 56.2 (OCH_3), 71.0 (OCH_2), 104.9 (CH ar.), 110.1 (CH ar.), 110.2 (CH ar.), 113.9 (CH ar.), 119.4 (CH ar.), 119.9 (=CH), 127.2 (CH Bn), 127.9 (CH Bn), 128.6 (CH Bn), 130.5 (C ar.), 131.8 (=CH), 131.9 (C ar.), 135.1 (C ar.), 137.0 (C Bn), 148.5 (C ar.), 148.7 (C ar.), 149.7 (C ar.), 168.7 (C=O), 168.8 (C=O) ppm. MS (EI) *m/z* (%): 462 ($M^{+\cdot}$, 65), 432 (12), 371 (30), 329 (76), 299 (28), 287 (31), 255 (54), 227 (12), 91 (100), 43 (66).

*(Z)-4′-benzyloxy-2,5-dihydroxy-3,3′-dimethoxystilbene (**IZ**)*: By irradiation with UV light (λ ≈ 350 nm), compound **I** (50 mg, 0,13 mmol) in methanol (10 mL) solution degassed by bubbling nitrogen was converted to compound **IZ** ([**IZ**]:[**I**] = 90:10. The NMR data on **IZ** were obtained on the mixture after evaporation of the solvent and after subtracting the contribution of **I**. The electronic absorption spectrum of **IQ** was obtained with the diode array detector of the HPLC system (eluent: methanol). The mass spectrum of **IQ** was obtained using HPLC–MS technique with acetonitrile as eluent for the HPLC and electrospray for the ionization mode. UV λ_{max} (MeOH): 300 nm. ^1H NMR ($CDCl_3$) δ: 3.63 (s, 3H, OCH_3), 3.81 (s, 3H, OCH_3), 5.09 (s, 3H, OCH_2), 6.27 (d, 1H, H_4, *J* = 2.44 Hz), 6.35 (d, 1H,

H_6, J = 2.44 Hz), 6.55 (s, 2H, CH=CH), 6.76 (s, 1H), 6.77 (d, 1H, J = 1.83 Hz), 6.88 (d, 1H, J = 1.53 Hz), 7.25–7.45 (m, 5H, ArH) ppm. ^{13}C NMR ($CDCl_3$) δ: 55.7 (OCH_3), 56.1 (OCH_3), 70.9 (OCH_2), 98.8 (CH ar.), 106.9 (CH), 112.2 (CH), 113.4 (CH), 122.0 (CH), 122.9 (CH), 123.3 (CH), 127.3 (CH Bn), 127.4 (CH Bn), 127.9 (CH Bn), 128.6 (C ar.), 129.3 (C ar.), 130.2 (C ar.), 130.7 (C ar.), 137.1 (C ar.), 137.3 (C ar.), 147.4 (C ar.), 148.4 (C ar.) ppm. HPLC–MS (solvent acetonitrile, negative mode); *m/z*: 377 $(M - H)^-$.

2.2 Diphenyl ethane compounds

4′-benzyloxy-2,5-dihydroxy-3,3′-dimethoxydiphenylethane (II)

*4′-benzyloxy-5-formyl-2-hydroxy-3,3′-dimethoxydiphenylethane (**4**)*: Hydrogenation of compound **3** (500 mg, 1.28 mmol) in ethyl acetate (100 mL) containing 50 mg of $RhCl(PPh_3)_3$ was accomplished by treating the mixture under hydrogen pressure (180 bar, 1 bar = 10^5 Pa) for 5 h at 80°C. The mixture, after filtration on a silica gel to removed the catalyst, afforded a white solid (500 mg, yield 100%). ^{1}H NMR ($CDCl_3$) δ: 2.9 (s, 4H, CH_2-CH_2), 3.8 (s, 3H, OCH_3), 3.9 (s, 3H, OCH_3), 5.0 (s, 2H, OCH_2), 6.5 (s, 1H, OH), 6.6–7.4 (m, 10H, ArH), 9.8 (s, 1H, CHO) ppm.

*4′-benzyloxy-2,5-dihydroxy-3,3′-dimethoxydiphenylethane (**II**)*: A solution of compound **4** (300 mg, 0.8 mmol) in a mixture of THF (20 mL)–water (5 mL) was treated with potassium carbonate (72 mg, 0.8 mmol) and hydrogen peroxide (150 µL, 1.4 mmol). After being stirred at room temperature for 1 h, the reaction was stopped by addition of 1 mL of acetic acid. The residue was reacted with a solution of hydrochloric acid (10%). The aqueous layer was extracted with CH_2Cl_2. The combined organic layers were washed with water, dried over $MgSO_4$, filtered, and concentrated under vacuum. The residue was purified by crystallization in a mixture of CH_2Cl_2–petroleum ether (1v:1v) affording the expected stilbene **II** as a white solid (200 mg, yield 70%, mp 119°C). UV λ_{max} (MeOH)/nm : 270 (ε/L mol^{-1} cm^{-1} 6800). IR (KBr) ν : 730, 790, 1030, 1090, 1150, 1220, 1390, 1440, 1480, 1510, 2930, 3320 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ: 2.86 (s, 4H, CH_2-CH_2), 3.85 (s, 3H, OCH_3), 3.88 (s, 3H, OCH_3), 4.80 (s, 1H, OH), 5.16 (s, 2H, OCH_2), 5.32 (s, 1H, OH), 6.17 (d, 1H, H_4, J = 2.64 Hz), 6.34 (d, 1H, H_6, J = 2.64 Hz), 6.72 (dd, 1H, $H_{6'}$, J = 1.95 and 8.10 Hz), 6.77 (d, 1H, $H_{2'}$, J = 1.95 Hz), 6.84 (d, 1H, $H_{5'}$, J = 8.10 Hz), 7.30–7.55 (m, 5H, ArH) ppm. ^{13}C NMR ($CDCl_3$) δ: 31.9 (CH_2), 35.4 (CH_2), 55.8 (OCH_3), 55.9 (OCH_3), 71.1 (OCH_2), 97.3 (CH ar.), 107.9 (CH ar.), 112.4 (CH ar.), 114.1 (CH ar.), 120.2 (CH ar.), 127.2 (CH Bn), 127.6 (CH Bn), 127.7 (C ar.), 128.4 (CH Bn), 135.4 (C ar.), 137.2 (C ar.), 137.3 (C ar.), 146.7 (C ar.), 148.3 (C ar.), 149.2 (C ar.) ppm. MS (EI) *m/z* (%): 380 ($M^{+\cdot}$, 30), 289 (35), 227 (40), 153 (33), 91 (100).

*2,5-diacetoxy-4′-benzyloxy-3,3′-dimethoxydiphenylethane (**IV**)*: Hydrogenation of **III** (300 mg, 0.72 mmol) in ethyl acetate (50 mL) containing 30 mg of $RhCl(PPh_3)_3$ was accomplished by treating the mixture under hydrogen pressure (180 bar, 1 bar = 10^5 Pa) for 5 h at 80°C. After filtration on silica gel, the solvent was removed under vacuum The compound **IV** was obtained as a white solid (300 mg, yield 100%, mp 130°C). UV λ_{max} (MeOH)/nm : 260 (ε/L mol^{-1} cm^{-1} 6900). IR (KBr) ν : 1030, 1090, 1140, 1180, 1220, 1510, 1760, 2930 cm^{-1}. ^{1}H NMR ($CDCl_3$) δ: 2.28 (s, 3H, CH_3), 2.33 (s, 3H, CH_3), 2.78 (s, 4H, CH_2-CH_2), 3.80 (s, 3H, OCH_3), 3.86 (s, 3H, OCH_3), 5.14 (s, 2H, OCH_2), 6.54 (d, 1H, H_4, J = 2.75 Hz), 6.61 (d, 1H, H_6, J = 2.75 Hz), 6.65 (dd, 1H, $H_{6'}$, J = 1.83 and 8.24 Hz), 6.69 (d, 1H, $H_{2'}$, J = 1.83 Hz), 6.82 (d, 1H, $H_{5'}$, J = 8.24 Hz), 7.25–7.50 (m, 5H, ArH) ppm. ^{13}C NMR ($CDCl_3$) δ: 20.6 (OAc), 21.2 (OAc), 32.4 (CH_2), 35.6 (CH_2), 55.9 (OCH_3), 56.1 (OCH_3), 71.2 (OCH_2), 104.3 (CH ar.), 112.0 (CH ar.), 112.3 (CH ar.), 114.2 (CH ar.), 120.2 (CH ar.), 127.3 (CH Bn), 127.8 (CH Bn), 128.6 (CH Bn), 134.6 (C ar.), 135.5 (C ar.), 135.7 (C ar.), 137.4 (C ar.), 146.5 (C ar.), 148.5 (C ar.), 149.5 (C ar.), 151.6 (C ar.), 168.9 (C=O), 169.4 (C=O) ppm. MS (EI): *m/z* (%): 464 ($M^{+\cdot}$, 51), 422 (12), 380 (27), 331 (30), 289 (27), 257 (11), 227 (34), 195 (37), 183 (27), 137 (77), 91 (100), 43 (48).

Compound **IV** was also prepared in quantitative yield by acetylation of compound **II** using the procedure described for the synthesis of compound **III**.

2,5,4′-trihydroxy-3,3′-dimethoxydiphenylethane (6)

*2,5-diacetoxy-4′-hydroxy-3,3′-dimethoxydiphenylethane (**5**)*: Hydrogenation of **III** (300 mg, 0.65 mmol) in anhydrous THF (50 mL) containing 30 mg of Pd–C was accomplished by treating the mixture under hydrogen pressure (80 bar, 1 bar = 10^5 Pa) for 24 h at 60°C. The mixture, after filtration on silica gel to removed the catalyst, afforded compound **5** (300 mg, yield 100%). ^{1}H NMR ($CDCl_3$) δ: 2.20 (s, 3H, OAc), 2.25 (s, 3H, OAc), 2.38 (s, 4H, CH_2-CH_2), 3.72 (s, 3H, OCH_3), 3.76 (s, 3H, OCH_3), 6.1–7.0 (m, 5H, ArH) ppm.

*2,5,4′-trihydroxy-3,3′-dimethoxydiphenylethane (**6**)*: A solution of **5** (300 mg, 0.8 mmol) in methanol (25 mL) was treated with K_2CO_3 (350 mg, 4 mmol). After being stirred at 90°C for 4h, the solution was reacted with a solution of hydrochloric acid (10%). The aqueous layer was extracted with CH_2Cl_2. The combined organic layers were washed with water, dried over $MgSO_4$, filtered, and concentrated. The reacting mixture was analyzed by ^{1}H NMR and by GC–MS after silylation. ^{1}H NMR ($CDCl_3$) δ: 2.20 (s, OAc), 2.41 (s, 4H, CH_2-CH_2), 3.75 (s, 3H, OCH_3), 3.78 (s, 3H, OCH_3), 6.0–7.0 (m, 5H, ArH) ppm. The observation of the peak at 2.20 ppm reveals the presence of compound **6Ac** (50%) in addition to compound **6** (50%). This proportion was also revealed by GC–MS when the mixture was silylated by treatment with pyridine (10 µL), BSTFA (100 µL) in dichloromethane. MS (EI) **6** silylated *m/z* (%): 433 ($(M - 1)^+$, 33), 223 (14), 209 (100), 193 (11), 75 (12), 73 (34). MS (EI) **6Ac** silylated *m/z* (%): 476 ($M^{+\cdot}$, 14), 434 (57), 209 (100), 179 (15), 75 (13), 73 (41). This spectra indicates the incorporation of two trimethylsilyl groups in the molecule, the OH in the 2 position being too hindered to be substituted by the bulky TMS group.

2.3 Formation of p*-quinonoid compounds*

Quinone diphenylethane (IIQ)

Oxidation with $NaIO_4$: A solution of compound **II** (100 mg, 0.26 mmol) in a mixture of acetic acid (12 mL) – water (8 mL) was treated with sodium periodate (85 mg, 0.40 mmol). After being stirred at room temperature for 4h,

© 2000 NRC Canada

the organic layer was extracted with dichloromethane, dried over $MgSO_4$, and reduced under vacuum. The expected compound **IIQ** was obtained as a pale yellow oil (100 mg, yield 100%). IR (NaCl film) ν : 2930, 1680, 1650, 1600, 1510, 1450, 1260, 1230, 1025, 790, 760 cm^{-1}. ^1H NMR ($CDCl_3$) δ: 2.75 (s, 4H, CH_2-CH_2), 3.82 (s, 3H, OCH_3), 3.88 (s, 3H, OCH_3), 5.13 (s, 3H, OCH_2), 5.88 (d, 1H, H_4, J = 2.44 Hz), 6.44 (d, 1H, H_6, J = 2.44 Hz), 6.65 (dd, 1H, $H_{6'}$, J = 2.14 and 8.24 Hz), 6.73 (d, 1H, $H_{2'}$, J = 2.14 Hz), 6.80 (d, 1H, $H_{5'}$, J = 8.24 Hz), 7.2–7.5 (m, 5H, ArH) ppm.

Oxidation with Fremy's salt: A solution of compound **II** (100 mg, 0.26 mmol) in methanol (20 mL) was treated with Fremy's salt $(KSO_3)_2NO$ (110 mg, 0.42 mmol) in water (5 mL) After being stirred at room temperature for 4h, the organic layer was extracted by dichloromethane, dried over $MgSO_4$, and reduced under vacuum. The expected compound **IIQ** was obtained as a pale yellow oil (100 mg, yield 100%).

Quinone stilbene (IQ): A solution of compound **I** (10 mg, 0.026 mmol) in acetonitrile was oxidized into quinone **IQ** by treatment under pressure of oxygen (20 bar, 1 bar = 10^5 Pa) at 60°C for 5 h. After evaporation of the solvent, the mixture was analyzed by HPLC and ^1H NMR. Products **I** and **IQ** were obtained in a 50:50 mixture. Various tentatives to isolate **IQ** as a pure compound by preparative chromatography were not successful due to the high reactivity of the quinone. So, the ^1H NMR spectrum of **IQ** was obtained from the reacting mixture spectrum by subtracting the contribution of compound **I**. The electronic absorption spectrum of **IQ** was obtained with the diode array detector on the HPLC system (eluent: methanol). The mass spectrum of **IQ** was obtained using HPLC–MS technique with acetonitrile as the eluent for the HPLC and electrospray for the ionization mode. This analysis did not allow the observation of the $(M - 1)^-$ peak as for **I**, but a peak was observed which corresponded to the addition of acetonitrile followed by the elimination of CO. UV λ_{max} (MeOH): 280 and 480 nm. ^1H NMR ($CDCl_3$) δ: 3.90 (s, 3H, OCH_3), 3.96 (s, 3H, OCH_3), 5.20 (s, 2H, OCH_2), 6.25 (d, 1H, H_4, J = 2.70 Hz), 6.55 (d, 1H, H_6, J = 2.70 Hz), 6.8–7.1 (4H, ArH and =CH), 7.25–7.6 (m, 6H, ArH and = CH) ppm. HPLC–MS (solvent acetonitrile, negative mode) *m/z*: 388 $(M + CH_3CN–CO–H)^-$.

Quinone stilbene (IZQ): The stilbene quinone **IZQ** formed by irradiation of **I** in non-degassed solutions was characterized by HPLC equipped with a diode array detector (eluent: methanol) and HPLC–MS technique with acetonitrile as eluent for the HPLC and electrospray for the ionization mode. As for **IQ**, this analysis did not allow the observation of the $(M - 1)^-$ peak, but a peak was observed which corresponds to the addition of acetonitrile followed by the elimination of CO. UV λ_{max} (MeOH): 270 and 470 nm. HPLC–MS (solvent acetonitrile, negative mode) *m/z* : 388 $(M + CH_3CN–CO–H)^-$.

3. UV–Irradiation of models I, II, III and IV adsorbed on cellulose matrix

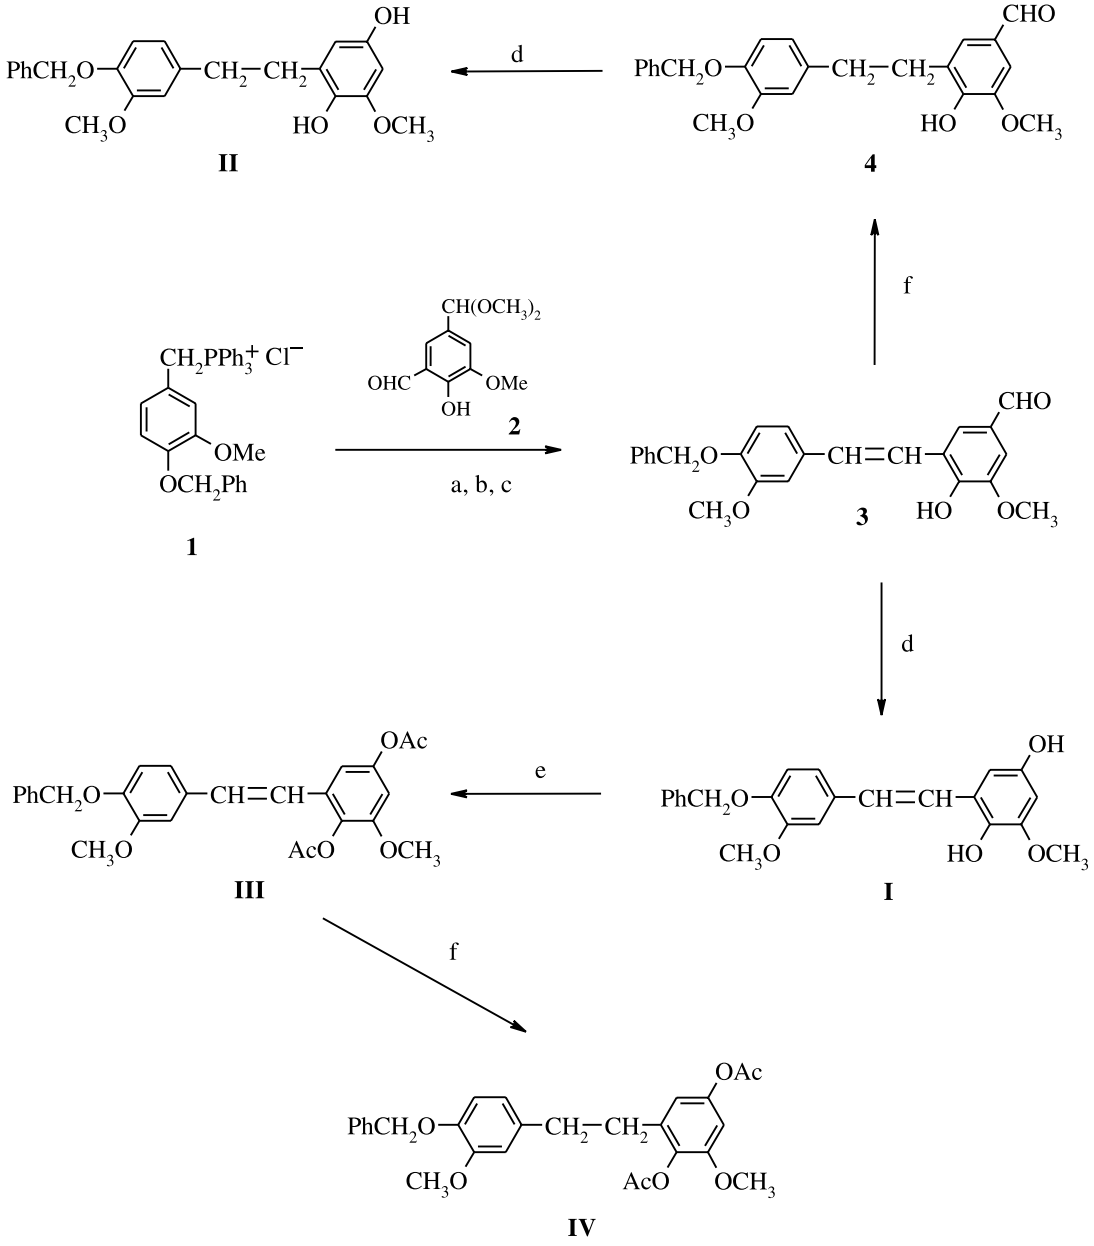
Four paper sheets (3 cm × 3 cm) made from a kraft pulp (30 g/m^2) were separately impregnated with 2.0 mg of each compound in CH_2Cl_2 (1 mL) and dried with a nitrogen stream. The paper sheets were irradiated with three black light UV lamps (Mazdafluor TFWN 18) emitting mainly in the 350 nm wavelength range. The distance between the lamp and the sheets was 20 cm. The temperature of the irradiation was maintained at 25°C by a fan. The reflectance of the sheets backed with a black and white backgrounds were measured at appropriate irradiation time intervals. The absorption (K) given by the Kubelka–Munk theory (17) was calculated and plotted as the difference between non irradiated and irradiated samples versus irradiation time.

4. Attempt to detect stilbene–hydroquinone chromophore in bleached mechanical pulp

Peroxide bleaching of mechanical pulp (BMP) and acetylation

Unbleached softwood mechanical pulp (20 g), kindly provided by Dr. Petit-Conil (Centre Technique du Papier, Grenoble), was treated in a polyethylene bag with the bleaching liquor (200 mL) constituted by hydrogen peroxide (3% oven dry pulp, odp), NaOH (1.5% odp), $MgSO4{\cdot}7H_2O$ (0.5% odp), sodium silicate (3.5% odp), and DTPA (0.25% odp) at 60°C for 4 h. Then the pulp was filtered and bleached for a second time in the same conditions with fresh liquor (200 mL). At the end of the bleaching, the pulp was washed with distilled water and diluted hydrochloric acid to pH 4.5. Before acetylation, the pulp (1 g) was made alkaline by soaking it in a potassium carbonate solution (1 mol L^{-1}) for 15 min and filtrated under vacuum to remove the major part of the water. The pulp was then exposed to acetic anhydride vapor for 1 h and after was washed with water, ethanol and water to pH 4.5. At the end, the pulp was dried at 30°C for 24 h.

Hydrogenation of the acetylated BMP



Hydrogenation of the pulp (300 mg) impregnated with a solution of $RhCl(PPh_3)_3$ (15 mg) in ethyl acetate (3 mL) was accomplished under 180 bar (1 bar = 10^5 Pa) of hydrogen pressure for 4 h at 60°C in presence of 3 mL of ethyl acetate in the bottom of the reactor as described previously (14). After cooling the reactor, the pulp was washed with ethyl acetate, methanol, and CH_2Cl_2 to remove the catalyst and then washed with water and dried at 40°C for 24 h.

Thioacidolysis and Acidolysis with $AlCl_3$

100 mg of pulp were treated with 20 mL of thioacidolysis solution (10 mL EtSH + 2.4 mL BF_3–Et_2O + 80 mL dioxan) at 100°C for 4 h under gentle magnetic stirring. After hydrolysis with diluted $NaHCO_3$ solution until pH 3–4, the reaction mixture was extracted with dichloromethane. The organic phase was washed with water, dried over magnesium sulfate, and evaporated under vacuum. The residue was dissolved in benzene (30 mL) and was treated with 10 mg of $AlCl_3$ at 90°C for 12 h, then the reacting mixture was hydrolyzed with water and extracted with CH_2Cl_2. The organic phase was dried over magnesium sulfate concentrated under vacuum and silylated with BTSFA (50 µL), pyridine (10 µL) in THF (50 µL) at room temperature. The silylated mixture was analyzed by GC–MS.

Results and discussion

1. Syntheses

The route chosen for the synthesis of compounds **I**, **II**, **III**, and **IV** is outlined in Fig. 2. The preparation of compound **I** which was similar to the Lee and Sumimoto (13) procedure, consists in the Wittig coupling between the ylide, generated by action of *n*-butyl lithium on the substituted benzyltriphenyl phosphonium chloride **1** (14), and the substituted salicylaldehyde **2** (16). The protection of the aldehyde group, needed for the coupling, was easily removed by treatment with hydrochloric acid at the end of the synthesis. Despite several attempts to improve the Wittig coupling e.g., by changing the reaction solvent, the yield was in our hands, lower (37%) than the one given by Lee (65%) (13) for the synthesis of a similar compound, but it was of the same order that we got for the syntheses of other lignin stilbene models (14). The hydroquinone **I** (*E* configuration) was obtained by Dakin reaction in mild conditions (room temperature and moderate pH given by the use of sodium carbonate). Compound **III** was synthesized in high yield (93%) by acetylation of compound **I**, using the catalytic action of 4-*N*,*N*-dimethylaminopyridine (DMAP) as for other lignin model compounds (18). Hydrogenation of compound **III**, was realized using experimental conditions set up previously for a study on the role of stilbenes issued from β-1 units on the photoyellowing of lignin rich pulps (14). Compound **II** which was prepared by catalytic hydrogenation of compound **3** followed by Dakin reaction at moderate pH, was quantitatively transformed into compound **IV** by acetylation.

Compound **IZ** was produced as a major product by irradiation of **I** in degassed methanol solution (Fig. 3). It was char-

acterized by ^1H and ^{13}C NMR and HPLC–MS (electrospray in the negative mode) spectroscopies (see experimental part).

In contrast to compound **II**, which gave the *p*-quinone **IIQ** by oxidation by sodium periodate or Fremy's salt, compound **I** did not produce the quinone **IQ** using the same reagents. The latter compound, very reactive and sensitive to chromatographic phases and eluents was obtained by oxidation of **I** in acetonitrile by oxygen under pressure (20 bar, 1 bar = 10^5 Pa) at 60°C (Fig. 3). The structure of **IQ** was determined by ^1H NMR and HPLC–MS (electrospray in the negative mode) spectroscopies (see experimental part). The structure of **IZQ** was assigned by comparison of its HPLC–UV spectrum and its HPLC–MS peaks with those of the quinone isomer **IQ** (see experimental part).

In order to characterize the presence of stilbene–hydroquinone chromophores in bleached pulps, compounds **5** and **6** were synthesized. Following a procedure previously used (14), and due to the high reactivity of the stilbene and hydroquinone units, the pulp was acetylated and hydrogenated prior to thioacidolysis and acidolysis with aluminum trichloride. The diphenylethane incorporating hydroquinone entities obtained from the pulp after the degradative treatment were expected to be in the form of their acetates or trimethylsilyl derivatives. The mild deacetylation procedure, very efficient for lignin models (18), and applied to compound **5**, produced a mixture of compounds **6** and **6Ac** (50%–50%). This mixture was silylated and used for the GC–MS analysis of the pulps, because it is likely that these two structures will be detected if the stilbene hydroquinone entities would be present in the peroxide bleached pulp. It is noticeable that silylation of compound **6** was incomplete, the OH in the 2 position being too hindered to react with the bulky trimethylsilyl group.

2. Electronic absorption and emission spectroscopies

Absorption spectra

The electronic absorption spectra of the stilbenes **I**, **III** and of the diphenylethanes **II**, **IV** are reported on Fig. 5.

The two diphenylethanes present a significant absorption above 300 nm, so they can absorb the solar light and so they can give colored species and contribute to the yellowing of peroxide-bleached high-yield pulps as already shown (19). The presence of the stilbene double bond increases the ab-

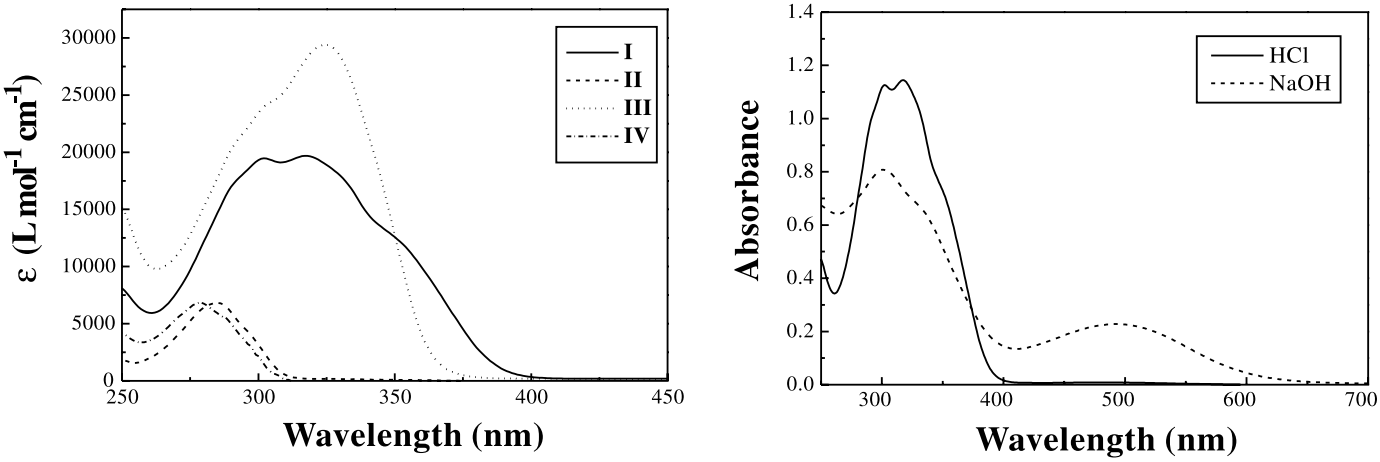
Fig. 5. Electronic absorption spectra of compounds **I**, **II**, **III,** and **IV** in methanol solutions (left) and of compound **I** in acidic and alkaline methanol solutions (right).



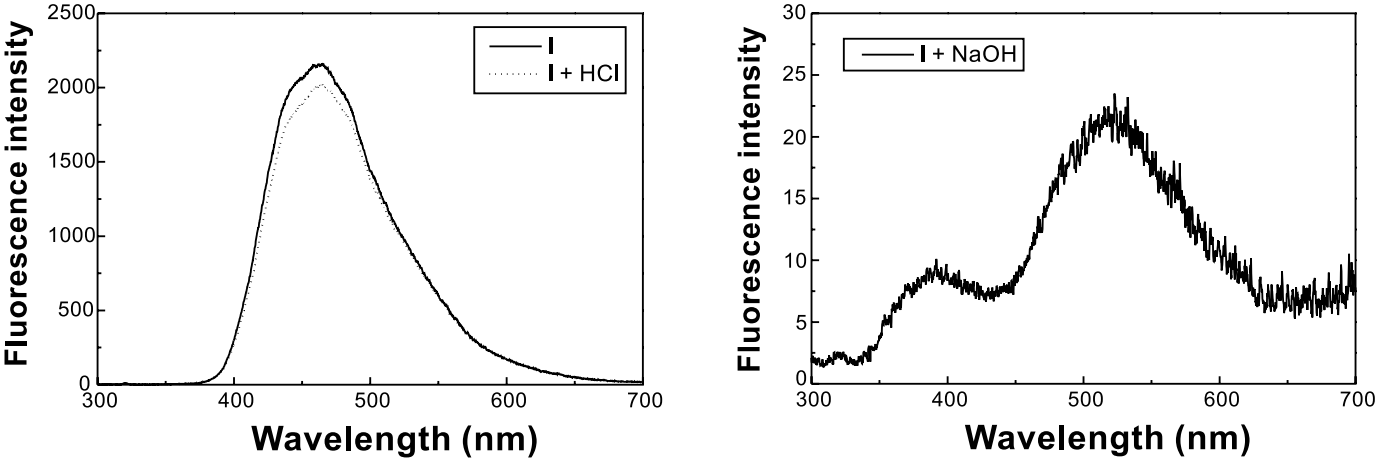


Fig. 6. Fluorescence emission spectra of compound **I** in ethanol solution. Left: neutral and acidic media; right: alkaline medium (λ_{exc} = 320 nm).

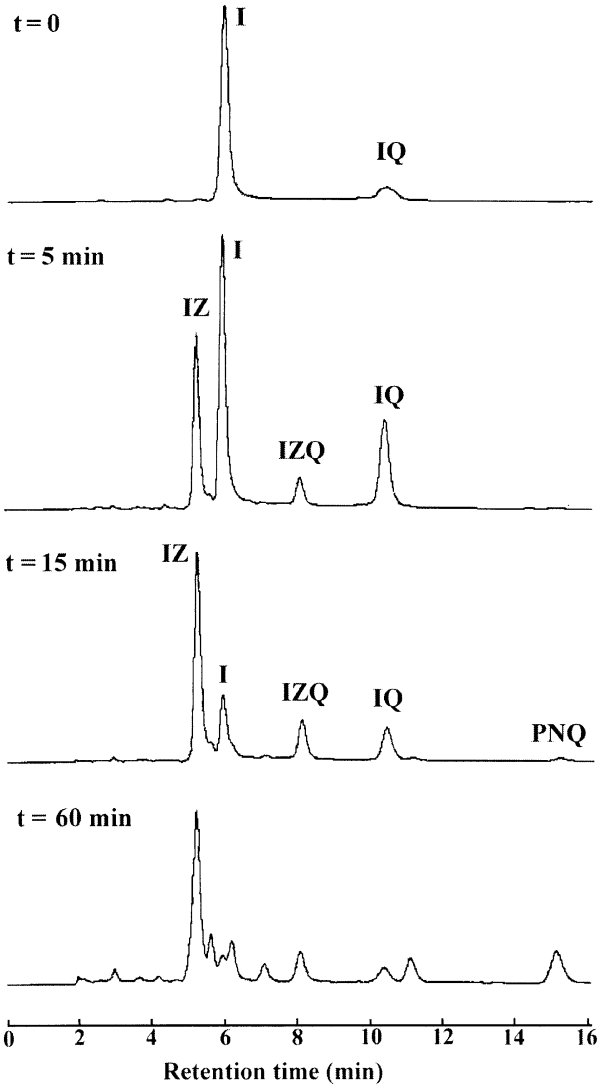
sorption above 300 nm compared to diphenylethanes, and so compound **I** which presents a very oxidizable phenol functional group, should be very sensitive to UV–irradiation. Moreover, phenols are in equilibrium with their phenolate anions and this equilibrium depends on the pH of the medium. In acidic or neutral media, the absorption of compound **I** is the same (Fig. 5). In contrast, in alkaline medium, compound **I** displays some absorption between 400 and 600 nm. The pulp industry usually produces papers with a basic reserve such as calcium carbonate for long term storage (20) but this alkaline treatment can induce a coloration of the materials if structures like compound **I**, which is ionized at pH 9, are present in lignin.

Fluorescence spectra

The interpretation of fluorescence spectra from wood, pulp, and paper samples is particularly cumbersome due to the physical heterogeneity and chemical complexity of the lignocellulosic matrix (21–23). Based on model studies (21, 22), it was shown that, in addition to cellulose emission, several chromophores of the lignin polymer are emitting in the region 330–430 nm. In contrast, the fluorophores at the origin of the emission of the pulp in the long wavelength range (430–530 nm) are still unknown. It is remarkable that the fluorescence emission, recorded for the stilbene **I** in neutral or acidic methanol solutions (Fig. 6), displays emission in this wavelength range (quantum yield ≈ 0.5 and lifetime ≈ 4 ns). This represents a bathochromic shift compared to other non-cyclic stilbene lignin models (22) and cyclic stilbene lignin model of the phenylcoumarone type (8*b*). In alkaline solution, the emission of compound **I** is shifted to longer wavelengths and its intensity is reduced, probably due to a highest reactive deactivation channel from the phenolate anion.



3. UV–irradiation of model I in solution

Compound **I** was irradiated in aerated methanol solutions (concentration ≈ 10^{-3} mol L^{-1}) with UV black lamps ($\lambda \approx 350$ nm). The irradiated solutions were analyzed by HPLC at different irradiaton times and some chromatogram traces are reported in Fig. 7.

The assignment of the HPLC peaks was carried out by comparison with samples analyzed by NMR and mass spectro-

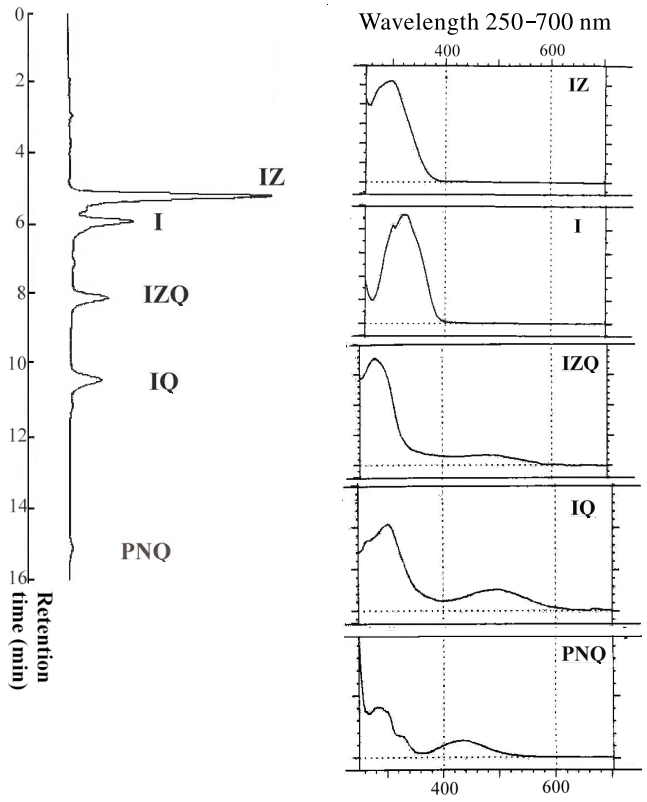

Fig. 7. HPLC analyses of photoproducts formed during irradiation of **I** in methanol.

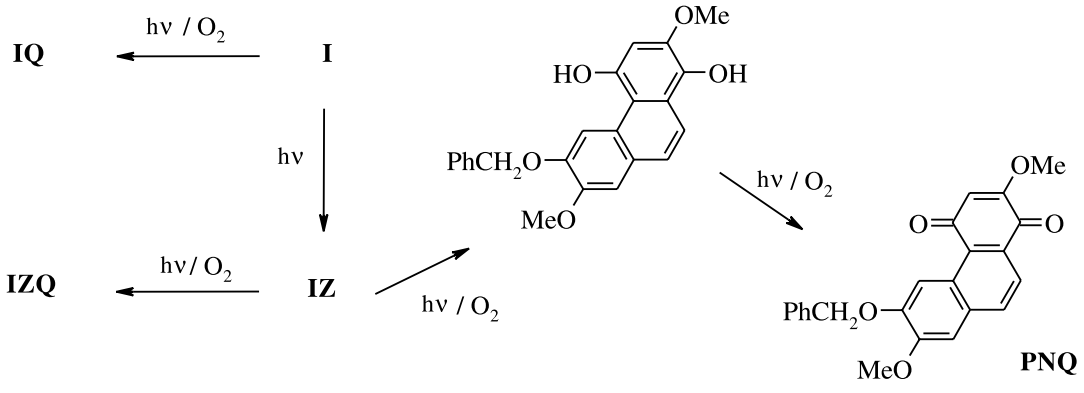
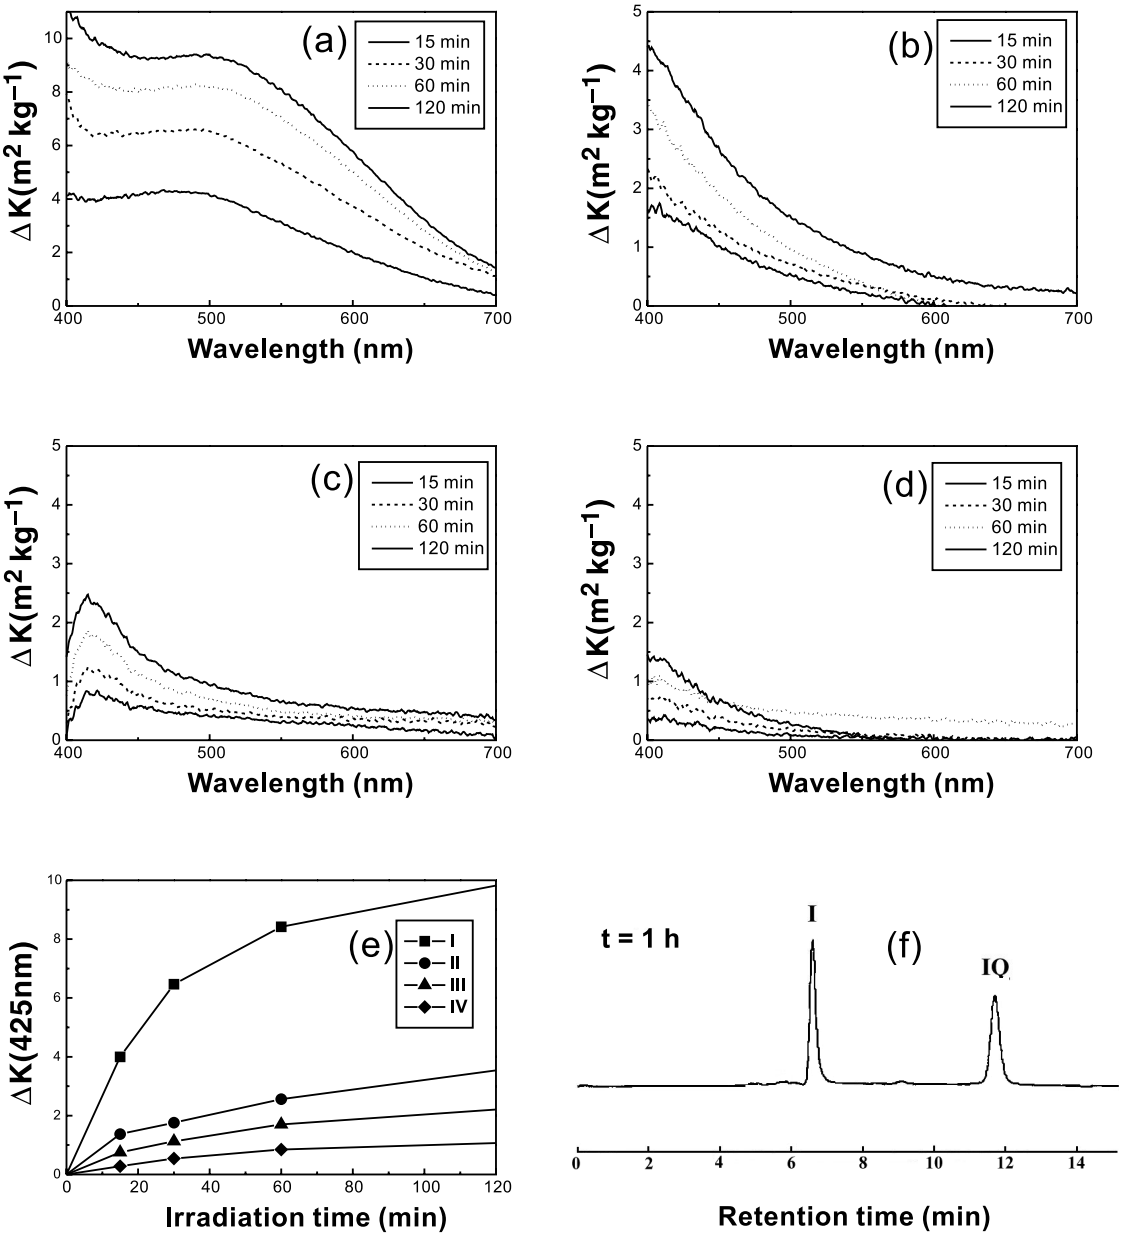
scopies. The structure of the phenanthrene quinone derivative was assumed according to its UV absorption spectrum.



The UV absorption spectra of the photoproducts which were obtained with a diode array detector on the HPLC system are drawn in Fig. 8. One can observe a hypsochromic shift (20 nm) for the absorption of the **IZ** isomer compared to the *E* isomer (this shift was already found by Stomberg et al. (24) on other lignin stilbene-like structures). Also a shift to the short wavelength (10 nm) is observed for the quinone IZQ compared to the *E* quinone **IQ**, both for $n\pi^*$ visible and for $\pi\pi^*$ UV transitions.

Fig. 8. HPLC–UV analyses of photoproducts formed during irradiation of **I** in methanol.



It is known that *Z* stilbenes are able to photocyclize to give phenanthrene derivatives (25). The dihydroxyphenanthrene formed by oxidative photocyclization of compound **IZ** might be transformed into p-phenanthrene quinone. The compound formed after 15 min of irradiation and having a retention time equal to 15 min might belong to this type of structure (Fig. 9). The photochemistry of compound **I** in methanol or acetonitrile solution is depicted in Fig. 9.

(*a*), (*b*), (*c*), (*d*): ΔK vs. λ for compounds **I**, **II**, **III**, and **IV** respectively.; (*e*) ΔK (425 nm) vs. irradiation time; (*f*) HPLC trace of extracted irradiated paper doped with compound **I**.

4. UV–irradiation of model I, II, III, and IV adsorbed on cellulose matrix.

The behavior of the lignin model compounds **I**, **II**, **III**, and **IV** adsorbed on cellulose paper were comparatively irradiated with UV light (see experimental part). The photocoloration was evaluated using the absorption coefficient given by the Kubelka–Munk theory (26). Fig. 10 (a–e) shows the difference of absorption coefficient (ΔK) of the lignin models adsorbed on cellulose paper before and after irradiation with UV light ($\lambda \approx 350$ nm) ranging from 5 min to 120 min. As observed for stilbenes formed from β-1 units (14), hydrogenated and acetylated chromophores display less variation of ΔK, which means less yellowing.

The kinetics confirm the great reactivity of compound **I**. Its coloration is reduced by acetylation. Hydrogenation of compound **I** followed by acetylation leads to a very stable compound **IV**. In contrast, hydrogenation of **I**, which gives hydroquinone structure **II**, is not sufficient enough to stop the yellowing completely. The variations of ΔK observed for compound **II** is reminiscent to what was observed for 2-methoxyhydroquinone in 2-hydropropylcellulose films (19).

After irradiation, the cellulose paper incorporating model **I** was extracted with solvent and analyzed by HPLC (Fig. 10*f*). Only the formation of quinone **IQ** is observed with no isomerization occurring. This is probably due the hydrogen bonding between the product and the cellulose

© 2000 NRC Canada

matrix which locks the configuration of the stilbene double bond. This confirms the key role of the environment in photochemical reactions.

5. Search for stilbene–hydroquinone chromophores in peroxide-bleached high-yield pulps

In order to assess and quantify the contribution of stilbene–hydroquinone chromophores in the photoreversion of high-yield pulps, we have attempted to find and quantify this structure in peroxide-bleached mechanical softwood pulp. For this purpose, we have used the same experimental procedure successfully set up for stilbenes emerging from β-1 lignin structures (14). In addition to the previous procedure, the pulp was first acetylated in the vapor phase in order to block the reactive hydroquinone groups. Even so, it was shown that catechol structures survive after the thioacidolysis (27). Therefore, after acetylation, hydrogenation, thioacidolysis with EtSH – BF_3–Et_2O in dioxane, and desulfurization with raney nickel, the organic residue was treated with $AlCl_3$ in benzene. The reacting mixture was analyzed by GC–MS. Careful inspection of the mass spectra of the chromatogram did not detect the silylated compounds **6** or **6Ac**. So, it seems that a mechanical treatment is not strong enough to produce structures resembling compound **I** by mechanochemistry in high-yield pulps. However, we can never neglect that the chemical treatment, used to liberate the stilbene chromophore before analyses, is not efficient enough if the chromophore is situated in the bulk of the lignin polymer.

Conclusions

We studied stilbene–paraquinone models formed by mechanochemistry from β-5 units during grinding and disk-refining of pulp. The contribution of these structures to the photoyellowing of bleached high-yield pulps was evaluated examining the photochemistry of model **I** which was hydrogenated and (or) acetylated. Photoproducts formed during irradiation of compound **I** were characterized. In particular, the isomerization of compound **I** into **IZ** was found to be the main process in solution. In aerated solution, the stilbenes **I** and **IZ** were oxidized in paraquinones **IQ** and **IZQ** respectively. The isomerization of **I** was not observed when adsorbed on cellulose paper, only the formation of quinone **IQ** was obtained. Comparative irradiation of different models, adsorbed on thin sheets of cellulose paper, showed the greatest reactivity of model **I**. Hydrogenation coupled with acetylation produced an efficient stabilization of this compound. The detection and quantification of stilbene–hydroquinone units, present in peroxide-bleached mechanical pulp, could not be determined. This might be due to inefficient mechanochemistry in pulp, as suggested by Zhu's studies (28), or it might be due to inappropriate experimental conditions necessary to liberate the acetylated hydroquinone diphenylethane entities, these structures being characteristic of the stilbene–hydroquinone units formed from β-5 elements in lignin.

Assisted hydrolysis of *cis*-2-(3-phenylthioureido)cyclopentane-carbonitrile in alkaline solution. Solvent dependent switch from hydrolysis to rearrangement of the iminothiooxopyrimidine intermediate

Ergun Atay, Iva B. Blagoeva, Francis L. Chubb, John T. Edward, Ivan G. Pojarlieff, and Maria M. Toteva

Abstract: The *cis* and *trans* isomers of 2-(3-phenylthioureido)cyclopentanecarbonitrile, **1**, and the respective carboxamides, **3**, and acids, **4**, have been prepared. Acid cyclization of both nitriles, faster with the *cis* isomer, gave the more stable *cis*-2-thiooxo-cyclopenta[*d*]pyrimidin-4-one, **7**. In base *cis*-**1** formed the *cis* 4-imino-2-thiooxopyrimidine **2** which in aqueous alkali broke down via **3** to the acid **4**; while in the presence of 66% acetonitrile **2** rearranged to the 4-phenyliminopyrimidine **5** to give as final product the thioureido acid **6** carrying no phenyl group. The ^{1}H NMR data for imino and phenylimino derivatives **2** and **5** showed strong bias for conformation **A** with 1-N pseudoaxial in the cyclopentane ring. Spectra of the *E* and *Z* isomers of the iminopyrimidine **2** under slow exchange could be recorded in DMSO-d_6. The phenylimino tautomer of **5** is observed in CD_3OD and in $CDCl_3$ with the *E* and *Z* isomers in a 1:1 ratio. In DMSO-d_6 the phenylamino tautomer **5a** is also detected. The first process in aqueous KOH, the conversion of nitrile *cis*-**1** into the imino intermediate **2**, reaches an equilibrium which shifts towards the nitrile at higher alkalinities because of ionization of the phenylthioureido group (K_e = [**2**]/[**1**] = 2.43 and pK_{AH} = 12.74). The cyclization of **1** to **2** is first order in [OH^-] while the slower breakdown of **2** is pH independent. The latter is 10^4 times faster than the hydrolysis of acetonitrile evidencing substantial anchimeric assistance. The change in the reaction route towards the rearranged phenyliminopyrimidine **5** upon addition of acetonitrile can be caused by the lower dielectric constant favouring the elimination step leading to the intermediate isothiocyanate, and by increased activity of OH^- accelerating the (presumably) second order elimination step as opposed to the pH-independent hydrolysis of the imino derivative **2**.

Key words: anchimeric assistance, phenylthioureido nitriles, iminothiooxopyrimidine tautomers, alkaline hydrolysis, solvent effects.

Résumé : On a préparé les isomères *cis* et *trans* du 2-(3-phénylthiouréido)cyclopentanecarbonitrile (**1**) et des carboxamides (**3**) et acides (**4**) correspondants. La cyclisation des deux nitriles, plus rapide pour l'isomère *cis*, conduit dans chaque cas à la *cis*-2-thiooxocyclopenta[*d*]pyrimidin-4-one (**7**), l'isomère le plus stable. En milieu basique, l'isomère **1**-*cis* conduit à la formation de la *cis*-4-imino-2-thiooxopyrimidine (**2**) qui, dans ces conditions, se décompose en acide **4** par le biais de **3**; toutefois, dans un milieu contenant 66% d'acétonitrile, le produit **2** se réarrange en 4-phényliminopyrimidine (**5**) qui se transforme pour fournir comme produit final l'acide thiouréido **6** où la groupe phenyle est absent. Les données de RMN du ^{1}H pour les dérivés imino et phénylimino **2** et **5** montrent que la conformation **A** est fortement favorisée, avec le 1-N en position axiale par rapport au cyclopentane. En opérant dans le DMSO-d_6, on a pu enregistrer les spectres des isomères *E* et *Z* de l'iminopyrimidine dans des conditions d'échange lent. Dans le CD_3OD et dans le $CDCl_3$, on peut observer le tautomère phénylamino de **5**; les isomères *E* et *Z* se trouvent dans un rapport de 1:1. On a aussi détecté le tautomère phénylamino **5a** dans le DMSO-d_6. Le premier processus réactionnel observé dans le KOH aqueux, la conversion du nitrile 1-*cis* en intermédiaire imino **2** atteint un équilibre qui, en raison de l'ionisation du groupe phénylthiouréido (K_e = [**2**]/[**1**] = 2,43 et pK_{AH} = 12,74), se déplace vers le nitrile à des niveaux d'alcalinité élevés. La cyclisation de **1** et **2** est du premier ordre en [OH^-] alors que la décomposition plus lente de **2** est indépendante du pH. Cette dernière réaction est 10^4 fois plus rapide que l'hydrolyse de l'acétonitrile; ceci confirme l'importance de l'assistance anchimérique. Le changement de la voie réactionnelle

conduisant à plus de phényliminopyrimidine réarrangée **5** par addition d'acétonitrile peut être provoqué par une baisse de constante diélectrique favorisant l'étape d'élimination qui conduit à l'intermédiaire isothiocyanate et par une activité accrue des ions OH^- qui augmente la vitesse de l'étape d'élimination que l'on croit être du deuxième ordre par opposition à l'hydrolyse du dérivé imino **2**, qui est indépendante du pH.

Scheme 1.

Introduction

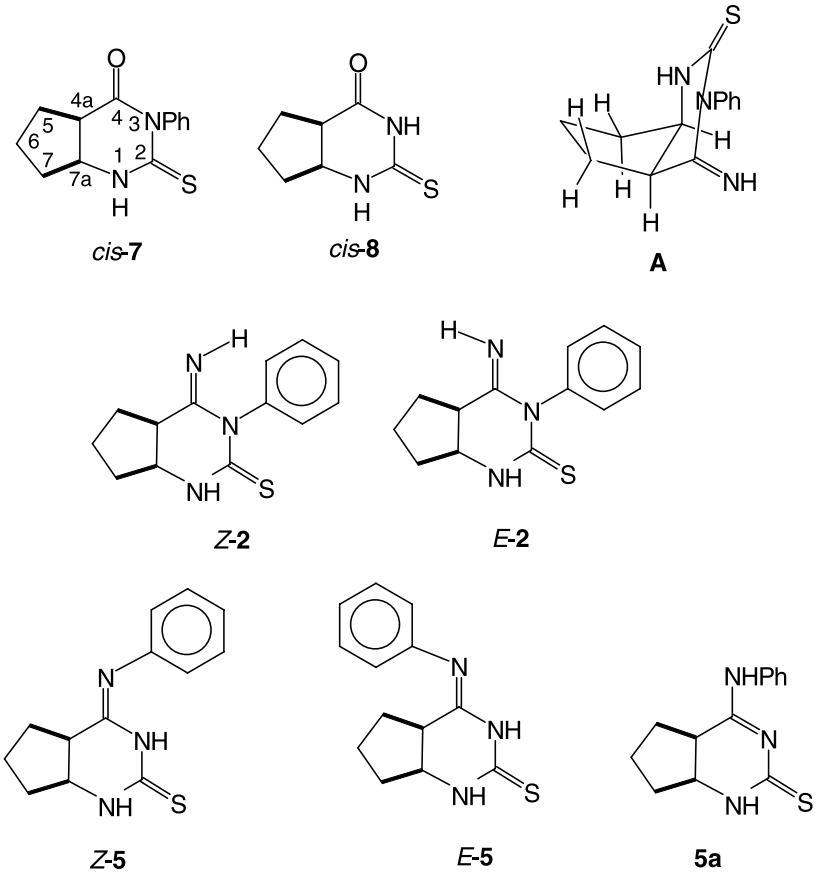
Ureido or thioureido nitriles, readily available from amino nitriles, have been widely used (1) in the synthesis of aminopyrimidines, aminoimidazoles, or thiazoles. On a preparative level the ring-closure was found to be base catalyzed (2). The products of attack of the ω-nitrogen of the ureido group are formed from thioureido nitriles in neutral and basic media (3).

We now report that the hydrolysis of a nitrile group is anchimerically assisted by a suitably orientated β-phenylureido group as in *cis*-**1**. The latter compound, in 0.01 M aqueous alkali, converts into the amide **3** 10^4 times faster than acetonitrile (4). The hydrolysis is facilitated by the formation of the iminopyrimidine **2** as shown in Scheme 1.

However, hydrolysis of aminopyrimidine **2** to **3** and further to the phenylthiouredo acid **4** was observed in aqueous alkali with a low (1–2%) content of acetonitrile. When the concentration of MeCN was increased to 66% (v/v) the major products were the rearranged pyrimidine **5**, hydrolyzing ultimately to the thioureido acid **6** without the phenyl group.

Results and discussion

Preparation and configuration of 2-phenylthioureidocyclopentanecarboxylic acid and 4-oxo-2-thioxooctahydrocyclopenta[*d*]pyrimidine derivatives



2-Aminocyclopentanecarbonitrile is obtained as a mixture of *cis* and *trans* isomers which have not yet been separated, but the phenylthioureido derivatives **1** are readily separated by column chromatography.

The configurations of the thioureido nitriles **1** were assigned from their behaviour in 1:2 HCl. Upon refluxing, the two isomers both cyclized in high yield to produce the single product *cis* 2-thiodihydrouracil **7** (Scheme 2). The latter has recently been obtained by cyclization of the respective *cis* thioureido ethyl ester in hydrochloric acid solution (5) and assigned as *cis* from bandwidths of the signals for 4a-H (ca. 25 Hz) and 7a-H (ca. 12 Hz) in the ^{1}H NMR (6). We proved this independently by double resonance experiments[2] which showed $J_{4a,7a}$ to be 6.5 Hz, which fell within the usual range for *cis* coupling in dihydrouracils (7). The 7a-H signal splittings due to the neighbouring methylene hydrogens were considerably smaller than those for 4a-H, indicating that the NH group is pseudoaxial in the presumably half-chair conformation of the cyclopentane ring. Cyclization of *cis* and *trans* **1** under milder conditions (2 h in 1 M HCl at 50°C) gave 86% and 15% *cis*-**7**, respectively. Whatever the reaction path from *cis*- or *trans*-**1** to *cis*-**7**, it can be safely assumed that the more readily cyclizing isomer has the same configuration as the ring product. Isomerization most likely occurs by acid catalyzed enolization which requires prior protonation of the carbonyl or imino function. It has been previously shown (8) that upon cyclization of ureido acids to dihydrouracils, isomerization occurs with the more basic ring compounds. Under the conditions used for obtaining the amides **3** on a

[2] Irradiation of H-6 of thiodihydrouracil decreased the 4a-H band by 6.5 Hz. Irradiation of 1-H sharpened the signal for 7a-H to a multiplet of 8 lines with couplings 6.6, 5.3, and 4.2 Hz. In the multiplet for 4a-H these couplings are 6.6, 7.8, and 9.0 Hz.

© 2000 NRC Canada

Scheme 2.

preparative scale (hydrolysis of the nitriles **1** in 60% sulfuric acid) the *cis* nitrile gave *cis* amide, shown by TLC to be free of the *trans* amide, while the *trans* nitrile hydrolyzed to a mixture of *cis* and *trans* isomers. Since the *trans* nitrile **1** and amide **3** are certainly more stable than *cis*-**1** and **3**, the isomerization must occur after the formation of a bicyclic derivative more stable in the *cis* configuration.

Greater stability of the *cis* isomer of dihydrouracil **7** can be understood by reference to the hydrindane system (bicyclo[4,3,0]nonane) (9). The *trans* hydrindane is more stable (ΔH) by 1.1 kcal mol^{-1} as the result of two conflicting forces: the unavoidable axial interactions in the *cis* isomer and the mismatch of torsion angles between the five and six membered rings. In a *trans* junction these can be accommodated by unfavourable greater puckering. Because dihydrouracils are considerably planar (10) with the torsion angles between the *trans* diequatorial bonds ca. 90°, *trans* fusion to a cyclopentane with an endocyclic torsion angle of ca. 45° would require considerable strain, which is apparently the main factor in determining the relative stability of the two isomers. Exclusive preference for *cis*-annelation has also been observed in the formation of 3-aryl-2,4-dioxo-octahydrocyclopenta[*d*]pyrimidines in a ring expansion reaction (6).

Acid *cis*-**4** was readily available by means of alkaline hydrolysis of *cis* dihydrouracil **7** while *trans* acid **4** was obtained under milder acid hydrolysis of *trans* nitrile **1** along with some *cis* dihydrouracil **7**. Acid *trans*-**4** has been isolated in high yield from the ethyl ester in an attempt to cyclize the latter under reflux in hydrochloric acid (5).

Preparation of 4-imino and 4-phenylimino-2-thiooxooctahydrocyclopenta[*d*]pyrimidine

When the hydrolysis of *cis* thioureido nitrile **1** was monitored by UV in aqueous alkaline media containing only 1–2% acetonitrile, a decrease of absorption at 245 nm due to NHCSNHPh and an accompanying increase in absorption at 267 nm were observed. The latter reached a maximum after which the absorption at 245 nm was restored in a slower process. Detailed product analysis (*vide infra*) showed that the intermediate formed broke down to amide *cis*-**3** and this in turn to *cis*-acid **4** with both compounds having the same UV absorption as the initial nitrile. The intermediate, expected to be the iminopyrimidine **2**, however, proved elusive. The usual work up gave the rearranged product, the phenyliminopyrimidine **5**. Its structure was deduced from the products of hydrolysis: in base the thioureido acid **6**, while in acid the known thiodihydrouracil **8** (11) without the phenyl group. Compounds **6** and **8** could be readily interconverted in acid or base as appropriate. Under the conditions described in the experimental section no isomerization was observed because ^{1}H NMR evidence demonstrated retention of *cis* configuration.

Under conditions where imines similar to **2** have been obtained from ureido nitriles our starting nitrile *cis*-**1** either remained unchanged (refluxing in benzene (3a,b)) or yielded the rearranged phenylimino product **5** directly (refluxing in methanol (3a) or in EtOH–EtONa (3c)). As the behaviour of *cis*-**1** in aqueous alkali could only be explained by the participation of imine **2** as depicted in Scheme 1, an attempt was

[a]Resonances of the major isomer.

made to obtain it in this medium. To avoid the inconvenience of the limited solubility of *cis*-**1** in water, the experiment was carried out with 0.01 M KOH in a water–acetonitrile 1:2 mixture. Unexpectedly the reaction proceeded by the completely different course shown in Scheme 2. This meant that the rate of isomerization became faster than the rate of hydrolysis of the imine **2** to amide **3**. The procedure for obtaining the non-rearranged imine *cis*-**2** described in the experimental was based on the kinetic study of the hydrolysis of the nitrile **1**. Conditions were chosen where formation of *cis*-**2** was rapid and, at the moment of its maximum formation, the mixture was quenched in acid. The reaction is reversible and in acid unconverted nitrile was extracted from the aqueous solution. The water layer could be used as a stock solution of *cis*-**2**. The latter was isolated as a solid by rapid alkalization of the acid solution from which the nitrile has been removed, extraction with methylene chloride, and evaporation in vacuo. The ^1H NMR of the solid showed small admixtures of *cis*-**1** and the rearranged product *cis*-**5**, both most likely formed during the work up. In solution the imino compound converted into the phenylimino one with a rate dependant on the solvent. Rough estimates of the half lives (in min) were: 16 in DMSO, 130 in CD_3OD, and 400 in $CDCl_3$ (monitored by NMR at room temperature).

The structure of *cis*-**2** followed from the chemical transformations discussed above. The other possible structure, that of a iminothiazinone resulting from sulfur attack on the nitrile group can be refuted from the ^{13}C spectra of the final product of the transformations in Scheme 2. As shown in Table 1 the thioureido acid *cis*-**6** shows resonances for CS and COOH at 182.8 and 174.8 ppm respectively. It can be readily shown that the thiazine would ultimately afford an ureido thioacid for which resonances are expected at ca. 160 and 195 ppm for CO and CSOH (12). In DMSO the structurally similar R^*,R^*-2-methyl-3-ureidobutanoic acid showed resonances at 176.2 (COOH) and 158.5 ($NHCONH_2$).[3]

Tautomers and configurations of the imines.

The amidine moiety in iminopyrimidine *cis*-**2** is fixed and allows no tautomers. However, two geometrical isomers around the C=N bond are possible. According to Perrin (13) it is especially unusual to see separate forms such as *Z*-**2** and *E*-**2** (Scheme 2), since proton exchange interconverts them. Accordingly in CD_3OD and $CDCl_3$ the ^1H NMR spectrum showed only one, apparently time averaged, set of signals. In DMSO, however, spectra under fast and slow exchange were observed with various samples. Under fast exchange 1-H resonated at 9.26 ppm while =N*H* was hidden under the multiplet for the *m*-H and *p*-H at ca. 7.35 ppm, integrating for 4 protons. Under slow exchange 1-H gave rise to two signals: 9.38 (0.4H) and 9.15 (0.6H) ppm. The signals for =NH were at 8.59 (0.6H) and 6.58 (0.4H) ppm respectively. The 2 ppm upfield shift can be attributed to the ring current effect of the 3-phenyl group in the *Z*-isomer because the benzene ring is not in the plane of the heterocyclic ring in similar systems (14). Other samples showed intermediate exchange. On standing all of them converted cleanly into the phenyliminopyrimidine **5**, indicating that the initial spectra dealt with the same compound. In view of the rapid conversion in DMSO of **2** into **5** and the difficulty in controlling chemical exchange, further investigation was discontinued.

With compound **5** two tautomers are possible: the phenylimino and phenylamino isomers shown. Similar cyclic acylated phenylamidines such as 3-aryliminoisoindolinones have been found to be only in the phenylimino tautomeric form (15). This is also the predominant form with phenyliminopyrimidine **5**. An IR band at 1664 cm^{-1} is observed in $CHCl_3$ which is within the characteristic range for exocyclic C–N double bonds non-conjugated to an acyl group (16). Another feature is the upfield chemical shifts of the *o*- and *p*-protons and carbons of the phenyl ring which is due to better conjugation with the electron pair on nitrogen than is the case when interaction with an acyl group (C=S) is possible, as in **5a** (15) (see Tables 1 and 2). However, in DMSO a third set of signals could be detected which was assigned to the amino form **5a**. The assignment was supported by variable temperature measurements. Notably a doublet of the **5a** set at 7.89 ppm did not exchange with D_2O and coalesced with the *ortho* protons upon heating. That this belongs to the interchanging system is supported by the fact that at 383 K the *m*- and *p*-protons had already coalesced to sharp triplets while the signal for the *o*-protons at ca. 6.8 ppm was still broad due to the greater chemical shift difference (>1 ppm between the imino and amino forms). The greater significance of the amino form compared to the above mentioned isoindolinones can be attributed to the greater acidity of thioamides compared to ordinary amides. The isomer ratio is *E*-**5**:*Z*-**5**:**5a** = 7.5:1.5:1.

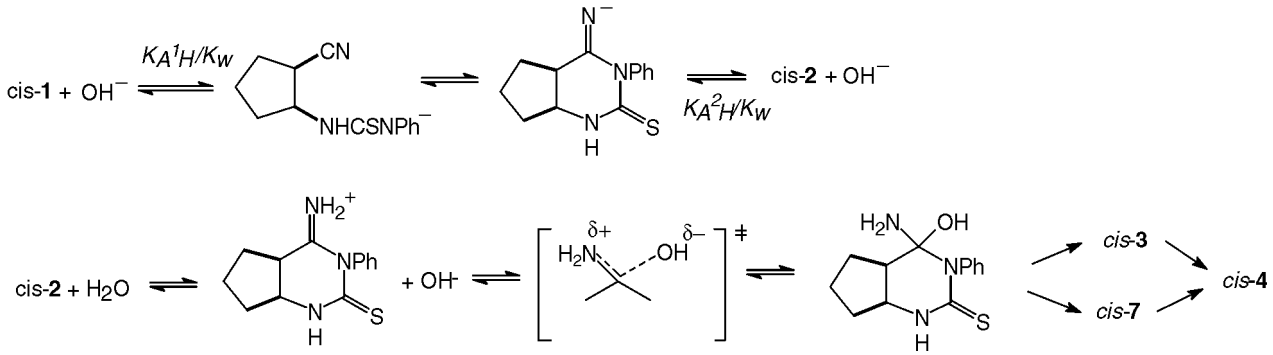
[t]Could not be assigned.
[u]*E*:*Z* = 1:1.
[v]Broadened.



In CD_3OD only, a 1:1 ratio of the imino *Z* and *E* isomers was observed. The signals of one of the isomers were broadened, which is most likely due to exchange with the amino form. In $CDCl_3$ only two sets of signals, both sharp, in 1:1 ratio were observed. This could be due either to fast exchange with the amino isomer or to its absence in significant amounts.[4]

The assignment of *Z* or *E* configurations was based on the expected upfield shift of 4a-H and 7a-H caused by the ring current effect of the phenyl group, because in the *E*-isomer

[4]One of the referees has suggested that the doubling of the NMR resonances could be due to dimer-polymer equilibria. We believe that the amidines studied in ca. 0.04 M solutions are unlikely to give associates, particularly in DMSO and MeOH.

Scheme 3.

allylic strain will force it into a perpendicular position. Such an assignment readily explains the favouring of the *E*-isomer in DMSO: solvation at 3-NH will hinder the phenyl group in the *Z*-isomer. The conformation, *syn* or *anti,* of the **5a** isomer could not be assigned.

Noteworthy is the strong bias of *cis*-**2** for conformation **A** (Scheme 2) suggested by the bandwidths of the signals for protons 4a and 7a in DMSO: 22.2 and 11.5 Hz respectively. 7a-H is axial in the pyrimidine ring thus J_{HNH} will be 0–1 Hz (7) and pseudoequatorial in the cyclopentane ring so that the sum of 11.5 Hz has to be made up of three gauche couplings. The signals for the 4a- and 7a-protons in the imino tautomers of compound **5** were better resolved than those for the iminopyrimidine **2**. Again the bandwidths for the 7a-H signals are very small: 8.4–9.0 Hz in CD_3OD and $CDCl_3$. The signals are triplets which can be due to two couplings of ca. 4 Hz. This is the value of a *cis*-coupling in dihydrouracils in cases of a directed electronegativity effect (7), i.e., when an electronegative atom is *anti* to one of the coupled protons. In conformation **A,** shown on Scheme 2 for compound **2,** the ring nitrogen is *anti* to 4a-H and to the neighbouring *cis* cyclopentane ring proton which accounts for the low couplings. The coupling with the *trans* proton of the pentane ring with a torsion angle of ca. 90° can be close to zero and thus not seen. The sextets observed for 4a-H can be accommodated by two couplings of 9–10 Hz and one of ca. 4 Hz. The latter is of course $J_{4a,7a}$ while the large couplings are the expected ones with torsions of ca. 30 and 150° with the *cis* and *trans* cyclopentane ring protons, respectively.

Kinetics of alkaline hydrolysis of nitrile *cis*-1

The equilibrium nitrile cis-*1*-*imine* cis-*2*

As described above when the hydrolysis of *cis*-**1** in aqueous hydroxide is monitored by UV, the peak at 245 nm decreases while a new absorption at 267 nm appears due to *cis*-**2**. The latter then breaks down by a much slower process and the absorption at 245 nm is restored. Quantitative estimates showed that the conversion of *cis*-**1** into *cis*-**2** is incomplete and an equilibrium is established (Scheme 3). At an [OH^-] higher than 0.01 M the amount of *cis*-**2** at equilibrium decreased. This can be explained by considerable ionization of the phenylthioureido group.

Table 3. Absorbance ratios in 0.1 M HCl for determining K_e = [*cis*-**2**]/[*cis*-**1**] and pK_{AH} of the phenylthioureido group of nitrile *cis*-**2** (25.0°C and ionic strength of 1 M (KCl)).

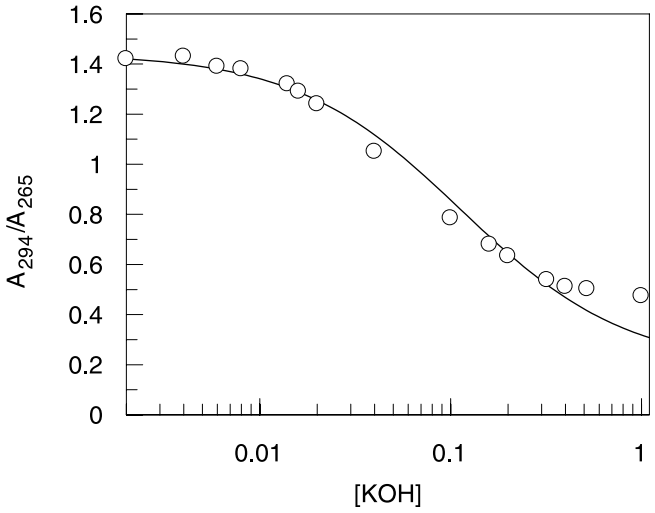
[a] $A^\circ_{1,294}$ = 1 870, $A^\circ_{2,294}$ = 11 200.
[b] $A^\circ_{1,265}$ = 9810, $A^\circ_{2,265}$ = 4260.
[c] Ratios are averages from several experiments.

Defining K_e = [*cis*-**2**]/[*cis*-**1**] as the equilibrium constant between the neutral species, then upon considerable ionization of the thioureido group the apparent equilibrium between the stoichiometric concentrations is given by eq. [1]:



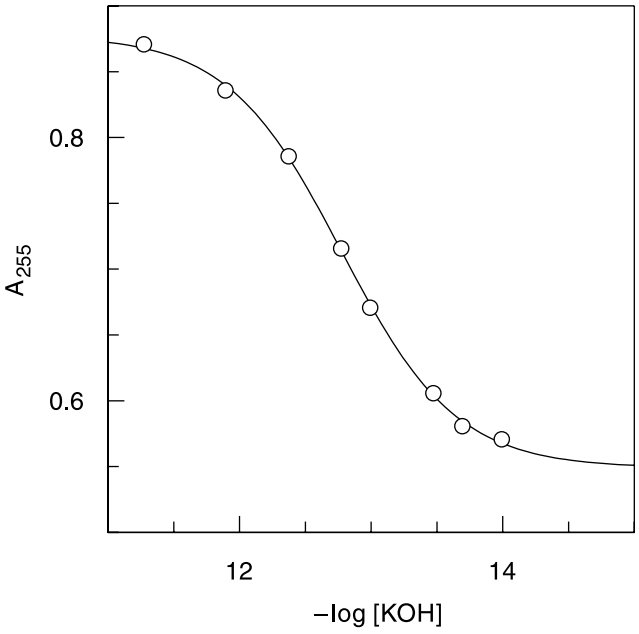
$$[1] \qquad K_{app} = \frac{[cis\text{-}\mathbf{2}]_{st}}{[cis\text{-}\mathbf{1}]_{st}} = \frac{K_e}{1 + [OH^-]K^N_{AH}/K_w}$$

The equilibrium mixture was analyzed by quenching the reaction mixture with hydrochloric acid at the moment of reaching the maximum of absorption at 267 nm, when the final products could still be neglected. HCl was added to a final concentration of ca. 0.1 M. Under these conditions the imine *cis*-**2** was fully protonated (pK_{BH^+} was determined spectrophotometrically to be 6.40 ± 0.11)[5] and hydrolysis is relatively slow. To avoid errors due to dilution, the equilibrium constant (K_e) and the dissociation constant for the CSNHPh group (K^N_{AH}) was determined from the ratio of the absorbances at two wave lengths:

[5] p*K* values for 4-imino-3-phenylhydantoins ranging from 6.1 to 6.5 have been reported in ref. 17.

© 2000 NRC Canada

Fig. 1. Semilogarithmic plot of A_{294}/A_{265} against [OH^-]. Curve is drawn by means of eq. [2] and parameters in text.



$$[2] \qquad \frac{A_{l1}}{A_{l2}} = \frac{A^{\circ}_{l1} + A^{\circ}_{21}K_e/(1 + K^N_{AH}[OH]/K_w)}{A^{\circ}_{l2} + A^{\circ}_{22}K_e/(1 + K^N_{AH}[OH]/K_w)}$$

where A^0_{ii} are the molar absorbances, the first subscript denoting the compound and the second one the wave length. A curve fit of the ratios A_{294}/A_{265} (Table 3) to eq. [2] in the interval 0.002 to 1 M KOH gave $K_e = 2.43 \pm 0.11$ and $K^N_{AH}/K_w = 18.0 \pm 2.1$ (I = 1 M (KCl)). Taking $K_w = 1 \times 10^{-14}$ and [OH^-] = a_{OH} gave a pK^N_{AH} of 12.74. These parameters resulted the fit shown in Fig. 1. The positive deviation of the points in 0.5 and 1 M KOH could be due to deprotonation of the amidine **2** (18) but attempts to include such an ionization in eq. [2] were unsuccessful.

Due to the rapid conversion of the nitrile *cis*-**1** in the region of ionization its p*K* could not be determined independently by spectroscopy. To check whether the value was reasonable, the p*K* for the ionization of the phenylthioureido group of the related amide *cis*-**3** was determined in KOH solutions (I = 1 M (KCl)). Again using –log [KOH] as the acidity function and $pK_w = 14$, a pK_{AH} of 12.78 ± 0.02 was obtained (Fig. 2).

Fig. 2. Determination of pK_{AH} for ionization of the phenylthioureido group in carboxamide *cis*-**3**.

$$[3] \qquad k_{obs} = k_f[OH^-]/(1 + K^N_{AH}[OH^-]/K_w) + k_f[OH^-]/K_e$$

The experimental data were fitted eq. [3] using the ionization and equilibrium constants found above as fixed parameters. This afforded $k_f = 4.24 \pm 0.08$ dm^3 mol^{-1} s^{-1} (Fig. 3). A $k_r$value of 1.74 dm^3 mol^{-1} s^{-1} was calculated from the equilibrium constant.

The kinetics observed indicate that the reactive form of *cis*-**2** is the ureide anion. According to the principle of microscopic reversibility the return path will involve the amidine anion.

The breakdown of the iminopyrimidine *cis*-**2** to products was found to be independent of the concentration of OH^- between 0.001 and 0.012 M KOH, where the observed first-order rates averaged to 2.21×10^{-4} s^{-1}. The somewhat higher rate observed in 0.1 M KOH indicates that a first order in [OH^-] process sets in. Actually, taking into account the lower fraction of *cis*-**2** at equilibrium in 0.1 M KOH, a lower pseudo-first-order constant should have been observed if only the pH-independent reaction took place. pH-independent rates are often encountered in the hydrolysis of amidines (18) in the alkaline region. The reaction can be formulated as attack of water on neutral iminopyrimidine, however, attack of OH^- on the protonated form as shown in Scheme 3 appears more appealing. The tetrahedral intermediate could either lose ammonia to give the pyrimidine **7** which would rapidly hydrolyze[6] to the acid **4**, or open the cycle to form the amide **3** which would then hydrolyze to the same acid **4**.[7] ^{1}H NMR of extracts of the acidified reaction mixture leaving *cis*-**2** as salt in the acid solution showed that the second route through the amide is preferred. After 110 min in 0.01 M KOH at room temperature (around two half-lives of *cis*-**2**) nitrile *cis*-**1** gave a mixture of *cis*-**3**:*cis*-

Rates of formation of imine *cis*-2 and its breakdown

The large difference in the rates of formation of *cis*-**2** from *cis*-**1** and the breakdown of the former allowed these to be measured as two separate first-order processes. The formation and breakdown were measured only up to 0.04 M KOH because of the considerable drop (due to the ionization of the ureido group at the higher alkalinities) in the amount of intermediate **2** formed at equilibrium. Furthermore, the rate of formation became too fast to measure by conventional means.

The cyclization of ureido nitrile **1** was found to be first order in [OH^-] at lower alkalinities. Taking into account the equilibria in Scheme 3, the following expression for the dependence of k_{obs} on [OH^-] can be derived:

[6] At pH 9.18 *cis*-**7** hydrolyzes with an observed rate of 0.0015 s^{-1}.
[7] Thin layer chromatography showed general retention of configuration. Only trace *trans* isomers of the products were found.

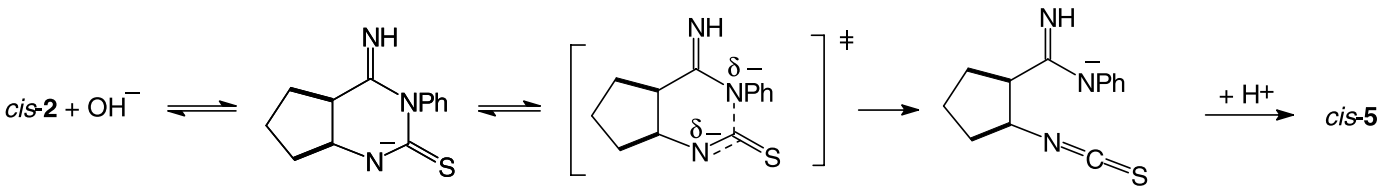
Scheme 4.



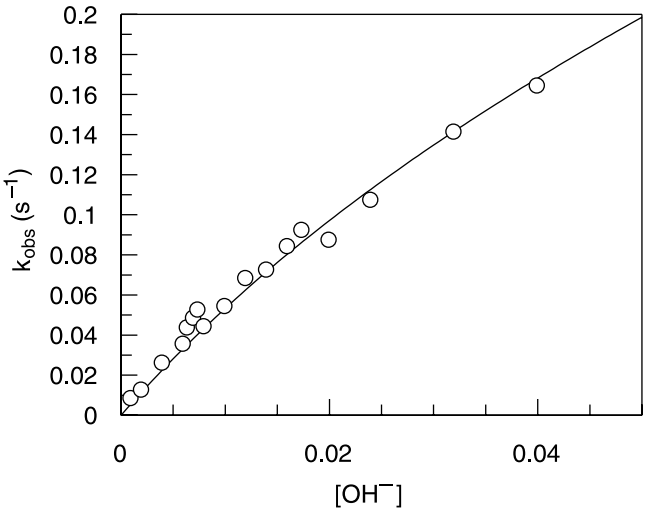


Fig. 3. Pseudo first order rate constants for the cyclization of nitrile **1**. Curve calculated by means of eq. [3] with parameters in text.

4:*cis*-**1** in a ratio of 57:30:13. After 7 h [*cis*-**3**]:[*cis*-**4**] = 19:81 and in 24 h the extract was pure acid *cis*-**4**.

In the introduction the magnitude of the anchimeric assistance to the alkaline hydrolysis of the nitrile group by the neighbouring phenylthioureido one is quoted as 1×10^4. This is estimated by comparing the rate of breakdown of *cis*-**2** with the second order rate constant of alkaline hydrolysis of acetonitrile. Another comparison could be provided by the hydrolysis of the nitrile group in *trans*-**1** which has a closer similarity with respect to steric and electronic influences. For 18 days at room temperature in aqueous 0.01 M KOH *trans*-**1** degraded only around 50%, the products were not, however, the amide *trans*-**3** or the acid *trans*-**4** (^{1}H NMR), and probably result from transformations of the thioureido group. If that time is compared with the half-life of *cis*-**2** of 50 min, the *trans* nitrile is at least 500 times more stable towards alkali.

Solvent effect on the breakdown of imine *cis*-2

The most likely transition states for the reaction of *cis*-**2** in water and in a mixture of water:acetonitrile (1:2 v/v) are shown on Schemes 3 and 4. The zero order in [OH^-] hydrolysis of **2** proceeds as suggested above as an attack by OH^- on the protonated form of the imine. On the other hand, the slow step in the isomerization is usually (19) a base catalyzed elimination giving the thioisocyanate shown on Scheme 4. The first reaction involves charge separation in the transition state while the second one dispersal of charge. Decreasing the dielectric constant by addition of acetonitrile will favour the second and disfavour the former reaction. Addition of a polar aprotic solvent will raise specifically the activity of the ground state of the elimination reaction (OH^-) and thus further accelerate elimination over hydrolysis.

Experimental

Unless otherwise stated IR-spectra are in nujol mulls on a Bruker IFS instrument, frequencies are in cm^{-1}, wavelengths are in nm. Instruments included a Bruker Spectrospin WM 250 NMR spectrometer (chemical shifts in ppm against TMS, couplings in Hz), a Jeol-D 300 mass spectrometer and a Unicam SP 800 UV spectrophotometer. Uncorrected melting points were determined in capillaries.

Inorganic reagents for kinetic measurements were of analytical grade and were used without further purification.

cis- *and* trans-*2-(-3-Phenylthioureido)cyclopentanecarbonitrile (**1**)*: The parent 2-aminocyclopentanecarbonitrile was prepared as a crude oil as follows. A solution of 2-amino-1-cyanocyclopentene (20) (7.3 g, 68 mmol) in methanol (100 mL) was made acid to bromocresol green with 1 N methanolic HCl. Sodium cyanoborohydride (4.9 g) was added by portions while the solution was kept acidic by the addition of more methanolic HCl. After stirring for 3 h the reaction mixture was concentrated. The residue was treated with 10% aqueous NaOH (68 mL) and NaCl (14 g), and taken up in dichloromethane (4 × 50 mL). It was removed from dichloromethane with 10% HCl (4 × 50 mL). The aqueous extract was made basic with 20% aqueous NaOH and extracted with dichloromethane (4 × 50 mL). The dichloromethane solution was dried (Na_2SO_4) and concentrated under reduced pressure to yield 2-aminocyclopentanecarbonitrile (6.53 g, 88%) as a colourless oil. IR (Nujol) ν_{max}: 3370, 3305 (NH), 2220 (CN) 1600 (NH_2).

A solution of phenylisothiocyanate (2.80 g, 21 mmol) in ether (5 mL) was slowly added to a solution of the above 2-aminocyclopentanecarbonitrile (2.2 g, 20 mmol) in ether (5 mL). A crystalline precipitate formed which was filtered and washed with petroleum ether to give the crude *cis* and *trans* isomers of **1** (4.4 g, 88%). The crude mixture (2 g) was chromatographed on 60 g "Florosil" with chloroform as the eluent. 50 mL fractions were taken and fractions 4 to 7 yielded the more mobile *cis* isomer while 9 to 25 yielded the

trans isomer. Crystallization from ethanol-water (2:1) yielded 0.67 g solid *cis*-**1** (mp 163–164°C). λ_{max} (H_2O): 245; IR (KBr disk) ν_{max}: 3230 (NH), 2232 (CN) 1546 (NHCSNHPh); MS *m/z*: 245. Anal. calcd. for $C_{13}H_{15}N_3S$: C 63.6, H 6.2; found: C 63.3, H 6.15. *trans*-**1** (1.07 g) had a mp 156–157°C. λ_{max} (H_2O): 244; IR (KBr disk) ν_{max}: 3295, 3181 (NH), 2240 (CN); MS *m/z*: 245. Anal. calcd. for $C_{13}H_{15}N_3S$: as above; found: C 63.25; H 6.5.

cis-*2-(3-Phenylthioureido)cyclopentanecarboxamide (*cis-***3***)*: The *cis* nitrile **1** (0.30 g, 1.2 mmol) was stirred in 60% sulfuric acid (5 mL). When solution was complete (1 h) it was diluted with water (15 mL) under cooling. The mixture was extracted with chloroform and the chloroform layer washed with 5% sodium carbonate and water, dried, and evaporated to dryness. TLC of the solid residue of *cis* amide **3** showed no appreciable admixture of the *trans* amide. Recrystallization from $CHCl_3$–petroleum ether yielded 0.15 g, 47% (mp 160–161°C after second crystallization). λ_{max} (H_2O): 245. IR (KBr disk) ν_{max}: 3388, 3356, 3277, 3165 (NH), 1662 ($CONH_2$), 1541 (NHCSNHPh). MS *m/z*: 263. Anal. calcd. for $C_{13}H_{17}N_3OS$: N 15.96; found N 15.54.

trans-*2-(3-Phenylthioureido)cyclopentanecarboxamide (*trans-***3***)*: The same procedure with *trans* nitrile **1** (0.30 g, 1.2 mmol) in which the dilution with water followed 5 min of stirring afforded, after two recrystallizations from chloroform-petroleum ether, 0.16 g (50%) of *trans*-**3** (mp 155–156°C, the crude product contained considerable amounts of the *cis* amide-**3** (determined by TLC)). λ_{max} (H_2O): 245. IR (KBr disk) ν_{max}: 3346, 3209 (NH), 1660, 1633 ($CONH_2$), 1541 (NHCSNHPh). Anal. calcd. for $C_{13}H_{17}N_3OS$: N 15.96; found N 15.95.

cis-*4-Oxo-1,2,3,4a,5,6,7,7a-octahydro-3-phenyl-2-thiooxocyclopenta[*d*]pyrimidine (*cis-***7***)*: (a) *cis* Nitrile **1** (0.305 g, 1.24 mmol) in 1:2 HCl (30 mL) was refluxed for 30 min. Cooling and filtering afforded 0.289 g (94%) of the crude thiouracil **7** (mp 267–269°C, ethanol, lit. mp 285–287°C (5)). λ_{max} (H_2O): 278; IR (Nujol) ν_{max}: 3171 (NH), 1711 (CO), 1564 (NHCSNPh); MS *m/z*: 246. Anal. calcd. for $C_{13}H_{14}N_2OS$: C 63.4; H 5.7; found: C 63.6; H 5.8. (b) Refluxing the *trans* nitrile **1** (60 mg, 0.24 mmol) in 1:2 HCl (30 mL) for 1 h, cooling, and standing overnight gave as precipitate 47 mg (78%) of pure (determined by ^{1}H NMR) *cis* pyrimidine **7**.

trans-*2-(3-Phenylthioureido)cyclopentanecarboxylic acid (*trans-***4***)*: Refluxing the nitrile *trans*-**1** (52 mg, 0.21 mmol) in 1:2 HCl for 30 min after cooling and standing overnight afforded 30 mg of a 4:1 mixture (^{1}H NMR) of the *cis* pyrimidine **7** and the *trans* acid **4**. Evaporating the mother liquor with a rotary evaporator yielded 19 mg, 34% of pure *trans* acid (mp 146–147°C, lit. mp 142–144°C(5)); λ_{max} (H_2O): 245; IR (KBr disk) ν_{max}: 3346, 3169 (NH), 1701, 1687 (CO), 1549 (NHCSNHPh). Anal. calcd. for $C_{13}H_{16}N_2O_2S$: C 59.1; H 6.1; N 10.6; found: C 59.0; H 6.32; N 10.8.

cis-*2-(3-Phenylthioureido)cyclopentanecarboxylic acid (*cis-***4***)*: The *cis* pyrimidine **7** (0.5 g, 2.03 mmol) dissolved easily in warm 0.5 M NaOH (20 mL). After acidifying the cooled solution with conc. HCl (2 mL) the *cis* acid **4** separated as a gum which crystallized rapidly to give 0.53 g. 99% of solid (mp 152–153°C, (chloroform-petroleum ether), resolidifies and melts again at 230°C). λ_{max} (H_2O): 245; IR (Nujol) ν_{max}: 3344, 3167 (NH), 1686 (CO), 1536 (NHCSNHPh). MS *m/z*: 264. Anal. calcd. for $C_{13}H_{16}N_2O_2S$: C 59.1; H 6.1; found: C 58.9; H 6.3.

cis-*4-Imino-1,2,3,4a,5,6,7,7a-octahydro-3-phenyl-2-thiooxocyclopenta[*d*]pyrimidine (*cis-***2***)*: The *cis* nitrile **1** (36 mg, 0.146 mmol) was dissolved by warming in acetonitrile (2 mL) and subsequently mixed with 0.01 M KOH (100 mL) at room temperature. After 3 min the mixture was transferred to a cooled separatory funnel containing ice and HCl, the amount of the latter dependant on the desired final acid concentration. The solution was extracted rapidly with dichloromethane (3 × 40 mL) in the course of five to eight min and passed through a fluted filter. The dry residues of the extracts amounted to 30–35% (by weight) of the starting material and consisted of (according to ^{1}H NMR) mixtures of the initial nitrile and the *cis* amide, the amount of the latter varying from trace to 30%). The aqueous layer was made alkaline (ca. 0.01 M in [OH^-]) and extracted twice rapidly with chloroform (ca. 12 min from the start of the experiment). The organic layer was filtered, dried with $MgSO_4$, and evaporated to give a solid, the iminopyrimidine *cis*-**2** (25 mg, containing up to ca. 15% the *cis* nitrile according to ^{1}H NMR). λ_{max} (H_2O): 267, (0.1 M HCl 295); IR ($CHCl_3$) ν_{max}: 3409, 3288, 3199b (NH), 1647 (C=N), 1528 (NCSNH).

cis-*4-Phenylimino-1,2,3,4a,5,6,7,7a-octahydro-3-phenyl-2-thiooxocyclopenta[*d*]pyrimidine (*cis-***5***)*: A solution of 0.5 g (2 mmol) of *cis*-2-(3-phenylthioureido)cyclopentyl cyanide in 80 mL of absolute methanol was refluxed for 3 h. The solvent was removed by a rotatory evaporator and the solid residue recrystallized from MeOH–MeCN to give 0.39 g (78%) of solid *cis*-**5** (mp 231–2°C). MS *m/e*: M^+ 245; λ_{max} (H_2O): 269, 242; IR (KBr disk) ν_{max}: 1670 (C=N), 1564 (δ NH), 1346 (NHCSNH), 3170, 3460 (NH); IR ($CHCl_3$) ν_{max}: 1664 (C=N) 1535 (δ NH), 1348 (NHCSNH), 3226, 3408 (NH). Anal. calcd. for $C_{13}H_{15}N_3S$: C 63.63, H 6.16, N 17.13, S 13.07; found: C 63.78, H 6.45, N 16.85, S 13.18.

cis-*1,2,3,4a,5,6,7,7a-Octahydro-4-oxo-2-thiooxocyclopenta[*d*]-pyrimidine (*cis-***8***)*: (a) From phenyliminopyrimidine *cis*-**5**. The phenyliminopyrimidine *cis*-**5** (0.37 g, 1.5 mmol) was dissolved with gentle heating in 30 mL of MeOH and 10 mL of MeCN. 40 mL of distilled water and 15 mL of 1M HCl were further added. The solution was left at ambient temperature for 75 min and then evaporated to dryness until HCl was completely removed in vacuo. Recrystallization from MeOH–petroleum ether afforded 0.180 g (80%) of solid (mp 198–9°C, lit. mp 206–208°C(11)); MS *m/e*: M^+ 170; IR (KBr disk) ν_{max}: 1693 (CO), 1362 (NHCSNH), 3182, 3460w (NH). Anal. calcd. for $C_7H_{10}N_2OS$: C 49.39; H 5.92; N 16.46; S 18.91; found C 49.50; H 6.03; N 16.77; S 18.91.

(b) From cyclization of *cis*-2-thioureidocyclopentanecarboxylic acid (*cis*-**6**). The acid *cis*-**6** (0.150 g) was dissolved in 8 mL of MeCN and 4 mL of MeOH. 12 mL of 1 M HCl were added and the mixture left at room temperature for 20 h. The solvent removed and the dry residue recrystallized from MeCN and petroleum ether to yield 0.085 g (63%) of

[a]Experiment conducted at pH 10.49 in carbonate buffer 70% base.

solid *cis*-**8** (mp 197–199°C) identical with the above product according to spectral data and mixed mp.

cis-*2-Thioureidocyclopentanecarboxylic acid (*cis-***6***)*: (a) 0.31 g of phenyliminopyrimidine *cis*-**5** were dissolved by gentle heating in 20 mL of MeOH. 20 mL of aqueous 1 M KOH were added and the solution left at room temperature for 12 h. Most of the MeOH in the solution was removed on a rotary evaporator and the alkaline solution extracted twice with 20 mL portions of ether. The organic layers were dried and the solvent removed to yield an reddish-brown oil identified as aniline: M^+ 93; same IR and UV spectra as that of an authentic sample. The aqueous layer was neutralized with 2 equivalents of cationite Dowex 50x8 in H^+ form. The solution (pH two to three) was evaporated and the residue recrystallized twice from MeCN with addition of petroleum ether to yield 0.045 g (19%) of *cis*-**6** (mp 155–157°C). MS *m/e*: M^+ 188. λ_{max} (H_2O): 230 (log ϵ = 3.9), 280 (log ϵ = 3.1). IR (KBr disk) ν_{max}: 1635, 1560 (delta NH) 1703 (COOH), 3186, 3300, 3350 (NH,OH). Solution resulted a single spot on TLC and no admixtures were observable in the ^1H NMR spectrum. (b) 0.095 g of *cis*-**8** were dissolved in five mL of MeOH by gently heating and 10 mL of 1 M aqueous KOH added. Similar work up yielded 0.097 g of raw *cis*-**6** identical (according to ^1H NMR) to the product obtained in (a).

Kinetic measurements

The rates were measured under pseudo first order conditions in the thermostated cell compartment of a Unicam SP 800 spectrophotometer. The reactions were initiated by injecting 20 to 80 μL of a 10^{-2} to 10^{-3} M stock solution of the substrate in MeCN, to the preheated KOH solution of ionic strength 1 M (KCl). The conversion of *cis*-**1** into *cis*-**2** was monitored by the increase of absorption at 267 nm while the degradation of the latter was monitored by the decrease at the same wavelength. Pseudo-first-order rate constants (k_{obs}) were calculated by the least squares procedure from plots of either ln ($A_t - A_{inf}$) or ln ($A_{inf} - A_t$) (as appropriate) versus time, where A_{inf} was the absorbance after ten half-lives.

Equilibrium between the *cis* nitrile 1 and *cis* iminopyrimidine 2

Under the conditions of the rate experiments a solution of the *cis* nitrile **1** in MeCN was added to the preheated at 25.0°C KOH solution so that the final concentration of **2** was 7–8 × 10^{-5} M. When maximum absorption at 267 nm (λ_{max} (H_2O) of *cis*-**2**) was reached, the solution in the cell was acidified with a predetermined amount of HCl so that its final concentration was ca. 0.1 M and the spectrum of the solution taken immediately. The ratio [*cis*-**2**]:[*cis*-**1**] was determined from the ratio of the absorbances at the two wave lengths as well as the known extinction coefficients at these wavelengths of the two compounds in HCl solutions. Making the solution alkaline after the measurement restored the pre-acidification spectrum by better than 5%.

Product analysis

The course of the alkaline hydrolysis of *cis*-**1** was also followed by ^1H NMR in order to identify the products. For these large scale experiments the substrate was dissolved in an appropriate amount of MeCN so that when added to the KOH solution, the final concentration of MeCN equalled that in the kinetic experiment. After being kept at 25°C for the appropriate period of time, aliquots were acidified and extracted with dichloromethane, the solvent removed and the composition determined by ^1H NMR.

Determination of p*K*-values

(*a*) *cis*-Amide **3**. A solution (20 μL) of the amide (0.01 M) in MeCN was added to a 25.0°C (2.7 cm^{-1}) preheated solution of KOH (0.002 to 1 M, I = 1 M (KCl)) in a UV cell, and the absorbance measured at 255 nm. The pK was obtained by a nonlinear regression fit of the equation

$$K = (A_{AH} - A)[H^+]/(A - A_{A^-})$$

where A is the absorbance, A_{AH} and A_{A^-} the limiting absorbances at low and high basicity respectively. $[H^+]$ was assumed equal to antilog(14 – log $[OH^-]$).

(*b*) *cis*-Iminopyrimidine **2**. The compound was isolated as a solid as described above and as a solution prepared in MeOH which was kept cooled in ice/water. Aliquots (10 μL) were injected into UV cells containing 25.0°C preheated 0.1 M buffer solutions (formate, acetate, and phosphate) with I = 1 M (KCl). The absorbances were measured at 295 nm and the p*K* was calculated as above using the pH-values measured by means of a Radiometer pHM 84 Research pH-meter with a GK 2401 electrode.

Gas-phase luminescence of aromatic carbonyl compounds in excited nitrogen at atmospheric pressure[1]

Zhong-Ping Lin and Walter A. Aue

Abstract: Certain types of aroyl compounds such as benzaldehyde, acetophenone, benzophenone, and anthraquinone produce intense gas-phase luminescence in excited nitrogen at atmospheric pressure. This luminescence was measured in pressure ranges of 1.00–1.67 atm and temperature ranges of 343–473 K. A novel, radioactively (Ni-63) stimulated, high-voltage (≤1750 V/mm), low-current (≤35 nA) discharge in high-purity nitrogen was used for gas chromatographic detection and spectral excitation. The gas-phase luminescence spectra of about sixty aroyl compounds — introduced as gas chromatographic peaks — could thus be measured and compared with literature spectra obtained by conventional excitation in *condensed* phases. Only a few *gas*-phase spectra are available from the literature, and these did agree well with the spectra of this study. A speculative luminescence mechanism is proposed, in which ground-state N_2 becomes excited by collision with fast electrons. This is followed by efficient triplet–triplet energy transfer from $N_2(A\ ^3\Sigma_u^+)$ to the $n\rightarrow\pi^*$ excited aroyl compound.

Key words: aroyl phosphorescence, excited-nitrogen excitation, aroyl triplet–triplet excitation, aroyl luminescence detection, gas-phase phosphorescence spectra, gas-phase aroyl detection.

Résumé : En phase gazeuse, en présence d'azote excité, à pression atmosphérique, certains types de composés aroyles tels que le benzaldéhyde, l'acétophénone, la benzophénone et l'anthraquinone produisent une luminescence intense. On a mesuré cette luminescence à des pressions allant de 1,00 à 1,67 atm. et à des températures allant de 343 à 473 K. Pour la détection chromatographique et l'excitation spectrale, on a fait appel à une nouvelle décharge dans de l'azote purifié, stimulée d'une façon radioactive (Ni-63), à l'aide d'une tension élevée (≤1750 V/mm) et un faible courant (≤35 nA). On a ainsi pu mesurer les spectres de luminescence en phase gazeuse d'environ soixante composés aroyles — introduits sous la forme de pics chromatographiques — et on les a comparés avec des spectres rapportés dans la littérature et obtenus par une excitation conventionnelle dans des phases condensées. Dans la littérature, on ne retrouve que quelques spectres en phase gazeuse et ils sont en bon accord avec les spectres obtenus au cours de cette étude. On propose un mécanisme spéculatif pour la luminescence; il implique le passage de N_2 de l'état fondamental à l'état excité sous l'influence des collisions avec des électrons rapides. Cette excitation serait suivie d'un transfert d'énergie triplet-triplet efficace de $N_2(A\ ^3\Sigma_u^+)$ vers le composé aroyle excité $n\rightarrow\pi^*$.

Mots clés : phosphorescence d'aroyle, excitation par de l'azote excité, excitation triplet–triplet aroyle, détection de la luminescence aroyle, spectre de phosphorescence en phase gazeuse, détection aroyle en phase gazeuse.

[Traduit par la Rédaction]

Introduction

Photophysics and photochemistry of aromatic carbonyl molecules have been extensively studied, typically by optical excitation (1, 2) or electron impact (3, 4). Most investigations have been restricted to the condensed phases, in which these organic molecules often show photochemical or photophysical properties different from those observed in the gas phase. In this paper we report that a radioactively stimulated, high-voltage, low-current discharge in high-purity nitrogen was used to excite certain aromatic carbonyl compounds at *atmospheric* pressure and *high* temperature in the *gas* phase. The emission spectra of some sixty aroyl compounds were measured and compared with spectral data from other excitation systems (where available in the literature). Our objective was to develop an understanding of the general photophysical characteristics of these molecules under the specific gas-phase conditions of high temperature and atmospheric pressure, as well as to investigate their excitation, i.e., energy transfer mechanism.

Fig. 1. Block diagram of the experimental set-up for obtaining gas-phase luminescence spectra of aroyl compounds. ALD = aroyl luminescence detector.

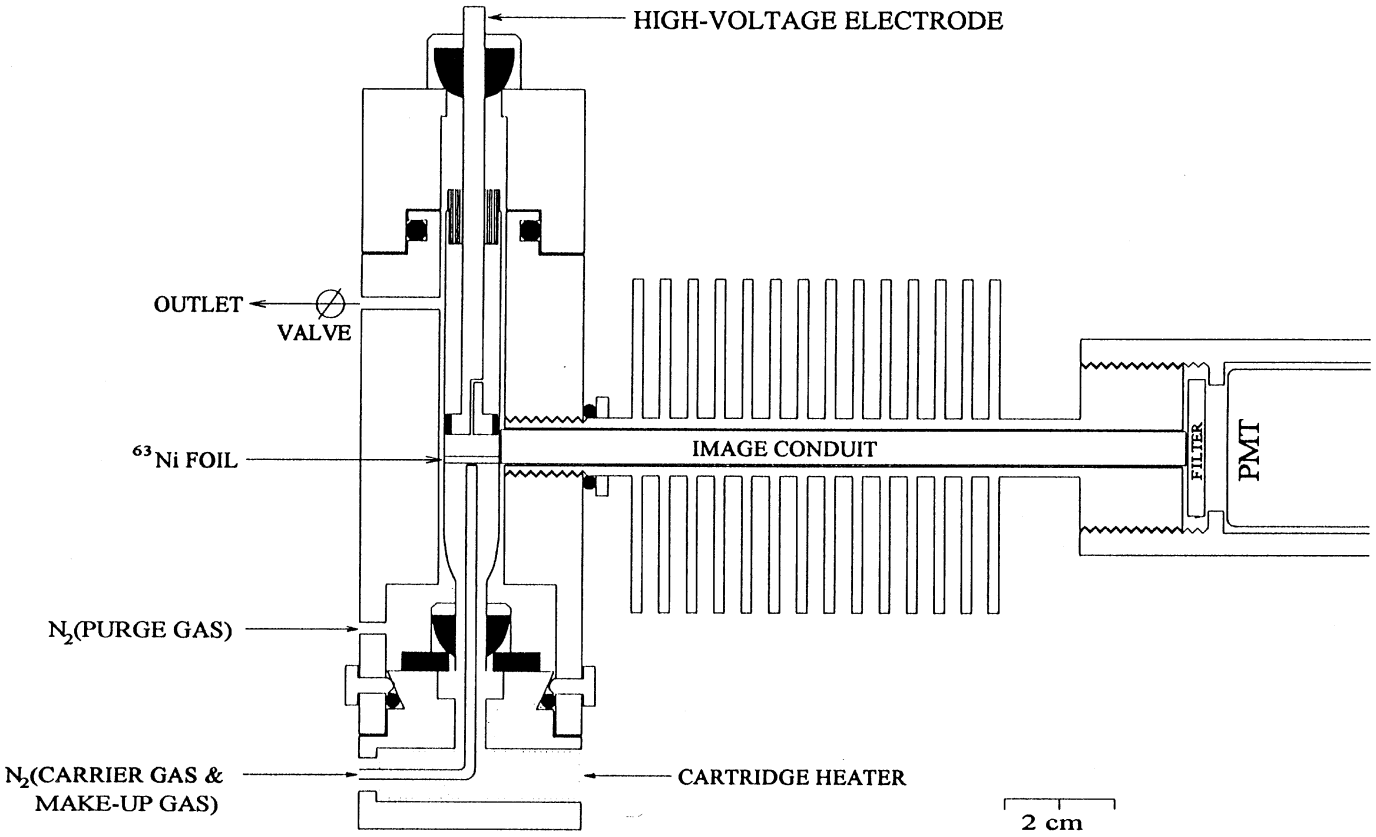
as GC carrier gas, purge gas and reagent gas for the "aroyl luminescence detector" (ALD). Prior to entering the injection port, nitrogen gas was purified by passage through molecular sieve 5A (Guild Corp., Bethel Park, Penn.) and heated zirconium sponge ("gas purifier"; Supelco, Bellefonte, Penn.). Carrier gas and make-up gas were mixed, if needed, with a doping gas at the entrance of the ALD. Purge gas was used to flush air or impurities out of the detector.

A 12 kV Spellman model HS5P30/CR/X769 (High Voltage Electronics Corp., Bronx, N.Y.), or a 5 kV Hipotronics model no. R10B (Brewster, N.Y.) DC high-voltage power supply was employed to polarize the ALD electrode. A current-limiting resistor of 5×10^6 ohm was installed between the DC power supply and the electrode for safety reasons.

The ALD signal (analyte luminescence) was measured with a Hamamatsu photomultiplier tube, typically an R-374 or R-268 PMT (Hamamatsu Corp., Middlesex, N.J.), and amplified with a Tracor electrometer (Tracor, Austin, Tex.). The signal was displayed on a Linear two-pen chart recorder, or stored in a computer for subsequent processing. Either Ditric (no longer in business) or Oriel (Stratford, Conn.) optical interference or colored-glass filters were used as needed.

2. Gases and chemicals

Nitrogen (prepurified, 99.998%), hydrogen (prepurified, 99.99%) and air (extra dry, maximum moisture 10 ppm) were the products of Linde Union Carbide Canada Ltd. (Toronto, Ont.). Argon of ultra-high-purity grade was obtained from Matheson Gas Products (Toronto, Ont.). All chemicals (95+% purity) were purchased from commercial sources, e.g., from Aldrich Chemical Company (Milwaukee, Wis.); Fluka Chemical Corp. (Ronkonkoma, N.Y.); or Sigma Chemical Company (St. Louis, Mo.). The chemicals were used without further purification.



3. Aroyl Luminescence Detector

Both a single-channel and a triple-channel aroyl luminescence detector were used in this study. A detailed diagram of the single-channel ALD is shown in Fig. 2. The de novo design of this detector was based on the earlier described nitrogen-plasma photometric detector (NPPD) (5), which had been constructed by modifying a Shimadzu flame photometric detector (FPD). The two basic requirements in designing the new detector were (*i*) to ensure gas tightness, and (*ii*) to obtain maximal light output and throughput from the emission zone. Thus the detector cell was constructed with a 7.5 cm × 8 mm i.d. quartz tube of 1 mm thickness, which was fixed on the detector base with a Swagelock nut and a lab-made Teflon ferrule. A high-voltage electrode was inserted from the top of the detector into the quartz tube. The electrode was insulated from the detector body by a Teflon tube and a Swagelock fitting with Teflon ferrule. The distance between the polarized electrode and the nozzle (i.e., the detector jet, which also served as the grounded counter electrode) was adjustable, but was normally kept at 4 mm. A 1 mm high ^{63}Ni/Au cylindrical foil was held inside the quartz tube by friction fit, with the lower edge of the foil at the same level as the top of the nozzle. The detector volume was kept to 200 µL (and the luminescing zone much smaller than that), in order to maintain chromatographic peak resolution. A 6 in.(1in. = 25.4 mm) long, 6 mm o.d. high-quality glass image conduit (Edmund Scientific, Barrington, N.J.) was shielded from the room lights by an aluminum housing, inserted through the detector wall, and moved against the quartz tube to pick up as much light as possible. (The glass light guide was replaced by a quartz rod for any measurement — e.g., that of the nitrogen second-positive background system — for which UV transmission was important.) Enough space was left between the other end of the image conduit and the PMT to allow insertion of an optical filter (if needed). The detector was made light- and also gas-tight by silicone O-rings, Teflon ferrules, and Teflon stoppers. Even so, purge gas was required to flush traces of room air or other impurities out of the detector. The detector was exhausted through a long copper tube, which prevented the entry of light. A valve in the exhaust line kept the detector at a slight overpressure under normal operating conditions, in order to minimize back-diffusion of atmospheric oxygen. This valve was connected to a Matheson pressure gauge or to a MacLeod vacuum gauge for experiments run under other than the usual ambient pressure.

The triple-channel aroyl luminescence detector consisted of the detector cell, two photometric detection channels (together forming the "response-ratio channel"), and a "spectral

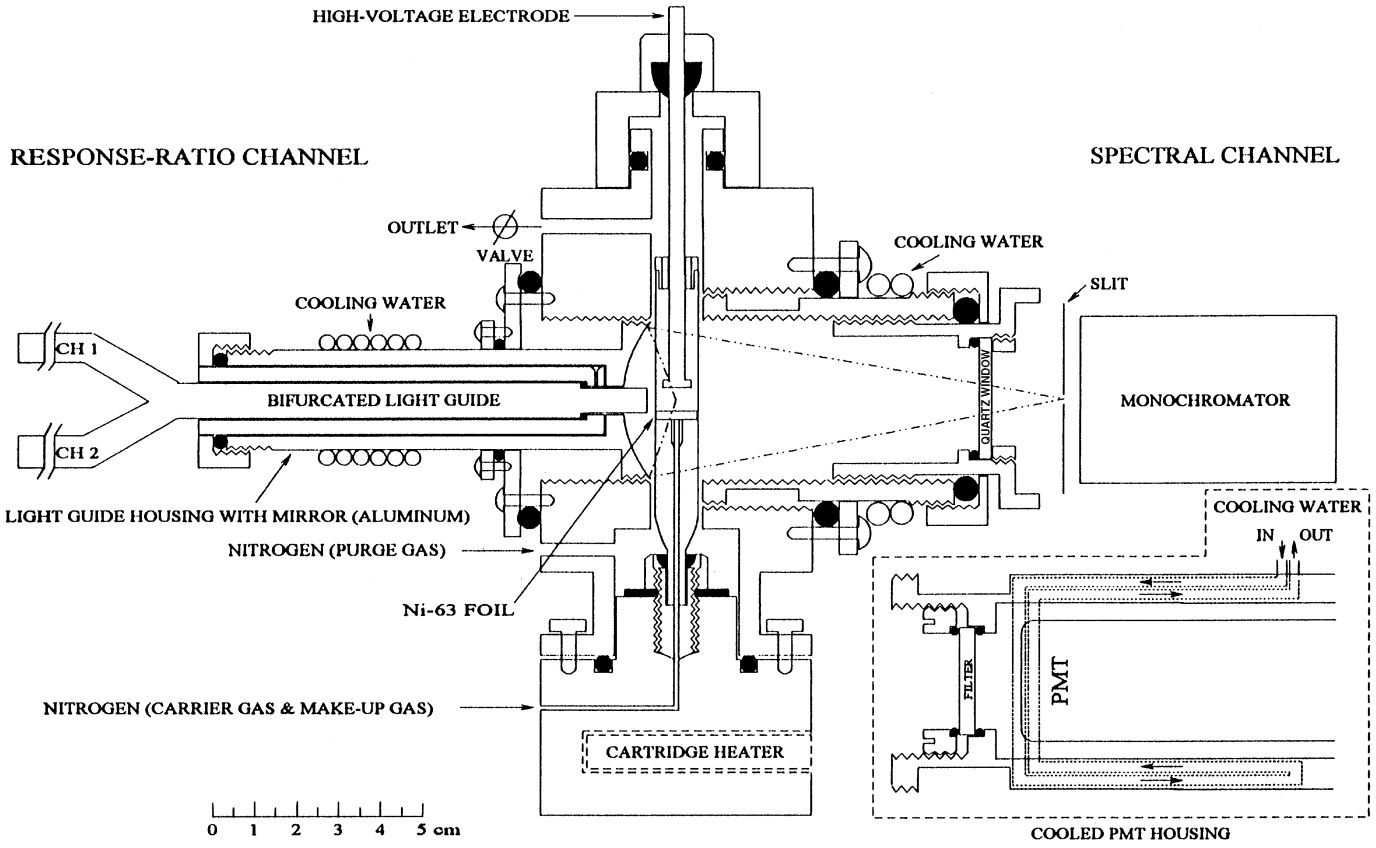
© 2000 NRC Canada

Fig. 2. Schematic of the single-channel aroyl luminescence detector.

channel." Figure 3 shows a diagram of the triple-channel ALD unit. The detector cell was constructed similar to that of the single-channel ALD. The two photometric channels consisted of a bifurcated optical glass fiber bundle (Item 77533; Oriel, Stratford, Conn.), with optical filters as needed, and two Hamamatsu R-268 PMTs installed in lab-made housings. An aluminum tube was used to hold the optical fiber bundle. It was positioned inside the light-guide housing, which ended in a lab-made spherical aluminum mirror of 31 mm diam. and 15 mm focal length. This aluminum mirror had a 6 mm diam. axial aperture (central hole) to accommodate the image conduit. The arrangement was inserted through the detector wall to a distance where the mirror would best focus the luminescence onto the slit of a monochromator in the spectral channel. This channel consisted of an aluminum tunnel connecting the detector body and the monochromator, of a quartz window installed at the end of the tunnel to make the detector gas-tight, and of a monochromator (vide infra for specs) with a Hamamatsu PMT to monitor the luminescence spectrum. The distances from the emission zone to the mirror on one side and the monochromator on the other could be adjusted. The purpose of adjustment was to focus the beam onto, and nigh fill the acceptance cone of, the monochromator aperture, so as to maintain optimal light throughput. To keep the photomultipliers and the monochromator cool, both the photometric detection channels and the spectral channel were equipped with water-flushed copper cooling coils. In addition, the spectral channel could be replaced by a PMT held in a water-cooled housing for more sensitive detection, as indicated at the lower right of Fig. 3. The whole detector was kept gas-tight by silicone O-rings and Teflon ferrules.

4. Spectral measurements

Repeated-injection mode



The image conduit of the single-channel ALD was replaced by a quartz rod of equal dimensions. Either a Jarrell–Ash model 82-415 quarter-meter monochromator of *f*/3.5 effective aperture ratio, with a 1180 grooves/mm grating blazed for 500 nm and fixed-width pairs of slits (0.5, 1, 2, or 4 mm; reciprocal dispersion 3.3 nm/mm); or an Oriel model 7155 filter monochromator (range 400–700 nm) for weakly emitting compounds, with slit options of 1, 2, 4, and 6 mm (corresponding to 11–40 nm bandpass at 550 nm), were employed to measure the spectra. In this mode, analytes were repeatedly injected while the wavelength drive was manually advanced.

Continuous-doping mode

In this mode, spectra were obtained from the quarter-meter monochromator described above. Liquid analytes were vaporized in a doping vessel to present a constant, nitrogen-diluted stream to the ALD. For solid compounds, the analytes were placed into a capillary tube, which was then inserted into the GC injection port and heated to produce a constant stream of analyte. The luminescence from the analyte was scanned with the help of an automatic wavelength drive.

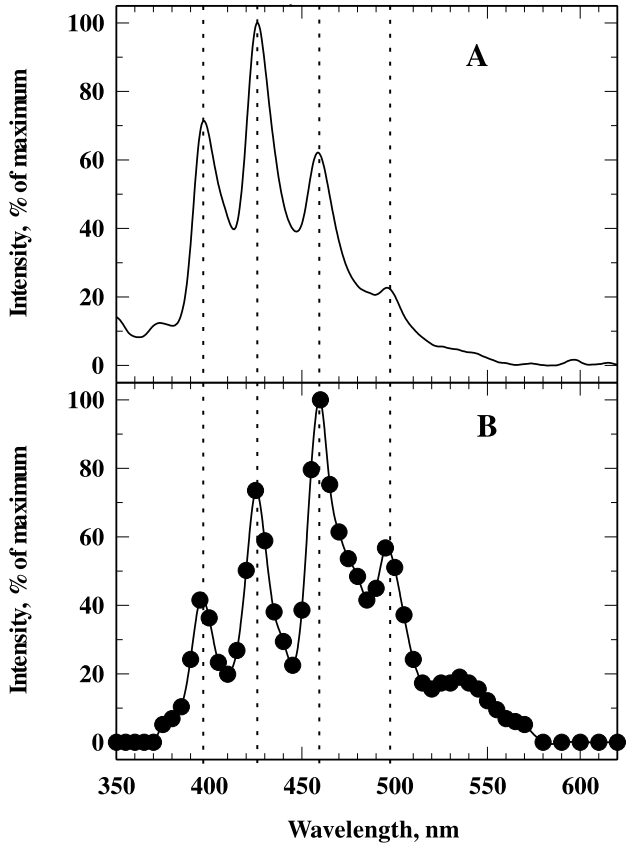
Fig. 3. Schematic of the triple-channel aroyl luminescence detector.

Single-peak mode



The triple-channel ALD and an Oriel model 77250 eighth-meter monochromator, *f*/3.7, with a no. 77298 grating (1200 lines/mm, 500 nm blaze) and 0.02–3.2 mm variable slits (reciprocal dispersion 6.4 nm/mm), were used in this mode. The single-peak scanning mode had been developed in our laboratory (6) for accurate spectral scans of GC peaks passing through a dual-channel FPD. An Oriel no. 77325 stepping motor, driven by a lab-built circuit with scan speeds from 0.25 to 315 nm/min, was used to record the spectra of luminescent GC peaks traversing the ALD. To correct for the analyte peak's first increasing and then decreasing concentration, the true intensity distribution of the spectrum was obtained by measuring the ratio of two channels. One was the dispersive spectral channel scanning through the desired wavelength region; the other a non-dispersive channel of constant wavelength (one of the response-ratio channels). The spectrum from the dispersive and the chromatogram from the non-dispersive channel were simultaneously recorded by a dual-channel program called CHROM 8 (7). The stored data were converted to an ASCII file and exported to a commercial program (SigmaPlot, Jandel Scientific, San Rafael, Calif.) for further manipulation.

The luminescence measurements were made by using one or more of three different recording modes. For strongly luminescing compounds such as benzaldehyde, the gas-phase spectrum was obtained with a Jarrell–Ash model 82-415 quarter-meter monochromator and (later) with an Oriel model 77250 eighth-meter monochromator (vide supra). The spectra from the two monochromators were equivalent, differing only in intensity distribution due to the distinctly different light transmission profiles of the two gratings (cf. Fig. 4). In most cases, the spectra reported are those obtained by the eighth-meter monochromator used in single-peak mode (i.e., by scanning a single chromatographic peak and employing dual-channel correction to account for the change in concentration profile during peak elution). For some weakly emitting compounds such as 1,4-naphthoquinone, a low-resolution device with a far higher light throughput, the Oriel "filter monochromator," was employed to map the spectra; and argon was added to the carrier gas to enhance aroyl luminescence.

For strongly luminescing compounds, a sample amount of 10 ng was typically required for injection into the triple-channel ALD system running in single-peak mode. However, spectra could still be measured from a peak of less than 10 ng, though with some loss in resolution (due to a wider slit and (or) a longer time constant). To secure as good a spectrum as possible from a single peak, samples corresponding in amount to the upper end of the linear calibration range were routinely introduced into the ALD. A background spectrum of pure nitrogen (the so-called second positive system) was always present at high amplification. To obtain spectra that accurately correlated spectral information with concentration, such a spectral background had to be subtracted from the raw spectrum as seen by the dispersive channel. While the "referenced" spectra of this study were corrected for the peak concentration profile and the nitrogen

Fig. 4. Gas-phase luminescence spectrum of benzaldehyde in excited nitrogen, as obtained from a 100 ng peak with the 1/8 meter grating monochromator (A); and by repeatedly injecting 100 ng benzaldehyde, with the 1/4 meter grating monochromator (B).

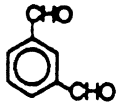
background, none were corrected for photomultiplier quantum yield, monochromator grating efficiency, or other instrumental parameters. Only the wavelength indicator on the monochromator was recalibrated from time to time with the help of a low-pressure mercury lamp. The slit width was usually set at 1 or 2 mm (about 6.6 and 13 nm bandpass, respectively), in accord with the innate spectral bandwidth.

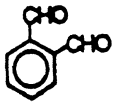
Results and discussion

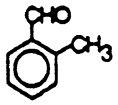
Selectivity

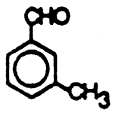
Very few types of organic compounds emitted light in the ALD. Only compounds containing an aroyl moiety in the form of an aromatic aldehyde, ketone, or quinone luminesced strongly. Most aromatic nitriles, esters, chlorides, alcohols, amines, and sulfides did not respond, even at the 1 µg level. Among aroyl-type compounds, particular ring substituents such as nitro-, amino-, and hydroxy- groups, as well as certain substituents in particular ring positions (mainly *ortho*), did severely depress or even eliminate luminescence. For these and other cases, a flame ionization detector (FID) was employed—in conjunction with temperature-programmed separation—to ensure that these organics did, in fact, properly elute from the GC column. Typical non-responding organic compounds are mentioned in Table 1, while Table 2 lists responding (and also some non-responding) aroyl compounds together with their relative luminescence intensities (vis-á-vis benzaldehyde), both according to structural similarity.

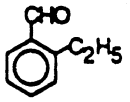
Table 1. Non-responding compounds in the ALD.

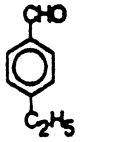


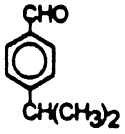


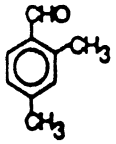


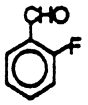


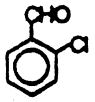


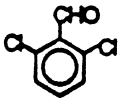


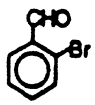


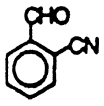


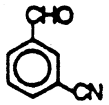


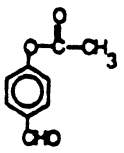


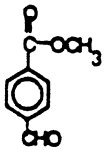


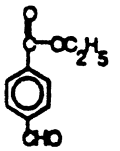


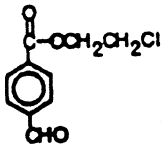


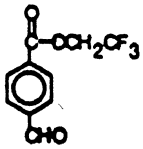


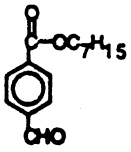


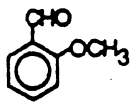


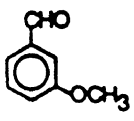


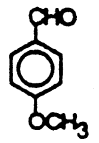


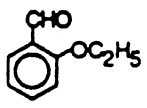


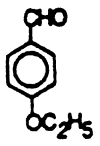


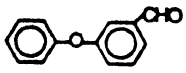












Aliphatic hydrocarbons	Fluoranthene
Aliphatic aldehydes	Pyrene
Aliphatic ketones	Benzo[*a*]pyrene
Aliphatic alcohols	2*H*-pyran-2-one
Aliphatic amines	Biacetyl
Aliphatic nitriles	Acetylacetone
Aliphatic sulfides	*p*-Benzoquinone
Aliphatic halides	Phenyl-1,4-benzoquinone
Aliphatic esters	Pyridazine
Aliphatic ethers	Pyrazine
Benzene	Pyrimidine
Nitrobenzene	Pyridine
1,3,5-Triethylbenzene	2,2′-Pyridil
Benzonitrile	Quinoxaline
Benzylether	Quinoline
Benzylchloride	Isoquinoline
Benzylalcohol	1-Benzosuberone
Benzylamine	Piperonal
Diphenylether	2-Phenyl-1,3-indandione
Diphenylsulfide	Benzalphthalide
Benzoylchloride	Furil
Phenylacetate	Benzil
Phenylacetaldehyde	Cumarin
Benzylacetate	Flavone
Phenylacetonitrile	3*H*-1,2-Benzodithiol-3-one
2-Phenylethylacetate	1,1′-Carbonyldiimidazole
Phenyl-2-propanone	3-Formylchromone
2-Phenylethylalcohol	3-Formyl-6-nitrochromone
3-Phenyl-1-propanol	2-Fluorene-carboxaldehyde
Naphthalene	Dibenzoylmethane
1-Methylnaphthalene	1-Benzoylacetone
Acenaphthene	*n*-Butyrophenone
Anthracene	Benzanthrone
Phenanthrene	Dibenzosuberenone

Spectra and interpretation

The photochemical behavior and photophysical properties of selected aromatic carbonyl compounds have been thoroughly studied both in condensed phases and in the gas phase. It is generally assumed that *unsubstituted* aromatic carbonyl compounds emit phosphorescence only, because the overall intersystem crossing $S_1 \rightarrow T_1$ is very efficient (8, 9). Some *substituted* aromatic carbonyl compounds also exhibit solely phosphorescence, while others display both phosphorescence and fluorescence (10). The triplet state gives rise to many photochemical reactions (11). The nature of the lowest excited state happens to be a subject of great interest. It is well established that T_1, the lowest excited triplet state of typical aromatic carbonyl compounds such as benzaldehyde or benzophenone, is $^3(n,\pi^*)$ both in non-polar solvents and in the gas phase. In contrast, T_1 of some substituted compounds that possess an electron-donating group at the para position is attributed to $^3(\pi,\pi^*)$ excitation (2, 12). The nature of the triplet state can be assigned to π,π^* or n,π^* based on several factors including (*i*) lifetime and polarization, (*ii*) electron

Table 2 (*concluded*).

spin resonance, (*iii*) triplet-singlet splitting, (*iv*) vibrational structure, and (*v*) the heavy-atom solvent effect on the $n\rightarrow\pi^*$ absorption. It is very common that emission spectra from an n,π^* state of aromatic carbonyls will contain the C=O vibrational structure. All these findings are based on experiments carried out by using photon or electron impact for excitation. In this study, as well as in studies involving the ALD's predecessor (5, 13–15), it was found that only certain aromatic carbonyl compounds luminesce in this radioactively stimulated, high-voltage, low-current nitrogen discharge; others do not. It is therefore of substantial interest to investigate the photophysical properties of those aroyls that do luminescence in excited nitrogen, and to establish their excitation mechanism.

Benzaldehydes

Benzaldehyde, the simplest of the carbonyl-containing molecules, has been spectroscopically and photochemically

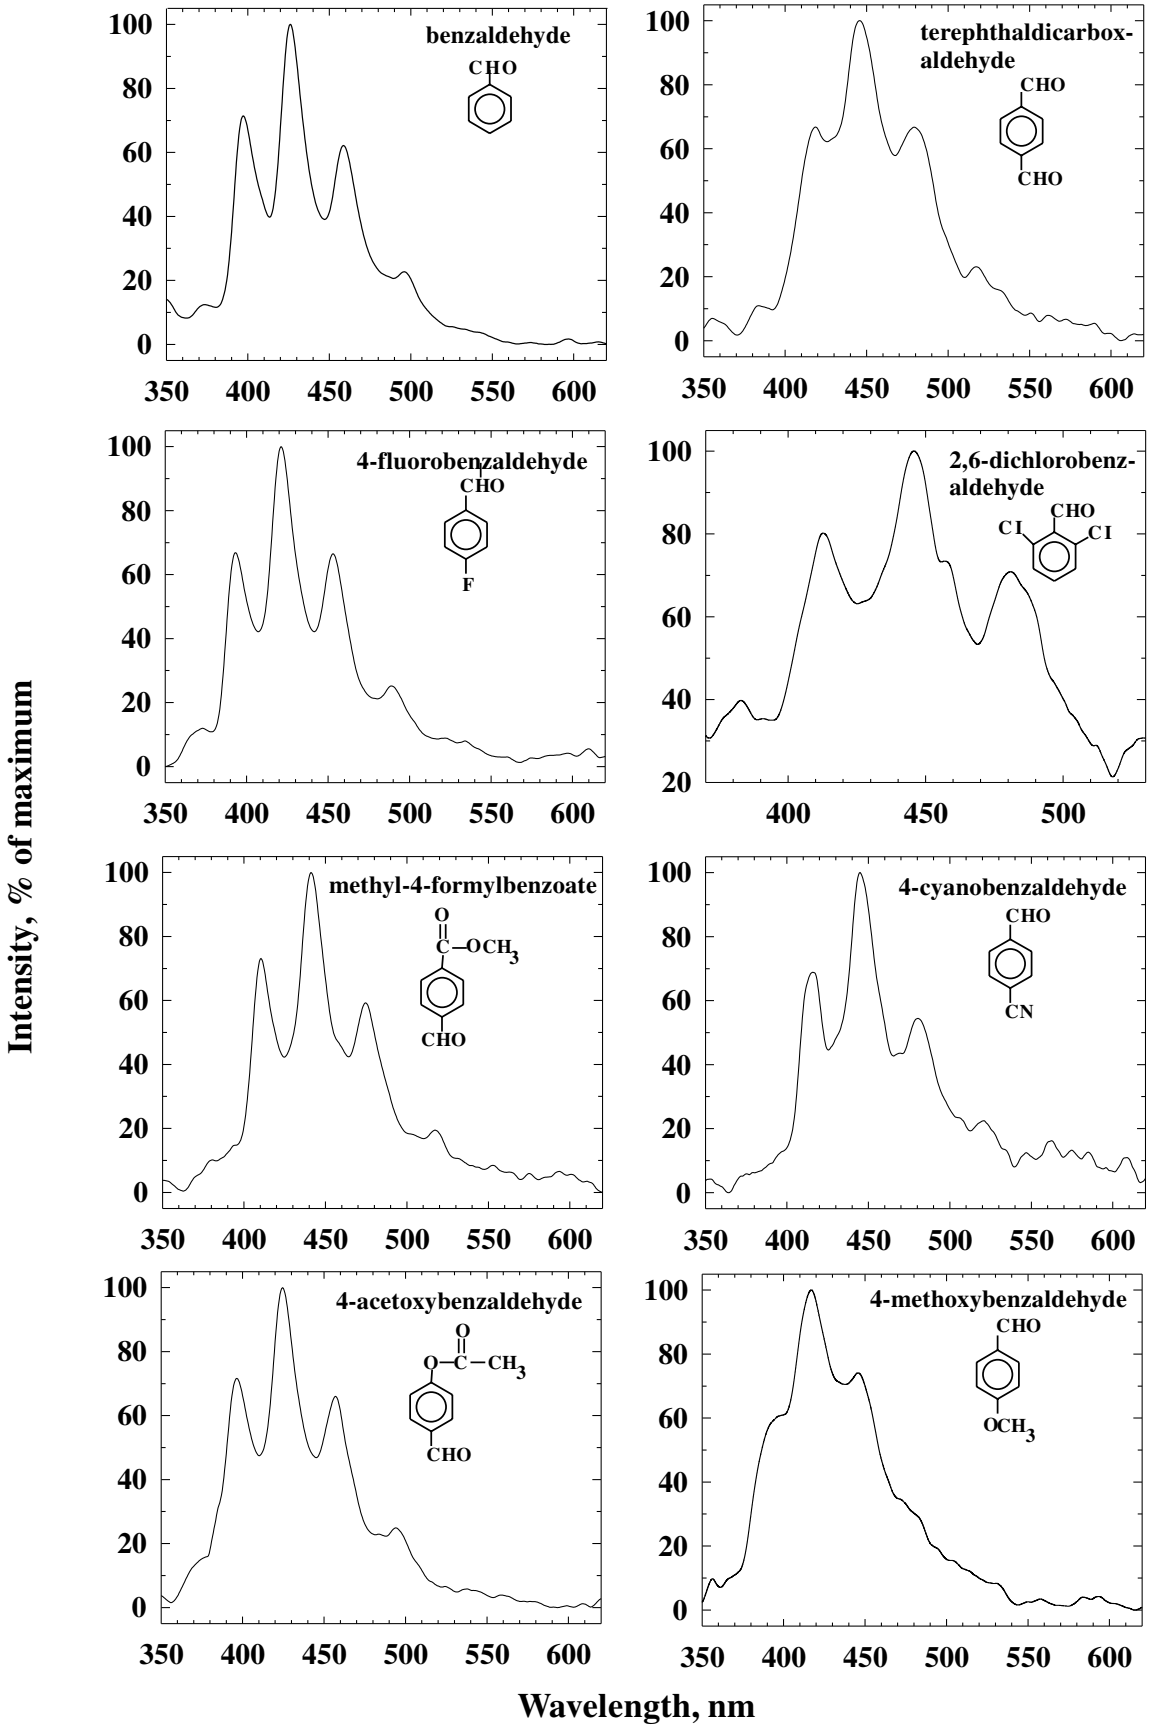
[a]The + and – signs indicate blue and red shifts, respectively. The correct number of significant digits is indicated by the wavelength data (nm).



well investigated (1, 16–19), and these studies have served as the basis for understanding more complex aromatic carbonyl spectra. As mentioned before, the unsubstituted carbonyl-containing molecules usually emit phosphorescence only (10). The phosphorescence of benzaldehyde can be induced by optical excitation (2, 17–20), electron impact (3) or active nitrogen (21) in the condensed (2, 17, 18) or the gas phase (3, 21–24). The spectrum obtained in this investigation exhibits prominent peaks at 397, 427, 460, and 498 nm. This spectrum resembles the phosphorescence spectrum of benzaldehyde measured in a rigid medium (2) or in the gas phase (3, 21–24). The bands obtained in this study at high temperature and ambient pressure are, not surprisingly, somewhat broader than the ones measured at room temperature and reduced pressure in the gas phase. The C=O stretching progression with a spacing of about 1730 cm^{-1} appears prominent in the gas-phase luminescence spectrum. Based on the literature and these observations, then, the present spectrum is clearly that of benzaldehyde phosphorescence. Prominent peaks at 397, 427, 460 and 498 nm were assigned to the 0–0 band and progressions in the C=O stretching mode. The phosphorescence of benzaldehyde originates from the $T_1(n,\pi^*) \rightarrow S_0$ transition. $T_1(n,\pi^*)$ at 397 nm (25 189 cm^{-1} or 3.12 eV or 301 kJ/mol) is the lowest triplet state in benzaldehyde (2, 10). This assignment agrees with the previously reported assignment (2, 3), and is useful in locating $T(n,\pi^*)$ triplet states in substituted benzaldehydes.

The gas-phase luminescence spectra of benzaldehyde and of a selected few substituted benzaldehydes are shown in Fig. 5. The spectroscopic data for all investigated benzaldehydes of adequate luminescence are given in Table 3. For space reasons, however, Fig. 5 was only permitted to include those spectra that deviate most from that of benzaldehyde itself, or that are of particular interest for structural or spectroscopic reasons. Most spectra are quite similar to that of unsubstituted benzaldehyde, except for the spectral shift caused by the substituent(s). All of these spectra exhibit the same vibrational progression characteristic of the C=O stretching frequency (about 1700 cm^{-1}), and all can therefore be assigned to a $T_1(n,\pi^*) \rightarrow S_0$ transition. The spectroscopic data are in agreement with vapor phase data where such are available (23), or close to data obtained in nonpolar solvents (20). Electron-*donating* groups at the para-position cause a blue shift of the $T_1(n,\pi^*) \rightarrow S_0$ transition, whereas electron-*withdrawing* groups at the para-position cause a red shift (except for 4-fluorobenzaldehyde). On the other hand, the transitions are red-shifted in meta-substituted benzaldehydes relative to those of benzaldehyde. It is interesting to note that, while 4-fluorobenzaldehyde exhibits a large blue shift relative to benzaldehyde, the 2- and 3-fluorobenzaldehydes show a red shift. Fluorine thus behaves here like an alkyl or alkoxy group. This observation agrees with previous reports (20, 25).

Figure 6 shows the gas-phase phosphorescence spectrum of benzaldehyde at different temperatures. Within error limits, there is no change in wavelength and little if any change in relative band intensity. This means that the spectroscopic nature of benzaldehyde luminescence does not change with temperature (i.e., that there is no evidence of thermal activation). The emission intensity of phosphorescence increased

slightly as temperature increased (possibly because of the lower gas density), and the vibrational structure of the phosphorescence spectrum became slightly more diffuse (temperature broadening). The latter agrees with photophysical studies of other aroyl compounds in the gas phase (26, 27), but disagrees with studies in rigid media (28, 29).

Acetophenones

Acetophenone is the simplest aromatic ketone and has long been the subject of spectroscopic and photophysical studies (2, 23, 29–33). However, ambiguity remains concerning the assignment of the lowest triplet state of acetophenone (and of substituted acetophenones) in various environments (32, 34). The gas-phase luminescence spectrum of acetophenone is shown in Fig. 7; it is very similar to the spectra of several substituted acetophenones that could not be included here because of space limitations, but whose spectroscopic data are presented in Table 4. Figure 8 adds the spectra of two of the structurally related acetylpyridines (Note: 4-acetylpyridine looks much like 2-acetylpyridine). A severe loss of resolution is observed in these spectra compared to those of the benzaldehydes, because the slow torsional vibrations of the methyl group result in spectral congestion (33). The spectrum of acetophenone measured in this study exhibits peaks at ca. 394, 420, and 450 nm, and it shows a prominent C=O stretching vibrational progression with a spacing of about 1600 cm^{-1}. This spectrum is very similar in shape to that of acetophenone phosphorescence obtained in a rigid medium (2), the gas phase (23), or on Whatman no. 1 filter paper (29). Thus we conclude that the present gas-phase luminescence spectrum is mainly if not exclusively the phosphorescence spectrum of acetophenone. The lowest triplet state of acetophenone in the gas phase is of normal n,π^* character, because it is well known that n,π^*-type phosphorescence spectra exhibit a clear progression of the carbonyl vibration (10). The luminescence spectra of the substituted acetophenones are also considered to be phosphorescence spectra owing to their similarity to that of acetophenone.

Fig. 7. Gas-phase luminescence spectrum of acetophenone. Single-peak mode, 1/8 meter grating monochromator with R-374 PMT. Bandpass: 6.6 nm.

The 0–0 transitions of acetophenones are blue-shifted by electron-donating, red-shifted by electron-withdrawing groups at the para-position. The direction of shift parallels that of the substituted benzaldehydes. This similarity reflects the similar nature of the triplet state, which is T(n,π^*) for both benzaldehydes and acetophenones.

Benzophenones

Benzophenone has been investigated extensively as a triplet energy donor (1, 35), and its luminescence in various me-

dia was thoroughly studied (1, 2, 4, 8, 23, 29, 36, 37). In early papers it was reported that benzophenone shows solely phosphorescence from a $T_1(n,\pi^*)$ state in a rigid matrix at 77 K (1, 2, 36, 37). Sun et al. (26) demonstrated that the luminescence of benzophenone in CCl_4 solutions consists mainly of delayed fluorescence and phosphorescence originating from thermally equilibrated S_1 and T_1 states. The observation of delayed benzophenone fluorescence in solution (38, 39) and in rigid media (40) was confirmed by other researchers. Gated nanosecond time-resolved laser spectroscopy proved well suited to studying such luminescent processes of low quantum efficiency and (or) several competing modes of emission (39). The luminescence of benzophenone in the *gas* phase was first reported by Borisevich and Gruzinskii (41). Based on the appreciable overlap of the absorption and emission spectra, and on the long decay time of the emission, these authors concluded that the luminescence is thermally-activated delayed fluorescence (41). Dorokhin and Kotov (42) investigated the effect of temperature on the delayed luminescence of benzophenone, and showed that, as the temperature rises, the fraction of thermally activated delayed fluorescence in the total emission increases, similar to what had been reported for benzophenone in the condensed phase (26, 40). Itoh et al. (23) interpreted the gas-phase emission spectrum of benzophenone as being composed mainly of phosphorescence, accompanied by very weak E-type delayed fluorescence at shorter wavelengths. Inoue (4) measured the emission spectrum of benzophenone induced by electron impact, and assigned the spectrum to benzophenone phosphorescence with the origin at 390 nm (25 641 cm^{-1}).

Figure 9 shows the gas-phase luminescence spectrum of benzophenone in excited nitrogen. The spectra of various substituted benzophenones, including the benzoylpyridines, look very similar; they could not be reproduced here for space reasons. The ALD spectrum of benzophenone is very similar in shape to those spectra of benzophenone that had been assigned to mainly E-type fluorescence and phosphorescence (23, 26, 39, 40), but differs from the pure phosphorescence spectrum of benzophenone in rigid media (1, 2, 36, 37). It seems therefore reasonable to conclude that the gas-phase luminescence of benzophenone consists mainly of E-type fluorescence and phosphorescence with origins at about 380 nm (26 316 cm^{-1}) and 420 nm (23 809 cm^{-1}), respectively. Owing to the similarity of the substituted-

benzophenone spectra we tentatively assume that these, too, originated from a combination of E-type delayed fluorescence and phosphorescence. The substitutents shift only slightly the 0–0 transition of phosphorescence, but the direction of shift again parallels shifts observed in substituted benzaldehydes and acetophenones. Again, this similarity reflects the similar nature of the lowest triplet state for these three types of aromatic carbonyl compounds.

Anthraquinones

Anthraquinone is another aroyl compound whose photophysical and photochemical behavior was extensively investigated (43–56). The compound (9,10-anthraquinone by its complete name) shows comparatively strong emission in the visible region in various rigid media (16, 43, 45). This emission has been identified as phosphorescence from the lowest triplet state of the n,π^* type, originating at about 455 nm (22 000 cm^{-1}) (45–47, 50, 52). It is also known that anthraquinone exhibits weak emission in the gas phase. The gas-phase emission was obtained by Singh and Singh (53) and later by Longin (54) by discharge excitation. The former authors regarded the luminescence in the 420–540 nm region as fluorescence and that in the 590–690 nm region as phosphorescence, while Longin assigned the emission to dual fluorescence with origins at 421.4 and 422.7 nm. Later Rogozhin and co-workers (55) obtained highly resolved emission spectra of anthraquinone vapor at relatively high temperature. To clarify the nature of gaseous anthraquinone luminescence, emission and excitation spectra were measured and compared with those in the condensed phases by Itoh (56). Although the spectra obtained under different conditions differed with respect to band resolution and shape, the author's interpretation was that the emission of anthraquinone vapor consisted of $S_1(n,\pi^*) \rightarrow S_0$ fluorescence and $T_1(n,\pi^*) \rightarrow S_0$ phosphorescence, with origins at about 422 nm (23 700 cm^{-1}) and 455 nm (22 000 cm^{-1}), respectively.

In the present study, anthraquinone vapor exhibited very strong luminescence in excited nitrogen. Figure 10 shows the gas-phase luminescence spectrum of anthraquinone, to which the spectra of some substituted anthraquinones — which could not be printed here for editorial reasons — are very similar. Some of their spectroscopic data are found in Table 5. The main bands of the anthraquinone spectrum occur at around 425, 452, 487, and 530 nm. This spectrum is quite different from the phosphorescence spectra of anthraquinone obtained in rigid media and at low temperature (44, 46, 50), but very similar in respect to band position and shape to spectra obtained by Longin (54) and Itoh (56) in the gas phase. Hence, we presume that the anthraquinone spectrum in excited nitrogen consists of $S_1(n,\pi^*) \rightarrow S_0$ E-type fluorescence and T_1 $(n,\pi^*) \rightarrow S_0$ phosphorescence with origins at about 425 nm (23 529 cm^{-1}) and 452 nm (22 124 cm^{-1}), respectively. The prominent peaks at 452, 487, and 530 nm are assigned to the 0–0 band and progressions of the C=O stretching mode. From the 0–0 band position, the singlet–triplet energy gap, $\Delta E_{S-T,}$ is found to be 1405 cm^{-1}.

The gas-phase luminescence spectra of substituted anthraquinones are essentially identical to the spectrum of anthraquinone itself; they all exhibit the principal vibrational structure of the carbonyl stretching frequency (1590–1660 cm^{-1}) and can therefore be regarded as consisting of $S_1 \rightarrow S_0$ E-type fluorescence and $T_1 \rightarrow S_0$ phosphorescence from a T_1 state of n,π^* character. It is noteworthy that no significant wavelength shift has been observed among the anthraquinones tested (see Table 5).

1,4,4a,9a-Tetrahydroanthraquinone	23419 (427)	22124 (452)
Benz[*g*]isoquinolon-5,10-dione	23474 (426)	22124 (452)

1,4-Naphthoquinone and its 2-methyl derivative

1,4-Naphthoquinone is one of the prototype quinones and several studies were reported of its photophysical properties. Kuboyama and Yabe (45) recorded the strong visible emission of 1,4-naphthoquinone in a rigid glass solution at 77 K. This emission has been assigned to an n,π^*-type phosphorescence from the lowest triplet state. In the gas phase, 1,4-naphthoquinone shows weak emission. The first gas-phase emission spectra of 1,4-naphthoquinone were obtained in the presence of flowing benzene vapor by Singh and Singh (57), and later by Longin (54) by discharge excitation. Singh and Singh assigned the emission to fluorescence and phosphorescence with origins at 21 945 cm^{-1} (455 nm) and 18 782 cm^{-1} (532 nm), respectively, while Longin thought that the gas-phase emission consisted of two kinds of fluorescence with origins at 22 163 cm^{-1} (451.2 nm) and 21 974 cm^{-1} (455.1 nm). The carbonyl compounds, having a small singlet-triplet energy gap, often exhibit weak E-type delayed fluorescence (35). Itoh and Baba (58) took this into account in their assignment of the emitting states of 1,4-naphthoquinone. They investigated the temperature dependence of both the luminescence spectrum and the lifetime in the presence of foreign gases, and showed that the emission consists of phosphorescence and delayed fluorescence from the lowest triplet and singlet states at 20 460 cm^{-1} (488.8 nm) and 21 830 cm^{-1} (458.1 nm), respectively. In addition to the phosphorescence and E-type delayed fluorescence at low pressure (10^{-3}–10^{-1} Torr)(1 Torr = 133.3 Pa), these authors also reported a prompt fluorescence (59). It is known that the often non-fluorescent nature of aromatic carbonyl compounds is caused by a fast transition from S_1 to T_1; hence their speculation that the prompt fluorescence could be due to isoenergetic intersystem crossing from the lowest triplet to the lowest singlet state under collision-free conditions. More recently, Itoh (27) reported that the gas-phase emission spectrum of 1,4-naphthoquinone consists of dual phosphorescence from $T_1(n,\pi^*)$ and $T_2(n,\pi^*)$ with origins at 20 295 cm^{-1} (488.4 nm) and 20 475 cm^{-1} (492.0 nm), respectively (in addition to the weak E-type delayed fluorescence). This clarified the doublet structures in the main emission bands of 1,4-naphthoquinone vapor.

The emission spectrum of 2-methyl-1,4-naphthoquinone vapor was reported by Baruah et al. (60), and later by Itoh and Baba (58). The former authors interpreted the emission as consisting of fluorescence from an $S_1(n,\pi^*)$ state and phosphorescence from a $T_1(n,\pi^*)$ state, with origins at 22 075 cm^{-1} (453.0 nm) and 20 262 cm^{-1} (493.5 nm), respectively. The latter authors regarded the spectrum as consisting of $T_1(n,\pi^*) \rightarrow S_0$ phosphorescence and weak E-type delayed fluorescence from $S_1(n,\pi^*)$ with origins at 20 340 cm^{-1} (491.6 nm) and 21 950 cm^{-1} (455.6 nm), respectively.

Figure 11 shows the weak gas-phase luminescence spectra of 1,4-naphthoquinone and 2-methyl-1,4-naphthoquinone in excited nitrogen. The spectra lie entirely within the visible region (i.e., no emission below 400 nm). They consist of broad and diffuse bands located at about 450, 485, 525, and 575 nm for 1,4-naphthoquinone; and 455, 490, 530, and 580 nm for 2-methyl-1,4-naphthoquinone. These bands form a prominent C=O stretching progression. They resemble the corresponding gas-phase emission spectra obtained by Itoh (27) and Itoh and Baba (58, 59), and they also agree in band position with the spectra recorded in refs. 54, 57, and 60. We therefore consider the gas-phase luminescence spectra of 1,4-naphthoquinone and 2-methyl-1,4-naphthoquinone to consist of phosphorescence from $T_1(n,\pi^*)$ and E-type delayed fluorescence from $S_1(n,\pi^*)$, with origins at 22 222 cm^{-1} (450 nm) and 20 619 cm^{-1} (485 nm) for 1,4-naphthoquinone; and 21 978 cm^{-1} (455 nm) and 20 408 cm^{-1} (490 nm) for 2-methyl-1,4-naphthoquinone, respectively.

Xanthone and thioxanthone

Xanthone is one of a number of carbonyl compounds that exhibit anomalous emission behavior. Pownall and Huber (61) reported that the emission spectrum of xanthone in 3-methylpentane at 77 K is due to phosphorescence from a triplet n,π^* state with origin at 25 905 cm^{-1} (386 nm) and that it shows four fundamental vibrations with frequencies of 260, 530, 930 and 1665 cm^{-1}, while the polar-solvent phosphorescence originates from a triplet π,π^* state. Later, based on a study of xanthone emissions at about 2 and 77 K, Pownall et al. (62) concluded that xanthone exhibits "dual" phosphorescence at 77 K in a 3-methylpentane glass matrix, owing to emission from two triplet n,π^* states with origins at 25 905 cm^{-1} (386 nm) and 25 650 cm^{-1} (389 nm). They also reported the phosphorescence spectrum to be very sensitive to temperature. This phenomenon was confirmed by Terada and co-workers in a polyethylene matrix (63). However, the latter authors identified the lowest triplet state as π, π^*, which is in agreement with emissions from the crystal and from a diphenylmethane matrix at 1.5 K (64). Kanda and co-workers (65) reported that xanthone shows phosphorescence consisting of mainly three emission systems, whose origins are located at 25,751 cm^{-1} (389 nm), 25 766 cm^{-1} (388 nm) and 25 774 cm^{-1} (387 nm). They also gave a quantitative explanation for the origin of such multiple phosphorescence levels (66).

All these photophysical studies of xanthone were made in rigid media or crystals, with no reports available from the

gas phase. In our study, xanthone luminesced strongly in excited nitrogen and turned out to be the strongest emitter among the sixty-odd compounds investigated. Figure 12 shows the gas-phase luminescence spectra of xanthone and thioxanthene-9-one in excited nitrogen. The emission of xanthone exhibits little structure and shows a maximum at about 24 154 cm^{-1} (414 nm) with two shoulders at about 25 773 cm^{-1} (388 nm) and 22 573 cm^{-1} (443 nm). These are also the main peaks in the phosphorescence spectrum of xanthone in 3-methylpentane at 77 K (61). It is therefore reasonable to conclude that the gas-phase luminescence of xanthone in excited nitrogen is due to phosphorescence from a $T_1(n,\pi^*)$ state, with the 0,0 band at about 25 773 cm^{-1} (388 nm). The bands at 24 154 cm^{-1} (414 nm) and 22 573 cm^{-1} (443 nm) are then the progressions of the C=O stretching mode. However, a more detailed analysis of vibrational structure cannot be made at this time due to spectrum congestion.

Thioxanthene-9-one also shows strong emission in excited nitrogen. Its gas-phase spectrum, but for the change in relative band intensity, resembles that of xanthone. (The agreement of wavelengths has been verified by making use of the "repeated-injection" mode — see Experimental — but the spectra are not shown here for space reasons.) Given this similarity, we suggest that the gas-phase emission spectrum of thioxanthene-9-one is caused by phosphorescence from a triplet n,π^* state with origin at about 26 316 cm^{-1} (380 nm). The 0–0 band is the strongest in the phosphorescence spec-

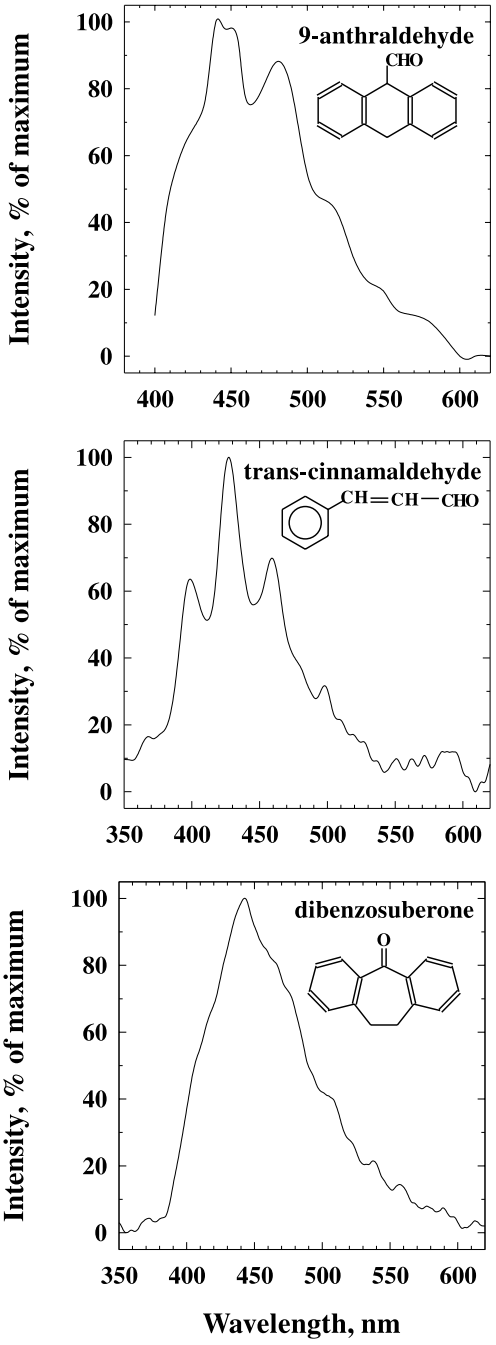
trum of thioxanthene-9-one. This is in striking contrast to the case of xanthone, whose main radiative mechanism is possibly vibronic. This result differs substantially from the few condensed-phase emission data available on thioxanthene-9-one (67).

α-*Tetralone*

The phosphorescence behavior of this type of aromatic ketone is rather complex. Dual and even triple phosphorescence has been reported (65, 68–70). Several emission studies of α-tetralone have been done in rigid media (37, 69–71) or in a single durene crystal (72). It was reported that α-tetralone shows phosphorescence from a triplet n,π^* state with origin at about 25 450 cm^{-1} (393 nm) (37, 69–72). Kanda et al. (69) concluded that — unlike 1-indanone, which exhibits dual phosphorescence from a short-lived (1.5–2 ms) triplet n,π^* state and a long-lived (0.15–0.22 s) triplet state with mixed n,π^* and π,π^* character due to the reversible photochemical formation of the enolate anion — α-tetralone does not emit dual phosphorescence in accord with its lower acidity. This was, however, disputed by Chu and Kearns (70), who did manage to observe dual phosphorescence. They attributed the short-lived emission of α-tetralone to a $T_1(n,\pi^*)$ state, but considered the long-lived emission due to a mixture of photoreduction products. Their "authentic" phosphorescence spectrum of α-tetralone from the triplet n,π^* state contained three main peaks at about 25 253 cm^{-1} (396 nm) 23 641 cm^{-1} (423 nm) and 21 882 cm^{-1} (457 nm).

The emission spectrum of α-tetralone in the gas phase had not been reported before. Our spectrum (Fig. 13) was obtained in excited nitrogen to which argon had been added. (Note: the addition of argon was used in this study to boost the emission intensity of some rather weakly luminescing aroyl compounds such as α-tetralone, 9-anthraldehyde, and dibenzosuberone. Before using this technique for the acquisition of weak spectra, however, argon doping was thoroughly tested on such compounds as benzaldehyde and anthraquinone to ensure the absence of any change in wavelength and relative band intensity for both the aroyl analyte and the second-positive system of nitrogen. The *first*-positive system of nitrogen begins to show up under argon doping; however, this emission is extremely faint and does not compromise the spectral results.) The spectrum of α-tetralone shows little structure, with a maximum at 23 529 cm^{-1} (425 nm) and two shoulders at about 25 125 cm^{-1} (398 nm) and 21 925 cm^{-1} (456 nm). This spectrum is very similar in band position and relative intensity to the phosphorescence spectrum reported of α-tetralone in rigid media (37, 69, 70). We therefore tentatively assign the gas-phase luminescence spectrum of α-tetralone to phosphorescence from a $T_1(n,\pi^*)$ state with origin at about 25 125 cm^{-1} (398 nm). (Note that the undulations in Fig. 13 at $\lambda > 520$ nm are acquisition noise caused by the necessary high amplification.)



Anthrone

The photophysical and photochemical behavior of carbonyl compounds has been the subject of numerous studies, but among these anthrone received only very limited attention. It was reported that, in rigid media, anthrone exhibits phosphorescence from an n,π^* state with origin at 25 150 cm^{-1} (397.6 nm) (1, 37, 73). The other prominent peaks occur at about 23 331 cm^{-1} (430 nm), 21 739 cm^{-1} (460 nm), 20 202 cm^{-1} (495 nm), and 18 691 cm^{-1} (535 nm), and exhibit the pattern expected of aromatic C=O vibration (37).

Figure 13 shows the gas-phase luminescence spectrum of anthrone in excited nitrogen. It differs greatly from the pure phosphorescence spectrum of anthrone in rigid media (37), but is very similar in spectral shape and band position to the gas-phase luminescence spectrum of benzophenone in excited nitrogen, which was assigned to a mixture of E-type delayed fluorescence and phosphorescence. Given this similarity and the structural analogy between anthrone and benzophenone, the same assignment may be made for anthrone.

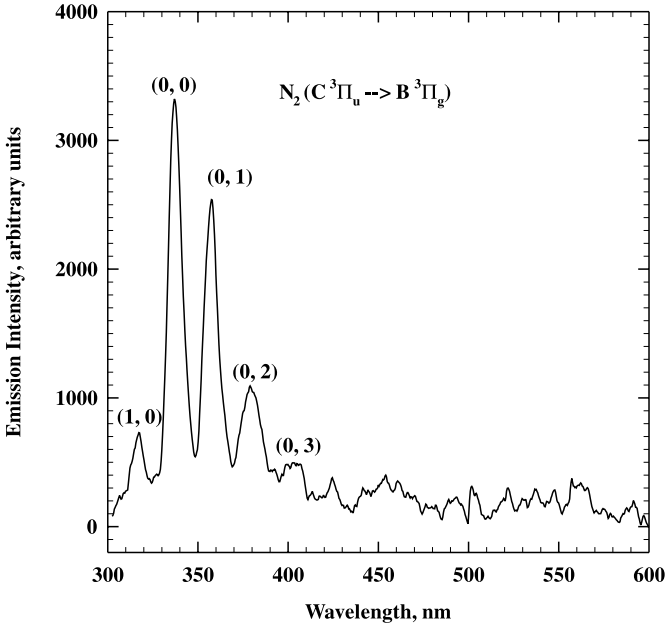
A similar comparison in regard to their photochemical behavior was made by Scaiano and Lee (74).

9-Anthraldehyde

Yang (75) reasoned, by analogy, that the triplet state of 9-anthraldehyde lies at the low value of 14 800 cm^{-1} (676 nm) and is π,π^* in nature. Warwick and Wells (76) confirmed the lowest π,π^* triplet state in 9-anthraldehyde by the oxygen perturbation technique. Hirayama (77) carried out kinetic studies relevant to the excited singlet and triplet states on eighteen anthracene-based carbonyl compounds in EPA at 77 K. He concluded that the 0–0 fluorescence band lies at 21 598 cm^{-1} (463 nm); and that the phosphorescence, which occurs from a triplet π,π^* state with origin at 13 790 cm^{-1} (725 nm), is very similar to that of anthracene in spectral shape and T_1 energy.

In excited nitrogen, 9-anthraldehyde shows relatively weak emission. The gas-phase luminescence spectrum of 9-anthraldehyde (Fig. 14) has two main peaks at 22 471 cm^{-1} (445 nm) and 20 833 cm^{-1} (480 nm), with two shoulders at about 24 096 cm^{-1} (415 nm) and 19 230 cm^{-1} (520 nm). This spectrum is very similar to the fluorescence spectrum in rigid media, both in spectral shape and band position. If the phosphorescence of 9-anthraldehyde occurred in the long-wavelength region (650–850 nm), we would not have observed it due to the limited wavelength range (400–700 nm) of the filter monochromator (which had to be used for this very weak emission).



trans-*Cinnamaldehyde and dibenzosuberone*

To the best of our knowledge, the photophysical behaviors of *trans*-cinnamaldehyde and dibenzosuberone have not been investigated either in solution or in the gas phase. This is not surprising: dibenzosuberone is a rather obscure molecule, and the carbonyl group of the much more prominent *trans*-cinnamaldehyde does not adjoin the aromatic ring. (Thus considered, *trans*-cinnamaldehyde is an "aroyl" only by conjugation, not definition.) In this study, both compounds emitted weakly in excited nitrogen. The spectra of *trans*-cinnamaldehyde and dibenzosuberone are shown in Fig. 14. *trans*-Cinnamaldehyde emits a gas-phase spectrum similar to that of benzaldehyde, except for a slight red shift. The spectrum displays prominent peaks at about 25 063 cm^{-1} (399 nm), 23 366 cm^{-1} (428 nm), 21 739 cm^{-1} (460 nm), and 20 040 cm^{-1} (499 nm), and it shows a typical aromatic C=O vibrational spacing of 1674 cm^{-1}. We regard the present spectrum therefore to be that of *trans*-cinnamaldehyde phosphorescence from a $T_1(n,\pi^*)$ state. This means that the C=C group, which establishes conjugation between the carbonyl group and the benzene ring, does not appreciably alter the nature of the excited state as compared to that of benzaldehyde. However, it does lower the energy of the excited triplet state because of the conjugative effect (10). (Again, the spectral undulations above ca. 500 nm are random instrumental noise and should be disregarded.)

The gas-phase luminescence spectrum of dibenzosuberone exhibits a broad band with a maximum at about 22 573 cm^{-1} (443 nm); closest, perhaps, to that of anthrone. There is no literature available concerning the luminescence spectrum of dibenzosuberone. Since the luminescing compounds investigated in this study are all excited to the triplet state and emit mainly phosphorescence, we tentatively regard the gas-phase luminescence spectrum shown as that of dibenzosuberone phosphorescence. Also, since all compounds that gave note-

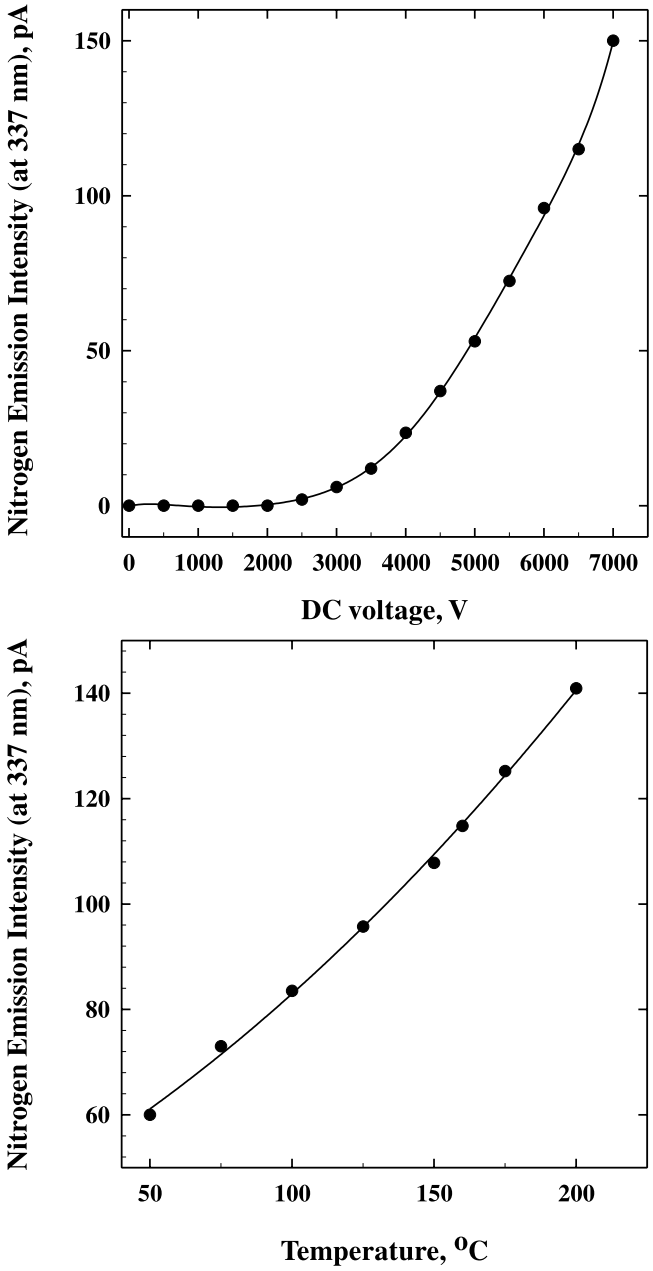
Fig. 15. Nitrogen background spectrum (second positive system) in the ALD.

worthy response in the ALD did so via n→π* (as opposed to π→π*) excitation, we presume dibenzosuberone to emit from a $T_1(n,\pi^*)$ state.



A speculative mechanism for luminescence of aroyl compounds in excited nitrogen

Background Luminescence in the ALD

Figure 15 shows the spectral background, i.e., the nitrogen luminescence of the ALD. The emission was scanned between 200 and 800 nm under various experimental conditions, and consisted solely of the well-known nitrogen "second positive" band system. This system results from the radiative decay of triplet-state nitrogen molecules, $N_2(C\ ^3\Pi_u) \rightarrow N_2(B\ ^3\Pi_g)$, and is seen in the 300–400 nm range, with the most intense band centered at 337.1 nm. It is very weak in the ALD**,** barely visible to the dark-adapted eye and instrumentally undetectable at the sensitivity setting used to record typically strong luminescence spectra. (However, when acquiring weaker spectra, the nitrogen background had to be subtracted, see Experimental.) The ALD differs markedly in this respect from the dielectric discharge system, in which a blue, flame-like nitrogen second-positive emission can be observed even under full room lights (78, 79). Figure 16 shows the intensity of the second-positive system's 0,0 band at 337.1 nm increasing with voltage and temperature. The nitrogen emission intensity was also measured as a function of pressure. As shown in Fig. 17, and as expected, the emission intensity of the nitrogen second-positive system increased as the pressure was lowered (even though the DC voltage had to be lowered simultaneously to avoid sparking).

The ALD is a radioactively stimulated, high-voltage, low-current (<35 nA) discharge. Thus, as expected, increasing its voltage did exponentially increase both its optical emission and its electrical current (5). (The current plots have been omitted to conserve space.) No other nitrogen emission could

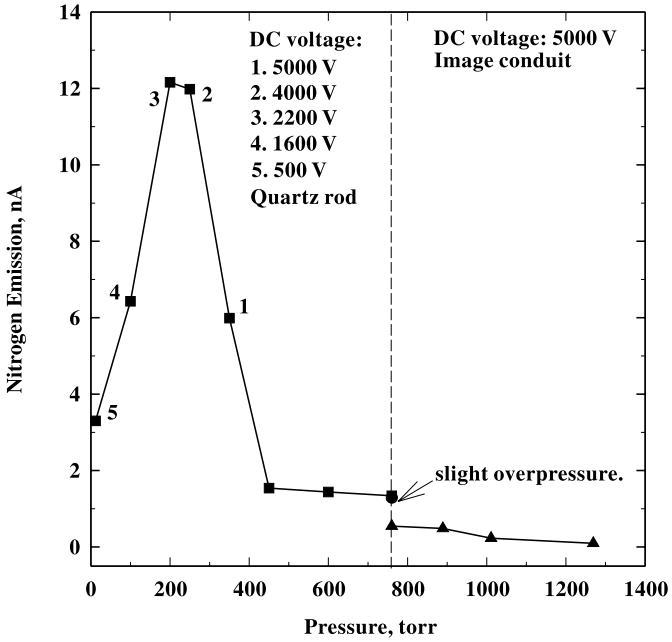


Fig. 16. Nitrogen second-positive emission at 337 nm as a function of applied DC voltage (top) and temperature (bottom).

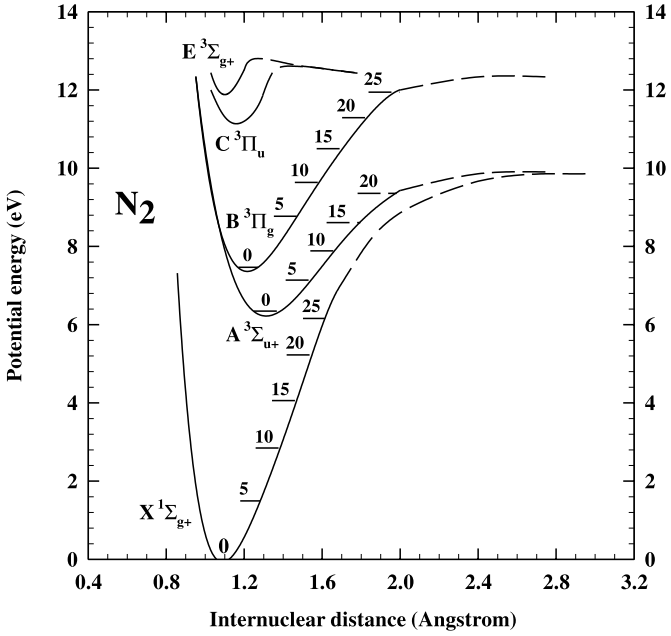
be detected in the ALD system beside the nitrogen second-positive system, although a careful search for the possible nitrogen first-positive system, $N_2(B\ ^3\Pi_g) \rightarrow N_2(A\ ^3\Sigma_u^+)$, and the Vegard–Kaplan system, $N_2(A\ ^3\Sigma_u^+) \rightarrow N_2(X\ ^1\Sigma_g^+)$, was carried out. (Note: extremely faint traces of the nitrogen first-positive system do, however, show up when nitrogen is doped with argon.) Apparently, in pure nitrogen, the second-positive transition is able to generate only those low vibrational levels of the B state ($v < 6$) from which no visible emission is observed in the $N_2(B\ ^3\Pi_g) \rightarrow N_2(A\ ^3\Sigma_u^+)$ transition (80). The absence of the Vegard–Kaplan band system, $N_2(A\ ^3\Sigma_u^+) \rightarrow N_2(X\ ^1\Sigma_g^+)$, may be due to some rapid reactions of the $N_2(A\ ^3\Sigma_u^+)$ state, or to its meager overall yield in the ALD (cf. 78, 81).

© 2000 NRC Canada

Fig. 17. Nitrogen background emission in the ALD as a function of pressure. Note: Voltage settings at subambient pressure conditions are selected close to sparking. The quartz rod, used for the vacuum experiments, transmits more light at 337 nm than the image conduit.



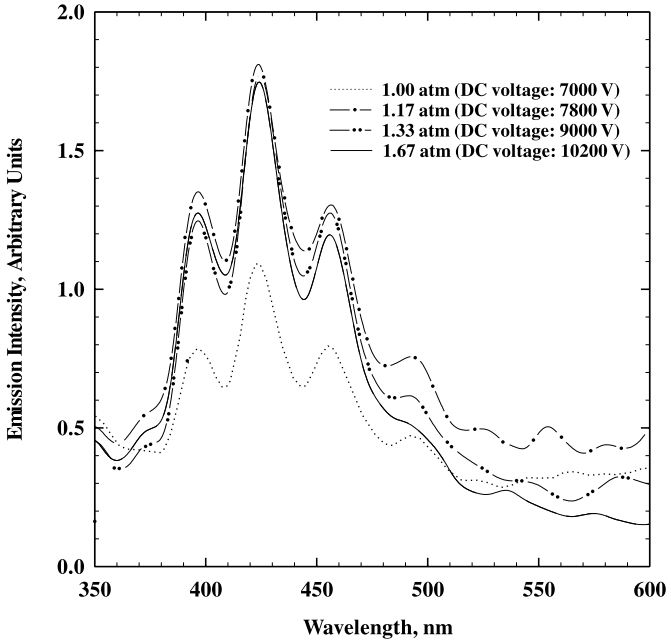
A partial energy-level diagram of dinitrogen and some of its excited states is shown in Fig. 18 for the reader's convenience. The first triplet state, metastable $N_2(A\ ^3\Sigma_u^+)$, with a long radiative lifetime ($\tau \leq 3.5$ s at low pressure) (82) and (at $v = 0$) 6.17 eV (594.9 kJ/mol) of energy above the $N_2(X\ ^1\Sigma_g^+)$ ground-state, can be obtained from electron exchange (83). The short-lived $N_2(B\ ^3\Pi_g)$ triplet state (τ ~10 ns) at 7.35 eV (708.7 kJ/mol) may also be excited from the singlet ground-state by electron exchange (83). The energetic $N_2(C\ ^3\Pi_u)$ state, with a radiative lifetime of 0.1 ms to 10 ns and 11.03 eV (1063.5 kJ/mol) of energy, may be populated by electron impact or triplet-triplet annihilation of $N_2(A\ ^3\Sigma_u^+)$ (84):

$$N_2(A\ ^3\Sigma_u^+) + N_2(A\ ^3\Sigma_u^+) \rightarrow N_2(X\ ^1\Sigma_g^+) + N_2(C\ ^3\Pi_u)$$

It has been observed under circumstances otherwise similar to those of the ALD, that (much weaker) luminescence of aroyl compounds can be observed even in the *absence* of an electric field (5), with the required energy being supplied by the beta rays emanating from the Ni-63 foil. Thus it is reasonable to assume that it is an excited state of nitrogen — as produced in the weak discharge of the ALD — that is causing aroyl excitation. This agrees with the fact that, on a relative basis, aroyl emission intensities are much stronger in the ALD than in the classical vacuum systems of the literature and that, furthermore, no other carrier (pure He, Ar, CO, and a host of other test gases) produced any aroyl emission in the ALD. Also, all excited aroyl states so far found to luminesce were of the $n \rightarrow \pi^*$ (as opposed to the $\pi \rightarrow \pi^*$) type. In the energy-transferring collision between triplet dinitrogen and singlet aroyl molecules, a preference for the larger and easier accessible *n* orbitals of carbonyl oxygen could be expected. While this "steric" explanation is clearly speculative,

Fig. 18. Partial energy-level diagram of N_2, showing species considered relevant to this study.

it would neatly serve to rationalize the conspicuous absence of $\pi \rightarrow \pi^*$ excitation in the ALD. That leaves the question which excited nitrogen species is(are) the source for aroyl emission, and what is the excitation process.



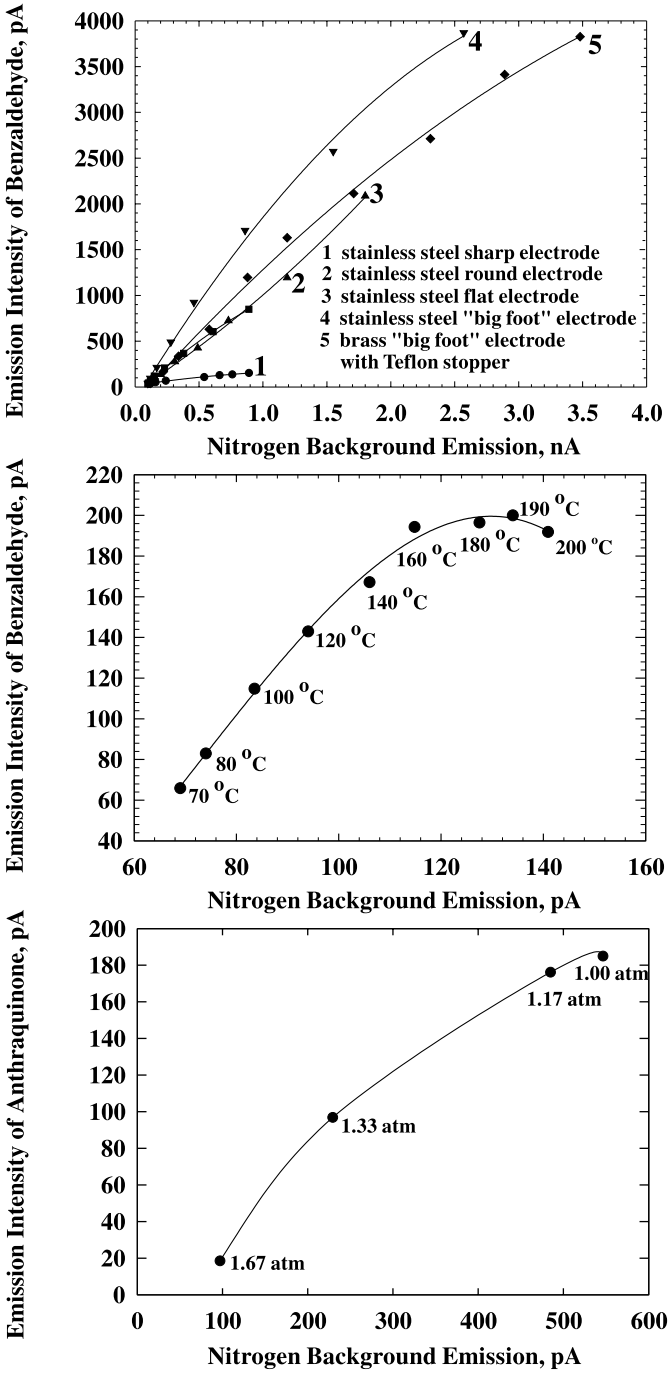
Energy transfer at atmospheric pressure

Generally, phosphorescence originates from excited molecules in their lowest triplet state and is distinguished by a long lifetime (10^{-4}–10 s). Therefore, collisional transfer of energy to molecules of the host gas, or to impurity molecules, is highly probable. At one atmosphere pressure, a molecule experiences close to 10^{10} collisions per second. As a consequence, metastable molecules typically lose their energy by collision before they have a chance to phosphoresce. In literature experiments, gas pressures much lower than ambient are therefore chosen to reduce the collision frequency and hence the collisional quenching of the desired phosphorescence.

In this study, aroyl compounds exhibit intense phosphorescence in the gas phase at atmospheric or even higher pressure. Figure 19 shows the effect of pressure on the relative intensity of gaseous benzaldehyde phosphorescence, as measured under conditions of *constant* nitrogen background emission. (Note: the nitrogen background emission is taken here as a comparative and convenient measure of the "strength" or optical emissivity of the excitation source under a particular set of conditions; it is therefore being held at the same value by correspondingly varying the DC voltage). Figure 19 clearly shows that, under thus "normalized" conditions, the emission intensity of benzaldehyde even increases slightly with increasing pressure. However, there is almost no effect of this pressure increase on spectral resolution. These observations can be rationalized in terms of the collisional excitation of benzaldehyde, with transfer of energy occurring from an excited state of nitrogen. High-purity nitrogen thus acts as both collision and excitation gas in the

© 2000 NRC Canada

Fig. 19. Pressure effect on the relative intensity of benzaldehyde gas-phase phosphorescence.



ALD (while the addition of any other molecular gas but induces quenching).

A speculative mechanism

The obvious question then becomes which nitrogen species is likely serving as the carrier of aroyl excitation energy. The weak background emission of the pure-nitrogen ALD originated solely from the so-called second positive system, $N_2(C\ ^3\Pi_u) \rightarrow N_2(B\ ^3\Pi_g)$. Therefore, the correlation between the nitrogen second-positive emission and the aroyl luminescence was checked by varying the applied DC voltage (from 0 to 7000 V), temperature (from 70 to 200 °C), and pressure (from 1.00 to 1.67 atm). The results are shown in Fig. 20 for either benzaldehyde or anthraquinone as test compound. By virtue of curvature, the data fail to implicate the C state, $N_2(C\ ^3\Pi_u)$, as being responsible for the collisional energy transfer to aroyl compounds (although they do not completely exclude it, either). In addition, the shorter (vacuum) lifetimes of $N_2(C)$ (0.1 ms–10 ns) and $N_2(B)$ (~10 ns) indicate that their concentrations may be small — a point reinforced by the (very weak) spectral background — and hence it is doubtful that $N_2(C)$ and (or) $N_2(B)$ would contribute significantly to aroyl excitation. The ALD, in contrast to other excitation sources, is a very "mild" discharge ($I \leq 35$ nA!). Furthermore, $N_2(A\ ^3\Sigma_u^+)$ has a much longer lifetime (≤3.5 s in high vacuum) and a greater stability toward deactivating collisions (83). Plus, its lower energy fits much better the excitation potential of typical aroyl compounds. $N_2(A)$ can therefore be speculatively considered to be the most likely carrier of excitation energy for aroyl luminescence in the ALD system.

In the literature, either metastable triplet state molecules, $N_2(A\ ^3\Sigma_u^+)$, or vibrationally excited ground-state molecules, $N_2(X\ ^1\Sigma_g^+)$, are believed to have served as principal energy carriers for *atomic* excitation in the nitrogen afterglow produced by electric discharges (78, 79). The technique of obtaining a relatively pure supply of $N_2(A\ ^3\Sigma_u^+)$ — with a minimum number of nitrogen atoms — by the reaction $Ar^*(^3P_{0,2}) + N_2 \rightarrow N_2(C)^* \rightarrow N_2(B)^* + h\nu \rightarrow N_2(A)^* + h\nu$ has been reported by Stedman, Setser and co-workers (82, 84, 85); and $N_2(A\ ^3\Sigma_u^+)$ generated by this source has been used as an efficient energy-transfer agent. Devolder et al.

Fig. 20. Emission intensity of aroyl compound versus nitrogen background for (top) DC voltage varied from 0 to 7000 V; (middle) temperature varied from 70 to 200°C; and (bottom) pressure varied from 1.00 to 1.67 atm. Note: different types of electrodes (91) are shown on top for general information; however, all other experiments of this study were carried out with electrode no. 5.

(21, 86, 87) observed phosphorescence of aromatic carbonyl compounds (but also of hydrocarbons!) in their reaction with active nitrogen, which was produced in a microwave discharge at low pressure. The excitation mechanism they proposed also involved the metastable $N_2(A\ ^3\Sigma_u^+)$ state.

Generally, high-energy discharges such as microwave sources produce large amounts of nitrogen atoms, which then rapidly recombine to form metastable $N_2(A\ ^3\Sigma_u^+)$. Electric discharges with a discharge current of about 11.2 mA produce very few nitrogen atoms (78). Instead, the $N_2(A\ ^3\Sigma_u^+)$ state is populated via initial excitation of nitrogen to the $N_2(C\ ^3\Pi_u)$ state. The formation of $N_2(A\ ^3\Sigma_u^+)$ is then believed to result from the following two steps, which are responsible for the appearance of the second positive and the first positive spectrum, respectively:

[1] $N_2(C\ ^3\Pi_u) \rightarrow N_2(B\ ^3\Pi_g)$ (second positive system)

[2] $N_2(B\ ^3\Pi_g) \rightarrow N_2(A\ ^3\Sigma_u^+)$ (first positive system)

In this study, a very mild, low-energy discharge with a discharge current of ≤35 nA — several orders of magnitude lower than the current mentioned in reference (78) — is used as the excitation source for nitrogen. We believe that ground-state N_2 is excited directly to the lowest triplet $N_2(A\ ^3\Sigma_u^+)$ state by collision with fast "secondary" electrons. These secondary electrons are produced by the β-induced ionization of N_2 (as well as by subsequent electron multiplication processes) and acquire their energy mainly from the electric field. (Note: electrons created directly by β-ray impact are, in fact, epithermal; however, they are slowed down quickly by collisions with nitrogen molecules.) Thus metastable $N_2(A\ ^3\Sigma_u^+)$ is assumed responsible for the excitation of aroyl molecules by an efficient triplet-triplet energy transfer process. $N_2(A\ ^3\Sigma_u^+)$ is also considered responsible for producing $N_2(C\ ^3\Pi_u)$ by an energy-pooling process (84), which is followed by the weak emission of the second positive system. In this manner, aroyl and background luminescence in excited nitrogen can be accounted for on the basis of the following mechanistic sequences:

1. Nitrogen is ionized (and occasionally excited) by β-particles from the ^{63}Ni source. Thus, $10^{\ 2}$–$10^{\ 3}$ secondary electrons are produced per β ray:

[3] $\beta + N_2(X\ ^1\Sigma_g^+) \rightarrow \beta' + N_2^+(X\ ^2\Sigma_g^+) + e^-$ (secondary electron)

[4] $\beta + N_2(X\ ^1\Sigma_g^+) \rightarrow \beta' + N_2(C\ ^3\Pi_u)$ (83) (minor process)

2. Singlet ground-state nitrogen is excited by secondary electrons (accelerated by ≤1750 V/mm) to produce $N_2(A\ ^3\Sigma_u^+)$:

[5] $N_2(X\ ^1\Sigma_g^+) + e^-$ (fast) $\rightarrow N_2(A\ ^3\Sigma_u^+) + e^-$ (slow)

3. This is followed by triplet–triplet energy transfer from $N_2(A\ ^3\Sigma_u^+)$ to an aroyl molecule (A):

[6] $N_2(A\ ^3\Sigma_u^+) + A(^1S_0) \rightarrow N_2(X\ ^1\Sigma_g^+) + A(^3T_1)$

and accompanied by some energy pooling of $N_2(A\ ^3\Sigma_u^+)$:

[7] $N_2(A\ ^3\Sigma_u^+) + N_2(A\ ^3\Sigma_u^+) \rightarrow N_2(X\ ^1\Sigma_g^+) + N_2(C\ ^3\Pi_u)$

4. Finally, the phosphorescence (or E-type delayed fluorescence) of aroyl compounds, and the emission of the second positive system of nitrogen take place:

[8] $A(^3T_1) \rightarrow A(^1S_0) + h\nu$ (phosphorescence, detector signal)

or

[9] $A(^3T_1) \rightarrow A(^1S_1)$ (intersystem crossing for close energy levels)

and

[10] $A(^1S_1) \rightarrow A(^1S_0) + h\nu$ (E-type fluorescence, detector signal)

plus

[11] $N_2(C\ ^3\Pi_u) \rightarrow N_2(B\ ^3\Pi_g)$ (second positive system, detector background)

It should again be noted that the metastable $N_2(A\ ^3\Sigma_u^+)$ state, which we propose to be the primary excitation source for the aroyl compounds of this ALD-based study, has long been used as a very efficient triplet-energy transfer agent, both in the gas phase (83, 81, 79, 82, 85–89) and in solid matrices at 4.2 K (90).

Conclusions

Phosphorescence in the gas phase is, as a rule, a very weak and very rare event. Almost all studies of the literature use reduced pressure in order to reduce quenching. In this study, however, very intense gas-phase $n\rightarrow\pi^*$ phosphorescence (or E-type delayed fluorescence) of certain types of aroyl compounds was observed in excited nitrogen at high temperature and atmospheric or higher pressure. A novel, radioactively stimulated, high-voltage, low-current (≤35 nA) discharge in high-purity nitrogen was used to excite the aroyl compounds. Our speculative luminescence mechanism for aroyl compounds suggests that ground-state N_2 is excited to the triplet metastable $N_2(A)$ state by collision with a fast electron, and that this is followed by efficient triplet-triplet energy transfer from $N_2(A\ ^3\Sigma_u^+)$ to the aroyl compound. Thus, for the experimentally ("sterically"?) favored $n\rightarrow\pi^*$ process, this novel excitation source can be used to produce large populations of aroyl triplet states in the gas phase. Such high concentrations of triplet states — which would otherwise be difficult to obtain at atmospheric pressure — can be put to good analytical (and perhaps other) use. The gas-phase luminescences of some sixty compounds were therefore recorded in an effort to assist such endeavors. As it turned out, most of the charted phosphorescences had never before been obtained in the gas phase. While only a few of these spectra could be reproduced in this manuscript because of space limitations, the fact that they can be obtained with ease from the ALD (91), and that some of the relevant spectral data can now be found in the Tables, should significantly

enlarge the analytical and physicochemical data base for their use.

Acknowledgements

This work was supported by the Natural Sciences and Engineering Research Council of Canada (NSERC) individual research grant A-9604. We thank C.G. Eisener for machining the ALD, Brian Millier for electronic help, and Jim Pincock for organic advice. Particular thanks are due to You-Zhi Tang, who obtained the first aroyl phosphorescence spectra from excited nitrogen (5), and who supplied this study with an initial list of relative aroyl responses.

Characterization of phosphorus chemical shielding tensors in a phosphole tetramer: a combined experimental and theoretical study

Myrlene Gee, Roderick E. Wasylishen, Klaus Eichele, Gang Wu, T. Stanley Cameron, F. Mathey, and F. Laporte

Abstract: Phosphorus-31 1D NMR spectra of a stationary powder sample of a phosphole tetramer containing two phosphorus spin pairs have been obtained at 4.7 T and 9.4 T. In order to separate ^{31}P–^{31}P spin-spin coupling from anisotropic chemical shielding, 2D spin–echo NMR spectra have been acquired. Phosphorus-31 CPMAS NMR experiments indicate that the two spin pairs of the tetramer are equivalent and each may be treated as an isolated spin pair. Within a given spin pair, the difference between the isotropic chemical shifts of two directly bonded phosphorus nuclei is 1.7 ppm. As well, they are spin–spin coupled by both the indirect and direct interactions, $^1J(^{31}P, ^{31}P)$ = –362 Hz and R_{DD} = 1.80 kHz, respectively. The principal components and relative orientation of the two phosphorus chemical shielding tensors have been determined using the dipolar-chemical shift technique; however, since the dipolar tensor is axially symmetric, ambiguities in the chemical shielding tensor orientation relative to the molecular framework result. Using ab initio calculations and simulations of the 2D spin–echo spectra, many of these ambiguities have been resolved. The spans and skews of the phosphorus shielding tensors for all four three-coordinate phosphorus nuclei are the same within experimental error, 115 ppm and 0.70, respectively. Combined experimental and theoretical results indicate that the phosphorus shielding tensor orientations are dictated by the local environment. For both shielding tensors, the most shielded component, δ_{33}, is approximately 78° from the P—P bond and in the phosphole ring plane. The relative orientation of the δ_{33} components is described by a dihedral angle of 82°, similar to the dihedral angle of approximately 76° defining the twist of the phosphole rings about the bridging P—P bond.

Key words: solid-state ^{31}P NMR, phosphorus chemical shielding tensors, phosphole tetramer, ^{31}P–^{31}P spin pairs, ab initio calculations.

Résumé : On a enregistré à 4,7 T et à 9,4 T les spectres de RMN 1D du phosphore 31 à l'état solide à partir d'un échantillon d'un tétramère phosphole, sous forme de poudre, contenant deux paires de spin de phosphore. Dans le but de séparer les constantes de couplage spin-spin ^{31}P-^{31}P des blindages chimiques anisotropiques, on a enregistré également les spectres de RMN 2D spin écho. Les expériences de RMN CPMAS du phosphore-31 indiquent que les deux paires de spins du tétramère sont équivalentes et que chacune peut-être traitée comme une paire isolée. Pour une paire de spins donnée, la différence entre les déplacements chimiques isotropiques de deux noyaux phosphore directement liés est de 1,7 ppm. Les interactions directes et indirectes de ces noyaux donnent également un couplage spin–spin de $^1J(^{31}P, ^{31}P)$ = –362 Hz et R_{DD} = 1,80 kHz respectivement. Utilisant la technique de déplacement chimique-dipolaire, on a déterminé les composantes principales et l'orientation relative des deux tenseurs de blindage chimique; cependant, puisque le tenseur dipolaire est de symétrie axiale, il en résulte des ambiguïtés dans l'orientation du tenseur de blindage chimique par rapport au squelette moléculaire. Les calculs ab initio et les simulations de spectres 2D spin écho ont permis de résoudre plusieurs de ces ambiguïtés. L'envergure et l'obliquité des tenseurs de blindage chimique des quatre noyaux de phosphore tricoordonnés sont identiques, dans les limites des erreurs expérimentales, elles sont respectivement de 115 ppm et de 0,70. La combinaison des résultats expérimentaux et théoriques révèle que les orientations du tenseur de blindage du phosphore dépendent de l'environnement local. Pour les deux tenseurs de blindage, la composante la plus blindée, δ_{33}, est approximativement de 78° à partir de la liaison P—P et dans le plan du cycle du phosphole. L'orientation relative des composantes δ_{33} est décrite par un angle dièdre de 82°, semblable à l'angle dièdre de 76° approximativement définissant la torsion des cycles phosphole autour de la liaison P—P en pont.

Mots clés : RMN du ^{31}P à l'état solide, tenseurs de blindage chimique du phosphore, tétramère phosphole, paire de spins ^{31}P–^{31}P, calculs ab initio.

Scheme 1. Molecular structure of the phosphole tetramer (**1**) and a three-dimensional representation of **1**. For clarity, the methyl and phenyl groups have been removed from the 3D representation. Molecule **2** has been used as a model system of **1** for the ab initio calculations.

Introduction

The phosphole tetramer, **1** (Scheme 1), was first synthesized in 1982 (1) and the X-ray crystal structure was reported subsequently (2). Solid-state NMR investigations of similar systems where two three-coordinate phosphorus nuclei are directly bonded are relatively rare (3). In the case of the phosphole tetramer, analysis of the ^{31}P NMR spectra acquired with cross polarization (CP) and magic angle spinning (MAS) revealed a difference in the isotropic phosphorus chemical shifts of 1.7 ppm with $^1J(^{31}P, ^{31}P)$ = –362 Hz (4, 5). Here, we use the presence of ^{31}P–^{31}P spin pairs to characterize the phosphorus chemical shift (CS) tensors via the dipolar-chemical shift NMR technique (6–8). In contrast to the earlier ^{31}P MAS NMR investigations (4, 5), we have fully analyzed NMR spectra of stationary samples obtained at different applied magnetic fields. We also demonstrate that analysis of the ^{31}P 2D spin–echo NMR spectrum of the phosphole tetramer is invaluable for refining the coupling parameters. In combination with ab initio calculations to verify the phosphorus shielding tensor orientations, this strategy of combining experimental and theoretical methods (7) is extremely powerful for accurately characterizing CS tensors in powdered samples. Inconsistencies between the NMR data (vide infra) and the original X-ray data (2) prompted a redetermination of the crystal structure.

Homonuclear Spin Pairs — Background Theory

The most reliable experimental method available for characterizing nuclear magnetic shielding tensors is single-crystal NMR (3*d*, 9). Unfortunately, single crystals of sufficient size and quality are frequently unavailable. However, the presence of isolated hetero- or homonuclear spin pairs in a molecule affords an opportunity to gain some information about the CS tensor orientation from NMR spectra of powdered samples by the application of dipolar-chemical shift NMR (6). As described below, the NMR spectra of a homonuclear spin pair will depend on the principal components of the chemical shielding tensor for each nucleus and the relative orientation of these tensors. In general, four transition frequencies with relative intensities P_i are observed for homonuclear spin-1/2 pairs (the two nuclei are labelled A and B respectively) (6, 10):

$$[1] \quad \nu_1 = \frac{1}{2}(\nu_A + \nu_B - A - D) \qquad P_1 = 1 - \frac{B}{D}$$

$$[2] \quad \nu_2 = \frac{1}{2}(\nu_A + \nu_B + A - D) \qquad P_2 = 1 + \frac{B}{D}$$

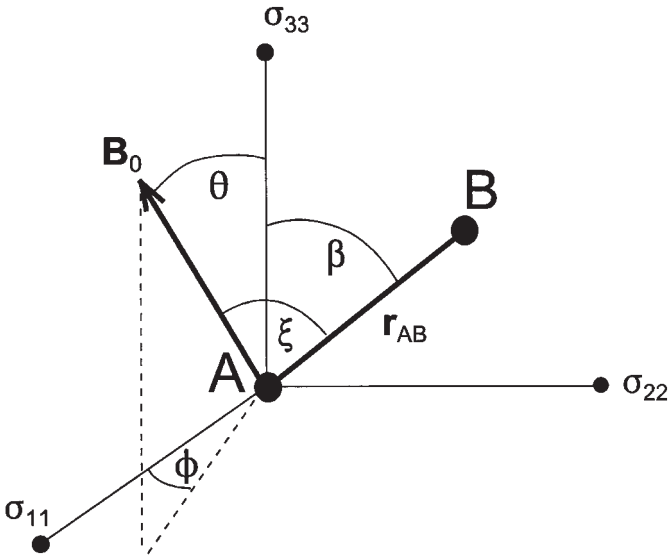
$$[3] \quad \nu_3 = \frac{1}{2}(\nu_A + \nu_B - A + D) \qquad P_3 = 1 + \frac{B}{D}$$

$$[4] \quad \nu_4 = \frac{1}{2}(\nu_A + \nu_B + A + D) \qquad P_4 = 1 - \frac{B}{D}$$

The frequencies ν_A and ν_B are given by

$$[5] \quad \nu_i(\theta, \phi) = \nu_0[1 - (\sigma^i_{11}\sin^2\theta\cos^2\phi + \sigma^i_{22}\sin^2\theta\sin^2\phi + \sigma^i_{33}\cos^2\theta)]$$

where ν_0 is the Larmor frequency, and σ_{11}, σ_{22}, and σ_{33} are the principal components of the chemical *shielding* tensor such that $\sigma_{11} \le \sigma_{22} \le \sigma_{33}$. In eq. [5], the polar angles θ and ϕ describe the orientation of the principal axis system (PAS) of the CS tensor with respect to the applied external magnetic field, $\mathbf{B}_0$ (Fig. 1). In practice, it is the chemical *shift* which is measured. It is related to the chemical shielding by $\delta = 10^6(\sigma_{ref} - \sigma)/(1 - \sigma_{ref})$, where σ_{ref} is the absolute nuclear magnetic shielding of the reference (328.35 ppm for the phosphorus atom of 85% H_3PO_4 (11) in the case of ^{31}P NMR studies). The principal components of the chemical shift tensor are defined such that $\delta_{11} \ge \delta_{22} \ge \delta_{33}$. The isotropic chemical shift, δ_{iso}, is $(\delta_{11} + \delta_{22} + \delta_{33})/3$ and the span and skew of the chemical shift tensor are defined as $\Omega = \delta_{11} - \delta_{33}$ and $\kappa = 3(\delta_{22} - \delta_{iso})/\Omega$, respectively (12). The terms *A*, *B*, and *D* in eqs. [1]–[4] are dependent on the isotropic indirect spin–spin coupling constant, J_{iso}, and the effective direct dipolar coupling constant, R_{eff}:



$$[6] \quad A = J_{iso} - R_{eff}(3\cos^2\xi - 1)$$

$$[7] \quad B = J_{iso} + \frac{1}{2}R_{eff}(3\cos^2\xi - 1)$$

$$[8] \quad D = [(\nu_A - \nu_B)^2 + B^2]^{\frac{1}{2}}$$

Fig. 1. An illustration of the angles which define the orientation of the applied magnetic field, $\mathbf{B}_0$, the internuclear vector, $\mathbf{r}_{AB}$, and the principal axis system of the chemical shielding tensor, indicated by σ_{11}, σ_{22}, and σ_{33}. The nuclei of the spin pair are labelled A and B.

where ξ is the angle between the internuclear vector, $\mathbf{r}_{AB}$, and $\mathbf{B}_0$ (Fig. 1), and R_{eff} is given by (10*e*):

$$[9] \qquad R_{eff} = R_{DD} - \frac{\Delta J}{3}$$

The dipolar coupling constant, R_{DD}, is dependent on the vibrationally averaged inverse cube of the internuclear distance, r_{AB}:

$$[10] \qquad R_{DD} = \frac{\mu_o}{4\pi} \frac{1}{\left\langle r_{AB}^3 \right\rangle} \gamma^2 \left(\frac{\hbar}{2\pi} \right)$$

In eq. [9], ΔJ is defined as the anisotropy in the indirect spin–spin coupling tensor, **J** (for an axially symmetric tensor).

The relative orientations of the CS tensors on each nucleus of the spin pair and $\mathbf{r}_{AB}$ are most conveniently described by the Euler angles, α, β, and γ, such that the rotation matrix to transform from the molecular frame of reference to the CS tensor PAS is (13):

$$[11] \qquad \mathbf{R}(\alpha, \beta, \gamma) = \mathbf{R}_{z'}(\gamma)\mathbf{R}_{y}(\beta)\mathbf{R}_{z}(\alpha)$$

where, for example, $\mathbf{R}_z(\alpha)$ is a rotation of α degrees about the z-axis. The axis z′ is the new z-axis generated by $\mathbf{R}_y(\beta)$.

In a microcrystalline powder sample, all possible orientations of the CS tensor PAS with respect to $\mathbf{B}_0$ are present; however, the NMR spectrum is still sensitive to the relative orientations of the CS and dipolar tensors (8). Unfortunately, difficulties can arise when one attempts to extract this orientational information from the NMR spectra of powder samples. In principle, the observed line shape will depend on two sets of CS tensor principal components, two sets of Euler angles, the **J** tensor, and R_{eff}. The analysis can be simplified by independent measurements of some parameters. For example, spectra obtained under conditions of rapid MAS provide the isotropic chemical shift and *J*-coupling constant. Bond lengths available from diffraction experiments provide a starting value for R_{eff} since $\Delta J/3$ is expected to be much smaller than R_{DD} (14). In some cases, trial and error analysis of NMR spectra obtained under conditions of slow MAS may provide a wealth of information (5, 15); however, we believe it is also prudent to analyze the NMR spectra of non–spinning samples. In the case of stationary samples, an independent measurement of the spin–spin coupling constants (R_{eff} and J_{iso}) can be obtained from the 2D spin–echo experiment, whereby the spin–spin coupling and the chemical shielding interactions can be separated for homonuclear spin pairs (3*a*). Nakai and McDowell (3*c*) have derived expressions for the free induction decays, $s(t_1)$ and $s(t_2)$, of the 2D spin–echo NMR experiment:

$$\begin{aligned} [12] \qquad s(t_1) = {} & \cos^2 2\xi \, [\exp(i\pi A t_1) + \exp(-i\pi A t_1)] \\ & + 1/2 \sin 2\xi \, (1 + \sin 2\xi) \, [\exp(i\pi\{D - A\}t_1) \\ & + \exp(-i\pi\{D - A\}t_1)] \\ & - 1/2 \sin 2\xi \, (1 - \sin 2\xi) \, [\exp(i\pi\{D + A\}t_1) \\ & + \exp(-i\pi\{D + A\}t_1)] \end{aligned}$$

$$\begin{aligned} [13] \qquad s(t_2) = {} & (1 - \sin 2\xi) \exp(i2\pi\nu_1 t_2) \\ & + (1 + \sin 2\xi) \exp(i2\pi\nu_2 t_2) \\ & + (1 + \sin 2\xi) \exp(i2\pi\nu_3 t_2) \\ & + (1 - \sin 2\xi) \exp(i2\pi\nu_4 t_2) \end{aligned}$$

where $\cos 2\xi = (\nu_A - \nu_B)/D$, $\sin 2\xi = B/D$ and the ν_is (i = 1 – 4) are given by eqs. [1]–[4]. Following Fourier transformation, the F1 projection of the 2D NMR spectrum is a Pake doublet with splittings dependent on the magnitudes and relative signs of R_{eff} and J_{iso}. The F2 projection is the normal 1D NMR spectrum of a stationary sample. Two dimensional spin–echo NMR spectroscopy has been used extensively to characterize homonuclear spin pairs in solids, especially ^{31}P–^{31}P systems such as Ph_2PPPh_2 (3*c*, 16), $Mes^*P = PMes^*$ (Mes^* = (2,4,6-tri-*tert*-butyl)phenyl) (3*a*), $[Mes^*NP\text{-}PPh_3][SO_3CF_3]$ (17), the pyrophosphate anion in $Na_4P_2O_7 \cdot 10H_2O$ (3*c*, 18), Lawesson's reagent, $(C_6H_4OCH_3PS_2)_2$ (19), and most recently in some molybdenum phosphine complexes (3*d*).

Despite the arsenal of experimental methods available for investigating spin pairs in powder samples, there is one fundamental property that prevents the unambiguous determination of the CS tensor orientation with respect to the molecular axis system, namely the axial symmetry of the dipolar tensor. Hence NMR spectra are invariant to simultaneous rotation of the two CS tensors about $\mathbf{r}_{AB}$. However, due to advances in computational chemistry, it is now possible to fix the orientations of chemical shielding tensors in the molecular framework with some confidence, provided one is dealing with first- and second-row elements. The present status of theoretical methods has been discussed in a number of recent reviews (20). It is well known that large basis sets are essential to obtain reliable results. Furthermore, methods capable of treating electron correlation are desirable for molecules containing multiple bonds or formal electron lone pairs. As well, relativistic effects may become important for heavier nuclei (21), but are unlikely to be sig-

nificant for phosphorus and influence CS tensor orientations. In an effort to deal with the electron correlation problem, researchers have used either Møller–Plesset (MP) perturbation theory (22) or density functional theory (DFT) (23). With advances in computation techniques and the advent of faster computers, the reliability of the calculations will continue to improve.

Experimental

The synthesis of the phosphole tetramer has been described previously (1).

Phosphorus-31 NMR spectra: All ^{31}P NMR spectra of stationary and MAS samples were acquired on Bruker MSL 200 (4.7 T), Chemagnetics CMX Infinity 200 (4.7 T), and Bruker AMX 400 (9.4 T) spectrometers operating at ^{31}P NMR frequencies of 81.03 MHz and 161.98 MHz, respectively. Cross polarization under the Hartmann–Hahn match condition and high power ^{1}H decoupling were used for all NMR experiments. At the lower field, double air bearing MAS probes were used with the sample packed in 7 mm o.d. (for the MSL) and 7.5 mm o.d. (for the CMX) zirconium dioxide rotors. For the stationary sample, 2180 transients were acquired with a ^{1}H $\pi/2$ pulse of 3.6 μs, contact time of 5 ms, and a recycle delay of 5 s, while 256 transients were acquired with the sample spinning at 1500 or 2000 Hz. A double air bearing MAS probe was used at the higher field as well, with the sample packed in a zirconium dioxide rotor (4 mm o.d.). A ^{1}H $\pi/2$ pulse of 3.6 μs with a contact time of 3 ms and a recycle delay of 10 s were used to acquire 458 transients. With MAS at 2000 or 4000 Hz, 512 transients were acquired. Gaussian line broadening of 20 to 100 Hz was applied before Fourier transformation. All ^{31}P NMR spectra are referenced to the primary standard, 85% H_3PO_4(aq) by setting the ^{31}P isotropic peak of solid $NH_4H_2PO_4$ to +0.8 ppm. Spectra of stationary samples at both fields were simulated using WSOLIDS, a program developed in this laboratory which incorporates the POWDER routine of Alderman et al. (24). Spectra of MAS samples were calculated using NMRLAB[2], which uses the Monte Carlo method to sample crystal orientations for powder averaging. In our calculations, 10 000 orientations were used. Gaussian line broadening of between 100 and 150 Hz was applied to the calculated spectra to approximate the experimental line broadening.

2D Spin–echo ^{31}P NMR spectrum: The 2D spin–echo NMR spectrum was acquired at 4.7 T (Bruker MSL 200) with a standard spin–echo pulse sequence using the phase cycling of Rance and Byrd (25) where the evolution time between the contact pulse and the π pulse (t_1) was incremented (3*c*). A ^{1}H $\pi/2$ pulse of 5.5 μs was used with a contact time of 5.5 ms and a recycle delay of 10 s. For each t_1 increment, 64 transients were acquired for a total of 64 increments. Gaussian line broadening of 200 Hz and 100 Hz were applied to the F1 and F2 projections respectively. The F1 projection was calculated using eq. [12] and eq. [13] with SpinEcho, a program developed in this laboratory. The experimental and calculated 2D NMR spectra were processed in magnitude mode.

X-ray data collection and processing: An orange crystal of approximate dimensions 0.10 × 0.10 × 0.10 mm, recrystallized from chlorobenzene, was mounted on a glass fibre. A Rigaku AFC5R diffractometer was used for all measurements. Calculations were performed using teXsan.[3] The orange crystals have cell dimensions a = 11.523 (4) Å, b = 23.083 (1) Å, c = 15.115 (1) Å, α = 89.99 (1)°, β = 92.71 (1)°, and γ = 89.99 (1)°. The merging R_{int} for the reflection data, merged on the assumption that the cell is monoclinic, is 3.04% for 244 equivalent reflections with $I > 5\sigma(I)$. The reflections for which $h = 2n + 1$ are weak in intensity and are generally diffuse. The strong reflections thus belong to a cell where a = 5.762 (1) Å. Both cells have systematic absences consistent with a space group $P2_1/c$. The molecule for the structure in the larger cell refines to R = 4.7%. The refinement used unit weights.

Computational details: Theoretical calculations were performed with the Gaussian 94 suite of programs[4] running on an IBM RISC/6000 computer. Using Restricted Hartree–Fock (RHF) theory and Gauge Independent Atomic Orbitals (GIAO) (26), the ^{31}P CS tensors were determined for the model geometry, **2** (Scheme 1), of the phosphole tetramer based on the X-ray crystallography results for half of the molecule where the methyl and phenyl groups are replaced by hydrogen atoms. A partial geometry optimization using RHF with the 6–311G basis set on all the atoms was carried out. The P—P bond length, the dihedral angle between the rings, and the C—H bond lengths were fixed at the X-ray structure values for the optimization. Shielding calculations were carried out using the 6–311++G(d,p) basis set on phosphorus and neighbouring nuclei, while the 6–311G basis set was used on the remaining atoms in order to keep computation time within reasonable limits (27). To compare with experimental results, the calculated phosphorus chemical shielding is converted to chemical shift by using the absolute shielding of 328.35 ppm for the phosphorus chemical shift reference, 85% H_3PO_4(aq) (11).

Results and discussion

Experimental determination of phosphorus CS tensors in the phosphole tetramer

The observed and calculated ^{31}P CP NMR spectra of stationary samples of the tetramer are shown in Fig. 2, while NMR spectra of MAS samples are shown in Figs. 3 and 4.

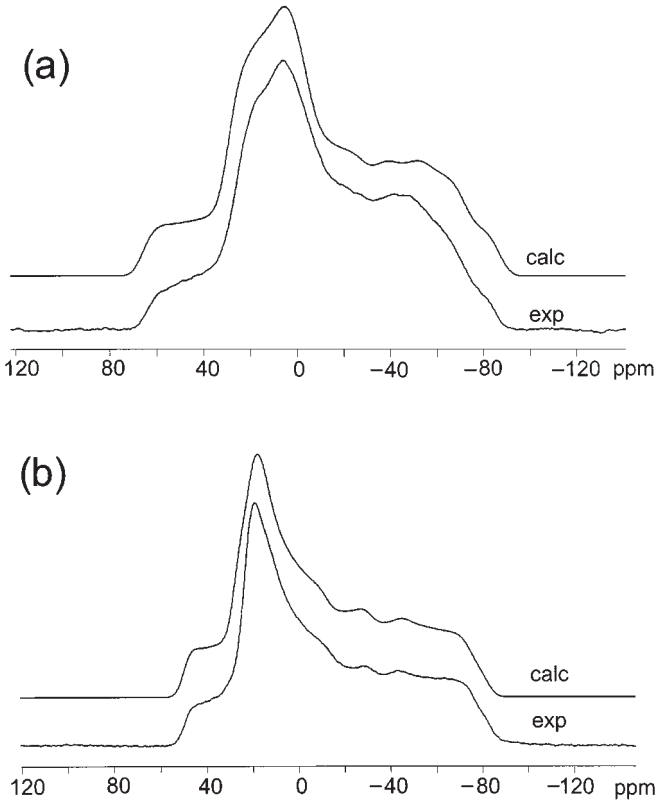

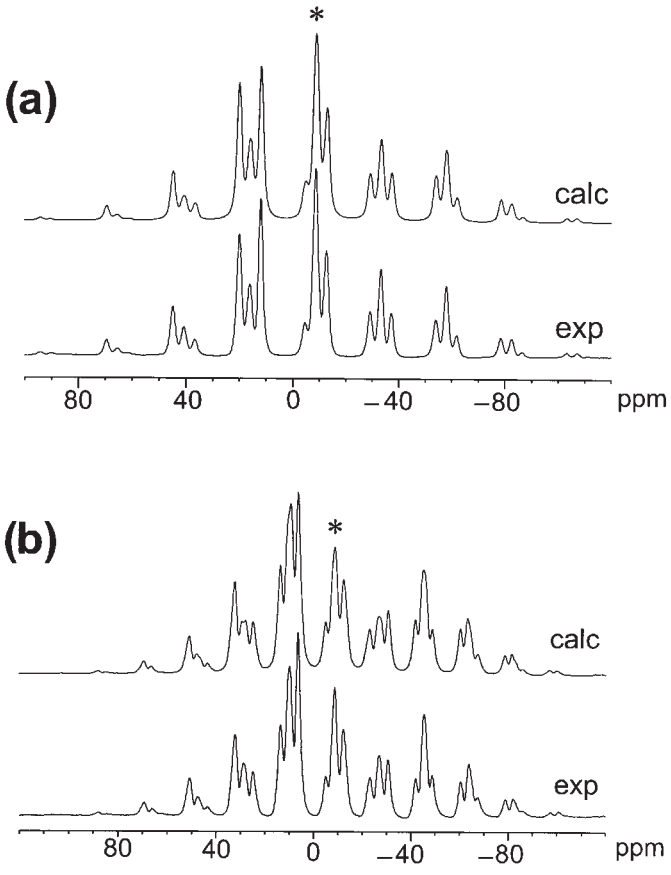

Fig. 3. Experimental and calculated ^{31}P NMR spectra of crystalline powder samples of the phosphole tetramer spinning at the magic angle, acquired at 4.7 T for sample spinning at (**a**) 2.0 kHz and (**b**) at 1.5 kHz. The asterisk indicates the average position of δ_{iso}.

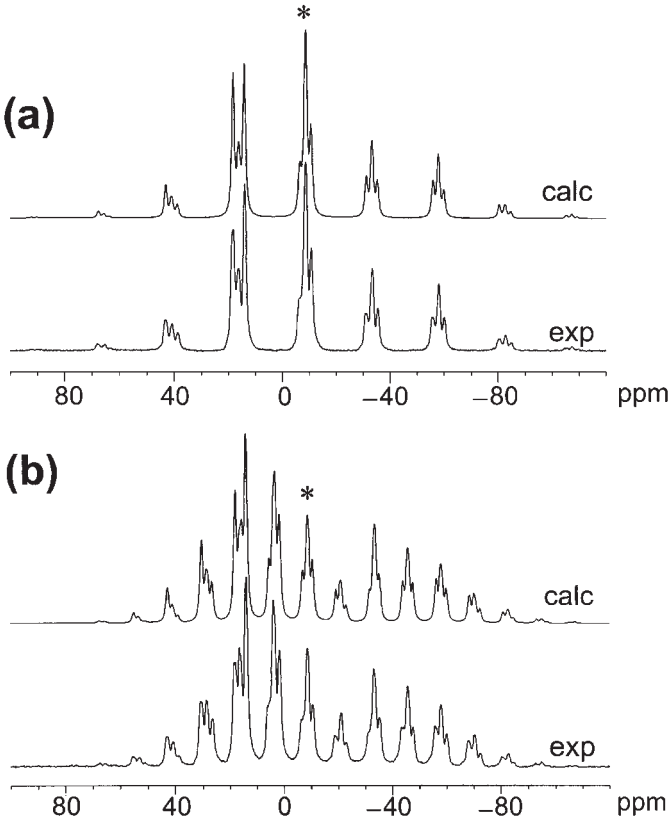

Best-fit parameters are given in Table 1. In the text to follow, a brief account of how these parameters were obtained is presented.

The ^{31}P CPMAS NMR spectra of the phosphole tetramer indicate the presence of a unique ^{31}P–^{31}P spin pair in the crystal (4, 5) and, as indicated in Table 1, the NMR spectra have been analyzed accordingly. However, in the previously reported crystal structure of the phosphole tetramer (2) there are two molecules in the asymmetric unit related by a pseudo mirror plane, hence four unique P—P bond lengths were reported; r = 2.198(6), 2.191(6), 2.201(6), and 2.175(6) Å (2). Given the reported X-ray structure, one would expect to see potentially eight different phosphorus sites in the ^{31}P MAS NMR spectrum; similarly up to 16 different methyl carbon sites could be anticipated in the ^{13}C MAS NMR spectrum. Experimentally, we observe only two unique ^{31}P sites at both 4.7 and 9.4 T. Carbon-13 CP MAS NMR spectra revealed two ^{13}C sites at both fields (δ_{iso} = 15.5 ± 0.1 ppm and 17.1 ± 0.1 ppm). This apparent disagreement between our NMR results and the reported X-ray data prompted a redetermination of the X-ray data. Repeated attempts were made to grow suitable single crystals; however, the best crystals obtained were less than ideal for X-ray diffraction. The R factor for our X-ray data is 0.047, compared to the R factor of 0.089 reported previously (2).

The space group obtained from the new X-ray data is $P2_1/c$ with the asymmetric unit consisting of one molecule, rather than a space group of $P\bar{1}$ with two molecules in the

Fig. 4. Experimental and calculated ^{31}P NMR spectra of crystalline powder samples of the phosphole tetramer spinning at the magic angle, acquired at 9.4 T for sample spinning at (**a**) 4 kHz and (**b**) 2 kHz. The asterisk indicates the average position of δ_{iso}.

asymmetric unit as had been previously reported (2), hence there are four crystallographically non-equivalent phosphorus sites and potentially eight non-equivalent methyl groups. In both cases, the unit cell contains four molecules. The molecular structure obtained from our X-ray data is essentially the same as the reported structure (2); however, our results indicate that the molecule contains a near perfect C_2 axis which relates the two pairs of phosphorus atoms (see Scheme 1). This reduces the number of different phosphorus sites from four to two and the number of different methyl carbons to four. Given that the isotropic ^{31}P chemical shifts of the two phosphorus sites only differ by 1.7 ppm (4, 5), it is not surprising that the four methyl carbons at the C_3 position (see Scheme 1) are isochronous; similarly for those at position 4.

Within the unit cell, pairs of phosphorus atoms related by the near perfect C_2 axis have very similar environments though the two atoms of each pair are in different environments. It would appear from the diffuse reflections for which $h = 2n + 1$ that there are stacking errors in the a direction. The molecules pack in layers approximately perpendicular to the a direction. Unfortunately there are too few reflections for which $h = 2n + 1$ (51 out of a total of 766) to test this suggestion. Using eq. [10], and an average P—P bond length of 2.192 Å from the new X-ray crystal structure, R_{DD} = 1.873 kHz with an estimated error of ±50 Hz, based on the error in the X-ray data. Also, with four phosphorus nuclei in each molecule, each ^{31}P–^{31}P spin pair is not truly isolated since there will be mutual dipolar coupling. From the internuclear distances between phosphorus nuclei that are not directly bonded to each other, the R_{DD}s are 233 Hz (r = 4.392 Å) and 169 Hz (r = 4.882 Å), hence the NMR spectral features are largely determined by the much larger dipolar coupling between directly bonded phosphorus nuclei rather than the phosphorus nuclei forming the other spin pairs in the molecule.

Before analyzing the 1D ^{31}P NMR spectra, R_{eff} is first independently measured by using the 2D spin–echo experiment. Fig. 5*a* shows the ^{31}P 2D spin–echo NMR spectrum of **1** with the experimental and calculated F1 projections shown in Figs. 5*b*–5*d* (the large central peak is an experimental artifact). Using J_{iso} = –362 Hz (4, 5), the best value of R_{eff} is 1.80 ± 0.05 kHz (Fig. 5*b*), which is in good agreement with the value calculated from the crystal structure. The difference, R_{eff} - R_{DD} = 73 ± 50 Hz, is very small and could arise from vibrational averaging and possibly anisotropy in the **J** tensor. The smaller dipolar couplings between the phosphorus nuclei that are not directly bonded to each other most likely contribute to line broadening; however, it is possible they could slightly modify the value of R_{eff}. The sensitivity of the F1 projection to R_{eff} can be seen in Fig. 5*c*, where the agreement between the calculated and experimental spectra is not as good using R_{eff} = R_{DD} = 1.873 kHz. As well, the poor fit in the simulation using $^1J(^{31}P, ^{31}P)$ = +362 Hz with R_{eff} = 1.80 kHz (Fig. 5*d*) indicates that R_{eff} and J_{iso} must have opposite signs. In fact, for $^1J(^{31}P, ^{31}P)$ to be positive, R_{eff} must be less than 1.20 kHz to obtain a satisfactory fit of the two most intense peaks, which seems unreasonable in light of previous investigations of ^{31}P–^{31}P spin-spin couplings (14). A negative J-coupling constant is consistent with INDO calculations of $^1J(^{31}P, ^{31}P)$ as a function of the dihedral angle, ϕ, between formal lone pairs (28). For example, the calculated $^1J(^{31}P, ^{31}P)$ in $(CH_3)_2P$-$P(CH_3)_2$, is –254 Hz for ϕ = 74°, which is similar to the dihedral angle for the phosphole tetramer (ϕ = 78°). Using these spin–spin coupling data (J_{iso} = –362 Hz and R_{eff} = 1.80 kHz), the experimental ^{31}P NMR spectra of a stationary sample shown in Fig. 2 were simulated to obtain the CS principal components given in Table 1 and tensor orientation information discussed below. The experimental error in the principal components of the two chemical shift tensors is estimated to be ±5 ppm. As a result, δ_{11}, δ_{22}, and δ_{33} are virtually identical for the two ^{31}P CS tensors; this is reasonable given that the isotropic shifts are different by only 1.7 ppm (4, 5). The NMR spectra of MAS samples, shown in Figs. 3 and 4, demonstrate that the quality of the simulations using these new parameters is comparable to previously published work (4, 5). Although the agreement between the calculated and experimental NMR spectra is good at both fields for stationary and MAS samples, there are some subtle differences between observed and calculated NMR spectra. These differences probably arise because neither of the two phosphorus spin pairs in the molecule are strictly isolated (i.e., these spin pairs interact with one another).

As detailed in the background section, it is possible to obtain some CS tensor orientation information from the NMR spectra of stationary samples. For the phosphole tetramer, the NMR lineshape is particularly sensitive to $\Delta\alpha$, which is

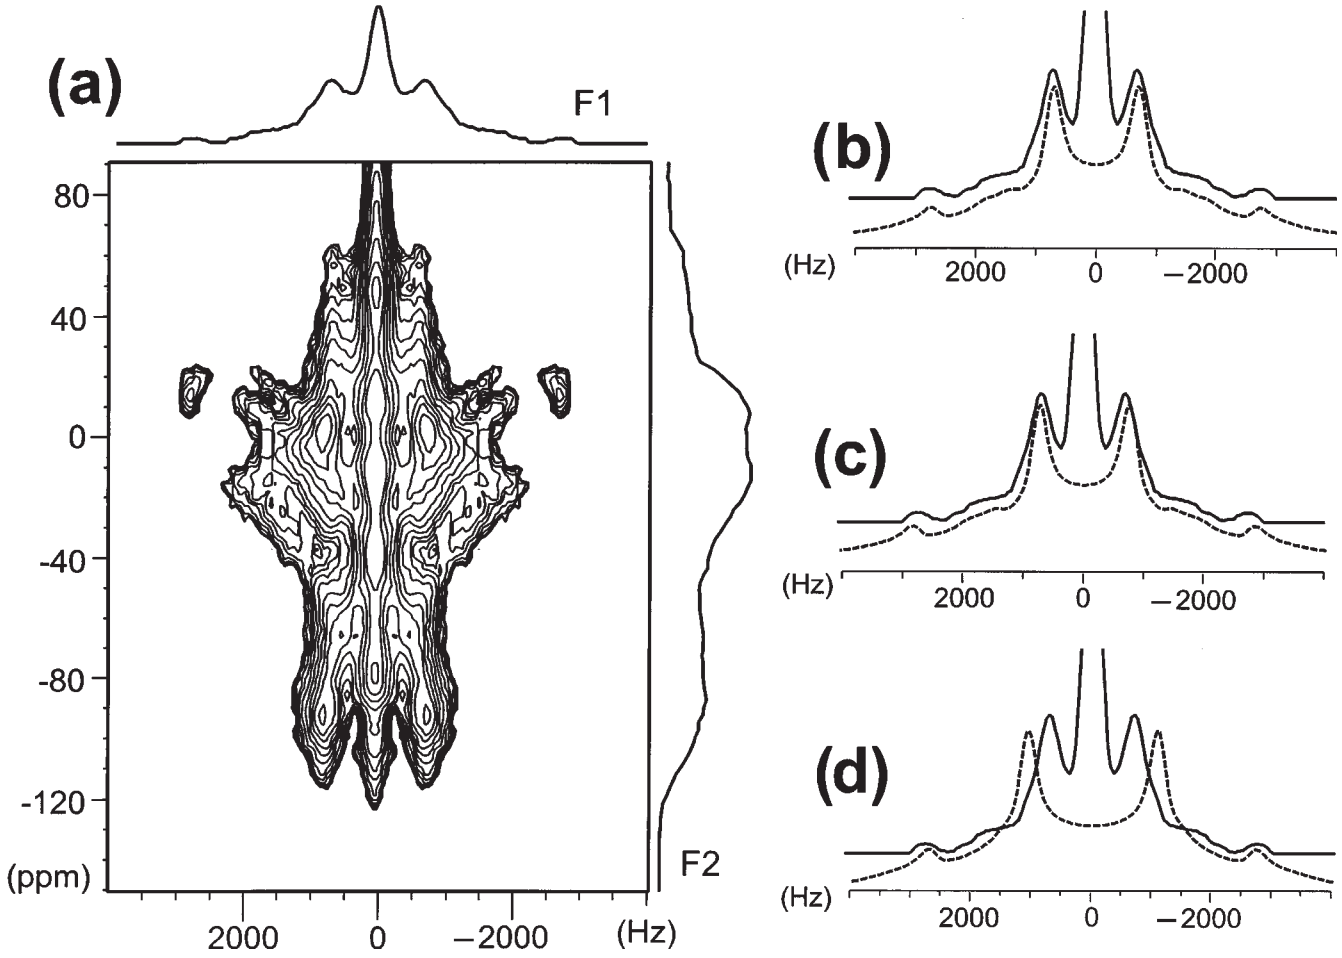
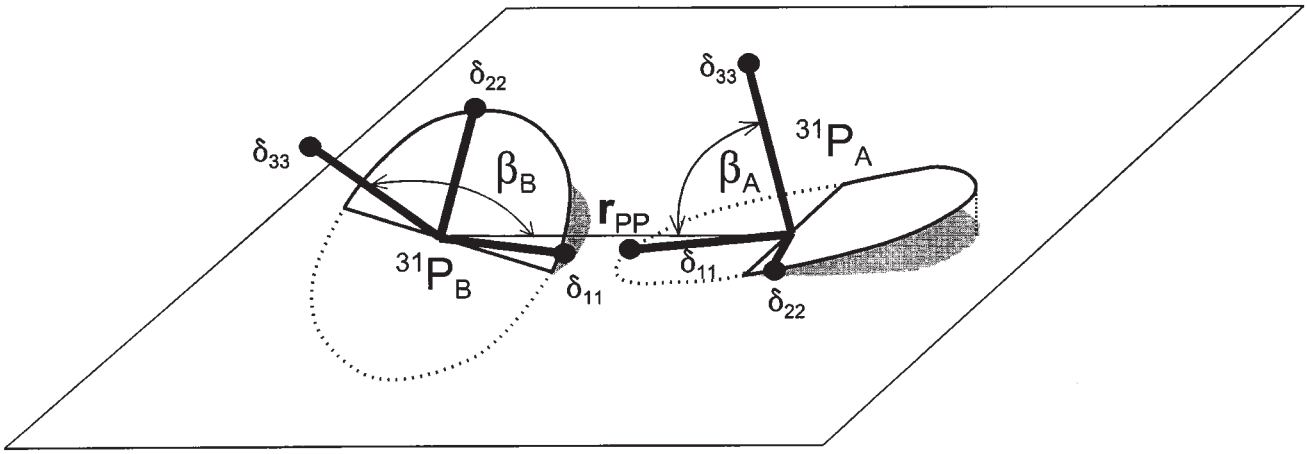
Fig. 5. (**a**) The 2D spin–echo ^{31}P NMR spectrum of the phosphole tetramer, acquired at 4.7 T. The calculated (dashed line) and experimental (solid line) F1 projections are shown for (**b**) R_{eff} = 1.80 kHz, J_{iso} = –362 Hz, which produce the best fit, (**c**) R_{eff} = R_{DD} = 1.873 kHz, J_{iso} = –362 Hz, and (**d**) R_{eff} = 1.80 kHz, J_{iso} = +362 Hz.





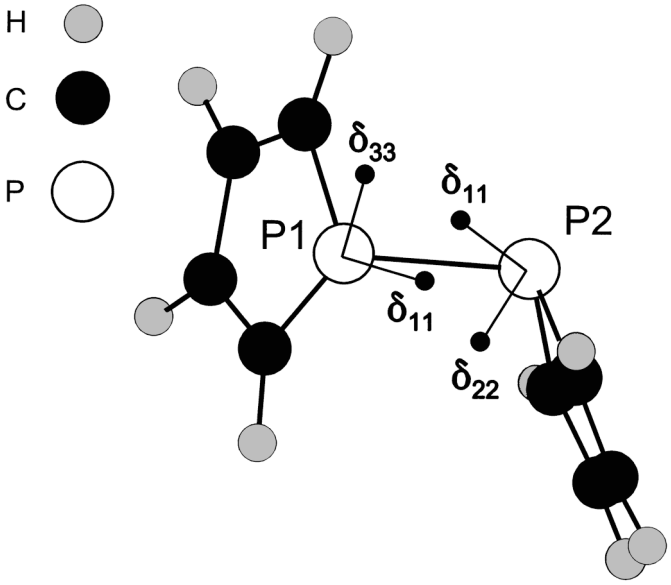


Fig. 6. The relative orientation of the two ^{31}P CS tensors in the phosphole tetramer, determined from simulation of the ^{31}P NMR spectra acquired at 4.7 T and 9.4 T for a stationary sample. For P_A, the Euler angles are α = 0°, β = 78°, and γ = 167°. For P_B, α = 82°, β = 78°, and γ = 167°.

the dihedral angle between the δ_{33} components of the two ^{31}P CS tensors. Best-fit calculated NMR spectra were obtained with $\Delta\alpha$ = 82 ± 3°. For both phosphorus CS tensors, the δ_{33} component is tipped away from the internuclear vector by β = 78 ± 5°. The relative orientation of the two ^{31}P CS tensors is illustrated in Fig. 6. In both cases, γ = 167 ± 5°

© 2000 NRC Canada

Fig. 7. The ^{31}P CS tensor orientations for **2** determined by ab initio calculations. For P1, δ_{22} is directed below the plane of the page, while for P2, δ_{33} is approximately out of the plane. In the case of P1, the δ_{11} and δ_{33} components are situated at angles of 19.3° and 79.1° respectively from the internuclear vector. For P2, δ_{11} is at an angle of 27.5° and δ_{33} at an angle of 79.0° from $\mathbf{r}_{PP}$.

places the least shielded component, δ_{11}, closest to $\mathbf{r}_{PP}$. Unfortunately, the ambiguities associated with the dipolar-chemical shift method prevent the determination of the absolute orientation of the CS tensor in the molecular frame of reference.

Ab Initio Calculations of Phosphorus Shielding Tensors.

As already mentioned, we use the ab initio calculations to fix the relative orientations (Fig. 6) in the molecular axis system (Fig. 7). Ab initio calculation results for the phosphorus chemical shielding tensors in the model system, **2**, for the phosphole tetramer are given in Table 1. The two phosphorus sites are labelled as P1 and P2 rather than P_A and P_B (Scheme 1) since it is not known how the two sites in the NMR spectra should be assigned to the molecule. In a partial optimization of the geometry, the P—C bond lengths and the ring bond angles were allowed to change, resulting in changes that were within the errors stated in the crystal structure (2). The calculated tensor orientations, depicted in Fig. 7, are similar for both P1 and P2 with respect to the local geometry about each phosphorus nucleus. The δ_{11} components are closest to the P—P bond at angles of 19.3° and 27.5° for P1 and P2, respectively while the δ_{33} component for P1 forms an angle of 79.1° with the internuclear vector, and the corresponding angle for P2 is 79.0°. The calculated orientations of δ_{11} and δ_{33} for both phosphorus nuclei are consistent with the experimental observations. In addition, the dihedral angle between the δ_{33} principal components is 87.8°, in good agreement with the value of 82° determined by analysis of ^{31}P NMR spectra. These ab initio calculations indicate that the δ_{33} components are not aligned in the general direction of the formal lone pairs, as had been previously suggested (4, 5). In fact, δ_{22} is closest to the direction of the formal lone pairs. For the phosphole tetramer, the δ_{33} components are in the plane of the respective phosphole rings and approximately perpendicular to the P—P bond. In the absence of single-crystal NMR data and (or) reliable first principles calculations, it is impossible to orient the CS tensors in the molecular frame.

With respect to the magnitudes of the principal components, the experimental and calculated results show similar trends (Table 1). The small calculated isotropic ^{31}P chemical shift difference (4 ppm) between the two sites is consistent with experiment. The calculations also predict that δ_{11} and δ_{22} are similar, while δ_{33} is quite distinct, as reflected in the skews of about 0.5, comparable to the skews of 0.7 observed experimentally. However, the calculated isotropic chemical shifts are too shielded by about 43 ppm and the spans are significantly larger than the experimental values. There are several possible reasons to account for these differences. First, a significant shift is anticipated due to the change in phase. For example, PH_3(g) is more shielded by 28 ppm compared to PH_3(l) (11) and P_4(g) is more shielded by 93.0 ppm compared to P_4(l) (29). In addition, the calculations are carried out on isolated gas phase molecules while the shielding will be affected by intermolecular interactions in the solid state. Another factor which may be responsible for part of the discrepancy between calculated and experimental results is the neglect of electron correlation in the RHF method. Inclusion of electron correlation has been shown to be important for obtaining good quantitative agreement between calculated and experimental shielding tensors in systems with formal lone pairs and multiple bonds (20). The importance of lone pairs in determining the chemical shielding in phospholes has been demonstrated recently in a series of ab initio calculations on phospholes and the phospholide ion (30). A recent investigation of some model phosphorus systems, for example PH_3, indicates that the inclusion of electron correlation in ab initio calculations yields improved results for isotropic chemical shielding (31). The use of a model geometry consisting of half of the phosphole tetramer may also contribute to this discrepancy. Given these factors, quantitative agreement between the experimental and ab initio values is not expected, and seemingly good calculated results may be due to the fortuitous cancellation of errors. Our primary goal with respect to ab initio calculations of chemical shielding tensors is to obtain the tensor orientation in the molecular frame of reference. Calculations on the model system H_2PPH_2 reveal that changes in the phosphorus tensor orientations are minor when various levels of theory (RHF or Møller–Plesset theory) are compared.[5]

The relative orientation of the δ_{33} components of the two phosphorus shielding tensors in the phosphole tetramer appears to be related to the relative orientation of the adjacent phosphole rings (see Fig. 7). In the crystal structure (2), the rings are arranged such that the ring planes are approximately parallel to each other and twisted about the bridging P—P bond. The dihedral angle between adjacent phosphole rings, ϕ_{ring}, ranges between 102°–105°, which can be equally well described by the supplement angle range of 75°–78°. This agrees well with the dihedral angle between the δ_{33}

components at each phosphorus nucleus, ϕ_{33}, which is 82° determined experimentally and 87.8° from ab initio calculations. This structure-tensor relationship can be further demonstrated by ab initio calculation of the phosphorus tensor orientations at various ϕ_{ring}. Further calculations on our model system using ϕ_{ring} = 0°, 70°, 110°, and 180° indicate that the δ_{33} components are oriented relative to the local geometry in a similar manner as shown in Fig. 7, with ϕ_{33} reflecting ϕ_{ring} (ϕ_{33} = 0°, 60.5°, 109.5°, and 180° for the corresponding ϕ_{ring} listed above).

There has been some discussion in the literature over the aromaticity of phospholes (32), recently revived by the synthesis of some planar phospholes (33). While ^{31}P solution NMR has been used routinely to characterize this important class of compounds, there are few comprehensive NMR investigations of the chemical shift (CS) tensors. The ^{31}P CS tensors of several phosphole derivatives have also been characterized recently by solid-state NMR (34). Comparison of the phosphorus CS tensors in phospholes (Table 2), reveals that δ_{33} in the phosphole tetramer is relatively shielded. For all phospholes investigated by ^{31}P solid-state NMR thus far, the spans of the phosphorus CS tensors are small compared with systems where the phosphorus nucleus is known to be participating in a delocalized electron framework. For example, the span of the ^{31}P CS tensors in Mes^*P = $PMes^*$ is 1239 ppm (3*a*) and in benzo-1,3,2-dithiaphospholium aluminum chloride, Ω = 779 ppm (36). In the latter two systems, the phosphorus environment is formally two-coordinate, hence the larger span may be attributed to efficient $n \rightarrow \pi^*$ mixing. This mixing is absent in systems where the phosphorus nucleus is formally three-coordinate.

Conclusions

The analysis of ^{31}P CP NMR spectra of a stationary sample of the phosphole tetramer as well as with MAS indicates that the principal components of the two ^{31}P CS tensors are virtually identical. Regarding the CS tensor orientation, the δ_{11} components of both CS tensors are approximately along the dipolar vector, while the δ_{33} components are tilted away at an angle of 78°, in addition to being twisted relative to each other by an angle of 82°. This latter angle is thought to reflect the relative orientation of the phosphole rings, which are related by a dihedral angle ranging from 75° to 78°. Ab initio results support the experimental conclusions and indicate that the δ_{33} components are not aligned with the formal lone pairs on the phosphorus nuclei. The characterization of the phosphorus CS tensors in the phosphole tetramer is greatly aided by the 2D spin–echo experiment as well as by employing ab initio calculations to suggest an orientation of the tensor in the molecular frame.

Acknowledgments

We are grateful to Guy M. Bernard, David L. Bryce, Scott Kroeker, Michael D. Lumsden, and Robert W. Schurko for many helpful comments and suggestions on this work. R. E. W. thanks the Natural Sciences and Engineering Research Council (NSERC) of Canada for operating and equipment grants and the Canada Council for a Killam Research Fellowship. $Mn(OAc)_3$-promoted hydroxylation of α-carbomethoxy-γ-lactones by molecular oxygen

Laurent Lamarque, Alain Méou, and Pierre Brun

Abstract: The $Mn(OAc)_3$-mediated hydroxylation of a series of α-carbomethoxy-γ-lactones by molecular oxygen is described. The reaction is regio- and stereoselective and gives α-carbomethoxy-α-hydroxy-γ-lactones.

Key words: manganese acetate, γ-lactones, hydroxylation, molecular oxygen.

Résumé : L'hydroxylation d'une série d'α-carbométhoxy-γ-lactones par l'oxygène moléculaire, en présence d'acétate de manganèse, est décrite. La réaction est régio- et stéréosélective et conduit à des α-carbométhoxy-α-hydroxy-γ-lactones.

Mots clés : acétate de manganèse, γ-lactones, hydroxylation, oxygène moléculaire.

Introduction

$Mn(OAc)_3$ promotes the oxidation of β-dicarbonyl compounds giving electrophilic radicals that have been extensively used for intra- and intermolecular annulation of unsatured compounds (1–5). It has also been reported that, in some cases, these radicals can react with molecular oxygen. For instance, Kurosawa (6, 7–10, 11, 12, 13, 14) has shown that when 1,1-diarylethene derivatives are reacted with β-keto esters, β-diketones, β-keto amides, β-keto sulfoxides, acetylacetonitrile, or pyrrolidine-2,3-dione and $Mn(OAc)_3$ in acetic acid, in the presence of molecular oxygen, depending on the temperature, either 1,2-dioxan-3-ols (room temperature) or 4,5-dihydrofurans (70°C) are formed. It has also been described by Shibasaki (15) that the electrophilic radical prepared by oxidation of a β-keto ester with $Mn(OAc)_3$ can be directly trapped by molecular oxygen and converted to a δ-hydroxy-β,γ-unsaturated-α-keto ester. Similar results were also observed in intramolecular reactions (16, 17). Recently, Nair (18) has shown that dialkyl malonates can be hydroxylated by cerium^{IV} ammonium nitrate (CAN) in methanol, under an air atmosphere.

Results and discussion

In a previous study, we described the formation of a mixture of the two lactones **1a** and **2a** when (+)-Δ^3-carene is reacted, under N_2, with monomethyl malonate in the presence of $Mn(OAc)_3$ (2.2 equiv.) (19). We later observed that, under an air atmosphere, the same reaction led to a third product identified as the α-carbomethoxy-α-hydroxy-γ-butyrolactone **3a** (Scheme 1, Table 1).

The formation of **3a** can be accounted for by the subsequent hydroxylation of the first formed lactone **1a** by atmospheric oxygen. Indeed, when pure lactone **1a** was reacted with $Mn(OAc)_3$ under an O_2 atmosphere, at 70°C in acetic acid, lactone **3a** and its epimer **4a** were obtained in higher yields (Table 2, entry 1).

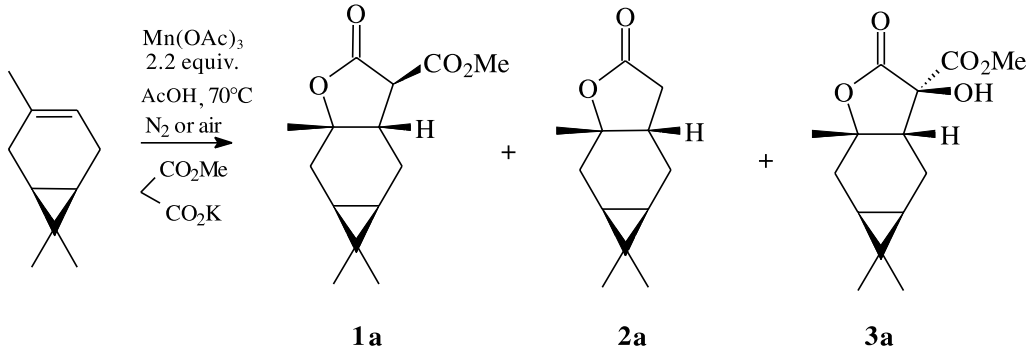
As, to our knowledge, such $Mn(OAc)_3$-mediated hydroxylation of α-carbomethoxy-γ-lactones has not been described, we decided to study the behavior of a series of α-carbomethoxy-γ-lactones obtained previously (19) (Scheme 2). The reactions were realized in acetic acid until discoloration of the reaction medium (Mn^{III} reduced into Mn^{II}). In these conditions, although in most cases an excess of Mn^{III} was used, the reaction did not go to completion. Our results are summarized in Table 2.

The α-carbomethoxy-α-hydroxy-γ-lactones are formed as a mixture of the two epimers **3** and **4** which can be readily separated by flash chromatography.

Structural determinations

The structure and relative configuration of the major isomers **3a, 3c** were determined by X-ray crystallography. Upon catalytic hydrogenation, **3c** (known configuration) and **3d** gave the same hydroxylactone **3e** thus establishing unambiguously the structure of **3d** and **3e**. The configuration of **3b** is based upon the chemical shift of the carbon bearing the carbomethoxy and the hydroxyl group which happens, in each case, to be lower in **3** than in the respective isomer **4**. The structure of the minor isomers **4a–e** was ascertained by comparison of their ^1H and ^{13}C NMR spectra with those of the major isomers **3a–e**.

For each lactone tested, a high or very high selectivity in favor of the epimer in which the hydroxyl group is in a *cis* relationship with the vicinal hydrogen is obtained. This selectivity is similar to the one observed for the addition of



Accepted October 26, 1999.

monomethyl malonate onto cycloalkenes and cycloalkadienes in the presence of $Mn(OAc)_3$ (19).

The influence of some experimental factors on the overall yield (**3**+**4**) has been investigated starting from lactone **1e** (entries 7–10): (*i*) in the absence of $Mn(OAc)_3$, no reaction is observed (entry 7); (*ii*) an enhanced yield is obtained when using less than 2.2 equiv. of $Mn(OAc)_3$ (compare entries 5 and 8); (*iii*) the reaction can be performed at room temperature by employing less than one equivalent of $Mn(OAc)_3$ (entry 9); (*iv*) the replacement of $Mn(OAc)_3$ by $Mn(OAc)_2$ (in situ generation of Mn^{III} salts) does not affect the course of the reaction (compare entries 5, 8, 9, 10).

The formation of these α-carbomethoxy-α-hydroxy-γ-butyrolactones can be explained by a mechanism similar to the one postulated by Nair (18): formation of a carbon-centered radical α- to the carbomethoxy group followed by reaction with molecular oxygen.

Such a radical could also explain the formation of 2-ethoxycarbonyl-4,4-diphenylbut-2-en-4-olide when monoethyl malonate is reacted with 1,1-diphenylethene in the presence of Mn^{III} (20). Although we do not have any evidence for the mechanism of the alcohol formation from a peroxyl radical, a mechanism similar to the one demonstrated for the formation of 2-hydroxymalonic acid when malonic acid is oxidized by Ce^{IV} in the presence of oxygen can be envisioned (21).

The decarbomethoxylation reaction of **3a** has been achieved using the Krapcho procedure (22) and gives the two epimeric α-hydroxy-γ-lactones **5a** + **5b** as a mixture (68:32) in good yield (84%). In the major epimer **5a**, the hydroxyl group is in a *cis* position with respect to the adjacent hydrogen (Scheme 3).

Conclusions

We have shown that α-carbomethoxy-α-hydroxy-γ-lactones can be prepared by Mn^{III}-mediated regioselective hydroxylation of α-carbomethoxy-γ-lactones using air or molecular oxygen as oxidant. Although some examples of such hydroxylations have been described using Ce^{IV}, it is the first case in which such a series of α-hydroxy-γ-lactones have been prepared using Mn^{III}. As exemplified by our results with Δ^3-carene, the overall transformation can be directly realized starting from the parent olefin by reaction with monomethyl malonate under an oxidative atmosphere in the presence of Mn^{III} (Table 1). Moreover, owing to the easy decarbomethoxylation of α-carbomethoxy-α-hydroxy-γ-lactones, this approach could be elaborated as a convenient two-step preparation of α-hydroxy-γ-lactones starting from olefins.

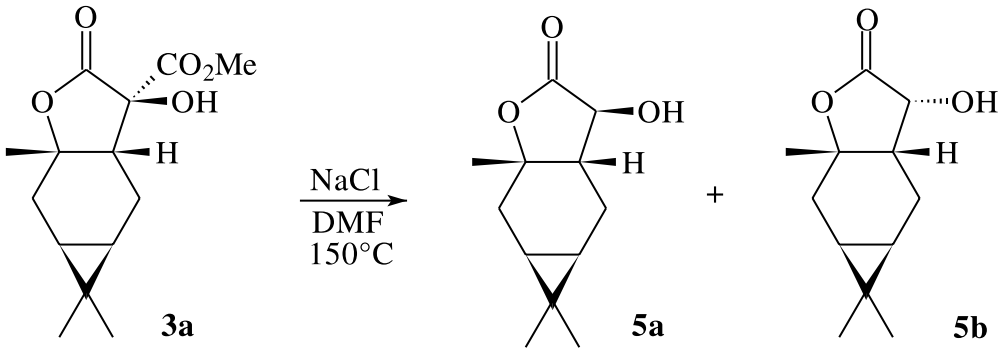
Experimental

General experimental procedures



IR spectra were recorded on a Perkin–Elmer 297 apparatus, neat or in $CHCl_3$. ^1H NMR spectra were recorded in $CDCl_3$ on a Bruker AC 250 spectrometer operating at 250 MHz. Chemical shifts are reported in parts per million and are given in δ units; coupling constants are given in Hertz. We used the following symbols to report the multi-

Scheme 3.

plicity and shape of signals: s (singlet), d (doublet), t (triplet), m (multiplet). ^{13}C NMR spectra were recorded on the same spectrometer, operating at 62.5 MHz. Melting points were determined in capillary tubes using an Electrothermal IA 9100 apparatus. The progress of chromatographic separations was monitored by TLC on silica gel plates (Merck Kieselgel 60 F_{254}). Column flash chromatography was performed on silica gel (Merck Kieselgel 60H).

General procedure for hydroxylation

A two-necked 50 mL round-bottomed flask equipped with a reflux condenser was charged with α-carbomethoxy-γ-lactone **1** (1 mmol) and $Mn(OAc)_3{\cdot}2H_2O$ (see Table 2) in glacial acetic acid (10 mL). The solution was stirred for 10 min at room temperature under a stream of O_2 and the flask then placed in an oil bath at 70°C for the time indicated in Table 2. After cooling, the reaction mixture was poured into brine (40 mL) and extracted with Et_2O (4 × 10 mL). The organic layer was washed with a saturated $NaHCO_3$ solution to remove acetic acid and dried over $MgSO_4$. Removal of the solvent under reduced pressure at room temperature afforded an oily residue which was flash chromatographed (eluent: hexane–Et_2O gradient) to give the pure α-carbomethoxy-α-hydroxy-γ-lactones **3** and **4**.

*(1S,3S,5R,7R,8R)-1,4,4-Trimethyl-8-carbomethoxy-8-hydroxy-10-oxatricyclo[5.3.0.0^{3,5}]decan-9-one (**3a**)*: mp 221°C. IR ν_{max} cm^{-1} (KBr): 3480 (OH), 1760 (C=O, γ-lactone), 1740 (C=O, ester). ^{1}H NMR: δ ppm: 0.64–0.80 (m, 2H), 0.94 (dd, ^2J 15.3, ^3J 8.2 Hz, 1H), 0.97 (s, 3H), 1.03 (s, 3H), 1.07–1.17 (m, 1H), 1.56 (s, 3H), 1.66–1.77 (m, 1H), 2.26 (dd, ^2J 15.3, ^3J 7.0 Hz, 1H), 2.35 (d, ^3J 7.5 Hz, 1H), 3.93 (s, 3H), 4.10 (s, 1H). ^{13}C NMR: δ ppm: 14.69, 16.56, 17.89, 18.58, 20.45, 28.37, 28.73, 30.25, 50.89, 53.53, 83.02, 86.35, 170.68, 172.79.$[\alpha]^{20}_D$ = –38.4° (c 2.08, MeOH). Procedure for the decarbomethoxylation of 3a

A 10 mL round-bottomed flask, equipped with a reflux condenser, was charged with **3a** (238 mg, 0.89 mmol), NaCl (79 mg, 1.35 mmol), and H_2O (30 μL, 1.66 mmol) in DMF (2 mL). The mixture was stirred for 3 h at 150°C. It was then cooled, poured into brine (10 mL), and extracted with Et_2O (4 × 5 mL). The organic layer was washed with brine and dried over $MgSO_4$. Removal of the solvent under reduced pressure at room temperature afforded an oily residue which was purified by flash chromatography (eluent: hexane–Et_2O gradient) to give α-hydroxy-γ-lactones **5a** and **5b** (84% yield).

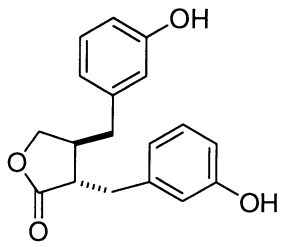
A short synthesis of both enantiomers of enterolactone

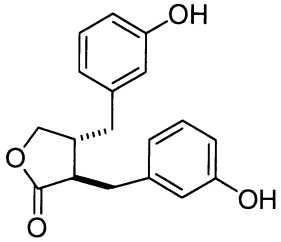
Mukund P. Sibi, Pingrong Liu, and Michael D. Johnson

Abstract: A short and efficient synthesis of both enantiomers of enterolactone, a mammalian lignan, is described. The overall yield for the natural enterolactone, over seven steps, was 19% and for its enantiomer 27%.



Key words: enterolactone, 4-diphenylmethyl-2-oxazolidinone, succinate, enantioselective synthesis.

Résumé : On décrit une synthèse courte et efficace des deux énantiomères de l'entérolactone, un lignane extrait de mammifères. Le rendement global en entérolactone naturelle après une synthèse en sept étapes est de 19% et il est de 27% pour son énantiomère.

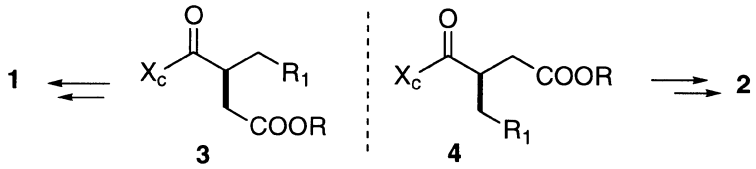


Mots clés : entérolactone, 4-diphénylméthyl-2-oxazolidone, succinate, synthèse énantiosélective.

[Traduit par la Rédaction]

Lignan natural products continue to receive attention due to their interesting biological profile (1). For example, enterolactone, a lignan present in human urine, has been shown to possess protective properties towards certain types of cancers (2). Neither enterolactone, nor its bioprecursor(s), secoisolariciresinol and matairesinol, are commercially available. Only a few routes to enantiomerically pure enterolactone have been reported (for racemic synthesis see ref. 3; for enantioselective synthesis see ref. 4). Availability of both enantiomers is important to establish biological efficacy. We have now developed a synthesis of enterolactone in both enantiomeric forms (**1**, **2**) in good overall yields. The novelty of the approach is that a single chiral auxiliary provides access to both targets and these details are presented in this article.

1 (+)-Enterolactone



2 (–)-Enterolactone

We have been interested in developing a general methodology for the regio- and stereoselective functionalization of linear dicarboxylic acids and its application in natural product synthesis. The successful execution of this protocol in the synthesis of paraconic acid natural products (5) and seco lignans–peperomins (6), has been reported from our laboratory (for a similar strategy to butyrolactones involving the alkylation of acyloxazolidinones with halo acetates see ref. 7*a*; for another example of enolate alkylation leading to similar structures see ref. 7*b*). We were interested in extending the method to the synthesis of enterolactone enantiomers. The key step in the method was the preparation of the diastereomeric succinates **3** and **4** (R_1 = 3-methoxybenzyl) and chemoselective hydrolysis of the chiral auxiliary (X_c) followed by conversion to the target natural products (eq. [1]).

The synthesis of the unnatural (+)-enterolactone **1** is shown in Scheme 1. This involved the preparation of the monosubstituted succinate **3** in optically pure form by a stereoselective alkylation of a chiral imide. The sequence began by the acylation of the chiral oxazolidinone **5** (8)[2] with 3-methoxy dihydrocinnamoyl chloride under standard conditions to give **6** in excellent yield. Introduction of the acetate side chain was carried out using NaHMDS to provide the succinate **7** in good yield as a single diastereomer (for selected examples of alkylation using different bases leading

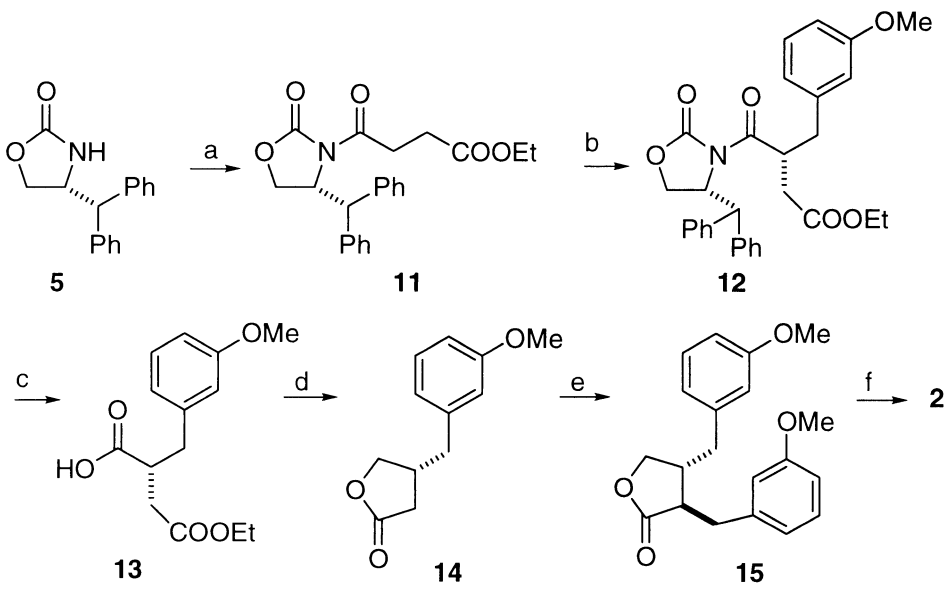
Scheme 1.

a, *n*-BuLi, THF, −78°C, $ClCO(CH_2)_2Ph$-3-OMe, 93%; b, 1.1 equiv. NaHMDS, −78 °C, ICH_2COOt-Bu, 85%; c, LiOH, H_2O_2, THF−H_2O, 0°C, 85%; d, (*i*) BH_3THF, THF, 0°C, 80%; (*ii*) PTSA, benzene, 92%; e, NaHMDS, THF, 3-OMe-$PhCH_2I$, −78°C to −54°C, 69%; f, BBr_3, CH_2Cl_2, 0°C to −18°C, 78%.

to succinates see ref. 9). Chemoselective removal of the chiral auxiliary was carried out using LiOH–H_2O_2 to furnish the succinate monoester **8** (85%) (10). The chiral auxiliary **5** could be recovered in >95% yield. Selective reduction of the carboxylic acid in the presence of the ester functionality using borane–THF followed by acid catalyzed cyclization gave the known lactone **9** in 74% overall yield over two steps (4b). The introduction of the second benzylic fragment onto **9** was carried out successfully by enolate generation with NaHMDS followed by treatment with 3-methoxy benzyl iodide to furnish **10**.[3] This procedure avoids the use of HMPA as reported by Doyle for the same alkylation using the corresponding benzyl bromide as the alkylating agent (4*b*). The lactone **10** was converted to the unnatural (+)-enterolactone **1** by demethylation using BBr_3. The spectral and analytical characteristics of **1** were identical to the data reported in the literature (4*a*, *b*). The overall yield for the unnatural isomer over seven synthetic steps was 27%.

The synthesis of the natural (–)-enterolactone **2** is shown in Scheme 2. The synthesis of this target involved the regio- and stereoselective alkylation of a succinate to provide **4** as the key step. To this end, acylation of **5** with the mono ethyl succinoyl chloride under standard conditions gave the succinate **11** in excellent yield. Treatment of **11** with 1.1 equiv. of NaHMDS in THF at –78°C for 75 min followed by quenching with 3-methoxybenzyl iodide furnished the mono alkylated succinate **12** in good chemical yield and high diastereoselectivity. Temperature and counterion play an important role in the generation of the enolate. When reactions were warmed to above –48°C after sodium enolate generation, cleavage of the chiral auxiliary was observed. Similarly, lithium enolates were found to be unstable at –78°C. The regioselectivity observed in enolate generation from **11** may be attributed to the increased acidity of these α-hydrogens adjacent to imide over the ester (for selective alkylation of a similar C-4 unit see ref. 11). The next step was the chemoselective hydrolysis of the imide. The rest of the synthesis followed the same sequence as described in Scheme 1. The overall yield for **2** was 19%.

In conclusion, we have developed an efficient strategy for the preparation of mammalian lignan enterolactone in either enantiomeric form using a single chiral auxiliary. The methodology is short and is amenable to scale up. The extension of the selective alkylation protocol to the synthesis of other lignans of biological interest is underway.



Experimental

Methylene chloride was distilled from calcium hydride. Tetrahydrofuran and benzene were distilled from benzophenone–ketyl prior to use. Thin layer chromatographic analyses were performed on silica gel Whatmann-60F glass plates and components were visualized by illumination with UV light or by staining with phosphomolybdic acid. Flash chromatography was performed using E. Merck silica gel 60 (230–400 mesh). All glassware was oven- and (or) flame-dried, assembled hot, and cooled under a stream of dry nitrogen or argon before use. Reactions with air sensitive materials were carried out by standard syringe techniques.

[3] On certain occasions less than 5% of the dialkylated product was also obtained.

Scheme 2.

a, *n*-BuLi, THF, −78°C, ethyl succinoyl chloride, 85%; b, 1.1 equiv. NaHMDS, -78°C to −54°C, 3-OMe-PhCH$_2$I, 60%; c, LiOH, H_2O_2, THF−H_2O, 0°C, 80%; d, (*i*) BH_3THF, THF, 0°C, 78%; (*ii*) PTSA, benzene, 97%; e, NaHMDS, THF, 3-OMe-PhCH$_2$I, −78°C to −54°C, 69%; f, BBr_3, CH_2Cl_2, 88%.

^{1}H NMR was recorded on a 400 or a 300 MHz spectrometer. ^{13}C NMR were recorded on a 400 (100) MHz and 300 (75) MHz spectrometers using broad band proton decoupling. Rotations were recorded on a JASCO-DIP-370 instrument. Elemental analyses were performed on a Perkin–Elmer Series II CHNS/O Analyzer 2400.

(4*R*)-4-(Diphenylmethyl)-3-[3-(3′-methoxyphenyl)propanoyl]-2-oxazolidinone (6)

4-Diphenylmethyl-2-oxazolidinone (**5**) (10.50 g, 41.52 mmol) in THF (160 mL) under N_2 was cooled to –78°C. *n*-BuLi (18.63 mL, 2.34 M in hexanes, 43.60 mmol) was then added dropwise over a period of 20 min. The reaction was stirred at that temperature for 30 min, then a solution of 3-methoxyhydrocinnamoyl chloride (9.07 g, 45.67 mmol) in THF (8 mL) was added dropwise over a period of 10 min. After stirring at –78°C for 2.5 h, the reaction mixture was quenched with saturated aqueous NH_4Cl (30 mL). The mixture was extracted with ethyl acetate. The organic layers were combined, washed with brine, dried over $MgSO_4$, and concentrated. The crude product was purified by flash column to afford the acylated product **6** (16.00 g, 93%). R_f 0.57 (50:50, EtOAc:hexanes). Colorless oil. $[\alpha]_D^{25}$ –95.98 (*c* 1.02, CH_2Cl_2). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 2.89 (m, 2H), 3.18 (m, 2H), 3.82 (s, 3H), 4.38 (d, *J* = 5.36 Hz, 2H), 4.71 (d, *J* = 5.92 Hz, 1H), 5.33 (m, 1H), 6.79 (dd, *J* = 2.16, 8.32 Hz, 1H), 6.85 (m, 2H), 7.07–7.37 (m, 11H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 172.1, 159.8, 153.5, 142.3, 139.7, 138.1, 129.6, 129.4, 129.0, 128.8, 128.5, 128.0, 127.2, 121.1, 114.4, 111.8, 65.2, 56.4, 55.3, 51.0, 37.2, 30.4. Anal. calcd. for $C_{26}H_{25}NO_4$: C 75.16, H 6.06, N 3.37; found: C 75.35, H 5.72, N 3.29.

(4*R*)-4-(Diphenylmethyl)-3[(2*S*)-2-(*tert*-butyloxycarbonyl)methyl]3-(3′-methoxyphenyl)]-2-oxazolidinone (7)

Acyloxazolidinone **6** (13.50 g, 32.55 mmol) in THF (160 mL) under N_2 was cooled to –78°C. NaHMDS (35.81 mL, 1.0 M in THF, 35.81 mmol) was then added dropwise over a period of 40 min. The mixture was stirred at that temperature for 1 h. *tert*-Butyl iodoacetate (5.67 mL, 39.06 mmol) was added dropwise over a period of 8 min. After stirring at –78°C for 6 h, the reaction was quenched with saturated aqueous NH_4Cl (30 mL). The mixture was extracted with ethyl acetate. The organic layers were combined, washed with brine, dried over $MgSO_4$, and concentrated. The crude product was purified by flash column to afford the alkylated product **7** (14.66 g, 85%). R_f 0.63 (50:50, EtOAc:hexanes); mp 97–99°C. $[\alpha]_D^{25}$ –209.42 (*c* 1.21, CH_2Cl_2). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.46 (s, 9H), 2.32, (dd, *J* = 4.56, 16.64 Hz, 1H), 2.58 (dd, *J* = 8.84, 12.88 Hz, 1H), 2.74 (dd, *J* = 9.96, 16.68 Hz, 1H), 2.96 (dd, *J* = 6.48, 12.92 Hz, 1H), 3.78 (s, 3H), 4.24 (t, *J* = 8.36 Hz, 1H), 4.37 (dd, *J* = 2.44, 9.16 Hz, 1H), 4.47 (m, 1H), 4.74 (d, *J* = 3.48 Hz, 1H), 5.14 (m, 1H), 6.76 (dd, *J* = 2.68, 8.32 Hz, 1H), 6.81 (m, 2H), 7.05 (d, *J* = 7.52 Hz, 2H), 7.18 (t, *J* = 7.80 Hz, 1H), 7.24–7.35 (m, 8H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 174.9, 171.4, 159.7, 152.9, 140.2, 139.8, 138.1, 129.8, 129.4, 128.8, 128.7, 128.3, 127.7, 127.0, 121.7, 114.5, 112.6, 80.8, 64.3, 56.7, 55.3, 50.0, 41.5, 38.2, 36.5, 28.2. Anal. calcd. for $C_{32}H_{35}NO_6$: C 72.57, H 6.66, N 2.64; found: C 72.64, H 6.82, N 2.62.

tert-Butyloxycarbonyl (2*S*)-(carboxymethyl)-3-(3′-methoxyphenyl)propionic acid (8)

Oxazolidinone **7** (2.00 g, 3.82 mmol) in THF (30 mL) and H_2O (10 mL) was cooled to 0°C. 30% H_2O_2 (1.56 mL,

© 2000 NRC Canada

15.28 mmol) was added dropwise over a period of 3 min. Then LiOH–H_2O (321 mg, 7.64 mmol) in H_2O (4 mL) was added dropwise over a period of 6 min. The mixture was stirred at 0°C for 1.5 h, then at room temperature for 3 h. The reaction mixture was cooled to 0°C before quenching with the solution of $NaHSO_3$ (2.00 g) in H_2O (5 mL). The mixture was acidified with HCl (1 M) and then made basic with NaOH (2 M) before being extracted with CH_2Cl_2. The organic layers were combined to recover the chiral auxiliary. The aqueous layer was acidified to pH = 2 with HCl (5 M) before extraction with ethyl ether. The organic layers were combined, washed with brine, dried over $MgSO_4$, and concentrated. The crude product was purified by flash column to afford the acid **8** (952 mg, 85%). R_f 0.33 (50:50-EtOAc:hexanes). Colorless liquid. $[\alpha]_D^{25}$ +150.0 (c 0.02, CH_2Cl_2). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.41(s, 9H), 2.34 (dd, *J* = 4.39, 16.84 Hz, 1H), 2.55 (dd, *J* = 8.79, 16.84 Hz, 1H), 2.72 (dd, *J* = 10.62, 15.38 Hz, 1H), 3.09 (m, 2H), 3.78(s, 3H), 6.72–6.80 (m, 3H), 7.21 (t, *J* = 8.06 Hz, 1H), 11.45 (broad, 1H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 180.9, 171.1, 159.8, 139.7, 129.7, 121.5, 114.8, 112.2, 81.2, 55.2, 43.2, 37.4, 36.1, 28.1. Anal. calcd. for $C_{16}H_{22}O_5$: C 65.29, H 7.53; found: C 65.24, H 7.67.

(4*S*)-[(3-Methoxyphenyl)methyl]dihydro-2(3*H*)-furanone (9)

Reduction and lactonization

Acid **8** (1.00 g, 3.40 mmol) in dry THF (20 mL) under N_2 was cooled to 0°C. BH_3·THF (5.10 mL, 1 M in THF, 5.10 mmol) was then added dropwise over a period of 10 min. After stirring at that temperature for 1.5 h, the mixture was slowly warmed up to room temperature and stirred for another hour. The reaction mixture was cooled to 0°C before slow quench with methanol. The solvent was removed under reduced pressure, water was added, and CH_2Cl_2 was used to extract the organic compound. The organic layers were combined, washed with brine, dried over $MgSO_4$, and concentrated. The crude product was purified by flash column to afford alcohol (760 mg, 80%).

The alcohol (900 mg, 3.21 mmol) and PTSA (5 mg) in benzene (10 mL) under N_2 was heated to reflux for 2 h. The mixture was then cooled to room temperature. The mixture was washed with saturated aqueous $NaHCO_3$ and water before extracting with ethyl acetate and drying over $MgSO_4$. The extraction was concentrated and purified by flash column to afford the lactone **9** (608 mg, 92%). R_f 0.39 (50:50, EtOAc:hexanes). Pale yellow oil. $[\alpha]_D^{25}$ –6.76 (*c* 1.04, $CHCl_3$) (lit. (12) value: +6.40 (*c* 1.0, $CHCl_3$)) (also see ref. 4*a*). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 2.29 (dd, *J* = 7.0, 17.44 Hz, 1H), 2.60 (dd, *J* = 8.08, 17.48 Hz, 1H), 2.74 (apt dd, *J* = 3.24, 7.0 Hz, 2H), 2.85 (m, 1H), 3.80 (s, 3H), 4.03 (dd, *J* = 6.2, 9.16 Hz, 1H), 4.33 (dd, *J* = 7.0, 9.16 Hz, 1H), 6.69 (d, *J* = 1.88 Hz, 1H), 6.73 (d, *J* = 7.52 Hz, 1H), 6.78 (dd, *J* = 1.88, 7.52 Hz, 1H), 7.23 (t, *J* = 7.76 Hz, 1H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 176.9, 160.0, 139.9, 129.9, 121.0, 114.7, 111.9, 72.7, 55.3, 39.1, 37.2, 34.3. Anal. calcd. for $C_{12}H_{14}O_3$: C 69.89, H 6.84; found: C 69.44, H 6.48.

(3*S*,4*S*)-3,4-Bis[(3-methoxyphenyl)methyl]dihydro-2(3*H*)-furanone (10)

To lactone **9** (0.45 g, 2.17 mmol) in THF (8 mL) under N_2 was cooled to –78°C. NaHMDS (3.25 mL, 1 M in THF, 3.25 mmol) was added dropwise over a period of 5 min. After stirring at that temperature for 1 h and 15 min, a solution of 3-methoxybenzyl iodide (1.16 g, 3.91 mmol) in THF (4 mL) was added dropwise over a period of 5 min. The reaction mixture was then warmed up to –54°C and stirred at this temperature for 22 h. The reaction mixture was quenched with saturated aqueous $NaHCO_3$ and extracted with diethyl ether. The organic layers were combined, washed with brine, dried over $MgSO_4$, and concentrated. The crude product was purified by column to afford the alkylated product **10** (490 mg, 69%). Pale yellow oil. $[\alpha]_D^{25}$ +42.0 (*c* 1.0, $CHCl_3$) (lit. (4*b*) value: $[\alpha]_D^{23}$ +40.9 (*c* 1.2, $CHCl_3$)). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 2.43–2.62 (m, 4H), 2.90 (dd, *J* = 7.24, 13.96 Hz, 1H), 3.05 (dd, *J* = 5.08, 13.96 Hz, 1H), 3.76 (s, 3H), 3.77 (s, 3H), 3.83 (dd, *J* = 7.28, 16.40 Hz, 1H), 4.09 (dd, *J* = 7.52, 9.00 Hz, 1H), 6.53 (s, 1H), 6.59 (d, *J* = 7.60 Hz, 1H), 6.73–6.79 (m, 4H), 7.15–7.25 (m, 2H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 178.6, 159.9, 139.7, 139.4, 129.8, 129.7, 121.7, 121.0, 114.9, 114.5, 112.4, 111.9, 71.3, 55.3, 55.2, 46.4, 41.3, 38.6, 35.1.

(3*S*,4*S*)-3,4-Bis[(3-hydroxyphenyl)methyl]dihydro-2-(3*H*)-furanone 1: (+)-Enterolactone

Literature procedure as described in ref. 4*b* was used for the synthesis of **1**. Yield: 78%. Colorless solid. $[\alpha]_D^{25}$ +38.6 (*c* 0.24, $CHCl_3$) (lit. (4*b*) value: $[\alpha]_D^{23}$ +38.3 (*c* 0.24, $CHCl_3$)). ^{1}H NMR (300 MHz, acetone-d_6) δ: 2.46–3.00 (m, 6H), 3.06 (s, 1H), 3.85–4.06 (m, 2H), 6.59–6.78 (m, 6H), 7.06–7.16 (m, 2H), 8.29 (s, 1H). ^{13}C NMR (65 MHz, acetone-d_6) δ: 178.7, 158.4, 141.3, 140.8, 130.4, 130.3, 121.5, 120.6, 117.1, 116.4, 114.5, 114.2, 71.5, 46.8, 42.2, 38.7, 35.3.

(4*R*)-4-(Diphenylmethyl)-3-[3-(ethoxypropanoyl]-2-oxazolidinone (11)

A solution of **5** (10.00 g, 39.53 mmol) in THF (160 mL) under N_2 was cooled to –78°C. *n*-BuLi (17.38 mL, 2.5 M in hexane, 43.45 mmol) was added dropwise over a period of 20 min. The mixture was stirred at that temperature for 30 min. A solution of ethyl 4-chloro-4-oxobutyrate (6.75 mL, 47.40 mmol) in THF (8 mL) was added dropwise over a period of 10 min. After stirring at –78°C for 2.5 h, the reaction mixture was quenched with saturated aqueous NH_4Cl (30 mL). The mixture was extracted with ethyl acetate, washed with brine, dried over $MgSO_4$, and concentrated. The crude product was purified by column to afford the acylated product **11** (12.80 g, 85%). R_f 0.77 (50:50, EtOAC:hexanes). Colorless solid; mp 106°C. $[\alpha]_D^{25}$ –184.5 (*c* 0.12, CH_2Cl_2). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.27 (t, *J* = 7.28, 3H), 2.58 (m, 2H), 3.04–3.25 (m, 2H), 4.15 (q, *J* = 7.28, 2H), 4.40–4.48 (m, 2H), 4.71 (d, *J* = 5.36, 1H), 5.30(m, 1H), 7.07–7.15 (m, 4H), 7.24–7.36 (m, 6H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 172.5, 171.7, 153.5, 139.6, 138.0, 129.4, 129.0, 128.8, 128.4, 128.0, 127.1, 65.2, 60.8, 56.3, 50.5, 30.9, 28.3, 14.3. Anal. calcd. for $C_{22}H_{23}NO_5$: C 69.28, H 6.08, N 3.67; found: C 69.14, H 6.07, N 3.72.

(4*R*)-4-(Diphenylmethyl)-3[(2*R*)-2-(ethoxycarbonyl)methyl]3-(3′-methoxyphenyl)]-2-oxazolidinone (12)

A solution of acyloxazolidinone **11** (5.80 g, 15.20 mmol) in THF (160 mL) under N_2 was cooled to –78°C. NaHMDS

© 2000 NRC Canada

(16.72 mL, 1 M in THF, 16.72 mmol) was added dropwise over a period of 25 min. After stirring at that temperature for 1 h and 15 min, a solution of 3-methoxybenzyl iodide (6.79 g, 22.80 mmol) in THF (20 mL) was added dropwise over a period of 30 min at –78°C. The mixture was allowed to warm up to –54°C slowly and stirred at this temperature for 22 h. The reaction mixture was quenched with saturated aqueous $NaHCO_3$ and extracted with diethyl ether. The organic layers were combined, washed with brine, dried over $MgSO_4$, and concentrated. The crude product was purified by column to afford alkylated product **12** (4.57 g, 60%). R_f 0.80 (50:50, EtOAc:hexanes). Colorless solid; mp 140°C. $[\alpha]_D^{25}$ –62.7 (*c* 0.11, CH_2Cl_2). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.17 (t, *J* = 7.12 Hz, 3H), 2.11 (dd, *J* = 11.04, 13.16 Hz, 1H), 2.24 (dd, *J* = 3.48, 17.20 Hz, 1H), 2.72 (dd, *J* = 10.28, 17.20 Hz, 1H), 2.89 (dd, *J* = 4.04, 13.16 Hz, 1H), 3.79 (s, 3H), 4.01 (q, *J* = 7.12, 2H), 4.19–4.26 (m, 1H), 4.38–4.49 (m, 2H), 4.68 (d, *J* = 6.48 Hz, 1H), 5.37 (m, 1H), 6.76- 6.85 (m, 3H), 7.09–7.32 (m, 11H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 174.8, 172.4, 159.9, 153.4, 139.9, 139.7, 138.2, 129.6, 129.3, 129.0, 128.7, 128.6, 128.0, 127.2, 121.7, 114.6, 112.6, 65.5, 60.7, 56.7, 55.3, 51.6, 41.3, 37.6, 34.6, 14.2. Anal. calcd. for $C_{30}H_{31}NO_6$: C 71.84, H 6.23, N 2.79; found: C 71.41, H 6.33, N 2.78.

Ethoxycarbonyl-(2*R*)-(carboxymethyl)-3-(3′-methoxyphenyl)propionic acid (13)

Lithium hydroxide – H_2O_2 hydrolysis of the oxazolidinone **12** as described before gave the acid **13**. Yield: 80%. R_f 0.37 (50:50, EtOAc:hexanes). Colorless liquid. $[\alpha]_D^{25}$ +114.7 (*c* 0.034, CH_2Cl_2). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.23 (t, *J* = 7.2 Hz, 3H), 2.39 (dd, *J* = 4.76, 16.84 Hz, 1H), 2.59–2.76 (m, 2H), 3.13 (m, 2H), 3.78 (s, 1H), 4.10 (q, *J* = 6.96 Hz, 2H), 6.75 (m, 3H), 7.20 (m, 1H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 180.5, 172.0, 159.9, 139.7, 129.8, 121.6, 114.9, 112.4, 61.1, 55.4, 43.1, 37.6, 34.9, 14.4. Anal. calcd. for $C_{14}H_{18}O_5$: C 63.15, H 6.81; found: C 62.92, H 7.18.

(4*R*)-[(3-Methoxyphenyl)methyl]dihydro-2(3*H*)-furanone (14)

A procedure as described for **9** was employed to obtain **14** from **13**. Reduction yield: 78%. Acid catalyzed cyclization yield: 97%. Colorless liquid. $[\alpha]_D^{25}$ +6.7 (*c* 1.66, $CHCl_3$).

(3*R*,4*R*)-3,4-Bis[(3-methoxyphenyl)methyl]dihydro-2(3*H*)-furanone (15)

A procedure as described for **10** was employed to obtain **15** from **14**. Yield: 69%. Colorless liquid. $[\alpha]_D^{25}$ –38.8 (*c* 1.06, $CHCl_3$) (lit. (4*b*) value $[\alpha]_D^{23}$ –39.2 (*c* 0.78, $CHCl_3$)).

(3*R*,4*R*)-3,4-Bis[(3-hydroxyphenyl)methyl]dihydro-2-(3*H*)-furanone 2: (–)-Enterolactone

A procedure as described for **1** was employed to obtain **2** from **15**. Yield: 88%. Colorless solid. $[\alpha]_D^{25}$ –38.3 (*c* 0.29, $CHCl_3$) (lit. (4*b*) value $[\alpha]_D^{23}$ –38.4 (*c* 0.25, $CHCl_3$)).

Investigations on nonradiative transitions in different environments using excited (or ground state) 1,2,3,4-tetrahydroquinoline (THQ) as donor and ground state (or excited) 9-fluorenone (9FL) or 2-nitro-9-fluorenone (2N9FL) as acceptors

Avijit K. De and Tapan Ganguly

Abstract: By using steady state and time resolved spectroscopic techniques, investigations were made on the nature and mechanisms of different nonradiative processes involved within the excited donor (or acceptor) and ground state acceptor (or donor) in nonpolar *n*-heptane (NH), polar protic ethanol (EtOH), and polar aprotic acetonitrile (ACN) solvents at the ambient temperature as well as in EtOH rigid glassy matrix at 77 K. The bicyclic molecule 1,2,3,4-tetrahydroquinoline (THQ) was used as a donor (D) in the present investigation whereas 9-fluorenone (9FL) and 2-nitro-9-fluorenone (2N9FL) were chosen as electron acceptors (A). When the donor chromophore was excited in presence of an acceptor, highly exothermic electron transfer (ET) reactions seemed to occur from observed large negative driving energy (ΔG^0) values, measured by electrochemical techniques, Förster's type energy transfer, static quenching, etc. An attempt was made to estimate separately the contributions of static and dynamic quenching modes in the overall quenching mechanism of donor fluorescence by using a model of modified Stern–Volmer (SV) relation. From this relation it seemingly indicated that the major contribution in quenching originated from the static mode. When excited acceptors react with the ground state donor THQ it is primarily ET reactions that seem to occur. Observations of the transient absorption spectra, by laser flash photolysis techniques, of contact ion-pairs of the present D–A systems along with the triplet absorption spectra of the monomeric acceptor (9FL and 2N9Fl) corroborate our views regarding the occurrence of photoinduced ET reactions within the present reacting systems. At 77 K the combined effect of Förster type energy transfer and static quenching seems to be responsible for observed lowering of donor fluorescence emission intensity in presence of acceptors (9FL or 2N9FL). However, the phosphorescence lifetime measurements reveal that the triplet donor might be involved in photoinduced ET reaction with the unexcited acceptor in rigid glassy matrix at 77 K and this possibly causes the reduction in the phosphorescence band intensity of the donor THQ in presence of the latter one.

Key words: electron transfer, static quenching, fluorescence quenching, phosphorescence, energy transfer.

Résumé : Les méthodes de spectroscopie en régime stationnaire et résolue dans le temps ont été utilisées pour examiner la nature et le mécanisme de différents processus non-radiatifs qui existent dans les réactions entre un donneur (ou accepteur) éxcité et un accepteur (ou donneur) en état d'équilibre dans un solvant non-polaire *n*-heptane (NH), un solvant protique polaire éthanol (EtOH) et un solvant aprotique polaire acétonitrite (ACN) à la température ambiante et aussi dans une matrice vitreuse rigide (EtOH à 77 K). Une molécule à deux boucles, 1,2,3,4-tetracyanoquinoline (THQ) a été utilisée comme donneur dans cette étude, les molécules 9-fluorénone (9FL) et 2-nitro-9-fluorénone (2N9FL) ont été choisies comme accepteurs d'électrons. L'excitation d'un chromophore donneur en présence d'un accepteur semble entraîner des réactions éxothérmiques de transfert d'un électron (puisque la valeur de l'énergie de transfert, ΔG^0, mesurée par des méthodes électrochimimiques, est grande et négative); et aussi transfert d'énergie de type Förster, l'éxtinction statique, etc. On a aussi essayé d'évaluer séparément les contributions statiques et dynamiques de l'extinction de la fluorescence des donneurs, en utilisant un modéle de la relation Stern–Volmer (SV) modifié. Nous avons pu déduire à partir de cette relation, que la contribution majeure de l'extinction, a pour origine le mode statique. Les réactions entre les accepteurs excités avec le donneur THQ en état d'équilibre, semblent provoquer surtout des réactions de transfert d'un électron. Les observations des spectres d'absorption transitoires, par des techniques de photolyse par flash laser, des paires d'ion contact dans ces systémes D–A avec les spectres d'absorption des triplets de l'accepteur monomére (9FL et 2N9FL) confirment notre hypothése concernant l'existence de réactions ET photoinduites

à l'intérieur de ces systémes réactifs. À 77 K les effets de transfert de l'énergie de type Förster et l'extinction statique ensemble, semblent entraîner l'extinction de la fluorescence du donneur en présence des accepteurs (9FL ou 2N9FL). Mais les mesures de la durée de vie de la phophorescence montrent, que la réaction de transfért d'un électron, sous irradiation, entre le donneur triplet et les accepteurs en état d'équilibre, est possible dans une matrice vitreuse rigide à 77 K; ce qui vraisemblablement explique la diminution de l'intensité de la bande phosphorescence du donneur THQ en présence des accepteurs en état d'équilibre.

Mots clés : transfert d'électron, extinction statique, extinction de la fluorescence, phosphorescence, transfert d'énergie.

Introduction

In solutions the predominant mechanisms for the bimolecular fluorescence quenching of electronically excited molecules are generally through photoinduced ET (1–8), energy transfer (8–11) and static or transient (12, 13) effect. In nonpolar solvents there may be a charge transfer (CT) between the donor and acceptor molecules to produce a light emitting species such as exciplex. On the other hand in highly polar solvent like acetonitrile (ACN) it is a solvent separated radical ion pair (SSIP), a non-light emitting species, that is generally formed. Investigations were previously made on intermolecular/intramolecular ET reactions along with several other concurrent nonradiative processes (8, 9, 14–16). In these studies the emphasis was given mainly to the free energy (ΔG^0) dependence of the kinetic of charge separation (CS) and charge recombination (CR) processes in order to detect the Marcus inverted region (mir) in these systems. Testing of Marcus theory, especially in the cases of highly exothermic ET reactions, has become nowadays a useful practice. It is known (17–20) that ET rates and efficiencies are greatly influenced by several factors, of which solvent orientation dynamics is one. Most of the authors reported that in solution phase the intermolecular ET reactions, even in the highly exothermic cases, generally do not exhibit inverted behavior. From the experimental work Rehm and Weller (21) long ago established a correlation between the bimolecular dynamic fluorescence quenching rate constants, k_q and ΔG^0, for photoinduced ET reactions in cases of some typical electron donor-acceptor systems in ACN solvent. They showed that the correlation was in agreement with the prediction made by Marcus in his outstanding electron transfer theory but only in the normal region (endothermic or slightly exothermic region). They didn't observe inverted behavior, as proposed by Marcus, in the highly exothermic or exergonic region but instead observed a diffusion-limited rate (k_d) there. Mataga et al. (22) however, demonstrated the energy gap dependence in the inverted region but in the cases of the charge recombination only of the ion pair produced from intermolecular ET reactions. However, in cases of some intramolecular ET within some bichromophoric systems of organic donors and acceptors Marcus theory was found to be valid over the entire region (16, 23) of exothermicity. From the recent investigations made by our research group on some organic electron donor and acceptor systems it was observed (8) that the first order intermolecular ET (forward charge separation) rates within these systems seem to proceed through mir. In evaluating the first order rates within the D–A systems, the recently developed diffusion mediated theory (24) was considered. Lately studies, using steady state and time resolved spectroscopic techniques, on the effects of the protic and aprotic polar solvents on nonradiative transitions involving dimethyl substituted donors and well-known acceptor tetracyanoquinodimethane (TCNQ) (25) were made. From these investigations it was revealed that the ET reactions in both the polar solvents occur in mir. In nonpolar media (e.g., cyclohexane, *n*-heptane, etc.) generally low exothermicity (low negative ΔG^0 values) was reported (8). It is logical to presume that in this media ET reactions should proceed through downhill region. Thus studies on the nature of the photoinduced ET reactions within the different donor–acceptor systems in solvents of different polarities seem worthwhile because by changing the polarities of the surrounding media we could control the rates associated with electron transfer reactions.

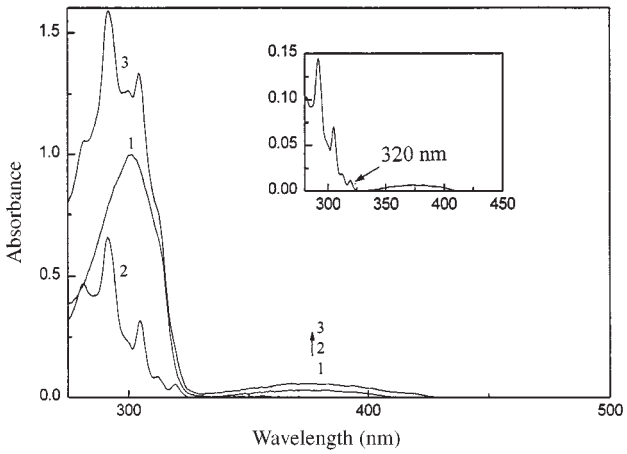
Apart from searching the mir another interesting part of such type of investigation is that when the donor chromophore is excited in presence of a suitable acceptor, not only ET but several other nonradiative processes might also occur concurrently. The nature of these nonradiative processes originates due to interactions between the donor and acceptor molecules and may be different in different surrounding media having different polarities. Lack of systematic studies on such types of problems prompted us to undertake the present work. The present paper describes the studies made to reveal the nature of the mechanisms of the different nonradiative processes such as: ET, energy transfer, static quenching, etc., which might be involved with the 1,2,3,4-tetrahydroquinoline (THQ) and acceptors 9-fluorenone (9FL) and 2-nitro-9-fluorenone (2N9FL) in different solvents like *n*-heptane ($\varepsilon_s \sim 2.07$), EtOH ($\varepsilon_s \sim 24.55$), and ACN ($\varepsilon_s \sim 37.5$). The present donor THQ possesses a bicyclic structure where one ring is aromatic but the other has an alicyclic-like ring of flexible structure. Studies of photoinduced quenching reactions using this type of molecule as the donor species are not common. In the present work we examined the nature of photoinduced ET reactions and associated nonradiative processes in different polarity solvents. Studies were also made to detect Marcus inverted regions (which are not common phenomena in intermolecular cases) especially in highly polar environments (e.g., acetonitrile (ACN), ethanol (EtOH), etc). The fluorescence quenching studies by steady state/time resolved techniques, considering the various organic donor and acceptor systems, would seem to be very useful because these intermolecular studies would help to reveal the nature of the mechanism of intramolecular ET reactions when these donors and acceptors would be connected by various spacers. However, to build bichromophores only those donors and acceptors would be chosen which would be found to undergo, from intermolecular investigations, highly exothermic ET reactions in the Marcus inverted region (mir). It is well known that mir is a key to design molecular assem-

© 2000 NRC Canada

blies for artificial photosynthesis. Thus it is expected that these bichromophores might serve as efficient photoconducting materials or polymers (when bichromophoric units are connected through polymeric chains) which would be useful in photographic and xerographic industries, and also in developing molecular electronic devices.

An attempt was also made to correlate the rates associated with the several nonradiative processes, as discussed above, in the fluid solution at the ambient temperature and to examine the fate of these nonradiative processes in rigid glassy EtOH matrix at 77 K. The studies were made by using steady state and time resolved spectroscopic techniques. The low temperature investigations using the other two solvents NH and ACN as surrounding media were not possible as these media do not form glass at this low temperature.

Experimental



Materials and their purifications

The samples 1,2,3,4-tetrahydroquinoline (THQ), 9-fluorenone (9FL) and 2-nitro-9-Fluorenone (2N9FL), supplied by Aldrich were purified carefully by vacuum sublimation. The spectroscopic grade solvents acetonitrile (ACN), ethanol (EtOH), and *n*-heptane (NH) supplied by E. Marck were distilled under reduced pressure and tested for the absence of any emission in the wavelength region studied.

Experimental apparatus

The steady state electronic absorption and emission spectra of moderate to dilute (10^{-3}–10^{-6} M) solutions of the samples at ambient temperature were recorded by a Shimadzu UV-VIS spectrophotometer of model 2101PC and Hitachi F-4500 fluorescence spectrophotometer respectively. Fluorescence lifetimes of the samples were measured by using a time correlated single photon counting (TCSPC) fluorimeter, model 199 Edinburgh Instruments U.K., having conventional L format arrangement. The excitation source consists of an all metal coaxial N_2 flash lamp with an instrumental response function of about 1.2 ns FWHM at 30 kHz repitition rate. The fluorescence decays were analyzed by using deconvolution fit over the entire decay including the rising edge. The goodness of the fit was assessed with the help of some statistical parameters (e.g., χ^2) and Durbin–Watson (DW) values. Transient absorption spectra at the different delay times between the exciting and analyzing pulses were measured with the help of nanosecond flash photolysis setup (Applied Photophysics) comprised of Nd:YAG laser (DCR-11, Spectra Physics). The sample was excited by 355 nm laser light (third harmonic) (FWHM ~ 8ns). The pulsed Xe lamp of 250 W was used as probe. The photomultiplier (IP 28) output was fed into a storage oscilloscope (TDS-540 Tektronix, 500 MHz, 1 Giga sampling, GS, s^{-1}) and the storage data were transferred to a computer through a GPIB/IEEE interface. All the solutions used for the room temperature measurements were deoxygenated by a flushing argon gas stream for about 30 minutes. Electrochemical measurements were done by using PAR model 370-4 electrochemistry system incorporating a model 174A polarographic analyzer, model 175 universal programmer model RE0074X-Y recorder. Three electrode systems including SCE were used in the measurements. Tetraethylammonium perchlorate (TEAP) in ACN was used as supporting electrolyte. The fluorescence quantum yield (ϕ_f^0) of donor THQ in ACN fluid solution was determined at room temperature (296K) relative to that of 3-methylindole in CH solvent ($\phi_f^0 = 0.40 \pm 0.03$) (26). The necessary solvent corrections were made.

Fig. 1. Room temperature electronic absorption spectra in *n*-heptane (NH) of (1) THQ (2.5×10^{-5} mol dm^{-3}), (2) 9FL (2.77×10^{-4} mol dm^{-3}), and (3) mixture of THQ (2.5×10^{-5} mol dm^{-3}) and 9FL (2.77×10^{-4} mol dm^{-3}). Inset: 9FL (6.24×10^{-5} mol dm^{-3}) in *n*-heptane (NH) fluid solutions.

Results and discussion

1. Electronic absorption spectra at the ambient temperature

At the ambient temperature and in solvents of different polarities (e.g., NH, EtOH, and ACN) the electronic absorption spectra of THQ in presence of an acceptor (9FL or 2N9FL) show the superposition of the absorption bands of the individual donor and acceptor moieties (Fig. 1). This observation excludes the possibility of formation of ground state charge transfer (CT) complex within the reactants at the room temperature.

2. Fluorescence emission at the ambient temperature and quenching studies

(A) When the donor is excited to its S_1 level

The acceptor molecules (9FL or 2N9FL) used in the present investigation, cause drastic changes in the intensity of the donor (THQ) fluorescence emission spectra produced by singlet (S_1) excitation of the molecule. In nonpolar NH, polar protic EtOH, and polar aprotic ACN the fluorescence spectral intensity of THQ falls off remarkably without any noticeable spectral shift in the presence of both 9FL and 2N9FL molecules (Figs. 2*a*–2*c*). However, with the addition of the former quencher 9FL, a very weak but genuine long wavelength band is found to develop only in the highly polar ACN (ε_s ~37.5) environment, with concomitant reduction of the fluorescence emission band intensity of THQ (Fig. 2*a*). In the inset of Fig. 2*a*, the magnified version of this long wavelength band, whose envelope is around the 500–550 nm region, is shown. It is apparent from the figure that the long wavelength band, though very weak in nature, is forming at

© 2000 NRC Canada

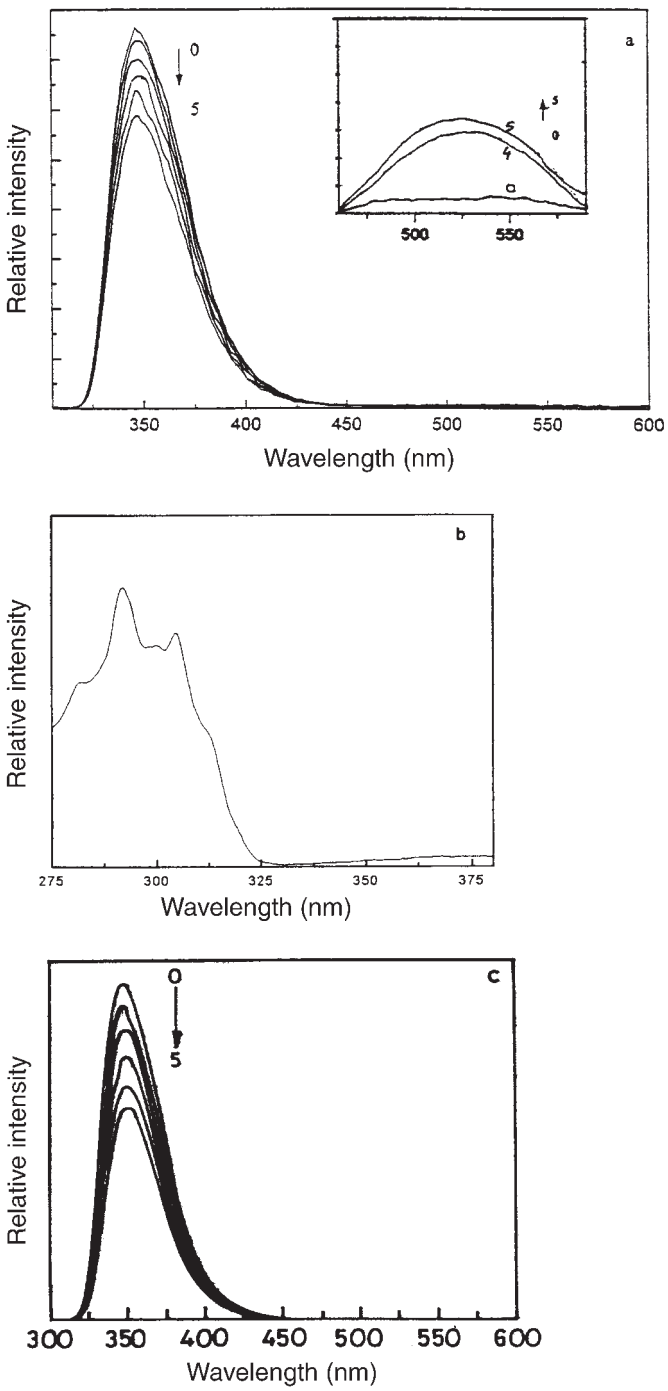


Fig. 2. (*a*) Fluorescence emission spectra of THQ donor (λ_{exc} = 320 nm) (to avoid inner filter effect) in ACN solvent of concentration (2.5×10^{-5} mol dm^{-3}) at 300 K in presence of acceptor 9FL whose concentrations (mol dm^{-3}) were: (0) 0, (1) 1.04×10^{-5}, (2) 2.08×10^{-5}, (3) 3.12×10^{-5} (4) 4.16×10^{-5}, (5) 6.24×10^{-5} (inset shows the magnified version of the longer wavelength band at 507 nm region); (*b*) Fluorescence excitation spectra of THQ donor (λ_{em} ~ 380 nm) in ACN solvent (~2.5×10^{-5} mol dm^{-3}) at 300 K in presence of acceptor 9FL (~6.24×10^{-5} mol dm^{-3}); (*c*) Fluorescence emission spectra of THQ donor (λ_{exc} = 320 nm) in ACN solvent of concentration (2.5×10^{-5} mol dm^{-3}) at 300 K in presence of acceptor 2N9FL whose concentrations (mol dm^{-3}) were: (0) 0, (1) 2.96×10^{-6}, (2) 5.92×10^{-6}, (3) 1.18×10^{-5}, (4) 1.78×10^{-5}, (5) 2.37×10^{-5}.

the expense of the fluorescence of the donor THQ molecules. As this band was not observed in nonpolar NH or in polar protic EtOH solvents, the band could not be assigned to the exciplex band which is generally formed in nonpolar environment. As it is known that 9FL fluoresces around the 510 nm region in ACN medium it is most likely that this long wavelength band (observed in only the ACN environment) might be due to the fluorescence of the acceptor 9FL and there is a high probability this might result from the $S_1^D \rightarrow S_1^A$ energy transfer process. The absence of this long wavelength band in the other two solvents (NH and EtOH), might be due to the non-fluorescent character of 9FL in these solvents. It seems the energy transfer might be of Förster type (dipole-dipole interaction) as this process generally sensitizes the acceptor fluorescence which was actually observed from the present steady state measurements. Fluorescence decay analysis of this band system was made by TCSPC technique monitoring at 508 nm wavelength. The value of fluorescence lifetime (τ) was found to be very similar to that of the acceptor 9FL (~14.6 ns). This observation corroborates our propositions, made from steady state measurements, that the long wavelength 500 nm band observed in the fluorescence emission spectra of THQ in presence of 9FL might be due to the fluorescence emission of 9FL resulting from the Förster type energy transfer process within the lowest excited singlet states (S_1) of the donor THQ and the lower lying corresponding level of the acceptor 9FL. Moreover the fluorescence excitation spectra of the mixture of THQ and 9FL in ACN corresponds to the absorption spectra of the same mixture (Fig. 2*b*). Thus from the comparison of the above two spectra the occurrence of Förster's energy transfer from the electronically excited THQ to 9FL is further confirmed. In the case of the other acceptor 2N9FL, such spectral argument in favor of occurrence of energy transfer is lacking possibly due to non-fluorescence behavior of this acceptor. However, it should be pointed out that in the present investigation the donor THQ chromophore was excited selectively at around 320 nm whereas the present acceptors, due to the low concentrations (~10^{-5} or 10^{-6} mol dm^{-3}) used in the present investigation, possess negligible absorbance (Fig. 1). In this way the competitive absorption by the acceptor 9FL (or 2N9FL) and its filtering effect on the donor emitted light were avoided. Furthermore as it has been discussed in Section 1, the ground state complex which might be responsible for the fluorescence quenching is also absent in the present case. Moreover an attempt was made to record fluorescence spectra of only 9FL in ACN solvent (choosing the same concentrations as were used in studying fluorescence quenching of the donor THQ

[a]The * denotes the excited singlet state S_1.

as shown above) by using 320 nm as an excitation wavelength. As expected, no 9FL fluorescence emission was observed. This indicates that the possibility of direct excitation of the acceptor 9FL when an excitation energy of 320 nm is used to excite the donor moiety is very slim.

Thus one of the processes responsible for nonradiative deactivation of the lowest excited singlet state S_1 of THQ in presence of the quenchers (electron acceptor) 9FL and 2N9FL in solvents of different polarities seems to be a Förster-type energy transfer process. However, THQ was found earlier (14, 27) to be a good electron donor and 9FL and 2N9FL are well known for their good electron accepting abilities (16, 28). Thus the possibility of the occurrence of photoinduced electron transfer (ET) reaction as a concurrent process with energy transfer within the present reacting systems could not be ruled out. Apart from these two basic quenching reactions several other nonradiative processes might also be responsible for the observed THQ fluorescence quenching, e.g., static or instantaneous (similar to static) quenching processes. Systematic studies were made on the present donor and acceptor molecules to reveal the mechanism of nonradiative processes involved within these reacting systems. The results obtained from the study have been described in details in the following sections.

(A1) Possibility of occurrence of photoinduced ET reactions within the present donor-acceptor systems

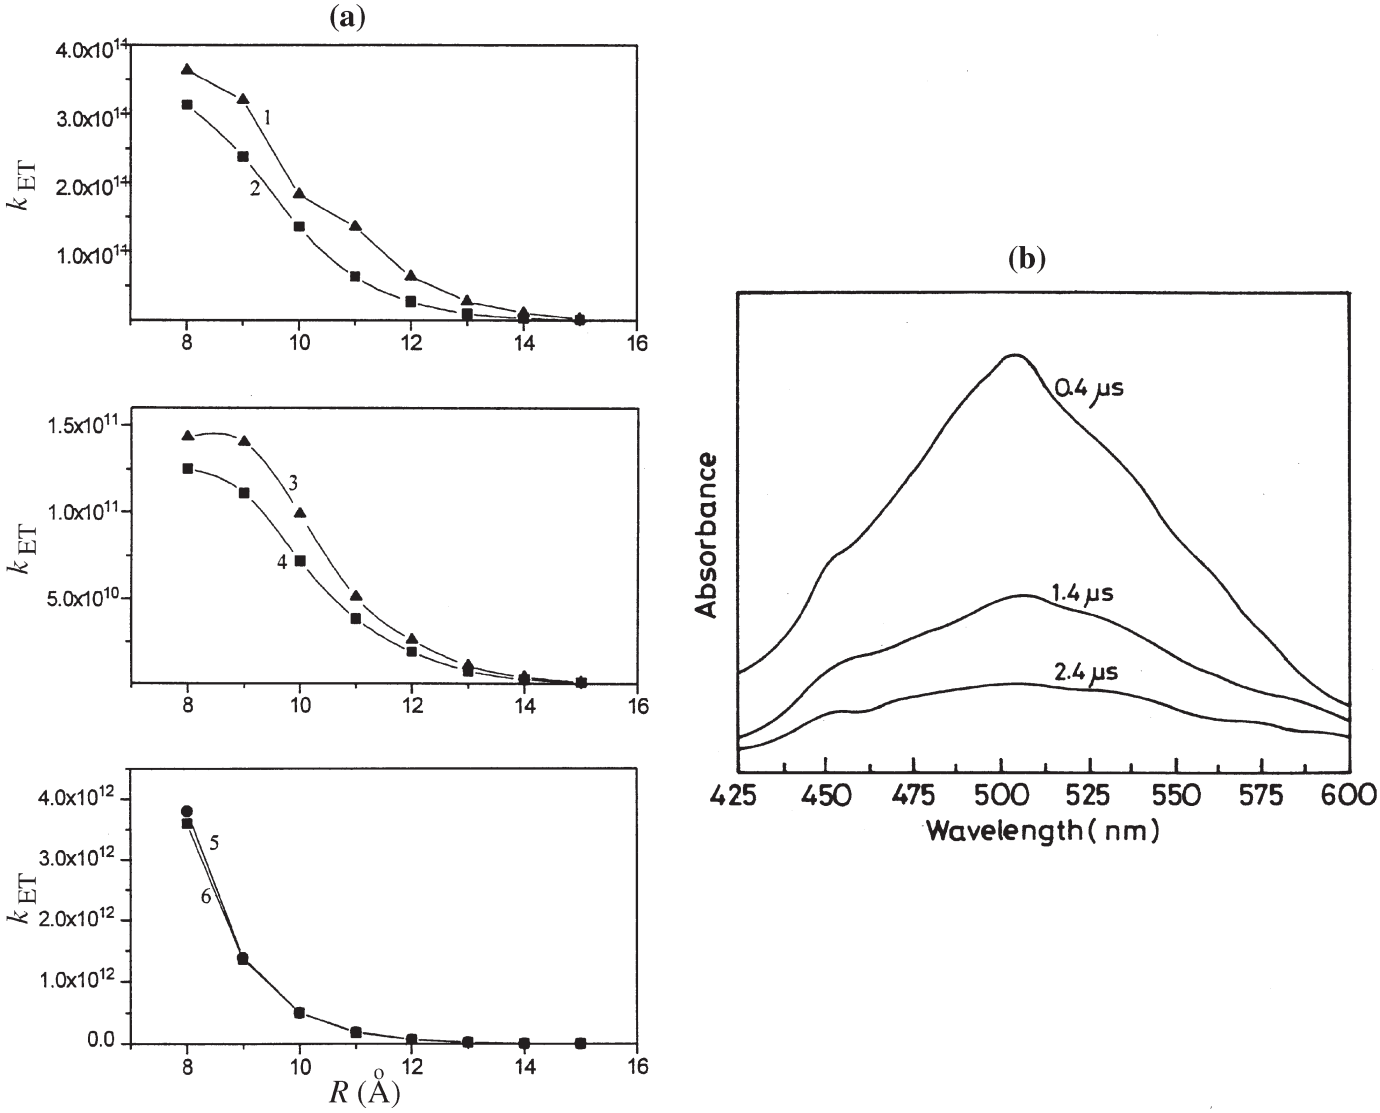
The half wave oxidation and reduction potentials of the donor THQ and the acceptor 9FL (or 2N9FL), denoted by $E^{OX}_{1/2}(D/D^+)$ and $E^{RED}_{1/2}$ (A^-/A) respectively, were measured in ACN environment by electrochemical techniques (see experimental section).

Using the Rehm–Weller relationship [1] the free energy change, ΔG^0, associated with radical ion pair formation could be computed from (21, 29)

$$[1] \qquad \Delta G^0 = E^{OX}_{1/2}(D/D^+) - E^{RED}_{1/2}(A^-/A) - E^{*}_{0,0} - C$$

Where $C = e^2/(4\pi\varepsilon_0\varepsilon_s R)$ is the Coulomb stabilization term which measures the gain in free energy due to stabilization of the ion pair compared to the free ions due to the proximity of the oppositely charged ions. $E^{*}_{0,0}$ is the (0,0) level of the lowest lying excited electronic singlet state (S_1) of the donor. ε_s is the static dielectric constant of the solvent. R is the distance of separation of the redox sites.

In highly polar ACN, ΔG^0 was estimated for the present donor-acceptor systems using the measured redox potential values. The Coulomb term was neglected in the calculations as its contribution in the highly polar ACN is very small (~ 0.06 eV) (16). The ΔG^0 values are listed in Table 1 where it can be seen that the ET reaction in ACN is highly exergonic ($\Delta G^0 < 0$) and hence energetically favorable when an excited donor reacts with ground state acceptors (9FL or 2N9FL). Positive values of ΔG^0, as found in the cases of the unexcited reactants (Table 1), clearly demonstrate the lack of occurrence of ET in the ground state. Moreover, when an excited acceptor chromophore undergoes an ET reaction with the ground state donor THQ, large negative ΔG^0 values (Table 1), though relatively smaller in magnitude than the corresponding values observed in the cases of D*–A pair, indicate the possibility of ET reactions even when the acceptor is excited.



Because it is not possible to measure the redox potentials in the nonpolar NH and polar protic EtOH solvents, we estimated the ΔG^0 values in these solvents by considering the solvation energies in these media (30). However, in the two solvents the coulomb term is not negligible. In nonpolar NH solvent, the coulomb term we kept fixed at 0.2 eV as suggested by Weller (31) and in the case of EtOH we fixed it as 0.1 eV (32). The solvation energy ΔG^0_s was computed by using the relation [2] of Kavarnos and Turro (30)

$$[2] \qquad \Delta G^0_s = -\frac{e^2}{2}\left(\frac{1}{r_D} + \frac{1}{r_A}\right)\left(1 - \frac{1}{\varepsilon_s}\right)$$

From the values of ΔG^0 of the present D–A systems shown in Table 1, it is apparent that both in ACN and EtOH, the highly exothermic (large negative ΔG^0, $\Delta G^0 < 0$) ET reaction might occur within the present D*–A and D–A* systems (* denotes the first excited singlet state) whereas in nonpolar NH relatively much lower exothermicity ($\Delta G^0 \approx -0.24$ eV for THQ*–9FL and –0.18 eV for THQ*–2N9FL, (Table 1)) was observed. When the acceptors are excited, the possibility of occurrence of photoinduced ET reactions in this nonpolar environment appears to be slim from the thermodynamical point of view, as ΔG^0 acquires very low positive values, +0.13 and +0.19 eV in case of THQ–9FL* and THQ–2N9FL* systems respectively (Table 1). This region is known as endothermic region.

Fig. 3. (*a*) Variations of first order electron transfer rate constant (k_{ET}) with the distance of separation (R (Å)) between the present D and A molecules, where ΔG^0 in eV in (1) –1.72 in THQ* + 2N9FL + ACN, (2) –1.78 in THQ* + 9FL + ACN, (3) –1.77 in THQ* + 2N9FL + EtOH, (4) –1.83 in THQ* + 9FL + EtOH, (5) –0.18 in THQ*+ 2N9FL + NH, and (6) –0.24 in THQ* + 9FL + NH; (*b*) Transient absorption spectra of 9FL (excitation wavelength ~355 nm) (third harmonic of Nd:YAG laser system), obtained by laser flash photolysis techniques, in ACN at the ambient temperature in presence of the donor THQ at the different delay times. The delay times are shown on the graph.

We computed Marcus first order electron transfer rates k_{ET}, for the present D–A systems in different solvents by using the relation [3] as shown below.

$$[3] \qquad k_{ET} = \frac{2\pi}{\hbar} \frac{J^2}{\sqrt{4\pi k_B T \lambda}} \exp\left[-\frac{(\Delta G^0 + \lambda)^2}{4 k_B T \lambda}\right]$$

J is the transfer integral and λ is the reorganization energy parameter. J depends exponentially on the separation (between donor and acceptor) distance R through the expression

$$[3a] \qquad J^2 = J_0^2 \exp\left[-\beta\,(R - (r_D + r_A))\right]$$

J_0 denotes the transfer integral at $R = r_D + r_A$.

β is the attenuation coefficient with R.

The distance dependence of k_{ET} is computed from the relation [3] by assuming $J_0 = 100$ cm^{-1} and $\beta = 1$ Å^{-1} as proposed by Tachiya and Murata (24) and the variation is shown in Fig. 3*a*. It appears that in non-polar *n*-heptane (NH), k_{ET} is maximum at the encounter distance and decreases very fast with increase of separation distance between D and A. Thus it is logical to presume that at the

[e]Computed from τ_0/τ versus [Q] plots.

contact distance ($r_D + r_A$) the probability of occurrence of ET reactions is maximum in non-polar NH.

In other two solvents ACN and EtOH, the rate was found to diminish slowly (Fig. 3) with increase of *R*, though the maximum value of k_{ET} was found at the encounter distance as it was observed in the case of non-polar environment.

Thus the value of reaction radius remains nearly the same (~8 Å) within the present reacting systems in solvents of different polarities used in the present investigation though the exothermicity of the ET reactions increases largely with the change of the environment from non-polar NH (~ –0.2 eV) to highly polar ACN (–1.78 eV) as it was shown above. As the magnitudes of the measured ΔG^0 values of all the present donor–acceptor systems in polar solvents (ACN and EtOH) are very close to each other (Table 2), the effect of ΔG^0 on the k_{ET} values, to show the energy gap dependence of Marcus inverted behavior, is not very clear. However inverted behavior was apparent from the observed values of λ, nuclear reorganization energy parameter, which was estimated from the relation [3*b*] shown below.

The total reorganization energy λ consists of two parts, λ_I and λ_S. The former is the contribution coming from intermolecular bond length changes and the latter one is the solvent reorganization energy (given by the expression [3*b*]) which was computed by using the dielectric continuum model as proposed by Marcus (8, 16),

$$[3b] \qquad \lambda_s = \frac{e^2}{4\pi\varepsilon_0}\left(\frac{1}{2r_D}+\frac{1}{2r_A}-\frac{1}{R}\right)\left(\frac{1}{\varepsilon_{op}}-\frac{1}{\varepsilon_S}\right)$$

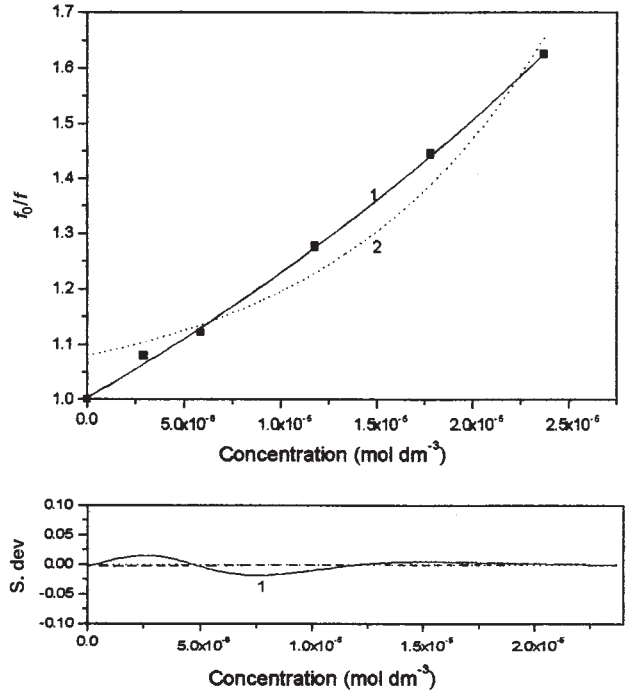
where the meanings of the symbols are given elsewhere (16).

The radii of the oxidized donor (r_D) and the reduced acceptor (r_A) have been computed from the molecular volume of the neutral molecules (8).

We have chosen a fixed value of λ_I (= 0.3 eV) which is the characteristic value of organic donor and acceptor systems. The values of λ are shown in Table 2. In the present systems of donor and acceptor, λ values are found to be lower than $-\Delta G^0$ (Table 2) ($-\Delta G^0 > \lambda$) in polar environments (ACN and EtOH) which indicates the presence of Marcus inverted region. However, this phenomenon is very rare for intermolecular systems and so for conclusive evidence more investigations should be carried out with similar other donor–acceptor systems which possess different ΔG^0 values.

However, from the observed rate constant (k_{ET}) values (Table 2) it seemingly indicates that the electron accepting power of both the acceptors studied in the present investigation is nearly the same. Almost the same reduction potential values, obtained from the electrochemical measurements, of the two acceptors (Table 1) further corroborate our presumption.

For the direct evidence of the occurrences of photoinduced ET reactions the transient absorption spectra of the acceptor in presence of the donor THQ was measured by flash photolysis techniques. The results are described below.



(A1.1) Transient absorption spectra

Pulsed laser excitation was performed at a wavelength of 355 nm with the help of a Nd:YAG laser system in order to excite only the acceptor moiety from the mixture of the donor THQ and the acceptor in ACN solvent. This excitation produced a transient species which absorbed at nearly 510 nm, along with a shoulder at around 450 nm region (Fig. 3*b*). Following the observations made earlier (16) the shoulder at 450 nm was assigned to the triplet-triplet absorption band of 9FL having lifetimes in the microsecond time scale. However we measured the transient absorption spectra of the fluorenone acceptors (9FL and 2N9FL) in ACN environment. The absorption band at about the same energy position (~450 nm) was found.

With an increase of the delay times between the exciting and analyzing pulses (Fig. 3*b*) the 510 nm band was observed to diminish very quickly relative to the 450 nm shoul-

Fig. 4. Plot of f_0/f versus [Q] for THQ donor and acceptor 9FL in EtOH solvent at the ambient temperature. The non-linear least square curve fitting procedure was used to treat the data according to the following models. (1) f_0/f = (exp (V[Q])) (1 + K_{SV}[Q])l' (both static and dynamic contributions are present, see text); the very nice fitting curve ($\chi^2 \approx 1.0$) is obtained (shown in the solid line); the standard deviation data was also shown. (2) f_0/f = exp (V[Q]) (only static part present) very poor fitting is obtained (shown by dotted line).

der. This shows the two different species should be responsible for these two bands. The band at 510 nm could be assigned to the band of contact ion-pair (CIP) of 9FL (or 2N9FL) radical anion according to what is known on the flash photolysis of fluorenone in ACN (33).

In comparing the magnitudes of the intensity ratio I_{450}/I_{510} at the different delay times, it can be seen that this ratio increases from 0.50 to 0.54 to 0.63 as the delay time increases from 0.4 to 1.4 to 2.4 μs (Fig.3*b*). It appears that the build up of monomeric triplet of 9FL (or 2N9FL) occurs in the same time interval during which the radical anionic species of it disappears. This might be due to the production of triplet of the fluorenone acceptor by the ion recombination mechanism.

The observations of transient absorption bands of ion-pair were in accord to our expectation as the large negative ΔG^0 values of the present D–A systems were found from the electrochemical measurements.

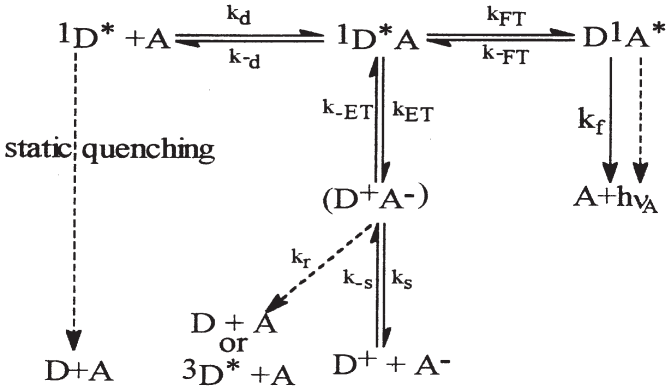
(A2) Possibility of occurrence of energy transfer

The existence of partial overlapping between the fluorescence emission spectra of the donor and the electronic absorption of the acceptors (9FL or 2N9FL) further confirms our proposition, as described in Section 2A, about the occurrence of nonradiative (Förster's type) energy transfer processes, along with photoinduced ET.

The rate constants, k_{FT}, associated with the nonradiative energy transfer process were computed by using the well known relation (8) and are listed in Table 2. For a particular donor–acceptor system k_{FT} values were found to remain nearly unchanged with the polarity of the environment (Table 2). These observations were in accord with our expectation for the Förster type energy transfer processes occurring within the present D*–A systems. It is relevant to point out that the contribution of the Dexter's exchange mechanism within the present reacting systems appears to be low in energy transfer process due to large Förster's critical transfer distance R_0 values (13–23 Å) though the values of $R$was chosen as 8 Å.

From a comparative study of the two rate constants k_{ET} and k_{FT} (Table 2) it could be seen that in the cases of all the donor-acceptor systems studied in the present investigation $k_{ET} > k_{FT}$. Thus in nonradiative transitions ET process plays a dominant role though as an associated process energy transfer is also present concurrently. This observation was made irrespective of the polarity of the environment.

(A3) Possibility of occurrence of static quenching process



To examine the possibility of the presence of static quenching phenomena, apart from energy transfer and ET processes, Stern–Volmer (SV) plot of intensity variation as a function of quencher concentration was drawn for the D*–A pairs. By plotting f_0/f versus [Q], the upward curvature (Fig. 4) was found in each case except the system THQ*–9FL (* denotes the excited state S_1) in ACN where linear plot was observed. The positive deviations from the linearity indicate the possibility of the presence of static quenching. In case of THQ* + 9FL + ACN system the linear plot indicates that the dynamic quenching might be active in this system. To substantiate the fact another SV relation $\tau_0/\tau = 1 + K_{SV}[Q] = 1 + k_q\tau\,[Q]$ was plotted by using fluorescence lifetimes of the donor without and in presence of quencher (acceptor). As shown in the Table 2, no significant changes occur in the values of K_{SV} and k_q evaluating from intensity as well as lifetime plots, thus $f_0/f = \tau_0/\tau$. This observation shows that only dynamic quenching is operative within this D–A system. However, in the rest of the donor-acceptor systems, static quenching seems to play major role. In these systems the fluorescence lifetime of THQ remains more or less unaffected in presence of the acceptor, which suggests in favor of static quenching. However, electrochemical and transient absorption measurements indicate the possibility of the presence of dynamic quenching reactions also within the present reacting systems. Unaffected τ values of the donor THQ in presence of the acceptors might be due to the fact that large static effect may overwhelm the dynamic processes. Nevertheless, an attempt was made to dissect the static and dynamic quenching modes separately by using a model which is the modified form of SV relation. The modified relation is shown below:

$$[4] \qquad \frac{f_0}{f} = \exp(V[Q])(1 + K_{SV}[Q])l'$$

where V is the static parameter and $l' = 1 + K$[Q], where K is the equilibrium constant for the formation of ground state complex. V could provide us the information about the local distribution of the quencher around a fluorescer. Using non-

Scheme 1.

linear least square curve fitting procedure the data were treated according to eq. [4] and a nice fitted curve ($\chi 2$ = 1.01) (Fig. 4) was obtained. The values of V, K_{SV} and l' are obtained separately and presented in Table 2. As the values of K_{SV} were found to be small, it seems that the dynamic quenching though present has a minor role in quenching mechanism whereas large values (>500 dm^{-3} mol^{-1}) of V indicates the static component is so dominating over dynamic processes that the upward curvature of SV plot was obtained as a resulting effect. These observations are in accord to our speculations as discussed above. Thus, it could be presumed that within all the present systems of donor and acceptor studied (except THQ* + 9FL in ACN) at least three processes are involved in fluorescence quenching mechanism of THQ which are: static effect, energy transfer (Förster's type) and ET processes.

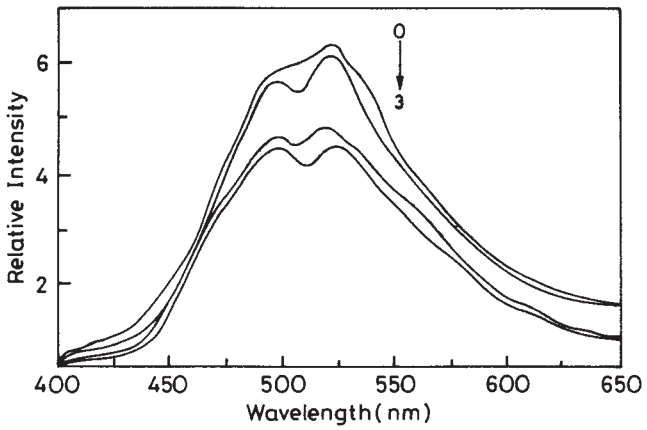
The values of K_{SV}, k_q and l' are listed in Table 2. As expected, l' values were found to be nearly one because this shows K = 0. As no ground state CT complex was visible in the electronic absorption spectra of the mixture of donor and acceptor in a solvent, it might be logical to presume that no such complex is formed. Scheme 1 depicts the photophysical processes within the present donor-acceptor systems when donor is excited at the ambient temperature.

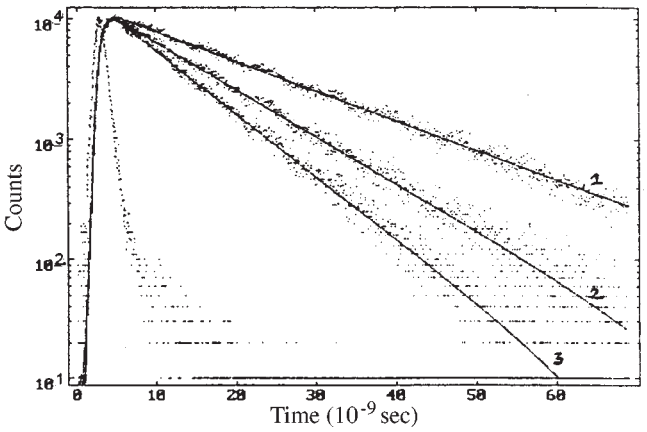
Neglecting the dynamic part in the expression [4] we used another model f_0/f = exp (V[Q]) in which only static part is present. However this model exhibits very poor fitted curve (shown by dotted lines in Fig. 4). This indicates that to examine the fluorescence quenching data of the donor THQ in presence of the acceptor 9FL (or 2N9FL) the model expressed by the eq. [4], where both static and dynamic contributions are included, should be more appropriate.

(B) When the acceptor is excited to its S_1 *state*

The situation became simpler when the acceptor, instead of donor, was excited to its lowest excited singlet state in presence of the unexcited donor. As it could be seen from the Fig. 5, the excitation wavelength was chosen at 378 nm for exciting the fluorescence emission of 9FL. At this wavelength there is no absorption of the donor molecules, so the donor filtering effect on the acceptor emission will not be present. Moreover due to higher lying electronic excited singlet level S_1 of the donor THQ molecule, energy transfer from S_1 of the acceptor to this level is forbidden. With increase of donor concentration, the fluorescence emission of the acceptor 9FL was found to be reduced regularly without any noticeable spectral shift (Fig. 5). The reduction of 9FL fluorescence by the donor THQ obeys simple SV relation as evidenced from linear SV plot. Further the fluorescence lifetime (τ) of 9FL also decreases with increase of the concentration of THQ (Fig. 6).

Fig. 5. Fluorescence emission spectra of 9FL (λ_{exc} = 378 nm) in ACN solvent of concentration (1.66 × 10^{-4} mol dm^{-3}) at 300 K in presence of THQ whose concentrations (mol dm^{-3}) were: (0) 0, (1) 2.5 × 10^{-5}, (2) 1.25 × 10^{-4}, (3) 2.5 × 10^{-4}.





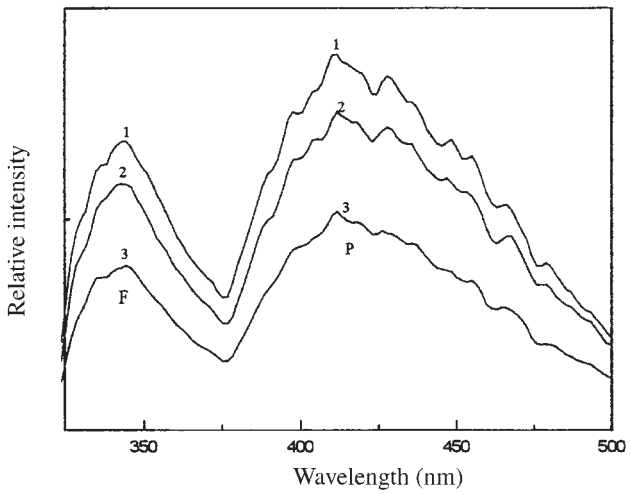


Fig. 6. Fluorescence decay curves (λ_{exc} = 378 nm, λ_{em} = 500 nm).associated with the lamp profile showing the single exponential decay of 9FL (3.61 × 10^{-4} mol dm^{-3}) in ACN in presence of THQ whose concentrations in mol dm^{-3} were: (1) 0, (2) 8.75 × 10^{-5}, and (3) 1.5 × 10^{-4} at room temperature. Their χ^2 values varied within 1.1 to 1.2 of each other.

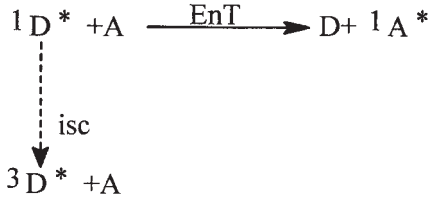
Using two types of SV relations (from fluorescence intensity and fluorescence lifetime) K_{SV} and k_q were computed (Table 2). These quantities are found to be nearly the same (Table 2) and the relation $f_0/f \approx \tau_0/\tau$ holds. All these observations strongly suggest that when the acceptor moiety is excited, the quenching is of dynamic nature unlike the situation when the donor chromophore is excited where both static and dynamic type quenching might participate. Moreover, k_q for 9FL* + THQ system in ACN was found to be of the order of 10^{10} dm^3 mol^{-1} s^{-1} which is the upper limit (diffusion controlled limit) of the rate of photoinduced ET reaction. Thus it seems when excited acceptor reacts with

© 2000 NRC Canada

Fig. 7. Emission spectra of THQ donor (λ_{exc} = 320 nm) in EtOH rigid glassy matrix of concentration 2.5 × 10^{-5} mol dm^{-3} at 77 K in the presence of acceptor 9FL whose concentrations (mol dm^{-3}) were: (1) 0, (2) 2.25 × 10^{-5}, (3) 8.8 × 10^{-5}. F: fluorescence; P: phosphorescence.



ground state donor, mainly ET process becomes operative. However, the similar experiment as above was not possible with the other acceptor 2N9FL due to lack of its fluorescence emission. The large negative ΔG^0 value (~ –1.41 eV) for 9FL* + THQ system, as shown in Table 1, substantiates the fact that the possibility of occurrence of ET within this system is high.

It is observed from the above findings that when the acceptor 9FL is excited in presence of the donor THQ molecule, the fluorescence quenching of the former species is observed to be of dynamic nature. 9FL quenching does not show any noticeable positive deviation in an SV plot. Following the observations made earlier by Eftink and Ghiron (12) it could be inferred that as 9FL is longer-lived species (longer fluorescence lifetime than THQ, Table 2) its fluorescence quenching by THQ may be ascribed due to the presence of dominating dynamic (collisional) processes. As it was observed in the case of acrylmide quenching of some longer-lived fluorescent molecules (12), in the quenching mechanism of 9FL fluorescence also it is possible that the dynamic component is so overwhelming (large K_{SV}) over the static one that the SV plots simply appears to be linear. However, the probable cause of the absence of static contribution in the quenching of fluorescence emission of THQ by 9FL is not comprehensible at the present stage of investigation. Further studies considering several other donor and acceptor systems might be helpful to understand this phenomena. Investigations in this direction are now underway.

3. Fate of the non-radiative processes due to lowering of temperature down to 77 K

At 77 K in EtOH rigid glassy matrix both the fluorescence and phosphorescence of THQ (λ_{exc} ~ 320 nm) gradually diminish with the increase of concentration of 9FL (or 2N9FL) (Fig. 7). ET, being a thermally activated process, seems to have less effect on fluorescence and phosphorescence emission quenching. However, it appears that another nonradiative channel energy transfer process of Förster's

Scheme 2.

type might be responsible for observed quenching at 77 K. Nearly same R_0 (≈26 Å) values, as observed at the ambient temperature, were obtained at this low temperature. Moreover, f_0/f versus [Q] plots clearly show positive deviation from linearity which seems to indicate that at 77 K, like the situation observed at the ambient temperature, static quenching is also present along with energy transfer and might be jointly responsible for nonradiative depletion of the donor's lowest excited singlet state. As ACN does not form glass, the above experiment was not possible with this solvent.

The quenching observed in the phosphorescence band intensity of a THQ donor in presence of acceptor 9FL (or 2N9FL) may not be due to triplet-triplet energy transfer process because of the large R_0 (~26 Å) value. This transfer requires the reactants to approach closer than 26 Å. One plausible explanation may be that with the increase of acceptor concentration, energy transfer (Förster) efficiency will be increased because more and more donor molecules will be involved in transferring their excitation energy to the singlet (S_1) of acceptors. Consequently the triplet of the donor, which is formed by isc process (another path for nonradiative depletion of donor lowest excited singlet), would be less populated resulting in the decreasing quantum yield of the phosphorescence of the donor. In Scheme 2, the possible non-radiative processes at 77 K within the present reacting systems are shown.

Another interesting finding is that the phosphorescence lifetime (τ_p) of the donor THQ (~3.4 s) was reduced considerably (~1.1 s) in presence of the acceptor 9FL (1.76 × 10^{-4} mol dm^{-3}). This indicates that the lifetime reduction was not only due to less population in the triplet level of the donor, as discussed above, but also because there is a possibility of the occurrence of ET reactions between the triplet state of the donor and ground state acceptor. This might cause noticeable reduction in the triplet lifetime of the former species. In favor of such a proposition the exothermicity of such reactions will be lowered by the difference between the first excited singlet and triplet states of the donor, but from the thermodynamic point of view there is a possibility of occurrence of ET reactions between the triplet donor THQ and the unexcited acceptor 9FL as the value of ΔG^0 is still negative, ~ –1.14 eV (Table 1) which is obtained from the relation (34–37)

$$\Delta G^0_{TET}(EtOH) = \Delta G^0_{SET}(EtOH) + \Delta E_{S_1-T_1}$$

$$\Delta G^0_{SET}(EtOH) = \Delta G^0_{SET}(ACN) + \Delta G^0_d$$

where,

$$\Delta G^0_d = \frac{e^2}{\varepsilon_S}\left(\frac{1}{2r_D} + \frac{1}{2r_A} - \frac{1}{R}\right) - \frac{e^2}{\varepsilon_{S'}}\left[\frac{1}{2r_D} + \frac{1}{2r_A}\right]$$

© 2000 NRC Canada

ΔG_d^0 is the ion pair destabilization energy due to the decrease in the polarity of the environment from ACN fluid solution at 296 K to EtOH glass at 77 K.

Similar quenching phenomena, both in phosphorescence intensity and the triplet lifetime of the donor THQ, were also observed in the presence of the other quencher 2N9FL. The ΔG^0 for this system was found to be around –1.08 eV. Thus at 77 K the triplet THQ seems to also be involved in ET reactions with this acceptor.

The above steady state and time resolved studies using TCSPC and flash photolysis methods at both the ambient temperature and at 77 K demonstrate the occurrences of photoinduced ET reactions along with several other nonradiative processes in the present reacting systems in solvents of different polarities, especially in those cases when one of the reactants is in the electronic excited state.

Concluding remarks

Steady state electronic absorption spectra observed at the ambient temperature do not exhibit any ground state CT complex between THQ and 9FL/2N9FL, irrespective of the polarity of the environment.

The large fluorescence quenching of the donor THQ molecule observed at the room temperature, in presence of the acceptors 9FL or 2N9FL, seemed to be due to the combined effect of static and dynamic processes involved in which the contribution of the former in the overall quenching mechanism appears to be significantly large. However, relatively weaker dynamic quenching processes, such as photoinduced ET and energy transfer (Förster mechanism) seemed to also be operative within the present reacting systems. Within these systems (D*–A) highly exothermic (large negative ΔG^0) ET reactions were observed both in the polar protic EtOH and aprotic ACN solvents. Conclusive evidence for the occurrence of inverted behavior in ET reactions was not observed due to the closer values of ΔG^0 in the present D–A systems. When the acceptor moiety was excited in presence of ground state THQ, the quenching was found to be primarily due to ET in ACN solvent. Observations of the transient absorption spectra of contact ion-pair of the acceptor radical anion provide us the direct evidence of occurrence of photoinduced ET reactions within the donor THQ and the acceptor 9FL or 2N9FL in ACN solvent. At 77 K, the combined effect of Förster type energy transfer and static quenching appears to be responsible for donor fluorescence quenching. The possibility of ET reactions between the triplet donor and ground state acceptor is hinted from the observed shortening of the donor phosphorescence lifetime (τ_p), and negative ΔG^0 values (<0).

Thermodynamic properties of aqueous diethanolamine (DEA), *N*,*N*-dimethylethanolamine (DMEA), and their chloride salts: apparent molar heat capacities and volumes at temperatures from 283.15 to 328.15 K

Christopher Collins, Joelle Tobin, Dmitri Shvedov, Rom Palepu, and Peter R. Tremaine

Abstract: Apparent molar heat capacities $C_{p,\phi}$ and apparent molar volumes V_ϕ for aqueous diethanolamine $(HOC_2H_4)_2NH$, diethanolammonium chloride $(HOC_2H_4)_2NH_2Cl$, *N*,*N*′-dimethylethanolamine $(HOC_2H_4)(CH_3)_2N$, and *N*,*N*′-dimethylethanolammonium chloride $(HOC_2H_4)(CH_3)_2NHCl$ were determined from 283.15 to 328.15 K with a Picker flow microcalorimeter and vibrating tube densimeter. The experimental results have been analyzed in terms of Young's Rule with the Guggenheim form of the extended Debye–Hückel equation and appropriate corrections for chemical relaxation effects. These calculations lead to standard partial molar heat capacities and volumes for the neutral amines, $(HOC_2H_4)_2NH(aq)$ and $(HOC_2H_4)(CH_3)_2N(aq)$, and the ions $(HOC_2H_4)_2NH_2^+(aq)$ and $(HOC_2H_4)(CH_3)_2NH^+(aq)$ over the experimental temperature range.

Key words: standard partial molar volumes, standard partial molar heat capacities, diethanolamine, dimethyethanolamine, aqueous alkanolamine ionization.

Résumé : Faisant appel à un microcalorimètre à écoulement de Picker et à un densimètre à tube vibrant, on a déterminé les capacités calorifiques molaires apparentes, $C_{p,\phi}$, ainsi que les volumes molaires apparents, V_ϕ, de solutions aqueuses de diéthanolamine, $(HOC_2H_4)_2NH$, de chlorure de diéthanolammonium, $(HOC_2H_4)_2NH_2Cl$, de *N*,*N*′-diméthyléthanolamine, $(HOC_2H_4)(CH_3)_2NH$, et de chlorure de *N*,*N*′-diméthyléthanolammonium, $(HOC_2H_4)(CH_3)_2NH_2Cl$. Les résultats expérimentaux ont été analysés en fonction de la règle d'Young en utilisant la forme de Guggenheim de l'équation élargie de Debye–Hückel, en y apportant les corrections appropriées pour les effets de relaxation chimique. Ces calculs ont permis de déduire les capacités calorifiques et les volumes molaires partiels standards des amines neutres, $(HOC_2H_4)_2NH(aq)$ et $(HOC_2H_4)(CH_3)_2NH(aq)$ et de leurs ions $(HOC_2H_4)_2NH_2^+(aq)$, $(HOC_2H_4)(CH_3)_2NH_2^+(aq)$ sur toute la plage des températures expérimentales.

Mots clés : volumes molaires partiels standards, capacités calorifiques molaires partielles standards, diéthanolamine, diméthyléthanolamine, ionisation aqueuse d'alcanolamines.

Introduction

Aqueous alkanolamines are employed in industry for the removal of acidic components from natural and refinery gas streams, and as pH control agents in the steam generators of nuclear and thermal power stations. Thermodynamic properties of these species are needed to model speciation and vapour–liquid equilibria, and to develop predictive models for their behaviour at elevated temperatures and pressures. Diethanolamine (DEA) is important in the context of natural gas processing because it can be used when there is a significant quantity of carbonyl sulfide in the gas stream without forming irreversible reaction products. *N*,*N*′-Dimethylethanolamine (DMEA) is an example of a tertiary

alkanolamine used in gas processing applications to avoid the formation of aqueous carbamates. DMEA has also been considered as a candidate amine for use in the boilers of nuclear and thermal electric power stations as a pH additive.

Jones and Arnett (1) have reviewed the literature on DEA, DMEA, and other aqueous amines before 1974. More recent work in several laboratories has determined new values for the ionization constants (2, 3), enthalpies of ionization (2), viscosities (4), densities (4–6), and surface tension (4) of aqueous diethanolamine. Maham et al. (7) have measured the heat capacity of liquid DEA and DMEA over a range of temperatures.

Partial molar heat capacities and volumes of aqueous alkanolamines in their neutral and ionized forms are important parameters because they define the temperature and pressure dependance of the ionization constant, enthalpy of ionization and activity coefficients, respectively. Volumetric data leading to the standard partial molar volumes of DEA and DMEA have been reported by Maham et al. (5) and Zhang et al. (6) respectively. However, no measurements of the apparent molar heat capacities of aqueous DEA and its salts have been reported in the literature. Cobble and Turner (8) have determined apparent molar heat capacities for DMEA(aq) and its chloride salt at 298.15 K. No temperature-dependant studies have been reported.

Recently, our laboratories have undertaken a systematic program to determine pressure- and temperature-dependant thermodynamic properties of aqueous amines relevant to the natural gas and electric power industries (8–10). In this paper we report apparent molar heat capacities and volumes for diethanolamine, *N*,*N*′-dimethylethanolamine, and their chloride salts, leading to standard partial molar heat capacities and volumes for the neutral amines, DEA(aq) and DMEA(aq), and the ions, $(HOC_2H_4)_2NH_2^+$(aq) ($DEAH^+$(aq)) and $(CH_3)_2(HOC_2H_4)NH^+$(aq) ($DMEAH^+$(aq)), over the temperature range 283.15–328.15 K.

Experimental

Diethanolamine and *N*,*N*′-dimethylethanolamine (Aldrich, analytical reagent grade, 99+%) from freshly opened bottles were used without further purification. A stock solution of each amine was prepared by mass and then standardized by titration with HCl. The results agreed to within 0.1 mol percent. Stock solutions of diethanolammonium chloride and *N*,*N*′-dimethylethanolammonium chloride were prepared by adding a weighed excess of standard HCl solution to the standard amine solutions. More dilute solutions were prepared from the stock by mass, using boiled, deionized water. Nanopure water (resistivity >17 $M\Omega\cdot cm^3$) was used to prepare all solutions. NaCl solutions were prepared by mass after first drying the salt for 24 h at 120°C. HCl solutions were prepared from a 15 mol kg^{-1} stock solution (Fischer A.C.S. certified reagent grade) and standardized by titration against TRIS (tris(hydroxymethyl)aminoethane; Aldrich, 99.9+ %).

A Sodev CP-C flow microcalorimeter (11) and a Sodev 03D vibrating flow densitometer (12) equipped with platinum cells were employed in this work. The temperatures of the calorimeter and densitometer were independently controlled to ±0.01 K by two Sodev CT-L circulating baths. The thermistors (Omega, 44 107) used to measure the temperatures of calorimeter and densitometer were calibrated with a Hewlett–Packard 2804A quartz-crystal thermometer traceable to NBS standards. The densitometer was calibrated daily with pure water (13) and standard 1 mol kg^{-1} NaCl(aq) solution. The experimental values of $(1 - (c_p\rho / c_{p,1}^*\rho_1^*))$ for the standard NaCl(aq) were compared with literature values complied by Archer (14) to correct for a small heat-leak effect, according to method of Desnoyers et al. (15). Heat-leak correction factors (±0.005) were 1.025, 1.018, 1.007, and 1.001 at T = 283.15 K, 298.15 K, 313.15K, and 328.15 K. Here, $c_p\rho$ and $c_{p,1}^*\rho_1^*$ are the products of specific heat capacity and density of the solution and H_2O(l), respectively.

Results and discussion

Apparent Molar Properties

The experimental values for the heat capacity ratios $(1 - (c_p\cdot\rho/c_{p,1}^*\cdot\rho_1^*))$ and relative densities $(\rho - \rho_1^*)$ for diethanolamine and diethanolammonium chloride are listed in Tables 1–4, while those for *N*,*N*′-dimethylethanolamine and *N*,*N*′-dimethylethanolammonium chloride are listed in Tables 5–8. The tables also tabulate the experimental apparent molar volumes $V_{\phi,2}^{exptl}$ and heat capacities $C_{p,\phi,2}^{exptl}$, which were calculated from these results using densities and specific heat capacities of pure water taken from Hill (13). By definition,

$$[1] \qquad Y_\phi = (Y(sln) - 55.509\cdot Y_1^*) / (m_2 + m_3)$$

where Y_1^* is the molar heat capacity or volume of pure H_2O(l), m_2 is the molality of DEA(aq) or $DEAH^+Cl^-$(aq), and m_3 is the molality of excess hydrochloric acid, if present. The effect of the small amount of excess HCl was subtracted by applying Young's rule according to the procedure used by Hovey et al. (16, 17). Briefly, the contribution of each solute can be described by the expression (18, 19):

$$[2] \qquad Y_\phi = (m_2 / (m_2 + m_3))Y_{\phi,2} + (m_3 / (m_2 + m_3))Y_{\phi,3} + \delta$$

Here, $Y_{\phi,2}$ and $Y_{\phi,3}$ are the values for the hypothetical solution of the pure components with speciation and ionic strength identical to the mixture; and δ is an excess mixing term, which usually may be ignored in calculating the properties of the major components where there is a common cation or anion. Both $C_{p,\phi,3}$ and $V_{\phi,3}$ were calculated as functions of ionic strength and temperature from the equations for HCl reported by Hershey et al. (20) and Tremaine et al. (21), respectively. The resulting values of $C_{p,\phi,2}$ and $V_{\phi,2}$ for diethanolammonium chloride are tabulated in Tables 3 and 4 and for *N*,*N*′-dimethylethanolammonium chloride in Tables 7 and 8.

The ionization constants reported by Jones and Arnett (1) indicate the formation of diethanolamine is negligible in the diethanolammonium chloride solutions over the temperature range and molalities used in this investigation, in part because of the presence of excess HCl. No similar excess of NaOH was used to suppress the ionization of neutral species in the diethanolamine solutions. Therefore, the resulting $C_{p,\phi}$ and V_ϕ values for diethanolamine must be corrected for the reaction:

[3] $(HOC_2H_4)_2NH(aq) + H_2O(l) \leftrightarrows (HOC_2H_4)_2NH_2^+(aq) + OH^-(aq)$

using Young's rule, (eq. [2]). The calculation for $C_{p,\phi,2}$ requires an additional term to account for the shift in the ionization constant caused by the temperature increment in the heat capacity measurement, $C_{p,\phi,2}^{rel}$, the "chemical relaxation" effect described by Mains et al. (22) and Woolly et al. (23), to yield the expression:

[4.1] $$C_{p,\phi}^{exptl} = (1 - \alpha)C_{p,\phi,2}[(HOC_2H_4)_2NH(aq)] + \alpha C_{p,\phi}((HOC_2H_4)_2NH_2Cl(aq)) + \alpha C_{p,\phi}(NaOH(aq)) - \alpha C_{p,\phi}(H_2O(l)) - \alpha C_{p,\phi}(NaCl(aq)) + C_{p,\phi,2}^{rel}$$

where

[4.2] $$C_{p,\phi,2}^{rel} = (\Delta_r \bar{H})^2\alpha(1 - \alpha) / (RT^2(2 - \alpha))$$

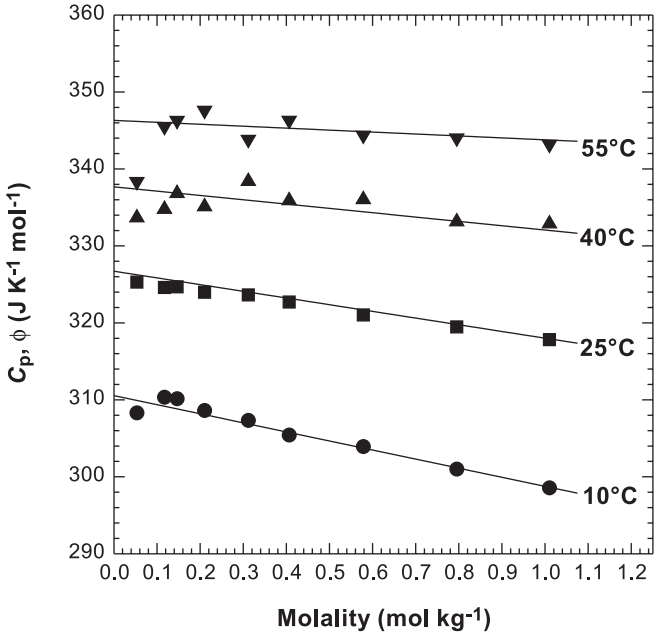
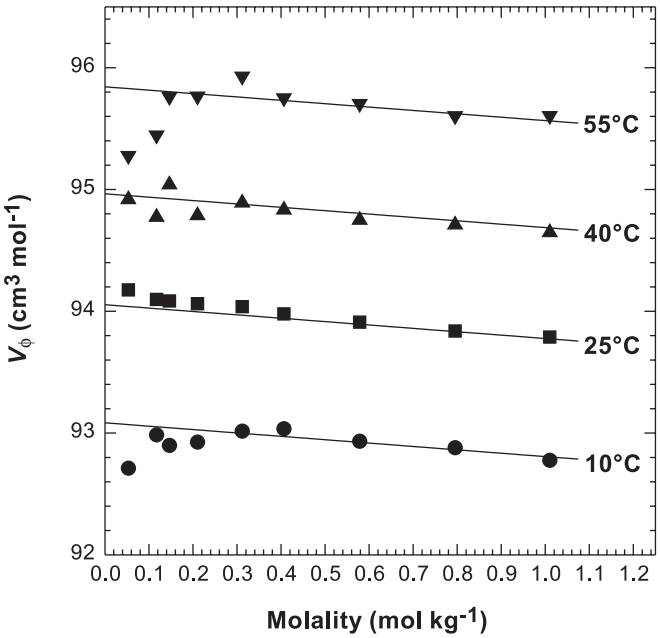
Fig. 1. The apparent molar heat capacities $C_{p,\phi,2}$ of diethanolamine from 283.15 to 328.15 K plotted as a function of molality. Symbols, experimental results; lines, global least-squares fit to eq. [7].





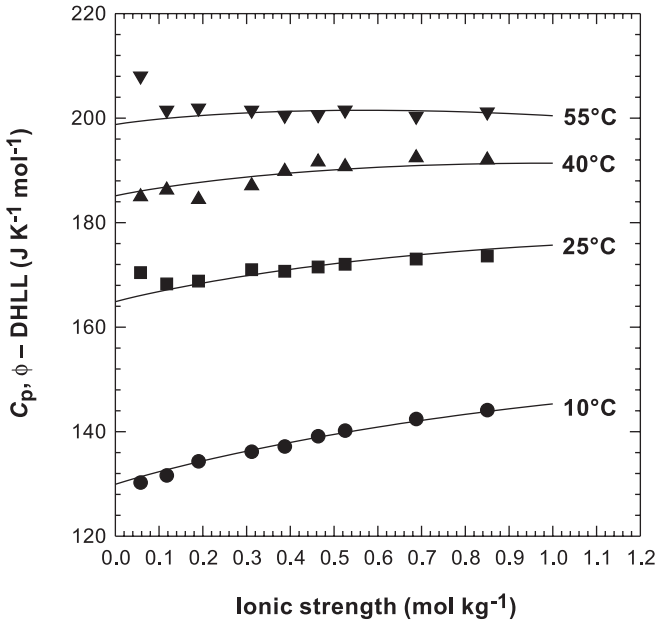


Fig. 2. The apparent molar volumes $V_{\phi,2}$ of diethanolamine from 283.15 to 328.15 K plotted as a function of molality. Symbols, experimental results; lines, global least-squares fit to eq. [8].

Here α is the fraction of stoichiometric $(HOC_2H_4)_2NH$ that is ionized and $\Delta_r\bar{H}$ represents the partial molar enthalpy of ionization of $(HOC_2H_4)_2NH$ at the molality and temperature of the $C_{p,\phi}^{exptl.}$ measurement. Eq. [4] is based on the generalized analysis by Mains et al. (22) for equilibria of the form AB ⇄ A + B. Because α is small under our experimental conditions, the partial molar properties of the minor species

Fig. 3. The apparent molar heat capacities $C_{p,\phi,2}$ of diethanolammonium chloride from 283.15 to 328.15 K plotted as a function of ionic strength I after subtracting the Debye–Hückel limiting law term. Symbols, experimental results; lines, least-squares global fit to eq. [11].

in eq. [4] were approximated by the values at infinite dilution, $Y_\phi \approx Y°$, $\Delta_r H \approx \Delta_r H°$. $\Delta_r H°$ at T = 298.15 K was taken from Jones and Arnett (1) and values for other temperatures were determined using $\Delta_r C_p^o$ at T = 298.15 K where:

$$[5]\quad \Delta_r C_p^o = C_p^o((HOC_2H_4)_2NH_2Cl(aq)) - C_p^o(Cl^-(aq)) + C_p^o(OH^-(aq)) - C_p^o((HOC_2H_4)_2NH(aq)) - C_p^o(H_2O(l))$$

$$[6]\quad \Delta_r H° = \Delta H°_{298.15} + \Delta_r C^o_{p,298.15}(T - 298.15)$$

For the purposes of this calculation $\Delta_r C_p^o$ was assumed constant over the temperature range. Values for $C_p^o((HOC_2H_4)_2NH(aq))$ and $C_p^o((HOC_2H_4)_2NH_2Cl(aq))$ were obtained from our own results. $C_p^o(H_2O(l))$ was taken from Jones and Arnett (1), and $C_p^o(Cl^-(aq))$ and $C_p^o(OH^-(aq))$ were obtained from values tabulated by Hovey et al. (17) The relaxation corrections $C_{p,\phi,2}^{rel}$ for the aqueous solutions of diethanolamine are listed in Table 1, along with the corrected values for $C_{p,\phi,2}$ (DEA (aq)). The results for $V_{\phi,2}$ and $C_{p,\phi,2}$ for DEA(aq) and $DEAH^+Cl^-(aq)$ are plotted in Figs. 1–4.

Identical procedures were used to analyse the data for *N*,*N*′-dimethylethanolamine and *N*,*N*′-dimethylethanolammonium chloride except that the excess of HCl(aq) in the solutions of the chloride was much lower. The results are found in Tables 5–8 and plotted in Figs. 5–8.

Data Treatment

The apparent molar properties of both amines could be closely described over the temperature range of 283.15 ≤ T ≤ 328.15 K using the following equations:

Fig. 8. The apparent molar volumes $V_{\phi,2}$ of *N*,*N*′-dimethylethanolammonium chloride from 283.15 to 328.15 K plotted as a function of ionic strength *I* after subtracting the Debye–Hückel limiting law term. Symbols, experimental results; lines, least-squares global fit to eq. [13].

$$[7] \quad C_{p,\phi,2} = C^{o}_{p,\phi,2} + (c_4 + c_5T)m + (c_6)m^2$$

$$[8] \quad V_{\phi,2} = V^{o}_{\phi,2} + (v_4 + v_5T)m$$

$$[9] \quad C^{o}_{p,\phi,2} = c_1 + c_2T + c_3 / (T - \Theta)^2$$

$$[10] \quad V^{o}_{\phi,2} = v_1 + v_2T + v_3 / (T - \Theta)$$

Here, the terms c_i and v_i are species-dependent fitting coefficients, and $\Theta = 228$ K is a solvent-dependent parameter associated with the anomalous behaviour of super-cooled water (24).

The functional dependence of the apparent molar heat capacities $C_{p,\phi,2}$ and volumes $V_{\phi,2}$ for the alkanolammonium salts were well represented by Debye–Hückel equations:

$$[11] \quad C_{p,\phi,2} = C^{o}_{p,2} + 1.5\omega A_c[I - 2I^{1/2} + 2 \ln (1 + I^{1/2})] / I + (c_4 + c_5T)I + (c_6)I^{3/2}$$

$$[12] \quad V_{\phi,2} = V^{o}_{2} + 1.5\omega A_v[I - 2I^{1/2} + 2 \ln (1 + I^{1/2})] / I + (v_4 + v_5T)I$$

where $I = \omega m = 1/2 \sum m_i z_i^2$, A_c in eq. [11], and A_v in eq. [12] are the Debye–Hückel limiting slopes for the heat capacity and for the volume, respectively, whose values were taken from the compilation by Archer and Wang (25).

The isothermal forms of eqs. [7–12] were fitted to the experimental results at each temperature by the Marquardt–Levenberg non-linear least-squares algorithm within the commercial software package SigmaPlot©, using weighting factors proportional to molality (9). The entire array of values at all temperatures and all molalities was then used to optimize the parameters in eqs. [7–12] in order to obtain a global fit to the data. The fitted parameters are listed in Tables 9–12, along with the overall standard deviations in $C_{p,\phi,2}$ and $V_{\phi,2}$, $\sigma_{C_p\phi}$, and $\sigma_{V\phi}$, respectively.

Discussion

The molality dependence of the apparent molar properties was found to be represented well by the treatment described above, as illustrated in Figs. 1–8. Values for the standard partial molar heat capacities and volumes from the global fit are tabulated in Tables 13 and 14 and plotted in Figs. 9–12. Data for the apparent molar volumes of diethanolamine at 298.15 K reported by Maham et al. (5), which are included in Fig. 10, agree with our results to within the combined experimental uncertainties. Values of the ionic properties of $C^o_p(DEAH^+(aq))$ and $V°(DEAH^+(aq))$, found in Table 15, were calculated on the conventional scale, $Y°(H^+(aq)) \equiv 0$, using expressions for $C^o_p(Cl^-(aq))$ and $V°(Cl^-(aq))$ taken from Hovey et al. (17). These are based on measurements on HCl(aq) by Tremaine et al. (21), Allred and Woolley (26), and Herrington et al. (27), and are consistent with recent measurements on $LaCl_3(aq)$ and $La(ClO_4(aq))$ by Tremaine and Xiao (28). The uncertainty limits in Tables 14 and 15 are estimates of *relative* accuracy, based on the 90% confidence lim-

its from the isothermal fits, the difference in standard state properties from the isothermal and global fits, and the performance of the equipment as the measurements were made. Further uncertainties in the *absolute* accuracy due to systematic errors in sample purity and calibration are estimated to be no more than ±1 J K^{-1} mol^{-1} and ±0.1 cm^3 mol^{-1}.

Aqueous diethanolamine is heavily hydrogen bonded and it is interesting to compare the experimental results at 298.15 K to those predicted by group additivity models, such as those developed by Guthrie (29), Perron and Desnoyers (30), and Cabani et al. (31). The predicted values for standard partial molar volumes from (29), $V°$(DEA(aq)) = 94.0 cm^3 mol^{-1}, and $V°(DEAH^{+}Cl^{-}(aq))$ = 107.5 cm^3 mol^{-1} are in excellent agreement with the experimental results in Table 13, 94 cm^3 mol^{-1} and 105.8 cm^3 mol^{-1} respectively. Ref. (30) does not have a value for the >NH or $>NH_2Cl$ groups, however Guthrie has reported values for C^{o}_{p}(>NH(aq)) that yield C^{o}_{p}(DEA(aq)) = 312 J K^{-1} mol^{-1}. This compares rather poorly to the experimental value C^{o}_{p}(DEA(aq)) = 327 J K^{-1} mol^{-1}. Applying the model to our earlier data on dimethylamine (DMA) (10), also yields a significant disagreement but of the opposite sign (292 J K^{-1} mol^{-1} vs. the experimental value of 260 J K^{-1} mol^{-1}). Similarly, it was not possible to chose a value for $>NH_2Cl$ group that gave agreement with the experimental results for the salts, $C^{o}_{p}(DEAH^{+}Cl^{-}(aq))$ = 165 J K^{-1} mol^{-1} and $C^{o}_{p}((CH_3)_2NH_2Cl(aq)$ = 104 J K^{-1} mol^{-1} to better than ±50 J K^{-1} mol^{-1}. The results from the group additivity model developed by Cabani et al. (31) are similar. The calculated values of C^{o}_{p} and $V°$ for DEA(aq), DMEA(aq), and dimethylamine are too positive by ~ 50 J K^{-1} mol^{-1}, and ~2 cm^3 mol^{-1} respectively. The sign of the deviation is consistent with the deviation reported by Cabani et al. (31) for bifunctional alkanolamines. Many authors have shown that C^{o}_{p} is sensitive to secondary solvation effects, while $V°$ primarily reflects the intrinsic volume of the solute molecule and effects in the primary solvation sphere. These results strongly suggest that the proximity to the hydrogen bonded amine or ammonium group acts by perturbing the secondary solvation sphere about the nearby alkyl or alkanol substituent.

1999 Alfred Bader Award Lecture From early developments in multi-step organic synthesis on solid phases to multi-nuclear phthalocyanines[1]

Clifford C. Leznoff

Abstract: Early developments in solid phase organic synthesis are traced. Particular emphasis is placed on the use of cross-linked polystyrene in the first general method of monoblocking symmetrical difunctional compounds. The monoprotected polymer-bound symmetrical starting materials were then used in multi-step syntheses of a variety of compounds, particularly insect pheromones. Asymmetric synthesis on polymer supports was demonstrated. Diels–Alder and 1,3-dipolar additions on polymer supports proceeded readily as did macrocyclic formation of porphyrins and phthalocyanines. All of these reactions clearly showed that most organic chemical reactions could be performed on solid phases and laid the basis for the development of combinatorial chemistry. The first unsymmetrical phthalocyanine was prepared using the solid phase method and this led eventually to solution phase methods of preparing bi-, tri-, tetra-, and even a dendritic-like pentanuclear phthalocyanine.

Key Words: solid phase organic synthesis (SPOS), phthalocyanines.

Résumé : On retrace les développements de la synthèse organique en phase solide. On insiste sur l'utilisation du polystyrène réticulé dans la première méthode générale de bloquer une seule des deux fonctions de composés bifonctionnels symétriques. Les produits de départ symétriques reliés par une seule liaison à un polymère étaient ensuite utilisés dans des synthèses en plusieurs étapes d'une grande variété de composés, en particulier des phéromones d'insectes. La possibilité de réaliser des synthèses asymétriques sur des polymères solides a été démontrée. On a aussi montré que, sur des supports solides, on peut effectuer facilement des additions de Diels–Alder et des additions 1,3-dipolaires ainsi que la formation de macrocycles, comme les porphyrines et les phtalocyanines. Toutes ces réactions ont clairement démontré que la plupart des réactions organiques peuvent être réalisées en phases solides et ont servi de base au développement de la chimie combinatoire. La première phtalocyanine non symétrique a été préparée en faisant appel à la phase solide et ceci a conduit aux préparations, par des méthodes de phase en solution, de bi-, tri-, tétra- et même d'une phtalocyanine pentanucléaire de nature dendritique.

Mots clés : synthèse organique en phase solide (SOPS), phtalocyanines.

[Traduit par la Rédaction]

Introduction

Organic chemists have long been wedded to the practice of performing chemical reactions in homogeneous media. Hence, the idea that organic reactions could be performed on insoluble polymer supports was indeed revolutionary (1, 2). This concept was initially applied to solid phase synthesis of polypeptides (1, 3), polynucleotides (4–6), and later polysaccharides (7). These topics have been reviewed often (8–10). The general advantage of organic synthesis on insoluble polymer supports (usually cross-linked polystyrene) is particularly favourable for repetitive synthesis of like units such as the sequential addition of amino acids to a polymer support. Thus, polypeptides can be prepared on solid phases, whereby the only mechanical operations involved are stirring (or shaking), filtration, and washing. In some respects, these repetitive syntheses are easy in that only a very few different reactions at room temperature are required. It is so easy, in fact, that the process was automated even using pre-computer technology (11). Even so, difficulties abounded; however, multiple parallel synthesis of polypeptides using computer-controlled robotic systems is now routine (12, 13).

During this era, reagents attached to insoluble polymer supports, useful for organic synthesis, were developed. The work of Patchornik's group (14, 15) on the use of reagents for polypeptide synthesis was noteworthy. Polymer-bound reagents (15, 16) and catalysts (16, 17) in which the organic reagent or catalyst is bound to the polymer (with the organic substrate always remaining in solution) has found its place in many applications but is beyond the scope of this article.

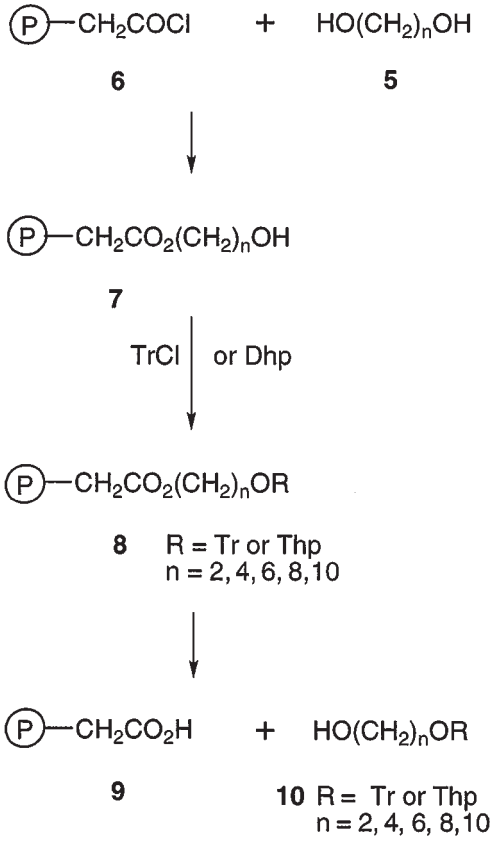
Scheme 1.

A post-doctoral fellowship in Letsinger's laboratory (2, 4) in 1964 piqued my curiosity to the possibility of using polymer supports in organic synthesis. Coincidentally, during our research project on the synthesis of annulenes in another post-doctoral sojourn in Sondheimer's group (18), we were faced with the problem of reacting *trans*-1,4-dichloro-2-butene (**1**) with ethynyl magnesium bromide. Invariably, an inseparable mixture of **1**, the bis reacted product *trans*-4-octen-1,7-diyne (**2**) and the desired *trans*-6-chloro-4-hexen-1-yne (**3**) was obtained. These compounds had very similar boiling points and they could not be separated by distillation. Ultimately, conversion of the mixture of **1–3** with NaI led to I_2, butadiene, **2**, and *trans*-6-iodo-4-hexen-1-yne (**4**) which was separable by distillation (Scheme 1). This problem led to the germination of an idea that insoluble polymer supports could be an advantage in addressing the whole concept of monoreactions of symmetrically difunctionalized organic compounds.

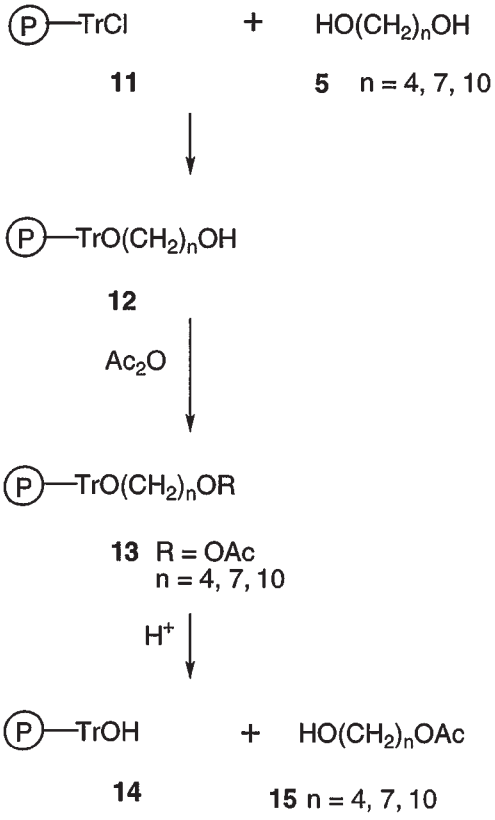
Insoluble polymers supports as blocking groups of symmetrically disubstituted compounds

Solid phase organic synthesis (SPOS) usually refers to general organic synthesis on polymer-supports, outside the repetitive syntheses of polypeptides, polynucleotides, and polysaccharides. The synthesis of a threaded rotaxane in 1967 (19) on a polymer support probably represents the first example of SPOS. Our own early efforts focussed on the use of polymer supports as monoblocking agents of completely symmetrical difunctional compounds. Monoreactions of reagents such as acetyl chloride with a compound such as 1,10-decanediol (**5**) in a 1:1 ratio would give 25% of the bis reacted product, 50% of the desired monoreacted product, and 25% of unreacted starting material. A large excess of (**5**), for example, would give mainly the desired monoreacted product and unreacted starting material but separating the minor product (the monoreacted product) from a sea of unreacted starting material could be difficult. This separation could be readily achieved, however, by simple filtration if the monoreacted product remained attached to an insoluble polymer and "fished out" of the excess starting material which could be recovered. The process would be particularly important for the longer chain symmetrical difunctional compounds such as **5**, as short chain monoreaction products of say ethylene glycol could be achieved by other methods such as ring opening reactions of ethylene oxide. Thus treatment of polymer-bound[3] phenylacetylchloride (**6**) (20) with a large excess of symmetrical diols (**5,** n = 2, 4, 6, 8, 10) gave the polymer-bound monoprotected diols (**7**). Subsequent reaction of **7** with chlorotriphenylmethane (TrCl) or dihydropyran (dhp) gave polymer-protected monoether **8**. Cleavage of **8** with NH_4OH gave polymer-bound phenylacetic acid (**9**) and the liberated monoprotected ethers of the symmetrical diols (**10**) (21, 22) (Scheme 2). Recovered **9** was converted back to **6** but the synthesis of **10** (n = 10) on once used **9** gave **10** in lower yield.



In order to obtain a more recyclable polymer, a polymer-bound trityl chloride[3] (**11**) was prepared by our direct lithiation method (23, 24). Treatment of **11** with symmetrical diols (**5**, n = 4, 7, 10) gave the polymer-bound monotrityl ether **12**. Acetylation gave the polymer-bound monotrityl monoacetates (**13**) which on acid cleavage gave polymer-bound trityl alcohol (**14**) and the desired symmetrical diol monoacetates (**15**) (23, 24) (Scheme 3). Polymer **14** was readily recyclable to give products in undiminished yield from used **14**.

The successful monoprotection of symmetrical diols encouraged us to explore the monoprotection of other symmetrical difunctional compounds, particularly symmetrical dialdehydes. For this purpose, a polymer-bound 1,2-diol (**16**) was developed (25). Treatment of **16** with terephthalaldehyde (**17**) gave the polymer-bound monoacetal (**18**). It should be noted that such a reaction in solution gives only bis acetal and unreacted **17** as the mono product is normally more reactive



[3] The use of a ℗ used by Merrifield, Letsinger and others to represent the polymer has in recent times been replaced by a solid sphere. It is unlikely that the P could be confused for phosphate in the context used and the more currently used symbol, the solid grey or black sphere, could also be confused with current representations of solid metallic clusters, the latter use being more reasonable as the solid ball is solid like the cluster. In addition, the P can be replaced by Si for silica polymers and PEG for polyethylene glycol polymers, etc., and, hence, is more flexible. In this paper the polymer is, polystyrene, cross-linked with 1–3% divinylbenzene. In the trityl containing polymer (**11**), one phenyl group of the polymer is actually part of the trityl group.

that the starting dial, containing two electron-withdrawing groups. Conversion of **18** to a polymer-bound Wittig reagent (**19**) in four steps and further reaction with symmetrical dial **17** led to polymer-bound **20**. Acid cleavage of **20** gave **16**, that could be recovered, and the symmetrical diformylstilbene (**21**) in the first multi-step (7 reactions) SPOS on polymer supports (26). Interestingly **18** was also converted to a helicene (27). A linear conjugated symmetrical dialdehyde, 2,7-dimethyl-2,4,6-octatrien-1,7-dial reacted with **16** to give the polymer-bound monoprotected **22**. The Wittig reaction of **22** gave the polymer-bound polyenes **23,** which on acid cleavage provided conjugated aldehydes, useful in carotenoid synthesis (28). Even symmetrical aliphatic dialdehydes may be monoprotected using **16** giving polymer-bound **24**, which with PhMgBr and acid cleavage, gives **25** (29) (Scheme 4). The symmetrical isophthalaldehyde can be monoprotected with **16** as well to give the polymer-bound monoblocked acetal **26**. Wittig reactions on **26** give the formyl diene **28** via polymer-bound butadiene **27**, oximation of **26** gives a polymer-bound acetal oxime which yields monooxime **29**, while an aldol condensation of **26** gives polymer-bound chalcone **30** and ultimately formyl chalcone **31** (25**)** (Scheme 5). In all cases recovered **16** is fully recyclable.

These formyl compounds **28**, **29**, and **31** and their *p*-analogs (25) are difficult to prepare in solution. Symmetrical diketones can be monoprotected with **16**. Thus, *p*-diacetylbenzene reacts with **16** to give the polymer-bound monoacetal (ketal) **32**, which with PhMgBr gives **33** and acid cleavage gives the *p*-acetylstyrene **34** (30). Alternatively, the Wittig reaction of **32** gives polymer **35** which liberates a *p*-acetylstilbene (**36**) (31). Symmetrical cyclic diketones such as 1,3-cyclohexanedione react with polymer **16** to give the monoprotected **37** which on Grignardization and acid cleavage liberates 3-phenyl-2-cylohexen-1-one (**38**) (Scheme 6). Again polymer **16** is recovered for reuse with undiminished capacity. Recently, polymer **16** has been used in palladium coupling reactions (32).

Other polymer-bound 1,2 and 1,3-diols were also used in similar reactions but the polymers were not always recyclable (33). Interestingly, the reverse of the procedures described

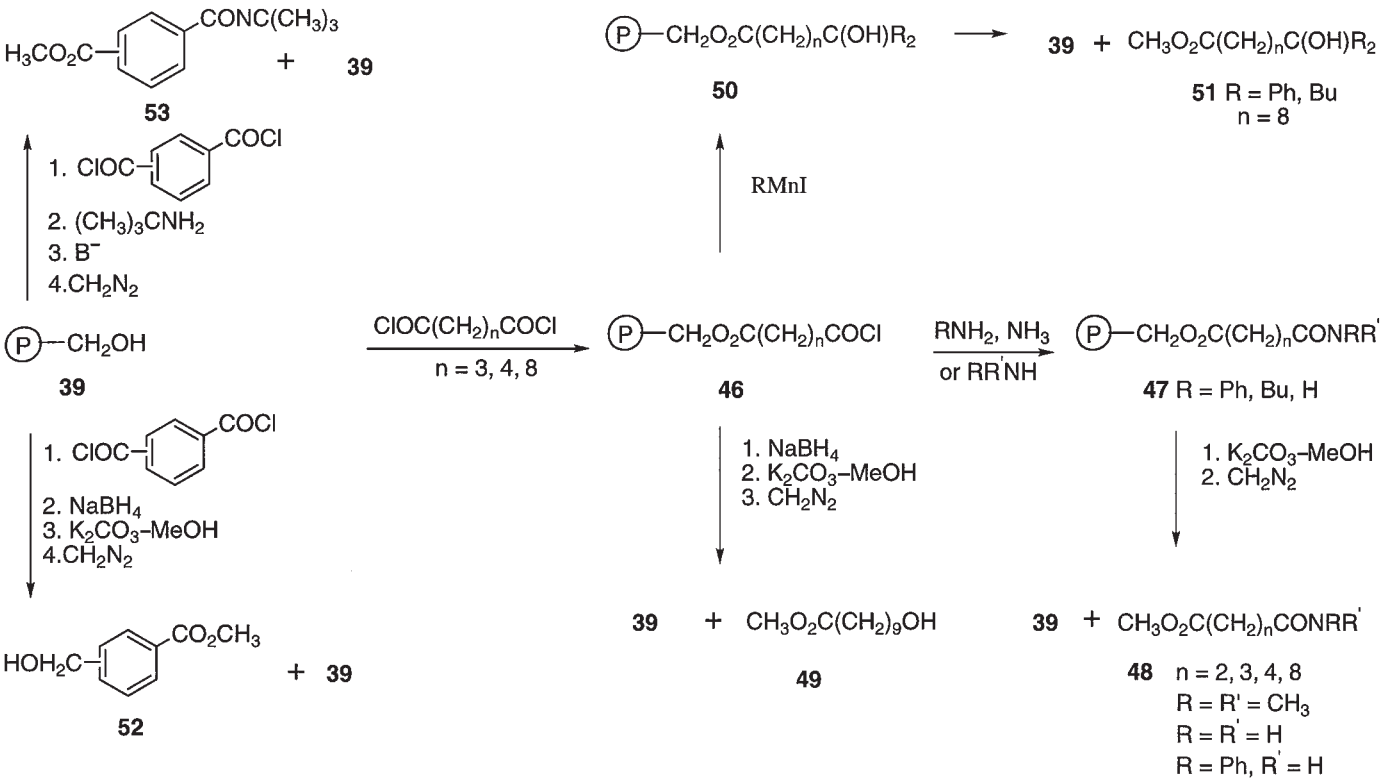
© 2000 NRC Canada

Scheme 7.

in Schemes 4–6 has been described recently in which a polymer-bound aldehyde has been used to monoblock symmetrical tetraols (34). Polymer-bound boronic acids have been used to selectively extract *cis*-diols from mixtures (35).

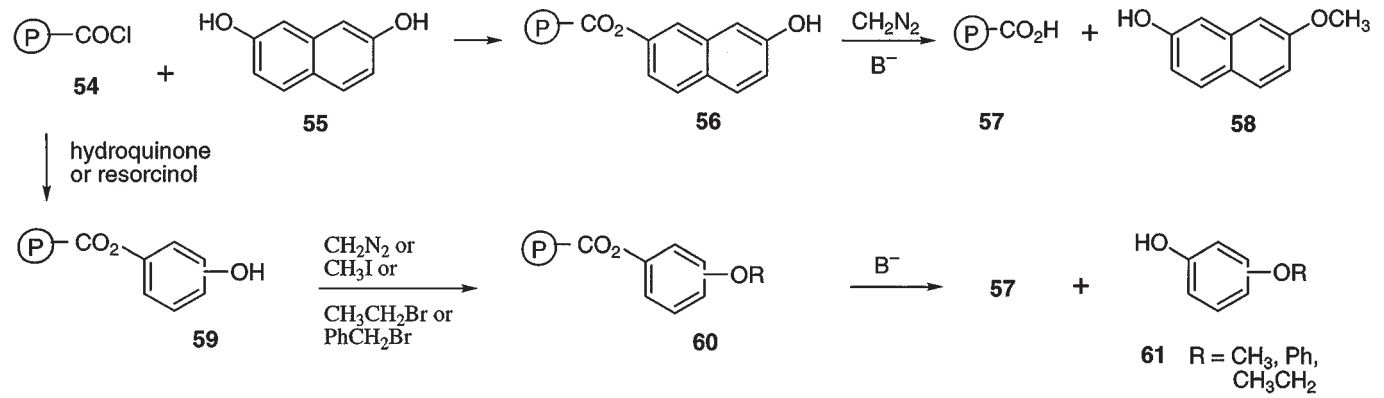
Polymer supports have been used to monoprotect symmetrical diamines. Thus, polymer-bound benzyl alcohol (**39**) on treatment with *p*-nitrophenyl chloroformate yielded the polymer-bound carbonate (**40**) which on reaction with the symmetrical diamines (**41**, n = 4, 6, 8, 10, 12) yielded the polymer-bound monoprotected carbamates (**43**). Subsequent treatment with benzoyl chloride or *p*-toluenesulfonyl chloride (TsCl) gave polymers **43**. Treatment of **43** with trifluoroacetic acid gave recyclable polymer **39**, the desired unsymmetrical amides (**44**, n = 4, 6, 8, 10, 12), and some bistrifluoroacetamide (**45**) of their respective diamines (36) (Scheme 7). The trifluoroacetamido groups of **44** are easily cleaved by mild base. Some recent examples using polymer-bound monoprotected symmetrical diamines in SPOS have been reported (37).

Symmetrical diesters, diacids, and diacid chlorides can be monoblocked most readily using diacid chlorides, which is general for both linear and aromatic diacid chlorides. Thus, polymer **39** readily reacts with a series of diacid chlorides ($ClOC(CH_2)_n$ $COCl$ (n = 2, 3, 4, 8)) to give the polymer-bound monoester mono-acid chlorides (**46**). These versatile monoblocked derivatives (**46**) may be treated with amines to give polymer-bound ester amides (**47**) which can be cleaved and esterified to the free methyl ester amides (**48**). Alternatively, **46** (n = 8) may be reduced selectively to methyl 10-hydroxydecanoic acid (**49**) (38, 39). Treatment of **46** with phenyl or butylmanganese iodide (40) gave polymers (**50**) resulting from selective addition to the acid chloride. Cleavage and methylation readily yielded **51** (41). In all cases, **39** was recovered and was recyclable. Similarly, aromatic diacid chlorides such as terephthaloyl and isophthaloyl chloride provided the ester alcohols **52** and aromatic ester amides **53** (Scheme 8). Polymer-bound monoester succinic acid was formed via succinic anlydride (42) and recently the malonic analog via Meldrum's acid (43) and other activated acids (44) were monoprotected using polymers. Only rigid diacids such as fumaric and 2-butyne-1,4-dioic acid can be reacted directly with a polymer support (45, 46) as intraresin reactions strongly interfere (47, 48).



Dihydroxy aromatic compounds are also readily monoprotected using a polymer-bound benzoyl chloride (**54**). Thus, treatment of **54** with 2,7-dihydroxynaphthalene (**55**) gave the polymer-bound monoester mononaphthol (**56**), which on reaction with diazomethane and cleavage gave recovered polymer-bound benzoic acid (**57**) and 7-methoxy-2-naphthol (**58**). Simpler phenols such as resorcinol and hydroquinone also gave polymer-bound monoprotected phenols **59** which on alkylation gave **60** and cleavage yielded the *m*- or *p*-monoalkyl ethers of phenol (**61**) (50) (Scheme 9).

In all of the above examples, it is possible for the polymer support to react with both ends of the insoluble polymer support, the so called "double binding" problem. This problem has been discussed in some of the earliest reviews on SPOS (47–49) and in more recent reviews (49). Double binding can usually be diminished greatly by using a vast excess of starting symmetrical difunctional compound and indeed most of the examples listed show minimal double binding, but symmetrical diols can give up to 40% double binding and aliphatic diacids up to 100% double binding (47–50). Even when double binding occurs, it usually doesn't interfere in the reactions of SPOS but does reduce capacity. Although double binding can be eliminated by putting the polymer-bound functional group at a cross-linked position, capacity is reduced (23, 51).



New methods of monoprotecting symmetrical difunctional compounds *in solution* have been developed, particularly with respect to diols (52–55), tetraols (56), dihydroxy-aromatic compounds (57, 58), dials (59, 60), diones (61), diamines (62–64), diesters (65, 66), diacids (67, 68), and dihalides (69, 70). Some of these methods still rely on statistical strategies using excess substrate (69, 70); others rely on specific properties of the monoprotected products such as precipitation (52*a*), solubility (54*b*), and enzymatic activity (55), while additional routes feature reactivity profiles (53), solid phase catalysis (54*c*, 65, 68), or alternative synthesis (69). All of these solution methods are, unfortunately, applicable not only to a specific symmetrical difunctional group, but to defined sub classes of that group and hence, are not general methods like the polymer support method. Despite this, specific methods are used more generally both

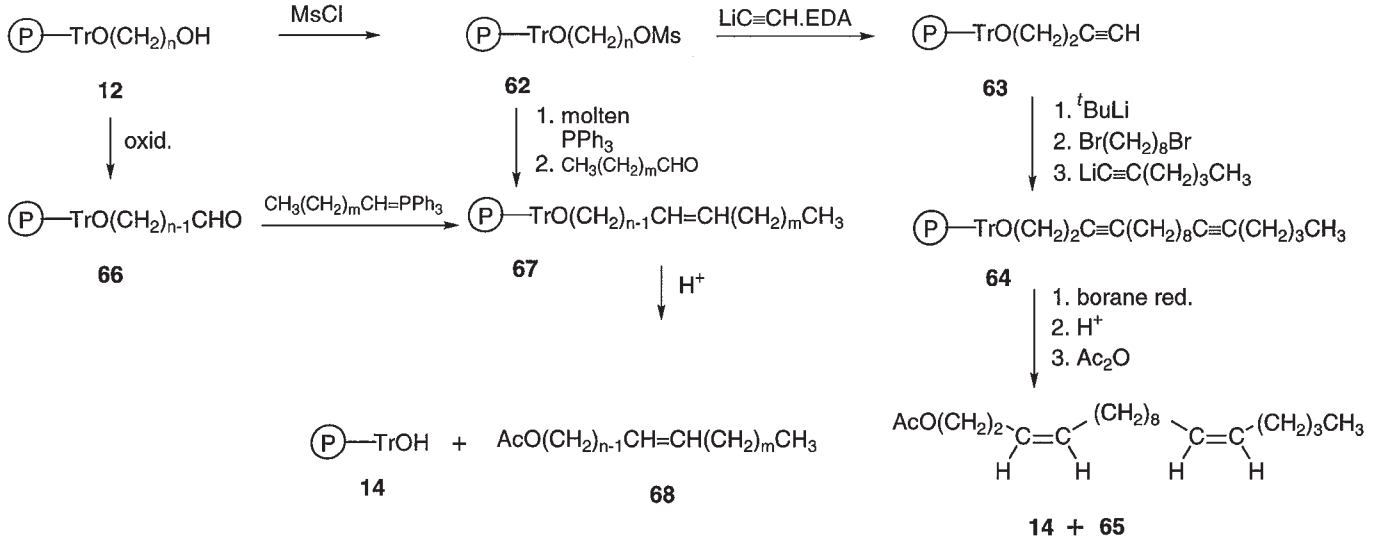
Scheme 8.

Scheme 9.



academically and industrially where a single particular difunctional compound can be monoblocked by methods peculiar to that compound. With the advent of combinatorial chemistry (71–73), it is important to have a general method of monoprotection of symmetrical substrates for elaboration into the preparation of chemistry libraries and this method is being used now in this context (37*b*, *c*).

Multi-step solid phase organic synthesis

The synthesis of polypeptides, polynucleotides, and polysaccharides all depend on the selective attachment to the polymer support of a difunctional compound containing two different functional goups. The monoblocking of symmetrical difunctional compounds, having two identical functional groups, on solid phases opened the way to using simple inexpensive materials in multi-step solid phase organic synthesis (SPOS). Although **21** (Scheme 4) was synthesized before in a multi-step synthesis, our major effort was devoted to SPOS of insect pheromones (74–80), which has been reviewed (77) previously. Three routes to insect pheromones on solid phases were paramount. Thus, polymer-bound trityl-blocked symmetrical diols (**12**) (23), were treated with mesyl chloride to yield to polymer-bound mesylate (**62**) which, in the alkyne route, reacted with lithioacetylide to

© 2000 NRC Canada

Scheme 10.

give the polymer-bound terminal alkyne (**63**, n = 2). Lithiation of **63**, followed by treatment with the symmetrical alkylating agent, 1,8-dibromooctane, gave the monoalkylated product, which was coupled with 1-lithio-1-hexyne to give the polymer-bound diyne (**64**). Although catalytic reduction of **64** with insoluble Pd or Pt catalysts was not possible, borane reduction proceeded even more easily than in solution as organoborane by-products were easily removed by simple filtration. Acid cleavage and acetylation readily gave **65**, an insect sex attractant of the lesser peach borer, *Synanthedon pictipes* (76, 77) (Scheme 10). Alternatively, polymer **12** can be oxidized with di-*tert*-butyl chromate to give the polymer protected ether aldehyde **66**. Reaction of **66** with Wittig reagents, the Wittig route, give a variety of polymer-bound insect pheromones **67**, containing up to 33% of the *E* isomer. On the other hand, in a "reverse" Wittig route, conversion of **62** with *molten* PPh_3 gave a polymer bound Wittig reagent, which on treatment with aliphatic aldehydes again gave **67** (n = 10, m = 2) with less than 9% of the *E* isomer. Acid treatment and acetylation of **67** gave recovered polymer **14** and insect attractants (**68**) (78) (Scheme 10). It is notable, in the alkyne route, that the polymer-bound synthesis uses two steps to monoreact symmetrical disubstituted substrates and a borane reduction step to such an advantage that this sequence cannot be readily performed in solution. Natural insect pheromones often contain mixtures of *E*, *Z* components so that the Wittig routes can be selected to give the desired mixture. The polymer support does affect the stereochemistry of the Wittig reactions (79). Large scale synthesis of pheromones using over 50 g of polymer supports and yielding up to 5 g of product have been reported (80). The synthesis of an insect pheromone using a polymer-bound silyl chloride and a more convenient Moffatt–Swern oxidation is interesting (81) as is the recent related polymer-supported Cadiot–Chodkiewicz coupling (82) giving conjugated unsymmetrical diynes, suitable for pheromones (82, 83).

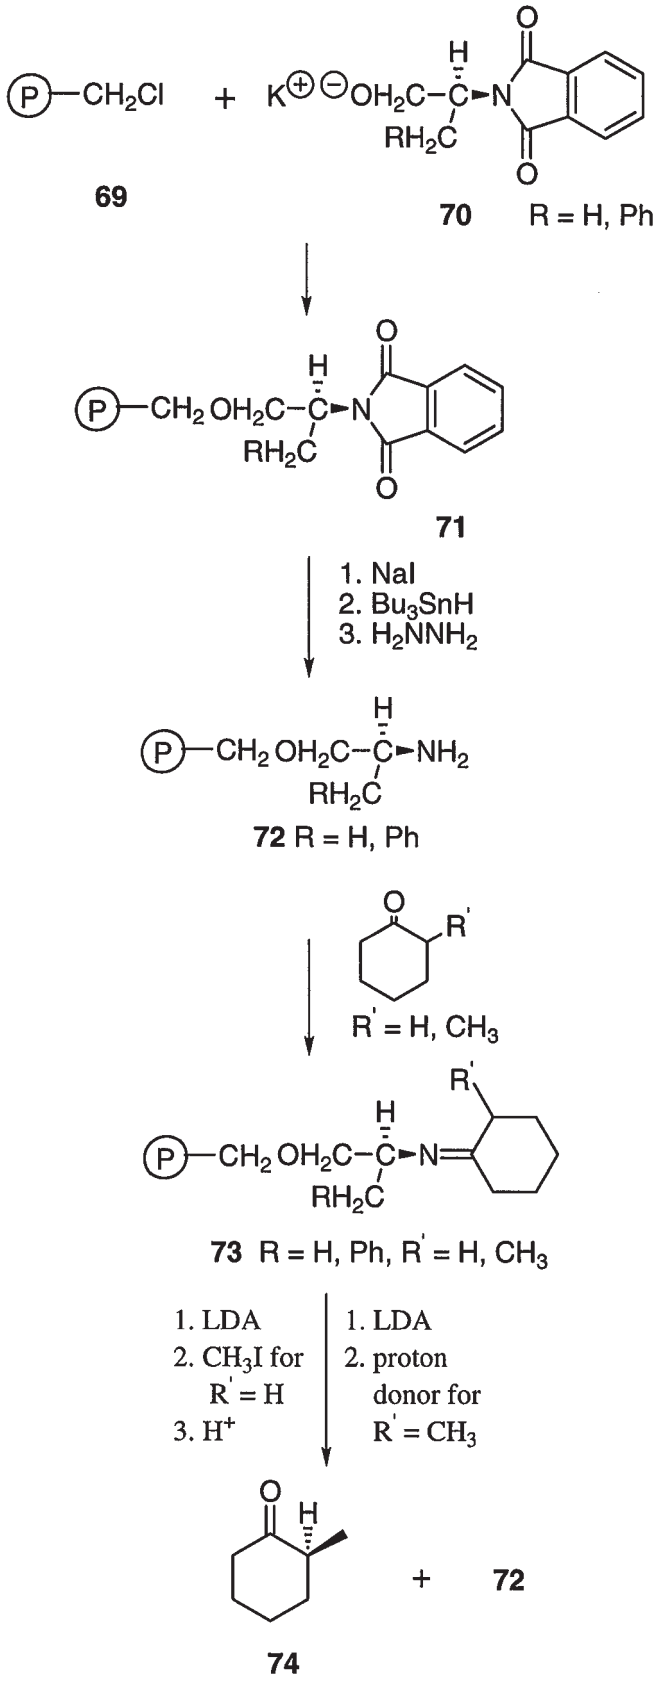
One early example of a polymer-supported asymmetric synthesis (84) and high enantiomeric excesses (ee) achieved in solution (85) encouraged us to apply solid phases in asymmetric synthesis. Thus, Merrifield's polymer **69** reacted with the chiral blocked aminoalcohols **70** to give the polymer-bound chiral reagents **71**. Some unreacted chloro groups in **71** interfered with subsequent asymmetric synthesis, but these were converted to inactive methyl groups by treatment with NaI and reduction with tri-*n*-butyltin hydride. Deblocking with hydrazine gave the polymer-bound chiral reagents **72**. Treatment of **72** with cyclohexanone gave polymer-bound chiral imine **73** which on alkylation and cleavage gave the valuable recovered polymer-bound chiral reagent **72** and (*S*)-2-methylcylohexanone (**74**)(86). Alternatively, in the first example of an asymmetric protonation (87) on polymer supports (88), addition of racemic 2-methylcyclohexanone to **72** gave **73** which on deprotonation and asymmetric protonation gave **74** (Scheme 11). The ee of **74** was comparable to that obtained using solution methods (85). As in polypeptide syntheses, partially reacted substrates on the polymer may be carried forward and interfere in a polymer-supported multi-step synthesis and awareness of this problem (**71**→**72**) is a necessity.

Multi-step synthesis of cyclic compounds on solid phases became our next priority. Although a few Diels–Alder reactions had been performed on solid phases for mechanistic (89) or environmental purposes (89*d*), we wished to examine the effect of the polymer on regioselectivity in cycloaddition reactions (90). Thus, **69** reacted with acryloyl chloride to give polymer-bound acrylate (**75**), which on treatment with 1-phenyl-1,3-butadiene or methyl 2,4-pentadienoate gave the polymer-bound cyclohexenes **76** in good yield. Base cleavage and treatment with diazomethane gave a ratio of the *ortho* to *meta* Diels–Alders adducts **77,** similar to that achieved in solution, and hence the polymer support in this reaction did not affect the regiochemistry (Scheme 12). A polymer-bound chiral acrylate (**78**) was achieved by treatment of **69** with chiral 2-methyl-1,3-butanediol, esterification with acryloyl chloride, and blocking of unwanted primary alcohol groups with trityl chloride. Asymmetric Diels–Alder reactions of **78** using various titanium isopropoxy chlorides

© 2000 NRC Canada

gave the polymer-bound chiral cyclohexenes **79**. Reduction with $LiAlH_4$ liberated the free chiral 3-cyclohexenylmethanols **80** plus recovered polymer **39**.

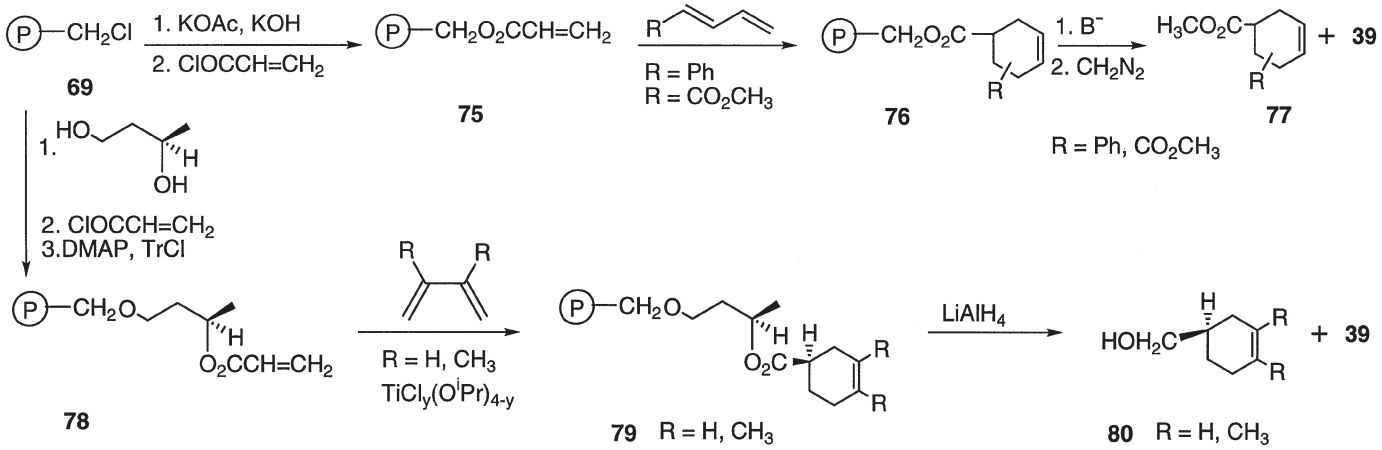
In this example the polymer-bound asymmetric synthesis also yielded product having a similar ee to that achieved in solution and hence the bulk of the polymer did not aid in giving higher ee's (91). Again note that side reactions encountered in going from **69**→**78** caused difficulties in this synthesis, but it was possible to take countervailing measures (Scheme 12).



Cycloaddition of 1,3-dipolarophiles on polymer supported alkynes gave simple heterocyclic compounds. Thus, **39** was treated with propiolic acid (**81** R = H) or phenylpropiolic acid (**81** R = Ph) with an acid catalyst to give the polymer-bound alkynes **82**. The 1,3-dipolar addition (90) with benzonitrile *N*-oxide gave the polymer-bound isoxazoles **83** (from **82** R = H) and **84** (from **82** = Ph). Base cleavage of **83** and **84** and esterification with diazomethane gave the pure regioisomeric isoxazoles **85** and **86**. The regioselectivity of **86** via the solid phase method was opposite to that observed in solution and hence, polymer-supported reactions can be different than their solution analogs (92, 93) (Scheme 13).

A report on the synthesis in very low yield of an unsymmetrical tetraarylporphyrin in solution (94) led us to examine the syntheses of heterocyclic macrocyclic compounds on polymer supports. Thus, polymer-bound acid chloride **54** was treated with *m*- or *p*-hydroxybenzaldehyde (**87**) to give the polymer-bound aldehydes **88**. Treatment of **88** with pyrrole and excess tolualdehyde gave, after filtration from the excess symmetrical *meso*-tetratolylporphyrin produced, the unsymmetrical polymer-bound porphyrins **89**. Cleavage of **89** with base gave in higher yield the unsymmetrical *m*- and *p*-hydroxyphenyl tritolylporphyrins **90** (95) (Scheme 14). This synthesis represents another example of the "fishhook" principle (47), whereby the minor desired component **89** on the polymer is fished out from the major symmetrical product in solution.

Pure unsymmetrical phthalocyanines were virtually unknown prior to 1980 and hence the polymer supported synthesis of porphyrins, described above, is eminently suited to be applied to the more complex heterocyclic macrocycles, the phthalocyanines (Pcs). For example, polymer-supported monotrityl hexanediol (**12**) underwent an aromatic nucleophilic displacement reaction with 4-nitrophthalonitrile and a phase transfer reagent in nitrobenzene to give the polymer-bound phthalonitrile (**91**). Conversion of **91** with base and NH_3 gave the polymer-bound diiminoisoindoline (**92**). Treatment of **92** with a large excess of the isoindoline of 4-isopropoxyphthalonitrile gave the polymer-bound unsymmetrically substituted phthalocyanine **93** as the minor product and a large excess of the symmetrical phthalocyanine (Pc) (**94**). Again, simple filtration afforded pure **93** by the fishhook principle. Acid cleavage of **93** provided the first pure unsymmetrical Pc **95** (96) (Scheme 15). Other examples followed (97, 98).



Our early forays into the use of polymer-supports as monoblocking agents of symmetrical difunctional compounds led us to develop multi-step synthesis of linear compounds, such as insect pheromones and carotenoids, cyclic and heterocyclic compounds, such as cyclohexanes and isoxazoles, chiral compounds, and finally macrocyclic

compounds such as porphyrins and phthalocyanines. Perhaps most importantly, it was demonstrated that a wide variety of common organic reactions could be performed readily on solid phases. These included ether and ester formation, Wittig and organometallic reactions, aldol condensations, oximation, amide formation, borane, borohydride and tin hydride reductions, non-chiral and chiral alkylations, mesylations, alkyne couplings, oxidations, Diels–Alder and 1,3-dipolar additions, and finally Rothemund type (99, 100) prophyrin and Linstead (101) phthalocyanine macrocyclic formations. Some more recent reactions that are noteworthy include the "traceless" attachment of substrates to polymer supports (102, 103), the four component Ugi reaction (104), the Pauson–Khand reaction (105), soluble palladium coupling reactions (106), and other protocols on solid phases (107). Other reactions are outlined in a number of early (47–49) and more recent reviews on SPOS (108, 109) and in reviews on the applications of polymer-supported synthesis in combinatorial chemistry (71–73, 109).

Phthalocyanines

Our synthesis of the first characterized unsymmetrically substituted Pc (96) whetted our appetite for further studies in phthalocyanine chemistry (110–113). During this time, it was shown that certain bridged binuclear porphyrins (114–116) were able to act as catalysts in the 4e-reduction of H_2O to hydrogen and oxygen, although the catalysts tended to decompose with time. Since it was known that Pcs are very much more robust than porphyrins and Pcs can even be used as paint coatings for automotibles, we embarked on a program to make hitherto unknown bridged binuclear phthalocyanines and study their electrocatalytic properties. To

solubilize the rather insoluble pthhalocyanines, we used the bulky neopentoxy (2,2-dimethyl-1-propoxy) group as a solubilizing substituent. Since bridged binuclear Pcs are essentially unsymmetrical Pcs in which one substituent is simply another Pc group, our prior experience in synthesizing an unsymmetrical Pc on a polymer support served us well. Thus, treatment of 2-ethyl-2-methyl-1,3-propanediol (**96**) with base and 4-nitrophthalonitrile gave the bisphthalonitrile (**97**). Conversion of **97** to its bisdiiminoisoindoline (**98**) as before, followed by condensation with a large excess of the diiminoisoindoline (**99**) of 4-neopentoxyphthalonitrile, resulted in a mixture of a large amount of mononuclear 2,9,16,23-tetraneopentoxyphthalocyanine and some binuclear phthalocyanines (**100**) as a metal-free derivative into which various metals could be inserted (117, 118). Amusingly, gel permeation chromatography (94, 118), using the same 2% cross-linked polystyrene used in SPOS, was crucial in separating the mono- and binuclear Pcs in a final purification step (Scheme 16) in this and other polynuclear phthalocyanines (119–122). The method of synthesis of **100** gives the binuclear Pcs as a mixture of regioisomers which is actually beneficial as this mixture helps promote the solubility of **100**. More recently, we substituted the *tert*-butylalkynyl group for the neopentoxy group and we were able to make a binuclear Pc as the pure single isomer **101** (123) (Scheme 17).

Other rigid bridged binuclear Pcs based on attachment of Pcs to the 1,8-positions of anthracene (**102**) (124), naphthalene (125), and phenanthrene (126) were also synthesized (Scheme 17). Trinuclear (121), tetranuclear **103** (127) (Scheme 17), and even a dendriditic-like pentanuclear phthalocyanine (**104**) (128) succumbed to the synthetic anvil (Scheme 18). Cyclic voltammetry (128, 129) and Langmuir–Blodgett studies (130) of the polynuclear phthalocyanines yielded many insights on intraphthalocyanine interactions (128) including step by step oxidation–reductions of the Pcs rings. However, in all cases, the two electron reduction of O_2 to H_2O_2 was observed (most efficiently with tetranuclear Pc **104**).

Currently, we are interested in preparing polyalkynyl phthalocyanines (122*b*, 123, 131–33) for use in nonlinear optics (134) and in shifting the absorption maxima of Pcs towards longer wavelengths. To this end, the 2,3,9,10,16,

© 2000 NRC Canada

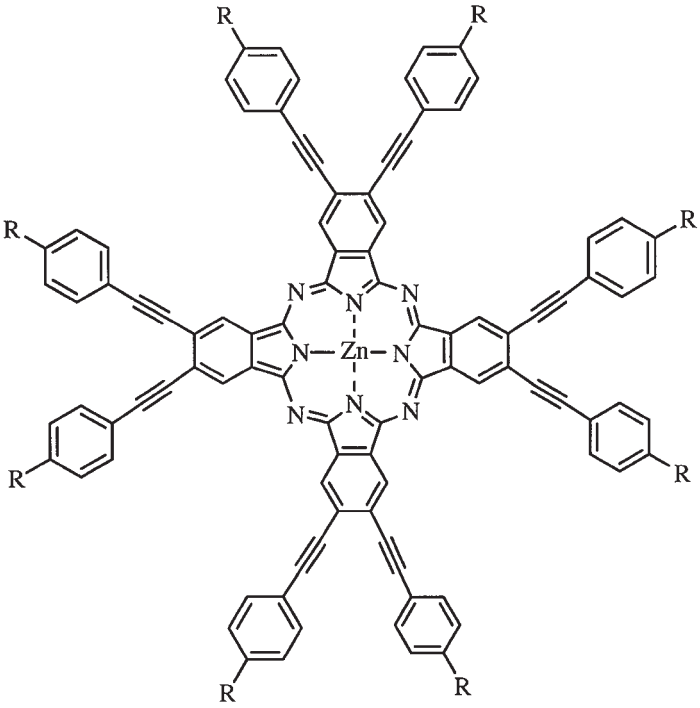
Scheme 18.

17,23,24-octaphenylethynylphthalocyanines **105** and **106** have been prepared. Phthalocyanine **105** is extremely insoluble, but again, the neopentoxy groups in **106** provide this very planar Pc with enough bulkiness to prevent aggregation and enhance solubility. The polyoctabutadiynyl Pc **107**, although soluble, is fairly unstable and decomposes slowly (135).

Conclusions

In the 1970's, SPOS was considered as unusual and impractical, but through the advent of combinatorial chemistry, has become an important endeavour in the 1990's. I have shown how our curiosity-driven research later came to have important practical considerations, and led us to develop a new interest in phthalocyanine chemistry, the applications of which are only now beginning to be realized.

Acknowledgement



I would like to thank the many outstanding graduate students, postdoctoral fellows, research associates, and collaborators at York, as well as those at other institutions who have made this work possible and indeed enjoyable and whose names appear in the references quoted. We thank the Natural Sciences and Engineering Research Council of Canada for major support through operating, strategic, and collaborative grants. Other agencies supporting this research included the Petroleum Research Fund, the Ontario Ministry of the Environment, and the Office of Naval Research (U.S.A.).

Solubility of the pesticide diuron in organic nonelectrolyte solvents. Comparison of observed vs. predicted values based upon Mobile Order theory

Karina M. De Fina, Tina L. Sharp, Michael A. Spurgin, Ivette Chuca, William E. Acree, Jr., Caroline E. Green, and Michael H. Abraham

Abstract: Experimental solubilities are reported at 25.0°C for diuron (also called 3-(3,4-dichlorophenyl)-1,1-dimethyl urea) dissolved in 49 different organic nonelectrolyte solvents containing ether-, chloro-, hydroxy-, ester-, methyl-, and *tert*-butyl-functional groups. Results of these measurements are used to test the applications and limitations of expressions derived from Mobile Order theory. For the 28 nonalcoholic solvents for which predictions could be made computations show that Mobile Order theory does provide fairly reasonable estimates of the saturation mole fraction solubilities. Average absolute deviation between predicted and observed values is 60.1%. Diuron solubilities in the alcohol solvents are used to calculate stability constants for presumed solute-solvent hydrogen bonds that are believed to occur in solution.

Key words: pesticide, diuron solubilities, organic nonelectrolyte solvents, solubility predictions.

Résumé: On a déterminé les solubilités expérimentales de la 1,1-diméthyl-3-(3,4-dichlorophényl)urée (nom générique, diuron), 25,0°C, dans divers solvants organiques non électrolytiques portant, comme substituants, des atomes de chlore, des groupes ester, éther, hydroxyle, méthyle et *tert*-butyle. On a utilisé les résultats de ces mesures pour évaluer les applications et les limitations d'expressions dérivées de la théorie de l'ordre mobile. Pour les 28 solvants non alcooliques pour lesquels il a été possible de faire des prédictions, les calculs montrent que la théorie de l'ordre mobile conduit à des évaluations assez raisonnables des solubilités exprimées en fractions molaires de saturation. La déviation absolue moyenne entre les valeurs prédite et observée est de 60,1%. Les solubilités du diuron dans les solvants alcooliques ont été utilisées pour calculer les constantes de stabilité des liaisons hydrogènes qui se produiraient en solution.

Mots clés: pesticide, solubilités du diuron, solvants organiques non électrolytiques, prédictions des solubilités.

[Traduit par la Rédaction]

Introduction

Solid-liquid equilibrium data of organic nonelectrolyte systems are becoming increasingly important in the petroleum industry, particularly in light of present trends towards heavier feedstocks and known carcinogenicity and mutagenicity of many of the larger polycyclic aromatic compounds. Solubility data for a number of polycyclic aromatic hydrocarbons (e.g., anthracene and pyrene) and heteroatom polynuclear aromatics (e.g., carbazole, dibenzothiophene, and xanthene) have been published in the recent chemical literature (for listing of references see Acree (1–3)). Despite efforts by experimentalists and scientific organizations, both in terms of new experimental measurements and critically-evaluated data compilations, there still exist numerous systems for which solubility data are not readily available.

To address this problem, researchers have turned to group contribution methods and semiempirical expressions to predict desired quantities. Group contribution methods have proved fairly successful in estimating solid solubility in pure and binary solvent mixtures from structural information (4–11). Practical application though, is limited to systems for which all group interaction parameters are known. Interaction parameters can be evaluated from liquid-vapor, liquid-liquid, and solid-liquid equilibria data. It is important that the data base contain as many different functional groups as possible, preferably with adequate representation from both mono- and multi-functional solute/solvent molecules to permit eval-

uation of potential synergistic effects. The data base should contain sufficient experimental values near infinite dilution in the event that one wishes to determine separate interaction parameters for finite concentration and infinite dilution activity coefficient predictions.

Abraham and coworkers (12, 13) recently developed a general solvation equation that can be used in the correlation and understanding of physicochemical and biochemical phenomena. Physical properties that have been correlated include gas/solvent partition coefficients (as log L)

$$[1] \quad \log L = c + rR_2 + s\pi_2^H + a\sum\alpha_2^H + b\sum\beta_2^H + d \log L^{16}$$

and water/solvent partition coefficients (as log P)

$$[2] \quad \log P = c + rR_2 + s\pi_2^H + a\sum\alpha_2^H + b\sum\beta_2^H + vV_x$$

where R_2 and V_x refer to the excess molar refraction and McGowan volume of the solute, respectively, π_2^H is the solute dipolarity/polarizability descriptor, $\sum\alpha_2^H$ and $\sum\beta_2^H$ are measures of the solute's hydrogen bond acidity and hydrogen bond basicity, and L^{16} is the solute's gas-liquid partition coefficient on hexadecane at 298 K. For any given solvent, numerical values of the seven curve-fit coefficients (c, r, s, a, b, d, and v) are deduced by regressing experimental partition coefficient data in accordance with eqs. [1] and [2]. The input partition coefficients were sometimes calculated as the ratio of the solute molar solubilities in the organic solvent and water, $P = C_A^{org}/C_A^{aq}$, and as the ratio of the solute molar solubility in the organic solvent and vapor concentration, $L = C_A^{org}/C_A^{gas}$. Published papers have reported regressional coefficients for water (12, 13) and a few select organic solvents (13, 14)[2].

To increase the solubility database available for developing group contribution methods and general solvation correlations, we are in the process of measuring solubility data for several crystalline organic compounds. In the present communication, we report diuron (also called 3-(3,4-dichlorophenyl)-1,1-dimethyl urea) solubilities at 25°C in 49 different organic solvents of varying polarity and hydrogen bonding capability. Results of the measurements are used to further test the applications and limitations of predictive expressions derived from Mobile Order theory. A subsequent study[3] will use the experimental solubility data to determine the numerical values for diuron's solute descriptors based upon eqs. [1] and [2] and known solvent coefficients. At the present time, we have solvent coefficients for 27 of the organic solvents studied. Solute descriptors allow one to estimate biological properties involving blood-brain distribution (15), brain perfusion (16), water-skin permeation (17), tadpole narcosis (18), nasal pungency thresholds in man (19), upper respiratory tract irritation in mice (20), and eye irritation in mice (21) and man (22) from previously published correlation equations. Once the solute descriptors are calculated, we plan to use the remaining solubility data, together with other data, in the determination of c, r, s, a, b, d, and v values for additional organic solvents.

Materials and methods

Diuron (Sigma, 98%) was used as received. *n*-Hexane (Aldrich, 99%), *n*-heptane (Aldrich, HPLC), *n*-octane (Aldrich, 99+%, anhydrous), *n*-nonane (TCI, 99+%), *n*-decane (TCI, 99+%), *n*-hexadecane (Aldrich, 99%), cyclohexane (Aldrich, HPLC), methylcyclohexane (Aldrich, 99+%, anhydrous), cyclooctane (Aldrich, 99+%), 2,2,4-trimethylpentane (Aldrich, HPLC), *tert*-butylcyclohexane (Aldrich, 99+%), methanol (Aldrich, 99.9+%), ethanol (Aaper Alcohol and Chemical Comp., absolute), 1-propanol (Aldrich, 99+%, anhydrous), 2-propanol (Aldrich, 99+%, anhydrous), 1-butanol (Aldrich HPLC, 99.8+%), 2-butanol (Aldrich, 99+%, anhydrous), 1-pentanol (Aldrich, 99+%), 2-pentanol (Acros 99+%), 1-hexanol (Alfa Aesar, 99+%), 1-heptanol (Alfa Aesar, 99+%), 2-methyl-2-butanol (Acros, 99+%), 2-methyl-1-propanol (Aldrich, 99+%, anhydrous), 3-methyl-1-butanol (Aldrich, 99+%, anhydrous), 1-octanol (Aldrich, 99+%, anhydrous), 4-methyl-2-pentanol (Acros, 99+%), 2-ethyl-1-hexanol (Aldrich, 99+%), 2-methyl-1-pentanol (Aldrich, 99%), 2-methyl-2-propanol (Arco Chemical Comp., 99+%), 1-decanol (Alfa Aesar, 99+%), cyclopentanol (Aldrich, 99%), ethylene glycol (Aldrich, 99.8%, anhydrous), benzene (Aldrich, HPLC, 99.9+%), toluene (Aldrich, 99.8%, anhydrous), chlorobenzene (Aldrich, HPLC, 99.9+%), ethylbenzene (Aldrich, 99.8%, anhydrous), tetrahydrofuran (Aldrich, 99.9%, anhydrous), 1,4-dioxane (Aldrich, 99.8%, anhydrous), dibutyl ether (Aldrich, 99%), carbon tetrachloride (Aldrich, HPLC, 99.9+%), chloroform (HPLC, Aldrich, 99.9%), 1-chlorobutane (Sigma-Aldrich, HPLC, 99.5+%), 1-chlorooctane (Aldrich, 99%), chlorocyclohexane (Aldrich, 99%), dichloromethane (Aldrich, 99.8%, anhydrous), 1,2-dichloroethane (Aldrich, HPLC, 99.8%), ethyl acetate (Aldrich, HPLC, 99.9%), butyl acetate (Aldrich HPLC, 99.7%), and acetonitrile (Aldrich, 99.8%, anhydrous) were stored over molecular sieves and distilled shortly before use. Gas chromatographic analysis showed diuron to have a purity of 99.5 mole percent, and solvent purities to be 99.7 mole percent or better.

Excess solute and solvent were placed in amber glass bottles and allowed to equilibrate in a constant temperature water bath at 25.0 ± 0.1°C for at least three days (often longer). Attainment of equilibrium was verified both by repetitive measurements after several additional days and by approaching equilibrium from supersaturation by pre-equilibrating the solutions at a higher temperature. Aliquots of saturated diuron solutions were transferred through a coarse filter into a tared volumetric flask to determine the amount of sample and diluted quantitatively with 2-propanol for spectrophotometric analysis at either 254 nm (alkane solvents and dibutyl ether) or 286 nm (all other solvents) on a Bausch and Lomb Spectronic 2000. Concentrations of the dilute solutions were determined from a Beer–Lambert law absorbance vs. concentration working curve for nine standard solutions. The calculated molar absorptivity of

[2] M.H. Abraham, J. Le, and W.E. Acree, Jr. Manuscript in preparation.
[3] C.E. Green, M.H. Abraham, and W.E. Acree, Jr. Manuscript in preparation.

© 2000 NRC Canada

diuron at 254 nm varied slightly with concentration, ranging from a value of $\epsilon \approx 20\,950$ L mol^{-1} cm^{-1} (1.83×10^{-5} M) to $\epsilon \approx 19\,580$ L mol^{-1} cm^{-1} (9.16×10^{-5} M). At 286 nm the calculated molar absorptivity of $\epsilon \approx 1395$ L mol^{-1} cm^{-1} was constant over the concentration range of 1.97×10^{-4} M – 1.18×10^{-3} M. Molar solubilities in the six water-saturated solvents were determined in similar fashion, except that a known volume of sample was removed from the amber glass bottles for spectroscopic analysis.

Experimental molar concentrations were converted to (mass/mass) solubility fractions by multiplying by the molar mass of diuron, volume(s) of volumetric flask(s) used, and any dilutions required to place the measured absorbances on the Beer–Lambert law absorbance vs. concentration working curve, and then dividing by the mass of the saturated solution analyzed. Mole fraction solubilities were computed from (mass/mass) solubility fractions using the molar masses of the solute and solvent. Experimental mole fraction solubilities, X_A^{sat}, are listed in Tables 1 and 2 for diuron dissolved in 49 dry organic solvents and in six water-saturated organic solvents, respectively. Numerical values were obtained using diuron as received from the supplier, and they represent the average of between four and eight independent determinations. The measurements were reproducible to within ±2%. We did recrystallize several grams of the solid from methanol for solubility determinations in a few select solvents (benzene, methanol, heptane, tetrahydrofuran, chloroform, and butyl acetate). To within the stated experimental uncertainty of ±2%, there was no difference in the experimental solubilities using the recrystallized and unrecrystallized samples.

Results and discussion

Solvents listed in Table 1 include both noncomplexing alkanes and self-associating alcohols. Of the many solution models proposed in recent years, Mobile Order theory is perhaps the only one that is capable of describing solute behavior in such a wide range of solvent mixtures. The basic model (23–30) assumes that all molecular groups perpetually move, and that neighbors of a given kind of external atom in a molecule constantly change identity. All molecules of a given kind dispose of the same volume, equal to the total volume V of the liquid divided by the number N_A of molecules of the same kind, i.e., Dom A = V/N_A. The center of this domain perpetually moves. The highest mobile disorder is achieved whenever groups visit all parts of their domain without preference. Preferential contacts lead to deviations with respect to this "random" visiting. This is especially true in the case of hydrogen-bonding as specific interactions result in a specific orientation of the "donor" molecule with respect to an adjacent "acceptor" molecule.

In the case of an inert crystalline solute dissolved in a self-associating solvent, Mobile Order theory expresses the volume fraction saturation solubility, ϕ_A^{sat}, as

$$[3]\quad \ln \phi_A^{sat} = \ln a_A^{solid} - 0.5(1 - V_A/V_{solvent})\phi_{solvent} + 0.5 \ln [\phi_A^{sat} + \phi_{solvent}(V_A/V_{solvent})] - \phi_{solvent}^2 V_A(\delta'_A - \delta'_{solvent})^2(RT)^{-1} - r_{solvent}(V_A/V_{solvent})\phi_{solvent}$$

where the $r_{solvent}(V_A/V_{solvent})\phi_{solvent}$ term represents the contributions resulting from hydrogen-bond formation between the solvent molecules. For most of the published applications, $r_{solvent}$ was assumed to be unity for strongly associated solvents with single hydrogen-bonded chains such as monofunctional alcohols, to be two for water or diols, and to equal zero for non-associated solvents such as saturated hydrocarbons. A more exact value for alcoholic solvents can be calculated based upon

$$[4]\quad r_{solvent} = (K_{solvent}\ \phi_{solvent}/V_{solvent})/(1 + K_{solvent}\ \phi_{solvent}/V_{solvent})$$

with a numerical value of $K_{solvent} = 5000$ cm^3 mol^{-1} assumed for all mono-functional alcohols.

If complexation does occur between the crystalline solute and solvent

$$[5]\quad \ln \phi_A^{sat} = \ln a_A^{solid} - 0.5(1 - V_A/V_{solvent})\phi_{solvent} + 0.5 \ln [\phi_A^{sat} + \phi_{solvent}(V_A/V_{solvent})] - \phi_{solvent}^2 V_A(\delta'_A - \delta'_{solvent})^2(RT)^{-1} + \ln [1 + \phi_{solvent}(K_{ASolvent}/V_{solvent})]$$

then an additional term involving the solute–solvent equilibrium constant, $K_{ASolvent}$, must be introduced to describe the solubility enhancement that arises as a result of specific interactions. A slightly more complex expression applies in the case of solute complexation with a self-associating solvent. The expression's mathematical form depends to a large extent upon the number and type of hydrogen-bond acid and hydrogen-bond base functional groups in the solute molecule being studied. In the present case, diuron contains an -NC(O)NH- moiety which could conceivably act as both a hydrogen-bond base (through the lone electron pairs on the oxygen and nitrogen atoms) and hydrogen-bond acid.

Examination of the solubility data in Table 1 reveals that diuron is 10 times more soluble in dibutyl ether ($X_A^{sat} = 0.0005037$) than in the two saturated hydrocarbons, *n*-octane ($X_A^{sat} = 0.00002934$) and *n*-nonane ($X_A^{sat} = 0.00003615$) of comparable size. The large solubility enhancement observed by the introduction of the ether functional group into an alkane solvent suggests formation of a diuron – dibutyl ether association complex. If such complexation does occur then diuron's -NC(O)NH- functional group must act as a hydrogen-bond acid. The ether oxygen on dibutyl ether has no choice other than to act as a hydrogen-bond base. We do not believe, however, that the observed solubility enhancement results from complexation. As shown in the third and fourth columns of Table 1, eq. [3] of Mobile Order theory predicts the mole fraction solubility of diuron in dibutyl ether to within 9.1% without introducing any solute–solvent stability constants. Based upon these observations we feel that if diuron does interact specifically with alcohol solvent molecules in solution, the -NC(O)NH- functional group will act as a hydrogen-bond base, rather than as a hydrogen-bond acid.

An "O contribution" (see Ruelle et al. (29, 30))

$$[6]\quad O = \sum v_{Oi} \ln \{1 + K_{Oi} [(\phi_{solvent}/V_{solvent}) - v_{Oi} (\phi_A^{sat}/V_A)]\}$$

Butyl acetate	0.07477	0.1032

[a]Molarities in the dry solvents were calculated from the experimentally measured mole fraction solubilities using the ideal molar volume approximation and V_{diuron} = 164.8 cm^3 mol^{-1}.

must be added to eq. [3] to describe the effect on the solubility of the H-bonds formed between the hydrogen-bond base sites on the solute and hydrogen-bond acid sites on the solvent. Each particular H-bond interaction like oxygen–alcohol (or nitrogen–alcohol) contributes to increase solubility, and is characterized by the group interaction stability constant K_{Oi}. For crystalline proton-acceptor solute molecules having limited solubility ($\phi_A^{sat} \approx 0$) the predictive expression becomes

$$[7] \quad \ln \phi_A^{sat} = \ln a_A^{solid} - 0.5(1 - V_A/V_{solvent})\phi_{solvent} + 0.5 \ln [\phi_A^{sat} + \phi_{solvent}(V_A/V_{solvent})] - \phi_{solvent}^2 V_A(\delta'_A - \delta'_{solvent})^2(RT)^{-1} - r_{solvent}(V_A/V_{solvent})\phi_{solvent} + \sum \nu_{Oi} \ln \{1 + K_{Oi}[(\phi_{solvent}/V_{solvent})\}$$

where ν_{Oi} is the number of active and independent type *i* proton-acceptor sites on the solute molecule. Equation [7] assumes specific interactions in solution, but not in the solid state. The crystalline phase in equilibrium with the saturated solution is taken to be pure diuron. The existence of molecular association complexes in solution does not necessarily require that the complex must also exist in the solid phase. Packing constraints in the crystalline phase may prevent the formation of solid molecular complexes.

The symbols δ'_A and $\delta'_{solvent}$ in eqs. [3], [5], and [7] denote the modified solubility parameters of the solute and solvent, respectively, V_i is the molar volume, and a_A^{solid} is the activity of the solid solute. This latter quantity is defined as the ratio of the fugacity of the solid to the fugacity of the pure hypothetical supercooled liquid. The numerical value of a_A^{solid} can be computed from

$$[8] \quad \ln a_A^{solid} = -\Delta H_A^{fus}(T_{mp} - T)/(RTT_{mp}) + (\Delta C_{p,A}/RT)(T_{mp} - T) - (\Delta C_{p,A}/T) \ln (T_{mp}/T)$$

the solute's molar enthalpy of fusion, ΔH_A^{fus}, and heat capacity difference, $\Delta C_{p,A}$, at the normal melting point temperature, T_{mp}. Contributions from nonspecific interaction are incorporated into Mobile Order theory through the $\phi_{solvent}^2 V_A(\delta'_A - \delta'_{solvent})^2(RT)^{-1}$ term. Ruelle and co-workers (26–30) have presented an impressive set of comparisons between experimental and predicted values for anthracene, naphthalene, pyrene, biphenyl, carbazole, benzil, *p*-benzoquinone, tricosane, octacosane, 10-nonadecanone, 11-heneicosanone, and 12-tricosanone solubilities in a wide range of both noncomplexing and complexing solvents to document the predictive ability of Mobile Order theory.

Predictive application of eqs. [3], [5], and [7] is relatively straightforward. First, an average numerical value of δ'_{diuron} = 24.57 MPa$^{1/2}$ is computed by requiring that each equation (with $r_{solvent}$ = 0 and (or) $K_{ASolvent}$ = 0) perfectly describes diuron mole fraction solubility data in *n*-hexane (δ'_{diuron} = 24.66 MPa$^{1/2}$), *n*-heptane (δ'_{diuron} = 24.46 MPa$^{1/2}$), and *n*-octane (δ'_{diuron} = 24.58 MPa$^{1/2}$). The numerical value of a_A^{solid} = 0.01590 is calculated using eq. [6] with ΔH_A^{fus} = 33 890 J mol^{-1} and T_{mp} = 429.7 K (31). The two heat capacity terms in eq. [8] were set equal to zero as we were unable to find heat capacity data for the subcooled liquid solute. A numerical value of V_{diuron} = 164.8 cm^3 mol^{-1} was used for the molar volume of the hypothetical subcooled liquid solute. The solute's molar volume was estimated using a group contribution method and molar volumes of dichlorobenzene and organic molecules having amide and methyl functional groups.

Table 1 summarizes the predictive ability of Mobile Order theory for the 28 different organic solvents for which both diuron solubility data and modified solubility parameters could be found. Solvent molar volumes and modified solubility parameters are listed in Table 3. We were unable to find modified solubility parameters for all of the secondary and branched alcohols. The modified solubility parameters account for only nonspecific interactions, and in the case of the alcoholic solvents the hydrogen-bonding contributions have been removed. Numerical values of $\delta'_{solvent}$ were obtained from published compilations (26, 27, 29, 30), and were either deduced by regressing actual solubility data of solid *n*-alkanes in organic solvents in accordance with the configurational entropic model of Huyskens and Haulait-Pirson (32) or estimated using known values for similar organic solvents. Examination of the entries in Table 1 reveals that Mobile Order theory does provide fairly reasonable (though by no means perfect) estimates of the solubility behavior of diuron in a wide range of nonalcoholic organic solvents. Average absolute deviation between predicted and observed values is 60.1%. Expressed on a natural logarithmic mole fraction scale, Mobile Order theory predicts the diuron solubilities to within an average absolute deviation of ±0.52 ln units. The arithmetic average of the ln X_A^{sat} difference is –0.06, which indicates a slight systematic error in the predicted values. Many solution models express the differences the between predicted and observed values in terms of the standard deviation. In the case of Mobile Order theory, the standard deviation for the diuron predictions is 0.75 ln units. We do note that Mobile order theory grossly overpredicts the solubility of diuron in acetonitrile. Similar failures were noted previously in the case of anthracene (33), fluoranthene (34), pyrene (34), and phenanthrene (35). We suspect that the overprediction results from either failure of the Scatchard–Hildebrand solubility parameter theory to describe the nonspecific interactions between acetonitrile and the various solutes, or perhaps from an incorrect value for this solvent's modified solubility parameter.

Ethyl acetate	98.5	20.79
Acetonitrile	52.9	23.62
Diuron[b]	164.8[c]	24.57[d]

[a]Tabulated values are taken from a compilation given in Ruelle et al. (26, 27, 29, 30).

[b]The numerical value of a_A^{solid} = 0.01590 was calculated from eq. [8] using ΔH_A^{fus} = 33 890 J mol^{-1} and T_{mp} = 429.7 K (31).

[c]Numerical value of V_{diuron} = 164.8 cm^3 mol^{-1} was estimated using a group contribution method and molar volumes of dichlorobenzene and molecules having amide and methyl functional groups.

[d]Numerical value was calculated using the measured diuron mole fraction solubilities in *n*-hexane, *n*-heptane, and *n*-octane, in accordance with Eqs. [3] and [5]; with $r_{solvent}$ = 0 and (or) $K_{ASolvent}$ = 0.

Alcoholic solvents were excluded from all statistical analyses because the observed mole fraction solubility was used to determine the K_{Oi} stability constant for each diuron–alcohol solvent pair in solution using eq. [7] with v_{oi} set equal to one. Hence, the numerical entries in the third column of Table 1 represent back-calculated mole fraction solubilities, rather than predicted values. The numerical value of K_{Oi} was found to increase with increasing alcohol size, ranging from a lower limit of about $K_{Oi} \approx 2500$ cm^3 mol^{-1} for methanol to an upper value of about $K_{Oi} \approx 32\,000$ cm^3 mol^{-1} for both 1-octanol and 1-decanol. This observation was not unexpected in that diuron is more soluble on a mole fraction basis in the larger alcohols than in the much smaller methanol and ethanol solvents. From a strictly mathematical point-of-view, this requires that the "O contribution" in eq. [7] must become larger with increasing alcohol. Moreover, the increased O contribution must offset the fact that the negative $-\phi^2_{solvent} V_A(\delta'_A - \delta'_{solvent})^2(RT)^{-1}$ term becomes more negative as $\delta'_{solvent}$ moves further away from δ'_{diuron}. This is what happens as one progresses in alcohol size from methanol to 1-decanol. The modified solubility parameter of methanol ($\delta'_{methanol}$ = 19.25 MPa$^{1/2}$) is much closer to the modified solubility parameter of diuron (δ'_{diuron} = 24.57 MPa$^{1/2}$) than is the modified solubility parameter of 1-decanol (δ'decanol = 16.35 MPa$^{1/2}$). Without the O contribution and without a larger K_{Oi} value, Mobile Order theory would have predicted that diuron would be significantly less soluble in 1-decanol than in methanol. Such predictions would be inconsistent with the observed mole fraction solubility data.

Readers are reminded that in evaluating the applicability of Mobile Order theory one must realize that many of these particular systems are highly nonideal, and that the experimental solubility data covers over a 1700-fold range in mole fraction. Had an ideal solution been assumed, then the predicted mole fraction solubility would be $X_A^{sat} = a_A^{solid} = 0.01590$ for each solvent. The ideal solution approximation corresponds to a considerably larger average absolute deviation of 17 590% between predicted and observed values for the nonalcoholic solvents studied.

Excited state intramolecular proton transfer in 2-(2′-hydroxyphenyl)-1*H*-naphth-[2,3-*d*]-imidazole: effects of solvents and pH

Somes K. Das, G. Krishnamoorthy, and Sneh K. Dogra

Abstract: The solvent dependent study of absorption, fluorescence, and fluorescence excitation spectra of 2-(2′-hydroxyphenyl)-1*H*-naphth-[2,3-*d*]-imidazole (HPNI) have indicated the presence of different rotamers and tautomers in the S_0 and S_1 states. Similarity of the absorption and fluorescence spectra of HPNI in protic solvents with those of 2-(2′-methoxyphenyl)-1*H*-naphth-[2,3-*d*]-imidazole (MPNI) suggests that the normal emission is observed from the rotamers **2** and **4**, whereas the tautomer emission is observed from the tautomer **3**, formed by the excited state intramolecular proton transfer (ESIPT) in the rotamer **1** (Scheme 1). Ground state geometries of rotamers **1**, **2**, and the tautomer **3** were optimized using AM1 method. The results show that the rotamer **2** is the most stable and its stability further increases in polar and protic solvents due to the dipolar solvation interaction. The increase in the fluorescence quantum yield of the normal band when methanol or water is added to dioxane is due to: (*i*) the formation of rotamer **4**, where ESIPT is not possible and (*ii*) the decrease in the rate of non-radiative decay process. Very large red shifted fluorescence bands of the monocations of HPNI and MPNI in different solvents have been assigned to the charge transfer band.

Key words: 2-(2′-hydroxyphenyl)-1*H*-naphth-[2,3-*d*]-imidazole, ESIPT, prototropic reactions, fluorescence, 2-(2′-methoxyphenyl)-1*H*-naphth-[2,3-*d*]-imidazole.

Résumé : L'influence du solvant sur les spectres d'absorption, de fluorescence et d'excitation de fluorescence du 2-(2-hydroxyphényl)-1*H*-napht-[2,3-*d*]-imidazole (HPNI) suggère la présence de divers rotamères et tautomères dans les états S_0 et S_1. Les similarités entre les spectres d'absorption et de fluorescence du HPNI dans les solvants protiques et ceux du 2-(2-méthoxyphényl)-1*H*-naph-[2,3-*d*]-imidazole (MPNI) suggèrent que l'émission normale est observée à partir des rotamères **2** et alors que l'on observe l'émission tautomère à partir du tautomère **3** qui se forme par un transfert intramoléculaire de proton dans l'état excité (TIPEE) du rotamère **1** (Schéma **1**). Les géométries des rotamères **1** et **2** et du tautomère **3** dans leur état fondamental ont été optimisées à l'aide de la méthode AM1. Les résultats montrent que le rotamère **2** est le plus stable que sa stabilité est accrue par les solvants polaires et protiques en raison de l'interaction de solvatation dipolaire. L'augmentation du rendement quantique de fluorescence de la bande normale par addition de méthanol ou d'eau au dioxane résulte de: (*i*) la formation du rotamère **4** dans les cas où le TIPEE n'est pas possible; et (*ii*) de la diminution de la vitesse du processus de décroissance non radiative. Les importants déplacements vers le rouge des bandes de fluorescence des monocations du HPNI et du MPNI dans différents solvants ont été attribués à la bande de transfert de charge.

Mots clés : 2-(2-hydroxyphényl)-1*H*-napht-[2,3-*d*]-imidazole, TIPEE, réactions prototropiques, fluorescence, 2-(2-méthoxyphényl)-1*H*-naph-[2,3-*d*]-imidazole.

[Traduit par la Rédaction]

1. Introduction

The excited state intramolecular proton transfer (ESIPT) reactions have been an attractive topic of recent investigations as it is a possible mechanism for a number of photochemical (1–6) and photobiological processes (7). The main requirement of this process is that intramolecular hydrogen bonding should be present between the acidic and the basic moieties of the molecule in the ground state. Upon excitation to the first singlet state, the charge densities are changed on these basic centres, thereby drastically altering the acidic and the basic properties of these groups and thus leading to the intramolecular proton transfer. The acidic groups are in general -OH and -NH_2 and the basic groups are =N- and >C=O. Thus phototautomerism could be keto–enol or amine–imine tautomerization. It has been found that this process is extremely fast and requires nearly zero activation energy (7–10), and also occurs in frozen and solid states. Recently many molecules (1–12) showing ESIPT process have been investigated thoroughly and these molecules have been used in the action of many lasing dyes (13–18), polymer photostabilizers, (19) etc.

Scheme 1.

Recently we have studied ESIPT in a large number of molecules containing keto–enol (20–22) or amine–imine (23–25) phototautomerism and have started using these molecules as probes to study the characteristics of the organized assemblies (26–28). Some of these molecules exhibit dual fluorescence (20–23) and the others only one fluorescence band (24–25). Acuna et. al. (15) have shown that 2-(2′-hydroxyphenyl)benzimidazole (HPBI) molecule can be used as a tunable dye laser in the range of 440–470 nm. In continuation of our work in this area (ESIPT), we have synthesized HPNI and carried out this study from the following angles: (*i*) being a larger condensed ring (naphthalene), we are expecting that the low energy fluorescence band of HPBI will be further red shifted in HPNI and thus may provide a tunable dye laser range towards the red side of 470 nm; and (*ii*) HPNI will be more hydrophobic than HPBI. It will be present in the interior of the micelles, and thereby may provide the information about the core of the micelles and, (*iii*) effect of the increase in conjugation in the side of the imidazole moiety to the property of ESIPT. To supplement the above study, MPNI has also been synthesized and studied. Since MPNI will not show keto–enol tautomerization, the spectral characteristics of MPNI will help in assigning the spectra of HPNI to different species.

2. Materials and methods

HPNI and MPNI were synthesized by condensing 2,3-diaminonaphthalene and 2-hydroxy- and 2-methoxybenzoic acid (all from Aldrich) in polyphosphoric acid medium at 140°C as suggested in the literature (29). Both these compounds were purified by repeated crystallization from methanol. The purity of the compounds were checked by TLC, absorption spectra, NMR, and by getting similar fluorescence spectra in any one particular solvent when excited at different wavelengths. All the solvents were AnalR grades. Cyclohexane (S.D. Fine Chemicals), dioxane, ether, acetonitrile, methanol (all E. Merck), and ethanol were further purified according to the procedure suggested in the literature (30). Ethylacetate and *n*-butanol (E. Merck) were used as received. All these solvents were free from spurious emission when excited at the normal range. Triply distilled water was used for making aqueous solutions.

Absorption spectra were recorded on a Shimadzu spectrophotometer model UV 190, equipped with a 135 U chart recorder. Fluorescence measurements were carried out on the scanning spectrofluorimeter, fabricated in our laboratory, and the details are available elsewhere (31). Fluorescence excitation spectra were recorded on Perkin–Elmer Luminescence Spectrophotometer Model LS 50B equipped with a Wipro Geneous PC 386X (both excitation and emission slit widths used were 2.5 nm). Fluorescence spectra were corrected according to the Parker's method (32). Fluorescence quantum yields were determined with solutions having absorbance less than 0.1 and using quinine sulphate in 0.1 N H_2SO_4 as a reference (33) (ϕ = 0.55). Excited state lifetimes were measured on a time correlated single photon counting nanosecond spectrofluorimeter, supplied by Applied Photophysics Limited (details are available in our recent paper (34)). Due to the poor solubility of HPNI in cyclohexane and water, saturated solutions were used. In other solvents, the concentrations of HPNI and MPNI were 1×10^{-5} M. In the study of prototropic reactions, the amount of methanol used did not exceed more than 5% (V/V) and the concentrations of the compounds were maintained at 1×10^{-5} M. pH in the range of 3–11 was maintained by adding appropriate amounts of NaOH and orthophosphoric acid. Modified Hammett's acidity functions (35) (H_o) for H_2SO4–H_2O solutions and Yagil's basicity scale (36) for NaOH–H_2O solutions were used for solutions with pH < 1 and pH > 13 respectively. pH of the solutions were measured on Toshniwal pH meter model CL 46A.

Results and discussion

3. MPNI

3.1 Effect of solvents on the spectral characteristics

Absorption band maxima (λ_{max}^{ab}), log ε_{max} (wherever MPNI is soluble), fluorescence band maxima (λ_{max}^{fl}), and fluorescence quantum yield (ϕ_{fl}) recorded in seven different solvents are compiled in Tables 1 and 2. Absorption spectrum (Fig. 1*a*) is not affected much with the change in the polarity of solvents, except that it is slightly blue shifted in water. The structured absorption spectrum of MPNI in nonpolar or weakly polar solvents is nicely described by a vibrational frequency of 1400 ± 50 cm^{-1}. The structure is lost as the polarity and hydrogen bonding capacity of the solvent increases.

The structured fluorescence spectrum (Fig. 2*a*) of MPNI in cyclohexane is also described by a vibrational frequency of 1450 ± 50 cm^{-1}. Similar to the absorption spectrum, structure is lost in highly polar and protic solvents. These results resemble the vibrational frequencies observed in the condensed aromatic hydrocarbons containing more than two rings and this vibrational frequency corresponds to the frequency of the dominant C-C vibrational modes (37). Further,

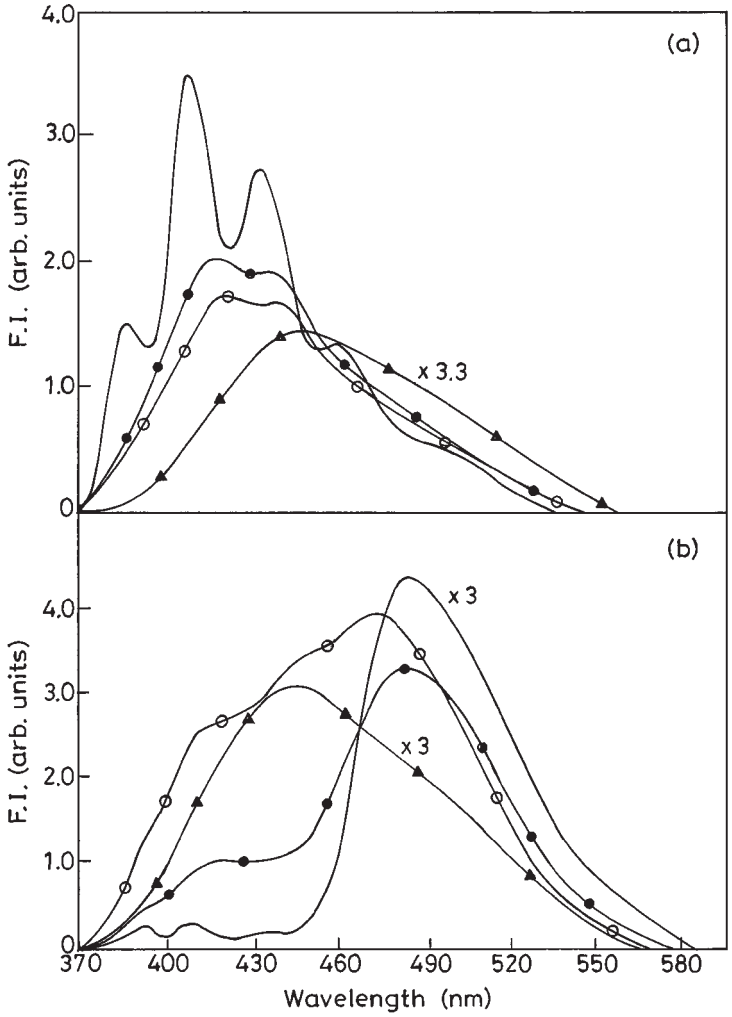
Fig. 1. Absorption spectra of (*a*) MPNI and (*b*) HPNI in different solvents at 298 K. [MPNI] or [HPNI] = 1×10^{-5} M. _____, cyclohexane (saturated solution); ·___·___·, acetonitrile; o___o___o, methanol; ▲___▲___▲, water (saturated solution).

the fluorescence band maxima and the fluorescence quantum yields observed in MPNI in all the solvents are independent of wavelength of excitation. This clearly indicates that the fluorescence is occurring from the most relaxed state in all the solvents and the solvent relaxation time is much smaller than the radiative lifetime as observed in other cases (38, 39). The fluorescence excitation spectra recorded at different emission wavelengths are similar to each other as well as to the absorption spectra. This suggests that not much change is observed in the geometry of MPNI, when excited to the S_1 state and similar vibrational frequencies observed in the absorption and the fluorescence spectra reflect the mirror image symmetry (37).



Excited state lifetimes of MPNI were measured at 440 nm by exciting at 337 nm in five different solvents. The fluorescence decay followed a single exponential in each case having χ^2 in the range of 1.0 ± 0.15 and nice autocorrelation function. Figure 3*a* depicts the fluorescence decay curve in water as a representative curve and the relevant data are compiled in Table 2. The results of lifetime data also substantiate the results of solvent study that similar to the ϕ_{fl}, the lifetimes are not much affected by the solvents except water.

3.2 Effect of pH on the spectral characteristics

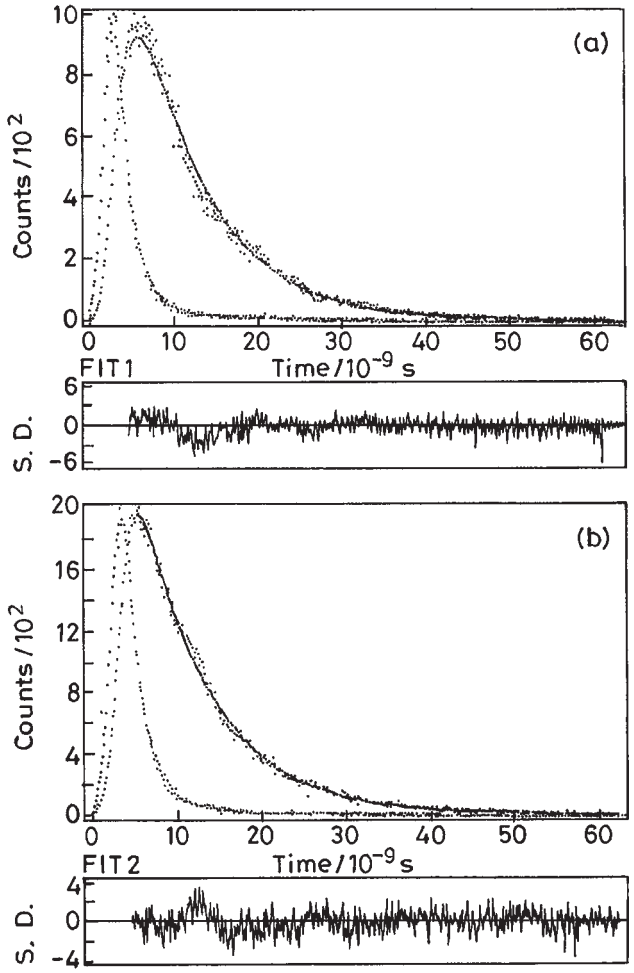
The absorption and the fluorescence spectra of the various prototropic species of MPNI were recorded at different acid-base concentrations. The relevant data are mentioned in Table 1 and Table 2, whereas Scheme 1 depicts the various proton transfer reactions of MPNI in the ground and the first excited singlet states. Figures 4(*a*) and 4(*b*) depict the absorption and the fluorescence spectra of the different prototropic species of MPNI in aqueous medium. The data clearly show that MPNI is a neutral species in the pH range of 7–12; the monocation (MC) at pH < 2 and the monoanion (MA) above H_= 15. Red shifts observed in the absorption spectra of the MC and the MA in comparison to the neutral species are consistent with the protonation of the -N= atom and deprotonation of the >NH moiety, respectively (40). The fluorescence spectrum of MPNI remained unchanged in the basic range even up to H_= 16 (formation of the MA by deprotonating the >NH group), whereas the fluorescence spectrum of the MC is largely red shifted. Similar behaviour is also observed during the deprotonation and protonation reactions of 2-phenylbenzimidazole (41) (PBI) and thus supports the assignment of the respective spectrum to the formation of the MA and the MC. It has been established (42–44) that hardly any change is observed in the fluorescence spectra of the MCs of benzimidazoles if the transition involved is of π–π^* in nature and large red shifts are ob-

© 2000 NRC Canada

Fig. 2. Fluorescence spectra of (*a*) MPNI and (*b*) HPNI in different solvents at 298 K. [MPNI] or [HPNI] = 1×10^{-5} M. λ_{exc} = 350 nm. _____, cyclohexane; ·___·___·, acetonitrile; o___o___o, methanol; ▲___▲___▲, water (5% methanol).

served in the emission spectra of the MCs if the transition is of charge transfer in character. Fluorescence spectral data of the MC of MPNI, recorded in different solvents (Table 2), clearly established that the fluorescence spectrum of the MC of MPNI involves the charge transfer character, similar to some of the benzimidazoles (42, 43).

The pK_a values of the MC–N and the N–MA equilibria were calculated using absorption spectral data and the excited state pK_a (pK_a^*) value for the MC–N equilibrium has been determined using the fluorimetric titration method (Fig. 5). The pK_a^* for the N–MA equilibrium could not be determined because hardly any changes were observed either in the fluorescence band maxima or in the fluorescence intensities of MPNI. pK_a values are listed above the arrows and pK_a^* values below the arrows of the prototropic reactions given in Scheme 1. Similar to the spectral characteristics, pK_a values are also consistent with the prototropic reactions of PBI (41) and thus the addition of one benzo ring to BI does not affect the basicity of the =N- atom. Observation of similar pK_a and pK_a^* values for the MC–N equilibrium indicate that the equilibrium is not established in the S_1 state. Since the intersection point between the increase in the fluorescence intensity curve of $HMPNI^+$ and the decrease in the fluorescence intensity curve of neutral MPNI is at $I/I_o = 0.5$, it clearly suggests that no other reaction is taking place except protonation of MPNI and deprotonation of $HMPNI^+$ in the S_1 state. As pointed out by Schulman (45), the fluorimetric titration curves give the ground state pK_a values if the rate of the pseudo-first-order dissociation of an excited acid or protonation of an excited base is small (~10%) in comparison to the reciprocal of the lifetime of the excited acid or base and the rate of protonation of the excited conjugate base ($k_{-1}[H^+]$) or deprotonation of the excited conjugate acid is small (~10%) in comparison to the reciprocal of the lifetime of the excited base or acid. As mentioned above, since the prototropic equilibrium between $HMPNI^+$ and MPNI is not established during the lifetime of these conjugate acid-base pairs, it suggests that $k_1 < 1.8 \times 10^7$ s^{-1} and similarly $k_{-1}[H^+] < 1.4 \times 10^7$ s^{-1} at pH 2.



4. HPNI

4.1 Absorption Spectrum

The absorption characteristics of HPNI in different solvents are compiled in Table 3 and the spectra are shown in Fig. 1*b*. In the nonpolar and polar/aprotic solvents, the

© 2000 NRC Canada

Fig. 3. Fluorescence decay curve for (*a*) MPNI (*b*) HPNI in water. λ_{exc} = 337 nm. For MPNI, λ_{em} = 405 nm; for HPNI, λ_{em} = 490 nm.

absorption maxima are at ~342 and 350 nm, whereas in the polar/protic solvents, the band maximum is at ~343 nm with shoulders at ~360 and 380 nm. The tail part of the absorption spectrum is more stretched towards the red in the latter solvents and resembles the absorption spectrum of MPNI, where only one rotamer is expected.

The absorption spectrum of HPNI in pure water, methanol, and acetonitrile media under acidic and basic conditions have also been studied. Figure 6*a* only depicts the absorption spectra of these ionic species in methanol and the relevant data are compiled in Table 3. Under the mildly basic conditions (pH 13.5 in water and 0.6M NaOH in methanol), the red shifted absorption spectrum of HPNI in comparison to the neutral species can be assigned to the MA formed by deprotonating the -OH group. No further change was observed in the absorption spectrum of HPNI even up to H_= 16 in aqueous medium, indicating that the deprotonation of >NH does not occur in HPNI. The pK_a value for the N-MA equilibrium is found to be 10.4.

Under acidic conditions, the absorption spectrums of the neutral species in all the solvents are nearly similar to one another except water where there is only one absorption maximum (342 nm) and the structured band is replaced by a broad band with a maxima at ~340 nm and a shoulder at ~355 nm, as observed in the case of MPNI. The species so formed is the MC, obtained by the protonation of =N- atom. The pK_a value for the protonation reaction of HPNI is found to be 4.9. This is slightly lower than that of MPNI and could be due to the presence of intramolecular hydrogen bonding between = N- and hydroxyl proton. Small differences in the pK_a values for the hydroxy and methoxy derivatives have also been observed in HPBI(20) and 2-(2′-hydroxyphenyl)benzoxazole (HPBO) (46).

4.2 Fluorescence Spectrum

On excitation at 350 nm, dual fluorescence was observed in all the solvents. The relevant data are compiled in Table 4 and the fluorescence spectra in different solvents are shown in Fig. 2*b*. The fluorescence band maximum of the short wavelength (SW) band is red shifted and the long wavelength band (LW, tautomer, T-band) is blue shifted with increases in the polarity and hydrogen bonding capacity of the solvents. In water, the two bands are mixed to such an extent that it is very difficult to resolve them. The structure observed in the SW band of HPNI in nonpolar or weakly polar solvents is not as sharp as observed in MPNI. The fluorescence quantum yield of the SW band (ϕ_{fl}^{N}) increases under the above environments, whereas that of the tautomer band (ϕ_{fl}^{T}) remains nearly constant in polar/aprotic solvents but decreases with increases in the hydrogen bonding capacity of the solvents. The ϕ_{fl} of both the bands could not be measured in protic solvents because of their mixing. This is also evident from the fact that the band width at half the maximum height (BWHMH) is larger in protic solvents in comparison to that of aprotic solvents. No effect is observed on the fluorescence band maxima of both the bands (when excited with different wavelengths towards the red) but ϕ_{fl}^{T} decreases and ϕ_{fl}^{N} increases.

The fluorescence excitation spectra of HPNI have been recorded in all the solvents except *n*-butanol at seven different emission wavelengths in the range of 385–525 nm. Figure 7 depicts the above spectra in dioxane and methanol recorded only at two extreme wavelengths (i.e., 510 nm and 410 nm in dioxane and 490 nm and 390 nm in methanol are representative of the region 490–525 nm and 385–460 nm respecticely). It is clear from the results that the fluorescence excitation spectra recorded in the range of 490–525 nm are similar to the absorption spectrum of HPNI recorded in nonpolar and polar/aprotic solvents and those recorded in the range of 385–460 nm are similar to the absorption spectra of HPNI recorded in polar/aprotic solvents as well as to the absorption spectrum of MPNI. This difference clearly suggests that the normal and the tautomer emissions originate from two distinctly different species.

Excited state lifetimes of HPNI were measured at 405 nm (N-band) and 520 nm (T-band) in different solvents. The fluorescence decays observed in nonpolar and polar/aprotic solvents of the tautomer band follow a single exponential decay with χ^2 in the range of 1.0 ± 0.1, whereas double exponential decay is observed for the tautomer emission in dioxane containing even a slight amount (5%) of water. In case of the dioxane/water mixture, both the lifetimes (τ_{T1} and τ_{T2}) increase with an increase of water content. Amplitude of the short-lived component decreases and that of the long-lived component increases with an increase of water. The value of

the longer component (τ_{T2}) in pure water nearly resembles that of MPNI in water. A single exponential is also observed for the fluorescence decay of the normal band in nonpolar and polar–aprotic solvents. In dioxane containing slight amount of water, the biexponential decay is observed in the normal emission. The lifetime of the fast-decaying component (τ_{f1}) remains nearly unchanged, whereas the value of the slow-decaying component (τ_{f2}) increases with increase of water content in dioxane. The amplitude of the fast-decaying component decreases whereas that of slow-decaying component increases under the above environment. Further, the values of τ_{T2} and τ_{f2} are nearly similar to each other but those of τ_{f1} are shorter than those of τ_{T1}. The relevant data are compiled in Table 5 and Fig. 3*b* represents the fluorescence decay of the tautomer emission in water as a representative plot.

The fluorescence spectra of HPNI in all the solvents under acidic conditions are largely red shifted and the red shift increases with the increase in polarity of the solvents. The fluorescence band maxima of all the ionic species of HPNI are independent of λ_{exc} (between 325 –370 nm in all these solvents). The fluorescence band maximum, as well as, BWHMH of HPNI do not change in the pH/H_o range of 2.5 to –7 in aqueous medium and up to 0.002–3.0 M acids in nonaqueous solvents. The fluorescence band maximum of the MC of HPNI and that of MPNI in the aqueous medium are nearly at the same wavelength. A large blue shift (447 nm) is observed at $H_o < -7$ in the fluorescence spectrum of the MC of HPNI, indicating the formation of the DC protonating the hydroxyl group (20). Under basic conditions, the fluorescence band maximum of HPNI observed in protic solvents are nearly at the same wavelength and are not dif-

ferent from that of neutral HPNI in water. The relevant data are compiled in Table 4 and the fluorescence spectra of the prototropic species are shown in Fig. 6*b*. The excited state pK_a value for the MC-N equilibrium has been determined with the help of fluorimetric titrations as shown in Fig. 5, whereas that of the N–MA equilibrium could not be determined as hardly any change in the band maximum or fluorescence intensity was observed with increase of pH. The pK^*_a values using the Forster cycle method could not be calculated because the absorption or the fluorescence spectra were representing two rotamers. The pK^*_a value from the fluorimetric titrations were given below the arrows of Scheme 1.

4.3 Spectral characteristics of HPNI in mixed solvents

Absorption spectrum of HPNI has been studied in dioxane–water and dioxane–methanol mixtures. The changes observed in the absorption spectra are only in the long wavelength band, whereas the other band systems at 310 nm and 297 nm are not affected. The 350 nm band maximum in pure dioxane is replaced by a 343 nm band with a shoulder at 380 nm when only 10% methanol or water is added to dioxane. Further addition of methanol or water does not lead to any change in the absorption spectrum. Figure 8*a* depicts the absorption spectra of HPNI in different proportion of dioxane–water (V/V) mixtures.

Dual fluorescence is observed in pure dioxane as said earlier. The ratio of ϕ^T_{fl}/ϕ^N_{fl} is 5 in pure dioxane. With the addition of only 10% methanol or water, the fluorescence intensity of the tautomer band measured at 520 nm decreases very sharply to 66% of that observed in pure dioxane, followed by slow decrease to 40% in pure water. On the other hand, the fluorescence intensity of the normal band increases very sharply by 6 times with the addition of only 20% water, remains nearly constant up to 70% of water, and then decreases to half of its maximum intensity. But it is still larger by a factor of three when compared to that in pure dioxane. This behaviour is different from that observed in HPBI (26), in the sense, that emission intensities of the tautomer and the normal bands of HPBI increased when water was added to dioxane. The fluorescence band maximum of the normal emission does not change much after a 20% addition of protic solvents to dioxane, but that of the tautomer band is blue shifted under similar environments. Similar to the results in the pure solvents, changing the excitation wavelength from 350 to 380 nm does not shift the band maxima of both the emissions, but fluorescence intensity of the normal band increases by a factor of 2, whereas not much

change is observed in the emission intensity of the tautomer band. Unlike that observed in pure solvents, the normal emission follows double exponential decay in mixed solvents (Table 5). Figure 8*b* depicts the fluorescence spectra of HPNI, whereas Fig. 9 shows the variation of the fluorescence intensities of both the bands when water is added to dioxane.

4.4 Quantum mechanical calculations

The PC MODEL 2 program (47) was used to find the starting geometries of the species **1**, **2**, and **3**. The ground state geometries of all the species were then fully optimized by the AM1 method (48) (QCMP 137, MOPAC 6/PC). It is evident from the data of Table 6 that the two rings (i.e., naphthimidazole and hydroxyphenyl), although connected by the intramolecular hydrogen bonding, are not completely coplanar in the rotamers **1** and **2**, whereas the tautomer **3** is planar. This is also reflected by the bond lengths between C_2 and C_1' in three different species. Energies of the rotamers **1** and **2** were also calculated by taking different dihedral angles (ϕ) and the energies so obtained are plotted as a function of angle ϕ in Fig. 10, which describes the potential energy

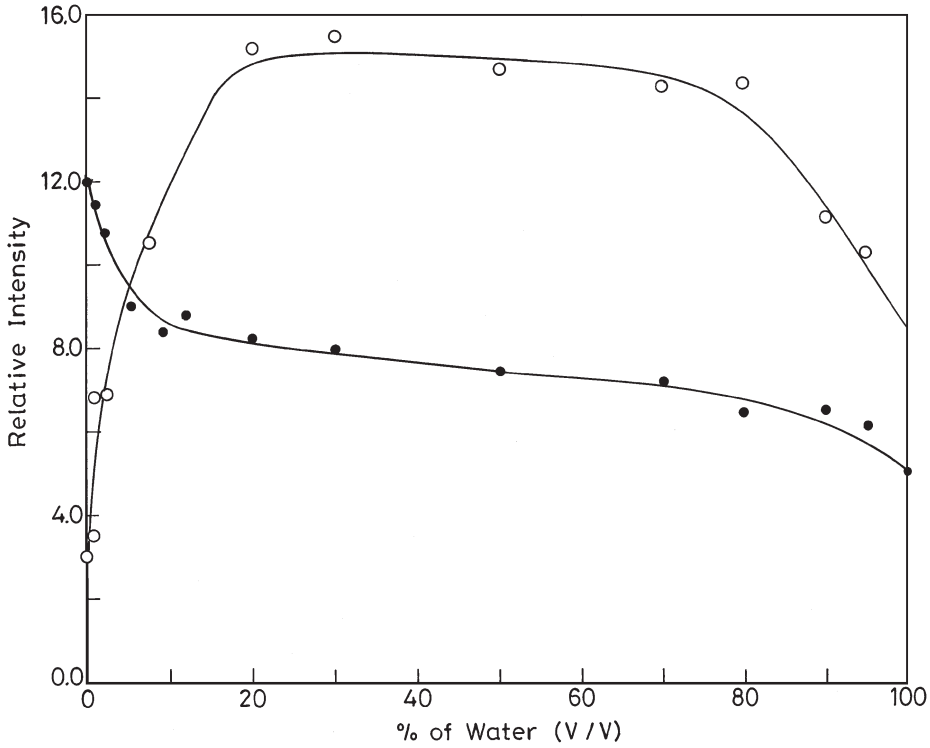
	$O_{7'}$ = 6.249	$O_{7'}$ = 6.269	$O_{7'}$ = 6.411
	$H_{8'}$ = 0.750	$H_{8'}$ = 0.770	$H_{8'}$ = 0.687

curve for the interconversion of the rotamers **1** and **2** in the ground state. For the isolated molecule and in the ground state the barrier height for the interconversion of rotamer **2** to **1** is 7.43 kJ mol^{-1}. The dipolar solvation energy (49, 50) is calculated using the following relation:

$$E_{sol} = -[\mu_g^2/4\pi\varepsilon_o a^3] f(\varepsilon)$$



where $f(\varepsilon) = (\varepsilon - 1)/(2\varepsilon + 1)$, μ_g is the ground state dipole moment, a is the Onsager cavity radius, and ε is the dielectric constant of the solvent.

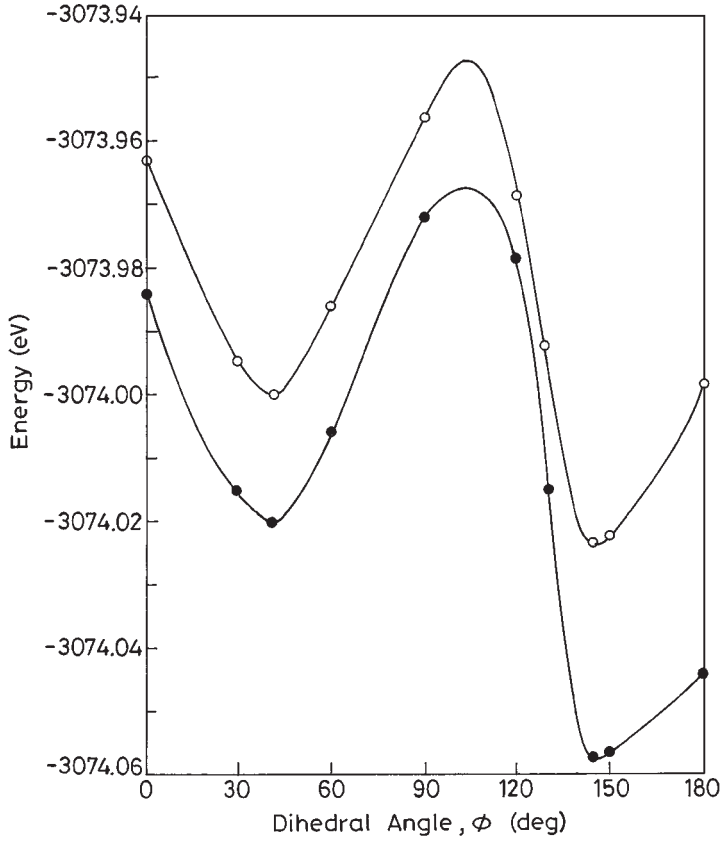
4.5 Discussion

The large red shifted absorption spectrum of HPNI in comparison to that of naphthalene (51) and similar to that of 2-(3′-hydroxy-2′-naphthyl)benzimidazole (4) (HNB), as well as, the vibrational frequencies in the absorption and fluorescence spectra of MPNI or in the normal emission of HPNI, are consistent with the spectral properties of the linearly condensed ring system (37, 51). The values of the molecular extinction coefficients of different bands and the fluorescence quantum yields are indicative of π–π^* transition in HPNI (37, 51). The resemblance of the absorption spectra of HPNI in protic solvents with that of MPNI clearly suggests

© 2000 NRC Canada

Fig. 9. Variation of fluorescence intensities of HPNI at 414 nm (o___o___o) and 520 nm (·___·___·) in different proportions of dioxane–water mixtures. λ_{exc} = 350 nm. [HPNI] = 1 × 10^{-5} M.

that the possibility of the formation of the MA of HPNI in polar/protic solvents (as suggested in the case of HPBI (52)) or of the tautomer as observed in case of 2-(3′-hydroxy-2′-pyridyl)benzimidazole (HPyBI (53)) in the ground state can be rejected. It may be proposed that 350 nm band belongs to the rotamer **1** and the 343 nm band with a shoulder at 380 nm can be assigned to the rotamer **2**.



The absorption and the fluorescence spectra in different solvents, fluorescence excitation spectra recorded at different emission wavelengths, and two distinctly different lifetimes observed for the normal and the tautomer emissions clearly demonstrate the presence of at least two species in the ground state and excited state. Since the lifetimes observed for the two emission bands are different in all the solvents, it further suggests that the rotamers responsible for these emissions are not in equilibrium with each other in the S_1 state. Based on the earlier results in other molecules (12, 54), the tautomer emission in HPNI also results from the species **3**, formed from by the ESIPT in the rotamer **1**.

Based on the following results, the normal emission in nonpolar solvents is assigned only to the rotamer **2**: (*i*) the fluorescence excitation spectra recorded at normal band agree with the absorption spectra of MPNI where only one type of rotamer **2** is possible. AM1 calculations have further shown that the rotamer **1** is less stable by 13.0 kJ mol^{-1} compaired to the rotamer **2** for MPNI in the gaseous state. Similar behaviour has also been observed in HPyBI (3); (*ii*) the ϕ_{fl}^{N} increases with an increase in the excitation wavelength; (*iii*) in dry nonpolar solvents, the competition between the intra- and intermolecular hydrogen bonding is completely absent, and (*iv*) the rotamer **2** can not undergo ESIPT in any solvent.

The large increase in ϕ_{fl}^{N} in protic solvents can not be accounted for simply due to the increase in the population of the rotamer **2** over **1** by the polarity factor, as explained below. Semiempirical quantum mechanical calculations using the AM1 method (48) have shown (Table 6) that in isolated condition and in the ground state, the rotamer **2** is more stable than the rotamer **1** and the tautomer **3** by 2.33 and 30.79 kJ mol^{-1} respectively, whereas in methanol and water the rotamer **2** is more stable by 3.54 and 29.03; 3.57 and 28.98 kJ mol^{-1} respectively. Based on the Maxwell–Boltzmann's distribution, the additional stability of the rotamer **2** will increase its population over the rotamer **1**in the latter solvents by a factor of exp(–$\Delta E/RT$), i.e., approximately a 30% increase at 298 K in these solvents when compared to that in dioxane or cyclohexane. This will only increase ϕ_{fl}^{N} by 30% which is too small to account for a 4–5-fold increase observed in protic solvents. In other words, in strong hydrogen bonding solvents like alcohols and water, the population of the rotamer **4** will increase at the expense of the rotamer **1** (specially) and may be at the removal of the rotamer **2** also. In the presence of protic solvents, while the rotamer **2** continues to give normal fluorescence, an additional increase in the fluorescence intensity of the normal band arises from the rotamer **4**, formed from the rotamer **1** by disrupting the intramolecular hydrogen bond between =N- and the hydroxyl proton. Since the ESIPT process cannot take place in the rotamer **4**, the fluorescence occurring from it energetically will be similar to the normal fluorescence and thus will increase the fluorescence quantum yield. The results observed in dioxane–methanol and dioxane–water mixtures substantiate the above assignment. Similar enhancement of ϕ_{fl}^{N} has also been observed in other

© 2000 NRC Canada

Fig. 10. Potential energy curves for the interconversion of rotamer **1** and **2** of the HPNI molecule as isolated (o___o___o) and solvated (·___·___·) in the S_o state.

molecules (54, 55) and a similar mechanism has been proposed (9). The time dependence fluorescence decay of the normal emission in dioxane–water solution has also supported more than one species as being responsible for this emission. Unlike in pure solvents, the fluorescence decay of the tautomer emission in water or in dioxane containing water is always biexponential. The lifetime and the amplitude of the long-lived species increase with an increase in the amount of water. Since the lifetime of the long-lived species in the tautomer band is nearly equal to the lifetime of the long-lived species in the normal emission, as well as, it also resembles with that of MPNI in different solvents, it may be suggested that the biexponential decay observed in the tautomer band is due to the mixing of two emission bands as mentioned earlier i.e., tautomer emission and normal emission originating from the rotamer **2**. The smaller value of the amplitude of τ_{T2} in comparison to that of τ_{f2} could be due to the small proportion of the fluorescence intensity of the normal emission at ~500 nm. Lastly, the values of the lifetimes observed in the N-emission are different from each other and the lifetime of the fast-decaying component is smaller than that of the tautomer emission. This clearly suggests the fast-decaying lifetime is not from the tautomer emission and thus can be assigned to the species **4**.

Effect of pH: In each solvent, the fluorescence band of HPNI at an acid concentration of 0.001 M is very large red shifted in comparison to the normal emission of the neutral HPNI and emission follows a single exponential decay when monitored at either 445 nm or at 495 nm. This clearly establishes that there is only one kind of MC, formed by protonating the $=N_3$- atom. Although the fluorescence band maxima in different solvents at 0.001 M acid concentration are close to the tautomer emission band maxima in these nonaqueous solvents, the tautomer formation can be rejected on the following grounds: (*i*) it is well known that the aromatic alcohols become stronger acids on excitation and also the rate of deprotonation in aromatic alcohols is much greater in water than in alcoholic solvents such as methanol (40) or in polar–aprotic solvents. Had the deprotonation of hydroxyl group been occurred in the protic nonaqueous solvents, it should have also been observed in water. But the emission band observed from the species under acidic condition in aqueous medium is very large red shifted in comparison to the normal or the tautomer band in water under neutral condition. It also agrees with the emission band maximum noted in the MC of MPNI in water. Further the deprotonation of the hydroxyl group would have been the slowest in acetonitrile; (*ii*) no further change is observed in the fluorescence band maxima and BWHMH even up to 3 M H_2SO_4 in ethanol, 1M in acetonitrile, and H_o –6 in water, and (*iii*) the fluorescence excitation spectra resemble the absorption spectra of the MC of HPNI. Thus based on the above arguments and large red shifts observed in the fluorescence band maxima of the MC of MPNI with increase in the polarity of the solvents, the emission in the MC of HPNI

© 2000 NRC Canada

can also be assigned to the charge transfer band. A similar behavoiur has also been observed in the emission spectra of the MCs of benzimidazole and its alkyl derivatives (42, 44).

Under basic conditions and in all solvents, fluorescence excitation spectra overlap with the absorption spectra, fluorescence spectra exhibit normal Stokes shifted band, and emission in each solvent follows the single exponential decay. These observations suggest that emission at 445 nm is attributed to the MA, formed by the deprotonation of hydroxyl group. The pK_a and pK_a^* observed for the deprotonation of HPNI is lower than that of MPNI. This is because the former molecule involves the deprotonation of the -OH proton, whereas the latter one involves the deprotonation of the >NH proton. No further changes in the spectral characteristics of HPNI suggest that the bond between >NH and O^- is very strong and can not be broken even at $H_- = 16$. Similar behaviour is also observed in HPBI (20). This is further substantiated by the vibrational structure observed in the absorption spectrum of the MA of HPNI.

6. Conclusions

The following conclusions can be drawn from the above study: (*i*) in nonpolar solvents, the LW emission is observed from the tautomer **3**, formed by the ultrafast ESIPT processes from the rotamer **1**, whereas the normal emission is from the rotamer **2**. Rotamer **2** is predominant in nonpolar solvents, whereas in the protic solvents, species **4** may be more predominant; (*ii*) the fluorescence quantum yield of the normal emission increases in polar/protic solvents whereas that of the tautomer band nearly remains constant in polar/aprotic solvents, but decreases as the hydrogen bonding capacity of the solvent increases; (*iii*) the time-resolved studies have shown that rotamer **1** and **2** are distinctly different in the S_1 state and the equilibrium is not established between them in the excited state. Rotamers **2** and **4** on excitation give normal emission, where rotamer **1** on electronic excitation produces the tautomer **3** in the ultrafast time scale; (*iv*) the fluorescence spectrum of the MC involves the charge transfer band, whereas the fluorescence spectrum of the MA involves π–π^* transition.

A performance comparison between the CEP effective core potential/triple-split basis set approach and an all-electron computational method with emphasis on small Ti and V alkoxide complexes

Gustavo Larsen

Abstract: The structures of 30 neutral and positively charged small clusters were optimized and a number of hypothetical reaction pathways were investigated to compare the performance of the B3LYP/CEP-121G(d) Effective Core Potential/triple-split basis set method (ECP, method 1) and the B3LYP/6-311G(d) approach (method 2) for geometry optimizations. In addition, single point calculations at the B3LYP/CEP-121+G(d,p) (on geometries optimized by method 1) and at the B3LYP/6-311+G(d,p) (on optimized structures from methods 1 and 2) levels were also carried out. The augmented CEP-121G scheme is roughly 1.4 to 2.0 times computationally cheaper than full electron calculations, and is able to reproduce structures, infrared frequencies, thermochemical parameters and dipole moments predicted by the all-electron basis set employed in this study. From a practical viewpoint, the results confirm that ECPs can be used in combination with density functional methods, despite the fact that the former are typically generated via a Hartree–Fock approach.

Key words: CEP, Effective Core Potentials, alkoxides, DFT, Ti.

Résumé : On a optimisé les structures de 30 petits agrégats neutres ou chargés positivement et on a étudié un certain nombre de voies réactionnelles hypothétiques afin de pouvoir comparer la performance pour fins d'optimisation de la géométrie du potentiel effectif de coeur B3LYP/CEP-121-G(d) avec ensemble de base à triple dédoublement (« ECP », méthode 1) et l'approche B3LYP/6-311G(d) (méthode 2). De plus, on a effectué des calculs ponctuels aux niveaux B3LYP/CEP-121-G(d,p) (sur des géométries optimisées à l'aide de la méthode 1) et B3LYP/6-311+G(d,p) (sur des structures optimisées à l'aide des méthodes 1 ou 2). La méthode CEP-121-G améliorée est environ 1,4 à 2,0 fois moins coûteuse, d'un point de vue temps de calcul, que les calculs impliquant tous les électrons et elle permet de reproduire les structures, les fréquences infrarouges, les paramètres thermodynamiques et les moments dipolaires obtenus par l'ensemble de base comportant tous les électrons utilisé dans cette étude. D'un point de vue pratique, ces résultats confirment que l'on peut utiliser les ECP combinées aux méthodes de densité fonctionnelle même si celles-ci sont généralement générées par une approche de Hartree–Fock.

Mots clés : « CEP », potentiels effectifs de coeur, alcoolates, « DFT », Ti.

Introduction

A number of Effective Core Potential (ECP) methods for the treatment of inner shell electrons have been proposed in the past. In particular, the Hay and Wadt (1), the Cundari and Stevens (2), and the relativistic ECPs from Ross et al. (3) have gained popularity to evaluate both geometry and energetics of molecules containing post-second row elements. While all-electron Hamiltonians are generally preferred, an ECP approach is often a practical choice to study relatively large systems in which molecular structure and energetics of reactions involving similar species are sought.

Accepted September 15, 1999.

Several authors have pointed to the fact that ECPs are generally adjusted to reproduce the properties of isolated atoms at the Hartree–Fock (HF) level, and that their use in density functional calculations (DFT) is not a priori justified (4, 5). This is chiefly due to the fact that exchange-correlation functionals are nonlinear with electron density, which results in core and valence contributions that are difficult to uncouple. However, Russo et al. (4) noted that all-electron basis sets such as 6-31G that implicitly contract the core often perform very well, and there is certainly no restriction as to their use in DFT studies. Indeed, these authors demonstrated that, for a small number of first-row transition metal complexes, the Hay and Wadt core potentials can be used in DFT studies to obtain accurate results. In any event, the combination of DFT methods with core potentials might constitute an important computational convenience if structures and energies are determined to be accurate, even if the theoretical justification for such approach is still a subject of debate. For example, Kovacs and Frenking (6) employed a

number of basis sets (primarily B3LYP and MP2) with relativistic and non-relativistic effective core potentials to study the structures of several Cu, Ti, Au, and Ag organometallic complexes. These authors found very good agreement among the geometries predicted by each method, even though they did not discuss the issue of the physical meaning of combining ECP and DFT methods. Similarly, Lee and Wright (7) studied the geometry and energetics of neutral and positively charged BBr_2 and BI_2 species using the Hay and Wadt (1) nonrelativistic ECPs in combination with hybrid density functionals. Again, these authors also did not discuss the physical appropriateness of a hybrid DFT/ECP approach. Another report on the practical aspects of adopting such hybrid methodology is that of Glukhovstev et al. (8). This group mentioned that the applicability of a combined DFT/ECP approach is beginning to be realized, and compared experimental data and relatively high-level calculations (QCISD(T), CCSD(T), etc.) with the DFT/ECP approach for a limited set of Fe complexes containing Fe—C bonds. Their findings on dissociation energies are encouraging, given that deviations from experimental values were well within experimental error. Another more recent report by Hay and Martin (9) deals with the structure and energetics of UF_6, NpF_6, and PuF_6 as evaluated by a hybrid DFT/ECP approach. Hay and Martin (9), who showed excellent awareness of the concern of transferring ECPs to DFT calculations, found that the local density (SVWN) and hybrid functional (B3LYP) presented the smallest deviations relative to experimentally determined structural parameters of these fluorides. In summary, while the combined use of high-quality ECPs and DFT methods is appealing from a computational efficiency viewpoint, studies leading to demonstrate the applicability of the technique are still in demand if the method is intended to enjoy some level of generality.

First-row transition elements represent an interesting case since the impact of neglecting relativistic terms when carrying out an all-electron calculation within the non-relativistic HF formalism on the accuracy of results may well be small, perhaps smaller than the errors associated with the introduction of an inert core. In the case of small Ti chloro-amine complexes, Baboul and Schlegel (10) chose to perform geometry optimizations at the B3LYP/6-311G(d) level, followed by high quality (modified G2 level) calculations to determine accurate atomization and dissociation energies. It has long been known that when energy differences between similar molecules are sought, and in which the splitting of species into atoms or elementary ions is not involved, triple-split basis sets augmented with diffuse and polarization functions are often able to describe the energetics of the system reasonably well.

Our interest stems from the need for a description of potential stable intermediates in the acid-catalyzed hydrolysis and condensation reactions of Ti and Si alkoxides to form mixed glasses via sol-gel chemistry (11). This issue clearly influenced the choice of certain complexes and molecules reported in this study. Titania-silica alcogels find use as high surface area amorphous solid catalysts and adsorbents.

Very recently, we used the sol-gel technique to prepare organic and inorganic TiO_2–SiO_2 materials, based on mixtures of tetraethylorthosilicate ($Si(OEt)_4$, TEOS) and permethylated oligosiloxane rings ($(Me_2SiO)_n$, n = 3–5) as the silicon source (11). To load such materials with Ti, $TiCl_2(i\text{-}OPr)_2$ was prepared in situ as previously reported (12). Such high-surface area materials display improved olefin epoxidation activities (13) relative to those found in alcogels where $Ti(i\text{-}OPr)_4$ is used as the Ti source instead (12).

There exist several difficulties associated with the tracking of Ti species formed early in the Ti alkoxides reactions with preformed silica alcogels, including the high reactivity of the former, and the low concentrations of Ti alkoxides in the sol to achieve high Ti dispersions. These two limitations render a number of spectroscopic techniques (e.g., EXAFS and EPR) ineffective to obtain reliable structural data on stable intermediates under realistic reaction conditions.

When studying Ti solution chemistry, the possibility of coordination expansion of the Ti center must be considered. Dimeric $TiCl_4$ and $TiCl_4$ complexes with chelating esters have been recognized for some time (14, 15). The formation

of penta- and hexacoordinated $TiCl_4$-$(H_2CO)_n$ (n = 1 or 2) complexes is predicted by theory (16). Several hexacoordinated complexes of $TiCl_3$(i-OPr) with THF, diethylether, formaldehyde, and esters have been reported (17). Still, X-ray absorption studies of several Ti alkoxides in solution including Ti(i-OPr)$_4$, Ti(i-OAm)$_4$, and Ti(OEt)$_4$ reveal that their structures may or may not be tetrahedral (18). For example, Ti(i-OPr)$_4$ and Ti(i-OAm)$_4$ appear to adopt the conventional tetrahedral geometry, while Ti(OEt)$_4$ seems to be oligomeric (18). Based on an extensive literature search, we found no research describing the geometry of Ti chloroalkoxides in solution. Thus, this contribution is aimed at setting up the stage for studying the structure of Ti chloroalkoxides via theoretical methods. Emphasis is made on determining whether a hybrid (pseudopotentials and DFT), more computationally efficient method is appropriate to model the chemistry of such complexes. A more thorough study on the structure and energetics of tetra- and pentacoordinated Ti alkoxide species in acidic media will be presented in a separate paper. In addition, many other small molecules and hypothetical reactions involving Ti-free species were also studied, to confirm that the generalizations made in this contribution are unlikely to be case dependent. However, for some of the conclusions reached in this manuscript to be extended freely to other regions in the periodic table a more extensive study should be conducted. The ultimate goal of this paper is to determine what parameters are affected, relative to an all-electron method, when using an augmented ECP and triple-split basis set in combination with hybrid functionals on Ti and V complexes and on a number of simple molecules containing first- and second-row elements. Frequency and thermochemistry data, relative to the all-electron method adopted, are also reported. For "absolute" corrections to these parameters, the reader is referred to the comprehensive work of Scott and Radom (19).

Computational methods

The three-parameter Becke style hybrid functional (20), with the correlation functional of Lee et al. (21) was adopted. The ECPs from Cundari and Stevens (2), as built in the Gaussian 98 program[2] with a triple-split basis set (CEP-121G) were used. In order to compare the performance of this method with that of B3LYP/6-311G(d), one d-type polarization function was added to each first and second row element present in the molecule (or one f function for post second row atoms) for geometry optimizations. For single point energy calculations on optimized structures, this CEP-121G(d) basis set was further augmented by adding one p-type function to each hydrogen atom, and one suitable diffuse function to each heavy atom. The recommended auxiliary polarization and diffuse functions used in this study are presented in Table 1 in standard Gaussian® nomenclature.[2] In this study, the terminology adopted is B3LYP/CEP-121G(d) for geometry optimizations, and B3LYP/CEP-121+G(d,p) for single-point energy calculations. These are to be compared to the reference computational method adopted, namely B3LYP/6-311G(d), and B3LYP/6-311+G(d,p), respectively. In addition, single-point energy calculations at the B3LYP/6-311+G(d,p) level on CEP-121G(d) optimized structures were also carried out. Throughout this paper, each parameter (e.g., ΔE_{el}, μ, etc.) will generally carry a subscript such as "ref" (all-electron calculations), "CEP" (CEP-based computations), or "mix" (CEP-based optimized structures followed by a single-point all electron calculation). All calculations were carried out using Alpha-DEC Workstations with a single 667 MHz processor and 1 Gb SDRAM.

Results and discussion

Table 2 lists all molecules and ions evaluated in this study. Figure 1 shows the geometry of a representative Ti chloroalkoxysiloxane species, with a number of its structural parameters being presented in Table 3 for each geometry optimization method used. In all chemical species investigated in this work, key geometrical features (e.g., point group, similar dihedral angles, etc.) were always found to remain the same when going from the all-electron method to the ECP-based approach. The latter produced slightly larger

bond distances, and these deviations were always found to be consistent (Fig. 2 and Table 3).

Nearly 300 frequencies were animated and their values from the two methods were carefully compared (Fig. 3). Overall, the CEP method performs satisfactorily in this category as well, the only apparent drawback being the reproducibility of very low frequencies. This is known to be a problem that does not depend on the method of choice, because very low frequencies typically arise from the wagging or rocking of large groups, and small deviations in bond angles, distances, and bond orders necessarily translate into large frequency deviations. Though still very small, somewhat larger relative deviations were observed for the low-frequency vibrations involving heavier atoms (e.g., Cl, Si, Ti, V, and Br). Any partition of the range of frequencies produced by the calculations in this paper would be arbitrary. Nevertheless, it appears that the 400–900 cm^{-1} range (which is largely dominated by stretching frequencies involving post second row elements) should be scaled by a factor of 1.025 relative to B3LYP/6-311G(d), whereas differences between the two methods in the 1000–4000 cm^{-1} range are clearly small enough to recommend the use of B3LYP/CEP-121G(d) frequencies without scaling. As mentioned earlier, and since Scott and Radom (19) have reported on "absolute" scale factors (including values for the reference method selected here), adjustment of frequencies to results reported in ref. 5 becomes trivial. However, it must be mentioned that other authors have used calculated frequencies at the B3LYP/6-311G(d) level without scaling, since they appear to be in excellent agreement to experimental values for small Ti complexes (10). Again, in the absence of studies involving a number of other heavy atoms and the monitoring of thousands (instead of a few hundreds) of different vibrational modes, scale factors reported here should be taken with caution.

Table 4 shows thermodynamic data on a number of hypothetical reaction pathways. In general, all three methods yield comparable results. Relative deviations in the thermochemical parameters are shown in Figs. 4 and 5, with the lines S_{ref}/S_{CEP} and E_{ref}/E_{CEP} equal to one shown in the interest of clarity. These deviations were also small enough to recommend no scaling for ZPVE-corrected thermal energies

$CBrH_3$	2.05
$VO_2(OMe)$	1.36

and entropies predicted by the augmented B3LYP/CEP method, relative to B3LYP/6-311G(d). The latter has been proposed to require scaling by a factor of 0.9806 for thermochemistry to yield accurate results (19), which indicates that a correction factor of 0.98 for values predicted at the B3LYP/CEP-121G(d) level should be adopted. In spite of the fact that the pool of species selected in this study is not very large, results from Table 4 appear to indicate that the B3LYP/6-311+G(d,p)//CEP-121G(d) single-point/geometry combined approach might be the most computationally efficient and reliable of all three.

Table 5 shows a few examples on the computational efficiency of the full-electron reference method and the augmented CEP approach. In practice, the situation is somewhat more favorable for the CEP method, since it was observed that a smaller number of cycles were normally required for tight convergence of the augmented CEP method.

Figure 6 shows the relative deviations in the dipole moments obtained from single-point calculations on optimized structures for both the "mix" and the "CEP" methods. In general, these can be considered small, and a "mix" approach does not improve the relative accuracy of the μ values to any significant extent. It should be mentioned however, that the predicted Mulliken populations derived from the CEP method differ considerably from those of the "mix" and the all-electron approach (see examples in Table 6). However, since atomic charge is not a quantum chemical observable, its evaluation via choosing a certain method is still somewhat arbitrary. For example, it has long been known that the Mulliken population analysis is essentially based on a balanced partition of the overlap region, but this does not necessarily translate into a very precise description of the electron density distribution. The differences between the two methods shown in Table 6 are thus expected, since the hybrid method obviously treats inner shells as a lump (core) contribution. Nevertheless, the "mix" approach (i.e., a hybrid optimization followed by an all-electron single point calculation) is clearly the method of choice if charge populations from all-electron methods are deemed more reliable. Note that in Table 6, Mulliken charges derived from the "mix" method do not differ significantly from those of the all-electron reference method.

[a]In some cases, there were be more than one non-equivalent O atom with double (=) or single (—) bond character in each molecule.

Finally, the issue of projected level of agreement between the proposed hybrid CEP/DFT approach and experiment, i.e. beyond a comparison between all-electron methods and CEP/DFT needs to be briefly discussed. At this point emphasis needs to be made on early transition and other heavy element work, because these represent an adequate reference to some of the species studied this work. The enthalpies of formation of several hydroxo-, and oxo- species of Fe, as well as FeS, $FeCH_2^+$, and $FeCH^+$ calculated (8) at the B3LYP level with the Stuttgart group (22) effective core potentials were found to be within experimentally determined values. As mentioned earlier, the combined ECP/B3LYP approach predicts vibrational frequencies and bond lengths that are in very good agreement with experiment for three uranide fluorides (9). In addition to these observations, one could stress the fact that since the all-electron method used in this study and the proposed hybrid CEP/B3LYP approach are in close internal agreement, comparisons between theoretical calculations at a good quality DFT/all-electron level with experiment should also provide a reliable model validation reference frame. For example, Ziegler (23) provided a comprehensive list of computations including a number of small first-row transition element molecules to show the accuracy of DFT methods for predicting bond energies and enthalpies of formation. It must be emphasized that thermochemistry data involving atomization and dissociation of molecules into elements or elementary ions constitute a particularly tough test that computations at a comparable level to the one used in the present work appear to pass (8, 22, 23). Thus, there is a priori no reason to believe that in reactions that do not involve atomization or fragmentation into elementary ions one should expect unusually large discrepancies between theory and experiment. Nevertheless, at least a limited set of very high level computations (e.g., G2) will be carried out in future studies dealing with Ti alkoxide condensations to further strengthen the validity of the proposed computational approach.

Conclusions

The use of DFT methods in combination with the ECPs from Cundari and Stevens (2) yield geometries and energetics that are in very good agreement with those derived from the classical B3LYP/6-311+G(d,p)//B3LYP/6-311G(d) approach. Calculated frequencies, thermochemistry, and geometrical parameters require essentially no scaling.

The solid-state structures of (–)-scopolamine free base, (–)-scopolamine methobromide, (–)-scopolamine hydrobromide trihydrate, and of the pseudopolymorphic forms of (–)-scopolamine hydrochloride anhydrate and 1.66hydrate[1]

Robert Glaser, Dror Shiftan, and Marc Drouin

Abstract: (–)-Scopolamine hydrochloride anhydrate gives crystals belonging to the orthorhombic space group $P2_12_12_1$ and at 293(2) K: a = 7.097(2), b = 10.686(2), c = 22.623(2) Å, V = 1715.7(6) Å^3, Z = 4, $R(F)$ = 0.039, and $R_w(F)$ = 0.053. (–)-Scopolamine hydrochloride 1.66hydrate yields crystals belonging to the tetragonal space group $P4_32_12$ and at 293(2) K: $a = b$ = 11.843(6), c = 26.211(4) Å, V = 3676(3) Å^3, Z = 8, $R(F)$ = 0.047, and $R_w(F^2)$ = 0.135. (–)-Scopolamine methobromide affords crystals belonging to the orthorhombic space group $P2_12_12_1$ and at 293(2) K: a = 7.0403(8), b = 10.926(2), c = 23.364(5) Å, V = 1797.2(6) Å^3, Z = 4, $R(F)$ = 0.039, and $R_w(F)$ = 0.052. The two hydrochloride pseudopolymorphs were isostructural to the corresponding two hydrobromide analogues. Both hydrohalide hydrated crystals have a water molecule occupying a general position of symmetry, and another water molecule occupying a special position of C_2-rotation symmetry. The hydrated hydrochloride salt also had an additional 0.322(17) partial occupancy water molecule (absent in the hydrobromide sesquihydrate) occupying another special position of C_2-rotation symmetry, i.e., the extra water molecule occupied the special position in statistically ca. one-third of the unit-cells to give a total hydrate stoichiometry of 1.66 molecules of water. While the two hydrohalide anhydrates exhibited extended tropate ester conformations (phenyl-ring antiperiplanar to oxirane moiety) vs. compact conformations (phenyl-ring near the scopine underside) for the two hydrated hydrohalides, all four displayed other common structural features: axial *N*-methyl stereochemistry, antiperiplanar methylol oxygen/aromatic C(*ipso*) relationships, and phenyl-ring eclipsing of the C(α)—H bond. The CPMAS ^{13}C NMR spectrum of (–)-scopolamine hydrobromide "trihydrate" shows it to be a conglomerate of (–)-scopolamine hydrobromide sesquihydrate plus two or more hydrated species (three ca. equal intensity carbonyl signals at 5.0 kHz spin-rate). High-speed rotor spinning (e.g., ca. 10 kHz and higher) causes a temperature-induced phase-transition to yield only the sesquihydrate form. The same transformation was noted with a 18 K rotor-temperature increase and an invariant 5.0 kHz spin-rate. The sesquihydrate spectrum remained after spin-rate decrease to 5.0 kHz, but the three component mixture 5.0 kHz spectrum was regenerated after three weeks sample storage within the capped rotor. The (–)-scopolamine free base crystalline melt CPMAS spectrum also shows a mixture of at least three hydrated species.

Key words: stereochemistry, X-ray crystallography, solid-state NMR, CPMAS, anticholinergic.

Résumé : Le chlorhydrate de la (–)-scopolamine anhydre forme des cristaux orthorhombiques du groupe d'espace $P2_12_12_1$ qui, à 293(2) K, présentent les caractéristiques suivantes: a = 7,097(2), b = 10,686(2) et c = 22,623(2) Å, V = 1715,7(6) A^3, Z = 4, $R(F)$ = 0,039 et $R_w(F)$ = 0,053. Le chlorhydrate de la (–)-scopolamine hydraté par 1,66 moles d'eau, existe sous la forme de cristaux tétragonaux du groupe d'espace $P4_32_12$ qui, à 293(2) K, présentent les caractéristiques suivantes: $a = b$ = 11,843(6) et c = 26,211(4) Å, V = 3676(3) A^3, Z = 8, $R(F)$ = 0,047 et $R_w(F^2)$ = 0,135. Le méthobromure de la (–)-scopolamine forme des cristaux orthorhombiques du groupe d'espace $P2_12_12_1$ qui, à 293(2) K, présentent les caractéristiques suivantes: a = 7,0403(8), b = 10,926(2) et c = 23,364(5) Å, V = 1797,2(6) A^3, Z = 4, $R(F)$ = 0,039 et $R_w(F)$ = 0,052. Les deux chlorhydrates pseudopolymorphes sont isostructuraux avec les deux bromhydrates correspondants analogues. Les cristaux des deux dérivés halogénés hydratés comportent une molécule d'eau qui occupe une position de symétrie générale et une autre qui occupe une position spéciale de symétrie de

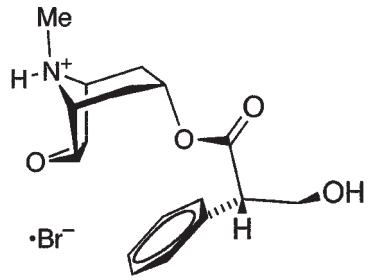
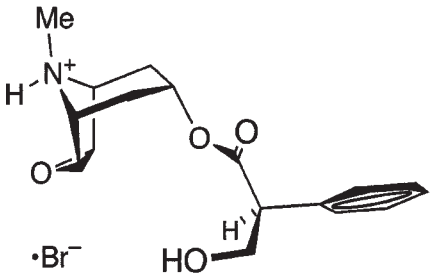
rotation C_2. Le chlorhydrate hydraté comporte une fraction additionnelle de molécule d'eau (0,0322(17)) (absente dans le sesquihydrate du bromhydrate) qui, d'un point de vue statistique, occupe une autre position spéciale, soit le tiers des mailles élémentaires et il en résulte que la stoechiométrie totale de l'hydrate est égale à 1,66 molécules d'eau. Alors que la conformation de l'ester tropate des deux dérivés halogénés anhydres est de forme étendue (noyau phényle *antipériplanaire* par rapport à la portion oxirane), celle que l'on observe pour les deux dérivés halogénés hydratés se présente sous une forme compacte (avec un noyau phényle près de la partie inférieure de la scopine); les quatre présentent toutefois des caractéristiques structurales communes: stéréochimie *axiale* du *N*-méthyle, relation antipériplanaire entre l'oxygène du méthylol et le C(*ipso*) aromatique et le noyau phényle qui éclipse la liaison C(α)—H. Le spectre RMN du ^{13}C par la technique de la polarisation croisée avec rotation à l'angle magique (« CPMAS ») du bromhydrate de (–)-scopolamine « trihydraté » met en évidence qu'il s'agit d'un conglomérat de bromhydrate de (–)-scopolamine sesquihydraté en présence de d'au moins deux autres espèces hydratées (trois signaux d'intensités approximativement égales découlant de carbonyles, à une vitesse de spin de 5,0 kHz). Une vitesse de spin du rotor plus élevée (par exemple, environ 10 kHz ou plus) provoque une transition de phase induite par la température qui permet de n'observer que la forme sesquihydratée. On a observé la même transformation avec une augmentation de température de 18 K du rotor tout en maintenant la vitesse de spin à 5,0 kHz. Le spectre du sesquihydrate est conservé après une diminution de la vitesse de spin à 5,0 kHz; toutefois, après avoir conservé l'échantillon pendant trois semaines dans le rotor fermé, on régénère le spectre du mélange à trois composants à 5 kHz. Faisant appel à la technique de la polarisation croisée avec rotation à l'angle magique, on a déterminé le spectre RMN du ^{13}C de la base libre de la (–)-scopolamine fondue qui met aussi en évidence la présence d'un mélange d'au moins trois espèces hydratées.

Mots clés : stéréochimie, diffraction des rayons X, RMN à l'état solide par la technique de la polarisation croisée avec rotation à l'angle magique (« CPMAS »); anticholinergique.



Introduction

(–)-Scopolamine hydrobromide [(–)-hyoscine hydrobromide, **1**] is a well known anticholinergic drug, and is also used in the treatment of motion sickness (1). (–)-Hyoscine is a tropane alkaloid natural product isolated from the belladonna plant *Hyoscyamus niger* (henbane) and consists of the (*S*)-(–)-tropic acid ester (2) of the 3-*endo*-substituted amino-alcohol scopine. Scopolamine has two stereogenic chirotopic (3) atoms: the relatively stereostable α-carbon and the stereolabile nitrogen.



1

Pauling and Petcher (4) reported the first X-ray crystallographic single-crystal structure determination of (–)-hyoscine hydrobromide (**1**). It was described as a hemihydrate and the pictorial representation showed an *axial N*-methyl group, a "compact" conformation (phenyl-ring under the oxiranyl moiety, see iconic projection **2**), and an antiperiplanar (ca. 180°) phenyl – to – methylol-OH arrangement (4). Other stereochemical studies of this molecule, its derivatives, and analogues made use of this early X-ray determined structure (5–10), but no atomic coordinates were presented nor were any to be found in the *Cambridge Crystallographic Data Base*. In addition, it was reported that the structure converged only to an *R(F)* = 0.09 value upon refinement (4). A new single crystal X-ray diffraction analysis of **1** was undertaken by us to obtain the needed coordinates (11). However, this study produced a pseudopolymorph ((N*r*,Cα-*S*)-(–)-scopolamine hydrobromide anhydrate) with an "extended" solid-state conformation (see **3**, a 2D-iconic projection[4] of the X-ray determined 3D-structure) that was different from that depicted for the hemihydrate (11).

The trihydrate form of **1** is listed in the *United States Pharmacopeia 23 Official Monographs* (12). In a desire to obtain the structure of this hydrated crystal, **1** was recrystallized from water. The resulting crystal was a new pseudopolymorph in the form of a sesquihydrate (see iconic projection **2**), having a compact conformation (13). Both the crystal and molecular geometries of **2** were the same as that of the hemihydrate form reported earlier by Pauling and Petcher (4). Crystals of the hemihydrate were reported as belonging to the tetragonal $P4_12_12$ space group, and at presumed ambient temperature, a = 11.965(7), c = 26.52(2) Å, Z = 8, and $R(F)$ = 0.09. Those of the sesquihydrate differed in the left-handedness of the 4_3-screw in the tetragonal $P4_32_12$ space group, and at 293 K: a = 11.9667(8), c = 26.528(2) Å, Z = 8, and $R(F)$ = 0.051 (13). It is noted that all four of the reported pseudopolymorphs of **1** (the anhydrous form (11), hemihydrate (4), the sesquihydrate (13), and the trihydrate (12)) meet the USP requirements for water content, since only a maximum permissible weight loss of 13.0% after drying at 105°C for 3 h is stated, while no lower limits for weight loss are given (12).

NMR spectroscopy has been shown to be a useful tool to determine the stereochemistry of scopolamine and related compounds in solution. Under slow exchange limit (SEL) ^{1}H and ^{13}C NMR (acidic D_2O or CD_2Cl_2) conditions for the prototropic shift – nitrogen inversion epimerization mechanism, axial, and equatorial *N*-methyl diastereomers (**4a**, **4e**) can be observed for solutions of **1** (14). The major:minor, axial:equatorial *N*-methyl diastereomeric bias in D_2O became inverted in CD_2Cl_2 (14).

4a

4e

A recent solid-state CPMAS ^{13}C NMR study of crystalline scopolamine tertiary and quaternary ammonium salt analogues of known structures, clearly showed that the methylol (CH_2OH) chemical shift was diagnostic for the conformation about the C(carbonyl)—C(α) bond (15). In the synperiplanar (ca. 0°) O = C-C(α)-CH_2OH *compact* conformation, δ(CH_2OH) and δ(C = O) values were found to be closer to TMS than corresponding values in the *(+)*-synclinal (ca. +60°) O = C-C(α)-CH_2OH extended conformation (15). As a result of the solid-state CPMAS studies, the solution-state conformational preference about the C(carbonyl)—C(α) bond could then be ascertained from deconvolution of the weighted time-average values measured in various solvents (15). One axial *N*-methyl scopolammonium bromide phenyl-ring face is solvent exposed in the compact conformation predominating in D_2O medium, while both faces are solvent accessible in the *extended* major conformational contributor in CD_2Cl_2 solution (15). Similarly, the methylol OH group is more solvent exposed in the compact conformation predominating in D_2O medium, while it is near the scopine underside in the axial *N*-methyl scopolammonium bromide extended major conformational contributor in CD_2Cl_2 solution (15). The compact conformation has been described as the bioactive conformation based upon structural comparisons with other muscarinic receptor antagonists (16), and on modeling of ligand/muscarinic-m1 subtype receptor complexes (17).

The main impetus for this study was to obtain additional crystallographically determined scopolamine structures needed to define the linear correlationship between the O = C–C(α)–CH_2OH torsion angle and the δ(CH_2OH) and δ(C = O) solid-state CPMAS chemical shift values reported in our earlier study on the pseudopolymorphic forms of the hydrobromide drug (15). As a result, the structures of the analogous crystalline (–)-scopolamine hydrochloride anhydrate (**5**), (–)-scopolamine hydrochloride 1.66-hydrate (**6**), and (–)-scopolamine methobromide (**7**) were determined, and their details are reported herein. In addition, the solid-state CPMAS NMR characterization of (–)-scopolamine free base crystalline melt (**8**) and the hydrobromide trihydrate (**9**) are also described.

Experimental section

(–)-Scopolamine HBr, HCl, and methobromide were purchased from Sigma. (–)-Scopolamine HBr trihydrate and (–)-scopolamine free base crystalline melt were gifts of Phytex Australia Pty. Ltd., and another (–)-scopolamine HBr trihydrate sample was a gift of Boehringer Ingelheim KG.

Crystallography

(–)-Scopolamine hydrochloride anhydrate (**5**) and methobromide (**7**) were recrystallized by vapor diffusion of acetone into an abs ethanolic solution of the appropriate salt. (–)-Scopolamine HCl 1.66H_2O (**6**) was obtained by dissolving the hydrochloride anhydrate salt in water followed by slow evaporation to dryness. Intensity data from the clear colorless prism crystals were collected at 293(2) K on an Enraf–Nonius CAD-4 automatic diffractometer. Table 1 provides crystallographic and data collection details.

[a]The final discrepancy index $R(F) = (\Sigma_i||F_{obs}|_i - |F_{calc}|_i|)/(\Sigma_i|F_{obs}|_i)$.

[b]The weighted value $R_w(F) = \mathrm{SQRT}[(\Sigma_i\{w_i(|F_{obs}|_i - |F_{calc}|_i)\}^2)/(\Sigma_i\{w_i(|F_{obs}|_i)\}^2)]$, and $R_w(F^2) = \mathrm{SQRT}[(\Sigma_i\{w_i(F_{obs}^2{}_i - F_{calc}^2{}_i)\}^2)/(\Sigma_i\{w_i(F_{obs}^2{}_i)\}^2)]$, where the particular weighting factor used is given in Table 1.

[c]Goodness of fit = SQRT[$(\Sigma_i\{w_i(|F_{obs}|_i - |F_{calc}|_i)\}^2)$/(no. of reflections – no. of parameters)].

[d]Goodness of fit = SQRT[$(\Sigma_i\{w_i(F_{obs}^2{}_i - F_{calc}^2{}_i)\}^2)$/(no. of reflections – no. of parameters)].

Cell constants and an orientation matrix for data collection, were obtained from a least-squares refinement using the setting angles of 24 carefully centered reflections in the range $40° \le 2\theta \le 50°$ for **5**, 26 reflections in the range $32° \le 2\theta \le 44°$ for **6**, and 24 reflections in the range $40° \le 2\theta \le 50°$ for **7**. Space group determination was based upon systematic absences, packing considerations, a statistical analysis of intensity distribution, and the successful solution and refinement of the structure. The NRCCAD program (18) was used for centering, indexing, and data collection. Two standard reflections were measured every 60 min.

The NRCVAX programs (19) were used for crystal structure solution (Cα-*S*-absolute configuration for the (–)-enantiomer (2, 11, 13)) by application of direct methods for **5**–**7**, and for refinement by full-matrix least squares on *F* (for **5** and **7**). Atomic scattering factors in the NRCVAX programs are from ref. 20. The *SHELX-97* program[5] was used for refinement by full-matrix least squares on F^2 (for **6**). The

absorption coefficients (μ) are listed in Table 1. Psi scans based empirical absorption corrections were made; the maximum and minimum transmission factors are given in Table 1. No significant decay was observed during data collection for **5**–**7**. Isotropic extinction coefficients were included in the refinement to account for secondary extinction effects (21); their values are given in Table 1.

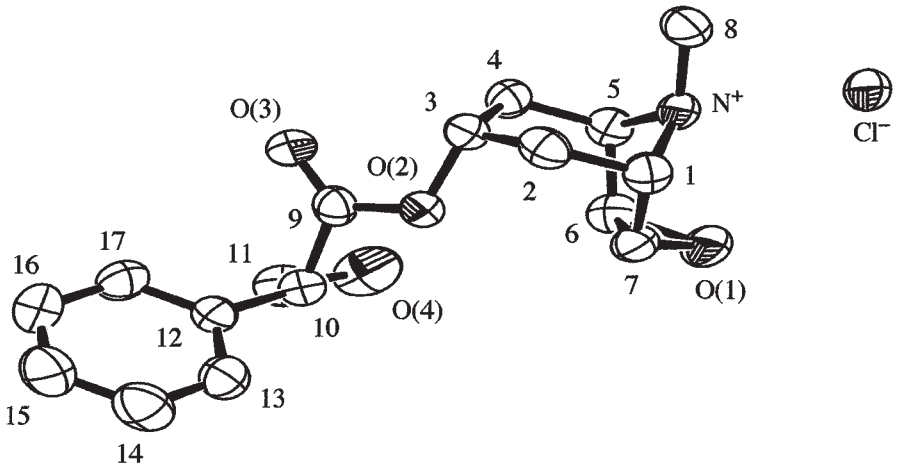
Hydrogens for **5** and **7** were all geometrically placed and the respective final refinements included anisotropic thermal parameters for the non-hydrogen atoms, and isotropic thermal parameters for the hydrogen atoms. Structure determination of **6** afforded one water molecule at a fully occupied general position of symmetry, one water molecule at a fully occupied special position of C_2 symmetry, and one water molecule with 0.322(17) partial occupancy at a special position of C_2 symmetry (i.e., 13.288 total water molecules for the eight scopolamine HCl molecules in one complete unit cell, or $1.66H_2O$ for one scopolamine HCl molecule in the asymmetric unit). Hydrogens were all geometrically placed except for those on oxygen. Individual displacement parameters were fixed at $U(H) = 1.5 \times U_{eq}$ (C-methyl, OH) or $U(H) = 1.2 \times U_{eq}$ (C and N) and were treated as riding for refinement. The H_2O protons were calculated for the best hydrogen bond. Their positions were refined to fit the residual densities but restrained to have O—H set to 0.85 Å and H–O–H angle at 110.0° [$U(H) = 1.2 \times U_{eq}$]. The non-hydrogen atoms were refined anisotropically (with the exception of O(7) which was refined isotropically).

The $R(F)$ and $R_w(F)$ (or $R_w(F^2)$) final discrepancy indices at convergence for the $I_{net} \geq n\sigma(I_{net})$ (n = 2.5 for **5** and 2.0 for **6**, **7**) significant reflections, the number of restraints and variables, and the GoF are listed in Table 1 for **5**–**7**.

Molecular graphics

2D-iconic projections of the X-ray crystallographic (**2**, **3**, and Fig. 1) or molecular modeling (**11**–**17**) 3D-structures were generated using the combination of CS-Chem3D Pro 5.0 and CS-ChemDraw Ultra 5.0 programs.[4] Superimposition of molecular structures were performed with the MacMimic 3.0 program.[6]

NMR Spectroscopy

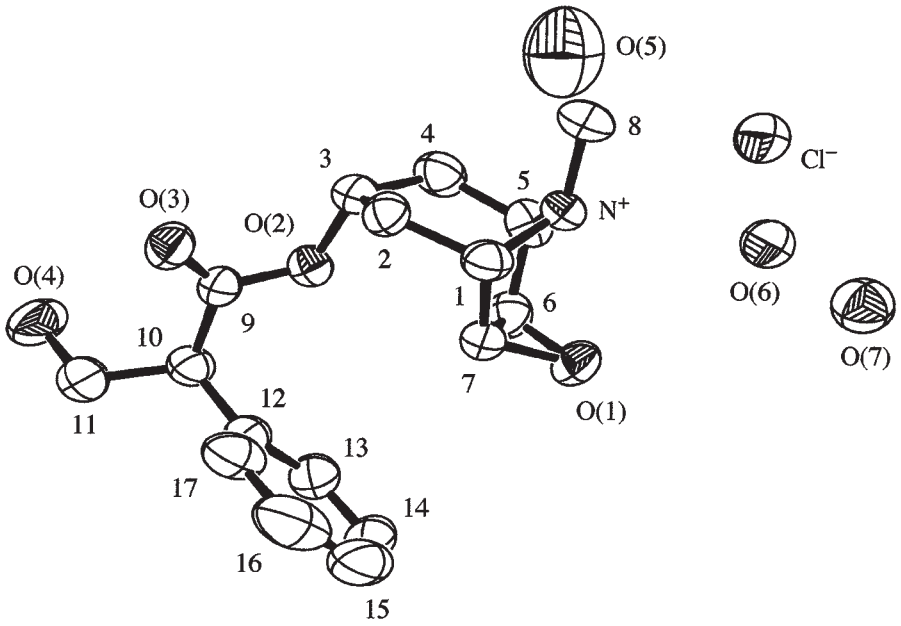


Solid-state CPMAS ^{13}C NMR spectra were recorded at 125.76 MHz at ambient temperature on a Bruker DMX-500 digital FT NMR spectrometer equipped with a BL-4 CPMAS probehead and a High Resolution/High Performance (HPHP) ^1H preamplifier for solids. Spectra were calibrated with an external spectral reference (glycine δ carbonyl = 176.03). A vacptppm (variable amplitude cross-polarization/two pulse phase modulation decoupling) pulse-program was used for CPMAS spectra. Vacptppmnqs (non-quaternary and non-methyl signal suppression) and cppi (22) pulse-programs were utilized to afford spectral-editing giving "quaternary-methyl-only" and "methylene-only" spectra, respectively. Nqs spectra used a 50 μs T_2 dipolar dephasing delay period. The fast inversion-recovery technique utilized a 20 s T_1 delay to afford spectra without methyl carbon signals. Samples were placed in 4 mm zirconia rotors, and spun at a rate of 11.0 kHz for all spectra (with the exception 5.0 kHz for cppi).

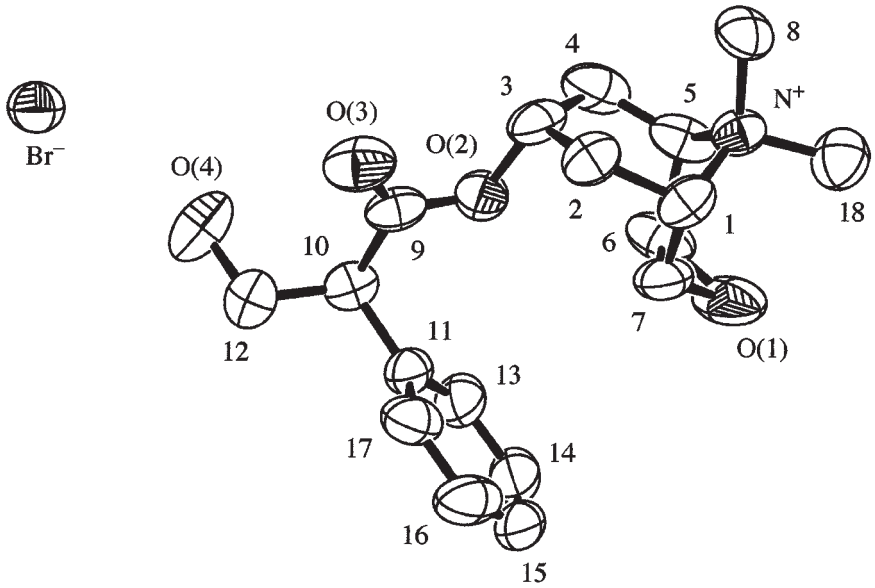
Results and discussion

Crystallographic details, non-hydrogen atom fractional coordinates for (–)-scopolamine hydrochloride anhydrate (**5**), (–)-scopolamine hydrochloride 1.66-hydrate (**6**), and (–)-scopolamine methobromide (**7**) are given in Tables 1–4, respectively.

(–)-Scopolamine hydrochloride anhydrate



(–)-Scopolamine hydrochloride anhydrate (**5**) gave crystals belonging to the same space group and packed in the same motif as that previously reported (11) for the hydrobromide anhydrate analogue (**3**). The axial *N*-methyl scopolammonium cations in both HCl and HBr anhydrate salts were structurally the same as shown by superimposition[6] of non-hydrogen atoms in **5** (with the exception of the halide



5

6

7

anion) upon corresponding atoms in **3** to give a root mean square (RMS) difference of only 0.080 Å. Both **3** and **5** have extended conformations as shown by three characteristic torsion angles, e.g., 158.5(4)° antiperiplanar C(9)–O(2)–C(3)–C(2), –77.3(3)° *(–)*-synclinal C(9)–O(2)–C(3)–C(4), and 53.3(3)° *(+)*-synclinal O(3)–C(9)–C(10)–C(11) for **5**. In both **3** and **5**, the halide anion is hydrogen bonded to N(1). The Br···N(1),Cl···N(1) distances are 3.210, 3.070 Å, the Br···H(N1),Cl···H(N1) distances are 2.317, 2.175 Å, and the Br···H(N1)–N(1),Cl···H(N1)–N(1) angles are 133.0°, 146.1°.

In **3** and **5**, the perpendicular distance of nearest neighbors to the top and bottom faces of the phenyl ring best plane were ca. 3.0 Å or more away, thus enabling the phenyl ring to undergo a CPMAS ^{13}C NMR observed π-flip about the C(10)—C(12) bond axis (15). In the CPMAS ^{13}C NMR spectra of both **3** and **5**, the "off-axis" *ortho* and *meta* carbon atom signals appear as a broadened hump between relatively sharp signals arising from the "on-axis" *ipso* and *para* carbons (15). The phenyl-ring π-flip involves significant van der Waals contacts, and thus requires lattice deformations to permit ring dynamics (23). These occur in a different timeframe than that observed by X-ray crystallography, since the staccato rotation of the off-axis *ortho* and *meta* carbon atoms is not expressed in higher anisotropic thermal parameters for

[a] B_{eq} is one-third of the trace of the orthogonalized *U*.

C(13, 14, 16, 17), as opposed to those for the on-axis *ipso* and *para* carbons C(12, 15). Crystalline Buscopan methanol solvate adduct (**10**) ((–)-hyoscine equatorial-*n*-butylbromide methanol solvate adduct (8)) also exhibits an extended conformation, and its phenyl ring also undergoes a π-flip as observed in the CPMAS ^{13}C NMR spectrum (15).

(–)-Scopolamine hydrochloride 1.66hydrate

(–)-Scopolamine hydrochloride 1.66hydrate (**6**) was crystallized from water giving 1.66hydrate crystals (**6**) belonging to the same tetragonal, $P4_32_12$ space group, and, with the exception of an additional O(7) labeled water, it packed in the same motif as that previously reported (13) for the hydrobromide sesquihydrate analogue (**2**). The axial *N*-methyl scopolammonium cations in both HCl and HBr hydrated salts were structurally identical, as shown by superimposition of non-hydrogen atoms in **6** (with the exception of halide anion and water oxygens) upon corresponding atoms in **2** to give an RMS difference of only 0.039 Å. Both **2** and **6** have compact conformations as shown by three characteristic torsion angles, e.g., 72.6(4)° *(+)*-synclinal C(9)–O(2)–C(3)–C(2), –164.7(3)° antiperiplanar C(9)–O(2)–C(3)–C(4), and 17.8(6)° synperiplanar O(3)–C(9)–C(10)–C(11) for **6**. Crystalline (–)-hyoscyamine hydrobromide (**11**) (6, 7), the optically active form of atropine hydrobromide (a deoxiranyl analogue), also exhibits a similar compact conformation.

Both hydrated crystals **2** and **6** have an O(5) labeled water molecule occupying a similar general position of symmetry, and an O(6) labeled water molecule occupying a special position of C_2-rotation symmetry. In addition, the hydrated hydrochloride (**6**) had a 0.322(17) partial occupancy O(7) labeled water molecule (absent in the hydrobromide sesquihydrate) occupying another special position of C_2-rotation symmetry, i.e., the extra water molecule occupied the special position in statistically ca. one-third of the unit-cells to give a total hydrate stoichiometry of 1.66 molecules of water. In **2** and **6**, the perpendicular distances of nearest neighbors to the top and bottom faces of the phenyl ring best plane were only ca. 2.5 Å (i.e., closer than those for the anhydrate), thus the phenyl ring is immobile (no π-flip, since six aromatic sharp ^{13}C NMR signals were clearly observed in the CPMAS spectrum) (15). Crystalline (–)-hyoscyamine hydrobromide (**11**) (6, 7) also does not show CPMAS evidence for a π-flip (15).

Table 3. Fractional coordinates and anisotropic equivalent (U_{eq}) displacement parameters for (–)-scopolamine hydrochloride 1.66hydrate (**6**); esd of last digit in parentheses.[a]

[a] B_{eq} is one-third of the trace of the orthogonalized *U*.

ride are in the (1 – *y*, 1 – *x*, 0.5 – *z*) symmetry equivalent molecule A. The upper right-hand scopolammonium cation (containing the O(4) label) is in the (–0.5 + *y*, 1.5 – *x*, 0.25 + *z*) symmetry equivalent molecule B. The upper left-hand scopolammonium cation (containing the O(4′) label) is in the (*x* – 1, *y*, *z*) symmetry equivalent molecule C. The far-left chloride and O(5′) is in the (*y*, *x*, –*z*) symmetry equivalent molecule D. The far-right chloride and O(5′) are in the (1 – *x*, 1 – *y*, 0.5 + *z*) symmetry equivalent molecule E. The upper right- and left-hand remote phenyl-R partial structures are in the respective (1 – *y*, 2 – *x*, 0.5 – *z*) and (*x* – 1, *y*, *z*) symmetry equivalent molecules F and G.

Inspection of the center of the figure shows a diamond-shaped cyclic network bisected by a C_2-axis. It involves chloride anions hydrogen-bonding to each of the O-H protons in the two specially positioned O(6), O(7) water molecules. The O(6)···O(7) and Cl···Cl(A) interatomic distances in the diamond arrangement are 3.40(2) and 5.348(3) Å, respectively (the perspective in Fig. 1 makes the Cl···Cl(A) distance appear smaller than that of O(6)···O(7)). The O(6)···Cl and O(7)···Cl hydrogen-bonding distances are quite similar (3.163(3) and 3.177(10) Å, respectively). The O(6) water molecule is very strongly anchored in the crystal since each of its two lone-pairs hydrogen-bond to scopolammonium $^{+}$N-H protons. Thermogravimetric analysis of the analogous HBr sesquihydrate (**2**) showed weight loss in two stages: ~4% at 90°C (1.0 H_2O), plus an additional ~2% at 102°C (0.5 H_2O) (13).

Chloride anions participate in four hydrogen-bonding interactions, e.g., Cl^- (the middle left-hand anion) is bound to protons on O(5), O(6), O(7) water molecules, and a methylol O(4B)-H proton. The general positioned O(5) water molecule has an O(5D) C_2-symmetry related neighbor (labeled O(5′) in the figure). These two oxygen atoms are 2.90(1) and 2.82(1) Å apart in hydrochloride **6** and hydrobromide **2**, respectively. In both **6** and **2**, they have the highest anisothermal thermal parameters of all the non-hydrogen atoms. Crystallographic C_2-symmetry considerations do not permit strong hydrogen-bonding between these stoichiometrically full water molecules (O(5), O(5D)). The O(5)–H(O51)···O(5D) angular arrangement cannot approach linearity, since H(O51D) in the C_2-symmetry related O(5D)–H(O51D)···O(5) counterpart would then lie almost on top of the H(O51) proton. The O(5)–H(O51)···O(5D)/O(5D)–H(O51D)···O(5) angles are thus rather shallow (only 117.9°).

The hydrogen-bonding network in the corresponding hydrobromide sesquihydrate **2** is identical to that found for **6** with the exception of the absence of specially-positioned O(7) and the obvious change of bromide anions for chlorides. The partial occupancy O(7) water molecule resides in a cavity surrounded by four scopolammonium cations. The cavity's boundaries are the two full cations in symmetry equivalent molecules B, C, and the phenyl rings (Ph-R) from the symmetry equivalent F, G cations depicted in Fig. 1. Nearest neighbors to O(7) are H(16F) (2.31 Å), H(10B) (2.70 Å), and H(13B) (2.75 Å). The O(7) position is unoccupied in the corresponding hydrobromide analogue **2**. A hydrogen-bonding network similar to that in **6** was modeled for **2** using data sets measured at 180 and 293 K temperature. The 5.428 Å Br···Br(A) interatomic distance and 3.260(3) Å O(6)···Br hydrogen-bonding distance in **2** using the 180 K data set (293 K data set: 5.401 and 3.259 Å, respectively) are indeed similar to values for corresponding parameters measured in **6** reported above (also at 293 K). A diamond-shaped network was then constructed placing a specially positioned O(7) oxygen "dummy atom" 3.260(3) Å away from each of the Br, Br(A) anions. Nearest neighbors in the hydrobromide calculated model were then measured and found to be H(16F) (2.17 Å), H(10B) (2.71 Å), and H(13B) (2.46 Å) from the 180 K data set, and H(16F) (2.15 Å), H(10B) (2.68 Å), and H(13B) (2.60 Å) from the 293 K data set.

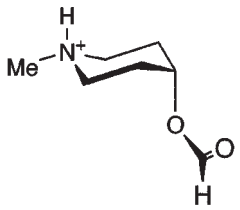
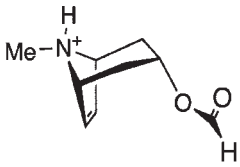
Fig. 1. Iconic projection of X-ray crystallographically determined structure of packing arrangement in the (–)-scopolamine HCl 1.66hydrate (**6**) crystal. The hydrogen-bonding network includes the O(5) labeled water molecule occupying a general position of symmetry (occupancy factor 1.000), and the O(6) and O(7) labeled water molecules both occupying special positions of C_2-symmetry (occupancy factors of 1.000 and 0.322(17), respectively) to afford a total stoichiometry of 1.66 water molecules. For clarity, two of the six scopolammonium cations are depicted only as partial structures (i.e., Ph-R).

than those obtained by crystallization of the corresponding methiodide (**12**) (monoclinic $P2_1$ (10)) from aqueous ethanol. However, the scopolammonium cations in both methohalide salts **7** and **12** are isostructural, as shown by superimposition of non-hydrogen atoms in **7** (with the exception of the halide anion) upon corresponding atoms in **12** to give an RMS difference of only 0.065 Å. Both **7** and **12** have compact conformations, similar to those of **2** and **6**, as shown by three characteristic torsion angles, e.g., 87.0(3)° (+)-synclinal-like C(9)–O(2)–C(3)–C(2), –148.4(4)° antiperiplanar-like C(9)–O(2)–C(3)–C(4), and 5.3(2)° synperiplanar O(3)–C(9)–C(10)–C(11) for **7**. The bromide anion is hydrogen-bonded to the methylol O(4)–H proton. In this arrangement, the Br···O(4) distance is 3.281 Å, the Br···H(O4) distance is 2.502 Å, and the Br···H(O4)–O(4) angle is 158.3°.



Placement of an equatorial *N*-methyl group [C(18)] in close juxtaposition to the transannular oxiranyl O(1) results in torque about the C(1)—N(1)/C(5)—N(1) bonds. As a result, C(8) is pushed away from O(1) and the axial *N*-methyl group [C(8)] is pushed inward towards C(2), C(4). This is clearly seen by an increase in the N(1)···O(1) interatomic distance: 2.693 and 2.728 Å in **7** and **12**, respectively, vs. 2.498 and 2.531 Å in **2** and **3**, respectively. It is also apparent in closing the C(2,4)···N(1)–C(8) angles: 88(1)° in **7** and 88.7(5)° in **12**, vs. 94.4(1)° in **2** and 96.5(6)° Å in **3**, respectively.

Stereochemistry of scopolamine-analogue models



The tropate ester moiety in both scopine and tropine crystalline **2**, **3**, **5–7**, **10**, **11** all share common stereochemical features: a phenyl-ring *ortho* carbon eclipses the C(10)—H(10) bond, and there is an antiperiplanar C(12)–C(10)–C(10)–O(4) arrangement between the phenyl and the methylol oxygen. On the other hand, *N*-methyl groups on the scopine moiety are all axial in crystalline **2**, **3**, **5**, **6**, while they are equatorial in tropine-type alkaloids such as **11**. The effects of equatorial or axial *N*-methyl groups upon the molecular geometry of the scopine skeleton were recently investigated using RHF/6–31G* basis set ab initio[7] molecular modeling techniques (24). Due to *cis*-1,3-diaxial type interactions in the protonated axial *N*-methyl-3-*O*-formyl-piperidine model (see iconic projection **13** of the actual 3D-molecular model), the bulky axial *N*-methyl group is tilted outward away from each of the neighboring two axial C(2)—H/C(4)—H bonds (99.5(1)° C(2,4)···N(1)–C(8) angles), while the axial N—H bond is approximately parallel to these same axial *C*—H bonds in the equatorial *N*-methyl epimer (89.0(1)° C(2,4)···N(1)–H angles) (see projection **14**) (24). These calculations show that a consequence of both ethano- and etheno-bridge (see projection **15**) "pinching" of the piperidine moiety in N-protonated *O*-formyltropine is a tilt of the axial N-proton inward towards the neighboring two axial C—H bonds (81.9(1)° C(2,4)···N(1)–H angles) (24). Increased *cis*-1,3-diaxial interactions of the type noted above was assumed to be the cause of the lowered stability of the axial *N*-methyl N-protonated *O*-formyltropine model (96.4(1)°C(2,4)···N(1)–C(8) angles) relative to that of the equatorial epimer (24). On the other hand, a non-protonated (exomethylene) carbon or oxygen at the apex of a three-membered ring fused to the 6,7-positions of the *O*-formyltropine skeleton results in severe transannular interactions involving the neighboring equatorial *N*-methyl group. As a result, the axial N-H proton is pushed inward even closer towards its axial C-H neighbors (see projections **16** and **17**, C(2,4)···N(1)–H angles: 76.5(1)° in **16** and 78.1(1)° in **17**), whereas this close juxtaposition is reduced with the smaller

19

equatorial N-H proton. Transannular interactions result in the axial *N*-methyl diastereomeric models **18**, **19** (C(2,4)···N(1)–C(8) angles: 96.0(1)° in **18** and 97.6(1)° in **19**) being more stable than the epimeric equatorial cases (**16**, **17**) (24). Based upon these earlier theoretical studies, we suggest that the observation of *axial N*-methyl diastereomers for crystalline **2**, **3**, **5**, and **7** should be explained in terms of greater stability of the axial vs. the equatorial *N*-methyl epimer.

(–)-Scopolamine free base

Scopolamine free base (**8**) is utilized in transdermal patches to treat motion sickness (1, 25). CPMAS ^{13}C NMR spectroscopy provides insight into the solid-state stereochemistry of the crystalline melt, mp 58–61°C (monohydrate lit. (1) mp 59°). While only one carbonyl resonance (δ 170.6) was found for **8**, most other nuclei afforded multiple signals in the CPMAS spectrum. These multiple signals readily testify to a mixture of hydrated species in the crystallized melt. For example, four signals (δ 170.6 (high intensity) and three ca. 1:1:1 ratio lower intensity δ 46.8, 45.1, 43.6) were observed in the spectral-edited nqs (*n*on-*q*uaternary and non-methyl carbon *s*uppression) spectrum. The three almost-equal intensity resonances are all unequivocally assigned as more mobile *N*-methyl signals, since they diasppear in an inversion-recovery experiment (20 s T_1 delay). By analogy with the δ*C*H$_3$ 45.06 scopolamine hydrobromide equatorial *N*-methyl major diastereomer in CD_2Cl_2 solution (14), it is clear that all of the *N*-methyl groups are also equatorially disposed in the solid-state. Signals at δ 66.6, 65.9, and 64.6 were assigned to C(3) by analogy with the time-averaged δ 66.9 value reported (21) for C(3) in $CDCl_3$ solution. The δ 61.8 methylol C(11) signal found in the "methylene-only" spectral-edited cppi (cross polarization/polarization inversion) spectrum, is closer to TMS than those values noted above for alkoxy C(3). By analogy with our earlier CPMAS studies on scopolamine salts (15), $\Delta\delta > 0$ (where $\Delta\delta = \delta C(3) - \delta CH_2OH$) strongly suggests a compact conformation for the solid-state free base. In addition to tropate ester conformational interconversion, epimerization at the stereolabile nitrogen via nitrogen inversion can occur in solutions of the free base. The δ*C*H$_3$ 42.2 (15, 26) *N*-methyl, δC(3) 66.9 (26), and δC(11) 64.0 (24) values measured for the free base in $CDCl_3$ solution show that the dominant contributor to the weighted time-averaged free base **8** structure is very similar to the equatorial *N*-methyl compact conformation postulated for the crystalline solid. Similar to the case of the crystallographically determined structures **2**, **3**, **5**–**7**, **10**, **11** free base vicinal coupling constants ($^3J_{HH}$) show a bias for the antiperiplanar C(12)-C(10)-C(11)-O(4) conformation in solution (26).

(–)-Scopolamine hydrobromide trihydrate

The USP-grade, pharmacologically relevant trihydrate (12), like many other hydrate drugs, takes up or releases water upon exposure to air at various relative humidities (27). For example, at 25, 66, and 71 percent relative humidity

© 2000 NRC Canada

(18°C), the trihydrate (**9**) sample was reported to have 1.71, 2.31, and 2.55 moles of water, respectively (27). Solid-state CPMAS ^{13}C NMR spectroscopy was performed on two bona fide trihydrate samples. The 5.0 kHz spin-rate spectra (30 min acquisition) of each of these samples clearly showed signals from multiple species, i.e., the USP- EUP-grade trihydrate is not a single distinct entity. For example, three almost-equal intensity δ 173.5, 172.5, and 171.5 carbonyl signals were found for an 11.6% water content (Karl–Fischer) sample, while a ca. 1:1:2 ratio was measured for these same peaks for another supplier's sample. Increasing the spin-rate of the same 1:1:2 ratio sample to 11.5 kHz (50 min acquisition) afforded signal intensity reductions from two of the three species (e.g., carbonyl ratio now ca. 1:1:4, major species: sesquihydrate **2**). A further spin-rate increase to 13.5 kHz (10 min acquisition), afforded a spectrum identical in all respects to that of pure **2**. Single species **2** was still observed, rather than the original mixture of three components, upon reduction of the spin-rate to 5.0 kHz. After storing the capped rotor overnight, only the sesquihydrate species spectrum was measured at 5.0 kHz spin-rate. The original three component 5.0 kHz spin-rate spectrum was regenerated after ca. three weeks storage inside the capped rotor.

To ascertain if a centripetal pressure or rotor-friction temperature effect was at the root of this phase-transition phenomenon, the sample temperature within the rotor was determined at various rates of spin using the known lead nitrate (28) chemical shift temperature effect technique. The narrow line-widths observed in the ^{207}Pb NMR spectrum testified to a uniform temperature within the sample. The rotor-spinning air overcomes frictional heat felt by the spinning rotor at 5.0 kHz, since the internal temperature change was –0.8 K relative to the temperature of the non-spinning rotor. At 13.5 kHz spin-rate, the ^{207}Pb chemical shift increased by 15.8 ppm. The change in ^{207}Pb chemical shift as a function of spectrometer variable-temperature (VT) control panel setting was then measured. It was found that the VT setting had to be +18 K higher than the 295.3 K non-spinning rotor reference temperature to afford a +15.8 ppm δ^{207}Pb increase. The CPMAS spectrum of a fresh scopolamine hydrobromide trihydrate sample was measured at 5.0 kHz (three hydrated species seen), and the VT setting was then increased 18° to 313.3 K with invariant 5.0 kHz spin-rate. The same single sesquihydrate species **2** spectrum was observed under these conditions, showing a temperature effected phase-transition rather than one from increased centripetal force. Again, **2** remained as the sole observable species upon cooling the rotor back down to ambient temperature. It has been reported that the temperature effect of spinning in a 4 mm Bruker MAS probe with zirconia rotors could be fitted by a spin-rate to the second-power relationship (29).

Conclusions

The three new crystal structures reported above provided needed additional members in the series of scopine alkaloids investigated earlier by CPMAS ^{13}C NMR spectroscopy (15). In this series, the compact conformation (–)-scopolamine methobromide (**7**) played a very important role since it exhibited the smallest O(3)–C(9)–C(10)–C(11) torsion angle (5°). The γ-gauche effect was nicely seen by the δ 59.7 methylol C(11) and δ 61.4 alkoxy C(3) values measured for **7**, compared with the δ 65.5 methylol C(11) and δ 61.6 alkoxy C(3) values found for extended conformation Buscopan methanol solvate adduct (**10**) having the largest O(3)–C(9)–C(10)–C(11) torsion angle (61°) (15). While the reported dihydrate form (1) of scopolamine hydrochloride was not found, one can readily envision crystalline species containing up to a stoichiometric maximum of two water molecules per unit-cell. This dihydrate maximum hydration would arise from full occupancy of the special position of C_2 symmetry by the O(7) water molecule to afford a unit-cell consisting of two stoichiometrically half-molecules of water (O(6) and O(7)) plus one full O(5) water molecule.

Finally, the CPMAS NMR spectroscopic investigations of scopolamine free base monohydrate and hydrobromide trihydrate now show that these pharmacologically useful materials are really conglomerates of hydrated species. The diamond-shaped hydrogen-bonding network found for the hydrochloride 1.66hydrate (**6**) might be a very suitable model to explain the location of at least some of the water molecules in the trihydrate.

Theoretical studies of azulene and its derivatives

Bo-Cheng Wang, Yun-Shan Lin, Jian-Chuang Chang, and Pei-Yu Wang

Abstract: The results of ab initio calculations with the 6–31G basis sets on azulene and its derivatives (including azulenequinones and diazoazulenequinones) are presented in accordance with considerations of their structures and bonding. Azulene is a non-alternant compound with ten π electrons and has either a C_s or C_{2v} symmetry depending on the different carbon bonding. The semiempirical and HF ab initio calculations converge to a C_s symmetry and the DFT and MP2 calculations converge to a C_{2v} symmetry as a ground state structure of azulene. The CIS calculations describe the excited state of azulene and the first excitation energy ($S_0 - S_1$) is 533 nm (CIS/6–31+G*), which could illustrate the azure color of azulene. According to the geometry analysis, there are 16 geometrical isomers in azulenequinone conjugated diketones of azulene. Ab initio calculation with the 6–31G basis set generates 1,5- and 1,7-azulenequinone being the most stable isomers of azulenequinone. Theoretically, the relative stability of the bromination product of azulenequinones indicates that 7-bromo-1,5-azulenequinone and 3-bromo-1,7- azulenequinone (for monobromoazulenequinones) and 3,7-dibromo-1,5- azulenequinone and 3,5-dibromo-1,7-azulenequinone (for dibromoazulenequinones) are more stable isomers. The product of diazotization of amino- bromoazulenes is diazoazulenequinone in which a diazo group replaces a ketone group. Isomeric 1,8- and 1,2-diazoazulenequinones are the most stable isomers of diazoazulenequinone according to the theoretical consideration. Due to the resonance and relative stability, diazoazulenequinone may easily extrude nitrogen and form the corresponding triplet ketocarbene intermediate and electronic isomers that undergo photoreaction with THF leading to a polyether bridged azulene (crown type ether). The cyclic reactions in diazoazulenequinone are also studied.

Key words: azulene, azulenequinone, diazoazulenequinone, ab initio.

Résumé: Utilisant des ensembles de base 6–31G, on a effectué des calculs ab initio sur l'azulène et un certain nombre de ses dérivés, dont des azulènequinones et des diazoazulènequinones; les résultats sont présentés avec des considérations sur leurs structures et leurs modes de liaison. L'azulène est un composé non alternant comportant dix électrons π et de symétrie C_s ou C_{2v} selon les types de liaison des carbones. Les calculs semiempiriques et les calculs ab initio HF convergent vers une symétrie C_s alors que les calculs DFT et MP2 convergent vers une symétrie C_{2v} pour la structure de l'état fondamental de l'azulène. Les calculs CIS permettent de décrire l'état excité de l'azulène et la première énergie d'excitation ($S_0 - S_1$) est 533 nm (CIS/6–31+G*) qui pourrait expliquer la couler azur de l'azulène. Selon l'analyse géométrique, il existe seize isomères géométriques dans les dicétones conjuguées de l'azulènequinone. Les calculs ab initio avec l'ensemble de base 6–31G suggèrent que les 1,5- et 1,7-azulènequinones sont les isomères les plus stables. D'un point de vue théorique, les stabilités relatives des produits de bromation des azulènequinones indiquent que les bromo-1,5-azulènequinone et 3-bromo-1,7-azulènequinone (pour les monobromoazulènequinones) et les 3,7-dibromo-1,5-azulènequinone et 3,5-dibromo-1,7-azulènequinone (pour les dibromoazulènequinones) sont les isomères les plus stables. Le produit de diazotation des aminobromoazulènes est la diazoazulènequinone dans laquelle le groupe diazo remplace un groupe cétonique. Sur la base de considérations théoriques, les 1,8- et 1,2-diazoazulènequinones sont les isomères les plus stables des diazoazulènequinones. À cause de la résonance et de la stabilité relative, la diazoazulènequinone peut facilement éliminer de l'azote et conduire à la formation de l'intermédiaire triplet cétonecarbène correspondant et à ses isomères électroniques qui subissent des photoréactions avec le THF pour fournir un azulène à pont polyéther (éther de type couronne). On a aussi étudié les réactions cycliques des diazoazulènequinones.

Mots clés: azulène, azulènequinone, diazoazulènequinone, ab initio.

[Traduit par la Rédaction]

Introduction

In ancient Egypt, azulene derivatives were used for dying of cotton, since it has the natural blue color (called azure). Actually, azulene was generated from several kinds of plants through distillation, extraction, and other chemical treatment. In 1937, azulene, the parent compound, was synthesized by Plattner and Pfau (1) for the first time. About 30 years later, Nozoe (2) published a new method to synthesize azulene derivatives. In the meantime, the study of azulene

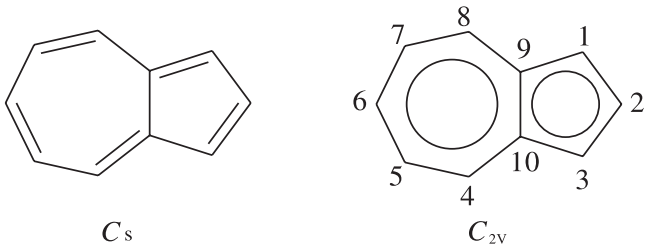
has become one of the most popular topics in organic, inorganic, medicinal, and theoretical chemistry as well as in the dye industry.



Azulene contains fused five-membered and seven-membered rings as a bicyclic structure and it is a nonalternant polycyclic aromatic compound with a 10 π electron system (3). Although azulene and naphthalene have the same 10 π electrons, they exhibit quite different properties in a number of respects.

For the last two decades, several theoretical studies of azulene have been published using semiempirical, ab initio, and DFT calculation methods (4–7). Recently, Kozlowski et al. (7) used both ab initio and DFT methods to determine the ground state structure and vibrational frequencies for azulene with C_s and C_{2v} symmetry. Experimentally, several attempts have been made to determine the molecular structure of azulene based on the X-ray analysis (8–10). Neither theoretical calculations nor experimental investigation have completely resolved the geometry of the ground state structure of azulene. Since azulene not only has a beautiful deep blue color, but also has a large dipole moment (μ = 0.8 – 1.08 D) and unusual photophysical properties, the excited states and electronic spectrum of azulene are of interest for theoretical and spectral studies (7). Natural compounds have a color due to the absorption of certain wavelengths of visible light. The particular structures necessary for this transition are unsaturated groups undergoing $\pi - \pi^*$ or $n - \pi^*$ transition. Azulene and its derivatives have a unique electronic structure for fluorescence properties. Michl and Thulstrup (11) described the color difference between anthracene and azulene by applying a simple MO picture to describe the electronic excitation energy.

Azulene with a diketone substituent is called azulenequinone. As early as 2700 B.C., quinone was used for Chinese medical, antifungal, antibiotic, or dyestuff purposes. The first unsubstituted azulenequinone was generated with an organic synthesis method by Morita (12) in 1980. Then Li and Scheuer (13) found the first natural occurrence of an azulenequinone, which was called guaiazulenequinone. Since azulenequinones contain a diketone substituent, they may have 16 structural isomers. Scott et al. (14) used theoretical calculations to predict the structures, spectral properties, relative stability, and reactivity for the selected isomers of azulenequinones. Various azulenequinones can be derived by nucleophilic reaction on bromoazulenequinones. Recently Nozoe et al. (15) discovered a standard procedure for the synthesis of 3-bromo-1,5- and -1,7-azulenequinones.

A replacement of a carbonyl C=O group by a diazo $C=N_2$ group gives diazoazulenequinone. As early as in the 1960s, diazoazulenequinone had been proposed by Hafner (16). Then, in 1974 Nozoe's group (17) obtained 2,6-azulenequinone-2-diazides by the diazotization of 2-amino-6-bromoazulene, which is one of the precursors of diazoazulenequinone. Recently, the new and efficient method to synthesize diazoazulenequinone was determined by Lin's group (18). They have also successfully isolated 2-diazo-2,6-azulenequinone and 2-diazo-2,4-azulenequinone (18). Particularly, these diazoazulenequinones could be used in the conjugated ketocarbene precursor of polyether bridged azulene reaction and as stabilizers for polymers as well as in the development of photo lithographic materials. Very recently, Lin's group (19) proposed a new method for the synthesis of polyether bridged azulene with three, four, and five THF (tetrahydrofuran) for 2-diazo-2,6-azulenequinone. This reaction is generated from azulenequinone diazides.

Fig. 1. Geometrical structure of azulene in C_s (bond alternate) and C_{2v} (bond equalized) symmetry.

The purpose of the present article is to study: the ground and the excited state of azulene, the relative stability of azulenequinone, bromoazulenequinone, diazoazulenequinone, and their isomers, and to predict the reactivity of diazoazulenequinone and the corresponding conjugated ketocarbene intermediates.

Computational methods

Ab initio calculations with the self-consistent field (SCF) theory using the standard Gaussian basis sets 6–31G, and second-order Møller–Plesset perturbation theory (MP2) as well as density function theory (DFT) using B3LYP/3–21G and B3LYP/6–31G were used to determine the optimized geometry of azulene. Ab initio calculations using the 6–31G basis sets were used to determine the electronic structure, the relative stability, and other physical properties for azulenequinones, bromoazulenequinones, and diazoazulenequinones. In order to study the electronic excited state and photochemistry properties, the configuration interaction with single excitations (CIS) with different basis sets (6–31+G and 6–31+G*) was used. The ab initio and DFT calculations were carried out on a version of the Gaussian 94 program[2], which was modified for an SGI workstation.

Results and discussion

Azulene

According to the bond analysis, azulene may have either the bond-equalized structure with C_{2v} symmetry or the bond-alternate structure with C_s symmetry (Fig. 1). Both semiempirical and ab initio calculations (HF with STO–3G and 3–21G) show the structure of azulene converged to a C_s structure (4, 14). Recently, Kozlowski et al. (7) performed

calculations on azulene that are at higher level (B3LYP/3–21G, B3LYP/6–31G basis set) than any of the methods which have been used before. This calculation converges the structure of azulene to a C_{2v} symmetry and it provided the most accurate results. For the investigation of the optimized structure of azulene, Robertson (8) reported the X-ray data of azulene with the conclusion was that the symmetry of the molecule is C_{2v}. Table 1 shows the geometry optimization for C_{2v} symmetry of azulene with different computational methods. According to this result, the bond lengths in the five-membered ring and those in the seven-membered ring are approximately equal. Thus, we conclude that the electrons are delocalized in the five- and seven-membered rings respectively.

Since azulene has a beautiful azure color, it must have a $S_0 - S_1$ absorption in the visible region. In photochemical studies, azulene also has greatly interesting properties, e.g., the observed fluorescence corresponding to $S_2 - S_0$ transition. To investigate this special property of azulene, we performed the ab initio CIS calculation using the Gaussian 94 program with the 6–31+G and 6–31+G* basis sets. The first excitation energy ($S_0 - S_1$) is calculated to be at 518 nm (6–31+G) and 533 nm (6–31+G*) (Table 2). These values fall in the visible region and clearly illustrate the color of azulene. The experimental absorption peak is at 585 nm which is reasonably close to the theoretical value (20).

Azulenequinones

The generic names of quinones are cyclohexadiendiones also commonly called *p*-benzoquinones. But they are named as some derivatives of aromatic systems: benzoquinones are derived from benzene, toluquinones from toluene, naphthoquinones from naphthalene. Azulenequinones are derived from azulene containing a diketone group spaced by one or more double bonds. The geometrical analysis shows that there are 16 possible geometrical isomers for azulenequinones, among them 11 azulenequinones which can be drawn by Kekule structures (also called classical azulenequinone) (Fig. 2) and five are nonclassical azulenequinones, which cannot be drawn in terms of simple Kekulé structures. However, Scott et al. (14) proposed their structures and relative stability with a semiempirical MINDO/3 calculation. The more quantitative results have not been reported. In the present work, we used the ab initio HF method with the 6–31G basis set to investigate the relative stability of these eleven classical azulenequinones only, since the nonclassical azulenequinones have smaller energy gap $\Delta\varepsilon$ (the energy gap between HOMO and LUMO) and higher heats of formation (ΔH_f) than the corresponding classical azulenequinones (14). Table 3 shows the energy, LUMO, HOMO, and $\Delta\varepsilon$ of azulenequinones which are generated by the ab initio calculations. The azulenequinones can be ranked from the lowest to the highest in order of their energy, computed at the Hartree–Fock level.

1,5 < 1,7 < 1,4 < 1,6 < 1,2 < 4,7 < 1,8 < 2,6 < 2,4 < 4,5 < 5,6

In conclusion, the relative stability of azulenequinone depends on the number of double bonds in the five-membered ring and the tropone ring. The structures of 1,5- and 1,7-azulenequinones contain one double bond in the five-membered ring and have a tropone unit in the seven-membered ring, which may stabilize the structure. The structure of 1,2-azulenequinone contains one double bond in the five-membered ring and the 1,2-diketone substitute that should increase the strain energy of the five-membered ring. Whereas 1,4-, 1,6-, and 1,8-azulenequinones have two double bonds in the five-membered ring (one double bond is located in the fusing junction), that decrease the stability of azulenequinone. Considering the structure, these azulenequinones have a tropone and a cyclopentadienone, which cannot be generated under normal laboratory conditions and is chemically unstable. 2,4- and 2,6-Azulenequinones contain a cyclopentadienone (which contains two double bonds in the five-membered ring) and do not have a typical tropone structure. Moreover, 4,5-, 4,7-, and 5,6-azulenequinones have a diketone substitute located in the seven-membered ring that should decrease the stability of azulenequinone. The calculation also indicated that 4,5-, 4,7-, and 5,6-azulenequinones are significantly non-planar, which should increase the strain energy and decrease the resonance energy. Concerning the aromaticity of plane, azulenequinones may obey the $4n + 2$ rule for free $p\pi$ electrons in five- and seven-membered rings. 1,5-, 1,7-, and 1,2-Azulenequinones have two and six $p\pi$ electrons in the five- and seven-membered rings respectively. Although 1,4-, 1,6-, and 1,8-azulenequinones have two (in the five-membered ring) and six (in the seven-membered ring) free $p\pi$ electrons, they include one double bond in the fused position of two rings. This should decrease the relative stability of azulenequinones.

According to the above calculations, 1,5- and 1,7-azulenequinones should be the most stable isomers in the azulenequinones. Morita et al. (21) synthesized 1,5- and

[a]All calculations were performed using the ab initio HF method with the 6–31G basis set.

energy according to ab initio calculations and the experimental results confirmed the theoretical prediction in this azulenequinone study (21).

For the reactivity study of azulenequinone, the donor substitution (nucleophilic attack) should occur in the position with the largest π–LUMO coefficient. Table 4 shows the calculated π–LUMO coefficient of azulenequinone by the ab initio HF/6–31G calculation. 3, 7 and 3, 5 are the most possible positions for the nucleophilic attack in 1,5- and 1,7-azulenequinones, respectively. Experimentally, through repeated bromination in aqueous acetic acid, an azulenequinone affords a mixture of monobromoazulenequinone together with that of dibromoazulenequinones (24). These bromoazulenequinones could be the precursors for the formation reaction of polymers (23, 24). Actually, we select the most thermodynamically stable isomers 1,5- and 1,7-azulene- quinones as the precursors for the study of the bromoazulenequinone and dibromoazulenequinone isomers. The ab initio HF/6–31G calculated energy of six monobromoazulenequinones and 15 dibromoazulenequinones are given in Tables 5 and 6, respectively. The result shows that 3-bromo-1,5-azulenequinone and 3-bromo-1,7-azulenequinone are the major products for the bromination of 1,5- and 1,7-azulenequinones. Nozoe et al. (15) obtained 3-bromo-1,5-azulenequinone and 3-bromo-1,7-azulenequinone in agreement with the theoretical prediction. According to Table 5, 3,7-dibromo-1,5-azulenequinone and 3,5-dibromo-1,7-azulenequinone are the most stable isomers for dibromoazulenequinone in the ground state. 2,3-Dibromo-1,5-azulenequinone and 2,3-dibromo-1,7-azulenequinone are the next stable isomers of this compound. This theoretical prediction may provide the possible structures for organic chemists to design the new reaction path.

The electronic transition energy of $S_0 - S_1$ ($\pi - \pi^*$) is related to the color of the compound. Scott et al. (14) have obtained the π–HOMO/LUMO gap and colors of azulenequinones. Calculation results indicated that these compounds have intense-purple to blue-green colors. Table 6 shows the

$S_0 - S_1$ electronic excitation energies of the monobromoazulenequinones, which are all in the UV region (between 311 nm and 364 nm).

Diazoazulenequinone

Anilines undergo diazotization under acidic condition to give diazonium ions as a reaction intermediate. Nozoe et al (17) and Lin and coworkers (18) have shown that the diazotization of 2-amino-6-bromo-1,3-dicyanoazulene to generate the diazoazulenequinone, which contained a conjugated ketone and diazo functional group, that endow a wide range of reactivity (18). While the symmetry consideration allow diazoazulenequinones to have 32 isomers, the Kekulé aromatic theory limits the possible structures of diazoazulenequinone to 22. Other isomers of diazoazulenequinone have nonclassical structure and are ignored in this study. The resonance structures of diazoazulenequinone may have a quinoid form or a diazonium azulenolate form. Due to the resonance, the structures of the aliphatic diazo compound are described as in Fig. 3. In quinoid form, none of the electron pairs can be delocalized into the functional group, which results in resonance structures containing a double bond between the azulene ring and the attached nitrogen. Azulenolate form presumes a positive charge on the diazo side and a negative charge on the carbonyl side. Since the five-membered ring of azulene contains a higher negative charge, the diazonium cation should be more stabilized on the five-membered ring. Therefore, in the calculations of relative stability of the diazoazulenequinone isomers, only those containing the diazo group located in the five-membered ring were considered. The ab initio HF calculation with the 6–31G basis set were used to generate the relative stability for these structures and the results are given as follows (Table 7):

Table 7. Calculated energy, HOMO, LUMO (Hartree) and Δε (kcal/mol) for diazoazulenequinones (DAQ)[a].

m,n-DAQ	Energy	HOMO	LUMO	Δε
1,2-DAQ	–565.58630	–0.2775	0.0412	200
1,4-DAQ	–565.58673	–0.2912	0.0326	203
1,5-DAQ	–565.57755	–0.2745	0.0456	201
1,6-DAQ	–565.58400	–0.2907	0.0284	200
1,7-DAQ	–565.57841	–0.2735	0.0434	199
1,8-DAQ	–565.59438	–0.2848	0.0433	206
2,4-DAQ	–565.58112	–0.2831	0.0265	194
2,6-DAQ	–565.57958	–0.2963	0.0261	202
4,5-DAQ	–565.56915	–0.2763	0.0165	184
4,7-DAQ	–565.56225	–0.2751	0.0187	184

[a]All calculations were performed using the ab initio HF method with the 6–31G basis set.

$$1,8 < 1,4 < 1,2 < 1,6 < 2,4 < 2,6 < 1,7 < 1,5 < 4,5 < 4,7$$

According to the above results, 1,8-, 1,4-, and 1,2-diazoazulenequinones have high chemical stability. But most of the diazoazulenequinones are derived from 2-amino-6-bromoazulenes and 2-amino-4-bromoazulenes, so that 2,6- and 2,4- should be the most probable diazoazulenequinone products (25). In a simple structural consideration, the relative stability of diazoazulenequinones depends on a tropone ring and a diazocyclopentadiene ring. Particularly, 1,8-, 1,4-, and 1,6-diazoazulenequinones contain a tropone unit and a diazocyclopentadiene ring. The azulenolate form should transfer the electron density to the ring and increase the aromatic character in the ring. Consequently, 2,4-, 2,6-, 1,7-, and 1,5-diazoazulenequinones contain a tropone unit and no cyclopentadiene, which may decrease the relative stability. As the result of the theoretical prediction, 4,5- and 4,7-diazoazulenequinones (diazo and carbonyl functions are located in the same ring) are nonplanar compounds and they may decrease the resonance energy and chemical stability.

For the geometrical structures of other possible isomers of diazoazulenequinone, like 1,2-quinondiazide, the diazo and the carbonyl group are brought closer sterically, which should

[b]$\Delta E = E_{cyclic\ comp.} - E_{comp.}$.

be responsible for the partial interaction of the carbonyl oxygen with the nitrogen end atom of the diazo group to form a five-membered heterocycle. Blocher and Zeller (26) proposed that the *o*-quinone diazide (benzene) and *o*-quinone diazide (naphthalene) should favor the cyclic structure of the benzo-[1,2,3]-oxadiazole and naphtho-[2,3-*d*]-[1,2,3] oxadiazole, respectively. Accordingly, 1,2-, 1,8-, 4,5-, and 5,6-diazoazulenequinones have diazo and carbonyl groups in the neighboring positions which could result in cyclic reaction to provide the existence of a five- or a six- membered heterocycles, which are shown in Fig. 4. We study the relative preference for these cyclic reactions by theoretical calculations (Table 8). Since the energy difference is very small, only 1,8-diazoazulenequinone may favor the cyclic reaction to produce a six-membered ring heterocycle compound, which is an isomeric structure.

Diazotization of aniline gives a relatively stable arenediazonium salt. When arenediazonium ions are heated, the nitrogen extrusion is easy and the very reactive phenyl cation is produced. Similarly, diazotization of 2-amino-6-bromo-1,3-dicyanoazulene or 2-amino-4-bromo-1,3-dicyanoazulene produced a conjugated ketocarbene intermediate, which is a precursor for the reaction with THF. For the carbene studies, several results have been reported in the literature about the theoretical calculation to describe the energy difference between the singlet and triplet substituted carbenes (27–29). Carbenes contain two valence electrons. According to the electronic configuration analysis, the singlet ground state has

a pair of spin coupled electrons localized on the sp^n orbital and the triplet ground state has one electron on the sp^n orbital and the other is on the $p\pi$ orbital. Thus, there is more $p\pi$ character in the triplet ground state, which should aid its electron delocalization. This conjugated ketocarbene intermediate has either singlet or triplet ground state. The results of the HF/6–31G calculations for this conjugated ketocarbene intermediate are shown in Table 9 in which triplet ketocarbene possesses a lower energy than that of singlet ketocarbene, by about 35 kcal/mol and 96 kcal/mol for conjugated 2,6- and 2,4-ketocarbenes with the 1,3-dicyano group, respectively. Furthermore, the conjugated ketocarbene should play an important role in the formation mechanism of polyether bridged azulene. Recently, diazoazulenequinone was found to undergo photoreactions with different numbers of THF substitutes leading to a polyether bridged azulene, such as diazoazulenequinone–3THF, diazoazulenequinone–4THF, and diazoazulenequinone–5THF (Fig. 5) (19). This polyether bridged azulene presents very special stereoselectivity in the reaction, and we are going to investigate this later.

Conclusions

The relative stability investigation shows that 1,5- and 1,7-azulenequinones are the most favorable (or stable) isomers, which depends on the number of double bonds in the five-membered ring and the tropone structure in the seven-membered ring. Bromination of 1,5- and 1,7-azulenequinones should produce 3-bromo-1,5-azulenequinine and 3-bromo-1,7-azulenequinone as monobromoazulenequinone, as well as 3,7-dibromo-1,5-azulenequinone and 3,5-dibromo-1, 7-azulenequinone as dibromoazulenequinone stable products, respectively.

The relative stability of diazoazulenequinones depends on a tropone unit and a diazocyclopentadiene ring. Thus, 1,8-, 1,4-, 1,2-, and 1,6-diazoazulenequinones are the favorable isomers. Due to the partial interaction of the carbonyl oxygen with the nitrogen end of the diazo group, it should form a heterocycle. 1,8-Diazoazulenequinone favors this cyclic reaction to give a six-membered ring heterocyclic compound.

Recently, the research on azulene and its derivatives has developed considerably and rapidly. Their chemical transformations along with the relative availability disclose a wide prospective for the production of various derivatives of heterocyclic compounds, polymers, and azulene. The results of the present calculation provide more accurate geometric structures, electronic structures, and spectroscopic data as well as other physical properties for azulene, azulenequinones, diazoazulenequinones, and bromoazulenequinones. They are

© 2000 NRC Canada

interesting precursors for the formation of azulene-based material and the starting material for the formation of polymers.

Interaction of hydroxyphenyl alkyl ketones with β-cyclodextrin

Alicia Viviana Veglia and Rita Hoyos de Rossi

Abstract: Binding constants of β-cyclodextrin with six hydroxyphenyl alkyl ketones having a general structure Z-Ph-CO-$(CH_2)_n$CH$_3$ (Z = *o*-OH or *p*-OH and *n* = 0, 1, or 3) were measured at 25°C by UV–vis spectrophotometry. In all cases the formation of 1:1 host-guest complexes was established. NMR chemically induced shifts indicated mixed complexation modes. Equilibrium constants are around 200 M^{-1} for some of the compounds and for the others around 1000 M^{-1}. It is suggested that complexes with different geometries coexist in the solution with predominance of those with the aryl group ($K_{SCD} \approx 200$ M^{-1}) or alkyl group ($K_{SCD} \approx 1000$ M^{-1}) inside the cavity.

Key words: inclusion complex, β-cyclodextrin, hydroxyphenyl alkyl ketones, association constants, UV–vis spectrophotometry.

Résumé : Faisant appel à la spectrométrie UV–vis et opérant à 25°C, on a mesuré les constantes de fixation de la β-cyclodextrine avec six hydroxyphénylalkylcétones de structure générale Z-Ph-CO-$(CH_2)_n$CH$_3$ (Z = *o*-OH ou *p*-OH et *n* = 0, 1 ou 3). Dans chacun des cas, on a pu établir qu'il se forme des complexes hôte-invité 1:1. Les déplacements RMN induits chimiquement suggèrent l'existence de modes de complexation mixtes. Les constantes d'équilibre de certains de ces composés vont de 200 M^{-1} à 1000^{-1}. Ces données suggèrent que des complexes de géométries différentes coexistent en solution et qu'il y a prédominance de ceux dans lesquels les groupes aryle ($K_{SCD} \approx 200$ M^{-1}) ou alkyle ($K_{SCD} \approx 1000$ M^{-1}) se trouvent à l'intérieur de la cavité.

Mots clés : complexe d'inclusion; β-cyclodextrine; hydroxyphénylalkylcétone; constantes d'association; spectrophotométrie UV–vis.

Introduction

Cyclodextrins are doughnut-shaped molecules formed by six, seven, or eight glucose units (α, β, or γ) linked together covalently by glycosidic oxygen atoms. They have the secondary hydroxy groups on the wider rim of the cavity and the primary OH groups at the narrower one (1). They are able to form inclusion complexes with a great variety of compounds and this property is responsible for changes in reactivity and selectivity of organic reactions (2, 3). This property has been reported to have analytical implications ((4) and refs. therein).

Moreover, the interaction of cyclodextrins with organic compounds of different structures is a field of great interest because it may help in the understanding of the catalytic action of enzymes (5).

In previous work, we have studied the photochemical rearrangement of aryl esters of different alkyl chain lengths which lead to *ortho*- (**1**) and *para*- (**2**) hydroxyphenyl alkyl ketones (6, 7) in the presence of β-cyclodextrin (CD). We thought it would be of interest to determine the equilibrium constants for the association of **1** and **2** with CD in order to establish the effect of the position of the hydrophilic OH group and the length of the alkyl chain on the nature of the interaction.

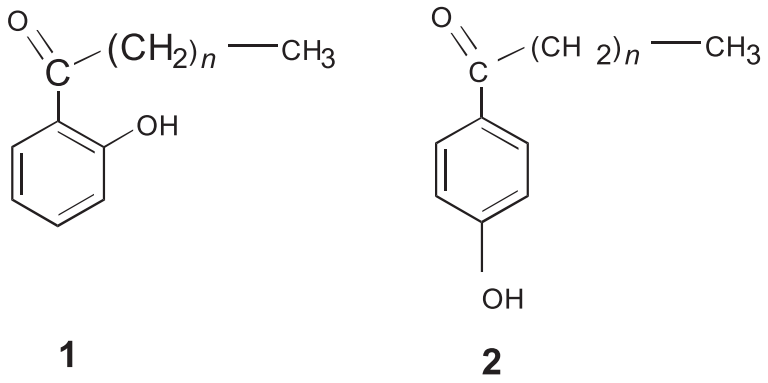
Results and discussion

Association constants determination. The addition of 10 mM of CD to aqueous solutions of substrates (S) **1** and **2** produces a bathochromic shift of about 3 nm in the UV–vis spectra. When the CD concentration is varied from 0–10 mM, there is not a well defined isosbestic point (Fig. 1 is representative). In all cases the corresponding blank of CD was subtracted. We did not find evidence for the formation of complexes with stoichiometry higher than 1:1, therefore we considered that the lack of an isosbestic point was probably due to some type of medium effect on the species (8). The addition of glucose in an equivalent weight of 10 mM CD did not produce any change on the absorbance of compounds **1** and **2,** which indicates that there are some specific interactions between the substrates and the CD.

The difference spectrum between a solution having the maximum of cyclodextrin concentration used (10 mM) and that without CD shows the wavelength (λ) of maximum absorbance differences (ΔA_{max}) in each case. These wavelengths which are collected in Table 1 were selected for the measurements.

The change in absorbance with the concentration of CD can be represented as in eq. 1

 © 2000 NRC Canada



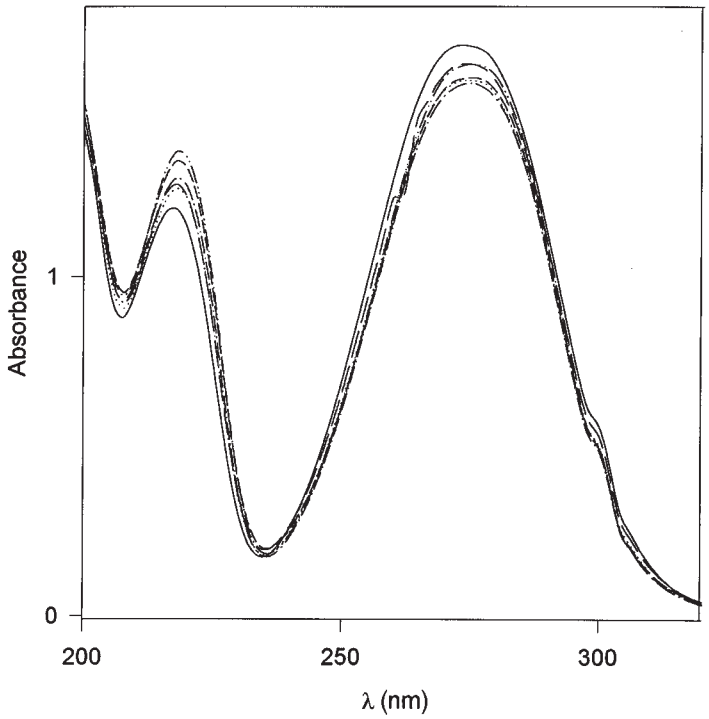


Fig. 1. UV–vis spectrum for *p*-hydroxyacetophenone (**2**, $n = 0$) 5×10^{-5} M with 0, 2, 4, 6, 8, and 10 mM of β-cyclodextrin, indicated in this order with lines —, — —,...., —. —, – – –, –.. –. At 224.6 nm the absorbance increases with the increase of β-cyclodextrin concentration.

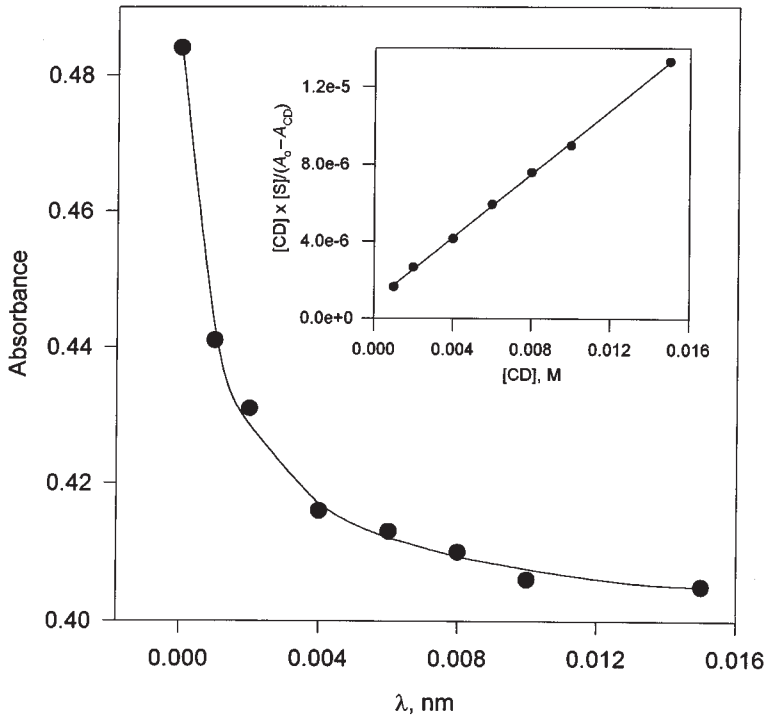
$$[1] \qquad A = A_0 + \frac{\Delta A_{max} K_{SCD}[CD]}{(1 + K_{SCD}[CD])}$$

where A and A_0 are the absorbances at a given wavelength for the solutions with and without CD, ΔA_{max} represents the change in A between the complexed and free substrate, K_{SCD} is the association constant for the reaction described in eq. [2].

$$[2] \qquad S + CD \rightleftharpoons SCD$$

Alternatively, eq. [1] can be transformed into eq. [3] where Δε represents the difference in the extinction coefficients of the included and that of the free substrate.

$$[3] \qquad \frac{[S]_0[CD]}{\Delta A} = \frac{1}{K_{SCD}\Delta\varepsilon} + \frac{[CD]}{\Delta\varepsilon}$$



The measured values of absorbance were adjusted to eq. [1] (Fig. 2 is representative). The linear plot according to eq. [3] (Fig. 2 inset) confirms the 1:1 stoichiometric ratio (9). Both methods give the same value of K_{SCD} within experimental error.

log K_{SCD}	2.38	2.18	2.18	2.92	2.95	3.11

Fig. 2. Absorbance of 7×10^{-5} M *o*-hydroxyvalerophenone (**1**, n = 3) as a function of β-cyclodextrin concentration at 246 nm. Inset: plot according to a linearized equation (see text eq. [3]).

For *o*-hydroxyvalerophenone (**1,** n = 3**)** and *p*-hydroxyvalerophenone (**2,** n = 3) the values of K_{SCD} reported in Table 1 are the average of the determination at two wavelengths, namely 223.0 nm and 246.0 nm for the former and 224.8 nm and 296.1 nm for the latter. For all the other substrates, there was only one wavelength where the ΔA_{max} is 0.1, so we used this value for equilibrium constant determination.

The K_{SCD} values determined in this study, for **1** and **2**, show better interaction with β-cyclodextrin relative to α-cyclodextrin, since the K_{SCD} values reported for substrates **2** with n = 0 and 3 and α-cyclodextrin were 14.9 and 41 M^{-1}, respectively (10). This behaviour ($K_{SCD}^{\beta} > K_{SCD}^{\alpha}$) was also observed for monosubstituted benzene derivatives (11).

The values of the K_{SCD} are in the range expected according to literature values (12). They can be grouped in two sets: one with K_{SCD} around 200 M^{-1} and one with K_{SCD} around 1000 M^{-1}.

The influence of the position of the hydroxyl group substituent of the aromatic rest can be observed from the dependence of the log K_{SCD} vs. the number of carbons (n) of the alkyl chain for the **1** and **2** series of compounds (Table 1). The polar group in the *para* position drives the change of the binding constant faster from ≈200 to ≈1000.

As in the literature (12), it is reasonable to infer, in the absence of 2:1 (S_2 : CD) complex, that the CD binding site is presumably the wider (secondary hydroxyl) end. In complexes between bencene derivatives and CD the orientation of the substrates in the cavity commonly observed (but not universally) is with the nonpolar group deeply inserted in the cavity of CD and the polar group located near the secondary hydroxyl's rim or it may even protude from the cavity (12).

The substrates studied here have a polar substituent (the OH group), a hydrophobic aromatic rest, and an acyl ($CO(CH_2)_nCH_3$) substituent with increasing hydrophobicity with n. Evidently the polar characteristics of these substituents are important in establishing the structure of the complexes with CD.

By the above general considerations, it is likely that in the case of the substrates studied here, the polar OH tend to be outside the cavity and the aryl part of the molecule or the acyl group is inside the cavity being the dispersive and hydrophobic interactions, the primarily driving force for the association in solution (13).

The fact that the OH group of S (S = **1** or **2**) probably is located near the wider rim forming hydrogen bonds with CD oxygen or interacting with the surrounding water shell, was

[a]In D_2O at room temperature.

[b]H_o indicates the aromatic proton(s) in the *ortho* position of the -CO-$(CH_2)_n$$CH_3$ or -O-CO-$(CH_2)_n$$CH_3$ groups, being H_6 for **1** (2-hydroxyphenylketone), and H_2 and H_6 for **2** (4-hydroxyphenylketone) and for phenylalkanoates.

[c]H_p indicates the aromatic proton in the *para* position of the -O-CO-$(CH_2)_n$$CH_3$ or -CO-$(CH_2)_n$$CH_3$ group for phenylalkanoates and for **1** (2-hydroxyphenylketone), and H_3 and H_5 for **2** (4-hydroxyphenylketone).

also proposed for phenol and *p*-cresol from molecular mechanics, semiempirical methods, and circular dichroism (14).

The dependence of complex stability on the guest structure can provide information about the mode of inclusion. For instance, for a series of substrates containing the *trans*-cinnamoyl group (12), that have two potential binding sites, the phenyl and the side chain, binding constants around 1000 were interpreted as side chain inclusion.

The values for the binding constant determined in this work may indicate preferential aryl inclusion ($K_{ass} \approx 200$ M^{-1}) or alkyl inclusion ($K_{ass} \approx 1000$ M^{-1}). In the case of the complexes of other substituted phenols with β-CD (15), the relative hydrophobicity of the potential binding sites, determine which end of the guest molecules goes in. In the case of substrate **1** the fact that the OH is close to the hydrocarbon chain may be the reason why the predominance of complexes with the alkyl inside geometry takes place at a longer chain length than those for compounds **2**.

NMR determinations

The NMR (200 MHz) spectrum of compounds **1** and **2** were run in D_2O at the maximum possible concentration of the substrates which is 1.5 mM for **1** and **2** (n = 0) and 0.2 mM for all the other substrates. The CD concentration used was that required to have at least 70% of the substrate complexed, so the CD concentration was 2 mM for the substrates with K_{SCD} in the order of 1000, whereas for those with K_{SCD} in the order of 200, the CD concentration was 10 mM.

Table 2 shows some selected induced chemical shifts ($\Delta\delta$) which are those where the more significant changes were observed. Also included, for comparison, are the data for phenyl acetate, phenyl propionate, and phenyl valerate. The values obtained are in all cases small compared with data from the literature (16), so only limited information can be obtained from these data.

The reasons for the very small induced shifts observed in this study can be attributed to the low magnetic field of the available NMR instrument. An additional factor may be that the signals are the average of free and complexed substrates and the presence of mixed complexation modes (aryl and alkyl inclusion). Similar explanation was given to the small chemically induced shifts in the phenyl alkyl carboxylic acid series (n = 0 to 4) (11). For the later compounds it was demonstrated the formation of complexes with the phenyl group in and out the cavity.

The fact that for the compounds studied here the CIS are observed for the aryl as well as alkyl protons may indicate the presence in the solution of complexes with different geometries.

Experimental section

Reagents

The water was obtained from a Millipore apparatus. Compounds **1** and **2** were prepared or used as before (5,6). β-cyclodextrin (Roquete)was used as received.

Apparatus

The spectrophotometric determinations were carried out in a Shimadzu UV 260, controlling the temperature of the cell compartment at 25.0 ± 0.1°C with a Haake circulator. ^{1}H NMR spectra were recorded in a Bruker 200 FT instrument in D_2O solutions.

Medium-sized cyclophanes. part 51.[1] Acylation of [2.2]metaparacyclophanes: through-space electronic interactions between two benzene rings

Takehiko Yamato, Kiwamu Tokuhisa, and Hirohisa Tsuzuki

Abstract: The acylation of 8-methyl- (**1b**) and 8-methoxy[2.2]metaparacyclophane **1c** with 1.1 equiv. of acetyl chloride in CS_2 solution in the presence of aluminum chloride afforded 15-acetyl-8-methyl- (**2b**) and 12-acetyl-8-methoxy[2.2]metaparacyclophanes (**3c**) with 65 and 41% yields, respectively. The different orientations for the electrophilic substitution were observed to be dependant on the substituent at the 8 position. On the other hand, when the same reaction was carried out under the same reaction conditions with the corresponding 5-*tert*-butyl derivatives (**11**), *ipso*-acetylation at the *tert*-butyl group was observed along with acetylation on the *para*-benzene ring. The substituent effect on the 8-position was also observed in the present *ipso*-acetylation. The *ipso*-acylation at the *tert*-butyl group of 5-*tert*-butyl-8-methoxy[2.2]metaparacyclophane (**11c**) is attributed to the highly activated character of the aryl ring and the increased stabilization of a σ-complex intermediate arising from the dienone-type σ-complex intermediate possible in the case of a internal methoxy substituent. However, the present *ipso*-acetylation has not been observed in mild reaction conditions such as acetyl chloride in the presence of $TiCl_4$ catalyst due to deactivation of the second aromatic ring by the introduced acetyl group on the *para*-benzene ring. The mechanism of these novel reactions is also discussed.

Key words: cyclophanes, electrophilic aromatic substitution, regioselectivity, through-space electronic interaction, *ipso*-acylation.

Résumé : L'acylation des 8-méthyl- (**1b**) et 8-méthoxy[2.2]métaparacyclophanes (**1c**) avec 1,1 équivalents de chlorure d'acétyle, en solution dans le CS_2 et en présence de chlorure d'aluminium conduit aux 15-acétyl-8-méthyl- (**2b**) et 12-acétyl-8-méthoxy[2.2]métaparacyclophanes (**3c**) avec des rendements de 65 et 41% respectivement. La substitution électrophile se fait avec des orientations différentes suivant la nature du substituant en position 8. Par ailleurs, lorsqu'on a effectué la même réaction sur les dérivés 5-*tert*-butylés correspondants (**11**), on a observé une acétylation *ipso* au niveau du groupe *tert*-butyle en plus de l'acétylation sur le benzène en para. L'effet de substituant sur la position 8 a aussi été observée dans l'acétylation *ipso*. Cette acétylation *ipso* au niveau du groupe *tert*-butyle du 5-*tert*-butyl-8-méthoxy[2.2]métaparacyclophane (**11c**) est attribué au caractère fortement activé du noyau aromatique et à l'augmentation de la stabilisation d'un σ-complexe intermédiaire découlant d'un σ-complexe intermédiaire de type diénone qui peut se former dans le cas d'un substituant méthoxy en position interne. Toutefois, l'acétylation *ipso* n'a pas été observée dans les conditions douces, telles que celles impliquant le chlorure d'acétyle en présence d'un catalyseur comme le $TiCl_4$ en raison d'une désactivation du deuxième noyau aromatique par le groupe acétyle introduit sur le noyau benzénique para. On discute aussi du mécanisme de ces réactions nouvelles.

Mots clés : cyclophanes, substitution aromatique électrophile, régiosélectivité, interaction électronique à travers l'espace, acétylation *ipso*.

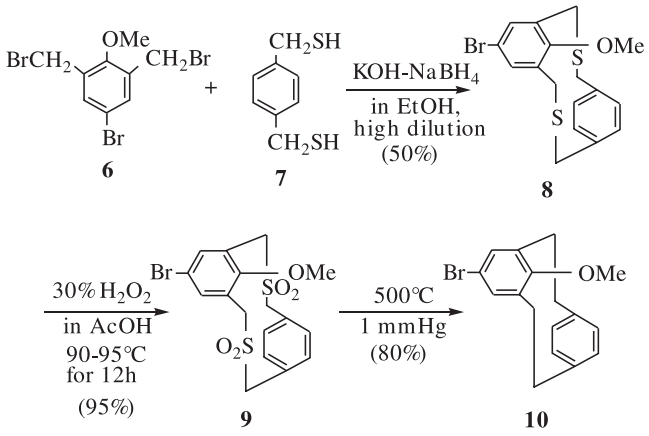
Introduction



[2.2]MPCP (MPCP = metaparacyclophane) **1a** was first prepared by Cram et al. (2) via acid-catalyzed rearrangement of [2.2]paracyclophane. Later, **1a** became available owing to synthetic methods developed by other research groups (3). A versatile procedure, appropriate for the synthesis of substituted derivatives, makes use of 2,11-dithia[3.3]MPCP as a precursor (3*a*). The *meta*-bridged benzene ring of [2.2]MPCP **1a** has been shown to undergo conformational flipping (4) with a substantial energy barrier (ca. 20 kcal mol^{-1}). According to X-ray crystallographic studies of **1a** (5), the deformations of benzene rings are similar to those of the corresponding

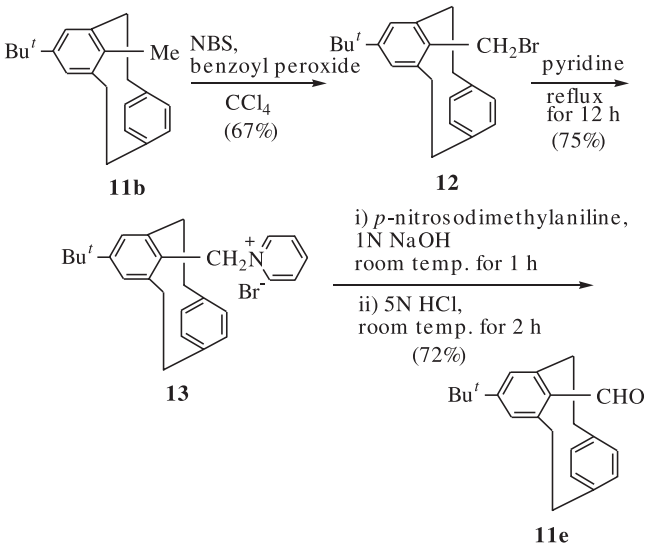
Scheme 1.

Scheme 2.



rings in *para*- and *meta*-[2.2]cyclophanes, with *para*- and *meta*-bridged rings bent in a boat- and a chair-like form, respectively. The angle between the two aromatic planes defined by the carbon atoms, 3, 4, 6, and 7, on one hand; and 12, 13, 15, and 16, on the other, is about 13°. It should be noted that the angle between the 11, 12, 16-plane and 10, 11-bond vector (or between 13, 14, 15-plane and 1, 14-bond vector) is even larger than the analogous angle in [2.2]paracyclophane. Introduction of substituents at the 8-position increases the strain in the molecule in comparison with unsubstituted [2.2]MPCP **1a**; the deformation of *para*-benzene ring of 8-methyl[2.2]MPCP was estimated to be 15° by our recent X-ray crystallography (6).

Cram and Hefelfinger reported (7) the acetylation of [2.2]MPCP **1a** with acetyl chloride in the presence of aluminum chloride to afford three kinds of monoacetylated derivatives **2a**, **3a**, and **4** along with the tetracyclic ketone **5**. However, since **2a** and **3a** equilibrate by ring rotation at room temperature, the orientation of acetylation to *para*-bridged benzene ring of **1a** has not yet been established.

Thus there is substantial interest in investigating the acetylation of 8-substituted [2.2]MPCPs, which might afford single mono-acetylated derivatives because the ring rotation of the meta-bridged benzene ring is impossible at room temperature. Also, in order to study the orientation of acetylation of *para*-bridged benzene ring in detail and the through-space electronic interactions between two benzene rings, we attempted to protect the 5-position of [2.2]-MPCPs by the bulky substituent, *tert*-butyl group. We report

Scheme 3.

here on the acylation of 5-*tert*-butyl 8-substituted [2.2]MPCPs.

Results and discussion

Synthesis of 8-substituted [2.2]MPCPs (1)

The preparation of 8-substituted [2.2]MPCPs (**1b** and **1c**) have already been described in an earlier paper (6) except 5-bromo-8-methoxy[2.2]MPCP (**10**). Preparation of **10** was carried out as shown in Scheme 2. The cyclization of 4-bromo-2,6-bis(bromomethyl)anisole (**6**) and 1,4-bis(mercaptomethyl)benzene (**7**) was carried out under highly diluted conditions in 10% ethanolic KOH in the presence of a small amount of $NaBH_4$, giving the desired 9-methoxy-2,11-dithia[3.3]MPCP (**8**) in 50% yield. Oxidation of **8** with 30% hydrogen peroxide in acetic acid, afforded the corresponding bissulfone **9** in 95% yield. Pyrolysis of **9** under reduced pressure (1 mm Hg (1 mm Hg = 133.322 Pa)) was carried out according to the reported method (8) to afford 8-methoxy[2.2]MPCP (**10**) in 80% yield.

Preparations of 5-*tert*-butyl-8-substituted [2.2]MPCPs (**11b**–**d**) were previously described (6). We have newly prepared 5-*tert*-butyl-8-substituted [2.2]MPCPs (**11e**–**g**) from 5-*tert*-butyl-8-methyl[2.2]MPCP (**11b**) as shown in Schemes 3 and 4.

Previously we reported (9) the conversion of 8-bromomethyl-16-methyl[2.2]metacyclophane to the corresponding 8-substituted 16-methyl derivatives in good yield. Thus, we have carried out the reaction of 5-*tert*-butyl-8-methyl[2.2]MPCP (**11b**) with *N*-bromosuccinimide in the presence of benzoyl peroxide in refluxing carbon tetrachloride; the desired 8-bromomethyl-5-*tert*-butyl[2.2]MPCP (**12**) was obtained in 67% yield. The reaction of 5-*tert*-butyl-8-(pyridiniomethyl)[2.2]MPCP bromide (**13**), which was easily prepared by the reaction of **12** with pyridine in 75% yield, with *p*-nitrosodimethylaniline was carried out at room temperature according to the Kröhnke's procedure (10) to give the corresponding nitrone in good yield. When the nitrone was treated with 5 N HCl solution at room temperature for

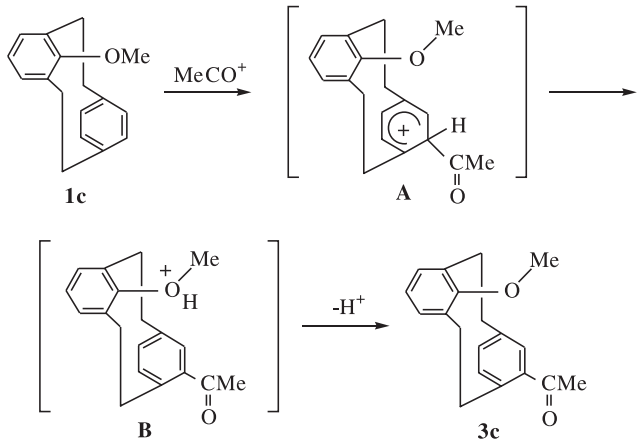
Scheme 5.

2 h, the desired 5-*tert*-butyl-8-formyl[2.2]MPCP (**11e**) was obtained in 72% yield.

5-*tert*-Butyl-8-cyano[2.2]MPCP (**11f**) was obtained by the reaction of aldehyde **11e** with hydroxylamine followed by treatment of oxime **14** with boiling acetic anhydride in good yield. Reaction of aldehyde **11e** with methylmagnesium iodide afforded the corresponding alcohol **15** in 60% yield, which was converted to 8-acetyl-5-*tert*-butyl[2.2]MPCP **11g** in 85% yield by oxidation with PCC at room temperature for 24 h.

Acetylation of 8-substituted [2.2]MPCPs (1)

Acetylation of 8-methyl[2.2]MPCP (**1b**) with 1.1 equiv. of acetyl chloride in methylene dichloride solution in the presence of aluminum chloride afforded 15-acetyl substitution product **2b** in 65% yield along with starting compound. No acetyl substitution at the 12-position was observed. Same result was obtained in the case of 3 equiv. of acetyl chloride under the same reaction conditions to also afford 15-acetyl substitution product **2b** in 87% yield. In contrast, 8-methoxy derivative **1c** afforded a mixture of 12-acetyl substitution product **3c** and 5-acetyl derivative **16c** in 41 and 23% yield, respectively (Table 1). It was also found that the same tendency was observed in the diacetyl substitution in **1c** with 3 equiv. of acetyl chloride to give 5,12-diacetyl derivative **17c** in 65% yield.



The structures of the products obtained in the present work were determined from their elemental analyses and spectral data. The ^1H NMR spectrum of **2b** in $CDCl_3$ shows a doublet (J = 2.0 Hz) at δ 6.44 for one aromatic C-16 proton, which is in a strongly shielding region of opposite meta-bridged benzene ring, and δ 7.11 and 7.16 for external aromatic C-13 and C-12 protons, respectively. On the other hand, the signals of two aromatic protons for C-15 and C-16 of **3c** were both observed at upper field of δ 5.96 and in turn the signals for external aromatic C-13 proton was deshielded at δ 7.62 by the neighbouring carbonyl group. These data strongly support the assignment of structure **2b** to 15-acetyl[2.2]MPCP and **3c** to 12-acetyl[2.2]MPCP.

Mechanism of acetylation

The different directive effects of 8-substituent to *para*-bridged benzene ring on the position of electrophilic substitution were first observed with these compounds. According to X-ray crystallographic studies of 8-methyl[2.2]MPCP (6), the 8-methyl group is located on the opposite *para*-bridged benzene ring which apparently sterically blocks electrophilic attack at 12,13-position. Therefore, internal attack of the electrophile on the *para*-bridged benzene ring of **1b** exclusively proceeds to give 15-acetyl derivative **2b**. On the other hand, with methoxy group at this position, acetylation occurs predominantly in the pseudo-geminal position in spite of the above steric hindrence. This pseudo-geminal directing effect of methoxy group might be attributed to the basicity and geometric availavility of the oxygen of the methoxy group. The oxygen is probably the strongest base in the medium. In the rate- and product-controlling step, the oxygen accepts a proton from the pseudo-geminal σ-complex (**A**) to form intermediate (**B**), and thus producing a pseudo-geminal substituted product **3c** as shown in Scheme 6. This result is consistent with Cram's reports (7, 11) that acetyl and nitro groups in the position of the [2.2]paracyclophane nucleous directed acetyl substitution to occur nearly exclusively in the 12-position to give the pseudo-geminal disubstituted hydrocarbon.

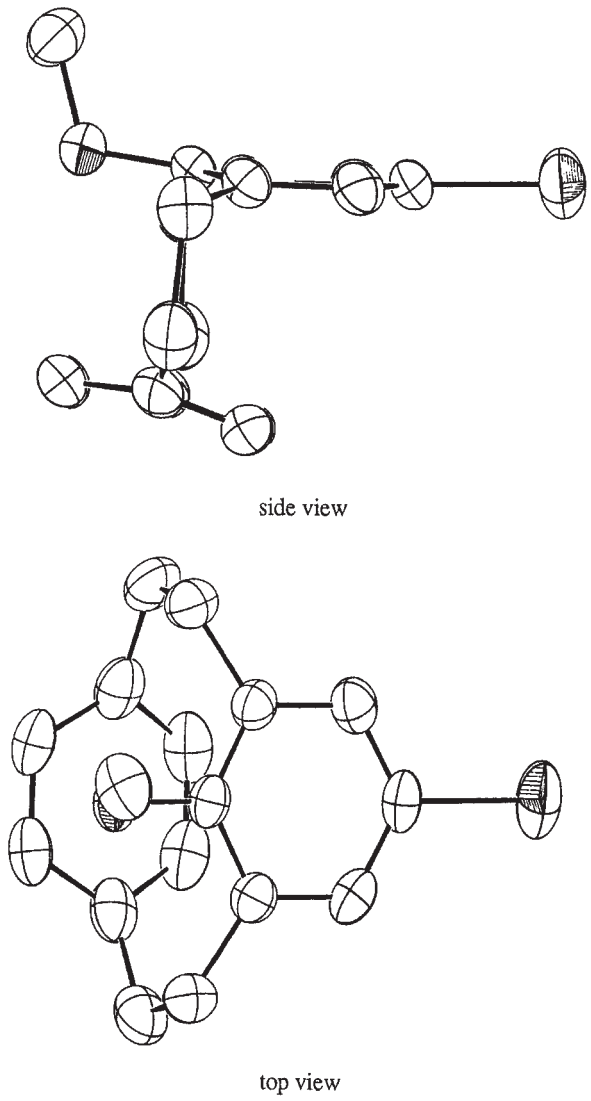
Scheme 6.



To confirm the present explanation of the regioselectivity on the acetylation of 8-substituted [2.2]MPCPs, we attempted to measure the X-ray analyses of [2.2]MPCPs. Fortunately, we have succeeded the single-crystal X-ray diffraction of 5-bromo-8-methoxy[2.2]MPCP (**10**).

Single colorless crystals of 5-bromo-8-methoxy[2.2]MPCP (**10**) suitable for X-ray crystallography were available by recrystallization from methanol. The perspective ORTEP drawing of **10** is illustrated in Fig. 1 with the atom numbering system. Compound **10** crystallized in the monoclinic space group $P2_1/a$. (No. 14). Two aromatic rings, which include the plane defined by the carbons, 3, 4, 6, and 7 and 11, 14, 15, and 16, tilt with a dihedral angle of about 12° and the strained form of the rings greatly differ with each other. The *meta*-benzene ring distorts like a boat shape and the carbons, 5 and 8, are out of the plane defined by the carbons, 3, 4, 6, and 7; the dihedral angle between the plane defined by the carbons, 3, 4, 6, and 7 and 3, 7, and 8 is about 11°. This value is much larger than the angle (about 5°) between the plane defined by the carbons, 3, 4, 6, and 7 and 4, 5, and 6. On the other hand, the *para*-benzene ring deforms like a roof shape and the dihedral angle between the plane defined by the carbons, 11, 12, 13, and 14, and 11, 14, 15, and 16, are about 16° which is closely similar to that in 8-methyl[2.2]MPCP (6). The oxygen, 1 is located just above the carbons, 12 and 13 and the intramolecular distance of the oxygen, 1 and the plane defined by the carbons, 11, 12, 13, and 14 is about 2.8 Å. Thus, according to X-ray crystallographic studies of **10**, the 8-methoxy group is located on the opposite *para*-bridged benzene ring which might assist in accepting a proton from the pseudo-geminal σ-complex (**A**) to form intermediate (**B**), thus electrophilic attack at the 12-position might preferentially occur.

Acylation of 5-*tert*-butyl-8-substituted [2.2]MPCPs (11)

In order to study this acetylation reaction more detail, we attempted to protect the 5-position of 8-substituted [2.2]MPCPs by the bulky substituent, *tert*-butyl group. The acetylation of 5-*tert*-butyl-8-methyl[2.2]MPCP (**11b**) with 1.2 equiv. of acetyl chloride in CS_2 solution in the presence of aluminum chloride afforded 15-acetyl-5-*tert*-butyl-8-methyl[2.2]MPCP (**18b**) in 86% yield along with trace amount of diacetylation product, 5,15-diacetyl-8-methyl[2.2]MPCP (**20**). Similarly,

Fig 1. Ortep drawing of 5-bromo-8-methoxy[2.2]meta-paracyclophane **10**. Thermal ellipsoids are drawn at the 50% probability level. All hydrogen atoms are omitted for clarify.

the reaction of 8-bromo derivative **11d** with acetyl chloride gave exclusively the corresponding 15-acetyl[2.2]MPCP (**18d**) in 61% yield. In contrast, when 5-*tert*-butyl-8-methoxy[2.2]MPCP (**11c**) was treated under the same reaction conditions, 12-acetyl-5-*tert*-butyl-8-methoxy[2.2]MPCP (**19c**) was obtained in 70% yield along with diacetylated prduct **17c** arising from the *ipso*-acetylation on the *tert*-butyl group at the 5-position (12,13).

The different orientation for the electrophilic substitution was observed depending on the substituent at 8 position. In contrast, the reaction of **11e**–**11g**, having electron-withdrawing groups such as formyl, cyano, and acetyl at the 8 position, did not afford any reaction product, and **11e**–**11g** were recovered in quantitative yield. It seems to assume that when R (in **11**) is electron donating, the σ-complex intermediate during the acetylation on the *para*-benzene ring could be stabilized by the through-space electronic interaction. In contrast, when R is electron-attracting groups such as CHO, CN, and Ac (e.g., in **11e**–**11g**), the σ-complex intermediate

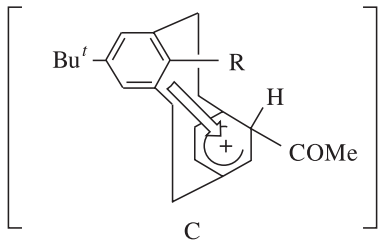
[e]Diacetyl compound **17c** was obtained in 15% yield.

Scheme 7.



does not form because of deactivation of the *para*-benzene ring by these groups due to the through-space electronic interaction (13).

The acetylation of 5-*tert*-butyl-8-methoxy[2.2]MPCP (**11c**) with large excess (8.0 equiv.) of acetyl chloride in methylene dichloride solution in the presence of $AlCl_3$-$MeNO_2$ afforded diacetylated product **17c** in 85% yield arising from the *ipso*-acetylation on the *tert*-butyl group as well as the acetylation at 12-position of *para*-benzene ring. From the navigation of the reaction, it is clear that the the latter reaction was much faster than the former *ipso*-acetylation on the *tert*-butyl group since no formation of 5-acetyl-8-methoxy[2.2]MPCP (**16c**) has been observed under the reaction conditions used. It was also found that the *ipso*-acylation was completed within 30 minutes.

The *ipso*-acylation at the *tert*-butyl groups of 5-*tert*-butyl-8-methoxy[2.2]MPCP (**11c**) is attributed to the highly activated character of the aryl ring and the increased stabilization of a σ-complex intermediate arising from the dienone-type

Fig. 2. Through-space electronic interaction.

σ-complex intermediate possible in the case of an internally methoxy substituent (13). However, the present *ipso*-acetylation has not been observed in the mild reaction conditions such as acetyl chloride in the presence of $TiCl_4$ catalyst because of deactivation of the second aromatic ring by the introduced acetyl group on the *para*-benzene ring.

Similarly, acylation of **11c** with propionyl chloride and benzoyl chloride in the presence of $AlCl_3$-$MeNO_2$ led to the *ipso*-acylation at the *tert*-butyl group to give 5,12-diacyl-8-methoxy[2.2]MPCPs (**17h–i**) in quantitative yield, but longer reaction times (4 h) are required in the case of benzoylation. In contrast, in spite of prolonged reaction times and increased amounts of catalyst, the diacetylated compound **17j** was not obtained in the case of succinic anhydride, only the mono acylation product **19j** being obtained in quantitative yield.

In the MPCP system an initial σ-complex intermediate during the acetylation on the *para*-benzene ring would be stabilized by a through-space electronic interaction with the opposing *meta*-benzene ring, thus accelerating the reaction. However, in turn when *tert*-butyl group at 5-position is *ipso*-acylated, the deactivation of the second aromatic ring by the acyl group increased (13, 14).

Owing to electronic interaction between the two benzene rings and the considerable strain energy, [2.2]MPCP is prone to give isomerization and transannular cyclization reaction products under electrophilic reaction conditions (15). In fact, by treatment with $AlCl_3$-$MeNO_2$ in benzene 5-*tert*-butyl-8-methoxy[2.2]MPCP (**11c**) was isomerized to the strainless 5-*tert*-butyl-8-methoxy[2.2]metacyclophane (**21**) and then converted into the tetrahydropyrene **22**. This novel isomerization reaction might attributed to the methoxy group at the 8-position, which increase the strain in the molecule in

Scheme 8.

Scheme 9.

comparison with the unsubstituted [2.2]MPCP **1a**. Therefore, the present acetylation in the system might compete with the transannular cyclization reaction to afford **22**.

However, under the present acylation conditions of 5-*tert*-butyl-8-methoxy[2.2]MPCP (**11c**), no formation of the isomerization and transannular cyclization reaction products has been observed. Only diacetylation product was obtained. This result strongly suggests that the acetylation at 12-position of *para*-benzene ring might occur much faster than the isomerization and transannular cyclization reaction to tetrahydropyrene. Thus acetylation product at *para*-benzene ring might deactivate the transannular cyclization reaction by the introduced acetyl group.

In conclusion, the different directive effects of 8-substituents on the *para*-bridged benzene ring on the position of electrophilic substitution were first observed with 8-substituted [2.2]MPCP derivatives. The presently developed procedure was further applied to the direct removal of a *tert*-butyl group by electrophilic substitution of 5-*tert*-butyl-8-methoxy[2.2]MPCP (**11c**) which are prone to give transannular reaction products under the electrophilic reaction conditions. The selective *ipso*-acylation of 5-*tert*-butyl-8-methoxy[2.2]MPCP (**11c**) can be attributed to the highly activated character of the aryl ring and the increased stabilization of the σ-complex intermediate arising from a dienone-type σ-complex intermediate possible in the case of a methoxy substituent. Further studies on the electrophilic substitution of 8-substituted [2.2]MPCPs **1** and **11** are now in progress.

Experimental

All melting points (Yanagimoto MP-S1) were uncorrected. Proton nuclear magnetic resonance (^{1}H NMR) spectra were recorded on a Nippon Denshi JEOL FT-270 spectrometer. Chemical shifts are reported as δ values (ppm) relative to internal Me_4Si. Mass spectra were obtained on a Nippon Denshi JMS-01SG-2 mass spectrometer at an ionization energy of 70 eV; *m*/*z* values reported include the parent ion peak. Infrared (IR) spectra were obtained on a Nippon Denshi JIR-AQ2OM spectrophotometer as KBr disks. Elemental analyses were performed by Yanaco MT-5. G.L.C. analyses were performed by Shimadzu gas chromatograph, GC-14A; Silicone OV-1, 2 m; programmed temperature rise, 12°C/min; carrier gas nitrogen, 25 mL/min.

Materials

2,6-Bis(bromomethyl)-4-bromoanisole (**6**) and 1,4-bis(mercaptomethyl)benzene (**7**) were prepared according the reported procedure (9). Preparations of 8-substituted [2.2]MPCPs (**1b**, **c**) and 5-*tert*-butyl-8-substituted [2.2]MPCPs (**11b**–**d**) were previously described (6).

© 2000 NRC Canada

*Preparation of 6-bromo-9-methoxydithia[3.3]metaparacyclophane (**8**)*: A solution of 2,6-bis(bromomethyl)-4-bromoanisole (**6**) (8.58 g, 23 mmol) and 1,4-bis(mercaptomethyl)benzene (**7**) (3.91 g, 23 mmol) in benzene (50 mL) and ethanol (50 mL) was added dropwise from a Hershberg funnel with stirring under nitrogen to a solution of potassium hydroxide (4.2 g, 28 mmol) and sodium borohydride (1.0 g, 26.4 mmol) in ethanol (4 L). When addition was complete (24 h), the reaction mixture was concentrated and the residue was extracted with CH_2Cl_2 (200 mL × 3). The combined extracts were washed with water, dried over Na_2SO_4 and concentrated. The residue was chromatographed over silica gel (Wako, C-300; 300 g) with benzene:hexane (1:1) as eluent to give a colorless solid. Recrystallization from hexane afforded 6-bromo-9-methoxy-2,11-dithia[3.3]metaparacyclophane (**8**) (4.4 g, 50%) as colorless prisms (hexane); mp 190–192°C; IR (KBr) ν_{max}: 2949, 2920, 1426, 1250, 1104, 1091 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 3.30 (2H, d, *J* = 15.6), 3.32 (3H, s), 3.65 (2H, d, *J* = 15.6), 3.72 (2H, d, *J* = 13.2), 3.85 (2H, d, *J* = 13.2), 6.58 (2H, d, *J* = 1.0), 6.97 (2H, d, *J* = 1.0), 7.29 (2H, s); MS *m*/*z*: M^+ 380, 382. Anal. calcd. for $C_{17}H_{17}BrOS_2$: C 53.54, H 4.49; found: C 53.26, H 4.32.

*Preparation of 6-bromo-9-methoxy-2,11-dithia[3.3]metaparacyclophane-2,2,11,11-tetraoxide (**9**)*: A mixture of **8** (3.5 g, 9.19 mmol), 30% hydrogen peroxide (7.5 mL), and glacial acetic acid (54 mL) was heated at 85–90°C for 12 h. The reaction mixture was poured into a cold solution of sodium hydroxide (10 g) in water (140 mL) and the resulting paste was allowed to cool to room temperature. The prepicitate was filtered off and washed with water and a small amount of ethanol to afford 9-methoxy-2,11-dithia[3.3]metaparacyclophane-2,2,11,11-tetraoxide (**9**) (3.9 g, 95%) as colorless prisms; mp 135–137°C; ^1H NMR ($CDCl_3$-DMSO-d_6): 3.34 (3H, s), 3.80 (2H, d, *J* = 15.1), 4.34 (2H, d, *J* = 13.7), 4.43 (2H, d, *J* = 15.1), 4.50 (2H, d, *J* = 13.7), 6.83 (2H, d, *J* = 1.0), 7.23 (2H, d, *J* = 1.0) and 7.79 (2H, s); MS *m*/*z*: M^+ 444, 446. Anal. calcd. for $C_{17}H_{17}BrO_5S_2$: C 45.85, H 3.85; found: C 45.65, H 3.90.

*Pyrolysis of disulfone **9** to give 5-bromo-8-methoxy[2.2]metaparacyclophane (**10**)*: Pyrolysis of disulfone **9** was carried out in an apparatus consisting of a horizontal tube (15 mm in diameter) passing through two adjacent tube furnace, each of which 20 cm long. The first furnace provided a temperature that would induce sublimation of the sulfone; the second was used at a higher temperature (500°C) that would assure pyrolysis. A vacuum pump was connected at the exit from the second furnace. Disulfone **9** (1 g, 2.25 mmol) was pyrolyzed at 500°C under reduced pressure (1 mm Hg) in the above apparatus as follows. The sample of disulfone was placed in the first furnace and small glass beads were packed into the second furnace. The product which sublimed was collected and chromatographed on silica gel with hexane to yield the desired [2.2]metaparacyclophane. Recrystallization from methanol afforded 5-bromo-8-methoxy[2.2]metaparacyclophane (**10**) (571 mg, 80%) as colorless prisms; mp 144–146°C; ^1H NMR ($CDCl_3$) δ: 2.33–2.51 (4H, m), 2.66–2.76 (2H, m), 3.13 (3H, s), 3.13–3.19 (2H, m), 5.98 (2H, d, *J* = 2.0), 6.88 (2H, s) and 7.07 (2H, d, *J* = 2.0); MS *m*/*z*: M^+ 316, 318. Anal. calcd. for $C_{17}H_{17}BrO$: C 64.37, H 5.4; found: C 64.45, H 5.51.

*Preparation of 8-bromomethyl-5-*tert*-butyl[2.2]metaparacyclophane (**12**)*: After a mixture of **11b** (3.03 g, 9.55 mmol), *N*-bromosuccinimide (2.32 g, 13.06 mmol), and benzoyl peroxide (100 mg) in carbon tetrachloride (150 mL) was refluxed for 7 h, the formed precipitates were filtered off. The filtrate was washed with 10% sodium hydroxide and water. The organic layer was dried over sodium sulfate and evaporated in vacuo to leave the colorless solid which was recrystallized from hexane to give **12** (2.30 g, 67%) as colorless prisms; mp 163–164°C; IR (KBr) ν_{max}: 2970, 2920, 2850, 1580, 1550, 1500, 1470, 1455, 1440, 1355, 1320, 1220, 1190, 1180, 1105, 995, 935, 875, 815, 800 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.32 (9H, s), 2.65–2.82 (6H, m), 3.16–3.20 (2H, m), 4.23 (2H, s), 5.77 (2H, d, *J* = 1.2), 6.81 (2H, s), 6.96 (2H, d, *J* = 1.2); MS *m*/*z*: M^+ 355, 357. Anal. calcd. for $C_{21}H_{25}Br$: C 70.59, H 7.05; found: C 70.69, H 7.11.

*Preparation of 5-*tert*-butyl-8-(pyridiniomethyl)[2.2]metaparacyclophane bromide (**13**)*: A mixture of 8-bromomethyl-5-*tert*-butyl[2.2]- metaparacyclophane (**12**) (250 mg, 0.70 mmol) and pyridine (10 mL) was boiled under reflux for 12 h. After the reaction mixture had cooled, hexane (10 mL) was added to give a solid which was washed with hexane to give the salt **13** (230 mg, 75%) as colorless prisms; mp 269–273°C; ^1H NMR ($CDCl_3$) δ: 1.33 (9H, s), 2.63–3.46 (8H, m), 5.80 (2H, s), 5.81 (2H, s), 6.95 (2H, s), 7.54 (2H, s), 7.85 (2H, dd, *J* = 6.0, 8.0), 8.24 (1H, dd, *J* = 8.0, 1.0), 8.94 (2H, dd, *J* = 6.0, 1.0); MS *m*/*z*: M^+ 435, 437. Anal. calcd. for $C_{26}H_{30}BrN$: C 71.55, H 6.93, N 3.21; found: C 71.30, H 6.88, N 3.22.

*Preparation of 5-*tert*-butyl-8-formyl[2.2]metaparacyclophane (**11e**)*: To a magnetically stirred solution of **13** (900 mg, 2.06 mmol) and *p*-nitrosodimethylaniline (342 mg, 2.28 mmol) in ethanol (25 mL) was added aqueous sodium hydroxide solution (900 mg in 2 mL water) at room temperature. After 5 min, the green solution turned to pale yellow solid precipitate. To the stirred reaction mixture was then added 10% aqueous HCl (20 mL) at room temperature. After a few min, the pale yellow suspension turned to reddish brown and a pale yellow solid precipitated. The reaction mixture was extracted with methylene dichloride; the extract was dried (Na_2SO_4) and evaporated under reduced pressure to leave a residue which was purified by column chromatography (silica gel) with hexane:benzene (1:1) as eluent to afford the colorless solid which was recrystallized from hexane to give aldehyde **11e** (430 mg, 72%) as colorless prisms; mp 102–104°C; IR (KBr) ν_{max}: 1650 (C = O) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.32 (9H, s), 2.53–3.58 (8H, m), 5.80 (2H, d, *J* = 1.2), 6.80 (2H, s), 7.03 (2H, d, *J* = 1.2), 9.75 (1H, s); MS *m*/*z*: M^+ 292. Anal. calcd. for $C_{21}H_{24}O$: C 86.26, H 8.27; found: C 86.31, H 8.38.

*Reaction of **11e** with hydroxylamine — preparation of **14***: A mixture of **11e** (200 mg, 0.685 mmol), hydroxylamine (111.2 mg, 1.60 mmol), sodium hydroxide (64 mg, 1.60 mmol) and ethanol (20 mL) was refluxed for 2 h. After the reaction mixture was cooled, the solvent was removed in vacuo to leave the residue, which was washed with water and recrystallized from ethanol to give **14** (200 mg, 95%) as colorless prisms; mp 178–180°C; IR (KBr) ν_{max}: 3240, 2952, 1593, 1478, 1380, 1221, 956, 944, 888 cm^{-1}; ^1H NMR

($CDCl_3$) δ: 1.34 (9H, s), 2.57–2.70 (4H, m), 3.00–3.20 (4H, m), 5.80 (2H, d, *J* = 2.0), 6.83 (2H, s), 7.04 (2H, d, *J* = 2.0) and 8.03 (1H, s); MS *m/z*: M^+ 307. Anal. calcd. for $C_{21}H_{25}NO$: C 82.04, H 8.2, N 4.56; found: C 81.90, H 8.10, N 4.43.

*Preparation of 5-*tert*-butyl-8-cyano[2.2]metaparacyclophane (**11f**)*: A suspension of **14** (100 mg, 0.325 mmol) in acetic anhydride (10 mL) was refluxed for 3h. On cooling, the reaction mixture was poured into a large amount of water (100 mL), stirred for over night and extracted with methylene dichloride. The extract was washed with water (50 mL × 2), dried with Na_2SO_4, and evaporated in vacuo to leave a residue, which was recrystallized from hexane to give **11f** (75.1 mg, 80%) as colorless prisms; mp 119–121°C; IR (KBr) ν_{max}: 2208 (CN) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.32 (9H, s), 2.55–2.65 (2H, m), 2.76–2.95 (4H, m), 3.26–3.35 (2H, m), 5.71 (2H, d, *J* = 2.0), 6.92 (2H, s), 7.33 (2H, d, *J* = 2.0); MS *m/z*: M^+ 289. Anal. calcd. for $C_{21}H_{23}N$: C 87.15, H 8.01, N 4.84; found: C 86.9, H 8.05, N 5.03.

*Reaction of **11e** with methylmagnesium iodide*: To a solution of MeMgI (prepared from methyl iodide (1.70 g, 12 mmol) and magnesium (243 mg, 10 mmol)) in ether (16 mL) was added a solution of **11e** (584 mg, 2 mmol) in ether (10 mL) dropwise under the conditions of gentle refluxing. After the reaction mixture was refluxed for an additional 3 h, it was quenched with 10% ammonium chloride and extracted with methylene dichloride (2 × 50 mL). The methylene dichloride extract was dried over Na_2SO_4 and evaporated in vacuo to leave the residue, which was which was chromatographed on silica gel with hexane:benzene (1:1) to afford a colourless solid. Recrystallization from hexane gave **15** (370 mg, 60%) as colorless prisms; mp 109°C; IR (KBr) ν_{max}: 3550, 2960, 2950, 2860, 1210, 1120, 1065, 790, 725 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 0.93 (3H, d, *J* = 6.4), 1.31 (9H, s), 2.57–2.73 (5H, m), 3.10–3.18 (2H, m), 3.57–3.64 (1H, m), 4.69 (1H, d, *J* = 6.4), 5.80 (2H, s), 6.72 (2H, s), 7.05 (2H, s); MS *m/z*: M^+ 308. Anal. calcd. for $C_{22}H_{28}O$: C 85.66, H 9.15; found: C 85.46, H 9.35.

*Preparation of 8-acetyl-5-*tert*-butyl[2.2]metaparacyclophane (**11g**)*: To a suspension of $C_5H_5NH^+CrO_3Cl^-$ (2.30 g, 10.67 mmol) and CH_2Cl_2 (20 mL) was added a solution of **15** (1.0 g, 3.24 mmol) in CH_2Cl_2 (5 mL) at 0°C. The reaction mixture had been stirred at room temperature for 24 h. The reaction mixture was filtered and the filtrate was extracted with CH_2Cl_2 (30 mL × 3). The extract was dried over Na_2SO_4 and concentrated. The residue was subjected to silica-gel (Wako, C–300; 100 g) column chromatography using as eluent benzene to give the title compound **11g** (843 mg, 85%) as colorless prisms (hexane); mp 148–150°C; IR (KBr) ν_{max}: 1683 (C=O) cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.34 (9H, s), 1.97 (3H, s), 2.54–2.76 (6H, m), 3.20–3.29 (2H, m), 5.71 (2H, d, *J* = 1.2), 6.86 (2H, s) and 7.07 (2H, d, *J* = 1.2); MS *m/z*: M^+ 306. Anal. calcd. for $C_{22}H_{26}O$: C 86.23, H 8.55; found: C 86.36, H 8.45.

*Acetylation of **1** with acetyl chloride in the presence of aluminum chloride — typical procedure*: To a solution of **1c** (238 mg, 1 mmol) in CS_2 (12 mL) was added a solution of aluminum chloride (300 mg, 2.3 mmol) and acetyl chloride (94.2 mg, 1.2 mmol) in CS_2 (6 mL) at –15°C. After the reaction mixture was stirred at –15°C for 15 min, it was poured into a large amount of water. The organic layer was extracted with methylene dichloride. The extract was washed with 10% hydrochloric acid and water, dried with Na_2SO_4, and evaporated in vacuo to leave a residue, which was chromatographed on silica gel with benzene to give **3c** (114 mg, 41%) and **16c** (63 mg, 23%) as a colourless solid, respectively.

*12-Acetyl-8-methoxy[2.2]metaparacyclophane (**3c**)*: Colorless prisms (hexane); mp 162–163°C; IR (KBr) ν_{max}: 2965, 2932, 2820, 1671, 1461, 1436, 1428, 1352, 1286, 1255, 1235, 1206, 1171, 1018, 774 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 2.66 (3H, s), 2.43–4.17 (8H, m), 3.13 (3H, s), 5.96 (2H, d, *J* = 2.4), 6.79 (3H, m), 7.62 (1H, s); MS *m/z*: M^+ 280. Anal. calcd. for $C_{19}H_{20}O_2$: C 81.40, H 7.19; found: C 81.73, H 7.17.

*5-Acetyl-8-methoxy[2.2]metaparacyclophane (**16c**)*: Colorless prisms (hexane); mp 140°C; IR (KBr) ν_{max}: 2923, 1666, 1588, 1412, 1358, 1286, 1200, 1184, 1155, 1013, 805, 727 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 2.56 (3H, s), 2.49–3.19 (8H, m), 3.18 (3H, s), 5.81 (2H, d, *J* = 1.0), 7.09 (2H, d, *J* = 1.0), 7.39 (2H, s); MS *m/z*: M^+ 280. Anal. calcd. for $C_{19}H_{20}O_2$: C 81.40, H 7.19; found: C 81.57, H 7.16.

Reaction of **1b** with acetyl chloride in CS_2 was carried out using the same procedure as described above and details of the products and yields are compiled in Table 1.

*15-Acetyl-8-methyl[2.2]metaparacyclophane (**2b**)*: Colorless prisms (hexane); mp 133–135°C; IR (KBr) ν_{max}: 3045, 3000, 2970, 2922, 2853, 1669, 1555, 1478, 1456, 1444, 1436, 1350, 1257, 1197, 1170, 953, 776, 737, 722, 609 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.76 (3H, s), 2.25 (3H, s), 2.64–4.00 (8H, m), 6.44 (1H, d, *J* = 2.0), 6.58 (1H, dd, *J* = 7.0, 2.0), 6.74 (1H, dd, *J* = 7.0, 2.0), 6.81 (1H, t, *J* = 7.0), 7.11 (1H, d, *J* = 7.3), 7.16 (1H, dd, *J* = 7.3, 2.0); MS *m/z*: M^+ 264. Anal. calcd. for $C_{19}H_{20}O$: C 86.32, H 7.63; found: C 85.90, H 7.61.

*5,12-Diacetyl-8-methoxy[2.2]metaparacyclophane (**17c**)*: Colorless prisms (ethanol); mp 142–143°C; IR (KBr) ν_{max}: 2926, 1669, 1355, 1289, 1257, 1197, 1160, 1015 cm^{-1}; ^1H NMR ($CDCl_3$) δ 2.57 (3H, s), 2.65 (3H, s), 2.37–3.28 (7H, m), 3.18 (3H, s), 4.16–4.27 (1H, m), 5.94 (2H, d, *J* = 2.0), 7.40 (1H, d, *J* = 2.4), 7.43 (1H, d, *J* = 2.4), 7.63 (1H, s); MS *m/z*: M^+ 322. Anal. calcd. for $C_{21}H_{22}O_3$: C 78.2, H 6.87; found: C 78.45, H 7.12.

*Acetylation of **11** with acetyl chloride in the presence of aluminum chloride — typical procedure*: To a solution of **11b** (278 mg, 1 mmol) in CS_2 (12 mL) was added a solution of aluminum chloride (300 mg, 2.3 mmol) and acetyl chloride (94.2 mg, 1.2 mmol) in CS_2 (6 mL) at –15°C. After the reaction mixture was stirred at –15°C for 15 min, the reaction mixture was treated as described above to give **18b** (275 mg, 86%) and trace amount of diacetylated product **20**.

*15-Acetyl-5-*tert*-butyl-8-methyl[2.2]metaparacyclophane (**18b**)*: Colorless prisms (hexane); mp 96–97°C; IR (KBr) ν_{max}: 2963, 2952, 2923, 1672, 1479, 1360, 1255, 1198, 880, 732, 620, 611 cm^{-1}; ^1H NMR ($CDCl_3$) δ: 1.17 (9H, s), 1.65

*Crystallographic data for 5-bromo-8-methoxy[2.2]metaparacyclophane (**10**)*:

Crystal data

$C_{17}H_{17}BrO$, M = 317.23, Monoclinic, a = 13.883 (1), b = 12.7430 (11), c = 8.2263 (9) Å, β = 104.9466° (70), V = 1406.1 (2) $Å^3$ (by least-squares refinement on diffractometer angles for 25 automatically centered reflections), space group $P2_1/a$ (No. 14), Z = 4, D_x = 1.498 g/cm^3, colorless, prism, crystal size 0.40 × 0.30 × 0.25 mm, μ(Cu-K_α) = 39.0 cm^{-1}; total no. of unique reflections: 2204; R = 0.043, R_w = 0.070

Data correction and procedure

Enraf-Nonius CAD4 FR586 diffractometer, ω/2θ mode with ω scan width = 0.8 + 0.140 tan θ, scan speed 1.0 to 7.0 deg min^{-1}, graphite-monochromated Cu-K_α radiation; 2684 reflections were measured (4.8° = θ = 64.9°, $-h$, k, l). 2204 unique (merging R = 0.043 no absorption correction), Linear and approx. isotopic crystal decay, ca. –1.8% corrected during procedure.

Structure analysis and refinement

The structure was solved by direct method (MULTAN 11/80)[3]. Full-matrix least-squares refinement on F with all non-hydrogen atoms anisotropic and hydrogens isotropic fixed at Beq 4.0 $Å^2$. The weighting scheme is $\omega = 4F_0^2/[(\sigma I_0)^2 + 0.0016F_0^4]$. Final R and R_w values are 0.043, 0.070 (refined on F). All calculations were performed on a MicroVAX3100 using MolEN[4].

The refined non-hydrogen atomic coordinates are listed in Table 4 whilst the hydrogen coordinates, temperature factors (anisotropic for carbon atoms), scale factor, and secondary estimation coefficient are available, on request, from the Cambridge Crystallographic Data Centre.[5]

Two novel Diels–Alder adducts from *Hippocratea celastroides* roots and their insecticidal activity

M. Jiménez-Estrada, R. Reyes-Chilpa, S. Hernández-Ortega, E. Cristobal-Telésforo, L. Torres-Colín, C.K. Jankowski, A. Aumelas, and M.R. Van Calsteren

Abstract: Two novel compounds, celastroidine A (**1**) and B (**2**), were isolated from the roots of *Hippocratea celastroides* K. Their structures were elucidated by spectroscopical and X-ray diffraction studies. Celastroidine A (**1**) ($C_{50}H_{74}O_5$) was identified as a Diels–Alder adduct of a triterpene plus a diterpene and celastroidine B (**2**) as a beyerane, a type of dimer of two diterpene ($C_{40}H_{60}O_4$). Both compounds could be formed in vivo by a Diels–Alder reaction. Celastroidine A showed some antifeeding activity against the stored grain insect *Sitophyllus zeamays*.

Key words: *Hippocratea celastroides*, Hippocrataceae, roots, Diels–Alder adducts, diterpenoids, triterpenoids, x-ray diffraction, insect antifeedants, stored grain insects, *Sitophyllus zeamays*, insecticidal plants, Diels–Alderase.

Résumé : Deux nouveaux terpènes, célastroïdines A (**1**) et B (**2**) ont été isolés à partir des racines d'*Hippocratea celastroides* K. Leurs structures ont été étudiées par des méthodes spectroscopiques (en particulier par RMN et rayons X). La célastroïdine A (**1**), un pentaterpène, a été identifié comme l'adduit du type de Diels–Alder entre des résidus di- et triterpéniques et la célastroïdine B (**2**) comme un dimère beyerane à C_{40} résultant de l'addition de deux unités diterpéniques réagissant en tant que diène et dièneophile. Les deux substances peuvent être formées in vivo suite à cette addition. La célastroïdine A (**1**) montre une activité bloquant le réflexe d'alimentation chez les insectes de stockage de grains *Sitophyllus zeamays*.

Mots clés : *Hippocratea celastroides*, hippocratacées, racines, adduits de Diels–Alder, diterpénoïdes, triterpénoïdes, diffraction des rayons X, antiappétants pour les insectes, insectes de stockage de grains, *Sitophyllus zeamays*, plantes insecticides, Diels–Aldérase.

Introduction

Hippocratea celastroides Kunth (also known as *H. acapulcensis*) is a shrubby vine which grows in the tropical deciduous forest in Mexico. The seeds and fruits are used in folk-medicine against head lice and skin mite parasites (1, 2). In a previous work, we reported that the organic extracts from the roots, especially acetone and methylene chloride extracts, have antifeeding activity against the stored grain insect *Sitophyllus zeamays*.[2] Chemical studies have shown that *H. celastroides* leaves contain the triterpenes: friedelin, friedelan-3β-ol (epifriedelinol), 3-oxo-lup-20-en-30-ol, and lup-20-en-3β,30-diol (3), meanwhile the roots contain the alditol galactitol.[2] Continuing our studies on *H. celastroides* roots, we wish now to report the isolation and structure elucidation of two novel compounds celastroidine A (**1**) and B (**2**) (Fig. 1), as well as the evaluation of their toxicity and antifeedant activity against *S. zeamays*.[3]

Toxicity and antifeeding properties of celastroidine A and B were examined against the stored grain pest *S. zeamays*. Celastroidine A (**1**) inhibited the feeding of the insect in 88.7%, but only increased mortality in 2%. On the other hand, celastroidine B (**2**) showed both low antifeeding activity (9.6%) and mortality (5.2%) rates. We have previously

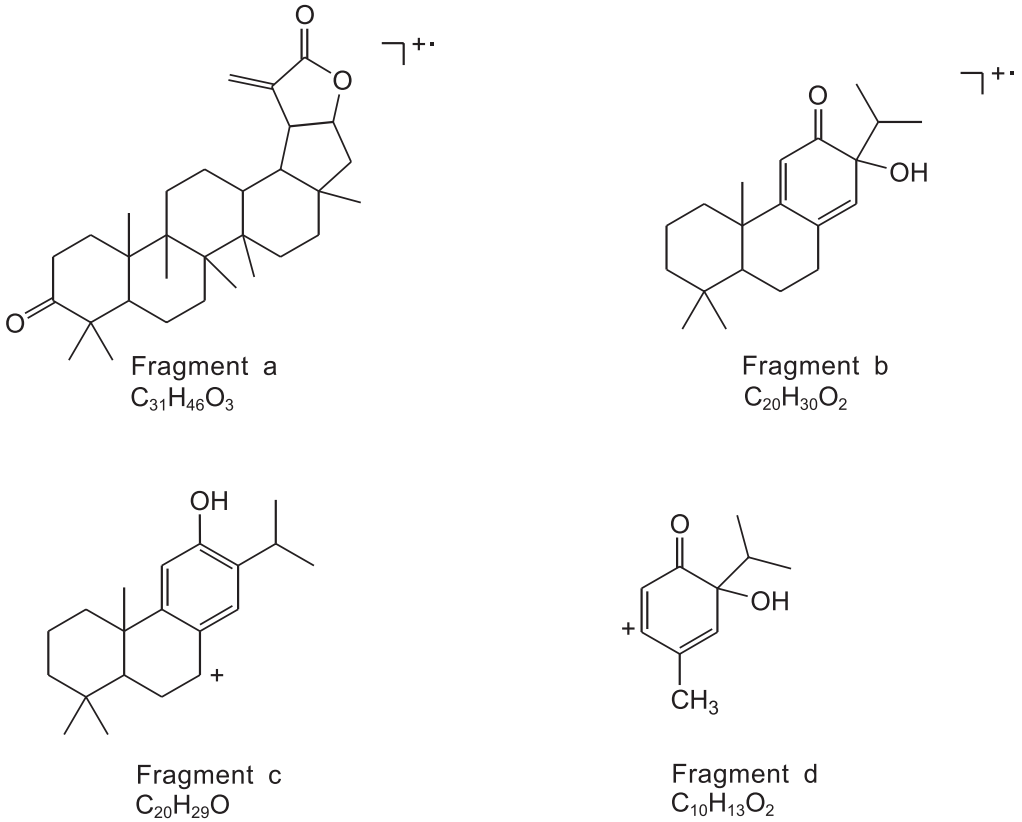
reported that the total methylene chloride extract from *H. celastroides* roots has good antifeeding activity (70.3%) and low mortality (9.4%) when tested with *S. zeamays*.[2] The celastroidine A activity is quite similar and since is the most abundant component of this extract (~10.7%), and it seems to be its active principle.

Results and discussion



The methylene chloride root extract afforded celastroidine A (**1**) and B (**2**) in good yield. The petroleum ether extract produced celastroidine B and β-sitosterol. Celastroidine A was isolated as a white powder. According to spectral and X-ray diffraction evidence, the celastroidine A molecular structure corresponds to a Diels–Alder adduct of a triterpene on a diterpene (**1**). The IR spectrum showed absorption bands (cm^{-1}) for hydroxyl (3565) together with a lactone carbonyl (1759) and two ketones on the six member rings (1709 broad). The FAB mass spectrum confirmed the molecular mass at 754 corresponding to the formula $C_{50}H_{74}O_5$. Fragments of *m/z* 737 and 452 were attributed to the loss of water (MH^+–18), and to a lupen triterpene $C_{30}H_{42}O_3$ moiety (fragment **a**) as indicated in Fig. 2 from the protonated molecular ion. This last fragment also appeared in the EIMS and CIMS (as the quasimolecular ion). The difference among M^+ and fragment **a** accounts for *m/z* 302, equivalent to the molecular weight of a $C_{20}H_{32}O_2$ diterpene of the abietane type (fragment **b**). In addition, FABMS showed a peak at *m/z* 285 corresponding to fragment **c** originated from fragment **b** by loss of OH followed by ring aromatization. Fragment **d** (at *m/z* 165) could also be related to **b** (Fig. 2).

Structures **1** and **2** were supported by the ^{1}HNMR and ^{13}CNMR data. The assignment of their 1H and 13 C spectra was carried out from the analysis of a COSY, TOCSY, HSQC, and HMBC experiments (Table 1). The ^{13}C NMR (DEPT) spectrum of the compound **1** indicated 45 sp^3 carbon atoms, 11 methyls, 15 methylenes, 10 methines, nine quaternary C, and five sp^2 carbons (3 C=O, and 2 C=C).

Celastroidine A (**1**) has 11 methyl signals, five of them are part of the diterpene moeity, and six to the triterpene moiety. This part of the skeleton is related to lupene triterpenoids previously isolated from the same species (3). Further evidence came from comparison of ^{13}C NMR data of three compounds to those previously reported (3) (e.g., for 3-oxo-

Fig. 2. Fragmentation pattern of celastroidine A (FAB)

lup-20-en-30-ol (**3**) (Table 1, Fig. 1)). From this comparison, the signal at 217.9 ppm was readily assigned to the C-3 ketone. Therefore the signal at 213.4 ppm was assigned to the C-12′ ketone. This carbon showed couplings with H-11′ (2.92 ppm) and H-14′ (2.74 ppm).

Finally, the signal at 177.7 ppm was assigned to the C-30 carbonyl of a γ-lactone ring. This ring was indirectly confirmed by the presence of a tertiary carbon in position 21 whose ^{13}C (81.1 ppm) and ^{1}H (5.02 ppm) chemical shifts are typical of an ether or ester substitution. As expected, the COSY experiment showed interactions of H-21 proton with another tertiary proton (H-19 2.49 ppm) and with H-22 methylene protons (2.15 and 1.29 ppm). On the diterpene moiety the molecule bears one double bond and an isopropyl group. The C-8′—C-9′ double bond is unambiguously characterized by carbon signals at 136.1 and 134.9 ppm, respectively.

The isopropyl group was clearly identified with ^{1}H spectrum by the presence of two doublets for methyl groups at 0.84 (CH_3-16′) and 0.97 (CH_3-17′) ppm coupled to the H-15′ proton (1.78 ppm).

The bridge between diterpene and triterpene moieties was evidenced by HMBC and COSY experiments. For instance, H-14′ (2.74 ppm) on the diterpene side showed a long distance coupling with C-29 (23 ppm) on the triterpene side. The C-12′ signal showed couplings with H-11′ (2.92 ppm) and H-14′ (2.74 ppm).

Celastroidine A (**1**) did not hydrolyze under mild acidic conditions (HCl (aq)) and was recovered unaltered, excluding the possibility of an ether bridge presence. Acetylation under mild conditions with acetic anhydride in pyridine did not work, but the compound could be reduced with $NaBH_4$ in THF. The product **1a**, was a white solid. The IR spectrum did not show any carbonyl absorption, nevertheless hydroxyl bands were evident. The $^{1}HNMR$ spectrum showed a multiplet centered at 4.19 ppm which was assigned to the H-3 proton. This signal was duplicated and suggested a stereoisomer mixture. Two doublets, at 1.17 and 1.38 ppm, were assigned to C-16′ and C-17′. Other methyl signals appear among 1.2–1.4 ppm (7 singlets). The FAB mass spectrum showed the molecular ion at *m*/*z* 760 (3), and others similar to ***1*** fragments e.g., loss of water. Structure **1** was definitely confirmed by X-ray diffraction (Fig. 3).

Celastroidine B (**2**) was also isolated as a white powder. The IR spectrum showed two carbonyl absorptions at 1608 and 1712 cm^{-1} of a conjugated and deconjugated cyclohexenone respectively. Its molecular structure was deduced as **2** and corresponds to a $C_{40}H_{60}O_4$ diterpene dimer formed by a Diels–Alder reaction (Fig. 1). The PI mass spectrum obtained by FAB and EIMS showed the 100% ion at *m*/*z* 302 and the molecular mass at 604, therefore suggesting that compound ***2*** could be formed by attachment of two identical $C_{20}H_{30}O_2$ fragments. This retro-Diels–Alder fragment structure should be considered as a hypothetical diene (or dienophile) leading to formation of either **1** or **2**. This fragment is more intense (100%) for dimer **2** than for celestroidine A (**1**) (54%) for which it plays a role of diene only. A fragment of *m*/*z* 165 was also noticed and corresponds to structure **d** (Fig. 2).

$^{1}HNMR$ and $^{13}CNMR$ spectra (Table 2) suggested that the diterpene monomer has an abietane type skeleton, as already indicated for celastroidine A (**1**). All assignments were

supported by homo- and heteronuclear NMR experiments. Two methine doublets at 3.11 ppm (*J* = 2.5 Hz) and 2.56 ppm (*J* = 2.5 Hz) integrating for one proton were assigned to H-14 and H-14′, respectively. Carbons C-14 and C-14′ bearing these protons, appeared at 45.4 and 43.3 ppm (Table 2). A singlet at 6.15 ppm was assigned to the vinylic proton H-11′ of the α,β-unsaturated ketone system. Carbons C-11′ and C-9′ supporting this double bond position were assigned at 120.0 (C-11′) and 172.6 ppm (C-9′). The second diterpene unit should bear a nonprotonated double bond as indicated by signals at 138.6 and 138.5, that corresponded to C-8 and C-9. A broad singlet at 3.46 ppm was assigned to H-11, while the carbon bearing this proton appeared at 57.8 ppm (CH). Two quaternary carbons appeared at 78.7 (C) and 76.1 (C) and correspond to C-13′ and C-13, respectively. Both carbons are substituted with a hydroxyl group. Ketone carbonyls on C-12′ and C-12 appeared at 200.6 and 213.4 ppm. A doublet at ~0.53 ppm was assigned to H-17′. Signals for nine additional methyls were also assigned as in the Table 1. The structure of *2* was confirmed by the X-ray diffraction studies (Fig. 4).

The preliminary molecular mechanics modeling of the stereochemistry of the central part of the celastroidine B (**2**) indicates a photochemical pathway for the retro Diels–Alder reaction leading to the monomeric dienone of fragment b-like structure. The mechanism of the formation and its stereoselectivity should be fully analyzed (endo/exo and specific diastereofacial stereochemistry of adducts).

Celastroidine A and B are Diels–Alder adducts. Several natural products, presumably arising from a Diels–Alder reaction, according to metabolic or enzymatic pathways, have previously been isolated from microorganisms, plants, and marine animals. These compounds included polyketides, terpenoids, and alkaloids (4). Involvement of the Diels–Alder reaction in biosynthesis has been suggested, but a definitive proof has been lacking due to unsuccessful attempts to obtain the corresponding enzymes or starting diene (5). Nevertheless, the isolation of a crude enzyme from the phytopathogenic fungus *Alternaria solanii* has recently been reported enable to catalyze the [4 + 2] cycloadditions (e.g., necessary to synthesize two solanopyrones phytotoxins) (4). Isolation of celastroidine A and B, therefore suggests that

Fig. 3. X-ray of celastroidine A (**1**).

H. celastroides roots could also bear enzymes able to catalyze Diels–Alder reactions.

Experimental

Hippocratea celastroides Kunth was collected near Tucumán (State of Morelos, Mexico). A voucher is deposited at MEXU Herbarium. The roots (1.610 kg) were ground and extracted at room temperature with petroleum ether, and CH_2Cl_2. The extracts were concentrated under reduced pressure. The CH_2Cl_2 extract (14.1 g) was dissolved with acetone obtaining a white precipitate (1.4 g). The precipitate was subjected to column chromatography on silica gel eluting with petroleum ether (pet et), CH_2Cl_2, and mixtures of these solvents. Two products were obtained. Fractions 24–72 eluted with a (7:3) mixture afforded a white powder (610 mg). This product was recrystallized from CH_2Cl_2–MeOH obtaining a crystalline solid (mp 198–9°C).. which was named as celastroidine A (**1**). The acetone soluble portion of the CH_2Cl_2 extract (12.7g) was subjected to CC (Silica Gel 60) eluting with pet et–CH_2Cl_2. Fractions 56–65 eluted with a mixture (8:2) yielded 224 mg of a white powder (mp 189–190°C) named as celastroidine B (**2**). Fractions 66–89 eluted with a mixture (8:2) afforded celastroidine A (902 mg) again. The pet et extract (6.18 g) under column chromatography (Silica Gel 60) and elution with mixtures of petroleum ether–ethyl acetate, also afforded celastroidine B, especially from fractions 30–42 eluted with a 9:1 mixture.

Insecticidal tests

Toxicity and antifeeding activity of isolated compounds against *Sitophyllus zeamays* was evaluated as described.[2]

Experimental NMR

Materials and methods

The samples were dissolved in $CDCl_3$ and all NMR experiments were recorded at 27° on Bruker spectrometers, operating at 300, 500, and 600 MHz for ^1H nucleus and up to 150 MHz for ^{13}C nucleus. Chemical shifts are quoted relative to the $CDCl_3$ resonance fixed at 7.24 ppm for the proton and 77.0 ppm for the carbon. The multiplicity of carbon signals was established by using the DEPT experiment.

DQF–COSY spectra (6) were collected into a 800 × 1024 data matrix with 32 scans per tl value and TOCSY (7) spectra were collected with a mixing time of 80 ms into a 512 × 1024 data matrix with 16 scans per tl value.

HSQC (8, 9) experiments were recorded with a delay of 3.5 ms ($^1J_{CH}$ = 143 Hz) and HSQC–TOCSY (10, 11) experiments with a mixing time for proton–proton transfer of 80 ms (400 × 1024) with 32 scans per tl value to identify the one-bond carbon–proton and the network of proton–proton conectivities, respectively. The HMBC experiment (400 × 10 240) was recorded with a delay of 50 ms with 64 scans per tl value to identify long range proton–carbon connectivities. All data were processed with the UXNMR software. DQF–COSY and TOCSY data, one zero filling and a π/4 phase-shifted sine bell window function were applied in both dimensions before Fourier transform. For HSQC, HSQC–TOCSY, and HMBC data, a zero filling and a π/2 phase-shifted sine bell window function were applied in F2 dimension and a linear prediction was applied to 1024 points in F1 dimension prior to processing. The assignment of ^{1}H and ^{13}C resonances of celastroidine A and B spectra was carried out from analysis of DQF–COSY, TOCSY, DEPT, HSQC, HSQC–TOCSY, and HMBC data. All 2D NMR data and additional spectral material are available on request from CKJ (Moncton, Canada).

Celastroidine A (1): $C_{50}H_{74}O_5$, white powder, mp 198–199°C, [α] = +7.5° ($CHCl_3$). IR (cm^{-1}), ν max, ($CHCl_3$): 3565, 2960, 2873, 1759, 1709, 1462, 1386, 1367, 1311, 1178, and 1145. Synthesis and structural characterization of zirconium complexes containing aminodiolate ligands and their use as Lewis acid catalysts

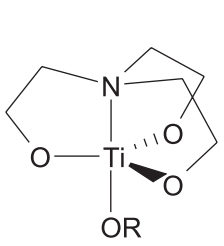
Pengcheng Shao, Roland A.L. Gendron, and David J. Berg

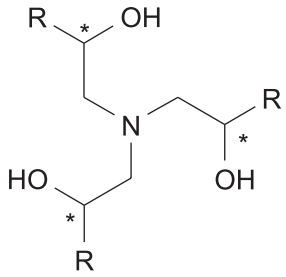
Abstract: A series of aminodiols $RN(CH_2CH_2C(OH)R'_2)_2$ (R, R′ = Me, Me **4**; Me, Ph **5**; *tert*-butyl, Me **6**; *tert*-Bu, Ph **7**; (*S*)-PhCH(Me), Me **8**) were prepared by the Michael addition of a primary amine to methyl acrylate followed by reaction of the resulting aminodiester with excess methyl or phenyl lithium. Reaction of two equivalents of the aminodiols **4–8** with tetrabenzylzirconium afforded the zirconium bis(aminodiolates) **10–14** in excellent yield. Complex **11** (R, R′ = Me, Ph) adopts a *cis*, *fac*-octahedral geometry in solution and in the solid state. Complexes **10–14** are fluxional in solution by NMR spectroscopy: small substituents at nitrogen and large substituents at the alkoxide carbons slow the rate of exchange. The chiral complex **14** functions as a Lewis acid catalyst in the nitroaldol (Henry) reaction and the oxidation of geraniol by *tert*-butyl hydroperoxide with modest enantioselectivities (30 and 46% enantiomeric excess (ee), respectively).

Key words: diol, Michael addition, zirconium, synthesis, structure, fluxional, alkoxide, Lewis acid, catalysis.



Résumé : On a préparé une série d'aminodiols, $RN(CH_2CH_2C(OH)R_2)_2$ (R, R′ = Me, Me **4**; Me, Ph **5**; *tert*-butyl, Me **6**; *tert*-butyl, Ph **7**; (*S*)-PhCH(Me), Me **8**), par le biais d'une addition de Michael d'une amine primaire sur l'acrylate de méthyle, suivie par une réaction de l'aminodiester qui en résulte avec un excès de méthyl ou de phényllithium. La réaction de deux équivalents des aminodiols **4–8** avec du tetrabenzylzirconium conduit aux bis(aminodiolates) de zirconium **10–14** avec d'excellents rendements. En solution ainsi qu'à l'état solide, le complexe **11** (R, R′ = Me, Ph) adopte une géométrie octaédrique *cis*, *fac*. En solution, la spectroscopie RMN indique que les complexes **10–14** sont en état de flux: des substituants de faibles tailles au niveau de l'azote et de taille importante au niveau des carbones des alcoolates ralentissent l'échange. Le complexe chiral **14** agit comme acide de Lewis pour catalyser la réaction de nitroaldol (Henry) et l'oxydation du géraniol par l'hydroperoxyde de *tert*-butyle avec des énantiosélectivités modestes (30 et 46% respectivement).

Mots clés : diol, addition de Michael, zirconium, synthèse, structure, fluxion, alcoolate, acide de Lewis, catalyse.



[Traduit par la Rédaction]

Introduction

Alkoxides (1), aryloxides (2), and siloxides (3) have been extensively used as ancillary ligands in group 4 organometallic chemistry. In addition, chelating biphenolates (4) and binaphtholates (5) have been employed, the latter being especially important in asymmetric catalysis due to its inherent C_2 symmetry. Chelating tripodal alkoxides based on triethanolamine have been extensively investigated by Verkade et al. (6) who demonstrated the hydrolytic stability of the chelate array in complexes such as **I**. Nugent has developed a C_3 chiral analog of **I**, using the homochiral triol **II**, which shows high catalytic enantioselectivity in the ring opening of meso epoxides by azidotrialkylsilanes (7).

I

II

Ligands such as those derived from triethanolamine or triol **II** are best suited to forming complexes with smaller metals such as titanium. In order to form monomeric zirconium complexes, additional steric bulk is required and this is most easily achieved by the introduction of two substituents at the alkoxide carbon. Replacement of one chelate arm by an alkyl group allows for further steric tuning by variation of the substituent at nitrogen and lowers the charge to two. This latter point is important because an aminodiolate ligand

[a]Recorded at 360 MHz in C_6D_6; chemical shifts (δ) in ppm relative to TMS; multiplicity and coupling constants (where measured) are given in brackets; singlets have not been denoted.

[b]Partially obscured.

[c]Recorded at 80°C.

[d]^{1}H–^{13}C COSY shows the following pairs of resonances are due to protons attached to the same carbon: 3.14, 1.00; 2.94, 1.38; 2.53, 2.29; 2.11, 1.93.

[e]Recorded at 70°C.

allows access to dialkyls, alkyl cations, imides, and many other important classes of compounds not possible for systems such as **I**. In this contribution, we describe the synthesis of several aminodiolate ligands and their zirconium coordination complexes. The nature of the alkoxide carbon and nitrogen substituents will be shown to control the fluxional behaviour of these complexes.

Experimental section

General procedures

All manipulations were carried out under an argon atmosphere, with the rigorous exclusion of oxygen and water, using standard glovebox (Braun MB150–GII) or Schlenk techniques. Tetrahydrofuran (THF), hexane, and toluene were dried by distillation from sodium benzophenone ketyl under argon immediately prior to use. Tetrabenzylzirconium was prepared according to the literature (8).

^{1}H, ^{13}C, and all variable temperature NMR spectra were recorded on a Bruker AC–300 or AMX–360 MHz spectrometer. Spectra were recorded in C_6D_6 or C_7D_8 solvent, previously distilled from sodium under argon, using 5 mm tubes fitted with a teflon valve (Brunfeldt). ^{1}H and ^{13}C NMR spectra were referenced to residual solvent resonances. ^{1}H NMR data for the ligands and their precursors are given in Table 1 while data for their zirconium complexes are listed in

© 2000 NRC Canada

Table 2; ^{13}C NMR data is given in the following section. Melting points were recorded using a Reichert hot stage and are not corrected. Elemental analyses were performed by Canadian Microanalytical, Delta, B.C. or Atlantic Microanalytical, Atlanta, Ga. Mass spectra were recorded on a Finnegan 3300 or a Kratos Concept H spectrometer using chemical ionization or electron impact (70 eV) sources, respectively.

Aminodiester preparation

The esters **1–3** were prepared by Michael addition of the appropriate amine to methyl acrylate. In a representative procedure, the amine (0.1 mol) was dissolved in 200 mL methanol in a 1 L round bottom flask fitted with a dropping funnel and reflux condenser. Dropwise addition of methyl acrylate (0.2 mol) over a period of 1 h followed by stirring at room temperature for 5 h was sufficient to complete the formation of ester **1**. In contrast, overnight reflux was necessary to complete the addition in the case of **3** and prolonged reflux (1 week) still resulted in a mixture of mono and diester for **2**. After cooling, methanol and any low boiling materials were removed by rotary evaporation using a water aspirator. The remaining liquids were then distilled under reduced pressure (0.1 Torr (1 Torr = 133.3 Pa)). In the case of **2**, the monoester was easily removed by fractional distillation leaving the pure diester as the higher boiling fraction.

Aminodiol preparation

Treatment of aminodiesters (**1–3**) with an excess of methyl or phenyllithium allowed isolation of a series of aminodiols (**4–8**). In a typical preparation, a 10-fold excess of methyl or phenyllithium was generated in situ from iodomethane and lithium or bromobenzene and *n*-butyllithium, respectively (diethyl ether solvent). The lithium reagent was then added by dropping funnel to a solution of the aminodiester in diethyl ether cooled to 0°C. The resulting turbid solution was stirred for 1 h at 0°C and allowed to warm to room temperature overnight. The reaction mixture was subsequently quenched with ice water, extracted with dichloromethane and the organic extract dried over anhydrous $MgSO_4$. Filtration and removal of the solvent under reduced pressure yielded the aminodiols as white crystals or colourless oils. The secondary amino alcohol **9** was obtained as a byproduct in the preparation of **8** and was separated by fractional distillation. Further drying over molecular sieves (4 Å) in toluene solution was carried out prior to reaction with tetrabenzylzirconium.

*MeN($CH_2CH_2C(OH)Me_2$)$_2$ (**4**)*: Colourless oil. Yield: 81%; $^{13}C(^1H)$ NMR ($CDCl_3$) δ: 70.6 (*C*OH), 53.9 (NCH_2), 41.9 (N*Me*), 38.8 (*CH_2*CO), 29.7 (C(OH)*Me*). The resonance at 3.6 ppm disappears after treatment with D_2O.

Zirconium complexes

Complexes **10–14** were prepared by adding a solution of two equivalents of aminodiol **4–8** in toluene to a stirred toluene solution of tetrabenzylzirconium. After stirring for 1 h, the volatiles were removed under reduced pressure and the crude solid product was recrystallized from a mixture of toluene and hexane.

Lewis acid catalysis

Hetero Diels–Alder reaction

Ethyl vinyl ether was dried for several days over molecular sieves and then vacuum transferred (5 mL) to a Schlenk flask fitted with a Kontes valve. Under an argon atmosphere, 0.2 mL *trans*-crotonaldehyde was added to the ethyl vinyl ether solution followed by a solution of **14** (5 mol%) in 0.5 mL toluene. The flask was sealed and the reaction mixture was stirred at room temperature for 4 days. At the end of this period, the reaction vessel was opened to air and the solvent was removed by rotary evaporation (water aspirator, 35°C). Examination of the residue by ^{1}H NMR revealed the presence of trace *cis*-2-ethoxy-4-methyl-3,4-dihydro-2-pyran (9) δ: 6.20 (1H, dd, =C*H*CHMe, *J* = 6, 2 Hz), 4.87 (1H, dd, OC*H*(OEt), *J* = 9, 2 Hz), 4.53 (1H, m, =C*H*(O)). The remaining resonances of this product were obscured by unreacted starting material and free ligand signals.

Nitroaldol reaction

A solution of **14** (5 mol%) in 10 mL dry nitromethane was prepared under argon in a Kontes valve flask. Approximately 0.5 g of ArC(O)H (Ar = phenyl or β-naphthyl) was added, the flask sealed and the reaction mixture stirred at room temperature for up to 7 days. Samples were periodically removed and examined by ^{1}H NMR to monitor the progress of the reaction. At the end of each run, the solvent was removed under vacuum and the residue was chromatographed on silica gel using 75:25 CH_2Cl_2–hexane as eluant. The dinitro products eluted first along with any unreacted aldehyde followed by the β-nitroalcohol.

PhCH(OH)CH$_2$NO$_2$: ^{1}H NMR ($CDCl_3$) δ: 7.37 (5H, m, Ph*H*), 5.45 (1H, m, C*H*(OH)), 4.54 (2H, m, C*H*$_2$NO$_2$); ^{13}C(^{1}H) δ: 138.08 (*quat*-aryl*C*), 129.05, 129.00, 125.93 (aryl*C*), 81.21 (*C*H$_2$NO$_2$), 71.01 (*C*H(OH)). The ^{1}H and ^{13}C data agree with that reported in the literature (10, 11, 12).

PhCH(CH$_2$NO$_2$)$_2$: ^{1}H NMR ($CDCl_3$) δ: 8.09 (2H, d, Ph*H*), 7.63 (1H, m, Ph*H*), 7.35 (2H, m, Ph*H*), 4.76 (4H, dd, C*H*$_2$NO$_2$, *J* = 1.8, 7.0 Hz), 4.30 (1H, pentet, C*H*(CH$_2$NO$_2$)$_2$, *J* = 7.0 Hz); ^{13}C(^{1}H) δ: 133.88, 129.61, 128.49, 127.35 (aryl*C*), 76.73 (*C*H$_2$NO$_2$), 41.77 (*C*H(CH$_2$NO$_2$)$_2$). The ^{1}H and ^{13}C NMR data are very similar to those reported in the literature (13).

β-*NaphCH(OH)CH$_2$NO$_2$*: ^{1}H NMR ($CDCl_3$) δ: 7.85 (4H, m, β-naph*H*), 7.49 (2H, m, β-naph*H*), 7.42 (1H, d, β-naph*H*), 5.60 (1H, br d, C*H*(OH)), 4.61 (2H, m, C*H*$_2$NO$_2$); ^{13}C(^{1}H) δ: 135.40, 133.42, 133.19 (*quat*-β-naph*C*), 129.03, 128.07, 127.80, 126.74, 126.71, 125.35, 123.20 (β-naph*C*), 81.19 (*C*H$_2$NO$_2$), 71.16 (*C*H(OH)). β-*NaphCH(CH$_2$NO$_2$)$_2$*: ^{1}H NMR ($CDCl_3$) δ: 7.78–8.00 (4H, m, β-naph*H*), 7.49–7.68 (2H, m, β-naph*H*), 7.36 (1H, d, β-naph*H*), 4.85 (4H, d, C*H*$_2$NO$_2$, $^3J_{HH}$ = 7.2 Hz), 4.48 (1H, pentet, C*H*(CH$_2$NO$_2$)$_2$, $^3J_{HH}$ = 7.2 Hz); ^{13}C(^{1}H) δ: 133.31, 133.24, 131.37 (*quat*-β-naph*C*), 129.73, 127.92, 127.77, 127.04, 126.98, 124.22 (β-naph*C*), 76.73 (*C*H$_2$NO$_2$), 41.92 (*C*H(CH$_2$NO$_2$)$_2$). Exact Mass MS, anal. calcd. for $C_{13}H_{12}N_2O_4$: 260.0797; found: 260.0797 amu.

Geraniol oxidation

Geraniol (0.309 g, 2.0 mmol) was dissolved in 10 mL dry, distilled CH_2Cl_2 and a solution of **14** (0.050 g, 3.7 mol%) in 5 mL CH_2Cl_2 was added under argon in a Kontes flask. After stirring 10 min, 0.5 mL of a 5 M solution of *tert*-butyl hydroperoxide in decane was added via syringe (2.5 mmol). The flask was sealed and the reaction mixture stirred at room. Aliquots (1 mL) were withdrawn daily and examined by ^{1}H NMR to monitor the progress of the reaction. The reaction appeared to reach a plateau at 65% completion after 3 days so an additional 2.5 mL *tert*-butyl hydroperoxide was added. The reaction was stopped after 6 days at ca. 85% completion since no further conversion was evident. The reaction mixture was extracted with 10 mL water and the

© 2000 NRC Canada

CH_2Cl_2 phase was taken to dryness. Chromatography on silica gel using 50:50 Et_2O–hexane as eluant removed all traces of free ligand from the product but did not separate the geraniol from its epoxide. Geraniol epoxide was identified by NMR (14): ^1H ($CDCl_3$) δ: 5.00 (1H, m, =C*H*), 3.75–3.80 and 3.60–3.65 (2H, m, CH_2OH), 2.88 (1H, m, C*H*(O)), 1.98–2.08 (2H, m, =CHCH_2), 1.63 and 1.56 (3H, s and 3H, =C*Me*$_2$), 1.39–1.49 (2H, m, CH_2C(O)), 1.28 (3H, s, CH_2C*Me*(O)); $^{13}C(^1H)$ δ 132.10 (=*C*Me$_2$), 123.31 (=*C*HCH$_2$), 63.13 (*C*H(O)), 61.33 (*C*H_2OH), 59.27 (*C*H_2CMe(O)), 38.48 (=CH*C*H_2), 25.64 (CH_2C*Me*(O)), 23.64 (*C*H_2CH(O)), 17.61, and 16.71 (=C*Me*$_2$).

Epoxide cleavage with azidotrimethylsilane

Dry, distilled cyclohexene oxide (0.1 mL, 1 mmol) was added to a solution of **14** (0.037g, 5 mol%) dissolved in 5 mL toluene under argon in a Kontes flask. Neat azidotrimethylsilane (Aldrich, 0.13 mL, 1.0 mmol) was added to the stirred solution via syringe and the vessel was sealed. The reaction was allowed to continue until no cyclohexene oxide remained (^1H NMR, 4 days). Removal of the solvent under reduced pressure afforded a colourless, viscous oil which possessed an extremely complex NMR spectrum. This material was shown to contain cyclohexanol, cyclohexanone, and at least eight other compounds by GC analysis.

Determination of enantiomeric excess

Enantiomeric excesses were determined using Yb(hfc)$_3$ (hfc = 3-(heptafluoropropylhydroxymethylene)-(+)-camphorate), Aldrich). For the β-nitroalcohols, splitting of the resonances due to the α-hydrogens C*H*(OH)) was monitored as a function of lanthanide shift reagent (LSR) concentration. The ee's reported for these products are very crude estimates since the α-hydrogen resonances of the two enantiomers were only partially resolved. In the case of geraniol oxidation, the resonances due to the methyl groups of the two enantiomeric epoxides were fairly well resolved and better estimates of the ee was obtainable in this case (See Fig. S2 of the supporting information).

X-ray crystallographic studies

Crystallographic data for **11** is summarized in Table 3. Crystals of **11** (0.4 × 0.4 × 0.4 mm) were loaded into glass capillaries in the glove box and subsequently flame sealed. The crystals were transferred to a Nonius CAD4F diffractometer equipped with Mo Kα radiation. The unit cell of **11** was refined using 24 reflections in the 2θ range of 30–35°. An experimental density was not obtained because of the air sensitivity of the compound. Five standard reflections, measured periodically during data collection (4, 2, –12; 2, –6, 2; 3, 1, 11; 7, 0, 0; 0, 7, 0), showed less than a 3% decline in intensity during data collection. Intensity measurements were collected over one half of the sphere. After the usual data reduction procedures, including an absorption correction (max and min transmission: 0.9939, 0.8507) according to a measured PSI scan, the structure was solved by Patterson methods.[2] The refinements minimised $\Sigma w((|F_o| - |F_c|)^2)$ and proceeded normally using teXsan98.[3] Criteria for inclusion of reflections were $I > 3.0\sigma(I)$. The weighting scheme was determined by counting statistics using $w = 1/(\sigma^2(F) + 0.001F^2)$. Convergence was satisfactory: max shift/esd <0.01; the largest positive and negative peaks in the final difference map were 3.26 and –0.86 e/Å^3, respectively. A total of 630 parameters were refined; the toluene of solvation was refined as a rigid group. Hydrogen atoms were placed in calculated positions. No intermolecular contacts shorter than 3.5 Å were observed. The structural perspective plots were drawn using ZORTEP.[4] Complete tables of bond distances, angles, and anisotropic temperature parameters have been deposited as supplementary material.[5]

Results and discussion

The aminodiol ligands **4–8** were prepared in good yield by the two step procedure shown in Scheme 1. As might be expected, the rate of Michael addition to methyl acrylate is strongly dependent on the steric bulk of the amine. Thus, *tert*-butylamine fails to give complete conversion to the aminodiester even after 1 week at methanol reflux. Nevertheless, pure aminodiester **2** is easily obtained by fractional

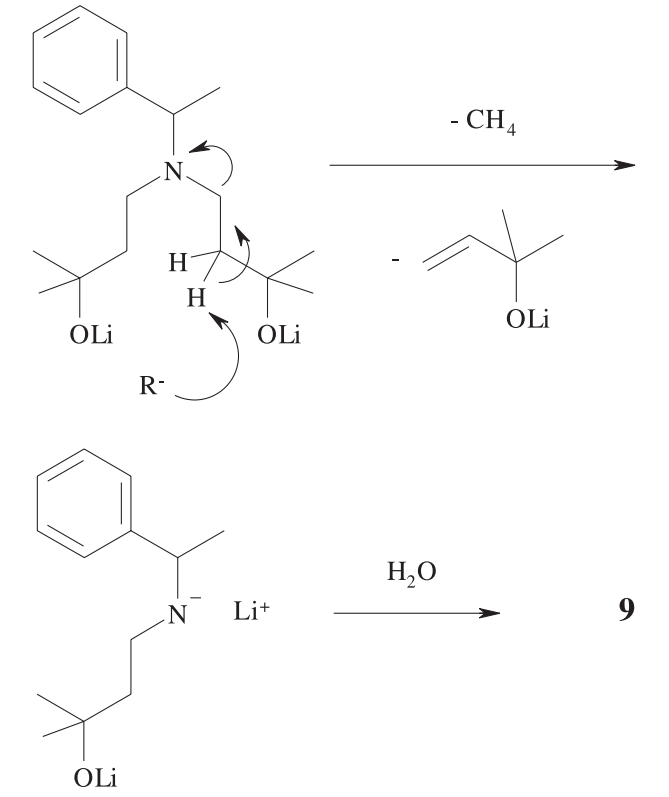

Scheme 1.

distillation of the reaction mixture. Treatment of aminodiesters **1**–**3** with a large excess of methyl or phenyl lithium afforded the aminodiols **4**–**8** after aqueous work up. In the case of **8**, a secondary amine byproduct (**9**) was also observed. Presumably, this product results from competing deprotonation of the protons α to the ester carbonyl by methyl lithium (Scheme 2). Attempts to prepare the R′ = Ph analog of **8** failed, possibly due to even more extensive α-deprotonation with phenyl lithium. The aminodiols bearing methyl alkoxide substituents were obtained as oils (**4**, **8**) or low melting solids (**6**) while those bearing phenyl substituents (**5**, **7**) were isolated as colourless crystals.

Addition of two equivalents of aminodiol **4**–**8** to tetrabenzylzirconium resulted in formation of the corresponding bis(ligand) complexes **10**–**14** (eq. 1). The complexes bearing methyl alkoxide substituents (**10**, **12**, and **14**) were extremely soluble in hexane and could not be purified by recrystallization. However, both **10** and **14** were isolated as analytically pure solids after removal of solvent. The phenyl substituted complexes, **11** and **13**, could be recrystallized from toluene–hexane mixtures.

Scheme 2.

[1] $2\ H_2L + Zr(CH_2Ph)_4 \rightarrow ZrL_2 + 4\ PhCH_3$

H_2L = **4–8** **10–14**

Molecular ions showing the expected isotopic distribution were observed for **10**, **11**, **13**, and **14**. Despite the observation of molecular ions by mass spectroscopy, dimeric and oligomeric solution structures are very common for zirconium alkoxides (15). However, cryoscopic molecular weight measurements on **10–14** indicated that these complexes are also monomeric in solution. Thus it appears that two aminodiolate ligands are sufficient to saturate the zirconium coordination sphere.

The monomeric solution structures of **10–14** greatly facilitate structural studies by NMR spectroscopy. Proton NMR evidence points to a *cis*, *fac*-octahedral (C_2) geometry (Fig. 1(*a*)) for both **10** and **11** since eight resonances are observed in the room temperature spectrum for the backbone CH_2 protons (Table 2). A *trans*, *fac* geometry (Fig. 1(*b*)) can be excluded since it would have C_{2h} symmetry and must therefore exhibit only four CH_2 resonances. Although a *trans*, *mer* ligand arrangement is also theoretically possible, the geometry of the aminodiolate ligand itself appears predisposed to form a *fac* donor arrangement. The *cis*, *fac* structure was confirmed in the solid state for **11** by an X-ray crystallographic study (*vide infra*).

The ^{1}H NMR resonances of **10** are not as sharp as those of **11** at room temperature suggesting that a dynamic process may be operative for the former. Indeed, when a NMR sample of **10** is heated, further broadening of the backbone

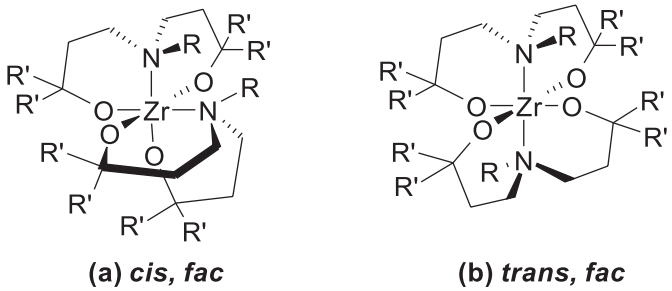

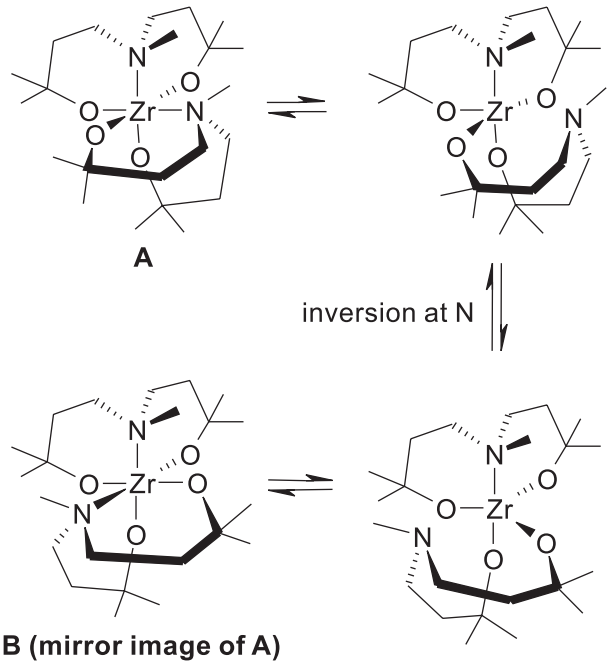

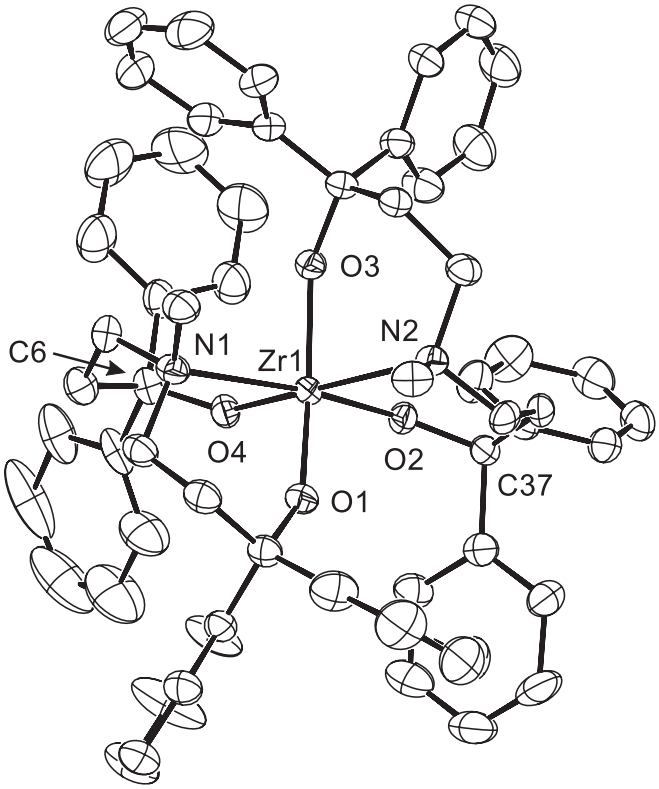

Fig. 2. A possible fluxional process for **10**.

resonances occurs leading to coalescence at 42°C. At 80°C, a simple spectrum is obtained which shows a single resonance integrating to eight protons for each chemically distinct CH_2 (Table 2). From the coalescence temperature, the free energy of activation for this process is calculated to be $\Delta G^{\ddagger} = 66.7 \pm 0.5$ kJ mol^{-1}.[6] A process that accounts for this behaviour is shown in Fig. 2. Amine dissociation to produce a five coordinate complex, followed by inversion at nitrogen and re-coordination exchanges all backbone CH_2 resonances of a given type. It should be noted that nitrogen inversion is required to exchange inequivalent protons on each backbone carbon; simple pseudorotation of the five coordinate intermediate can be ruled out since this will only exchange protons on different arms. Inversion at nitrogen is normally a low energy process (17) and dissociation of a single amine is also expected to require relatively little energy (18), so the low activation energy required to exchange the backbone protons is not surprising. A similar process has been proposed to account for the equivalence of the chelate arm resonances in the trigonal bipyramidal complex $Zr\{(Me_3Si)N(CH_2CH_2N(SiMe_3))_2\}\{CH_2Ph\}_2$ (19).

Fig. 3. ZORTEP plot (30% probability) of **11** (toluene of solvation omitted).

The ^{1}H NMR resonances of **11** also broaden on heating but in this case coalescence is not reached even at 110°C. The much higher barrier to exchange for **11** deserves some comment. Of the two processes involved, amine dissociation will be enhanced by steric congestion at the metal centre while nitrogen inversion may be hindered if it requires bulky substituents to pass by one another. Since the alkyl substituent at nitrogen is the same (methyl) in **10** and **11**, it seems reasonable to assume that amine dissociation will be favoured in **11** due to the phenyl substituents at the alkoxide carbon creating a more crowded coordination environment. Therefore the observation of a higher barrier to exchange can reasonably be ascribed to the second process, inversion at nitrogen. It is possible that the phenyl groups at the alkoxide carbon hinder the necessary rearrangement of the ligand required during inversion since they must pass by one another in order for the amine to recoordinate to the metal centre.

The simplicity of the NMR spectra for **12–14** (Table 2) indicates that these complexes are already undergoing a rapid fluxional process at room temperature. The presence of bulky groups at nitrogen (**12** and **13**, *tert*-butyl; **14**, α-methylbenzyl) likely leads to weaker amine binding which should enhance the rate of exchange. In fact, the observation

[6] The free energy of activation was calculated from the coalescence temperature (T_c) using the equal population, two site exchange equation: $\Delta G^{\ddagger} = (1.912 \times 10^{-2})(T_c)[9.972 + \log(T_c/\delta\nu)]$ in kJ mol^{-1} where $\delta\nu$ is the separation of the resonances in Hz at coalescence and T_c is in K (16). The error in $\Delta G^{\ddagger}$ was estimated to be ±0.5 kJ mol^{-1} assuming a liberal error of ±2°C in estimation of T_c.

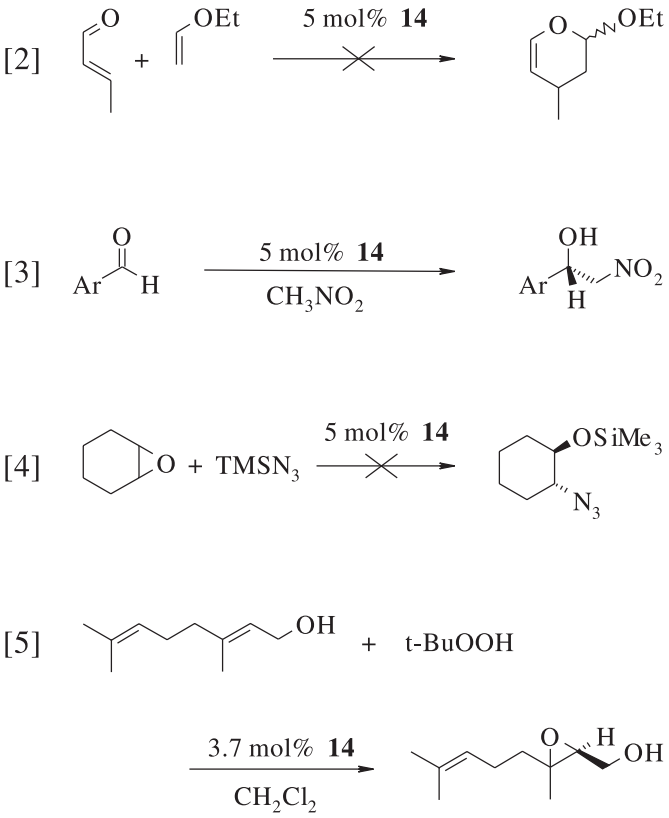
[a]Estimated standard deviations are given in parentheses.

that the ^{1}H NMR spectra for **12** and **14** remain sharp to –80°C may indicate that these complexes exist as ground state five coordinate structures similar to that shown in Fig. 2. At present, there is no evidence to distinguish this possibility from a fluxional six coordinate structure such as those shown in Fig. 1. The observation of fluxional behaviour for **13** even at room temperature appears to contradict the explanation given for the static behaviour of **11** at the same temperature. However, it is noteworthy that **13** is considerably more crowded than **11** and it is possible that exchange proceeds for **13** by dissociation of both amine nitrogens to give a four coordinate intermediate. In any case, further attempts to study the fluxional behaviour of this complex were hindered by its rather low solubility.

The solid state structure of **11** was investigated by X-ray crystallography. The structure is shown in Fig. 3 and significant bond lengths and angles are collected in Table 4. In agreement with the solution structure, the complex consists of a distorted *cis*, *fac*-octahedral coordination environment. The zirconium-amine nitrogen bond lengths in **11** (2.545(5), 2.562(5) Å) are shorter than might be predicted from the closely related five coordinate complexes $Zr\{(Me_3Si)N(CH_2CH_2N(SiMe_3))_2\}\{Cl\}\{CH(SiMe_3)_2\}$ and $Zr\{(Me_3Si)N(CH_2CH_2N(SiMe_3))_2\}\{BH_4\}_2$ (2.770(5) and 2.561(4), respectively) (20).[7] This is not surprising because the steric and electronic effects of the trimethylsilyl substituent at nitrogen combine to make this a much less basic amine than the methyl substituted amine in **11**. Obviously, the presence of a bulky alkyl group contributes to the very long Zr—N distances in $Zr\{(Me_3Si)N(CH_2CH_2N(SiMe_3))_2\}\{Cl\}\{CH(SiMe_3)_2\}$.

In comparison, the titanium-amine nitrogen bond in $\{Ti[NMe_2][N(CH_2CH_2O)_3]\}_2$ is only 2.270(2) Å, much shorter than that observed in **11**, even allowing for the difference in metal ionic radii (ca. 0.12 Å in six coordination) (6*a*, 21). However, the apical nitrogen of an atrane ligand is forced into close proximity with the metal in order to accommodate coordination of the three pendant alkoxide groups. Since the aminodiolate ligand in **11** possesses only two pendant alkoxide groups, the amine nitrogen is not constrained to a particular distance and can adopt a distance reflective of the strength of the amine binding.



The zirconium-alkoxide oxygen distances in **11** (1.961(4)–1.996(5) Å) are very similar to those observed in the related six coordinate complexes, Zr[*O*-2,6-*tert*-$Bu_2C_6H_3]_2$[OCH(Me)NC_5H_3CH(Me)O][py] ($Zr\text{-}O_{aryloxide}$ = 2.006(5), 2.015(6); $Zr\text{-}O_{alkoxide}$ = 1.988(5), 2.034(5) Å) (22) and $Cp_2Zr(m\text{-}OCH_2(C_6H_4)CH_2O)ZrCp_2$ (1.946(6) Å) (1*b*). The Zr-O-C angles in **11** (145.8(4)°–153.5(4)°) are similar to those in the alkoxide-bridged zirconocene above (155.1(5)°). Interestingly, the Zr-O-C bond angles for the tridentate ligand in Zr[*O*-2,6-*tert*-$Bu_2C_6H_3]_2$[OCH(Me)NC_5H_3CH(Me)O][py] are only 126.7(6)° and 129.5(6)° while the $Zr\text{-}O\text{-}C_{aryl}$ angles in the same complex are nearly linear (172.8(5)°, 178.8(5)°). Presumably, the intermediate angles in **11** do not reflect any significant angular strain.

III

[7]Typically, five–coordinate zirconium complexes display bond lengths 0.06 C shorter than their six-coordinate analogues (24). The predicted Zr—N bond lengths for **11** based on these two complexes would therefore be 2.83 and 2.62 Å.

© 2000 NRC Canada

Verkade rationalized the *cis* arrangement of the amine and amide groups in **III** in terms of electronic properties of the ligands: strongly electron donating amide and amine groups preferring to occupy sites *trans* to the more electron withdrawing alkoxide ligands and *cis* with respect to one another (6). It is possible similar electronic factors are responsible for the *cis* disposition of the amine donors in **11** although steric effects cannot be ruled out.

Chiral complex **14** was also briefly screened for Lewis acid catalytic activity using four typical test reactions (eq. 2–5). The complex proved to be an effective catalyst for the nitroaldol (Henry) reaction (eq. 3)[8] and for the oxidation of geraniol with *tert*-butyl hydroperoxide (eq. 5). The nitroaldol reaction proceeded smoothly to give the β-nitroalcohols in good yield but low enantiomeric excess (Table 5). At longer reaction times (>48 h), in nitromethane as solvent, increasing amounts of the dinitro products $ArCH(CH_2NO_2)_2$ were obtained.

The oxidation of geraniol slowly proceeded over a period of 4 days and it was necessary to add excess *tert*-butyl hydroperoxide to achieve good yields. Nevertheless, the reaction does not proceed in the absence of **14** and the product is formed with very high selectivity (no other products derived from geraniol were detected at any stage of the reaction). That even moderate enantioselectivity is obtained (46% ee, Table 5) is somewhat surprising because ligand loss might be expected in the presence of a large excess of geraniol and *tert*-butyl hydroperoxide. Indeed, small amounts of free ligand were observed in the reaction mixture by ^1H NMR after one day.

Table 5. Lewis acid catalyst screen for **14**.

Attempts to carry out a hetero Diels–Alder reaction (eq. 2) or the addition of azidotrimethylsilane to cyclohexene oxide (7*a*) (eq. 4) using **14** as a catalyst failed. The hetero Diels–Alder reaction is particularly challenging because it requires a fine balance of Lewis acidity: catalysts that are too acidic (eq. $Yb(OTf)_3$) result in ethyl vinyl ether (dienophile) polymerization, while those that are too mild do not effect the reaction (23). Less than a 5% yield of the desired dihydropyran product was obtained after 4 days at room temperature using **14** as catalyst. No polymerization of ethyl vinyl ether was observed indicating that **14** is indeed a mild Lewis acid. This result is not surprising because the alkoxide groups are good donors and relatively low zirconium Lewis acidity is to be expected. In contrast, reaction of azidotrimethylsilane with cyclohexene oxide in the presence of **14** resulted in the slow consumption of the starting materials and formation of a complex mixture of products. GC analysis showed that at least 10 compounds were formed in significant amounts during this reaction. The reason for the lack of selectivity is not clear.

In summary, the aminodiolate ligands developed here form simple, monomeric zirconium complexes of good hydrocarbon solubility. The tendency towards amine dissociation and fluxional behaviour is dependent on the nature of the substituents at nitrogen and the alkoxide carbon. The most stable six coordinate geometry is obtained with small nitrogen substituents (e.g., methyl) and large alkoxide substituents (e.g., phenyl). The chiral complex **14** is a mild Lewis acid catalyst for the nitroaldol reaction and the oxidation of geraniol with low to moderate stereocontrol.

Acknowledgements

We thank Mrs. C. Greenwood for assistance in recording the NMR spectra and Dr. David McGillivray for obtaining the mass spectra. This research was supported by the NSERC (Canada) and a University of Victoria Internal Research Grant (to D.J.B.)

[8] Strictly speaking, the nitroaldol reaction is not an example of simple Lewis acid catalysis because the alkoxide groups must act as bases in the deprotonation of nitromethane. However, it is likely that coordination of the aldehyde also takes place and that this plays some role in rate acceleration.

Ethylene-polymerization by surface supported Cr(IV) species: possible reaction mechanisms revisited by theoretical calculations

Rochus Schmid and Tom Ziegler

Abstract: Possible reaction mechanisms of olefin polymerization catalyzed by surface supported Cr(IV) species have been investigated by first principles density functional theory (DFT). Pathways starting from neutral alkylidene or bisalkyl complexes were found to suffer from high ethylene insertion barriers, whereas a cationic system formed by protonation of the alkylidene show a low barrier for chain propagation.

Key words: density functional theory, alkylidene, olefin polymerization, Cr(IV) species.

Résumé : En faisant appel aux principes fondamentaux de la théorie de la densité fonctionnelle (TDF), on a évalué les divers mécanismes possibles pour la réaction de polymérisation des oléfines catalysées par des espèces Cr(IV) supportées par une surface. On a trouvé que les voies partant de complexes alkylidène ou bisalkyle neutres impliquent des barrières élevées pour l'insertion de l'éthylène alors qu'un système cationique formé par protonation de l'alkylidène ne présente qu'une faible barrière à la propagation de la chaîne.

Mots clés : théorie de la densité fonctionnelle, alkylidène, polymérisation d'oléfine, espèce Cr(IV).

[Traduit par la Rédaction]

Introduction

A number of industrially important ethylene polymerization processes depend on surface supported organometallic complexes, for example the Cr/SiO_2 catalysts developed by Phillips (1) and Union-Carbide (2). In contrast to the well defined, so-called "single site" homogeneous polymerization catalysts (3), neither the oxidation state nor the exact coordination environment of the active species are known with certainty (4). Therefore, the reaction mechanism for chain propagation and termination is often based on pure speculation. To solve this problem, homogeneous model systems of Cr(III) have been synthesized. Various N-donating bi- and tridentate ligands have been employed in order to model the hard coordination environment of a silica surface (5). Systems of Ti(III), V(III), and Cr(III) were found to be active in ethylene polymerization (6). Interestingly, these systems resemble the well known N-chelating ligands of early and late transition metal homogeneous polymerization catalysts (3). In addition to this strategy, well defined surface supported complexes can be studied. Recently, Amor Nait Ajjou and Scott (7) succeeded in the preparation of a silica-supported alkyl chromium(IV) system. After thermolysis of the bisalkyl complex, a new species is formed which polymerizes ethylene on the surface (8, 9). Our continuing interest in the mechanism of olefin polymerization (10) and our recent investigations of polymerization catalysts with occupied *d*-levels (footnote 3) (as it is the case for Cr(IV)) has prompted us to study the catalytic system discovered by Scott and coworkers (8, 9) by means of first principles calculations employing density functional theory (DFT) (11).

Computational details

All structures were fully optimized without symmetry constraints in a high-spin electronic state (spin unrestricted calculations) by standard optimization techniques with a gradient corrected functional (BP86 (12)) using the ADF 2.3 program package (13). Transition state searches were performed by linear transit calculations with a constrained reaction coordinate and subsequent use of a transition state search algorithm. First order scalar relativistic corrections were added to the total energy, since a perturbative approach is sufficient for first row transition metals (14). For Cr a triple-ζ Slater type basis set (3*s*, 3*p*, 3*d*, and 4*s* valence shells plus one 4*p* polarization function) was used and for Si a triple-ζ STO basis set (3*s* and 3*p* valence shell plus one 3*d* polarization function) was used. Non-metal atoms were described by a double-ζ STO basis with one 3*d* (C, N, and O) or one 2*p* (H) polarization function (15). The frozen core approximation was employed throughout. A set of auxiliary *s*, *p*, *d*, *f*, and *g* STO functions, centered on all nuclei, was used to fit the

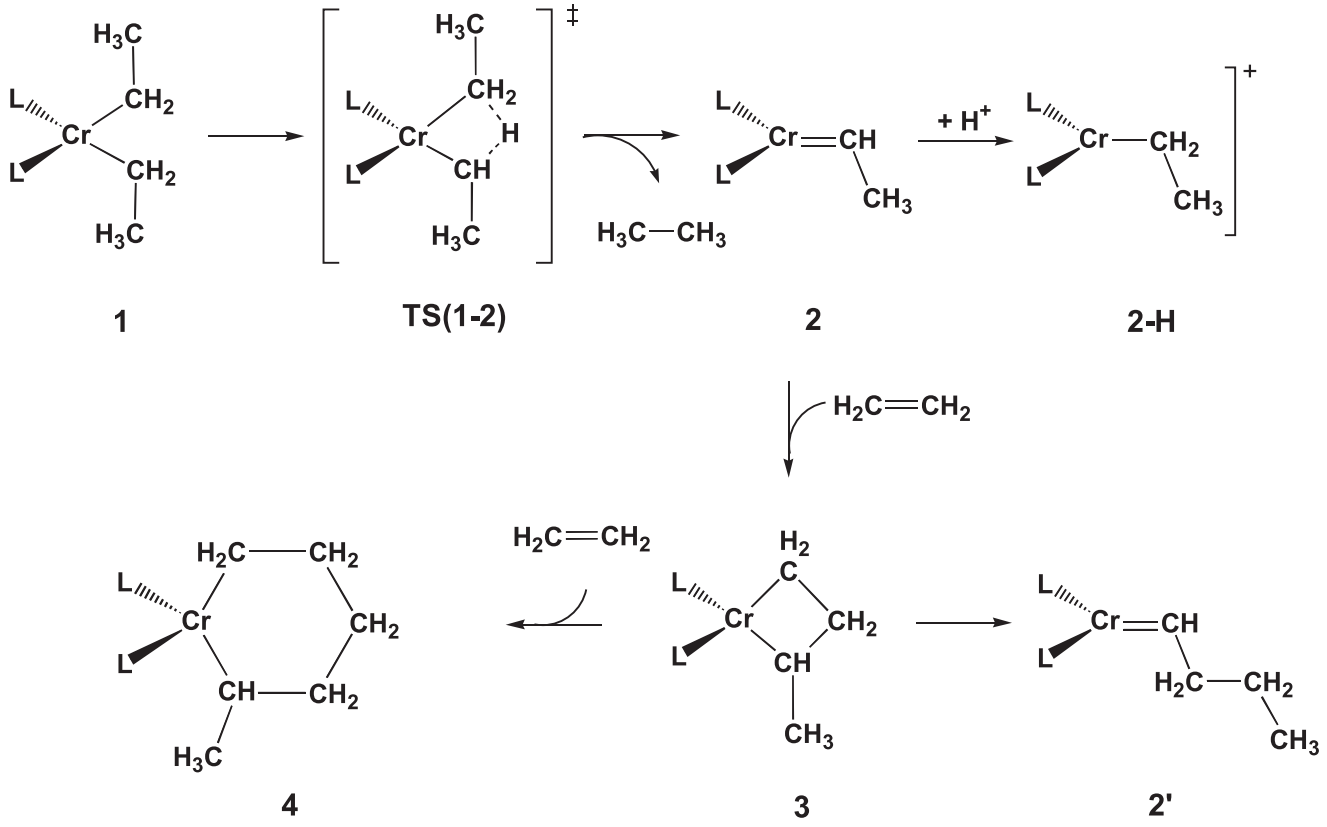
molecular density and present Coulomb and exchange potentials accurately in each SCF cycle. This level of theory has been proven to be reliable for both structures and energetics of transition metal systems (16).



Results and discussion

Because of the large numeric effort with first principle methods in general, we limited ourselves to the model systems shown as **A** in Scheme 1. The neopentyl groups were reduced to an ethyl chain and the silica surface was simulated by two -O-SiH_2- units connected by an additional oxygen atom in order to include the "chelating" constraint present on the surface. Calculations with two amide ligands (**B**) were performed in order to compare with our results on systems of standard $[L_2MR]^+$ polymerization catalysts (footnote 3) and the findings of Theopold et al. (6).

Starting from homoleptic alkyls of Cr(IV) and dehydroxylated silica, Amor Nait Ajjou and Scott (7) could, depending on the conditions and the preconditioning of the silica, produce uniform surfaces with either one or two alkyl groups replaced by a Si-O unit. These bis or tris alkyl Cr(IV) complexes do not polymerize ethylene. However, by thermolysis of the $(\equiv SiO)_2CrR_2$ system with R = neopentyl (**1**) at only 60°C, one equivalent of neopentane is liberated and a new surface supported species is formed, which could either be a metallacycle or a rather unusual alkylidene-complex. Recent results on reactions with agents attacking specifically M=C bonds make it very plausible that the formed product is a surface stabilized alkylidenecomplex of Cr(IV) (**2**). In contrast to the bisalkyl complex (**1**), this new species polymerizes ethylene at room temperature (8). A mechanism of chain propagation has been proposed (Scheme 2), which is based on the assumption of an initial [2 + 2] addition of ethylene to the M=C bond under formation of a metalla-cyclobutane (**3**). A subsequent 1,3-hydrogen shift would reform the alkylidenecomplex (**2′**) with a chain length increased by one monomer.

Our calculations show that the initial step leading from the bis alkyl complex **1** to the alkylidenecomplex **2** is very endothermic (24.6 kcal/mol for **A**). Wu et al. (17) found a reaction energy for the equivalent methane elimination from $TiMe_4$ of 37.5 kcal/mol which is reduced for the sterically encumbered system $TiNp_4$ (Np = neopentyl) to 18.4 kcal/mol. For analogous reasons, a lower endothermicity of the

Fig. 1. Transition state **TS(1→2)** for system **A** (important bond lengths are given in Å).

surface supported bis-neopentyl Cr-species can be expected. In addition, the entropic driving force from the formation of the volatile alkane can be estimated to contribute about –10 kcal/mol to the total free reaction energy. This makes the formation of alkylidene feasible (footnote 4, 18), especially because the alkane elimination on the support would be irreversible with complete alkane loss. In Table 1 the reaction energies for the alkylideneformation are given for **A**, **B**, and also intermediate model systems with OH and $OSiH_3$ as ligands. The thermodynamic energy difference for the step **1→2** is not significantly affected by the type of ligand, which justifies the use of **A** as a model for the surface supported system.

The calculated energies of all investigated stationary points for **A** and **B** are given in Table 2 with respect to the corresponding bisalkyl complex (**1**). The large kinetic isotope effect for **1→2** for α-deuterated alkyl complexes experimentally proves this to be a α-hydrogen transfer reaction (8). Kinetic measurements of this reaction suggest a two-step mechanism, which has been interpreted in terms of the formation of a stable Cr(VI) hydrido intermediate (9). Our calculations, however, show no preference for the latter and **TS(1→2)** is a direct hydrogen transfer with a barrier of 37.3 kcal/mol (**A**). No stationary point for a Cr(VI) hydrido species could be located. Similar barriers have been calculated by Wu et al. (17) for the alkane elimination from TiR_4 (R = Me: 41.2, R = Np: 32.8 kcal/mol) and also the geometry of the transition state closely resembles the one calculated for TiR_4 (Fig. 1). The Cr—C bond to the carbon atom in the forming ethylene molecule is elongated to 2.204 Å, whereas the generated alkylidene bond is shortened to 1.839 Å. The corresponding C—H bond length shows the opposite asymmetry. It is important to note that for the alkane elimination from TiR_4 the activation barrier was calculated to be less sensitive to the nature of the alkyl substituent than the reaction energy. Furthermore, our model (using ethyl) deviates from the real system for this initial activation process only, whereas in consecutive steps ethylene is a reasonable model for the growing polymer chain.

Ethylene can react with **2** in a [2 + 2] fashion to give a metallacycle **3** (8). This process occurs without any barrier and is about 40 kcal/mol exothermic by irrespective of the nature of the system (**A** or **B**). In the presence of ethylene, **3** must be seen as a strong thermodynamic sink and therefore represents the resting state of the system. A viable polymerization mechanism must allow for a repetitive olefin incorporation with reasonable barriers of activation. As shown in Scheme 2, a 1,3-hydrogen shift from **3** would lead to a alkylidene complex **2′** with a chain length increased by one monomer unit. It should be noted, however, that this hydrogen transfer is equivalent to the "activation" by thermolysis of **1**. Experimentally, it has been observed that for **1→2** elevated temperatures are necessary, but the polymerization occurs at room temperature. For both **A** and **B** our calculations show an activation barrier of about 55 kcal/mol for the hydrogen shift reaction, which is even larger than the barrier for **TS(1→2).** The ring strain in the four-membered metallacycle **3** does not lower the barrier. Figure 2 displays the transition state **TS(3→2′)** for **A**, which very much resembles the geometry in **TS(1→2)**. However, the structural deformations necessary for this 1,3-hydrogen transfer in the

[4] The estimation of the entropic contribution to ΔG is based on a reaction entropy (mostly rotational and translational contributions) of $\Delta S \sim 35$ cal mol^{-1} K^{-1} and a temperature of 300 K (see also Ref. 18).

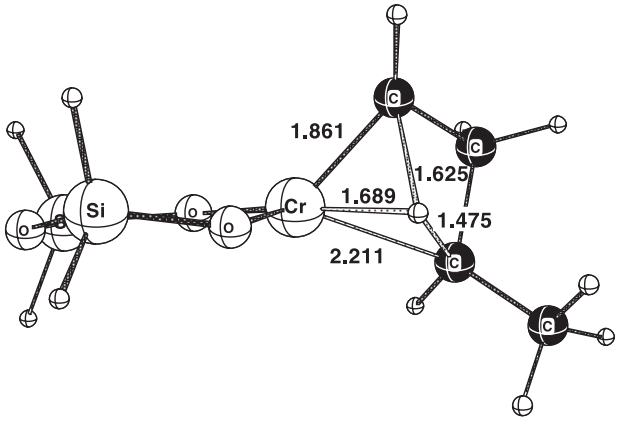
Fig. 2. Transition state **TS(3→2′)** for system **A** (important bond lengths are given in Å).



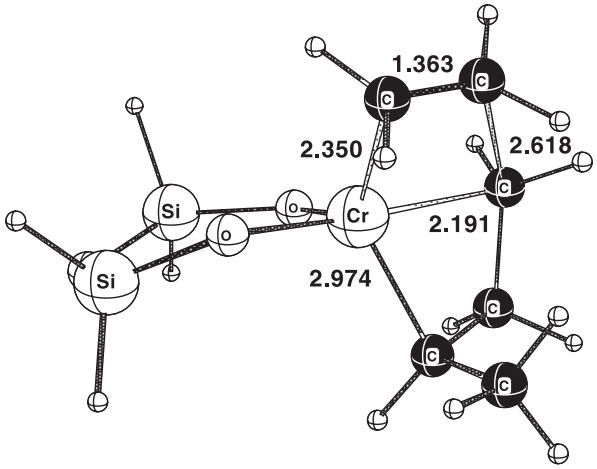


Fig. 3. Transition state **TS(3→4)** for system **A** (important bond lengths are given in Å).

metallacycle are much larger than for the corresponding **TS(1→2)** (Fig. 1), which explains the increase of 20 kcal/mol in the barrier. Our results do not support the sequence **2→3→2′** as a pathway for chain propagation in these systems.

Alternatively we considered direct ethylene insertion into one of the Cr—C bonds of **3**. We were not able to locate a stable olefin complex on the potential energy surface. However, with a barrier of 21.9 kcal/mol for **A** (18.0 kcal/mol for **B**) this is a more facile process than the 1,3-hydrogen shift reaction. The reaction leads directly to the metalla-cyclohexene **4**. Figure 3 shows the transition state **TS(3→4)** for system **A**. The thermodynamic exothermicity for the reaction step **3→4** is about 30 kcal/mol, again similar for systems **A** and **B**, and about 10 kcal/mol higher than the energy gain for the incorporation of ethylene into a linear alkyl chain. This is due to the release of ring strain when going from the four membered to the six membered ring.

Direct insertion mechanisms leading to larger and larger metallacycles have been discussed in the literature for the oligomerization of ethylene (18). It appears, however, to not be a viable pathway for chain propagation for the surface supported Cr(IV) systems considered here. A barrier of more than 20 kcal/mol for the insertion of ethylene into system **A** must be seen as prohibitive for polymerization. In addition, the consecutive insertion steps will suffer from lack of ring strain in the larger metallacycles, which will reduce the exothermicity while raising the insertion barrier. We did not investigate a 1,3-hydrogen shift reaction from **4**, which would reform an alkylidene complex similar to **2** with a chain length increased by two monomer units. Because of the similarity between the metalla-cyclohexane **4** and the bisethyl complex **1** this reaction can be expected to have an activation barrier of above 35 kcal/mol, which excludes this pathway as well.

Since all reaction steps including either a hydrogen transfer reaction or a direct insertion into a four coordinated Cr(IV) complex show very high activation barriers we suggest a possible alternative to explain the polymerization activity observed experimentally for the silica stabilized systems. Trace amounts of remaining acidic sites on the silica surface (Si-OH groups) are likely to protonize some of the alkylidene species, forming a cationic Cr(IV) alkyl complex **2-H**. Similar systems with two stabilizing auxilliary ligands are well known to effectively catalyze ethylene polymerization. In a recent theoretic investigation, Cr(IV) systems with a d^2-electron configuration have been found to be especially effective catalysts. For both systems **A** and **B** an olefin complex **3-H** is formed with respective ethylene binding energies of 23.1 (**A**) and 18.3 kcal/mol (**B**), respectively. The following step of the olefin insertion into the Cr—C bond proceeds with a very low activation barrier of only 10.5 kcal/mol for **A**. System **B** has, similar to the direct olefin insertion into the metalla-cyclopropane **3**, an even lower barrier of only 6.2 kcal/mol. For a detailed analysis of the electronic effects responsible for the low barrier in **B** we refer here to footnote 3.

Conclusions

We conclude from our calculations that any chain propagation pathways starting from the alkylidene complex **2**, involving either hydrogen transfer reactions or direct insertions into neutral bis-alkyl complexes, suffer from very high activation barriers. This might be altered by further surface-catalyst interactions, which are not accounted for in our calculations on model systems. However, by protonation of **2** a well known cationic alkylcomplexe **2-H** can be formed, which can act as an efficient ethylene polymerization catalyst with a very low activation barrier. This involves a standard reaction mechanism, which is known for a large number of known cationic homogeneous polymerization catalysts. Alternatively, the cationic alkyl could be formed by protonation of the metallacyclobutane species **3**.

A new short synthetic approach to chlorocyclopentenones related to cryptosporiopsin via a ring expansion strategy: first synthesis of a fungitoxic metabolite from *Sporormia affinis*[1]

Sidima Kabanyane, Andreas Decken, Chao-Mei Yu, and George M. Strunz

Abstract: A metabolite of the coprophilous fungus, *Sporormia affinis*, 2-*trans*-allyl-5-chloro-1-hydroxy-4-oxo-2-cyclopentene-1-carboxylic acid methyl ester, **2**, was synthesized in racemic form, by an eight-step sequence, in 11% overall yield. Departing from previous ring-contraction strategies for synthesis of chlorocyclopentenones in the cryptosporiopsin series, the key step in the new synthesis was ring expansion of a substituted cyclobutanone, the product of [2+2] cycloaddition of dichloroketene with methyl 2-trimethylsilyloxyhex-2-enoate.

Key words: *Sporormia affinis*, cryptosporiopsin, chlorocyclopentenone, dichloroketene, [2+2] cycloaddition, ring expansion, selenium dioxide.

Résumé : Nous avons synthétisé, sous forme racémique, en huit étapes et avec un rendement global de 11%, l'ester méthylique de l'acide 2-*trans*-allyl-5-chloro-1-hydroxy-4-oxocyclopent-2-ène-1-carboxylique, **2**, un métabolite du champignon coprophileux, *Sporormia affinis*. Les chlorocyclopentènones de la série de la cryptosporiopsine ont été synthétisées antérieurement par le biais d'une contraction de cycle. Par ailleurs, l'étape clé de la nouvelle synthèse consiste en une extension de cycle d'une cyclobutanone substituée, obtenue par une cycloaddition [2+2] du dichlorocétène sur l'ester méthylique de l'acide 2-trimethylsilyloxyhex-2-enoïque.

Mots clés : *Sporormia affinis*, cryptosporiopsine, chlorocyclopenténone, dichlorocétène, cycloaddition [2+2], extension de cycle, dioxyde de sélénium.

Isolation of the chlorine-containing fungitoxic cyclopentenone cryptosporiopsin (**1**) and several biogenetic congeners was reported by independent groups in 1969, from the coprophilous fungus *Sporormia affinis* (1*a*, cf. 1*b*), from a *Cryptosporiopsis* sp. (2), and from *Periconia macrospinosa* (3). In 1973, we published the first synthesis of cryptosporiopsin by a formally biomimetic route (4). The key step, based on the ring contraction of a phenolic precursor through the action of alkaline hypochlorite (5), was a capricious and low yield process. A subsequent synthesis, via a more readily controllable benzillic acid-type rearrangement of a suitably substituted quinone, produced the metabolite in better yield (6).

In this paper we describe a new concise synthetic approach (Scheme 1) to chlorine-containing cyclopentenones related to cryptosporiopsin, by way of ring expansion of a readily accessible cyclobutanone, a fundamental departure from the previously exploited ring contraction strategy. The methodology is employed towards the first reported synthesis of the *Sporormia affinis* metabolite, **2** (1*a*).

Cycloaddition of dichloroketene to the trimethylsilyl enol ether (**3**) of methyl 2-oxohexanoate appeared to offer a promising entry to a suitably substituted cyclobutane precursor. Dichloroketene is known to react with unsymmetrical olefins in a regiospecific manner, such that the most nucleophilic carbon of the olefin is always bonded to the *sp* hybridized carbon of the ketene (7). In the present instance, the reaction proceeded efficiently to give an 87% yield of a homogeneous product (**4**) hose regiochemistry was clearly evident from the mass spectral fragmentation pattern, and confirmed by NMR studies on a lower homologue (8). In the mass spectrum, ions corresponding to C_5H_8O and $C_7H_{12}O_3Cl_2Si$ were particularly diagnostic. The depicted relative stereochemistry follows from that established for a later intermediate (**7**) by nOe and X-ray diffraction studies.

The strategy for ring expansion of **4** as originally conceived, via fragmentation of an intermediate such as **6**, was thwarted by the failure of enol-ether **5** to react with dichlorocarbenoid species generated by several different methods (9) and under various conditions, including phase-transfer catalysis. Reaction of **4** with diazomethane, however, afforded a highly efficient alternative method of ring expansion. The regioselective reaction, conducted in ether containing a small amount of methanol, produced cyclopentanone (**7**), in almost

Scheme 1.

quantitative yield (cf. 10). The relative stereochemistry of **7** (although not relevant to the outcome of the synthesis) was determined by ^{1}H NMR studies, in which significant nOe enhancement between the methyl ester protons and the C-5 methine hydrogen established their spatial proximity. An X-ray crystal structure analysis[3] confirmed this assignment, which also allowed the relative stereochemistry of precursor **4** and the *Z*-geometry of **3** to be inferred. Desaturation of cyclopentanone **7** could be accomplished by treatment of its trimethylsilyl enol ether with $Pd(OAc)_2$ (11), but the yield of the desired cyclopentenone product **8** was modest (~25%). A more direct and efficient procedure was developed with the observation that simply heating **7** with SeO_2 in toluene furnished **8** in 77% yield.

The additional (conjugated) side-chain unsaturation required for the synthesis was most effectively introduced via γ-phenylselenenylation (82%) of the trimethylsilyl enol ether, **9**, readily prepared (89%) from **8**. Oxidation to the selenoxide (12), followed by elimination then afforded the dienone **10** in 60% yield. Partial reduction of the *gem*-dichloride with zinc-acetic acid furnished **11**, and removal of the trimethylsilyl protecting group under mild conditions (13), produced the (racemic) *Sporormia affinis* product **2** in 38% yield (overall yield for the synthesis from methyl 2-oxohexanoate, ~11%). The identity of the product was verified by comparison of its spectra with data reported for the natural product (1*a*).

It is worth noting that although assignment of the relative configuration of **11** was not pursued, its conversion to the synthetic product **2** of known relative stereochemistry (also confirmed by nOe experiments with the dihydro derivative of **2**) was expected, being consistent with our previous observation (14) that treatment of cryptosporiopsin with methanol-d_1 in pyridine-d_5 effects exchange of the C-5 hydrogen

[3] A. Decken. Unpublished results.

without epimerization, i.e., the *anti* orientation of Cl and OH is the favored configuration for compounds in this series when formed under, or subjected to equilibrating conditions.

In summary, we have accomplished the first synthesis of the racemate of **2**, a fungitoxic metabolite of *Sporormia affinis*, using an efficient ring expansion strategy, that may also provide an entry to other chlorinated cyclopentenones in the cryptosporiopsin series. The methodology appears amenable to enantioselective modification, and this is currently under investigation in our laboratory.

Experimental

General

Melting points were determined on a hot-stage apparatus and are uncorrected. Infrared spectra were recorded in $CHCl_3$ on a Philips Pye Unicam PU9516 infrared spectrophotometer and as films on a Bruker IF-S25 FTIR spectrometer. The ultraviolet spectra were recorded on a Hewlett Packard Diode Array Spectrophotometer, Model 8452A. Mass spectra were recorded on a VG Autospec instrument. NMR spectra were recorded in $CDCl_3$ at ambient temperature on a Varian XL-200 spectrometer operating at a frequency of 200.068 MHz for ^1H, and at 25°C on a Varian Unity 400 operating at a frequency of 399.946 MHz for ^1H and 100.564 MHz for ^{13}C.

*Methyl 2-trimethylsilyloxyhex-2-enoate, **3***: The precursor for the title compound, methyl 2-oxohexanoate, was prepared as follows (cf. 15): The Grignard reagent, prepared in dry THF (30 mL) under nitrogen, from *n*-butyl bromide (1.5 mL, 1.91 g, 14 mmol) and magnesium turnings (400 mg, 16.5 mg-atom) was added dropwise at 0°C to a solution of dimethyl oxalate (2.0 g, 16.9 mmol) in dry THF (100 mL). The reaction mixture was set aside with stirring in a nitrogen atmosphere at 0°C for 2 h. It was then allowed to attain ambient temperature, before being diluted by addition of ether (100 mL). The mixture was washed with cold 5% HCl solution (3 × 50 mL) and brine and the organic phase was dried over $MgSO_4$ and evaporated to dryness *in vacuo*. The crude oily residue was purified by chromatography on a silica gel column (hexane:EtOAc, 10:1) to give methyl 2-oxohexanoate (1.88 g, 94% from bromide, 77% from oxalate) as a colorless oil. The keto ester was characterized spectroscopically; IR (film) ν_{max}: 2958, 1734, 1730, 900, and 650 cm^{-1}; ^1H NMR ($CDCl_3$, 200 MHz) δ 3.85 (3H, s), 2.85 (2H, t, J = 6.8 Hz), 1.75–1.60 (2H, m), 1.50–1.20 (2H, m), 0.90 (3H, t, J = 7.0 Hz).

A mixture of methyl 2-oxohexanoate (1.60 g, 11.1 mmol) and chlorotrimethylsilane (1.82 mL, 1.56 g, 14.4 mmol) in dry THF (10 mL) was added slowly to a solution of triethylamine (2.3 mL, 1.67 g, 16.5 mmol) in THF (20 mL). The mixture was heated under reflux in an atmosphere of dry nitrogen for 12 h, and after cooling to attain room temperature, it was diluted by addition of ether (50 mL). The resulting mixture was filtered through Celite and the filtrate was washed with with cold 5% HCl and brine. The organic layer was dried over $MgSO_4$ and concentrated under reduced pressure. Fractional distillation of the crude product afforded methyl 2-trimethylsilyloxyhex-2-enoate, **3**, (2.35 g, 98%) as a colorless oil: IR ($CHCl_3$) ν_{max}: 2985, 1720, 1650, 1230, 900, and 840 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 6.07 (1H, t, J = 7.5 Hz), 3.75 (3H, s), 2.11 (2H, dd J = 7.5 and 14.8 Hz), 1.52–1.38 (2H, m), 0.95 (3H, t, J = 7.5 Hz) and 0.20 (9H, s); ^{13}C NMR δ: 165.3, 140.4, 123.7, 51.8, 27.8, 21.9, 13.9, 0.37; LREIMS *m/z* (relative intensity) (ion): 216 (6) $(M)^+$, 215 (8) $(M–H)^+$, 201 (100) $(M–CH_3)^+$, 187 (31) $(M–C_2H_5)^+$, 157 (14) $(M–CO_2CH_3)^+$, 89 (87) $(OSiMe_3)^+$, 73 (88) $(SiMe_3)^+$, 59 (15) $(CO_2CH_3)^+$.

*Methyl 2,2-dichloro-3-oxo-4-*n*-propyl-1-trimethylsilyloxycyclobutyl carboxylate, **4***: A solution of trichloroacetyl chloride (1.0 mL, 1.63 g, 8.96 mmol) in dry ether (20 mL) was added dropwise over a 4 h period under an argon atmosphere to a stirred suspension of activated zinc dust (16) (700 mg, 10.7 mg-atom) and methyl 2-trimethylsilyloxyhex-2-enoate (2.0 g, 9.24 mmol) in ether (50 mL) at ambient temperature. The reaction mixture was set aside with stirring for 12 h. It was then filtered, and the filtrate was evaporated *in vacuo* to about 10 mL. The residue was diluted by addition of pentane (50 mL) with vigorous stirring. The resulting suspension was set aside until the zinc salt separated, and the supernatent was decanted. The pentane solution was washed with cold 5% $NaHCO_3$ solution and brine, dried ($MgSO_4$) and distilled under reduced pressure.

The cyclobutane product, **4**, (2.64 g, 87%) was collected as a pale yellow oil, bp 89–92°C/1.4 Torr; IR (film) ν_{max}: 2960, 2878, 1818, 1755, 1460, 1292, and 846 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ: 4.01 (1H, t, J = 7.6 Hz), 3.86 (3H, s), 1.80–1.71 (2H, m), 1.56–1.43 (2H, m), 0.93 (3H, t, J = 7.2 Hz), and 0.26 (9H, s); ^{13}C NMR δ: 194.7, 169.0, 128.3, 81.3, 62.9, 52.8, 27.7, 20.7, 13.8, and 1.3; LREIMS *m/z*: 311 $(M–CH_3)^+$.

*Methyl 4,4-dichloro-2-*n*-propyl-1,3-bistrimethylsilyloxycyclobut-2-ene carboxylate, **5***: To a stirred solution of cyclobutanone, **4**, (1.0 g, 3.06 mmol) in dry dimethoxyethane (20 mL) cooled to –70°C under argon was added 1,4 diazabicyclo[2.2.2]octane (140 mg, 1.25 mmol). Freshly distilled chlorotrimethylsilane (0.5 mL, 0.428 g, 3.94 mmol) was added by syringe via a septum, and the mixture was allowed to attain ambient temperature and stirred for 24 h. After dilution of the milky brown reaction mixture by addition of pentane (30 mL), it was filtered through Celite. The filtrate was washed successively with ice-cold 5% $NaHCO_3$ solution and brine and then dried over $MgSO_4$. The solvent was removed under reduced pressure and chromatography of the residue on silica gel (hexane:EtOAc, 5:1) afforded the trimethylsilyl enol ether, **5**, (1.03 g, 87%) as a colorless oil; IR (film) ν_{max}: 2950, 1743, 1642, and 851 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$) δ: 3.74 (3H, s), 2.20–2.00 (2H, m), 1.50–1.45 (2H, m), 0.82 (3H, t, J = 7.3 Hz), 0.33 (9H, s) and 0.26 (9H, s).

*Methyl 2,2-dichloro-3-oxo-5-*n*-propyl-1-trimethylsilyloxycyclopentane carboxylate, **7***: To a stirred solution of cyclobutanone, **4**, (1.0 g, 3.06 mmol) in dry ether (30 mL), cooled in an ice-bath, was added slowly a freshly prepared 0.22 M solution of diazomethane (29 mL, 6.38 mmol), followed by methanol (5 mL). The cooling bath was then removed and the mixture was set aside at ambient temperature for 30 min, when reaction was judged to be complete on the basis of TLC analysis. Addition of a few drops of acetic acid ensured

© 2000 NRC Canada

that no excess diazomethane remained, and the solution was then washed successively with saturated $NaHCO_3$ solution and brine. It was then dried over $MgSO_4$ and the amorphous material remaining after removal of solvent *in vacuo* was purified by flash chromatography on a column of silica gel (hexane:EtOAc, 5:1), affording the pure cyclopentanone, **7** (2.04 g, 98%) as fine crystals, mp 101–103°C; IR ($CHCl_3$) ν_{max}: 2989, 1780, 1750, 900, and 750 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ: 3.84 (3H, s), 3.10–3.00 (1H, m), 2.75 (1H, dd, *J* = 18.9 and 8.9 Hz), 2.05 (1H, dd, *J* = 19.0 and 11.1 Hz), 1.60–1.20 (4H, m), 0.90 (3H, t, *J* = 7.4 Hz) and 0.25 (9H, s); ^{13}C NMR δ: 198.7, 167.9, 87.2, 87.0, 52.5, 38.9, 36.4, 32.5, 20.7, 14.1, and 1.6; HREIMS *m/z* (ion): 340.0665, M^+, (calcd. for $C_{13}H_{22}O_4Si^{35}Cl_2$: 340.0664).

*Methyl 5,5-dichloro-4-oxo-2-*n*-propyl-1-trimethylsilyloxy-cyclopent-2-ene carboxylate*, ***8***: A mixture of cyclopentanone (**7**) (1.0 g, 2.93 mmol) and selenium dioxide (467 mg, 4.21 mmol) in toluene was heated under reflux in an atmosphere of argon for 12 h. The reaction mixture was allowed to attain room temperature, and was then diluted by addition of hexane (50 mL) and filtered through Celite. The filtrate was evaporated to dryness *in vacuo*, and the residue was purified by chromatography on a column of silica gel (hexane:EtOAc, 10:1), affording cyclopentenone **8** (767 mg, 77%) as a pale yellow oil; IR (film) ν_{max}: 2960, 1755, 1743, and 851 cm^{-1}; UV λ_{max} (EtOH): 246 nm (ε = 10,900); ^1H NMR (400 MHz, $CDCl_3$) δ: 6.20 (1H, t, *J* = 1.5 Hz), 3.76 (3H, s), 2.25 (2H, ddd, *J* = 5.4, 7.3, and 16.5 Hz), 1.55 (2H, dt, *J* = 7.3 and 16.8 Hz), 0.98 (3H, t, *J* = 7.4 Hz) and 0.30 (9H, s); ^{13}C NMR δ: 189.9, 175.5, 168.8, 125.3, 124.9, 87.7, 53.4, 30.8, 19.8, 13.6, and 2.1; HREIMS *m/z* (ion): 323.0281, $(M–CH_3)^+$, (calcd for $C_{12}H_{17}O_4Si^{35}Cl_2$: 323.0273).

Preparation of silyl enol ether, ***9***: A solution of cyclopentenone, **8** (1.01 g, 2.98 mmol) and chlorotrimethylsilane (0.5 mL, 428 mg, 3.94 mmol) in dry tetrahydrofuran (10 mL) was added dropwise to a mixture of dry triethylamine (0.6 mL, 4.30 mmol) and sodium hydride (cf. 17) (7.2 mg, 0.30 mmol) in tetrahydrofuran (20 mL). The mixture was set aside with stirring at ambient temperature under an argon atmosphere for 30 min, and was then heated under reflux for 15 h. The reaction mixture was allowed to attain room temperature and was then diluted by addition of ether (100 mL) and filtered through Celite. The filtrate was washed successively with cold 5% HCl solution, saturated $NaHCO_3$ solution, and brine and then dried over $MgSO_4$. The solvent was removed under reduced pressure to yield the silyl enol ether, **9** (1.09 g, 89%) sufficiently pure to be used directly for the subsequent reaction; IR (film) ν_{max}: 2936, 1742, and 1225 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ: 5.58 (1H, s), 5.20 (1H, t, *J* = 3.9Hz), 3.65 (3H, s), 2.10–2.00 (2H, m), 0.95 (3H, t, *J* = 7.0 Hz), 0.35 (9H, s), and 0.31 (9H, s); LREIMS *m/z* (relative intensity) (ion): 339 (6) $(M–^{35}Cl–H^{35}Cl)^+$, 321 (5) $(M–OSiMe_3)^+$, 295 (16), 279 (11), 205 (21), 89 (33) $(OSiMe_3)^+$, 73 (100) $(SiMe_3)^+$, 59 (21) $(CO_2CH_3)^+$.

Preparation of dienone, ***10***: To a solution of phenylselenenyl chloride (464 mg, 2.42 mmol) in dichloromethane (10 mL), cooled to –10°C, was added 1 M $TiCl_4$ (2.5 mL, 2.5 mmol). The mixture was cooled to to –78°C and a solution of silyl enol ether, **9**, (1.00 g, 2.43 mmol) in dichloromethane (20 mL) was gradually added from a dropping funnel over a 1 h period. The reaction mixture was stirred at –78°C for 4 h and was then allowed to warm up to ambient temperature. A cold saturated solution of NH_4Cl (30 mL) was added and the mixture was extracted with ether (3 × 50 mL). The extracts were washed with brine, dried ($MgSO_4$), and evaporated to dryness *in vacuo*. The residue was purified by flash chromatography on a column of silica gel (hexane:EtOAc, 10:1) furnishing the allylic phenyl selenide (980 mg, 82%) as a pale yellow oil; IR (film) ν_{max}: 2959, 1740, 1738, 1520, and 840 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ: 7.4 (5H, m), 5.72 (1H, s), 3.66 (3H, s), 3.58 (1H, t, *J* = 6.7 Hz) 1.90–1.70 (2H, m), 0.90 (3H, t, *J* = 7.0 Hz), and 0.36 (9H, s); LREIMS *m/z* (relative intensity) (ion): 492 (8) (M^+), 477 (16) $(M–CH_3)^+$, 434 (3) $(MH–CO_2CH_3)^+$, 336 (23) $(M–PhSe)^+$, 322 (47), 294 (41) $(M–C_3H_6PhSe)^+$, 278 (100), 156 (37) $(PhSe)^+$, 93 (33), 89 (25), $(OSiMe_3)^+$,73 (82) $(SiMe_3)^+$.

The γ-phenyl selenide product (500 mg, 1.01 mmol) was dissolved in dry THF (10 mL). To the resulting solution, cooled to 0°C, was added 30% H_2O_2 solution (0.9 mL, ~7.9 mmol) and the mixture was set aside at 0°C with stirring for 2 h. The reaction mixture was then diluted by addition of ether (20 mL), and the solution was washed with saturated $NaHCO_3$ solution (2 × ~20 mL), dried ($MgSO_4$), and evaporated to dryness under reduced pressure. The residue was purified by chromatography on a column of silica gel (hexane:EtOAc, 10:1), furnishing the pure dienone, **10** (202 mg, 60%) as a pale yellow oil; IR (film) ν_{max}: 3440, 2954, 1740, 1738, 1600, 1200, and 956 cm^{-1}; UV λ_{max} (EtOH): 282 nm (ε = 16,800); ^1H NMR (400 MHz, $CDCl_3$) δ: 6.65 (1H, dt, *J* = 6.9 and 16.0 Hz), 6.30 (1H, s), 6.28 (1H, d, *J* = 15.8 Hz), 3.68 (3H, s), 1.90 (3H, d, *J* = 6.8 Hz), and 0.34 (9H, s); ^{13}C NMR δ: 189.8, 169.1, 165.9, 142.2, 123.2, 122.8, 89.6, 88.2, 53.5, 19.7, and 1.8; LREIMS *m/z* (relative intensity) (ion): 336 (8) (M^+), 320 (39) $(M–CH_3\text{-}H)^+$, 278 (75) $(MH\text{-}CO_2CH_3)^+$, 276 (79) $(M–CO_2CH_3\text{-}H)^+$, 242 (25) $(C_7H_{12}O_3Si^{35}Cl_2)$, 149 (100), 73 (82) $(SiMe_3)^+$.

Methyl 5-chloro-4-oxo-2-propenyl-1-trimethylsilyloxy-cyclopent-2-ene carboxylate, ***11***: The dienone **10** (300 mg, 0.99 mmol) was dissolved in 1:1 acetic acid-water (20 mL). Zinc powder (57 mg, 0.87 mg-atom) was added in one portion and the mixture was set aside with stirring at ambient temperature for 10 min. It was then diluted by addition of water (50 mL) and the mixture was extracted with ether (3 × 50 mL). The extracts were washed with saturated $NaHCO_3$ solution (3 × ~25 mL) and brine and then dried ($MgSO_4$) and evaporated to dryness under reduced pressure. The residue was purified by chromatography on a column of silica gel (hexane:EtOAc, 10:1), affording methyl 5-chloro-4-oxo-2-propenyl-1-trimethylsilyloxy-cyclopent-2-ene carboxylate, **11**, as a single epimer (183 mg, 68%); IR (film) ν_{max}: 2958, 2878, 1762, 1750, 1620, and 844 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ: 6.80–6.60 (1H, m), 6.27 (1H, s), 6.20 (1H, d, *J* = 1.6 Hz), 4.45 (1H, s), 3.80 (3H, s), 1.95 (3H, dd, *J* = 1.6 and 5.9 Hz), and 0.24 (9H, s); ^{13}C NMR δ: 194.5, 169.5, 167.6, 141.5, 126.1, 123.4, 67.7, 67.5, 53.0, 19.6, and 1.0; LREIMS *m/z* (relative intensity) (ion): 303 (3) (MH^+), 287 (17) $(M–CH_3)^+$, 259 (6) $(M–C_3H_7)^+$, 243 (31) $(M–CO_2CH_3)^+$, 73 (100) $(SiMe_3)^+$.

Methyl 5-chloro-1-hydroxy-4-oxo-2-propenyl-cyclopent-2-ene carboxylate, Sporormia affinis *metabolite*, ***2***: To a cold stirred solution of methyl 5-chloro-4-oxo-2-propenyl-1-trimethylsilyloxy-cyclopent-2-ene carboxylate, **11** (180 mg, 0.59 mmol) in methanol (~25 mL) was added K_2CO_3 (98 mg, 0.71 mmol) in one portion. Stirring of the cooled reaction mixture was continued until no starting material remained (TLC analysis), and the mixture was then poured into cold water and extracted with ether (3 × 10 mL). The extracts were dried ($MgSO_4$) and evaporated to dryness *in vacuo*. The residue was purified by chromatography on a column of silica gel (hexane:EtOAc, 1:1), affording **2** (77 mg, 56%) as a colorless oil; IR (film) ν_{max}: 3470, 2908, 1742, 1710, 1663, and 838 cm^{-1}; UV λ_{max} (EtOH): 278 nm (ϵ = 23095); ^{1}H NMR (400 MHz, $CDCl_3$) δ: 6.70 (1H, dt, J = 6.8 and 16.0 Hz), 6.28 (1H, s), 6.24 (1H, d, J = 16 Hz), 4.60 (1H, s), 4.35 (1H, s, exchangeable with CD_3OD) 3.80 (3H, s) and 1.90 (3H, d, J = 6.7 Hz); ^{13}C NMR δ: 193.9, 171.2, 164.9, 141.4, 127.8, 123.2, 84.2, 67.1, 54.2, and 19.7; HREIMS *m*/*z* (ion): 230.0342 $(M)^+$, (calcd. for $C_{10}H_{11}O_4{}^{35}Cl$: 230.0346).

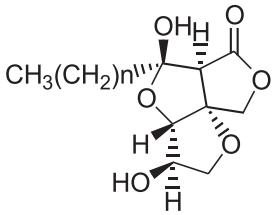
Enantioselective synthesis of syringolide 2 from D-arabinose

Robert Chênevert and Mohammed Dasser

Abstract: Syringolide 2, a bacterial signal molecule which elicits active defence in resistant plants, has been synthesized in 9 steps from 2,3:4,5-di-*O*-isopropylidene-D-arabinose, a known derivative of D-arabinose.

Key words: syringolide, arabinose, synthesis.



Résumé : Le syringolide 2, un signal moléculaire bactérien induisant une défense active chez les plantes résistantes, a été préparé en 9 étapes à partir du 2,3:4,5-di-*O*-isopropylidène-D-arabinose, un dérivé connu du D-arabinose.

Mots clés : syringolide, arabinose, synthèse.

Introduction

Syringolides 1 and 2, the first non-proteinaceous elicitors, were isolated from the plant pathogen bacterium *Pseudomonas syringea* pv. *tomato* by Sims and co-workers in 1993 (1). These elicitors trigger a hypersensitive defence response in soybean plants carrying a resistance gene (2). The hypersensitive defence phenomenon involves the localized cell death in the infected tissues and production of phytoalexins. Syringolides attract considerable interest since they have features in common with antigens recognized by the immune systems of vertebrates. Research on this defence mechanism could lead to cloning of disease-resistance genes and plant immunization through molecular genetic manipulation.

Four different strategies have been proposed for the synthesis of these C-glycosides possessing a new oxygen rich tricyclic structure. Syringolides have been synthesized from xylose (3–5), tartaric acid derivatives (6, 7), butenolides (8, 9), or via the Sharpless catalytic asymmetric dihydroxylation (10). In this paper, we report the enantioselective synthesis of syringolide 2 from D-arabinose.

Syringolide 1 (n=4)
Syringolide 2 (n=6)

Results and discussion

D-Arabinose (**1**) was transformed into di-*O*-isopropylidene-D-arabinose (**2**) in a three step sequence according to known procedures (11) (Scheme 1). Aldehyde **2** was reduced with $NaBH_4$ in ethanol to afford **3**. Alcohol **3** was protected by reaction with *p*-methoxybenzyl chloride (MPM-Cl) in the presence of NaH to give **4**. Regioselective deprotection of **4** was achieved by treatment with methanol under acidic catalysis (*p*-toluenesulfonic acid). The primary alcohol of **5** was selectively acylated with acetyl chloride in the presence of 2,4,6-collidine at –78°C. The Swern oxidation of **6** provided ketone **7**. The acetate group of **7** was selectively removed by transesterification with ethanol in diisopropyl ether in the presence of *Candida antarctica* lipase.

Acylation of **8** with the Meldrum's acid derivative **9** (12) in refluxing THF gave the unstable β-keto ester **10** (Scheme 2). Any attempt to purify **10** by chromatography on silica gel gave **11**, the product of the intramolecular Knoevenagel condensation; thus, **10** was stirred with silica gel in ethyl acetate – hexanes to give **11** in 71% yield for the two last steps. The *p*-methoxy-phenylmethyl (MPM) protecting group was removed by treatment with dichlorodicyanoquinone. All previous syntheses of syringolides invariably involved acid treatment of analogs of compound **12** to give syringolides in very low yields. Recently, Wong et al. (8) reported that the use of *p*-toluenesulfonic acid in large excess improved the yield of this rearrangement. Thus, treatment of **12** with a large excess of *p*-toluenesulfonic acid in acetone–water provided syringolide 2 (**13**) in 54% yield after recrystallization ($[\alpha]_D^{25}$ –75.1 ($CHCl_3$, *c* 0.06); litt. (1) $[\alpha]_D^{24}$ –75.91 ($CHCl_3$, *c* 0.22)). The spectroscopic data of the synthetic syringolide 2 (**13**) were identical to those reported in the literature.

Scheme 1.

Scheme 1. Reagents: (a) $NaBH_4$, EtOH (b) NaH, p-methoxybenzyl chloride, DMF; (c) MeOH, TsOH; (d) AcCl, 2,4,6-collidine, -78°C; (e) $(COCl)_2$, DMSO; (f) *Candida antarctica* lipase, EtOH, diisopropyl ether.

Scheme 2.

Scheme 2. Reagents: (a) THF, reflux; (b) SiO_2, hexanes/EtOAc 9:1; (c) DDQ, CH_2Cl_2-H_2O; (d) TsOH, acetone-H_2O.

In conclusion, syringolide 2 has been synthesized in 9 steps and 15.3% overall yield from diisopropylidene-D-arabinose. Previous syntheses of syringolides from the sugar chiral pool involved the tedious and inefficient isomerization (~7% yield) of xylose to xylulose isolated as its acetonide. Both enantiomers of the starting material, arabinose, are readily

© 2000 NRC Canada

available at a reasonable cost. The use of *p*-toluenesulfonic acid in large excess greatly improved the yield of the last step (rearrangement of **12** to syringolide 2).

Experimental section

Candida antarctica lipase, fraction B (chirazyme L-2, carrier-fixed, lyo., 500 U/mg dry carrier) was purchased from Boehringer Mannheim. Melting points are uncorrected. NMR spectra were recorded at 300 MHz (^{1}H) and 75.44 MHz (^{13}C).

1,2:3,4-Di-*O*-isopropylidene-D-lyxitol (3)

Sodium borohydride (566 mg, 15.28 mmol) was added to a solution of aldehyde **2** (3.52 g, 15.29 mmol) in ethanol 95%. The mixture was stirred at room temperature for 6 h. The mixture was cooled to 0°C and acidified with 1 N HCl. The solvent was evaporated and the residue was dissolved in ether (200 mL), washed with 1 N HCl (30 mL), saturated aqueous $NaHCO_3$ (30 mL) and brine (2 × 20 mL). The organic layer was dried ($MgSO_4$) and evaporated. Flash chromatography on silica gel (EtOAc:hexane, 3:7) gave **3** (3.2 g, 90%) as a colorless oil. $[\alpha]_D^{25}$ –1.0 ($CHCl_3$, *c* 3.38); IR (neat) ν_{max}: 3700–3000, 3000–2800, 1380, 1370, 1300–1100 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 4.05 (1H, dd, J_1 = 8.4 Hz, J_2 = 6.0 Hz), 3.92 (3H, m), 4.27 (1H, dd, J_1 = 11.7 Hz, J_2 = 4.3 Hz), 3.62 (2H, m), 2.75 (1H, s), 1.33 (3H, s), 1.31 (3H, s), 1.29 (3H, s), 1.25 (3H, s); ^{13}C NMR ($CDCl_3$) δ: 109.57, 109.20, 80.75, 78.65, 76.95, 67.62, 62.51, 26.77, 26.70, 26.42, 24.97; HRMS (CI, NH_3) *m/z*: calcd. for $C_{11}H_{21}O_5$: 233.1389 (MH^+), found 233.1393 ± 0.0007.

1,2:3,4-Di-*O*-isopropylidene-5-*O*-*p*-methoxybenzyl-D-lyxitol (4)

To a suspension of NaH (359.6 mg, 14.98 mmol) in dry DMF (10 mL) at 0°C and under dry nitrogen atmosphere was added dropwise a solution of **3** (2.23 g, 9.99 mmol) in DMF (50 mL). The mixture was stirred for 30 min at 0°C and the *p*-methoxybenzyl chloride (1.625 mL, 11.98 mmol) was added. The mixture was stirred for 1 h at 0°C and then overnight at room temperature. The mixture was then filtered through Celite and the filtrate was diluted with ether (300 mL), washed with water (3 × 60 mL). The organic phase was dried ($MgSO_4$) and evaporated. Flash chromatography on silica gel (ether:petroleum ether, 1:4) gave **4** (3.21 g, 91%) as a colorless oil. $[\alpha]_D^{25}$ +8.0 ($CHCl_3$, *c* 3.0); IR (neat) ν_{max}: 3090–3000, 2900–2800, 1380, 1370, 1300–1100 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 7.24 (2H, d, *J* = 8.6 Hz), 6.84 (2H, d, *J* = 8.6 Hz), 4.50 (2H, s), 4.42–3.99 (3H, m), 3.86 (1H, m), 3.75 (3H, s), 3.70 (2H, m), 3.52 (1H, dd, J_1 = 10 Hz, J_2 = 6 Hz), 1.38 (3H, s), 1.36 (3H, s), 1.31 (3H, s), 1.29 (3H, s); ^{13}C NMR ($CDCl_3$) δ: 159.04, 130.95, 129.16, 113.55, 109.56, 109.39, 79.58, 77.57, 77.43, 72.93, 70.20, 67.39, 55.05, 26.92, 26.47, 25.10; HRMS (CI, NH_3) *m/z*: calcd. for $C_{19}H_{28}O_6$: 352.1886 (M^+), found 352.1893 ± 0.0010.

3,4-*O*-Isopropylidene-5-*O*-*p*-methoxybenzyl-D-lyxitol (5)

To a solution of diacetonide **4** (4.0 g, 11.34 mmol) in anhydrous methanol (40 mL) maintained at ~ 10°C was added *p*-toluenesulfonic acid (80 mg). The reaction was followed by thin layer chromatography (EtOAc; **4**, rf = 0.9; **5**, rf = 0.2, corresponding tetraol, rf = 0) and stopped after ~ 10 h. Triethylamine (1 mL) was added and the solvent was evaporated. Flash chromatography of the crude product (gradient from ether:hexane 1:1 to 4:1 and then pure MeOH) provided **5** (2.6 g, 73%) as a colorless oil along with starting material **4** (200 mg) and the corresponding tetraol (182 mg). $[\alpha]_D^{25}$ –15.52 ($CHCl_3$, *c* 1.15); IR (neat) ν_{max}: 3600–3100, 3000–2050, 2950–2850, 1380, 1370, 1300–1100 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 7.17 (2H, d, *J* = 8.5 Hz), 6.80 (2H, d, *J* = 8.5 Hz), 4.45 (2H, s), 4.00 (1H, m), 3.72 (3H, s), 3.70–3.53 (5H, m), 3.46 (1H, dd, J_1 = 9.1 Hz, J_2 = 7.4 Hz), 1.30 (6H, s); ^{13}C NMR ($CDCl_3$) δ: 159.45, 129.56, 128.74, 113.85, 109.23, 80.51, 77.89, 73.48, 72.17, 70.20, 63.80, 55.13, 26.66; HRMS (CI, NH_3) *m/z*: calcd. for $C_{16}H_{24}O_6$ 312.1573 (M^+), found 312.1581 ± 0.0009.

1-*O*-Acetyl-3,4-*O*-isopropylidene-5-*O*-*p*-methoxybenzyl-D-lyxitol (6)

To a solution of **5** (1.83 g, 5.86 mmol) in dry CH_2Cl_2 (60 mL) cooled to –78°C was added freshly distilled 2,4,6-collidine (1.55 mL, 2 equiv.). After stirring for 5 min, acetyl chloride (0.55 mL, 1.2 equiv.) was added dropwise and the solution was stirred for 2 h at –78°C. Dichloromethane (200 mL) was added and the resulting organic phase was washed with 0.5 N HCl (1 × 50 mL), saturated aqueous $NaHCO_3$ (1 × 50 mL) and water (2 × 50 mL). The organic layer was dried ($MgSO_4$) and evaporated. Flash chromatography on silica gel (EtOAc:hexane, 3:7) gave **6** (1.87 g, 90%) as a colorless oil. $[\alpha]_D^{25}$ –1.0 ($CHCl_3$, *c* 2.45); IR (neat) ν_{max}: 3600–3150, 3010–2980, 2980–2800, 1740, 1380, 1370, 1300–1000 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 7.24 (2H, d, *J* = 8.6 Hz), 6.87 (2H, d, *J* = 8.6 Hz), 4.52 (2H, s), 4.37 (1H, dd, *J* = 2.3 Hz), 4.06 (2H, m), 3.79 (4H, m), 3.70 (2H, m), 3.53 (1H, dd, J_1 = 9.3 Hz, J_2 = 6.7 Hz), 3.43 (1H, br s), 2.09 (3H, s), 1.36 (6H, s); ^{13}C NMR ($CDCl_3$) δ: 171.05, 159.31, 129.41, 129.11, 113.75, 109.37, 78.97, 78.51, 73.27, 70.98, 70.11, 66.08, 55.06, 26.67, 20.70; HRMS (CI, NH_3) *m/z*: calcd. for $C_{18}H_{26}O_7$: 354.1678 (M^+), found 354.1672 ± 0.0010.

(3*R*,4*R*)-1-Acetyl-3,4-isopropylidene-5-*p*-methoxybenzyl-1,3,4,5-tetrahydroxy-2-pentanone (7)

A solution of DMSO (872 µL, 11.33 mmol) in dichloromethane (6 mL) was added to a solution of oxalyl chloride (546 µL, 6.2 mmol) in dichloromethane (6 mL) at –78°C. The mixture was stirred for 20 min under dry nitrogen atmosphere. A solution of alcohol **6** (1.70 g, 4.783 mmol) in dichloromethane (50 mL) was added dropwise and the solution was stirred for 2 h at –78°C. Triethylamine (2.96 mL, 23.92 mmol) was added and the solution was allowed to reach room temperature. The reaction was diluted with dichloromethane (250 mL) and washed with water (40 mL), saturated aqueous $NaHCO_3$ (40 mL) and brine (3 × 40 mL). The organic phase was dried ($MgSO_4$) and evaporated. The crude product was purified by flash chromatography on silica gel (AcOEt:hexane, 3:7) to give ketone **7** (1.466 g, 87%) as a colorless oil. $[\alpha]_D^{25}$ –12.65 ($CHCl_3$, *c* 2.6); IR (film) ν_{max}: 3100–3000, 3000–2800, 1760, 1730, 1380, 1370, 1300–1100 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 7.17 (2H, d, *J* = 8.6 Hz), 6.79 (2H, d, *J* = 8.6 Hz), 4.99 (1H, d, *J* = 17.8 Hz), 4.79 (1H, d, *J* = 17.8 Hz), 4.45 (2H, s), 4.26 (1H, d, *J* = 7.9 Hz), 4.20 (1H, m), 3.71 (3H, s), 3.64 (2H, dd, J_1 = 11.0 Hz, J_2 = 2.9 Hz), 3.51 (2H, dd, J_1 = 11.0 Hz,

© 2000 NRC Canada

J_2 = 5.1 Hz), 2.08 (3H, s), 1.39 (3H, s), 1.37 (3H, s); ^{13}C NMR ($CDCl_3$) δ: 202.46, 170.01, 159.13, 129.76, 129.18, 113.66, 111.34, 80.14, 77.38, 73.10, 69.18, 66.10, 55.08, 26.53, 25.97, 20.21. HRMS (CI, NH_3) *m*/*z*: calcd. for $C_{18}H_{24}O_7$: 352.1522 (M^+), found 352.1529 ± 0.0010.

(3*S*,4*R*)-3,4-Isopropylidene-5-*p*-methoxybenzyl-1,3,4,5-tetrahydroxy-2-pentanone (8)

Candida antarctica lipase (800 mg, total weigh enzyme on carrier, 500 U/mg dry carrier) and ethanol (1.0 mL, 17.0 mmol) were added to a solution of compound **7** (1.2 g, 3.4 mmol) in diisopropyl ether (30 mL) and the reaction mixture was stirred at room temperature. The reaction was followed by thin layer chromatography (ether:hexane, 1:1) and stopped when all the starting material was gone (~15 h). The reaction mixture was filtered and evaporated. Flash chromatography on silica gel (ether:hexane, 1:1) gave **8** (897 mg, 85%) as a colorless oil. $[\alpha]_D^{25}$ –7.7° ($CHCl_3$, *c* 1.45); IR (film) ν_{max}: 3600–3100, 3100–3000, 2990–2800, 1730, 1380, 1370, 1300–1100 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 7.18 (2H, d, *J* = 8.6 Hz), 6.80 (2H, d, *J* = 8.6 Hz), 4.47 (2H, s), 4.44 (2H, m), 4.31 (1H, d, *J* = 8.0 Hz), 4.11 (1H, m), 3.72 (3H, s), 3.67 (1H, dd, J_1 = 3.1 Hz, J_2 = 10.7 Hz), 3.55 (1H, dd, J_1 = 5.2 Hz, J_2 = 10.7 Hz), 2.88 (1H, t, *J* = 5.0 Hz), 1.39 (3H, s), 1.34 (3H, s); ^{13}C NMR ($CDCl_3$) δ: 209.10, 159.21, 129.67, 129.22, 113.72, 111.36, 79.98, 76.90, 73.21, 69.23, 66.12, 55.13, 26.65, 26.01; HRMS (CI, NH_3) *m*/*z*: calcd. for $C_{16}H_{22}O_6$: 310.1416 (M^+), found 310.1421 ± 0.0009.

(1′*R*,2′*R*)-3-[1′,2′-(Isopropylidenedioxy)-3′-(*p*-methoxybenzyloxy)propyl]-2-octanoyl-2-buten-4-olide (11)

The octanoyl Meldrum's derivative **9** was prepared by stirring equimolar amounts of Meldrum's acid (2,2-dimethyl-1,3-dioxane-4,6-dione) and *n*-octanoyl chloride in dichloromethane at 0°C for 8 h.

A solution of alcohol **8** (380 mg, 1.224 mmol) and Meldrum's derivative **9** (397 mg, 1.469 mmol) in THF was brought to reflux during 3 h. The solvent was evaporated and the residue was dissolved in hexane:ethyl acetate 9:1 (15 mL) in the presence of silica gel (1 g). The mixture was stirred at room temperature for 18 h. Silica gel was filtered and the solvents were evaporated. Flash chromatography on silica gel (ethyl acetate:hexane, 3:7) gave **11** (402 mg, 71%) as a colorless oil. $[\alpha]_D^{25}$ –23.6 ($CHCl_3$, *c* 1.2); IR (film) ν_{max}: 3080–2990, 2990–2800, 1780, 1700, 1640, 1370, 1360, 1300–1100 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 7.23 (2H, d, *J* = 8.6 Hz), 6.84 (2H, d, *J* = 8.6 Hz), 5.43 (1H, d, *J* = 8.2 Hz), 5.03 (1H, d, *J* = 19.8 Hz), 4.83 (1H, d, *J* = 19.8 Hz), 4.55 (1H, d, *J* = 11.6 Hz), 4.45 (1H, d, *J* = 11.6 Hz), 3.97 (1H, m), 3.78 (3H, s), 3.72 (2H, d, *J* = 4.8 Hz), 2.91 (2H, t, *J* = 7.0 Hz), 1.57 (2H, m), 1.43 (6H, s), 1.27 (8H, m), 0.86 (3H, t, *J* = 5.7 Hz); ^{13}C NMR ($CDCl_3$) δ: 196.56, 172.47, 170.08, 159.16, 129.69, 129.31, 126.71, 113.61, 110.96, 80.69, 73.76, 73.15, 69.78, 68.88, 55.10, 41.84, 31.53, 28.95, 28.87, 26.64, 23.03, 22.45, 13.92; HRMS (CI, isobutane) *m*/*z*: calcd. for $C_{26}H_{36}O_7$: 460.2461 (M^+), found 460.2464 ± 0.0014.

(1′*R*,2′*R*)-3-[3′-(Hydroxy)-1′,2′-(isopropylidenedioxy)propyl]-2-octanoyl-2-buten-4-olide (12)

Compound **11** (350 mg, 0.76 mmol) was dissolved in a mixture of CH_2Cl_2 (10 mL) and water (0.5 mL). DDQ (266 mg, 1.5 equiv.) was added and the mixture was stirred at room temperature. The reaction was followed by TLC and quenched after 4 h. The reaction mixture was diluted with CH_2Cl_2 (60 mL), filtered and washed with saturated aqueous $NaHCO_3$ (10 mL) and brine (3 × 10 mL). The organic layer was dried (Na_2SO_4) and evaporated. The crude product was purified by flash chromatography on silica gel (ethyl acetate:hexane, gradient 1:4 to 2:3) to give **12** (215 mg, 83%) as a colorless oil. $[\alpha]_D^{25}$ –60.0 ($CHCl_3$, *c* 1.6); IR (film) ν_{max}: 3600–3100, 2990–2800, 1790, 1710, 1620, 1370, 1360, 1300–1100 cm^{-1}; ^{1}H NMR ($CDCl_3$) δ: 5.39 (1H, d, *J* = 8.0 Hz), 5.10 (1H, d, *J* = 19.8 Hz), 4.85 (1H, d, *J* = 19.8 Hz), 3.96–3.80 (3H, m), 3.09 (1H, m), 2.92 (1H, m), 1.58 (2H, m), 1.45 (6H, s), 1.27 (8H, m) 0.97 (3H, t, *J* = 7.0 Hz); ^{13}C NMR ($CDCl_3$) δ: 198.75, 173.33, 169.74, 126.75, 110.54, 81.44, 73.82, 69.02, 61.42, 41.92, 31.49, 28.91, 28.84, 26.65, 23.04, 22.46, 13.93; HRMS (CI, NH_3) *m*/*z*: calcd. for $C_{18}H_{29}O_6$: 341.1964 (MH^+), found 341.1956 ± 0.0010.

Syringolide 2 (13)

A solution of **12** (140 mg, 0.411 mmol) and *p*-toluenesulfonic acid (782 mg, 10 equiv.) in acetone:water (1:1.2, 10 mL) was stirred for 56 h at room temperature. The solution was neutralized with saturated aqueous $NaHCO_3$ (2 mL) and extracted with ethyl acetate (3 × 20 mL). The organic layer was washed with brine (3 × 5 mL), dried over Na_2SO_4 and evaporated. The residue was redissolved in EtOAc (3 mL) and the solution was filtered through silica gel and evaporated. The product was washed with hexane to give syringolide 2 (95 mg, 77%) as a pale yellow solid. A fraction was recrystallized in pentane:ether 2:1 to give pure syringolide 2 (66.5 mg, 54%) as a colorless solid. Mp 122–123°C; $[\alpha]_D^{25}$ –75.1 ($CHCl_3$, c 0.06); lit. (1) mp 123–124°C $[\alpha]_D^{24}$ –75.91 ($CHCl_3$, *c* 0.22); IR (KBr) ν_{max}: 3600–3100, 2990–2800, 1770, 1300–1100 cm^{-1}; ^{1}H NMR (acetone-d_6) δ: 5.38 (1H, d, *J* = 1.9 Hz), 4.68 (1H, d, *J* = 10.2 Hz), 4.49 (1H, br s), 4.33 (1H, d, *J* = 10.2 Hz), 4.30 (1H, d, *J* = 4.2 Hz), 4.13 (1H, m), 3.94 (1H, dd, J_1 = 10.1 Hz, J_2 = 1.0 Hz), 3.83 (1H, dd, J_1 = 10.1 Hz, J_2 = 2.8 Hz), 3.10 (1H, s), 1.89 (2H, m), 1.70–1.40 (2H, m), 1.30 (8H, m), 0.87 (3H, t, *J* = 7.0 Hz); ^{13}C NMR (acetone-d_6) δ: 172.70, 108.72, 99.00, 92.16, 75.50, 75.32, 74.81, 59.63, 39.36, 32.40, 30.45, 29.40, 24.27, 23.15, 14.18. HRMS (CI, NH_3) *m*/*z*: calcd. for $C_{15}H_{25}O_6$: 301.1651 (MH^+), found 301.1657 ± 0.0009.

Pseudo-oxocarbons complexes — complexation of 2,4-bis(dicyanomethylene)-cyclobutane-1,3-dione dianion with copper. X-ray identification and electrochemical properties of the dianion and copper(I) and (II) complexes[1]

Paul-Louis Fabre, Christophe Pena, Anne Marie Galibert, Brigitte Soula, Gérald Bernardinelli, Bruno Donnadieu, and Paule Castan

Abstract: The compound $(Ph_4P)_2$(*trans*-cdcb)·$2H_2O$ (*trans*-$cdcb^{2-}$ = 2,4-bis(dicyanomethylene)-cyclobutane-1,3-dione dianion) has been synthesized and characterized by X-ray crystallography. Crystal data: triclinic, space group $P\bar{1}$, a = 10.829(2) Å, b = 11.297(2) Å, c = 11.515(2) Å, α = 79.61(1)°, β = 68.54(1)°, γ = 63.49(1)°, V = 1172.9(4) Å^3, Z = 1, R = 0.036, Rw = 0.047. With the dianion as a ligand, two complexes have been obtained and characterized by X-ray crystallography, UV–visible spectroscopy, and electrochemistry. The copper(II) complex [Cu(*trans*-cdcb)$(H_2O)_4$·$2H_2O]_n$ consists of polymeric chains with copper atoms bonded to two of the nitrile groups of the ligand. Crystal data: monoclinic, space group $P2_1/c$, a = 9.6366(6) Å, b = 7.1292(3) Å, c = 10.7018(6) Å, β = 99.603(4)°, V = 724.92(7) Å^3, Z = 2, R = 0.026, Rw = 0.041. The copper(I) complex[Cu_2(*trans*-cdcb)$(CH_3CN)_4$·$2CH_3CN]_n$ consists of polymeric chains with copper atoms bonded by all the four nitrile groups of the ligand. Crystal data: monoclinic, space group $P2_1/n$, a = 10.654(2) Å, b = 8.736(1) Å, c = 14.654(3) Å, β = 109.01(2)°, V = 1291.3(9) Å^3, Z = 2, R = 0.037, Rw = 0.041. In CH_3CN solution, the copper complexes are dissociated. Moreover, copper(II) is reduced into copper(I) by the dianion. Electrochemistry in the solid state (polymer coated electrode) showed the redox transitions of the different compounds.

Key words: pseudo-oxocarbons, X-ray diffraction, copper(II) complex, copper(I) complex, electrochemical behaviour.

Résumé : Le composé $(Ph_4P)_2$(*trans*-cdcb)·$2H_2O$ (*trans*-$cdcb^{2-}$ = dianion 2,4-bis(dicyanométhylène)-cyclobutane-1,3-dione) a été synthétisé et caractérisé par diffraction des rayons X. Données cristallographiques : triclinique, groupe d'espace $P\bar{1}$, a = 10.829(2) Å, b = 11.297(2) Å, c = 11.515(2) Å, α = 79.61(1)°, β = 68.54(1)°, γ = 63.49(1)°, V = 1172.9(4) Å^3, Z = 1, R = 0.036, Rw = 0.047. Avec le dianion comme ligand, deux complexes ont été obtenus et caractérisés par diffraction des rayons X, spectroscopie UV–visible et électrochimie. Le complexe du cuivre(II) [Cu(*trans*-cdcb)$(H_2O)_4$·$2H_2O]_n$ se présente comme une chaîne polymérique d'atomes de cuivre pontés par le ligand *trans*-cdcb et liés à deux des groupements nitrile du ligand. Données cristallographiques : monoclinique, groupe d'espace $P2_1/c$, a = 9.6366(6) Å, b = 7.1292(3) Å, c = 10.7018(6) Å, β = 99.603(4)°, V = 724.92(7) Å^3, Z = 2, R = 0.026, Rw = 0.041. Le complexe du cuivre(I) [Cu_2(*trans*-cdcb)$(CH_3CN)_4$·$2CH_3CN]_n$ se présente comme une chaîne polymérique d'atomes de cuivre liés aux quatre groupements nitrile du ligand. Données cristallographiques : monoclinique, groupe d'espace $P2_1/n$, a = 10.654(2) Å, b = 8.736(1) Å, c = 14.654(3) Å, β = 109.01(2)°, V = 1291.3(9) Å^3, Z = 2, R = 0.037, Rw = 0.041. En solution dans l'acétonitrile, les complexes du cuivre sont dissociés. De plus, le cuivre(II) est réduit en cuivre(I) par le dianion. Déposés sur une électrode recouverte d'un polymère, les composés sont électroactifs et présentent des processus redox.

Mots clés : pseudo-oxocarbones, diffraction des rayons X, complexe du cuivre(II), complexe du cuivre(I), électrochimie.

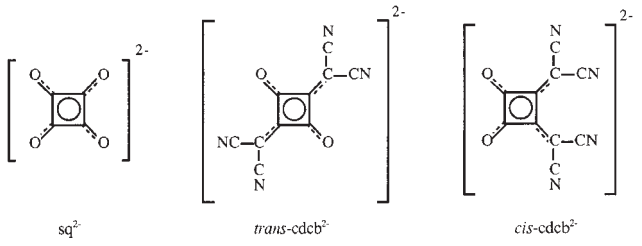
Introduction



Magnetic interactions between paramagnetic centres can be propagated, not only through single atoms, but also through multi-atom bridges (3). Actually, metal dimers or chains with oxalate and dithiooxalate bridges have been known for some time, and relatively strong interactions have been observed. For example, the variable temperature magnetic susceptibility of $Cu(C_2O_4)\cdot 1/3H_2O$ was measured many years ago by a number of investigators (4), and more recently the symmetry factors governing the magnetic behavior of (μ-oxalato)copper(II) complexes were studied (5, 6).

Like oxalate, the squarate ion $C_4O_4^{2-}$ is an intriguing ligand because of its high symmetry and its electronic delocalization. Habenschuss and Gerstein's study (7) of the X-ray structure and magnetic properties of $Ni(C_4O_4)\cdot(H_2O)_2$ revealed an unexpected polymeric solid-state structure and a very low temperature ferromagnetic behaviour. In view of magnetic interactions between metal ions, a lot of copper(II) squarate complexes have been investigated (8–11).

Several species, derived from squarate entity, have been synthesized, in which one or more oxygen atoms have been substituted by other atoms or groups (sulfur, selenium, nitrogen or dicyanomethylene); they are called pseudo-oxocarbons. Among these pseudo-oxocarbons, our interest is focused on derivatives in which one or more oxygen atoms are replaced by dicyanomethylene, $C(CN)_2$, groups (12). They lead to brilliantly colored compounds which may be regarded as cyanine dyes. They are characterized by extensive π electron delocalization, interesting redox behaviour and, for some of them, intrinsic electrical conductivity.

These compounds can react with transition metals to lead to new complexes: molecular materials characterized by electron transport chains, compounds exhibiting magnetic exchange between metal ions, or electrochromic materials. We recently reported (1) on the first complex obtained with *cis*-cdcb^{2-} (3,4-bis(dicyanomethylene)-cyclobutane-1,2-dione dianion).[3] Regardless of the starting copper salt (Cu^I or Cu^{II}) used, only crystals of the copper(I) complex $[\{Cu_2(cdcb)(CH_3CN)_2\}_n]$ were obtained.

According to the synthetic pathway used with *trans*-cdcb^{2-} (2,4-bis(dicyanomethylene)-cyclobutane-1,3-dione dianion), the reduction of copper(II) may be prevented. Therefore copper(II), as well as copper(I), complexes of the dianion could be obtained. We report here on the syntheses and crystallographic investigations of the dianion *trans*-cdcb^{2-} itself and its Cu^I and Cu^{II} complexes. Electrochromic properties of *trans*-cdcb^{2-} and electrochemical behaviour of the two copper complexes are also presented.

Experimental

Reactants and methods

Squaric acid was purchased from Aldrich. CuI was prepared according to Inorganic Syntheses (13). All other chemicals and solvents were reagent grade. IR spectra were recorded in the solid state on nujol mulls or KBr pellets on a Perkin–Elmer 983 G spectrometer. UV–visible reflectance spectra were run in the solid state on a Perkin–Elmer Lambda 9 spectrophotometer. Magnetic susceptibility measurements in the 2–300 K temperature range were carried out with a Faraday-type magnetometer equipped with a continuous-flow Oxford Instruments cryostat. $HgCo(NCS)_4$ was used as a calibrant (susceptibility at 20°C, 16.44×10^{-6} cm^3 mol^{-1}). The molar susceptibilities were corrected for diamagnetism using Pascal's constants (14). The corrections were estimated at -1.5×10^{-5} cm^3 mol^{-1} for all the atoms of **3′**.

Powder conductivities were determined on compressed pellets with a Keithley 224 bridge.

Electrochemical measurements were carried out with a home-made potentiostat or an Autolab (EcoChemie) controlled by a PC computer at room temperature. The electrochemical cell (10 mL) was a conventional one with three electrodes: a working electrode, Pt (diameter 2 mm, EDI Tacussel) for rotating disk electrode experiments (LSV, linear sweep voltammetry) and Pt (disk diameter 0.5 mm) for cyclic voltammetry (CV) experiments; a counter electrode, Pt wire; and a reference electrode, double junction SCE. The experiments were carried out in CH_3CN–Bu_4NPF_6 (0.1 mol L^{-1}) under an argon atmosphere. CH_3CN and Bu_4NPF_6 (electrochemical grade) were used without further purification. A solution of Bu_4NPF_6 was scanned before use to check the purity of the solvent. The reported $E_{1/2}$ values were determined from stationary experiments at a rotating electrode (LSV).

Solid state electrochemistry was carried out according to the technique of polymer coated electrode (15, 16) which protects the electroactive substance from the solvent. The polymer coated electrode was prepared according to a reported procedure (16). A glassy carbon disk electrode (diameter 3mm, EDI Tacussel) was polished and sonicated in methanol and then one drop of a solution of the electroactive compound (50 mg in 5 mL of methanol) was applied to the electrode surface. After the electrode surface was air dried, one drop of the coating solution was added to overcoat the electrode surface. The coating solution was made of 1 g of polyacrylic acid (Aldrich, M_{ave} = 450 000) and 1 g of Bu_4NClO_4 in 15 mL of methanol. The electrode was again air dried. The electrochemical measurements were carried out in the same analytical cell using 0.1 mol L^{-1} CH_3CN–Bu_4NClO_4 as the solvent. The current interrupt method was used to measure the electrode potential in order to compensate for the ohmic drop (17).

[3] In precedent literature the name "carbodicyano" was given to the $C(CN)_2$ group and the acronym "cdcb" to the corresponding cyclobutanedione derivatives. According to the present use, we have adopted the name "dicyanomethylene" for the $C(CN)_2$ unit, but we have maintained the above acronym generally used by others.

Syntheses

*(i) Synthesis of 2,4-bis(dicyanomethylene)-cyclobutane-1,3-dione disodium salt [Na_2(trans-cdcb)·1/2H_2O] (**1**)*

This compound was obtained by reaction of malononitrile on 2,4-dianilinocyclobutene diylylium-1,3-diolate (18) by means of a method derived from that proposed by Seitz and co-workers (19).

To a solution of squaric acid (4.00 g, 0.035 mol) in 35 mL of DMF was added 6.52 g (0.070 mol) of aniline. The yellow solution was heated under reflux for 2 h and during this period a yellow precipitate appeared. Addition of 150 mL of water caused precipitation. The precipitate was separated by filtration and washed with water to remove the mono-adduct which is also obtained during the course of this synthesis. It was then washed several times with hot methanol to remove by-products. After exhaustive washing with warm DMF in order to remove the *cis*-isomer, the remaining yellow precipitate of 2,4-dianilinocyclobutenediylylium-1,3-diolate was dried and used without further purification (55%).

2,4-dianilinocyclobutenediylylium-1,3-diolate (5.30 g, 0.02 mol) was added by parts to a solution of sodium ethoxide (Na, 920 mg, 0.04 mol in dry ethanol 150 mL). After addition of malononitrile (2.64 g, 0.04 mol) the mixture was refluxed for 3 h. During this time the color changed from yellow to orange. After filtration, an orange precipitate was obtained. It was solubilized in 50 mL of hot water and the hot solution was filtered off. Orange needles of **1** were obtained by cooling the solution. Anal. calcd. for $C_{10}H_1N_4Na_2O_{2.5}$: C 45.65, H 0.38, N 21.29; found: C 45.20, H 0.31, N 21.00.

*(ii) [(Ph_4P)$_2$(trans-cdcb)]·2H_2O (**2**)*

This salt was prepared by mixing in 2:1 ratio Ph_4PBr and Na_2(*trans*-cdcb) in water. The orange solid which precipitated immediately was isolated and recrystallized from hot acetonitrile.

*(iii) [Cu(trans-cdcb)(H_2O)$_4$·2H_2O]$_n$ (**3**)*

This compound was obtained by reaction of **1** (0.131 g, 0.5 mmol) in water (25 mL) with $CuCl_2$·2H_2O (0.085 g, 0.5 mmol) in water (10 mL). From the first drops of **1** added to the copper salt, a violet precipitate appeared. This precipitate (**3a**) was filtered off. From the intensely violet filtrate solution, large bronze–violet crystals of **3** with a metallic lustre deposited. Out of the solution, these crystals became amorphous (**3′**) with loss of water. Recrystallization of **3a** or **3′** in water gave bronze–violet crystals of **3**. For **3′**: anal. calcd. for $C_{10}H_8CuN_4O_6$: C 34.94, H 2.35, N 16.30; found: C 33.72, H 2.45, N 16.10. This analysis agrees with the loss of two water molecules from **3**. Crystal structure of **3** is described.

*(iv) [Cu_2(trans-cdcb)(CH_3CN)$_4$·2CH_3CN]$_n$ (**4**)*

Method A: An aqueous solution of **1** (0.131 g, 0.5 mmol in 75 mL of water) was added dropwise to a solution of $CuCl_2$·2H_2O (0.085 g, 0.5 mmol) dissolved in a mixture of water–acetonitrile (5 and 150 mL). From the first drops of **1**, a red color appeared, then the solution became brown. After slow evaporation, orange crystals (**4**) were obtained.

Method B: An aqueous solution of **1** (0.131 g, 0.5 mmol in 50 mL of water) was added to a stoichiometric amount of CuI in acetonitrile (150 mL). The orange solution thus obtained deposited orange crystals (**4**) suitable for crystallographic analysis. **4** immediately became amorphous (**4′**) when the crystals were extracted from the solution. For **4′**: anal. calcd. for $C_{14}H_6Cu_2N_6O_2$: C 40.29, H 1.45, N 20.14; found: C 41.05, H 1.70, N 20.69. This analysis fits the loss of four acetonitrile molecules from **4**.

Crystallography

*X-ray structure determination of **2** and **3***

Selected crystal data, intensity measurements and structure refinement data for **2** and **3** are summarized in Table 1. Unit cell parameters and diffracted intensities were measured at 200 K on a Stoe–Stadi4 diffractometer with graphite monochromated CuKα radiation (λ = 1.5418 Å). For data collection of **3**, a crystal was immersed in RS 3000 oil (Riedel-de Haën) to prevent decomposition and mounted on a quartz fibre. The structure was solved by direct methods (MULTAN 87)[4] and refined by full-matrix least-squares with the XTAL 3.2 program (20). The data were corrected for Lorentz and polarization effects. Absorption corrections were applied with transmission factors ranging between 1.124–1.405 for **2** and 1.201–1.632 for **3**. Atomic scattering factors and anomalous dispersion terms are taken from reference 21. All coordinates of the H atom have been observed and refined using fixed U_{iso} at 0.04 Å^2 for **2** and **3**.

*X-ray structure determination of **4***

Selected crystal data, intensity measurements and structure refinement data for **4** are summarized in Table 1. To prevent decomposition during data collection, the crystal was immersed in RS 3000 oil (Riedel-de Haën) and mounted on a quartz fiber. Unit-cell parameters and diffracted intensities were measured at 160 K with the scan rotation phi mode on a Stoe-I.P.D.S. diffractometer equipped with an Oxford cryosystems cooler device. MoKα (λ = 0.71073 Å) was employed as X-ray source. The structure was solved by direct methods (SIR 92) (22) and refined by least-squares procedures on F_0. H atoms are calculated and not refined. Numerical absorption corrections applied are taken from footnote 5. Atomic scattering factors are taken from reference 21.

Results and discussion

A. Solution studies

As evidenced by conductivity measurements in water, in acetonitrile and DMF, the copper(I) and copper(II) complexes completely dissociate in solution at concentrations required for analytical studies. This is confirmed by electrochemical measurements in CH_3CN–Bu_4NPF_6 0.1 mol L^{-1} at concentration around 10^{-3} mol L^{-1}.

By linear sweep voltammetry at a rotating Pt electrode (Fig. 1), the voltammogram of the free *trans*-cdcb^{2-} ligand

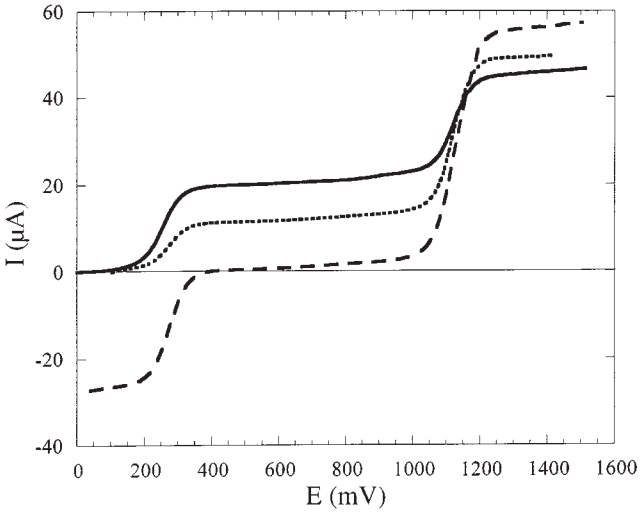
[a]J.R. Carruthers and D.J. Watkin. Acta Crystallogr. Sect. A: Cryst. Phys. Diffr. Theor. Gen. Crystallogr. **A35**, 698 (1979).

shows two oxidation waves (full line) which appear monoelectronic and reversible as previously reported (23, 24):

$$\textit{trans}\text{-cdcb}^{2-} \rightleftharpoons \textit{trans}\text{-cdcb}^{\cdot -} + e^- \quad E^1_{1/2} = 0.255 \text{ V}$$



$$\textit{trans}\text{-cdcb}^{\cdot -} \rightleftharpoons \textit{trans}\text{-cdcb} + e^- \quad E^2_{1/2} = 1.129 \text{ V}$$

The *trans*-cdcb$^{\cdot -}$ radical anion is very stable. Its potential domain ($E^2_{1/2} - E^1_{1/2}$) depends on the solvent: 0.85 V in CH_3CN and 0.73 V in DMF. The *trans*-cdcb$^{\cdot -}$ radical anion is less stabilized in DMF than in CH_3CN. By exhaustive electrolysis of the dianion on the first plateau (0.6 V), the light orange solution turned deep red. Further electrolysis on the second plateau (1.4 V) yielded a transparent solution which is unstable. Only the first redox process is fully reversible and may be used for electrochromic applications.

The voltammogram (dotted line) of a saturated solution (6×10^{-4} mol L^{-1}) of the copper(I) complex (**4′**) presents the same pattern:

- a first oxidation wave ($E^1_{1/2}$ = 0.275 V) attributed to the first oxidation of the dissociated *trans*-cdcb^{2-} ligand, and
- a second oxidation wave ($E^2_{1/2}$ = 1.120 V) which is three times higher than the first one. The observed current ratio is in agreement with a process which involves the second oxidation ($E^2_{1/2}$ = 1.129 V) process of the dissociated *trans*-cdcb^{2-} ligand and the free copper(I) oxidation ($E_{1/2}$ = 1.04 V) into copper (II).

Fig. 1. Voltammograms at a rotating Pt disk electrode (diameter 2 mm, rotation speed 1000 rpm) in acetonitrile–Bu_4NPF_6 0.1 mol L^{-1}: $(Ph_4P)_2$(*trans*-cdcb) 1 mmol L^{-1} (——); copper(I) complex (**4′**) 0.6 mmol L^{-1} (⋯); copper(II) complex (**3′**) 1 mmol L^{-1} (– – –). Potentials are measured versus SCE.

© 2000 NRC Canada

As the dissociation of the complex gives two Cu^+ for one ligand, the ratio 1:3 was observed for the two oxidation waves:

$$Cu^+ \rightleftharpoons Cu^{2+} + e^- \qquad E_{1/2} = 1.04 \text{ V}$$

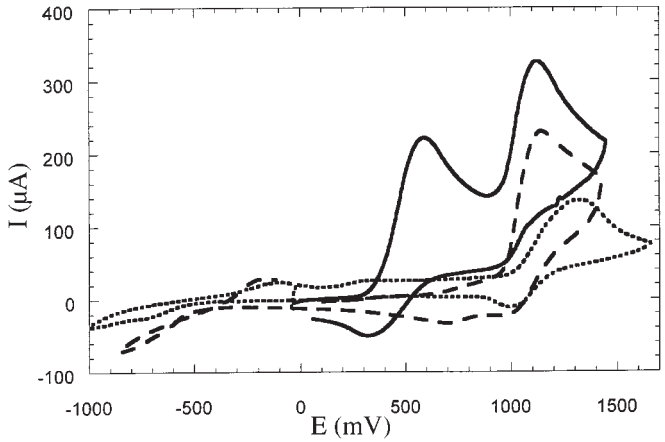
In this case, the invariance of the half-wave potentials is due to the dissociation of the copper(I) complex.

The voltammogram (dashed line) of a 10^{-3} mol L^{-1} solution of the copper(II) complex (**3′**) is slightly different but presents the same general pattern:

- a reduction wave ($E^1_{1/2}$ = 0.275 V) whose half-wave potential matches that of the first electron transfer of the free ligand and

- an oxidation wave ($E^2_{1/2}$ = 1.120 V) which is two times higher than the reduction wave. In the synthesis of **4**, method A, we might expect, through the dissociation of the complex, the oxidation of the *trans*-$cdcb^{2-}$ ligand by Cu^{2+} in CH_3CN solution. This oxidation reaction yields one *trans*-$cdcb^{\cdot -}$ radical anion and one Cu^+:

$$\textit{trans}\text{-}cdcb^{2-} + Cu^{2+} \longrightarrow \textit{trans}\text{-}cdcb^{\cdot -} + Cu^+$$



The recorded voltammogram agrees with this reaction: the reduction wave (one electron) is attributed to the reduction of the radical anion *trans*-$cdcb^{\cdot -}$ and the oxidation wave (one + one electron) is attributed to the oxidation of the radical anion *trans*-$cdcb^{\cdot -}$ and the oxidation of Cu^+ into Cu^{2+}.

From these studies, it appears that the copper complexes show low solubilities and that their dissolution implies dissociation and formation of $[Cu(CH_3CN)_4]^+$ in acetonitrile. The main question: is there a monomeric complex in solution?

The oxidation voltammograms of a Cu disk electrode were recorded as a function of *trans*-$cdcb^{2-}$ concentration. The displacement of the potential at a constant current was then related to the reactions occuring in solution (25). The variations of the potential versus the logarithm of the ligand concentration showed two linear domains: at a *trans*-$cdcb^{2-}$ concentration lower than 10^{-2} mol L^{-1}, a 1:1 complex may be expected, while at higher concentration the precipitate is formed. Unfortunately, the non-Nernstian behaviour of the electrode did not give reliable constant values: the complex formation constant of [Cu(*trans*-cdcb)]$^-$ is around 200. The solubility constant was determined from the voltammogram of a saturated solution (Fig. 1) by the measurement of the limiting current: K_s (Cu_2L) = 2×10^{-10}.

Polarographic measurements were carried out on the polymeric copper(II) complex which is synthesized in water in order to get information on its stability constants. In a typical experiment, a 10^{-4} mol L^{-1} solution of Cu^{2+} was analyzed by tast polarography as a function of *trans*-$cdcb^{2-}$ concentration. For a *trans*-$cdcb^{2-}$ concentration lower than 10^{-4} mol L^{-1}, only the Cu^{2+}–Cu(Hg) couple was observed. When the *trans*-$cdcb^{2-}$ concentration was increased, the polarographic wave turned into two waves, the first one related to the *trans*-$cdcb^{2-}$ concentration. With an increasing amount of *trans*-$cdcb^{2-}$, the copper(II) complex precipitated and the variations of the limiting current led to the determination of the solubility constant: K_s(CuL) = 3×10^{-7}. The splitting of the polarographic wave of the Cu^{2+}–Cu(Hg) couple showed the stabilization of a copper(I) complex as in the case of Cu^{2+}–Cu(Hg) reduction in presence of NH_3 (26). The variations of the half-wave potential versus the logarithm of the ligand concentration did not provide the evidence of the formation of a monomeric copper(II) complex.

Fig. 2. Cyclic voltammograms at a polymer coated glassy carbon disk electrode (diameter 3 mm) in CH_3CN–Bu_4NClO_4 0.1 mol L^{-1}: $(Ph_4P)_2$(*trans*-cdcb) (——); copper(I) complex (**4′**)(···); copper(II) complex (**3′**) (– – –); potential scan speed 0.05 V s^{-1}. Potentials are measured versus SCE.

B. Solid state studies

Bearing in mind the loss of solvent observed for the complexes **3** and **4**, only crystallographic measurements have been performed effectively on **3** and **4**. Spectroscopies, magnetic studies, as well as electrochemical measurements have been performed on **3′** and **4′**.

Least-squares fitting the μ_{eff} values of **3′** within the 2–300 K domain (1.929 at 300 K and 1.780 at 2 K) range to the Curie–Weiss law. This resulted C = 0.4607 cm^3 mol^{-1} K and Θ = –2.641 K. This magnetic behaviour can be easily understood when considering the very weak interaction between the copper(II) ions through the (μ-1,3) bismonodentate ligand (Cu···Cu = 13.1524(6) Å). However, we are not sure that the structure of **3** is retained in **3′**. Compound **4′** is diamagnetic as expected.

TCNQ[6] and its radical anion easily form metal salts (27) and Melby et al. (28) have reported the syntheses and conductivity properties of some TCNQ-transition metal complexes. The addition of dicyanomethylene groups $=C(CN)_2$ on the squarate ring leads to an extension of π delocalization and this ligand strongly looks like TCNQ. Moreover, charge-transfer salts, which are semiconductors, have been already obtained with cyanocroconates (C_5 pseudo-oxocarbon) (29). Considering the metallic lustre of **3′**, conductive properties may be expected. However, because its room temperature electrical conductivity on pressed pellets is 2×10^{-8} Ω^{-1} cm^{-1} it must be considered a poor conductor.

Solid state electrochemistry

Within the electroactive domain of the polymer coated electrode, the voltammograms were recorded by cyclic

[6] TCNQ = 7,7,8,8-tetracyano-*p*-quinodimethane.

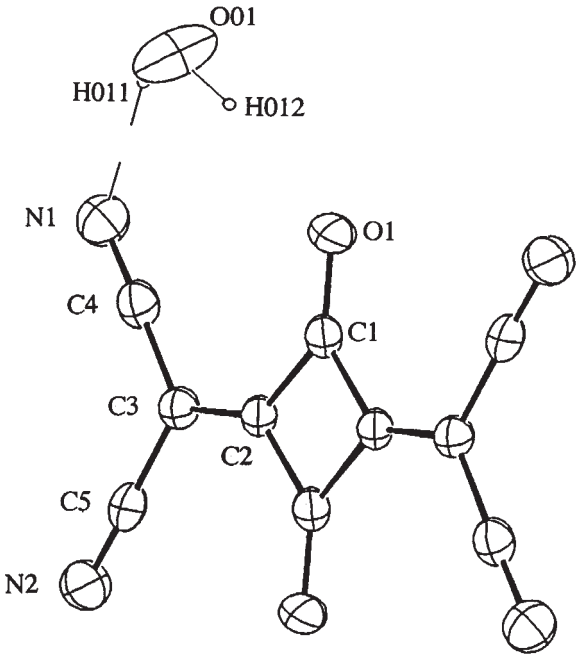
voltammetry at a potential scan speed of 50 mV/s and starting towards anodic potential (Fig. 2). The voltammogram of the free *trans*-cdcb^{2-} ligand shows two oxidation processes (full line) which appear nearly reversible as in solution:

$$\textit{trans}\text{-cdcb}^{2-} \rightleftharpoons \textit{trans}\text{-cdcb}^{\cdot -} + e^- \quad E^1{}_p = 0.585 \text{ V}$$

$$\textit{trans}\text{-cdcb}^{\cdot -} \rightleftharpoons \textit{trans}\text{-cdcb} + e^- \quad E^2{}_p = 1.120 \text{ V}$$



The oxidation process goes through the radical anion *trans*-cdcb$^{\cdot -}$, which must be stable. However, its potential domain ($E^2{}_p - E^1{}_p = 0.53$ V) is smaller than in solution (0.85 V in CH_3CN and 0.73 V in DMF). This is attributed to the *trans*-cdcb^{2-} ion-pairing in the solid phase, which is equivalent to a complexation and shifts the oxidation potential towards positive potentials. On the other hand, the second oxidation step is not displaced.

The voltammogram of the copper(II) complex (dashed line in Fig. 2) is different. The reduction of Cu^{2+} is observed around –0.5 V and on the anodic side only one oxidation process is observed. The potential of the oxidation peak is equivalent to that of the *trans*-cdcb$^{\cdot -}$/*trans*-cdcb oxidation peak. This indicates that the radical state of the ligand is unstable in the copper(II) complex. The voltammogram of the copper(I) complex (dotted line in Fig. 2) is similar to that of the copper(II) complex. On the cathodic side, the reduction of Cu^+ is observed around –0.5 V and on the anodic side only one oxidation process is also observed corresponding to the *trans*-cdcb$^{\cdot -}$/*trans*-cdcb oxidation potential. It can be pointed out that because the oxidation peak is large, it may involve the oxidation of the ligand and subsequent oxidation of Cu^+. The two complexes present the same electrochemical behaviour in the solid phase: the radical state of the ligand is unstable in both copper complexes and the oxidation of the ligand goes through a bielectronic transfer as in water.

Spectroscopies

The spectroscopic studies are related to **3′** and **4′**. The infrared study of several alkanes and cycloalkanecarbonitriles, and of their carbanions has been recently reported (30). Calculations confirm experimental data, with a marked decrease of nitrile band frequencies when going from the neutral molecule to the ionic form. We compare here the vibrational spectra of the free dianion of **1** with the spectra of the metal coordinated dianion. While the shift of the carbonyl or PO (in phosphine oxide) stretching frequencies is generally negative upon metal coordination, an increase in the frequency of the nitrile absorption appears to be quite a general phenomenon (31–34). This is expected due to the σ donation from the nitrogen lone pair of the nitrile which have antibonding character. Theoretical calculations involving the dianion (35) have shown that the negative charge is localized on the carbon atom bonded to the nitrile groups: the ligand may be considered as a nitrile rather than a cyanide ion. The vibrational spectrum of the dianion has already been reported (19). Two intense bands at 2223 and 2186 cm^{-1} are attributed to ν(CN) stretching frequencies. As expected for a nitrile group, the ν(CN) are shifted to higher frequencies in the copper(II) complex **3′**, i.e., at 2238 and 2206 cm^{-1}. Because the change from **3** to **3′** only consists of the loss of two crystallization water molecules, **3′** spectra are characteristic of complex **3**. In contrast, changing from **4** to **4′** results in a significant transformation of the copper atom environment. The metal, which is tetra-coordinated in **4**, is probably tri-coordinated in **4′**, surrounded by two nitrogen atoms from the ligands and one from an acetonitrile molecule. For **4′**, the ν(CN) are observed at 2197 and 2182 cm^{-1}, appreciably lower than those observed for the free dianion. We have already observed the same negative shift in the copper(I) complex obtained with the *cis*-ligand (1). This lowering of the CN stretching frequencies must not be related to the non-linearity of the Cu-N-C group, since this non-linearity is observed in both copper(I) and (II) complexes. Moreover, for the copper(I) complex **4′**, in the same region a band of weak intensity at 2296 cm^{-1} is attributed to the ν(CN) of acetonitrile, while the absorption band corresponding to free acetonitrile is observed at 2253 cm^{-1} (34, 36). It may be noticed that in **4′**, while the stretching frequencies of the nitrile group of *trans*-cdcb decrease upon complexation, the frequencies of the nitrile group of acetonitrile increase as expected. The vibrational assignments in the 1600–1400 cm^{-1} region are very difficult to make due to the strong coupling of the C=O and C=C oscillators. The band at 1604 cm^{-1} observed in the free ligand is shifted to 1568 cm^{-1} in **3′** but is unaffected in **4′**. In the same way, the two bands at 1462 and 1378 cm^{-1} in the free ligand are not affected upon complexation. In the far-infrared spectra of **3′** (450–200 cm^{-1}), the band observed at 436 cm^{-1} is assigned to the copper-oxygen stretching vibration. Nakagawa and Shimanouchi (32, 37) have carried out normal coordinate analyses of many $[M(H_2O)_4]^{n+}$ ions and indicate 440 and 442 cm^{-1} as the respective observed and calculated ν(Cu—O_{water}) values in $[Cu(H_2O)_4]^{2+}$. The 330 cm^{-1} band observed in the same spectrum is assigned to the metal-ligand stretching frequency (32–34, 37, 38).

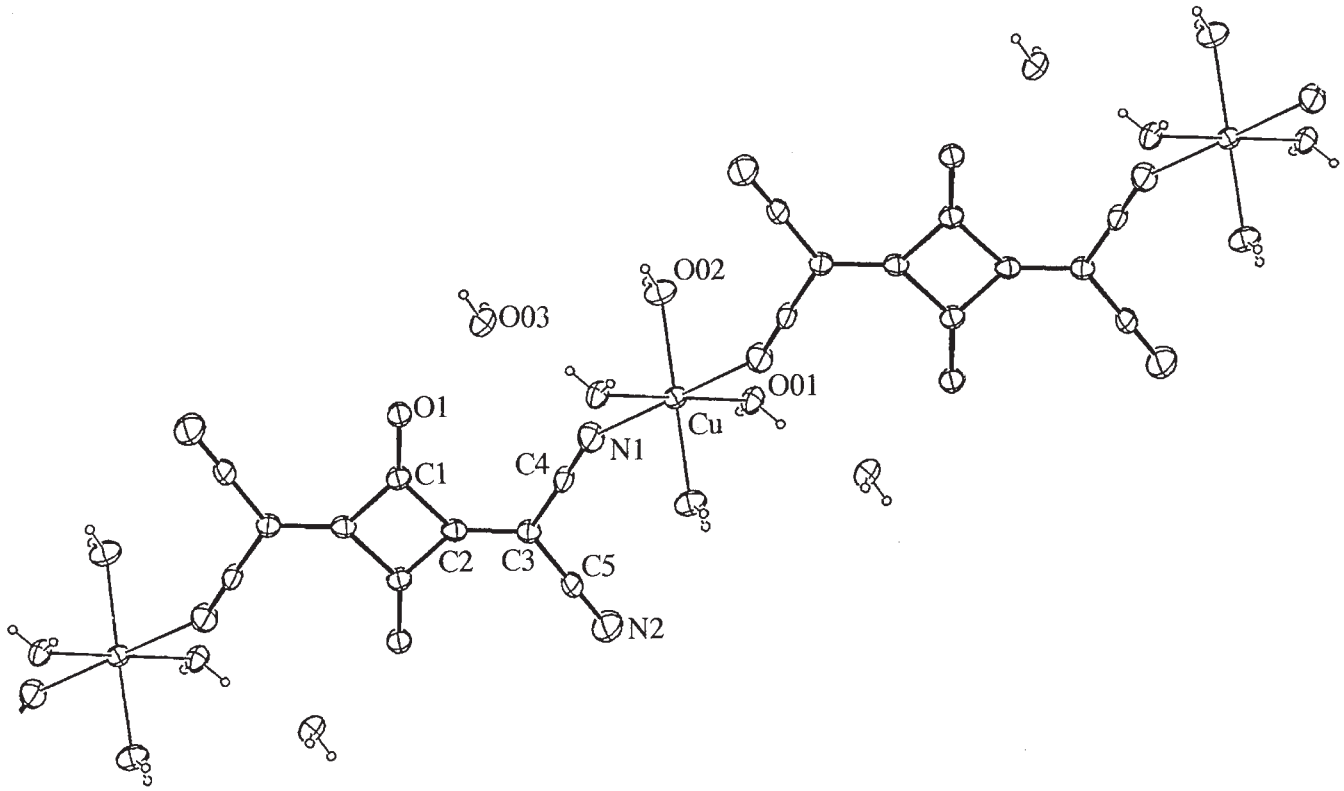
The UV–visible region of the electronic spectrum of the ligand consists of a band at 430 nm. In the electronic spectra of **3′**, two bands are observed: the first at 487 nm is characteristic of the complexed ligand while the second broad band observed at 689 nm corresponds to *d–d* transitions. In the electronic spectra of **4′** only the band corresponding to an absorption within the ligand dianion is observed at 490 nm.



Structure of $[(Ph_4P)_2(trans\text{-}cdcb)]\cdot 2H_2O$ (2)

A view of the dianion, along with the numbering scheme, is shown in Fig. 3. Selected interatomic distances and bond angles are given in Table 2. The *trans*-$cdcb^{2-}$ ions are stacked along the b axis. The planar ring, which is nearly a square, is located around a crystallographic inversion center (0 0 1/2). This plane includes the atoms directly attached to it, O1 and C3. However, the dicyanomethylene group is slightly rotated about the C—C bonds. The mean plane through the five atoms of the dicyanomethylene group forms an angle of 2.71(3)° with the plane defined by the ring atoms. This deviation is in the order of those observed in the *cis*-$cdcb^{2-}$ salts (39, 40), and we can consider the occurrence of an intrinsically planar system.

The 1.459(5) Å distance C1—C2 is indicative of a perfectly π delocalized system. The 1.238(4) Å C1—O1 distance is normal for a carbonyl group. The 1.393(4) Å C(ring)—$C(CN)_2$ bond length is similar to the one observed in the isomeric *cis*-ligand regardless of whether it was

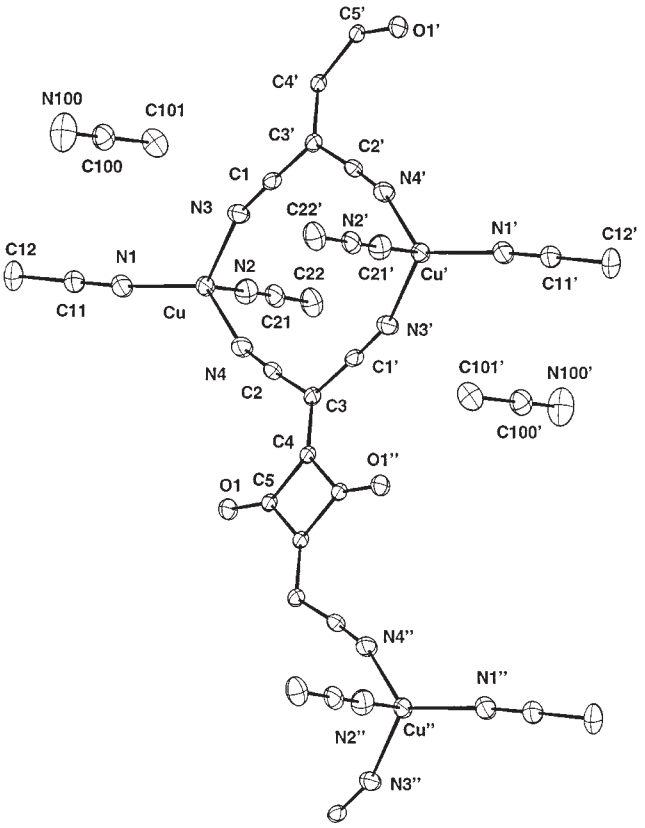
© 2000 NRC Canada

Fig. 4. Representation of the polymeric structure of $[Cu(trans\text{-}cdcb)(H_2O)_4 \cdot 2H_2O]_n$ (**3**).

coordinated or not. The structure of this planar ion indicates that all other bond distances observed are very similar to those observed for the *cis*-isomer, the only differing characteristic being a better π electron delocalization, as expected for symmetry. The distances and angles at the tetraphenylphosphonium ion are normal and are given as supplementary materials.[7]

Structure of $[Cu(trans\text{-}cdcb)(H_2O)_4 \cdot 2H_2O]_n$ (3)

A view of the molecule, along with the numbering scheme, is shown in Fig. 4. Selected bond lengths and angles are listed in Table 2. The structure of **3** is made of infinite chains located in the ac plane and parallel to the [101] direction (Fig. 4). These chains are built from $[Cu(trans\text{-}cdcb)(H_2O)_4]$ units and inside the chain the shortest Cu···Cu distance is 13.1524(6) Å (while the shortest interchain Cu···Cu is 7.1292(3) Å). A *trans*-cdcb unit bridges copper(II) ions acting in an *N*-bis(monodentate) mode. Each copper(II) ion situated on a crystallographic inversion center is octahedrally coordinated and the observed angles do not differ significantly from the ideal value (87.39(8)° to 92.61(8)°). However, the bond distances are notably different. The structure is better described as a (4 + 2) geometry and the important difference between equatorial and apical bond distances is indicative of an important Jahn–Teller effect associated with a semi-coordination of nitrogen of the cdcb ligand. The metal atom is linked to four water molecules in the equatorial plane and two nitrogen atoms from different cdcb are located at the apical sites. The copper—nitrogen distance of 2.357(2) Å is particularly longer than those already observed in copper(II)–nitrogen complexes (mean distance of ≅ 2 Å). Moreover, this distance is far from the Cu—N distances observed in the Cu(I) complex (crystal **4**) with the same ligand (2.019(2) and 1.982(2) Å) although the copper(I) ion is larger than the copper(II) ion. This structure may be related to that of the hexacoordinated copper(II) in $Cu(H_2O)_4(SO_4) \cdot H_2O$ (42) which involves a tetrahydrate copper(II) cation (Cu—O = 1.97 Å) and bridging semicoordinate SO_4^{2-} anion (Cu—O = 2.4 Å).



The *trans*-$cdcb^{2-}$ dianion is a potential multidentate ligand with coordination occurring by oxygen or nitrogen atoms, but more probably by nitrile groups. However, it may be underlined that contrary to the *cis* ligand, for which all the nitrile groups are involved in coordination, only two of the nitrogen atoms of the dicyanomethylene groups are coordinated in this complex. While the two nitrile groups are chemically distinct, they present similar C—N bond distances (1.146(3) and 1.143(4) Å for the bonded and nonbonded groups respectively) which are quite identical to those observed in compound **2**. The N1-C4-C3 and N2-C5-C3 angles at coordinated and non-coordinated cyanomethylene groups are 178.4(3)° and 178.3(3)° respectively. These values show that the cyanomethylene group is essentially linear as expected. However, the angle Cu-N1-C4 at 156.2(2)° deviates greatly from the expected value of 180°.

The square ring is planar with a crystallographic inversion center in the middle of the ring. However, while the deviation of the dicyanomethylene group from the ring is very

[7] The distances and angles at the tetraphenylphosphonium ion have been deposited as supplementary material and may be purchased from: The Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Ontario, Canada, K1A 0S2.

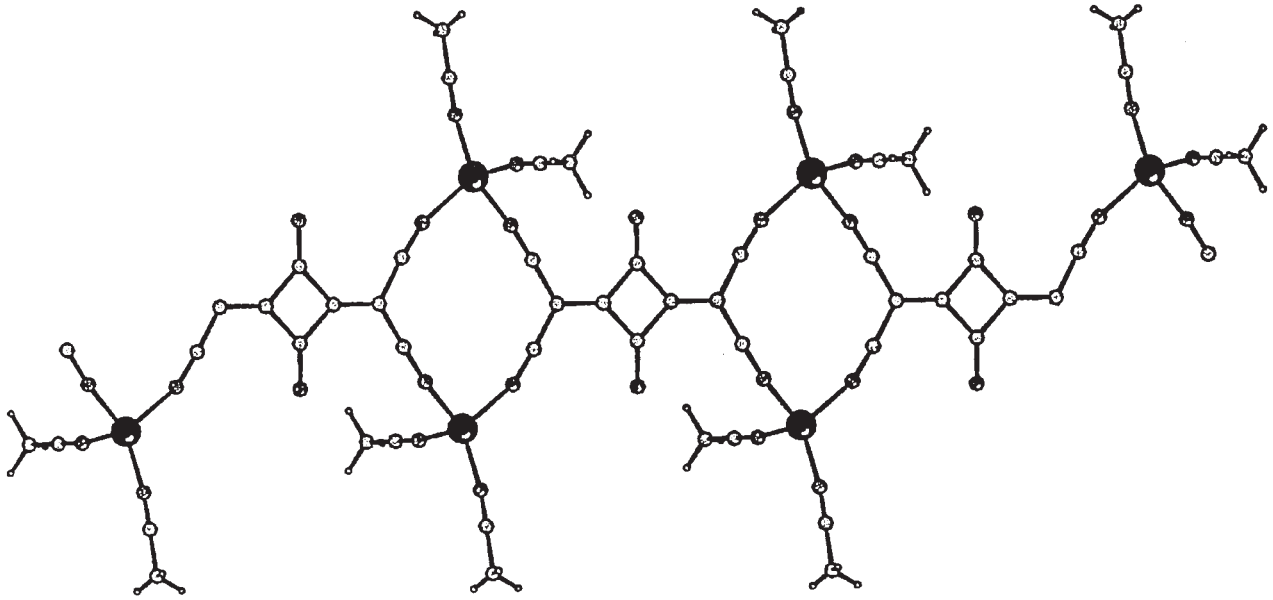
Fig. 5. Structure of the unit of $[Cu_2(trans\text{-cdcb})(CH_3CN)_4\cdot 2CH_3CN]$ (**4**).

small in crystal **2**, the loss of planarity is important in crystal **3**. All the atoms of the dicyanomethylene group are coplanar and the dihedral angle between this plane and the square ring plane is 12.72(4)°. A similar deviation was observed in a copper(I) complex (1) obtained from the *cis*-ligand, but in the case of the *trans* ligand, it can't be explained by steric hindrance. Elsewhere, the bonds distances of the ligand are not affected by coordination.



The hydrogen bond network involves the two water molecules located in the lattice, the bonded water molecules and the non-bonded nitrogen atoms of the cyano groups.

Structure of $[Cu_2(trans\text{-cdcb})(CH_3CN)_4\cdot 2CH_3CN]_n$ (4)

A view of the molecule, along with the numbering scheme, is shown in Fig. 5. Selected bond lengths and angles are listed in Table 2. The structure of **4** is made of infinite chains (Fig. 6). Within the chain, the geometry at copper(I) is nearly tetrahedral: the metal is linked to two acetonitrile ligands and two nitrogen atoms of two different dicyanomethylene groups belonging to two different *trans*-cdcb ligands. Moreover, two acetonitrile molecules are present in the lattice. The cation $[Cu(CH_3CN)_4]^+$ is easily obtained in acetonitrile. By substitution reaction on this cation, the tetrahedral geometry is most often retained. Actually, in the formation reaction of complex **4**, two acetonitrile molecules remain bonded to copper(I) and the two other molecules are present in the lattice.

It appears that there is little energetical difference between four-coordinated tetrahedral Cu(I) complexes and three-coordinated planar Cu(I) complexes. In the presence of soft donor atoms, the stereochemistry of copper(I) is very flexible: with the same metal and ligand stoichiometry, we may find complexes with different stereochemistries; otherwise, complexes with different stoichiometries may occur with the same ligand. Using *cis*-cdcb as the ligand, we obtained a planar tricoordinated copper(I) complex; with *trans*-cdcb as the ligand, we obtained a tetracoordinated complex. The Cu—N (*trans*-cdcb) distances (1.982(2) and 2.006(2) Å) are longer than those observed for Cu—N (*cis*-cdcb) (1.904(4) and 1.903(3) Å). Moreover, the Cu—N (acetonitrile) distances are also longer in the tetracoordinated complex. The study by Lippard et al. (42) of dichlorotris(triphenylphosphine)dicopper(I) complex, which contains both three- and four-coordinated copper(I), clearly reveals the shorter bond

Fig. 6. Representation of the polymeric structure of **4**.

© 2000 NRC Canada

lengths around the trigonal copper atom. A comparison of Cu—S distances in tetramethyl-thiourea copper(I) complexes (43, 44) produces similar results. These observations are in agreement with considerations based upon the steric repulsions around tetrahedrally or trigonally coordinated copper atoms. Out of the solvent, we observed the loss of four acetonitrile molecules during conversion from **4** to ***4′***. This implies the loss of the two non-coordinated solvent molecules and of two coordinated acetonitrile molecules (one on each copper atom) resulting in tricoordinated copper(I) atoms.

The *trans*-cdcb is potentially multidentate and acts as tetradentate in the present molecule. The four nitrogen atoms are linked to four different copper atoms, and, inside the chain, the shortest Cu···Cu distance is 6.796(1) Å.

While the Cu-N bonds are normal, bond distances of the ligand are not significantly affected by complexation as observed for complex **3**. The square ring is planar and an inversion center stands in the middle of the plane. The dihedral angle of the dicyanomethylene group from the mean plane is only 1.2° and lies in the order observed for the ligand. The angles Cu-N-C(acetonitrile) are normal (173.3(2)° and 171.6(2)°) and as expected; however, the values of Cu-N-C(cyanomethylene) (159.9(2)° and 162.5(2)°) are, as in the case of **3**, far from the expected 180° value.

The reaction of a Cu(II) salt with the *trans*-cdcb^{2-} ligand produces two different complexes, depending on the solvent used. In a water–CH_3CN mixture, the reduction of copper(II) occurs and leads to a copper(I) complex; in water alone, the copper(II) complex is obtained. While the redox potentials of the *trans*-cdcb^{2-} and *cis*-cdcb^{2-} dianions are of the same order of magnitude ($E^1_{1/2}$ = 0.255 V, $E^2_{1/2}$ = 1.129 V and $E^1_{1/2}$ = 0.243 V, $E^2_{1/2}$ = 1.068 V respectively) only a copper(I) complex has so far been obtained with the *cis*-dianion. This difference is attributed to kinetic effects.

Unfortunately, the copper complexes described in this paper dissociate in solution. In the solid state, electrochemical results showed that the complexes are electroactive and spectroelectrochemical experiments have yet to be carried out to determine the possible electrochromic properties of the complexes.

The effect of aspirin–HSA complexation on the protein secondary structure

J.F. Neault, A. Novetta-Delen, H. Arakawa, H. Malonga, and H.A. Tajmir-Riahi

Abstract: This study was designed to determine the secondary structure of human serum albumin (HSA) in the presence of aspirin in H_2O and D_2O solutions at physiological pH, using aspirin concentrations of 0.0001–5 mM with final protein concentration of 2% w/v. UV–vis spectra and Fourier transform infrared (FTIR) difference spectroscopy with its self-deconvolution, second derivative resolution enhancement, and curve-fitting procedures were applied to characterize the drug binding mode, the binding constant, and the protein secondary structure in the aspirin–HSA complexes. Spectroscopic evidence showed that no aspirin–protein interaction occurs at very low drug concentration (0.0001 mM), whereas at higher drug contents (0.001–0.1 mM) the aspirin anion binding (H-bonding) is mainly through the ε-amino NH_3^+ group with overall binding constant of $K = 1.4 \times 10^4$ M^{-1}. At high drug concentrations (1–5 mM), acetylation of Lys-199 was observed. Aspirin binding results in protein secondary structural changes from that of the α-helix 55% (free HSA) to 49%, β-sheet 22% (free HSA) to 31%, β-anti 12% (free HSA) to 4% and turn 11% (free HSA) to 16% in the aspirin–HSA complexes.

Key words: aspirin, protein, drug, binding mode, binding constant secondary structure, FTIR spectroscopy.

Résumé : Ce travail a comme objet de déterminer la structure secondaire de l'albumine de sérum humain (ASH) en présence d'aspirine, dans des solutions de H_2O ou de D_2O, au pH physiologique, à des concentrations d'aspirine allant de 0,0001 mM à 5 mM, avec une concentration finale de protéine de 2% p/v. On a utilisé la spectroscopie UV–vis et la spectroscopie infrarouge par transformée de Fourier (FTIR) différentielle en appliquant les méthodes d'autodéconvolution, d'augmentation de la résolution de la deuxième dérivée et d'ajustement des courbes pour caractériser le mode de fixation du médicament, la constante de fixation ainsi que la structure secondaire de la protéine dans les complexes aspirine-ASH. Les données expérimentales montrent qu'il ne se produit pas d'interaction aspirine-protéine à basses concentrations de médicament (0,0001 mM) alors que, à des concentrations plus élevées de médicament (de 0,001 à 0,1 mM), la fixation de l'anion de l'aspirine (fixation-H) se fait principalement par le biais du groupe ε-amino, NH_3^+, et que la constante globale de fixation, $K = 1{,}4 \times 10^4$ M^{-1}. À des concentrations élevées de médicament (1 à 5 mM), il se produit une acétylation de la Lys-199. La fixation de l'aspirine provoque des changements dans la structure secondaire de la protéine qui passe de 55% d'hélice-α (dans l'ASH libre) à 49%, de 22% de feuillet-β (dans l'ASH libre) à 31%, de 12% β-anti (dans l'ASH libre) à 4% et de 11% de décalement (dans l'ASH libre) à 16% dans les complexes aspirine-ASH.

Mots clés : aspirine, protéine, médicament, mode de fixation, constante de fixation, structure secondaire, spectroscopie IR à transformée de Fourier.

Introduction

Aspirin belongs to the nonsteroidal anti-inflammatory drugs and it is used extensively as a painkiller. It exerts an anti-inflammatory effect through selective acetylation of serine 530 on prostaglandin H_2 synthase (1). Aspirin has been shown previously to transfer its acetyl group to the ε-amino group of Lys-199 of human serum albumin under physiological conditions in vitro and in vivo and thus, this interaction increases the ability of HSA to bind the anionic drugs (2, 3). However, there has been no report on the effect of aspirin–HSA complexation on the protein secondary structure in aqueous solution.

Human serum albumin represents important and the most abundant protein constituent of blood plasma and serving as a protein storage component. Recently, the three-dimensional structure of human serum albumin was determined through X-ray crystallographic measurements (4). This globular protein consisting of a single polypeptide chain of 585 amino acids, which has many important physiological functions (5, 6). HSA considerably contributes to colloid osmotic blood pressure and realizes the transport and distribution of many molecules and metabolites such as fatty acids, amino acids, hormones, cations and anions, and many diverse drugs. It also makes possible to bind and carry through the bloodstream many drugs, which are poorly soluble in water (6). It has been shown that the distribution, free concentration, and the metabolism of various drugs can be significantly altered as a result of their bindings to HSA (7). Therefore, the inter-

action of aspirin with human serum albumin has major biochemical importance.

We now report the FTIR and UV–vis spectroscopic results on the interaction of aspirin with human serum albumin, in aqueous solution at physiological pH, using drug concentrations of 0.0001–5 mM with a final HSA (fatty acid free) concentration of 2% w/v. Spectroscopic evidence regarding the drug binding mode, drug binding constant, and the protein secondary structural changes are provided here. To our knowledge, our structural information provides the first spectroscopic evidence regarding aspirin–HSA interaction and should help to elucidate the nature of this biologically important complex formation in vitro and in vivo.

Materials and methods

Materials

Human serum albumin (fatty acid free) fraction V was purchased from Sigma Chemical Co., and used as supplied. Aspirin was from Sigma Chemical Co., and used without further purification. D_2O (99.98%) was from Aldrich Chemical Co. Other chemicals were of reagent grade.

Preparation of stock solution

Human serum albumin (fatty acid free) was dissolved in aqueous solution to 4% w/v (40 mg/mL) containing phosphate buffer and 0.05 M NaCl. The solutions of aspirin 0.2 μM to 10 mM were prepared by dissolving aspirin in double distilled water (pH 6–7). In the final step, the solution of drug was added dropwise to the protein solution with constant stirring to ensure the formation of homogeneous solution and to attain the desired drug concentrations of 0.0001–5 mM with a final protein concentration of 2% w/v. Equal volumes of aspirin and HSA solutions were incubated for 2 h at room temperature before spectral measurements. The deuterated samples were prepared in D_2O in the same way as described for H_2O solutions. The pH or pD of the solution was adjusted to 6.8–7.4 by the addition of NaOH or NaOD (0.1 M).

Absorption spectra

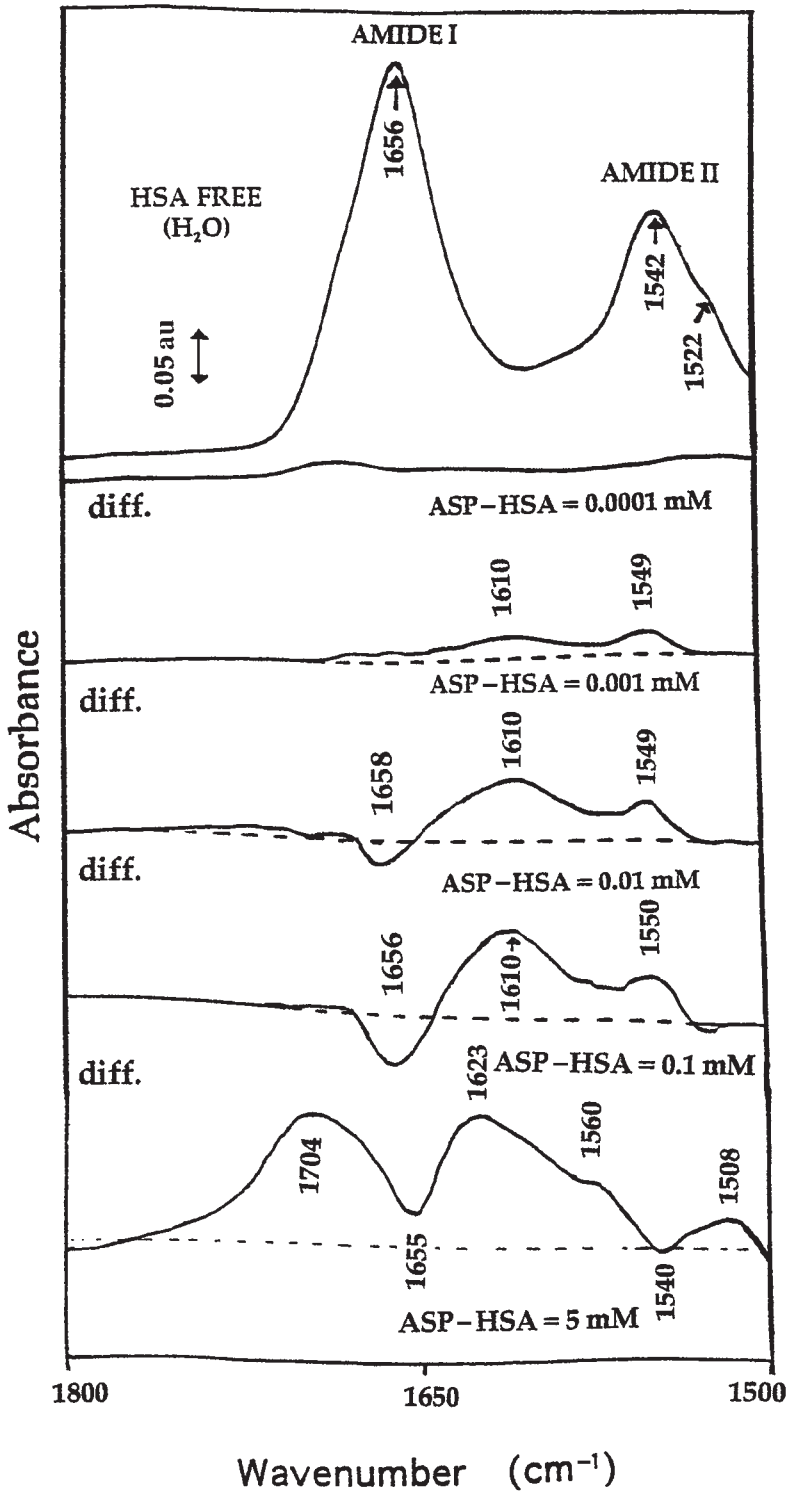
The absorption spectra were recorded on a Hewlett–Packard 8452A Diode Array Spectrophotometer.

FTIR spectroscopic measurements

Infrared spectra were recorded on a BOMEM DA3–0.02 Fourier transform infrared spectrometer equipped with a nitrogen cooled HgCdTe detector and a KBr beam splitter. Solution spectra were taken, using AgBr windows with resolution of 2 cm^{-1} and 100–500 scans. The subtraction of H_2O or D_2O from protein solution was carried out as reported in our previous reports (8). The difference spectra [(protein solution + aspirin anion solution) – (protein solution)] were generated using the polypeptide antisymmetric and symmetric C-H stretching bands (9), located at 2900–2800 cm^{-1} as internal standard. The protein C-H stretching vibrations exhibit no spectral changes upon drug interaction and they are cancelled on spectral subtraction. The accuracy of this method of subtraction was tested by using several control samples with the same protein or drug concentrations, that resulted in a similar flat baseline formation. However, a similar absorption scale was used, for the spectra of the free protein and its aspirin complexes as well as for the difference spectra produced here. This method allowed us to obtain meaningful spectral differences between the free protein and its drug complexes at different aspirin concentrations. Such spectral differences were used here, in order to characterize the nature of the drug–protein interaction.

Analysis of protein secondary structure

Determination of the secondary structure of HSA and its aspirin complexes was carried out on the basis of the procedure described by Byler and Susi (10). The protein secondary structure is determined from the shape of the amide I band, located at 1650–1660 cm^{-1}. Fourier self-deconvolution and second derivative resolution enhancement were applied to increase the spectral resolution in the region of 1700–1600 cm^{-1}. The second derivatives were produced using a point convolution of 11 or 13. The resolution enhancement resulting from self-deconvolution and the second derivative is such that the number and the position of the bands to be fitted are determined. In order to quantify the area of the different components of amide I contour, revealed by self-deconvolution and second derivative, a least-square iterative curve-fitting was used to fit the Lorentzian line shapes to the spectra between 1700–1600 cm^{-1}. Before curve-fitting was done, a straight baseline passing through the ordinates at 1700 and 1600 cm^{-1} was subtracted. The baseline is then modified again by the least-square curve-fitting, which allowed for a horizontal baseline to be adjusted as an additional parameter in order to obtain the best fit. It is known that no meaningful curve-fitting can be performed by simple examination of the original infrared spectra, that is why the self-deconvolution procedure has to be carried out first. The curve-fitting was done using a number of 25 simulations. The resulting curve fitted is analysed as follows: each Lorentzian band is assigned to a secondary structure according to the frequency of its maximum; α-helix (1656–1657 cm^{-1}), β-sheet (1616–1635 cm^{-1}), turn (1673–1678 cm^{-1}), random coil (1640–1645 cm^{-1}), and β-antiparallel (1684–1692 cm^{-1}). The area of all the component bands assigned to a given conformation are then summed and divided by the total area. The number obtained is taken as the proportion of the polypeptide chain in that conformation. These assignments are consistent with the previous values determined theoretically (9) and experimentally (10). The accuracy of this method was tested on several proteins of the known conformational contents (through X-ray diffraction analysis), such as cytochrome c (α-helix 49%) and RNase A (α-helix 27%) (11–13) that resulted in 2–3% differences. The data treatments of protein conformational analysis are also reported in our recent publication (8). The aspirin–protein binding constants were calculated based on the UV absorption method (14).



Results and discussion

Aspirin–HSA interaction

Since there was no major spectral shifting for the protein amide I band at 1656 cm^{-1} (mainly C=O stretch) and amide II band at 1542 cm^{-1} (C-N stretch coupled with N-H bending mode) (9, 10), the difference spectra [(protein solution +

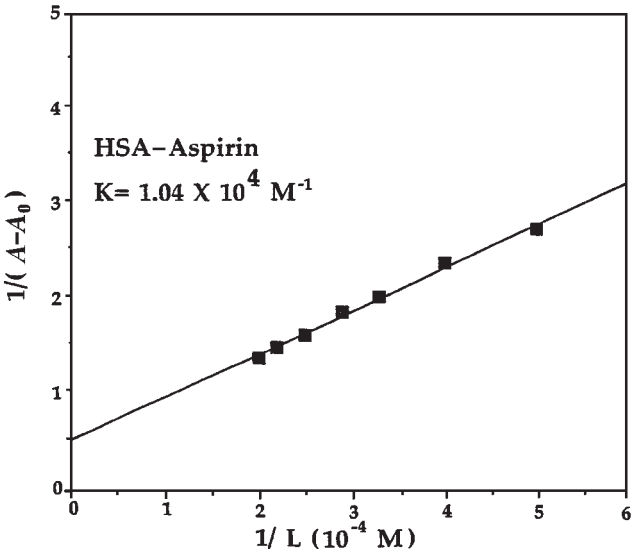
Fig. 1. FTIR spectra (top first curve) and difference spectra [(protein solution + aspirin solution) – (protein solution)] (bottom four curves) of the free human serum albumin (HSA) and its aspirin anion complexes in aqueous solution at physiological pH with different drug concentrations in the region of 1800–1500 cm^{-1} (the baseline shown as broken lines).



aspirin solution) – (protein solution)] were obtained in order to monitor the intensity variations of these vibrations and the results are shown in Fig. 1. The overall binding constants of the aspirin–HSA complexes were determined using UV absorption spectroscopy and the results are presented in Fig. 2. Similarly, the infrared self-deconvolution with second derivative resolution enhancement and curve-fitting procedures (10–13), were used to determine the protein secondary structure in the presence of aspirin anion and the results are given in Fig. 3 and Table 1.

At very low aspirin concentration (0.0001 mM), no spectral changes (intensity or shifting) occurred for the amide I

© 2000 NRC Canada

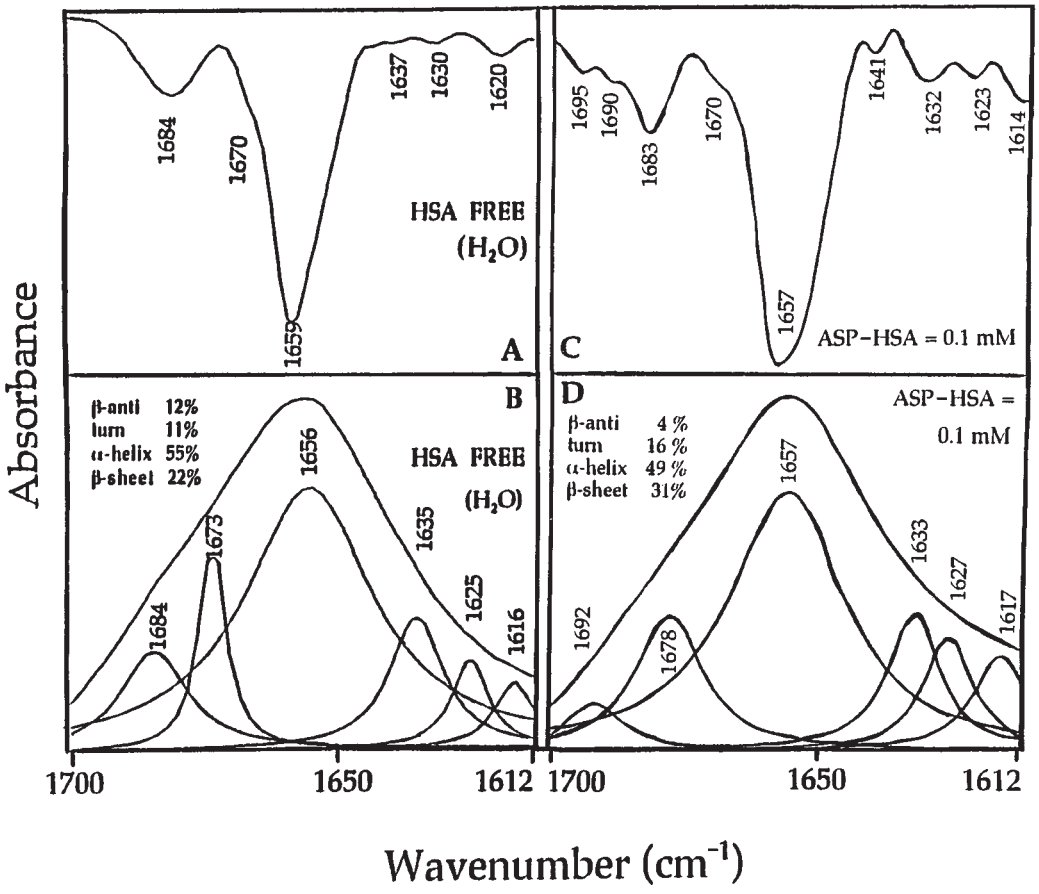


Fig. 2. The plot of $1/(A - A_0)$ vs. (1/L) for HSA and its aspirin complexes where A_0 is the initial absorption band of protein (275 nm) and A is the recorded absorption at different drug concentrations (L).

band at 1656 cm^{-1} and amide II band at 1542 cm^{-1}, as it is evident from the difference spectrum obtained at low drug concentration (Fig. 1, 0.0001 mM). This is indicative of no aspirin–HSA interaction at very low drug concentration. At higher drug content (0.001 mM), two weak positive features were observed at 1610 and 1549 cm^{-1}, due to an increase in the intensity of the amide II vibration and the alterations of the amide I vibration (Fig. 1, 0.001). The observd spectral changes are attributed to aspirin–HSA interaction through protein N-H group. Further evidence for aspirin interaction with the protein N-H group comes from the shift of the amide A (protein N-H stretching mode) (9, 10) at 3303 cm^{-1} towards a lower frequency at 3300 cm^{-1}, in the spectra of the drug–protein complexes. The band at 1522 cm^{-1}, in the spectrum of the free HSA, which is assigned to the tyrosine residue vibrational frequency (15–19), exhibited no spectral changes upon drug interaction (Fig. 1). This is indicative of no participation of the tyrosine moiety in the aspirin–protein complexation.

As drug concentration increased (0.01 and 0.1 mM), the two positive features at 1610 and 1540 cm^{-1} grew in intensities, while a negative feature was observed at 1658 and 1656 cm^{-1} (Fig. 1). The observed spectral changes (positive peaks) are due to continuation of drug binding to protein N-H group and the reduction of the protein α-helix structure (negative peak), upon aspirin–HSA complexation.

Fig. 3. Second derivative resolution enhancement and curve-fitted amide I region (1700–1612 cm^{-1}) and secondary structure determination of the free human serum albumin (curves A and B) and its aspirin complexes (curves C and D) in aqueous solution with 0.1 mM drug concentration.

1640–1645	(11 ± 1.0)	(12)	(12)	(13)	(14)
Random					
1635–1616	22 ± 2	24	29	31	31
β-Sheet	(22 ± 2)				

Additional evidence for the aspirin–HSA interaction also comes from the shift ($\Delta\nu$ = 10 cm^{-1}) of the aspirin anion C=O, C=C, and C-O stretching vibrations at 1770, 1746, 1609, 1598, and 1565 cm^{-1} towards lower frequencies, on aspirin complexation (spectrum is not shown).

The calculation of the overall binding constants were carried out using UV spectroscopy as reported (14). If the equilibrium for aspirin anion and HSA is established as

[1] HSA + aspirin $\Leftrightarrow$ HSA: aspirin K

The binding constant of aspirin anion complexes with HSA can be described as

$$[2] \qquad K = \frac{[\text{HSA:aspirin}]}{[\text{HSA}][\text{aspirin}]}$$

The double reciprocal plot of 1/[complexed aspirin] vs. 1/[aspirin] is linear (Fig. 2) and the binding constant (K) is calculated from the ratio of the intercept on the vertical coordinate axis to the slope (14). Concentrations of complexed aspirin were determined by subtracting absorbance of uncomplexed HSA at 275 nm from those of complexed HSA. Concentrations of free aspirin were determined by subtracting those of complexed drug from total drug used for the experiment. Our data of 1/[complexed aspirin] almost proportionally increased as a function of 1/[free aspirin], and the overall binding constant for the aspirin–HSA complexes was estimated to be K = 1.4 × 10^4 M^{-1} (Fig. 2).

The binding constant calculated for the aspirin–HSA complexes shows a weak aspirin–protein interaction with respect to the other strong drug–HSA complexes with binding constants ranging from 10^5 M^{-1} to 10^6 M^{-1} (7).

Recently, the interaction of inorganic anions such as F^-, Cl^-, Br^-, ClO_4^-, SO_4^{2-}, HPO_4^{2-} with human serum transferrin has been reported and a possible mode of action is suggested (20). Similarly, the binding constants of several inorganic and organic anions to cytochrome c were determined (21). A weak protein-anion interaction was found for these anions with overall binding constants of 10–100 M^{-1} (20, 21). A model for protein-anion binding was suggested in which the anion negative charged atom forms a stable hydrogen bonding with the protein NH groups (A^-...HN-protein), stabilizing the protein-anion complexes (21). On the other hand, oxyanions such as, VO_3^- (vanadate) showed marked affinity towards ε-amino NH_3^+ groups of human serum albumin with K ≃10^3 M^{-1} (22). On the basis of our infrared spectroscopic results that showed marked spectral similarities between the aspirin–HSA and VO_3–HSA complexes in the amide I and amide II regions, thus, one can assume a similar binding mode for both aspirin and vanadate anions in these anion-protein complexes at low anion concentrations (0.001–0.1 mM). The major spectral changes (shiftings and intensity variations) observed for the amide A band at 3300 cm^{-1} (protein N-H stretching) and the amide II band at 1545 cm^{-1} (C=N + N-H modes), are due to the formation of H-bonding between the positively charged protein N-H groups and the negatively charged aspirin anion oxygen atom (ε-amino NH_3^+..O^-), in these drug-HSA complexes.

However, at high aspirin concentrations (1–5 mM), acetylation of the Lys-199 occurs, which is accompanied by major spectral changes of the amide A at 3303, amide I at 1656, and amide II at 1542 cm^{-1}. The protein amide A band (N-H stretching) at 3303 cm^{-1} was shifted towards a lower frequency at 3295 cm^{-1}, the amide II band at 1542 cm^{-1} lost intensity and displaced toward lower frequency at 1540 cm^{-1} upon acetylation. The amide I band at 1656 cm^{-1} lost intensity and shifted towards a lower frequency at 1640 cm^{-1} (spectra not shown). The presence of a strong positive feature at 1704 cm^{-1} in the difference spectra of drug-HSA complexes is coming from the aspirin C=O stretching vibrations at 1770 and 1746 cm^{-1}, that were shifted towards lower frequencies upon acetyl group transfer (Fig. 1, 5 mM). These spectral changes are due to the acetylation of the lysine residue upon aspirin complexation. The acetylation of the Lys-199 of the HSA is well known (2, 3). Recent structural analysis of the HSA in the presence of aspirin anion shows that the aspirin binding is in sites I and II, where the Lys-199 is located (4, 23). Our spectroscopic results are in a good agreement with those of the literature reports that show acetylation of HSA occurs at high aspirin concentrations (2, 3). However, based on our infrared results alone, we can not locate the position of the lysine residue in order to establish the transfer of the acetyl group from aspirin to Lys-199.

A quantitative analysis of the HSA secondary structure in H_2O and D_2O is given in Table 1. The free protein contained major α-helix 55%, β-sheet 22%, turn structure 11%, and

© 2000 NRC Canada

β-antiparallel 12%. The β-sheet structure is composed of three components at 1616 cm^{-1} (inter β-strand), 1625 cm^{-1} (intra β-strand), and 1635 cm^{-1} (hydrated) (Fig. 3), that are consistent with the recent spectroscopic studies of the human serum albumin (24, 25). In D_2O solution, due to the isotopic substitution (D/H), the presence of a new component band at 1644 cm^{-1} in the spectrum of the free HSA was attributed to the contribution of the random structure 11% (Table 1). Upon aspirin complexation, the α-helix structure was reduced from 55% to 49%; the β-sheet increased from 22% to 31%; the β-anti changed from 12% to 4%, and the turn structure increased from 11% to 16% at high drug concentration in H_2O solution (Fig. 3 and Table 1, 0.1 mM). However, no major alterations were observed for the random structure on drug complexation (Table 1). The observed spectral changes are consistent with the major perturbations of the HSA secondary structure upon aspirin anion interaction. The secondary structural changes observed can be attributed to the interaction of the aspirin anion with the ε-amino NH_3^+ groups. The reduction of the α-helix in favor of the β-sheet structure is indicative of a partial unfolding of the protein structure, in the presence of aspirin anion at high drug concentration. Similar conformational transition from α-helix to β-sheet structure was observed for the protein unfolding, upon protonation and heat denaturation (26–28). At higher drug concentrations (1–5 mM), where acetylation of the lysine residue occurs, major loss of the intensity of the amide I band at 1656 cm^{-1} with an increase in the intensity of the band at 1637 cm^{-1} are observed (Fig. 1). These spectral changes are due to the reduction of the α-helix structure in favor of the β-sheet upon protein acetylation. Attempts to analyse the protein secondary structural changes upon acetylation (1 and 5 mM aspirin) were not successful, due to the overlapping of the protein amide I band at 1656 cm^{-1} with the aspirin C=O vibrational frequencies in the region 1700–1600 cm^{-1}.

In conclusion, the infrared spectroscopic results presented here for the first time, show that at low drug concentrations (0.001–0.1 mM), aspirin binds human serum albumin mainly through the polypeptide ε-amino NH_3^+ with overall binding constant $K = 1.4 \times 10^4$ M^{-1}. The low stabilities of the complexes formed are due mainly to the H-bonding interaction between protein polar groups and the anion donor atoms. At high drug contents (1–5 mM), acetylation of Lys-199 occurs. The aspirin–HSA complexation leads to the alterations of the protein secondary structure from that of the α-helix to β-sheet conformation. This study provides additional evidence regarding protein structural changes, induced by aspirin anion interaction.

Benzooxirene, naphthooxirenes, and anthraceneoxirenes: the stabilization of the oxirene system by bond fixation in acenes. A comparison of ab initio and DFT in the investigation of annelated oxirenes

E. Lewars

Abstract: The effect on the stabilities of benzoannelated oxirenes (oxacyclopropenes) of variations in the C—C bond electron density (as measured by Löwdin bond order) was studied computationally. Benzo[*b*]oxirene (**4ox**), naphtho[2,3-*b*]oxirene (**5ox**), naphtho[1,2-*b*]oxirene (**6ox**), anthro[2,3-*b*]oxirene (**7ox**), and anthro[1,2-*b*]oxirene (**8ox**) were investigated using the DFT pBP/DN* method as implemented in the program Spartan. This method was chosen because with **4ox** it gave results similar to those from the much slower QCISD(T)/6–31G*//MP2(full)/6–31G* and MP4SDTQ/6–31G*//MP2(full)/6–31G* methods. The calculated barriers to oxirene ring opening for the "linear" **4ox**, **5ox**, and **7ox** (bond orders 1.35, 1.24, and 1.20, respectively) were 23.6, 39.9, and 46.6 kJ mol^{-1}, in contrast to the "angular" **6ox** and **8ox** (bond orders 1.50 and 1.59, respectively), with barriers of ca. 0 kJ mol^{-1}. The high-barrier vs. low-barrier series corresponds to the stabilities expected from the resonance structures of the oxirenes or their formal precursor acenes. Empirically, the ring-opening barriers were linearly related to the oxirene bond orders, and extrapolation to tetracene using this relationship gave a barrier of ca. 50 kJ mol^{-1}, which seems to be the limiting barrier in the linear series. In several cases the oxirene isomerized to a ketene without going through an oxo carbene (ketocarbene). Benzoannelation is only the second kind of substitution (after dimethyl substitution) that has been indicated, computationally, to be able to stabilize oxirenes.

Key words: oxirenes, ketocarbenes, benzooxirenes, AM1, ab initio, DFT.

Résumé : Faisant appel à des calculs théoriques on a déterminé l'effet (mesuré par l'ordre de liaison Löwdin) de variations de la densité électronique dans des liaisons C—C sur les stabilités d'oxirènes (oxacyclopropènes) portant un noyau benzénique. On a étudié les benzo[*b*]oxirène (**4ox**), naphto[2,3-*b*]oxirène (**5ox**), naphto[1,2-*b*]oxirène (**6ox**), anthro[2,3-*b*]oxirène (**7ox**) et anthro[1,2-*b*]oxirène (**8ox**) à l'aide de la méthode DFT pBP/DN* en relation avec le programme « Spartan ». On a choisi cette méthode parce que, avec le **4ox**, elle donne des résultats semblables à ceux obtenus avec les méthodes beaucoup plus lentes QCISD(T)/6–31G*//MP2(full)/6–31G* et MP4SDTQ/6–31G*//MP2(full)/6–31G*. Les barrières calculées pour l'ouverture de cycle des oxirènes « linéaires » **4ox**, **5ox** et **7ox** (ordres de liaison de 1,35, 1,24 et 1,20 respectivement) sont de 23,6, 39,9 et 46,6 kJ mol^{-1}; ces valeurs diffèrent grandement de celles calculées pour les produits « angulaires », **6ox** et **8ox**, (ordres de liaison de 1,50 et 1,59 respectivement) pour lesquels les barrières sont d'approximativement de 0 kJ mol^{-1}. Les séries à barrière élevée ou basse correspondent aux stabilités attendues sur la base des structures de résonance des oxirènes ou de leurs acènes précurseurs formels. D'un point de vue empirique, les barrières aux ouvertures de cycle sont reliées de façon linéaire aux ordres de liaison des oxirènes et une extrapolation au tétracène en faisant appel à cette relation conduit à une barrière d'environ 50 kJ mol^{-1} qui semble être la barrière limite dans la série linéaire. Dans plusieurs cas, l'oxirène s'isomérise en cétène sans passer par un oxocarbène (cétocarbène). La benzoannellation n'est que le deuxième type de substitution (après la substitution diméthyle) qui, sur la base de calculs, semble capable de stabiliser les oxirènes.

Mots clés : oxirènes, cétocarbènes, benzooxirènes, AM1, ab ititio, DFT.

Introduction

Oxirenes (oxacyclopropenes, **1**) are interesting for three reasons: there are very few reports of the preparation of any derivatives of this system (1), high-level computational investigations indicate that the very ability of the parent compound to exist is somewhat problematic (2, 3), with disubstitution by groups of widely different electronic proclivities stabilizing the ring only for the methyl case (4), and oxirenes appear to be involved in the important Wolff rear-

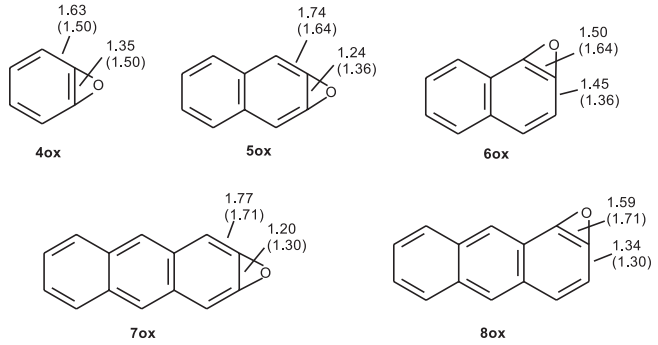
rangement of diazoketones to oxo carbenes ("ketocarbenes") (5). Calculations indicate that benzo substitution stabilizes the oxirene system (6); on the other hand, push–pull substituents, which are effective in stabilizing another presumably antiaromatic (7) system, cyclobutadiene (8), apparently do not have such an effect on oxirene (9). The oxirene literature to 1983 has been reviewed (10).

Attempts to prepare oxirenes tend to be thwarted by the only known reaction of the system: rearrangement to oxo carbenes, **2**, which undergo facile rearrangement to ketenes, **3**, and in some cases may not even be discrete compounds (5, 10).



Since, besides dimethyl substitution (4), only fusion to a benzene ring has been shown (computationally) to inhibit this ring-opening, I addressed the question of the limits to stabilization of oxirenes by benzo-type annelation. The reasoning is based on the simple idea that to the extent that the electron density in the C—C double bond can be decreased, the electronic factor(s) (antiaromaticity?) that engenders instability will be ameliorated. Polycyclic acenes (naphthalene, anthracene, etc.) offer a choice of formal double bonds to which an oxirene ring may be attached. Figure 1 shows the oxirenes that are investigated here, **4ox**–**8ox**, and the relevant Löwdin bond orders (11) of the oxirenes and their formal precursor acenes. The bond orders clearly suggest that for **4ox**, **5ox**, and **7ox** the dimethyleneoxirane-type structure is a more accurate representation of the electron distribution than is the oxirene structure, e.g., **5ox** and **5ox′** rather than **5ox″**.

For the polybenzenoid acenes **5ox**–**8ox**, the main resonance form is expected to be that with the maximum number of benzenoid rings, as shown in Fig. 1.

In this paper I show that where "bond fixation" (12, 13) imposes a structure predominantly of the dimethyleneoxirane resonance form, the oxirene is strongly stabilized compared to molecules in which the main contribution is from the oxirene canonical form, and that the stabilization is correlated with the oxirene C—C bond order. I also show that density functional (DFT) calculations (14) on these molecules give results quite comparable to those from the much slower MP2 (15) method, the traditional workhorse for electron-correlated calculations on molecules of reasonable size.

Fig.1. Relevant Löwdin bond orders of oxirenes and (in parentheses) the corresponding acenes. In each case the resonance structure with the maximum number of formal benzene rings is shown. Bond orders are from HF/6–31G* single-point calculations on DFT pBP/DN* geometries.

Computational methods

Structures were constructed with the interactive model builder of the Spartan program[2] and subjected to a preliminary geometry optimization with molecular mechanics, which in relevant cases was also used to create the desired symmetry, then geometries and frequencies were calculated at the AM1 (16) level, giving reasonable geometries and Hessians for ab initio (17) and DFT (14) geometry optimizations. The ab initio calculations were at the HF/6–31G* level; the DFT calculations, designated pBP/DN*, employed the Becke–Perdew perturbational procedure (18) and the numerical DN* basis set (19). HF/6–31G* geometry optimizations were performed with Spartan version 3.1 on an SGI R4000 workstation, and the pBP/DN* calculations with Spartan version 5.0 on an SGI RS4000 workstation. The MP2 calculations were MP2 frozen core with the 6–31G* basis set, i.e., MP2(fc)/6–31G*, and were done by submitting AM1 geometries to the Gaussian 94W program[3] on a 200 MHz Pentium Pro computer with the Windows NT operating system.

Optimized HF and DFT geometries were subjected to frequency calculations (20) at the same level to verify that the structure was the desired relative minimum (no imaginary frequencies) or transition state (one imaginary frequency), and to obtain zero-point energies (ZPEs) to correct the frozen-nuclei energy. The frequency calculations for the HF/6–31G* geometries were done with Gaussian 92[4] on a Hewlett-Packard 9000/733 computer at the University of Toronto. For most of the MP2 structures frequency calculations

Table 1. Energies, zero-point energies (ZPEs), ZPE-corrected energies (hartrees), and relative energies (kJ mol^{-1}) of **4ox** and derived species (see Fig. 2). The basis is 6–31G* throughout. HF energies were corrected with HF/6–31G* ZPEs, and MP2, MP4, and QCI energies with MP2(fc)/6–31G* ZPEs; DFT ZPEs were calculated at the same DFT (pBP/DN*) level. The HF ZPEs have been multiplied by 0.9135 and the MP2(fc) ZPEs by 0.9670 (21); DFT ZPEs are uncorrected. NSP means the species was not a stationary point at that level; QCI calculations were impracticably long for **4k** and failed for **4tk**.

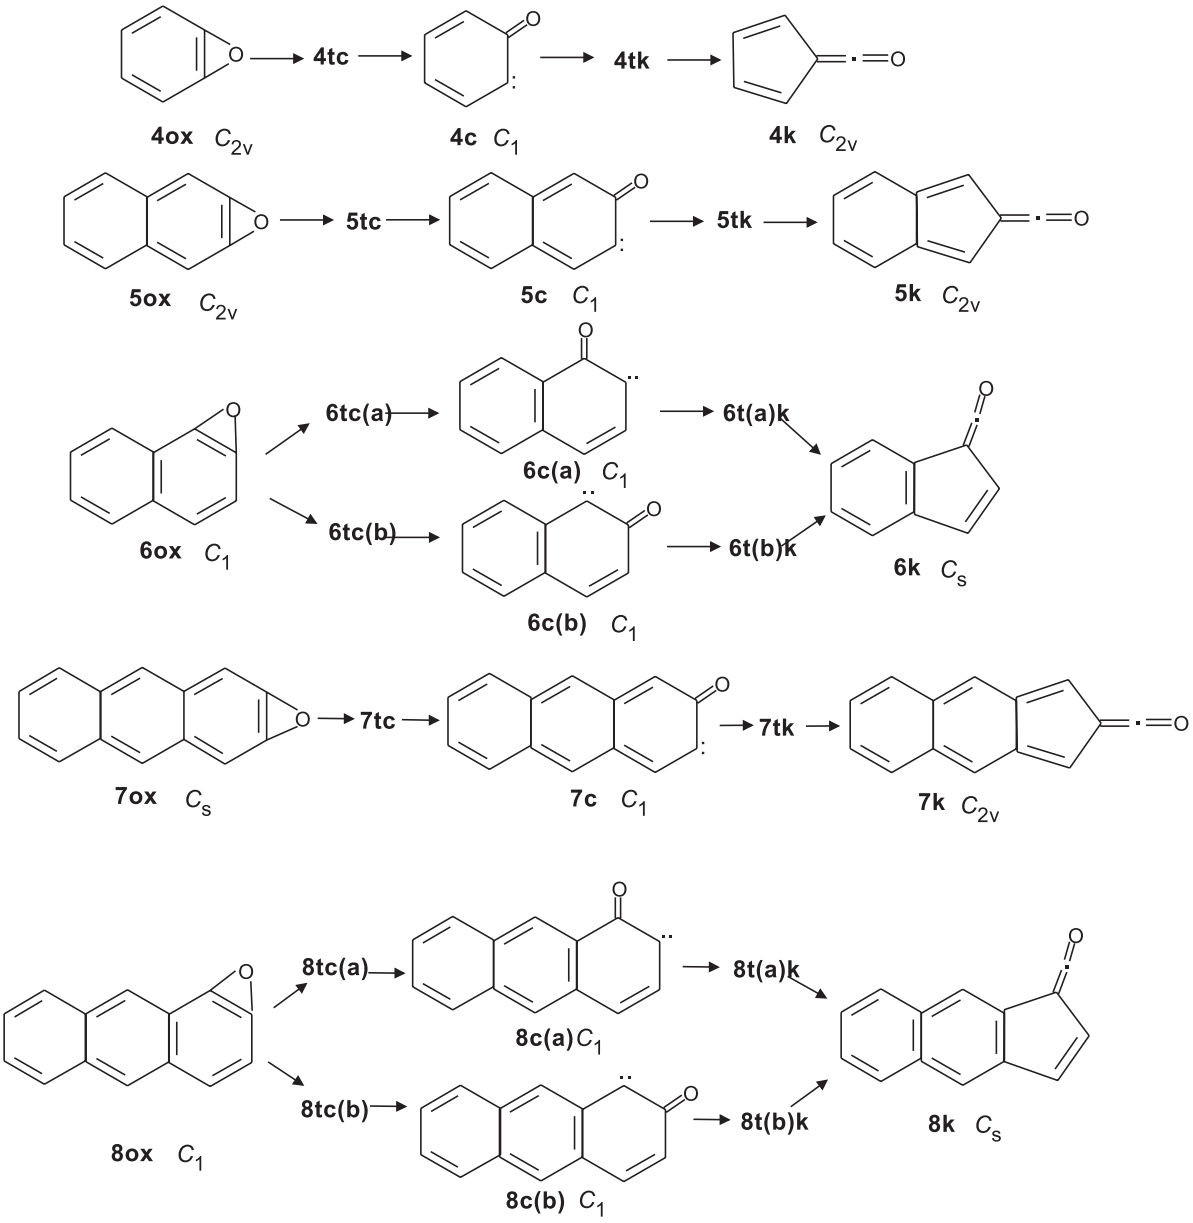
were impractical, but the structures could be confidently assigned as minima or transition states from their relative energies and their resemblance to the corresponding HF and DFT species; the HF ZPE corrections were used for the MP2 structures. The MP2(full), MP4SDTQ, and QCISD(T) energies of **4ox** (Table 1) were corrected with ZPEs from MP2(fc)/6–31G* frequency calculations, which also verified the nature of the stationary points **4ox**, **4c**, **4k**, **4tc**, and **4tk** at the MP2(fc)/6–31G* level; the MP4 and QCI calculations were done on a 200 MHz Pentium Pro machine. For the anthracene derivatives the times for MP2 and even HF calculations were expected to be impracticably long, and only AM1 and DFT calculations were performed for these molecules. HF ZPEs were corrected by multiplying them by 0.9135 (21); the correction factor for the DFT pBP/DN* frequencies was expected (21) to be close to 1.0, and no correction was applied to these.

Gaussian geometries were visualized with Spartan and Gaussian frequencies were animated with Molwin[5] (Spartan has its own graphical interface). Löwdin bond orders were calculated with Spartan.

Results and discussion

Reliability of the computational methods: benzooxirene as a probe. Comparison of pBP/DN* and CCSD(T)/6–311G(df,p) for the parent oxirene



The isomerization reactions of interest for **4ox**–**8ox** are shown in Fig. 2. Table 1 shows the energy values for **4ox** and the species **4c**, **4k**, **4tc**, and **4tk** involved in its isomerization to the ketene. The energies of the carbene **4c** and the transition state **4tc** leading to it differ very slightly from those reported previously (6), because for the ZPEs MP2(full) (rather than MP2(fc)) frequencies and a slightly different correction factor were used in the earlier work. The results at the HF/6–31G*, MP2(fc)/6–31G*, MP4SDTQ/6–31G*//MP2(full)/6–31G*, QCISD(T)/6–31G*//MP2(full)/6–31G*, and DFT (pBP/DN*) levels appear (Table 1) to be converging toward a reaction profile in which **4ox** opens with a barrier of 22–24 kJ mol^{-1} to give **4k**, which lies 262–272 kJ mol^{-1} below the oxirene. The carbene **4c** is either not a stationary point (DFT; i.e., **4ox** rearranges directly to **4k**), or rearranges to **4k** with a very low barrier only. At the MP2 and MP4//MP2 levels **4c** and **4tk** have essentially the same energy without the ZPE; with the ZPE, **4tk** has 3 and 0.5 kJ mol^{-1} less energy than the carbene (for very low barriers a slightly negative barrier can result from applying a ZPE calculated at one level to a single-point energy from a higher-level calculation). The carbene, therefore, seems to be either nonexistent or a mere dimple on the potential energy surface, ca. 8–21 kJ mol^{-1} below the oxirene (the inversion seen at the MP2 level can be ascribed (6) to the known tendency of this method to overshoot in recovering correlation energy).

As a further test of the reliability of the pBP/DN* method for these species, for the parent oxirene (C_2H_2O) the reaction profile for this method was compared that reported (5) for the CCSD(T)/6–311G(df,p) profile. The main differences

Fig. 2. The species (oxirenes, carbenes, ketenes, transition states: **ox**, **c**, **k**, **t**) and reactions examined in this paper. All the transition states have C_1 symmetry; the symmetry of the other species is given.

between the curves (Fig. 3) were that for the CCSD(T) method the oxirene ring opens with a small (ca. 2 kJ mol^{-1}) barrier after which the energy falls to ca. –4 kJ mol^{-1} in the carbene region and then rises to ca. 21 kJ mol^{-1} for the hydrogen shift that leads to the ketene; for the pBP/DN* curve the oxirene opens without a barrier and the energy falls to ca. –25 kJ mol^{-1}, then rises to ca. 14 kJ mol^{-1}. If we accept the CCSD(T) results as definitive, then, at least for the parent system, the pBP/DN* level seems to somewhat overestimate the stability of the carbene and slightly underestimate the height of the critical barrier. Neither of these possible defects is relevant to the purpose for which the method was applied to the reaction profiles of **4ox**–**8ox**, namely, to observe the trends among these systems, and to obtain at least a semiquantitative estimate of the oxirene stabilities.

Comparison of the oxirenes 4ox–8ox using DFT (pBP/DN*)

DFT pBP/DN* calculations (Table 2 and Fig. 4) show that benxooxirene (**4ox**) and the "linear" species **5ox** and **7ox** have *relatively* high barriers to ring-opening (24, 40, and 46 kJ mol^{-1}) while the "angular" oxirenes **6ox** and **8ox** have very low barriers (ca. 1 kJ mol^{-1} or less; see below). This is as expected from the bond fixation view, where for **4ox**, **5ox**, and **7ox** the oxirene C—C bond has a relatively low bond order (ca. 1.2–1.4), while for **6ox** and **8ox** the oxirene C—C bond order is 1.6–1.7 (Fig. 1). Although it is a C—O bond rather than a C—C bond that is broken in oxirene ring opening, a high C—C bond order is expected to correlate with high electron density in the oxirene ring, i.e, with increased oxirene, rather than oxirane, character.

Table 2. Energies, zero point energies (ZPEs), and ZPE-corrected energies of the species discussed in this paper (see Fig. 2). AM1 energies were not ZPE-corrected; MP2 energies were corrected with HF/6–31G* ZPEs. The HF/6–31G* ZPEs shown are the calculated ones multiplied by a correction factor of 0.9135 (21); the DFT ZPEs shown are uncorrected. AM1 energies are heats of formation in kJ mol^{-1}; HF and DFT energies are in hartrees. Numbers in parentheses are relative energies in kJ mol^{-1} for a family of species (e.g., **4ox**, **4c**,..., **4tk**) at the same level (e.g., AM1). NSP means the molecule did not exist (was not a stationary point) at that level, and NF means the transition state was not found. Where the carbene is not a stationary point, the transition state for oxirene to carbene (e.g., **4tc** for DFT) really denotes the transition state for direct conversion of the oxirene to the ketene. The **7** and **8** species were not examined at the HF and MP2 levels.

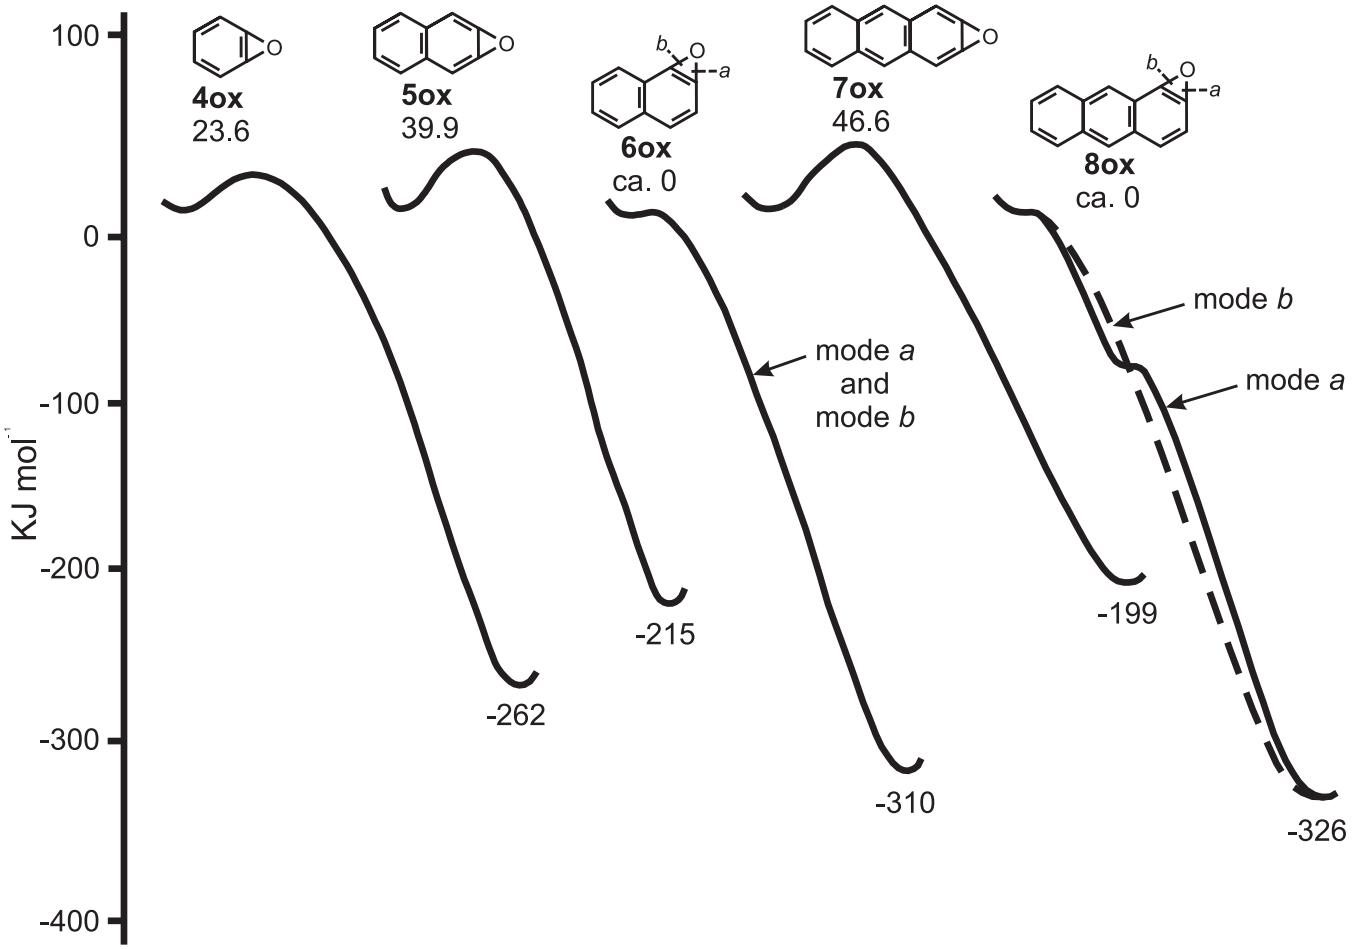
The nonlinear oxirenes **6ox** and **8ox** have two potential ring-opening modes, designated *a* and *b* in Fig. 4. These lead to different transition states and different putative carbenes (Fig. 2; the calculations indicate that the carbenes are either not stationary points, or have very low barriers for isomerization to the ketenes), but in the absence of isotopic labelling the ketenes are the same, e.g., for **6ox**.

The two modes have quite similar activation energies for **6ox** (–1.65 and –0.3 kJ mol^{-1} for modes *a* and *b*, respectively, with ZPE, and 0.81 and 1.1 without ZPE) and for **8ox** (–2.7 and –1.9 kJ mol^{-1} for modes *a* and *b*, respectively, with ZPE, and –1.4 and –1.8 kJ mol^{-1} without ZPE). The slightly negative barriers can be ascribed to errors in the DFT calculation caused by the grid or by the perturbational approximation in the pBP method. At the pBP/DN* level, only for mode *a* of **8ox** is a carbene (**8c(a)**, Fig. 2) an actual intermediate (a stationary point with all vibrational frequencies real); the barrier for conversion of the carbene to the ketene is 4.8 kJ mol^{-1}.

The correlation of the ring-opening barriers with the oxirene C—C Löwdin bond orders is shown in Fig. 5. The barriers for **6ox** and **8ox** have been simply set equal to zero. Although there is no clear theoretical basis for it, the empirical fact is that the linear relationship seen in Fig. 5 holds. An estimate of the ring-opening barrier of the linear tetracene oxirene was obtained from its calculated oxirene C—C Löwdin bond order and Fig. 5, bypassing a lengthy geometry optimization and frequency calculation on the transition state, which is not only big, but lacks symmetry

Fig. 3. Comparison of pBP/DN* (- - -) and CCSD(T)/6–311G(df,p) (5) (—) reaction profiles for the parent oxirene (C_2H_2O).



(the tetracene oxirene, slightly curved along the sequence of four benzene rings, has C_s symmetry). The barrier for the linear tetracene oxirene, with a bond order of 1.18, is estimated at 48 kJ mol^{-1}, only slightly higher than for the anthracene oxirene **7ox** (46.6 kJ mol^{-1}). Thus the ring-opening barrier for linear acene oxirenes appears to level off with four or five benzene rings, at about 50 kJ mol^{-1}. The borderline activation energy for observability at room temperature is about 100 kJ mol^{-1}, so it seems unlikely that any of these acene oxirenes will be isolable at room temperature. All of them, however, should be readily observable by matrix-isolation techniques.

These calculations indicate that not only can bond alternation in acenes be utilized to stabilize oxirenes, but that the

Fig. 4. Reaction profiles for the oxirenes **4ox**–**8ox** to give the corresponding ketenes, using the pBP/DN* method, with ZPE included. Only for ring-opening mode *a* of **8ox** was a carbene (**8c(a)**, Fig. 2) a stationary point. For **6ox** the activation energies denoted "ca. 0" are –1.65 and –0.3 kJ mol^{-1} for ring-opening modes *a* and *b*, respectively, with ZPE, and 0.81 and 1.1 without ZPE. For **8ox** the activation energies denoted "ca. 0" are –2.7 and –1.9 kJ mol^{-1} for ring-opening modes *a* and *b*, respectively, with ZPE, and –1.4 and –1.8 kJ mol^{-1} without ZPE. The barrier for conversion of **8c(a)** (the carbene formed by mode *a* ring opening) to the ketene was 4.8 kJ mol^{-1}.

oxirene system has the ability to impose on a benzene ring a large degree of bond alternation. This is seen for benzooxirene (6) and, more dramatically, for benzo*tris*oxirene **9** (Fig. 6). The *tris*oxirene is, judging by the bond orders, electronically essentially a cyclohexatriene. The bond orders (Löwdin bond orders calculated with the HF/6–31G* wavefunction using pBP/DN* geometries) are 1.84 and 1.05, and the bond lengths are not very different from those of a normal C—C double bond and a C—C single bond between sp^2 carbons: 1.316 Å and 1.401 Å (Fig. 6), cf. 1.32 Å and 1.48 Å, respectively (22). Molecule **9** appears not to have been previously studied, although related heterocyclopropene species, the silicon (23) and the nitrogen and boron (24) analogues, have been computationally investigated and show some bond fixation. In this work, **9** and **10** were found to be relative minima (no imaginary frequencies) of D_{3h} symmetry on the pBP/DN* hypersurface. That the bond fixation in **9** is largely due to the strong tendency of the oxirene system to exclude electrons from its C—C bond, rather than being mainly some kind of ring-strain effect, is shown by the fact that the corresponding benzo*tris*cyclopropene (**10**, Fig. 6) shows considerably less bond fixation: bond orders of 1.56 and 1.31, and bond lengths of 1.361 Å and 1.393 Å. The moderate degree of bond fixation in **10** found here is in accord with that reported in other computational studies of this molecule (23–25). The search for cyclohexatriene-like benzene rings is an active area of research (26), and **9**, with predicted bond lengths of 1.316 Å and 1.401 Å, evidently shows bond alternation comparable to that in the most cyclohexatriene-like "monobenzene" derivative whose geometry has been experimentally (X-ray analysis) confirmed: a *tris*-1,4-cyclobutadiyl-substituted benzene with bond lengths of 1.350 Å and 1.439 Å (27).

AM1, HF/6–31G* and MP2 calculations, compared to those at the DFT level

As shown above, a series of calculations (HF/6–31G*, MP2(full)/6–31G*, MP4SDTQ/6–31G*//MP2(full)/6–31G*, QCISD(T)/6–31G*//MP2(full)/6–31G* and pBP/DN* DFT; above) on **4ox** suggested that the reaction profile was converging at the last three levels, and that the DFT method was a practical way to obtain results similar to those at the much

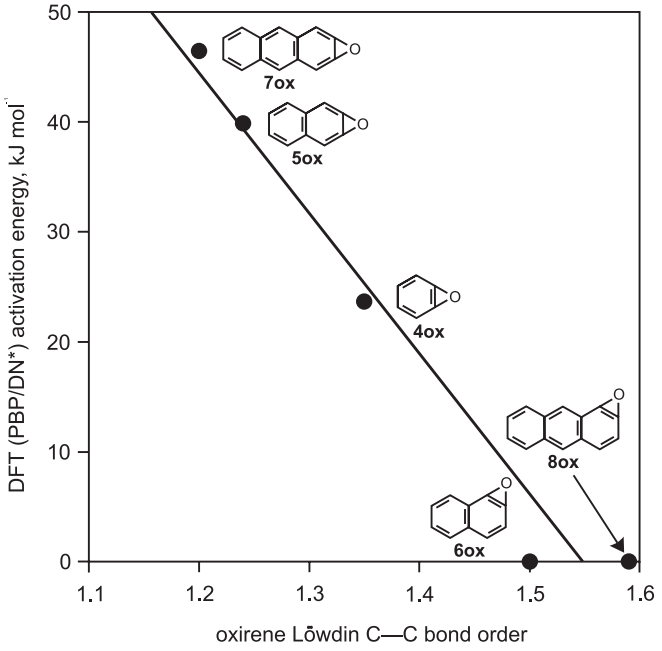
Fig. 5. Correlation of DFT (pBP/DN*) ring-opening barriers with oxirene C—C Löwdin bond orders for **4ox**–**8ox**. Bond orders are from HF/6–31G* single-point calculations on DFT pBP/DN* geometries.



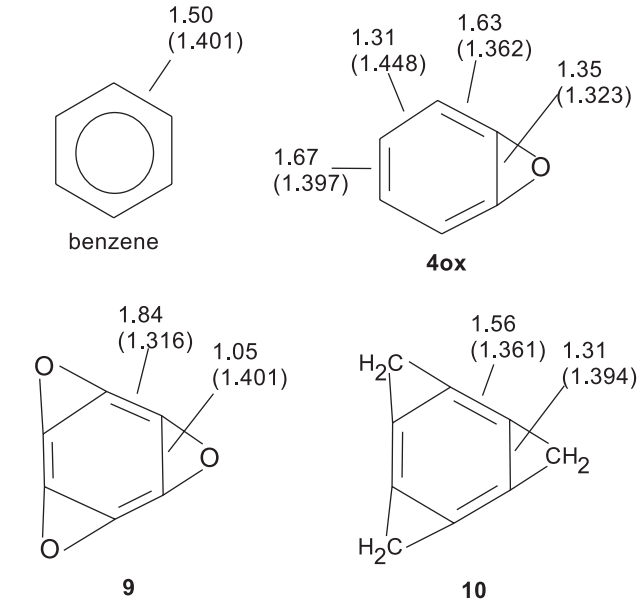


Fig. 6. Bond fixation in annelated benzenes. Löwdin bond orders and (in parentheses) bond lengths (Å) for benzene and oxirene-annelated and cyclopropane-annelated derivatives. Bond orders are from HF/6–31G* single-point calculations on DFT pBP/DN* geometries.

slower MP4SDTQ/6–31G*//MP2(full)/6–31G* and QCISD-(T)/6–31G*//MP2(full)/6–31G* levels. If we accept that the DFT calculations give realistic results for these systems, then we can judge the quality of the AM1, HF, and MP2 calculations by comparing them with the DFT ones. The main points of interest for **4ox**–**8ox** using these four methods (Table 2) are the height of the ring-opening barrier and the stability of the carbenes which might result from this opening (Fig. 2). The ring-opening barrier decreases almost monotonically from AM1 to DFT, and the changes are large: e.g., from 95 to 23.6 kJ mol^{-1} for **4ox**, and from 58 to essentially zero for **6ox**. Even the MP2 barrier is evidently unrealistically high: 49.1 cf. 23.6 for **4ox**, 74.7 cf. 39.9 kJ mol^{-1} for **5ox**, and 19.4 or 27.9 kJ mol^{-1} cf. essentially zero for and for **6ox**. The AM1 and (for **4ox**–**6ox**) the HF and MP2 calculations give the same ordering of barrier heights as do the DFT calculations, but the barriers are overestimated compared to the DFT results (greatly so for AM1).

The energies of the carbenes relative to the oxirenes, and the barrier to rearrangement of the carbenes to the ketenes, are also quite sensitive to the method. In all cases except **8c(a)** (Fig. 2) the DFT method predicts that the carbenes are not stationary points, but rather that the oxirene rearranges to the ketene without an intermediate (even for **8c(a)** the DFT barrier for rearrangement to the ketene is only 4.8 kJ mol^{-1}). AM1 and, to a lesser extent HF, overestimate (compared to DFT) the stability of the carbenes; for MP2 the barrier to carbene rearrangement to the ketene was low, in those cases where the transition state was found. All four methods agree that the ketenes lie ca. 200–400 kJ mol^{-1} below the oxirenes.

Conclusions

DFT calculations using the pBP/DN* method appear to be adequate to investigate the energetics of ring-opening of benzoannelated oxirenes; for benzooxirene the barrier is similar to that from QCISD(T)/6–31G* or MP4SDTQ/6–31G* calculations on MP2(full)/6–31G* geometries. The DFT calculations indicate that the stabilities of the oxirenes toward ring-opening increase with decreasing electron density in the C—C bond, as inferred from the calculated bond order, the barrier reaching about 50 kJ mol^{-1} for the linear anthracene oxirene or (estimated from bond order) tetracene oxirene. The tendency of the oxirene system to exclude electron density from the CC bond imposes strong bond alternation on annelated benzene rings: benzo*tris*oxirene is calculated to have distinct cyclohexatriene character. In most cases the carbene, the formal proximate product of ring-opening, is not a stationary point, but rather the oxirene is transformed in one step into the ketene. AM1, HF, and MP2 calculations overestimate the barrier to oxirene ring-opening.

Electrocatalytic hydrogenation of lignin models at Raney nickel and palladium-based electrodes

André Cyr, Florence Chiltz, Paul Jeanson, Anna Martel, Louis Brossard, Jean Lessard, and Hugues Ménard

Abstract: The electrocatalytic hydrogenation (ECH) of β-O-4 lignin model compounds has been carried out at constant current at Raney nickel and palladium-based cathodes in aqueous sodium hydroxide solution at temperatures ranging from 25 to 75°C. It was found that the hydrogenolysis of phenolic β-arylethyl-aryl ethers with one β-O-4 linkage takes place at both types of electrodes to give a mixture of phenolic compounds. The ECH of 1-(4-hydroxy-3-methoxyphenyl)-2-(2-methoxyphenoxy)-1-ethanol (model **1**) at Raney nickel gives guaiacol (**9**), acetovanillone (**11b**), α-methylvanillyl alcohol (**12b**), and products derived from their further hydrogenation. The β-O-4 bond is more difficult to cleave upon replacing one hydrogen of the methylene group of **1** by a hydroxymethyl group (see **2**). However, model **4** with two β-O-4 linkages obtained by the introduction of an α-methylvanillyl group at the phenolic position of **1** is hydrogenolysed at the same rate as **1** at Raney nickel. Only the C—O aryl bond attached to the hydroxyethylphenol moiety is cleaved. At palladium, the hydrogenolysis of **1** requires only half of the theoretical amount of electricity due to the generation of chemisorbed hydrogen by dehydrogenation of **1** followed by hydrogenolysis of the resulting ketone. A general reaction scheme is proposed for the ECH of model **1**.

Key words: Lignins, lignin models, electrocatalytic hydrogenation, Raney nickel electrodes, palladium electrodes.

Résumé : L'hydrogénation électrocatalytique (HEC) de composés modèles contenant une(des) liaison(s) β-O-4 des lignines a été effectuée sur cathodes de nickel de Raney et de palladium dans des solutions aqueuses d'hydroxyde de sodium et à des températures variant de 25 à 75°C. L'hydrogénolyse, sur ces électrodes, d'éthers phénoliques β-aryléthyl-aryle ayant une liaison β-O-4 a donné un mélange de composés phénoliques. L'HEC du 1-(4-hydroxy-3-méthoxyphényl)-2-(2-méthoxyphénoxy)-1-éthanol (modèle **1**) sur nickel de Raney a donné le guaiacol (**9**), l'acétovanillone (**11b**), l'alcool α-méthylvanillique (**12b**) et des produits de leur hydrogénation subséquente. La liaison β-O-4 du modèle **2** dans lequel un des hydrogènes du groupe méthylène de **1** a été remplacé par un groupement hydroxyméthyle s'est avérée plus difficile à hydrogénolyser. Cependant, la vitesse d'hydrogénolyse, sur nickel de Raney, du modèle **4** ayant deux liaisons β-O-4 et obtenu par l'introduction d'un groupement α-méthylvanillyle sur la fonction phénol du composé **1** était la même que celle du modèle **1**. Seule la liaison C—O aryle fixée au reste hydroxyéthylphénol a été hydrogénolysée. Sur cathode de palladium, l'hydrogénolyse du modèle **1** n'a consommé que la moitié de la quantité théorique d'électricité dû à la formation d'hydrogène chimisorbé par déshydrogénation de **1** suivie de l'hydrogénolyse de la cétone ainsi formée. Un schéma général de réaction est proposé pour l'HEC du modèle **1**.

Mots clés : Lignines, modèles de lignines, hydrogénation électrocatalytique, électrodes de nickel de Raney, électrodes de palladium.

Introduction

Historically, chemical treatments of lignins, such as oxidation in alkaline nitrobenzene or permanganate solutions, hydrogenolysis, and ethanolysis (1) have given an insight into the lignin structure, but have also revealed the potential use of this biopolymer as a feedstock for the preparation of low molecular weight chemicals. Since most of the lignins generated by the pulp and paper industry are still exploited only as fuel, there is an economic interest to develop methods of cleaving lignins into valuable monomers (2). Generally, oxidative methods have the objective of producing vanillin and syringaldehyde. Typical oxidation treatments involve nitrobenzene (3), metal oxides (3), oxygen[2, 3], and

electrolysis (4, 5).[4] Catalytic hydrogenation has also been studied as a method for production of phenolic monomers (6). A variety of catalysts have been used, including Raney nickel (7), copper chromite (8), supported rhodium (9, 10), ruthenium or palladium (11), and nickel boride[5]. Interesting compounds such as 4-*n*-propylguaiacol and dihydroconiferyl alcohol have been generated from aspen wood using Raney nickel (7) or supported rhodium (9, 10). With a palladium catalyst, a high selectivity has been reported for the formation of dihydroconiferyl alcohol (11). The use of nickel boride has led to the production of 4-ethylguaiacol and 4-ethylsyringol from wood.[5]

In a recent article (12), we prepared basic nonphenolic models of α-O-4 and β-O-4 bonds in lignins to demonstrate the potential of electrocatalytic hydrogenation (ECH) as an alternative method for lignin depolymerization. ECH is an advantageous combination of electrochemical and catalytic methods (for a review on ECH, see ref. 13). In ECH, chemisorbed hydrogen (H)M is generated in situ on the electrocatalyst surface by electroreduction of water at a low overpotential (rxn. [1]) and reacts with the adsorbed organic substrate (rxns. [2]–[4]). However, hydrogenation (rxns. [2]–[4]) competes with hydrogen desorption (rxns. [5] and (or) [6]) and this may decrease the current efficiency (13). This method of generating chemisorbed hydrogen allows one to carry out reactions similar to catalytic hydrogenation but at lower temperatures and pressures (13). Furthermore, the concentration of chemisorbed hydrogen can be controlled by adjustment of the current density.

ECH at electrodes made of Raney-type materials has been applied successfully to the selective hydrogenation of many types of molecules (13). In principle, all catalytic powders used in catalytic hydrogenation can also be used in ECH, provided that the catalyst can be immobilized on (or supported by) a conductive material or cast into a solid conductive piece. The simplest electrode set up is to spread the catalytic powder onto a conductive plate, but such a design is not fully satisfactory from a practical point of view. Several approaches have been developed to prepare electrodes from catalytic powders, including electromagnetic deposition (14), electrocodeposition (15), lanthanum phosphate polymerization,[6] and embodiment in a reticulated vitreous carbon support (16). The latter two methods have been used in this work.

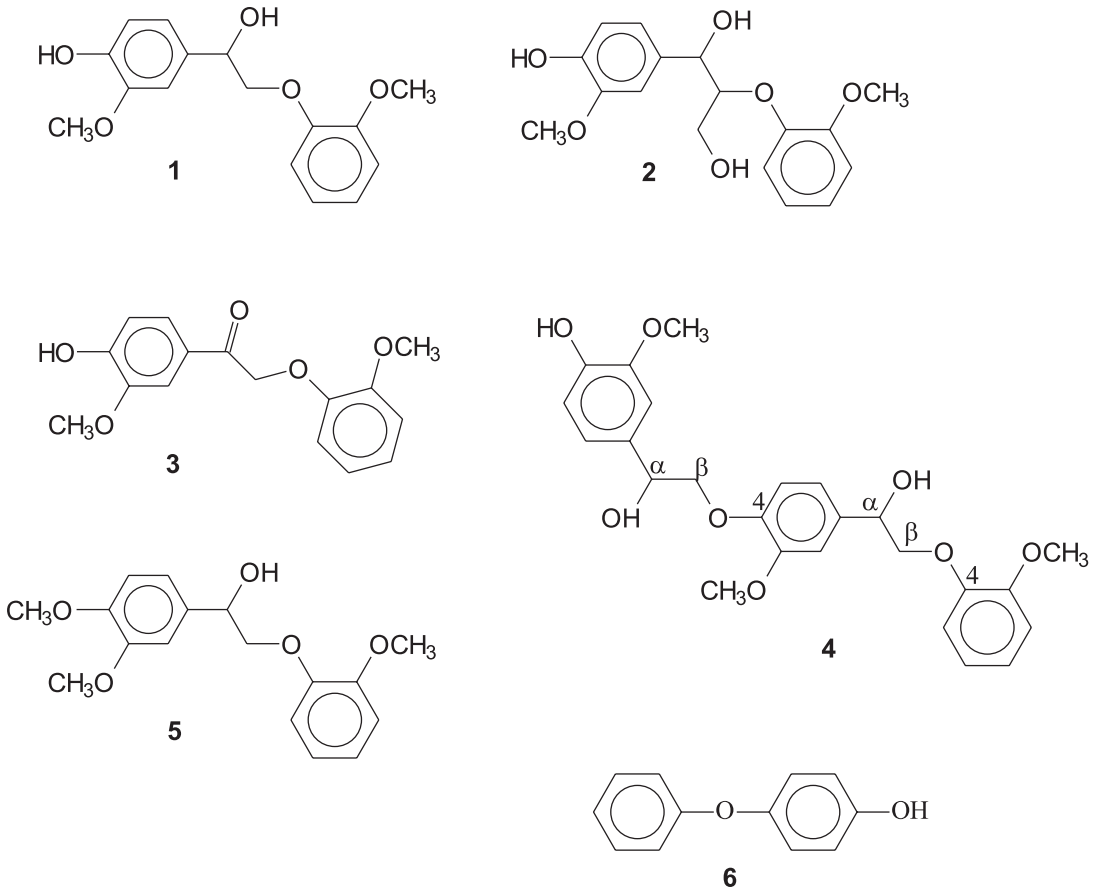
As an extension of our previous work (12), we report in this paper the results of the ECH of phenolic lignin models (which are soluble in aqueous alkali) on Raney nickel and palladium-based electrodes. It has been recognized that the β-O-4 linkage (see **4** in Fig. 1) is the most important type of structural element in native lignins. We therefore studied the following models (see Fig. 1 for structures): (*i*) three compounds having one β-O-4 linkage and referred to as phenolic monoethers: 1-(4-hydroxy-3-methoxyphenyl)-2-(methoxyphenoxy)-1-ethanol (**1**), its hydroxymethyl derivative **2**, and its keto derivative **3**; (*ii*) phenolic diether **4** with two β-O-4 linkages; (*iii*) 1-(3,4-dimethoxyphenyl)-2-(methoxyphenoxy)-1-ethanol (**5**), a non-phenolic monoether (β-O-4 linkage); and (*iv*) 4-phenoxyphenol (**6**), a model of 4-O-5 linkages in which two aryl groups are directly bound to an oxygen atom. Raney nickel has proven to be a versatile hydrogenation electrocatalyst (13), and supported palladium was chosen in view of its well known activity in catalytic hydrogenolysis (17).

Experimental

Organic substrates and products

Phenolic monoethers **1** (18), **2** (19), **3** (18), and **5** (5) are known compounds and were synthesized according to published procedures. Phenolic diether **4** is also a known compound and was prepared from *O*-isopropyl-α-bromoacetovanillone (prepared according to ref. 20) by described procedures (18, 21). The following compounds (Fig. 2) were obtained from commercial sources: 4-phenoxyphenol (**6**), guaiacol (**9**), ethylphenol (**10a**), acetovanillone (**11b**), and 4′-hydroxypropiophenone (**11c**) from Aldrich; cyclohexanol (**7**) and phenol (**8**) from BDH; 4-ethylguaiacol (**10b**), 4-*n*-propylphenol (**10c**), and 4-*n*-propylguaiacol (**10d**) from Lancaster; 4′-hydroxyacetophenone (**11a**) from Eastman. The alcohols **12a, b** (Fig. 2) were prepared by catalytic hydrogenation of the corresponding ketone using nickel-aluminum alloy in 10% sodium hydroxide at 15°C (in situ generation of Raney nickel and chemisorbed hydrogen) (22). All compounds had ^{1}H NMR, ^{13}C NMR, IR, and mass spectral data in accordance with their structure.

Electrodes and electrolyses



Raney nickel electrodes were made by mixing and grinding 45% of Raney alloy (Fluka), 45% of fractal nickel powder (Inco Type 250), and 10% of lanthanum phosphate[6]. About 40 g of this powder was pressed into a plate 3mm thick at about 1000 kg/cm^2 into a 5 × 71/2 cm^2 mould from which 2 × 21/2 cm^2 plates were cut. These plates were heated at 800°C for 4 h under an argon atmosphere. The electrical contact was made with a nickel stripe. The plates were leached in NaOH 30% at 75°C for 24 h to remove aluminum. In order to eliminate the chemisorbed hydrogen formed in the leaching process (reduction of water by aluminum), the Raney nickel plate was treated with a solution of *trans*-cinnamic acid (5 g in 200 mL of 1 M NaOH) at room temperature for at least 18 h (hydrogenation to phenylpropionic acid) prior to electrolysis.

The palladium-based electrode consisted of a 2 × 2.5 × 0.6 cm^3 piece of 100 ppi reticulated vitreous carbon (Electrosynthesis Co.) into which 0.20 g of catalyst

Fig. 1. Lignin models studies.

(palladium 5% on alumina from Aldrich) was embedded (16). This physical embodiment of the particles into the vitreous carbon reticulated structure occurred spontaneously when the powder was stirred in the catholyte solution for about one hour in the presence of the vitreous carbon matrix. The particles remained in contact with the carbon matrix despite vigorous stirring, provided that there was no sudden perturbation (16).

The electrolyses were carried out with a 410 Potentiostatic Controller coupled to a 640 digital coulometer (Electrosynthesis Co.). A two-compartment jacketed glass H-cell with a Nafion-324 membrane (E.I. duPont de Nemours & Co.) and condensers was connected to a temperature-regulated circulating bath. Both compartments were filled with 30 mL of 1 M NaOH (except for the electrolysis of **5**:1 M NaOH in 1:1 ethanol–water) and 0.75 mmol of organic substrate (0.38 mmol for compound **4** as it contains two β-O-4 links) was added to the catholyte stirred magnetically. A graphite rod was used as anode. A constant current was applied (5 or 20 mA) and samples of the catholyte were taken at regular intervals. The electrolysis of **1** at 75°C and 5 mA was conducted under a nitrogen atmosphere in order to avoid chemical degradation (23).

Work-up procedures and analyses

Part of the catholyte was neutralized with 10% acetic acid in water, then diluted to a fixed volume with 20% acetonitrile in water and analyzed by HPLC (C_{18} column packing, Beckman 100A pumps, Beckman 420 controller, Hitachi 100-40 spectrophotometer at λ = 272 nm, and HP3390A integrator) with the help of calibration curves for compounds **1**–**6**, **8**, **9**, **10a**–**c**, **11a**–**c** and **12a, b**. The best overall separation was achieved with the following eluent program at a flow rate of 1.0 mL/min: 90% of 4% acetic acid in water – 10% CH_3CN for 5 min, then adding 0.5% CH_3CN per min up to 45% CH_3CN.

Product identification was performed by GC–MS (Hewlett–Packard 5890, 30 m DB-5 column and HP5971 mass-selective detector) and complementary quantitative analyses were done by GC–FID (Perkin–Elmer 8500, 30m DB-1 capillary column and HP3390A integrator), when needed, using internal standards. Response factors were approximated for compounds for which authentic samples were not available (**10e**, **11d**, **12c**–**e**). The thermally unstable compounds **1, 2,** and **12a**–**e** were characterized as their acetate derivatives. Acetylation of the hydroxyl groups was accomplished overnight with a 1:1 pyridine – acetic anhydride mixture (24). For the GC analyses of the acetylated derivatives, part of the catholyte was neutralized with 1 M HCl then extracted with ethyl acetate, the organic layer was dried with magnesium sulfate and the solvent removed under vacuum.

Results and discussion

ECH at Raney nickel

The ECH of model **1** in alkaline solution was studied as a function of temperature and current density (Table 1). At

(e) $R_1 = CH_2OH, R_2 = OCH_3$

room temperature (entries 1 and 2), the hydrogenolysis of the β-O-4 bond occurs readily to give about equal amounts of guiacol (**9**) and α-methylvanillyl alcohol (**12b**) (see Figs. 1, 2, and 4 for structures) as expected and the electrohydrogenolysis is much less efficient at a current of 20 mA (entry 2: 40% conversion after a charge of 18 F mol^{-1}) than at a current of 5 mA (entry 1: 94% conversion). The effect of increasing the current becomes less and less important as the temperature is increased to 50°C (compare entries 3 and 4) then to 75°C (compare entries 5 and 6). At a given current, an increase of temperature leads to higher conversion rates and to further hydrogenation of guaiacol (**9**) to phenol (**8**) and cyclohexanol (**7**) and of α-methylvanillyl alcohol (**12b**) to 4-(1-hydroxyethyl)phenol (**12a**), 4-ethylguaiacol (**10b**) and 4-ethylphenol (**10a**) (compare entries 1 and 3, compare entries 2, 4, and 6). Thus, an increase of temperature and a lower current density favor the hydrogenation process (rxns. [2]–[4]) over hydrogen desorption (hydrogen evolution, rxns. [5] and (or) [6]) as observed with other substrates (13). As shown in Table 2, independent studies confirmed the hydrogenation, under the ECH conditions, of guaiacol (**9**) to phenol (**8**) and cyclohexanol (**7**) (entry 4), of phenol (**8**) to cyclohexanol (**7**) (entry 5), and of α-methylvanillyl alcohol (**12b**) to 4-(1-hydroxyethyl)phenol (**12a**), 4-ethylguaiacol (**10b**) and 4-ethylphenol (**10a**) (entry 1). Figure 3 (variation of the product distribution during the ECH of model **1** at 50°C and 5 mA) also shows that alcohol **12b** is hydrogenolysed further to 4-ethylphenol (**10a**).

It is noteworthy that, during the ECH of model **1**, acetovanillone (**11b**) was present along with methylvanillyl alcohol (**12b**) at the beginning of the electrolysis, whatever the temperature and the current. This is clearly seen in Fig. 3 which shows that an equimolar amount of ketone **11b** and alcohol **12b** was present after 2 F mol^{-1} in an electrolysis carried out at 50°C and 5 mA. Furthermore, the amount of ketone **11** formed is more important the higher the temperature (compare entries 2, 4, and 6 of Table 1). This demonstrates that a secondary benzyl alcohol can be dehydrogenated to the corresponding ketone on a polarized Raney nickel catalyst (reverse of rxns. [4], [3], and [2]) and that dehydrogenation

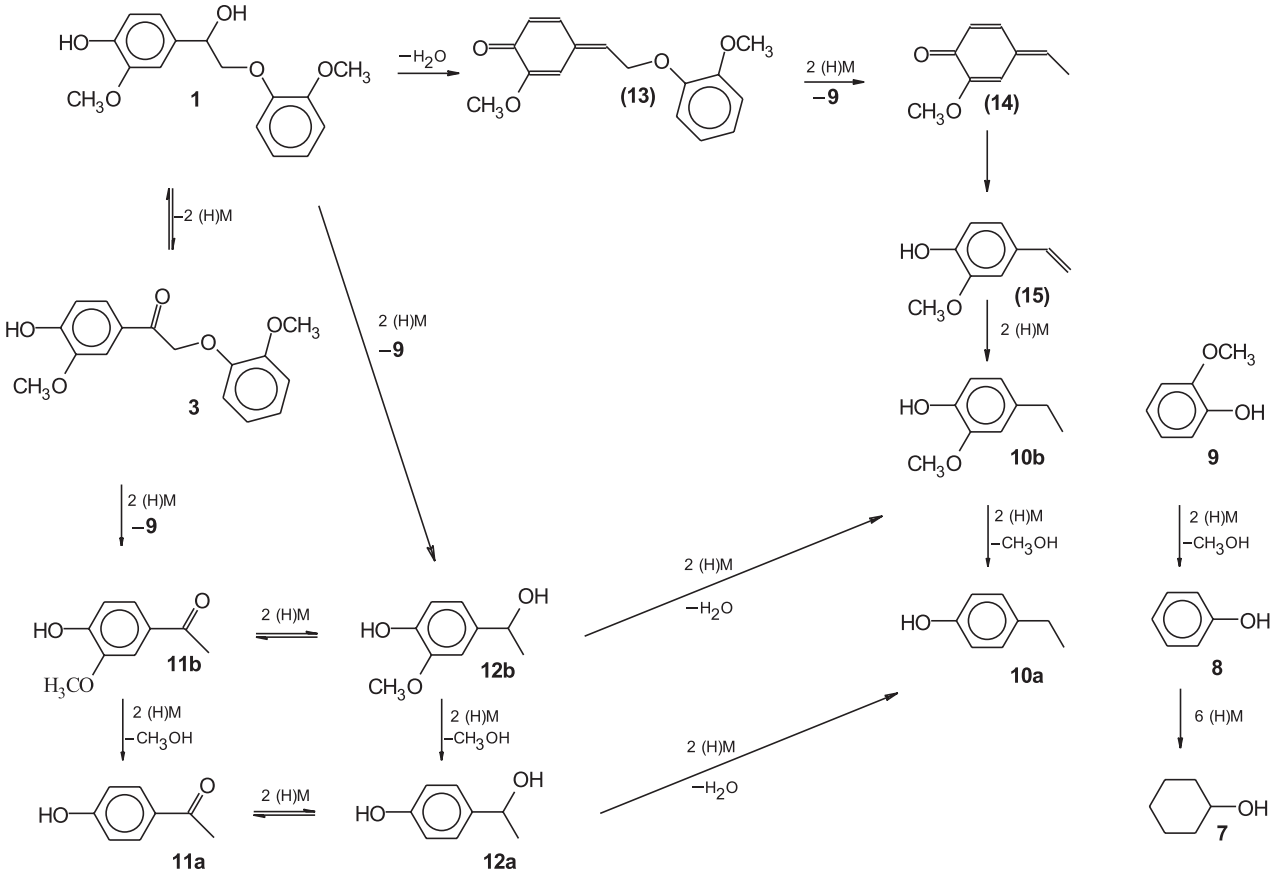
[b]Q in F mol^{-1} is the charge corresponding to the number of moles of electrons per mole of substrate.

[c]No unreacted **3** was detected.

Fig. 3. Evolution of the product distribution with the charge (F mol^{-1}) for the ECH of model **1** at a Raney nickel electrode at 50°C and 5mA: ● unreacted **1**, ▲ guaiacol (**9**), ○ α-methylvanillin (**12b**), ■ 4-ethylphenol (**10a**), □ acetovanillone (**11b**).



is faster at higher temperatures. The fact that dehydrogenation of a benzyl secondary alcohol could effectively take place under the electrolysis conditions was confirmed by carrying out the ECH of alcohol **12b** (Table 2, entry 1) under the same conditions (alcohol **12b** is stable under the electrolysis conditions in the absence of an electrode): acetovanillone (**11b**) is formed rapidly in the cell, then is slowly converted back to alcohol **12b** which, as already observed, is hydrogenolysed to 4-(1-hydroxyethyl)phenol (**12a**) (also dehydrogenated to 4′-hydroxyacetophenone (**11a**)), 4-ethylguaiacol (**10b**), and 4-ethylphenol (**10a**). After 18 F mol^{-1}, there was still 38% of alcohol **12b** and 21% of ketone **11b** present together with 9% of alcohol **12a**, 3.5% of ketone **11a**, 6% of 4-ethylguaiacol (**10b**), and 13% of 4-ethylphenol (**10a**). The ECH of ketone **11b** (entry 2) did give alcohol **12b** which is hydrogenolysed further to **12a** (also dehydrogenated to **11a**), **10b**, and **10a** as expected. Thus, there is a benzyl alcohol – ketone interconversion (dehydrogenation–hydrogenation) during the ECH of secondary alcohols at Raney nickel in aqueous alkali and this interconversion is faster the higher the temperature. Such dehydrogenation of alcohol **1** to ketone **3** during the ECH of **1** certainly occurs even if ketone **3** is not detected during the ECH of **1.** In fact, the electrohydrogenolysis of ketone **3** at 50°C and 5 mA occurs readily (Table 2, entry 3): after 8 F mol^{-1}, the conversion is complete and the products formed are: guaiacol (**9**) (48%); α-methylvanillyl alcohol (**12b**) (15%) together with acetovanillone (**11b**) (27%), its dehydrogenation product; 4-(1-hydroxyethyl)phenol (**12a**) (1.5%) and its dehydrogenation product, 4′-hydroxyacetophenone (**11a)** (1%). Ketone **3** also undergoes rapid degradation under the conditions used for ECH.

A scheme for the formation of most of the products isolated and detected in the ECH of **1** (Table 1) and in the ECH of some of the products isolated (Table 2), at a Raney nickel electrode, is shown in Fig. 4. Two possible pathways for the formation of α-methylvanillyl alcohol (**12b**) are illustrated: (1) direct hydrogenolysis of the β-O-4 bond of **1** (**1** → **12b** + guaiacol (**9**)), and (2) dehydrogenation of **1** to ketone **3** followed by its hydrogenolysis to acetovanillone (**11b**) and guaiacol (**9**), **11b** being hydrogenated to **12b** (**1** → **3** → **11b** → **12b**). The hydrogenolysis of ketone **3** should be faster than that of alcohol **1** because, in the former, the β-O-4 bond is conjugated to the carbonyl group of an acetophenone (to a π-electron system). So pathway (2) is probably the main route to alcohol **12b**. The two most probable routes to 4-ethylguaiacol (**10b**) are: (*i*) hydrogenolysis of α-methylvanillyl alcohol (**12b**) (**12b** → **10b**) and (or) (*ii*) dehydration of **1** to quinonemethide **13** followed by easy hydrogenolysis of the β-O-4 bond (**13** → **14** + **9**), then rapid tautomerization of **14** to the more stable styrene **15** which would be rapidly

© 2000 NRC Canada

Fig. 4. Reaction pathways for the formation of the various products in the ECH of model **1**.

hydrogenated to **10b**. The hydrogenolysis of the C—O aryl bond of quinonemethide **13** should be easy because the C—O bond is conjugated to the quinonemethide π-bond system. Quinonemethides **13** and **14** as well as styrene **15** were not detected during the ECH of model **1**, which means that, if pathway (*ii*) was occurring, their conversion is faster than their generation. Dehydrations similar to the dehydration of **1** to quinonemethide **13** were shown to occur under the drastic conditions of alkali pulping (25) but should be slower at temperatures of 75°C or lower (5). Finally, 4-ethylphenol (**10a**) might have been formed by demethoxylation of 4-ethylguaiacol (**10b**) and(or) by hydrogenolysis of 4-(1-hydroxyethyl)phenol (**12a**) and there are two possible routes to **12a**: **12b** → **12a** and(or) **11b** → **11a** → **12a**.

For the demethoxylation of 2-methoxyphenols (guaiacol (**9**) to phenol (**8**), 4-ethylguaiacol (**10b**) to 4-ethylphenol (**10a**), acetovanillone (**11b**) to 4′-hydroxyacetophenone (**11a**), α-methylvanillyl alcohol (**12b**) to 4-(1-hydroxyethyl)phenol (**12a**)), direct hydrogenolysis is not very probable due to the fact that the C—OCH_3 bond should be quite strong since the carbon is a sp^2 carbon and the C—O bond is not conjugated to a π-electron system. So demethoxylation most probably takes place on the less stable (nonaromatic) 6-methoxycyclohexa-1,4-dien-1-one tautomer (keto–enol tautomerism). Two routes are possible: (*i*) hydrogenolysis of the C—OCH_3 bond which should occur readily since the methoxy group is attached to a sp^3 carbon and the C—O bond is conjugated to a cyclohexadienone π-electron system; (*ii*) hydrogenation of the dienone to a 6-methoxycyclohexa-1,4-dien-1-ol followed by elimination of methanol. The fact that 2-methoxycyclohexanol was not detected during the ECH of guaiacol (**9**) to phenol (**8**) and cyclohexanol (**7**) (Table 2, entry 9) indicates that the hydrogenation of the aromatic ring takes place only after the methoxy group has been removed. As a matter of fact, cyclohexanol (**7**) was the only saturated compound detected in this study of ECH of model **1** and the other models.

The hydrogenolysis of the β-O-4 bond of model **2** with a hydroxymethyl group attached to the β carbon is more difficult than that of model **1** as shown by the lower conversion rates of entries 1 to 3 of Table 3. The mixture of compounds formed is more complex than that obtained from the ECH of **1** because compounds with a phenylpropane structure (**10c**, **10e**, **11c**, **11d**, **12c**, **12d**, **12e**) are formed in addition to those with a phenylethane structure (**10a**, **10b**, **11a**, **11b**, **12a**, **12b**) identified from the ECH of **1**. In the ECH of **2**, none of the compounds, besides guaiacol (**9**), is obtained with a high degree of selectivity. Compounds **12** (**12a**–**e**) were the most abundant with a total yield of 12% only (see Table 3, entry 2). Again, exhaustive electrolysis should favor compounds **10** (**10a**–**e**). Despite the relatively low yields, ECH appears more interesting than electrooxidation which causes much polymerization of **2** (and of **1** also) (5).

Expanding model **1** by adding a methylvanillyl alcohol unit to the phenolic end (see model **4** which has two β-O-4 bonds) appears to have little influence on the ease of hydrogenolysis. Indeed, (*i*) the extent of hydrogenolysis after a given charge (the current efficiency), for an ECH carried

[a]Some compounds giving rise to GC–MS peaks could not be identified and they were not taken into account in the calculation of the yields.

[b]*Q* in F mol^{-1} is the charge corresponding to the number of moles of electrons per mole of β-O-4 bonds.

[c]Other products identified were ketone **4a** (2.0%), ketone **3** (2.0%), and model **1** (0.2%). There was as much as 7% of compound **1** accumulated after 3 F mol^{-1}.

Fig. 5. Influence of temperature and current on the rate of hydrogenolysis of model **4** : ▲ 25°C, 20 mA, ● 50°C, 20 mA, ■ 75°C, 20 mA, ○ 50°C, 5mA, □ model **1**: 50°C, 20 mA.

out at 50°C and at a current of 20 mA, is about the same for model **4** as for model **1** as shown in Fig. 5 and (*ii*) the product distribution after 18 F mol^{-1} for an ECH carried out at 75°C and a current of 20 mA is similar for model **4** (entry 4, Table 3) and model **1** (entry 6, Table 1). This is because the same type β-O-4 bond is hydrogenolysed in both model **4** and model **1**, the C—O aryl bond attached to a hydroxyethylphenol moiety. Figure 5 shows that the efficiency of hydrogenolysis increases with increasing temperature and decreases with increasing current as observed for the ECH of model **1**. Again dehydrogenation of secondary benzylic alcohols did occur as already noted since both the ketone resulting from dehydrogenation of model **4** and ketone **3** resulting from dehydrogenation of model **1** are formed in the ECH of **4**.

The fact that model **1** and its corresponding dehydrogenation product, ketone **3**, are formed in the ECH of **4** indicates that hydrogenolysis of one of the β-O-4 bonds, the C—O aryl bond attached to the hydroxyethylphenol moiety, is faster than the hydrogenolysis of the other β-O-4 bond, the C—O aryl bond attached to the *O*-alkylated hydroxyphenol moiety. In fact, model **5** in which the phenolic group had been methylated (structure akin to the *O*-alkylated hydroxyphenol moiety of model **4**) was recovered quantitatively after electrolysis under the same conditions as those used for the ECH of models **1**, **2**, and **4**. There are two possible explanations for the faster hydrogenolysis of the C—O aryl bond attached to the hydroxyethylphenolate moiety: (*i*) the hydrogenolysis takes place on the ketone resulting from

[a]Pd 5% on charcoal or alumina in contact with a reticulated carbon matrix (see Experimental).

[b]Experimental conditions : 50°C and 5 mA. The lower mass balance for ECH on Pd–C compared to ECH on Pd–Al_2O_3 is due to the stronger adsorption of organics on charcoal than on alumina (16).

[c]Q in F mol^{-1} is the charge corresponding to the number of moles of electrons per mole of substrate.

[d]Not detected.

dehydrogenation of **4** and the dehydrogenation of the hydroxy group at the benzylic position of the electron-rich (negatively charged) phenolate ring is faster than that of the other benzylic alcohol; and (or) (*ii*) hydrogenolysis takes place from the quinonemethide resulting from elimination of the hydroxy group at the benzylic position of the phenolate ring which would indeed be faster than the elimination of the other benzylic alcohol because a negatively charged oxygen atom (phenolate anion) is a better electron donor than an alkoxy group.

The aryl-O-aryl bond of phenoxyphenol (**6**) is easily hydrogenolyzed to phenol at a Raney nickel cathode and at 50°C and 5 mA (Table 3, entry 5). This type of linkage is most frequent in the Kraft lignin (26). A study of the ECH of this compound as function of the electrode material has been reported elsewhere (16). It must be noted that phenol was the sole product formed. Neither benzene nor *p*-cresol were detected. Thus, only the C—Oaryl bond attached to the phenol ring was cleaved. This can be readily explained if the hydrogenolysis takes place via the cyclohexadienone tautomer in which the C—Oaryl bond is attached to a sp^3 carbon and conjugated to a cyclohexadienone π-electron system as suggested above for the demethoxylation of 2-methoxyphenols by ECH.

Finally, an electrolysis has been attempted on 2,2′-biphenyl which is representative of 5—5′ bonds in lignins. Such carbon–carbon bonds between two sp^2 carbons are particularly strong and, as expected, the unreacted substrate was quantitatively recovered.

ECH at palladium

The results are presented in Table 4. The ECH of model **1** at a cathode made of 5% Pd–C or 5% Pd–Al_2O_3 particles embedded in a matrix of reticulated vitreous carbon (16, see Experimental) gave an unexpected result (entries 1 and 3): the substrate was completely converted to guaiacol (**9**) and acetovanillone (**11b**) after only 1 F mol^{-1}, that is after consumption of only half of the theoretical amount of electricity required for complete hydrogenolysis. The reaction was quantitative with Pd–Al_2O_3 (entry 3) but the mass balance was 72% only with Pd–C due to the strong adsorption of organics on activated charcoal as reported previously (16). In a blank test performed under the same conditions as those of entry 3 (Pd–Al_2O_3) but with a nonpolarized electrode (open circuit), **1** was first dehydrogenated to ketone **3** (see Fig. 4). After a period of time corresponding to the duration of an electrolysis, some guaiacol (**9**) and acetovanillone (**11b**) were formed in small amounts thus showing that a small quantity of the hydrogen atoms generated at the surface of the palladium catalyst by dehydrogenation of **1** is used in the hydrogenolysis of ketone **3**. On the polarized catalyst, about 50% of the hydrogen atoms generated at the surface of the palladium electrode by dehydrogenation of **1** must have been used for the hydrogenolysis of ketone **3** in order to explain the low charge corresponding to 1 F mol^{-1} (50% of the theoretical charge) consumed for complete conversion of model **1**. Electrocatalytic hydrogenolysis of ketone **3** did indeed occur readily at these palladium cathodes to give guaiacol (**9**) and acetovanillone (**11b**) plus an unidentified compound resulting form the degradation of **3** in basic medium. Because of such degradation, the yield of **9** and **11b** was not determined. When an electrolysis at Pd–C was pursued up to 18 F mol^{-1} (entry 2), slow electrocatalytic hydrogenation of acetovanillone (**11b**) to alcohol **12b** did occur as shown by the decrease of the amount of **11b** and increase of the amount of **12b**.

Conclusions

Electrocatalytic hydrogenation has been applied successfully to the low-temperature hydrogenolysis of representative lignin phenolic models with β-O-4 bonds at Raney nickel and palladium electrodes in basic aqueous medium. The hydrogenolysis does not take place if the phenolic group is alkylated. This fact suggests that hydrogenolysis would occur on intermediates in which the C—O aryl bond is conjugated to a π-electron array such as in ketone **3** or quinonemethide **13**, and that the formation of those intermediates would be significantly faster with the electron-rich phenolate anion than with the *O*-alkylated derivative less rich in electrons. 4-Phenoxyphenol (**6**) is cleaved easily and exclusively to phenol at a Raney nickel electrode, showing that hydrogenolysis of a 4-O-5 linkage by ECH is also possible and most probably takes place on the cyclohexadienone tautomer of the phenol in which the C—O aryl bond is again conjugated to a π-electron array. The 4-O-5 type of linkage is abundant in Kraft lignins produced by the pulp and paper industry. The results of this paper infer that lignins could be

depolymerized and converted to useful basic organics by ECH.

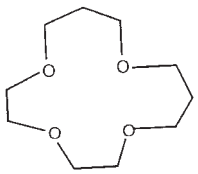
Solid state stereochemistry of crown ethers: X-ray crystal structure and ^{13}C NMR studies of the LiNCS complex of 1,4,7,11-tetraoxacyclotetradecane

G.W. Buchanan, A.B. Driega, and G.P.A. Yap

Abstract: The title complex is asymmetric in the crystal due to the spatial orientation of the NCS function. The space group has been determined to be $P2_1$ with a = 9.496(3), b = 8.736(3), c = 9.676(3) Å, β = 117.859(5)°, and Z = 2. The solid state ^{13}C NMR spectrum is consistent with the lack of symmetry in the crystal and there is little evidence for large amplitude motion in the macrocycle as determined from the dipolar dephased spectrum.

Key words: macrocyclic crown ether, lithium complex.

Résumé : À l'état cristallin, le complexe mentionné dans le titre est asymétrique en raison de l'orientation spatiale de la fonction NCS. On a déterminé que le groupe d'espace est $P2_1$ avec a = 9,496(3), b = 8,736(3) et c = 9676(3) Å, β = 117,859(5)° et Z = 2. Le spectre RMN du ^{13}C à l'état solide est en accord avec un manque de symétrie dans le cristal et, sur la base du spectre déphasé dipolaire, il y a peu d'indications pouvant suggérer l'existence d'un mouvement de grande amplitude dans le macrocycle.



Mots clés : éther couronne macrocyclique, complexe de lithium.

[Traduit par la Rédaction]

Introduction

A number of publications from these laboratories (1–5) have dealt with large amplitude motion in crown ethers and their complexes in the solid state. To date, systems examined have been limited to 18-crown-6 complexes (1–3), a 12-crown-4 complex (4), as well as a benz-annelated 24-crown-8 molecule (5). In addition, the complementarity of X-ray crystallography and solid state NMR has been well demonstrated in the general area of solid state crown ether stereochemistry (6–8).

For complexation of the biologically important Li^+ ion, the 14-crown-4 ether system has the most nearly "ideal" cavity dimensions. Although the benz-annelated and cyclohexano-14-crown-4 systems have been studied in detail (7), no studies on any of the isomeric 14-crown-4 crown complexes themselves have appeared. In the present work, we report the synthesis and X-ray crystallographic study of the LiNCS complex of 1,4,7,11-tetraoxacyclotetradecane **1** (below), as well as a comparison of its solution phase and solid state ^{13}C NMR spectra.

Results and discussion

The ORTEP plot of **1**.LiNCS. is presented in Fig. 1. In Fig. 2 are presented the normal (*a*) and dipolar dephased 50.3 MHz ^{13}C solid state Cross Polarized Magic Angle Spinning (CPMAS) spectra. Atomic bond lengths are collected in Table 1, with the bond angles and torsion angles appearing in Table 2. Crystallographic data are presented in Table 3 and the atomic coordinates in Table 4. Solution and solid state ^{13}C NMR chemical shifts are in Table 5. Structure factor tables and anisotropic temperature factors are available as supplementary data.[2]

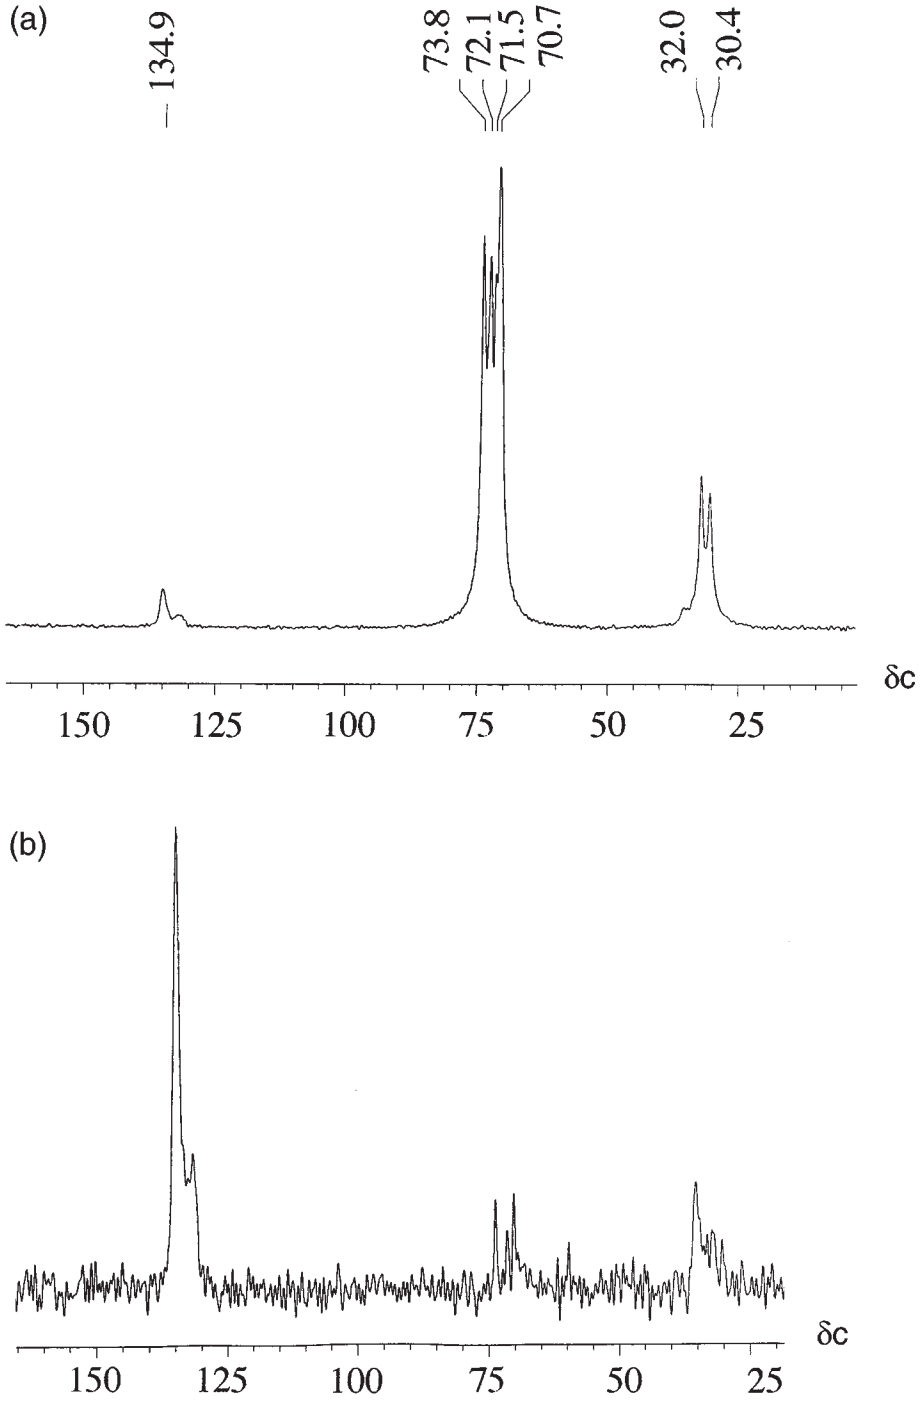
ether unit only, shows that there is a plane of symmetry passing through O2-Li-O4, which effectively bisects the molecule. However, the overall structure lacks a symmetry element due to the fact that the O1-Li-N-C11 torsion angle is –143.4(9)°, while that for the O3-Li-N-C11 unit is 24.0(11)°. A significant difference from the expected opposite signs is also observed in the torsion angles for the N-Li-O2-C3 unit (105.6°) vs. the N-Li-O2-C2 (–125.1°) unit.



The lithium ion is coordinated by the four oxygens and the nitrogen in a distorted square-pyramidal geometry. The average Li—O bond distance of 2.023 Å is between the

mean value of 1.98 Å for tetrahedral complexes and 2.07 Å for pentacoordinated complexes with other macrocyclic ligands (9).

The O-C-C-O torsion angles in the complex are both within 4° of being perfectly gauche, in accordance with normal preferred complexation geometries for these units in related molecules (10–12). With respect to the overall conformation, it is of interest to compare the structure of the present complex with those found for other 14-crown-4 isomers. The crystal conformation of the uncomplexed isomeric 1,4,8,11-tetraoxacyclotetradecane has been determined at –150°C (12). A conformation having approximate twofold rotational symmetry was found. Stereochemistry in the CCCO and OCCO units was observed to be similar to that found herein, namely gauche type structures. For free 1,3,8,10-tetraoxacyclotetradecane, the crystal structure shows a rectangular centrosymmetric conformation (13).

(*ii*) ^{13}C NMR spectra

The general features of the solid state spectrum show the NCS peak at ca. 135 ppm, with the oxygenated aliphatic carbons in the 70–74 ppm range and the non-oxygenated

carbons near 30 ppm. The multiplicity observed in the normal solid state spectrum is consistent with the lack of overall symmetry in **1**.LiNCS. Even though the C6 and C9 sites are relatively remote from the NCS group, there is a difference of 1.6 ppm in the chemical shift observed for these carbons (i.e., 30.4 vs. 32.0 ppm). With respect to the oxygenated carbons, one expects to see eight different resonances in the solid state spectrum. However only four of these resonances are resolved. The fact that these four lines are not of equal intensity also reflects the lack of overall symmetry in **1**.LiNCS.

The dipolar dephased spectrum shows little residual intensity for the protonated carbon resonances, which indicates that there is no substantial overall large amplitude motion in this complex. This is in contrast to some recent observations in these laboratories on the LiNCS complex of the isomeric 14-crown-4 system (1,4,8,11-tetraoxacyclotetradecane).[3]

In solution, the ^{13}C spectrum is consistent with the existence of rapid conformational averaging since only five resonances are observed (Table 5). Lowering the temperature to 200K produced no changes other than minor temperature dependent chemical shifts indicating that conformational interconversions remain fast on the NMR timescale.

With respect to assignments, one can employ the COSY, NOESY, and ^1J HETCOR experiments to obtain a partial assignment of connectivities. Specifically, one observes $^1H^1H$ COSY and NOESY connections between protons on C6 with those on C5 and C7 (and equivalently between protons on C9 with those on C8 and C10). A subsequent ^1H, ^{13}C, ^1J HETCOR experiment shows that ^{13}C resonances at 69.4 and 70.6 ppm connect to the protons on C5, C7, C8, and C10, thereby permitting distinction between these oxygenated carbons and the C1, C4 and C2, C3 sites.

Experimental

(*i*) Materials

The free crown ether **1** was synthesized via a reaction of 4-oxa-1,7-heptanediol (**A**) with diethylene glycol ditosylate. **A** was prepared by reduction of diethyl-4-oxa-heptanedioate (**B**) (15).

For the preparation of **B** the following procedure was employed. A round bottom flask was charged with 2-cyanoethyl ether (12.4 g, 0.1 mol) and 40 mL of 37% aqueous HCl. The flask was fitted with an efficient reflux condenser and the contents were heated to 80°C with stirring. The reaction quickly became exothermic, at which point heating was removed. After the boiling ceased (15 min) heating was resumed for 5 h. The solution was concentrated by rotary evaporation at 65°C and the residue was then titrated with hot acetone and filtered. After concentration by rotary evaporation at room temperature, an oil remained which fully crystallized after cooling overnight in a freezer. Recrystallization from a diethyletherpetroleum ether solvent pair yielded pure diacid in 93% yield, mp 59–60°C (reported (15) 60–61°C). ^{13}C NMR($CDCl_3$) δ_c: 175.1, 65.5, 34.2.

Esterification was accomplished by refluxing the diacid (16.5 g) for 2 h in absolute EtOH (175 mL) containing 1.6 g of concentrated H_2SO_4. The solution was then cooled and neutralized with 5% ethanolic KOH. Subsequently the mixture was poured into a separatory funnel with a suspension

containing $CHCl_3$ (125 mL) and H_2O (125 mL) and shaken. After allowing 20 min for separation, the organic layer was drawn off and the aqueous phase was extracted with $CHCl_3$ (2 × 100 mL). The combined organic extracts were concentated to a volume of ca. 100 mL by rotary evaporation, washed with saturated NaCl (100 mL), and dried over anhydrous Na_2SO_4. After filtration, solvent evaporation *in vacuo* gave the diester **B** as an oil (21.6 g). ^1H NMR (in $CDCl_3$ at 400 MHz): 1.24 ppm (6H, triplet), 2.55 ppm (4H, triplet), 3.71 ppm (4H, triplet), 4.13 ppm (4H, quartet); ^{13}C NMR ($CDCl_3$) δ_c: 171.2, 66.1, 60.2, 34.8, 13.9.

Reduction of **B** to **A** was accomplished in 90% yield in the following manner. To a cooled stirred solution of $LiAlH_4$ (4.9 g, 0.13 mol) in THF (175 mL) under an argon atmosphere, was added **B** (21.6 g, 0.1 mol) in 100 mL of THF over 90 min. The cooling was removed and the reaction mixture was stirred for an additional 45 min. Subsequently ca. 10 mL of 20% aqueous H_2SO_4 was added with stirring. Following filtration and drying over Na_2SO_4, the solvent was removed *in vacuo* at 50°C to yield 11.9 g of **A** as an oil, bp 110–115°C (0.3 Torr (1 Torr = 133.3 Pa)). Reported (16) bp 95–125°C (0.3 Torr). ^1H NMR: 1.84 ppm (4H, quintet), 3.57 ppm (4H, triplet),3.68 ppm (4H, triplet), 3.10 (2H, broad); ^{13}C NMR ($CDCl_3$) δ_c: 68.6, 60.2, 31.9.

Preparation of **1** was carried out as follows. A stirred solution of KOtBu (21.9 g, 0.02 mol) in a 3-neck flask equipped with a thermometer, condenser, and dropping funnel under nitrogen, was heated to 40°C while **A** (11.4 g, 0.085 mol) in THF (60mL) was added over 30 min. The mixture was brought to reflux and after 45 min, diethylene glycol ditosylate (17) (35.2 g., 0.085 mol) in THF (500mL) was added. A gummy precipitate was noticed which redissolved in a few hours. After a 6 day reflux, the mixture was cooled and filtered and the filtrate was concentrated *in vacuo*. The residue was titurated with hot pentane (5 × 15 mL) and from the pentane extracts was obtained 2.9 grams of an oil, judged to be ca. 75% pure by ^{13}C NMR. Purification was accomplished by vacuum distillation (0.1 mm Hg (1 mm Hg = 133.3 Pa)) in a Kugelrohr assembly with an oven temperature of 95 to 100°C. An overall yield of 12% (2.1 g of **1**) was obtained. ^1H NMR ($CDCl_3$) δ: 1.75 ppm (4H, quintet), 3.54 ppm (4H, triplet), 3.65 ppm (12H, multiplet); ^{13}C NMR ($CDCl_3$) δ_c: 70.6, 69.4, 66.5, 66.0, 30.1; MS (CI) *m/z*: 205 (M+1).

For the preparation of **1**.LiNCS, **1** (0.40g, 2.0 mmol) in 0.6 mL of ethyl acetate was added to LiNCS (0.17 g, 2.0 mmol) in hot ethyl acetate (7 mL). The solvent volume was then reduced by boiling to ca. 5 mL, with slow addition of acetone (1 mL) in order to maintain solution homogeneity. Heating was then removed and crystallization proceeded for a few hours at room temperature, followed by overnight in the freezer to give 0.26 g of colourless opaque crystals. These crystals were then redissolved in hot acetone and the solution was filtered. Slow recrystallization of the filtrate at 35 to 40°C in a loosely covered flask gave large hexagonal prisms of **1**.LiNCS, mp 235–237°C.

(*ii*) X-ray crystallographic studies and structure refinement

Suitable crystals were selected, mounted on thin glass fibres using viscous oil and cooled to the data collection temperature. Data were collected on a Bruker AX SMART 1k CCD diffractometer using 0.3° scans at 0, 90, and 180° in. Unit cell parameters were determined from 60 data frames collected at different sections of the Ewald sphere. Semi-empirical absorption corrections based on equivalent reflections were applied (18).

Unit cell parameters and systematic absences in the diffraction data are consistent with space groups $P2_1$ (No. 4) and $P2_1/m$ (No. 11). The occupancy of two and absence of inversion or a mirror plane in the molecule is consistent with the acentric option. Solution in $P2_1$ yielded chemically reasonable and computationally stable results of refinement. The structure was solved by direct methods, completed with difference Fourier syntheses and refined with full-matrix least -squares procedures based on F^2. All non-hydrogen atoms were refined with anisotropic displacement parameters and hydrogen atoms were treated as idealized contributions. All scattering factors and anomalous dispersion factors are contained in the SHEXTL 5.1 program library.

(*iii*) ^{13}C NMR spectra

Both solid and solution phase spectra were obtained using routine methods described previously (19). For the dipolar dephased ^{13}C CPMAS spectra, the ^1H decoupler was switched off for 40 μs before data acquisition. All solution NMR spectra were recorded using a Bruker AMX–400 spectrometer, while solid phase ^{13}C spectra were obtained with a Bruker ASX–200 system.

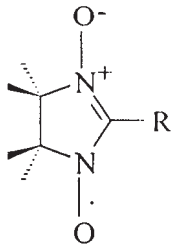
Crystal structure and ferromagnetic behavior of a *cis*-Co(II) complex with nitronyl nitroxide

Bai-Wang Sun, Qi-Hua Zhao, Dai-Zheng Liao, Zong-Hui Jiang, Shi-Ping Yan, Geng-Lin Wang, Xin-Kai Yao, and Hong-Gen Wang

Abstract: Bis(hexafluoroacetylacetonate)cobalt(II), $Co(hfac)_2$, reacted with the nitronyl nitroxide radical 2-(4-methylphenyl)-4,4,5,5-tetramethylimidazoline-1-oxyl-3-oxide, NITPhMe, to yield an octahedral adduct of formula $Co(hfac)_2(NITPhMe)_2$. The X-ray crystal structure shows that it crystallizes in the space group $P\bar{1}$, with a = 9.837(3), b = 11.618(3), c = 20.502(4) Å, α = 81.22(2), β = 87.93(2), γ = 72.24(3)°, V = 2205(1) Å^3, Z = 2. The mechanism of ferromagnetic exchange between cobalt(II) and the radical can be qualitatively understood in terms of a charge-transfer interaction (J being 25.7 cm^{-1}, the Hamiltonian is written in the form $\boldsymbol{H} = -2J(\boldsymbol{S}_{Rad1}\cdot\boldsymbol{S}_{Co} + \boldsymbol{S}_{Co}\cdot\boldsymbol{S}_{Rad2})$).

Key words: crystal structure, cobalt(II) complex, nitronyl nitroxide, magnetic property.



Résumé : Le bis(hexafluoroacétylacétonate) de cobalt(II), $Co(hfac)_2$, réagit avec le radical nitroxyde de nitronyle, 3-oxyde de 2-(4-méthylphényl)-4,4,5,5-tétraméthylimidazoline-1-oxyle, NITPhMe, et conduit à la formation d'un adduit octaédrique de formule $Co(hfac)_3$. La diffraction des rayons X permet de montrer que le produit cristallise dans le groupe d'espace $P\bar{1}$, avec a = 9,837(3), b = 11,618(3) et c = 20,502(4) Å, α = 81,22(2), β = 87,93(2) et γ = 72,24(3)°, V = 2205(1) Å^3 et Z = 2. D'un point de vue qualitatif, on peut comprendre le mécanisme d'échange ferromagnétique entre le cobalt(II) et le radical en fonction d'une interaction de transfert de charge pour laquelle J = 25,7 cm^{-1} et l'hamiltonien est de la forme $H = -2J(\boldsymbol{S}_{Rad1}\cdot\boldsymbol{S}_{Co} + \boldsymbol{S}_{Co}\cdot\boldsymbol{S}_{Rad2})$).

Mots clés : structure cristalline, complex du cobalt(II), nitroxyde de nitronyle, propriété magnétique.

[Traduit par la Rédaction]

Introduction

The nitronyl nitroxides, NITR = 2-*R*-4,4,5,5-tetramethylimidazoline-1-oxyl 3-oxide, with R = methyl, ethyl and phenyl, etc., have proven to be extremely versatile magnetic ligands toward metal ions (1–4). The general formula of NITR is

Up to now, a number of nitronyl nitroxides compounds including copper(II) and manganese (II) have been synthesized, such as high-spin clusters (5), ferromagnetic chains (6), and compounds showing spontaneous magnetization (7). The mechanism of magnetic interaction in those compounds have been well discussed in recent years (1, 2, 8, 9). Very few cobalt – nitronyl nitroxides complexes have been reported, and relatively little work has been devoted to the study of the relationship between the structure and the magnetic properties in cobalt(II)–radical compounds(10–12).

In this contribution, we report a new adduct of formula $Co(hfac)_2(NITPhMe)_2$ (hfac = hexafluoroacetylacetonate, NITPhMe = 2-(4-methylphenyl)-4,4,5,5-tetramethylimidazoline-1-oxyl-3-oxide) which shows a moderate ferromagnetic coupling, J being 25.7 cm^{-1} (the Hamiltonian is written in the form $\boldsymbol{H} = -2J(\boldsymbol{S}_{Rad1}\cdot\boldsymbol{S}_{Co} + \boldsymbol{S}_{Co}\cdot\boldsymbol{S}_{Rad2})$). We wish to report here the crystal structure of this compound and the discussion of the subtle mechanism of exchange between cobalt(II) and nitroxide.

So far, there are three types of ferromagnetic interaction between metal and radical when oxygen of radical bound to metal have been reported. The first type is an axially coordinated nitroxide–copper compound (13): two magnetic orbitals, π^* of the radical and $dx^2 - y^2$ of copper(II), are orthogonal to each other, thus resulting in weak ferromagnetic interaction between copper and the radical. The second type is in a gadolinium(III)–radical compound (14): a fraction of π electron density in the radical transfers into the empty 6*s* orbital in the Gd(III) ion, thus leading to weak ferromagnetic coupling. The mechanism of ferromagnetic exchange reported

 © 2000 NRC Canada

in this paper belongs to a third type of ferromagnetic interaction pathway by MLCT charge transfer in metal–radical compounds (15).

Experimental

Synthesis

H_2hfac was purchased from Aldrich. Co(hfac)$_2$2H_2O (10) and NITPhMe radical (16) were prepared according to established procedure.

0.10 mmol (50.9 mg) of Co(hfac)$_2$2H_2O was dissolved in 20 mL of hot dry *n*-heptane, then 0.22 mmol (54.4 mg) of NITPhMe radical was added, and the solution was stirred for 10 min and filtered. After 6 h, dark green well-developed crystals were collected. The compound analyzed satisfactorily for Co(hfac)$_2$(NITPhMe)$_2$. Mp: 130–132 °C. Selected spectroscopic data: UV (nm): 375 ($\pi\rightarrow\pi^*$, ONCNO), 263 ($\pi\rightarrow\pi^*$, benzene), and 560 ($n\rightarrow\pi^*$, ONCNO). IR (KBr, cm^{-1}): 1650($\nu_{C\cdots O}$), 1466($\nu_{C\cdots O}$), and 1375($\nu_{N\text{-}O}$). Anal. calcd. for $C_{38}H_{40}N_4O_8F_{12}Co$: C 47.17, H 4.17, N 5.79, Co 6.09%; found: C 47.34, H 4.03, N 5.44, Co 6.32%.

Crystallographic data collection and structure determination

The structure was solved by direct methods using the program MULTAN. The Co-atom position was located in the initial *E*-maps. The other non-H-atoms were determined with successive difference-Fourier syntheses. The main feature of the present structure lay in the disorder and (or) thermal motion in the CF_3 groups. Nevertheless, it did not seriously affect the precision of the structural results, and the final refinement by full-matrix least-squares with anisotropic thermal parameters for non-H-atoms was converged with unweighted and weighted agreement factors of 0.070 and 0.071. The highest peak on the final difference-Fourier map was 0.45 e/Å^3. All data calculations were performed using the SDP-PLUS program system. Crystal data are reported in Table 1.

Physical measurements

Elemental analyses for C, H, and N were performed with a Perkin–Elmer Model 240 elemental analyzer. Metal content was determined by EDTA titration. IR spectra were recorded on a Shimadzu Model 408 IR spectrophotometer, using KBr pellets and the electronic spectra (in *n*-heptane) were measured on a Hitachi-240 spectrophotometer. Variable temperature magnetic susceptibilities were carried out at a field strength of 1.0 T with a vibrating sample magnetometer, Model CF-1 (sensitivity m = 10^{-4}emu). This equipment was built jointly by the Institute of Physics, Chinese Academy of Sciences, and the Laboratory of Louis-Neel CNRS, France. Diamagnetic corrections were made with Pascal's constants for all the constituent atoms. ESR spectra were measured with a JES-FEIXG ESR apparatus using the X-band.

Results and discussion

ESR spectra

The X-band powder ESR spectra at room temperature for the complex shows a broad band at the center of g = 2.1. It is clear that this feature reflects the exchange coupling between Co(II) and the radical. According to Kambe's approach (17), coupling the three spins S_{Rad1}–S_{Cot}–S_{Rad2}, $S_{Rad1} = S_{Rad2} = 1/2$ and $S_{Co} = 3/2$, yields one sextet, two quartets, and one doublet state. On the basis of Boltzmann's distribution, four states are all populated at room temperature. Thus, the broad ESR signal may be ascribed to the complex in these states.

Description of the structure

The cobalt atom is bound to two chelating hfac ligands and two nitroxides in a *cis*-octahedral configuration. A view of the molecular structure is given in Fig. 1. The final atomic positional parameters are listed in Table 2. Selected bond distances and angles are given in Table 3.

Three oxygen atoms of hfac (O_1, O_2, O_3) and one oxygen atom of the radical (O_6) form the equatorial plane, the M—O bond lengths being 2.071(6), 2.033(8), 2.046(7), and 2.058(6) Å, respectively. Another oxygen atom of hfac (O_4) and one oxygen atom from the second radical (O_5) occupy two axial positions, and the bond lengths are 2.073(7) and 2.107(8) Å, respectively. All these distances are typical for a cobalt(II) – nitroxide compound (10). The Co–O–N angles, which are relevant to the mechanism of exchange between metal and nitroxides, are 128.2(6) and 125.2(6)°. The

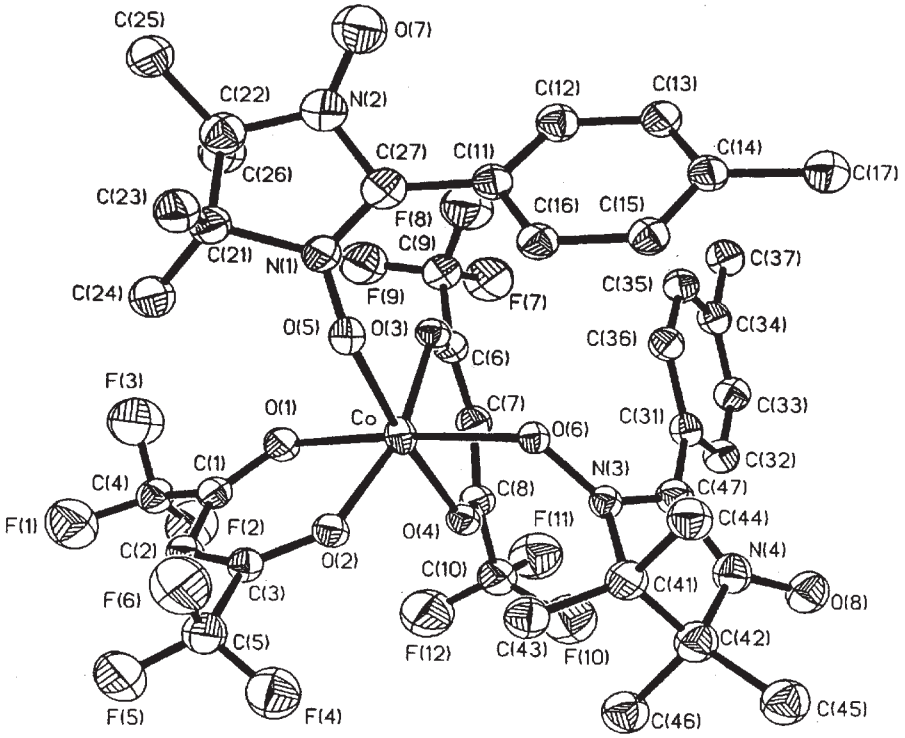

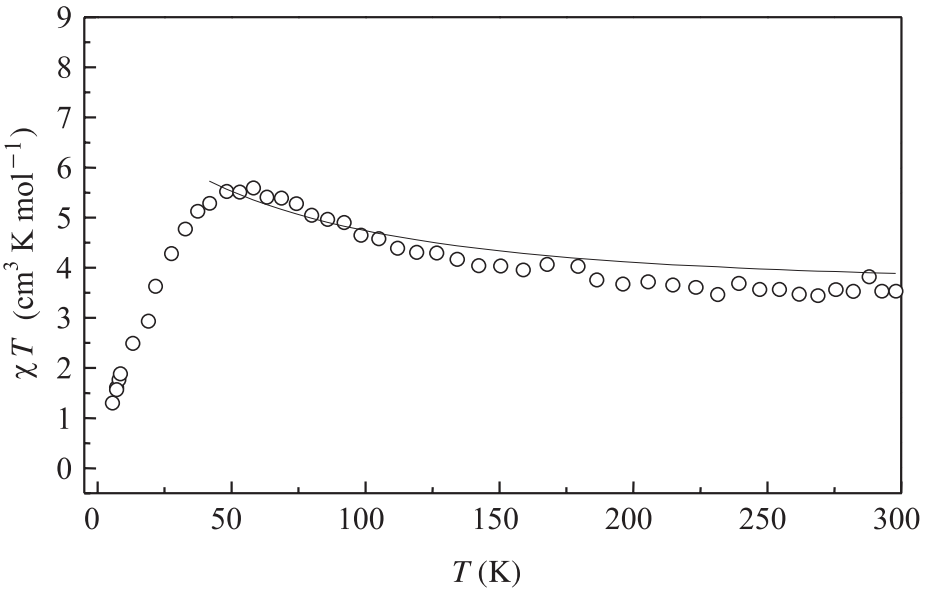

Fig. 2. Variable temperature magnetic susceptibility for $Co(hfac)_2(NITPhMe)_2$ in the form χT (cm^3 K mol^{-1}) vs. T (K). o: experimental data, _____: calculated curves.

ONCNO planes of two nitroxides make angles of 140.8(0.4) and 63.6(0.3)° with the equatorial plan, respectively. The phenyl rings of the two radicals make angles of 29.4(0.6) and 153.8(0.4)° with the planes of their radical five-member rings.

No significant intermolecular contacts are observed.

Magnetic Properties

In the case of the present complex, the cobalt(II) ion has a d^7 electron configuration with a distorted octahedral field and two unpaired electrons in d_{x2-y2} and d_{z2}, and one unpaired electron resides in the degenerate orbital (d_{xy}, d_{yz}, and d_{xz}). Therefore, at least one of them must have nonzero overlap with the radical π* orbital, and the coupling is expected to be an antiferromagnetic interaction according to the orthogonality of the magnetic orbital. But the experimental data of the title complex indicates a ferromagnetic interaction between cobalt(II) and the radical. Figure 2 shows the temperature dependence of the magnetic susceptibility of $Co(hfac)_2(NITPhMe)_2$ in the form χT vs. T. The room-temperature value of χT, 3.54 cm^3 K mol^{-1}, is very close to the value (3.45 cm^3 K mol^{-1} for g_{Co} = 2.4, g_{Rad} = 2.0) expected for the compound in the absence of exchange.

[a]Anisotropically refined atoms are given in the form of the isotropic equivalent displacement parameter defined as: *B*eq = (4/3) × [$a^2 \times \beta(1,1) + b^2 \times \beta(2,2) + c^2 \times \beta(3,3) + ab(\cos\gamma) \times \beta(1,2) + ac(\cos\beta) \times \beta(1,3) + bc(\cos\alpha) \times \beta(2,3)$]. Note: The multiplicities of atoms F(10) and F(10′ are 0.5, respectively. The multiplicities of the others are 1.

χT increases as temperature decreases, reaching a rounded maximum at about 60 K, corresponding to χT = 5.6 cm^3 K mol^{-1}. Below 60 K, χT decreases, reaching the value of 1.3 cm^3 K mol^{-1} at 4.2 K.

Since the magnetic behavior cannot be interpreted by the orthogonality of the magnetic orbital, it is necessary to consider that some other exchange interaction is operative in the title complex. Following Miller et al. (15, 18) and McConnell (19), we assumed a charge-transfer (CT) interaction from one of the 3*d* orbitals of the cobalt(II) ion to the SOMO (singly occupied molecular orbital) of the NITPhMe. Cobalt(II) ion with $t_{2g}^5 e_g^2$ has three single electrons in partially occupied molecular orbitals (POMO), while each radical has one electron in a nondegenerate π^* POMO. In the absence of spin interactions there are four possible ground states for this $s^1_{(Rad)}$–$d^7_{(Co(II))}$–$s^1_{(Rad)}$ spin system. The ferromagnetically coupled, GS_F, and antiferromagnetically coupled, GS_{AF}, states exist at equal energy (19). Spin interactions among the metal and radicals can stabilize either ferro- or antiferromagnetic coupling, i.e., lower either GS_F or GS_{AF}. The GS lowered has the greatest admixing with the lowest energy virtual charge transfer excited state. In the title complex, both ferromagnetic and antiferromagnetic CT excited states are possible (Fig. 3). However the splitting energy (Δ) maybe smaller than the electronic repulsion in the paired electrons (P), due to the strong negative contribution from π of hfac for the title complex (Δ < P) (20). From Hund's rule, the metal ion should prefer a high spin ground state. This means that a transfer will leave a higher spin multiplicity in cobalt(III), namely, the ferromagnetic CT excited state (S = 2) is energetically advantageous. The admixture of the ferromagnetic CT excited state results in a stabilization of the ferromagnetic interaction between Co(II) and radical.

To understand quantitatively the magnitudes of spin-exchange interaction between Co(II) and the radical, a magnetic analysis was performed with the susceptibility equation based on Heisenberg spin-exchange operator: $\boldsymbol{H} = -2J(\boldsymbol{S}_{Rad1}\boldsymbol{S}_{Co} + \boldsymbol{S}_{Rad2}\boldsymbol{S}_{Co}) - 2J'\boldsymbol{S}_{Rad1}\boldsymbol{S}_{Rad2}$ ($S_{Rad1} = S_{Rad2} = 1/2$ and $S_{Co} = 3/2$), where J is the interaction constant between Co(II) and the radical, and J' is the interaction constant between two radicals in the complex.

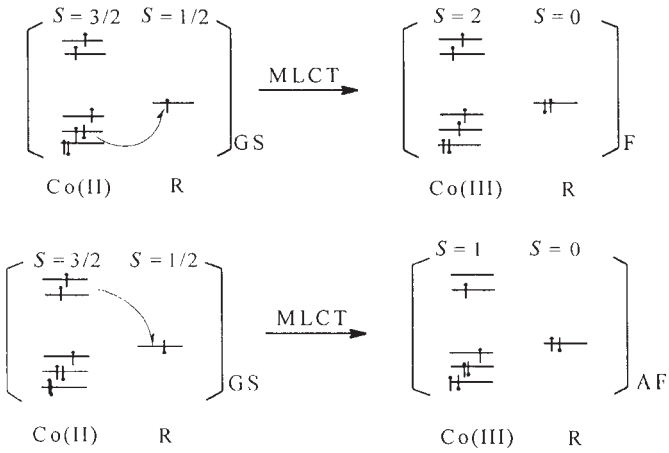
Scheme 1.



If the effect of J' is neglected and equal g values for Co(II) and the radical are used, the magnetic susceptibility data above 60 K are well simulated by eq. [2] based on the Heisenberg model (21)

$$[2] \qquad \chi M = \frac{Ng^2\beta^2}{4k(T-\theta)} \left\{ \left[\frac{10 + \exp(-5J/kT) + 10\exp(-2J/kT) + 35\exp(3J/kT)}{2 + \exp(-5J/kT) + 2\exp(-2J/kT) + 3\exp(3J/kT)} \right] (1-\rho) + 7\rho \right\} + N\alpha$$

where χ denotes the susceptibility per molar complex, θ is the intermolecular interaction, N is Avogadro's constant, β is the Bohr magneton, k is the Boltzmann constant, $N\alpha$ is the temperature-independent paramagnetism of the Co^{2+} ion. In addition, the data were corrected for the presence of a small proportion, ρ, of uncoupled spin center. We estimated the J value by taking data points above 60 K and fitted those values by using eq. [2] to obtain J = 25.7 cm^{-1} and g = 2.2, θ = –2 cm^{-1} and ρ = 0.002; F, defined here as $[(\chi T)_{obsd} - (\chi T)_{calcd}]^2/(\chi T)^2_{obsd}$, is then equal to 2×10^{-3}. The low-temperature magnetic behavior is difficult to analyze, because the Co(II) ion has unquenched orbital momentum. Since it ignores the effect of "spin-orbit" coupling within the $^4T_{1g}(F)$ ground term, the isotropic model is not strictly applicable for the estimation of exchange coupling, J, to the present complex. The $^4T_{1g}$ ground term for a Co(II) ion in an octahedral field yields $^4A_2$ + $^4B_1$ + $^4B_2$ terms in C_{2v} symmetry (idealized) each of them being split into two Kambe's doublets by spin-orbit coupling. Thus it is impossible to interpret the magnetic behavior of the

Comparative electronic analysis between hydrogen transfers in the CH_4/CH_3^+, $CH_4/CH_3^\bullet$, and CH_4/CH_3^- systems: on the electronic nature of the hydrogen (H^-, $H^\bullet$, H^+) being transferred. II. Analysis of electron-pair interactions from intracule and extracule densities

Xavier Fradera, Miquel Duran, and Jordi Mestres

Abstract: The nature of the hydrogen transferred in the CH_3/CH_4^+, $CH_3/CH_4^\cdot$, and CH_3/CH_4^- systems is investigated by analyzing the topology of the contracted intracule and extracule electron-pair densities and their respective Laplacians. The CH_3/CH_4^+, $CH_3/CH_4^\cdot$, and CH_3/CH_4^- systems are taken as simple models for the study of hydride (H^-), hydrogen ($H^\cdot$), and proton (H^+) transfer reactions, respectively, under a constrained C—C distance. The study is focused on the comparison of the intracule and extracule densities at the intermediate structures for the three H-transfer reactions, complementing a previous investigation of the same model reactions based on the analysis of one-electron densities. The results obtained by analyzing the contracted electron-pair densities are consistent with those obtained from the analysis of one-electron densities. The electronic nature of the H atom being transferred in the three systems can be differentiated by the topologies of the corresponding intracule and extracule densities. However, the analysis underlies also the difficulties to interpretation of the topologies of contracted electron-pair densities, as different electron–electron interactions may contribute to the same point in the intracule or extracule spaces. In particular, for the systems studied, the contribution of the electron–electron interaction associated to the probability of having two electrons on the H being transferred is not reflected separately neither in the intracule nor in the extracule distributions. Nevertheless, the nature of the H being transferred can still be studied by comparing the importance of the electron–electron interactions associated to the probability of having one electron in C and one in the transferring H. The effects of inclusion of electron correlation are also discussed by means of (HF-CISD//HF) intracule and extracule density difference maps.

Key words: hydrogen transfer, electron-pair density, intracule density, extracule density, topological density analyisis.

Résumé : En se basant sur une analyse de la topologie des densités des paires d'électrons intracule et extracule contractées et de leurs laplaciens respectifs, on a étudié la nature de l'hydrogène qui est transféré dans les systèmes CH_3/CH_4^+, CH_3/CH_4^- et $CH_3/CH_4^\cdot$. On a considéré les systèmes CH_3/CH_4^+, CH_3/CH_4^- et $CH_3/CH_4^\cdot$ comme des modèles simples pour l'étude des réactions de transfert respectivement d'hydrure (H^-), d'hydrogène ($H^\cdot$) et de proton (H^+) dans des conditions où la distance C—C est restreinte. On a focalisé cette étude sur la comparaison des densités intracule et extracule au niveau des structures intermédiaires pour les trois réactions de transfert d'hydrogène; il s'agit donc d'un complément à l'étude antérieure des réactions du même modèle sur la base d'une analyse de densités à un électron. Les résultats obtenus sur la base d'une analyse des densités des paires d'électrons contractées sont en accord avec ceux obtenus sur la base d'une analyse de densités à un électron. Il est possible de distinguer la nature électronique de l'électron transféré dans les trois systèmes à partir des topologies des densités intracule et extracule correspondantes. Toutefois, l'analyse met aussi en relief les difficultés d'interpréter les topologies des densités de paires d'électrons contractées puisque différentes interactions électron–électron peuvent contribuer au même point des espèces intracule ou extracule. Dans les systèmes étudiés, on note en particulier que la contribution de l'interaction électron–électron associée à la probabilité de transfert de deux électrons d'un H n'est pas reflétée séparément ni dans les distributions ni intracule ni extracule. Toutefois, la nature du H qui est transféré peut quand même être étudiée en comparant l'importance des interactions électron–électron associées à la probabilité d'avoir un électron du C et de l'hydrogène qui est transféré. On discute aussi des effets d'inclusion de la corrélation d'électron à l'aide de cartes de

différences de densité intracule et extracule (HF-CISD//HF).

Mots clés : transfert d'hydrogène, densité de paires d'électrons, densité intracule, densité extracule, analyse topologique de la densité.

[Traduit par la Rédaction]

Introduction

Hydrogen transfers are one of the most usual reactions in biochemistry. From a formal point of view, these processes have been usually classified as proton, hydrogen, and hydride transfers. However, the particular electronic nature of the hydrogen being transferred has often been a matter of controversy. Some studies have analyzed the electronic characteristics associated to different types of hydrogen transfer. In a pioneering work, Swain et al. (1) established the basic differences between the transition states of hydride and proton transfer reactions in terms of bonding and electron charge density. Williams et al. (2), using qualitative molecular orbital theory, discussed the change in orbital energy when modifying the C—C distance and the C-H-C angle for hydride and proton transfers in model three-center C-H-C systems. Later, Pain and Williams (3) performed a theoretical comparison of primary deuterium kinetic isotope effects between hydride and proton transfers in the $HNCH_2/HCNH^+$ and $HNCH_2/HCNH^-$ systems.

The CH_4/CH_3^+, $CH_4/CH_3^{\cdot}$, and CH_4/CH_3^- systems can be taken as simple models for the formal transfer of a hydride (H^-), a hydrogen ($H^{\cdot}$), or a proton (H^+) between two carbon atoms:

[1] $$CH_4 + CH_3^+ \rightarrow [CH_3\text{-}H\text{-}CH_3]^+ \rightarrow CH_3^+ + CH_4$$

[2] $$CH_4 + CH_3^{\cdot} \rightarrow [CH_3\text{-}H\text{-}CH_3]^{\cdot} \rightarrow CH_3^{\cdot} + CH_4$$

[3] $$CH_4 + CH_3^- \rightarrow [CH_3\text{-}H\text{-}CH_3]^- \rightarrow CH_3^- + CH_4$$

Reaction [1] consists of the transfer of an H^- between two CH_3^+ fragments, through a $[CH_3\text{-}H\text{-}CH_3]^+$ intermediate structure. Accordingly, reaction [2] consists of the transfer of a $H^{\cdot}$ between two $CH_3^{\cdot}$ fragments through a $[CH_3\text{-}H\text{-}CH_3]^{\cdot}$ intermediate structure. Finally, reaction [3] illustrates the transfer of a H^+ between two CH_3^- fragments through a $[CH_3\text{-}H\text{-}CH_3]^-$ intermediate structure.

Several studies have considered the H^+ transfer between CH_4 and CH_3^- from a theoretical point of view (4–6). The transition state in this system is characterized by a symmetric linear structure, with a distance of ca. 2.9 Å between the two carbons involved in the proton transfer. The formal $H^{\cdot}$ transfer in the $CH_4/CH_3^{\cdot}$ system has also been studied both theoretically (7–12) and experimentally (13). The transition state in this system is also characterized by a symmetric linear structure, with a C—C distance of ca. 2.9 Å. However, for the hydride transfer between CH_4 and CH_3^+, the structure having the H^- midway between the two CH_3^+ fragments is not a transition state, but a minimum in the potential energy surface (14). The study of the hydride transfer in this system can be performed by constraining the potential energy surface to a C—C distance larger than ca. 2.4 Å (depending on the level of theory employed) found for the minimum energy structure (14).

Recently, we carried out a comparative study of the hydrogen transfers taking place in the CH_4/CH_3^+, $CH_4/CH_3^{\cdot}$, and CH_4/CH_3^- systems (15). For all cases, the C—C distance was frozen at 3.20 Å (6.05 au) in order to allow for straightforward comparison of the electronic characteristics of the hydrogen being transferred in the three systems. Despite the convenience for a proper comparative study, this constraint is not arbitrary but derived from the fact that hydrogen transfers in biological systems take normally place also under constrained C—C distances (16). Indeed, under this constraint, one cannot strictly speak of stationary points. Following the notation of our previous study (15), the point on the reaction coordinate where the hydrogen being transferred begins to notice the polarization effect of the acceptor CH_3 fragment will be formally referred to as *reactant complex* (RC), whereas the point where the hydrogen is midway between the two CH_3 fragments will be formally labelled as *transition state* (TS).

In the previous comparative analysis of one-electron densities between the CH_4/CH_3^+, $CH_4/CH_3^{\cdot}$, and CH_4/CH_3^- systems at the TS (15), contour maps of the electron density were used to compare the electronic characteristics of the three systems, at the HF, CISD, and MP2 levels of theory. It was found that the charge density at the H being transferred (H_t) decreases in the order $CH_4/CH_3^+ > CH_4/CH_3^{\cdot} > CH_4/CH_3^-$, in agreement with the formal hydride, hydrogen, and proton character of H_t in these systems. Moreover, the gradient vector field and Laplacian maps of the electron density for the three TS structures showed a progressive decrease of the size of the atomic basin of H_t and a stronger overlapping of the H_t *s* shell with the adjacent C shells, along the CH_4/CH_3^+, $CH_4/CH_3^{\cdot}$, and CH_4/CH_3^- series. Bader atomic charge populations were also reported for these systems. It was found that, at the HF level of theory, the atomic charges of H_t (–0.23, 0.05, and 0.35 for CH_4/CH_3^+, $CH_4/CH_3^{\cdot}$, and CH_4/CH_3^- respectively) deviate quite significantly from the formal assignment of –1, 0, and +1 to a hydride, hydrogen, and proton transfer, respectively. The effect of considering electron correlation effects was assessed by means of (MP2-HF) density difference maps. The difference maps, as well as the comparison of the H_t atomic charges obtained at the HF, CISD, and MP2 levels of theory, revealed that electron correlation reduces the electronic differences between the formal hydride, hydrogen, and proton transfer reactions. Finally, molecular quantum similarity measures (17) were used to measure the degree of electron redistribution suffered by the three systems when evolving from RC to TS, revealing that this redistribution is larger in hydride and hydrogen transfers than in proton transfers.

Even though the topological analysis of the one-electron density has been shown to be extremely useful in the elucidation of the electronic characteristics of atoms and molecules (18), some analysis based ultimately on the electron-pair density have appeared within the framework of the theory of Atoms in Molecules. In particular, some studies based

© 2000 NRC Canada

on the Fermi or exchange-correlation density have provided interesting insights on the electron-pair characteristics of molecules (19, 20). In contrast, the topological analysis of molecular intracule and extracule densities has received less attention (21, 22). However, the availability of new and efficient procedures to compute molecular intracule and extracule densities (23) allows nowadays to extend the usual analysis of one-electron densities to contracted electron-pair densities. Thus, while focusing on the TS's of the CH_3/CH_4^+, $CH_3/CH_4^{\cdot}$, and CH_3/CH_4^- model reactions at the Hartree-Fock (HF) and CISD levels of theory, this paper aims at investigating how the hydride, hydrogen and proton nature of the H being transferred in these systems is reflected in the corresponding electron-pair densities. The ultimate purpose of this work is to investigate whether intracule and extracule densities (24) can become useful in the electronic analysis of small and medium-sized molecules from an electron-pair perspective.

Methodological aspects

Ab initio molecular orbital HF wave functions for the TS's of CH_4/CH_3^+, $CH_4/CH_3^{\cdot}$, and CH_4/CH_3^- systems were taken from the results in Ref. 15. All calculations were performed with the 6–311++G** basis set (25) using the restricted HF method (RHF) for the closed-shell systems and the unrestricted HF method (UHF) for the open-shell system. For the closed-shell systems, single-point CISD/6–311++G** wave functions were generated, using both the molecular geometries optimized at the same level of theory in Ref. 15, and the molecular geometries optimized at the HF level. CISD wave functions calculated at the optimized CISD and HF geometries will be labelled as CISD and CISD//HF, respectively. These calculations were carried out by means of the Gamess program (26), in order to obtain the second-order density matrices required for the calculation of intracule and extracule densities at the CISD level of theory.

Intracule and extracule density maps were computed from the HF, CISD//HF and CISD wavefunctions, following the procedure described in Ref. 23. Integral neglect thresholds of 10^{-3} for the maps, and 10^{-5} for the exact location of the maxima, were used to discard integrals carrying little contribution to the total $I(\mathbf{r})$ and $E(\mathbf{R})$ densities.

The topological analysis of the one-electron density, $\rho(\mathbf{r})$, is a widely used tool for the interpretation of molecular electronic structure, and is the basis for a rigorous definition of an atom in a molecule (18). In practice, the electron-pair density, $\Gamma(\mathbf{r}_1,\mathbf{r}_2)$, should provide more direct information than its one-electron counterpart, including information about electron–electron interactions in molecules (27). However, due to its complexity, little is known about the topology of molecular electron-pair density functions. Alternatively, intracule, $I(\mathbf{r})$, and extracule densities, $E(\mathbf{R})$, can be used to reduce the dimensionality of the original electron-pair density while keeping an electron-pair character. The use of an interparticle separation or intracule coordinate, $\mathbf{r} = \mathbf{r}_1 - \mathbf{r}_2$, and a center of mass or extracule coordinate, $\mathbf{R} = (\mathbf{r}_1 + \mathbf{r}_2)/2$, allows to express the intracule and extracule densities as (24):

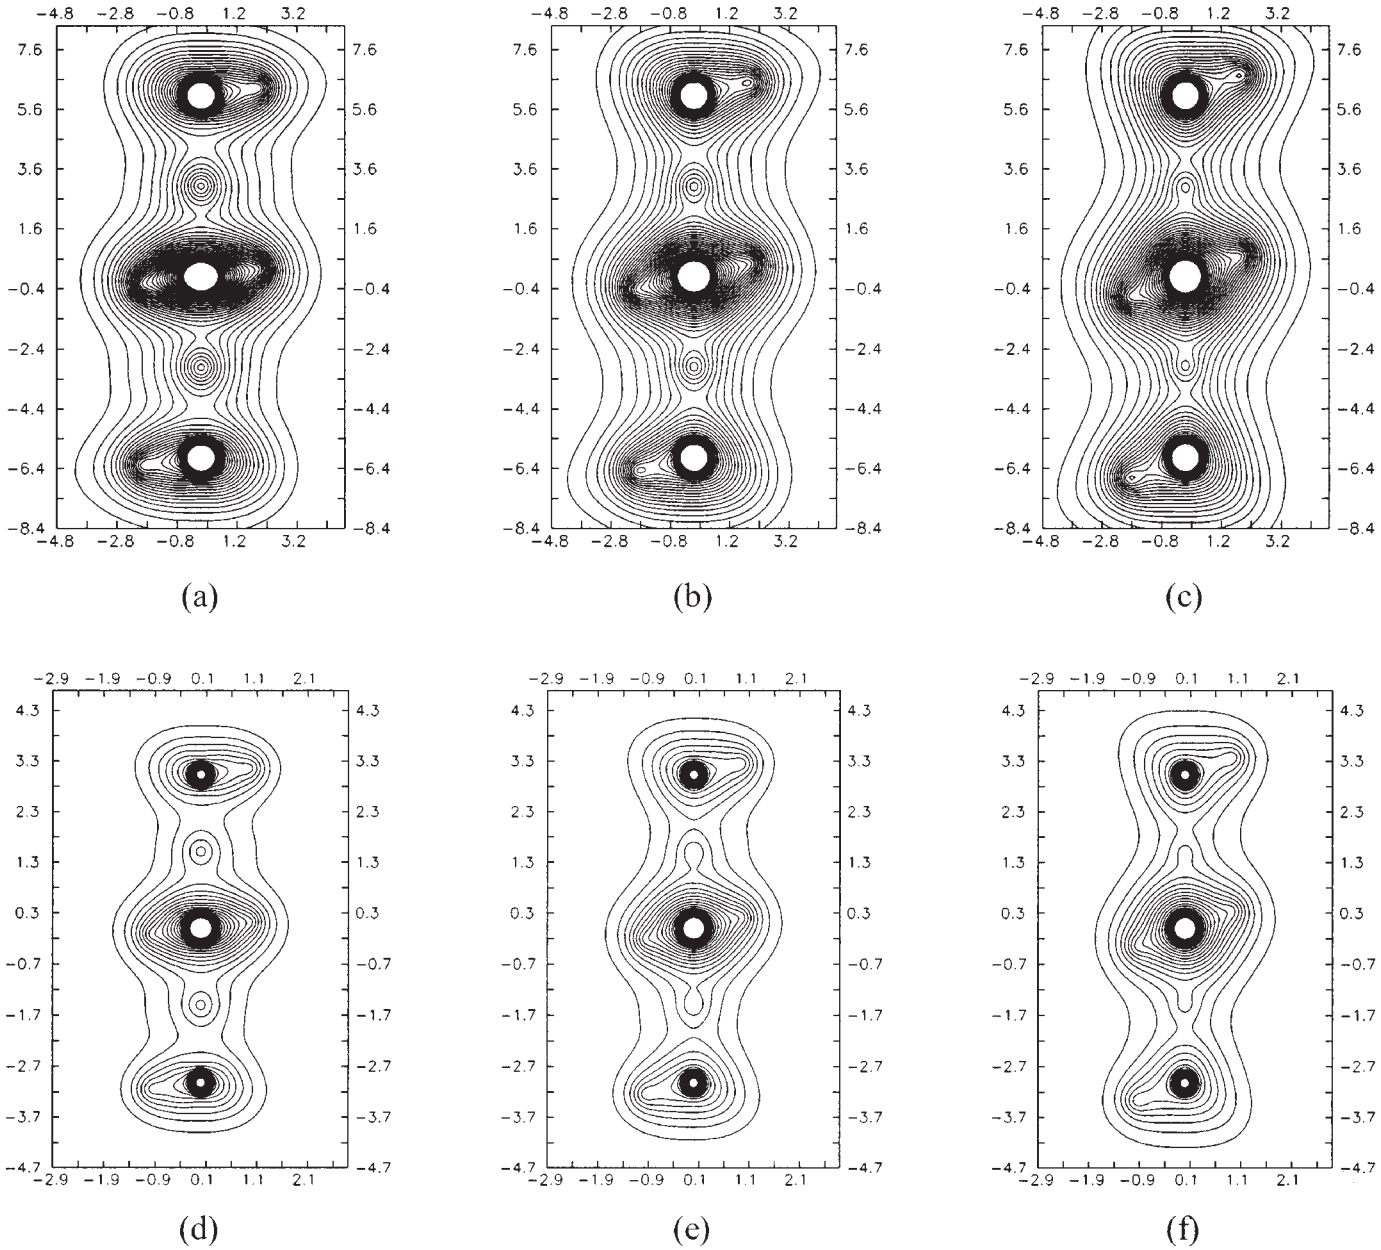
$$[4] \qquad I(\mathbf{r}) = \int \Gamma(\mathbf{r}_1, \mathbf{r}_2)\, \delta((\mathbf{r}_1 - \mathbf{r}_2) - \mathbf{r})\, d\mathbf{r}_1 d\mathbf{r}_2 \; ; \int I(\mathbf{r}) = \binom{N}{2}$$

and

$$[5] \qquad E(\mathbf{R}) = \int \Gamma(\mathbf{r}_1, \mathbf{r}_2)\, \delta\left(\frac{\mathbf{r}_1 + \mathbf{r}_2}{2} - \mathbf{R}\right) d\mathbf{r}_1\, d\mathbf{r}_2 \; ; \int E(\mathbf{R}) = \binom{N}{2}$$

respectively. On one hand, $I(\mathbf{r})$ distributions have the characteristic of always having a center of inversion at the origin, independent of the molecular symmetry, and being independent of any molecular translation. On the other hand, $E(\mathbf{R})$ distributions reflect the symmetry of the molecule. Both $I(\mathbf{r})$ and $E(\mathbf{R})$ integrate to the number of electron pairs in the molecule.

Although the topologies of atomic $I(\mathbf{r})$ and $E(\mathbf{R})$ distributions and the corresponding Laplacian functions have been studied in detail (28–33), calculations of anisotropic $I(\mathbf{r})$ and $E(\mathbf{R})$ densities for molecules have been few and focused mainly on diatomic molecules (34–40). However, HF $I(\mathbf{r})$ and $E(\mathbf{R})$ densities for some polyatomic molecules have been recently described in the literature (21, 22), and the corresponding Laplacian functions, $\nabla^2 I(\mathbf{r})$ and $\nabla^2 E(\mathbf{R})$, have also been investigated (22). It has been shown that the main topological features of molecular $I(\mathbf{r})$ and $E(\mathbf{R})$, and specially $\nabla^2 I(\mathbf{r})$ and $\nabla^2 E(\mathbf{R})$ distributions, can be understood in terms of electron–electron interactions, generated from the combination of electrons, each of them formally assigned to one of the atoms in the molecule (21, 22). Similarities between $I(\mathbf{r})$ and $E(\mathbf{R})$ densities for atoms and molecules have also been evaluated (41).



Results and discussion

Since the calculation of $I(\mathbf{r})$ and $E(\mathbf{R})$ density grids for small molecules at the HF and CISD levels of theory can now be routinely performed at a fairly low computational cost (21–23), it seems worthwhile to investigate the topologies of $I(\mathbf{r})$ and $E(\mathbf{R})$ densities for the CH_4/CH_3^+, $CH_4/CH_3^{\cdot}$, and CH_4/CH_3^- systems in order to study how they reflect the electronic differences between the three H-transfer processes. This analysis will be carried out at the TS's, because the molecular geometry at this point is the same for the three systems. Moreover, this point is illustrative enough of the electron rearrangements occurring along the reaction coordinate.

The discussion of the topological features of molecular $I(\mathbf{r})$ and $E(\mathbf{R})$ density distributions can be made by assigning a formal electron–electron interaction to each local maximum. Each electron–electron interaction will be labelled following a particular notation (22): $\{C_iC_j\}$ refers to electron–electron interactions between the two C atoms, $\{CH_t\}$ refers to electron–electron interactions between one of the C atoms and the H being transferred (H_t), and $\{C_{ii}\}$ and $\{H_{tt}\}$ refer to intraatomic interactions between electrons located on the same atom, C and H_t, respectively. Finally, the interaction labelled as $\{0\}$ refers to the maximum at the origin of each intracule and extracule density map. For the intracule densities, this interaction collects contributions from all the intraatomic pairs of electrons, which have a high probability of being close in space. For the extracule densities, the $\{0\}$ interaction is formed by the contributions of all the electron

(*a*) $I(\mathbf{r})$ for $[CH_3\text{-}H\text{-}CH_3]^+$, in contours of 0.05 au; (*b*) $I(\mathbf{r})$ for $[CH_3\text{-}H\text{-}CH_3]^{\cdot}$, in contours of 0.05 au; (*c*) $I(\mathbf{r})$ for $[CH_3\text{-}H\text{-}CH_3]^-$, in contours of 0.05 au; (*d*) $E(\mathbf{R})$ for $[CH_3\text{-}H\text{-}CH_3]^+$, in contours of 1 au; (*e*) $E(\mathbf{R})$ for $[CH_3\text{-}H\text{-}CH_3]^{\cdot}$, in contours of 1 au; (*f*) $E(\mathbf{R})$ for $[CH_3\text{-}H\text{-}CH_3]^-$, in contours of 1 au.

pairs being invariable upon a symmetry-inversion operation, provided that the molecular coordinates have been previously mass-centered. More electron–electron interactions arise by considering electrons formally assigned to terminal H atoms. However, these interactions are not considered relevant in order to investigate the electronic nature of H_t, and are not discussed. Furthermore, for the C atoms, the separate contributions of *core* and valence electrons are not resolved within this simple scheme, but they can be identified in the $\nabla^2 I(\mathbf{r})$ and $\nabla^2 E(\mathbf{R})$ distributions (*vide infra*).

Calculations at the HF level will be used for discussing the topologies of the $I(\mathbf{r})$ and $E(\mathbf{R})$ densities at the TS's for the three H-transfer model reactions. Since the electronic differences between hydride, hydrogen and proton transfers are overestimated at the HF level with respect to post-HF methodologies, the effect of adding Coulomb correlation energy at the CISD level will be discussed later by means of density difference maps.

Figure 1 shows the $I(\mathbf{r})$ and $E(\mathbf{R})$ density contour maps calculated at the HF level for the three TS's, labelled as $[CH_3\text{-}H\text{-}CH_3]^+$, $[CH_3\text{-}H\text{-}CH_3]^{\cdot}$, and $[CH_3\text{-}H\text{-}CH_3]^-$ for the CH_4/CH_3^+, $CH_4/CH_3^{\cdot}$, and CH_4/CH_3^- systems, respectively. First of all, the main topological features of the $I(\mathbf{r})$ maps will be assigned to the corresponding electron–electron

Table 1. Coordinates (z in au), intracule and extracule densities ($I(\mathbf{r})$ and $E(\mathbf{R})$, in au) for the $\{CH_t\}$ interaction localized in the $I(\mathbf{r})$ and $E(\mathbf{R})$ density maps of $[CH_3\text{-}H\text{-}CH_3]^+$, $[CH_3\text{-}H\text{-}CH_3]^{\cdot}$, and $[CH_3\text{-}H\text{-}CH_3]^-$. For the HF calculations, the contributions of the parallel ($\alpha\beta + \beta\alpha$) and antiparallel ($\alpha\alpha + \beta\beta$) spin components are also reported. For $[CH_3\text{-}H\text{-}CH_3]^+$ and $[CH_3\text{-}H\text{-}CH_3]^-$, CISD results are listed too. For all the systems, the distance between C and H_t is 3.024 au, and the center between the two atoms is located at 1.512 au in the molecular axis.

		Intracule		Extracule	
	Interaction	z	$I(\mathbf{r})$	z	$E(\mathbf{R})$
1a. $[CH_3\text{-}H\text{-}CH_3]^+$

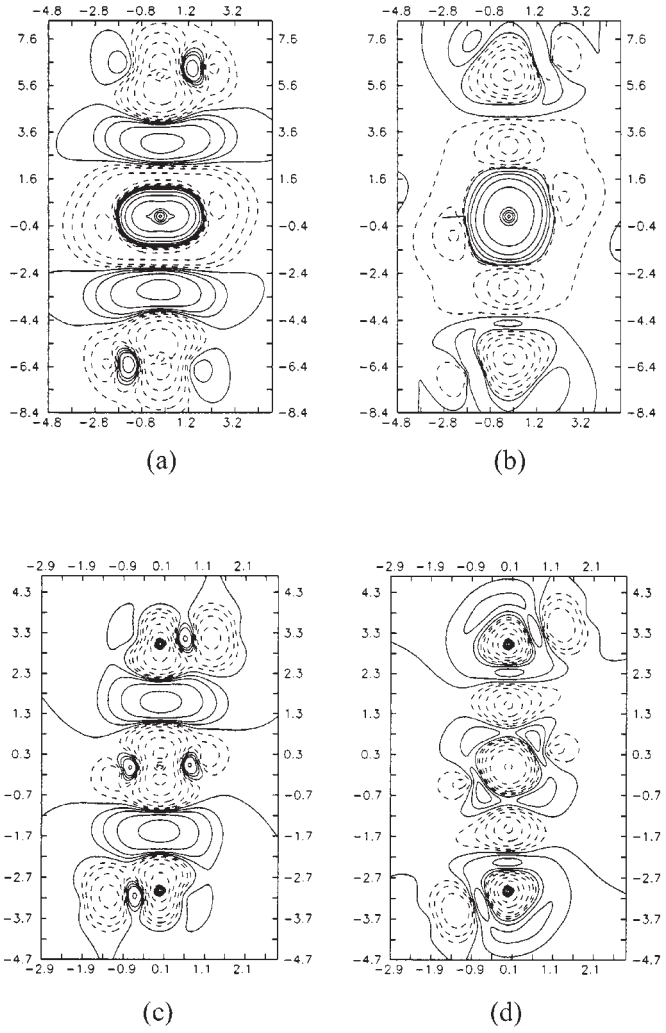
	$\{CH_t\}^{\alpha\beta+\beta\alpha}$	2.972	0.291	1.486	2.324
	$\{CH_t\}^{\alpha\alpha+\beta\beta}$	2.992	0.282	1.484	2.188
CISD	$\{CH_t\}$	2.976	0.595	1.490	4.660

interactions. Since the $I(\mathbf{r})$ maps for the three systems studied are equivalent from a topological point of view, this assignment is the same for $[CH_3\text{-}H\text{-}CH_3]^+$, $[CH_3\text{-}H\text{-}CH_3]^{\cdot}$, and $[CH_3\text{-}H\text{-}CH_3]^-$. Also, because of the symmetry inversion inherent to the intracule density distributions, only the upper half of each map needs to be discussed. For each map, the maximum located at 6.0 au on the vertical axis corresponds to the $\{C_iC_j\}$ interaction, while the maximum located at 3.0 au on the vertical axis can be assigned to the $\{CH_t\}$ interaction. Note that there are no maxima associated to the $\{H_{tt}\}$ and $\{C_{ii}\}$ interactions. Actually, these interactions, together with intraatomic contributions from the rest of H atoms, are responsible for the $\{0\}$ interaction at the origin. Other maxima which appear out of the vertical axis should be assigned to interactions between C and H atoms other than H_t.



The $E(\mathbf{R})$ maps are also topologically equivalent for the three systems studied. Again, because of the symmetry of the molecule, only the upper half of the map will be discussed. For each map, the maximum at the origin, labelled as $\{0\}$, is assigned to the $\{C_iC_j\}$ and $\{H_{tt}\}$ interactions, together with other interactions between terminal H atoms related by a symmetry-inversion operation. The maximum located at 3.0 au on the vertical axis corresponds to a $\{C_{ii}\}$ interaction, whereas the maximum located at 1.5 au on the vertical axis of each map is assigned to a $\{CH_t\}$ interaction. Finally, there are also maxima out of the vertical axis, corresponding to interactions between C atoms and terminal H atoms.

The difficulty in analyzing the topology of the electron-pair $I(\mathbf{r})$ and $E(\mathbf{R})$ densities is reflected by the fact that, depending on the molecular geometry, several electron–electron interactions can contribute to the same point in the intracule or extracule space. For instance, for the analysis of the electronic differences between the formal hydride, hydrogen, and proton transfers, the $\{H_{tt}\}$ interaction would be the most important to analyze, since it can be directly related to the probability of having a pair of electrons on the H_t atom. However, it is not possible to isolate a maximum corresponding only to the $\{H_{tt}\}$ interaction in the $I(\mathbf{r})$ nor in the $E(\mathbf{R})$ density maps of the systems studied. In the $I(\mathbf{r})$ maps, all the intraatomic electron pairs always contribute to the $\{0\}$ interaction, making it impossible to assess the contribution of a single intraatomic electron–electron interaction. In the $E(\mathbf{R})$ maps, because of the molecular symmetry of the TS's, the $\{C_iC_j\}$ and $\{H_{tt}\}$ interactions also contribute exactly to the same point in space. However, the $\{CH_t\}$ interaction can be isolated both in the $I(\mathbf{r})$ and $E(\mathbf{R})$ maps for the three TS's. Thus, the electron-pair differences between the hydride, hydrogen, and proton transfers will be assessed by studying the maxima assigned to $\{CH_t\}$. In fact, a visual comparison of the topological maps in Fig. 1 reveals that the major differences among the $I(\mathbf{r})$ density maps, on one hand, and the $E(\mathbf{R})$ density maps, on the other hand, of the $[CH_3\text{-}H\text{-}CH_3]^+$, $[CH_3\text{-}H\text{-}CH_3]^{\cdot}$, and $[CH_3\text{-}H\text{-}CH_3]^-$ systems are found in the region where the topological maximum assigned to the maximum probability for the $\{CH_t\}$ interaction is located.

A more quantitative analysis can be made by comparing the heights of the maxima located in the $I(\mathbf{r})$ and $E(\mathbf{R})$ maps that are associated to the $\{CH_t\}$ electron–electron interaction. The values of those maxima for the three H-transfer model systems are reported in Table 1. The $I(\mathbf{r})$ values associated to this interaction are 0.67, 0.62, and 0.57, for $[CH_3\text{-}H\text{-}CH_3]^+$, $[CH_3\text{-}H\text{-}CH_3]^{\cdot}$, and $[CH_3\text{-}H\text{-}CH_3]^-$, respectively. The same trend is found for the $E(\mathbf{R})$ values, which are 5.37, 4.97, and 4.51, respectively. Thus, the $I(\mathbf{r})$ and $E(\mathbf{R})$ values associated to the $\{CH_t\}$ interaction at the TS decrease along the series of formal hydride, hydrogen, and proton transfer reactions. However, the fact that these values are similar for the three transfer reactions confirms that the electronic differences between the H_t atoms in the three transfer reactions are very subtle, in agreement with the results obtained from

Fig. 2. (HF-CISD//HF) $I(\mathbf{r})$ and $E(\mathbf{R})$ difference maps for $[CH_3\text{-}H\text{-}CH_3]^+$ and $[CH_3\text{-}H\text{-}CH_3]^-$. (*a*) $I(\mathbf{r})$ for $[CH_3\text{-}H\text{-}CH_3]^+$, in contours of 0.001×2^n, $n = 1,2,...$ au; (*b*) $I(\mathbf{r})$ for $[CH_3\text{-}H\text{-}CH_3]^-$, in contours of 0.001×2^n, $n = 1,2,...$ au; (*c*) $E(\mathbf{R})$ for $[CH_3\text{-}H\text{-}CH_3]^+$, in contours of 0.01×2^n, $n = 1,2,...$ au; (*d*) $E(\mathbf{R})$ for $[CH_3\text{-}H\text{-}CH_3]^-$, in contours of 0.01×2^n, $n = 1,2,...$ au.

the analysis of the one-electron densities (15). In fact, the importance of the $\{CH_t\}$ interaction is proportional to the probability of having simultaneously one electron at one of the C atoms and another electron at H_t. The analysis of the one-electron densities carried out in Ref. 15 showed that the Bader electron population decreases for H_t and increases for the C atoms, along the $[CH_3\text{-}H\text{-}CH_3]^+$, $[CH_3\text{-}H\text{-}CH_3]^{\cdot}$, and $[CH_3\text{-}H\text{-}CH_3]^-$ series. However, for the C atoms, the increase in one-electron density takes place mainly in the valence shell, rather than in the core region of the C atoms, and the value of $\rho(\mathbf{r})$ at the C nuclei decreases only slightly along the series of TS complexes. Thus, it can be assumed that the importance of the $\{CH_t\}$ interaction along this series depends mainly on the one-electron density at H_t, in agreement with the $I(\mathbf{r})$ and $E(\mathbf{R})$ values reported in Table 1. Finally, one has to take into account that the $\{CH_t\}$ interaction will also be affected by the Fermi correlation or exchange between electrons in the C and H_t atoms. However, Fermi correlation is expected to have only a minor effect on the height of the maxima associated to the $\{CH_t\}$ interaction.[2]

The values of the $I(\mathbf{r})$ and $E(\mathbf{R})$ maxima associated to the $\{CH_t\}$ interaction at the CISD level for $[CH_3\text{-}H\text{-}CH_3]^+$ and $[CH_3\text{-}H\text{-}CH_3]^-$ follow the same trends found at the HF level. However, the differences between the hydride and proton transfer are reduced, ranging from 0.098 at the HF level to 0.063 at the CISD level for the $I(\mathbf{r})$ values, and from 0.87 at the HF level to 0.58 at the CISD level for the $E(\mathbf{R})$ values. The effect of electron correlation is that it decreases the importance of the $\{CH_t\}$ interaction for $[CH_3\text{-}H\text{-}CH_3]^+$, and increases its importance for $[CH_3\text{-}H\text{-}CH_3]^-$, both with respect to the HF reference. This can be appreciated visually in the (HF-CISD//HF) density difference maps presented in Fig. 2, where the exaggeration of the ionic structures at the HF level is evident. As can be observed, the region corresponding to the $\{CH_t\}$ interaction in the $I(\mathbf{r})$ and $E(\mathbf{R})$ maps is positive for $[CH_3\text{-}H\text{-}CH_3]^+$, and negative for $[CH_3\text{-}H\text{-}CH_3]^-$, reflecting the HF exaggeration of the hydride and proton nature, respectively, of the H atom transferred in the two systems. Note that, for the rest of electron–electron interactions discussed previously (namely $\{0\}$, $\{C_{ii}\}$, and $\{C_iC_j\}$) the same trends are found in the $[CH_3\text{-}H\text{-}CH_3]^+$ and $[CH_3\text{-}H\text{-}CH_3]^-$ (HF-CISD//HF) density difference maps. For the $I(\mathbf{r})$ maps, it is also interesting to discuss the effect of including Coulomb correlation at the CISD level on the $\{0\}$ interaction. In fact, since this interaction collects contributions from all pairs of electrons close in space, Coulomb correlation always diminishes its importance, for any system. This is actually the case for $[CH_3\text{-}H\text{-}CH_3]^+$ and $[CH_3\text{-}H\text{-}CH_3]^-$. Interestingly, the shape of the positive region in the origin of the intracule density (HF-CISD//HF) difference maps suggests that, for $[CH_3\text{-}H\text{-}CH_3]^+$, CISD adds electron correlation mainly in a direction perpendicular to the molecular axis. On the other hand, for $[CH_3\text{-}H\text{-}CH_3]^-$, CISD adds electron correlation principally along the molecular axis. This is related to the larger accumulation of electron density on the valence shells of the carbon atoms for the latter system, as revealed by the analysis of the $\nabla^2 I(\mathbf{r})$ and $\nabla^2 E(\mathbf{R})$ functions (*vide infra*).

The exact locations of the $\{CH_t\}$ maxima in the $I(\mathbf{r})$ densities for the three TS's provide some additional information about the electronic characteristics of the H being transferred. The interelectron distance at which a given electron–electron interaction is found depends on the internuclear distance of the two atoms involved. In fact, for interactions between C atoms, the interelectron and internuclear distances are exactly coincident. However, for electron–electron interactions involving at least one H atom, the most probable interelectron distances are generally found to be slightly shorter than the corresponding internuclear distances, due to the high polarizability of the electron cloud in H atoms (22). Actually, this is the case for the $\{CH_t\}$ interaction, according to the HF results presented in Table 1. For the $\{CH_t\}$ interaction, the electron–electron distances associated to the maxima in the $I(\mathbf{r})$ maps are 0.005, 0.017, and 0.041 au shorter than the internuclear C–H_t distance, for $[CH_3\text{-}H\text{-}CH_3]^+$,

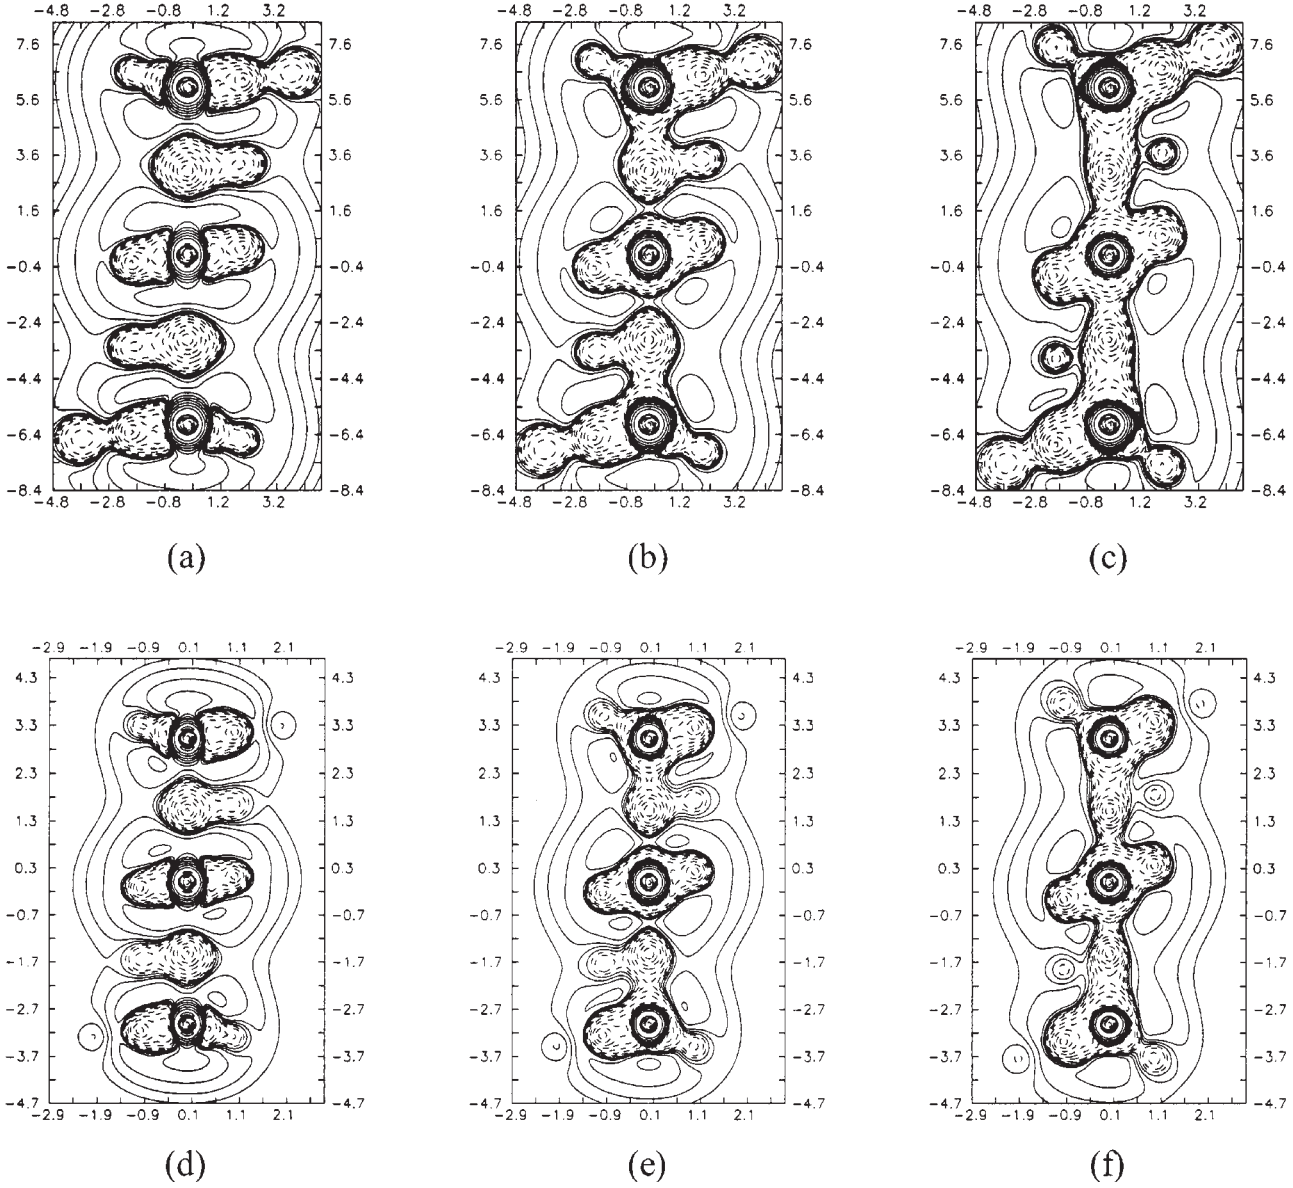
© 2000 NRC Canada

$[CH_3\text{-}H\text{-}CH_3]^{\cdot}$, and $[CH_3\text{-}H\text{-}CH_3]^{-}$, respectively. The difference between the interelectron and internuclear distances for the formal hydride, hydrogen and proton transfers agree with the increasing polarizability of the hydrogen being transferred. For $[CH_3\text{-}H\text{-}CH_3]^{+}$ and $[CH_3\text{-}H\text{-}CH_3]^{-}$, the same trends are found at the CISD level, with differences between interelectron and internuclear distances of 0.005 and 0.048 au, respectively. In the $E(\mathbf{R})$ maps, the maxima associated to $\{CH_t\}$ interactions are located nearer to H_t than to the C atom, for the three systems. At the HF level, along the $[CH_3\text{-}H\text{-}CH_3]^{+}$, $[CH_3\text{-}H\text{-}CH_3]^{\cdot}$, and $[CH_3\text{-}H\text{-}CH_3]^{-}$ series, this maximum is found progressively closer to the H_t atom, in agreement with the progressive buildup of charge density in the valence shells of the C atoms. However, this trend is not followed at the CISD level of theory. Then, $[CH_3\text{-}H\text{-}CH_3]^{+}$ is the system with the $\{CH_t\}$ maximum located nearest to H_t.

Local maxima corresponding to the $\{CH_t\}$ interaction located in the parallel and antiparallel spin–spin components of the $I(\mathbf{r})$ and $E(\mathbf{R})$ densities calculated at the HF level are also reported in Table 1. The parallel components take into account $\alpha\alpha$ and $\beta\beta$ interactions, which are equivalent for the closed-shell systems, while the antiparallel component takes into account $\alpha\beta$ and $\beta\alpha$ interactions, which are always equivalent. For the three TS's, the $I(\mathbf{r})$ and $E(\mathbf{R})$ values associated to the points of maximum probability for an antiparallel $\{CH_t\}$ interaction are slightly larger than those associated to a parallel interaction. Furthermore, for the three TS's, the maximum probability for a parallel $\{CH_t\}$ interaction is found at a larger interelectron distance than the corresponding antiparallel interaction. The subtle differences between parallel and antiparallel $\{CH_t\}$ electron interactions are due to the Fermi correlation, which is present only for pairs of electrons of same spin. The differences between parallel and antiparallel interactions should be more important for intraatomic interactions, such as $\{C_{ii}\}$. On the other hand, for interatomic interactions at large distance, parallel and antiparallel interactions should be totally equivalent.

Recently, it has been found that a VB analysis is useful for the interpretation of intracule and extracule density difference maps between HF and CISD results.[3] Within this type of analysis, the points of maximum probability of finding a given electron–electron interaction can be assigned to formal valence bond structures, and the different weights of ionic and covalent VB structures at the HF and CISD levels of theory are reflected in the corresponding intracule and extracule density difference maps. Thus, for electron–electron interactions associated to ionic VB structures, positive values are found in the (HF-CISD//HF) difference maps, in agreement with the exaggeration of the ionic contributions to the molecular wavefunction at the HF level of theory. Inversely, negative values in the difference maps are found for electron–electron interactions associated to covalent VB structures.[4] Following the same interpretative scheme for the $[CH_3\text{-}H\text{-}CH_3]^{+}$ and $[CH_3\text{-}H\text{-}CH_3]^{-}$ systems, six VB structures (three covalent and three ionic) are needed for the description of a three-center bond with two or four electrons. At the TS, the six VB structures in the RC converge to three symmetric VB structures, namely, $C^{-}H^{+}C^{+}$ (= $C^{+}H^{+}C^{-}$), $C^{\cdot}H^{\cdot}C^{+}$ (= $C^{+}H^{\cdot}C^{\cdot}$), and $C^{+}H^{-}C^{+}$ for the $[CH_3\text{-}H\text{-}CH_3]^{+}$ system; and $C^{-}H^{+}C^{-}$, $C^{\cdot}H^{\cdot}C^{-}$ (= $C^{-}H^{\cdot}C^{\cdot}$), and $C^{-}H^{-}C^{+}$ (= $C^{+}H^{-}C^{-}$) for the $[CH_3\text{-}H\text{-}CH_3]^{-}$ system. Each of the VB structures of the two systems can be associated to an electron–electron interaction and, consequently, to a certain region in the intracule space. Thus, all the ionic structures, which can be associated to intraatomic interactions, contribute to furnish the maximum at the origin, labelled as $\{0\}$. The covalent structures can be associated to the $\{CH_t\}$ interaction, and contribute to the corresponding maximum in $I(\mathbf{r})$. Note that the $C^{\cdot}H^{\cdot}C^{-}$ structure (for the $[CH_3\text{-}H\text{-}CH_3]^{-}$ system) has an ionic and covalent character at the same time, and contributes to both the $\{0\}$ and $\{CH_t\}$ maxima. Finally, one must take into account that, although each ionic structure contributes to the maximum at the origin, the simultaneous presence of two or more ionic structures can make a contribution to other electron–electron interactions. Thus, the C^{-} and H^{-} structures together also contribute to the $\{CH_t\}$ maximum, while two symmetric C^{-} structures together contribute to the $\{C_iC_j\}$ maximum. A similar reasoning can be carried out for the $E(\mathbf{R})$ densities, with the difference that the contribution of the $\{C_{ii}\}$ interaction can be isolated into a pair of symmetric maxima in $E(\mathbf{R})$, while both $\{H_{ii}\}$ and $\{C_iC_j\}$ contribute to the origin of the extracule map and furnish the local maximum labeled as $\{0\}$.



At the HF level of theory, the weights of ionic structures in the wave function are usually exaggerated. This overestimation is totally or partially corrected by post-HF methodologies, such as CISD. This trend can be reflected in the (HF-CISD//HF) difference maps of $I(\mathbf{r})$ and $E(\mathbf{R})$ densities for $[CH_3\text{-}H\text{-}CH_3]^{+}$ and $[CH_3\text{-}H\text{-}CH_3]^{-}$ (Fig. 2). The maxima at the origin of the intracule difference maps of the two systems (Figs. 2*a* and 2*b*) confirm that the contribution of the $\{0\}$ interaction, associated to the ionic VB structures, is greatly exaggerated at the HF level. Moreover, in the extracule (HF-CISD//HF) difference maps (Figs. 2*c* and 2*d*), local maxima appear in the positions assigned to $\{C_{ii}\}$ interactions, which can be associated to ionic C^{-} structures. Finally, for the $\{CH_t\}$ interaction, different trends are found for the two systems considered. In a valence bond language, the fact that electron correlation decreases the importance of this interaction for $[CH_3\text{-}H\text{-}CH_3]^{+}$ can be explained taking into account that, at the HF level, the contribution of the $C^{+}H^{-}C^{+}$ structure is exaggerated. On the other hand, for $[CH_3\text{-}H\text{-}CH_3]^{-}$, the increase of importance of the $\{CH_t\}$ interaction at the CISD level can be related to the overestimation of the contribution of the $C^{-}H^{+}C^{-}$ structure at the HF level. However, one must take into account that the importance

[3] X. Fradera, M. Duran, and J. Mestres. Submitted for publication.

[4] From a different point of view, it has been recently shown that considering electron correlation at the CISD level of theory increases the localization of electrons into each atom, while decreasing the electron delocalization between pairs of atoms, with respect to the HF approximation (20). For a pair of electrons shared between two atoms, A and B, electron localization is related to the probability of having each of the two electrons in a different atom, which corresponds to the covalent structure $A^{\cdot}\ B^{\cdot}$. In contrast, electron delocalization corresponds to the probability of the two electrons acting as a correlated pair, which can be at any of the atoms A or B, and corresponds to a pair of ionic structures, $A^{+}B^{-}$ and $A^{-}B^{+}$. Thus, the increasing electronic localization at the CISD level is related to the increasing contribution of the covalent VB structures to the molecular wave function.

Fig. 3. $\nabla^2 I(\mathbf{r})$ and $\nabla^2 E(\mathbf{R})$ topological maps for $[CH_3\text{-}H\text{-}CH_3]^+$, $[CH_3\text{-}H\text{-}CH_3]^{\cdot}$, and $[CH_3\text{-}H\text{-}CH_3]^-$ calculated at the HF level. (*a*) $\nabla^2 I(\mathbf{r})$ for $[CH_3\text{-}H\text{-}CH_3]^+$, in contours of 0.05×2^n, $n = 1,2,...$ au; (*b*) $\nabla^2 I(\mathbf{r})$ for $[CH_3\text{-}H\text{-}CH_3]^{\cdot}$, in contours of 0.05×2^n, $n = 1,2,...$ au; (*c*) $\nabla^2 I(\mathbf{r})$ for $[CH_3\text{-}H\text{-}CH_3]^-$, in contours of 0.05×2^n, $n = 1,2,...$ au; (*d*) $\nabla^2 E(\mathbf{R})$ for $[CH_3\text{-}H\text{-}CH_3]^+$, in contours of 1×2^n, $n = 1,2,...$ au; (e) $\nabla^2 E(\mathbf{R})$ for $[CH_3\text{-}H\text{-}CH_3]^{\cdot}$, in contours of 1×2^n, $n = 1,2,...$ au; (*f*) $\nabla^2 E(\mathbf{R})$ for $[CH_3\text{-}H\text{-}CH_3]^-$,.in contours of 1×2^n, $n = 1,2,...$ au.

of the $\{CH_t\}$ interaction depends also on the weight of the $C^-H^+C^+$ and $C^{\cdot}H^{\cdot}C^+$ structures for $[CH_3\text{-}H\text{-}CH_3]^+$, and the $C^-H^-C^+$ and $C^-H^{\cdot}C^{\cdot}$ structures for $[CH_3\text{-}H\text{-}CH_3]^-$. Unfortunately, the electron–electron interaction which reflects more directly the importance of the $C^+H^-C^+$ and $C^-H^+C^-$ structures is $\{H_{tt}\}$, which cannot be reflected separately in the intracule or extracule maps.

Finally, the Laplacians of the $I(\mathbf{r})$ and $E(\mathbf{R})$ densities for the systems studied are discussed. It is well known that the sign of the Laplacian of a function allows to detect where the function is locally concentrated (negative values) or locally depleted (positive values). For instance, zones of local charge concentration and depletion in atoms and molecules are revealed by means of the Laplacian of the one-electron density, $\nabla^2\rho(\mathbf{r})$ (18). This property gives $\nabla^2\rho(\mathbf{r})$ the ability of revealing the shell structure of atoms in molecules. Recently, it has been shown that the Laplacian functions of the intracule and extracule densities, $\nabla^2 I(\mathbf{r})$ and $\nabla^2 E(\mathbf{R})$, respectively, are also able to reveal the shell structure of atoms in molecules from an electron-pair perspective (22, 28, 41*a*). Moreover, many electron–electron interactions that are not reflected in the intracule or extracule density maps can be revealed in the maps of the corresponding Laplacian functions (22). $\nabla^2 I(\mathbf{r})$ and $\nabla^2 E(\mathbf{R})$ maps for $[CH_3\text{-}H\text{-}CH_3]^+$, $[CH_3\text{-}H\text{-}CH_3]^{\cdot}$, and $[CH_3\text{-}H\text{-}CH_3]^-$ calculated at the HF level are presented in Fig. 3.

Some electron–electron interactions between H atoms, not reflected in the $I(\mathbf{r})$ and $E(\mathbf{R})$ maps, are revealed in the Laplacian maps. However, the detection of these additional interactions is not relevant for the discussion of the electronic

© 2000 NRC Canada

nature of H_t. As in the $I(\mathbf{r})$ and $E(\mathbf{R})$ maps, the $\{H_{tt}\}$ interaction appears superimposed with other electron–electron interactions and cannot be isolated in the $\nabla^2 I(\mathbf{r})$ and $\nabla^2 E(\mathbf{R})$ maps. Nevertheless, Laplacian maps allow discussing in detail electron–electron interactions involving electrons of the carbon valence shell (22). When going from the hydride to the hydrogen and to the proton transfer, at the same time that the charge density at H_t decreases, there is an accumulation of charge density at the valence shell of the C atoms. This is reflected in the $\nabla^2 I(\mathbf{r})$ and $\nabla^2 E(\mathbf{R})$ maps of the three systems, for the electron–electron interactions involving pairs of electrons assigned to C atoms: $\{C_iC_j\}$ and $\{0\}$ in the intracule maps, and $\{C_{ii}\}$ and $\{0\}$ in the extracule maps. In the maps corresponding to $[CH_3\text{-}H\text{-}CH_3]^+$, these interactions reveal a negative shell, corresponding to the interaction between core electrons, surrounded by a positive shell. In contrast, for the same interactions, a second negative shell is found in the maps for the $[CH_3\text{-}H\text{-}CH_3]^{\cdot}$ and $[CH_3\text{-}H\text{-}CH_3]^+$ systems. For the interactions between C and H electrons, such as $\{CH_t\}$, no shell structure is found for any of the molecules studied. The progressive accumulation of charge density on the C-H_t-C region is also reflected in the $\nabla^2 I(\mathbf{r})$ and $\nabla^2 E(\mathbf{R})$ maps by the presence of negative Laplacian values connecting the different electron–electron interactions located on the vertical axis for $[CH_3\text{-}H\text{-}CH_3]^{\cdot}$, and specially for $[CH_3\text{-}H\text{-}CH_3]^+$.

Conclusions

The contracted electron-pair densities at the TS's corresponding to the formal hydrogen transfers in the CH_4/CH_3^+, $CH_4/CH_3^{\cdot}$, and CH_4/CH_3^- systems, constrained to a fixed C—C distance, have been investigated. The topological analysis of the corresponding intracule and extracule density and Laplacian functions complements, thus, a previous comparative electronic analysis of the same systems from the point of view of the one-electron density (15).

For the three systems considered, it has been shown that the topological characteristics of intracule and extracule densities can be readily interpreted in terms of formal electron–electron interactions. However, the $\{H_{tt}\}$ interaction, that could be directly related to the probability of having an electron pair in the H being transferred, cannot be isolated in the $I(\mathbf{r})$ or $E(\mathbf{R})$ distributions. Thus, the analysis of the electron-pair characteristics of the H being transferred has to be performed indirectly by analyzing the $\{CH_t\}$ interaction, whose contribution is more apparent in the $I(\mathbf{r})$ and $E(\mathbf{R})$ distributions. A comparative analysis of this interaction for the three systems shows that the nature of the hydrogen being transferred in each reaction is related to the heights of this maximum in each $I(\mathbf{r})$ or $E(\mathbf{R})$ map, although the differences between the formal hydride, hydrogen, and proton atoms transferred appear to be very subtle. The main shortcoming of this analysis is that the discussion of the electron-pair characteristics of H_t in terms of the $\{CH_t\}$ electron–electron interaction is not straightforward, because this interaction does not depend only on the nature of H_t, but depends also on the number of electrons present in C. The same difficulty arises when interpreting the differences between the HF and CISD $I(\mathbf{r})$ and $E(\mathbf{r})$ maps in terms of VB structures.

In summary, one can conclude that the topologies of intracule and extracule densities and their respective Laplacian functions are able to reflect the electron-pair characteristics of atoms and molecules. However, intracule and extracule densities present topologies considerably more complex than the one-electron densities, making the corresponding analysis more difficult. In addition, depending on the symmetry and size of the molecule studied, many different electron–electron interactions can contribute to the same regions of the intracule or extracule space. These drawbacks limit the current usefulness of topological analyses of intracule and extracule densities for molecules and complexes. More studies are required to find convenient tools for the analysis and interpretation of molecular contracted electron-pair densities that allow for unequivocally discriminating the contribution of the different electron–electron interactions.

Metabolism of analogs of the phytoalexin brassinin by plant pathogenic fungi

M. Soledade C. Pedras and Francis I. Okanga

Abstract: The metabolism of analogs of the cruciferous phytoalexin brassinin by the phytopathogenic fungi *Phoma lingam* (Tode ex Fr.) "virulent" and "avirulent" groups (sexual stage *Leptosphaeria maculans* (Desm.) Ces. et de Not.) and *Alternaria brassicae* (Berk.) Sacc. is reported. It was established that each pathogen detoxified methyl tryptamine dithiocarbamate, although yielding different metabolic products. While the biotransformation by virulent *P. lingam* proceeded to yield methyl 3a-hydroxy-3,3a,8,8a-tetrahydropyrrolo[2,3-*b*]indol-1(2H)-yl carbodithioate and indole-3-acetic acid as final products, avirulent *P. lingam* yielded indole-3-carboxylic acid via N_b-acetyltryptamine, and *A. brassicae* yielded N_b-acetyltryptamine, as final products. Furthermore, to establish the importance of the dithiocarbamate group in antifungal activity against *P. lingam* and *A. brassicae*, carbamates were compared with dithiocarbamates and it was established that carbamates were devoid of antifungal activity. These products, contrary to methyl tryptamine dithiocarbamate, showed no inhibitory activity against either pathogen.

Key words: *Alternaria brassicae*, brassinin, carbamates, detoxification, dithiocarbamates, *Leptosphaeria maculans*, *Phoma lingam*, phytoalexins.

Résumé : On a étudié le métabolisme d'analogues de la brassinine phytoalexine crucifère par *Alternaria brassicae* (Berk.) Sacc. et par les groupes « virulent » et « avirulent » des champignons phytopathogènes *Phoma lingam* (Tode ex Fr.) (stade sexuel *Leptosphaeria maculans* (Desm.) Ces. et de Not.). Il a été établi que chaque pathogène détoxifie le dithiocarbamate de la méthyltryptamine, même s'ils conduisent à ces produits de métabolisme différents. Alors que la biotransformation par le *P. lingam* virulent conduit au 3a-hydroxy-3,3a,8,8a-tétrahydropyrrolo[2,3-*b*]indol-1-(2*H*)-ylcarbodithionate de méthyle et à l'acide indole-3-acétique comme produits finaux, le *P. lingam* avirulent conduit à l'acide indole-3-carboxylique, via la N_b-acétyltryptamine, et *A. brassicae* conduit à la N_b-acétyltryptamine. De plus, afin d'évaluer l'importance du groupe dithiocarbamate dans l'activité antifongique contre *P. lingam* et *A. brassicae*, on a comparé les carbamates avec les dithiocarbamates et on a établi que les carbamates ne possèdent aucune activité antifongique. Contrairement à ce qui est observé avec le dithiocarbamate de la méthyltryptamine, ces produits ne présentent aucune activité inhibitrice contre l'un ou l'autre des pathogènes.

Mots clés : *Alternaria brassicae*, brassinine, carbamates, détoxification, dithiocarbamates, *Leptosphaeria maculans*, *Phoma lingam*, phytoalexines.

[Traduit par la Rédaction]

The role of phytoalexins in plant defense responses is becoming significantly better understood with the development of new transgenic and mutant organisms. For example, transformation of a fungus (*Cochliobolus heterostrophus*) nonpathogenic on pea (*Pisum sativum*) with a gene (cloned from the pea pathogen *Nectria haematococca*) responsible for detoxification of the pea phytoalexin pisatin, allowed the fungal transformant to become pathogenic on pea (1). These results indicated that the pisatin detoxifying gene was required for pathogenicity of *C. heterostrophus* on pea and that pisatin itself was a plant defense factor. On the other hand, a phytoalexin-deficient mutant of *Arabidopsis thaliana* showed significantly higher susceptibility to the fungus *Alternaria brassicicola* than wild-type parental plants; however, the reaction of the mutant to the pathogen *Botrytis cinerea* was similar to that of wild-type plants (2). Therefore, it is becoming indisputable that phytoalexins can be selectively inhibitory to plant pathogens and that plant pathogens can react differently to phytoalexins.

In instances where phytopathogens have been shown to react to plant defenses with metabolic detoxification, an environmentally attractive strategy to control such plant pathogens could involve application of selective inhibitors of those fungal enzymes utilized in detoxifying phytoalexins. Towards this end, we have been investigating the metabolism and detoxification (3) of cruciferous phytoalexins (4)[2] by

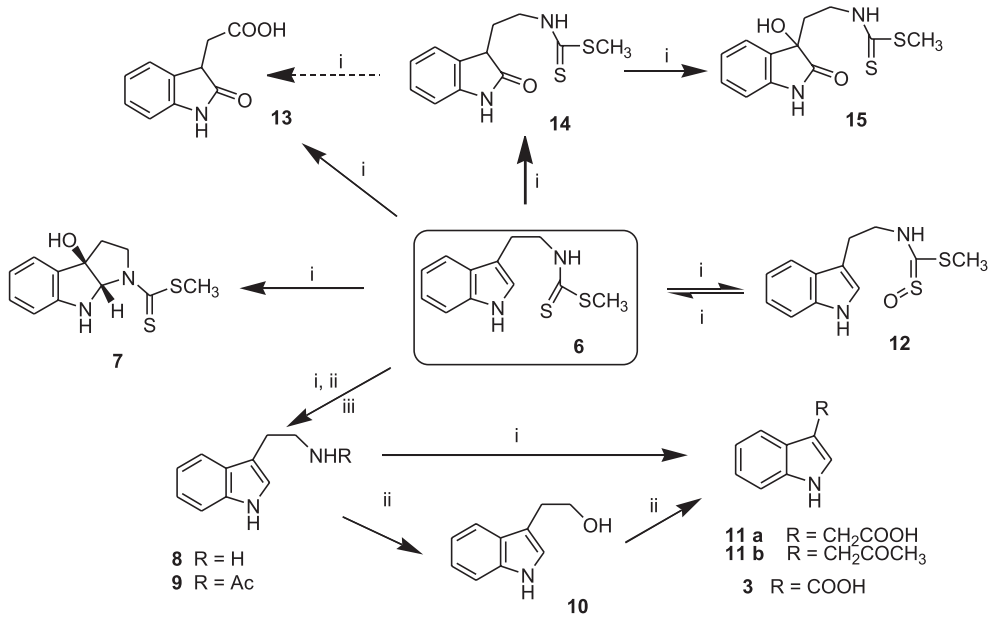
economically important phytopathogenic fungi, and have established that the phytoalexin brassinin (**1**) (5) was metabolized (6) and detoxified (7) by isolates of virulent and avirulent groups (8)[3] of the blackleg fungus (*Phoma lingam* (Tode ex Fr.) Desm., asexual stage of *Leptosphaeria maculans* (Desm.) Ces. et de Not. (Pleosporaceae)), one of the most important pathogens of the oilseeds rapeseed/canola (*Brassica napus*, *B. rapa*) (9).[4] These studies indicated that brassinin detoxification occurred via the so-called "virulent" route to yield **2** and **3** or "avirulent" route to yield **4** and **5**, depending on the isolate type, as depicted in Scheme 1 (7). In addition, due to studies with diverse dithiocarbamates (10), the dithiocarbamate group of brassinin (**1**) was thought to be essential for its antifungal activity.

Because methyl tryptaminedithiocarbamate (**6**) was significantly more inhibitory to *P. lingam* than brassinin, we examined its possible transformation by isolates of virulent and avirulent groups (8) of *P. lingam*. Furthermore, to establish the importance of the dithiocarbamate sulfur atoms, the corresponding carbamates of **1** and **6** were also examined and their antifungal activity established. A preliminary account of the metabolism of **6** by virulent type *P. lingam* was recently reported (11). Here we report for the first time the metabolism of **6** by avirulent type *P. lingam* and by *A. brassicae*, as well as the metabolism of methyl tryptamine carbamate (**16**) and N_b-carbomethoxyindole-3-methanamine (**17**) by both virulent and avirulent *P. lingam*. In addition, we propose a complete metabolic map of the metabolism of **6** by *P. lingam*, and compare the antifungal activities of brassinin (**1**), its homolog **6**, and corresponding carbamates **16** and **17**.

Results and discussion

The metabolism of methyl tryptamine dithiocarbamate (**6**) by virulent and avirulent isolates of *P. lingam* was investigated. Initially, experiments were carried out to compare the antifungal activity of dithiocarbamates **1** and **6**, as well as the time required for complete metabolism of **6**. Brassinin (**1**) was synthesized as previously described (7), and analog **6** was prepared as reported in the experimental. Fungal cultures and control medium were separately incubated with **1** (4×10^{-4} M) and **6** (2×10^{-4} M and 4×10^{-4} M) up to two weeks, and samples withdrawn at different times. Brassinin (**1**) was completely biotransformed within 2–4 days to yield the metabolites previously reported (6, 7). The HPLC chromatograms of extracts of cultures of either virulent or avirulent *P. lingam* incubated with methyl tryptamine dithiocarbamate (**6**) at the lower concentration (2×10^{-4} M) showed a decrease in the concentration of **6** as well as additional peaks not present in control cultures; however, at the higher concentration (4×10^{-4} M), no biotransformation occurred and the fungal mycelial growth was completely inhibited. These results established that methyl tryptamine dithiocarbamate (**6**) was biotransformed by either virulent (>14 days) or avirulent (ca. 4–6 days) types of *P. lingam* at a lower concentration (2×10^{-4} M), but at higher concentrations **6** inhibited primary metabolic steps, including mycelial growth (mycelial growth would resume upon dilution with culture medium). Therefore, biotransformation experiments to establish the structures of metabolites resulting from biotransformation of **6** were conducted at concentrations of 2×10^{-4} M.



First, the biotransformation of methyl tryptamine dithiocarbamate (**6**) by virulent *P. lingam* was investigated. The metabolites were isolated by flash column chromatography and (or) preparative TLC as described in the experimental, and characterized by spectroscopic techniques (FTIR, ^{1}H NMR, ^{13}C NMR, MS). As a result of the biotransformation of **6**, eight metabolites were isolated and identified: methyl 3a-hydroxy-3,3a,8,8a-tetrahydropyrrolo[2,3-*b*]indol-1(2H)-yl carbodithioate (**7**), tryptamine (**8**), N_b-acetyltryptamine (**9**), indole-3-acetic acid (**11a**), methyl indole-3-acetate (**11b**), methyl tryptamine dithiocarbamate-*S*-oxide (**12**), 2-oxindole-3-acetic acid (**13**), and methyl 2-oxotryptamine dithiocarbamate (**14**). The isolated metabolites accounted for ca. 70% of the original amount of **6** after 14 days of incubation (Scheme 2); compounds **7** and **11a** were the major metabolites, representing ca. 65% of the total amount of isolated metabolites, followed by acetyltryptamine (**9**) (15%), and minor components **12**–**14** and methyl indole-3-acetate (less than 5%). The structure of each compound was deduced from analysis of spectroscopic data as previously described (11) and confirmed either by comparison of its spectroscopic data with those of authentic samples (**8** and **11a**), or corroborated by synthesis (**7**, **9**, **11b**, and **12–14**), as described in the experimental.

To further prove the sequence of the metabolic steps carried out by virulent *P. lingam*, compounds **7–9** and **11–14** were administered to fungal cultures and control medium and incubated for several days, the cultures were extracted and the resulting extracts analyzed by HPLC. Where the biotransformation led to detection of new compounds (**15**), i.e., not detected in the biotransformation of methyl tryptamine dithiocarbamate, scale up experiments were carried out to isolate and characterize them. Methyl 3a-hydroxy-3,3a,8,8a-tetrahydropyrrolo[2,3-*b*]indol-1(2H)-yl carbodithioate (**7**), indole-3-acetic acid (**11a**), and oxindole-3-acetic acid (**13**) underwent no further biotransformation on incubation with the fungus for up to 14 days. Tryptamine (**8**) was rapidly (within 24 h) biotransformed to give N_b-acetyltryptamine (**9**) and indole-3-acetic acid (**11a**). N_b-acetyltryptamine (**9**) was partially (ca. 50%) transformed to indole-3-acetic

[3] Although no formal reclassification has been carried out, virulent and avirulent isolates of *P. lingam* are now considered different species, see for example ref. 8.
[4] For a review on the blackleg fungus see for example, ref. 9.

acid after 14 days of incubation. Methyl indole-3-acetate (**11b**) was biotransformed (within 48 h) into indole-3-acetic acid. Methyl tryptamine dithiocarbamate-*S*-oxide (**12**) was reduced (within 6 h) to methyl tryptamine dithiocarbamate (**6**). Methyl 2-oxotryptamine dithiocarbamate (**14**) yielded an apparently new metabolite which was isolated, characterized, and identified as methyl 3-hydroxy-2-oxotryptamine dithiocarbamate (**15**) based on a comparison of its spectroscopic data with those of its metabolic precursor **14**. In control experiments, each of the metabolites was stable in the cultures for up to 14 days of incubation.

The possible pathways for biotransformation of methyl tryptamine dithiocarbamate (**6**) and its metabolites by virulent *P. lingam* are shown in Scheme 2. There appear to be two major routes, one leading to acid **11** via tryptamine (**8**) and acetyltryptamine (**9**), and the other yielding dithiocarbamate **7**; neither **7** nor **11** appeared to be metabolized further. In addition, a minor pathway may lead to products **13** (≤1%) and **14** (≤1%). Although **14** appeared as a likely precursor of acid **13**, we did not detect **13** in cultures incubated with **14**. Surprisingly, although **6** is significantly more inhibitory to *P. lingam* than **12**, *S*-oxide **12** administered to fungal cultures was reduced to mostly **6**, in ca. 6 h. Control experiments indicated that **12** was stable under those incubation conditions for at least 48 h, suggesting that the transformation of **12** to **6** was an enzymatic process. Despite having investigated several biotransformations by fungi, this was the first time that we observed a reversible metabolic step in which one of the compounds (i.e., **6**) was clearly more inhibitory to the fungus. In this context, it is worthy to mention that structures such as **12**, i.e. containing a dithiocarbamate *S*-oxide, are rarely isolable and have been characterized mostly as mixtures (6, 12). Recently, however, the crystal structure of a stable dithiocarbamate *S*-oxide was determined by X-ray diffraction analysis (13). The *S*-oxide **12** is relatively more stable than the *S*-oxide of brassinin, perhaps due to the additional CH_2 group, which reduces the propensity for elimination of dithiocarbamic acid or equivalent. Although the decomposition of certain dithiocarbamate *S*-oxides was reported to lead mainly to the thiolocarbamates (sulfur extrusion), particularly in the presence of acid (12), we have not isolated such products from solutions containing **12**. Interestingly, the *S*-oxide **12** yielded oxindole **14** upon standing in acidic solvents such as $CDCl_3$; nonetheless, in fungal cultures **14** appeared to result from the enzymatic fungal transformation of **6**, since it was not detected in uninoculated control medium. Furthermore, similar to a previous observation with brassinin (**1**) (7), it was established during this process that, while **6** inhibited the synthesis of toxins produced by virulent *P. lingam*, neither dithiocarbamates **7** or **14** had noticeable effects.

Next, the biotransformation of methyl tryptamine dithiocarbamate (**6**) by avirulent *P. lingam* was examined; the biotransformation yielded indole-3-carboxylic acid (**3**), tryptamine (**8**), N_b-acetyltryptamine (**9**), tryptophol (**10**), and indole-3-acetic acid (**11a**). The total amount of isolated metabolites was ca. 70% of the initial amount of **6** after 4 days of incubation. Compounds **8**, **9**, and **11a** were also isolated from biotransformations with virulent isolates (Scheme 2). The structures of compounds **8**–**11a** were readily determined by comparison of their chromatographic and spectroscopic data (e.g., ^1H and ^{13}C NMR showed characteristic chemical shifts of indolyl moiety) with those of authentic samples. In order to establish the sequence of the biotransformation steps and hence the biotransformation pathway, each of the metabolites indole-3-carboxylic acid (**3**), tryptamine (**8**), N_b-acetyltryptamine (**9**), tryptophol (**10**), and indole-3-acetic acid (**11a**) were subjected to further incubation with

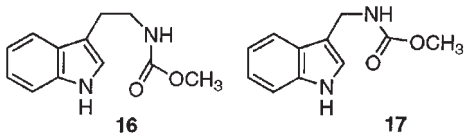

Scheme 3.

(i) *Phoma lingam* avirulent isolates.

avirulent *P lingam*. Indole-3-carboxylic acid (**3**) underwent no further transformation and was recovered unchanged from the cultures after 14 days. Tryptamine (**8**) was biotransformed via acetyltryptamine to tryptophol and indole-3-carboxylic acid. As expected, N_b-acetyltryptamine (**9**) yielded tryptophol and indole-3-carboxylic acid on further biotransformation by the fungus. Indole-3-acetic acid (**11a**) was completely transformed to indole-3-carboxylic acid (**3**), and tryptophol (**10**) was transformed (ca. 80%) to indole-3-carboxylic acid via indole-3-acetic acid, after 14 days incubation. In control experiments each of the compounds was stable in the cultures for at least 14 days. From these results, the pathway for biotransformation of methyl tryptamine dithiocarbamate (**6**) by avirulent *P. lingam* was inferred as shown in Scheme 3. Avirulent *P. lingam* biotransformed methyl tryptamine dithiocarbamate (**6**) through one major pathway to yield indole-3-carboxylic acid (**3**) via tryptamine (**8**), N_b-acetyltryptamine (**9**), tryptophol (**10**), and indole-3-acetic acid (**11a**).

Similarly, experiments carried out with *A. brassicae* incubated with tryptamine dithiocarbamate (**6**) at half of the concentration used in *P. lingam* cultures, showed that **6** was also completely metabolized by this pathogen in four days, to yield only two metabolites. These metabolites were identified as tryptamine (**8**) (less than 10%) and N_b-acetyltryptamine (**9**, ca. 70%). Importantly, it was established during these studies that dithiocarbamate **6** inhibited the production of the host-selective phytotoxin destruxin B by *A. brassicae.* In cultures incubated with tryptamine dithiocarbamate (**6**) the production of the toxin did not occur until complete metabolism of the compound by the fungus, while in control cultures the production of destruxin B occurred within 24 h.[5]

Methyl tryptamine carbamate (**16**) and N_b-carbomethoxyindole-3-methanamine (**17**) were chosen in order to probe the effect of substitution of oxygen for sulfur. Time-course experiments showed that methyl tryptamine carbamate (**16**) underwent little (<10%) transformation when incubated with virulent *P. lingam*. After 14 days incubation the major peak in the HPLC chromatogram of the neutral culture extract was that due to starting material (**16**) and phytotoxins produced by the fungus, while the acidic culture extract contained indole-3-acetic acid (**11a**). Further experiments showed that methyl tryptamine carbamate (**16**) was biotransformed by avirulent *P. lingam* (14 days) to yield two metabolites characterized by spectroscopic techniques and identified as tryptophol (**10**) and indole-3-carboxylic acid (**3**). Isolated metabolites accounted for ca. 40–50% of the initial amount of **16** after 14 days incubation.

Subsequent experiments with virulent *P. lingam* showed that N_b-carbomethoxyindole-3-methanamine (**17**) was biotransformed by the fungus, but compared to control cultures no additional metabolites (several known toxins (14) produced by the fungus were detected). Similar experiments with avirulent *P. lingam* indicated no biotransformation of N_b-carbomethoxyindole-3-methanamine by this fungal isolate. The compound was stable in the cultures with avirulent *P. lingam* for at least up to 14 days of incubation.

Bioassay results in liquid cultures inoculated with fungal spores and grown for 48 h before compound addition, indicated that methyl tryptamine dithiocarbamate (**6**) was more inhibitory to both virulent and avirulent *P. lingam* than brassinin (**1**); mycelial growth and metabolism of **6** were completely inhibited at 4×10^{-4} M, whereas brassinin caused a similar effect only at a concentration twice as high. However, the inhibitory effect of each compound decreased when fungal spores were incubated on solid medium containing either **1** or **6**. Nonetheless, as the results of Table 1 indicate, virulent *P. lingam* appeared more sensitive to **6** than to brassinin (**1**). It was observed that *P. lingam* spores germinated in 80–96 h on solid agar containing brassinin (at 5×10^{-4} M), but those spores germinated only after 100–120 h (results not shown) on solid agar containing **6** at similar concentration.

The results of bioassays of methyl tryptamine dithiocarbamate (**6**), methyl tryptamine carbamate (**16**), and N_b-carbomethoxyindole-3-methanamine (**17**) suggest that both the indole and the dithiocarbamate structural units are important for the antifungal activity of **6** against *P. lingam*. Compounds possessing the dithiocarbamate structural unit but lacking the indole unit such as methyl 2-oxotryptamine dithiocarbamate (**14**) and methyl 3a-hydroxy-3,3a,8,8a-tetrahydropyrrolo[2,3-*b*]indol-1(2*H*)-yl carbodithioate (**7**) were found to be much less active than methyl tryptamine dithiocarbamate (Table 1). Similarly, compounds possessing the indole unit but lacking the dithiocarbamate unit, such as methyl tryptamine dithiocarbamate-*S*-oxide (**12**) and indole-3-acetic acid (**11a**), were much less active. Furthermore, the growth and metabolism of *A. brassicae* was also strongly inhibited by **6**, as indicated by the results shown in Table 2; there was a significant inhibitory effect even at the lowest concentration. That is, **6** was more inhibitory to *A. brassicae* than to *P. lingam*. Finally, the bioassay results shown on Tables 1 and 2 indicate that none of the metabolic products of **6** displayed noticeable inhibitory activity against either *P. lingam* or *A. brassicae.*

[5] It was previously observed that brassinin caused a similar inhibitory effect on production of destruxins by *A. brassicae*, Pedras, M.S.C., unpublished results.

Virulent and avirulent *P. lingam* showed significant differences in their metabolism and detoxification of methyl tryptamine dithiocarbamate (**6**). The virulent isolates biotransformed methyl tryptamine dithiocarbamate (**6**) via two major and distinct pathways over a period of three weeks. The avirulent *P. lingam*, on the other hand, biotransformed methyl tryptamine dithiocarbamate (**6**) through one major pathway over a much shorter period (4–6 days). In both cases, however, the metabolism of dithiocarbamate **6** by virulent and avirulent *P. lingam* was a detoxification process. Importantly, the biotransformation pathways were somewhat different from those observed with brassinin; the transformation of **6** by virulent *P. lingam* occurred much slower (three weeks) than the transformation of brassinin (2–4 days). Furthermore, while brassinin (**1**) was detoxified by virulent *P. lingam* through one major pathway, to yield carboxylic acid **3** via aldehyde **2**, two major pathways occurred for detoxification of **6**, one which yielded **7** and the other one leading to indole-3-acetic acid (**11a**). On the other hand, both brassinin (**1**) and dithiocarbamate **6** were detoxified by avirulent *P. lingam* via acetylamines **5** and **9**, respectively, although acetylamine **5** was slowly oxidized to carboxylic

© 2000 NRC Canada

acid **3** via aldehyde **2**, whereas acetylamine **9** yielded carboxylic acid **3** via alcohol **10**.

Considering that brassinin (**1**) is produced by plants that virulent *P. lingam* attacks and colonizes, it is likely that virulent isolates have acquired very effective detoxification mechanisms to overcome this plant defense. The difference between the fungal metabolism of compounds **1** and **6** by virulent *P. lingam* may reflect the adaptation and specificity of the fungal enzymes involved in the detoxification of brassinin (**1**). Perhaps because those enzymes are not present in avirulent *P. lingam*, such differences are less obvious. These results, together with our previous studies (3), suggest that virulent *P. lingam* can detoxify dithiocarbamates effectively via pathways different from those followed by other species. Therefore, it should be possible to control virulent *P. lingam* with rationally designed inhibitors of dithiocarbamate detoxifying enzyme(s) without affecting other organisms.

Experimental

General

All chemicals were purchased from Sigma–Aldrich Canada Ltd., Oakville, ON. All solvents were HPLC grade and used as such, except for CH_2Cl_2 and $CHCl_3$ which were redistilled. TLC, and HPLC analyses were carried out as previously described (14).

NMR spectra were recorded on a Bruker AMX 300 or 500 spectrometer; for ^1H (300 or 500 MHz), δ values were referenced to CD_3OD (CD_2HOD at 3.31 ppm), CD_2Cl_2 ($CDHCl_2$ at 5.32 ppm), or $CDCl_3$ ($CHCl_3$ at 7.26 ppm), and for ^{13}C (75.5 or 125.8 MHz) referenced to CD_3OD (49.15 ppm), CD_2Cl_2 (54.00 ppm), or $CDCl_3$ (77.23 ppm). The multiplicities of ^{13}C NMR signals were determined based upon HMQC experiments.

Fungal cultures and bioassays

Phoma lingam virulent isolates BJ 125 and ENG 53, and avirulent isolate Unity, (virulent and avirulent isolates are considered a different species, although no formal reclassification has occurred) and *Alternaria brassica* isolates AB3 and IBJ were obtained from AAFC, G. Séguin-Swartz. Liquid cultures of *P. lingam* in 250 mL Erlenmeyer flasks containing 100 mL minimal medium inoculated with fungal spores at 2×10^9 per flask (15), and cultures of *A. brassicae* in 250 mL Erlenmeyer flasks containing 100 mL potato dextrose medium inoculated with fungal spores at 2.4×10^6 per flask (16), were used for the metabolism studies.

The antifungal activity of compounds **1** and **6**–**14** to *P. lingam* and *A. brassicae* was investigated using the mycelial radial growth bioassay previously reported (14). Each assay was conducted in triplicate and repeated at least three times.

Metabolism of methyl tryptamine dithiocarbamate (6)

Solutions of compounds under study (final concentration 2×10^{-4} M in cultures of *P. lingam*, and 1×10^{-4} M in cultures of *A. brassicae*) in DMSO (final concentration of DMSO in medium 0.5%, v/v) were administered separately to 48-hour-old liquid cultures and to uninoculated media. Cultures were incubated on a shaker at 150 rpm, at 24 ± 2°C. Samples (5–10 mL) were withdrawn immediately after addition of compound, and at different time intervals, and were either immediately frozen or filtered and extracted with Et_2O. The extracted broth was acidified to pH 2 with HCl and extracted with Et_2O, followed by neutralization with NaOH and extraction with $CHCl_3$ (containing 1% NH_4OH, (v/v)).

Isolation of metabolites of methyl tryptamine dithiocarbamate (6)

P. lingam *virulent isolate BJ 125*

From 10 flasks inoculated with fungal spores and incubated with methyl tryptamine dithiocarbamate (**6**) at 2×10^{-4} M for 14 days (final broth volume of 900 mL due to sampling over incubation period) neutral (60 mg) and acidic (75 mg) extracts were obtained. Preparative TLC (CH_2Cl_2:MeOH (97:3)) was carried out on the neutral extract to yield: methyl tryptamine dithiocarbamate (**6**, 10 mg), methyl 3a-hydroxy-3,3a,8,8a-tetrahydropyrrolo[2,3-*b*]indol-1(2*H*)-yl carbodithioate (**7**, 10 mg), N_b-acetyltryptamine (**9**, 5 mg), methyl tryptamine dithiocarbamate-*S*-oxide (**12**, 2 mg), 2-oxoindole-3-acetic acid (**13**, 1 mg), and methyl 2-oxotryptamine dithiocarbamate (**14**, 2 mg). Similarly, preparative TLC (CH_2Cl_2:MeOH (95:5)) carried out on the acidic extract afforded: indole-3-acetic acid (**11**, 5 mg) and methyl indole-3-acetate (**11b**, 1 mg). Similar results were obtained with isolate ENG 53.

Detection and isolation of tryptamine (**8**) in the biotransformation of methyl tryptamine dithiocarbamate (**6**): three flasks were inoculated with spores of *P. lingam* isolate BJ-125 and incubated with methyl tryptamine dithiocarbamate (**6**) as described above. Samples were taken immediately after adding the compound and subsequently every day over a period of 5 days. After 5 days the cultures were filtered, the combined broth (final broth volume of 280 mL due to sampling over incubation period) was extracted with diethyl ether to give a neutral extract. The broth was then basified to pH 10 with concentrated ammonia solution and extracted with $CHCl_3$:NH_4OH (98:2) to yield a basic extract (111 mg). The extracts were dried over Na_2SO_4, the solvent evaporated under reduced pressure and the basic residue analyzed by TLC ($CHCl_3$:MeOH:NH_4OH (80:20:1)). Preparative TLC ($CHCl_3$:MeOH:NH_4OH (80:20:1)) on the basic extract yielded 2 mg of tryptamine (**8**).

P. lingam *avirulent isolate Unity*

From five flasks inoculated with fungal spores and incubated with methyl tryptamine dithiocarbamate (**6**) at 2×10^{-4} M for five days (final broth volume of 350 mL due to sampling over incubation period) neutral (20 mg) and acidic extracts were obtained (16 mg). Preparative TLC (CH_2Cl_2:MeOH (96:4)) on the neutral extract led to the isolation of N_b-oxotryptamine (**9**, 2 mg), indole-3-acetic acid (**11a**, 2 mg), and tryptophol (**10**, 4 mg); prep. TLC on the acidic extract afforded indole-3-acetic acid (**11a**, 2 mg) and indole-3-carboxylic acid (**3**, 2 mg).

A. brassicae *IBJ and AB3*

From four flasks inoculated with fungal spores (two flasks per isolate) and incubated with methyl tryptamine dithiocarbamate (**6**) at 1×10^{-4} M for five days, from the

© 2000 NRC Canada

broth (final volume 120 mL per isolate) neutral (10 mg) and basic extracts (8 mg). Preparative TLC on the neutral extract led to the isolation of N_b-acetyltryptamine (**9**, 2 mg); prep. TLC on the basic extract afforded tryptamine (**8**, 1 mg). Similar experiments conducted in minimal medium yielded identical metabolites, but slower transformations were observed.

Biotransformation of metabolites of methyl tryptamine dithiocarbamate (6)

P. lingam *isolate BJ 125*

Methyl 3a-hydroxy-3,3a,8,8a-tetrahydropyrrolo[2,3-*b*]indol-1(2*H*)-yl carbodithioate (**7**), tryptamine (**8**), N_b-acetyltryptamine (**9**), indole-3-acetic acid (**11a**), methyl indole-3-acetate (**11b**), methyl tryptamine dithiocarbamate-*S*-oxide (**12**), oxindole-3-acetic acid (**13**), and methyl 2-oxotryptamine dithiocarbamate (**14**) were subjected to further biotransformation (final solution concentration of 2×10^{-4} M) by virulent *P. lingam*. If further biotransformation led to detection of new compounds, i.e., not detected in the biotransformation of methyl tryptamine dithiocarbamate, as in the case of **14**, scale up experiments were conducted to isolate and characterize them. All compounds were stable in uninoculated medium for at least 14 days, except for compound **12** which was kept in medium for no more than 48 h. The extracts were analyzed by HPLC and TLC.

Isolation of the metabolites of methyl 2-oxotryptamine dithiocarbamate (**14**): from eighteen flasks inoculated with fungal spores and incubated with methyl 2-oxotryptamine dithiocarbamate (**14**, final concentration 2×10^{-4} M) for 14 days, the broth (final volume 1700 mL) neutral extract (300 mg) was obtained; FCC (CH_2Cl_2:MeOH (95:5)) on the extract, followed by preparative TLC (ethyl acetate:hexane (80:20)) afforded methyl 3-hydroxy-2-oxotryptamine dithiocarbamate (**15**, 9 mg).

P. lingam *avirulent isolate Unity*

Indole-3-carboxylic acid (**3**), tryptamine (**8**), N_b-acetyltryptamine (**9**), tryptophol (**10**), and indole-3-acetic acid (**11a**) were subjected to further biotransformation (final concentration 2×10^{-4} M) by avirulent *P. lingam* as described above.

Biotransformation of methyl tryptamine carbamate (16)

P. lingam *virulent isolate BJ 125*

From eight flasks inoculated with fungal spores and incubated with methyl tryptamine carbamate (**16**, final concentration 2.0×10^{-4} M) in DMSO at 1×10^{-4} M for 14 days (broth final volume 750 mL) neutral (100 mg) and acidic extracts (110 mg). Preparative TLC (CH_2Cl_2:MeOH (95:5)) on the neutral extract led to isolation of recovered methyl tryptamine carbamate (**16**, 38 mg), phytotoxins, and lipid components. Preparative TLC on the broth acidic extract yielded indole-3-acetic acid (**11**, 2 mg), phytotoxins together with fatty acids.

P. lingam *avirulent isolate Unity*

From six flasks inoculated with fungal spores and incubated with methyl tryptamine carbamate (**16**, final concentration 2.0×10^{-4} M) in DMSO at 1×10^{-4} M for 14 days (broth final volume 550 mL) neutral (20 mg) and acidic extracts (110 mg) were obtained. Preparative TLC (CH_2Cl_2:MeOH (95:5)) on the neutral extract resulted in isolation of recovered methyl tryptamine carbamate (**16**, 2 mg), tryptophol (**10**, 2 mg), indole-3-carboxylic acid (**3**, 5 mg) together with unidentified UV-inactive components. The HPLC chromatograms of the acidic extract did not show UV active peaks of possible metabolites and was not fractionated further.

Syntheses and spectroscopic data of compounds

Methyl tryptamine dithiocarbamate (6)

Carbon disulfide (160 μL, 2.8 mmol) was added to a mixture of tryptamine (**8**, 320 mg, 2 mmol), triethylamine (360 μL), and pyridine (2 mL) at 0°C and the mixture stirred at 0°C for 1 hour. Methyl iodide (160 μL, 2.6 mmol) was added and the reaction mixture kept at 3°C for 15 h. The reaction mixture was then poured into 1.5 M H_2SO_4 (40 mL) and the crude product extracted with diethyl ether (3 × 50 mL). The combined extracts were successively washed with water (150 mL), saturated $NaHCO_3$ (150 mL), water (150 mL), and the ethereal solution dried over Na_2SO_4. Evaporation of the solvent under reduced pressure yielded 511 mg of crude product. Fractionation by flash column chromatography (CH_2Cl_2) yielded pure methyl tryptamine dithiocarbamate (**6**, 454 mg, 91%).

HPLC t_R = 20.4 min; ^{1}H NMR (500 MHz, $CDCl_3$) δ: 8.07 (1H, br s, D_2O exchangeable), 7.62 (1H, d, J = 8.0 Hz), 7.37 (1H, d, J = 8.0 Hz), 7.22 (1H, ddd, J = 8.0, 8.0, 1 Hz), 7.14 (1H, ddd, J = 8.0, 8.0, 1 Hz), 7.02 (1H, s), 7.00 (1H, br s, D_2O exchangeable), 4.04–4.07 (2H, m), 3.08–3.12 (2H, m), 2.56 (3H, s), and minor signals (ca. 1:4 intensity of the major ones) due to a rotamer at δ: 7.57 (d, J = 8.0 Hz), 3.74 (m), 2.68 (s); ^{13}C NMR (125.8 MHz, $CDCl_3$) δ 198.8 (s), 136.4 (s), 127.2 (s), 122.5 (d), 122.4 (d), 119.7 (d), 118.7 (d), 112.3 (s), 111.4 (d), 47.2 (t), 24.0 (t), 18.1 (q) and minor signals (ca. 1:4 intensity of the major ones) due to a rotamer at δ: 201.7 (s), 126.9 (s), 118.5 (d), 46.1 (t), 24.6 (t), 19.0 (q); FTIR (cm^{-1}): 3408, 3324, 2915, 1501, 1455, 1338, 1090, 934, 744; EIMS *m*/*z* (%): 250 (M^+, 6), 202 (68), 143 (63), 130 (100); FABMS *m*/*z* (%): 251 (M^+ + 1, 47), 144 (100); HREIMS *m*/*z*: calcd. for $C_{12}H_{14}N_2S_2$: 250.0598; found: 250.0600.

*Methyl 3a-hydroxy-3,3a,8,8a-tetrahydropyrrolo[2,3-*b*]indol-1(2*H*)-yl carbodithioate (7)*

Methyl tryptamine dithiocarbamate (**6**, 20 mg, 0.08 mmol) and Rose Bengal (8 mg, 0.008 mmol) were dissolved in 5% pyridine–methanol (5 mL) in a Pyrex test tube and irradiated with light (100 W halogen bulb) (17). Air was continuously bubbled through the solution while cooling in ice-water. After 2 h, the reaction mixture was transferred to a round bottom flask, dimethyl sulfide (200 μL) added and the solution stirred at room temperature; after two hours, the reaction mixture was diluted with toluene (5 mL) and the solvent evaporated under reduced pressure. Preparative TLC (CH_2Cl_2:MeOH (98:2)) on the crude reaction mixture yielded methyl 3a-hydroxy-3,3a,8,8a-tetrahydropyrrolo[2,3-*b*]indol-1(2*H*)-yl carbodithioate (**7**, 12.0 mg), 65% based on recovered starting material.

HPLC t_R = 14.5 min; $[\alpha]_D$ = +473 (CH_2Cl_2, *c* 0.14), obtained for the compound isolated from fungal metabolism of **6** (racemic synthetic material); ^{1}H NMR (300 MHz, CD_2Cl_2) δ: 7.33 (1H, d, *J* = 8.0 Hz), 7.18 (1H, ddd, *J* = 8.0, 8.0, and 1.0 Hz), 6.81 (1H, ddd, *J* = 8.0, 8.0, and 1.0 Hz), 6.64 (1H, d, *J* = 8.0 Hz), 5.71 (1H, s), 4.06–4.14 (1H, m), 3.28–3.37 (1H, m), 2.62 (3H, s), 2.52–2.59 (2H, m); ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 197.4 (s), 149.0 (s), 130.9 (d), 128.7 (s), 123.5 (d), 119.5 (d), 110.2 (d), 87.2 (d), 86.2 (s), 50.1 (t), 35.9 (t), 19.3 (q); FTIR (cm^{-1}): 3368, 3361, 2919, 2852, 1610, 1415, 1312, 1183, 1056, 949, 747; EIMS *m*/*z* (%): 266 (M^+, 100), 219 (21), 186 (45), 160 (41), 133 (61); HREIMS *m*/*z*: calcd. for $C_{12}H_{14}N_2OS_2$: 266.0548; found: 266.0547.

Methyl tryptamine dithiocarbamate-S-*oxide (**12**)*

Methyl tryptamine dithiocarbamate (**6**, 20 mg, 0.08 mmol) was dissolved in CH_2Cl_2 (2 mL) and the solution cooled to 0°C in ice-water. *m*-CPBA (18 mg, 0.08 mmol) was added to the solution and the reaction mixture stirred at 0°C for 30 min. After usual work up (addition of dimethyl sulfide, 500 μL, followed by successive washing with saturated $NaHCO_3$ and H_2O) the solvent was evaporated under reduced pressure, and the residue separated on TLC (CH_2Cl_2:MeOH (95:5)) to yield methyl tryptamine dithiocarbamate-*S*-oxide (**12**, 9 mg), 44% yield based on recovered starting material and methyl 2-oxotryptamine dithiocarbamate (**14**, 0.2 mg).

HPLC t_R = 11.6 min (broad); ^{1}H NMR (300 MHz, CD_2Cl_2) δ: 9.02 (br s, 1H, D_2O exchangeable), 7.57 (1H, d, *J* = 8.0 Hz), 7.36 (1H, d, *J* = 8.0 Hz), 7.16 (1H, ddd, *J* = 8.0, 8.0, 1.0 Hz), 7.09 (1H, ddd, *J* = 8.0, 8.0, 1.0 Hz), 7.02 (1H, s), 3.80 (1H, t, *J* = 7.0 Hz), 3.13 (1H, t, *J* = 7.0 Hz), 2.35 (3H, s); ^{13}C NMR (75.5 MHz, CD_2Cl_2) δ: 194.5 (s), 137.0 (s), 127.4 (s), 123.4 (d), 122.4 (d), 119.7 (d), 118.6 (d), 111.9 (d), 111.3 (s), 45.8 (t), 25.6 (t), 13.3 (q); FTIR (cm^{-1}): 3408, 3215, 2920, 2872, 1527, 1514, 1456, 1337, 905, 744; EIMS *m*/*z* (%): 266 (M^+, 2), 248 (7), 218 (5), 202 (8), 143 (59), 130 (100); HREIMS *m*/*z*: calcd. for $C_{12}H_{14}N_2OS_2$: 266.0548; found: 266.0447.

*Methyl 2-oxotryptamine dithiocarbamate (**14**)*

m-CPBA (52 mg, 0.24 mmol) was added to a solution of methyl tryptamine dithiocarbamate (**6**, 50 mg, 0.2 mmol) in CH_2Cl_2 (4 mL) cooled to 0°C, and the mixture stirred at 0°C. After 30 min a solution of *p*-toluene sulfonic acid (35 mg, 0.20 mmol) in methanol (0.5 mL) was added, the reaction mixture allowed to warm up to room temperature and kept stirring for 3 h. After usual work up, the solvent evaporated under reduced pressure, and the residue was subjected to preparative TLC (CH_2Cl_2:MeOH (97:3)) to yield methyl 2-oxotryptamine dithiocarbamate (**14**, 13 mg), 33% yield based on recovered starting material.

HPLC t_R = 12.5 min; $[\alpha]_D$ = –50 (CH_2Cl_2, *c* 0.08), for the compound isolated from fungal metabolism of **6** (racemic synthetic material); ^{1}H NMR (300 MHz, CD_2Cl_2) δ: 8.57 (1H, br s, D_2O exchangeable), 8.02 (1H, br s, D_2O exchangeable), 7.22–7.29 (2H, m), 7.07 (1H, dd, *J* = 8.0, 8.0 Hz), 6.92 (1H, d, *J* = 8.0 Hz), 4.04–4.10 (1H, m), 3.84–3.88 (1H, m), 3.55–3.59 (1H, m), 2.59 (3H, s), 2.38–2.45 (1H, m), 2.09–2.18 (1H, m); ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 199.0 (s), 180.7 (s), 140.9 (s), 128.9 (s), 128.4 (d), 124.1 (d), 123.0 (d), 110.1 (d), 45.4 (t), 45.0 (d), 28.7 (t), 18.0 (q); FTIR (cm^{-1}): 3234, 3204, 1700, 1619, 1519, 1470, 1335, 943, 751; EIMS *m*/*z* (%): 266 (M^+, 3), 218 (67), 159 (10), 146 (100), 133 (40); HREIMS *m*/*z*: calcd. for $C_{12}H_{14}N_2OS_2$: 266.0548; found: 266.0550.

*Methyl 3-hydroxy-2-oxotryptamine dithiocarbamate (**15**)*

HPLC t_R = 7.6 min; ^{1}H NMR (300 MHz, CD_3OD) δ 7.36 (1H, d, *J* = 8.0 Hz), 7.27 (1H, dd, *J* = 8.0, 8.0 Hz), 7.07 (1H, dd, *J* = 8.0, 8.0 Hz, 1H), 6.89 (1H, d, *J* = 8.0 Hz), 3.60–3.73 (2H, m), 2.50 (3H, s), 2.16–2.29 (2H, m); ^{13}C NMR (125.8 MHz, CD_3OD) δ: 199.8 (s), 181.6 (s), 142.5 (s), 132.5 (s), 130.7 (d), 125.2 (d), 123.8 (d), 111.4 (d), 76.5 (s), 43.0 (t), 36.6 (t), 17.8 (q); FTIR (cm^{-1}): 3305, 3271, 1715, 1622, 1471, 1188, 754; EIMS *m*/*z* (%): 282 (M^+, 5), 264 (7), 234 (15), 202 (8), 165 (15), 149 (100), 146 (25); FABMS *m*/*z* (%): 283 (M^+ + 1, 100), 269 (25), 217 (27), 158 (27); HREIMS *m*/*z*: calcd. for $C_{12}H_{14}N_2O_2S_2$: 282.0497; found: 282.0497.

*Methyl tryptamine carbamate (**16**)*

A solution of *N*,*O*-bis(trimethylsilyl)acetamide (1.5 mmol) in CH_2Cl_2 (1 mL) was added to a solution of tryptamine (**8**, 160 mg, 1.0 mmol) in CH_2Cl_2 (6 mL) under argon and the mixture stirred at 20°C for 1 hour (18). The reaction mixture was cooled to 0°C, and a solution of methyl chloroformate (1.5 mmol) in CH_2Cl_2 (1.5 mL) added. The reaction mixture was allowed to warm up to 20°C over 1 hour, stirred at 20°C for 1 h, cooled to 0°C, quenched with pH 7 buffer (10 mL), and extracted with diethyl ether (2 × 20 mL). The ether extract was washed with brine (40 mL), dried over Na_2SO_4, and evaporated under reduced pressure to afford methyl tryptamine carbamate (**16**, 187 mg), 86% yield.

HPLC t_R: 11.5 min; ^{1}H NMR (300 MHz, $CDCl_3$) δ: 8.13 (1H, br s, D_2O exchangeable), 7.61 (1H, d, *J* = 8.0 Hz), 7.38 (1H, d, *J* = 8.0 Hz), 7.23 (1H, dd, *J* = 8.0, 8.0 Hz), 7.14 (1H, dd, *J* = 8.0, 8.0 Hz), 7.03 (1H, s), 4.78 (1H, br s, D_2O exchangeable), 3.67 (3H, s), 3.53 (2H, m), 2.98 (2H, m); ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 157.1 (s), 136.5 (s), 127.3 (s), 122.2 (d), 122.1 (d), 119.5 (d), 118.7 (d), 112.9 (s), 111.2 (d), 52.0 (q), 41.4 (t), 25.8 (t); FTIR (cm^{-1}): 3409, 3322, 2945, 1700, 1524, 1457, 1261, 743; EIMS *m*/*z* (%): 218 (M^+, 29), 143 (38), 130 (100); HREIMS *m*/*z:* calcd. for 218.1055: $C_{12}H_{14}N_2O_2$; found: 218.1054.

N_b-*carbomethoxyindole-3-methanamine (**17**)*

Prepare as described for **16** with the following reagents: N,O-bis(trimethylsilyl)acetamide (3.5 mmol) in CH_2Cl_2 (3 mL), indole-3-methanamine (**4**, 415 mg, 2.8 mmol) in CH_2Cl_2 (10 mL); methyl chloroformate (3.5 mmol) in CH_2Cl_2 (3 mL); quenched with pH 7 buffer (20 mL), and extracted with diethyl ether (2 × 40 mL); N_b-carbomethoxyindole-3-methanamine (**17**, 430 mg), 74% yield.

HPLC t_R: 9.5 min; ^{1}H NMR (300 MHz, $CDCl_3$) δ: 8.13 (1H, br s, D_2O exchangeable), 7.66 (1H, dd, *J* = 8.0, 1.0 Hz), 7.39 (1H, dd, *J* = 8.0, 1.0 Hz), 7.23 (1H, ddd, *J* = 8.0, 8.0, 1.0 Hz), 7.13–7.18 (2H, m), 4.88 (1H, br s, D_2O exchangeable), 4.56 (2H, d, *J* = 5.0 Hz), 3.70 (3H, s); ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 157.1 (s), 136.5 (s), 126.5 (s), 123.0 (d), 122.4 (d), 119.8 (d), 118.8 (d), 113.1 (s), 111.4

42-crown-14-based [2]catenane

Harry W. Gibson and Sang-Hun Lee

Abstract: A compound isolated from a synthesis directed toward 42-crown-14 (42C14) has been purified and characterized by means of IR, HPLC, NMR, MS, and DSC techniques. Its infrared spectrum contains no OH, tosylate, or unsaturated unit signals. The HPLC retention time of the compound differs from that of "42C14" and other crown ethers examined. The chemical shifts of the singlets in the ^{1}H and ^{13}C NMR spectra differ from those of poly(ethylene oxide)s (PEOs), and crown ethers. The FAB mass spectra contain signals attributable to a compound with twice the mass of 42C14 and the fragmentation pattern is consistent with [2]catenane **9** based on interlocked 42C14 units, because the next major signals generally correspond to 42C14 and its adducts. The DSC results showed that the compound, a colorless wax at room temperature, was amorphous with a glass transition temperature which was 80° higher than those of aliphatic crown ethers, which are crystalline compounds with melting points >40°C. Considering the high yield of the compound (8% in the reaction mixture as determined by NMR, 1.7% isolated), it is believed that sodium cation–crown ether–linear ether complexation was involved in templating its formation. Evidence for such complexation was also observed in the FAB MS.

Key words: catenanes, crown compounds, macrocycles, template synthesis, rotaxanes.

Résumé : Un composé a été isolé d'une synthèse effectuée dans le but d'obtenir l'éther 42-couronne-14 (42C14); on l'a purifié et caractérisé par des techniques de IR, CLHP, RMN, SM et d'analyse calorimétrique différentielle (ACD). Son spectre IR ne présente aucun signal correspondant à des groupes OH, tosylate ou insaturé. Le temps de rétention de ce composé en CLHP diffère de celui du « 42C14 » ou de tous les autres éthers couronnes étudiés. Les déplacements chimiques des singulets dans les spectres RMN du ^{1}H et du ^{13}C diffèrent de ceux des poly(oxydes d'éthylène) (POE) et des éthers couronnes. Les spectres de masse impliquant un bombardement avec des atomes rapides (BAR) comportent des signaux que l'on pourrait attribuer à un composé de masse double de celle du 42C14 et son patron de fragmentation est en accord avec le [2]caténane **9** dont la base serait des unités 42C14 reliées puisque les signaux majeurs suivants correspondent au 42C14 et à ses adduits. Les résultats d'ACD montrent que le composé, une cire incolore à la température ambiante, est amorphe avec une température de transition vitreuse qui est de 80°C plus élevée que celles des éthers couronnes aliphatiques qui sont des composés cristallins dont les points de fusion sont supérieurs à 40°C. Considérant le rendement élevé de ce composé (8% du mélange réactionnel sur la base de la RMN et 1,7% de produit isolé), on croit qu'une complexation du cation sodique avec l'éther couronne linéaire conduit à un gabarit impliqué dans sa formation. On a aussi observé des données pouvant supporter l'hypothèse d'une telle complexation dans le SM avec BAR.

Mots clés : caténanes, composés couronnes, macrocycles, synthèse sur gabarit, rotaxanes.

Introduction

Large crown ethers have been prepared in our laboratory using a "2+2" method (1). For example, the synthesis designed to produce 42-crown-14 (42C14) involves tri(ethylene glycol) ditosylate (**2**) addition to the sodium dianion (**1**) of tetra(ethylene glycol) in tetrahydrofuran (THF) (Scheme 1) to initially form α-oxy-ω-tosylate derivative **3**, which can either cyclize to form 21-crown-7 (21C7) (**4**) or react with more **1** to produce the undeca(ethylene glycol) dianion (**5**). **3** can also react with **2** to form deca(ethylene glycol) ditosylate (**6**). After chain extension from the reaction of **2** and **5** or **1** and **6**, the resultant oxytosylate **7** can afford 42C14 (**8**) through cyclization. **7** can react further with **1** and (or) **2** to form linear oligomers or polymers and crown ethers larger than 42C14. In fact, recent studies indicate that the product is a mixture of large crown ethers with 7n ethyleneoxy units, whose average size estimated by mass spectrometry corresponds to 84C28.[2] For this reason throughout the remainder of the discussion we will use quotation marks to denote the target of the synthesis, i.e., "42C14," so as not to misrepresent the material as a pure single compound.

The reaction mixture is typically purified by recrystallization before application of chromatography and other methods (1). In examining the mother liquors from such purifications, an NMR signal at 3.659 ppm caught our attention in repeated syntheses. This signal cannot be assigned to PEOs (see below) or crown ethers whose chemical shifts

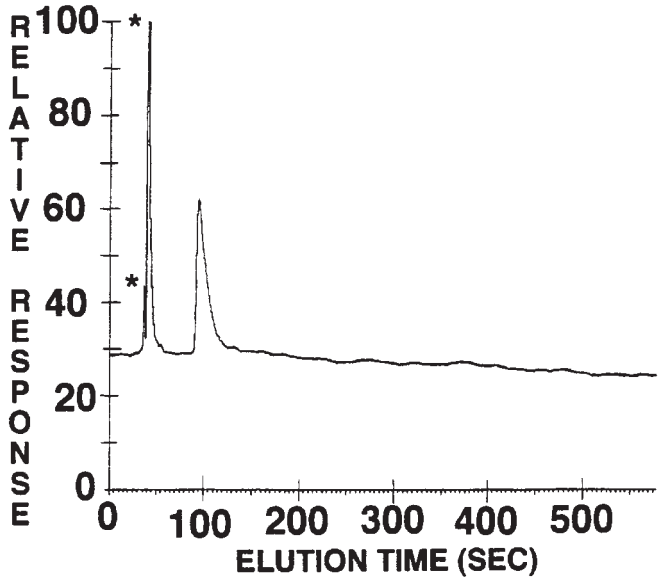
Scheme 1. Synthesis of 42C14 by "2+2" methodology.

under the same conditions range from 3.689 ppm for 18C6 up to 3.646 ppm for 60C20 (1, 2). We therefore set out to isolate and identify the source of this peak.

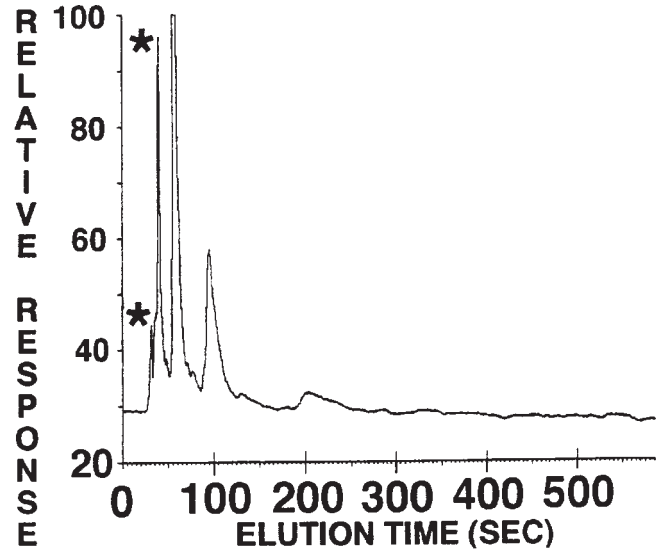
Results

A. Isolation

The isolation of the compound that gave rise to this signal was achieved by silica gel column chromatography of the mixture from the filtrate (after filtration of the "42C14") with acetone as eluent. In the ^{1}H NMR spectra in $CDCl_3$ the initial fractions gave several peaks, but consisted mainly of the 3.653 ppm signal, attributable to PEOs. The main peaks of the next fractions (nos. 16–55) appeared at 3.646 (PEOs) and 3.688 ppm (21C7). The peak at 3.659 ppm became a major peak of the later fractions (nos. 56–85). The spectra of last fractions (nos. 180–200) contained only a singlet at 3.659 ppm.



B. IR analysis

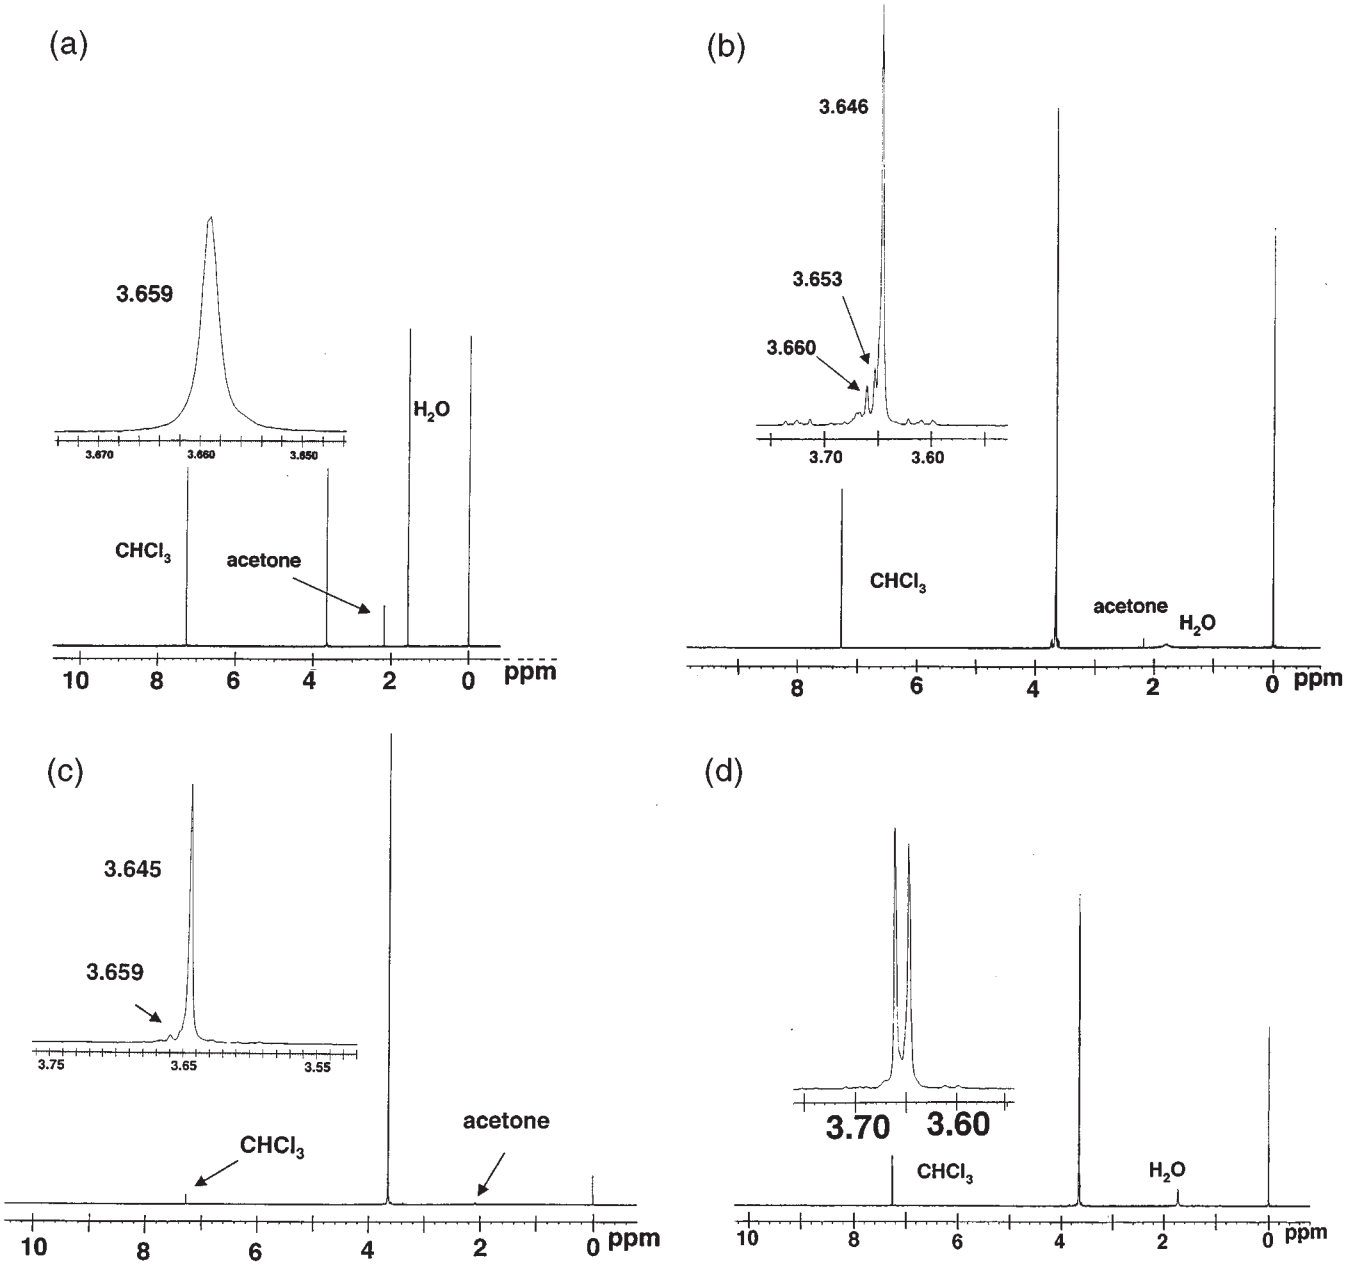


The infrared spectrum of the isolated compound did not contain OH or other extraneous signals; it was qualitatively the same as that of "42C14" or other aliphatic crown ethers.

C. HPLC analysis

The HPLC trace of the purified sample (Fig. 1*a*) does not contain the longer and shorter retention time impurities present in the starting mixture (Fig. 1*b*). It has a retention time of 93 s. As a reference point, 30C10 (3) has a retention time of 57 s under these conditions; 15C5 and 18C6 have shorter retention times. Furthermore, the major (~75%) peak in "42C14"[3] occurred at 105 s. Larger crown ethers have longer retention times.

Fig. 1. HPLC traces, H_2O:MeCN (70:30 v/v), 2 mL/min. Purified unknown, (*a*, top); crude starting mixture from filtrate, (*b*, bottom). Peaks that represent signals from the solvent are noted with an asterisk (*).



D. NMR analysis

The ^{1}H NMR spectrum of the purified sample is shown in Fig. 2*a*. It consists of a sharp singlet at 3.659 ppm without any side peaks or other signals as seen in PEOs (Fig. 2*b*). The spectrum of "42C14" (δ = 3.645 ppm) is shown in Fig. 2*c*. The spectrum of a mixture of the isolated material and "42C14" is shown in Fig. 2*d*; clearly the two can be readily distinguished. It is noteworthy that the signal for the new compound is downfield relative to "42C14."

[3] "42C14" in this case was synthesized following the "1+1" procedure of Chênevert and D'Astous (2) using hepta(ethylene glycol) and its ditosylate (4). The product was purified by column chromatography (ether, then ether:MeOH (1:1)) followed by recrystallization from toluene:hexane (1:8) twice. The HPLC trace contained peaks at shorter retention times as in Fig. 1*b*, corresponding to ca. 25% impurities. The identity of the major peak was verified by HPLC-mass spectrometry. Samples of "42C14" prepared by the method of ref. 1 also produced this same peak at 105 s along with longer retention time signals.

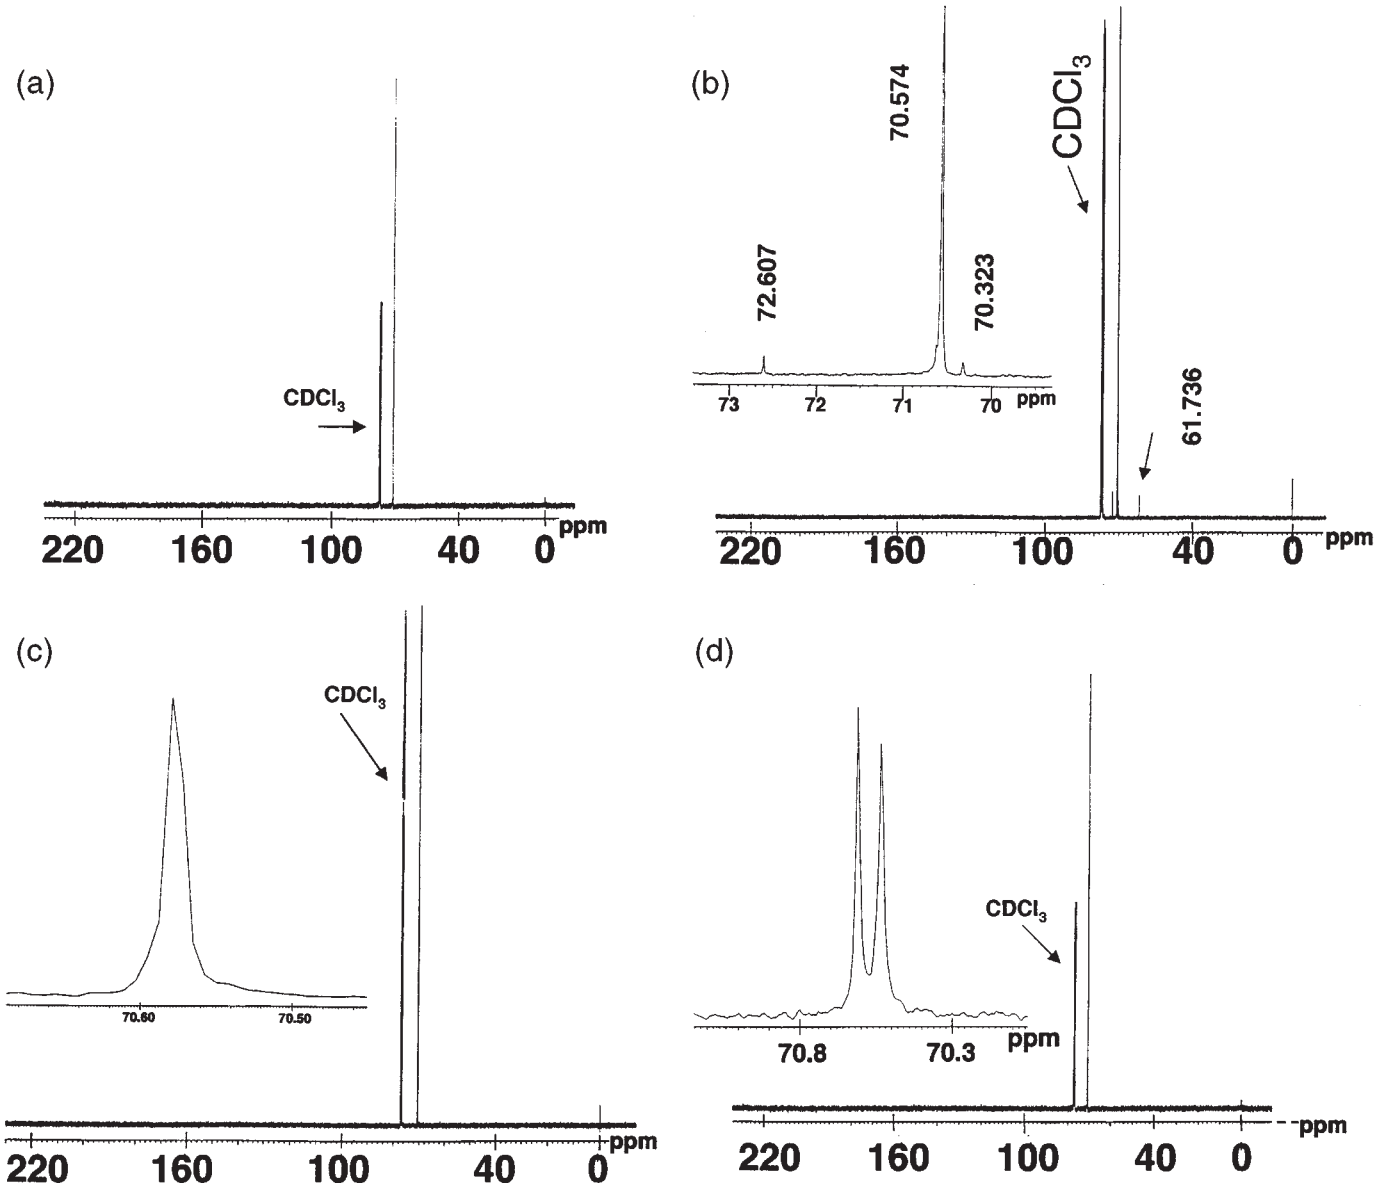
Fig. 2. 400 MHz ^{1}H NMR spectra in $CDCl_3$. (*a*) Purified unknown. (*b*) PEO (nominal molecular weight 1500). (*c*) "42C14"[3] (Note the small impurity signal at 3.659 ppm, corresponding to the present unknown). (*d*) Synthetic mixture of purified unknown + "42C14."[3]

The ^{13}C NMR spectrum of the new compound in $CDCl_3$ showed a single peak at 70.635 ppm (Fig. 3*a*) with no side peaks which appear in the case of linear PEOs (Fig. 3*b*). Compared to that of "42C14" (**8**) (δ = 70.555 ppm, corrected to $CDCl_3$, Fig. 3*c*) the ^{13}C NMR signal was shifted downfield by 0.080 ppm (reproducibility ±0.002 ppm). The spectrum of a mixture of the unknown and "42C14" (Fig. 3*d*) clearly shows the distinction between the two materials.

E. Mass spectrometric analysis

1. FAB in NBA/Cs$^+$ ion gun



The FAB mass spectrum of the unknown from 3-nitrobenzyl alcohol (NBA) matrix using Cs^+ bombardment showed *m*/*z* = 617.4 and 639.3 ion peaks, i.e., most likely 42C14 (**8**) derived species, namely $[42C14 + H]^+$ and $[42C14 + Na]^+$, but no signals corresponding to other molecular ions were observed.

2. FAB in GLY/TFA

However, in the FAB mass spectrum from glycerol/1% trifluoroacetic acid (GLY/1% TFA) matrix using xenon bombardment (Fig. 4*a*), ions with *m*/*z* values of 1231.5, 1253.3 and 1269.2 were detected along with ions with *m*/*z* values of 617.4 ($[42C14 + H]^+$), 639.3 ($[42C14 + Na]^+$), and 655.3 ($[42C14 + K]^+$). In a matrix of GLY/NaI the sodium adduct peaks at *m*/*z* = 1253.2 and 639.5 were enhanced at the expense of the other signals (Fig. 4*b*). Similarly "42C14"[3] in GLY/1% TFA afforded the *m*/*z* = 617.4 (major), 639.3 (minor, 20% of 617.3), and 655.3 (minor, 20% of 617.3)

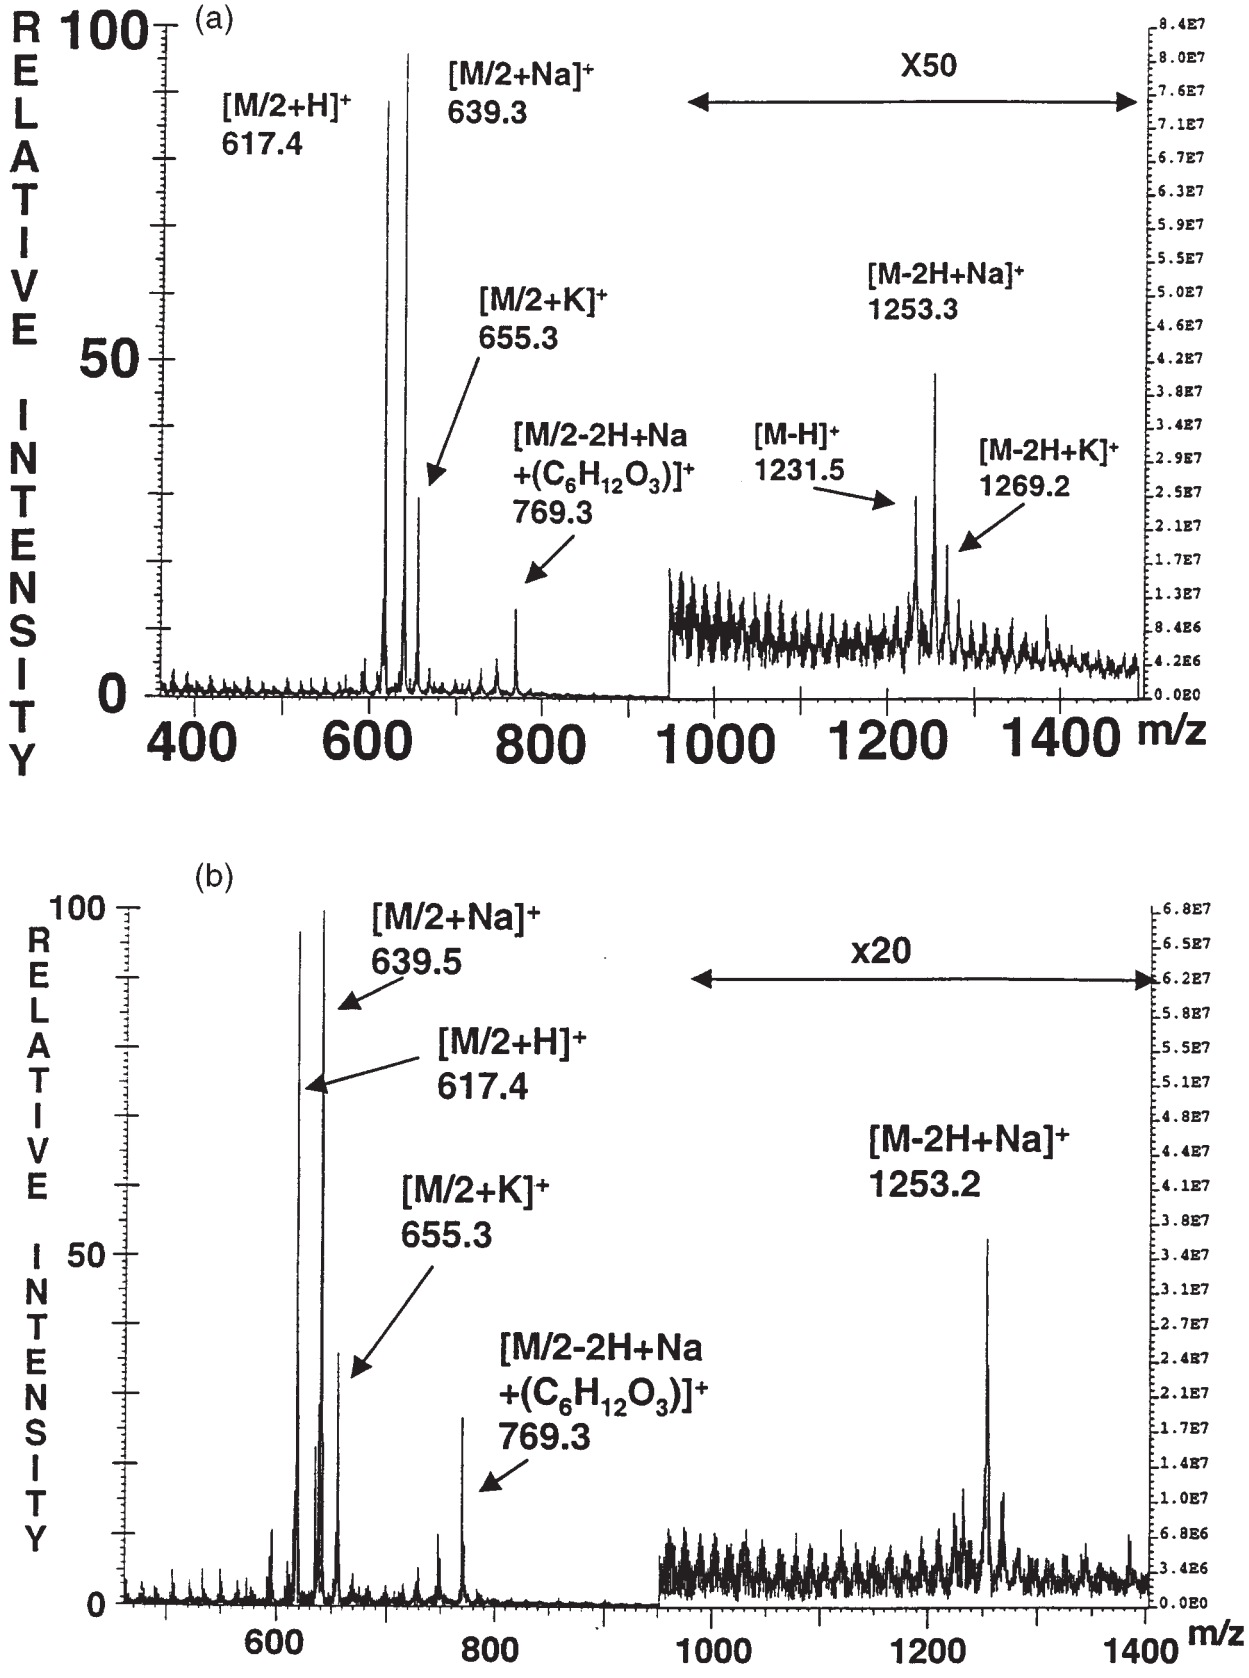
© 2000 NRC Canada

Fig. 3. 100 MHz ^{13}C NMR spectra in $CDCl_3$. (*a*) Purified unknown. (*b*) PEO (nominal molecular weight 1500). (*c*) "42C14."[3] (*d*) Synthetic mixture of purified unknown + "42C14."[3]

signals; with a GLY/NaI matrix the 617.4 and 655.3 peaks diminished into the noise. Notably in the spectra of the unknown (Fig. 4) the only other peak of significance is the *m*/*z* = 769.3 signal; there are no other fragments from the high mass signals, i.e., between *m*/*z* = 1231.5 and 769.3.

Upon increasing the amount of trifluoroacetic acid in the matrix (GLY/4% TFA) and changing over to Cs^+ ion bombardment, *m*/*z* = 1253.3 and 1269.2 ions were no longer detected (Fig. 5); only a strong *m*/*z* = 1231.7 ion was observed at high mass. Another new signal of lower intensity occurs at 1005.7, a strong signal was observed at *m*/*z* = 749.5 and there was also a new signal at *m*/*z* = 705.5. In the high resolution spectrum (Fig. 6) the *m*/*z* = 1231.7296 peak is consistent with $C_{56}H_{111}O_{28}$ = $(CH_2CH_2O)_{28}$ (calculated value = 1231.7262), with 2.7 ppm error; the isotopic peaks are present in approximately the abundances expected for this formula (M+1 and M+2 = 62 and 29%, respectively).

F. Thermal analysis



In the differential scanning calorimetric (DSC) traces (heating after slow cooling) the unknown compound displayed no melting endotherm or crystallization exotherm; the glass transition was observed at 13°C.

Discussion

Consideration of the results presented above has led us to conclude that the unknown compound is not a simple crown ether; the NMR chemical shifts conclusively argue against this; the mass spectral evidence to be discussed below supports this conclusion and the thermal properties also are inconsistent with the compound being a crown ether. The structure most consistent with these results is the [2]catenane (5) containing two 42C14 rings, i.e., **9**.

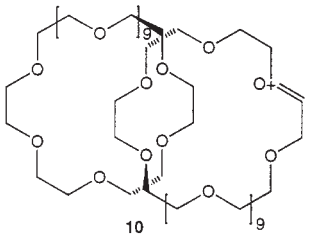
Fig. 5. FAB mass spectrum of purified unknown from GLY/4%TFA with Cs^+ ionization.

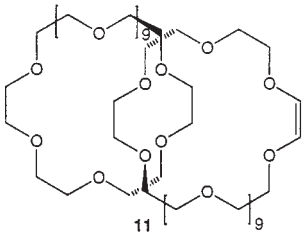
The results will now be discussed in detail in support of this assignment.

9



A. NMR results

In ^1H NMR downfield shifts relative to the individual components have been observed in hydrocarbon catenane systems (6). It was reasoned that because of the interlocked structure the intertwined segments of the macrocycles can not be solvated in the same manner as the unthreaded macrocycle and this lack of solvation results in the downfield shift of the ^1H NMR signal. In the present case the unknown exhibits a signal downfield from all the crown ethers larger than 30C10.

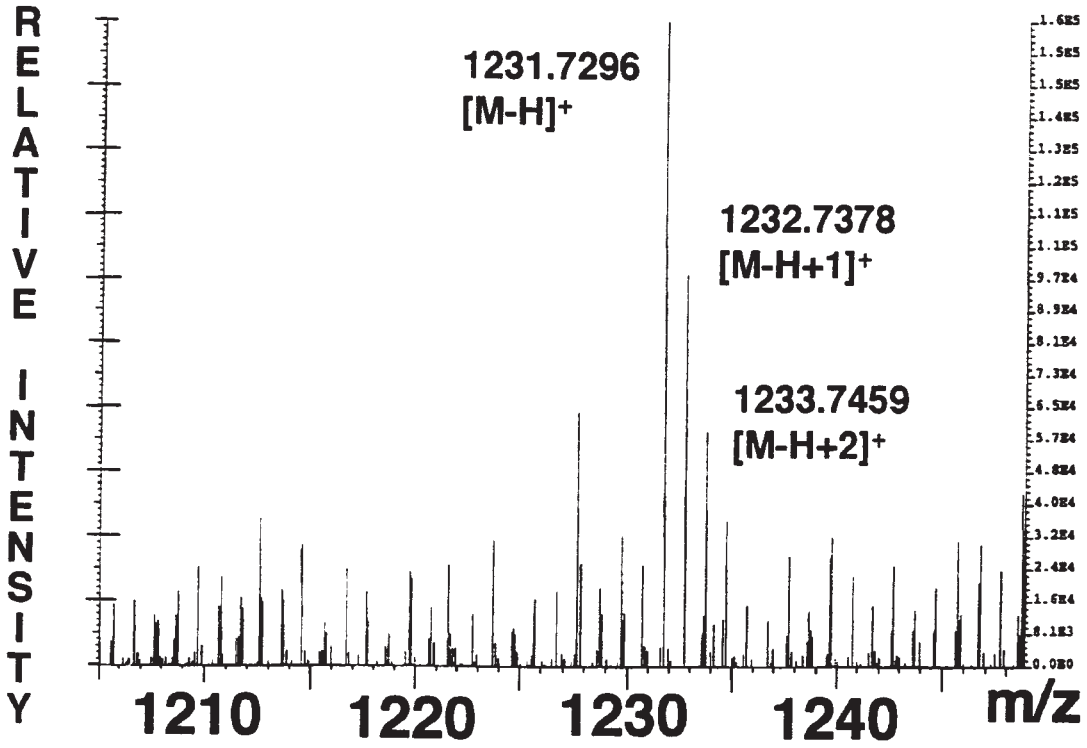


Similar shifts in ^{13}C NMR spectra have been observed in hydrocarbon catenanes relative to the individual macrocyclic components (6). These shifts to lower field were explained by interannular van der Waals interactions. In the present case again the signal of the unknown (70.635 ppm) appears well downfield from signals for crown ethers, both measured in our lab and those reported in the literature (70.53–70.44 ppm for crowns from 27C9 to 60C20 (2), and 70.30 for all large crowns (7) all in $CDCl_3$). Taken together, the NMR results conclusively argue against a crown ether structure for the unknown.

B. Mass spectral results

The lack of significant fragmentation signals between the high mass region and the low mass region corresponding to the component cyclic(s) constitutes classic mass spectral evidence for the catenane structure (8) that is now routinely sought (5). Thus, the m/z = 1231.5, 1253.3, and 1269.2 ions observed with the GLY/1% TFA matrix using xenon bombardment (Fig. 4*a*) are assigned to [**9**-H]$^+$ = **10**, [9–2H+Na]$^+$ = **11**·Na^+, and [9–2H+K]$^+$ = **11**·K^+. An alternative interpretation is that the high mass signals are due to formation of dimer structures from 42C14 in the gas phase; this possibility is inconsistent with the NMR results presented above and the thermal results presented below.

10



11

The observation of [M–H]$^+$ instead of M$^+$ in mass spectra of crown ethers is not unusual. In many cases of EI and FAB mass spectra of crown ethers [M+H]$^+$ and [M–H]$^+$ ions are detected instead of M$^+$ (9–12). In those cases, it is claimed that the [M+H]$^+$ ions are likely to exist in the form of open chains instead of closed rings (10). Therefore, there would be less chance to detect the [M+H]$^+$ ion peak of the 42C14-[2]catenane (**9**) because once a ring breaks down to the open chain, which is [(**9**/2)+H]$^+$ (assigned as [42C14 + H]$^+$ above), the charged linear species would dethread away from the

© 2000 NRC Canada

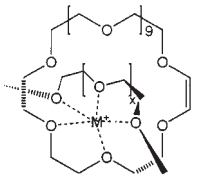


Fig. 6. High resolution FAB mass spectrum of purified unknown from GLY/4%TFA with Cs^+ ionization.

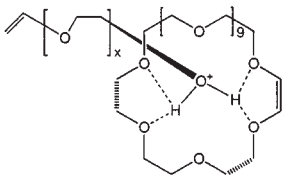
other 42C14 macrocycle. In contrast, $[M–H]^+$ ions of crowns are likely to retain the closed ring structure (9), so that the catenated $[M–H]^+$ ion **10** (*m*/*z* = 1231.5) could survive.

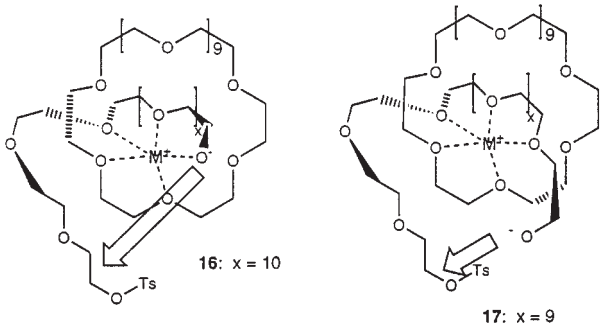


The observation of $[\mathbf{9}–2H+Na]^+$ and $[\mathbf{9}–2H+K]^+$ ions and the lack of $[\mathbf{9}+Na]^+$ and $[\mathbf{9}+K]^+$ peaks in Fig. 4 suggest that these latter metal ion complexes of the catenane are very readily converted to the former, i.e., $[\mathbf{11}+Na]^+$ and $[\mathbf{11}+K]^+$.

The modest peaks at *m*/*z* = 769.3 in Figs. 4*a* and 4*b* correspond to the $[(\mathbf{9}/2)–2H+Na+(C_6H_{12}O_3)]^+$ ion. This suggests that a neutral fragment derived from one 42C14 ring of the metal complexed catenane $[\mathbf{11}+Na]^+$ remains in the cavity of the other 42C14 because of template complexation by the metal ion, i.e., as pseudorotaxane **12** (13), until this species reaches the detector. A related phenomenon has been observed previously in the mass spectra of phenanthroline-Cu catenates, producing a Cu complex of two neutral acyclic species (14). And it appears to take place in catenanes based on cyclic amides (15). It is somewhat surprising that it has not been observed more frequently since the forces that lead to pseudorotaxane formation and thence catenation in solution should "live on" in the gas phase after one ring has been ruptured.

12: M = Na, x = 1
13: M = K, x = 6

In the mass spectra taken in GLY/4% TFA using Cs^+ ion bombardment (Figs. 5 and 6) only a strong $[\mathbf{9}–H]^+$ ion (**10**) was observed and no metal adducts. The high resolution results for this peak (*m*/*z* = 1231.7296, $C_{56}H_{111}O_{28}$ (calculated value = 1231.7262), 2.7 ppm error; isotopic peaks) support the molecular formula of the 42C14-[2]catenane (**9**). The peak at *m*/*z* = 1005.7 in Fig. 5 corresponds to $[(\mathbf{9}/2)–2H+K+(C_{16}H_{32}O_8)]^+$, presumably a complex of 42C14, K^+ and neutral linear $C_{16}H_{32}O_8$, i.e., pseudorotaxane **13**; indeed, the base peak in the spectrum corresponds to $[C_{16}H_{32}O_8+K]^+$, i.e., *m*/*z* = 391.3 (with intensity ca. 14 × *m*/*z* = 617.4). Again we speculate that **13** results from fragmentation of complex $[\mathbf{11}+K]^+$. Likewise the peaks at *m*/*z* = 705.5 and 749.5 may be due to pseudorotaxanes **14** and **15** derived from 42C14 and positively charged fragments $C_4H_9O_2^+$ and $C_6H_{13}O_3^+$, respectively, formed directly from catenane **9**.



14: x = 1
15: x = 2

In fact the observation of species **12** and **13** in the gas phase suggests that the relatively high yield of the isolated compound (8% based on NMR analysis of the crude reaction mixture and 1.7% isolated) is a result of the same templating effect of the metal ions. It has been well known from the beginning (16), of course, that monocyclic crown syntheses are templated in this manner by bringing the ends of the linear precursors into proximity (17). The templating could occur between 42C14 and the paired sodium and alkoxide ions

© 2000 NRC Canada

(**16**) or alternatively by complexation of the metal ion and the crown ether at the center of the threaded (pseudorotaxane (13)) oxytosylate (**17**), allowing cyclization to give **9**; as the displacement reaction proceeds and alkoxides are consumed more free sodium ions will be available in solution to act as templating species. In this same way Sauvage and coworkers have utilized copper(I) ion as the templating agent in their elegant syntheses of phenanthroline/crown ether-based catenanes and knots (14, 17, 18), forming pseudorotaxane (13) intermediates in the process. Of course this latter templating situation is much more effective because of the rigidity of the components and the stronger complexation. Crown ether-based catenane templating with paraquat and derivatives as utilized by Stoddart et al. (19) and Becher et al. (20) in a variety of modes also relies on relatively high association constants to form the precursor pseudorotaxanes (13). Nonetheless the present results suggest that the proper choice of templating species (in excess) could lead to improved yields of aliphatic crown ether-based catenanes, especially if preformed crown ether were present initially in high concentration.

C. Thermal analysis

Aliphatic crown ethers are crystalline substances with melting points above room temperature that increase with ring size up to an asymptotic limit above 50°C (1, 2, 7). The glass transition temperatures of the crown ethers are quite low, around –67°C ~ –70°C (1), reflecting their flexible nature. The melting point of 81c27 (molecular weight 1188 Da) is reported to be 41°C (7*b*) and the melting point of 273c91 is 53°C (7*d*). If the present sample were 84c28 it would melt between these temperatures, probably ca. 45°C; thus, the catenane structural assignment is consistent with its amorphous character. It is known that large crown ethers crystallize in lamellar structures in which the macrocycles are once or twice folded (7). It is believed that due to the interlocked structure there would be little chance for such a crystalline arrangement in the solid state of the catenane, which consequently is completely amorphous. The interlocking is also expected to constrain the rings severely from a conformational point of view; thus, the fact that the glass transition temperature of the catenane is much (>80°C) higher than that for aliphatic crown ethers is not surprising.

Conclusions

The unknown compound isolated from the reaction aimed at 42C14 has been assigned the structure of a [2]catenane in which both rings are 42C14.

Experimental

Materials

Tri(ethylene glycol), tetra(ethylene glycol), NaH, *p*-toluenesulfonyl chloride (Aldrich) and THF (Mallinckrodt) were used as received. Tri(ethylene glycol) ditosylate (**2**) was synthesized (1) by the reaction of tri(ethylene glycol) with *p*-toluenesulfonyl chloride.

42C14-[2]catenane (9). NaH (7.6 g, 80% dispersed in oil, 0.25 mol) was washed with hexane and THF (80 mL) was added. To the suspension tetra(ethylene glycol) (12.14 g, 62.5 mmol) in THF (40 mL) was added slowly and tri(ethylene glycol) ditosylate (**2**, 14.34 g, 31.3 mmol) in THF (40 mL) was added to the mixture dropwise over 50 min while the mixture was stirred vigorously at reflux. The mixture was allowed to stir for 5 h and diluted to 850 mL with THF. Tri(ethylene glycol) ditosylate (14.45 g, 31.4 mmol) in THF (50 mL) was added to the refluxing mixture dropwise over 1 h. The mixture was refluxed for 28 h. The excess NaH was destroyed by addition of water and the salts were filtered off. After the evaporation of the solvent the crude product was recrystallized at –20°C. The crystals (crude crown ethers) were filtered and from the filtrate a light brown oil (9.0 g) was obtained. 2.3 g of the oil was separated into 200 fractions through a column (silica gel, 3 cm diameter, 30 cm length) using acetone as the eluent. Each fraction was checked by TLC and analyzed by NMR, if needed. 170 mg of colorless wax was obtained from the last 20 fractions; corrected to the total filtrate residue, this corresponds to a 1.7% yield.

Characterization techniques

NMR was done on a Varian Unity 400 spectrometer at ambient temperature with tetramethylsilane and $CDCl_3$ as the internal references for ^1H and ^{13}C NMR spectra, respectively. A Perkin–Elmer 283B IR spectrometer was used. For the HPLC analysis, an ISCO model 2350 HPLC instrument was used with a Novapak-C_{18} column eluted with a mixture of water and acetonitrile (75:25 by vol) with a flow rate of 2 mL/min; a refractive index detector (Waters, Differential Refractometer R401) was used. Thermal analysis was done on a Perkin–Elmer DSC-4 instrument at 5°C/min. The sample was heated to 150°C and cooled slowly to 0°C. The second heating was run at 5°C/min. The FAB mass spectra were obtained from the Midwest Center for Mass Spectrometry (MCMS) at the University of Nebraska-Lincoln and the Washington University Mass Spectrometry Resource (WUMSR), St. Louis, Missouri. The experimental conditions for the FAB mass spectrometry at the MCMS were as follows: Fisons VG ZAB mass spectrometer operating at 8 keV, ionization by a Cs^+ ion gun operating at 25 keV, matrix: 3-nitrobenzyl alcohol or glycerol/4% trifluoroacetic acid. The experimental conditions for the FAB mass spectrometry at WUMSR were as follows: Fisons VG ZAB SE double-focusing mass spectrometer operating at 8 keV, ionization by xenon gas at 1 mA, matrix: glycerol/1% trifluoroacetic acid. Samples were scanned over a mass range of 100 to 1500 at 10 s/decade; data collection and processing were done with the VG OPUS data system.

Radicals from fragmentation of benzyloxymethoxycarbenes in solution

Nadine Merkley, Manal El-Saidi, and John Warkentin

Abstract: 2-Benzyloxy-2-methoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazolines, including the parent as well as *p*-substituted analogues, undergo thermolysis at 100°C in benzene to afford a mixture of products. Two primary fragmentations of the oxadiazolines were identified. The major pathway involves 1,3-dipolar cycloreversion to N_2 and the corresponding carbonyl ylides. The latter dissociate to acetone and the corresponding benzyloxy(methoxy)carbenes, which undergo fragmentation to $ArCH_2$ and MeOCO radical pairs that recombine to afford methyl arylacetates. Carbene dimers were not observed, showing that the fragmentation process is faster than carbene dimerization. A second fragmentation pathway observed for the oxadiazolines is an alternative cycloreversion to the corresponding benzyl methyl carbonate and 2-diazopropane. Products from diazopropane included acetone azine and, in some instances, traces of propene.

Key words: benzyloxy(methoxy)carbene, carbene, radical pair, rearrangement.

Résumé : Les 2-benzyloxy-2-méthoxy-5,5-diméthyl-Δ^3-1,3,4-oxadiazolines, y compris le produit fondamental ainsi que les analogues substitués en position *para*, donnent lieu à une thermolyse, à 100°C dans le benzène, qui conduit à un mélange de produits. On a identifié les deux fragmentations primaires des oxadiazolines. La voie principale implique une cycloréversion 1,3-dipolaire en N_2 et en ylures de carbonyles correspondants. Ces derniers se dissocient en acétone et en benzyloxy(méthoxy)carbènes correspondants qui se fragmentent en paires de radicaux $ArCH_2$ et MeOCO qui se recombinent pour donner des arylacétates de méthyle. On n'a pas observé la formation de dimères de carbènes ce qui démontre que le processus de fragmentation est plus rapide que la dimérisation des carbènes. Une deuxième voie de fragmentation observée pour les oxadiazolines est une cycloréversion alternative en 2-diazopropane et en carbonate de benzyle et de méthyle correspondant. Les produits résultant du diazopropane comprennent l'azine de l'acétone et, dans quelques cas, des traces de propène.

Mots clés : benzyloxy(méthoxy)carbène, carbène, paire de radicaux, réarrangement.

[Traduit par la Rédaction]

Introduction

There has been a resurgence of interest in the chemistry of dialkoxycarbenes (1) since the early work of Hoffmann (2), and Lemal et al. (3) with dialkoxycarbenes derived from norbornadien-7-one acetals. Much of the subsequent work was done by R.A. Moss and his group, who first generated dialkoxycarbenes from diazirines (4–10). Recently oxadiazolines (11) have also been used to generate dialkoxycarbenes, which were shown to react with a variety of unsaturated moieties including anhydrides (12), C60 (13–15), methylenecyclopropanes (16), alkynes (17, 18), fluorenone (19), α, β-unsaturated isocyanates (20, 21), a bisketene (22), and hexachlorocyclopentadiene (23), for example. They also attack aromatics substituted with electron-withdrawing groups to effect nucleophilic aromatic substitution (24).

Dialkoxycarbenes also undergo intramolecular rearrangements, at least in the gas phase in a mass spectrometer, to generate esters (25). Hoffmann et al. reported in 1972 that allyloxymethoxycarbene dissociates to allyl and methoxycarbonyl radicals in the gas phase (26). Intramolecular reactions of dialkoxycarbenes appeared to be slow in solution, the major products formed in the absence of a trap being the carbene dimers (4, 5, 27). However, a few cases of fragmentation of allyloxymethoxycarbenes to radical pairs, in solution at 110°C, were recently reported (28). In one of those cases, the carbene was intercepted with *tert*-butyl alcohol and the radicals were trapped with TEMPO. Thus the sequence oxadiazoline → carbene → radicals was established for the first time, ruling out a potential direct pathway from precursor to radicals.

We now report that the carbenes with a benzyloxy or *p*-substituted benzyloxy substituent ($ArCH_2O(MeO)C$:) also fragment to radicals in solution. Thermolysis of 2-benzyloxy-2-methoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazolines at 100°C in the presence of alcohols (ROH) affords orthoformates $(ArCH_2O)(MeO)(RO)CH$, formed by trapping $(ArCH_2O)(MeO)C$:. In the absence of a carbene trap however, the carbenes fragment to benzylic radicals and methoxycarbonyl radicals, both of which can be trapped with TEMPO. The radicals couple to afford methyl arylacetates, both in the presence or in the absence of TEMPO. Competing fragmentation of the oxadiazolines to the corresponding benzyl methyl carbonate and 2-diazopropane also occurs.

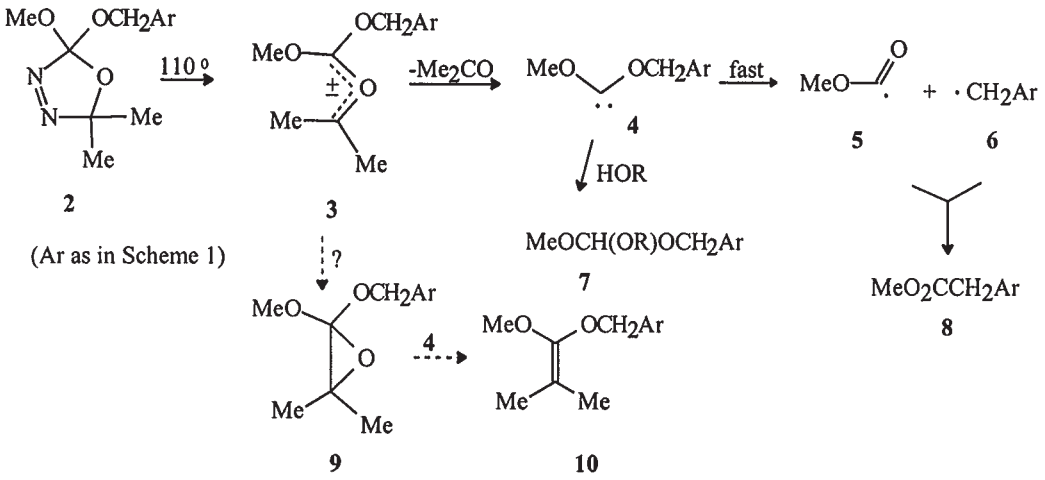
Methods, results, and discussion

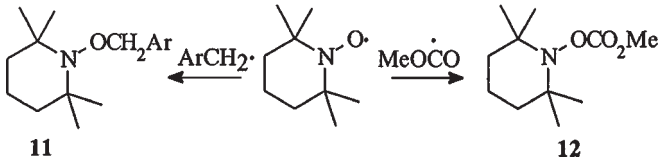
Oxadiazolines **2** were prepared from the methoxycarbonyl hydrazone of acetone via 2-acetoxy-2-methoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (**1**) by the exchange method (29), illustrated in Scheme 1. They were purified by chromatography on silica with a Chromatotron apparatus, and they were identified by means of ^{1}H and ^{13}C NMR spectroscopies at 200 and 50 MHz, respectively. Diastereotopicity of the CH_2 protons was evident. Moreover, the ^{13}C spectra are diagnostic for oxadiazolines of that type, with δ values near 137.5 for C-2 and 118.5 for C-5 (11). In the mass spectra, **2** afforded neither molecular ions nor M – N_2 ions.



Thermolyses were carried out with degassed solutions in benzene-d_6 (initial oxadiazoline concentration 0.1 M) at 100 ± 0.1°C. Reaction products were examined by ^{1}H NMR spectroscopy before the tube was opened (in cases of small scale runs with NMR tubes) to facilitate recognition of initial products rather than those that might have arisen from rearrangements or hydrolyses during separation procedures. The reported yields (isol) are probably considerably lower than the chemical yields because reactions were run on a small scale (one mmol or less) and because of some difficulties with the separation of recognized products from one another and from minor co-products.

Scheme 2 outlines the overall thermolysis chemistry of the benzyloxymethoxy oxadiazolines, including some reactions that are included on the basis of analogy. The major first step is 1,3-dipolar cycloreversion to N_2 and carbonyl ylide **3**, supported by the finding that the rate constants for oxadiazoline thermolysis are relatively insensitive to the *para* substituent, and in the order *p*-NO_2 > *p*-CF_3 > *p*-Cl > *p*-H > *p*-Me > *p*-OMe (2.83, 2.62, 2.55, 2.35, 2.11, and 2.09, all × 10^{-5} s^{-1}). The reverse order would be expected if the thermolyses gave carbenes in one step, as proposed by Smith (30). The step forming **3** was assigned by analogy to instances in which a carbonyl ylide intermediate is mandatory, because a ketene acetal was among the products (27). Ylide **3** fragments to carbene **4**, possibly in competition with electrocyclic ring closure to oxirane (**9**) (19), from which a ketene acetal (**10**) might be generated by abstraction of the ring oxygen by the carbene (31). In the present cases, ketene acetals were not detectable in the crude reaction mixtures by ^{1}H NMR spectroscopy nor were any isolated. Thus, they were probably either formed in minor yields or they were absent altogether.

Intermediacy of carbenes **4** was conveniently demonstrated in a few cases by running thermolyses of oxadiazolines from which the alcohol ($ArCH_2OH$) used in the exchange reaction had not been removed. The excess alcohol trapped the carbene to afford the appropriate orthoformate (**7**, R = CH_2Ar). In other cases, *tert*-butyl alcohol (0.5 M) was used to intercept carbenes by converting them into analogous orthoformates **7** (R = *t*-Bu). Fragmentation of the carbenes to radicals **5** and **6** is apparently slower than trapping with *t*-BuOH at [*t*-BuOH] = 0.5 M. To estimate the rate constant for fragmentation of **4**, we modeled trapping of **4** with *t*-BuOH at 100°C with analogous trapping of (*p*-$MeOC_6H_4)_2C$: at ambient temperature (k = 0.4 × 10^9 M^{-1} s^{-1}) (32). Taking $k_{100°C}$ = 10^9 M^{-1} s^{-1} and the efficiency of trapping to be at least 98%, the estimated fragmentation rate constant for **4** is ≤10^7 s^{-1}. A fragmentation rate constant of 10^5 s^{-1} would be more than sufficient to prevent carbene dimerization in the absence of a carbene trap, because the carbene is generated very slowly from the oxadiazoline and its concentration must be extremely low. Dialkoxycarbenes that do not fragment to radicals generally do afford carbene dimers when generated in unreactive solvents (4, 5, 27).



Radicals **5** and **6** must be born as a singlet pair (28), because the precursor carbene is a singlet lying below the triplet by more than 70 kcal mol^{-1} (4), and they couple to afford methyl arylacetates (**8**), Scheme 2. Only those radicals that have diffused out of the solvent cage in which they were born are trapped with TEMPO; in-cage coupling converts

Scheme 5.

pairs to methyl arylacetate. In accord with that mechanism, small amounts (ca. 8% in the case of **1a**) of 1,2-diarylethanes, from coupling of benzylic radicals (**6**) in the absence of TEMPO, were indicated by GCMS although none could be isolated. Several other minor products, indicated in GC traces, were not identified.

Most of the methyl arylacetates (**8**) are well known although some had not been characterized by NMR spectroscopy. The NMR data are therefore included here. Esters **8b** and **8d** were also prepared independently by acid catalysed esterification of appropriate arylacetic acids. Their spectra agreed well with the spectra of corresponding **8** from oxadiazoline thermolysis.

Thermolysis of **2** in the presence of 2,2,6,6-tetramethyl-1-piperdinyloxy (TEMPO, 0.5 M)) afforded **11** and **12**. Those adducts, which arise from the coupling of methoxycarbonyl- and benzylic radicals with TEMPO, Scheme 3, constitute firm evidence for the intermediacy of radicals. The fact that ester **8a** and **11** were formed in approximately 1:1 ratio is not surprising, because 0.5 M TEMPO is not expected to compete with in-cage coupling. Formation of a fraction of the **8a** by a 1,2-rearrangement of carbene **4a** cannot be excluded from the experimental evidence. However, a computational study of allyloxyhydroxycarbene clearly indicated that homolysis of that carbene is strongly favoured over 1,2-rearrangement[2] and we assume that the same would be true for carbenes **4**.

A minor product obtained in some cases was acetone azine, **13**. It cannot be accommodated easily within the ylide mechanism of Scheme 1. Although fragmentation of the ylide intermediate to dimethylcarbene and carbonate, in competition with its fragmentation to dialkoxycarbene and acetone, could be proposed, the dimethylcarbene would then have to attack the oxadiazoline starting material to generate acetone azine, as in Scheme 4. An analogous process was proposed earlier for reactions with much higher initial oxadiazoline concentrations (33). It is now known that dimethylcarbene undergoes 1,2-H migration with $k = 1.4 \times 10^8\ s^{-1}$ at room temperature (34–36). That fast rearrangement, which is probably still faster at 100°C, makes it unlikely that acetone azine arises according to Scheme 4 and, for that reason, a second 1,3-dipolar cycloreversion (Scheme 5) of some oxadiazolines (37) is proposed. The mechanism is not firmly established, however. Although the appropriate carbonate **14** was obtained, its formation is not necessarily diagnostic for the alternate cycloreversion because reaction of **9** with **4** would afford the same carbonate, together with **10**. A comparison of the yields of azine and **10**, which might have helped, was not possible because the composite ^1H NMR spectra of the crude reaction mixture were too complicated to exclude low yields of the ketene acetals, which might not totally survive the reaction conditions in any case (27).

Authentic methyl benzyl carbonates **14b** and **14e**, prepared from the appropriate $ArCH_2OH$ and methyl chloroformate, gave NMR spectra in agreement with those of the corresponding **14** from oxadiazoline thermolysis.

The alternative cycloreversion reaction of the oxadiazolines to a carbonate ester and diazopropane is not well understood. It may be a general, although minor, competitor in other oxadiazoline thermolyses, which commonly produce traces of by-products that have not been identified.

Summary

2-Benzyloxy-2-methoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazolines undergo thermolysis at 100°C in benzene, by competing cycloreversions, affording either N_2 and a carbonyl ylide or 2-diazopropane and a carbonate ester. The carbonyl ylide fragments to acetone and a benzyloxy(methoxy)carbene, which fragments further to the methoxycarbonyl radical and a benzylic radical. Those radicals couple to afford methyl arylacetates. Formation of 2-diazopropane was inferred from the presence of acetone azine among the products.

Experimental

For product isolation, thermolyses were carried out with degassed solutions of substrate (1 mmol in 30 mL of dry benzene, 96 h) in a constant temperature oil bath at 100 ± 0.1°C. Products were isolated by means of centrifugal chromatography. For examination of a crude reaction mixture by NMR spectroscopy, thermolyses were run with degassed solutions in sealed NMR tubes (ca. 10 mg in 0.5 mL of C_6D_6). Unless otherwise indicated, the reported NMR data refer to

$CDCl_3$ solutions containing TMS. In the MS data, numbers in brackets are relative intensities.

Synthesis of oxadiazolines

Oxadiazolines **2** were prepared from a mixture of 2-acetoxy-2-methoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (**1**, ca. 75%) and its acyclic isomer, methyl-2,3-diaza-4-methyl-4-acetoxypent-2-enoate (29) (ca. 25%) by treatment with the appropriate benzylic alcohol in dichloromethane containing acetic acid. For example, 3.6 mmol of **2** and 1.0 mmol of alcohol in CH_2Cl_2 (35 mL) containing acetic acid (1 mL) was refluxed for 48 h. Most of the solvent was removed with a rotary evaporator and the residue was stirred for one hour with 5% aqueous KOH. Extraction with CH_2Cl_2, drying over $MgSO_4$, and evaporation of the volatile components left the oxadiazolines in nearly pure form. Yields for the exchange step ranged from 60 to 90%, based on the alcohol. In some cases the analogous procedure, but with the alcohol in excess, gave an oxadiazoline containing about 20% of the alcohol. Thermolysis of those mixtures served as probes for the intermediacy of a carbene with the alcohol acting as a trap for it.

Acetone azine. ^{1}H NMR (C_6D_6) δ: 1.79 (3H, s), 1.81 (3H, s). The same spectrum was obtained with an authentic sample.

Rate constants for thermolysis of **2a–f** in C_6D_6 at 100°C were determined by means of ^{1}H NMR spectroscopy, with toluene as internal standard. Toluene did not react appreciably with radicals produced during the thermolyses. A sealed NMR tube containing the oxadiazoline (0.1 mmol) in C_6D_6 was withdrawn from the oil bath from time to time and cooled rapidly to room temperature before integration of the ^{1}H NMR spectrum. Typically, seven points were collected, covering the range from 0 to 87% of completion. The time scale was not corrected for the cooling and warm-up times. First order plots, which were linear, gave the rate constants reported in the text.

Multidimensional conformational analysis of allyl methyl disulfide: a key component of garlic

Alvin C. Lin, Salvatore J. Salpietro, Eugen Deretey, and Imre G. Csizmadia

Abstract: Organosulfur compounds in garlic, like allyl methyl disulfide, have been found to be involved in antimutagenic, anticarcinogenic, antithrombotic, and lipid-lowering activities, and it has also been found to act as an antioxidant. Ab initio molecular computations were performed on dihydrogen disulfide (**1**) with respect to torsional angle $\tau_1 = \tau(H{\cdot}S{-}S{\cdot}H)$, hydrogen methyl disulfide (**2**) with respect to torsional angle $\tau_1 = \tau(H{\cdot}S{-}S{\cdot}CH_3)$, and allyl methyl disulfide (**3**) with respect to torsional angles $\tau_1 = \tau(H_3C_2{\cdot}CH_2{\cdot}S{-}S{\cdot}CH_3)$, $\tau_2 = \tau(H_3C_2{\cdot}CH_2{-}S{\cdot}S{\cdot}CH_3)$, and $\tau_3 = \tau(H_3C_2{-}CH_2{\cdot}S{\cdot}S{\cdot}CH_3)$. Potential energy curves (PEC) were obtained from **1** and **2**, i.e., $E = E(\tau_1)$, from which optimized structures were obtained at the HF/6–31G* level of theory. These optimized structures were used to investigate the potential energy hypersurface surface (PEHS) of **3**, i.e., $E = E(\tau_1,\tau_2,\tau_3)$. One-dimensional scans along τ_2 and τ_3 (where $\tau_1 = \pm 90°$; $\tau_1 = 180°$) were performed at the HF/3–21G* level of theory. From these scans, six lower energy pairs of enantiomeric minima (i.e., [$g^+g^+g^+$ | $g^-g^-g^-$], [g^+ag^- | g^-ag^+], [$g^+g^-g^+$ | $g^-g^+g^-$], [$g^+g^+g^-$ | $g^-g^-g^+$], [g^+ag^- | g^-ag^+], and [$g^+g^-g^-$ | $g^-g^+g^+$]) as well as 3 higher energy minima (i.e., [g^+g^+s | g^-g^-s], [g^+as | g^-as], and [$g{+}g^-s$ | g^-g^+s]) were optimized at $\tau_1 = \pm 90°$ at the HF/6–31G* and B3LYP/6–31G* levels of theory. The global minimum was determined to be the [$g^+g^-g^+$ | $g^-g^+g^-$] enantiomeric pair of conformers, and the fully symmetrical *anti-anti-anti* [*a a a*] structure was determined to be a second-order saddle point on the PEHS of **3**. Although there are no stereocentres in **3**, there is chirality in the conformational twist with respect to the [*a a a*] conformation through $\tau_1 = \tau_2 = \tau_3 = 180°$. Based on the energies and MO diagrams of the HUMO and LUMO +1 of **3**, the anticarcinogenic and cholesterol lowering activity mechanism of **3** is presented.

Key words: ab initio MO computations, allyl methyl disulfide, multidimensional conformational analysis (MDCA), anticarcinogenic, cholesterol lowering.

Résumé : Il a été observé que les composés organosulfurés de l'ail, comme le disulfure d'allyle et de méthyle, sont impliqués dans des activités antimutagènes, anticancérigènes, antithrombiques et d'abaissement du niveau des lipides; il a aussi été observé qu'ils peuvent agir comme antioxydant. On a effectué des calculs moléculaires ab initio sur le disulfure d'hydrogène (**1**) en fonction de l'angle de torsion $\tau_1 = \tau(H{\cdot}S{-}S{\cdot}H)$, sur le disulfure d'hydrogène et de méthyle (**2**) en fonction de l'angle de torsion $\tau_1 = \tau(H{\cdot}S{-}S{\cdot}CH_3)$ et sur le disulfure d'allyle et de méthyle (**3**) en fonction des angles de torsion $\tau_1 = \tau(CH_2 = CH{\cdot}CH_2{\cdot}S{-}S{\cdot}CH_3)$, $\tau_2 = \tau(CH_2 = CH{\cdot}CH_2{-}S{\cdot}S{\cdot}CH_3)$, et $\tau_3 = \tau(CH_2 = CH{-}CH_2{\cdot}S{\cdot}S{\cdot}CH_3)$. On a obtenu des courbes d'énergie potentielle (CEP) pour le passage de **1** à **2**, c'est-à-dire $E = E(\tau_1)$ à partir desquelles on a obtenu des structures optimisées au niveau HF/6–31G de la théorie. On a utilisé ces structures optimisées pour étudier la surface d'hypersurface d'énergie de potentiel (SHEP) de **3**, c'est-à-dire $E = E(\tau_1, \tau_2, \tau_3)$. Opérant au niveau HF/3–21G* de la théorie, on a effectué des balayages unidimensionnels le long de τ_2 et τ_3 (où $\tau_1 = \pm 90°$; τ_1 180°). À partir de ces balayages et opérant aux niveaux HF/6–31G* et B3LYP/6–31G* de la théorie, on a optimisé les six paires d'énergie les plus faibles des minima énantiomères (c'est-à-dire, [$g^+g^+g^+$ | $g^-g^-g^-$], [g^+ag^- | g^-ag^+], [$g^+g^-g^+$ | $g^-g^+g^-$], [$g^+g^+g^-$ | $g^-g^-g^+$], [g^+ag^- | g^-ag^+] et [$g^+g^-g^-$ | $g^-g^+g^+$]) ainsi que trois minima d'énergie plus élevée (soit, [g^+g^+s | g^-g^-s], [g^+as | g^-as], et [$g{+}g^-s$ | g^-g^+s]) à $\tau_1 = \pm 90°$. On a déterminé que le minimum global correspond à la paire énantiomère de conformères [$g^+g^-g^+$ | $g^-g^+g^-$] et que la structure complètement symétrique *anti-anti-anti* [*a a a*] est un point de selle du deuxième ordre sur la SHEP de **3**. Même s'il n'existe aucun stéréocentre dans **3**, il existe une chiralité dans la déformation conformationnelle par rapport à la conformation [*a a a*] lorsque $\tau_1 = \tau_2 = \tau_3 = 180°$. En se basant sur les énergies et les diagrammes d'OM des HO et BV +1 de **3**, on propose un mécanisme pour l'activité anticancérigène et d'abaissement du niveau de cholestérol résultant de **3**.

Mots clés: ab initio, calculs d'OM, disulfure d'allyle et de méthyle, analyse conformationnelle multidimensionnionnelle (ACMD), anticancérigène, abaissement du niveau de cholestérol.

Fig. 1. Some organosulfur compounds found in garlic.

Introduction

Garlic has been one of the most popular medically researched plants, with over 1300 research articles in only the last 100 years (1). This growing interest is largely due to its therapeutic appeal, particularly in its anticarcinogenic, antimutagenic, antithrombotic, and lipid-lowering cardiovascular activities; and it has also been shown to act as an antioxidant. The following are a few examples. The title compound: allyl methyl disulfide and other allyl group-containing derivatives found in garlic were shown to inhibit benzo[*a*]pyrene-induced neoplasia of the forestomach and lungs of female mice (2). Other garlic constituents suggest effectiveness in binding to 7,12-dimethylbenz[*a*]anthracene, thereby preventing it from binding in vivo to DNA (3). Allicin (Fig. 1) and other organosulfur components in garlic extracts have been found to have significant radical scavenging capabilities (4–7), specifically a powerful scavenger of the OH radical (3). Garlic extracts have also been shown to have antimutagenic activity towards ionizing radiation, peroxides, adriamycin, and *N′*-methyl-*N′*-nitro-nitrosoguanidine (8). Allicin has also been found to inhibit platelet aggregation (9–13), along with ajoene, a colourless and odourless liquid isolated from methanolic extracts of fresh garlic (Fig. 1). In fact, ajoene actually inhibits aggregations even better than allicin in human whole blood (IC_{50} 60 μM vs. IC_{50} 90 μM) (14). In an other study, patients at risk of heart disease saw significant reductions in blood cholesterol and triglycerides levels after orally ingesting raw garlic daily (5g/day) for 2 to 3 months (15–19). A similar investigation also showed that a daily intake of garlic resulted in lower levels of cholesterol, triglycerides, low density lipoproteins, and very low density lipoproteins (commonly referred to as LDL, VLDL respectively) and an increase of high density lipoproteins (commonly referred to as HDL) (20). Garlic consumption has also significantly lowered the number of deaths due to gastric cancer in China (21), as well as in Italy (22), in comparison to regions with lower consumptions. Other anticancer effects have shown diallyl disulfide, the major constituent of garlic oil, to inhibit oxidative phosphorylation in hepatic mitochondria of mice (23).

It is interesting to note that although diallyl disulfide is the main constituent of garlic oil, it is diallyl trisulfide, a minor component, which is more reactive, and thus produces more of an inhibitory effect towards canine mammary tumor cells (24). Other trisulfides found in garlic include allyl methyl

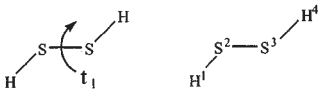
trisulfide, which has found to enhance glutathione *S*-transferase activity in mouse tissues (forestomach, small bowel mucosa, liver, and lung) (25).

Investigating the conformations of dihydrogen disulfide (**1**), hydrogen methyl disulfide (**2**), as well as the simplest allyl organosulfur component, allyl methyl disulfide (**3**), can hopefully provide a better understanding of its important role and the role of related compounds in biological processes. The structures of these three compounds are depicted below.

Stereochemical background



Disulfides (X·S–S·Y) have a torsional angle in the vicinity of 90°. This is manifested in previous computations reported on H·S–S·H and H·S–S·CH_3 (26–37). Geometrical parameters such as S—S, H—S, S—C bond lengths, HSS and SSC bond angles associated with the rotation about the S—S bond are summarized in Tables 1 and 2.

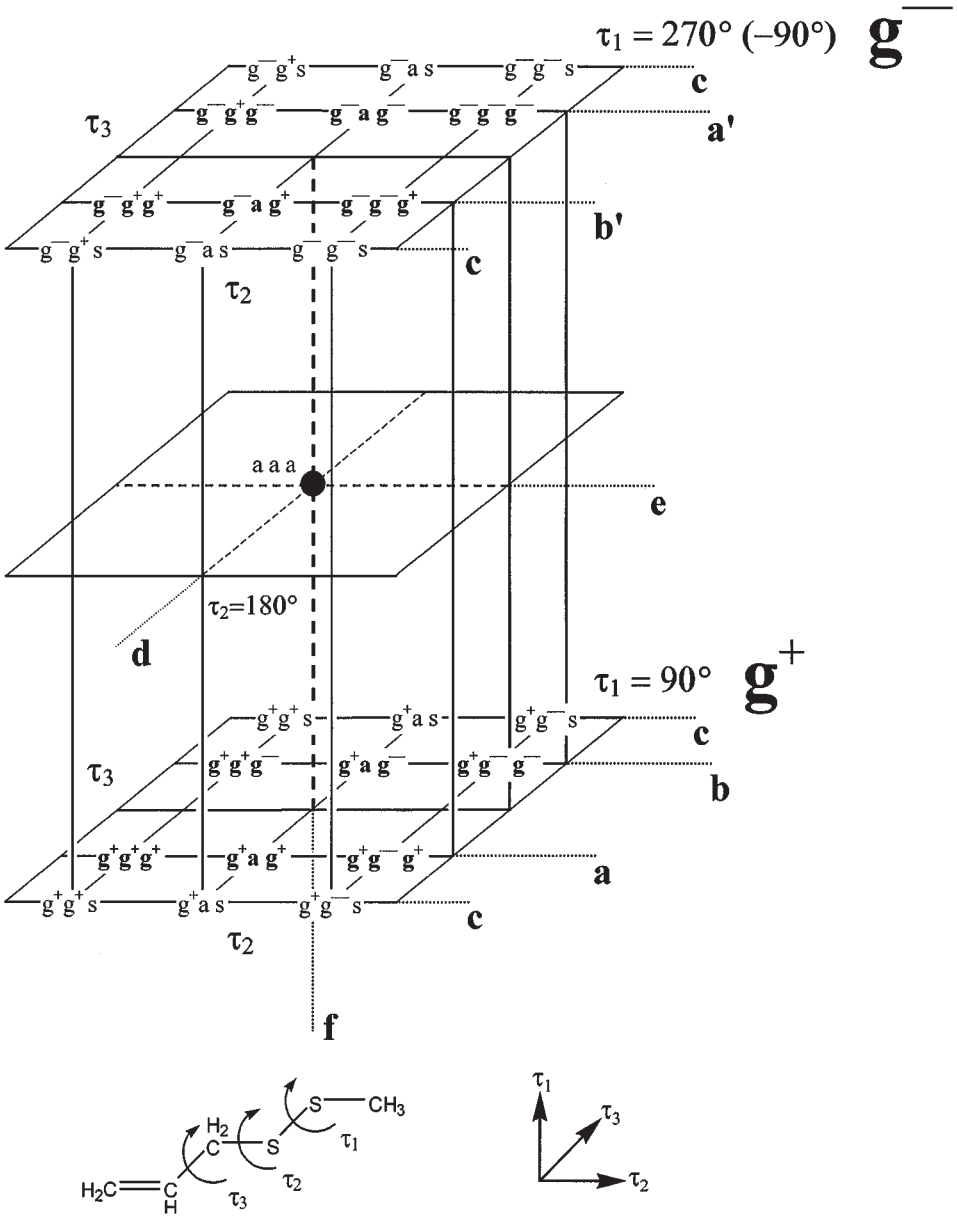
Fig. 5. PEC's of **3** (allyl methyl disulfide) along $\tau_1 = \tau(H_3C_2{\cdot}CH_2{\cdot}S\text{-}S{\cdot}CH_3)$. Note that the minima are occurring at analogous torsional angles of $\tau_1 \approx +90°$ and $\tau_1 \approx -90°$.

theory, and the PEC scans of **3** were calculated at the RHF/3–21G* level of theory. All conformers of **1** and **2** were optimized at the RHF/6–31G* level of theory, whereas all structures of **3** were optimized at both the RHF/6–31G* and B3LYP/6–31G* levels of theory. At termination, all critical points had gradients $<1.5 \times 10^{-5}$ au. The semiempirical potential energy surface (PES) scan of **3** was calculated using MOPAC. All points generated from the PEC and PES scans were plotted using Axum 5.0A, and all molecular orbital diagrams were generated using Molden 3.6.

Results and discussion



Multidimensional conformational analysis

Even after a first glance, it was apparently clear that allyl methyl disulfide (**3**) is more complex than its structure may suggest, largely because it contains three unique torsional angles $\tau_1 = \tau(H_3C_2{\cdot}CH_2{\cdot}S\text{–}S{\cdot}CH_3)$, $\tau_2 = \tau(H_3C_2{\cdot}CH_2\text{–}S{\cdot}S{\cdot}CH_3)$ and $\tau_3 = \tau(H_3C_2\text{–}CH_2{\cdot}S{\cdot}S{\cdot}CH_3)$. Based on these three torsional angles, the potential energy hypersurface (PEHS) of **3** needed to be explored, where

$$E = E(\tau_1, \tau_2, \tau_3)$$

© 2000 NRC Canada

Fig. 6. Topology of the PEHS of **3** (allyl methyl disulfide), where $E = E(\tau_1, \tau_2, \tau_3)$, indicating the notation of the 6 pairs of lower energy conformers in boldface, of the 3 pairs of higher energy conformers, and of the fully symmetrical *anti* structure. Note that the centre of symmetry (i.e., where $\tau_1 = \tau_2 = \tau_3 = 180°$) is denoted by a solid dot and corresponds to the [*a a a*] conformation shown in Fig. 8.

to determine its conformers. Thus, as a preliminary investigation, smaller disulfides, namely dihydrogen disulfide (**1**) and hydrogen methyl disulfide (**2**) were first examined. Specifically, ab initio PEC scan calculations on **1** and **2** and were performed with respect to their torsional angles: $\tau_1 = \tau(H{\cdot}S{-}S{\cdot}H)$ for **1,** and $\tau_1 = \tau(H{\cdot}S{-}S{\cdot}CH_3)$ for **2**. Not surprisingly, their PEC (Figs. 2A and 2B) showed that there are two minima at $\tau_1 \approx +90°$ (clockwise rotation) and $\tau_1 \approx -90°$ (counterclockwise rotation). These minima are enantiomeric in disulfides, analogous to the *gauche* conformers (i.e., g^+ and g^-) found in a 1,2-disubstituted ethane (e.g., butane), as illustrated in Fig. 3. (Note that although *gauche* (*g*) is a 60° torsional angle by convention, for the purposes of this investigation, an extension of the definition will include in the convention a 90° torsional rotation).

We then inferred that on the basis of the PEC of **1** and **2**, the value of τ_1 for **3** would be similar as well, namely $\tau_1 \approx \pm 90°$. The PEHS of **3**, i.e., $E = E(\tau_1,\tau_2,\tau_3)$, could now be investigated by first examining the PES of **3** when $\tau_1 = +90°$, i.e.,

$$E = E(\tau_2, \tau_3) \text{ for } \tau_1 = 90°$$

As a means of acquiring an idea of what this surface may look like, semiempirical PES scan calculations on **3** were performed using MOPAC at 30° rotational increments about torsional angles t_2 and τ_3, keeping τ_1 constant at +90°. From

Fig. 9. Optimized structures of the six pairs of lower energy minima conformers ($\lambda = 0$) of **3** (allyl methyl disulfide) computed at the HF/6–31G* level of theory.

the pseudo three-dimensional landscape representation and the two-dimensional contour plot of the surface shown in Figs. 4A and 4B, there was a strong suggestion that there existed at least six energy minima for **3**. Therefore, to help verify these preliminary findings and to further investigate the PEHS of **3**, it was convenient to then carry out one-dimensional ab initio scans along the three torsional angles coordinates τ_1, τ_2, and τ_3.

As expected, scanning along τ_1 (Fig. 5) confirmed that the $\tau_1 = +90°$ and $\tau_1 = –90°$ platform levels on the PEHS of **3** can be regarded as equivalent if all other torsional angles (τ_2 and τ_3) are identical. These two levels are presented in Fig. 6. Scanning along τ_2 revealed that there are indeed six energy minima at $\tau_1 = 90°$ as well as at $\tau_1 = –90°$ as shown in Fig. 7. Furthermore, scanning along τ_2 also revealed that the PECs are chiral. From the four PEC cross-sectional scans along τ_2 (**a**, **b**, and **a′**, **b′**), presented in Figs. 6 and 7, one can clearly see that **a** (where $\tau_1 = 90°$ and $\tau_3 = –108.51°$ or 251.49°) is the nonsuperimposable image of **a′** (where $\tau_1 = –90°$ or 270°, and $\tau_3 = 108.51°$). Similarly, **b** (where $\tau_1 = 90°$ and $\tau_3 = 108.51°$) is the nonsuperimposable image of **b′** (where $\tau_1 = –90°$ or 270°, and $\tau_3 = –108.51°$ or 251.49°). Therefore, although **3** has no stereocentres, we can see that the chirality of **3** is due to the chirality of torsional twist. Each clockwise and counterclockwise twist about τ_1, τ_2, and τ_3 generates an enantiomeric pair (Fig. 8), and from Figs. 6 and 8, it is clear that there are six of these enantiomeric pairs of conformers on the PEHS of **3**. We were then able to obtain six enantiomeric pairs of conformers, illustrated in Fig. 9, and their optimized parameters are provided in Tables 3 and 4. These six structures are also represented on the PEHS of **3** in boldface symbols in Fig. 6. Because they are enantiomeric, each diagonally opposed pair is identical in energy, as illustrated in boldface numbers in Fig. 10. From Fig. 10, it also becomes apparently clear that the centre of symmetry of the PEHS of **3** is at $\tau_1 = \tau_2 = \tau_3 = 180°$, i.e., at the fully *anti-anti-anti* orientation (cf. [*a a a*] structure in Fig. 8). Therefore, if an imaginary line can be drawn through the fully *anti*-centre (i.e., [*a a a*] or $\tau_1 = \tau_2 = \tau_3 = 180°$) from one energy platform to the other on the PEHS of

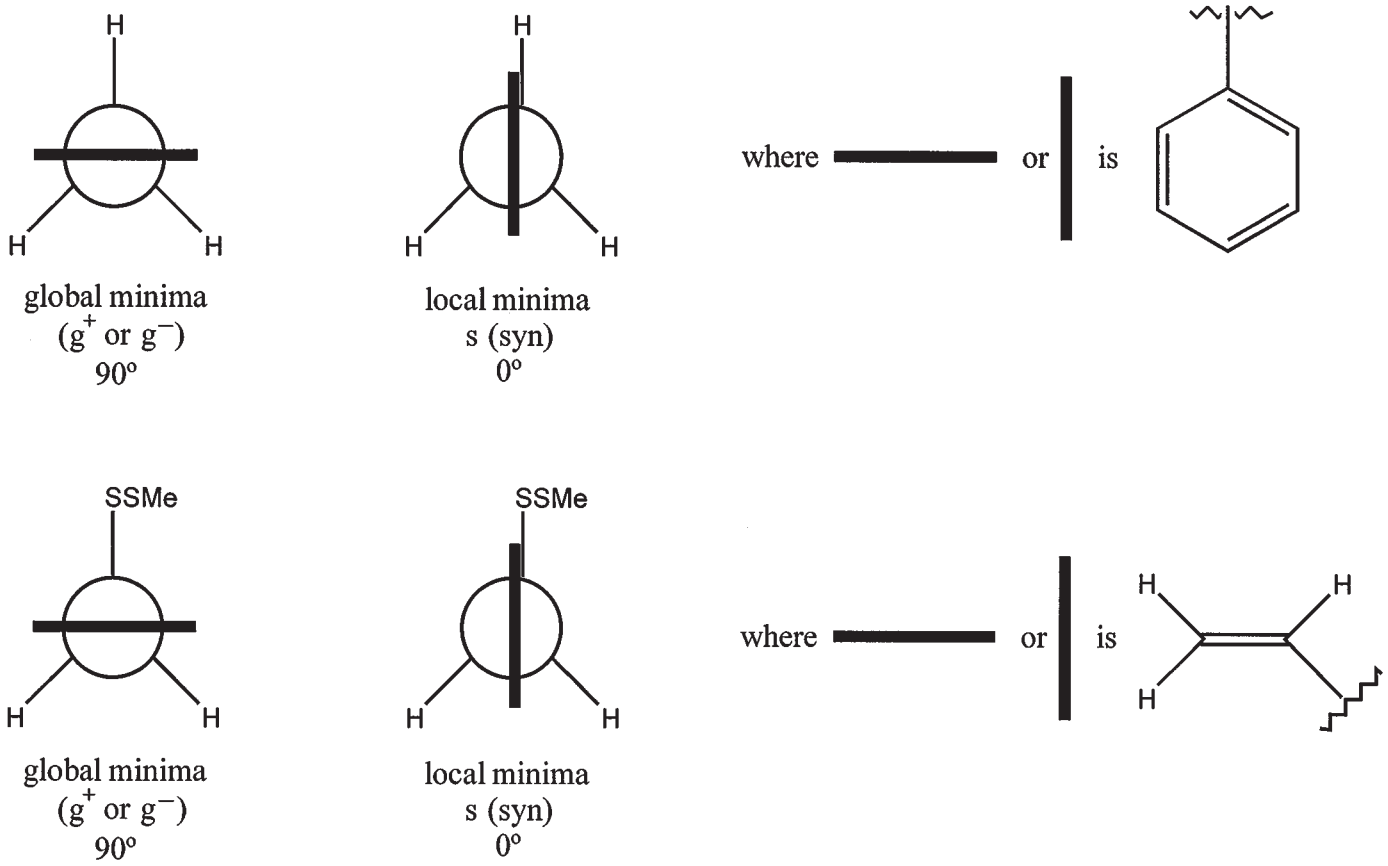
Fig. 10. Topology of the conformational the PEHS of **3** (allyl methyl disulfide), where $E = E(\tau_1, \tau_2, \tau_3)$, indicating the relative energies in kcal/mol of the 6 pairs of lower energy conformers in boldface, of the 3 pairs of higher energy conformers, and of the fully symmetrical *anti* structure. Note that the centre of symmetry (i.e., where $\tau_1 = \tau_2 = \tau_3 = 180°$) is denoted by a solid dot, and corresponds to the [*a a a*] conformation shown in Fig. 8. The energy values were computed at the HF/6–31G* level of theory.

3, then the structures along such a line are enantiomers. Conversely, if an imaginary line joining two conformers cannot be drawn through the fully *anti*-centre, then the structures are diastereomers.

To denote the enantiomeric relationship of each pair of conformers, a convenient notation has been adopted, with the symbol " | " representing a mirror plane between two enantiomers. Therefore, as illustrated in Fig. 8, the $g^+g^-g^+$ conformer is enantiomeric to the $g^-g^+g^-$ conformer, i.e., $[g^+g^-g^+ \mid g^-g^+g^-]$.

From our previous study on the multidimensional conformational analysis of ethyl benzene (38), we remembered that when a planar moiety is rotated against a tetrahedral moiety, very often two minima result, one of them being higher (0° rotation) and the other being lower (90° rotation) in energy, as illustrated in Fig. 11. In the case of **3**, the planarity of the allyl group led us to believe that an analogous relationship was also present. For this reason, one-dimensional scans along τ_2 and τ_3 were performed, generating PEC's where,



$$E = E(\tau_2)$$

and

$$E = E(\tau_3)$$

© 2000 NRC Canada

Fig. 11. Structural representation of ethyl benzene and **3** (allyl methyl disulfide) showing the two types of minima that result from rotating a planar moiety against a tetrahedral moiety.

respectively. Scanning along τ_2 (i.e., along **c** in Fig. 6) revealed that the possibility of three higher energy minima when the following constraint was applied: $\tau_1 = +90°$ and $\tau_3 = 0°$ (Fig. 12). On the same $\tau_1 = 90°$ platform of the PEHS of **3**, scanning along τ_3 confirmed that indeed there were three other higher energy minima. Therefore, just like in the case of ethyl benzene, the lower energy minima of **3** exist when the planar allyl moiety is perpendicular (90°) to the -H_2C—S- bond (*g*) and the higher minima exist when the same moiety is in alignment (*syn*) with that bond, as illustrated in Fig. 12. It is interesting to note that unlike the six pairs of lower minima, diastereomeric pairs were not found for these higher of conformers due to the internal symmetry at $\tau_3 = 0°$. The structures of these 3 higher minima are illustrated in Fig. 13, and their optimized parameters are provided in Tables 5 and 6. The relative energies for PEHS of **3** provided in Fig. 10 show, however, that the g^+ and g^- structures are enantiomers as manifested in the double degeneracy. Thus, on the basis of these one dimensional scans, six lower and three higher energy minima were optimized on both on the $\tau_1 = \pm 90°$ platforms. The global minimum conformer was found to be the enantiomeric [$g^+g^-g^+$ | $g^-g^+g^-$] pair of conformers, and their structures are shown in Fig. 8. As aforementioned, these diagonally opposed structures are enantiomeric in nature, and are therefore identical in energy.

Based on the enantiomeric relationship of the $\tau_1 = \pm 90°$ platforms, our ensuing investigation focused on the $\tau_1 = 180°$ platform of the PEHS of **3**, where the fully *anti* structure [*a a a*] of **3** can be found. As aforementioned, if an imaginary line joining two conformers of **3** can be drawn fully through *anti*-centre, then the structures are enantiomers. Thus, based on this relationship, enantiomeric pairs of **3** should exist, for example, between conformers along **d** on the $\tau_1 = 180°$ platform as shown in Fig. 6. Scanning along τ_3 (where $\tau_1 = 180°$ and $\tau_2 = 180°$) confirmed this enantiomeric relationship, as illustrated in the PEC shown in Fig. 14A. Furthermore, based on the relative energies provided in Fig. 10, the analogous rigid cross-sections along τ_3 at the $\tau_1 = \pm 90°$ platforms would not reveal this same element of symmetry due to the chirality created by the conformational twist about the -S—S- bond. It is interesting to note that the symmetrical cross-section shown in Fig. 14A is characteristic of rotating a bond connected to a prochiral centre. Allyl halides, which have been studied both experimentally (39–54) and computationally (55), are an example of compounds that contain such a bond.

The stereochemical significance of the fully symmetrical *anti* [*a a a*] structure of **3** (cf. the central achiral point or solid dot on the PEHS in Fig. 6) led us to its optimization, and the optimized parameters of this structure are summarized

Fig. 14. (A) PEC of **3** (allyl methyl disulfide) along $\tau_3 = \tau(H_3C_2\text{-}CH_2\cdot S\cdot S\cdot CH_3)$, computed at the HF/6–31G* level of theory. This symmetrical PEC is characteristic to the rotation about a bond connected to a prochiral centre. (B) Three PEC of **3** along $\tau_1 = \tau(H_3C_2\cdot CH_2\cdot S\text{-}S\cdot CH_3)$, $\tau_2 = \tau(H_3C_2\cdot CH_2\text{-}S\cdot S\cdot CH_3)$, and $\tau_3 = \tau(H_3C_2\text{-}CH_2\cdot S\cdot S\cdot CH_3)$, computed at the HF/3–21G* level of theory. Note that all three PEC cross through the fully symmetrical *anti-anti-anti* [*a a a*] structure (i.e., through $\tau_1 = \tau_2 = \tau_3 = 180°$) denoted by a solid dot, which is analogous to the one found on the PEHS in Figs. 6 and 10. The symmetrical [*a a a*] structure is above the global minimum by 9.51 kcal/mol computed at the HF/6–31G* level of theory.

[a]The three symbols in *a a a* is the conformational assignment for τ_1, τ_2, and τ_3, respectively.

in Table 7. As illustrated in Fig. 14B, scanning along τ_3, τ_2, and τ_1 (i.e., shown in Fig. 6 as **d**, **e**, and **f** respectively) revealed that this [*a a a*] structure is a second-order saddle point ($\lambda = 2$), which was confirmed by a subsequent frequency calculation. We have provided the vibrational frequencies, IR intensities, and Raman activities of this fully *anti* structure of **3** in Table 8.

Finally, it is worthy to note that under the same basis set (i.e., 6–31G*), the level of theory (i.e., HF and B3LYP) had little influence on the relative optimized energies of both the higher and lower energy minima conformers of **3**, as Tables 3 to 6 illustrated. In fact, the energy difference between HF and B3LYP optimizations was within 0.3 kcal/mol for any given enantiomeric pair of conformers. For the global

Fig. 15. MO diagrams of the (A) HOMO and the (B) LUMO +1 orbitals of **3** (allyl methyl disulfide).

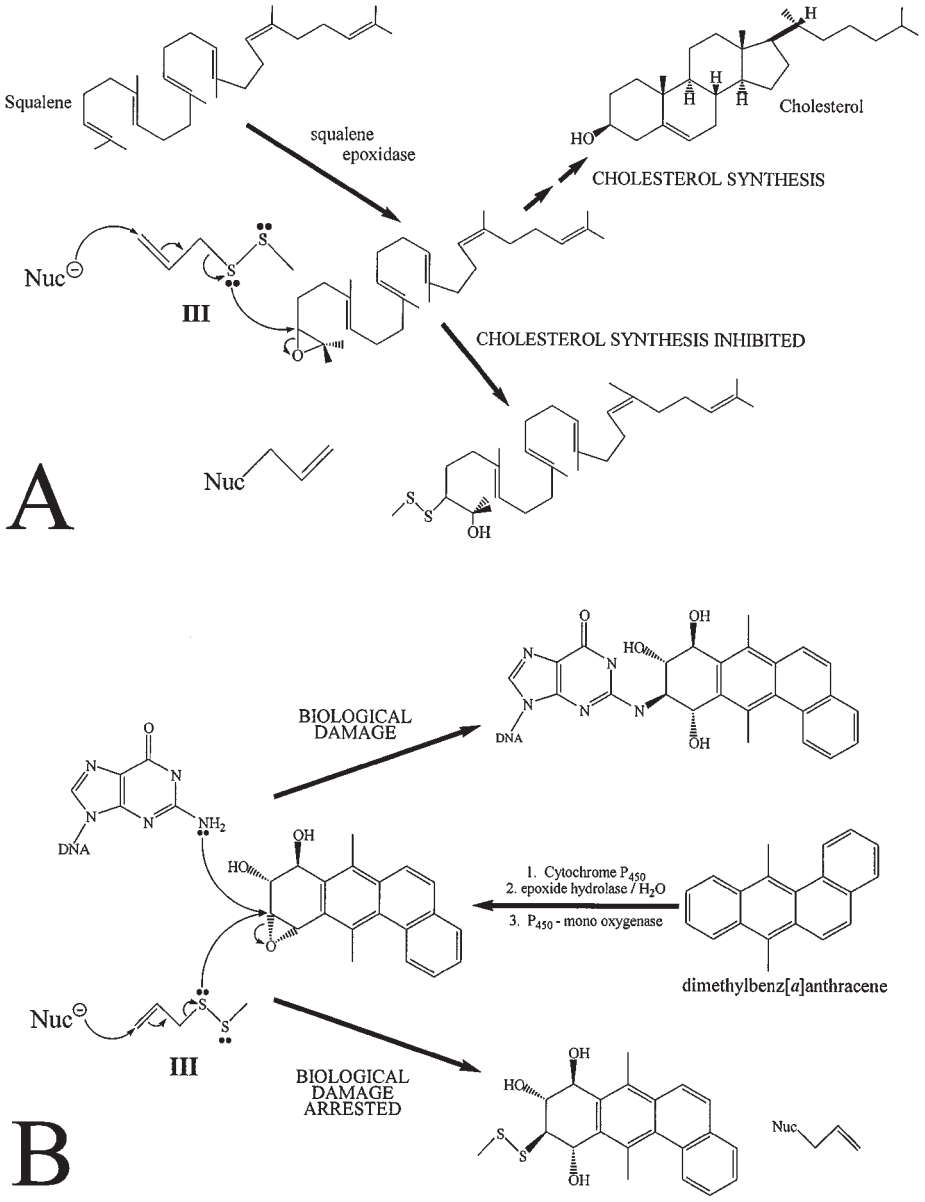
maximum conformation [*a a a*] of **3**, the level of theory had a slightly greater affect on the relative optimized energies, as the energy difference between the HF and B3LYP optimizations was 0.91 kcal/mol (Table 7).

Putative biomedical reaction mechanisms of allyl methyl disulfide

With a greater understanding of its structural behavior, the biological role of **3** was subsequently investigated. For the global minima conformers [$g^+g^-g^+$ | $g^-g^+g^-$], our examination of the HOMO (MO_{32}) and HOMO –1 (MO_{31}) orbitals revealed that they are almost energetically degenerate (MO_{32} = –0.23388 Hartree, and MO_{31} = –0.24048 Hartree); and likewise, the LUMO (MO_{33}) and LUMO +1 (MO_{34}) orbitals are similar in energy (MO_{33} = –0.02148 Hartree, and MO_{34} = –0.00129 Hartree). The relatively small negative energy values of the HOMO and HOMO –1 orbitals suggest that **3** can act as a nucleophile. Suprisingly, the energy values of the LUMO and LUMO +1 orbitals are negative, suggesting that **3** also has a strong tendency to accept electrons or act as an electrophile. Based on the similarities in energy values between the HOMO and HOMO –1 orbitals and between the LUMO and LUMO +1 orbitals, the shape of the MO will therefore largely determine which orbitals will be implicated in donating or accepting electrons in a reaction. By inspection, the HOMO and LUMO +1 orbitals would likely be involved as an electron donator and electron acceptor respectively, as shown in Fig. 15.

According to the HOMO and LUMO +1 diagrams of **3** shown in Fig. 15, one could envisage a mechanism of activity whereby allyl methyl disulfide (**3**) acts as both an electron donor and an electron acceptor, as illustrated in Fig. 16. According to Fig. 16A, disulfides like **3** lower cholesterol levels by reacting with squalene epoxide, a precursor in the biosynthesis of cholesterol. In a similar mechanism shown in Fig. 16B, the epoxy-based metabolite of the carcinogen dimethylbenz[*a*]anthracene could preferentially react with **3** instead of one of the DNA bases (e.g., guanine), thereby accounting for the anticarcinogenic activity of **3**.

Acknowledgements



The authors wish to thank Dr. T.-H. Tang for his helpful discussions, as well as the National Cancer Institute (NCI) for the use of their services at the Frederick Biomedical Supercomputing Centre. The continuous financial support of the Natural Sciences and Engineering Research Council (NSERC) of Canada is gratefully acknowledged. Also, one of the authors (A.C. Lin) wishes to express his thanks to NSERC for the Undergraduate Student Research Award.

Organometallic oxides: preparation of the cluster $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ by reduction of $[(\eta\text{-}C_5Me_5)MoCl(O)]_2(\mu\text{-}O)$ or $(\eta\text{-}C_5Me_5)MoCl_2(O)$

Frank Bottomley, Victor Sanchez, Robert C. Thompson, Olusola O. Womiloju, and Zhiqiang Xu

Abstract: Reduction of $[(\eta\text{-}C_5Me_5)MoCl(O)]_2(\mu\text{-}O)$ or $(\eta\text{-}C_5Me_5)MoCl_2(O)$ with sodium or magnesium amalgam, magnesium turnings, or tributyltin hydride produced $[(\eta\text{-}C_5Me_5)Mo]_4O_7$, with $[(\eta\text{-}C_5Me_5)Mo(O)(\mu\text{-}O)]_2$ as a co-product. $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ was characterized by X-ray diffraction, mass spectrometry, ^{1}H NMR and IR spectroscopies, and magnetism. Crystals of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ contained a tetrahedral $[(\eta\text{-}C_5Me_5)Mo]_4$ unit (Mo—Mo = 2.909 (3) Å) with the Mo_4O_7 core having the structure $Mo_4(\mu_2\text{-}O(b))_3(\mu_2\text{-}O(c))_3(\mu_3\text{-}O(a))$ (**3**). Microcrystalline samples of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ were paramagnetic over the temperature range 2–300 K, with an effective moment of 1.26 μ_B at 300 K. $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ was also paramagnetic in chloroform solution, over the temperature range 223–298 K, with an effective moment of 1.43 μ_B at 298 K. The ^{1}H NMR spectrum showed a broad resonance at 16.3 ppm ($\Delta\nu_{1/2}$ = 113 Hz) and two narrow resonances at 1.89 ppm and 1.69 ppm ($\Delta\nu_{1/2}$ = 5 Hz). The magnetism and NMR spectra showed that $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ existed in two forms which were in equilibrium in solution. One form was paramagnetic (S = 1), with the Mo_4O_7 core having the geometry **3**, and the other was diamagnetic (S = 0), with the Mo_4O_7 core having the geometry **4**.

Key words: cluster, cyclopentadienyl, molybdenum, oxide, paramagnetism.

Résumé : La réduction du $[(\eta\text{-}C_5Me_5)MoCl(O)]_2(\mu\text{-}O)$ ou du $(\eta\text{-}C_5Me_5)MoCl_2(O)$ par de l'amalgame de sodium ou de magnésium, des tournures de magnésium ou de l'hydrure de tributylétain conduit à la formation de $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ accompagné de $[(\eta\text{-}C_5Me_5)Mo(O)_2(\mu\text{-}O)]$ comme sous-produit. On a caractérisé le $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ par diffraction des rayons X, de la spectrométrie de masse, des spectroscopies IR et RMN du ^{1}H ainsi que par magnétisme. Les cristaux de $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ comprennent une unité tétraédrique de $[(\eta\text{-}C_5Me_5)Mo]_4$ (Mo—Mo = 2,909(3) Å dans laquelle le Mo_4O_7 fondamental possède la structure $Mo_4(\mu_2\text{-}O(b))_3(\mu_2\text{-}O(c))_3(\mu_3\text{-}O(a))$ (**3**). Les échantillons microcristallins de $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ sont paramagnétiques sur la plage de température allant de 2 à 300 K. À des températures allant de 223 à 298 K, le $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ est aussi paramagnétique en solution dans le chloroforme; à 298 K, le moment magnétique effectif est égal à 1,43 μ_B. Le spectre RMN du ^{1}H comporte une large bande de résonance à 16,3 ppm ($\Delta\nu_{1/2}$ = 113 Hz) et deux bandes de résonance étroites à 1,89 et 1,69 ppm ($\Delta\nu_{1/2}$ = 5 Hz). Le magnétisme et les spectres RMN démontrent que, en solution, le $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ existe sous deux formes en équilibre. Une forme est paramagnétique (S = 1) dans laquelle le Mo_4O_7 fondamental possède la géométrie **3** et une autre forme, diamagnétique (S = 0), dans laquelle le Mo_4O_7 fondamental possède la géométrie **4**.

Mots clés : agrégat, cyclopentadiényle, molybdène, oxyde, paramagnétisme.

[Traduit par la Rédaction]

Introduction

We have been preparing organometallic clusters that exhibit exchange interactions between the metal atoms (1–3). Of particular interest were the oxide cubanes of general formula $[(\eta\text{-}C_5R_5)M(\mu_3\text{-}O)]_4$ (**1**) (3–6) and the adamantanes $[(\eta\text{-}C_5Me_5)M]_4(\mu_2\text{-}O)_6$ (**2**) (7, 8), which contain tetrahedra of *d*-block metal atoms. The cubanes $[(\eta\text{-}C_5R_5)Cr(\mu_3\text{-}O)]_4$ (R = H (4), Me (6), $R_5 = MeH_4$ (5)) were antiferromagnetic and $[(\eta\text{-}C_5Me_5)V(\mu_3\text{-}O)]_4$ was paramagnetic (3). The adamantanes $[(\eta\text{-}C_5Me_5)M]_4(\mu\text{-}O)_6$ (M = Ti, V) were diamagnetic (3, 7, 8). Because of the magnetic behaviour of $[(\eta\text{-}C_5R_5)M(\mu_3\text{-}O)]_4$ and $[(\eta\text{-}C_5Me_5)M]_4(\mu\text{-}O)_6$, we wished to prepare the molybdenum analogs $[(\eta\text{-}C_5Me_5)Mo(\mu_3\text{-}O)]_4$ and $[(\eta\text{-}C_5Me_5)Mo]_4(\mu\text{-}O)_6$.

The $[(\eta\text{-}C_5R_5)Cr(\mu_3\text{-}O)]_4$ clusters were prepared by mild oxidation of $(\eta\text{-}C_5R_5)_2Cr$ (4, 6, 9) and $[(\eta\text{-}C_5Me_5)V]_4(\mu\text{-}O)_6$ was first obtained by oxidation of $(\eta\text{-}C_5Me_5)_2V$ (7, 10, 11). However, oxidation of the only readily available low-valent $(\eta\text{-}C_5R_5)Mo$ derivatives, $[(\eta\text{-}C_5R_5)Mo(CO)_n]_2$ (n = 2, 3), gave either dimolybdenum oxo complexes (12–14), or the clusters

$(\eta\text{-}C_5Me_5)_6Mo_8O_{16}$ (15) or $(\eta\text{-}C_5Me_5)_4Mo_5O_{11}$ (16). Recently we have been investigating the reductive aggregation of $(\eta\text{-}C_5Me_5)MCl_nA$ derivatives as a route to $[(\eta\text{-}C_5Me_5)M(\mu_3\text{-}A)]_4$ and $[(\eta\text{-}C_5Me_5)M]_4(\mu_2\text{-}A)_6$ clusters (A = N, O) (3, 17, 18). It was anticipated that reduction of $[(\eta\text{-}C_5Me_5)MoCl(O)]_2(\mu\text{-}O)$ (19, 20) would produce $[(\eta\text{-}C_5Me_5)Mo]_4(\mu\text{-}O)_6$ and reduction of $(\eta\text{-}C_5Me_5)MoCl_2(O)$ (19, 21) would produce $[(\eta\text{-}C_5Me_5)Mo(\mu_3\text{-}O)]_4$. However, we have found that reduction of $[(\eta\text{-}C_5Me_5)MoCl(O)]_2(\mu\text{-}O)$ or $(\eta\text{-}C_5Me_5)MoCl_2(O)$ gave the cluster $[(\eta\text{-}C_5Me_5)Mo]_4O_7$, which existed in paramagnetic and diamagnetic forms. The results are described in detail here.

Experimental

General information

All manipulations were performed using a standard double-manifold vacuum/argon line. Solvents were predried, stored on the vacuum line over a drying agent, and distilled directly onto reagents. The starting materials $(\eta\text{-}C_5Me_5)MoCl_2(O)$ and $[(\eta\text{-}C_5Me_5)MoCl(O)]_2(\mu\text{-}O)$ were prepared by the literature methods (19, 21–24). Sodium was freshly cut under argon and magnesium was flame dried under vacuum. Metal amalgams were prepared by using a syringe to add mercury to the predried metal under a counter flow of argon. Purification of the mercury was by washing with dilute nitric acid, then with distilled water until the washings were neutral, then with acetone. It was heated at 100°C under vacuum for 12 h before use.

Magnetic susceptibilities were measured on a Quantum Design (MPMS) SQUID magnetometer at the Advanced Materials and Process Engineering Laboratory (AMPEL) at the University of British Columbia. Measurements were made over the temperature range 2–300 K at an applied field of 10 000 G and susceptibilities were corrected for the background signal from the sample holder at all temperatures. Susceptibilities were corrected for the diamagnetism of all atoms using Pascal's constants (25) and are reported per mole of cluster. ^{1}H NMR spectra were measured on Varian XL200 or Unity 400 spectrometers. Mass spectra were measured by EI (70 eV) or by FAB methods, in the matrices specified, on a Kratos MS 50 instrument. IR spectra were measured as KBr pellets or Nujol mulls on a Perkin–Elmer 683 instrument. Extended Hückel molecular orbital calculations and molecular modeling were performed using the CAChe system.

Syntheses

Reaction of $[(\eta\text{-}C_5Me_5)MoCl(O)]_2(\mu\text{-}O)$ in toluene solution with sodium amalgam: formation of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$

A solution of $[(\eta\text{-}C_5Me_5)MoCl(O)]_2(\mu\text{-}O)$ (1.34 g, 2.31 mmol) in toluene (100 cm^3) was added to sodium amalgam (0.61 g, 26.5 mmol sodium in 9 cm^3 mercury). The mixture was stirred vigorously for 14 h, during which time the solution changed color from wine-red to black-green and a grey precipitate (presumed to be sodium chloride) formed. The solution was decanted from the mercury and the residue washed twice with toluene (15 cm^3). The filtrate and washings were combined and set aside for 24 h to allow the suspended solids to settle. The mixture was then filtered three times, slowly, through acid-free Celite, giving a black residue and a black-green filtrate. The solution was reduced to a volume of 30 cm^3 under vacuum, frozen in liquid nitrogen and hexane (80 cm^3) was layered onto it. On setting aside at –25°C for two days, black $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ precipitated. This was collected by filtration, washed with cold hexane (20 cm^3), and dried under vacuum. The product was recrystallized from toluene/hexane (20:80) at –25°C. Yield: 0.32 g, 26%, based on molybdenum.

Reaction of $(\eta\text{-}C_5Me_5)MoCl_2(O)$ in toluene solution with sodium amalgam: formation of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$

A solution of $(\eta\text{-}C_5Me_5)MoCl_2(O)$ (2.16 g, 6.79 mmol) in toluene (100 cm^3) was added to sodium amalgam (1.61 g, 70.1 mmol sodium in 23.7 cm^3 mercury). The mixture was stirred vigorously for 14 h, during which time the solution changed color from brick-red to black-green and a grey precipitate (presumed to be sodium chloride) formed. Work-up of the reaction was the same as for the reduction of $[(\eta\text{-}C_5Me_5)MoCl(O)]_2(\mu\text{-}O)$ described above. Yield of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$: 0.48 g, 27%, based on molybdenum.

Reaction of $[(\eta\text{-}C_5Me_5)MoCl(O)]_2(\mu\text{-}O)$ in tetrahydrofuran solution with tributyltin hydride: formation of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ and $[(\eta\text{-}C_5Me_5)Mo(O)(\mu\text{-}O)]_2$

To an ice-cold solution of $[(\eta\text{-}C_5Me_5)MoCl(O)]_2(\mu\text{-}O)$ (2.09 g, 3.6 mmol) in tetrahydrofuran (100 cm^3) was added $Bu^n{}_3SnH$ (2.2 cm^3, 2.4 g, 8.3 mmol) by syringe, against an argon purge. The mixture was stirred for 24 h at room temperature. The color of the solution changed from red to dark brown and $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ precipitated. The mixture was filtered, giving a dark brown filtrate and a dark blue-green solid, which was washed with hexane and dried under vacuum. Yield: 0.42 g, 22%, based on molybdenum.

The dark-brown filtrate was reduced to a volume of 30 cm^3 under vacuum, then hexane (100 cm^3) was layered onto it, after which it was set aside for 24 h at –25°C. The orange crystals of $[(\eta\text{-}C_5Me_5)Mo(O)(\mu\text{-}O)]_2$ that precipitated were collected by filtration, washed with hexane (20 cm^3) and dried under vacuum. Yield: 0.29 g, 15%, based on molybdenum. IR: 913 cm^{-1} (vs, ν(Mo=O)), 713 cm^{-1}

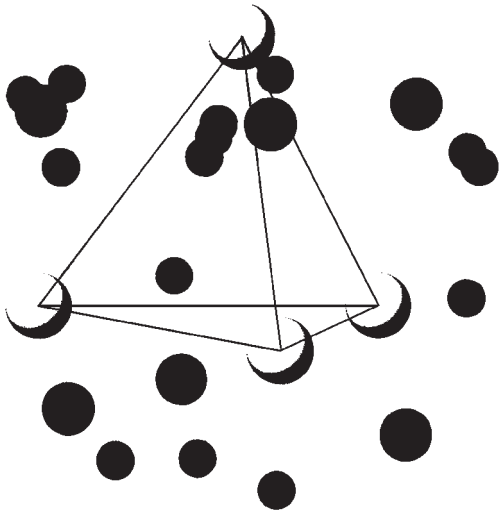
(s, δ(O-Mo=O)) (lit. (19): 914, 713 cm^{-1}). ^{1}H NMR (200 MHz, C^2HCl_3 solution): singlet, 1.97 ppm (lit. for *cis*-$[(\eta\text{-}C_5Me_5)Mo(O)(\mu\text{-}O)]_2$: 1.93 ppm (14), 1.97 ppm (19)). MS (EI, 70 eV) (*m/e*, % abundance, assignment): 526, 74, $\{C_{20}H_{30}Mo_2O_4\}^+$ ($\{[(C_5Me_5)MoO_2]_2\}^+$), with the appropriate isotopic pattern and fragments.

Reaction of $(\eta\text{-}C_5Me_5)MoCl_2(O)$ in tetrahydrofuran solution with tributyltin hydride: formation of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$

To an ice-cold solution of $(\eta\text{-}C_5Me_5)MoCl_2(O)$ (0.79 g, 2.5 mmol) in tetrahydrofuran (100 cm^3) was added $Bu^n{}_3SnH$ (4.2 cm^3, 4.51 g, 15.6 mmol) by syringe, against an argon purge. The mixture was stirred in an ice bath for 11 h, during which time the color of the solution changed from brick red to black-green. The solution was reduced to a volume of 30 cm^3 under vacuum, layered with hexane (60 cm^3) and set aside at –25°C for two days. The black precipitate of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ that formed was collected by filtration, washed twice with hexane (2 × 20 cm^3), and dried under vacuum. Yield: 0.22 g, 34%, based on molybdenum.

Reaction of $[(\eta\text{-}C_5Me_5)MoCl(O)]_2(\mu\text{-}O)$ in tetrahydrofuran solution with lithium nitride: formation of $[(\eta\text{-}C_5Me_5)Mo(O)(\mu\text{-}O)]_2$

A solution of $[(\eta\text{-}C_5Me_5)MoCl(O)]_2(\mu\text{-}O)$ (1.56 g, 2.68 mmol) in tetrahydrofuran (80 cm^3) was added to a suspension of lithium nitride (0.065 g, 1.87 mmol) in tetrahydrofuran (20 cm^3) and the mixture stirred for 14 h while warming to room temperature. The color of the solution changed from red to dark green. The mixture was then filtered through acid-free Celite and the volume of the filtrate reduced to 30 cm^3 under vacuum. The solution was then frozen in liquid nitrogen and hexane (60 cm^3) was layered onto it. On setting aside at –25°C for two days, a dark orange precipitate of $[(\eta\text{-}C_5Me_5)Mo(O)(\mu\text{-}O)]_2$ formed. This was collected by filtration, washed with cold hexane (20 cm^3), and dried under vacuum. It was recrystallized from toluene/hexane (20:80). Yield: 0.54 g, 38%, based on molybdenum. The product had identical spectroscopic properties to those given above for $[(\eta\text{-}C_5Me_5)Mo(O)(\mu\text{-}O)]_2$, obtained from $[(\eta\text{-}C_5Me_5)MoCl(O)]_2(\mu\text{-}O)$ and $Bu^n{}_3SnH$.



Characterization of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$

X-ray diffraction

The crystals of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ used for X-ray diffraction experiment A (see Table 1) were obtained by setting aside saturated toluene solutions of the material produced by reduction of $[(\eta\text{-}C_5Me_5)MoCl(O)]_2(\mu\text{-}O)$ with sodium amalgam, at room temperature for 10 weeks. Crystals B, C, and D were obtained by setting aside saturated toluene solutions

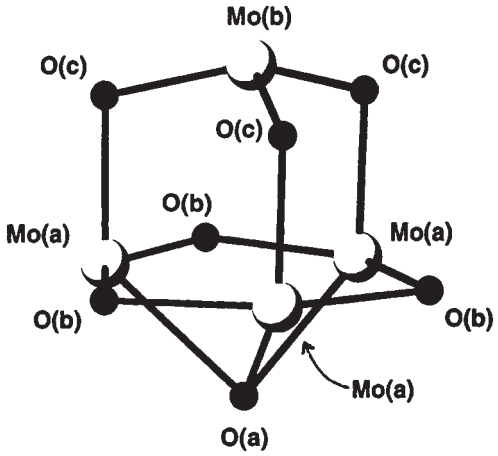
Fig. 1. Sites of electron density greater than 1.0 e $Å^{-3}$ in a difference Fourier map of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ phased on the $[(\eta\text{-}C_5Me_5)Mo]_4$ unit, determined using data from crystal C.

of material produced by reduction of $(\eta\text{-}C_5Me_5)MoCl_2(O)$ with sodium amalgam, at room temperature for four days, 19 weeks and eight weeks, respectively. Data common to the four crystals: empirical formula = $C_{40}H_{60}Mo_4O_7$, M_r = 1036.67, class = triclinic, space group = $P\bar{1}$, D_c = 1.67 mg m^{-3}, Z = 2, MoKα radiation, λ = 0.71073 Å, μ(MoKα) = 12.0 cm^{-1}. Other details of the crystals, data collection, and refinements are given in Table 1.

Identification and refinement of the tetrahedral $[(\eta\text{-}C_5Me_5)Mo]_4$ unit of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ (Mo = 2.91 Å) was routine in all four of the determinations, but the oxygen atoms in the Mo_4O_7 core were severely disordered. This was unexpected, since the unit cell and distribution of intensities for $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ were very similar to those of $[(\eta\text{-}C_5Me_5)M]_4(\mu\text{-}O)_6$ (M = Ti (8), V (7)) and $[(\eta\text{-}C_5Me_5)Cr(\mu_3\text{-}O)]_4$ (6), in which the M_4O_n cores were not disordered. Fig. 1 shows the 21 sites of electron density greater than 1.0 e $Å^{-3}$ in a difference Fourier synthesis phased on the $[(\eta\text{-}C_5Me_5)Mo]_4$ unit after isotropic refinement of the data from crystal C (Table 1). These sites were of three types. Four, designated O(a), with electron densities of 1.0 e $Å^{-3}$, bridged the three molybdenum atoms of each of the four Mo_3 faces of the tetrahedron. Eleven, designated O(b), with electron densities of 2.9–1.1 e $Å^{-3}$, bridged two molybdenum atoms and were located over the edges of each of the four Mo_3 faces of the tetrahedron. Six, designated O(c), with electron densities of 4.6–3.6 e $Å^{-3}$, bridged two molybdenum atoms and were located over the edges of the Mo_4 tetrahedron. It was found after many trials, which included structure **4**, that the correct geometry for the Mo_4O_7 core of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ was **3** (Fig. 2). The sites shown in Fig. 1 were observed because the μ_3-oxygen atom (O(a)) may bridge any of the four triangular faces of the tetrahedron, with the six μ_2-oxygen atoms (three O(b) and three O(c)) oriented accordingly. The short distance between oxygen atom sites of different orientations and further disorder in the $\eta\text{-}C_5Me_5$ ligand attached to Mo(3) prevented anisotropic refinement of these atoms. The refinements included the hydrogen atoms in fixed calculated positions, with C—H = 1.08 Å and $U_{eq}(H) = 0.01 + U_{eq}(C)$ (26). Tables of final parameters and derived distances and angles for all four crystals are available in the supplementary material.[2] The average metrical parameters are presented in Table 2 and a thermal ellipsoid plot of one orientation, using data from crystal C of Table 1, is shown in Fig. 3.

Fig. 2. Numbering scheme for the Mo_4O_7 core of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$.



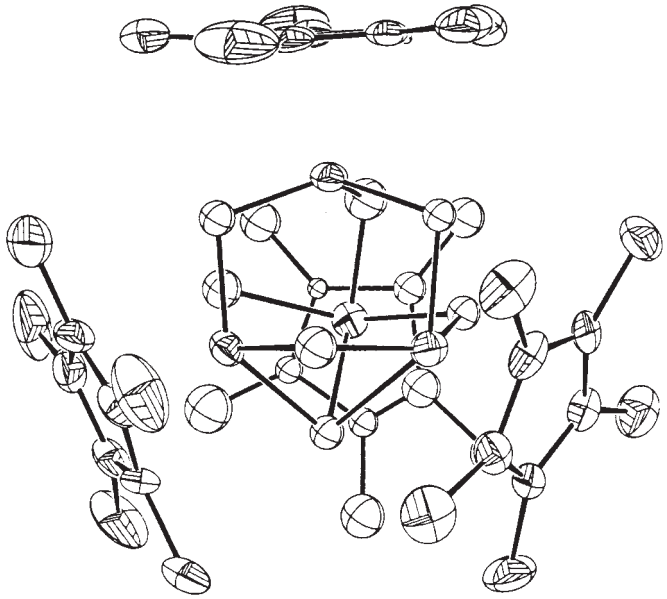


Fig. 3. Thermal ellipsoid plot of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$. The data were taken from crystal C. Only one of the four orientations of the Mo_4O_7 core of the cluster is shown.

Mass spectra

The assignments of the ions observed in the FAB mass spectrum of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ are given in Table 3. Representative spectra in NOBA, thioglycerol, dithiothrei-

[i]Distance of O(c) from the Mo(centroid)Mo(a)Mo(b) plane.

tol/dithioerythritol (magic bullet), and 2-nitrophenyl(octyl)ether as matrices are given in the supplementary material. There are seven naturally occurring isotopes of molybdenum: ^{92}Mo (natural abundance 14.8%), ^{94}Mo (9.3), ^{95}Mo (15.9), ^{96}Mo (16.7), ^{97}Mo (9.6), ^{98}Mo (24.1), ^{100}Mo (9.6). Thus, distinctive clusters of ions were observed. The isotopic distribution was calculated by simulation, using C, H, Mo, O, and Cl. The spectra were in excellent agreement with the structure of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ proposed below. Specifically, the parent ion $\{[(C_5Me_5)Mo]_4O_7\}^+$, was the most abundant of those ions with m/z > 400 and all $\{(C_5Me_5)_nMo_4O_7\}^+$ fragment ions for n = 3 – 0 were observed. Also observed were the fragment ions $\{(C_5Me_5)_nMo_3O_4\}^+$ (n = 3 – 0), derived from $[(C_5Me_5)Mo]_4O_7$ by loss of the $(C_5Me_5)Mo(b)(O(c))_3$ unit (see Fig. 2). A noticeable feature of all the mass spectra was the complete absence of the parent ions or fragments of $\{[(C_5Me_5)Mo]_4O_6\}^+$ or $\{[(C_5Me_5)MoO)]_4\}^+$.

^{1}H NMR spectra

The 200 MHz spectrum of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ ($C_6{}^2H_6$ solution, 298 K) is shown in Fig. 4. Three signals were observed: 16.3 ppm ($\Delta\nu_{1/2}$ = 113 Hz), 1.89 ppm ($\Delta\nu_{1/2}$ = 4 Hz), 1.69 ppm ($\Delta\nu_{1/2}$ = 5 Hz). The 400 MHz spectrum (C^2HCl_3 solution, 298 K) showed: 16.3 ppm ($\Delta\nu_{1/2}$ = 98 Hz), 1.99 ppm ($\Delta\nu_{1/2}$ = 3.5 Hz), 1.68 ppm ($\Delta\nu_{1/2}$ = 21 Hz). The assignments are discussed below.

Magnetism

The cluster $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ was paramagnetic, with μ_{eff} = 1.26 μ_B at 300 K in the solid state and μ_{eff} = 1.43 μ_B at 298 K in C^2HCl_3 solution (Evans NMR method). The magnetic behavior is shown as a function of temperature in Figs. 5 and 6 and discussed below. Complete magnetic data are given in the supplementary material.[2]

Infrared spectra

In addition to absorption bands assigned to vibrations of the η-C_5Me_5 ligands, an intense band at 707 cm^{-1} (KBr pellet) was assigned to a vibration of the Mo_4O_7 core.

Analyses

Calculated for $C_{40}H_{60}Mo_4O_7$: C 46.3, H 5.8; found, C 40.1, H 5.8; C 40.5, H 5.3. The former microanalysis was by the University of British Columbia microanalytical facility. The latter was by Galbraith Laboratories, Knoxville, TN and was reproduced on a different sample. We have no explanation for the low carbon analyses. Fettinger et al. (27) attributed similar low carbon analyses for related molybdenum compounds to "incomplete combustion".

Results and discussion

Formation of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$

The cluster $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ was formed by reaction of a toluene solution of either $[(\eta\text{-}C_5Me_5)MoCl(O)]_2(\mu\text{-}O)$ or $(\eta\text{-}C_5Me_5)MoCl_2(O)$ with sodium amalgam, or by reaction of a tetrahydrofuran solution of the same complexes with tributyltin hydride. The coproduct $[(\eta\text{-}C_5Me_5)Mo(O)(\mu\text{-}O)]_2$ (14, 19, 26) was isolated from the reaction between $[(\eta\text{-}C_5Me_5)MoCl(O)]_2(\mu\text{-}O)$ and tributyltin hydride. The reaction between toluene solutions of $[(\eta\text{-}C_5Me_5)MoCl(O)]_2(\mu\text{-}O)$ or $(\eta\text{-}C_5Me_5)MoCl_2(O)$ and magnesium amalgam or between

[c]$\{(NOBA)H\}^+ = 100$.

[d]Calculated using ^{96}Mo and ^{35}Cl.

tetrahydrofuran solutions of the same complexes and magnesium turnings also gave $[(\eta\text{-}C_5Me_5)Mo]_4O_7$, but the product was contaminated with insoluble impurities. Only $[(\eta\text{-}C_5Me_5)Mo(O)(\mu\text{-}O)]_2$ was isolated from the reaction between lithium nitride and $[(\eta\text{-}C_5Me_5)MoCl(O)]_2(\mu\text{-}O)$. The most convenient preparation of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ was the reduction of $[(\eta\text{-}C_5Me_5)MoCl(O)]_2(\mu\text{-}O)$ by sodium amalgam. The only difficulty was that repeated recrystallization was required to remove colloidal sodium chloride.

The reaction between $[(\eta\text{-}C_5Me_5)MoCl(O)]_2(\mu\text{-}O)$ and tributyltin hydride gave $[(\eta\text{-}C_5Me_5)Mo(O)(\mu\text{-}O)]_2$ (14, 19, 26) and the mass spectra of the crude products of all of the reactions which formed $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ showed an ion envelope at *m/z* = 527, assigned to $\{(C_5Me_5)_2Mo_2O_4\}^+$ (see Table 3). The mass spectra also showed ion envelopes at *m/z* = 599 and 564. These were assigned to $\{(C_5Me_5)_2Mo_2Cl_4\}^+$ and $\{(C_5Me_5)_2Mo_2Cl_3\}^+$, respectively. The ^1H NMR spectra (benzene solution) of crude samples of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$, prepared by any of the reactions, showed narrow resonances at 1.78 ppm and 1.83 ppm, assigned to $[(\eta\text{-}C_5Me_5)Mo(O)(\mu\text{-}O)]_2$ (14, 19) and $[(\eta\text{-}C_5Me_5)Mo(\mu\text{-}Cl)_2]_2$ (29, 30). Thus $[(\eta\text{-}C_5Me_5)Mo(O)(\mu\text{-}O)]_2$ was a coproduct of all the reactions. It is believed that $[(\eta\text{-}C_5Me_5)Mo(\mu\text{-}Cl)_2]_2$ was also a coproduct, but neither it, nor any other compound containing chlorine, was isolated in significant quantities. A probable reason for this is that monomeric $(\eta\text{-}C_5Me_5)MoCl_n$ (n = 2 (30), 3 (31), 4 (29, 32)) are insoluble in toluene or tetrahydrofuran and would therefore be removed in the first stage of work-up.

The formation of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ on reduction of either $[(\eta\text{-}C_5Me_5)MoCl(O)]_2(\mu\text{-}O)$ or $(\eta\text{-}C_5Me_5)MoCl_2(O)$ was very surprising. A cluster with an oxygen to molybdenum ratio of 1.75:1, containing no chloride and with a formal oxidation state of Mo_4^{18+}, was formed by treatment of $[(\eta\text{-}C_5Me_5)MoCl(O)]_2(\mu\text{-}O)$ (Mo^{5+}, O:Mo = 1.5:1, Cl:Mo = 1:1) or $(\eta\text{-}C_5Me_5)MoCl_2(O)$ (Mo^{5+}, O:Mo = 1:1, Cl:Mo = 2:1) with a powerful reducing agent. There were no extraneous sources of oxygen or chlorine. Thus a disproportionation involving both ligand exchange and electron exchange must have occurred. We observed a related disproportionation in the concurrent formation of $[(\eta\text{-}C_5Me_5)V]_4(\mu\text{-}O)_6$ and $[(\eta\text{-}C_5Me_5)V(\mu\text{-}Cl)_2]_3$ on reduction of $(\eta\text{-}C_5Me_5)VCl_2(O)$ (eq. [1]) (3).

$$[1]\quad 18(\eta\text{-}C_5Me_5)VCl_2(O) + 24/n[Red] \rightarrow 3[(\eta\text{-}C_5Me_5)V]_4(\mu\text{-}O)_6 + 2[(\eta\text{-}C_5Me_5)V(\mu\text{-}Cl)_2]_3 + 24/n[Red]Cl_n$$

In the present case, the products of the reactions between $[(\eta\text{-}C_5Me_5)MoCl(O)]_2(\mu\text{-}O)$ or $(\eta\text{-}C_5Me_5)MoCl_2(O)$ and sodium, magnesium or $Bu^n{}_3SnH$ were $[(\eta\text{-}C_5Me_5)Mo]_4O_7$, $[(\eta\text{-}C_5Me_5)Mo(\mu\text{-}Cl)_2]_2$ and $[(\eta\text{-}C_5Me_5)Mo(O)(\mu\text{-}O)]_2$. A reasonable scheme for the formation of these products is given by reactions [2]–[7].

$$[2]\quad (\eta\text{-}C_5Me_5)MoCl_2(O) + 1/n[Red] \rightarrow (\eta\text{-}C_5Me_5)MoCl(O) + 1/n[Red]Cl_n$$

[3] $2(\eta\text{-}C_5Me_5)MoCl(O) \rightarrow [(\eta\text{-}C_5Me_5)Mo(\mu\text{-}Cl)(\mu\text{-}O)]_2$

[4] $[(\eta\text{-}C_5Me_5)Mo(\mu\text{-}Cl)(\mu\text{-}O)]_2 \rightarrow (\eta\text{-}C_5Me_5)MoCl_2 + (\eta\text{-}C_5Me_5)MoO_2$

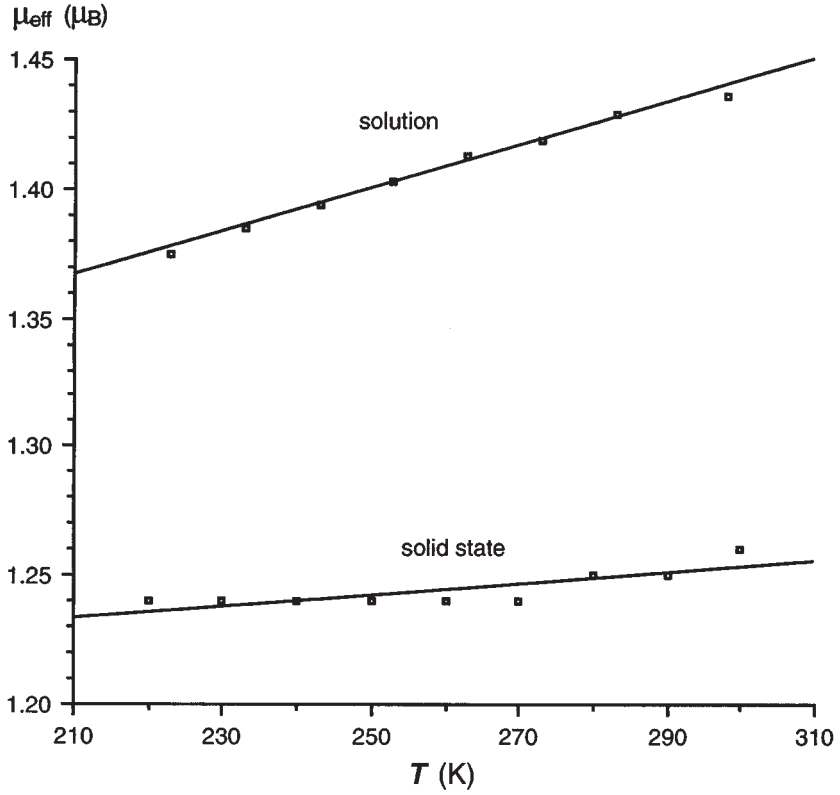
[5] $(\eta\text{-}C_5Me_5)MoCl_2(O) + (\eta\text{-}C_5Me_5)MoO_2 \rightleftharpoons [(\eta\text{-}C_5Me_5)MoCl(O)]_2(\mu\text{-}O)$

[6] $[(\eta\text{-}C_5Me_5)MoCl(O)]_2(\mu\text{-}O) + 2/n[Red] \rightarrow [(\eta\text{-}C_5Me_5)Mo(O)]_2(\mu\text{-}O) + 2/n[Red]Cl_n$

[7] $[(\eta\text{-}C_5Me_5)Mo(O)]_2(\mu\text{-}O) + (\eta\text{-}C_5Me_5)MoO_2 \rightarrow [(\eta\text{-}C_5Me_5)Mo]_4O_7$

The overall equation for the formation of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ from $[(\eta\text{-}C_5Me_5)MoCl(O)]_2(\mu\text{-}O)$ and sodium amalgam is [8] and based on this, the yield of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ was 40%. The overall equation for the formation of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ from $[(\eta\text{-}C_5Me_5)MoCl(O)]_2(\mu\text{-}O)$ and $Bu^n{}_3SnH$ is [9] and the yield of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ was 34% and of $[(\eta\text{-}C_5Me_5)Mo(O)(\mu\text{-}O)]_2$, 92%. The overall equation for the formation of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ from $(\eta\text{-}C_5Me_5)MoCl_2(O)$ and sodium amalgam is [10] and the yield was 61%.

[8] $6[(\eta\text{-}C_5Me_5)MoCl(O)]_2(\mu\text{-}O) + 8Na \rightarrow 2[(\eta\text{-}C_5Me_5)Mo]_4O_7 + [(\eta\text{-}C_5Me_5)Mo(O)(\mu\text{-}O)]_2 + [(\eta\text{-}C_5Me_5)Mo(\mu\text{-}Cl)_2]_2 + 8NaCl$



[9] $6[(\eta\text{-}C_5Me_5)MoCl(O)]_2(\mu\text{-}O) + 8Bu^n{}_3SnH \rightarrow 2[(\eta\text{-}C_5Me_5)Mo]_4O_7 + [(\eta\text{-}C_5Me_5)Mo(\mu\text{-}Cl)_2]_2 + [(\eta\text{-}C_5Me_5)Mo(O)(\mu\text{-}O)]_2 + 8Bu^n{}_3SnCl + 4H_2$

[10] $18(\eta\text{-}C_5Me_5)MoCl_2(O) + 20Na \rightarrow 2[(\eta\text{-}C_5Me_5)Mo]_4O_7 + [(\eta\text{-}C_5Me_5)Mo(O)(\mu\text{-}O)]_2 + 4[(\eta\text{-}C_5Me_5)Mo(\mu\text{-}Cl)_2]_2 + 20NaCl$

Reaction of $[(\eta\text{-}C_5Me_5)MoCl(O)]_2(\mu\text{-}O)$ with Li_3N gave $[(\eta\text{-}C_5Me_5)Mo(O)(\mu\text{-}O)]_2$, but no $[(\eta\text{-}C_5Me_5)Mo]_4O_7$, which indicated that Li_3N could not accomplish complete reduction of $[(\eta\text{-}C_5Me_5)MoCl(O)]_2(\mu\text{-}O)$ (reaction [6]). The cluster $[(\eta\text{-}C_5Me_5)Mo]_4(\mu\text{-}O)_6$ was not observed, presumably because the $[(\eta\text{-}C_5Me_5)Mo(O)]_2(\mu\text{-}O)$, produced by reaction [6], was captured by excess $(\eta\text{-}C_5Me_5)Mo(O)_2$ before dimerization occurred. The cubane cluster $[(\eta\text{-}C_5Me_5)Mo(\mu_3\text{-}O)]_4$ was not formed in any of the reactions, which indicated that none of the starting complexes or intermediates could be reduced to $(\eta\text{-}C_5Me_5)MoO$. Compounds of type $(\eta\text{-}C_5R_5)Mo^{III}O_mL_n$ have not been reported to our knowledge, presumably because it is not possible to reduce molybdenum to the oxidation state of III in compounds containing $\eta\text{-}C_5R_5$ and oxygen ligands. Therefore we are pessimistic that a $[(\eta\text{-}C_5P_5)Mo(\mu_3\text{-}O)]_4$ cubane can be synthesized.

Fig. 6. Comparison of the magnetic moment of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ in the solid state and in chloroform solution, over the temperature range 220–300 K.

Chemical properties of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$

The cluster $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ was a black, crystalline material which rapidly turned light brown on exposure to air. It was soluble in tetrahydrofuran and dichloromethane, moderately soluble in toluene and diethyl ether, but insoluble in hexane. These trends in solubility were similar to those of $[(\eta\text{-}C_5Me_5)M(\mu_3\text{-}O)]_4$ (M = V (3), Cr (6)), but in contrast to $[(\eta\text{-}C_5Me_5)V(\mu_3\text{-}N)]_4$ (18) and $[(\eta\text{-}C_5Me_5)M]_4(\mu\text{-}O)_6$ (M = Ti (8), V (7, 10)), which were very soluble in toluene and hexane. The reason for the differences in solubilities of these clusters is not clear, since they all have an essentially identical sheath of four $\eta\text{-}C_5Me_5$ ligands surrounding a tetrahedral Mo_4O_n core of similar size. The cluster reacted slowly with protonic reagents such as water or solvents such as chloroform to form a brown material that would not redissolve in any solvent. Evidence for the decomposition was the broadening of the signal at 16.3 ppm in the ^1H NMR spectrum, which was assigned to $[(\eta\text{-}C_5Me_5)Mo]_4O_7$, the appearance of a new signal at 11.5 ppm ($\Delta\nu_{1/2}$ = 440 Hz), and the formation of a precipitate. Decomposition also occurred in the solid state, unless the cluster was completely dry.

Structure of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ as determined by X-ray diffraction

The molecular structure of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ is shown in Fig. 3, the numbering scheme for the Mo_4O_7 core in Fig. 2 and the average distances and angles are given in Table 2. Because all of the crystals were small thin plates that did not diffract well and because of the severe disorder of the oxygen atoms, the accuracy of an individual determination was not high. However, this was compensated by the large number of independent measurements of a particular distance or angle.

It is seen from Table 2 and Fig. 3, that $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ contained an essentially planar, six member $[Mo(a)(\mu\text{-}O(b))]_3$ ring, in which there was a long-short alternation of the Mo(a)—O(b) distances. The six-member ring was capped on one side by the μ_3-oxygen atom (O(a)) and on the other side by three μ_2-oxygen atoms (O(c)) which connected the Mo(a) atoms of the ring to the Mo(b) atom. The O(c) atoms were located over the edges of the tetrahedron of molybdenum atoms, with Mo(a), O(c), Mo(b), and the centroid of the molybdenum atoms, forming an essentially perfect plane. Because of the alternation in the Mo(a)—O(b) distances, the octahedral packing of the O(b) and O(c) atoms was distorted, the O(b)–Mo(a)–O(c)–Mo(b) torsion angle being 70° instead of 60°.

The Mo(a)—Mo(a) and Mo(a)—Mo(b) distances in $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ should not be equal, because Mo(a) is seven-coordinate whereas Mo(b) is six (Figs. 2 and 3). Due to the disorder in the Mo_4O_7 core, only random variations in the Mo—Mo distances were observed; the average was 2.909 (3) Å. This distance is identical to that found in $(\eta\text{-}C_5R_5)_2(\eta\text{-}C_5R'_5)_2Mo_4(\mu_3\text{-}S)_4$ cubanes (2.902 (1) Å for R_5 = MeH_4, R′ = Me (33); 2.904 (1) Å for R = R′ = Pr^iH_4 (34, 35)). The determining factor in the Mo—Mo distance is the size and coordination number of oxygen or sulfur. Although sulfur is larger than oxygen, there are only four sulfur atoms in $(\eta\text{-}C_5R_5)_2(\eta\text{-}C_5R'_5)_2Mo_4(\mu_3\text{-}S)_4$ compared to seven oxygen atoms in $[(\eta\text{-}C_5Me_5)Mo]_4O_7$. The average Mo—Mo distance

© 2000 NRC Canada

for the three basal molybdenum atoms in $(\eta\text{-}C_5Me_5)_4Mo_5O_{11}$ was 2.731 (2) Å (16) and in $(\eta\text{-}C_5Me_5)_6Mo_8O_{16}$ it was 2.744 (1) Å (15). These distances are shorter than those in $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ because the three basal molybdenum atoms were bridged by both three μ_2- and three μ_3-oxygen atoms. There are several triangular clusters of general formulae $[L_mMo(\mu_2\text{-}OR)]_3(\mu_3\text{-}OR)_n(\mu_3\text{-}O)$ (m = 2 for n = 1, m = 3 for n = 0, R = H, R′, or zero) with single Mo—Mo bonds, in which the range of Mo—Mo distances is 2.48–2.80 Å (36–39).

The average Mo—(μ_3-O(a)) distance in $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ is 2.19 (5) Å, which is longer than the range of 1.95–2.05 Å observed in other molybdenum clusters containing the $[Mo(\mu_2\text{-}OR)]_3(\mu_3\text{-}O)$ unit (31, 37, 38, 40–45). The longer distance is ascribed to the planarity of the $[Mo(a)(\mu_2\text{-}O(b)]_3$ unit, which exerted steric pressure on the μ_3-oxygen.

An interesting feature of the $[(\eta\text{-}C_5Me_5)Mo(a)(\mu\text{-}O(b))]_3(\mu_3\text{-}O(a))$ unit of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ was the long-short alternation of the Mo(a)—O(b) distances on proceeding around the planar $[Mo(a)(\mu\text{-}O(b))]_3$ ring (Table 2). The overall average for the long Mo(a)—O(b) distances was 2.00 Å and for the short, 1.87 Å. A similar alternation appeared in the planar $[Mo(\mu\text{-}O)]_4$ rings of the polyoxometalates $[Mo_6O_{19}]^{2-}$ (46, 47), $[(\eta\text{-}C_5H_5)TiMo_5O_{18}]^{3-}$ (48), $[(\eta\text{-}C_5Me_5)Mo_6O_{18}]^-$ (49, 50), $[Mo_6O_{18}(N(\eta\text{-}C_5H_4))Fe(\eta\text{-}C_5H_5)]^{2-}$ (51) and $[W_6O_{18}(NAr)]^{2-}$ (52). Che et al. (48) ascribed this alternation to "off-center displacement of molybdenum atoms within a rigid, close-packed oxygen framework", a form of *trans* influence within the eight-membered $[Mo(\mu\text{-}O)]_4$ rings. This influence cannot be operative in the six-membered $[Mo(a)(\mu\text{-}O(b))]_3$ ring of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ and was not observed in any of the triangular $[L_mMo(\mu_2\text{-}OR)]_3(\mu_3\text{-}OR)(\mu_3\text{-}O)$ clusters, with the exception of $\{[(\eta\text{-}C_5H_5)Mo(CO)(\mu_2\text{-}CO)]_3(\mu_3\text{-}O)\}^+$, in which the Mo—($\mu_2$-CO) distances alternated, the shorter being 2.26 Å and the longer 2.49 Å (40). The alternation in the Mo—(μ_2-CO) distances was ascribed to an asymmetrical "freezing" of the fluxional migration of carbonyl ligands around the triangle of molybdenum atoms (40).

The cluster $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ appears to be the first example of a molybdenum oxide with a tetrahedral $[(\eta\text{-}C_5Me_5)Mo]_4$ unit to be structurally characterized. The cubanes $\{(\eta\text{-}C_5R_5)_2(\eta\text{-}C_5R'_5)_2Mo4(\mu_3\text{-}A)_4\}^{n+}$ (**1**) have been structurally characterized for $R_5 = R'_5 = Pr^iH_4$, A = S or Se, n = 0 (53) and A = S, n = 1 or 2 (34, 35); $R_5 = MeH_4$, R′ = Me, A = S, n = 0 (34). The only oxides which have been structurally characterized are $(\eta\text{-}C_5Me_5)_4Mo_5O_{11}$ (16) and $(\eta\text{-}C_5Me_5)_6Mo_8O_{16}$ (15), which contain distorted tetrahedra, with only three of the molybdenum atoms carrying $\eta\text{-}C_5Me_5$ ligands.

Magnetic properties of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$

The magnetism of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ in the solid state was determined using samples which were obtained by rapid precipitation from toluene solution on adding a large quantity of hexane. No macroscopic crystals were visible in these samples. The reciprocal susceptibility and magnetic moment are plotted as functions of temperature over the range 2–300 K in Fig. 5. The effective moment was 1.26 μ_B at 300 K and was virtually independent of temperature, except for a marked decrease at very low temperatures which indicated a weak zero field splitting. The cluster $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ has an even number of electrons, and must therefore have zero or two unpaired electrons, corresponding to $S = 0$ or $S = 1$, respectively. In agreement with this, the cluster did not show any EPR signal at temperatures of 150 K and above. The observed moment was greater than zero, but it was very much less than the spin-only value for two unpaired electrons per cluster (2.83 μ_B). Therefore the data were treated as arising from a sample which was a mixture of two forms, one with $S = 0$ and one with $S = 1$.

The expression for the molar magnetic susceptibility, χ_m, of an $S = 1$ system with zero field splitting is given in eq. [11] (54), where $x = D(kT)^{-1}$ and $C = Ng^2\beta^2(kT)^{-1}$, D being the zero field splitting parameter. The data were modelled using eq. [12], with $g = 2.00$ and the temperature independent paramagnetism (*TIP*) for both forms, the fraction of the sample in the $S = 1$ form (P), and D as variables in a least-squares fitting procedure that minimized the function F, defined in eq. [13].

$$[11]\quad \chi_m = 3^{-1}C[(2e^{-x})(1 + 2e^{-x})^{-1} + 2(2x^{-1})(1 - e^{-x})(1 + 2e^{-x})^{-1}]$$

$$[12]\quad \chi^{calc} = P(\chi_m) + TIP$$

$$[13]\quad F = \left[1/n\sum_{i=1}^{n}((\chi_i^{obs} - \chi_i^{calc})^2(\chi_i^{obs})^{-2})\right]^{0.5}$$

The best fit was obtained with $D = 2.24$ (6) cm^{-1}, $TIP = 64\ (2) \times 10^{-6}$ and $P = 0.176$, for which parameters $F = 0.0085$. This analysis indicated that 17.6% of the sample had $S = 1$, the remainder $S = 0$. The good agreement between the calculated and observed data is shown by the low value of F, and is illustrated in Fig. 5. The magnetic behaviour of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ was also determined over the temperature range 223–298 K in chloroform solution, by the Evans NMR method (55, 56). The effective moment decreased linearly from 1.44 (±0.01) to 1.37 (±0.01) μ_B on cooling from 298 to 223 K. The decrease was completely reversed on warming from 223 K back to 298 K. Since $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ must have either $S = 0$ or $S = 1$, the low magnetic moment in solution must be due to the sample being a mixture of two forms, one with $S = 0$ and one with $S = 1$, as discussed above for the solid state.

The magnetic behaviour in solution is compared to that in the solid state in Fig. 6. In the solid state, the form of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ having $S = 1$ was paramagnetic and the effective moment did not vary significantly with temperature over the range 220–300 K. The slope of the moment vs. temperature line for the solution sample is greater than the slope in the solid state, due to the change in the concentration of the paramagnetic form of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ with temperature. The reversibility of the change in moment with temperature showed that the two forms were in equilibrium with one another in solution. The system was treated as an equilibrium between a paramagnetic form of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ (which had $S = 1$ and a temperature independent spin-only moment of 2.83 μ_B) and a diamagnetic form. The standard eq. [14], relating magnetic susceptibility and moment, was used to calculate $\chi_{(S=1)}$ and the fraction of the sample which had $S = 1$ was then calculated using eq. [15]. It was determined

© 2000 NRC Canada

that 25.7% of the sample had $S = 1$ at 298 K and 23.4% at 223 K.

[14] $\mu_{B(S = 1)} = 2.828(\chi_{(S = 1)}T)^{0.5}$

[15] $P = \chi^{obs}(\chi_{(S = 1)})^{-1}$ ($\cong (\chi^{obs})T$)

^{1}H NMR spectra of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$

The ^{1}H NMR spectrum (200 MHz) of a benzene solution of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ is shown in Fig. 4. The broad resonance at 16.3 ppm ($\Delta\nu_{1/2}$ = 113 Hz) was assigned to the protons of $\eta\text{-}C_5Me_5$ attached to an Mo_4O_7 core that had a magnetic moment. The narrow resonances at 1.89 ppm ($\Delta\nu_{1/2}$ = 4 Hz) and 1.69 ppm ($\Delta\nu_{1/2}$ = 5 Hz) were assigned to the protons of $\eta\text{-}C_5Me_5$ attached to a diamagnetic Mo_4O_7 core. The integrated intensity of the resonance at 1.89 ppm and the integrated intensity of the resonance at 1.69 ppm were in a 1:1 ratio. The integrated intensity of the resonance at 16.3 ppm and the sum of the integrated intensities of the resonances at 1.89 ppm and 1.69 ppm were in a ratio of approximately 1:1.4. At 400 MHz in C^2HCl_3 solution at 298 K, the resonances were at 16.3 ppm ($\Delta\nu_{1/2}$ = 98 Hz), 1.93 ppm ($\Delta\nu_{1/2}$ = 3.5 Hz), and 1.67 ppm ($\Delta\nu_{1/2}$ = 21 Hz). In this solvent, both the shift and the line-width of the resonance at 16.3 ppm decreased with increasing temperature. A plot of the reciprocal of the magnitude of the shift as a function of temperature was linear, as expected for a paramagnetic species (4, 57). The ^{1}H NMR spectrum therefore showed that there were two forms of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$, one diamagnetic and one with a magnetic moment, which were in equilibrium in solution.

Structure of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ in the solid state and in solution

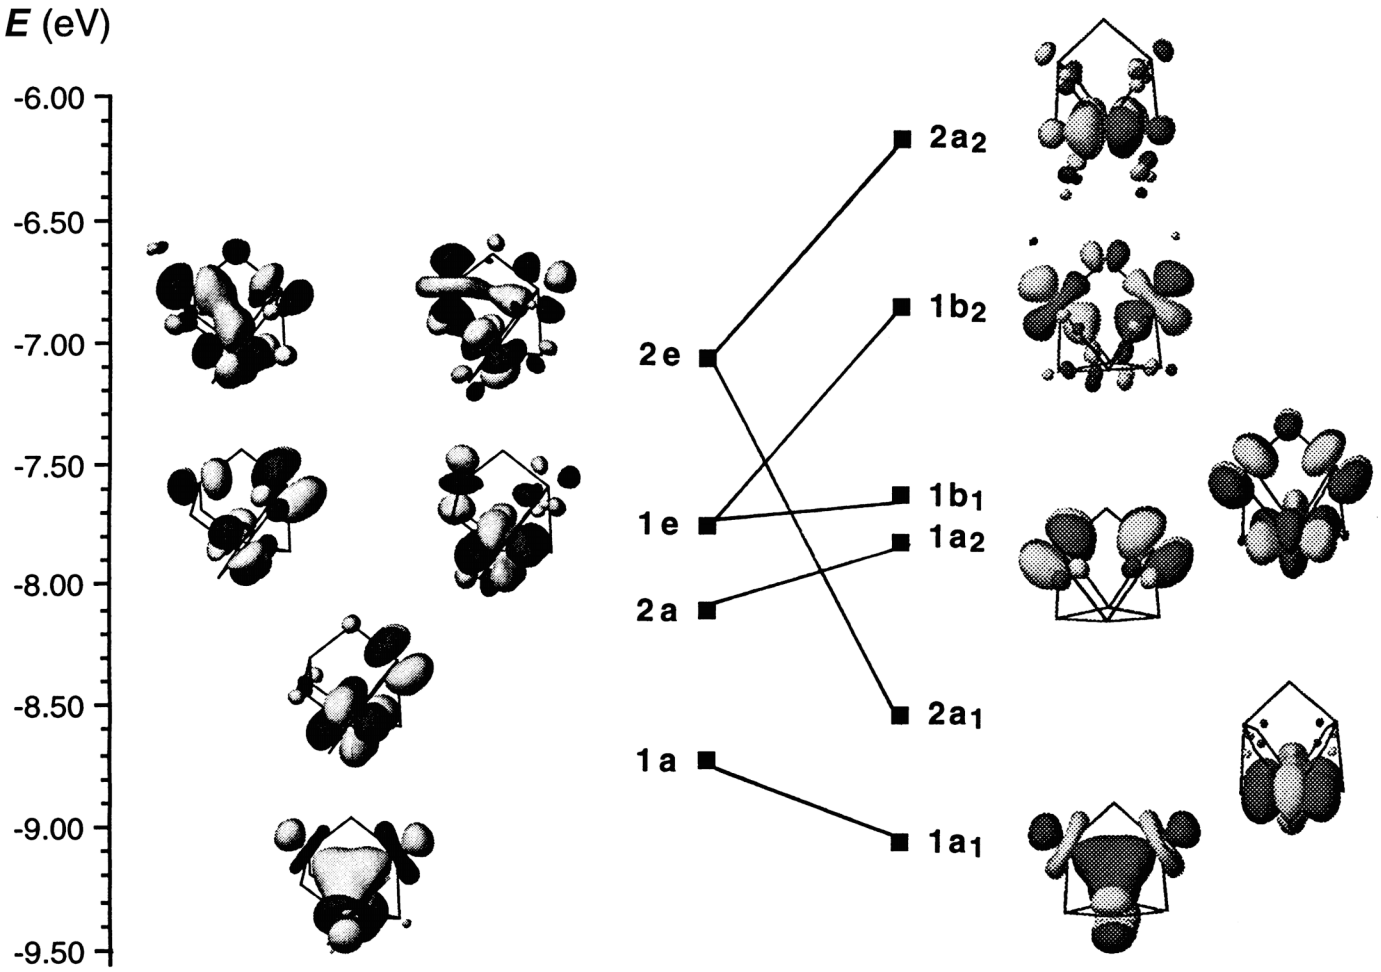
The geometry of the Mo_4O_7 core of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ can be described as $Mo_4(\mu_2\text{-}O(b))_3(\mu_2\text{-}O(c))_3(\mu_3\text{-}O(a))$ (**3**, C_3 symmetry, see Fig. 2). The only other M_4A_7 cores occur as $Mo_4(\mu_2\text{-}I(b))_4(\mu_2\text{-}I(c))(\mu_3\text{-}I(a))_2$ in $[Mo_4I_{11}]^{2-}$ (M = Mo (58–60), W (61)) (**4**, C_{2v} symmetry) and as $Ta_4(\mu_2\text{-}O(b))_4(\mu_3\text{-}O(a))_2(\mu_4\text{-}O)$ in $[(\eta\text{-}C_5Me_5)Ta]_2[(\eta\text{-}C_5Me_5)Ta(OH)]_2O_7$ (62) (**5**, C_{2v} symmetry). Conversion of **3** into **4** requires the formation of one Mo—O(a) bond, movement of two O(c) atoms into O(b) positions, and a relatively small distortion of the Mo_4 tetrahedron. Conversion of **3** into **5** requires the formation of one Mo—O(a) bond, two Mo—(μ_4-O) bonds, and a very large distortion of the Mo_4 tetrahedron.

In the ^{1}H NMR spectrum of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ (Fig. 4), the resonances at 1.89 ppm ($\Delta\nu_{1/2}$ = 4 Hz) and 1.69 ppm ($\Delta\nu_{1/2}$ = 5 Hz), which had a 1:1 intensity ratio, must be assigned to equal numbers of two types of $\eta\text{-}C_5Me_5$ attached to diamagnetic ($S = 0$) Mo_4O_7 and the resonance at 16.3 ppm ($\Delta\nu_{1/2}$ = 113 Hz) must be assigned to $\eta\text{-}C_5Me_5$ attached to paramagnetic ($S = 1$) Mo_4O_7. Therefore paramagnetic $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ had an Mo_4O_7 core with the geometry **3** and diamagnetic $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ had an Mo_4O_7 core with the geometry **4** or **5**. The magnetic results and the ^{1}H NMR spectra showed that the two forms of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ were in equilibrium with one another in solution, suggesting only a small change in the geometry of the Mo_4O_7 core. It is concluded that paramagnetic ($S = 1$) $[(\eta\text{-}C_5Me_5)Mo]_4O_7$, having an Mo_4O_7 core with the geometry **3**, was in equilibrium with diamagnetic ($S = 0$) $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ having an Mo_4O_7 core with the geometry **4**. These two forms were also present in the solid state, although only **3** was obtained as macroscopic crystals. The cluster $[(\eta\text{-}C_5Me_4Et)Mo]_2[(SPh)Co]_2(\mu_3\text{-}S)_4$ had a mixture of $S = 1$, $S = 2$, and $S = 3$ forms in the solid state and also a contribution from $S = 0$ in solution (63). It is the only other cluster which behaved like $[(\eta\text{-}C_5Me_5)Mo]_4O_7$.

The energy levels for the cluster orbitals of $[(\eta\text{-}C_5H_5)Mo]_4O_7$ with the Mo_4O_7 core having the geometry **3** or **4** were calculated by the extended Hückel method. The calculation on $[(\eta\text{-}C_5H_5)Mo]_4O_7$ with the Mo_4O_7 geometry **3** (C_3 symmetry) used the distances: Mo—Mo = 2.909 Å, Mo(a)—O(a) = 2.175 Å, Mo(a)—O(bl) = 1.975 Å, Mo(a)—O(bs) = 1.920 Å, Mo(a)—O(c) = 1.90 Å, Mo(b)—O(c) = 1.78 Å. The energy level diagram for the cluster orbitals is shown in Fig. 7. This diagram predicts that $[(\eta\text{-}C_5H_5)Mo]_4O_7$, which has six cluster electrons, will have the ground state $1a^2\ 2a^2\ 1e^2\ 2e^0$ and $S = 1$. The results are in agreement with the observed paramagnetism ($S = 1$) of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ with the Mo_4O_7 geometry **3**.

The calculation on $[(\eta\text{-}C_5H_5)Mo]_4O_7$ with the Mo_4O_7 geometry **4** (C_{2v} symmetry) used the Mo—Mo distances found in $[Mo_4I_{11}]^{2-}$: Mo(a)—Mo(a) = 2.55 Å, Mo(b)—Mo(b) = 3.05 Å, Mo(a)—Mo(b) = 2.70 Å; and the Mo—O distances: Mo—O(a) = 2.10 Å, Mo—O(b) = Mo—O(c) = 1.90 Å (59). The ground state was predicted to be $1a_1^2\ 2a_1^2\ 1a_2^2\ 1b_1^0$ and $S = 0$, with a HOMO–LUMO gap of 0.183 eV (17.7 kJ mol^{-1}, 1478 cm^{-1}). This provides further evidence that the form of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ with the Mo_4O_7 geometry **4** was diamagnetic. The correlation between the orbital energy levels for the C_3 and C_{2v} geometry is shown in Fig. 7. This diagram was obtained by assuming that both **3** and **4** were derived from an Mo_4O_7 unit with T_d symmetry. The most striking feature of the diagram is the split in the 2e level on going from $[(\eta\text{-}C_5H_5)Mo]_4O_7$ with the C_3 geometry **3** to $[(\eta\text{-}C_5H_5)Mo]_4O_7$ with the C_{2v} geometry **4**. Two factors may be responsible for these changes in the energies of the orbitals: the formation of a new Mo—(μ_3-O) bond on going from **3** to **4** and changes in the extent of Mo—(μ_2-O) π-bonding.

Conclusions



Disproportionation of $[(\eta\text{-}C_5Me_5)MoCl(O)]_2(\mu\text{-}O)$ or $(\eta\text{-}C_5Me_5)MoCl_2(O)$ on reduction by sodium or magnesium amalgam, magnesium turnings, or tributyltin hydride produced $[(\eta\text{-}C_5Me_5)Mo]_4O_7$. Crystals of $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ contained a tetrahedral $[(\eta\text{-}C_5Me_5)Mo]_4$ unit with the Mo_4O_7 core having the geometry **3**. The magnetic moment and NMR spectra showed that $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ existed in two forms, which were in equilibrium in solution. One form was paramagnetic ($S = 1$) $[(\eta\text{-}C_5Me_5)Mo]_4O_7$, with an Mo_4O_7 core which had the geometry **3** (C_3 symmetry). The other form was diamagnetic ($S = 0$) $[(\eta\text{-}C_5Me_5)Mo]_4O_7$ with an Mo_4O_7 core which had the geometry **4** (C_{2v} symmetry).

Peptide models XXVII. An exploratory ab initio study on the 21st amino acid side-chain conformations of *N*-formyl-L-selenocysteinamide (For-L-Sec-NH_2) and *N*-acetyl-L-selenocysteine-*N*-methylamide (Ac-L-Sec-NHMe) in their γ_L backbone conformation

Judith C. Vank, Carlos P. Sosa, Andras Perczel, and Imre G. Csizmadia

Abstract: Selenocysteine is expected to have 9 × 9 = 81 conformations [3 × 3 = 9 backbone: ψ (g^+,a,g^-) × ϕ (g^+,a,g^-) and 3 × 3 = 9 side-chain: χ_1 (g^+,a,g^-) × χ_2 (g^+,a,g^-)]. In the present study, all the torsional modes of the side-chain (χ_1: rotation about the C^α—C^β and χ_2: rotation about the C^β—Se bonds) were investigated in the relaxed γ_L backbone [(ϕ,ψ); (g^-,g^+)] conformation. Seven out of the nine expected minima were found at the RHF/3–21G level of theory for *N*-formyl-L-selenocysteinamide (For-L-Sec-NH_2) and *N*-acetyl-L-selenocysteine-*N*-methylamide (Ac-L-Sec-NHMe). The stabilization energy exerted by the -CH_2-SeH side-chain has been compared with that of -CH_2-SH and -CH_2-OH. Relative energies of the various conformers were also obtained via single point calculations at the B3LYP/6–31G(d,p) level of theory. Topological analysis of the electron density has been performed by Bader's Atoms in Molecule (AIM) approach using the results. The structures were also optimized at the B3LYP/6–31+G(d,p) level of theory.

Key words: selenocysteine side-chain conformations, ab initio MO study, Multidimensional Conformational Analysis (MDCA), Atoms in Molecules (AIM), Bader's electron density analysis.

Résumé : En théorie, la sélénocystéine peut avoir 9 × 9 = 81 conformations [3 × 3 = 9 squelettes: ψ(g^+,a,g^-) × ϕ(g^+,a,g^-) et 3 × 3 = 9 chaînes latérales: χ_1(g^+,a,g^-) × χ_2(g^+,a,g^-)]. Dans la présente étude, on a étudié tous les modes de torsion de la chaîne latérale (χ_1: rotation autour de C^α—C^β et χ_2: rotation autour des liaisons C^β—Se) dans la conformation détendue γ_L du squelette [(ϕ,ψ); (g^-,g^+)]. Opérant au niveau RHF/3–21G de la théorie, on a trouvé sept des neuf minima des *N*-formyl-L-sélénocystéinamide (For-L-Sec-NH_2) et *N*-acétyl-L-sélénocystéine-*N*-méthylamide (Ac-L-Sec-NHMe). On a comparé l'énergie de stabilisation exercée par la chaîne latérale -CH_2-SeH avec celles de -CH_2-SH et -CH_2-OH. On a obtenu les énergies relatives des divers conformères par le biais de calculs ponctuels au niveau B3LYP/6–31G(d,p) de la théorie. À l'aide de ces résultats, on a effectué une analyse topologique de la densité d'électrons à l'aide de l'approche de Bader des atomes dans la molécule. On a aussi optimisé les structures au niveau B3LYP/6–31+G(d,p) de la théorie.

Mots clés : sélénocystéine, conformations, chaîne latérale, étude d'OM ab initio, analyse conformationnelle multidimensionnelle, atomes dans la molécule, analyse, densité électronique, Bader.

[Traduit par la Rédaction]

1. Introduction

Selenocysteine is expected to exhibit a variety of side-chain/backbone interactions via hydrogen bonding and via intramolecular attractive non-covalent (i.e., charge transfer) interactions. This may occur between di- and tetracoordinated selenium from one side and oxygen or nitrogen atoms of neighbouring backbone amide groups from the other side. These interactions strongly affect the reactivity of selenocysteine and enhance the stability of a Se containing compound (1) analogously to sulfur–oxygen nonbonded interactions (2). They are also responsible for the high biological activity of the selenium, in particular selenoproteins and in nucleoside analogues. The conformation of the peptides

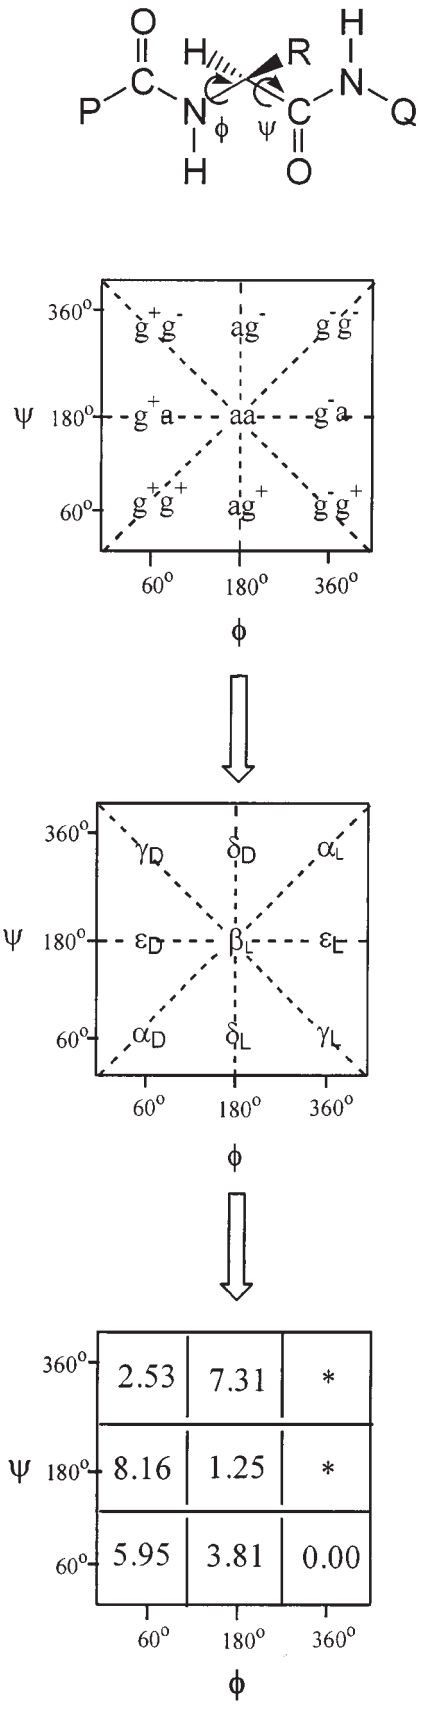

Fig. 1. Topological representation of the Ramachandran PES for an N- and C-protected amino acid (P and Q may be H or CH_3). The bottom matrix shows the relative energies for HCO-NH-CHMe-$CONH_2$ with *trans*-peptide bond computed at the RHF/3–21G level of theory.

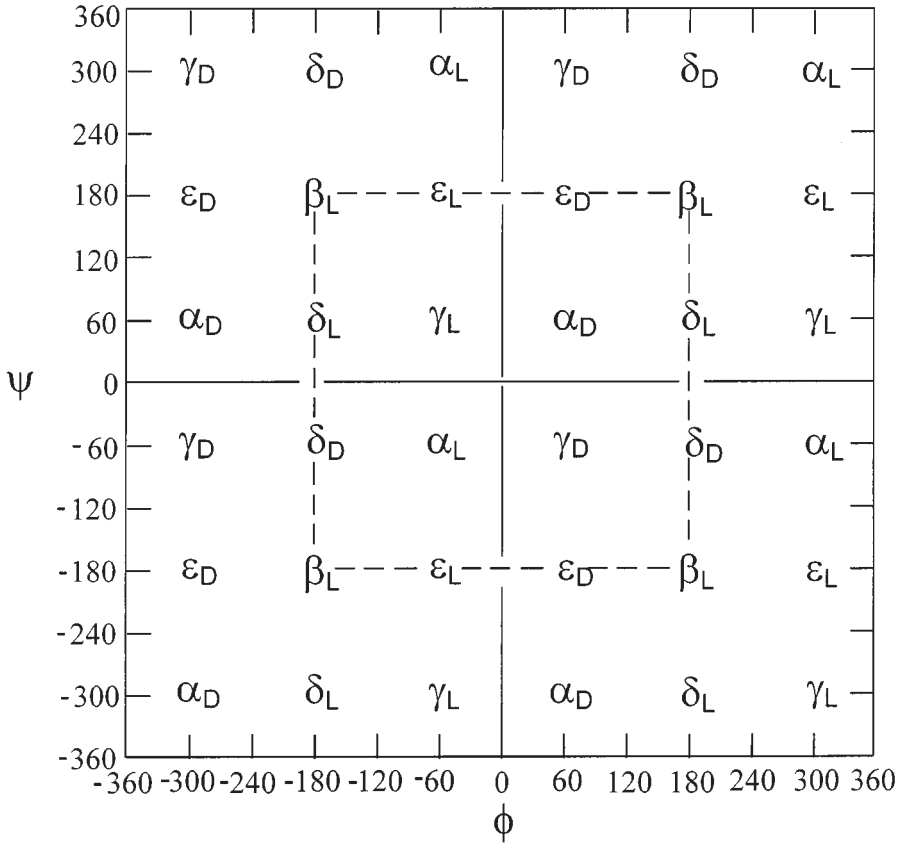
Table 1. Total energy values of the component molecules for isodesmic reactions.

Molecular System		Energy (Hartree)
P-CONH-CH_2-CONH-Q	P = Q = H	–373.648790
	P = Q = Me	–451.2942433
CH_3-R where R = CH_2-SeH		–2467.271761
CH_3-H		–39.976877

as well as the conformation (i.e., folding) of proteins can be defined in terms of the conformations of the amino acid residues. In general, peptides with *trans*-peptide bonds are studied, therefore, ω is optimized in the vicinity of 180°. Each protein molecule is folded in a particular way to fulfill its biological function. It has been the working hypothesis for some time that the primary structure (i.e., the sequence of the amino acids) predetermines the secondary and tertiary structures (global fold) of proteins (3). The very fact that every protein has a different amino acid sequence and a different folding pattern strongly suggests that the influence of amino acid side-chains on protein folding must be great. The global minimum for all peptides containing a single amino acid residue that have been studied computationally so far is the γ_L conformation (4). This is illustrated for *N*-formyl-L-alaninamide in Fig. 1.

2. Computational method



2.1 Conformational analysis

As a first approach, the nine side-chain conformations of the selenocysteine in its γ_L backbone conformation (cf. Ramachandran topology in Fig. 2) were determined, using the MDCA suggested input (5–7). The computation of the entire surface requires 12 × 12 = 144 SCF points if the grid search is executed by 30° increments. Although the resulting potential energy-surface is undoubtedly very visual, it also requires extensive CPU time. For this reason, in addition to geometry optimizations of the minima, only selected 1D cross-sections (i.e., potential energy curves: PEC) of the side-chain potential energy surface (PES) were generated. IUPAC–IUB recommended (8) the use of $-180° \le \chi_1 \le 180°$ and $-180° \le \chi_2 \le 180°$ torsional angles, where $0° \rightarrow +180°$ represents clockwise rotation and $0° \rightarrow -180°$ represents counterclockwise rotation.

However, occasionally for graphic presentation, we also use the traditional cut ($0° \le \chi_1 \le 360°$ and $0° \le \chi_2 \le 360°$) suggested previously by Ramachandran and Sasisekharan (9). The use of the latter is for sheer convenience since the nine minima are located within the traditional cut rather than on the edges and at its four corners (cf. Fig. 2).

© 2000 NRC Canada

Fig. 2. Topological representation of the Ramachandran map for an N- and C-protected amino acid PCO-NH-CHR-CO-NHQ (P and Q may be H or CH_3) showing two full cycles of rotation: $-360° \le \phi \le +360°$; $-360° \le \psi \le +360°$. The central box, denoted by broken line, represents the cut suggested by the IUPAC convention ($-180° \le \phi \le +180°$; $-180° \le \psi \le +180°$). The four quadrants denoted by solid lines are the conventional cuts (e.g., $0° \le \phi \le +360°$; $0° \le \psi \le +360°$). Most L-peptide residue exhibit nine unique conformations labeled as α_L, β_L, γ_L, δ_L, ε_L, α_D, γ_D, δ_D, and ε_D.

2.2 Molecular computations

To investigate the effects of side-chain/backbone conformational interactions, calculations were performed using GAUSSIAN 94[2] at RHF/3–21G (10) level of theory, which seemed suitable for the purpose of comparing similar results obtained for serine (11, 12) and even though the current trend is to rely on larger basis sets at a higher level of theory (13, 14). Single point calculations were carried out at B3LYP/6–31G(d,p) level of theory to compare to the relative energy values ($\Delta E_{rel.}$) computed at RHF/3–21G level of theory. The structures were also optimized at the B3LYP/6–31+G(d,p) level of theory.

2.3 Stabilization energies

The stabilization energies were calculated with respect to the γ_L backbone conformation of N- and C- protected glycine (15, 16) using the following isodesmic (same number of bonds) reaction, where P and Q may be H or CH_3 and R = CH_2-SeH.

$$\text{PCONH-CH}_2\text{-CONHQ} + \text{CH}_3\text{-R} \quad (\text{conformation } \gamma_L) \rightarrow \text{PCONH-CHR-CONHQ} + \text{CH}_3\text{-H} \quad (\text{conformation X})$$

The stabilization energy may be calculated as follows:

$$\Delta E_{\text{stabilization}} = \{E\,[\text{PCONH-CHR-CONHQ}]_X + E[\text{CH}_3\text{-H}]\} - \{E\,[\text{PCONH-CH}_2\text{-CONHQ}]_{\gamma L} + \text{CH}_3\text{-R}]\}$$

The components' energy values are summarized in Table 1.

The results of the structure optimizations, namely, geometrical parameters, total energies, relative energies, and stabilization energies as well as HOMO, LUMO energies obtained at the RHF/3–21G level of theory and B3LYP/6–31G(d,p)//RHF/3–21G are given in Table 2; similarly, the re-

sults of the full geometry optimization at B3LYP/6–31+G(d,p) level of theory are given in Table 3. The total, as well as the HOMO and LUMO energies are given in hartrees and the relative energies ($\Delta E_{rel.}$) and stabilization energies ($\Delta E_{stab.}$) are given in kcal mol^{-1} (using the conversion factor: 1 hartree = 627.5095 kcal mol^{-1}). The numbering system used for *N*-acetyl-L-selenocysteine-*N*-methylamide (P = Q = Me) and *N*-formyl-L-selenocysteinamide (P = Q = H) is shown in Fig. 3.

2.4 Topological analysis of electron densities

The topological analysis of electron density has been performed on the basis of Bader's theory of atoms in molecules (AIM) (17). In this theory, the topological properties of the electron density distribution were derived from the gradient vector field of the electron density $\nabla\rho(\mathbf{r})$ and on the Laplacian of the electron density $\nabla^2\rho(\mathbf{r})$. A critical point in the electron density, called the *bond critical point* (BCP), where $\nabla\rho = 0$, is formed for two interacting atoms in a molecule. A pair of gradient paths, which originate at a BCP and terminate at neighbouring nuclei define a *bond path*. The necessary condition for two atoms to be bonded to one another is therefore that their nuclei be linked by a bond path. The bond path is considered to be "a universal indicator of bonded interactions" (18). The method is widely used for the determination of hydrogen bonding (19).

3. Results and discussion

3.1. Structural characteristics

A relevant question is what atomic attributes does Se have that makes its presence necessary for enzyme activity and what accounts for the conformational differences of selenocysteine, if any, with respect to that of cysteine and serine? The similarities and differences of selenocysteine, cysteine, and serine hinge on the similarities and differences of the -CH_2SeH, -CH_2SH, and -CH_2OH groups. The Se atom is larger than that of S and O atoms and has a greater polarizability, hence it is a better nucleophile (20, 21). Since Se forms weaker σ-bonds than S, many reactions that involve the cleavage of C—Se, N—Se, or O—Se bonds are more rapid than cleavage of analogous bonds to sulfur (22, 23). The Se—C, Se—N, and Se—O bonds are shorter than the respective van der Waals contacts. Se is oxidized somewhat more easily to Se(IV) but with more difficulty to Se(VI) than the corresponding sulfur oxidations.

3.2 Conformational study

The nine side-chain conformations predicted by Multidimensional Conformational Analysis (MDCA) have been optimized at RHF/3–21G level of theory for N- and C-protected selenocysteine. For a non-ideal system, however, some of the expected conformers may disappear. This phenomenon is referred to as the annihilation of critical points (24, 25). The knowledge of all conformers with their relative energies ($\Delta E_{rel.}$) makes it possible to determine a conformational equilibrium distribution for the molecular system.

For φ and ψ input parameters, values characteristic for the γ_L conformation, –84.4° and +67.7° respectively (25), were used. However, they were allowed to relax during geometry optimization. The φ, ψ values thus are optimized, which

N-Formyl-L-Sec-amide

means that they change quantitatively but not qualitatively. The computations were carried out for both *N*-acetyl-L-selenocysteine-*N*-methylamide and *N*-formyl-L-selenocysteinamide.

From the nine legitimate side-chain conformations two legitimate conformations [($g^+ g^-$), ($a\ a$)] were annihilated and seven conformations have been located by geometry optimization [($a\ g^-$), ($g^- g^-$), ($g^+ a$), ($g^- a$), ($g^+ g^+$), ($a\ g^+$), ($g^- g^+$)] as illustrated in Fig. 4. The γ_L ($a\ a$) conformation has migrated to a different catchment region, to the γ_L ($a\ g^+$) minimum, and the γ_L ($g^+ g^-$) structure has migrated to the γ_L ($g^+ a$) minimum. This migration affected extensively the χ_1 and χ_2 values but only marginally the ϕ and ψ values, which were slightly shifted from the original input values. The relative energies ($\Delta E_{rel.}$) for *N*-acetyl-L-selenocysteine-*N*-methylamide and *N*-formyl-L-selenocysteinamide have been calculated at RHF/3–21G, B3LYP/6–31G(d,p)//RHF/3–21G and B3LYP/6–31+G(d,p) levels of theory and are also included in Table 2 and Table 3 respectively.

The obtained results agree with those obtained for *N*-acetyl-L-cysteine-*N*-methylamide[3] but differ from the corresponding serine (11) results as shown in Fig. 5.

The lower part of Fig. 5 also shows the calculated stabilization energies ($\Delta E_{stabil.}$). Side-chain R (CH_2-SeH) has a steric effect on the peptide backbone and it is important to determine whether the overall effect is stabilizing or

Fig. 4. The annihilation of the two minima [(g^+ g^+), (a a)] on the side-chain PES of N- and C-protected selenocysteine. The two vertical arrows, pointing downward, indicate the shift in torsional angles during geometry optimization.

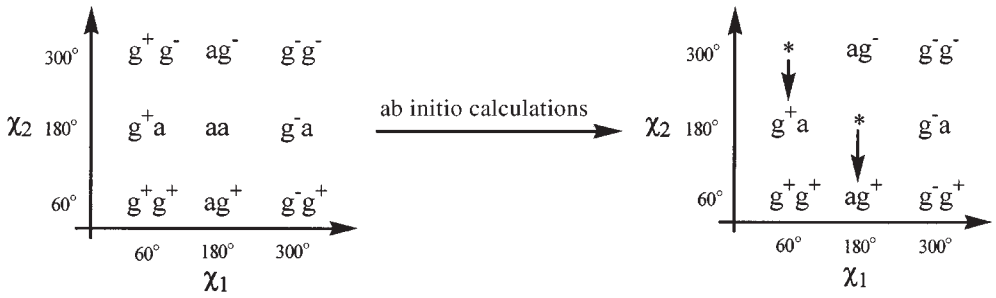

Fig. 5. Structures located on the side-chain PES of the γ_L backbone conformations of N- and C-protected serine, cysteine, and selenocysteine [HCO-NH-CH(CH_2-XH)-CO-NH_2]. The lower part of the figure collects the stabilization energies ($\Delta E_{stabil.}$), in kcal mol^{-1} units, exerted by the side-chain with respect to the glycine residue in its γ_L conformation.

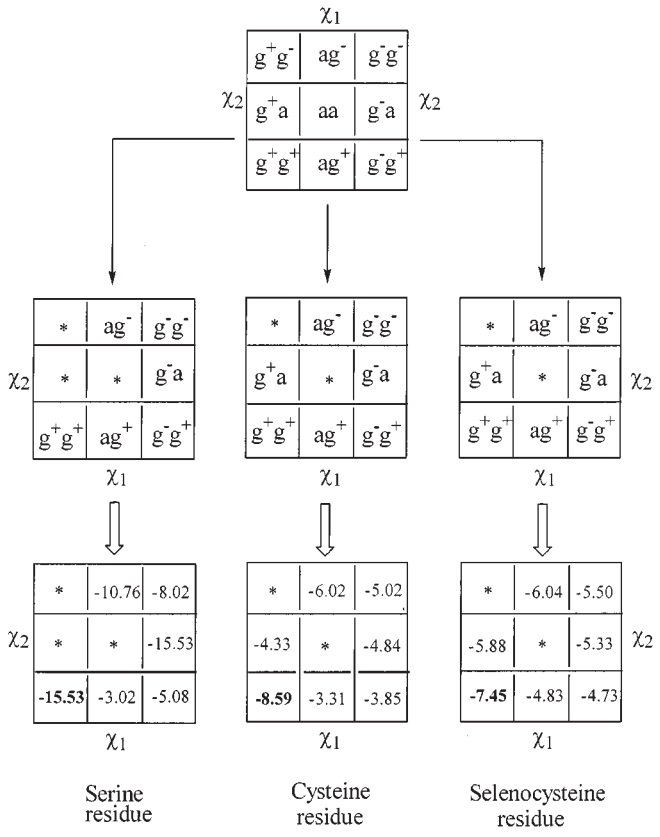

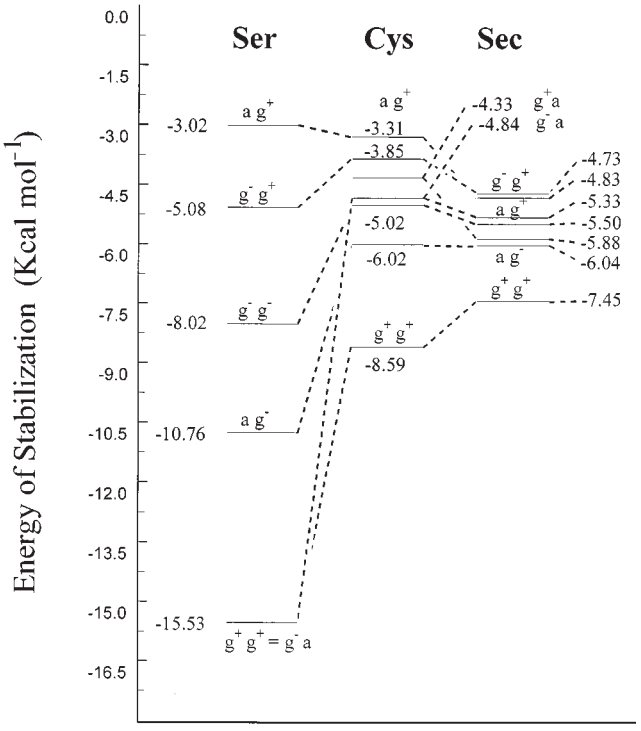

Fig. 6. Spectrum of conformational dependence of the side-chain stabilization energy on the γ_L backbone conformation of formyl ser-, cys-, and sec-amide.

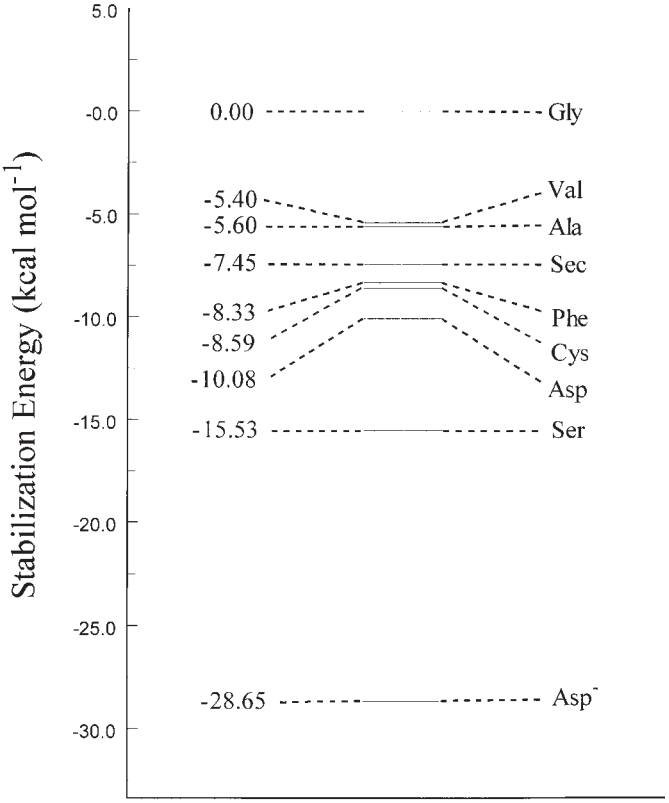
destabilizing. If the side-chain R contains a polar group, such as -SeH (or -OH, -SH), then the special H-bonded interactions may have specific stabilizing effects. The isodesmic reactions were constructed with the aid of the total energies summarized in Table 2 and Table 3 and of the other component molecules involved (Table 1). The energies of the isodesmic reactions measure the relative stabilities of analogous compounds containing O, S, Se (Fig. 6), or relative stabilities of different amino acids [Gly (26), Ala (27), Val (14), Phe (28–30), Asp (31), Ser (11, 32, 33), Cys[3]] with respect to glycine (Fig. 7).



From Fig. 6 we can observe that the effect of the orientation of the side-chain with respect to the peptide backbone, going from serine to selenocysteine, is gradually decreasing. This is due to increase in the size of the atoms O → S → Se and the resulting gradual lengthening of C—O → C—S → C—Se bond lengths as well as the reduced hydrogen bonding ability in going from OH to SH all the way to SeH.

In general, *N*-acetyl-L-*sec*-*N*-methylamide shows a greater stabilizing effect than *N*-formyl-L-*sec*-amide, however, the difference between the (g^+ g^+) conformers is only 0.01 kcal mol^{-1} which seems insignificant. The difference between the (a g^+) conformers of *N*-acetyl-L-*sec*-*N*-methylamide and *N*-formyl-L-*sec*-amide is the largest (1.13 kcal mol^{-1}).

The (g^+ g^+) conformer was subjected to a torsional angle scan at RHF/3–21G, where χ_1 was fixed at 52° and χ_2 was rotated every 30° between $0° \le \chi_2 \le 360°$. The value of χ_1 = 52° was chosen arbitrarily, taking into consideration that χ_1 = 51.9° is the torsional angle value of the optimized (g^+ g^+)

© 2000 NRC Canada

Fig. 7. Relative side-chain stabilization energy values of various side-chains in the γ_L backbone conformation of HCO-NH-CHR-CO-NH_2. Most side-chains have several conformations but here only the one, which exerted the greatest stabilization, is shown.

side-chain conformation of serine and $\chi_1 = 52.657°$ is the torsional angle value of the optimized (g^+ g^+) side-chain conformation of cysteine. The variation of the total molecular energy with a single torsional angle (χ_2) leads to a Potential Energy Curve (PEC), $E = E(\chi_2)$. The scan (Fig. 8) shows the existence of two minima, which confirms the existence of (g^+ g^+) and (g^+ *a*) and the annihilation of (g^+ g^-) at least at the RHF/3–21G level of theory. A second and a third scan, namely in the vicinity of conformer (*a a)*, were carried out in which case first χ_2 was fixed at 180° and χ_1 was rotated every 10° between $165° \le \chi_1 \le 195°$.

Secondly χ_1 was fixed at 180° and χ_2 has been rotated every 10° between $155° \le \chi_2 \le 195°$ (Fig. 9*a, b*).

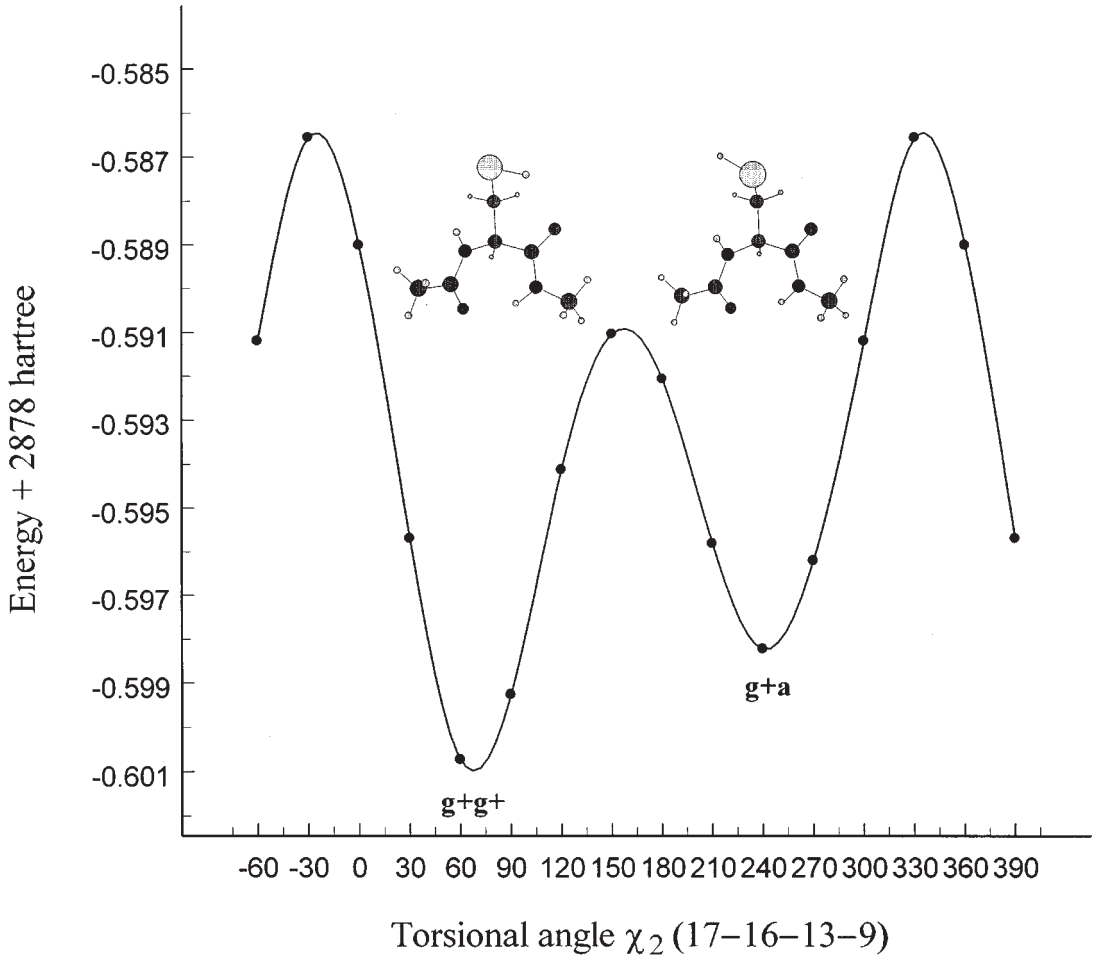
The two cross sections given in Fig. 9 clearly show that the (*a a*) conformation has indeed been anihilated. The (*a a*) conformer would exist if and only if both cross sections had a minimum energy point at or near 175°.

3.3 Intramolecular interactions

Intramolecular noncovalent attractive interactions exist between Se(II) or Se(IV) from one side and oxygen or nitrogen atoms from the other side. There is a strong dependence of the strength and length on the nature of the chalcogen atom, its valence state, and the electro-negativity of the attached substituents. These intra- and intermolecular contacts give rise to electrostatic effects, *d*-orbital participation and negative hyperconjugation (i.e., donation of an electron pair from the highest π or *n*-orbital of one center to the lowest lying σ^* orbital of the neighbouring center).

As presented in Fig. 10 the most important type of donor–acceptor interactions involve hydrogen bonding (i.e., O6···H19, O12···H17, Se16···H8 in *N*-acetyl-L-*sec*-*N*-methylamide as seen in **1b** and **1c** and O2···H15, O8···H13, Se12···H4 in *N*-formyl-L-*sec*-amide shown in **2b** and **2c** of Fig. 10). The hydrogen bonding between O6···H19 and O2···H15 is holding the backbone in the γ_L conformation and the last two structures of both molecules in Fig. 10 represent backbone/side-chain interactions.

Coordination or dative bonds (like those of Se16···O12 in *N*-acetyl-L-*sec*-*N*-methylamide, **1a** and Se12···O8 in *N*-formyl-L-*sec*-amide, **2a** of Fig. 10) may also form by the electron acceptor center (e.g., Se) with ligands donating electrons from lone-pairs or π orbitals (34, 35). In the case of the hydrogen bonding Brønsted complex (Fig. 10, **1c**, **2c**) the Se atom acquires a partial positive charge as it is accepting a proton. In contrast to the former, conformations **1a** and **2a** exhibit intramolecular Lewis complexes in which the Se acquires a partial negative charge, due to the transfer of electrons from the oxygen. In both *N*-acetyl-L-*sec*-*N*-methylamide and *N*-formyl-L-*sec*-amide, the interatomic distances between O6···H19, O12···H17 and O2···H15, O8···H13 are the shortest for the (g^+ g^+) conformations, which are the lowest in energy. Clearly, the geometrical proximity of the appropriate moieties in the (g^+ g^+) side-chain conformation is enhancing the intramolecular interaction, which in turn will lower the total molecular energy. In analyzing the (g^+ g^+) side-chain conformation, there seems to be no such correlation between the Se···N or Se···O interatomic distances and energy values.



Comparing the data of Table 2 with known atomic radii, we can see that certain Se16···N7 [(g^+ *a*), (g^+ g^+), (g^- g^-), (g^- *a*), and (g^- g^+) conformations], Se16···O12 [(g^+ *a*), (g^+g^+), and (*a* g^+) conformations] distanes of *N*-acetyl-L-*sec*-*N*-methylamide and Se12···N3 [(g^+ *a*), (g^+ g^+), (g^- g^-), (g^- *a*), and (g^- g^+) conformations], Se12···O8 [(g^+ *a*), (g^+ g^+), and (*a* g^+) conformations] distances of *N*-formyl-L-*sec*-amide fall between the sums of the non-bonded radii and that of van der Waals radii. This may indicate noticeable interactions. Elongation of C9—Se12 and C7—O8 bond lengths may accompany the interactions between Se···O and elongation of C9—Se12 and N3—H4 suggests Se···N interaction.

In four of the seven structures [(g^- g^-), (*a* g^+), (g^- *a*), and (g^- g^+)] there seems to be no hydrogen bonding between the side-chain -SeH group and the peptide backbone. In both cases, the Se12···H4 and O8···H13 distances in *N*-formyl-L-*sec*-amide are quite large (between 3.4 and 5.1 Å). Unlike serine, where both (g^+ g^+) and (g^- *a*) conformers are the lowest in energy (having the same value, probably due to accidental degeneracy), the most stable conformer of *sec* is (g^+ g^+). The least favoured is (g^- g^+) closely followed by (*a* g^+), both of which show slight destabilizing effects due to the lack of H-bonding.

The hydrogen bonds were verified by the existence of bond critical points in the A-H···B region. This was carried out by Bader's Atoms in Molecules (AIM) topological analysis of the electron density computed at the B3LYP/6–31G(d,p)//RHF/3–21G level of theory. Three conformations:

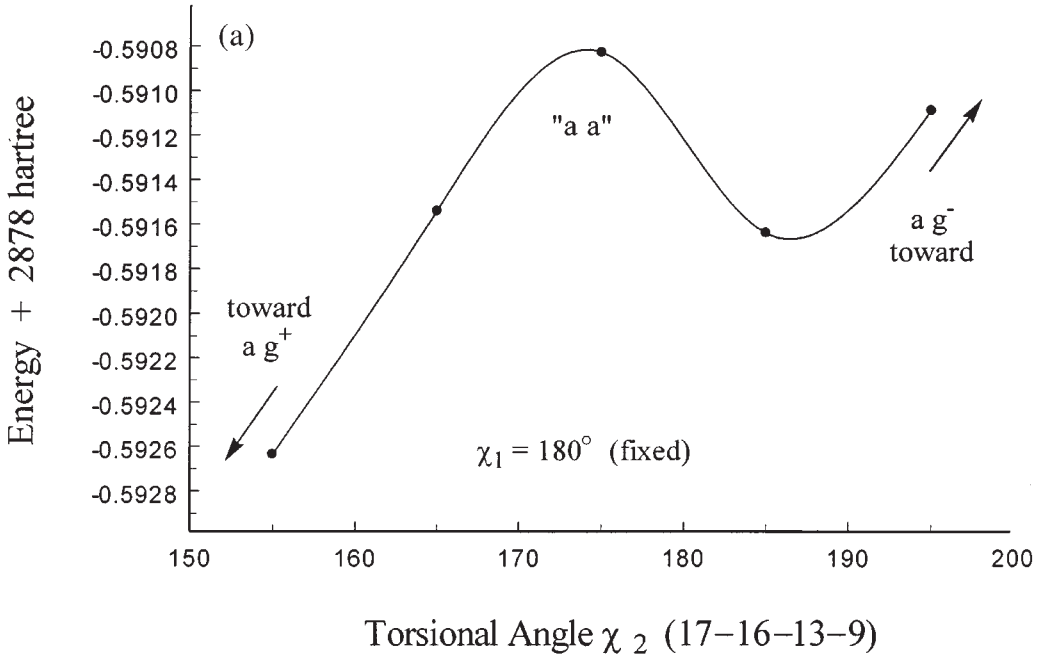
Fig. 8. Energy as a function of torsional angle χ_2 in Ac-L-Sec-NHMe including the (g^+ g^+) and (g^+ a) conformations. The value of χ_2 was incremented in 30° steps while χ_1 was fixed at 52° and the remaining geometrical parameters of the molecule were subjected to full geometry optimization.

(g^+ g^+), (g^+ a), and (a g^-) exhibited such interactions as illustrated graphically in Figs. 11, 12, and 13, for For-Sec-NH_2. The computed values obtained for Ac-Sec-NHMe and For-Sec-NH_2 reveal that the density (ρ_b) at the bond critical points of the various bonds assume roughly the following values:

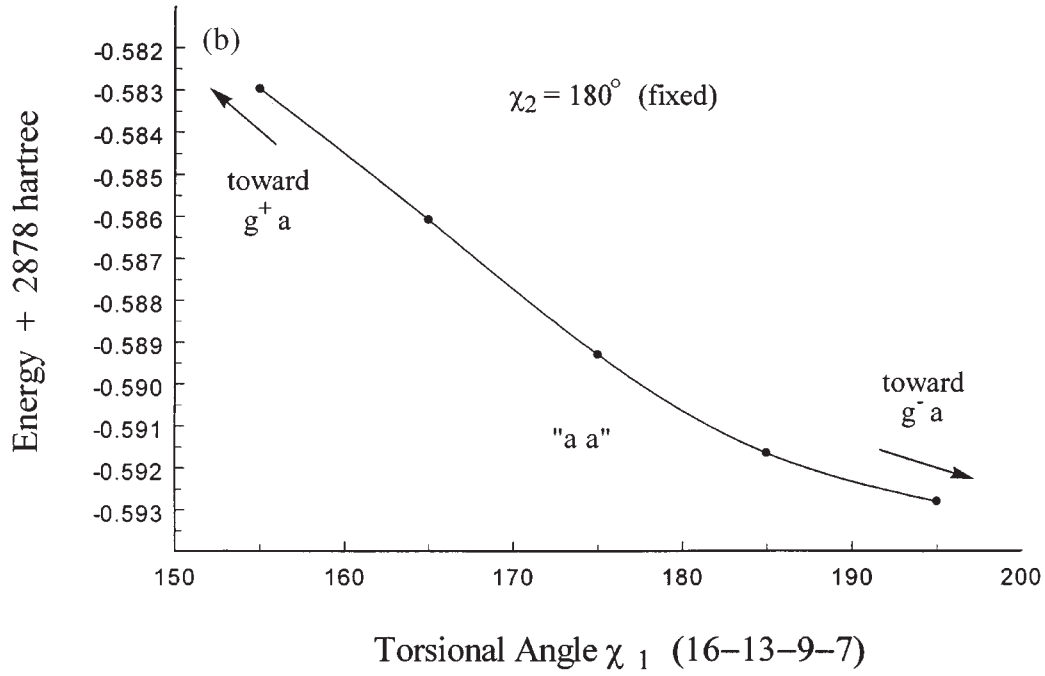
C = O ~ 0.40

N—H ~ 0.35

C—Se and Se—H ~ 0.15



hydrogen bond ~ 0.01



3.4 The effect of basis set and correlation energy on $\Delta E_{rel.}$

During the past decade it became clear by studying numerous N- and C-protected amino acids that the 3–21G basis set yielded fairly informative results at the HF level of theory (11, 12, 14–16, 25, 26–33) particularly when compared to large basis set MP2 calculations (14), while undoubtedly such qualitatively or sometime even semi-quantitatively acceptable results are fortuitous, nevertheless, they formed the basis of the advances in the 1990s. In all these compounds only C, H, N, and O atoms were present. It is of a fundamental question therefore whether such fortuitous results will persist when an O atom is replaced by a Se atom. Fig. 14 shows the relative energies of Ac-Sec-NHMe and For-Sec-NH_2 as computed at the RHF/3–21G and B3LYP/6–31G(d,p) levels of theory. The $\Delta E_{rel.}$ values of the two compounds are similar at the RHF/3–21G levels of theory. They are also comparable at the B3LYP/6–31G(d,p) levels. They all fall within a 3 Kcal/mol spread and the global minimum remains the same. However, when the DFT results are compared to those obtained at the RHF/3–21G level of theory, some differences may be noticed. Namely some of closely spaced levels are interchanged on the relative energy scale (Fig. 14) when one compares the RHF/3–21G and B3LYP/6–31+G(d,p) results. Nevertheless there seems to be no drastic change in stability. In conclusion, it is abundantly clear that for heavy elements, such as Se, one should aim to have better representation in terms of basis set and the inclusion of electron correlation than necessary for

Photoinduced birefringence in copolymers containing Disperse Red 1 and styrene

Gabriel Iftime, Lana Fisher, Almeria Natansohn, and Paul Rochon

Abstract: A series of copolymers of 4′-[[[2-(methacryloyloxy)ethyl]ethyl]amino]-4-nitroazobenzene (DR1M) and an optically "inert" styrene comonomer were tested for photoinduced birefringence. The level of saturated birefringence increased linearly with the content of DR1M in the copolymer. The birefringence per mole of azo chromophore was constant along the copolymer series.

Key words: azobenzene, photoinduced birefringence, copolymers, *trans-cis* isomerization.

Résumé : On a évalué le niveau de biréfringence photoinduite d'une série de copolymères du 4′-[[[2-(méthacryloyloxy)éthyl]éthyl]amino]-4-nitroazobenzène (DR1M) et d'un comonomère du styrène optiquement "inerte". Le niveau de biréfringence saturée augmente d'une façon linéaire avec la teneur en DR1M du copolymère. La biréfringence par mole de chromophore azo est constante pour toute la série de copolymères.

Mots clés : biréfringence photoinduite, copolymères, isomérisation *cis-trans*.

[Traduit par la Rédaction]

Introduction

Azo-based amorphous polymers are attracting much attention because they have proven to be good candidates for various optical applications. This research focuses on the utilization of amorphous (1) and liquid crystal polymers (2–3) as materials for photonic devices, mainly by photoinduced birefringence (4) and surface relief gratings (5–6) phenomena. The mechanism by which birefringence is obtained is based on photoinduced *trans-cis-trans* isomerization of the azobenzene groups, accompanied by their movement and re-arrangement perpendicular to the laser polarization direction. This "written" information can be "erased" locally by irradiation with circularly polarized light or globally by heating above the glass transition temperature (*Tg*) of the polymer film. Several structural factors were investigated and found to have an influence on the photo-driven orientation process. Among these factors are the polarity of the azobenzene groups (7), their bulkiness (8–9), the structure of the spacer between the azo group and the main chain (10), etc. One of the important factors is the concentration of the azo chromophore in the polymer film. To check this factor, several copolymer series containing azobenzene groups and optically "inert" groups were investigated. As expected, the photoinduced birefringence level increases with the increase of the concentration of the azo chromophore in the copolymer. However, some of the copolymers show a clear deviation from a postulated linear dependence, which has been assigned to a neighboring group effect. This phenomenon was first observed in poly{4′-[[[2-(methacryloyloxy) ethyl]ethyl]amino]-4-nitroazobenzene-*co*-methyl methacrylate} (poly(DR1M-*co*-MMA)) and poly{4′-[[[2-(acryloyloxy)ethyl]ethyl]amino]-4-nitroazobenzene-*co*-methyl methacrylate} (poly(DR1A-*co*-MMA)) (11). The structure of the monomers is given in Chart 1. Some form of dipolar interaction between the azo groups on the side chains that are next to each other appears to play a role in photo-orientation. The photoinduced birefringence calculated per azo unit in copolymers is higher at very low chromophore content than at high concentrations of DR1M (azo) groups. The effect is especially pronounced for a series of copolymers poly{4′-[[[2-(methacryloyloxy)ethyl]ethyl]amino]-4-nitroazobenzene-*co*-[[4-nitrophenyl-4′-[2-(methacryloyloxy)ethyl]benzoate]} (poly(DR1M-*co*-BEM)). The rigid ester group in BEM has a high dipole moment (about 7 D), comparable to the azo group in DR1M. The enhanced birefringence per azo unit was attributed to cooperative motion, i.e., the polar BEM group is being moved by the photoactivated DR1M motion. It was calculated that at low content of azo group in these polymers, up to 80% of the photoinduced birefringence may be due to the alignment of the optically inert polar comonomer groups (12). The explanation for this cooperative motion may be either a dipolar interaction or a steric factor or a combination of both. To understand which factor prevails (dipolar or steric interaction) one has to study each factor separately. Copolymers of DR1M with a less polar analogue of BEM, the NBEM with an ester group having a dipole moment of only 0.95 D but of comparable size to the BEM, were tested (13). In this case, there was much less cooperative motion, suggesting that polar interaction between the side group dipoles is more important, and that unlike in

Chart 1.

liquid crystals, the steric factor has probably a minor contribution in the cooperative motion of azobenzene and "inert" ester groups.

We report here the synthesis of a series of poly(DR1M-*co*-styrene) copolymers and their photoinduced birefringence. The nonpolar benzene group of the styrene comonomer is not expected to move in concert with the azobenzene and its steric effect is less important (its size being much smaller than that of the NBEM). Styrene can act as a diluent for the absorbing azobenzene group, allowing the use of thicker films in the photoinduced birefringence process.

Experimental

DR1M was prepared as previously reported, by reacting Disperse Red 1 (DR1) with methacryloyl chloride in the presence of triethylamine, in dry THF, under argon (14). The copolymers were obtained by free-radical polymerization in sealed ampoules, in dry toluene under argon atmosphere. Toluene and THF were dried over sodium with benzophenone indicator. Methacryloyl chloride was distilled under vacuum, triethyl amine and styrene were dried over calcium hydride. They were distilled prior to use and kept in sealed tubes under argon gas. The polymerization reactions were initiated with AIBN (5% of the total mass of the monomers), and were carried out at 60°C for four days. The copolymers were then isolated by precipitation in methanol. Purification was done by reprecipitation from THF/methanol, then by drying in a vacuum oven at 70°C overnight. ^{1}H-NMR spectra of the copolymers were measured on a Bruker AC-F 200 MHz spectrometer in deuterated dichloromethane solutions. Glass transition temperatures were measured on second heating scans on a Mettler TA-30 DSC instrument equipped with a TA-3000 processor at a scan rate of 10°C/min. UV–vis spectra of solutions and films of polymers were measured on a Shimadzu spectrophotometer. The average molecular weights and polydispersities of the polymers were estimated by gel permeation chromatography (polystyrene standard calibration), in THF, on a Waters liquid chromatograph equipped with a R410 differential refractometer. Films for birefringence measurements were prepared by spin coating solutions of polymers in THF onto clean glass microscope slides, and subsequently dried in an oven at 130°C for one hour to remove the THF. Films thickness ranging from 150 to 350 nm were determined with a Dektak profilometer. The densities of the films were measured as previously described (11). Optical anisotropy was induced using a linearly polarized 488 nm laser beam (100mW/cm^2) and measured using a diode laser beam at 670 nm.

Results and discussion

Synthesis and characterization of the polymers

For the purpose of this study, a series of nine copolymers with the DR1M molar fraction ranging from 0.10 to 1.00 were synthesized. They were obtained by free radical copolymerization of DR1M with styrene at various ratios in toluene at 60°C for four days. In all the reactions a 1g mixture of the two monomers (DR1M and styrene) at the indicated DR1M initial feed (molar fraction) were used. The yields for copolymers (g) are listed in Table 1. The copolymer compositions were determined by ^{1}H NMR. As an example the ^{1}H NMR spectrum of the copolymer **5** (46% mol DR1M) is shown in Fig. 1. The assignments were done by comparison with the spectra of the monomers. Glass transition temperatures (*Tg*) for all copolymers were between 97 and 113°C, as listed in Table 1.

In Fig. 2, the absorption maxima (λ_{max}) of the copolymers **1**–**9** in solution and in films are plotted as a function of copolymer composition. The electronic spectra for this copolymer series show a systematic shift of the λ_{max} to higher wavelength as the azo concentration decreases. The total shift in λ_{max} in films between polymer **1** containing 100% mol DR1M units and copolymer **9** containing only 10% mol DR1M units is about 17 nm. This shift is slightly less pronounced in solutions in chloroform (12 nm). This phenomenon

was previously assigned to an antiparallel arrangement of the dipoles (DR1M units) (11). The higher the concentration of polar azo groups, the higher the probability of dipolar antiparallel interactions between neighboring azo groups. However, the effect observed in these copolymer films is slightly smaller than that reported for the poly(DR1M-*co*-MMA) series, where the shift was 22 nm. If this is the only effect responsible for the red shift in absorption maxima of the DR1M units when the azo concentration decreases, then one would expect the two polymer series to give similar results, this phenomenon being governed only by the concentration of DR1M groups in the copolymers.

A second effect that can be active here is the dipolar interaction of the DR1M groups with the comonomer structural units. If the comonomer structural unit is polar (as is the case for MMA) then it may behave as a polar solvent, causing a positive solvatochromic effect (red shift of the λ_{max}) as its concentration increases. The lower polarity of the styrene structural unit in the copolymers can be an explanation for the smaller shift of the λ_{max} observed in this series when compared with the poly(DR1M-*co*-MMA) series.

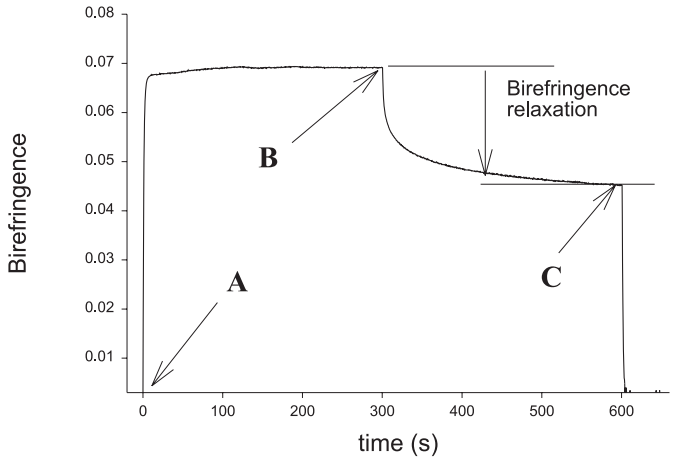
Fig. 3. Write-erase profile for optically induced and erased birefringence of poly(DR1M-*co*-styrene) copolymer **5**.



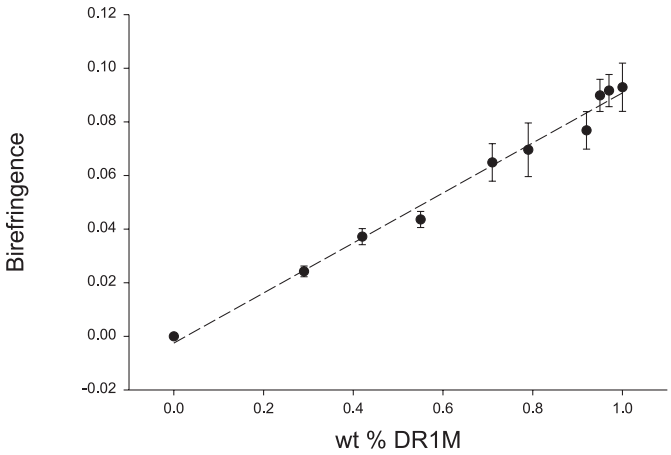


Fig. 4. Maximum induced birefringence (●) for the poly(DR1M-*co*-styrene) copolymer series as a function of DR1M weight fraction.

saturated level by a linearly polarized laser beam (488 nm, 100 mW/cm^2) at point A for 300 s. The relaxation starts at point B, when the laser beam is turned off for 300 s. At point C, the circularly polarized light is turned on and the birefringence is erased.

The maximum birefringence attained in the copolymer films after 300 s of writing is plotted as a function of DR1M content in Fig. 4. The photoinduced birefringence increases linearly with the DR1M content in the copolymer. This kind of graph has been previously observed for copolymers containing two different azo groups with one nonpolar azo unit, in poly{4′-[[[2-(methacryloyloxy)ethyl]ethyl]amino]-4-nitroazobenzene-*co*-4-[2-(methacryloyloxy)ethyl]azobenzene} (poly(DR1M-*co*-MEA)) (Chart 1) (15). In contrast, copolymers poly(DR1M-*co*-MMA), containing a more polar comonomer unit (MMA) showed a deviation from linearity at low content of DR1M. The results presented in Fig. 4 suggest that there is no cooperative effect in this copolymer series, and this can be explained by the low polarity of the styrene comonomer. No dipolar interactions between the two different structural units can occur.

The growth and the relaxation of the optically induced birefringence can be described by biexponential functions [1] and [2], respectively (8).

$$[1] \qquad \Delta n = A_n(1-\exp(-k_a t)) + B_n(1-\exp(-k_b t))$$

$$[2] \qquad \Delta n = C_n - \exp(-k_c t) + D_n - \exp(-k_d t) + E_n$$

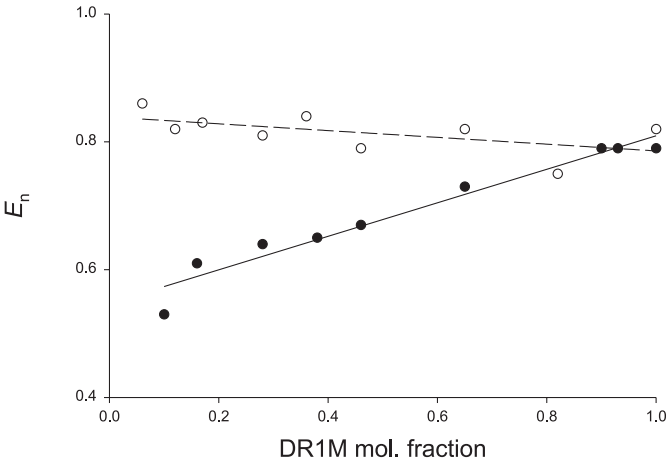
Both growth and relaxation processes involve a "fast" process and a "slow" process. The parameter A_n in eq. [1] represents the contribution of the fast growth process with rate constant k_a. The parameter B_n, represents the slow growth with rate constant k_b. To compare the behavior of the different polymers, these parameters are normalized so that $A_n + B_n = 1$. Fitting results, presented in Table 2, show that the A_n and B_n parameters are relatively constant at levels of 0.95 and 0.05, respectively. The time constants k_a and k_b varied, but no particular trend could be found.

When the "writing" laser beam is turned off, the birefringence decays to a stable level. The relaxation process can be fit by a biexponential eq. [2]. C_n, D_n, and E_n are normalized constants. The parameter C_n represents the contribution of the fast relaxation process with rate constant k_c, and the parameter D_n, represents the slow relaxation with rate constant k_d. E_n represents the residual long-term birefringence, stable in time, if the birefringence is not erased optically or by heating. The relaxation time constants k_c and k_d extracted from the relaxation curve appear to be relatively constant, having values of approximately 0.40 and 0.010 s^{-1}, respectively.

The long term stability E_n, for the poly(DR1M-*co*-styrene) series decreases with the decrease of DR1M content in the copolymer, from 0.79 for polymer **1** (100% mol DR1M) to 0.53 for polymer **9** (0.10% mol DR1M). This means that the photoinduced birefringence in copolymers with lower content

© 2000 NRC Canada

Fig. 5. Long-term stable birefringence after relaxation (E_n) as a function of composition. (●) poly(DR1M-*co*-styrene), (○) poly(DR1M-*co*-MMA).



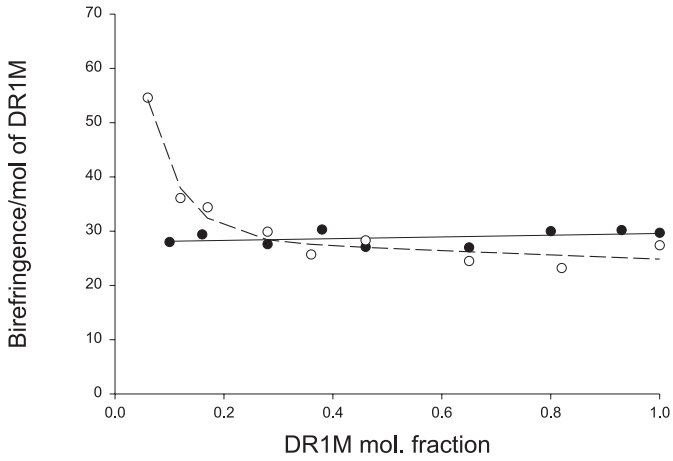


Fig. 6. Birefringence per mole of azo chromophore in copolymers as a function of composition. (●) poly(DR1M-*co*-styrene), (○) poly(DR1M-*co*-MMA).

of DR1M is less stable. The variation of the E_n parameter across the polymer series is shown in Fig. 5. There probably are at least two main separate processes that have an opposite influence to the long-term birefringence stability.

One relaxation process is due to the thermal *cis-trans* isomerization of the azobenzene groups that happen to be in the *cis* state when the writing laser beam is turned off. This phenomenon is specific to the azo groups, and has as an effect the randomization of the orientation of these groups.

A second factor is the dipolar interactions between the polar side groups. The local electric field existing in the film makes it difficult to move polar groups from their equilibrium position. This factor will enhance the stability of the photoinduced birefringence. For poly(DR1M-*co*-BEM) (12), where the polarity of the side group is similar, the sum of the two effects is relatively constant for the whole range of copolymer composition. In that case the stability is due to the fact that strong dipolar interactions exist at any content of azo chromophore in the copolymer. At high concentration, the interactions are mainly between DR1M neighboring groups, and at low concentrations, between DR1M and the polar BEM groups. In the poly(DR1M-*co*-styrene) series, the only polar group is the DR1M azo chromophore. In this case, the dipolar interactions between neighboring polar azo groups will be effective at high concentrations of the chromophore, giving a higher stability of the photoinduced birefringence (E_n parameter), as observed. At low concentrations of DR1M, the chromophores have mainly nonpolar styrene neighboring groups, and the chromophores will reorient independently since the nonpolar styrene group will not perturb the local electric field. The level of conserved birefringence is in this case lower at low DR1M concentrations in polymer.

A slight increase of the long-term stable birefringence with the content of azo chromophore was observed previously in the copolymer series containing as comonomer the NBEM group. NBEM has a low dipole moment but a similar size to the polar BEM groups. The increase of the long-term stable birefringence (E_n) as the concentration of DR1M increase is more pronounced in copolymers containing styrene. This suggests that the steric factor, i.e., the size of the comonomer groups, plays a role in the reorientation process. Indeed, the styrene group is much smaller than the NBEM group, which is similar in size to DR1M and BEM. This means that the azo groups have a higher degree of freedom, thus they are easier to randomize when a small side group is present.

The size of the MMA structural unit is similar to styrene. Relatively constant values were obtained for the E_n parameter for the poly(DR1M-*co*-MMA) series. For comparison, the E_n values obtained for poly(DR1M-*co*-MMA) are also plotted in Fig. 5 (11). For example, the ratio E_n (100% DR1M)/E_n(16% DR1M) is about 1.4 in poly(DR1M-*co*-styrene). The same ratio is 1 in poly(DR1M-*co*-MMA). This is probably due to the fact that the MMA group possesses a higher dipole moment than the styrene, so that at low content of DR1M, the dipolar interactions between DR1M and MMA can compensate the tendency of azo groups toward reorientation.

Another factor that may influence the relaxation process is the glass transition temperature (*Tg*) but the *Tg* for this series of copolymers is relatively constant at about 105°C, so no particular influence is expected.

The most useful comparison between this copolymer series and the copolymer series containing more polar comonomers, can be made by calculating the birefringence levels per azo unit. The molar density (MD) of the DR1M chromophore was calculated as follows

$$[3] \qquad MD = DF_w/M_{DR1M}$$

where D is the film density, F_w is the weight fraction of DR1M in the copolymer, and M_{DR1M} is the molecular weight of the azo chromophore. The film densities were measured as previously described (12). They show a linear increase from 1.05 g/cm^3 for the polystyrene (F_{DR1M} = 0) to 1.23 g/cm^3 for PDR1M (F_{DR1M} = 1, polymer **1**). The average contribution per mole of azo unit is obtained by dividing the maximum of photoinduced birefringence (at point B, in Fig. 3) by the calculated azo molar density (*MD*). Figure 6 shows the birefringence per azo chromophore in the poly(DR1M-*co*-styrene) copolymer series as a

© 2000 NRC Canada

function of copolymer composition. The birefringence per mole of dipole data is practically constant across the whole range of compositions. For comparison, the values obtained previously (11) for the poly(DR1M-*co*-MMA) series are also plotted in Fig. 6.

They show an increase up to two times at low content of DR1M. There is no explanation for this discrepancy at the present time. The poly(DR1M-*co*-styrene) data seem to suggest that there is little, if any, dipolar interaction between neighboring DR1M units, while the poly(DR1M-*co*-MMA) data indicated the presence of such interactions during photoisomerization. Verification of the measurement accuracy at very low DR1M composition in poly(DR1M-*co*-MMA) will be required.

Conclusions

A series of copolymers containing an azo chromophore DR1M, and an inert nonpolar and small group styrene, was synthesized and tested for the photoinduced birefringence. The levels of saturated birefringence and of conserved birefringence after relaxation increased linearly with the DR1M content in the copolymers. This is explained by the lack of dipolar interactions between the polar DR1M and the nonpolar styrene comonomer. The level of stable birefringence, conserved after relaxation, increased with the content of azo chromophore. This copolymer series shows a constant birefringence per DR1M unit. This result is in contrast with previously described copolymers containing polar optically inert groups (MMA). The level of stable birefringence is determined by the dipolar interactions between structural units. Steric factors have an influence as well, but to a lower extent than the dipolar interactions.

Atomic properties of selected biomolecules. Part 1. The interpretation of atomic integration errors

Fiona M. Aicken and Paul L.A. Popelier

Abstract: Reliable atomic properties can be obtained via the theory of "Atoms in Molecules" (AIM) via integration over a finite volume. These integrations are challenging because of the variety and complexity of the shape of the AIM atoms. In practice the integration of a large number of atoms (100–1000, sampled from many molecules) yields integration errors $L(\Omega)$ of varying magnitude. We prove that it is impossible to predict the size of an angular Gauss–Legendre grid (outside the β sphere) that guarantees a pre-set error. Hence it is incorrect to assume that a large grid (~23 000 angular grid points) will automatically yield a low $L(\Omega)$ value. The erratic relationship between the integration error and the grid size prompts a statistical interpretation of atomic integration, at a purely practical level. More importantly we have investigated the relationship between $L(\Omega)$ and seven atomic properties which include volume, energy, and the magnitudes of five electrostatic multipole moments. The electronic population ($N(\Omega)$) and the volume ($v(\Omega)$) of carbon is linearly correlated with $L(\Omega)$, enabling the interpolation or extrapolation of $N(\Omega)$ and $v(\Omega)$. Other properties of carbon and other atoms (N, O, and S) yield low correlation coefficients but occasionally trends can be observed. For example, we find that some properties are systematically underestimated if $L(\Omega)$ is negative. This work has led to an estimate of safe error bars of atomic properties for atoms occurring in biological molecules with reasonably sized integration grids. The most stable properties were found to be the energy and the population. Finally, we have observed that the influence of the grid orientation is less if $L(\Omega)$ is small, and that population and energy are the least affected.

Key words: electron density, topology, atoms in molecules, atomic properties, amino acids.

Résumé : La théorie des « atomes dans les molécules » (ADM) couplée à une intégration sur un volume fini permet d'obtenir des propriétés atomiques fiables. Ces intégrations présentent un défi en raison de la variété et de la complexité de la forme des atomes dans les molécules. En pratique, l'intégration d'un grand nombre d'atomes (entre 100 et 1000 prélevés au hasard à partir de plusieurs molécules) conduisent à des erreurs d'intégration $L(\Omega)$ d'amplitudes diverses. On démontre qu'il est impossible de prédire la taille d'une grille angulaire de Gauss–Legendre (à l'extérieur de la sphère β) qui permettrait de garantir une erreur prédéterminée. Il est donc incorrect de faire l'hypothèse qu'une grande grille (grille angulaire à ≈ 23 000 points) conduira automatiquement à une faible valeur de $L(\Omega)$. La relation erratique entre l'erreur d'intégration et la taille de la grille conduit, à un niveau purement pratique, à une interprétation statistique de l'intégration atomique. D'un point de vue plus important, on a étudié la relation entre $L(\Omega)$ et sept propriétés atomiques qui comprennent le volume, l'énergie et les amplitudes de cinq moments multipolaires électrostatiques. On a établi une corrélation linéaire entre $L(\Omega)$ et la population et le volume électroniques du carbone, respectivement $N(\Omega)$ et $v(\Omega)$ ce qui permet de faire des interpolations ou extrapolations de $N(\Omega)$ et $v(\Omega)$. D'autres propriétés du carbone ainsi que d'autres atomes (N, O et S) donnent de faibles coefficients de corrélation, mais occasionnellement on peut observer des tendances. Par exemple, on a trouvé que quelques propriétés sont systématiquement sous-évaluées si la valeur de $L(\Omega)$ est négative. Ce travail a permis de faire une évaluation des limites d'erreur admissible des propriétés atomiques pour les atomes que l'on retrouve dans les molécules biologiques en utilisant des grilles d'intégration de taille raisonnable. On a trouvé que les propriétés les plus stables sont l'énergie et la population. Enfin, on a observé que l'influence de l'orientation de la grille est moins importante si $L(\Omega)$ est faible et que la population et l'énergie sont les moins affectées.

Mots clés : densité d'électrons; topologie; atomes dans les molécules; propriétés atomiques; acides aminés.

[Traduit par la Rédaction]

1. Introduction

Chemical insight is largely based on the ability to ascribe the characteristics of a molecule to its constituent atoms. Many schemes have been proposed to partition molecular properties into atomic contributions, but only one scheme originates from a comprehensive theory whose scope and depth is unique, called "Atoms in Molecules" (AIM) (1, 2). Using the topology of the electron density (ρ), this theory defines an atom as a bounded portion of real space, denoted

by Ω. In contradistinction to partitioning methods defined in orbital space (3, 4) all information about a particular AIM atom is contained in its finite[2] volume. As a result the atom can be taken out of its chemical environment and compared with another atom originating from a different environment. In view of their finite shape (5), quantum mechanical roots (6), and basis set stability (7), AIM atoms are ideal for assessing the transferability of a molecular fragment (8). Moreover atomic properties, defined by AIM as integrations over the atomic volume, can be computed from experimental electron densities (9).

Integration of a property density over Ω yields atomic charges, dipole moments, quadrupole moments, volumes, energies, and other atomic properties. Atomic integration is a vital part of the practical application of AIM and since the development of the first integration algorithm (10) in the early eighties, several thousands of atoms have been integrated. When performed en masse atomic integration has led to remarkable results, such as the Transferable Atom Equivalent (TAE) method (11) and Quantitative Structure Property Relationships (QSPR) (12). Recently we have integrated a set of more than 700 atoms drawn from the 20 natural (free) amino acids and smaller derived molecules.[3] This data set comprises 57 molecules and is identical to the one studied before in connection with bond critical point properties (13).

Typically atomic integration is performed numerically. A typical integration algorithm either requires an a priori choice of a quadrature grid size, or a pre-set threshold for the integration error $L(\Omega)$. This quantity is defined below and must vanish for a perfect integration. It is important to point out that $L(\Omega)$ has no direct chemical meaning, i.e., it is not an atomic property of any relevance other than to measure the quality of the integration. In practice, when performing an integration one obtains a reasonable minimum $L(\Omega)$ value for a given CPU investment, without knowing how accurate the resulting atomic properties are. This paper attempts to answer the difficult question of what the error bars on atomic properties are. Some long overdue insight into this problem is warranted in view of the research activity of the AIM community. Indeed, according to a recent survey (14) more than 90 papers were published (by 60 different research groups), which contained substantial AIM contributions.

2. Atomic Integration

According to AIM a molecule is sub-divided into non-overlapping fragments, called atoms, which appear in the gradient vector field of the electron density. Each atom (Ω) is bounded by a surface (S) which satisfies a zero-flux boundary condition:

$$[1] \qquad \nabla\rho(\mathbf{r}) \cdot \boldsymbol{n}(\mathbf{r}) = 0 \qquad \forall\ \mathbf{r} \in S$$

An atomic property, $A(\Omega)$, is defined as a volume integral over the portion of real space the atom takes up, or

$$[2] \qquad A(\Omega) = \int_{\Omega} d\tau\ a(\mathbf{r})$$

where $a(\mathbf{r})$ is a property density. For example, $a(\mathbf{r})$ could be the charge density, $\rho(\mathbf{r})$, the dipole moment density, $\mathbf{r}_\Omega \rho(\mathbf{r})$, or the quadrupolar polarisation of an atomic density measured with respect to the z-axis, $(3z_\Omega^2 - \mathbf{r}_\Omega^2)\rho(\mathbf{r})$, where $\mathbf{r}_\Omega$ is a vector with origin at the nucleus inside the atom Ω.

In this work we monitor the following atomic properties: volume, energy, population, dipole, quadrupole, octopole, and hexadecupole moments. All atomic electrostatic moments are defined using the spherical tensor formalism (15), rather than the more common Cartesian multipole expansion (16). Although the spherical tensor formalism is mathematically more complex it has the advantage of generating $2\ell + 1$ non-redundant components for a moment of rank ℓ. A complete definition of the moments up to the hexadecupole moment has been given elsewhere (17). Here we list the definition of the moments Q_{lm} up to the quadrupole moment, $\ell = 2$, all in atomic units (au).

$$[3] \qquad Q_{00}(\Omega) = -\int_{\Omega} \rho(\mathbf{r})\, d\tau$$

$$[4] \qquad Q_{10}(\Omega) = -\int_{\Omega} z\rho(\mathbf{r})\, d\tau\ ;$$

$$Q_{11c}(\Omega) = -\int_{\Omega} x\rho(\mathbf{r})\, d\tau\ ;$$

$$Q_{11s}(\Omega) = -\int_{\Omega} y\rho(\mathbf{r})\, d\tau$$

$$[5] \qquad Q_{20}(\Omega) = -\int_{\Omega} \frac{1}{2}(3z^2 - r^2)\rho(\mathbf{r})\, d\tau\ ;$$

$$Q_{21c}(\Omega) = -\int_{\Omega} \sqrt{3}xz\,\rho(\mathbf{r})\, d\tau\ ;$$

$$Q_{21s}(\Omega) = -\int_{\Omega} \sqrt{3}yz\,\rho(\mathbf{r})\, d\tau\ ;$$

$$Q_{22c}(\Omega) = -\int_{\Omega} \frac{\sqrt{3}}{2}(x^2 - y^2)\rho(\mathbf{r})\, d\tau\ ;$$

$$Q_{22s}(\Omega) = -\int_{\Omega} \sqrt{3}xy\,\rho(\mathbf{r})\, d\tau$$

In this work we focus on the magnitude of the multipole moments, which is obtained by taking the square root of the sum of the squares of the components, or $Q_l = \sqrt{\sum_m Q_{lm}^2}$. This quantity does not depend on the orientation of the atom's axis system. The (electronic) population $N(\Omega)$ is trivially related to the monopole moment via $N(\Omega) = -Q_{00}(\Omega)$. The atomic volume is simply defined as $v(\Omega) = \int_{\Omega} d\tau$ and the atomic energy as $E(\Omega) = (1 + \gamma)\int_{\Omega} K(\mathbf{r})d\tau$ where $K(\mathbf{r})$ is a kinetic

[2] Strictly speaking the volume is not finite because atoms can extend to infinity at open sides. However, atoms are typically bounded by the $\rho = 0.001$ au contour envelope.

energy density (18) and γ is the virial ratio $< V > / < T >$ of the wave function. The integration error, $L(\Omega)$, is defined as $-\frac{1}{4}\int_\Omega \nabla^2 \rho(\mathbf{r}) d\tau$. Using Gauss' theorem it is straightforward to prove that the value of $L(\Omega)$ should be zero for a volume integral bounded by the zero-flux condition given in eq. [1]. The quantity $L(\Omega)$ measures the difference between the kinetic energy densities, $K(\mathbf{r})$ and $G(\mathbf{r})$(19) or $L(\Omega) = K(\Omega) - G(\Omega)$. To compute an atom's energy to within 1 kJ mol^{-1}, $L(\Omega)$ should be at most 4×10^{-4} au. An interesting question is whether this level of accuracy is necessary for the other atomic properties.

To address questions such as the one raised above we focus on three different carbon atoms, two nitrogen atoms, two oxygen atoms, and a sulfur, drawn from the data set described in the introduction. In particular we looked at the carbon in ethene, the carbon in methanethiol (CH_3SH) and the α carbon in alanine; the nitrogens in ammonia and alanine; the oxygens in the hydroxyl group of alanine and in water, and the sulfur in methanethiol. All the wave functions were generated using the GAUSSIAN94[4] program. The geometries were optimized at HF/6–31G(*d*) level with the single point calculation at B3LYP/6–311+G(2d,p) level. All integrations were carried out with the program MORPHY98,[5] which computes the atomic integral in spherical coordinates with a Gauss–Legendre quadrature in both the radial and angular integration variables. A separate grid is used for a sphere totally contained within the atom, traditionally called the β sphere (10).

There are six variables within the quadrature scheme, three variables within the β sphere and three outside this sphere. These six variables are denoted by ($n_r(\beta)$, $n_\theta(\beta)$, $n_\phi(\beta)$, n_r, n_θ, n_ϕ), where n_r is the number of quadrature points in the radial grid, and n_θ and n_ϕ the number of quadrature points in the angular grid, which consists of θ and ϕ. The atomic properties are influenced by both the size and the orientation of the integration grid atom relative to the atom's local axis system. We investigate both factors in turn.

3. Results and discussion

3.1 Grid size

A complete understanding of the dependence of the integration error $L(\Omega)$ on the quadrature grid would require a systematic scan through the six-dimensional space of integration variables ($n_r(\beta)$, $n_\theta(\beta)$, $n_\phi(\beta)$, n_r, n_θ, n_ϕ). To make this task more manageable we first focus on the β sphere. We have observed that $L(\Omega)$ is more dependent on the radial integration variable $n_r(\beta)$ than on the angular variables $n_\theta(\beta)$ and $n_\phi(\beta)$. In Table 1 we investigate the effect of an increase of the number of radial quadrature points, $n_r(\beta)$, for C, N, O, and S. Hydrogen atoms are omitted from this analysis because they do not have any core electrons and their $L(\Omega)$ values rarely exceed 10^{-4} au.

We see from Table 1 that only the atomic energy and $L(\Omega)$ are affected by the increase of $n_r(\beta)$. This effect can be explained by a well-known fact in the field of numerical analysis, namely that "high order is not the same as high accuracy" (20). In numerical integration high order translates only to high accuracy when the integrand is very smooth, in the sense of being well approximated by a polynomial. Both the Laplacian of the electron density, $\nabla^2\rho(\mathbf{r})$, which determines $L(\Omega)$, and the kinetic energy density $K(\mathbf{r})$ oscillate dramatically in the radial direction, near the nucleus. This explains why a large number of quadrature points are required to integrate the radial direction accurately. As the nuclear charge increases from C over N and O to S, more radial points are needed to obtain a good accuracy, i.e., a small $L(\Omega)$ value. Since $\nabla^2\rho(\mathbf{r})$ and $K(\mathbf{r})$ vary more smoothly along the angular integration variables values of $n_\theta(\beta) = 30$ and $n_\phi(\beta) = 40$ are sufficient. The fact that smoother functions are integrated better by modestly sized quadrature grids also explains why the electrostatic multipole moments do not change when $n_r(\beta)$ is increased. Indeed, the integrand for a multipole moment consists of ρ multiplied by a tensor (e.g., eq. [5]) and ρ decreases monotonically away from the nucleus, more smoothly than

[a]Remaining quadrature values, ($n_r(\beta)$, $n_\theta(\beta)$, $n_\phi(\beta)$, n_r) are set to (50, 30, 40, 50).

$\nabla^2\rho(\mathbf{r})$. Of course the smoothest integrand, the constant "1," occurs in the computation of the atomic volume. Consequently the atomic volume is invariant to an increasing value of $n_r(\beta)$.

Table 1 reveals that alteration of the β sphere radial grid has very little effect on the $L(\Omega)$ value of the carbon atom. For the other atoms, N, O, and S, there is a substantial improvement in the error of up two orders of magnitude. The energy suffers from an inaccurate grid within the β sphere, whereas all the other properties remain unchanged. Unsurprisingly sulfur, having the largest core, requires the largest value for $n_r(\beta)$. Apart from the fluctuations in both $\nabla^2\rho(\mathbf{r})$ and the energy the β sphere is very straightforward to integrate and $n_\theta(\beta)$, $n_\phi(\beta)$) = (30, 40) can be recommended for all atoms. We note that $n_r(\beta; C) = 50$, $n_r(\beta; N,O) = 90$ and $n_r(\beta; S) = 150$ yield satisfactory $L(\Omega)$ values and stable atomic properties. Therefore we conclude that the atomic core of most molecules of biological interest can be integrated with a number of points between 60 000 and 180 000, based on the product $n_r(\beta)\, n_\theta(\beta)\, n_\phi(\beta)$. Finally we have observed that the radial grid outside the β sphere has relatively little effect on the quality of the integration.[6]

Of the six parameters, ($n_r(\beta)$, $n_\theta(\beta)$, $n_\phi(\beta)$, n_r, n_θ, n_ϕ), that we are to investigate only the number of quadrature points in the angular grid outside the β sphere, denoted by n_θ and n_ϕ, remains. An angular grid is conveniently labelled as

(n_θ, n_ϕ) and the number of points it contains is simply $n_\theta n_\phi$. Integration experience reveals that the angular grid outside β is the most important factor in the determination of the quality of the integration and the hardest to judge. The angular grid determines in which directions the integration rays are shot, away from the nucleus, hence this grid determines how the atomic boundaries are probed. The integration error $L(\Omega)$ is dependent on how well this probing is done.

The values of n_θ and n_ϕ were systematically varied to investigate what effect the grid has on the quality of the properties for each atom type. Tables 2, 3, and 4 show the values of the atomic properties and $L(\Omega)$ for a set of angular grids for the carbon in ethene, the carbon in methanethiol and the α carbon in alanine respectively. Table 5 shows the same information for the nitrogen in alanine, Table 6 for the hydroxyl oxygen in alanine, and Table 7 for the sulfur in methanethiol. The behavior of the integration error as a function of the number of angular grid points is given in Fig.1. This figure consists of six plots (*a* to *f*) with each corresponding to data in Tables 2 to 7 respectively.

Figure 1 clearly shows that the relationship between the integration error, $L(\Omega)$, and the number of angular grid points is not trivial. The naïve expectation that a larger grid leads to a $L(\Omega)$ value nearer to zero cannot be fulfilled. Rather we confirm that high order does not necessarily mean high accuracy. For example, a grid of 6400 points leads to $L(\Omega)$ = –0.00041 au (Table 3) while a grid of 22 500 points yields an integration error that is about five times higher. The carbons drawn from three very different chemical environments show a dampened oscillatory behaviour. These oscillations are also present in the integrations of the nitrogen

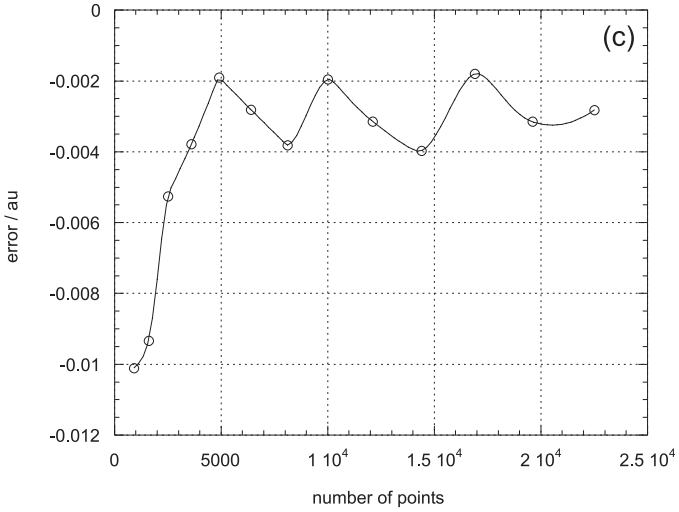
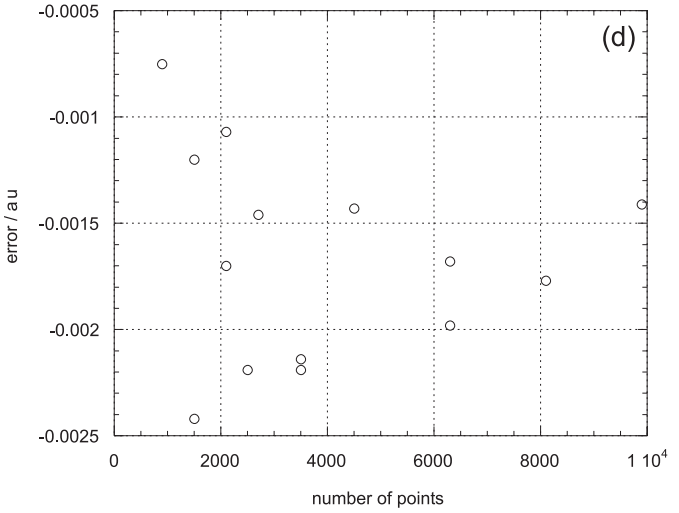
and the oxygen (Fig. 1*d*, *e*) but they are not shown by a curve. A curve could not be drawn because there are several instances where two different integration grids, with an equal number of points yield two different $L(\Omega)$ values. This phenomenon again proves the erratic relationship between $L(\Omega)$ and the number of grid points. For instance, the correlation coefficient for the data set of Fig. 1*d* (Table 5) is $R^2 = 0.01$.



The behaviour of $L(\Omega)$ versus the size of the integration grid suggests a statistical interpretation of atomic integration. This approach is very practical and means that we regard an integration with any reasonable angular grid size as a "measurement" of the atomic properties of an atom. Grids with much fewer than a thousand points produce excessively high integration errors and should therefore be discarded. The statistical interpretation suggests the computation of the mean value ($\bar{x}$) of an atomic property and its standard deviation, σ. The latter quantity can serve as an error bar to the property. Both quantities, $\bar{x}$ and σ, together with range, defined as the difference between the minimum and maximum values of a property, are given in Tables 2–7.



Although the statistical point of view may seem unorthodox for properties that are exactly obtainable in principle, it makes sense in practice, especially when a large set of atoms (order of hundreds) needs to be computed. There are three reasons why a statistical interpretation is appropriate at a practical level. The first reason is to enable the determination

Fig. 2. Plot of the atomic dipole moment against $L(\Omega)$ for the carbon in methanethiol.

of a practical error bar of an atomic property in the classification of atoms via cluster analysis. Indeed, it makes no sense to subdivide a group of atoms if the resulting subgroups can actually not be distinguished because of their overlapping error intervals. The second reason is that the relation between the integration error $L(\Omega)$ and the grid size is erratic. The third reason is that, in general, the relation between $L(\Omega)$ and atomic properties is also erratic. We now discuss the second and the third reason in detail.

Given that $L(\Omega)$ is the ultimate judge of the integration quality, rather than the grid size, it is desirable to have an integration algorithm which reaches a pre-set $L(\Omega)$ value (21). To systematically attain a pre-set error one would like to improve a quadrature grid gradually, without discarding previously computed grid points. This systematic improvement is possible with Simpson's rule (or extended trapezoidal rules) but not with Gauss–Legendre quadrature. However the Gauss–Legendre quadrature is superior to a trapezoidal rule because it needs fewer grid points. Consequently one is faced with the dilemma that a more efficient integration technique uses a grid such that points evaluated in a lower order grid cannot be re-used in a higher order grid. Although some progress has been made in quadrature schemes that can be refined until a pre-set accuracy is reached, the question whether the maximum degree of exactness can actually be achieved in practice remains unsolved (20). Therefore one can only guess a grid size and hope that it will deliver the desired $L(\Omega)$ value. Often very large angular integration grids turn out be prohibitive. Moreover small grids can produce low integration errors. It is clear from Fig. 1 that a given $L(\Omega)$ value cannot be translated into a particular angular grid, so we prefer to view integration with typical quadrature grids as a "measurement" of an atomic property.

The third reason to adopt the statistical point of view is related to the following question: how low must $L(\Omega)$ be to obtain an atomic property with an acceptable error bar? A direct way to answer this question is to monitor the behaviour of atomic properties with the indicator of integration quality, $L(\Omega)$. A typical example is given in Fig. 2, which shows how the magnitude of the dipole moment, μ, varies with $L(\Omega)$ for the carbon in methanethiol. This example is representative for all properties except the electronic population of the carbon atoms. Naïvely one would expect that the property in question converges, possibly asymptotically, to an ideal value. Instead of this behaviour we recover in Fig. 2 a scatter plot with $R^2 = 0.821$. Systematic omission of data points can produce a correlation coefficient as low as 0.650. Accepting the quasi-random data pattern we conclude that the dipole moment's magnitude is bracketed, or $\mu = 0.0560 \pm 0.0099$ au. This error bar is rather large because two fairly large errors (two points on the left on Fig. 2, corresponding to 900 and 2500 grid points) have been included. When these results are excluded we find that $\mu = 0.0554 \pm 0.0014$ au. This recalculation shows that the original standard deviation, $\sigma = 0.0099$, which is listed in Table 3, is rather tolerant or safe. Indeed, as illustrated here, closer inspection of the integration data show that σ could easily be ten times smaller. However, we choose to err on the side of safety and quote the higher, more tolerant standard deviation. This level of safety is justified because of the difficulties in obtaining low $L(\Omega)$ values for carbons. Furthermore, in view of our cluster analysis of the atoms in amino acids (which will be published in Part 2) we want to incorporate a realistic cluster resolution.

Within the statistical framework we can prove in a different way that the number of grid points can be misleading in judging the quality of an atomic property. For example, in Table 2 we find that 900 points yield $L(\Omega) = 0.00068$ au, and 1600 points $L(\Omega) = -0.00212$ au However the discrepancy from the mean volume is 1.48 au for the former grid and 1.70 au for the latter. So properties deviate less from the mean value if $L(\Omega)$ is low rather than when the number of grid points is large.

It is clear from Tables 2–7 that, in general, the relative standard deviations of atomic properties can be ranked from the smallest to the largest as follows: energy < population < dipole < quadrupole < octupole < hexadecupole < volume. This means that energy and the population (and thus the monopole moment) are the most stable properties and that, on the other hand, volume is very dependent on the value of $L(\Omega)$. The maximum deviations from the mean generally follow this pattern.

It is also possible to propose error bars on atomic properties for C, N, O, and S from the standard deviations listed in Tables 2–7. Table 8 lists the most tolerant error bars σ (i.e., largest standard deviations found) for each atomic property of atoms C, N, O, and S. This means that two atoms that differ in one property by more than 3σ (as listed in Table 8) are definitely different, given that they were integrated with a feasible and typical quadrature grid with more than a thousand points. Hence this work provides useful results for clustering and transferability studies for a large set of atoms.

The slightly different values for an atomic property obtained by different angular grids however, are not completely without pattern. We observed the trend that, with few exceptions, a positive $L(\Omega)$ value tends to underestimate the volume, population, and octopole and hexadecupole moments,

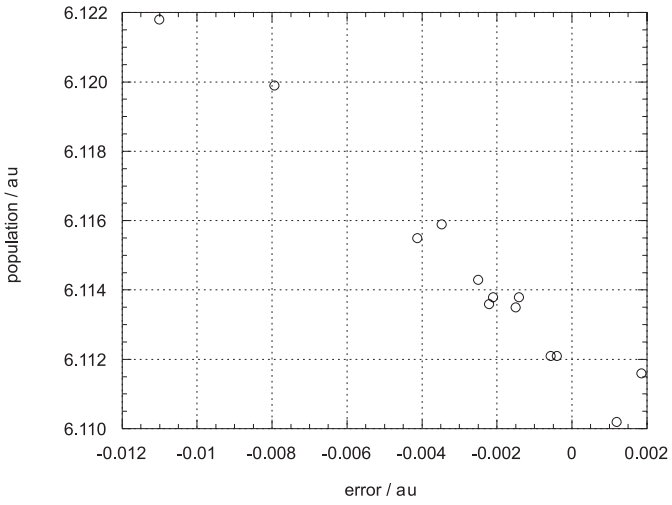

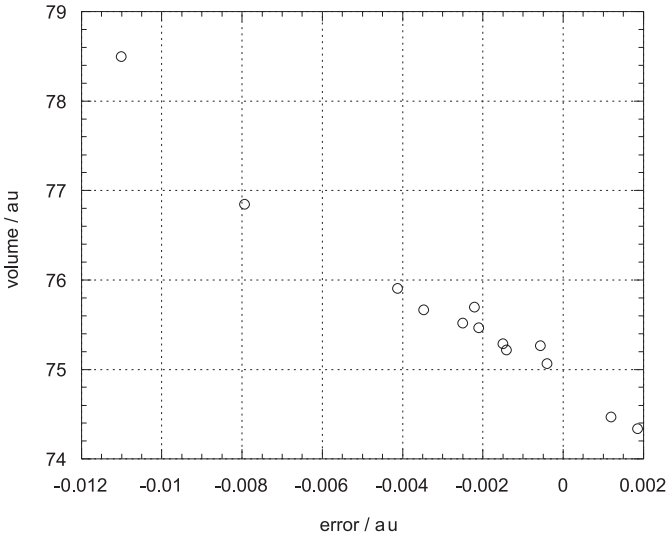

Fig. 4. Plot of the atomic volume $v(\Omega)$ against $L(\Omega)$ for the carbon in methanethiol.

while overestimating the magnitude of the energy, and the dipole and quadrupole moments. A negative error has the opposite effect. Regression analysis was carried out on the results to ascertain whether this trend was quantitative and therefore had predictive powers. Most properties were found to have no significant correlation with $L(\Omega)$ and could therefore not be used for interpolation or extrapolation.

The exceptions proved to be the population of the carbon atoms in the set and the volume of the carbon atom in methanethiol. Figure 3 shows the plot of the population, $N(\Omega)$, against $L(\Omega)$ for carbon in methanethiol. The corresponding R^2 value is 0.969. To check that the correlation observed was genuine, outlying points were removed, and R^2 was found to range from 0.945 to 0.987. The correlation coefficients are high enough to enable a meaningful interpolation to the desirable atomic property corresponding to $L(\Omega) = 0$. The regression equation is:

$$[6] \quad N(\Omega) = -0.90897\ L(\Omega)\ (\pm\ 0.049068) + 6.11207\ (\pm\ 0.00021)$$

It is clear that the ideal $N(\Omega)$ value is 6.11207 au, if $L(\Omega)$ is set to zero, which corresponds well with the result of the integration with the lowest error, which is 6.1121 au (see Table 3). A similar successful interpolation can be carried out with the volume of this carbon. Figure 4 shows the graph of the volume $v(\Omega)$ against $L(\Omega)$ where $R^2 = 0.966$ and the regression equation is:

$$[7] \quad v(\Omega) = -297.236\ L(\Omega)\ (\pm\ 16.812) + 74.853\ (\pm\ 0.072)$$

The ideal volume is thus predicted to be 74.853 au, which is 0.22 au lower (0.3%) than the best predicted value. A good estimate of the exact population of carbon in alanine (Fig. 5) can be made via extrapolation of the following regression equation:

$$[8] \quad N(\Omega) = -0.82405\ L(\Omega)\ (\pm\ 0.0491) + 5.66614\ (\pm\ 0.00013)$$

From this equation we predict that the population is 5.66614, which reduces the overall population, $\sum_{\Omega} N(\Omega)$, from 48.0087 to 48.0011. This means that the extrapolated population brings the overall population closer to the ideal value of 48.

We can also confirm the relationship reported before (22) between the overall sum of the integration errors of all atoms in a molecule $\sum_{\Omega} L(\Omega)$ and the deviation, $\Delta N(\Omega)$, of the sum of the populations, $\sum_{\Omega} N(\Omega)$, from the total population, N_{total}. The results from our data set of 57 molecules, including the twenty amino acids and smaller derived molecules[6] are plotted in Fig. 6.

It should be pointed out that our current findings are not due to well-known inadequacies of atomic integration, such as the "leakage" phenomenon. This means that MORPHY has a special algorithm built in (23) that prevents an integration ray from penetrating into an adjacent basin due to incorrect truncation. Furthermore, MORPHY does not allow poor analytical representations of interatomic surfaces (23), for example when they contain ring critical points. These precautions make us believe that the effects we observe are genuine, although admittedly there are several integration parameters (23), other than the number of quadrature points, that we have not systematically varied. Rather, they were kept fixed in this work, at values that we associated with reliable and efficient integration practice in the course of the development of MORPHY.

A final comment is concerned with a speculative explanation for the oscillating behaviour of $L(\Omega)$ versus the number of grid points. It is well known that Gauss–Legendre quadrature requires an enormous amount of grid points to integrate reasonably a function that contains a cusp. A cusp is a continuous point where the left and right derivatives are not the same, hence the derivative is not defined at a cusp. In our case the cusp originates from the geometrical shape of the atom. A function that measures the distance from the nucleus to a point on the atomic boundary has no derivative with respect to the angular displacement at a cusp point. Figure 7 shows an example of a cusp in benzene. The so-called ring line, which is perpendicular to the molecular plane is a collection of cusp points. Indeed, an integration ray sweeping the atom (as marked by the arrow) would see its length increase when approaching the cusp line and then suddenly decrease having passed the cusp line. In other words, the geometry of the atom is not experienced as a smooth object by the integration ray. As a result the Gauss–Legendre quadrature needs to be very large. However, we suspect that a coarse grid will not detect the cusp as well as a fine grid and

Fig. 7. A schematic illustration of a (geometrical) cusp occurring in a typical ring atom such as carbon in benzene. The three interatomic surfaces bounding the carbon atom are outlined. The circle represents the nucleus and the arrow indicates an integration ray hitting the cusp.

hence accurate integrations can occur with small grids. Moderate grids may then detect the cusp better but they would not be large enough to handle it properly. However, very large grids should again be adequate, both in detecting the cusp and managing to integrate properties in its presence.

Although a cusp line appearing in ring system is a clear case, many atoms are bounded by interatomic surfaces that almost touch in long narrow tails. Such a geometrical feature may be viewed as a pseudo-cusp, i.e., a sudden change in the length of an integration ray upon angular displacement. Table 3 (or Fig. 1*b*) reveals the extent to which a cusp can affect the integration. There is a significant improvement in the quality of $L(\Omega)$ where the number of points is equal to 6 400 and again at 19 600.

[a]Remaining quadrature values, ($n_r(\beta)$, $n_\theta(\beta)$, $n_\phi(\beta)$, n_r) are set to (50, 30, 40, 50).

3.2 Grid orientation

Finite grids produce properties that lack rotational invariance. This occurs because Gauss–Legendre quadrature samples the atom densely near the poles (θ near 0° or 180°) and the positive *x*-axis (φ near 0° or 360°). This effect can be illustrated by considering, for example, the four hydrogens in methane (24). By symmetry the hydrogens are expected to be identical but in practice they may not be, which can be explained as follows. The local axis system of a hydrogen atom is parallel to the molecular axis system, but the orientation of the hydrogen with respect to this axis system is of course different for each atom. The angular quadrature grids are constructed in the same way with respect to the local axis systems of the hydrogens, but each atom will have a different orientation with respect to this axis system. In other words, from the atom's point of view it is integrated via an angular grid with an orientation that is different for each hydrogen. Hence the molecular symmetry is not perfectly reflected in the atomic properties.

To assess the influence of grid orientation we have investigated carbon in methanethiol (Table 9) and oxygen in water (Table 10). In both cases we considered three different orientations, labeled *xy*, *xz*, and *yz*.[7] Carbon is generally harder to integrate than oxygen, presumably because it usually occurs tetra-coordinated, which leads to pseudo-cusps. Again the most stable properties are seen to be the energy and the population. It is clear that the same grid size leads to markedly different $L(\Omega)$ values dependent on the orientation, especially for carbon with its spike-like atomic tails. Such

[7]The Cartesian co-ordinates of the standard orientation were taken from the GAUSSIAN output file and the wave functions of the two new orientations were computed by interchanging the components of the axes alternately, i.e., the values of the *x*-axis and *y*-axis were exchanged as were those of the *x*-axis and *z*-axis. This resulted in one molecule lying in the *xy*-plane, one in the *xz*-plane and the third in the *yz*-plane.

yz	19500 (130,150)	–0.00146	75.33	–37.940763	6.1134	0.055	0.0945	3.3723	4.1366
xz	19500 (130,150)	–0.00224	75.47	–37.940631	6.1142	0.0554	0.0969	3.3789	4.1235
Difference		0.00078	–0.14	–0.000132	–0.0008	–0.0004	–0.0024	–0.0066	0.0131

unpredictable variation reinforces our statistical point of view. A comparison of the standard deviations in Table 9 with those in Table 6, and of those in Table 10 with those in Table 3 reveals that the grid size and grid orientation have a similar effect on the variation of atomic properties. The effect on atomic properties of the variation of the integration grid with the same orientation can be larger than between identical grids with a different orientation.

Finally we prove that generally the difference between atomic properties is smaller for small values of $L(\Omega)$ rather than for a large number of points in the angular grid. To illustrate this phenomenon we list in Table 11 atomic properties for carbon in methanethiol. All the properties, with the exception of the volume and the hexadecupole, show a smaller deviation for low values of $L(\Omega)$ than for a high number of grid points. As such the orientation study also confirms that a larger grid does not necessarily lead to better results.

4. Conclusions

The practical integration of nearly a thousand atoms[6] in molecules of biological interest has prompted concern about the reliability or stability of the obtained atomic properties and about how many quadrature points are required to obtain sufficiently stable atomic properties. The only direct measure for the integration quality is $L(\Omega)$, a quantity without any chemical meaning. In other words, $L(\Omega)$ is not useful as an atomic property other than to assess the integration quality. It is straightforward to determine an integration grid that accurately integrates the β sphere inside C, N, O, and S. On the other hand predicting an angular grid outside the β sphere, with a number of points between approximately 1 000 and 25 000, and that guarantees a low $L(\Omega)$ value, is virtually impossible. The naïve view that a feasibly large grid leads to low $L(\Omega)$ values proves to be wrong. Instead we find that $L(\Omega)$ depends on the number of grid points according to nontrivial patterns, which may exhibit oscillatory behaviour. Consequently, from a practical point of view, we regard an atomic integration as a "measurement" of an atomic property, which has an error bar associated with it. Based on systematic calculations we are able to present safe error bars for seven atomic properties for the most common atoms occurring in biological molecules, i.e., C, N, O, and S. The integrations of hydrogen usually yield $L(\Omega)$ values well below 10^{-4} au and can hence be considered as perfect.

We also investigated the dependence of seven atomic properties on $L(\Omega)$, i.e., volume, energy, and the magnitudes of five electrostatic moments. Whereas atomic properties and $L(\Omega)$ are typically poorly correlated, the electronic populations of carbon tends to correlate linearly with $L(\Omega)$. This fact can be used to interpolate and extrapolate the population corresponding to $L(\Omega) = 0$, resulting in the ideal value. In spite of the lack of correlation some properties are systematically overestimated by a negative $L(\Omega)$ value, and others underestimated. Finally we have observed that the influence of the grid orientation is reduced if $L(\Omega)$ is small.

Excess molar volumes and viscosities of binary mixtures of some *n*-alkoxyethanols with propylamine at 298.15 K

Amalendu Pal, Sanjay Sharma, and Harsh Kumar

Abstract: Excess molar volumes (V^E_m) and dynamic viscosities (η) for five (alkoxyethanol + propylamine) mixtures have been measured as a function of composition at 298.15 K and atmospheric pressure. The alkoxyethanols were 2-methoxyethanol, 2-(2-methoxyethoxy)ethanol, 2-(2-ethoxyethoxy)ethanol, 2-(2-butoxyethoxy)ethanol, and 2-{2-(2-methoxyethoxy)ethoxy}ethanol. The excess molar volumes V^E_m are all negative over the whole composition range. The viscosity data have been correlated by the methods of Kendall and Monroe, Grunberg and Nissan, Tamura and Kurata, Hind, Katti and Chaudry, and with McAllister correlations. From the experimental data, deviations in the viscosity ($\Delta\eta$) have been calculated. The results are discussed in terms of the interaction between components.

Key words: excess volume, viscosity, binary mixtures.

Résumé : Opérant à 298,15 K et à la pression atmosphérique, on a mesuré les volumes molaires en excès (V^E_m) et les viscosités dynamiques (η) de cinq mélanges (alkoxyéthanol + propylamine) en fonction de la composition. Les alkoxyéthanols utilisés sont: 2-méthoxyéthanol; 2-(2-méthoxyéthoxy)éthanol; 2-(2-éthoxyéthoxy)éthanol; 2-(2-butoxyéthoxy)éthanol et 2-{2-(2-méthoxyéthoxy)éthoxy}éthanol. Les volumes molaires en excès (V^E_m) sont négatifs à toutes les compositions. On a pu établir une corrélation entre les données de viscosité en faisant appel aux méthodes de corrélation de Kendall et Monroe, Grunberg et Nissan, Tamura et Kurata, Hind, Katti et Chaudry et de McAllister. À partir des données expérimentales, on a calculé les déviations dans la viscosité ($\Delta\eta$). On discute des résultats en fonction de l'interaction entre les composants.

Mots clés : volume en excès, viscosité, mélanges binaires.

Introduction

In continuation of our program of research on thermodynamic, acoustic, and transport properties of binary mixtures containing oxygen (-O-) and hydroxyl (-OH) functional groups (1–4), we report here new experimental data of the excess molar volumes (V^E_m) and viscosities (η) of binary solvent mixtures containing 2-methoxyethanol, 2-(2-methoxyethoxy)ethanol, 2-(2-ethoxyethoxy)ethanol, 2-(2-butoxyethoxy)ethanol, and 2-{2-(2-methoxyethoxy)ethoxy}ethanol with propylamine over the whole composition range at 298.15 K and atmospheric pressure. Investigations into the literature have shown that excess properties of binary mixtures of butylamine, dibutylamine, or tributylamine with a straight-chain, branched-chain, or cyclic ether have previously been studied by several authors (5–9). They have analyzed the results in terms of different correlating equations or Flory's theory that gave a better understanding about the association behaviour of the amine and the ether. Recently, few studies involving binary mixtures of propylamine with 1-alkanol have been carried out by some other authors (10–12). The present study was therefore undertaken to assess the effects of increasing the alkyl group size with a common polar head group, and of inserting oxyethylene groups with a common alkyl group in alkoxyethanol. An attempt is also made to interpret the results in terms of intermolecular interactions between amine and alkoxyethanol.

Experimental

Material

The propylamine and ethylene glycol monomethyl ether samples were obtained from Merck–Schuchardt with stated purities of >99% and 99.5% and were dried and fractionally distilled (13, 14). The origin and purities of other liquids used have been described (15, 16). All liquids were stored in dark bottles over 4 Å molecular sieves (Fluka, AG) to reduce water content. Prior to measurements, all liquids were partially degassed under vacuum. The densities, and viscosities of these liquids are measured and compared at (298.15 ± 0.01) K and atmospheric pressure with their corresponding literature values (14, 17–23) as shown in Table 1. The densities of pure liquids were measured with a bicapillary pycnometer that gave an accuracy of 5 parts in 10^5.

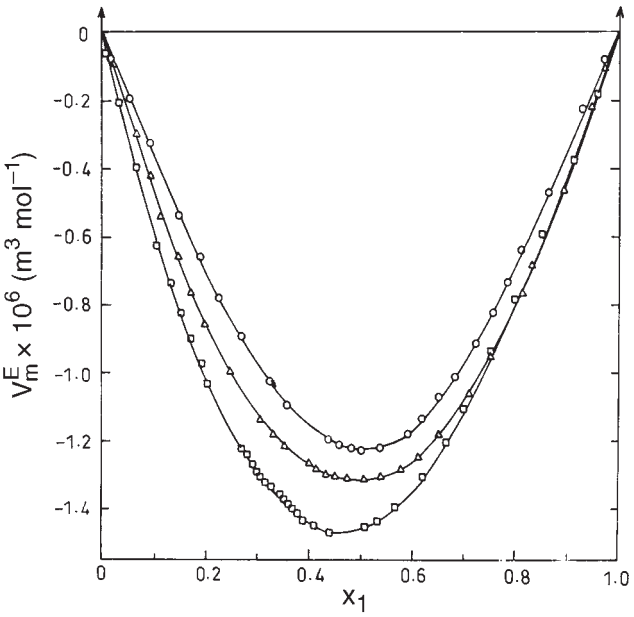
Apparatus and procedure

Excess molar volumes, which are reproducible to ±0.003 $\times 10^6$ m^3 mol^{-1}, were measured by means of a continuous dilution dilatometer in fashion similar to that described by Dickinson et al. (24). Details of its calibration and operational procedures have been described previously (25). Each run covered just over half of the mole fraction range, giving an overlap between two runs.

The kinematic viscosities of both the pure liquids and liquid mixtures were measured with a calibrated Ubbelohde suspended-level viscometer. Experimental details have been given previously (26, 27). Care was taken to prevent evaporation during the measurements. Four or five sets of readings for the flow times were taken for each liquid and the arithmetic mean was taken for the calculation of viscosity. The measured values of kinematic viscosities (ν) were converted to dynamic viscosities (η) after multiplication by the density. The values of η obtained are reproducible to 3×10^{-3} mPas. The flow time was measured with an accurate stop watch with a resolution of 0.01 s. The mole fraction of each mixture was obtained with an accuracy of 1×10^{-4} from the measured apparent masses of the components. All apparent masses were corrected for buoyancy. All the molar quantities were based upon the relative atomic mass table of 1986 issued by IUPAC (28). All the measurements were carried out in a thermostat-controlled well-stirred water bath, whose temperature was controlled to ±0.01 K.

Results



Results of measurements of excess molar volumes for all the binary mixtures at number of mole fractions at 298.15 K are given in Table 2 and are graphically represented in Figs. 1 and 2.

The viscosities were fitted to a polynomial of type:

$$[1] \qquad \eta = \sum_{i=1}^{n} A_i x_1^{\,i}$$

by the method of least squares with equal weights assigned to each point. The values of coefficients A_i and standard deviations σ are listed in Table 3(a).

Fig. 1. Experimental excess molar volumes for propylamine (2) + 2-methoxyethanol (1), ○; 2-(2-methoxyethoxy)ethanol (1), △; 2-{2-(2-methoxyethoxy)ethoxy}ethanol (1), □. Continuous curves were calculated from eq. [5].

The densities of the mixtures were obtained from the densities of the pure components and measurements on V_m^E for their binary mixtures according to the equation:

$$[2] \qquad \rho = (x_1M_1 + x_2M_2)/(V_m^E + x_1V_1 + x_2V_2)$$

where M_1 and M_2 represent molar masses.

The deviation in viscosity $\Delta\eta$ from a linear dependence on mole fraction average has been calculated from the following relation:

$$[3] \qquad \Delta\eta = \eta - x_1\eta_1 - x_2\eta_2$$

where x_1 and x_2 are the mole fractions, η is the dynamic viscosity of the mixtures and η_1 and η_2 are the viscosities of components 1 and 2, respectively. The estimated accuracy of ρ is about 1×10^{-1} kg m^{-3}.

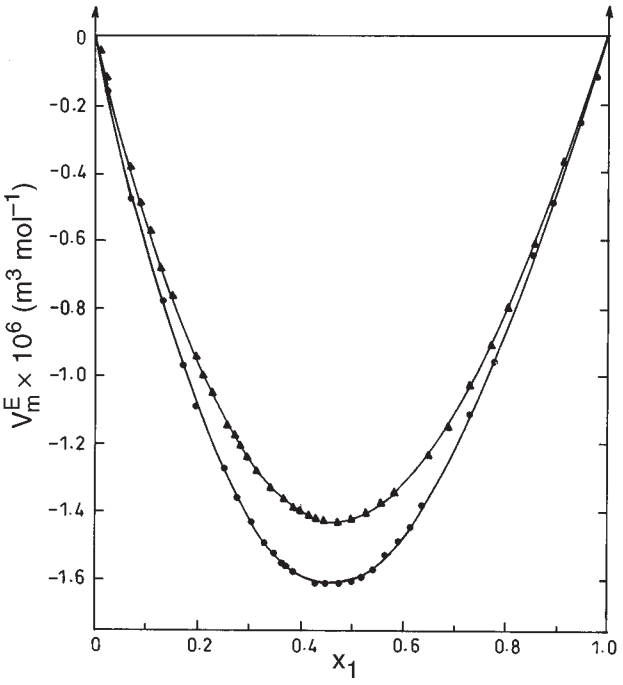

Fig. 2. Experimental excess molar volumes for propylamine (2) + 2-(2-ethoxyethoxy)ethanol (1), ●; 2-(2-butoxyethoxy)ethanol (1), ▲. Continuous curves were calculated from eq. [5].

On the basis of the theory of absolute reaction rate (29), the excess energies of activation ΔG^{*E} for viscous flow were obtained with the expression:

$$[4] \qquad \Delta G^{*E} = RT\{\ln (\eta V/\eta_2 V_2) - x_1 \ln (\eta_1 V_1/\eta_2 V_2)\}$$

where V is the molar volume of mixture and V_1 and V_2 represent molar volumes of the components 1 and 2. R and T have their usual meaning. Data on derived densities, viscosities and energies of activation for viscous flow for the different binary mixtures at 298.15 K are given in Table 4. The values of V^E_m, $\Delta\eta$, and ΔG^{*E} for each mixture have been fitted to the Redlich–Kister (30) polynomial equation:

$$[5] \qquad F(x) = x_1 x_2 \sum_{i=1}^{n} A_i (x_1 - x_2)^i$$

Values of the coefficients A_i and standard deviations are summarized in Table 3(b).

Correlating equations

Several relations have been proposed to evaluate the dynamic viscosity η of liquid mixtures by using classic laws of mixing representative of the viscosity of binary mixtures with an empirical adjustable parameter. In the literature, there are several laws of mixing, which can be classified according to the numbers of adjustable parameters used to account for the deviation from an ideal mixture. We will consider here some of the more commonly used semi-empirical models for analyzing viscosity of liquid mixtures based on zero, one and two parameters. An attempt has been made to check the suitability of the equation for experimental data fits by taking into account the number of empirical adjustment-coefficients.

One of the earliest and more effective equation to describe the dynamic viscosity of binary liquid mixtures as a function of those of the pure components is due to Kendall and Monroe (31) which has no parameter is expressed as

$$[6] \qquad \eta = (x_1 \eta_1^{1/3} + x_2 \eta_2^{1/3})^3$$

The equations of Grunberg–Nissan, Tamura and Kurata, Hind, and Katti and Chaudry have one adjustable parameter. Grunberg and Nissan provided the following empirical equation containing one adjustable parameter (32). The expression is

$$[7] \qquad \ln \eta = x_1 \ln \eta_1 + x_2 \ln \eta_2 + x_1 x_2 G_{12}$$

where G_{12} is a parameter proportional to the interchange energy. Tamura and Kurata developed the following expression for viscosity of binary mixtures (33):

$$[8] \qquad \eta = x_1 \phi_1 \eta_1 + x_2 \phi_2 \eta_2 + 2(x_1 x_2 \phi_1 \phi_2)^{1/2} T_{12}$$

where T_{12} is the interaction parameter and ϕ_1 and ϕ_2 are the volume fractions. Hind et al. (34) suggested the following equation:

$$[9] \qquad \eta = x_1^2 \eta_1 + x_2^2 \eta_2 + 2x_1 x_2 H_{12}$$

where H_{12} is attributed to unlike pair interactions.

Katti and Chaudry (35) derived the following equation:

$$[10] \qquad \ln \eta V = x_1 \ln V_1 \eta_1 + x_2 \ln V_2 \eta_2 + x_1 x_2 W_{vis}/RT$$

where V_i is molar volume of pure component i and W is an adjustable parameter.

McAllister's two-parameter equation (36), based on Eyring's theory of absolute reaction rates (37), takes into account interactions both of like and unlike molecules by a two-dimensional three-body model. The equation is:

$$[11] \qquad \begin{aligned} \ln \nu = {} & x_1^3 \ln \nu_1 + 3x_1^2 x_2 \ln Z_{12} + 3x_1 x_2^2 \ln Z_{21} \\ & + x_2^3 \ln \nu_2 - \ln (x_1 + x_2 M_2/M_1) \\ & + 3x_1^2 x_2 \ln (2/3 + M_2/3M_1) \\ & + 3x_1^2 x_2 \ln (1/3 + 2M_2/3M_1) + x_2^3 \ln (M_2/M_1) \end{aligned}$$

where Z_{12} and Z_{21} are interaction parameters and M_i and ν_i are the molecular mass and kinematic viscosity of pure component i.

To perform a numerical comparison of the correlating capability of eqs. [6–11] we calculated the standard percentage deviation (σ%) using the relation

$$[12] \quad \sigma(\%) = [1/(n - k) \times \Sigma(100(\eta_{exp} - \eta_{cal})/\eta_{exp})^2]^{1/2}$$

where n represents the number of experimental data and k the number of numerical coefficients in the respective equations.

Discussion

Figures 1 and 2 show that V^E_m values for all mixtures are negative over the whole mole fraction range. The value of V^E_m decreases with the addition of an OC_2H_4 group at the middle of the ether molecules, whereas V^E_m increases in the sequence 2-(2-methoxyethoxy)ethanol > 2-(2-butoxyethoxy)ethanol > 2-(2-ethoxyethoxy)ethanol. This behaviour may be compared with the V^E_m results for mixtures *n*-alkoxyethanols with alcohols (38–43); V^E_m decreases as the alkyl chain length as well as the polar head group of the alkoxyethanol increases. The large negative values of V^E_m is the result of contributions from several factors such as (*i*) the breakdown of self associated structure of alkoxyethanol and amine, (*ii*) the intermolecular hydrogen bond formation in the alkoxyethanol and the amine molecules, and (*iii*) specific interaction between alkoxyethanol and amine. With increasing the polar head group of the alkoxyethanol, interactions between unlike molecules become more important: V^E_m decreases and becomes more negative for the larger *n*-alkoxyethanols. In the same homologous series the algebraic values of V^E_m at $0.1 < x_1 < 0.8$ for the three binary systems with propylamine are in the order 2-(2-ethoxyethoxy)ethanol > 2-(2-butoxyethoxy)ethanol > 2-(2-methoxyethoxy)ethanol. The negative contribution to the V^E_m with 2-(2-ethoxyethoxy)ethanol caused due to strong association by hydrogen bonding and complex forming interaction giving higher negative values compared with those of the other two mixtures

Figure 3 shows that η increases with increase in the mole fraction x_1 of alkoxyethanol for all mixtures. Viscosities of all alkoxyethanol–propylamine binary mixtures increase with an increase in the alkyl group size as well as the polar head group in alkoxyethanol. The deviations in viscosity (Δη) and excess energies of activation for viscous flow (ΔG^{*E}) are represented in Figs. 4 and 5. All the mixtures show negative deviations from mole fraction linearity except small positive deviations in high mole fraction region of alkoxyethanol in alkoxyethanol + propylamine systems. The magnitude of negative deviations increases with increasing polar head group as well as the alkyl chain length of alkoxyethanol. This sequence, highly related to the strengthening of the heteroassociation of molecule with the increase of a $-OC_2H_4$ group in 2-methoxyethanol, is also observed for the excess molar volumes V^E_m of these mixtures. The values of ΔG^{*E} are positive for all the mixtures and increase with increasing the alkyl chain end length as well as the polar head group of alkoxyethanol. The positive values of ΔG^{*E} are attributed to the large size and cohesive energy difference between the two unlike components.

The positive η, Δη, and ΔG^{*E} are an indication of specific interactions (44, 45). In fact, the strong positive deviations in the viscosity for 2-{2-(2-methoxyethoxy)ethoxy}ethanol + propylamine, and 2-(2-butoxyethoxy)ethanol + propylamine

when mixture is rich in alkoxyethanol are observed. But negative deviations in viscosity are observed which regularly increase as the polar head group size or viscosity of the alkoxyethanol is increased. This suggests that the strength of intermolecular hydrogen bonding is not the factor influencing the viscosity deviation of liquid mixtures. The molecular size and shapes of the components also play an equally important role. Their behaviour also finds support from the

negative values of excess molar volumes. The large negative values of V_m^E and Δη were also observed for propylamine + 1-alkanol mixture (10) which were interpreted as strong H-bonding between unlike component molecules.

Table 5 gives the results of the correlating eqs. [6–11]. The values of the different adjustable parameters induced in eqs. [6–11] were determined for the systems using a least squares method, with equal weights assigned to each point. These values are reported in Table 5 together with the percentage standard deviations (σ%) between the calculated and experimental values. The values of σ are in the range from 13.9 to 21.7% for eq. [6] without any adjustable parameter; from 1.3 to 12.0% for single parameter eqs. [7–10]; from 0.9 to 1.6% for two parameters eq. [11]. As can be clearly seen by the results of eqs. [7–10] in Table 5, the two eqs. [7] and [10] of Grunberg–Nissan and Katti, and Chaudry give nearly identical results. They both represent the behaviour of the binary mixture satisfactorily as compared to Tamura and Kurata (33), and Hind et al. (34) (eqs. [8] and [9]). The equation of Kendall and Monroe (31) (eq. [6]) without any adjustable parameter is less suitable as the values of σ% are higher than that of the one parameter eqs. [7–10]. Use of the two parameters (eq. [11]) reduces the σ% values significantly below that of single-parameter equations. From this study, it can be concluded that the correlating ability significantly improves for these non-ideal systems as the number of adjustable parameters is increased.

Kinetics of acetal and orthobenzoate hydrolysis as probes of cyclodextrin–guest binding

Oswald S. Tee, Samer M. I. Hussein, Isabelle E. Turner, and Ogaritte J. Yazbeck

Abstract: Acid-catalyzed hydrolysis of acetophenone dimethyl acetal (ADMA) and trimethyl orthobenzoate (TMOB) is retarded by cyclodextrins (CDs): α-CD, β-CD, hp-β-CD = "hydroxypropyl-β-cyclodextrin", and γ-CD. The observed first order rate constants (k_{obs}) vary with [CD] in the manner expected for 1:1 binding between the substrates and the CDs. Similar behaviour was found recently for the hydrolysis of benzaldehyde dimethyl acetal (BDMA). With β-CD and hp-β-CD, the binding of all three substrates (BDMA, ADMA, TMOB) is strong and the CD-bound forms have very little reactivity. By contrast, substrate binding by α-CD is much weaker, and the CD-bound forms have appreciable, though reduced, reactivity. Substrate binding by γ-CD is also relatively weak, but the bound substrates have very low reactivities. The hydrolysis reactions of ADMA, TMOB, and BDMA have been evaluated as kinetic probes of the binding of guests to CD hosts. For α-CD, β-CD, and hp-β-CD, the addition of guests reduces the amount of free CD and thereby alleviates retardation of the hydrolysis by the CD. The resultant increases in hydrolysis rates can be analyzed to provide estimates of CD–guest dissociation constants, K_G. For aliphatic alcohols and ketones binding to β-CD and hp-β-CD, all three probe reactions provide values of K_G that agree well with each other and with literature values determined by other methods. The approach does not work well with α-CD because of its much weaker binding of the kinetic probes and their less pronounced dependence of k_{obs} on [α-CD]. In the case of γ-CD, the approach cannot be used because added guests cause a further lowering in the rate of hydrolysis, suggesting the formation of an unreactive ternary (substrate·CD·guest) complex.

Key words: acetal, hydrolysis, cyclodextrin, host–guest, binding.

Résumé : L'hydrolyse acidocatalysée du diméthylacétal de l'acétophénone (« ADMA ») et de l'orthobenzoate de triméthyle (« TMBO ») est ralentie par les cyclodextrines (CD), α-CD, β-CD, hp-β-CD (= hydroxypropyl-β-cyclodextrine) et γ-CD. L'influence de la [CD] sur les constantes de vitesse du premier ordre observées (k_{obs}) correspond à celle que l'on peut attendre en faisant l'hypothèse qu'il y a formation d'un complexe 1:1 entre les substrats et les CD. On a observé un comportement semblable récemment pour l'hydrolyse de l'acétal diméthylique du benzaldéhyde (« BDMA »). Avec la β-CD et la hp-β-CD, la fixation des trois substrats (BDMA, ADMA et TMOB) est forte et les formes liées aux CD n'ont qu'une faible réactivité. Par opposition, la fixation des substrats par l'α-CD est beaucoup plus faible et les formes liées aux CD sont assez réactives, même si celles-ci sont réduites. La fixation des substrats par la γ-CD est aussi relativement faible; toutefois, les substrats ainsi liés ont de très faibles réactivités. Les réactions d'hydrolyse des ADMA, TMOB et BDMA ont été évaluées comme sondes cinétiques de la fixation des invités aux CD hôtes. Pour les α-CD, β-CD et hp-β-CD, l'addition de molécules invitées réduit la quantité de CD libre et il en résulte que la CD atténue la diminution de la vitesse d'hydrolyse. L'analyse de l'augmentation qui en résulte dans les constantes de vitesse permet d'obtenir des évaluations des constantes de dissociation CD–hôte, K_G. Pour la fixation d'alcools et de cétones sur les β-CD et hp-β-CD, les trois réactions sondes conduisent à des valeurs de K_G qui sont en accord les unes avec les autres ainsi qu'avec les valeurs déterminées par d'autres méthodes rapportées dans la littérature. Cette approche ne donne pas de bons résultats avec l'α-CD en raison du fait que les sondes cinétiques se fixent beaucoup plus faiblement et que l'influence de la [α-CD] sur k_{obs} est beaucoup plus faible. Dans le cas de la γ-CD, il est impossible d'utiliser cette approche parce que les hôtes supplémentaires provoquent une diminution supplémentaire dans la vitesse d'hydrolyse; ceci suggère qu'il y a formation d'un complexe ternaire (substrat-CD-invité) qui n'est pas réactif.

Mots clés : acétal, hydrolyse, cyclodextrine, hôte–invité, fixation.

Introduction

Competitive inhibition kinetics (1) are widely used in enzymology to quantify the binding of substrate analogues and transition state analogues to enzymes (2). To a limited extent, similar methodology has been employed for assessing the binding of guests to cyclodextrin (CD) hosts (3). For example, VanEtten et al. (4) studied the inhibition of CD-induced ester cleavage and obtained estimates of dissociation

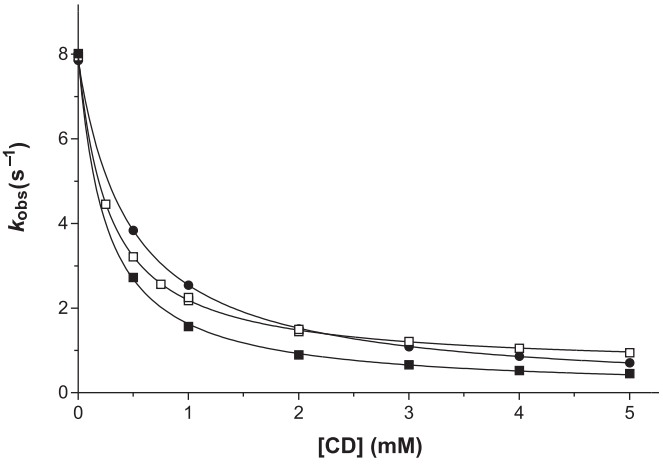
Fig. 1. Effects of cyclodextrins on rates of hydrolysis: ADMA and β-CD ■, TMOB and β-CD □, ADMA and hp-β-CD ●. The data for TMOB and hp-β-CD are not shown in the interests of clarity. The curves are calculated from eq. [4], with constants from Table 1.



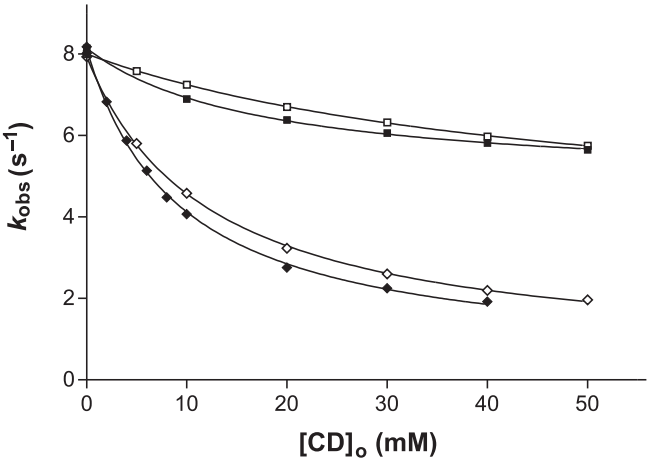


Fig. 2. Effects of cyclodextrins on rates of hydrolysis: ADMA and α-CD □, TMOB and α-CD ■, ADMA and γ-CD ◇, TMOB and γ-CD ◆. The curves are calculated from eq. [4], with constants from Table 1.

constants of CD–guest complexes (K_G, eq. [1]). We have used a similar approach on many occasions (5), although with a different form of data analysis from VanEtten's.

$$[1] \qquad CD + G \underset{K_G}{\overset{K_f}{\rightleftharpoons}} CD{\cdot}G;\ K_G = [CD][G]/[CD{\cdot}G] = 1/K_f$$

The basis of normal "inhibition" methods is that addition of an inhibitor (= guest, G), which binds to the catalyst (enzyme or CD host), reduces the concentration of the free catalyst, and so reduces the rate of the catalyzed reaction. Appropriate analysis of the rate reductions in terms of the amount of added guest then affords an estimate of the catalyst–guest dissociation constant (K_G)[2], or its inverse, the formation constant (K_f) (6).

Recently, we showed that the same approach can be used for a probe reaction that is retarded, rather than catalyzed, by cyclodextrins (CDs) (7). The acid-catalyzed hydrolysis of benzaldehyde dimethyl acetal (BDMA) is strongly retarded by binding to β-CD, hp-β-CD, and γ-CD, but less so by α-CD.[3] In simple cases, the addition of guests lowers the concentration of free CD, reduces the amount of CD-bound substrate, and so *increases* the rate of acetal hydrolysis. Analysis of the rate increases as a function of [guest] can be used to estimate K_G for the CD–guest complexation (7).

In the present paper we report studies of the effects of the same four CDs on the hydrolysis of two more substrates, acetophenone dimethyl acetal (ADMA) and trimethyl orthobenzoate (TMOB), as well as extensive studies of the use of the hydrolysis of BDMA, ADMA, and TMOB as kinetic probes of the binding of alcohols and ketones to CDs, using the methodology of "inhibition kinetics." We have also tried another way of analyzing the rate data to find K_G values. This work is part of our ongoing search for fast[4] and reliable methods of estimating the dissociation constants of host–guest complexes formed by CDs (5, 7).

Results

As found previously for BDMA (7), the acid-catalyzed hydrolysis of acetophenone dimethyl acetal (ADMA) and of trimethyl orthobenzoate (TMOB) are both sharply retarded by β-CD and hp-β-CD (Fig. 1), but much less so by α-CD and γ-CD (Fig. 2). The fitted curves in Figs. 1 and 2 are derived from the normal model for saturation kinetics (5, 7) which allows for 1:1 binding between the substrate (S) and the CD, reaction of the free substrate, eq. [2], and reaction of a substrate–CD complex (S·CD), eq. [3]. For this model the predicted variation of k_{obs} with [CD] is given by eq. [4], assuming that [CD] >> [S·CD] < $[S]_o$, which was valid for all experiments.

$$[2] \qquad S \xrightarrow{k_u} \text{products}$$

$$[3] \qquad S + CD \underset{K_S}{\rightleftharpoons} S{\cdot}CD \xrightarrow{k_c} \text{products}$$

$$[4] \qquad k_{obs} = \frac{(k_u K_S + K_c[CD])}{(K_S + [CD]}$$

Table 1 contains the parameters obtained from fitting eq. [4] to the data for ADMA and TMOB, and used to calculate the curves in Figs. 1 and 2. As seen by the standard errors and correlation coefficients, the fits to the data are good to excellent. Table 1 also contains parameters for BDMA, deter-

[2] In enzymology, K_G is usually referred to as an inhibition constant, K_I (1, 2).

[3] The three parent cyclodextrins are α-cyclodextrin (α-CD), β-cyclodextrin (β-CD), and γ-cyclodextrin (γ-CD), composed of six, seven, and eight glucose units, respectively (3). We also use hydroxypropyl-β-cyclodextrin (hp-β-CD), which is β-CD that has been reacted with propylene oxide so that most of its primary hydroxyl groups are alkylated (3*e*).

[4] Acetal hydrolysis was chosen as a kinetic probe because it is a fast reaction that came be monitored easily in dilute aqueous acid. The broad features of the reaction are well-known and will not be discussed here. Background references can be found in ref. (7).

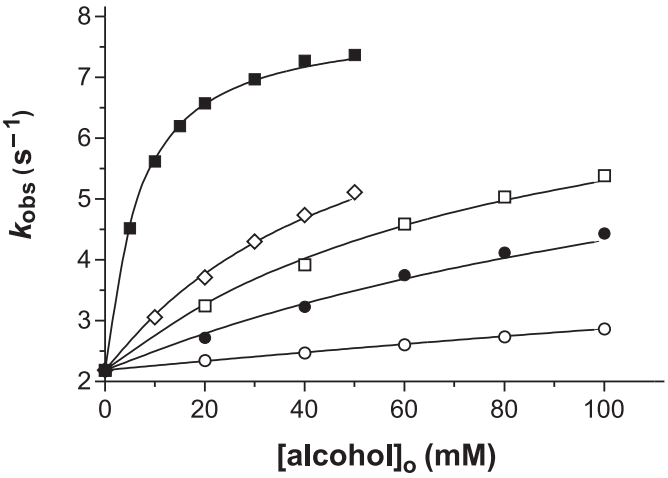
[a]At 25°C. Values of K_S and k_c were obtained by nonlinear fitting of eq. [4], usually with k_u fixed at the observed value. Where k_u is presented with errors, it was fitted. The errors cited are standard errors, r is the correlation coefficient, and N is the number of data points. Several examples of the data and fitted curves are shown in Figs. 1 and 2.

[b]In 0.010 M aqueous HCl.

[c]In 0.100 M aqueous HCl.

[d]Taken from ref. (7).



[e]Value fixed at zero. With k_c as a parameter, nonlinear fitting gave values indistinguishable from zero, and closely similar values of K_S. For details, see ref. (7).

mined earlier (7), which are included for comparative purposes, and which were necessary for binding studies discussed later. Note that in the case of the hydrolysis of BDMA, three of the CDs give values of k_c that are indistinguishable from zero, and such is almost the case for ADMA reacting in the presence of β-CD or hp-β-CD (Table 1).

We have carried out a large number of kinetic studies of the effects of guests on the CD-retarded hydrolysis of BDMA, ADMA, and TMOB, to ascertain the feasibility of using the rates of these reactions for estimating dissociation constants of CD–guest complexes. As remarked in the introduction, the addition of a guest, which binds to the CD in competition with the reacting substrate, should lead to an *increase* in k_{obs}, because $k_c < k_u$. Such behaviour has been observed for the hydrolysis of all three substrates in the presence of α-CD, hp-β-CD, and β-CD, with aliphatic alcohols and ketones as guests. Some examples involving the hydrolysis of TMOB, showing the effects of added alcohols and ketones, are presented in Figs. 3 and 4. Comparable behaviour has been found for the hydrolysis of ADMA and BDMA (some examples for BDMA were presented earlier (7)).

Substantial rate increases, such as those displayed in Figs. 3 and 4, can be analyzed to estimate the dissociation constants (K_G) of cyclodextrin–guest (CD·G) complexes using an approach developed some years ago (5*a*). The basis of the approach is utilization of eq. [5], derived from a rearrangement of eq. [4], to find [CD] from k_{obs} measured in the presence of an added guest, G. Using established parameters k_u, k_c, and K_S (Table 1), values of [CD] are calculated for

Fig. 3. Effects of alcohols on the rate of hydrolysis of TMOB in the presence of 1.00 mM β-CD: cyclohexanol ■, 1-pentanol ◇, *tert*-butanol □, 1-butanol ●, 2-propanol ○. The curves are calculated with K_G values from Table 2.

several $[G]_o$, and then estimates of K_G are evaluated, through the use of eq. [6],[5] and averaged. Calculations are carried out in a spreadsheet, as described earlier (5*a*, *c*).

$$[5] \qquad [CD] = \frac{(k_{obs} - k_u)K_S}{(k_c - k_{obs})}$$

$$[6] \qquad K_G = \frac{[CD]([G]_o - [CD]_o + [CD])}{([CD]_o - [CD])}$$

[5]Equation [6] is derived from the definition of K_G in eq. [1], along with the substitution of $[CD] = [CD]_o - [CD\cdot G]$ and $[G] = [G]_o - [CD\cdot G] = [G]_o - ([CD]_o - [CD])$.

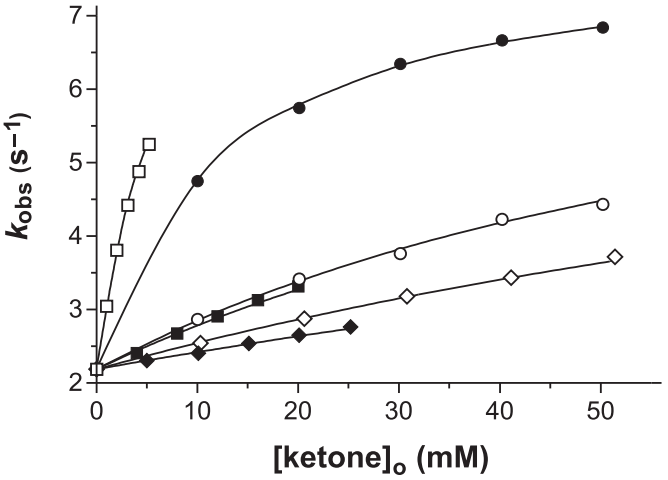
[a]At 25°C. The CD-retarded hydrolysis of ADMA was in 0.010 M aqueous HCl; that of TMOB and of BDMA were in 0.100 M aqueous HCl. Multiple entries for a particular guest reflect separate results from different experiments or different researchers.

[b]Values for BDMA and ketones were obtained in this work; those for BDMA and alcohols are taken from ref. (7).

[c]Literature values for β-CD and alcohols are given as the range of the most reasonable values to be found in Matsui and coworkers (8), two recent reviews (9), and other sources cited in ref. (7).

[d]Literature values for hp-β-CD and alcohols are from a method based on the inhibition of basic ester cleavage by the CD or a fluorescent probe displacement method (5*c*).



[e]Literature values for β-CD and ketones were obtained from the inhibition of CD-induced ester cleavage or from a fluorescent probe displacement method (5*d*). There are fewer entries for ketones and ADMA because of spectral interference by the ketone guest at the wavelength used to monitor the hydrolysis reaction (see text).

[f]The entry for this 3-isomer in Table 1 of ref. (7) is mislabelled as the 2-isomer.

Table 2 presents a large number of K_G values for the binding of aliphatic alcohols and ketones to β-CD and hp-β-CD, obtained through the use of eqs. [5] and [6], and the hydrolysis of ADMA, TMOB and BDMA as probes. Table 2 also contains literature values for comparison: those for alcohols binding to β-CD are taken primarily from Matsui and co-

Fig. 4. Effects of ketones on the rate of hydrolysis of TMOB in the presence of 1.00 mM β-CD: cycloheptanone □, cyclohexanone ●, cyclopentanone ○, 3-hexanone ■, 2-pentanone ◇, 3-pentanone ◆. The curves are calculated with K_G values from Table 2.

workers (8) and two recent compilations (9)[6] (most of the other values were determined in this laboratory by one or more different methods (5, 7)).

Attempts to use ADMA and TMOB hydrolysis to probe guest binding to α-CD gave results that were variable and hence unreliable, as found previously for BDMA (7). Equally disappointing, experiments on guest binding to γ-CD were unsuccessful since small *decreases* in the rates of hydrolysis of the kinetic probes were observed, instead of the increases that are required for simple 1:1 CD–guest binding.

In addition to the "spreadsheet" analysis, which was used to obtain the K_G values in Table 2, we have examined use of an expression which relates [CD] to the initial concentration of the guest. Expansion of eq. [6] leads to a quadratic in [CD] whose solution is given by eq. [7]. For several different $[G]_o$, non-linear fitting of eq. [7] to the values of [CD], calculated from eq. [5], was used to get an estimate of K_G. Table 3 presents several values obtained in this way, and Fig. 5 shows examples of the variation of [CD] with $[G]_o$, along with the fitted curves described by eq. [7]. It will be noted that the K_G values resulting from fitting to the quadratic solution are essentially identical to those obtained from the spreadsheet treatment, though with smaller standard errors (Table 3).

$$[7] \qquad [CD] = \{-B + (B^2 + 4K_G.[CD]_o)^{1/2}\}/2,$$

$$\text{where } B = ([G]_o - [CD]_o + K_G).$$

Discussion

The present work expands greatly on our initial study of the effects of CDs on the hydrolysis of BDMA (7). Similar behaviour has now been found for ADMA and TMOB (Table 1), and all three hydrolysis reactions can be used as kinetic probes of CD–guest binding, at least for β-CD and hp-β-CD (Table 2). Before discussing some aspects of this usage, we make a few remarks about the substrate binding and how it relates to the rate reductions.

Table 3. Dissociation constants (K_G, in mM) of β-CD–uest complexes, as calculated by the spreadsheet method and quadratic method.[a]

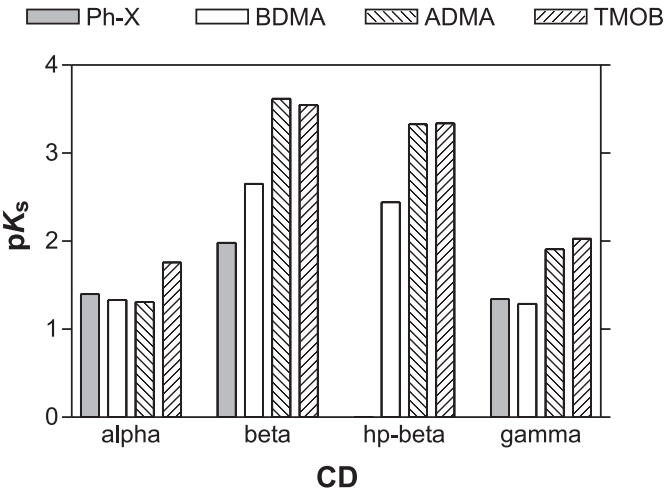
[a]At 25°C. The constants are values of $pK_d = -\log K_d = \log K_f$, where K_d has units of molarity. The first three rows, for BDMA, ADMA, and TMOB, are from the K_S values in Table 1. For the next 11 derivatives, the values are taken from literature compilations (9), or as noted.

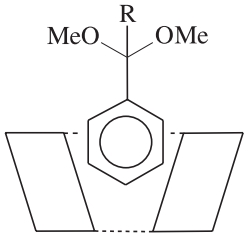
[b]From ref. (8*a*) or (8*b*).



[c]Unpublished work from this laboratory.

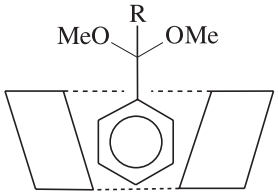
[d]Determined in this laboratory (5*d*, 7).

[e]Value for biphenyl minus 0.30, for the statistical correction (10).

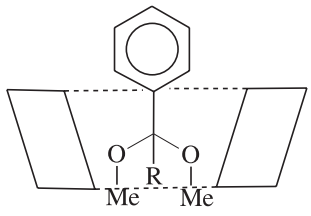


[f]The mean values for Ph-X, calculated by Gadre et al. (10), are based on the following number of derivatives: α-CD 15, β-CD 14, γ-CD 5.

Fig. 6. The relative strengths of binding of Ph-$CH(OMe)_2$, Ph-$CMe(OMe)_2$, and Ph-$C(OMe)_3$ to CDs, compared to the mean values for other phenyl-substituted derivatives.



seen there, for all three substrates the strength of binding follows the order: α-CD < β-CD ~ hp-β-CD > γ-CD. This order is typical for benzenoid compounds derivatives (7, 9), and to emphasize the point, Table 4 has the mean values of pK_S determined by Gadre et al. (10) for phenyl-substituted derivatives binding through their phenyl groups.[7] Compared to the mean values for Ph-X derivatives, the pK_S values for Ph-$CH(OMe)_2$, Ph-$CMe(OMe)_2$, and Ph-$C(OMe)_3$ are very similar in some cases, but appreciably higher in others. These trends are most clearly seen from the bar graphs in Fig. 6.



For binding to α-CD, the pK_S values of all three substrates are close to the mean value, consistent with the idea that they bind by their phenyl groups and sit more or less "perched" in the mouth of the CD cavity, as structure **1**. By contrast, substrate binding to β-CD is stronger than that of the mean of other phenyl derivatives, especially for $PhCMe(OMe)_2$ and $PhC(OMe)_3$, suggesting the involvement of some additional interactions. Conceivably, the substrates sit more deeply and snugly in the β-CD cavity, with some attractive interactions between the rim and the substituents (structure **2**). Alternatively, the stronger binding, particularly of ADMA and TMOB, may arise from binding of the substrates to β-CD with their substituents deep inside the CD cavity (structure **3**).

1

2

3

[7]The derivatives considered did not include carboxylic acids because they bind most strongly through their carboxyl groups (9, 10).

© 2000 NRC Canada

Because of its wider cavity (3), one expects γ-CD to show weaker binding than β-CD or hp-β-CD, and such is the case for all three substrates (Table 4). However, in the case of $PhCMe(OMe)_2$ and $PhC(OMe)_3$, their binding to γ-CD is stronger than expected from the mean value for other derivatives, which also may indicate additional interactions with the cavity rim (**2**) or that the substituents are buried inside the CD cavity (**3**).

Reactivity of CD-bound forms

The complexation of BDMA, ADMA, and TMOB by CDs reduces their reactivities in acid-catalyzed hydrolysis significantly (Figs. 1 and 2; Table 1). In the case of α-CD, the reactivities are attenuated by factors of k_u/k_c = 6.3, 2.3, and 1.7, respectively whereas with β-CD and hp-β-CD, both of which bind the substrates much more strongly, the rate reductions are by factors 14 to much more than 270. In the case of BDMA and the two β-CDs, the bound forms are essentially unreactive (Table 1). Even though γ-CD does not bind as strongly as β-CD, it also leads to large rate decreases by a factors of 18, 21, and much more.

In terms of our usual model of transition state stabilization (11), the low reactivities of the CD-substrate complexes mean that the hydrolysis transition states are bound less strongly than the substrates to the CDs ($k_u/k_c = K_{TS}/K_S > 1$). Previously, in our paper on BDMA hydrolysis (7), we argued that this weak transition state binding may be a consequence of the transition state being cationic, and CDs do not bind simple cations as well as neutrals. The same factor was later adopted by Iglesias and coworkers (12) to explain the rate-retarding effects of β-CD on the acid-catalyzed hydrolysis of phenylpropyl nitrites (12*a*) and on the nitrosation of the enol of benzoylacetone (12*b*). In the case of α-CD, where the substrates are most likely bound with their reactive groups exposed to the aqueous medium (**1**), this factor alone may be responsible for the relatively modest rate reductions. However, in the case of the two β-CDs, the much larger reductions in reactivity may result because the substrates are bound deeper within the CD cavity (**2**), and possibly with their substituents buried (**3**). In the latter case, the reactive groups would be more or less completely screened from the aqueous acidic medium and thus quite unreactive. Similar considerations apply to γ-CD, which also causes large rate reductions, even though its binding of the substrates is not as strong (Table 1).

Cyclodextrin–guest binding

In Table 2 are K_G values for various alcohols and ketones binding to β-CD and hp-β-CD, determined using the hydrolysis reactions of ADMA, TMOB, and BDMA as kinetic probes, and data analysis based on eqs. [5] and [6]. For these two CDs, the method works well in most cases, as can be appreciated from the calculated curves in Figs. 3 and 4, the standard errors, and comparisons with the literature values. The only sizeable deviations from the literature values are for quite small guests where the K_G values are large and less easily determined (5*c*, 5*d*, 6), and where there is a greater possibility of the guest not completely impeding the binding of the substrate. In the case of small ketones, like acetone and 2-butanone, there can be an additional problem of spectral interference, as outlined below.

In Table 2, under the column marked ADMA there are several blank entries for ketone guests. In these cases, kinetic experiments were unsatisfactory due to spectral interference by the ketones at the wavelength of 244 nm, used to monitor the appearance of the hydrolysis product, acetophenone. A similar problem was noted for the hydrolysis of BDMA to benzaldehyde, monitored at 252 nm, and it is the probable cause of the fairly large errors for acetone and 2-butanone, which must be added in high concentrations because they bind weakly. Generally speaking, however, the problem was less severe with BDMA than it is with ADMA and so there are more results for ketones under the column labelled BDMA in Table 2. There is no comparable problem of spectral interference when using the hydrolysis of TMOB as the probe because this reaction was monitored at 228 nm.

Previously, we found that the use of BDMA hydrolysis to probe guest binding to α-CD gave results that were not particularly reproducible and therefore unreliable (7). We have found the same to be true for the use of the hydrolysis of ADMA and TMOB. In all three cases, the difficulty is due to the low sensitivity of k_{obs} to [α-CD] (eg., Fig. 2) which arises because the values of k_c and k_u are not greatly different from one another, unlike the situation with β-CD or hp-β-CD (Table 1). As a consequence, relatively small errors in k_{obs} translate to larger errors in [α-CD] and even larger errors in estimates of K_G (7).

Our hopes of finding a new and fast method for assessing guest binding to γ-CD were not realized. None of several binding studies with γ-CD were successful since we observed decreases in the rates of hydrolysis of the probes, instead of the increases that are required for simple 1:1 CD–guest binding. As remarked previously (7), these decreases could arise from the formation of unreactive ternary complexes, composed of substrate, CD, and guest.

Conclusions

Cyclodextrins cause appreciable retardation of the acid-catalyzed hydrolysis of benzaldehyde dimethyl acetal, acetophenone dimethyl acetal, and trimethyl orthobenzoate. Using these three hydrolysis reactions as quantitative probes of CD–guest binding works very well for β-CD and hp-β-CD because these two CDs bind the substrates tightly and cause drastic reductions in their rates of hydrolysis. By contrast, the approach works poorly for α-CD because it does not bind the substrates strongly or reduce the substrate reactivities greatly. With γ-CD the approach is not applicable because added guests cause further reductions in the rates of hydrolysis, not increases, possibly due to formation of ternary (substrate·CD·guest) complexes. The findings also serve to emphasize that to be successful, competition methods for estimating host–guest binding must involve a host and probe that bind together tightly, so that little host or probe need be used, and that the host–probe binding should evoke a large response in some easily measurable property (5*c*, 6).

Experimental

The cyclodextrins were purchased from the Aldrich Chemical Co. or Wacker–Chemie (Munich), and used as supplied.

© 2000 NRC Canada

As previously (5, 7), the hydroxypropyl-β-cyclodextrin used was the Wacker product Beta W 7 HP 0.9, with an average molecular weight of 1500, corresponding to alkylation of six of the seven primary hydroxyl groups of β-CD by 2-hydroxypropyl groups. The substrates (BDMA, TMOB, and ADMA = (1,1-dimethoxy-ethyl)-benzene), alcohols, and ketones were all of the best grades available from Aldrich. Hydrochloric acid solutions were made by dilution of standard 1.00 M solutions obtained from American Chemicals Ltd (Montreal).

Hydrolysis reactions were initiated by 1:1 mixing in a stopped-flow spectrophotometer. Since the orthoester TMOB and the acetal ADMA both hydrolyze slowly but appreciably in water, the substrate solutions were made fresh for each set of kinetic runs, and made slightly basic with a drop of aqueous NaOH solution. These substrate (S) solutions (100 μM) were made up by dilution of a 0.10 M stock solutions in spectral grade acetonitrile, so as to give $[S]_o$ = 50 μM, after 1:1 mixing in the stopped-flow apparatus. For the experiments with varying $[CD]_o$ (eg., Fig. 1), one syringe of the stopped-flow apparatus contained 2 × 0.100 (or 0.010 M) aqueous HCl, and the other syringe held the substrate (100 μM) and the CD at twice the concentration desired in the final, reacting solution.

For the "inhibition" experiments, with fixed $[CD]_o$ and varying $[guest]_o$, one syringe contained 2 × $[CD]_o$ and 0.20 M aqueous HCl, and the other had the acetal (100 μM) and 2 × $[guest]_o$. The values of $[CD]_o$ were usually as follows: α-CD, 20.0 or 30.0 mM; β-CD, 1.00, 2.00, or 5.00 mM; hp-β-CD, 5.00 mM; γ-CD, 20.0 mM. The different values were chosen with regard to the K_S values of the CDs. The ranges of varying $[guest]_o$ used can be judged using the examples shown in Figs. 3, 4, and 5, and from those employed in previous studies involving the same guests (5, 7).

The hydrolysis of BDMA, ADMA, and TMOB was followed by monitoring the appearance of their products in the UV region: benzaldehyde at 252 nm, acetophenone at 244 nm, methyl benzoate at 228 nm. Pseudo-first-order rate constants were calculated from absorbance increases, measured using an Applied Photophysics SX17MV stopped-flow apparatus in the usual way (7). As explained in our initial study of BDMA (7), the first 5% of the absorbance trace was ignored to allow for the induction period that is a feature of acetal hydrolysis. The observation cell of the apparatus was kept at 25.0 ± 0.1°C.

Non-linear fitting of eqs. [4] and [7] was carried out with commercial software: GraphPad Prism, version 2.01. The estimation of dissociation constants of CD–guest complexes using the spreadsheet method and inhibition kinetics has been described in detail in previous publications (5, 7). The use of eq. [7] is described in the main text.

Excess molar volumes and viscosities of binary mixtures of triethylene glycol dimethyl ether (triglyme) with chloroalkanes at 298.15 K

Amalendu Pal and Gurcharan Dass

Abstract: Excess molar volumes (V^E_m) and viscosities (η) for mixtures of triethylene glycol dimethyl ether + dichloromethane, + trichloromethane, and + tetrachloromethane have been determined at 298.15 K and atmospheric pressure over the whole concentration range. From the experimental results, deviations in viscosities ($\Delta \ln \eta$) have been calculated. These properties were fitted to the polynomial relations to obtain the coefficients and the standard deviations. The results have been analysed in terms of molecular interactions between components.

Key words: experiments, data, excess volume, viscosity deviation, binary mixtures.

Résumé : Opérant à 298,15 K, à pression atmosphérique et sur l'ensemble de la plage de concentration, on a mesuré les volumes molaires en excès (V^E_m) et les viscosités (η) de mélanges de l'éther diméthylique du triéthylèneglycol additionné de dichlorométhane, de trichlorométhane ou de tétrachlorométhane. Sur la base des résultats expérimentaux, on a calculé les déviations dans les viscosités ($\Delta \ln \eta$). On a ajusté ces propriétés aux relations polynomiales pour obtenir les coefficients et les déviations standards. On a analysé les résultats en fonction d'interactions moléculaires entre les composants.

Mots clés : expériences, données, volume en excès, déviation de la viscosité, mélanges binaires.

[Traduit par la Rédaction]

Introduction

This is a part of an ongoing program of research in which we study thermodynamic, acoustic, and transport properties of binary mixtures containing alkoxyethanols as one of the components (1–4). The results on excess properties of volume, and viscosity for binary mixtures of *n*-butoxyethanols with chloroalkanes (2–4) were explained by considering the specific interactions between the components. In continuation of these investigations we report here the excess molar volume (V^E_m) and viscosity deviations ($\Delta \ln \eta$), at 298.15 K and atmospheric pressure, of binary mixtures of triethylene glycol dimethyl ether (triglyme) + dichloromethane (DCM), + trichloromethane (TCM), and + tetrachloromethane (TC). Investigations into the literature have shown that excess properties of binary mixtures containing chloroalkanes have previously been studied by several authors (5–7). The present study was therefore undertaken in order to compare the excess molar volumes and deviations in viscosity of triethylene glycol dimethyl ether + chloroalkanes with those of the results for diethylene glycol dimethyl ether + chloroalkanes (8) by the addition of an OC_2H_4 unit, for species with a common alkyl chain.

Experimental

Materials

Materials were the same origin and purity as used in earlier studies (2). Triethylene glycol dimethyl ether (Acros, U.S.A., 99+%) was fractionally distilled with sodium under reduced nitrogen gas pressure, and only the middle fraction was collected. Karl–Fischer titration gave water contents of 0.01 mass%. The densities and viscosities of these liquids are compared with their corresponding literature values (8–11) in Table 1. All liquids were stored in dark bottles over molecular sieves (Fluka, AG) to reduce water content. Before the measurements, all liquids were partially degassed under vacuum.

Apparatus and Procedure

The excess molar volumes were measured by means of a continuous-dilution dilatometer in fashion similar to that described by Dickinson et al. (12). Details of its calibration, experimental setup, and operational procedure have been described previously (13). The measured excess molar volumes were reproducible to $\pm 0.003 \times 10^6$ m^3 mol^{-1}. Each run covered just over half of the mole fraction range, giving an overlap between two runs. The mole fraction of each mixture was obtained with a precision of 1×10^{-4} from the measured apparent masses of the components. All apparent masses were corrected for buoyancy. All molar quantities are based on the relative atomic mass table of 1986 issued by IUPAC (14).

The kinematic viscosities in both the pure liquids and their mixtures were measured at 298.15 K and atmospheric

pressure, by using an Ubbelohde suspended-level viscometer (15), which was calibrated with doubly distilled water and benzene. The detailed procedure was described previously (16). Care was taken to prevent evaporation during the measurements. An average of four or five sets of readings for the flow times for each fluid were taken for the purpose of the calculation of viscosity. The measured values of kinematic viscosites (ν) were convereted to dynamic viscosites (η) after multiplication by the density. The values of η obtained were reproducible to 3×10^{-3} mPa s. The flow-time measurements were made with an accurate stopwatch with a precision of 0.01 s. The densities of pure liquids were measured with a bicapillary pycnometer, which gave an accuracy of 5 parts in 10^{-5}. The pycnometer was calibrated at 298.15 K and atmospheric pressure with twice-distilled water. All the measurements were carried out in a thermostatically controlled, well-stirred water bath, whose temperature was controlled to ±0.01 K.

Results

The experimental data of the excess molar volumes for triethylene glycol dimethyl ether + dichloromethane, trichloromethane, and tetrachloromethane for a number of mole fractions at atmospheric pressure and 298.15 K are reported in Table 2. The plots of excess molar volume together with the smoothing curves are given in Fig. 1.

From the measured values of excess molar volumes, densities of liquid mixtures were calculated using the following equation:

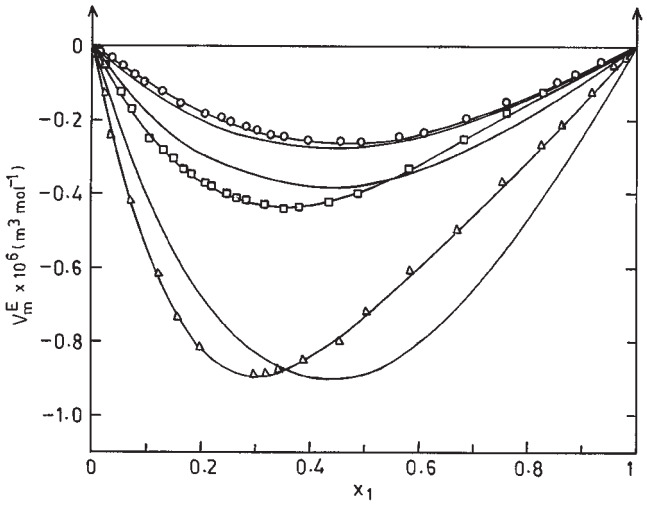
[1] $$\rho = (x_1M_1 + x_2M_2)/(V_m^E + x_1V_1 + x_2V_2)$$

where M_1 and M_2 represent molar masses.

The deviations of the viscosities from the ideal mixture values can be calculated from the following relationship (17–19):

[2] $$\Delta \ln \eta = \ln \eta - [\, x_1 \ln \eta_1 + x_2 \ln \eta_2]$$



where x_1 and x_2 are the mole fractions, η is the dynamic viscosity of the mixtures, and η_1 and η_2 are the viscosities of components 1 and 2. The derived densities, and viscosities for the three systems at 298.15 K are shown in Table 3. The estimated accuracy of ρ is about 1×10^{-1} kg m^{-3}.

The values of V_m^E and $\Delta \ln \eta$ for each mixture have been fitted to the Redlich–Kister (20) polynomial equation:

[3] $$F = x_1x_2 \sum_{i=1}^{m} A_i(x_1 - x_2)^{i-1}$$

where A_i is the polynomial coefficient and m is the polynomial degree. The values of the coefficients (A_i) obtained by the least-squares method with each points weighted equally are given in Table 4 along with standard deviations (σ).

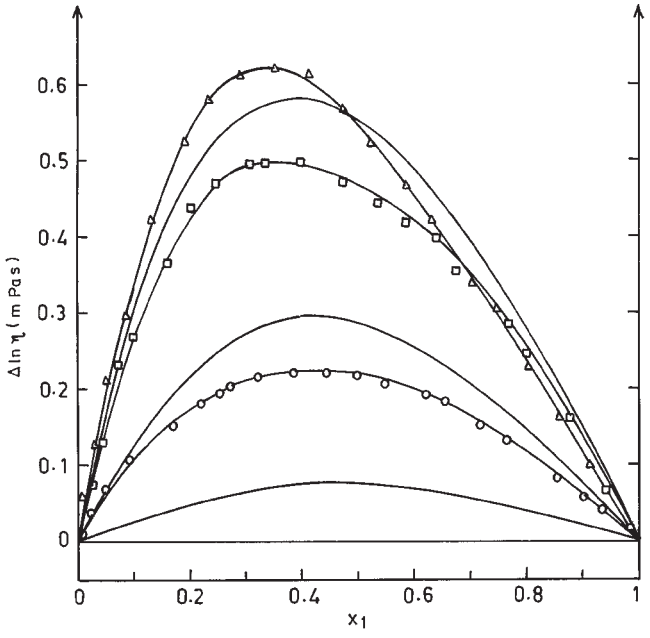
Tetrachloromethane	12.29 (11)	10.80 (11)	75.10	567	4695	1.2928	0.0635	–1.3

[a]Calculated from eq. $\kappa_T = \kappa_S + TV\alpha^2/C_{P,m}$; values $C_{P,m}$ calculated from group additivity and κ_S from footnote 2.[2]

In each case, the optimum number of coefficients was ascertained through an examination of the variation of the standard deviation with *m*:



$$[4] \qquad \sigma = [\sum (F_{cal} - F_{obs})^2/(n_{obs} - m)]^{1/2}$$

where n_{obs} is the number of measurements. *F* denotes either V^E_m or Δ ln η. For the mixtures, $\sigma(V^E_m) < 0.003$, in accord with the precision attainable with the dilatometer used.

Figure 1 shows that V^E_m values for these three mixtures are negative over the whole mole fraction range. The behaviour is similar for a diethylene glycol dimethyl ether (8) but with a marked decrease in V^E_m here. The value of V^E_m decreases as the chain length of the hydrophilic moiety $-OC_2H_4-$ increases. The magnitude of V^E_m is the result of contributions from different effects: (*i*) specific interactions due to possible association between the glyme and the chloroalkane molecules, (*ii*) contraction due to molar volume and free volume difference of unlike molecules, and (*iii*) possible association and (or) by hydrogen bonding and other complex forming interactions. It is important to note that a considerable amount of volume contraction is observed for the triglyme (1) + TCM (2) system. This reflects the possible chemical interactions between the oxygen and hydrogen atom of TCM.

The Prigogine–Flory–Patterson (PFP) (21–26) theory was used to correlate the V^E_m results for the present mixtures. The values of the parameters for the pure liquid components required in the PFP theory obtained from Flory's formalism are listed in Table 5. In the prediction of V^E_m values by PFP theory the interaction parameter χ_{12} is needed, this is usualy determined using H^E values. Since values of H^E are not available for these mixtures, the χ_{12} parameter was adjusted by fitting the experimental V^E_m results over the whole mole fraction range. Values of χ_{12} obtained from the PFP theory are listed in the last column of Table 5 and Fig. 1 gives the results estimated from the theory together with the experimental values. The much larger negative values of χ_{12} parameter for the triethylene glycol dimethyl ether (tri-EGDME) + trichloromethane (TCM) systems indicate the possible chemical interaction as suggested from the V^E_m results.

Fig.2. Experimental viscosity deviations for triethylene glycol dimethyl ether (1) + dichloromethane (2), □; + trichloromethane (2), △; and + tetrachloromethane (2), ○. Continuous curves were calculated from eq. [3] for experimental data and from Bloomfield and Dewan data (Bloomfield and Dewan, 1971).

We have determined the η and calculated Δ ln η at 298.15 K as shown in the Fig. 2. The positive values of Δ ln η would imply that the mixture is more viscous than (*i*) the corresponding ideal mixtures and (*ii*) the specific interactions

[2] A. Pal and A. Kumar. Indian J. Pure Appl. Phys. **37**, 810 (1999).

(27), as corroborated by the negative V^{E}_{m} values. There are different expressions available in the literature to calculate η. Here we have applied the method of Bloomfield and Dewan (28).

Bloomfield and Dewan developed an expression from the combination of the theories of free volume and absolute reaction rate. This expression is written

$$[5] \qquad \Delta \ln \eta = f(\tilde{v}) - \Delta G^{R}/RT$$

Where $f(\tilde{v})$ is the characteristic function of the free volumes defined by

$$[6] \qquad f(\tilde{v}) = 1/(\tilde{v} - 1) - x_1/(\tilde{v}_1 - 1) - x_2/(\tilde{v}_2 - 1)$$

and ΔG^{R} is the residual energy of mixing, calculated with the following expression (29):

$$[7] \qquad \Delta G^{R} = \Delta G^{E} + RT(x_1 \ln x_1/\phi_1 + x_2 \ln x_2/\phi_2)$$

The excess free energy can be obtained from the statistical theory of liquid mixtures proposed by Flory and co-workers (23) and is given by the following expression:

$$[8] \qquad \begin{aligned} \Delta G^{E} = {} & x_1 P_1^{*} V_1^{*}[1/\tilde{v}_1 \\ & - 1/\tilde{v} + 3\tilde{T}_1 \ln \{(\tilde{v}_1^{1/3} - 1)/(\tilde{v}^{1/3} - 1)\}] \\ & + x_2 P_2^{*} V_2^{*}[1/\tilde{v} - 1/\tilde{v} \\ & + 3\tilde{T}_2 \ln \{(\tilde{v}_2^{1/3} - 1)/(\tilde{v}^{1/3} - 1)\}] \\ & + (x_1 \theta_2 V_1^{*} \chi_{12})/\tilde{v} \end{aligned}$$

where the various symbols used have their usual meanings.

Using the χ_{12} values from fitting values of V^{E}_{m} and Table 5, ΔG^{R} and $f(\tilde{v})$ were estimated, and finally $\Delta \ln \eta$, according to the Bloomfield and Dewan relationship, which was compared with the experimental data as shown in Fig.2.

Solubility of diphenyl sulfone in organic nonelectrolyte solvents. Comparison of observed vs. predicted values based upon Mobile Order theory

Karina M. De Fina, Tiffany T. Van, Kristin A. Fletcher, and William E. Acree, Jr.

Abstract: Experimental solubilities are reported at 25.0°C for diphenyl sulfone dissolved in 25 different organic nonelectrolyte solvents containing ether-, chloro-, hydroxy-, ester, methyl-, and *tert*-butyl-functional groups. Results of these measurements, combined with previously reported diphenyl sulfone solubilities taken from the chemical literature, are used to test the applications and limitations of expressions derived from Mobile Order theory. For the 34 solvents for which predictions could be made, computations show that mobile order theory does provide fairly reasonable estimates of the saturation mole fraction solubilities. Average absolute deviation between predicted and observed values is 49.3%. In comparison, the average absolute deviation is 5 500% when ideal solution behavior is assumed.

Key words: diphenyl sulfone solubilities, organic nonelectrolyte solvents, solubility predictions.

Résumé : Opérant à 25,0°C, on a mesuré les solubilités expérimentales de la diphénylsulfone en solution dans vingt-cinq solvants organiques non électrolytiques qui comprennent des groupes substituants éther, chloro, hydroxyle, ester, méthyle et *tert*-butyle. On a utilisé les résultats de ces mesures, combinés aux valeurs retrouvées dans la littérature pour la solubilité de la diphénylsulfone, pour vérifier les applications et les limitations d'expressions dérivées du modèle de l'ordre mobile. Les trente-quatre solvants pour lesquels il a été possible de faire des calculs montrent que le modèle de l'ordre mobile conduit à des évaluations assez raisonnables des solubilités en fraction molaire de la saturation. La déviation absolue moyenne entre les valeurs prévues et observées est de 49,3%. Pour fins de comparaison, la déviation absolue moyenne est de 5 500% lorsqu'on fait l'hypothèse que le comportement de la solution est idéal.

Mots clés : solubilités de la diphénylsulfone, solvants organiques non électrolytiques, prévisions des solubilités.

Introduction

Solvation energies for solutes dissolved in organic nonelectrolyte solvents are important in thermodynamic modeling in that they provide valuable information in regards to the interaction of the solute with surrounding solvent molecules. Solvation energies can also be used to predict partition coefficients of solutes between water and an immiscible organic solvent and to estimate organic solvent – air partition coefficients, both of which are important properties in understanding the fate and transport of organic chemicals in the environment. There exists in the published chemical literature a fairly large body of experimental solubility and partition coefficient data for organic solvents such as 1-octanol and *n*-hexadecane. Sizeable solubility and partition coefficient databases are also available for several of the saturated alkane solvents, and for benzene, toluene, chloroform, and carbon tetrachloride. Very little experimental data has been published for solutes dissolved in many of the other organic solvents commonly encountered in chemical and engineering applications. Sparcity of experimental data seriously hinders development and testing of predictive linear free energy relationships (LFERs) for most of the individual solvents.

Proposed LFERs have taken several different mathematical forms, depending upon whether one wishes to predict gas/organic solvent partition coefficients (as log L) (1)

$$[1] \qquad \log L = c + r\cdot R_2 + s\cdot\pi_2^H + a\cdot\sum\alpha_2^H + b\cdot\sum\beta_2^H + l\cdot\mathrm{Log}\ L^{16}$$

$$[2] \qquad \log L = c + d\cdot\delta_2 + s\cdot\pi_2^H + a\cdot\sum\alpha_2^H + b\cdot\sum\beta_2^H + l\cdot\mathrm{Log}\ L^{16}$$

$$[3] \qquad \log L = c + r\cdot R_2 + q\mu_2^2 + a\cdot\sum\alpha_2^H + b\cdot\sum\beta_2^H + l\cdot\mathrm{Log}\ L^{16}$$

and water/organic solvent partition coefficients (as log P) (1–3)

Chlorocyclohexane	120.3	18.45
Diphenyl sulfone[b]	161.5[c]	23.65[d]

[a]Tabulated values are taken from a compilation given in Ruelle and coworkers (16, 17, 19, 20).

[b]The numerical value of a_A^{solid} = 0.1100 was calculated from eq. [9] using ΔH_A^{fus} = 21 780 J mol^{-1} and T_{mp} = 398.2 K.[2]

[c]Numerical value of $V_{dpsulfone}$ = 161.5 cm^3 mol^{-1} was estimated using the known molar volumes of dimethyl sulfoxide, diphenyl sulfide, and dimethyl sulfide.

[d]Numerical value was calculated using the measured diphenyl sulfone mole fraction solubilities in *n*-hexane, *n*-heptane, and *n*-octane, in accordance with eqs. [6] and [8] (with $r_{solvent}$ = 0 and (or) $K_{ASolvent}$ = 0).

deduced by regressing experimental partition coefficient data in accordance with eqs. [1]–[5]. At the present time coefficients are available for only 50 or so different water/organic solvent and gas/solvent systems (2, 3, 7–11). Equations [1]–[5] allow one to estimate water/organic solvent and gas/solvent partition coefficients for systems for which the solute descriptors and curve-fit coefficients are known.

If correlation equations are to be developed for still more organic solvents, then additional experimental data must be measured. Activity coefficients, partition coefficients, and saturation solubilities for a mininum of 40 or so different solutes are required to derive meaningful correlation equations. Moreover, the solutes used should span as wide of a range of solute descriptor values as possible. To increase the solubility database available for developing LFERs, we are in the process of measuring solubility data for polycyclic aromatic hydrocarbons (PAHs), polycyclic aromatic nitrogen hetero-atoms (PANHs), and other crystalline sulfur-containing nonelectrolyte solutes. In the present communication, we report diphenyl sulfone solubilities at 25°C in 25 different organic solvents containing ether-, chloro-, hydroxy-, ester, methyl-, and *tert*-butyl-functional groups. This brings the number of organic solvents for which we have reported diphenyl sulfone solubility data up to 43. Previously we had reported diphenyl sulfone solubilities in water and in eight alkane and ten alcohol solvents (12). Results of the measurements are used to further test the applications and limitations of predictive expressions derived from Mobile Order theory. Lack of enthalpy of fusion data for diphenyl sulfone prevented us from using Mobile Order theory at the time our first set of diphenyl sulfone solubility data was published.

Materials and methods

Diphenyl sulfone (Aldrich, 97%) was recrystallized several times from methanol. Methylcyclohexane (Aldrich, 99+%, anhydrous), *tert*-butylcyclohexane (Aldrich, 99+%), cyclooctane (Aldrich, 99+%), squalane (Aldrich, 99%), dibutyl ether (Aldrich, 99%), 2-pentanol (Acros Organics, distributed by Fisher Scientific, 99+%), 2-methyl-2-butanol (Acros, 99+%), 2-methyl-1-propanol (Aldrich, 99+%, anhydrous), 3-methyl-1-butanol (Aldrich, 99+%, anhydrous), 4-methyl-2-pentanol (Acros Organics, 99+%), 2-ethyl-1-hexanol (Aldrich, 99+%), 2-methyl-1-pentanol (Aldrich, 99%), 1-decanol (Alfa Aesar, 99+%), cyclopentanol (Aldrich, 99%), 1,4-dioxane (Aldrich, 99.8%, anhydrous), tetrahydrofuran (Aldrich, 99.9%, anhydrous), methyl *tert*-butyl ether (Arco, 99.9+%), ethyl acetate (Aldrich, HPLC, 99.9%), 2-methyl-2-propanol (Arco Chemical Co. 99+%), 1,2-dichloroethane (Aldrich, HPLC, 99.8%), 1-chlorobutane (Sigma–Aldrich, HPLC, 99.5+%), 1-chlorooctane (Aldrich, 99%), chlorocyclohexane (Aldrich, 99%), methyl acetate (Aldrich, 99.5%, anhydrous) and butyl acetate (Aldrich HPLC, 99.7%) were stored over molecular sieves before use. Gas chromatographic analysis showed solvent purities to be 99.7 mole % or better.

Excess solute and solvent were placed in amber glass bottles and allowed to equilibrate in a constant temperature water bath at 25.0 ± 0.1°C for at least three days (often longer). Attainment of equilibrium was verified both by repetitive measurements after several additional days and by approaching equilibrium from supersaturation by pre-equilibrating the solutions at a higher temperature. Aliquots of saturated diphenyl sulfone solutions were transferred through a coarse filter into a tared volumetric flask to determine the amount of sample and diluted quantitatively with methanol (or 2-propanol in the case of the larger alkane solvents) for spectrophotometric analysis at 267 nm on a Bausch and Lomb Spectronic 2000. Concentrations of the dilute solutions were determined from a Beer–Lambert law

© 2000 NRC Canada

absorbance vs. concentration working curve for nine standard solutions. The concentration of diphenyl sulfone in the standard solutions varied from 2.08×10^{-4} M to 9.35×10^{-4} M. The calculated molar absorptivity of the standard solutions varied slightly over the concentration range, from $\epsilon \approx 1850$ L mol^{-1} cm^{-1} (2.08×10^{-4} M) to $\epsilon \approx 1750$ L mol^{-1} cm^{-1} (9.35×10^{-4} M).

Experimental molar concentrations were converted to (mass/mass) solubility fractions by multiplying by the molar mass of diphenyl sulfone, volume(s) of volumetric flask(s) used, and any dilutions required to place the measured absorbances on the Beer–Lambert law absorbance vs. concentration working curve, and then dividing by the mass of the saturated solution analyzed. Mole fraction solubilities were computed from (mass/mass) solubility fractions using the molar masses of the solute and solvent. Experimental diphenyl sulfone solubilities, X_A^{sat}, in 25 organic solvents studied are listed in Table 1. Numerical values represent the average of between four and eight independent determinations, with the measurements being reproducible to ±1.5%. For each solvent studied, all experimental measurements fell within ±1.5% of the average value listed in Table 1.

Results and discussion

Solvents listed in Table 1 include both noncomplexing alkanes and self-associating alcohols. Of the many solution models proposed in recent years, mobile order theory is perhaps the only one that is capable of describing solute behavior in such a wide range of solvent mixtures. The basic model (13–20) assumes that all molecular groups perpetually move, and that neighbors of a given kind of external atom in a molecule constantly change identity. All molecules of a given kind dispose of the same volume, equal to the total volume V of the liquid divided by the number N_A of molecules of the same kind, i.e., Dom A = V/N_A. The center of this domain perpetually moves. The highest mobile disorder is achieved whenever groups visit all parts of their domain without preference. Preferential contacts lead to deviations with respect to this "random" visiting. This is especially true in the case of hydrogen-bonding as specific interactions result in a specific orientation of the "donor" molecule with respect to an adjacent "acceptor" molecule.

In the case of an inert crystalline solute dissolved in a self-associating solvent, Mobile Order theory expresses the volume fraction saturation solubility, ϕ_A^{sat}, as

$$[6]\quad \ln \phi_A^{sat} = \ln a_A^{solid} - 0.5(1 - V_A/V_{solvent})\phi_{solvent} + 0.5 \ln [\phi_A^{sat} + \phi_{solvent}(V_A/V_{solvent})] - \phi_{solvent}^2 V_A(\delta'_A - \delta'_{solvent})^2(RT)^{-1} - r_{solvent}(V_A/V_{solvent})\phi_{solvent}$$

where the $r_{solvent}(V_A/V_{solvent})\phi_{solvent}$ term represents the contributions resulting from hydrogen-bond formation between the solvent molecules. For most of the published applications, $r_{solvent}$ was assumed to be unity for strongly associated solvents with single hydrogen-bonded chains such as monofunctional alcohols, to be two for water or diols, and to equal zero for nonassociated solvents such as saturated hydrocarbons. A more exact value for alcoholic solvents can be calculated based upon

$$[7]\quad r_{solvent} = (K_{solvent}\phi_{solvent}/V_{solvent})/(1 + K_{solvent}\phi_{solvent}/V_{solvent})$$

with a numerical value of $K_{solvent} = 5\,000$ cm^3 mol^{-1} assumed for all monofunctional alcohols.

If complexation does occur between the crystalline solute and solvent

$$[8]\quad \ln \phi_A^{sat} = \ln a_A^{solid} - 0.5(1 - V_A/V_{solvent})\phi_{solvent} + 0.5 \ln [\phi_A^{sat} + \phi_{solvent}(V_A/V_{solvent})] - \phi_{solvent}^2 V_A(\delta'_A - \delta'_{solvent})^2(RT)^{-1} + \ln [1 + \phi_{solvent}(K_{ASolvent}/V_{solvent})]$$

then an additional term involving the solute–solvent equilibrium constant, $K_{ASolvent}$, must be introduced to describe the solubility enhancement that arises as a result of specific interactions. A slightly more complex expression applies in the case of solute complexation with a self-associating solvent. The symbols δ'_A and $\delta'_{solvent}$ denote the modified solubility parameters of the solute and solvent, respectively, V_i is the molar volume, and a_A^{solid} is the activity of the solid solute. This latter quantity is defined as the ratio of the fugacity of the solid to the fugacity of the pure hypothetical supercooled liquid. The numerical value of a_A^{solid} can be computed from

$$[9]\quad \ln a_A^{solid} = -\Delta H_A^{fus}(T_{mp} - T)/(RTT_{mp}) + (\Delta C_{p,A}/RT)(T_{mp} - T) - (\Delta C_{p,A}/T) \ln (T_{mp}/T)$$

the solute's molar enthalpy of fusion, ΔH_A^{fus}, and heat capacity difference, $\Delta C_{p,A}$, at the normal melting point temperature, T_{mp}. Contributions from nonspecific interaction are incorporated into mobile order theory through the $\phi_{solvent}^2 V_A(\delta'_A - \delta'_{solvent})^2(RT)^{-1}$ term. Ruelle and coworkers (16–20) have presented an impressive set of comparisons between experimental and predicted values for anthracene, naphthalene, pyrene, biphenyl, carbazole, benzil, *p*-benzoquinone, tricosane, octacosane, 10-nonadecanone, 11-heneicosanone, and 12-tricosanone solubilities in a wide range of both noncomplexing and complexing solvents to document the predictive ability of Mobile Order theory.

Predictive application of eqs. [6] and [8] is relatively straightforward. First, an average numerical value of $\delta'_{dpsulfone} = 23.65$ MPa$^{1/2}$ is computed by requiring that each equation (with $r_{solvent} = 0$ and (or) $K_{ASolvent} = 0$) perfectly describes diphenyl sulfone mole fraction solubility data in *n*-hexane ($\delta'_{dpsulfone} = 23.63$ MPa$^{1/2}$), *n*-heptane ($\delta'_{dpsulfone} = 23.63$ MPa$^{1/2}$), and *n*-octane ($\delta'_{dpsulfone} = 23.70$ MPa$^{1/2}$). The numerical value of $a_A^{solid} = 0.1100$ is calculated using eq. [9] with $\Delta H_A^{fus} = 21780$ J mol^{-1} and $T_{mp} = 398.2$ K.[2] The two heat capacity terms in eq. [9] were set equal to zero as we were unable to find heat capacity data for the subcooled liquid solute. A numerical value of $V_{dpsulfone} = 161.5$ cm^3 mol^{-1} was used for the molar volume of the hypothetical subcooled liquid solute. The solute's molar volume was estimated as the twice the molar volume of dimethyl sulfoxide ($V_{dmso} = 70.96$ cm^3 mol^{-1})

[2] J.W. McCargar. Unpublished data.

plus the molar volume of diphenyl sulfide ($V_{dpsulfide}$ = 166.62 cm^3 mol^{-1}) minus twice the molar volume of dimethyl sulfide ($V_{dmsulfide}$ = 73.52 cm^3 mol^{-1}). The calculation assumes that there is no change in volume for transferring the two oxygen atoms from dimethyl sulfoxide to diphenyl sulfide.

Table 1 summarizes the predictive ability of Mobile Order theory for the 34 different organic solvents for which both diphenylsulfone solubility data and modified solubility parameters could be found. Solubility data for diphenyl sulfone dissolved in several of the alkane and alcohol solvents were taken from an earlier study (12). Solvent molar volumes and modified solubility parameters are listed in Table 2. The modified solubility parameters account for only nonspecific interactions, and in the case of the alcoholic solvents the hydrogen-bonding contributions have been removed. Numerical values of $\delta'_{solvent}$ were obtained from published compilations (16, 17, 19, 20), and were either deduced by regressing actual solubility data of solid *n*-alkanes in organic solvents in accordance with the configurational entropic model of Huyskens and Haulait-Pirson (21) or estimated using known values for similar organic solvents. Examination of the entries in Table 1 reveals that Mobile Order theory does provide fairly reasonable (though by no means perfect) estimates of the solubility behavior of diphenyl sulfone in a wide range of organic solvents. Average absolute deviation between predicted and observed values is 49.3%. Expressed on a natural logarithmic mole fraction scale, Mobile Order theory predicts the diphenyl sulfone solubilities to within ±0.77 ln units. The arithmetic average of the ln X_A^{sat} difference is –0.56, which indicates a systematic underprediction in the predicted value. Many solution models express the difference between the predicted and observed in terms of the standard deviation. In the case of Mobile Order theory, the standard deviation for the diphenyl sulfone predictions is 1.03 ln units.

It is noted that eq. [6] did underpredict the solubility of diphenyl sulfone in all of the alcohol solvents, thus suggesting the possibility that the solute does interact specific with alcohol molecules. Based upon the molecular structure of diphenyl sulfone, it is very likely that the alcohol's acidic OH hydrogen atom can be involved in H-bond formation with one of the lone electron pairs on either of the two oxygen atoms of the sulfone functional group. If this does happen, then one would need to know the stability constant for the diphenyl sulfone – alcohol complex to estimate the enhanced solubility that would result from the molecular complexation. Readers are reminded that in evaluating the applicability of Mobile Order theory one must realize that many of these particular systems are highly nonideal, and that the experimental solubility data covers over a 200-fold range in mole fraction. Had an ideal solution been assumed, then the predicted mole fraction solubility would be X_A^{sat} = a_A^{solid} = 0.1100 for each solvent. The ideal solution approximation corresponds to a considerably larger average absolute deviation of 5 500% between predicted and observed values.

Synthesis, solid state structure, and solution behaviour of the lighter lanthanide bis(trimethylsilyl)amido chlorides, $[Ln\{N(SiMe_3)_2\}_2(THF)(\mu\text{-}Cl)]_2$ (Ln = Ce, Nd)

David J. Berg and Roland A.L. Gendron

Abstract: The synthesis of $[Ln\{N(SiMe_3)_2\}_2(THF)(\mu\text{-}Cl)]_2$ (Ln = Ce, **1**; Nd, **2**) by reaction of sodium bis(trimethylsilyl)amide (2 equiv.) with $LnCl_3$ is reported. The same complexes were also isolated from the ligand redistribution reactions of $Ln[N(SiMe_3)_2]_3$ and $LnCl_3$ (2:1 ratio) in THF at 80°C. The crystal structure of **2**, determined by X-ray diffraction, revealed a centrosymmetric dimer with bridging chlorides and pentacoordinate metal centres. ^{1}H NMR studies show that the solid state structure is not maintained in solution. NMR evidence for the presence of $Ln[N(SiMe_3)_2]_3$ and two other bis(trimethylsilyl)amide containing species, presumably $Ln[N(SiMe_3)_2]Cl_2(THF)_x$ and $Ln[N(SiMe_3)_2]_2Cl(THF)_y$, is presented.

Key words: lanthanide, amide, neodymium, cerium, crystal structure, X-ray, nuclear magnetic resonance, redistribution.

Résumé : On a effectué la synthèse du $[Ln\{N(SiMe_3)_2\}_2(THF)(\mu\text{-}Cl)]_2$ (Ln = Ce, **1**; Nd, **2**) par réaction du bis(triméthylsilyl)amide (2 équiv.alents) avec du $LnCl_3$. On a aussi isolé les mêmes complexes à partir de réactions de ligands de $Ln[N(SiMe_3)_2]_3$ et $LiCl_3$ (rapport 2:1) dans le THF à 80°C. La structure cristalline du produit **2**, déterminée par diffraction des rayons X, met en évidence la présence d'un dimère centrosymétrique comportant des atomes de chlore agissant comme pont et des centres métalliques pentacoordinés. Les études de RMN du ^{1}H montrent que la structure solide n'est pas maintenue en solution. On rapporte des données de RMN qui mettent en évidence la présence de $Ln(N(SiMe_3)_3]_3$ et de deux autres espèces contenant du bis(triméthylsilyl)amide, probablement du $Ln[N(SiMe_3)_2]Cl_2(THF)_x$ et $Ln[N(SiMe_3)_2]Cl(THF)_y$.

Mots clés : lanthanide, amide, néodyme, cérium, structure cristalline, rayons X, résonance magnétique nucléaire, redistribution.

[Traduit par la Rédaction]

Introduction

The incorporation of anionic ligands into lanthanide complexes is usually achieved by metathetical reactions between a lanthanide halide or alkoxide and a salt of the ligand (eqs. [1], [2]). While often useful, there are many instances when pure products can not be obtained by this method due to incomplete substitution of the leaving group or formation of an anionic "ate" complexes (an addition reaction, eq. [3]) (for some representative examples see ref. (1)). A protonolysis reaction between an acidic, protonated form of the incoming ligand and strongly basic anionic leaving groups is an attractive alternative in many cases, particularly when the leaving group has little propensity to coordinate to the product complex (eq. [4]). Bis(trimethylsilyl)amido complexes are attractive alternative precursors because the amido group is quite basic and the bis(trimethylsilyl)amine that is formed is noncoordinating and volatile, making its removal straightforward.

[1] $3\ M^+L^- + LnCl_3 \rightarrow LnL_3 + 3\ M^+Cl^- \downarrow$ (M = Li, Na, K)

[2] $3\ M^+L^- + Ln(OAr)_3 \rightarrow LnL_3 + 3\ MOAr \downarrow$ (Ar = 2,6-*t*-$Bu_2C_6H_3$)

[3] $3\ M^+L^- + LnCl_3 \rightarrow [LnL_3Cl]^-\ M^+ + 2\ M^+Cl^- \downarrow$ (M = Li, Na, K)

[4] $3\ HL' + LnL_3 \rightarrow LnL'_3 + 3\ HL$ (L = $N(SiMe_3)_2$)

The synthesis of mixed ligand complexes of the lanthanides by methathetical reactions is even more challenging because controlled substitution of the leaving groups is difficult and ligand redistribution often occurs under these conditions. (2) The successful isolation of mixed bis(trimethlsilyl)amido chloride complexes $[Ln\{N(SiMe_3)_2\}_2(THF)(\mu\text{-}Cl)]_2$ (Ln = Eu, Gd, Yb) by Aspinall et al. (3) using metathesis is noteworthy

because the products are suitable precursors to other mixed ligand complexes by protonolysis of the two silylamido groups. However, these authors did not attempt to isolate the analogous complexes for the lighter lanthanides because they assumed that these complexes would be too coordinatively unsaturated to exist as simple dimers. In this contribution we demonstrate that bis(amido) complexes of these metals are accessible both by metathesis or redistribution reactions.

Results and discussion

Synthesis

The bis(trimethylsilyl)amido chloride complexes $[Ln\{N(SiMe_3)_2\}_2(THF)(\mu\text{-}Cl)]_2$ (Ln = Ce, **1**; Ln = Nd, **2**) were initially prepared by stirring two equiv. of sodium bis(trimethylsilyl)amide with the appropriate trichloride in THF for 48 h, followed by filtration to remove NaCl, removal of the solvent and recrystallization of the residue from hexane at –30°C (eq. [5]). In agreement with earlier observations (2, 3), complexes **1** and **2** were more intensely coloured (**1**, canary yellow; **2**, lilac) and more soluble than their tris(amido) analogues, $Ln[N(SiMe_3)_2]_3$. The crystals are also easily distinguishable from the tris(amido) complexes by their form: both **1** and **2** are isolated as well-formed prisms, while the tris(amido) complexes of all the lanthanides form feathery needles.

$$[5]\quad 2\ Na^+[N(SiMe_3)_2]^- + LnCl_3 \xrightarrow{THF} [Ln\{N(SiMe_3)_2\}_2(THF)(\mu\text{-}Cl)]_2 + 2\ Na^+Cl^-$$

Ln = Ce (**1**), Nd (**2**)

Small amounts of the tris(amido) complexes were always isolated along with **1** and **2** during recrystallization but these products were very easy to separate. It is noteworthy that pure crystalline **1** and **2** inevitably produced some of the tris(amido) product during recrystallization supporting facile redistribution in solution. This fact was confirmed by ^{1}H NMR (vide infra) and by the successful synthesis of **1** and **2** from $LnCl_3$ and $Ln[N(SiMe_3)_2]_3$ by redistribution (eq. [6]). The yields obtained by redistribution were comparable to those obtained by metathesis.

$$[6]\quad 2\ Ln[N(SiMe_3)_2]_3 + LnCl_3 \xrightarrow[80°C]{THF} 3/2\ [Ln\{N(SiMe_3)_2\}_2(THF)(\mu\text{-}Cl)]_2$$

Ln = Ce (**1**), Nd (**2**)

Solid-state structure of $[Nd\{N(SiMe_3)_2\}_2(THF)(\mu\text{-}Cl)]_2$ (2)

The solid state structure of the neodymium complex **2** was determined by X-ray crystallography. Crystallographic data for **2** is summarized in Table 1, selected bond distances and angles are given in Table 2, and the structure is shown in Fig. 1. The complex is dimeric in the solid state and consists of two five-coordinate metal centres bridged by chloride ions. The geometry at the metal is approximately trigonal bipyramidal with one chloride and two amido ligands defining the equatorial plane. The observed structure is isostructural with those previously reported for the Gd and Yb analogues (3). The metal–ligand bond distances in **2** are,

© 2000 NRC Canada

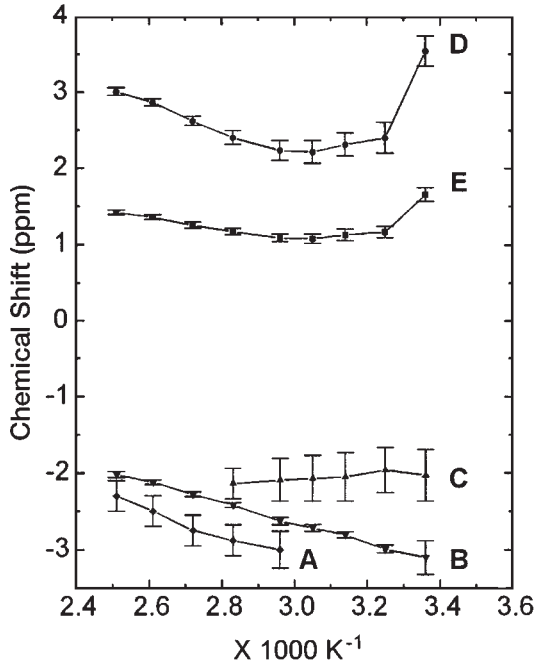
Fig. 1. ZORTEP plot (30% probability) of **2**.

on average, 0.06 and 0.14 Å larger than those found in the Gd and Yb complexes, respectively in keeping with the difference in ionic radii for these metals (0.04 and 0.11 Å, respectively) (4). The only significant differences between this structure and those for Gd and Yb is that the Ln–N–Si angles span a much wider range (110.2(4)–129.2(5)° vs. 117.4(3)–123.5(3)°) and the bridging chlorides display greater asymmetry (Δ = r(Ln-Cl) – r(Ln-Cl′) = 0.063(4) (Nd), 0.025(6) (Gd), 0.023(6) (Yb) Å) in complex **2**. The greater asymmetry in the chloride bridges is surprising because **2** is clearly the least sterically crowded of the three structures. A comparison of the Ln—Cl distances reveals that the shorter Nd—Cl distance in **2** is consistent with that predicted from the earlier Gd and Yb structures (predicted: 2.78(1) Å from both the Yb and Gd structures; observed: 2.791(3) Å). (4) In contrast, the longer Nd—Cl distance in **2** is significantly greater than expected based on the Gd and Yb structures (predicted: 2.80(1) Å; observed: 2.854(3) Å).

Solution behaviour

The solution behaviour of **1** and **2**, monitored in d_5-bromobenzene by variable temperature ^{1}H NMR spectroscopy (Figs. 2 and 3), clearly indicates that the solid state structure is not maintained in solution. For both complexes, five resonances were observed throughout the temperature range studied (20–125°C). The two smaller resonances (**D** and **E**) were established as THF signals by exchange with d_8-THF. One of the larger resonances (**B**) was established as due to $Ln[N(SiMe_3)_2]_3$ by addition of a large excess of the authentic tris(amido) complex. The remaining two resonances are tentatively assigned as the mono (**A**) and bis(amido) (**C**) complexes, $Ln[N(SiMe_3)_2]Cl_2(THF)_x$ and $Ln[N(SiMe_3)_2]_2Cl(THF)_y$, respectively on the basis of integration. It is not possible to know the state of aggregation of these two complexes in solution or the extent to which they are solvated by THF, although it is extremely unlikely that either exists as a base-free monomer. If it is assumed that these are the only species present then a plausible solution equilibrium is given in eq. [7].[2]

Fig. 2. Plot of chemical shift (ppm) vs. $1/T$ (× 1000 K^{-1}) for **1**. Assignments: $Ce[N(SiMe_3)_2]Cl_2(THF)_x$ (**A**), $Ce[N(SiMe_3)_2]_3$ (**B**), $Ce[N(SiMe_3)_2]_2Cl(THF)_y$ (**C**), α-CH_2THF (**D**), and β-CH_2THF (**E**).



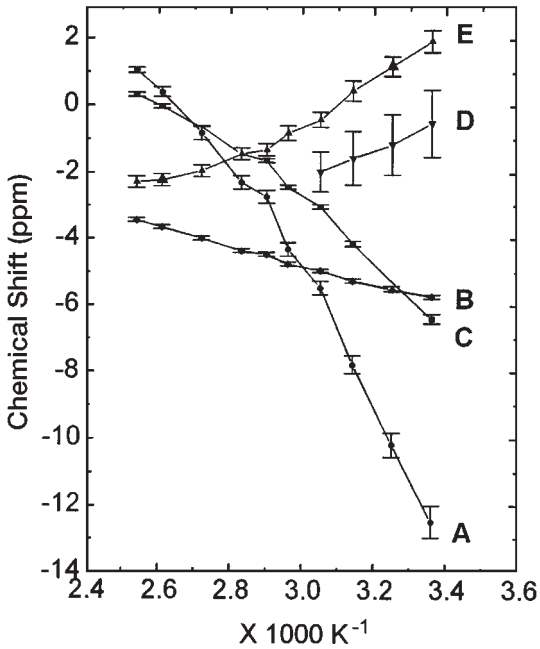


Fig. 3. Plot of chemical shift (ppm) vs. $1/T$ (× 1000 K^{-1}) for **2**. Assignments: $Nd[N(SiMe_3)_2]Cl_2(THF)_x$ (**A**), $Nd[N(SiMe_3)_2]_3$ (**B**), $Nd[N(SiMe_3)_2]_2Cl(THF)_y$ (**C**), α-CH_2THF (**D**) and β-CH_2THF (**E**).

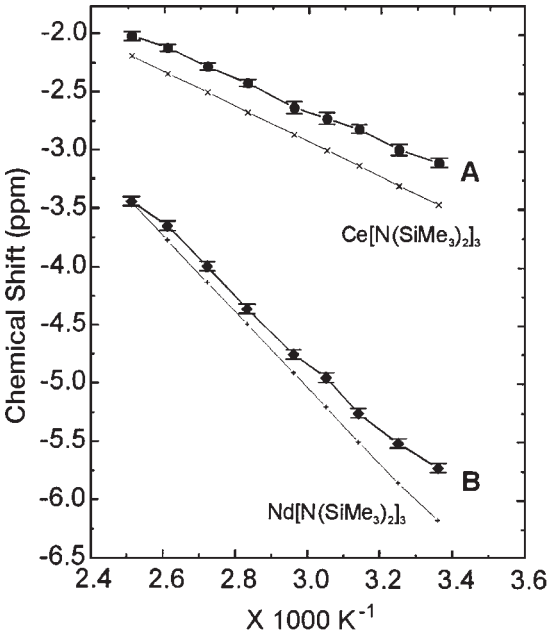

The silylamide integration ratio of $Ln[N(SiMe_3)_2]_3$ (**B**) relative to $Ln[N(SiMe_3)_2]Cl_2(THF)_x$ (**A**) remains approximately

[2] $LnCl_3$ may also form but this product cannot be observed by NMR and there was no visual evidence for its formation.

© 2000 NRC Canada

Fig. 4. Plot of chemical shift (ppm) vs. $1/T$ (× 1000 K^{-1}) for the $Ln[N(SiMe_3)_2]_3$ resonances of **1**(**A**) and **2** (**B**) and pure $Ln[N(SiMe_3)_2]_3$ (Ln = Ce (×), Nd (+)).

3:1 at all temperatures which is what would be expected based on eq. [7].

$$[7] \quad 2\ Ln[N(SiMe_3)_2]_2Cl(THF)_y \rightleftharpoons Ln[N(SiMe_3)_2]_3 + Ln[N(SiMe_3)_2]Cl_2(THF)_x$$

Resonances **A**–**C** for **1** follow nearly linear behaviour throughout the temperature range sampled. This is consistent with each resonance being due to a single well-defined species. The resonances due to the THF (**D**–**E**) do show curvature over this temperature range. The temperature dependence of the amido resonances for **2** show greater curvature although the resonance due to $Nd[N(SiMe_3)_2]_3$ (Fig. 3, **B**) is close to linear. The temperature dependence of the $Ln[N(SiMe_3)_2]_3$ resonances for **1** and **2** are compared with those for separate samples of pure $Ln[N(SiMe_3)_2]_3$ in Fig. 4. The close similarity between these plots confirms the assignments made in Fig. 2 and 3.[3] In addition, since the resonances in Fig. 4 are essentially unperturbed from those of pure $Ln[N(SiMe_3)_2]_3$, the forward and reverse reaction rates in eq. [7] must be slow on the NMR timescale over the entire temperature range studied.

The results presented here indicate that it is possible to isolate pure solid bis(amido) chloride complexes such as **1** and **2** for the lighter lanthanides. However, in solution ligand redistribution occurs readily so that mono and tris(amido) species are also present. This does not necessarily preclude the use of these complexes as precursors to other mixed ligand systems by protonolysis reactions. However, in cases where the reaction proceeds rapidly and irreversibly (for example, giving an insoluble product), it is useful to remember that this kinetic product may be derived from any of the three amido species present in solution.

Experimental

General procedures

All manipulations were carried out under an argon atmosphere, with the rigorous exclusion of oxygen and water, using standard glovebox (Braun MB150-GII) or Schlenk techniques. Tetrahydrofuran (THF) and hexane were dried by distillation from sodium benzophenone ketyl under argon immediately prior to use. $Ln[N(SiMe_3)_2]_3$ (Ln = Ce, Nd) were prepared according to the literature (5).

Variable temperature ^1H NMR spectra were recorded on a Bruker WM-250 MHz spectrometer. Spectra were recorded in C_6D_5Br dried over 4 Å molecular sieves for one week, using 5 mm tubes fitted with a teflon valve (Brunfeldt). The sample was allowed to equilibrate for 15 min at each temperature prior to recording the spectrum. Melting points were recorded using a Reichert hot stage and are not corrected. Elemental analyses were performed by Canadian Microanalytical, Delta, B.C. Mass spectra were recorded on a Kratos Concept H spectrometer using an electron impact (70 eV) source.

Preparation of $[Ln\{N(SiMe_3)_2\}_2(THF)(\mu\text{-}Cl)]_2$

In a typical preparation, a solution of sodium bis(trimethylsilyl)amide (2 equiv.) was added to a stirred suspension of $LnCl_3$ under argon at room temperature. The solution was stirred for 48 h and the solvent was removed under reduced pressure. The solid residue was extracted into hexane, filtered through a Celite pad to remove NaCl, and crystallized in the glovebox at –30°C. Generally this resulted in a large mass of block-like crystals of the bis(amide) surrounded by fine needles of $Ln[N(SiMe_3)_2]_3$. The smaller tris(amide) crystals can usually be removed with the mother liquor by a Pasteur pipette. Although the larger bis(amide) crystals are more soluble, they are slow to redissolve so washing with cold hexane is an ideal way to wash off the smaller tris(amide) needles.

Alternatively, the complexes were prepared in comparable yield by heating a THF solution of two equiv. $Ln[N(SiMe_3)_2]_3$ with one equiv. of $LnCl_3$ in a sealed Kontes flask at 80°C overnight. All solids dissolved on heating and remained in solution after the reaction mixture was cooled back to room temperature. The THF solvent was removed under reduced pressure and the residue was recrystallized from hexane in the glove box as described above. Complexes **1** and **2** are readily accessible on a 10 g scale by either preparative route.

X-ray crystallographic studies

Crystallographic data for **2** is summarized in Table 1. Crystals of **2** (0.5 × 0.5 × 0.5 mm) were loaded into glass capillaries in the glove box and subsequently flame sealed. The crystals were transferred to a Nonius CAD4F diffractometer equipped with MoKα radiation. The unit cell of **2** was refined using 24 reflections in the 2θ range of 38–42. An experimental density was not obtained because of the air sensitivity of the compound. Six standard reflections, measured periodically during data collection (9, 0, 7; 7, 0, 1; 8, 9, 0; 0, 7, 1; 0, 0, 8; 3, 5, 7) showed a 10% decline in intensity during data collection. Intensity measurements were collected over one quarter of the sphere. After the usual data reduction procedures, including an absorption correction (max/min transmission: 0.9939, 0.8507) according to a measured PSI scan, the structure was solved by Patterson methods.[4] The refinements minimized $w((F_o - F_c)^2)$ and proceeded normally using teXsan98.[5] Criteria for inclusion of reflections were $I > 3.5\sigma(I)$. The weighting scheme was determined by counting statistics using $w = 1/(\sigma^2(F) + 0.001F^2)$.

Convergence was satisfactory: max shift/esd < 0.01; the largest positive and negative peaks in the final difference map were 1.64 and –0.97 e/Å^3, respectively. A total of 227 parameters were refined. Hydrogen atoms were placed in calculated positions. No non-hydrogen intermolecular contacts shorter than 3.5 Å were observed. The structural perspective plots were drawn using ZORTEP.[6] Complete tables of bond distances, angles, and anisotropic temperature parameters have been deposited as supplementary material.[7]

Solubility of hexachlorobenzene in organic nonelectrolyte solvents. Comparison of observed vs. predicted values based upon Mobile Order model

Karina M. De Fina, Tiffany T. Van, and William E. Acree, Jr.

Abstract: Experimental solubilities are reported at 25.0°C for hexachlorobenzene dissolved in 42 different organic nonelectrolyte solvents containing ether-, chloro-, hydroxy-, ester, methyl-, and *tert*-butyl-functional groups. Results of these measurements are used to test the applications and limitations of expressions derived from Mobile Order model. For the 33 solvents for which predictions could be made computations show that Mobile Order model does provide fairly reasonable estimates of the saturation mole fraction solubilities. Average absolute deviation between predicted and observed values is 210%. In comparison, the average absolute deviation is 2 060% when ideal solution behavior is assumed.

Key words: hexachlorobenzene solubilities, organic nonelectrolyte solvents, solubility predictions.

Résumé : Opérant à 25,0°C, on a mesuré les solubilités expérimentales de l'hexachlorobenzène en solution dans quarante-deux solvants organiques non électrolytiques qui comprennent des groupes substituants éther, chloro, hydroxyle, ester, méthyle et *tert*-butyle. On a utilisé les résultats de ces mesures pour vérifier les applications et les limitations d'expressions dérivées du modèle de l'ordre mobile. Les trente-trois solvants pour lesquels il a été possible de faire des calculs montrent que le modèle de l'ordre mobile conduit à des évaluations assez raisonnables des solubilités en fraction molaire de la saturation. La déviation absolue moyenne entre les valeurs prévues et observées est de 210%. Pour fins de comparaison, la déviation absolue moyenne est de 2 060% lorsqu'on fait l'hypothèse que le comportement de la solution est idéal.

Mots clés : solubilités de l'hexachlorobenzène, solvants organiques non électrolytiques, prévisions des solubilités.

Introduction

Solid–liquid equilibrium data of organic nonelectrolyte systems are becoming increasingly important in the petroleum industry, particularly in light of present trends towards heavier feedstocks and known carcinogenicity and (or) mutagenicity of many of the larger polycyclic aromatic compounds. Solubility data for a number of polycyclic aromatic hydrocarbons (e.g., anthracene and pyrene) and heteroatom polynuclear aromatics (e.g., carbazole, dibenzothiophene, and xanthene) have been published in the recent chemical literature (for listing of references see Acree (1–3)). Despite efforts by experimentalists and scientific organizations, both in terms of new experimental measurements and critically evaluated data compilations, there still exist numerous systems for which solubility data are not readily available.

To address this problem, researchers have turned to group contribution methods and semiempirical expressions to predict desired quantities. Group contribution methods have proved fairly successful in estimating solid solubility in pure and binary solvent mixtures from structural information (4–11). Practical application though, is limited to systems for which all group interaction parameters are known. Interaction parameters can be evaluated from liquid–vapor, liquid–liquid, and solid–liquid equilibria data. It is important that the data base contain as many different functional groups as possible, preferably with adequate representation from both mono- and multifunctional solute/solvent molecules to permit evaluation of potential synergistic effects. The data base should contain sufficient experimental values near infinite dilution in the event that one wishes to determine separate interaction parameters for finite concentration and infinite dilution activity coefficient predictions.

Abraham and coworkers (12, 13) recently developed a general solvation equation that can be used in the correlation and understanding of physicochemical and biochemical phenomena. Physical properties that have been correlated include gas/solvent partition coefficients (as log L)

$$[1] \qquad \log L = c + r\cdot R_2 + s\cdot\pi_2^H + a\cdot\sum\alpha_2^H + b\cdot\sum\beta_2^H + d\cdot\log L^{16}$$

and water/solvent partition coefficients (as log P)

[2] $$\log P = c + r\cdot R_2 + s\cdot\pi_2^H + a\cdot\sum\alpha_2^H + b\cdot\sum\beta_2^H + v\cdot V_x$$

where R_2 and V_x refer to the excess molar refraction and McGowan volume of the solute, respectively, π_2^H is the solute dipolarity–polarizability descriptor, and $\sum\alpha_2^H$ and $\sum\beta_2^H$ are measures of the solute's hydrogen-bond acidity and hydrogen-bond basicity. For any given solvent, numerical values of the seven curve-fit coefficients (*c*, *r*, *s*, *a*, *b*, *d*, and *v*) are deduced by regressing experimental partition coefficient data in accordance with eqs. [1] and [2]. The input partition coefficients were sometimes calculated as the ratio of the solute molar solubilities in the organic solvent and water, $P = C_A^{org}/C_A^{aq}$, and as the ratio of the solute molar solubility in the organic solvent and vapor concentration, $L = C_A^{org}/C_A^{gas}$. Published papers have reported curve-fit coefficients for water (12, 13) and a few select organic solvents (13).

To increase the solubility database available for developing group contribution methods and general solvation correlations, we are in the process of measuring solubility data for polycyclic aromatic hydrocarbons (PAHs), polycyclic aromatic nitrogen heteroatoms (PANHs), and other crystalline nonelectrolyte solutes. In the present communication, we report hexachlorobenzene solubilities in 42 different organic solvents at 25°C. Results of the measurements are used to further test the applications and limitations of predictive expressions derived from Mobile Order model. Subsequent studies will use the experimental hexachlorobenzene solubilities, along with other published activity coefficient and solubility data, in developing gas/liquid partition and water/organic solvent partition correlations based upon eqs. [1] and [2].

Materials and methods

Hexachlorobenzene (Aldrich, 99%) was recrystallized several times from methanol. *n*-Hexane (Aldrich, 99%), *n*-heptane (Aldrich, HPLC), *n*-octane (Aldrich, 99+%, anhydrous), *n*-nonane (TCI, 99+%), *n*-decane (TCI, 99+%), *n*-hexadecane (Aldrich, 99%), cyclohexane (Aldrich, HPLC), methylcyclohexane (Aldrich, 99+%, anhydrous), 2,2,4-trimethylpentane (Aldrich, HPLC), *tert*-butylcyclohexane (Aldrich, 99+%), dibutyl ether (Aldrich, 99%), methanol (Aldrich, 99.9+%), ethanol (Aaper Alcohol and Chemical Comp., absolute), 1-propanol (Aldrich, 99+%, anhydrous), 2-propanol (Aldrich, 99+%, anhydrous), 1-butanol (Aldrich HPLC, 99.8+%), 2-butanol (Aldrich, 99+%, anhydrous), 1-pentanol (Aldrich, 99+%), 2-pentanol (Acros 99+%), 1-hexanol (Alfa Aesar, 99+%), 1-heptanol (Alfa Aesar, 99+%), 2-methyl-2-butanol (Acros, 99+%), 2-methyl-1-propanol (Aldrich, 99+%, anhydrous), 3-methyl-1-butanol (Aldrich, 99+%, anhydrous), 1-octanol (Aldrich, 99+%, anhydrous), 4-methyl-2-pentanol (Acros, 99+%), 2-ethyl-1-hexanol (Aldrich, 99+%), 2-methyl-1-pentanol (Aldrich, 99%), 1-decanol (Alfa Aesar, 99+%), cyclopentanol (Aldrich, 99%), 1,4-dioxane (Aldrich, 99.8%, anhydrous), tetrahydrofuran (Aldrich, 99.9%, anhydrous), methyl *tert*-butyl ether (Arco, 99.9+%), ethyl acetate (Aldrich, HPLC, 99.9%), 2-methyl-2-propanol (Arco Chemical Co. 99+%), 1,2-dichloroethane (Aldrich, HPLC, 99.8%), 1-chlorobutane (Sigma–Aldrich, HPLC, 99.5+%), 1-chlorohexane (Aldrich, 99%), 1-chlorooctane (Aldrich, 99%), chlorocyclohexane (Aldrich, 99%), methyl acetate (Aldrich, 99.5%, anhydrous), and butyl acetate (Aldrich HPLC, 99.7%) were stored over molecular sieves before use. Gas chromatographic analysis showed solvent purities to be 99.7 mole % or better.

Excess solute and solvent were placed in amber glass bottles and allowed to equilibrate in a constant temperature water bath at 25.0 ± 0.1°C for at least three days (often longer). Attainment of equilibrium was verified both by repetitive measurements after several additional days and by approaching equilibrium from supersaturation by preequilibrating the solutions at a higher temperature. Aliquots of saturated hexachlorobenzene solutions were transferred through a coarse filter into a tared volumetric flask to determine the amount of sample and diluted quantitatively with 2-propanol for spectrophotometric analysis at 291 nm on a Bausch and Lomb Spectronic 2000. Concentrations of the dilute solutions were determined from a Beer–Lambert law absorbance vs. concentration working curve for nine standard solutions. The concentration of hexachlorobenzene in the standard solutions varied from 1.41×10^{-3} M to 3.54×10^{-3} M. The calculated molar absorptivity of the standard solutions varied slightly over the concentration range, from $\epsilon \approx 230$ L mol^{-1} cm^{-1} (1.41×10^{-3} M) to $\epsilon \approx 222$ L mol^{-1} cm^{-1} (3.54×10^{-3} M). Experimental hexachlorobenzene solubilities, X_A^{sat}, in 42 organic solvents studied are listed in Table 1. Numerical values represent the average of between four and eight independent determinations, with the measurements being reproducible to ±1.5%. For each solvent studied, all experimental measurements fell within ±1.5% of the average value listed in Table 1.

Results and discussion

Solvents listed in Table 1 include both noncomplexing alkanes and self-associating alcohols. Of the many solution models proposed in recent years, Mobile Order model is perhaps the only one that is capable of describing solute behavior in such a wide range of solvent mixtures. The basic model (14–21) assumes that all molecular groups perpetually move, and that neighbors of a given kind of external atom in a molecule constantly change identity. All molecules of a given kind dispose of the same volume, equal to the total volume *V* of the liquid divided by the number N_A of molecules of the same kind, i.e., Dom $A = V/N_A$. The center of this domain perpetually moves. The highest mobile disorder is achieved whenever groups visit all parts of their domain without preference. Preferential contacts lead to deviations with respect to this "random" visiting. This is especially true in the case of hydrogen-bonding as specific interactions result in a specific orientation of the "donor" molecule with respect to an adjacent "acceptor" molecule.

In the case of an inert crystalline solute dissolved in a self-associating solvent, Mobile Order model expresses the volume fraction saturation solubility, ϕ_A^{sat}, as

[3] $$\ln \phi_A^{sat} = \ln a_A^{solid} - 0.5(1 - V_A/V_{solvent})\phi_{solvent} + 0.5 \ln [\phi_A^{sat} + \phi_{solvent}(V_A/V_{solvent})] - \phi_{solvent}^2 V_A(\delta'_A - \delta'_{solvent})^2(RT)^{-1} - r_{solvent}(V_A/V_{solvent})\phi_{solvent}$$

[a]Numerical values represent the average of between four and eight independent determinations, with the measurements being reproducible to ±1.5%.

[b]Deviations (%) = $100[(X_A^{sat})^{calc} - (X_A^{sat})^{exp}]/(X_A^{sat})^{exp}$.

where the $r_{solvent}(V_A/V_{solvent})\phi_{solvent}$ term represents the contributions resulting from hydrogen-bond formation between the solvent molecules. For most of the published applications, $r_{solvent}$ was assumed to be unity for strongly associated solvents with single hydrogen-bonded chains such as monofunctional alcohols, to be two for water or diols, and to equal zero for nonassociated solvents such as saturated hydrocarbons. A more exact value for alcoholic solvents can be calculated based upon

$$[4]\quad r_{solvent} = (K_{solvent}\phi_{solvent}/V_{solvent})/(1 + K_{solvent}\phi_{solvent}/V_{solvent})$$

with a numerical value of $K_{solvent}$ = 5 000 cm^3 mol^{-1} assumed for all monofunctional alcohols.

If complexation does occur between the crystalline solute and solvent

$$[5]\quad \ln \phi_A^{sat} = ln\ a_A^{solid} - 0.5(1 - V_A/V_{solvent})\phi_{solvent} + 0.5 \ln [\phi_A^{sat} + \phi_{solvent}(V_A/V_{solvent})] - \phi_{solvent}^2 V_A(\delta'_A - \delta'_{solvent})^2(RT)^{-1} + \ln [1 + \phi_{solvent}(K_{ASolvent}/V_{solvent})]$$

then an additional term involving the solute–solvent equilibrium constant, $K_{ASolvent}$, must be introduced to describe the solubility enhancement that arises as a result of specific interactions. A slightly more complex expression applies in the case of solute complexation with a self-associating solvent. The symbols δ'_A and $\delta'_{solvent}$ denote the modified solubility parameters of the solute and solvent, respectively V_i is the molar volume, and a_A^{solid} is the activity of the solid solute. This latter quantity is defined as the ratio of the fugacity of the solid to the fugacity of the pure hypothetical supercooled liquid. The numerical value of a_A^{solid} can be computed from

$$[6]\quad \ln a_A^{solid} = -\Delta H_A^{fus}(T_{mp} - T)/(RTT_{mp}) + (\Delta C_{p,A}/RT)(T_{mp} - T) - (\Delta C_{p,A}/T) \ln (T_{mp}/T)$$

the solute's molar enthalpy of fusion, ΔH_A^{fus}, and heat capacity difference, $\Delta C_{p,A}$, at the normal melting point temperature, T_{mp}. Contributions from nonspecific interaction are incorporated into Mobile Order model through the $\phi_{solvent}^2 V_A(\delta'_A - \delta'_{solvent})^2(RT)^{-1}$ term. Ruelle and coworkers (17–21) have presented an impressive set of comparisons between experimental and predicted values for anthracene, naphthalene, pyrene, biphenyl, carbazole, benzil, *p*-benzoquinone, tricosane, octacosane, 10-nonadecanone, 11-heneicosanone, and 12-tricosanone solubilities in a wide range of both noncomplexing and complexing solvents to document the predictive ability of Mobile Order model.

Predictive application of eqs. [3] and [5] is relatively straightforward. First, an average numerical value of $\delta'_{hexclbz}$ = 20.10 MPa$^{1/2}$ is computed by requiring that each equation (with $r_{solvent}$ = 0 and (or) $K_{ASolvent}$ = 0) perfectly describes hexachlorobenzene mole fraction solubility data in *n*-hexane ($\delta'_{hexclbz}$ = 20.24 MPa$^{1/2}$), *n*-heptane ($\delta'_{hexclbz}$ = 20.07 MPa$^{1/2}$), and *n*-octane ($\delta'_{hexclbz}$ = 20.00 MPa$^{1/2}$). The numerical value of a_A^{solid} = 0.01943 is calculated using eq. [6] with ΔH_A^{fus} = 23 850 J mol^{-1} and T_{mp} = 505.0 K (22). The two heat capacity terms in eq. [6] were set equal to zero as we were unable to find heat capacity data for the subcooled liquid solute. A numerical value of $V_{hexclbz}$ = 155.6 cm^3 mol^{-1} was used for the molar volume of the hypothetical subcooled liquid solute. The solute's molar volume was estimated as the molar volume of liquid 1,2-dichlorobenzene (V_{diclbz} = 112.8 cm^3 mol^{-1}) plus four times the difference between the molar

2-Methyl-2-propanol	94.3	15.78
1-Pentanol	108.6	16.85
1-Hexanol	125.2	16.40
1-Heptanol	141.9	16.39
1-Octanol	158.3	16.38
1-Decanol	191.6	16.35
Butyl acetate	132.5	19.66
Ethyl acetate	98.5	20.79
1,2-Dichloroethane	78.8	20.99
1-Chlorobutane	105.0	17.12
1-Chlorohexane	138.1	18.00
1-Chlorooctane	171.1	18.00
Chlorocyclohexane	120.3	18.45
Hexachlorobenzene[b]	155.6[c]	20.10[d]

[a]Tabulated values are taken from a compilation given in Ruelle and coworkers. (17, 18, 20, 21).

[b]The numerical value of a_A^{solid} = 0.01943 was calculated from eq. [6] using ΔH_A^{fus} = 23 850 J mol^{-1} and T_{mp} = 505.0 K (22).

[c]Numerical value of $V_{hexclbz}$ = 155.6 cm^3 mol^{-1} was estimated using the known molar volumes of 1,2-dichlorobenzene and chlorobenzene.

[d]Numerical value was calculated using the measured hexachlorobenzene mole fraction solubilities in *n*-hexane, *n*-heptane, and *n*-octane, in accordance with eqs. [3] and [5] (with $r_{solvent}$ = 0 and (or) $K_{ASolvent}$ = 0).

volumes of 1,2-dichlorobenzene and chlorobenzene (V_{clbz} = 102.1 cm^3 mol^{-1}). The difference represents the calculated incremental group value for replacing one of the hydrogen atoms on chlorobenzene with a chlorine atom.

Table 1 summarizes the predictive ability of Mobile Order model for the 33 different organic solvents for which both hexachlorobenzene solubility data and modified solubility parameters could be found. Solvent molar volumes and modified solubility parameters are listed in Table 2. The modified solubility parameters account for only nonspecific interactions, and in the case of the alcoholic solvents, the hydrogen-bonding contributions have been removed. Numerical values of $\delta'_{solvent}$ were obtained from published compilations (17, 18, 20, 21), and were either deduced by regressing actual solubility data of solid *n*-alkanes in organic solvents in accordance with the configurational entropic model of Huyskens and Haulait-Pirson (23) or estimated using known values for similar organic solvents. The predicted values do depend upon the numerical values assumed for the various input parameters. Computations using slightly different numerical values for a_A^{solid} and the molar volume of hexachlorobenzene (± 5 cm^3 mol^{-1}) indicate that the predicted value can vary by 10–15% as a result of small changes in these two input parameters. This would be true of any predictive thermodynamic model that uses solubility parameters and bases activity coefficients upon the thermodynamic properties of the hypothetical subcooled liquid solute.

Examination of the entries in Table 1 reveals that Mobile Order model does provide fairly reasonable estimates of the solubility behavior of hexachlorobenzene in a wide range of organic solvents. Average absolute deviation between predicted and observed values is 210%. Expressed on a natural logarithmic mole fraction scale, Mobile Order model predicts the hexachlorobenzene solubilities to within ±0.87 ln units. Readers are reminded that in evaluating the applicability of Mobile Order model one must realize that many of these particular systems are highly nonideal, and that the experimental solubility data covers over a 75-fold range in mole fraction. Had an ideal solution been assumed, then the predicted mole fraction solubility would be $X_A^{sat} = a_A^{solid}$ = 0.01943 for each solvent. The ideal solution approximation corresponds to a considerably larger average absolute deviation of 2 060% between predicted and observed values.

Dissolution of organic solvents from painted surfaces into water

J.C. Wren, D.J. Jobe, G.G. Sanipelli, and J.M. Ball

Abstract: The presence of volatile iodine in containment buildings is one of the major safety concerns in the potential event of nuclear reactor accidents. Organic impurities in containment water, originating from various painted structural surfaces and organic materials, could have a significant impact on iodine volatility following an accident. To determine the source and magnitude of organic impurities and their effects on time-dependent iodine volatility, the dissolution for organic constituents from paints used in reactor buildings has been studied under postulated accident conditions. The studies of the organic dissolution from carbon steel coupons coated with zinc-primed vinyl, epoxy-primed polyurethane or epoxy paints over the temperature range 25–90°C are reported. Relatively large activation energies were measured for the release of the principal organic compounds from painted surfaces, suggesting it is the release of the solvents from the paint matrix rather than their diffusion through the solution that is the rate determining step for the dissolution mechanism. The similarities in the values of activation energies for the dissolution of different organic compounds from the paints suggest the release rate is independent of the nature of the painted surface or the type of organic being released from the surface. These two observations indicate that it may be possible to write a generalized rate expression for the release of organic compounds from painted surfaces in containment following an accident. The possible implications of these results for predicting iodine volatility in containment are also discussed.

Key words: dissolution kinetics, organic solvents, painted surfaces, reactor accidents.

Résumé : La présence d'iode volatil dans les enceintes de confinement est une des préoccupations majeures en matière de sécurité dans les cas d'accidents de réacteurs nucléaires. Les impuretés organiques présentes dans l'eau de confinement, qui pourraient provenir de divers matériaux organiques et de surfaces structurales peintes, pourraient avoir des répercussions significatives sur la volatilité de l'iode après un accident. Dans le but de déterminer la source et l'amplitude des impuretés organiques ainsi que leurs effets sur la volatilité de l'iode en fonction du temps, on a étudié la dissolution des constituants organiques des peintures utilisées dans les édifices des réacteurs dans les conditions prévues en cas d'accident. On rapporte les résultats d'études, effectuées à des températures allant de 25 à 90°C, sur la dissolution des produits organiques provenant d'échantillons d'acier au carbone recouverts peintures époxy, au vinyle avec couche d'apprêt au zinc ou au polyuréthane avec couche d'apprêt époxy. On a déterminé que les énergies d'activation sont relativement élevées pour la libération des principaux produits organiques des surfaces peintes; cette observation suggère que l'étape déterminante du mécanisme de dissolution est probablement la libération des solvants à partir de la matrice de peinture plutôt que leur diffusion à travers la solution. Les similarités dans les valeurs des énergies d'activation pour la dissolution de différents composés organiques à partir des peintures suggèrent que la vitesse de libération est indépendante de la nature de la surface peinte ou du type de composé organique libéré de la surface. Ces deux observations indiquent qu'il serait vraisemblablement possible de définir une expression de vitesse généralisée permettant de décrire la libération des composés organiques, à partir de surfaces peintes sur les enceintes de confinement, à la suite d'un accident. On discute aussi des implications possibles de ces résultats pour prédire la volatilité de l'iode dans les enceintes de confinement.

Mots clés : cinétique de dissolution, solvants organiques, surfaces peintes, accidents dans des réacteurs.

[Traduit par la Rédaction]

I. Introduction

The time-dependent airborne concentration of iodine in the reactor containment building is one of the most important parameters used to evaluate the potential radiological consequences of a nuclear reactor accident. The parameter is important because of the large inventory of iodine in irradiated nuclear fuel, and the radiological impact to public dose from an airborne emission of volatile ^{131}I species which could be released to the outside atmosphere through contain-

ment leakage or controlled venting. The behaviour of iodine under containment accident conditions has thus been a subject of extensive studies for the nuclear industry world-wide including Atomic Energy of Canada Limited (AECL) for many years. Recent critical reviews on iodine behaviour (1–3) and references therein provide a comprehensive technical background on this subject.

The results of these studies have established that iodine behaviour in containment would depend strongly on the pH and the steady-state concentration of water radiolysis products such as ·OH, O_2^-:, and H_2O_2 in the containment sump water, both of which influence the rate of conversion of non-volatile I^- to volatile I_2 (1, 2, 4–7). Under accident conditions, organic impurities in containment water (or the sump), could significantly affect the pH and the concentrations of the water radiolysis products via the following reactions (1, 2, 4–7):

[1] $R + \cdot OH \rightarrow R\cdot + H_2O$

[2] $R\cdot + O_2 \rightarrow RO_2\cdot \rightarrow \rightarrow R'\cdot$, alcohols, aldehydes, acids and CO_2

where R and R· represent an organic compound and corresponding organic radical dissolved in water. Organic iodides would also be formed thermally and radiolytically through aqueous phase reactions of I_2 with the organic impurities:

[3] $R\cdot + I_2/HOI \rightarrow RI + I\cdot$

The formation and decomposition of organic iodides will influence iodine volatility by changing the steady-state concentration of volatile I_2. Some organic iodides are also volatile, and would contribute directly to the volatile iodine component in containment.

Although there are many different organic surfaces and impurities in containment, those that are dissolved in aqueous solutions and undergoing reactions [1] to [3] would have the largest effect on iodine volatility (1, 2). Consequently, the relative rates for the release of organic impurities from painted surfaces to the aqueous phase, and their subsequent degradation to organic acids and organic iodides, are important parameters required to describe iodine behaviour following an accident. The objective of the current study is to establish one of these parameters; the release rate of organic impurities into the sump water. The dissolution kinetics of organic solvents from paints have been studied using carbon steel coupons coated with zinc-primed vinyl, epoxy-primed polyurethane, or epoxy paint in a temperature range of 25–90°C. The studied temperature range is that expected in containment following an accident, and the vinyl, polyurethane, and epoxy paints have been used to coat the containment surfaces of CANDU®[3] nuclear generating stations. The results of the dissolution study are presented in this paper.

II. Experimental

The studies were performed under controlled temperature conditions in glass cells containing water at 25, 40, 60, 70, and 90°C. The temperature of the cell was controlled by either a circulating-water bath or heating tape. The solution pH was held constant at either pH = 5 or pH = 10 using a 0.1 mol dm^{-3} H_3BO_3–NaOH buffer. All solutions were made using filtered water from a Millipore Filtration System.

II.A Coatings and coupons

Release of organic compounds into both the aqueous and gas phases from painted surfaces immersed in water was studied using cylindrical carbon steel coupons coated with zinc-primed vinyl, epoxy-primed polyurethane, or epoxy coatings. The constituents of these paints as supplied by the manufacturer are listed in Table 1.

The coupons (geometric surface area = 5.7 cm^2) were sandblasted and within two hours spray-coated with the appropriate coating(s). For the zinc primer, a layer of approximately 0.015 cm was applied while for the other coatings, a thickness of approximately 0.025 cm was used. The epoxy-coated coupons and epoxy-primed-polyurethane-coated coupons were stored for 9 and 60 months, respectively, while the zinc-primed-vinyl-coated coupons were stored for various periods (15 days to 36 months). The coupons were stored in a ventilated area at room temperature (i.e., under conditions that did not inhibit solvent release by evaporation). The thinners used in applying the paints contained toluene, xylenes, methyl isobutyl ketone (MIBK), or 1,1,1-trichloroethane.

At the end of many of the dissolution experiments performed at 90°C there was evidence for blistering of the paint. The vinyl paint was particularly susceptible, with immersion resulting in the whole coupon surface being covered with blisters, 1 to 2 mm in diameter, and in some cases, exposure of the carbon steel on the edges of the coupon. A layer of the vinyl polymer was peeled, revealing yellow discoloration underneath, and ethanol and 2-propanol, the major solvent constituents of the zinc primer base undercoating, were observed in solution. Blistering was not observed at lower temperatures.

II.B Reaction vessel apparatus

Glass vessels were prepared from 500 cm^3 beakers, with final total volumes of 375 cm^3. These beakers were modified to accommodate a thermowell in the liquid phase for thermocouple readings, and a screw-on Teflon Mininert septum valve for sampling. The Mininert valve consisted of a push-type Teflon valve and a replaceable septum. The Teflon valve provided a seal when not sampling whereas the septum provided the only other seal when taking samples and allowed multiple punctures during the study. For studies at 60, 70, and 90°C the glass vessels were inserted into insulated machined-out aluminum cylinders, wrapped with heating tape. The temperature difference between the aluminum wall and the liquid phase was approximately 1 to 2°C. At 25 and 40°C, the glass vessels were kept in a circulating water bath.

The glass vessels, containing 60-cm^3 of air-sparged and buffered solutions, were heated to temperature at which point a single painted coupon was added to each vessel. Blank runs, for which no coupon was added to a vessel, were also conducted. There was no intentional mixing of the gas or liquid phase during the runs except when l.0-cm^3 gas and aqueous samples were removed using a Hamilton gas-tight syringe.

[d]One part A (hardener) mixed with 4 parts B (resin). Thinner added as required.

[e]One part A mixed with 0.15 parts B. Thinner added as required.

II.C Analyses

The gas-phase concentrations of the organic compounds were determined using a Model 3700 Varian Gas Chromatograph (GC) equipped with a HNU Model PI-52 photoionization detector. The GC was routinely calibrated using gas mixtures of known composition. Gas-phase constituents were identified using a Hewlett Packard (HP) Model 5890 GC fitted with a HP Series 5972 mass selective detector. The detection limit of the GC for the organic molecules was 0.05 $\times 10^{-6}$ mol dm^{-3}.

The concentrations of the aqueous-phase carbonyl species were determined using a Waters' HPLC (High Performance Liquid Chromatography) system, following derivatization by 2,4-dinitrophenylhydrazine (DNPH) (8). The aqueous organic species detected by this method were formaldehyde, acetaldehyde, acetone, methyl ethyl ketone, *n*-heptan-2-one, and MIBK. The detection limits of the HPLC/derivatization method ranged from 0.5×10^{-6} to 1×10^{-6} mol dm^{-3} for aldehydes and ketones and from 4×10^{-6} to 10×10^{-6} mol dm^{-3} for organic acids. The concentrations of aromatic compounds were too low to be detected by direct injections. At the end of each test, the pH was measured and the liquid sent for chloride analyses by ion chromatography. The statistical measurement uncertainties ($\pm 1\ \sigma$ with 95% confidence limits) of the gas and aqueous phase analysis were 12 and 5%, respectively, except for low concentrations near the detection limits.

During a typical experiment, one of the coupons was placed in the reaction flask containing the solution and the flask was sealed with a screwed septum cap. This arrangement provided a surface area to volume ratio in the aqueous phase (A_{surf}/V_{aq}) of ~0.095 cm^{-1} and a gas to aqueous volume ratio (V_g/V_{aq}) of approximately 5.25.

Both gas and aqueous samples were taken periodically using micro-syringes and analyzed for organic content; from every half an hour to an hour at 90°C to every 24 h at 25°C. Because of the small sampling volumes, the total reduction in the aqueous volumes due to sampling was no more than 8% by the end of the test. A test lasted until a steady-state was reached or up to 20 days.

III. Results

III.A Dissolution and partitioning of organic compounds between gas and aqueous phases

A number of organic compounds were found in the gas and aqueous phases in the presence of the three coatings. MIBK is common to all coatings as it was present in either the paint, the undercoating (e.g., it is not present in the polyurethane paint, but was present in the epoxy undercoating), or the thinner. One organic compound that appears in the epoxy and vinyl tests but is absent from the list of the manufacturer's ingredients is acetone. This component must have been present as either an impurity (present in the MIBK) or as a product of hydrolysis or oxidation of one of the other components. A number of other lower-weight aliphatic aldehydes and ketones which may be by-products of reactions or impurities were also identified. Components of the thinners, such as aromatic (toluene and *m*-xylene) and chlorinated (1,1,1-trichloroethane) hydrocarbons were also observed. For the organic compounds detected in the aqueous phase, the following sequence was observed for their concentrations in the presence of the three surfaces:

Epoxy: acetone > MIBK > *n*-heptan-2-one > *m*-xylene

Vinyl: acetone ≅ MIBK ≅ MEK ≅ acetaldehyde > formaldehyde

Polyurethane: MIBK > formaldehyde

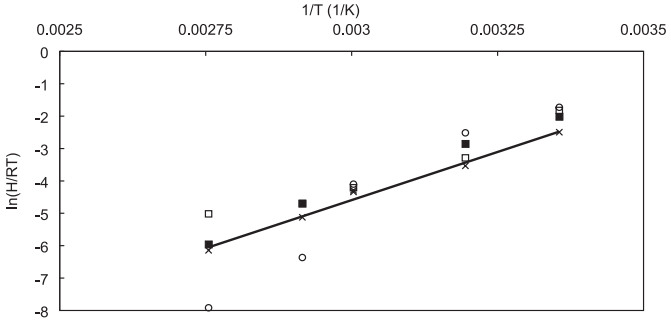
while in the gas phase:

Epoxy: *m*-xylene > MIBK ≅ *n*-heptan-2-one > acetone

Vinyl: MIBK > *m*-xylene > toluene

Polyurethane: MIBK > *m*-xylene >> 1,1,1-trichloroethane

The different order of abundance in the gas and aqueous phases is due to different partition coefficients of these compounds, where the partition coefficient (H) is defined as the ratio of the *aqueous* to the *gas*-phase concentration at equilibrium, and is related to the equilibrium constant K (Henry's law constant) obtained from the free energy, by the relationship $H = K(RT)$.



The equilibration of these organic compounds between the gas and aqueous phases in a shallow pool should be quite rapid and thus the concentrations of organic compounds in the gas phase should reflect those in the aqueous phase. This was confirmed experimentally by injecting MIBK at the bottom of an aqueous solution and then analyzing the gas phase for MIBK as a function of time. Equilibrium was obtained within 10 min, much faster than the time scale of these

Table 2. Values for the partition coefficient (H) for MIBK at 25, 40, 60, 70, and 90°C.

	H			
Temperature (°C)	Vinyl	Epoxy	Polyurethane	Water
25	330	204	440	400
40	150	76	210	97
50	—	—	—	83
60	38	36	46	41
70	26	17	4.9	26
90	7.8	6.5	1.1	20

Fig. 1. Plot of ln (H) versus 1/T(K) for the distribution of MIBK between the gas and aqueous phases in the absence of any surface (□) and in the presence of the epoxy (×), vinyl (■), and polyurethane (○) surfaces.

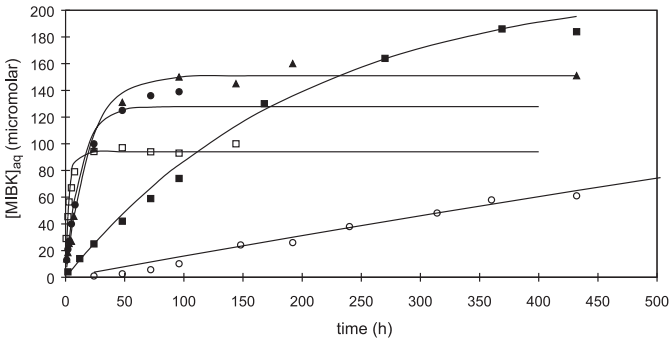
thermal dissolution studies. The fast equilibrium between the gas and aqueous phases enabled us to use both the aqueous- and gas-phase data to determine the dissolution rates.

The partition coefficient of MIBK as a function of temperature, measured in water in the absence of a painted surface, is listed in Table 2. Similar values, generally within a factor of two (which is within experimental uncertainties) were obtained using painted coupons as the source of MIBK. These values are also listed in Table 2. Note that the uncertainties are greater for lower partition coefficients (i.e., at higher temperatures).

A least-squares fit of ln (H/RT) versus 1/T(K) (Fig. 1) using all of the data in Table 2 yields a $\Delta H° = -(59 \pm 6)$ kJ mol^{-1} and $\Delta S° = -(214 \pm 16)$ J mol^{-1} K^{-1} for the transfer of MIBK from the gas phase to the aqueous phase using the slope and intercept, respectively (MIBK(g) = MIBK(aq)).

$$[4] \qquad \Delta G° = -RT \ln (H/RT) = \Delta H° - T\Delta S°$$

$$[5] \qquad \ln (H) - \ln (RT) = -(\Delta H°/R)\ (1/T) + \Delta S°/R$$



A similar analysis of the data obtained for *n*-heptan-2-one and acetone during the epoxy test gives the results in Table 3. The values for $\Delta H°$ are compared to literature values for the same compounds obtained from Ref. 9. $\Delta S°$ values for the ketones were not readily available from the literature, therefore $\Delta S°$ values for organic compounds having similar heats of vapourization e.g., ethanol and methanol are provided for comparison in Table 3 (10).

Table 3. Values of $\Delta H°$ and $\Delta S°$ for the gas–liquid phase partitioning of various organics in water.

Organic	$\Delta H°$ (kJ mol^{-1})	$\Delta S°$ (J K^{-1} mol^{-1})	Reference
MIBK	–(59 ± 6)	–(214 ± 16)	This study
	–1.4[a]		(9)
acetone	–(69 ± 13)	–(245 ± 13)	This study
	–46		(9)
n-heptan-2-one	–(57 ± 18)	–(210 ± 5)	This study
	–37		(9)
methanol	–46	–107	(10)
ethanol	–54	–134	(10)

[a]Both the reported partition coefficient and the reported activation energy are very low in comparison to those for similar compounds.

Fig. 2. Aqueous-phase concentrations of MIBK in the presence of the epoxy surface (pH = 10) at 25 (○), 40 (■), 60 (▲), 70 (●), and 90°C (□). The lines drawn through the data are those calculated using eq. [14].

III.B Dissolution of MIBK from coatings

To assess the release of organic compounds from the coatings under containment conditions, it is best to study the release of one representative compound common to all coatings. Since MIBK is present in varying degrees in all of the coatings (it is not present in the polyurethane coating per se., but is present in the epoxy undercoating), the MIBK data have been used to obtain the dissolution kinetics. The dissolution kinetics of MIBK from vinyl, epoxy, and polyurethane surfaces were studied at 25, 40, 60, 70, and 90°C. Some of the results are shown in Figs. 2 to 6. For each coating, additional analysis included several other organic compounds, ranging from other ketones (acetone, *n*-heptan-2-one), to aromatic compounds (*m*-xylene, toluene) and halogenated hydrocarbons (trichloroethylene, chloroform). All of these species showed dissolution kinetics very similar to MIBK.

Comparing the time dependent concentration profiles for the various surfaces, it appears that the final steady-state MIBK concentrations, which were far below the solubility limit of MIBK in water, depend on both coating type and paint aging. MIBK dissolution also follows the rate laws derived from the simple mechanism:

$$[6] \qquad \text{MIBK(ab)} \rightarrow \text{MIBK(aq)}$$

© 2000 NRC Canada

Fig. 3. Gas-phase concentrations of MIBK in the presence of the epoxy surface (pH = 10) at 25 (○), 40 (■), 60 (▲), 70 (●), and 90°C (□). The lines drawn through the data are those calculated using eq. [14].

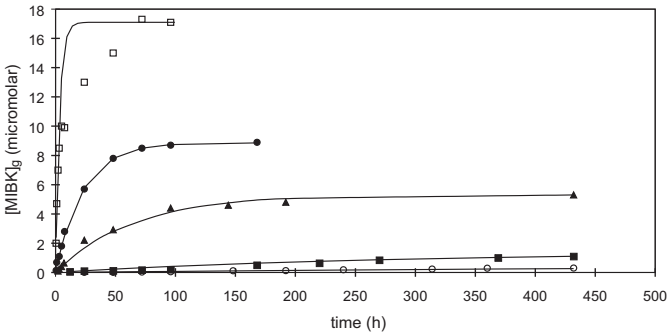


Fig. 4. Normalized concentrations of MIBK in the presence of the epoxy surface (pH = 10) at 25 (○), 40 (■), 60 (▲), 70 (●), and 90°C (□). The lines drawn through the data are those calculated using eq. [14] normalized to the steady-state concentration.

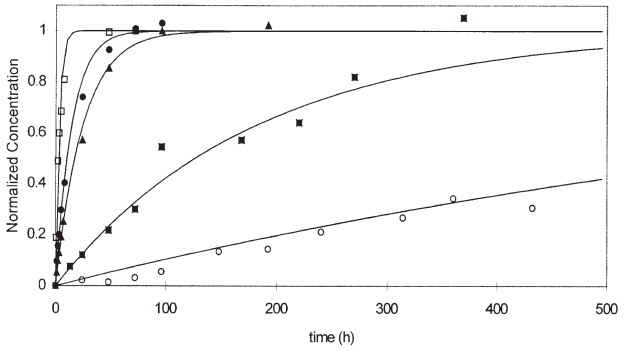

Fig. 5. Normalized concentrations of MIBK in the presence of the polyurethane surface (pH = 5) at 25 (○), 40 (■), 60 (▲), 70 (●), and 90°C (□). The lines drawn through the data are those calculated using eq. [14] normalized to the steady-state concentration.

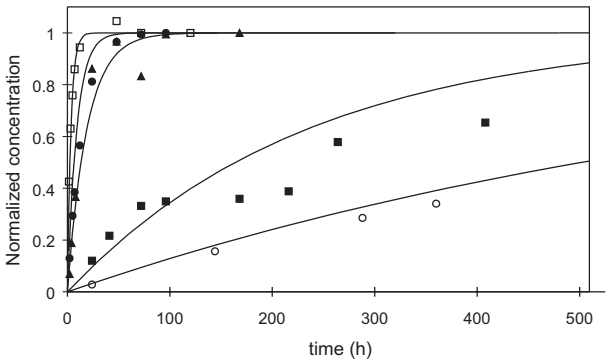

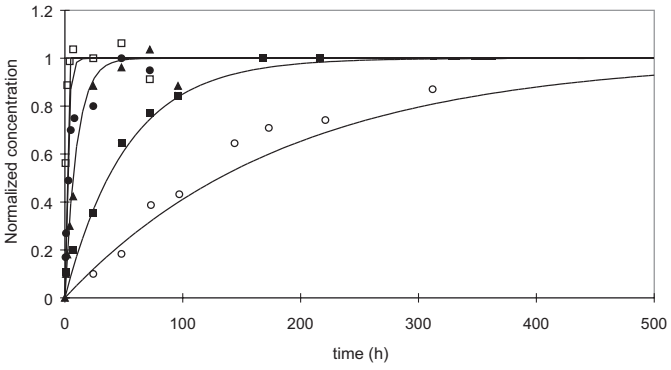

Fig. 6. Normalized concentrations of MIBK in the presence of the vinyl surface (pH = 10) at 25 (○), 40 (■), 60 (▲), 70 (●), and 90°C (□). The lines drawn through the data are those calculated using eq. [14] normalized to the steady-state concentration.

[7] MIBK(aq) ↔ MIBK(g)

where aq, ab, and g in the brackets represent aqueous, absorbed, and gas phase, respectively. Assuming a fast equilibrium for eq. [7] leads to the following equation for the concentration of MIBK in solution, $[MIBK(aq)]_t$ (μmol dm^{-3}):

$$[8] \quad [MIBK(aq)]_t = [MIBK(aq)]_\infty \cdot (1 - \exp(-kt))$$

$$[9] \quad = \alpha(1 - \exp(kt))$$

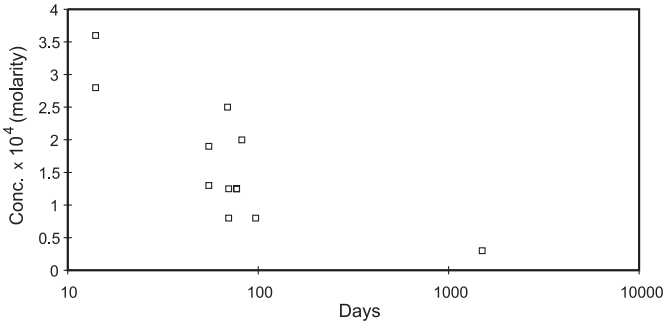
and for the gas-phase concentration of MIBK, $[MIBK(g)]_t$ (μmol dm^{-3}):

$$[10] \quad [MIBK(g)]_t = \frac{1}{H}[MIBK(aq)]_\infty (1 - \exp(-kt))$$

$$[11] \quad = \beta(1 - \exp(kt))$$

where k is the dissolution rate constant (s^{-1}), α and β are proportional constants, H is the partition coefficient, and $[MIBK(aq)]_\infty$ (μmol dm^{-3}) is the final MIBK concentration present in the water at the end of dissolution, and is related to the amount of MIBK present in the paint polymer initially, $[MIBK(ab)]_0$.

Table 4 shows the values of k and $[MIBK(aq)]_\infty$ that result from fitting eq. [8] to the observed time-dependent aqueous-phase concentrations for the epoxy, vinyl, and polyurethane surfaces. The amount of MIBK originally on the surface $[MIBK(ab)]_0$ is also shown in the table. $[MIBK(ab)]_0$ was calculated using the measured partition coefficient of MIBK in water at the appropriate temperature, (see Table 2), the surface area of the coupon, and the appropriate liquid and gas volumes. The aqueous-phase data for the test in the presence of the epoxy surface at pH = 10 is shown graphically in Fig. 2 while the gas-phase data for the same test is shown in Fig. 3. The lines drawn through the data are those predicted by eqs. [9] and [11] using the k and $[MIBK(aq)]_\infty$ values given in Table 4. In general, the calculated lines reproduce the data extremely well, indicating the simple mechanism represented by reactions [6] and [7] adequately describes the dissolution process.



From Table 4 (Fig. 2), it can be seen that the final steady-state concentration for MIBK, $[MIBK(aq)]_\infty$, in the presence of a painted surface varies from one test to another. The range of the final concentration is more than expected from the variations in paint thickness which were kept small. This variance is considered to be mainly due to the difference in

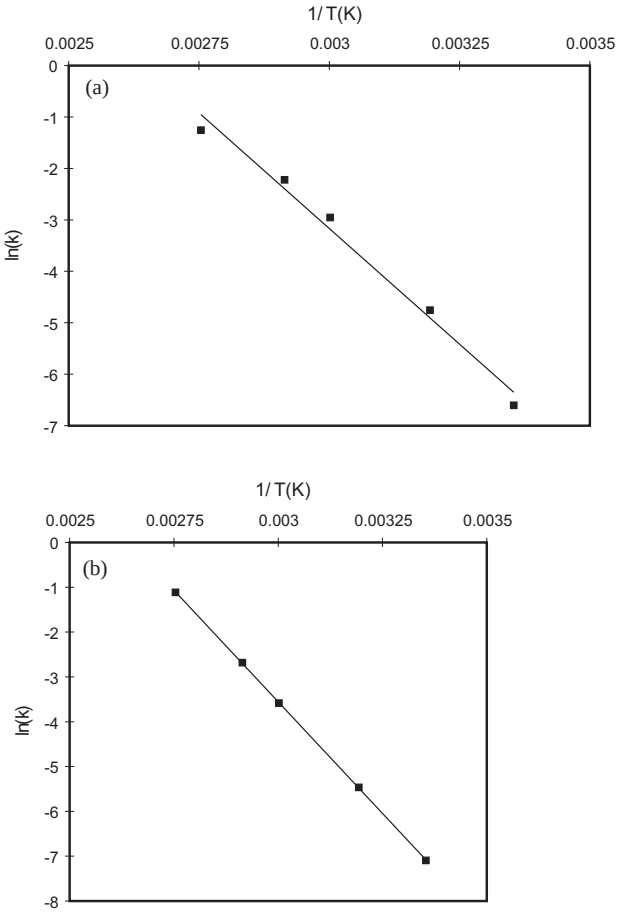
Fig. 7. The final steady-state concentration of MIBK released from vinyl-painted coupons as a function of the aging of paint.



the amount of solvent initially in the paint polymer, and related to the degree of aging of the paint. The maximum concentration of MIBK released into the aqueous phase from the vinyl painted coupons is shown as a function of paint aging in Fig. 7. Data obtained at different pH values and temperatures are all included in the figure. (We do not have enough data to establish the effect of aging for the other paints.) Although the data show large scatter, the effect of aging on the final concentration can be seen clearly. Therefore, it is assumed that the initial MIBK concentration within the coating surface controls the maximum MIBK concentration in solution and that the MIBK content in the coating decreases with aging due to evaporative losses.

To compensate for this aging effect in the graphical presentation, the concentrations of MIBK were normalized by dividing by final steady-state concentration. A plot of the normalized data for the epoxy, polyurethane, and vinyl surfaces can be found in Figs. 4–6, respectively. Only the initial data are shown for low temperature tests due to the variable time frame over which the tests were conducted, i.e., tests at 25°C take much longer to reach steady-state than tests performed at 90°C. The lines drawn through the data are those calculated using eq. [9] normalized to the final steady-state concentration.

The solution pH appears to have only a minor effect on the dissolution of MIBK. For most of the data, the dissolution behaviour of MIBK at pH 5 is not that much different than that at pH 10. For the most part, the time-dependent dissolution curves at the two pHs parallel each other for the three surfaces at the various temperatures; although generally, the dissolution curves at pH = 10 yield slightly higher final concentrations. This is unlikely to be a consequence of small variations in the painted samples, because the higher of the two final concentrations would be expected to be dis-

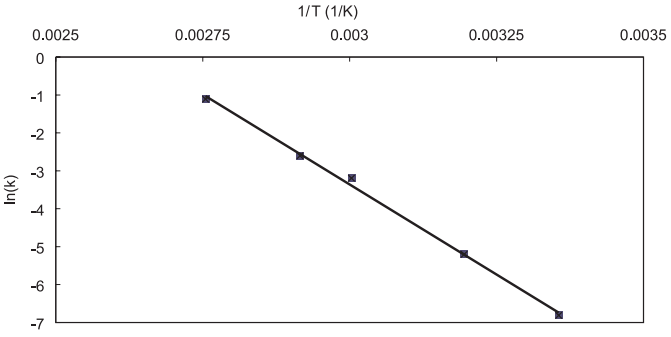
tributed randomly between the two pH values, which is not the case. It may be possible that the results obtained from the DNPH derivatization are pH dependent.



As can be seen in Figs. 4–6, the effect of temperature on dissolution is as expected, increasing the dissolution rate for MIBK sharply as the temperature increases. The dissolution rate constant for MIBK from polyurethane measured as a function of temperature is shown in an Arrhenius plot, i.e., ln k versus (1/T), in Fig. 8, where the slope of the plot provides the activation energy (E_a) of the dissolution process:

$$[12] \quad k = A \exp(-E_a/RT)$$

The rate constants obtained using the gas-phase data are nearly identical with those obtained from the aqueous-phase data for all paints studied. Arrhenius plots of the dissolution constants from epoxy and vinyl paints are shown in Figs. 9 and 10, respectively.

The activation energies determined from Arrhenius plots for the dissolution of MIBK are listed in Table 5. Table 5 includes data from all three surfaces at pH = 5 and 10 using both the aqueous and gas-phase measurements. The errors on E_a listed in Table 5 are those associated with the slopes based on a least-squares (Arrhenius) fit of the ln (k) and 1/T(K) values listed in Table 4. Except for some of the results obtained in the presence of the polyurethane surface,

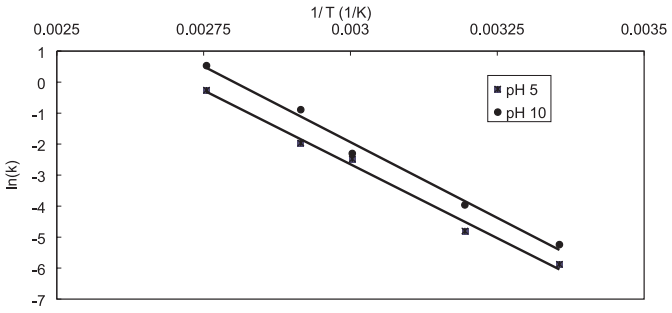
the E_a values are within experimental error of each other, yielding an average of E_a = 82 ± 11 kJ mol^{-1}.

We have also analyzed the data for acetone and *m*-xylene and obtained the activation energies for the dissolution of these compounds; E_a = 83 ± 3 and 65 ± 4 kJ mol^{-1} respectively, similar to those observed for MIBK.



IV. Discussion

Unlike the dissolution of a pure solid, the release of MIBK from the painted surface does not involve the rupture or hydrolysis of chemical bonds within the structure of the solid, but rather occurs through the diffusion of the organic compound out of the paint matrix. A typical final concentration for MIBK in the experiments is ~100 μmol dm^{-3}. For the 60 cm^3 of water, this indicates an overall release of ~6 μmoles or 4 × 10^{18} molecules of MIBK per coupon (surface area = 5.7 cm^2). Typical BET (Brunauer, Emmett and Teller) surface area measurements have shown that small organic molecules like pyridine usually occupy an adsorbed surface area of 26 × 10^{-16} cm^2 (11); therefore, it would have required a surface with an area of ~1 × 10^4 cm^2 to have released this amount of MIBK as an adsorbed monolayer. This is ~2000 times more than the surface area of the coupon; therefore, MIBK must be diffusing out of the paint matrix.

Except for one of the results obtained in the presence of the polyurethane surface, the E_a values are within experimental error of each other yielding an average of 82 ± 11 kJ mol^{-1}. The similar values of E_a obtained for the three surfaces imply that the diffusion of the organic solvents through the matrix is relatively independent of the chemical composition of the matrix of the paint. Furthermore, the absolute dissolution rate constants are very similar for the three surfaces, indicating that, for a given substrate (in this case sandblasted carbon steel), the painted surface area does not vary significantly with the type of paint. This is important, for if this assumption is valid, it is possible that a general expression can be used to predict the release rate and time dependent concentrations for MIBK from a painted surface, provided the surface concentration and temperature are known. This assumption can be extended one step further. Fits of the Arrhenius equation to the data obtained for acetone and *m*-xylene yield E_a = 83 ± 3 and 65 ± 4 kJ mol^{-1}, respectively. These values are similar to that obtained for

MIBK, which suggests that the dissolution rate is also independent of the type of organic compound.
