IUPAC Recommendations

Macromolecular Division
Commission on Macromolecular Nomenclature

Generic source-based nomenclature for polymers

Synopsis

The commission has already published two documents on the source-based names of linear copolymers and nonlinear polymers; however, in some cases this nomenclature leads to ambiguous names. The present document proposes a generic source-based nomenclature that solves these problems and yields clearer source-based names. A generic source-based name comprises two parts: (1) a polymer class (generic) name followed by a colon; and (2) the actual or hypothetical monomer name(s), parenthesized in the case of a copolymer.

The formula, the structure-based name, the source-based name, and the generic source-based name are given for each example in the document. In some cases, only generic source-based nomenclature gives unambiguous names — for example, when a polymer has more than one name or when it is obtained through a series of intermediate structures. The rules concern mostly polymers with one or more types of functional group or heterocyclic system in the main chain, but to some extent they are also applicable to polymers with side-groups, carbon-chain polymers such as vinyl or diene polymers, spiro and cyclic polymers, and networks.

Comments on these recommendations are welcome and should be submitted by February 28, 2001 to Prof. Ernest Maréchal, Laboratoire de Synthèse Macromoléculaire, Université Pierre et Marie Curie (Paris VI), Boîte 184 - Tour 54, 4e étage, 4 place Jussieu, F-75252 Paris CEDEX 05, France. Telephone: +33-1-44-27-38-04. Fax: +33-1-44-27-70-54. e-mail: marechal@ccr.jussieu.fr

A copy of the full recommendation is available from Dr. J.W. ApSimon, Vice-President (Research and External), Carleton University, 1125 Colonel By Drive, Ottawa, Ontario, Canada, K1S 5B6. Telephone: (613) 520-3570. Fax: (613) 520-2689.

Analytical Chemistry Division
Commission on Separation Methods in Analytical Chemistry

The hold-up volume concept in column chromatography

Synopsis

Revised recommendations are presented for the nomenclature of the *hold-up volume* in chromatography, updating those originally presented in the IUPAC document *Nomenclature for Chromatography (IUPAC Recommendations 1993)* (Pure Appl. Chem. **65**, 819 (1993)). A number of related and derived definitions for retention parameters are described, including a definition of the term "chromatographic system". The paper also compares methods used in the literature to determine the hold-up volume.

Comments on these recommendations are welcome and should be submitted by February 28, 2001 to Prof. José Antonio García Domínguez, Institute of Physical Chemistry "Rocasolano", Calle Serrano 119, E-28006 Madrid, Spain. Telephone: +34-91-651-9400. Fax: +34-91-564-2431. e-mail: jagd@iqfr.csic.es

A copy of the full recommendation is available from Dr. J.W. ApSimon, Vice-President (Research and External), Carleton University, 1125 Colonel By Drive, Ottawa, Ontario, Canada, K1S 5B6. Telephone: (613) 520-3570. Fax: (613) 520-2689.

Commission on Separation Methods in Analytical Chemistry

Retention parameters in gas chromatography

Synopsis

This paper presents a revision of terms in Chapter 3.6 The Mobile Phase and Chapter 3.7 Retention Parameters in Column Chromatography in *Nomenclature for Chromatography (IUPAC) Recommendations 1993)* (Pure Appl. Chem. **65**, 819 (1993)), with the aims of: (*i*) emphasizing the physical meaning of the terms; and (*ii*) specifying the temperatures and pressures for the terms for gas volumes and flow rates. A number of the original terms were found to be misleading or superfluous, including such terms as *corrected retention time*, *net retention time*, *total retention volume (time)*, *specific retention volume at 0°C*, *relative pressure*; and their usage is strongly discouraged. Chapter 1.1 Basic Definitions was supplemented with the terms *chromatographic system* and *chromatographic process*.

Comments on these recommendations are welcome and should be submitted by February 28, 2001 to Prof. Vadim A. Davankov, Institute of Organo-Element Compounds, Russian Academy of Sciences, Vavilov Street 28, RU-117813 Moscow, Russia. Telephone: +7-095-135-6471. Fax: +7-095-135-6471. e-mail: davank@ineos.ac.ru

A copy of the full recommendation is available from Dr. J.W. ApSimon, Vice-President (Research and External), Carleton University, 1125 Colonel By Drive, Ottawa, Ontario, Canada, K1S 5B6. Telephone: (613) 520-3570. Fax: (613) 520-2689.

Photolysis of tris(trimethylsilyl)silane: trapping of sisyl radicals

Mustafa Mohamed and Michael A. Brook

Abstract: The photolysis of tris(trimethylsilyl)silane (TTMSS) was studied in the absence and in the presence of added trapping agents such as alkenes and alcohols. It was found that, unlike the case with pyrolysis, silyl radicals rather than silylenes are produced. They may be efficiently trapped with alkenes, to give the hydrosilylation products, but not with alcohols. The major product from the photolysis of TTMSS in the absence of added trapping agent (or with alcohols as trapping agents) was tetrakis(trimethylsilyl)silane. Possible mechanisms to account for the photoproducts are presented.

Key words: hydrosilane, photolysis, silylenes, silyl radical, sisyl hydride.

Résumé : On a étudié la photolyse du tris(triméthylsilyl)silane (TTMSS) en l'absence et en présence d'agents de piégeage tels les alcènes et les alcools. On a trouvé qu'il se forme des radicaux silyles plutôt que des silylènes contrairement à ce qui se passe lors de la pyrolyse. Ces produits peuvent être piégés efficacement avec des alcènes, mais pas avec les alcools, pour donner des produits d'hydrosilylation. Le produit majoritaire de la photolyse du TTMSS en l'absence d'agents de piégeage (ou avec des alcools comme agents de piégeage) est le tétrakis(triméthylsilyl)silane. On présente un mécanisme possible qui justifie la formation des produits observés.

Mots clés : hydrosilane, photolyse, silylènes, radical silyle, hydrure de silyle.

[Traduit par la Rédaction]

Introduction

Unlike their carbon analogues, and in spite of the absence of π bonds, catenated oligosilanes are UV-active molecules. The long wavelengths of maximum UV absorption, which increase dramatically with chain length before levelling off at about 320 nm (for poly(dimethylsilylene), (1), have been attributed to extended σ conjugation (2). Even longer UV absorptions accompany polysilanes with appropriate (π-conjugating) substituents.

The chemistry of oligosilanes that can be initiated photochemically is indeed rich (3). The photoinduced silyl group rearrangement of oligosilanes led to the isolation of the first stable silicon–carbon double bond (4); many related sigmatropic photorearrangements of oligosilanes are known (for some selected examples, see ref. 5). In the absence of receptor functional groups to which they can rearrange, oligosilanes undergo photodecomposition via both silyl radical and silylene intermediates (6–9). These reactive species may be trapped by a variety of reagents, the most useful of which include hydrosilanes (R_3SiH), alcohols, and dienes for the silylenes, and alkenes for the silyl radicals (8).

Synthetically, one of the most useful oligosilanes is tris(trimethylsilyl)silane (sisyl hydride, TTMSS). Due in part to the relative weakness of the hydrogen–silicon bond in this molecule (ca. 85 kcal mol^{-1}, (10) the molecule can be used under radical conditions to reduce a wide variety of organic functional groups including alkyl halides, carbonyl groups, xanthates, etc. The compound also undergoes facile hydrosilylation with isolated alkenes and hydrosilylative coupling of α,ω-dialkenes (Scheme 1).

We have recently reported the use of the tris(trimethylsilyl)silyl group (sisyl) as a photoremovable protecting group for alcohols (11). The sisyl ethers undergo photodecomposition primarily via silylenes (12) as shown by trapping experiments; the regiochemistry of decomposition is affected by the steric bulk on the alcohol (Scheme 2, (13)). We were interested in establishing if sisyl hydride ($(Me_3Si)_3SiH$) could similarly be induced to undergo photodecomposition by silylene routes, as this would be complementary to the radical chemistry noted above. In this paper we describe studies of the photochemical decomposition of sisyl hydride on its own and in the presence of various trapping agents.

Results

Tris(trimethylsilyl)silane (**1**), tris(trimethylsilyl)methylsilane (**2**), and tetrakis(trimethylsilyl)silane (**3**) were prepared by the method of Gilman and Harrel, Jr. (14). Photolyses were undertaken in a Rayonet reactor with irradiation at 254 nm using low pressure mercury lamps. Major

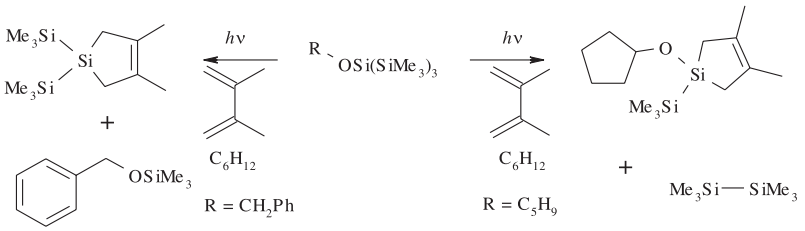
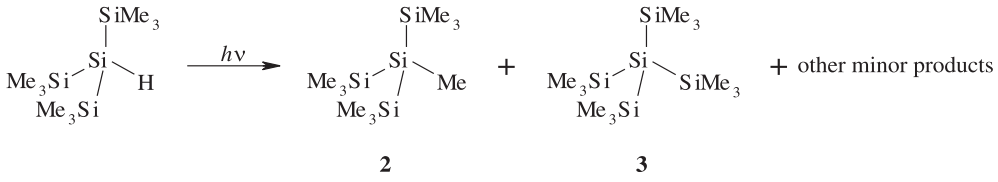
Scheme 1.

products and (some) minor products were identified by comparison of retention time and GC–mass spectra with those of authentic samples.



Photolyses of TTMSS

When a hexane solution of TTMSS was photolyzed over 8 h in the absence of added traps, GC–MS analysis of the volatile products showed formation of three different products and the presence of a great deal of residual starting material (78%). The major products are **2** and **3**; their identities were confirmed by comparison with authentic samples (Scheme 3). The formation of such products could be consistent with the intermediacy of either silylenes or silyl radicals. To throw light on this, TTMSS was photolyzed in the presence of alkenes and alcohols, which are known to be excellent traps for silyl radicals and silylenes, respectively.



Reaction with alkenes

The radically induced hydrosilylation of alkenes using TTMSS has been reported previously (15). To establish whether these reactions could similarly be photoinduced, the reaction of TTMSS with a series of alkenes was examined in hexane at room temperature in the absence of any radical initiators such as AIBN. The hydrosilylation products were obtained in good yield in less than 3 h of photolysis time, in all cases (Scheme 4).

Scheme 5.

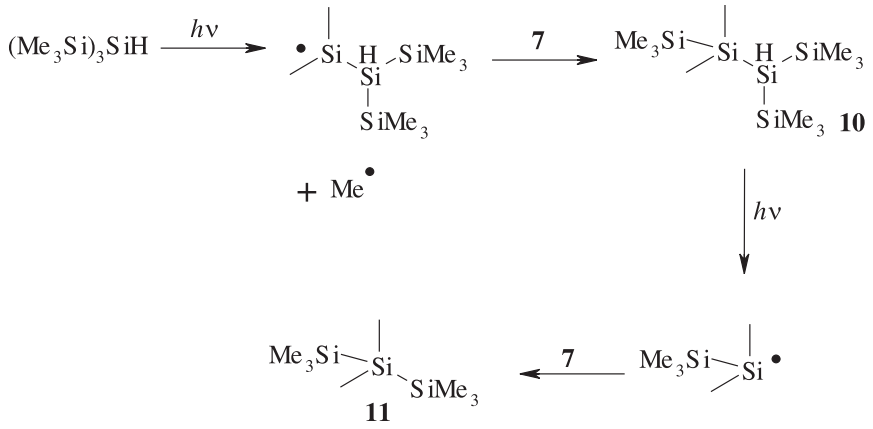
Reaction with alcohols

The photolysis of TTMSS in the presence of cyclopentanol was not very efficient; after 24 h mostly starting material (80%) remained. The major products included $(Me_3Si)_4Si$ (**3**), $(Me_3Si)_2SiH_2$ (**4**), $(C_5H_9O)SiMe_3$, and two others that have not yet been conclusively identified. In addition, the product of autoxidation of TTMSS, $(Me_3SiO)_2SiH(SiMe_3)$, previously described by Chatgilialoglu et al. (16), was also observed (Scheme 5, Path C). The latter product was also detected when methanol was used as a trap, but in none of the other experiments performed.

Photoreactions in the presence of methanol were similarly inefficient. After 2.5 h more than seven different volatile products with a total yield of less than 10% were present; the remaining 90% was unreacted starting material. Analysis of the products was complicated by the fact that few of the products showed a molecular ion in the mass spectrum. Three of the detected products were similar to those observed from the photolysis of TTMSS in the absence of added trapping agent: **2**, **3**, and **4** (Scheme 5). With prolonged photolysis of 24 h, over 80% of TTMSS remained. The character of the remainder of the GC–MS trace was, however, profoundly different than that from the shorter reaction time. Most of the volatile photoproducts had disappeared, and there was a concomitant increase in the relative concentration of $Si(SiMe_3)_4$.

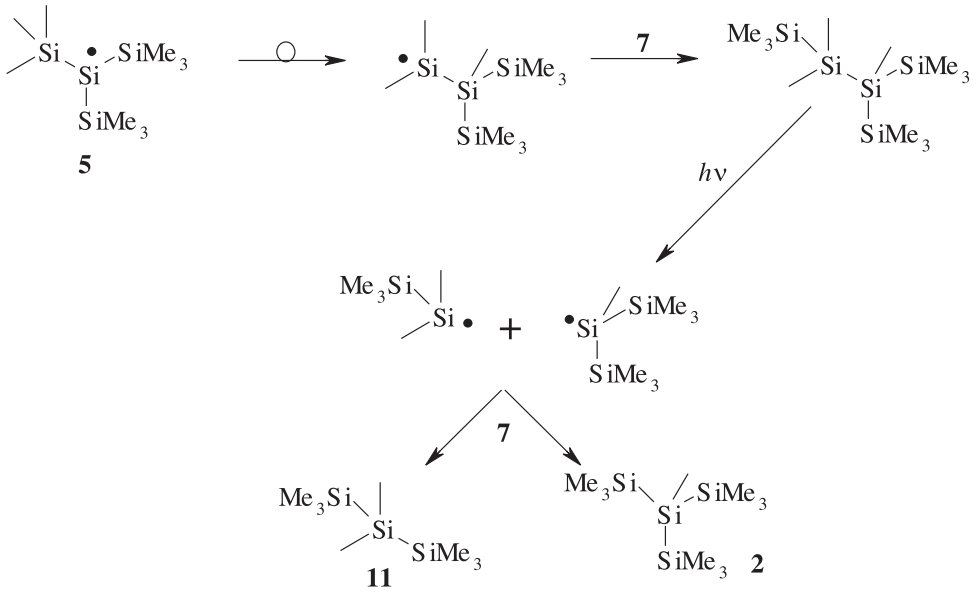
Discussion

The behaviour of TTMSS in the presence of alkenes, activated by photolysis, exactly mirrors the chemistry that takes place in the presence of radical initiators. Silyl radical hydrosilylation to form the terminal sisylalkane in good yield is observed. The process is efficient, going to completion within 3 h. There is no evidence of chemistry occurring via the intermediacy of silylenes.



When a radical trap, such as an alkene, is not present, TTMSS is presented with fewer accessible reaction pathways, and instead reacts inefficiently via silyl radicals to generate a myriad of photoproducts. The most stable of these, as evidenced by its increasing significance during the photolyses over time, is **3**.

Gaspar et al. (12) observed degradation via silylene intermediates during the pyrolysis of TTMSS; a major product was $(Me_3Si)_3Si\text{-}Si(SiMe_3)_2H$ which, as noted by them, could have its origins either in the silylene:$Si(SiMe_3)_2$ or the disilene $(SiMe_3)_2Si{=}Si(SiMe_3)_2$ derived from the silylene. No evidence for compounds of this type was obtained in the photolysis of TTMSS in the absence of trapping agents. Similarly, no evidence of trapping of silylenes by alcohols to form hydroalkoxysilanes (8) was observed. All this evidence, in addition to the radical hydrosilylation noted above, is consistent with radical formation as the predominant reaction for TTMSS under photolysis (9).



The presence of $Si(SiMe_3)_4$ as a major product in the absence of efficient radical traps such as alkenes can be explained by the following mechanism. Primary photocleavage of the relatively weak Si—H bond (85 kcal mol^{-1}, (7)), provides the sisyl radical **5** (Scheme 5, Path B). In the presence of alkenes, radical chain hydrosilylation is initiated, to give the products **6** shown in Path D, Scheme 5. In the absence of such traps, the sisyl radical can, among other reactions,

Scheme 6.

Scheme 7.

recombine with (adventitious) methyl (Path E → **2**) or trimethylsilyl radicals **7** (Path F → **3**), also likely generated from TTMSS (Path A), which is present throughout the photolyses in relatively high concentration. Hydrogen abstraction by the sisyl radical from TTMSS is, of course, a transparent reaction. The generation of **8** in Path A (Scheme 5) can also account for the formation of **4** via $H^{\cdot}$ recombination or abstraction from TTMSS (Path G). **8** can also lead to $(Me_3Si)_2Si(H)Si(H)(SiMe_3)_2$ (**9**) by dimerization (Scheme 5, Path H).

The most difficult molecules to account for mechanistically are the mono- and dimethylated compounds **2**, **10**, and **11**, respectively. The photocleavage of a Si-Me group is not very favourable. However, as noted this mechanism could account for the formation of **2** (Scheme 5, Path E) and compounds **10** and **11** (Scheme 6). A more reasonable proposal involves 1,2-methyl migration from **5** to give new oligosilanes that can then fragment to react with (readily available) $Me_3Si^{\cdot}$ to produce **2** and **11** (Scheme 7). It should be reiterated that these are mechanistic speculations; other mechanisms involving recombination and rearrangements are also possible. However, compounds derived from silylenes, which would have been particularly easy to identify in the photolyses in the presence of alcohols (11, 13), were not detected.

$(Me_3Si)_4Si$ was observed to be a major photoproduct and, over more extensive photolysis, the dominant photoproduct of TTMSS in the absence of trapping agents. This suggests that $(Me_3Si)_4Si$ does not easily undergo photoinduced degradation, particularly when compared with the other photoproducts. That is, the other photoproducts undergo further preferential photolysis or reaction with the dominant radicals $(Me_3Si)_3Si^{\cdot}$, $H^{\cdot}$, and $Me_3Si^{\cdot}$, eventually to give nonvolatile oligo- or polysilanes (2). The lack of photoreactivity of $(Me_3Si)_4Si$ has previously been shown, at least in the absence of photosensitizers (17).

These experiments indicate that TTMSS readily participates in radical reactions that are synthetically useful, particularly

© 2000 NRC Canada

when radical traps such as alkenes are present. However, the photochemical formation of silylenes from TTMSS could not be observed in the presence of standard silylene traps.

Experimental section

^1H and ^{13}C NMR spectra were recorded on a Bruker AC-200 spectrometer with $CDCl_3$ or C_6D_6 as an internal standard. IR spectra were recorded on a Biorad spectrometer. Electron impact (EI) and chemical ionization (CI, NH_3) mass spectra were recorded at 70 eV with a source temperature of 200°C on a VG Instruments analytical ZAB-R mass spectrometer equipped with a VG 11–250 data system.

Gas chromatographic (GC) analyses were carried out using a Hewlett–Packard 5890A gas chromatography equipped with a conventional heated injector, a flame ionization detector, a Hewlett–Packard 3393A integrator, and a DB-1 megabore capillary column (30 m × 0.54 mm, Chromatographic Specialties, Inc.). Mass spectra and GC–MS analyses were recorded on a Hewlett–Packard 5890II gas chromatograph equipped with a HP-5971A mass selective detector and a DB-5 fused silica capillary column (30 m × 0.25 mm, Chromatograph Specialties, Inc.). All syntheses were performed with dry glassware under an atmosphere of anhydrous nitrogen. Prior to photolysis, all the solutions were degassed with dry argon.

With the exception noted below, all reagents were purchased from Aldrich: vinyl acetate, ethyl vinyl ether, methyl vinyl ketone, allylbenzene, diethyl ether, chlorotrimethylsilane, MeMgBr, MeLi-Br hexane (Omni solvent), and THF. THF was distilled from benzophenone ketyl just before to use. Silicon tetrachloride was purchased from Gelest. $(Me_3Si)_4Si$, $(Me_3Si)_3SiH$, and $(Me_3Si)_3Me$ (14) were prepared by standard literature routes or are commercially available (Gelest).

Photolyses

With alkenes: hydrosilylation

A mixture of alkene and 1.2 equiv. of silane in a quartz tube was irradiated for 3 h in a Rayonet photochemical reactor equipped with low pressure mercury lamps emitting 254 nm radiation.

1-[Tris(trimethylsilyl)silyl]ethyl acetate: Vinyl acetate (0.53 g, 62 mmol), TTMSS (1.8 g, 7.4 mmol), hexane (10 mL); product was purified on silica gel (petroleum ether, 1.64 g, 79%). MS (EI, *m*/*z* (%)): 319 (M^+-15 (1.0)), 291 (3.2), 275 (4.2), 233 (39), 191 (33), 174 (20), 73 (100), 43 (50). IR (cm^{-1}) ν: 2954, 2897, 1742, 1247, 1046. ^1H NMR (300 MHz, C_6D_6) δ: 4.27–4.22 (t, 2H, *J*= 8), 1.70 (s, 3H), 1.32–1.26 (t, 2H), 0.17 (s, 27 H). ^{13}C NMR (MHz, C_6D_6) δ: 170.05, 64.60, 20.78, 8.9, 0.98.

2-(Ethoxy)-1-[tris(trimethylsilyl)silyl]ethane: Ethyl vinyl ether (0.35 g, 5 mmol), TTMSS (1.5 g, 6 mmol), hexane (10 mL); product was purified on silica gel (petroleum ether, 1.47 g, 92%). MS (EI, *m*/*z* (%)): 305 (M^+-15 (1.6)), 275 (0.5), 247 (2.1), 219 (12), 191 (12), 131 (11), 117 (15), 73 (100), 45 (27). IR (neat) ν: 2951, 2895, 2861, 1245, 1122, 1097. ^1H NMR (200 MHz, C_6D_6) δ: 3.53–3.47 (t, 2 H, *J*= 6), 3.35–3.28 (q, 2 H, *J* = 4), 1.28–1.22 (t, 2 H *J*= 6), 1.15–1.10 (t, 3H, *J*= 6), 0.20 (s, 27 H). ^{13}C NMR (50.3 MHz, C_6D_6) δ: 70.52, 65.83, 15.52, 9.81, 1.31.

3-Oxo-1-[tris(trimethylsilyl)silyl]butane: Methyl vinyl ketone (0.46 g, 6.6 mmol), TTMSS (1.9 g, 7.9 mmol), hexane (10 mL); product was purified on silica gel (petroleum ether, 1.58 g, 80%). IR (neat) ν: 2951, 2895, 1720, 1409, 1356, 1245, 840, 623. ^1H NMR (200 MHz, C6D6) δ: 2.38–2.32 (m, 2 H), 2.05 (s, 3 H), 0.96–0.91 (m, 2 H), 0.08 (s, 27H). ^{13}C NMR (50.3 MHz, C_6D_6) δ: 209.0, 42.65, 28.99, 1.45, 1.24. MS (EI, *m*/*z* (%)): 303 (M^+-15, 2.6), 245 (18), 191 (8), 175 (8), 131 (12), 117 (19), 73 (100), 45 (24).

3-Phenyl-1-tris(trimethylsilyl)silylpropane: Allylbenzene (0.96 g, 8.1 mmol), TTMSS (2.4 g, 9.7mmol), and 20 mL of hexane was placed in a quartz cell. After 8 h of photolysis, the reaction mixture was concentrated in vacuo, and the product purified on silica gel (5% ethyl acetate–hexane) to give (0.72 g, 75%). MS (EI, *m*/*z*): 366 (5.0), 351 (3.0), 293 (40), 219 (8.0), 204 (6.0), 175 (71), 117 (20), 73 (100). IR ν (cm^{-1}): 3086, 3064, 3028, 2950, 2894, 2856, 1604, 1496, 1453, 1397, 1245, 1069, 835, 746, 695, 623. ^1H NMR (200 MHz, $CDCl_3$) δ: 7.18 (m, 5 H, Ph), 2.61 (t, 2 H, *J* = 7), 1.68 (dd, 2 H, *J* = 7 and 4), 0.12 (s, 27 H $(CH_3)_3Si)_3$). ^{13}C NMR (50.3 MHz, $CDCl_3$) δ: 142.3, 128.4, 128.2, 125.6, 40.49, 30.91, 7.42, 1.15.

Without traps

A solution of TTMSS (0.30 g, 1.2 mmol) in hexane 10 mL was irradiated for 2 h to 20% conversion in the absence of added trapping agent. GC–MS analysis of the crude mixture led to many products in which the major product is $(Me_3Si)_4Si$, (4%, refers to GC area%, Table 1).

With alcohols as traps

Photolysis of TTMSS in the presence of methanol for 2.5 h: $(Me_3Si)_3SiH$ (90%), $(Me_3Si)_2SiH_2$ (0.8%) MS: 176 (M^+), 162, 161, 131,117, 101, 88, 73; $(Me_3SiO)_2Si(H)SiMe_3$ (1.5%) MS: 280 (6.4), 265 (6.4), 207 (47), 191 (100), 177 (18), 147 (14), 133 (18), 117 (18), 103 (4.3), 73 (21); $(Me_3Si)_3SiMe$ (**2**) (0.3%), $(Me_3Si)_4Si$ (**3**) (0.6%).

Prolonged photolysis of TTMSS in the presence of MeOH over 24 h led to the formation of two products: **3** (92%), unidentified product (5%), GS–MS: 353 (13), 264 (91), 235 (26), 219 (38), 205 (73), 189 (18), 175 (43), 159 (9), 131 (38), 117 (27), 89 (18), 73 (100), 59 (34), and TTMSS (3%).

A solution of TTMSS (0.248 g, 1.0 mmol) in hexane (10 mL) was photolyzed in the presence of cyclopentanol (0.086 g, 1 mmol) for 2.35 h. Six major products were produced: **3** (2.5%,), **4** (3%, for mass spectral data, see Table 1), $(C_5H_9O)SiMe_3$ (1.7%), GC–MS: 158, 143, 129, 115, 101, 75, 73; $(Me_3SiO)_2Si(H)SiMe_3$ (3.2%), GC–MS: 280, 265, 207, 191, 177, 147, 133, 117, 103, 87, 73, 59. The other two products could not be identified. Residual starting material (80%) accounted for the remainder of the products.

Bis(trimethylsilyl)methylamine (BSMA): tool or toy?[1]

Jean-Paul Picard

Abstract: Bis(trimethylsilyl)methylamine, BSMA, an original primary amine, was proven to be the source of a large variety of *N*-bis(trimethylsilyl)methylamino derivatives that otherwise have to be prepared indirectly. Because of the bulkiness of the bissilylmethyl group, regio- and stereoselectivities resulted in appropriated examples. Apart from the potential biological properties associated with the Si-C-N framework, these derivatives were powerful synthetic intermediates. Special emphasis was given to the chemistry of corresponding imines. Cleavage of Si—C bonds or abstraction of the methine proton afforded α-nitrogen carbanions in very mild conditions. Application of these results to the β-lactam chemistry allowed the introduction of new synthetic methodologies in this field. It results the $(Me_3Si)_2CH$- group could now be regarded as a Me_3SiCH_2- or a CH_3- group or a proton equivalent.

Key words: bis(silyl)methylamine, preparations, reactivity, nitrogen heterocycles, α-nitrogen carbanions.

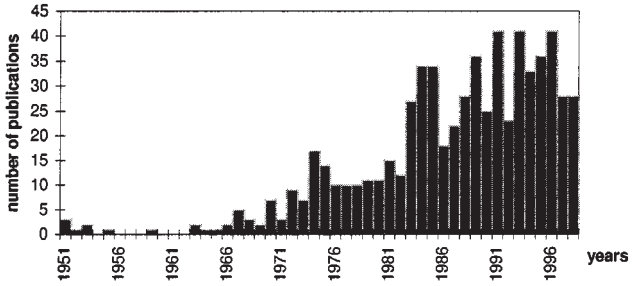
Résumé : Il a été montré que la bis(triméthylsilyl)méthylamine, BSMA, une amine primaire originale, peut être à la base d'une large variété de composés *N*-bis(triméthylsilyl)méthylaminés, qui ne pouvaient être obtenus qu'indirectement. La présence du groupe $(Me_3Si)_2CH$-, volumineux, sur l'azote induit une régio- et stéréosélectivité dans les cas appropriés. Mis à part la possibilité qu'ils puissent présenter une activité biologique (lie à l'enchaînement Si-C-N), ces composés sont des intermédiaires de synthèse puissants. Une attention spéciale a été portée aux imines correspondantes. La coupure des liaisons Si—C ou l'arrachement du proton méthine donne accès à des carbanions α-azotés dans des conditions douces. La chimie des β-lactames a largement tiré bénéfice de ces résultats. Finalement, le groupe $(Me_3Si)_2CH$- peut être considéré comme un équivalent synthétique des groupes Me_3SiCH_2- et CH_3-, et du proton.

Mots clés : bis(silyl)méthylamine, préparations, réactivité, hétérocycles azotés, carbanions α-azotés.

I. Introduction

Since the first α-C-silylated amino derivatives were reported independently by Speier and co-workers (1) and Sommer and Rocket (2), in 1951, compounds having a Si-C(sp^3)-N framework have been the subject of nearly 700 publications and 100 patents (Fig. 1).

Two important features characterize this type of compound:



Cleavage of the carbon—silicon bond

This can be achieved under mild and neutral conditions, leading to the corresponding α-nitrogen carbanions as exemplified by Katritzky and Sengupta (3) and Patel and Joule (4) (Scheme 1).

Biological activity

A number of α-C-silylated amino derivatives show significant biological activities (5–10) (Scheme 2). For example, flusilazole is an active fungicide, produced in tons. Aminomethyl(trimethyl)silane inhibits monoamine oxidase (MAO-B) whereas its carbon analogue, neopentylamine, is a substrate for the same enzyme.

Fig. 1. The publication history of compounds having a Si-C(sp^3)-N framework.

General comments

The above two features triggered our interest in the chemistry of α-C-silylated amines (or "silylmethylamines," SMA) which we divided into four classes according to their substitution patterns: monosilylmethylamine (MSMA), arylsilylmethylamine (ASMA), alkylsilylmethylamine (RSMA), and bissilylmethylamine (BSMA), respectively, (Scheme 3).

The purpose of this paper is to review the syntheses and the reactivity of BSMA and its derivatives, showing BSMA

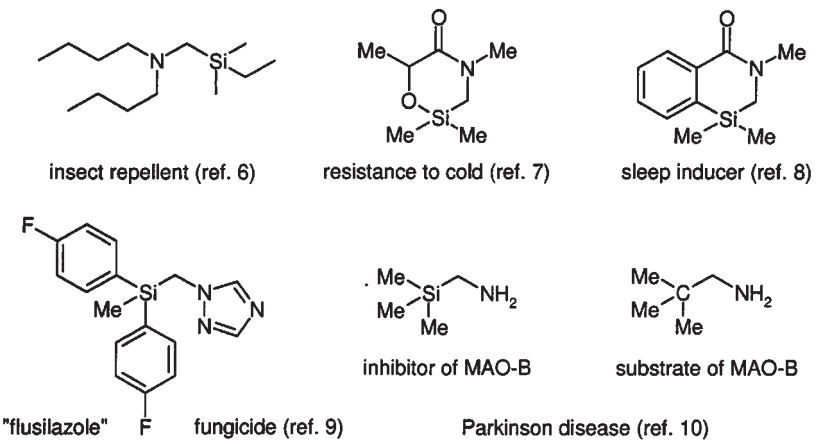
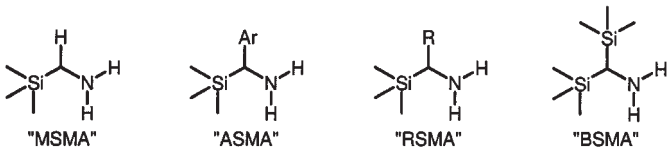
Scheme 1.



is a very useful and easily handled synthon at the disposal of organic synthetic chemists, as exemplified by the new developments these compounds have permitted in the chemistry of β-lactams.

The BSMA derivatives (BSMa) were obtained through successive replacement of two methyl hydrogens of *N*-methyl amino derivatives (11–15) (Scheme 4), and the strategy was successfully used in the preparation of BSMA benzamide (Scheme 5), BSMA isonitrile (Scheme 6), and BSMA benzotriazole (Scheme 7).



II. Syntheses of BSMA

We, on the other hand, thought bis(trimethylsilyl)methylamine derivatives (BSMa) could be obtained directly from parent amine (BSMA) using classical amine chemistry, which would provide an organometallic-free approach towards these derivatives.

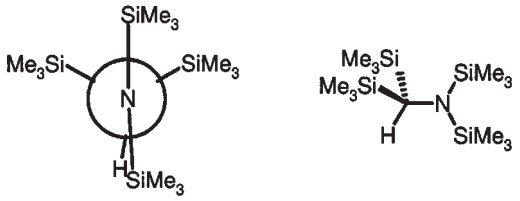
Amination

Bis(trimethylsilyl)methyl amine was first prepared by amination of the corresponding chloride (16) (Scheme 8), following a procedure parallel to that described by Letellier for MSMA (17), but the difficulty in obtaining the starting chloride made this synthesis undesirable for large scale preparations.

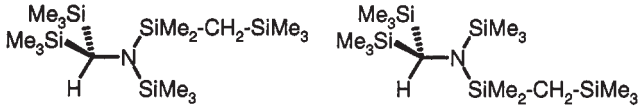
Reductive silylation

Reductive silylation of trimethylsilylcyanide (TMS-CN) provided an attractive solution. Thus, TMS-CN, when reacted with trimethylsilylchloride (TMSCl) and lithium sand in a THF–HMPA mixture,[3] afforded a mixture of the silazanes A and B, with the latter predominating (18). Hydrolysis of the N—Si bonds with TMSCl in MeOH[4] quantitatively produced the hydrochloride of BSMA, which was neutralized by solid KOH to give BSMA in good yields on a multigram scale (Scheme 9).



Other cyanides ($EtMe_2Si$-CN, *t*-$BuMe_2Si$-CN, Me_2N-CN) and *t*-butyl isonitrile were also tested as starting materials,

[3] This molecule that has been referred to as a "potential carcinogenic compound," is now referred to as a "useful aprotic solvent": cf. for instance, Sigma–Aldrich 1999–2000 catalogue, p. 919.



[4] Under these conditions, even tris(trimethylsilyl)amine was hydrolysed quantitatively within a minute into methoxytrimethylsilane and ammonium chloride (18*b*).

Scheme 11.

Scheme 12.

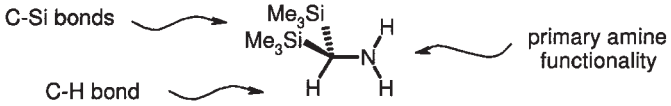
which gave rise to mixtures of the same silazanes A and B in different ratios.

A mechanism leading to the formation of the silazanes A + B has been proposed. Thus, successive electron transfer to the substrate to form anion-radicals and capture by TMSCl leads to the intermediate imine I (18) (Scheme 10). Imine I has never been isolated, probably because it is fast reduced to the intermediate AR. A facile [1,5]-H shift in AR gives rise to the new intermediate AR′, which, via successive electron transfer and reaction with TMSCl, leads to the silazanes A and B.

An equally efficient electrochemical version of this preparation, using a sacrificial anode technique (see for example ref. 19), has also been published (20).

Particular Properties of Silazanes A and B

The silazane A, previously obtained by another route (21), showed unusual ^{1}H, ^{13}C, and ^{29}Si NMR spectra (three lines for the trimethylsilyl groups), which were explained by a restricted rotation around the C—N bond, resulting in a favoured conformation with one N—Si bond eclipsing the C—H bond. A similar phenomenon has been observed with *N*,*N*-dimethylisopropylamine in the gaseous state (22).



A careful NMR study using 2D ^{13}C-^{1}H and ^{29}Si-^{1}H correlation methods confirmed this hypothesis and allowed complete assignment of signals. It also showed that two Me_3Si groups were linked to the central carbon atom and two other magnetically non-equivalent groups were attached to the nitrogen atom. The respective coupling constants $^{n}J(^{1}H$-$^{29}Si)$ were also determined.

Theoretical calculations estimated the energy of free rotation at ~35 Kcal/mol.[5] However, no change in the NMR spectra of silazane A were observed up to 180°C. This was quite surprising as rotation has been observed above 80°C with the symmetrical tetrakis(trimethylsilyl)ethane (23).

The silazane B was obtained as a 50:50 mixture of two rotamers, which were fully assigned by their NMR spectra (18) (Scheme 12).

III. Chemistry of BSMA and its derivatives

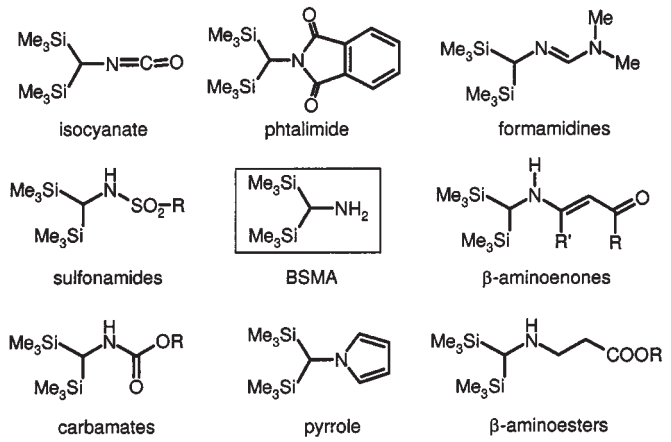
A priori, one may consider three sites of reactivity for BSMA: the amine function, the Si—C bonds, and the C—H bond. Reactions involving the latter two, however, require prior transformation of the amine group into another nitrogen functionality.

Reactivity of the amine function

General

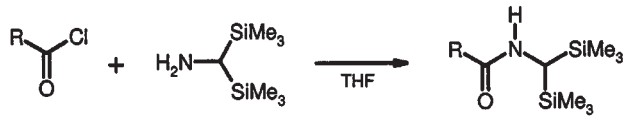
Like other organic primary amines, BSMA reacted easily with a large variety of reactants to directly and quantitatively yield BSMa derivatives: phthalimide with phthalic anhydride, formamidine with dimethylformamide dimethylacetal, sulphonamides with sulfonyl chlorides, carbamates with carbamoyl chlorides, isocyanate with phosgene and triethylamine, β-aminoesters with acrylates, pyrrole with 2,5-dimethoxy tetrahydrofurane, and β-aminoenones with β-diketones (24) (Scheme 13). It is important to note that the bis(silyl)methyl group was not affected during these transformations.

The above strategy allowed the direct preparation of BSMA amides and isonitrile (24) (Schemes 14 and 15), in a more practical way than those reported previously (Schemes 5 and 6). This isonitrile has been used by Battaglia to prepare the corresponding isothiocyanate (25).



A series of BSMA-cumulenes were also synthesized from BSMA iminophosphorane (25) (Scheme 16).

Aminolysis of epoxides



The opening of oxiranes by a primary amine is a useful way to get β-amino alcohols, an important class of organic compounds, especially in biochemical studies.

Using BSMA as the primary amine, ring opening of unsymmetrical epoxides yielded β-amino alcohols with high regiochemistry (26) (Scheme 17).

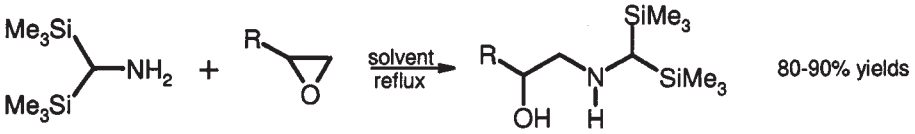
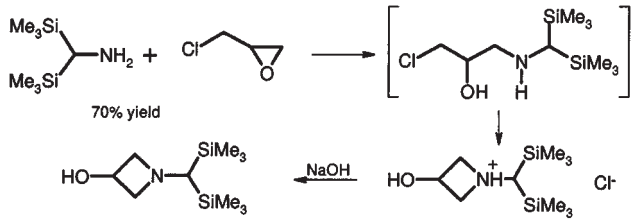
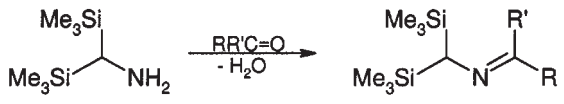


Scheme 15.



Scheme 16.

Scheme 17.



Scheme 18.

With epichlorohydrin, subsequent cyclization of the ring-opened intermediate led to the azetidinol as the sole product (26) (Scheme 18). This was particularly interesting as the silyl groups could be potentially removed (vide infra) to yield the *N*-methyl derivative, a compound that is not easily accessible via reaction of methylamine with epichlorohydrin (27).

Formation of imines

Condensation of BSMA with carbonyl compounds proceeds rapidly to produce the corresponding aldimines and ketimines almost quantitatively at room temperature in the presence of molecular sieves.

It was worth noting that the synthesis of *N*-[bis(trimethylsilyl)methyl]methylen imine occurred even in water medium (entry 1 in Table 1) in excellent yield. Moreover, this imine was quite stable and distillable (28), a feature that is not found for other methylene imines, except for those where the nitrogen atom is linked to a tertiary carbon atom (29).

Ultraviolet photoelectron, electron transmission, and ab initio studies of the factors which determine the stability of the BSMA aldimines has been made, which showed that the bissilylmethyl group altered the energy ordering and localisation properties of the valence molecular orbital where the lone pair orbital was no longer the HOMO (30).

Scheme 19.

Scheme 20.

Some representative exemples are listed in Table 1 (16, 28, 31–37) and Table 2 (32, 38).

BSMA imines have also been prepared from aldehydo- and ketosugars (39).

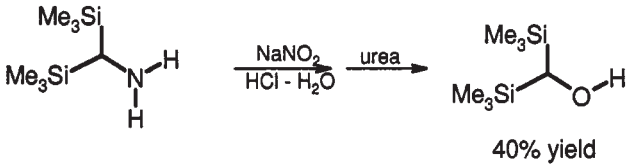
Alkylation

Imine formation with BSMA, followed by reduction of the double bond with sodium borohydride, provided an easy access to the corresponding secondary amines in good yields (16) (Scheme 19).

Addition of cuprates to 1-aza-1,3-butadienes obtained from BSMA and α,β-ethylenic aldehydes, occurred under mild conditions in the presence of BF_3,Et_2O with high regioselectivity (37). The latter was somewhat dependent on the nature of the ligand to be transferred from the organometallic reagent, alkyl and aryl ligands leading to imine A, and thienyl and furyl ligands to allylamine B (Scheme 20).

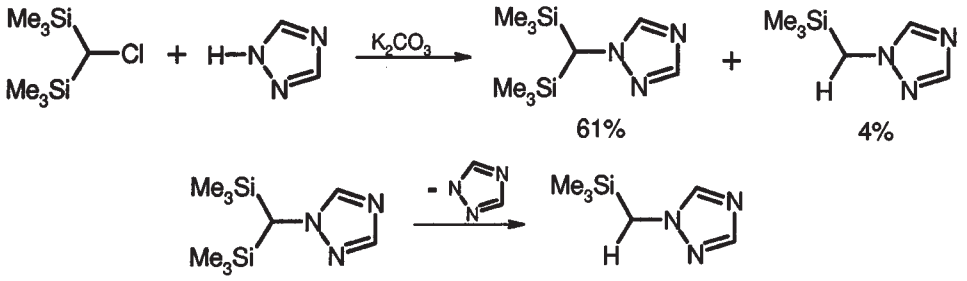
Deamination

Nitrous acid deamination of BSMA produced bis(trimethylsilyl)methanol in a moderate yield (Scheme 21).[6]



Cleavage of the Si—C bond

The importance of this cleavage reaction for SMA derivatives has long been appreciated. For BSMa, additional interest



[6]J.P. Picard and R. Ernst. Unpublished result.

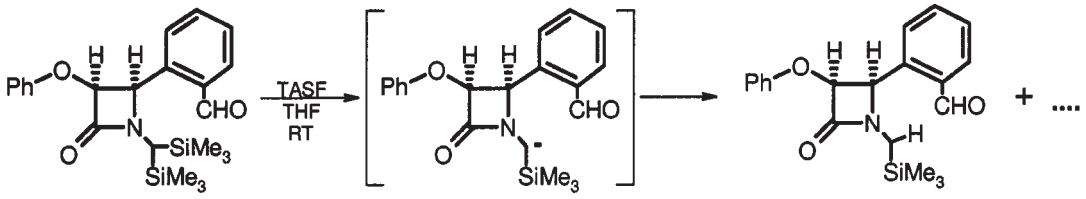
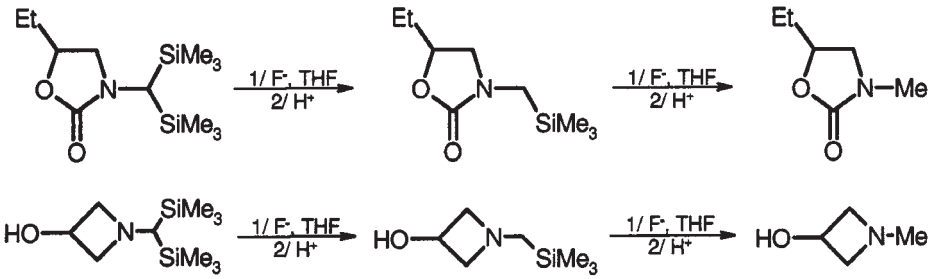


Scheme 21.



Scheme 22.

Scheme 23.

Scheme 24.

came from the presence of a second Si—C bond which allowed developing new chemistry.

Protonation (C-Si →C-H)

Protolytic cleavage of one Si—C bond of BSMa led to the parent MSMa. Some examples of this kind already existed, but as a side reaction. For instance, during preparation of *N*-[bis(trimethylsilyl)methyl]triazole, some monosilylated derivative was formed, probably under the action of the triazolyl anion onto the desired product (40) (Scheme 22).

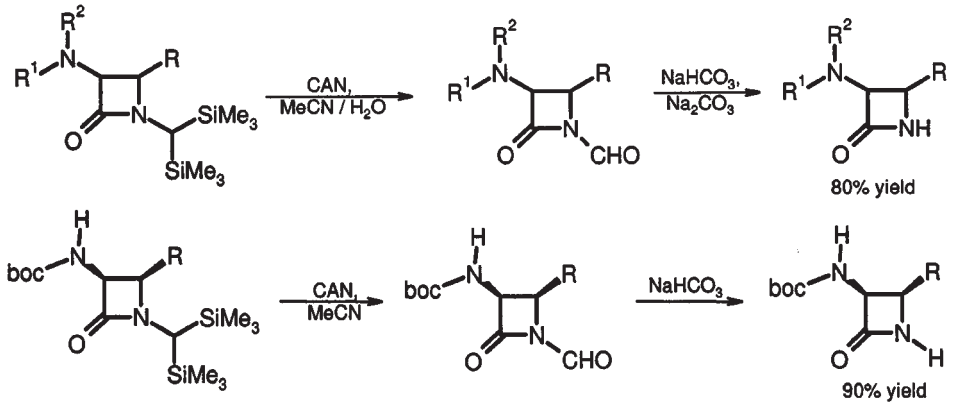
Similar protodesilylation during cyclization reaction to form the B ring of a carbacephem (vide infra) has been observed (41) (Scheme 23).

Protodesilylation can also be achieved by treating BSMa with one equivalent of fluoride anion and quenching with diluted acid in THF medium. Complete desilylation can also occur in a stepwise fashion with a second equivalent of fluoride anion (Scheme 24).[7]

These protodesilylation reactions show the importance of the bis(trimethylsilyl)methyl group as a methyl group equivalent.

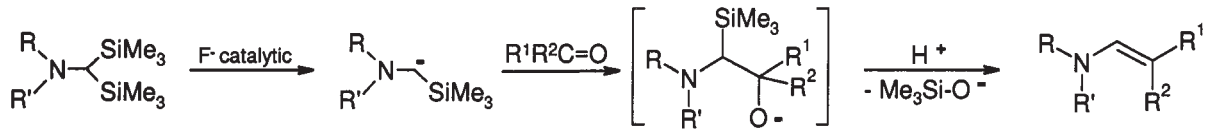
Oxidation (C-Si → C-O)

Ceric ammonium nitrate (CAN) was found to easily oxidize the C—Si bonds of BSMa to a formyl group. The formamide thus quantitatively formed could be hydrolyzed to the corresponding N-H derivative in excellent yields (31, 32). Thus, bis(trimethylsilyl)methyl group appeared to be an effective N-protecting group (Scheme 25). This was particularly useful in β-lactam synthesis.



Alkenation (C-Si → C=C)

Fluoride ion induced cleavage of the C—Si bond in presence of a carbonyl compound opens a direct and easy access to enamine derivatives. In these reactions, initial desilylative formation of a α-nitrogen carbanion followed by reaction with the carbonyl compounds yielded the corresponding



[7] J.P. Picard, S. Grelier, and T. Constantieux. Unpublished results.

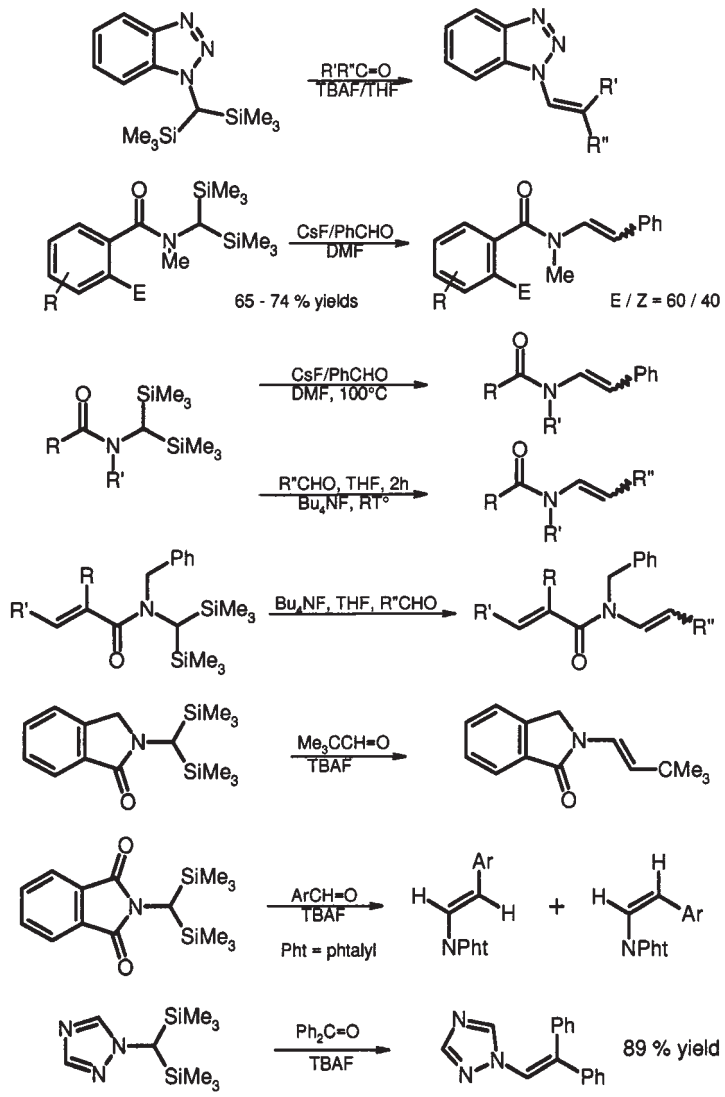
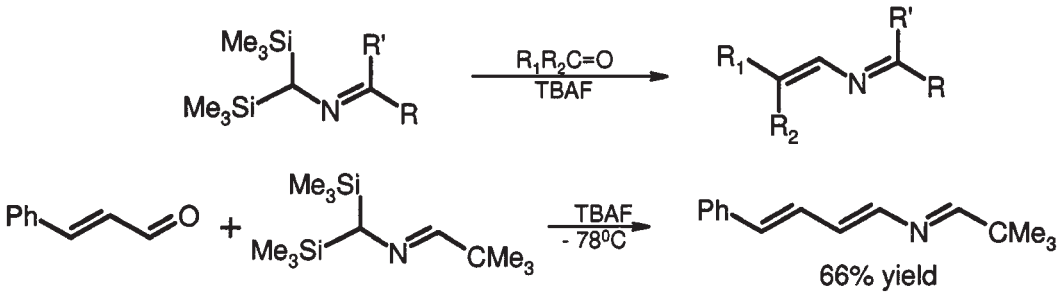
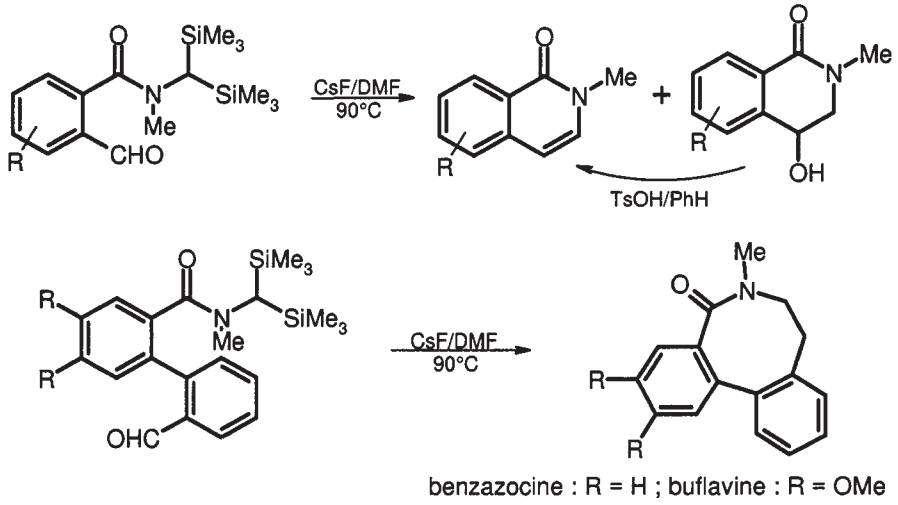


Scheme 25.

Scheme 26.



Scheme 27.



© 2000 NRC Canada

Scheme 28.

Scheme 29.

aminoalcohols which underwent a Peterson elimination through loss of silanol to give the enamines (Scheme 26).

This has been exploited to prepare *N*-vinyl benzotriazoles (42), *N*-vinyl amides (13, 16, 43), *N*-vinyl phtalimidine (24), *N*-vinyl phtalimide (34), and *N*-vinyl triazole (40) (Scheme 27).

Using BSMA imines as the starting materials, 2-aza-1,3-dienes were obtained under very mild conditions with good yields, avoiding the formation of any polymer, even when the reacting carbonyl was an α,β-ethylenic aldehyde (34) (Scheme 28).

An intramolecular version of this reaction has led to a rapid access to isoquinolones, benzazocine (43), buflavine (44) (Scheme 29), and β-lactams (vide infra).

This methodology has been also applied to a facile synthesis of dihydroisoquinoline derivatives (16). Incidentally, it was discovered that mono BSMA imine of *ortho*-phtalaldehyde was not stable, as attack of the lone pair electrons of nitrogen on the remaining aldehyde functionality took place, followed by an internal Cannizzaro reaction, to give rise to the corresponding phtalimidine with good yields (24) (Scheme 30). The condensation reaction of *o*-phtalic aldehyde with primary aromatic and aliphatic amines has some precedents (see for instance ref. 45).

Sometimes, results depended upon the geometry of the intermediate alcoxyde, as shown, for instance, by the addition to benzaldehyde of the carbanion generated from BSMA isothiocyanate. The expected oxazolidine-2-thione was formed in low yield whereas styryl isothiocyanate was obtained in much higher yield (46, 47) (Scheme 31).

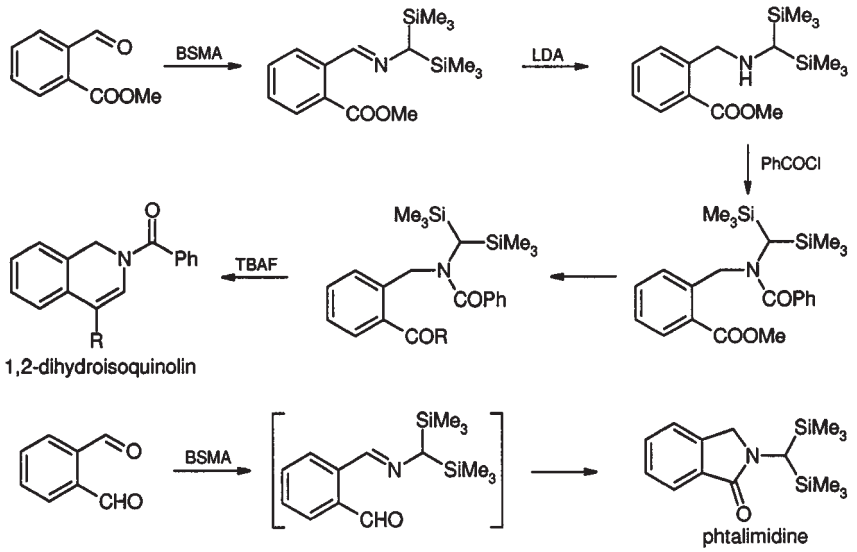
Precursors to 1,3-dipoles

SMA derivatives (imines, amides, etc…) haven proven to be excellent sources of unstabilized nitrogen ylids (or 1,3-dipoles) suitable for heterocyclic ring construction after reaction with dipolarophiles (48–53) (Scheme 32).

Benzamide and thiobenzamide have been converted to 1,3-dipoles via treatment with methyltriflate and caesium fluoride and reacted with methyl acrylate followed by DDQ oxidation, affording a mixture of 2-H and 2-silylpyrroles (13) (Scheme 33).

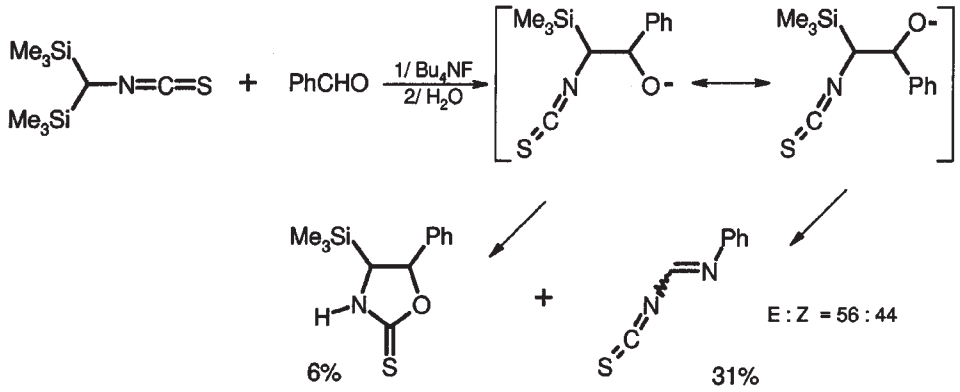
BSMA imines, upon reaction (quaternarization of the nitrogen atom) with an acyl chloride led to an ylid that was intercepted by dimethyl acetylenedicarboxylate to yield the corresponding *N*-acyl pyrrole. Reactions of aliphatic BSMA imines needed to be catalyzed with fluoride anion (TASF) (24) (Scheme 34).

However, BSMA imine derived from acetone did not give rise to cycloaddition reaction, instead leading to amide formation (24)[8] (Scheme 35).



Radical induced cleavage

In a study done by Walton et al. (54) dealing with the behaviour of different silylmethylamines in the presence of *t*-butyl peroxide, the radical induced cleavage of the C—Si bond has been reported. First formed at low temperature was



[8] Also formed in the reaction performed in THF was the adduct of THF to DMAD (40% yield).

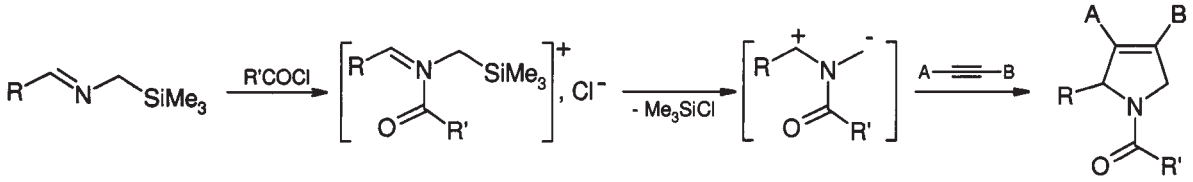


Scheme 30.

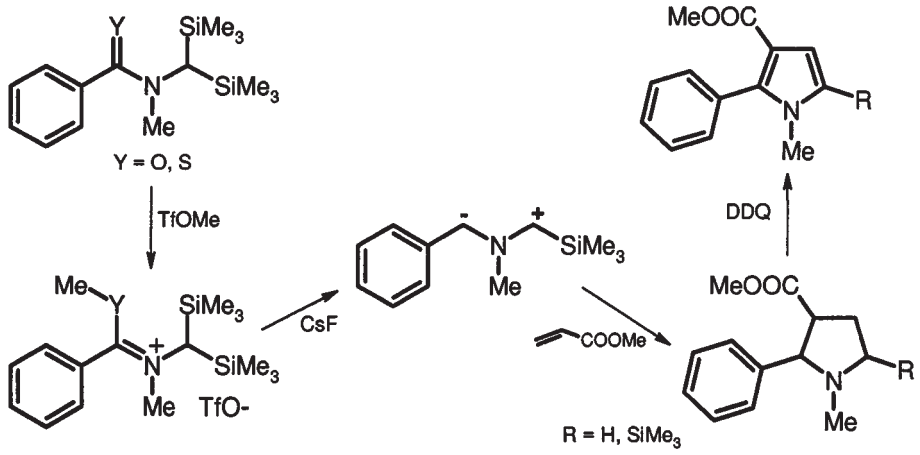
Scheme 31.

Scheme 32.

a mixture of the aminoalkyl and the aminyl radicals through abstraction of one hydrogen respectively from the methine and the amine. Aminyl radical was not directly detectable as it rearranged at upper temperature into a new carbon-centred radical in which the silyl group was located on nitrogen. Based on mechanistic evidences, intramolecular migration of the silyl group has been favoured, implying valence shell expansion of the silicon to five (Scheme 36).

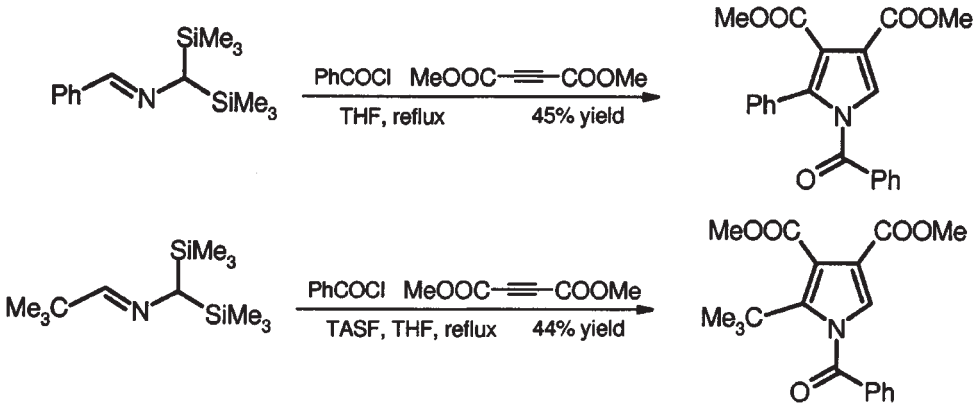
Thermally induced rearrangement

When *N*-[bis(trimethylsilyl)methyl]-1-aza-1,3-dienes were heated (neat) in a Kügelrohr oven at 200–240°C, ring closure occurred with migration of one trimethylsilyl group from carbon to nitrogen, to yield Δ^2-pyrroline derivatives in high yields and high stereo selectivity (*trans* only). From these Δ^2-pyrrolines, corresponding 1-trimethylsilyl-2,3-disubstituted pyrrolidines were easily prepared (55) (Scheme 37). The total stereocontrol of the three substituents was established by NOE experiments. Independently in the same year, Komatsu and co-workers (56) published a similar stereocontrolled cyclization from *N*-(α-trimethylsilyl) benzyl-1-aza-2, 3-dienes.



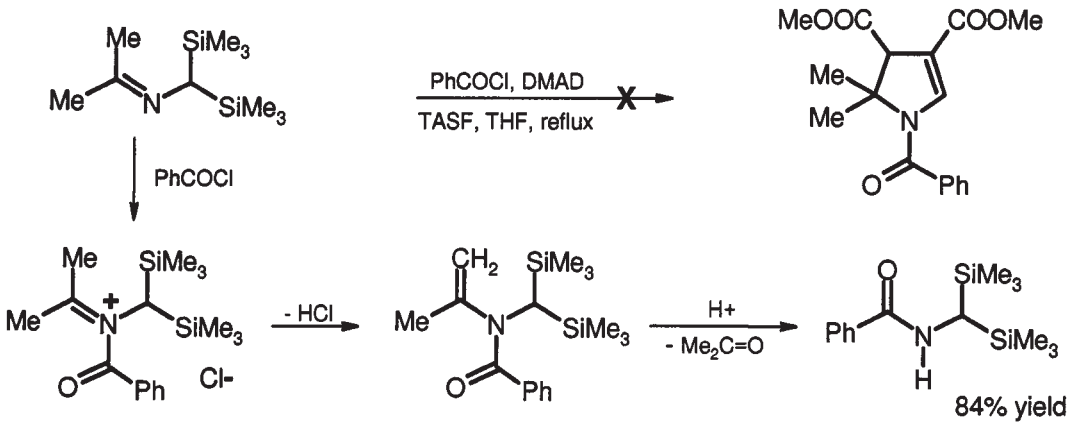
N-Trimethylsilyl-5-trimethylsilyl-3, 4-disubstituted Δ^2-pyrrolines, after treatment with an acyl chloride, were converted almost quantitatively into corresponding *N*-acyl pyrroles upon oxidation with DDQ, providing a novel route to 3,4-disubstituted pyrroles (57) (Scheme 37).

Cleavage of the C—H bond

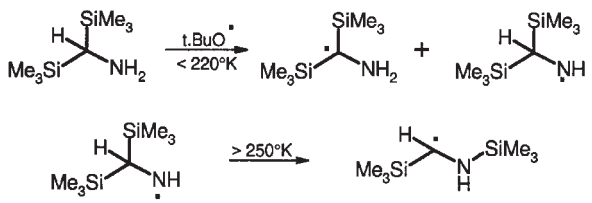


Owing to the electron withdrawing effect of the α-nitrogen atom on the one side and the ability of trimethylsilyl

© 2000 NRC Canada



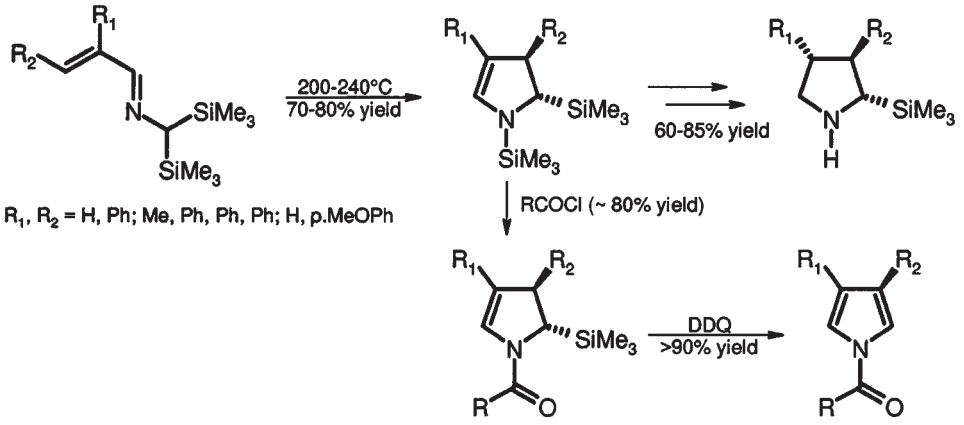
Scheme 33.



Scheme 34.

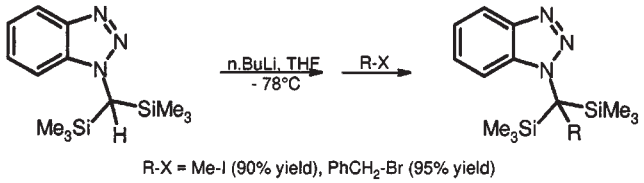
Scheme 35.

Scheme 36.



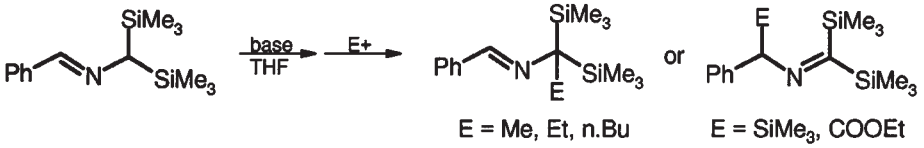
groups to stabilize a carbanion in α-position on the other side, abstraction of the central hydrogen atom in BSMA was expected to be quite facile. This has been shown starting from a benzotriazole derivative (42) (Scheme 38).

BSMA imines

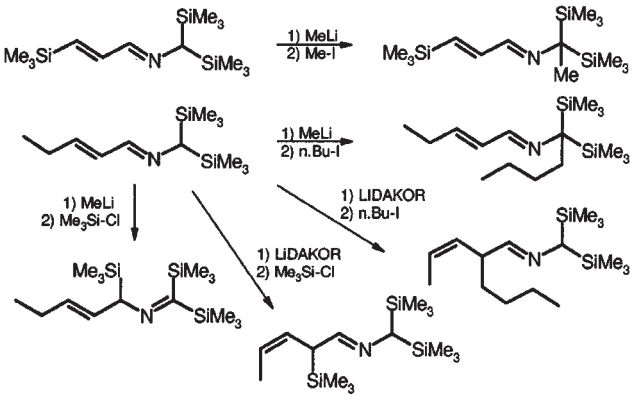


Abstraction of this hydrogen should be even easier in BSMA imines, as it is present in an "allylic" position. However, several bases (*n*-BuLi at –78°C, LDA, etc…) were tested unsuccessfully. It was subsequently found that "Lidakor" ("Schlosser base" (58)) and methyl lithium at

© 2000 NRC Canada



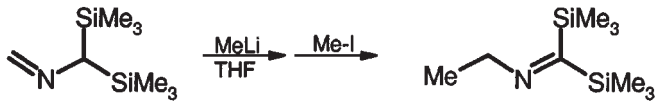
Scheme 37.



Scheme 38.

Scheme 39.

Scheme 40.



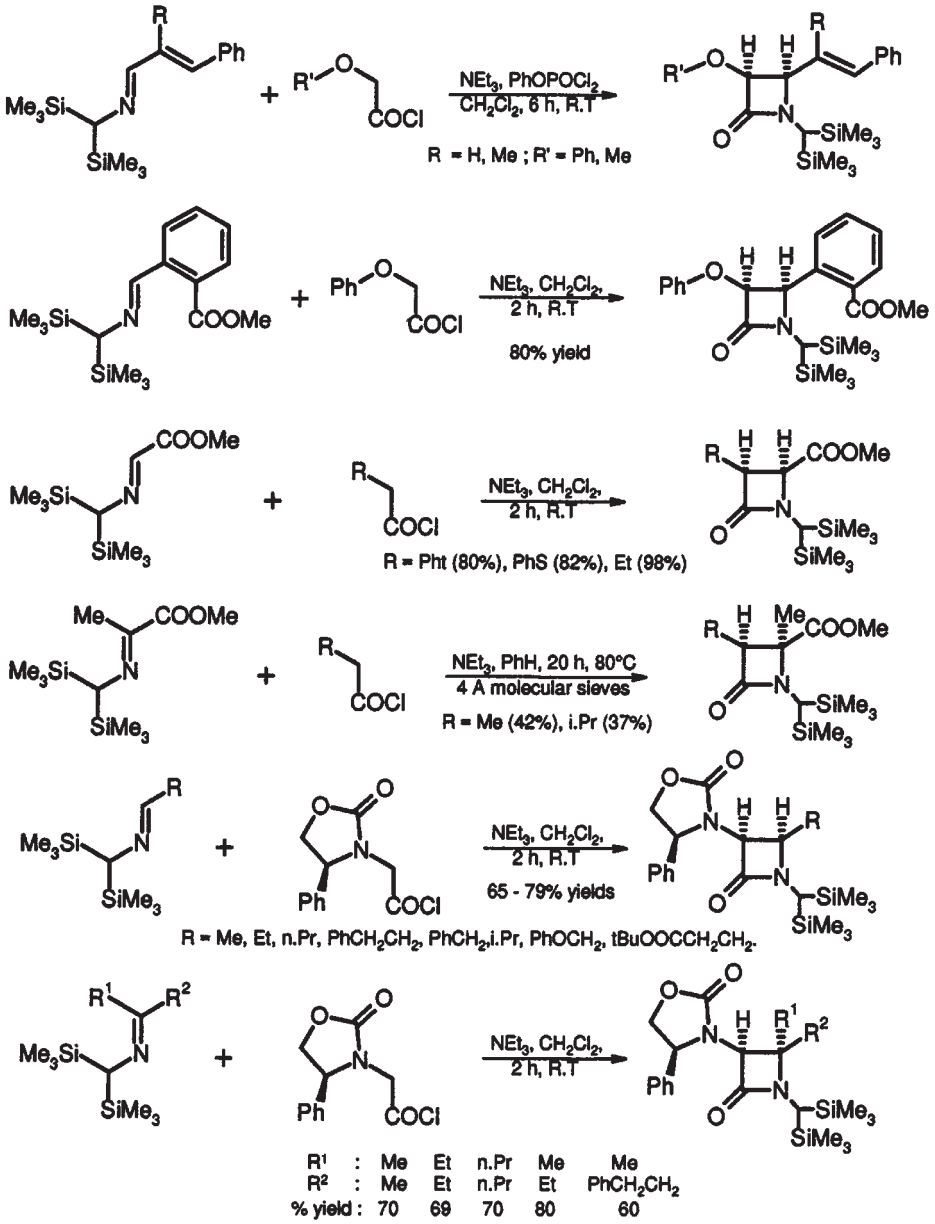
room temperature were able to deprotonate BSMA imines (35). Quenching with various electrophiles then afforded either the direct substitution product or the rearranged product, depending on the nature and the size of the electophile (Scheme 39).

BSMA imines from α,β*-ethylenic carbonyl compounds*

The same sequence on 1-aza-1,3-dienes led to the formation of products whose structure depended not only on the nature and the size of the electophile, but also on the nature of the base (35) (Scheme 40).

Scheme 41.

BSMA formaldimine



In the case of BSMA methylene imine, this reaction always occurred with transposition of the double bond, even when methyl iodide was used as the electrophile[9] (Scheme 41).

This sequence consisting of imine formation from formaldehyde followed by imine alkylation and hydrolysis, represents a one-carbon homologation of an organic halide into a primary amine. Another interesting feature is the formation of the new imine which can be considered to be derived from the quite sensible carbonyl compound, $(Me_3Si)_2C{=}O$. Such a type of imine was previously obtained by Y. Ito and co-workers (59, 60) (vide infra).

[9] J.P. Picard and L. Puysegu. To be published.

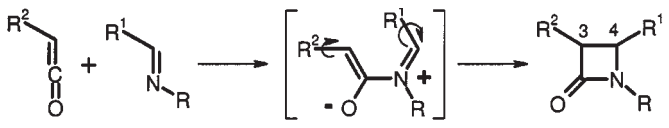
Scheme 42.



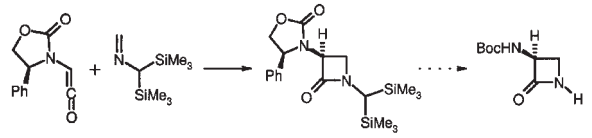
Application to β-lactam chemistry

Stereocontrolled formation of the azetidin-2-one ring

Staudinger reaction (62) of BSMA imines with ketenes in the presence of triethyl amine led to the corresponding β-lactams in excellent yields. Moreover, an unexpectedly high *cis* stereoselectivity was observed in these reactions (33, 34, 36, 38, 41, 62) (Scheme 42). In contrast, using *N*-(trimethylsilyl)methyl imines (MSMA imines) lead to a mixture of *cis* and *trans* β-lactams (63).

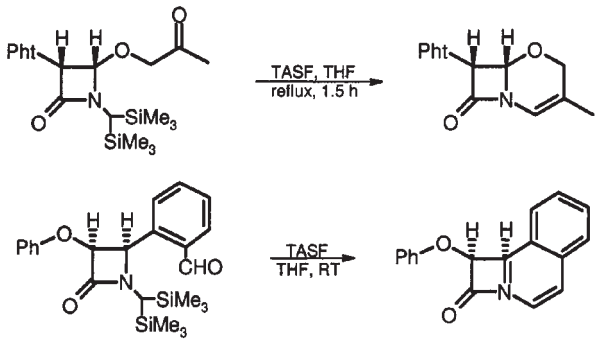
In the first step of this formal (2 + 2) cycloaddition reaction, nitrogen to carbonyl carbon bond is formed. Ring closure then occurs by a conrotatorial movement of the substituents on C_3 and C_4. Opposed to MSMA imines, conformation of BSMA imines is fixed, which leads to the strict stereochemical control in the formation of the C_3—C_4 bond of the ring:

Propagation of the chirality



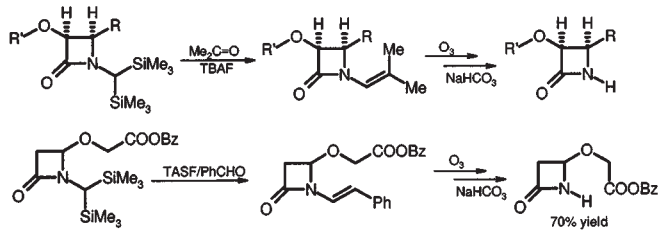
Advantage of the stereocontrolled ring closure was the propagation of the chirality from a chiral auxiliary at C_3 to C_3 and C_4 of the ring. Examples are given in Scheme 42 in which chiral azetidin-2-ones were obtained with excellent diastereoisomeric excesses (31, 38).

C_4 – Unsubstituted azetidin-2-ones



The readily availability of BSMA formaldimine allowed the synthesis of a class of synthetically interesting azetidin-2-ones, as they are valuable synthons in β-lactam antibiotics chemistry (see for instance ref. 64). As an example,

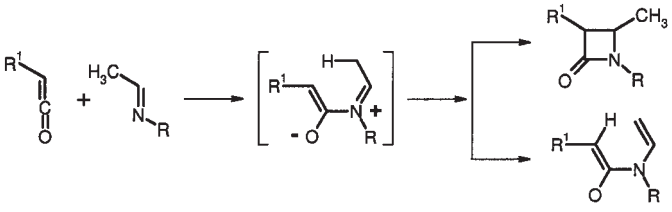
© 2000 NRC Canada



Scheme 43.

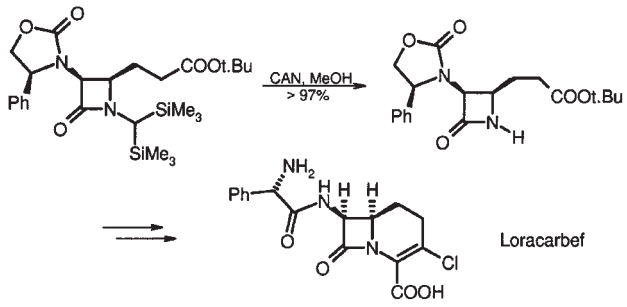
Scheme 44.

Scheme 45.



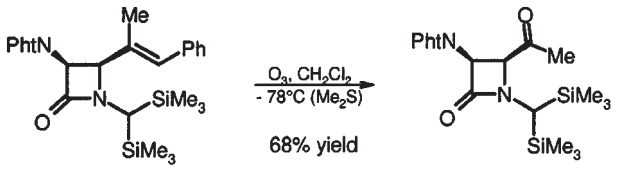
precursor of 3-amino-4-unsubstituted azetidin-2-one was easily obtained through the condensation of this imine with the ketene derived from Evans–Sjögren acetic acid (65) (Scheme 43).

This is a remarkable feature, as MSMA formaldimine, which exits only under the form of a trimer, did not lead to any azetidin-2-one.

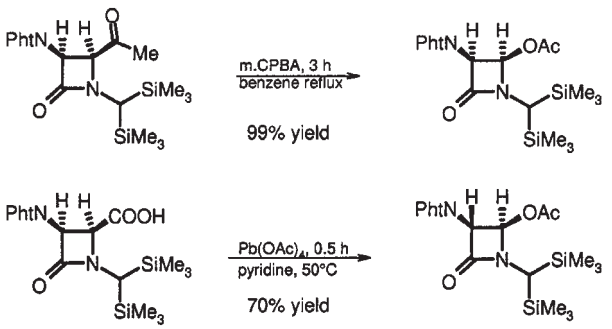


Azetidin-2-ones from enolizable carbonyl derivatives

Generally, condensation of ketenes with imines from enolizable carbonyl derivatives led to *N*-vinyl enamides. Interestingly, the use of the bis(trimethylsilyl)methyl group allowed the synthesis of azetidin-2-ones for the first time (33) (Scheme 42).



Probably, the inductive effect of the trimethylsilyl groups lowered the electron deficiency on nitrogen in the zwitterion, making the allylic proton less acidic and less available for undergoing a 1,5-migration through a concerted electronic transfer to give the enamide.



Scheme 46.

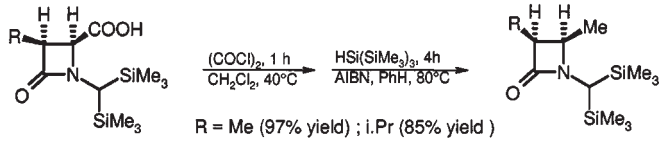
Scheme 47.

Scheme 48.

Formation of the B-ring of β-lactams

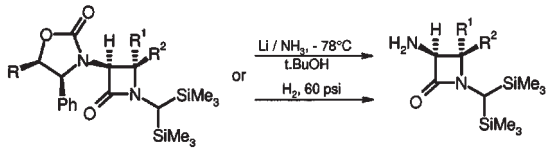
Many β-lactamic antibiotics are bicyclic compounds. Thus, Peterson olefination methodology has been applied to the construction of the B-ring of oxa- and carbacephem skeletons, starting from BSMA azetidin-2-ones bearing a substituent on C_4 with a carbonyl moiety at the suitable position (36, 41) (Scheme 44).

Deprotection of the N-atom (N-CHSi$_2$ – >> N-H)



The benefit of using BSMA imines to built azetidin-2-one derivatives has now been well established. However, key compounds for further chemistry in the β-lactam area are N-H azetidin-2-ones. It results that the bis(silyl)methyl group has to be cleaved off selectively. Two methodologies were proposed.

The first method is based on Peterson olefination reaction combined with ozonolysis of the double bond of the resulting vinyl amine, followed by decomposition of the formamide thus formed (34, 36) (Scheme 45).



The second method using ceric ammonium nitrate (CAN) has already been described (cf. Scheme 25, § B-b) and has been used several times (31, 62, 65), particularly as a key step in the synthesis of β-lactam Loracarbef (33) (Scheme 46).

Reactions not involving the bis(trimethylsilyl)methyl group

Many chemical transformations have been performed on BSMA azetidin-2-ones that kept the bis(silyl)methyl group intact. For instance, 4-acyl azetidinones were obtained through ozonolysis of the corresponding 4-vinyl derivatives (36) (Scheme 47).

Similarly, neither Baeyer–Villiger oxidation with m.chloroperbenzoic acid (36), nor oxidation with lead tetra acetate (36) did not affect this group (Scheme 48).

Katritzky and Lam (12) observed the cleavage of the C—Si bond of *N*-(trimethylsilyl)methyl benzotriazoles with acid chlorides. Such a cleavage has not been observed with BSMA azetidinones in a sequence where a carboxylic functionality was reduced into a methyl group (62) (Scheme 49).

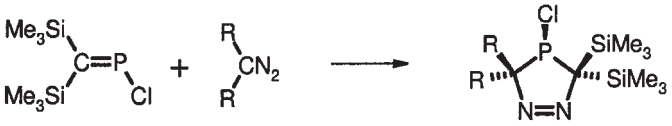
Deprotection of an amine on C_3 can be also performed using Li in liquid ammonia (31, 33, 62, 65) or hydrogen (60 psi) in the presence of $Pd(OH)_2$ catalyst (31) (Scheme 50).

IV. Miscellaneous

Obtention of some BSMa

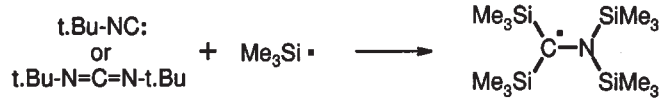
It should be mentioned that some particular BSMa have been obtained by specific routes.

Thus, sodium borohydride reduction of bis(trimethylsilyl) carbonyl imines formed by insertion of isonitriles into the Si—Si bond, led to the obtention of secondary BSMA amines (59, 60) (Scheme 51).



Under heating, trialkylamine stabilized silanimine gave rise to the formation of bis(aminosilyl)methylamine (66, 67) (Scheme 52).

Very recently, Oehme and co-workers (68, 69) published the synthesis of the very congested BSMA $[(Me_3Si)_3Si]_2C\text{-}NR_2$, (Scheme 53).



Cycloaddition of dialkyl, diaryl, and arylalky diazomethanes with C-bis(silyl)-P-chlorophosphaalkene yielded quantitatively not very stable BSMA cycloadducts (70) (Scheme 54).

Scheme 54.

Scheme 55.

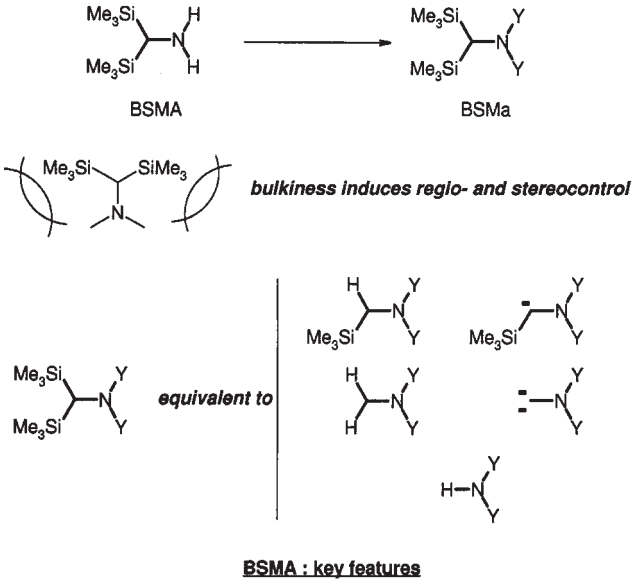
Bis(trimethylsilyl) [bis(trimethylsilyl)amino]carbinyl radical

Reacting trimethylsilyl radical with *t*-butyl isocyanide or carbodiimide led to this C-centred radical after a series of addition and elimination reactions (71–73) (Scheme 55).

V. Conclusions

Bis(trimethylsilyl)methylamine, BSMA, a very easily accessible original amine was proven to be an efficient synthon at disposal to organic synthetic chemists. It is the source of a large variety of derivatives (BSMa) that can be expected to have biological activity. The presence of the bis(trimethylsilyl)methyl group gives BSMa an enhanced solubility in less polar solvents and induces a selective (or specific) regio- and stereochemistry because of its bulkiness. Thus, a quite different chemistry can be performed, in comparison with current chemistry of methylamine and *N*-methyl nitrogen derivatives. Moreover, this group can be readily transformed into a trimethylsilylmethyl or a methyl group (Scheme 56).

More interesting is the easy cleavage of bis(trimethylsilyl)methyl group and its replacement by a proton that has given benefit, in particular, in β-lactam chemistry.



An important feature is that the catalytic cleavage of a silyl group by a fluoride anion delivers the corresponding α-nitrogen carbanion in very mild conditions. However, the remaining silyl group allows performing chemistry different from that performed using monosilylmethylamino derivatives.

In other words, BSMA is not simply another molecule in the extremely large collection of organic molecules. It is a real tool with which one can play efficiently. We are convinced that there is even more that can be done with BSMA, and new investigations are already underway in this domain.

VI. Acknowledgements

The author is very pleased to acknowledge all the persons who have contributed to this work. He would like to particularly thank his former students S. Grelier and T. Constantieux and Prof. J.M. Aizpurua, a former post-doc in his group, who initiated the research and established the basis of the chemistry of BSMA. Also acknowledged are the colleagues and their co-workers whose names appear along the references. Assistance by B. Barbe and M. Petraud (Cesamo, Université Bordeaux I) in solving difficult problems encountered in NMR analysis is well appreciated. Acknowledgements are due also to CNRS, Bordeaux I University, Aquitaine Regional Council and European Economic Community (Project SCI CT91/0648) whose financial support made this research possible.

Di[(hydroxyalkyl)dimethylammonium] tris[benzene-1,2-diolato(2–)]silicates and their germanium analogs: syntheses, crystal structure analyses, and NMR studies

Reinhold Tacke, Alistair Stewart, Joachim Becht, Christian Burschka, and Ingo Richter

Abstract: Treatment of $Si(OMe)_4$ with three molar equivalents of 1,2-$C_6H_4(OH)_2$ (= 1,2-dihydroxybenzene) and two molar equivalents of $HO(CH_2)_nNMe_2$ (n = 2, 3) in acetonitrile at room temperature yields the λ^6Si-silicates $(HO(CH_2)_nNMe_2H)_2(SiL_3)$ (**5**: n = 2; **6**: n = 3; L^{2-} = 1,2-$C_6H_4(O)_2^{2-}$ (= benzene-1,2-diolato(2–))). The analogous λ^6Ge-germanates $(HO(CH_2)_nNMe_2H)_2(GeL_3)$ (**7**: n = 2; **8**: n = 3) were synthesized analogously starting from $Ge(OMe)_4$. Compounds **5**·2CH_3CN and **6**–**8** were structurally characterized by single-crystal X-ray diffraction. In addition, aqueous solutions of the Si/Ge analogs **5**/**7** and **6**/**8** were studied by NMR spectroscopy. The title compounds may be regarded as model systems for the transport and storage of silicon in biological systems and as tools to investigate biosilification.

Key words: hexacoordinate silicon, hexacoordinate germanium, silicon biochemistry

Résumé : Le traitement de $Si(OMe)_4$ avec trois équivalents molaires de 1,2-dihydroxybenzène (= 1,2-$C_6H_4(OH)_2$) et deux équivalents molaires de $HO(CH_2)_nNMe_2$ (n = 2, 3), dans l'acétonitrile, à la température ambiante, conduit aux λ^6Si-silicates $(HO(CH_2)_nNMe_2H)_2(SiL_3)$ (**5**: n = 2; **6** n = 3; L^{2-} = 1,2-$C_6H_4(O)_2^{2-}$ (= benzène-1,2-diolato(2–))). Utilisant le $Ge(OMe)_4$ comme produit de départ, on a synthétisé les λ^6Ge-germanates analogues $(HO(CH_2)_nNMe_2H)_2(GeL_3)$ (**7**: n = 2; **8** n = 3). Faisant appel à la diffraction des rayons X, on a caractérisé la structure des composés **5**·CH_3CN et **6**–**8**. De plus faisant appel à la spectroscopie RMN, on a étudié les analogues Si/Ge **5**/**7** et **6**/**8** en solution. On peut considérer que les composés mentionnés dans le titre sont des systèmes modèles pour le transport et l'emmagasinage du silicium dans les systèmes biologiques et comme des instruments pour étudier la biosilification.

Mots clés : silicium hexacoordiné, germanium hexacoordiné, biochimie du silicium.

[Traduit par la Rédaction]

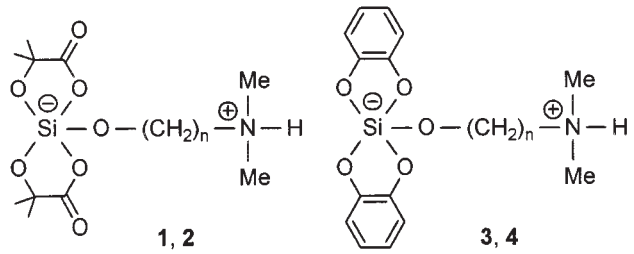
Introduction

As reported recently (1), tetramethoxysilane reacts with α-hydroxycarboxylic acids and aminoalkanols (molar ratio 1:2:1) in acetonitrile to yield zwitterionic λ^5Si-silicates with an SiO_5 skeleton, such as compounds **1** and **2** (for a comprehensive review dealing with zwitterionic λ^5Si-silicates see ref. 2). Surprisingly, all attempts to synthesize the related zwitterionic pentacoordinate silicon compounds **3** and **4** by using 1,2-dihydroxybenzene instead of 2-methyllactic acid failed. Even when using the required stoichiometric ratio 1:2:1 ($Si(OMe)_4$:1,2-$C_6H_4(OH)_2$:$HO(CH_2)_nNMe_2$), we rather isolated the ionic λ^6Si-silicates **5**·2CH_3CN and **6**. The corresponding germanium analogs, the ionic λ^6Ge-germanates **7** and **8**, can be prepared analogously starting from tetramethoxygermane. We report here on the optimized synthesis of compounds **5**·2CH_3CN and **6**–**8** and their structural characterization in the solid state (crystal structure analyses, ^{29}Si CP/MAS NMR studies) and in solution (^{1}H, ^{13}C, and ^{29}Si NMR investigations) (for a comprehensive review dealing with hexacoordinate silicon and germanium compounds see ref. 3). As will be discussed in the "Biological aspects" section, the title compounds may be regarded as model systems for the transport and storage of silicon in biological systems and as tools to investigate biosilification.

Experimental

Materials

All syntheses were carried out under dry nitrogen. The organic solvents and reagents were dried and purified according to standard procedures and stored under nitrogen.



Received July 15, 1999. Published on the NRC Research Press website on October 20, 2000.

This paper is dedicated to Professor Adrian Brook in recognition of his outstanding contributions to organosilicon chemistry.

Tetramethoxysilane, tetramethoxygermane, 1,2-dihydroxybenzene, 2-(dimethylamino)ethanol, and 3-(dimethylamino)propanol were purchased from Aldrich Chemical Co.

Physical measurements

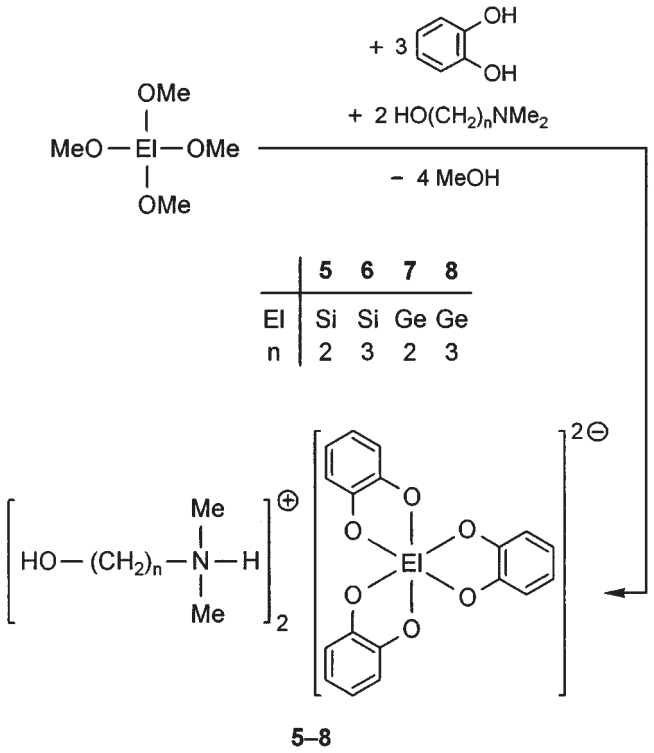
Melting points were determined with a Büchi Melting Point B-540 apparatus using samples in sealed capillaries. The ^{1}H, ^{13}C, and ^{29}Si solution NMR spectra were recorded at room temperature on a Bruker DRX-300 NMR spectrometer (^{1}H, 300.1 MHz; ^{13}C, 75.5 MHz; ^{29}Si, 59.6 MHz). D_2O was used as solvent. Chemical shifts (ppm) were determined relative to internal DHO (^{1}H, δ = 4.70) and external TMS (^{13}C, δ = 0; ^{29}Si, δ = 0). The ^{1}H NMR spectra of **5** and **6** were additionally recorded on a Bruker DRX-600 NMR spectrometer (^{1}H, 600.1 MHz) to resolve the ^{1}H spin systems of the benzene-1,2-diolato(2–) ligands. The ^{1}H spin systems were analyzed by using the Bruker program WINDAISY (4). Assignment of the ^{13}C NMR data was supported by DEPT 135 experiments. ^{29}Si CP/MAS NMR spectra were recorded at room temperature on a Bruker DSX-400 NMR spectrometer with bottom layer rotors of ZrO_2 (diameter 7 mm) containing ca. 300 mg of sample (79.5 MHz; TMS as external standard (δ = 0); spinning rate 5000 Hz; contact time 5 ms; 90° ^{1}H transmitter pulse length 3.6 μs; repetition time 4 s).

Syntheses

*Synthesis of di[(2-hydroxyethyl)dimethylammonium] tris[benzene-1,2-diolato(2–)]silicate–diacetonitrile (**5**·2CH$_3$CN)*

2-(Dimethylamino)ethanol (891 mg, 10.0 mmol) and then tetramethoxysilane (761 mg, 5.00 mmol) were added to a stirred solution of 1,2-dihydroxybenzene (1.65 g, 15.0 mmol) in acetonitrile (25 mL) at room temperature (formation of a precipitate after a few seconds). After the reaction mixture was kept for 24 h at room temperature, the precipitate was isolated by filtration, recrystallized from acetonitrile (slow cooling of a saturated boiling solution to room temperature and then to –20°C), washed with diethyl ether and dried in vacuo (0.01 torr (1 torr = 133.322 Pa), 20°C, 1 h) to give 2.46 g (92% yield) of a colorless crystalline product (loss of CH_3CN at ca. 80°C, mp 230°C, dec.). ^{1}H NMR (600.1 MHz, D_2O) δ: 1.99 (CH_3CN), 2.73 (s, 12 H, NCH_3), 3.07 (m, centered, 4 H, CCH_2N), 3.76 (m, centered, 4 H, CCH_2O), 6.56 (δ_A) and 6.58 (δ_B) (AA′BB′ system, $^{3}J_{AB} = {}^{3}J_{A'B'} = 7.6$ Hz, $^{3}J_{BB'} = 7.6$ Hz, $^{4}J_{AB'} = {}^{4}J_{A'B} = 1.5$ Hz, $^{5}J_{AA'} = 0.3$ Hz, 12 H, silicate anion); 6.75–6.87 (m, free 1,2-dihydroxybenzene). ^{13}C NMR (D_2O) δ: 1.19 CH_3CN), 43.2 (NCH_3), 55.9 (CCH_2N), 59.1 (CCH_2O), 111.3 (aromatic C-4/C-5), 118.3 (aromatic C-3/C-6), 119.6 (CH_3CN), 149.7 (aromatic C-1/C-2); 116.6, 121.0, 145.2 (free 1,2-dihydroxybenzene). ^{29}Si NMR (D_2O) δ: –144.0. ^{29}Si CP/MAS NMR (45 transients) δ: –141.2. Anal. calcd. for $C_{30}H_{42}N_4O_8Si$: C 58.61, H 6.89, N 9.11; found: C 58.57, H 6.74, N 9.02.

*Synthesis of di[(3-hydroxypropyl)dimethylammonium] tris[benzene-1,2-diolato(2–)]silicate (**6**)*



The same procedure was followed as described for the synthesis of **5**·2CH$_3$CN (tetramethoxysilane (761 mg, 5.00 mmol), 3-(dimethylamino)propanol (1.03 g, 10.0 mmol), 1,2-dihydroxybenzene (1.65 g, 15.0 mmol), acetonitrile (25 mL)). Compound **6** was isolated in 75% yield (2.09 g) as a crystalline solid (mp 238°C, dec.). ^{1}H NMR (600.1 MHz, D_2O) δ: 1.84 (m, centered, 4 H, CCH_2C), 2.74 (s, 12 H, NCH_3), 3.06 (m, centered, 4 H, CCH_2N), 3.59 (m, centered, 4 H, CCH_2O), 6.56 (δ_A) and 6.58 (δ_B) (AA′BB′ system, $^{3}J_{AB} = {}^{3}J_{A'B'} = 7.6$ Hz, $^{3}J_{BB'} = 7.7$ Hz, $^{4}J_{AB'} = {}^{4}J_{A'B} = 1.5$ Hz, $^{5}J_{AA'} = 0.4$ Hz, 12 H, silicate anion); 6.75–6.87 (m, free 1,2-dihyroxybenzene). ^{13}C NMR (D_2O) δ: 26.9 (CCH_2C), 43.1 (NCH_3), 55.9 (CCH_2N), 59.1 (CCH_2O), 111.3 (aromatic C-4/C-5), 118.3 (aromatic C-3/C-6), 149.7 (aromatic C-1/C-2); 116.5, 121.0, 145.2 (free 1,2-dihydroxybenzene). ^{29}Si NMR (D_2O) δ: –144.0. ^{29}Si CP/MAS NMR (830 transients) δ: –141.5. Anal. calcd. for $C_{28}H_{40}N_2O_8Si$: C 59.98, H 7.19, N 5.00; found: C 59.89, H 7.13, N 5.24.

*Synthesis of di[(2-hydroxyethyl)dimethylammonium] tris[benzene-1,2-diolato(2–)]germanate (**7**)*

The same procedure was followed as described for the synthesis of **5**·2CH$_3$CN, however, the product was crystallized by slow cooling to room temperature without further cooling to –20°C (tetramethoxygermane (492 mg, 2.50 mmol), 2-(dimethylamino)ethanol (445 mg, 4.99 mmol), 1,2-dihydroxybenzene (825 mg, 7.49 mmol), acetonitrile (15 mL)). Compound **7** was isolated in 81% yield (1.17 g) as a colorless crystalline solid (mp 266°C, dec.). ^{1}H NMR (D_2O) δ: 2.70 (s, 12 H, NCH_3), 3.04 (m, centered, 4 H, CCH_2N), 3.69 (m, centered, 4 H, CCH_2O), 6.54 (δ_A) and 6.59 (δ_B) (AA′BB′ system, $^{3}J_{AB} = {}^{3}J_{A'B'} = 7.7$ Hz, $^{3}J_{BB'} = 7.7$ Hz, $^{4}J_{AB'} = {}^{4}J_{A'B} = 1.5$ Hz, $^{5}J_{AA'} = 0.3$ Hz, 12 H, germanate anion). ^{13}C NMR (D_2O) δ: 43.0 (NCH_3), 55.4 (CCH_2N), 59.0 (CCH_2O), 112.3 (aromatic C-4/C-5), 118.3 (aromatic C-3/C-6), 149.2 (aromatic C-1/C-2). Anal. calcd. for $C_{30}H_{42}N_2O_8Ge$: C 54.12, H 6.29, N 4.86; found: C 54.00, H 6.02, N 4.85.

*Synthesis of di[(3-hydroxypropyl)dimethylammonium] tris[benzene-1,2-diolato(2–)]germanate (**8**)*

The same procedure was followed as described for the synthesis of **5**·2CH_3CN, however, the product was crystallized by slow cooling to room temperature without further cooling to –20°C (tetramethoxygermane (492 mg, 2.50 mmol), 3-(dimethylamino)propanol (515 mg, 4.99 mmol), 1,2-dihydroxybenzene (825 mg, 7.49 mmol), acetonitrile (15 mL)). Compound **8** was isolated in 84% yield (1.27 g) as a crystalline solid (mp 266°C, dec.). ^{1}H NMR (D_2O) δ: 1.80 (m, centered, 4 H, CCH_2C), 2.72 (s, 12 H, NCH_3), 3.04 (m, 4 H, CCH_2N), 3.54 (m, 4 H, CCH_2O), 6.55 (δ_A) and 6.60 (δ_B) (AA′BB′ system, $^3J_{AB} = {}^3J_{A'B'} = 7.7$ Hz, $^3J_{BB'} = 7.7$ Hz, $^4J_{AB'} = {}^4J_{A'B} = 1.5$ Hz, $^5J_{AA'} = 0.3$ Hz, 12 H, germanate anion). ^{13}C NMR (D_2O) δ: 26.7 (CCH_2C), 43.1 (NCH_3), 55.9 (CCH_2N), 59.0 (CCH_2O), 112.3 (aromatic C-4/C-5), 118.3 (aromatic C-3/C-6), 149.2 (aromatic C-1/C-2). Anal. calcd. for $C_{28}H_{40}N_2O_8Ge$: C 55.57, H 6.66, N 4.63; found: C 55.67, H 6.57, N 4.65.

Crystal structure analyses[2]

Suitable single crystals of **5**·2CH_3CN and **6**–**8** were obtained by crystallization from solutions in acetonitrile. The crystals were mounted in inert oil on a glass fiber and then transferred to the cold nitrogen stream of the diffractometer (Stoe IPDS, monochromated Mo Kα radiation (λ = 0.71073 Å)). No absorption correction was applied. The structures were solved by direct methods (5). All non-hydrogen atoms were refined anisotropically (6). A riding model was employed in the refinement of the C*H* hydrogen atoms. Except for **7**, the positions of the N*H* and O*H* hydrogen atoms were localized in difference fourier syntheses and refined freely. In the structure of **7**, the cation was found to be disordered at 263 K and hence none of its hydrogen atoms could be localized. As **7** undergoes a phase transition on cooling, a crystal structure analysis at 173 K failed.

Results and discussion

Syntheses

The ionic λ^{6}Si-silicates **5** and **6** were synthesized according to Scheme 1 by treatment of tetramethoxysilane with 1,2-dihydroxybenzene and the respective aminoalkanol (molar ratio 1:3:2). The corresponding λ^{6}Ge-germanates **7** and **8** were prepared analogously starting from tetramethoxygermane (Scheme 1). All syntheses were performed in acetonitrile at room temperature and the products **5**·2CH_3CN and **6**–**8** were isolated in high yields as crystalline solids (yields after recrystallization from acetonitrile: **5**·2CH_3CN, 92%; **6**, 75%; **7**, 81%; **8**, 84%). The identity of these compounds was established by elemental analyses (C, H, N), crystal structure analyses, as well as solid-state (^{29}Si) and solution (^{1}H, ^{13}C, ^{29}Si) NMR studies.

Physical and chemical properties

Compounds **5**·2CH_3CN and **6**–**8** are high-melting solids that are almost insoluble in non-polar and even in most polar organic solvents at room temperature. However, they were found to be soluble in DMSO and sparingly soluble in water.

Studies with freshly prepared aqueous solutions of **5**–**8** at room temperature (c = ca. 4×10^{-2} mol L^{-1}) revealed pH values of ca. 8.3 (λ^{6}Si-silicates) and ca. 7.4 (λ^{6}Ge-germanates), respectively (in this context, see also section "NMR studies"). Preliminary studies with **5** and **6** demonstrated breakdown of these λ^{6}Si-silicates upon a lowering of the pH value by addition of hydrochloric acid: At pH 6 (initial value) and after standing for three days at room temperature, a gel (silica gel; composition not yet studied in detail) was formed from aqueous solutions of **5** and **6**. Further experiments are necessary to study the kinetics of this process and to characterize the nature of the silica gel formed.

Crystal structure analyses

The crystal structures of compounds **5**·2CH_3CN and **6**–**8** were determined by single-crystal X-ray diffraction. The crystal data and experimental parameters used for these studies are given in Table 1 (for further details, see "Experimental section").

Compounds **5**·2CH_3CN and **7** crystallize in the space groups *C*2/*c* and *Fdd*2, respectively. The central silicon and germanium atom of the respective anions is located on a 2–fold axis (special positions: 0, *y*, 1/4 (**5**·2CH_3CN); 0, 0, *z* (**7**)). Thus, the asymmetric unit contains half of the anion and one cation (and one additional acetonitrile molecule in

[2] Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre (CCDC 129242 (**5**·2CH_3CN), CCDC 129243 (**6**), CCDC 129244 (**7**), and CCDC 129245 (**8**)). Copies of the data can be obtained, free of charge, on application to the Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. (Fax: 44-1223-336033 or e-mail: deposit@ccdc.cam.ac.uk).

the case of **5**·2CH_3CN). The Si/Ge analogs **6** and **8** crystallize in the space group $P2_1/c$ with two cations and one anion in the asymmetric unit, the crystal structures being isotypic.

The crystal structure analyses of **5**·2CH_3CN and **6**–**8** reveal the silicon and germanium atoms of the respective λ^{6}Si-silicate and λ^{6}Ge-germanate anions to be octahedrally coordinated (Figs. 1–3, Tables 2 and 3). There are only small distortions from the ideal octahedral geometry with O–Si–O (O–Ge–O) angles in the ranges 87.53(4)–95.00(5)° (86.01(17)–96.10(5)°) and 174.42(6)–176.80(5)° (172.93(18)–174.76(4)°). The Si–O (Ge–O) distances are in the range 1.7742(10)–1.7984(10) Å (1.8758(11)–1.9002(10) Å). The structural features observed for the SiO_6 and GeO_6 skeletons of **5**·2CH_3CN and **6**–**8** are similar to those already reported for other compounds containing the tris[benzene-1,2-diolato(2–)]silicate (7–9) and tris[benzene-1,2-diolato(2–)]germanate anion (10).

As expected from the presence of the potential N–H and O–H donor functions of the cations and the six potential oxygen acceptor atoms of the anions, both N–H···O and (except for **7**) O–H···O hydrogen bonds are observed in the crystals of **5**·2CH_3CN and **6**–**8**. Considering the relevant geometric parameters (11), the existence of intermolecular bifurcate N1–H1···O2/O3A and intermolecular nonfurcate O4–H4···O3A hydrogen bonds in the crystal of **5**·2CH_3CN can be assumed (Fig. 1, Table 4). In the case of compounds **6** and **8**, intermolecular bifurcate N1–H1···O3/O5 and N2–H2···O2/O6 hydrogen bonds as well as intermolecular nonfurcate O7A–H7A···O4 and O8A–H8A···O1 hydrogen bonds were observed (Fig. 2, Table 4). For compound **7**, the existence of an intermolecular bifurcate N1–H1···O2/O3A hydrogen bond can be assumed (Fig. 3).

A closer inspection of the hydrogen bonding systems observed for **5**·2CH_3CN, **6**, and **8** reveals that the protonated aminoalkanols are particularly useful cations for stabilizing the crystal structures of salts that contain anions of the tris[benzene-1,2-diolato(2–)]silicate and tris[benzene-1,2-diolato(2–)]germanate type. In addition to N–H···O interactions, cations of this particular type can also form O–H···O hydrogen bonds between cation and anion.

NMR studies

The silicon compounds **5**·2CH_3CN and **6** were investigated by ^{29}Si CP/MAS NMR experiments. The isotropic ^{29}Si

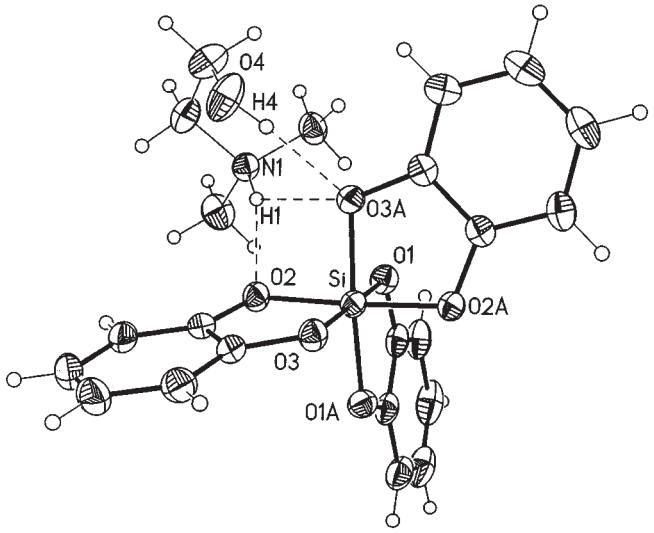

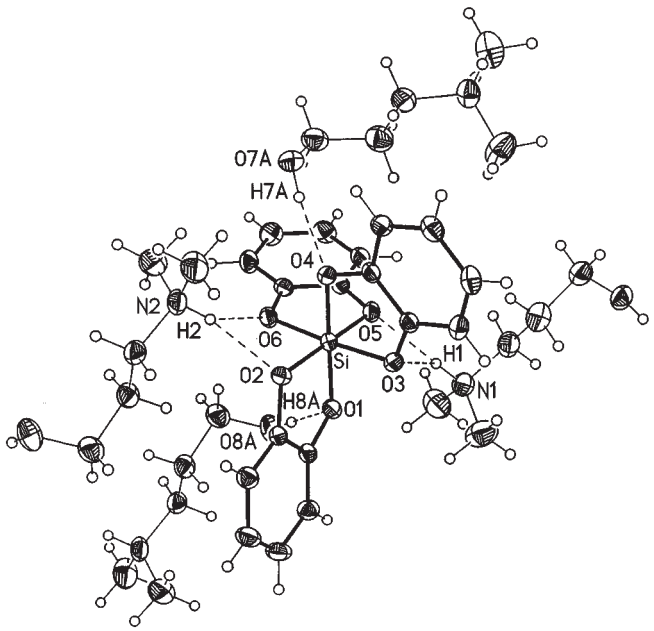

Fig. 2. Structure of the two crystallographically independent cations and the anion in the crystal of **6** (probability level of thermal displacement ellipsoids 50%). The dashed lines indicate hydrogen bonds between the cations and the anion. The crystal structure of the germanium analog **8** is isotypic.

chemical shifts obtained in these studies (**5**·2CH_3CN, δ = –141.2; **6,** δ = –141.5) clearly characterize the ^{29}Si resonances as arising from hexacoordinate silicon atoms. As these ^{29}Si chemical shifts are very similar to those obtained for **5** (δ = –144.0) and **6** (δ = –144.0) in D_2O, it is concluded that hexacoordinate silicon is also present in aqueous solution. Furthermore, both the ^1H and ^{13}C solution NMR data of **5**–**8** (solvent D_2O; $c = 4 \times 10^{-2}$ mol L^{-1}, room temperature) were found to be compatible with the presence of the λ^6Si-silicate and λ^6Ge-germanate anion of these compounds, the spectra of the respective Si/Ge analogs **5**/**7** and **6**/**8** being very similar. Thus, the results of the solid-state and solution NMR experiments unequivocally demonstrate that the tris[benzene-1,2-diolato(2–)]silicate and tris[benzene-1,2-diolato(2–)]germanate anion also exists in aqueous solution (for NMR studies of related λ^6Si-silicates with three bidentate ligands of the benzene-1,2-diolato(2–) type in aqueous solution, see ref. 13).

Interestingly, the ionic λ^6Si-silicates **5** and **6** are not sufficiently stable in D_2O to obtain ^1H and ^{13}C NMR spectra without resonance signals of the respective breakdown products: Even with fast measurement of freshly prepared solutions resonance signals corresponding to free 1,2-dihydroxybenzene were observed (Fig. 4). Formation of 1,2-dihydroxybenzene was found to occur immediately upon addition of **5**·2CH_3CN and **6** to D_2O; however, ^1H NMR studies showed this to be a

slow process. As demonstrated in Fig. 5, the molar ratio (λ^6Si-silicate anion):(1,2-dihydroxybenzene) was 86:14 after 30 min and after ca. 12 h the system achieved an apparent steady state at 65:35 and remained virtually unchanged for at least 7 days. An analogous behaviour was not observed for either **7** or **8**, both ionic λ^6Ge-germanates proving to be stable in aqueous solution (D_2O) with no formation of 1,2-dihydroxybenzene after two weeks.

Fig. 4. ^{1}H NMR partial spectra (300.1 MHz, room temperature) of 4×10^{-2} M aqueous solutions (D_2O) of the λ^6Si-silicate **6** (above) and the analogous λ^6Ge-germanate **8** (below). The spectrum of **6** shows already traces of free 1,2-dihydroxybenzene (concentration increasing with time; see Fig. 5), whereas the spectrum of **8** shows no free 1,2-dihydroxybenzene.

Biological aspects

A variety of marine organisms (e.g., diatoms, radiolarians, and sponges) and many higher plants (e.g., *Equisetum* species) are known to accumulate silicon and to deposit it as amorphous silica (14). Although significant progress in silicon biochemistry of marine organisms has been made in recent years (for a short review see ref. 15), still little is known about the chemical mechanisms that control the transport of silicon, its concentration (as soluble silicon pool), and its deposition (as silica). It has been speculated that organic chelate complexes of silicon, including hexacoordinate species, may be involved in these processes (16–18). Bidentate ligands of the benzene-1,2-diolato(2–) type are particularly promising candidates to form such complexes: Diols of the 1,2-dihydroxybenzene type are well known natural products that are found in many biological systems (see for example the derivatives identified in *Equisetum* species, such as caffeic acid esters (19, 20)) and that form hexacoordinate silicon complexes in aqueous solution.

The ionic λ^6Si-silicates **5**·2CH_3CN and **6** may be useful model compounds and tools to investigate the potential role of anionic species of the tris[benzene-1,2-diolato(2–)]silicate type in the above-mentioned biological processes. Both compounds can be easily synthesized and are soluble in aqueous solution. These solutions provide a source of orthosilicic acid ($Si(OH)_4$) which can be liberated in a controlled manner by regulating the pH value. The kinetics of this process can be monitored by ^{1}H NMR experiments (integration of the characteristic resonance signals of the aminoalkanol, tris[benzene-1,2-diolato(2–)]silicate anion, and free 1,2-dihydroxybenzene). Studies on silica formation from aqueous solutions of related tris[benzene-1,2-diolato(2–)]silicates under approximately neutral pH conditions have already been reported (21, 22) and the results obtained have been discussed with reference to biologically produced silica (21).

Related studies with the λ^6Ge-germanates **7** and **8** might also be of interest. Due to the lack of a convenient and practicable radioisotope of silicon (the half-life of ^{31}Si is 156 min), the radioisotope ^{68}Ge (half-life: 282 days) has been used as a probe for silicon in many biological studies (23, 24). However, the application of this particular tracer technique presupposes very similar chemical properties of the respective silicon and germanium species under investigation. Thus, comparative studies of the coordination chemistry of silicon and germanium in aqueous solution are desirable. The importance of such investigations is emphasized by the different chemical behaviour observed for the Si/Ge analogs **5**/**7** and **6**/**8** in aqueous solution.

Formation of organosilicon compounds 117:[1] C-brominated 1,3,5-trisilacyclohexanes and their reactions with BuLi

G. Fritz, M. Keuthen, F. Kirschner, E. Matern, H. Goesmann, K. Peters, E.-M. Peters, and H.G. von Schnering

Abstract: The photobromination of 1,1,3,3,5,5-hexamethyl-1,3,5-trisilacyclohexane (**1**) almost exclusively attacks CH_2 groups and results in 2,2-dibromo-trisilacyclohexane (**2**) as well as 2,2,4,4-tetrabromo-trisilacyclohexane (**3**) in high yields. Starting from a mixture of C-brominated trisilacyclohexanes the isomeric 2,2,9-tribromo-1,3,3,5,5,8,8,10,10,13,13-undecamethyl-1,3,5,8,10,13-hexasilabicyclo[7.2.2]tridec-6-yne (**6**) had been obtained in very low yield in an attempt to establish a preparative route to adamantanes with a C_4Si_6 skeleton, i.e., with C bridgeheads and SiR_2 bridges. By ICl-cleavage of a Si—methyl bond in **2** and subsequent substitution with Br_3CLi, the trisilacyclohexane **4** with functional groups in opposite positions of the ring can be obtained. Linking the step-by-step synthesized Cl-Me_2Si-C≡C-SiMe_2-CH_2-SiMe_2-Ph to the CBr_3 group of **4** results after HBr-cleavage of the Si—Ph bond in (ω-bromo-octynyl)-trisilacyclohexane (**12**). A ring closure of **12** would result in an isomeric hexasila-bicyclo[7.2.2]tridec-6-yne. The compounds were characterized by ^{1}H, ^{13}C, and ^{29}Si NMR spectra. Additionally, the molecular structures of **4** and **6** were confirmed by X-ray single crystal investigations.

Key words: 1,1,3,3,5,5-hexamethyl-1,3,5-trisilacyclohexane, bromination, 2,2,9-tribromo-1,3,3,5,5,8,8,10,10,13,13-undecamethyl-1,3,5,8,10,13-hexasilabicyclo[7.2.2]tridec-6-yne, carbosilane synthesis, NMR data, crystal structure investigation.

Résumé : La photobromation du 1,1,3,3,5,5-hexaméthyl-1,3,5-trisilacyclohexane (**1**) se fait presque exclusivement par une attaque des groupes CH_2 et elle conduit à la formation de 2,2-dibromotrisilacyclohexane (**2**) ainsi que de 2,2,4,4-tétrabromo-trisilacyclohexane (**3**) avec des rendements élevés. Dans un essai de démontrer la possibilité de préparer des adamantanes comportant un squelette C_4Si_6, c'est-à-dire les atomes de ponts C et les ponts SiR_2, on a déterminé que, en partant d'un mélange de trisilacyclohexanes C-bromé, on obtient le 2,2,9-tribromo-1,3,3,5,5,8,8,10,10,13,13-undécaméthyl-1,3,5,8,10,13-hexasilabicyclo[7.2.2]tridéc-6-yne (**6**) avec un faible rendement. Un clivage d'une liaison C—méthyle du composé **2** à l'aide de ICl, suivie d'une substitution subséquente avec du Br_3CLi permet d'obtenir le trisilacyclohexane **4** portant des groupes fonctionnels dans des positions opposées du cycle. La liaison du groupe CBr_3 du produit **4** au Cl-Me_2Si-C≡C-SiMe_2-CH_2-Ph synthétisé étape par étape conduit au (ω-bromo-octynyl)-trisilacyclo-hexane (**12**) après clivage de la liaison Si—Ph avec du HBr. Une fermeture du cycle du produit **12** devrait conduire à l'hexasilabicyclo[7.2.2]tridéc-6-yne. Les composés ont été caractérisés par spectroscopie RMN du ^{1}H, du ^{13}C et du ^{29}Si. De plus, on a confirmé les structures des composés **4** et **6** par diffraction des rayons X par des cristaux uniques.

Mots clés : 1,1,3,3,5,5-hexaméthyl-1,3,5-trisilacyclohexane, bromation, 2,2,9-tribromo-1,3,3,5,5,8,8,10,10,13,13-undécaméthyl-1,3,5,8,10,13-hexasilabicyclo[7.2.2]tridéc-6-ène, synthèse de carbosilanes, données de RMN, étude de structures cristallines.

[Traduit par la Rédaction]

1. Introduction

The gas phase pyrolysis of methylsilanes, among many other carbosilanes, yields 1,3,5,7-tetrasilaadamantanes, but only those with a Si_4C_6 skeleton were observed, i.e., Si occupies the bridgehead positions and CH_2 groups form the bridges in these adamantanes (1). Nevertheless, C bridgeheads exist in the barrelane $Si_4C_{11}H_{28}$ (2), in the asterane

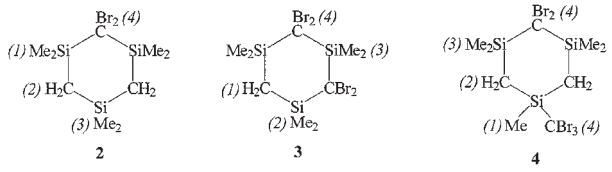
Scheme 1. Photobromination products of $(Me_2Si\text{-}CH_2)_3$ (**1**).



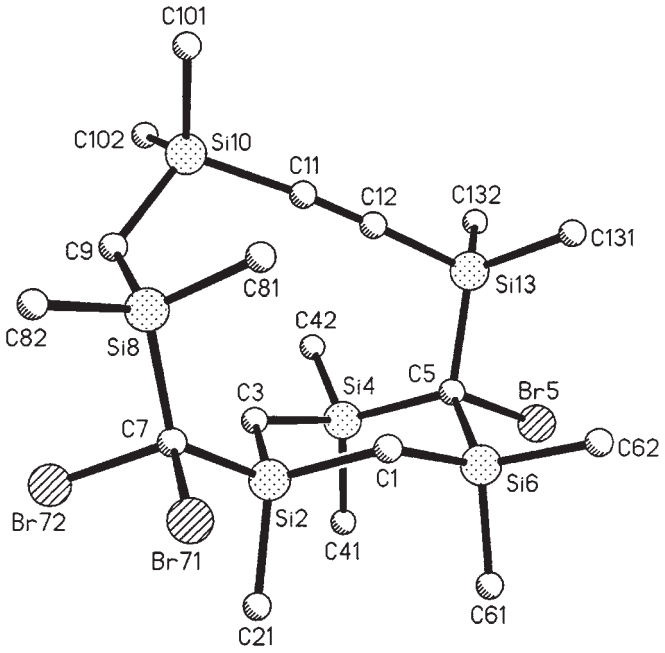


Fig. 1. Structure of 2,2,9-tribromo-1,3,3,5,5,8,8,10,10,13,13-undecamethyl-1,3,5,8,10,13-hexasilabicyclo[7.2.2]tridec-6-yne $Si_6C_{18}H_{39}Br_3$ (**6**) with the atomic labelling (hydrogen atoms omitted). For bond lengths and angles see Tables 4 and 5, respectively.

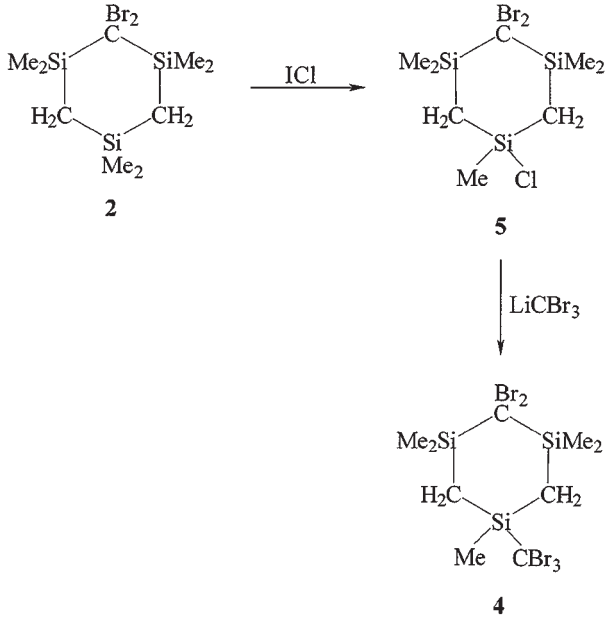
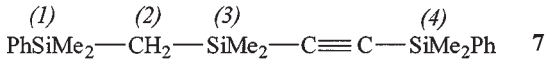




$Si_6Cl_8C_6H_8$ (3), in the di-adamantane $Si_7C_{16}H_{36}$ (4) and in the octamethyl-octasilaheptacyclooctadecane $Si_8C_{18}H_{40}$ (5), e.g., obtained either by pyrolysis or by organometallic synthesis. The synthetic approach to adamantanes with the "inverse" skeleton C_4Si_6 has to start from C-functional carbosilanes which at the same time carry less or non-reactive groups at Si. Unfortunately, these cannot simply be obtained by alkylating the readily available perchlorinated carbosilanes, because MeMgCl, for example, does not substitute the Si atoms in $(Cl_2Si\text{-}CCl_2)_3$. Instead, the reaction starts at a ring C atom and proceeds via ring contraction and ring cleavage to eventually lead to the linear $Me_3Si\text{-}CH_2\text{-}SiMe_2\text{-}C{\equiv}C\text{-}SiMe_3$ (6).

In addition, the photochlorination of Si-methylated carbosilanes does not provide a suitable pathway to the desired starting material, because photochlorination attacks both CH_3 and CH_2 groups at the same time. In contrast, the photobromination of hexamethyl-1,3,5-trisilacyclohexane **1** can be guided in a way that nearly exclusively attacks CH_2 groups (7) (Scheme 1).

In a first attempt to link the CBr_2 groups in a mixture of such C-functional trisilacyclohexanes by adding ^{n}BuLi, the compound $Si_6C_{18}H_{39}Br_3$ was isolated in a very low yield.

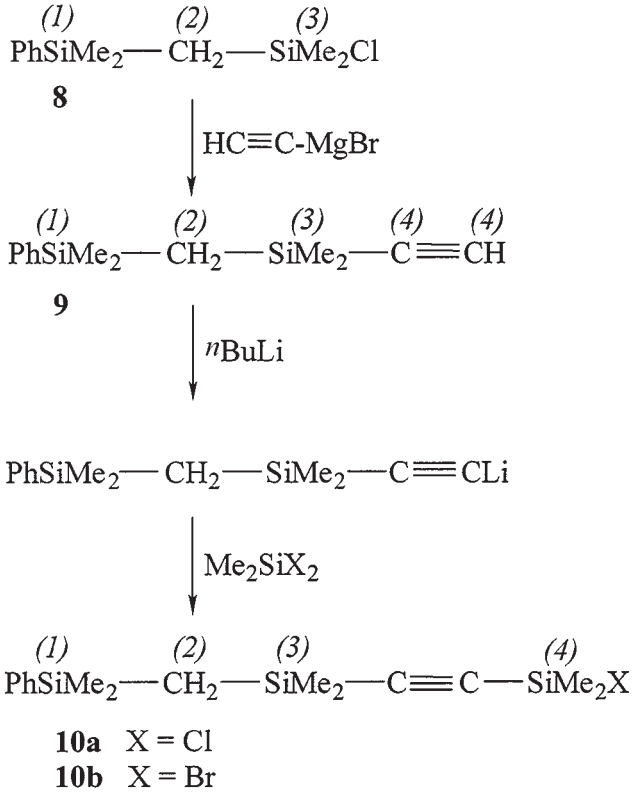
Scheme 2. Organometallic preparation of **4**.

According to the sum formula it might consist of two triply C-C linked trisilacyclohexanes in a wurtzite-like structure. The single crystal structure investigation of this product confirmed the heavy-atom formula $Si_6C_{18}Br_3$, while revealing a completely different and unexpected molecular structure (molecule **6** in Fig. 1). In this paper we first present a convenient preparative access to C-brominated derivatives of $(Me_2Si\text{-}CH_2)_3$ **1**, then we deal with the reactions of such derivatives with metal alkyls, and eventually we describe a reaction path for the synthesis of **6** as far as these steps have already been realized.

The structures of all mentioned compounds are to be found in Schemes 1–4 and NMR data are given in Table 1.

2. Results and discussion

2.1 Photobromination of $(Me_2Si\text{-}CH_2)_3$ (1)



A solution of $(Me_2Si\text{-}CH_2)_3$ (**1**) and *N*-bromosuccinimide in CCl_4 was irradiated (UV) until **2** and **3** reached a ratio of 1:1 and about 10% of **1** remained. If **2** and **3** are isolated at this point the compounds can be obtained in pure form. In the same manner **2** was further brominated to give **3** in an overall yield of about 90%. Only when trying to gain higher yields of the ring **3** with two CBr_2 groups or when trying to introduce a third CBr_2 group, some of the remaining ring **2** suffers bromination of a CH_3 to a CBr_3 group in opposite position to the CBr_2 group. This side product **4** is formed in a yield of 5–10% at most.

2.2 The reactions of 3 and 4 with metal alkyls

Whereas **3** is lithiated and subsequently alkylated by ^{n}BuLi, the reactions with ^{t}BuLi or MeMgBr proceed under ring

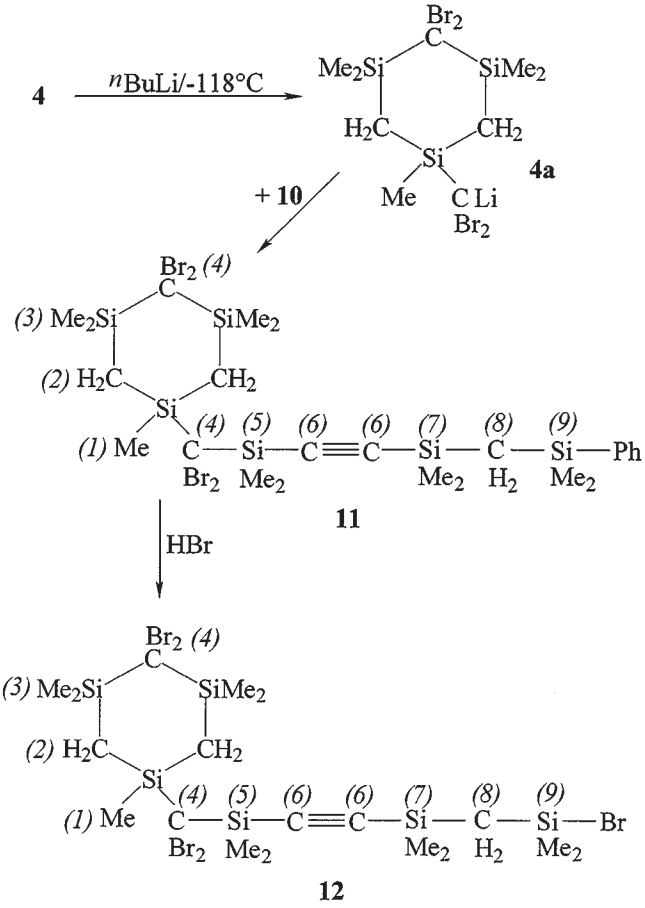
© 2000 NRC Canada

Scheme 3. Preparation of the functional trisilaoct-3-ynes **10a** and **10b**.

contraction and ring opening to $BrMe_2Si\text{-}CH_2\text{-}SiMe_2\text{-}C{\equiv}C\text{-}SiMe_2Br$ or $Me_3Si\text{-}CH_2\text{-}SiMe_2\text{-}C{\equiv}C\text{-}SiMe_3$, respectively, quite analogously to the reactions of $(Cl_2Si\text{-}CCl_2)_3$ (6) or of 1,3-disila-4-trimethylsilylcyclopentene (8) with MeMgCl.

In **4,** ^{t}BuLi first attacks the CBr_3 group as was proven by trapping the lithiated intermediate with MeI.

With the formation of **4** in the photobromination of **2**, and with $BrMe_2Si\text{-}CH_2\text{-}SiMe_2\text{-}C{\equiv}C\text{-}SiMe_2Br$ resulting from the rearrangement of the lithiated derivative of **3**, two molecules were independently isolated which may have been combined to give **6** in our orientating experiment. However, **6** could not be detected in repeated experiments when treating a mixture of **3** and **4** with ^{t}BuLi.



2.3 Organometallic synthesis of 6

On the way to **6**, the organometallic synthesis of **4** is quite a decisive step because **4** was not obtained in sufficient amounts by photobromination. Starting from **2**, a Si—Me bond has to be cleaved using ICl (9), then the intermediate -SiCl- unit can be substituted by Br_3CLi. In this manner, **4** could be prepared in a yield of 70% as shown in Scheme 2.

As a second building block, initially compound **7** was synthesized (Scheme 2). However it wasdecomposed by HBr to $BrMe_2Si\text{-}CH_2\text{-}SiMe_2Br$ and further products while cleaving the Ph—Si bonds. Therefore, the Si-functional 2,5,7-trisilaoct-3-yne **10** had to be synthesized according to a slightly changed reaction path (Scheme 3).

The linking of **4** with **10** was achieved via the Br_2CLi intermediate **4a** (10) as shown in Scheme 4. Then the remaining

Scheme 4. Linking of **10** and **4**, and reaction with HBr to give (ω-bromo-octynyl)-trisilacyclohexane **12**.

terminal Si atom of **11** could be functionalized using HBr. As CBr_2 groups are readily lithiated by ^{n}BuLi, a cyclization of **12** via elimination of LiBr was attempted. However, only oxygen-containing products, probably resulting from ether cleavage, were obtained. Therefore, a ring closure using metallic Li was tried. In mass spectra of two out of fifteen HPLC fractions (11) of this product mixture, a compound with the molecular mass of $Si_6C_{18}H_{41}Br$ could be detected which can be tentatively assigned to a partially hydrogenated isomer of **6**.

2.4 Conclusion

As only few crystals of **6** were initially obtained, it is not reasonable to derive a synthetic procedure from this single experiment. However, the investigations demonstrate a reproducible synthetic path from $(Me_2Si\text{-}CH_2)_3$ to 2,2,9-tribromo-1,3,3,5,5,8,8,10,10,13,13-undecamethyl-1,3,5,8,10,13-hexasilabicyclo[7.2.2]tridec-6-yne **6** even if the last step, i.e., the final ring closure has not yet been done.

2.5 Molecular structure determinations

The crystal structures of **6** and **4** were determined by X-ray single crystal methods. The crystallographic data are

listed in Table 2, and structural information is summarized in Tables 3–8.[3]

2,2,9-Tribromo-1,3,3,5,5,8,8,10,10,13,13-undecamethyl-1,3,5,8,10,13-hexasilabicyclo[7.2.2]tridec-6-yne $Si_6C_{18}H_{39}Br_3$ (**6**) crystallizes in the monoclinic space group $P2_1/a$ with 4 molecules in the unit cell (12). The molecule of **6** with the atomic labelling is shown in Fig. 1. Bond lengths and angles are listed in Table 4 and 5, respectively.

The standard deviations of about 1 pm do not allow for a sophisticated analysis. Nevertheless, some tendencies are obvious because the standard deviation of the averaged bond length *d*(Si—C) = 188(3) is three times as large as those for the single values. This results from two significantly different groups of bonds to be considered, namely the elongated ones to the atoms C5 and C7, which are bonded to bromine (*d*(Si—C5,7) = 192(1) pm); and the other ones (*d*(Si—C) = 186(1) pm). Moreover, the latter show a small differentiation of *d*(Si—C)*endo* = 187(1) > *d*(Si—C)*exo* = 186(1) > *d*(Si—CC) = 184(2) pm. At first glance the Si—CC bond shortening may indicate an influence of the C≡C triple bond. On the other hand, the internal tension of the seven-membered section (C7 → Si13) is reflected by the small bond angle C5-Si13-C12 (105.8°) and the large bond angles Si6-C5-Si13 (118.2°), Si8-C9-Si10 (122.0°), and Si2-C7-Si8 (125.5°) as well as by the deviation of the Si10-C11-C12-Si13 fragment from linearity (7–8°). This tension seems to be responsible for the shortening and bending of this fragment (Fig. 1). The axial ligands C21, C41, C61, and Si13 are shifted away from the central axis of the trisilacyclohexane ring. This demonstrates the six-membered ring to be arched, which is indicated, too, by the enlarged endocyclic angles at C1 and C3 (117–120°) and the smaller endocyclic angles at Si2 and Si4 (108–109°) as described by Fritz et al. (13).

Neglecting the C≡C group, the framework of **6** almost perfectly displays a diamond fragment with all six-membered rings being in the chair conformation (Fig. 2). It is noticeable,

[a]Equivalent isotropic *U* defined as one third of the trace of the orthogonalized tensor.

that only minor modifications are necessary to insert the C≡C group into this diamond fragment, namely rotations around the C9—Si10 and Si8—C9 bonds by angles of about 60° and 30°, respectively. These modifications result in the skew boat conformation of the six-membered ring fragment C81-Si8-C9-Si10-C11 (one atom is missing between C81 and C11).

A colourless single crystal of 2,2-dibromo-5-tribromomethyl-1,1,3,3,5-pentamethyl-1,3,5-trisilacyclohexane $Si_3C_9H_{19}Br_5$ **4** was selected for the X-ray structure determination and the results are summarized in Table 2. The molecule of (**4**) with the atomic labelling is shown in Fig. 3; fractional coordinates are given in Table 6; bond lengths and angles are listed in Table 7 and 8, respectively.

The trisilacyclohexane ring adopts the chair conformation with an equatorial CBr_3 group, which is the necessary conformation for a successful further synthesis. Also in this molecule the bond distances from the brominated carbon atoms to Si as well as to Br are significantly larger than standard average values (Table 7). The endocyclic angles Si-C-Si with an average value of 118.2° are larger than the tetrahedral angle whereas the angles C-Si-C don't show a common tendency. Due to the sterically requiring CBr_3 group, the angle C4-Si2-C7 of 111.1° is remarkably larger than those at Si1 and Si3 (Table 8). The mean value of 113.0° for all endocyclic angles indicates a slightly flattened conformation of the trisilacyclohexane chair.

3. Experimental

3.1 General procedures

All solvents were thoroughly dried, and the reactions run in a N_2 atmosphere. Gaseous Cl_2 was passed through a P_2O_5

Fig. 2. Below: the diamond fragment of the molecule **6** after abstracting the C≡C group (arrows). Real bonds are shown by full lines, dotted lines help to complete the six-membered rings (all in chair conformation) of the diamond fragment. Above: very small modifications allow for the insertion of the C≡C group (see text) by formation of only one skew boat fragment (atoms 81, 8, 9, 10, 11, and one atom missing between atoms 81 and 11).

tube (2 m × 8 cm). The photoreactions were run in quartz flasks using a water cooled Original Hanau mercury high pressure immersion lamp. HPLC analyses were performed according to ref. 11.

3.2 Photobromination of $(Me_2Si\text{-}CH_2)_3$ 1 to give 2,2-dibromo-1,1,3,3,5,5-hexamethyl-1,3,5-trisilacyclohexane (2)

Method 1: 21.6 g (100 mmol) of **1** + 3 drops of Br_2 without any solvent were irradiated. Only after the colour of Br_2 disappeared was a new portion of Br_2 added. Evolving HBr was collected in a cooling trap (slightly reduced pressure, liquid N_2). Whenever the mixture turned black from suspended carbon it had to be filtered. These steps were repeated until **3** became detectable in the ^1H NMR spectrum after a total irradiation time of about 150 h. The mixture was diluted in pentane and prepurified using a silicagel column (Merck 40–63 μm). Pentane and remaining **1** (10.6 g; 49 mmol) were removed, then 11.3 g (30.6 mmol, 60%) of **2** could be obtained as colourless crystals (mp 52°C).

Method 2: 21.6 g (100 mmol) of **1** + 19.6 g (110 mmol) of *N*-bromosuccinimide in CCl_4 were irradiated for 7 d. The insoluble succinimide was removed by filtration, Br_2 and CCl_4 stripped, the oily brown residue eluted with 1 L of pentane from an Al_2O_3 column (10 × 2 cm; Riedel de Haen Al_2O_3 S neutral active), and the solvent removed. With

another 19.6 g (110 mmol) of NBS, the full procedure was repeated. In a short path distillation apparatus (oil pump vacuum) first 2.3 g (11 mmol) of **1**, then 26.6 g (55 mmol) of **2** were collected. A third fraction of 8.3 g consisted of about 50 mol% of **2** and 50 mol% of **3**. 20.6 g of **2** (55%) remained after recrystallization from pentane. As the recovered starting material was re-used for further photobrominations, **2** could be obtained in an overall yield of 90%.

3.3 Photobromination of $(Me_2Si\text{-}CH_2)_3$ 1 to give 2,2,4,4-tetrabromo-1,1,3,3,5,5-hexamethyl-1,3,5-trisilacyclohexane 3 and 2,2-dibromo-5-tribromomethyl-1,1,3,3,5-pentamethyl-1,3,5-trisilacyclohexane (4)

According to method 2, 36.4 g of a mixture of about 10 mol% of **1**, 80 mol% of **2** and 10 mol% of **3** (^{1}H NMR analysis) + 19.6 g (110 mmol) of NBS in CCl_4 were irradiated for 10 d, and the procedure repeated for a second time. At 30–50°C, the collected residues were distilled in the mentioned apparatus yielding a main fraction which after recrystallization gave 12.4 g (33 mmol; 33%) of **2**, 16.5 g (31 mmol; 31%) of **3** as well as 1.8 g (3 mmol; 3%) of **4**. From the distillation residue another small amount of **4** and **3** was obtained by crystallization.

3.4 Cleavage of a Si—Me bond in 2 to give 2,2-dibromo-5-chloro-1,1,3,3,5-pentamethyl-1,3,5-trisilacyclohexane (5)

To 10 g (26.8 mmol) of **2** in 60 mL of CCl_4, a solution of 1.4 g of I_2 (20 mol%) was added; in the dark a slow stream of dry Cl_2 was applied for 2 min, and the mixture stirred for 15 min. This was repeated until the signals of **2** disappeared from the ^{1}H NMR spectrum of the solution. After all volatile components had been removed, 9.9 g (25.2 mmol; 94%) of **5** crystallized (mp 87.5°C).

3.5 Preparation of 4 from 5

At –110°C, 9 mL (13.5 mmol) of ^{n}BuLi were added dropwise to a solution of 5.0 g (15.2 mmol) of CBr_4 in 200 mL THF:pentane:Et_2O (4:1:1). After stirring for 1 h at this temperature the solution was frozen (liquid N_2). A solution of 5.4 g (13.7 mmol) of **5** in 50 mL THF–pentane–Et_2O was added, the reaction flask allowed to warm to –80°C and the mixture stirred for another 3 h at this temperature. After gradually warming to room temperature the solvents were removed, hexane added and the solution filtered. 5.9 g of **4** (9.7 mmol; 72%) were recrystallized from hexane (mp 137°C, decomp.).

3.6 Preparation of 5-phenyl-3,3,5-trimethyl-3,5-disilahex-1-yne (9)

75 g (0.31 mol) of **8** in 100 mL THF were added at 0°C to a solution of HC≡CMgBr (14) (8.5 g (0.35 mol) Mg turnings; 21.6 mL (0.35 mol) EtBr; 400 mL THF). After refluxing for 2 h, the ether was removed, the residue suspended in pentane and filtered, and the solvent stripped. A vacuum distillation yielded 51.7 g (0.22 mol; 71%) of **9** (bp 60°C; 2×10^{-3} mm Hg).

3.7 Preparation of Me_2SiBr_2

To 4.2 g (70 mmol) of Me_2SiH_2 (no solvent) at –35°C (cooling bath) very cautiously and as slowly as possible 22.1 g (140 mmol) of Br_2 were dropwise added. The reflux condenser of the apparatus was connected to a cryostate (–35°C). When the mixture turned brown, the remaining Br_2 was added at room temperature. Eventually the mixture was heated to 55°C until the ^{1}H NMR peak of Me_2SiHBr was no longer detectable. Distillation at normal pressure yielded 12.3 g (40 mmol) of Me_2SiBr_2.

3.8 Preparation of 2-chloro-7-phenyl-2,5,5,7-tetramethyl-2,5,7-trisilaoct-3-yne 10a and of 2-bromo-7-phenyl-2,5,5,7-tetramethyl-2,5,7-trisilaoct-3-yne (10b)

At 0°C, 15.7 mL (23.8 mmol) of ^{n}BuLi were added over 45 min to 5.8 g (25 mmol) of **9** dissolved in 50 mL hexane. After another 45 min stirring at room temperature, the mixture is transferred with 250 mL hexane into a dropping funnel and added over 7 h to 3.25 g (25 mmol) of Me_2SiCl_2 in 100ml hexane. Dry work-up with filtration and distillation yielded 3.3 g (10.2 mmol; 43%) of **10a** (bp 78°C; 5×10^{-3} mm Hg).

Similarly, from 13.5 g (58.2 mmol) of **9**, 35.5 mL (57.5mmol) of ^{n}BuLi and 12.6 g (58.3 mmol) of Me_2SiBr_2 a yield of 10.1 g (27.4 mmol; 48%) of **10b** (bp 91°C; 5×10^{-3} mm Hg) resulted.

3.9 Linking of 10 and 4 to give (ω-phenyl-octynyl)-trisilacyclohexane (11)

At –105°C, 4.0 mL (6.3 mmol) of ^{n}BuLi were added to 3.87 g (6.4 mmol) of **4** in 90 mL THF:pentane:Et_2O (4:1:1). After stirring for 30 min, 2.1g (6.5 mmol) of **10a** in 50 mL pentane were added at this temperature. The mixture was stirred at –105 to –85°C for another 2 h, then filtered and distilled in vacuo. 4.93 g of **11** were obtained as a slightly yellow, highly viscous oil.

Similarly, 8.2 g of **11** resulted from 6.8 g (11.2 mmol) of **4**, 6.9 mL ^{n}BuLi (11.2 mmol) and 4.2 g (11.4 mmol) of **10b**.

3.10 Reaction of 11 with HBr to give (ω-bromo-octynyl)-trisilacyclohexane (12)

4.3 g (5.25 mmol) of **11** were placed in an ampoule and frozen (liquid N_2). 6 mmol of HBr were added, the ampoule sealed and stored at –78°C. After 1 d, the ampoule was warmed to room temperature, vigorously shaken and stored again at –78°C. This was repeated for 7 d. A raw yield of 3.9 g of **12** remained when all volatile components had been removed.

3.11 Reaction of 12 with Li granules

Over 11 h, 1.95 g (2.4 mmol) of **12** in 500 mL THF were added to a vigorously stirred suspension of 44.3 mg (6.4 mmol) of Li (metal granules) in 50 mL THF. Dry work-up gave 1.28 g of raw product of which 533 mg were separated by HPLC.

Reduction of conjugate double bonds with trichlorosilane

Moni Chauhan and Philip Boudjouk

Abstract: A variety of α,β-unsaturated esters and cyclic ketones underwent smooth reduction of the carbon–carbon double bond with a combination of inexpensive and readily available trichlorosilane and $CoCl_2$. The reactions are performed under very mild conditions and products are obtained in high yields.

Key words: reduction, carbonyl compounds, trichlorosilane, ketones, chemoselectivity.

Résumé : Une grande variété d'esters et de cétones cycliques α,β-insaturés subissent une réduction facile de la double liaison carbone–carbone sous l'influence combinée du $CoCl_2$ et du trichlorométhane facilement accessible et peu dispendieux. Les réactions se produisent dans des conditions très douces et les produits sont obtenus avec des rendements élevés.

Mots clés : réduction, composés carbonyles, trichlorosilane, cétones, chimiosélectivité.

[Traduit par la Rédaction]

Introduction

Among the various reducible substrates of great relevance are those containing both a carbonyl group and a C=C bond such as α,β-unsaturated esters and ketones. Indeed, the capability of reducing only one group, leaving the other one unaffected, is a challenging task in organic synthesis, particularly for the preparation of pharmaceutical and agrochemical products. Chemoselective hydrogenation of double bonds in α,β-unsaturated carbonyl compounds has attracted much interest for more than two decades. A very convenient and fundamentally important route to these reactions is by metal-catalyzed hydrogenation (1). Practical motivations arise from the fact that such reactions are convenient in large scale synthesis since there is no need to employ a high hydrogen pressure or to use hazardous reducing agents. Transfer of organic groups of organosilanes to metallic species, transmetalation, and subsequent homocoupling reactions under mild conditions are well known (2). Recently, there have been reports of generating copper hydride species via transmetalation of a hydrogen atom on silicon to copper (3). Although this combination of a Cu(I) salt and dimethylphenylsilane is a useful reagent for conjugate reduction of α,β-unsaturated compounds, the hydrosilane is a fairly expensive starting material. Consequently this report introduces the use of the cheapest and most readily available silane, trichlorosilane, as a hydride source catalyzed by $CoCl_2$ in the presence of small amounts of DMI (1,3-dimethyl-2-imidazolidinone) or DMPU (1,3-dimethyl-3,4,5,6-tetrahydro-2(1 *H*)-pyrimidinone).

In our effort to find a new catalyst for hydrosilylation of acrylonitriles (4) and acrylates, we found that $CoCl_2$ and TMEDA (*N*,*N*,*N′*,*N′*-tetramethylethylenediamine) catalyzed the reduction of the double bond in acrylates and hydrosilylation (eq. [1]).

[1] $$CH_2{=}CHCO_2Me + HSiCl_3 \xrightarrow[CD_3CN,\,70°C,\,8\,h]{CoCl_2,\,TMEDA} Cl_3SiCH_2CH_2CO_2Me + CH_3CH_2CO_2Me$$

In contrast, in the presence of DMI or DMPU reduction of the carbon–carbon double bond was the exclusive reaction path resulting in efficient, high yield syntheses of saturated ketones and esters under mild conditions.

Experimental

General procedure

All reactions and manipulations were routinely performed under an argon atmosphere by using standard Schlenk techniques. Commercially available hexahydrated $CoCl_2$ was oven dried. All acrylates and ketones are commercial products and were distilled in an inert atmosphere prior to use. Trichlorosilane was purified by distillation over magnesium metal. TMEDA, DMI, or DMPU were used as received without further purification. Deuterated acetonitrile for the reaction was dried over molecular sieves. ^1H and ^{13}C NMR spectra were recorded on a JEOL GSX270 and JEOL GSX400 (operating at 100.53 MHz for ^{13}C) spectrometers respectively. All chemical shifts are reported in ppm and were measured relative to residual ^1H or ^{13}C resonances in a deuterated solvent (CD_3CN, δ 1.94).

Catalysis experiments

A typical procedure is given as follows: to a mixture of $CoCl_2$ (0.180 g, 1.4 mmol) and DMI (0.5 mL, 4 mmol) in CD_3CN (2 mL), methylacrylate (0.72 mL, 8 mmol) and then trichlorosilane (1.76 mL, 16 mmol) was added at room temperature. The resulting mixture was refluxed at 70°C and was monitored by ^1H and ^{13}C NMR. After 5 h the color of the reaction solution changed from blue to green, which indicated the complete consumption of methylacrylate. The solid formed in the reaction was filtered through a short-column chromatography (Florisil, CD_3CN:pentane = 1:2) to furnish pure reduction product.

Results and discussion

The catalysis was found to be quite general for the selective reduction of C=C bonds of α,β-unsaturated esters and ketones. Our results are summarized in Table 1 and show that all reactions exhibit excellent chemoselectivity, good catalytic activity, and essentially only one product: the corresponding saturated ester or ketone. The optimum reaction conditions from entry 1 were applied to ethylacrylate (entry 2) and ethylcinnamate (entry 3). This last reaction proceeds much slower and gives a lower yield of the desired product (50%) in comparison to the reactions in entry 1 (90%) and 2 (70%). We attribute this to a combination of steric and electronic effects arising from the phenyl ring.

We applied our reduction system to the α,β-unsaturated cyclic ketones. As is evident from Table 1, 2-cyclohexen-1-one (entry 4) and 2-cyclopenten-1-one (entry 5) underwent reduction reactions at room temperature which resulted in excellent yields (88–92%). It was observed that a reduction in the amounts of catalyst did not affect the rate or the yields of the reaction. In fact, the amount of $CoCl_2$ in this reaction can be reduced to 5 mmol% and DMI or DMPU can be used as low as 25 mmol%. On the other hand, 1-acetyl-1-cyclohexene and 3,5-dimethyl-2-cyclohexen-1-one were not reactive at room temperature. 1-acetyl cyclohexane was obtained in 75% yield after heating at 70°C for 2 h (entry 6) and 3,5-dimethyl-2-cyclohexane was obtained only in 50% yield after 12 h. Steric influence from methyl groups at the *meta*-position might be responsible for its low reactivity. Unfortunately, the silicon species formed in the present catalysis were difficult to identify.

To get an insight into the mechanism of these reactions, we treated dimethylphenylsilane with ethylacrylate and with 2-cyclopenten-1-one (entry 8 and 9). Notably, both reactions were homogeneous to give the corresponding saturated products. The silicon compounds formed in these reactions were isolated by dissolving the crude product in pentane and were identified by NMR as dimethylphenyldisiloxane. It is relevant to note that Mori et al. (3*b* and 3*c*) have recently reported the formation of this disiloxane from the reaction of CuCl and $PhMe_2SiH$ in DMF at room temperature for 1 h. The authors suggested that CuH and chlorodimethylphenylsilane first formed are converted to disiloxane via hydrolytic condensation. By analogy, we assume a similar pathway for the reactions in entry 8 and 9.

Conclusions

Trichlorosilane effects conjugate reduction with the aid of $CoCl_2$. This reduction method constitutes a simple and cheap alternative to literature procedures for the selective conjugate reduction of α,β-unsaturated carbonyl compounds. Further characterization of the reactive intermediates and elucidation of the mechanism is under active investigation.

Geminal bis(hypersilyl) compounds — the synthesis and structure of bis[tris(trimethylsilyl)silyl]silanes

Thoralf Gross, Helmut Reinke, and Hartmut Oehme

Abstract: Protodesilylation of diphenylsilane with trifluoromethanesulfonic acid and subsequent reaction of the obtained bis(trifluoromethanesulfonyloxy)silane with tris(trimethylsilyl)silyllithium (**1**) (molar ratio 1:2) afforded bis[tris(trimethylsilyl)silyl]silane (**8**). Methyl-bis[tris(trimethylsilyl)silyl]silane (**3**) and phenyl-bis[tris(trimethylsilyl)silyl]silane (**10**) were obtained by coupling reactions of **1** with $MeHSiCl_2$ or $PhHSiCl_2$, respectively, (2:1). By treatment with $HCBr_3$, the H-silanes **3**, **8**, and **10** were converted into the bromosilanes $[(Me_3Si)_3Si]_2SiR^1R^2$ (**9**: $R^1 = R^2 = Br$; **11**: $R^1 = Me$, $R^2 = Br$; **12**: $R^1 = Ph$, $R^2 = Br$). X-ray crystal structure analyses, performed for **3**, **10** and **12**, confirmed the expected distortions of the molecular skeletons of the compounds. Thus, e.g., in **10**, the spatial demand of the two extended hemispherical hypersilyl groups forces a widening of the Si-Si-Si angle at the central Si atom to a value of 128.3°.

Key words: silanes, sterically congested, bis(hypersilyl)silanes, hypersilylsilanes, bis(hypersilyl)germanes, tris(trimethylsilyl)silylsilanes.

Résumé : La protodésilylation du diphénylsilane par l'acide trifluorométhanesulfonique et la réaction du bis(trifluorométhanesulfonyloxy)silane qui en résulte avec du tris(triméthylsilyl)silyllithium (**1**) (rapport molaire 1:2) conduit à la formation de bis[tris(triméthylsilyl)silyl]silane (**8**). Les réactions de couplage de **1** avec le $MeHSiCl_2$ et le $PhHSiCl_2$ conduisent à la formation respectivement de méthyl-bis[tris(triméthylsilyl)silyl]silane (**3**) et de phényl-bis[tris(triméthylsilyl)silyl]silane (**10**). Par traitement avec du $HCBr_3$, les silanes **3**, **8** et **10** sont transformés en bromosilanes $[(Me_3Si)_3Si]_2SiR^1R^2$ (**9**: $R^1 = R^2 = Br$; **11**: $R^1 = Me$, $R^2 = Br$; **12**: $R^1 = Ph$, $R^2 = Br$). L'examen des composés **3**, **10** et **11** par diffraction des rayons X a permis de confirmer les déformations attendues pour les squelettes moléculaires de ces composés. Ainsi, par exemple, dans le composé **10**, la demande spatiale des deux groupes hypersilyles hémisphériques étendus provoque un agrandissement, jusqu'à une valeur de 128,3°, de l'angle Si-Si-Si au niveau de l'atome de Si central.

Mots clés : silanes, congestion stérique, bis(hypersilyl)silanes, hypersilylsilanes, bis(hypersilyl)germanes, tris(triméthylsilyl)silylsilanes.

[Traduit par la Rédaction]

Introduction

The tris(trimethylsilyl)silyl group, the hypersilyl group, proved to be a function with unusual steric and electronic properties, gaining increasing interest as a substituent suitable for protecting and stabilizing uncommon bonding states of main group as well as transition elements (1, 2). The spherical extension of the $(Me_3Si)_3Si$ group was found to cause considerable distortions of the molecular skeletons of respective hypersilyl derivatives (3) and, of course, particularly serious deviations from regular molecular structures were expected for compounds, in which two of these bulky groups are bound to the same central atom. Geanangel and co-workers (4) calculated the cone angles for $(Me_3Si)_3Si$-E fragments of, e.g., group 14 elements to be 168° for E = Sn, 175° for E = Ge, 182° for E = Si, and 199° for E = C, respectively, indicating that the access to geminal bis(hypersilyl) derivatives, especially to those with a nonlinear arrangement of the two groups, might be difficult. Nevertheless, in recent years a number of geminal bis(hypersilyl) compounds, preferably of the heavier main group elements, was synthesized and, in part, structurally characterized. Thus, bis(hypersilyl)galliumchloride (5*a*), the chlorobis(hypersilyl)gallium and indium complexes $[(Me_3Si)_3Si]_2MCl{\cdot}LiCl$ (M = Ga, In) (5*b*) as well as tetrakis-[tris(trimethylsilyl)silyl]digallium (5*c*), and tetrakis[tris(trimethylsilyl)silyl]dithallium (5*d*) were described. Biffar and Nöth (5*e*) succeeded in synthesizing methoxy-bis[tris(trimethylsilyl)silyl]boron and dimethylamino-bis[tris(trimethylsilyl)silyl]boron. Bis(hypersilyl) selenane (6*a*) and

bis(hypersilyl) tellurane (6*a*, 6*b*) were described, also bis(hypersilyl) derivatives of iron, chromium, manganese (7*a*), and of zinc and mercury (7*b*) are known.

Concerning group 14 elements, which are of special interest in the context of this paper, the carbene analogues $[(Me_3Si)_3Si]_2Sn$ (8*a*) and $[(Me_3Si)_3Si]_2Pb$ (8*b*) and their dimers were synthesized and structurally characterized. Bis(hypersilyl)tin dichloride was obtained by the reaction of tris(trimethylsilyl)silyllithium with tin tetrachloride (8*c*), and Klinkhammer (2) succeeded in synthesizing $NaSn[Si(SiMe_3)_3]_3$, the first compound bearing three hypersilyl groups at one central atom. There are reports in the literature about unsuccessful attempts of the synthesis of bis(hypersilyl) derivatives of germanium (8*c*, 8*d*) and silicon (8*d*, 8*e*), but recently Apeloig et al. (8*f*) described the synthesis of $[(Me_3Si)_3Si]_2SiHCl$ (**2**) by a coupling reaction of tris(trimethylsilyl)silyllithium (**1**) with trichlorosilane and its conversion into $[(Me_3Si)_3Si]_2SiHMe$ (**3**), $[(Me_3Si)_3Si]_2Si(Cl)Me$ (**4**), and $[(Me_3Si)_3Si]_2SiMe_2$ (**5**). Very recently Marschner (8*g*) obtained the nonasilane **5** by the reaction of $(Me_3Si)_3SiSiMe_2Br$ with tris(trimethylsilyl)silylpotassium.

Of particular interest from a structural point of view are geminal bis(hypersilyl) compounds with a central carbon atom, and rather unexpectedly we found that the placement of two bulky $(Me_3)Si)_3Si$ groups at one comparatively small sp^3 carbon atom can easily be achieved. Thus, we succeeded in synthesizing methoxybis[tris(trimethylsilyl)silyl]methane by the reaction of **1** with dichloromethyl-methylether (9*a*). Bis(hypersilyl)methanol was obtained from **1** and *tert*-butyl formate (9*b*) and, furthermore, **1** reacts with dialkyl(chloromethylene)ammonium chlorides to give dialkylaminobis[tris(trimethylsilyl)silyl]methanes (9*c*). Recently, we were also able to describe the parent compound of the series, bis[tris(trimethylsilyl)silyl]methane (9*d*). The structures of all these compounds are characterized by tremendous distortions of the molecular skeletons. In particular, the Si-C-Si bond angles at the central sp^3 carbon atoms are extremely widened to values up to 136.2°, the individual values being dependent on the space demand of the further *C*-substituents. In the present paper we describe the extension of these studies to geminal bis(hypersilyl) compounds with a central silicon atom with the aim of comparing the structural parameters of the silicon centered bis(hypersilyl) compounds with their carbon analogues.

Results and discussion

The syntheses of geminal bis(hypersilyl)silanes 8–12

Bis[tris(trimethylsilyl)silyl]silane (**8**) was obtained by treatment of bis(triflouromethanesulfonyloxy)silane (**7**) with tris(trimethylsilyl)silyllithium (**1**) (molar ratio 1:2) in toluene (Scheme 1). The silyltriflate **7** was prepared by protodesilylation of diphenylsilane (**6**) with trifluoromethanesulfonic acid (10) and was used without isolation and purification. The method gave **8** in a total yield of 19% (based on **6**).

In a very straightforward reaction dichloromethylsilane with two equiv. of **1** afforded methylbis(hypersilyl)silane (**3**). Similarly, dichlorophenylsilane with **1** gave phenylbis(hypersilyl)silane (**10**) (Scheme 2).

Despite the steric congestion of the molecules, the Si—H bonds in **3**, **8**, and **10** proved to be reactive and were converted into Si—Br functions. Thus, refluxing of **8** in tribromomethane for 10 h gave 40% of dibromobis[tris(trimethylsilyl)silyl]silane (**9**). For the comparable replacement of hydrogen by bromine in **3** and **10** the solutions of the H-silanes in $HCBr_3$ had to be heated for several days. Nevertheless the conversions of **3** and **10** were incomplete and in case of the synthesis of **11**, we did not succeed in a clean separation of the starting compound **3** from the formed bromosilane. The bromosilane **12** was obtained in a yield of 70%.

The direct coupling of **1** with dichlorodimethylsilane (2:1) appears not to be a practicable method for the synthesis of dimethylbis(hypersilyl)silane (**5**). Independent of the molar ratio of the components, we always obtained chlorodimethyl[tris(trimethylsilyl)silyl]silane $((Me_3Si)_3SiSi(Cl)Me_2)$ (**13**) (8*e*, 11). Obviously, the steric situation in **13** prevents the replacement of the chlorine atom by a second hypersilyl group.

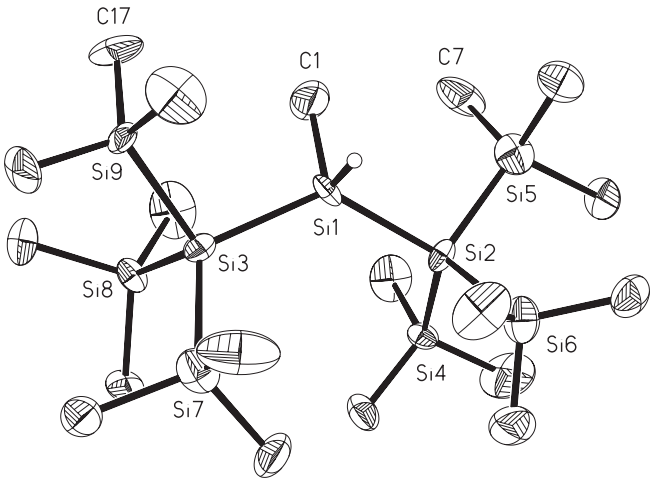
Selected bond lengths (Å): Si1—C1 1.784(9), Si1—Si2 2.374(9), Si1—Si3 2.360(10), Si2—Si4 2.343(8), Si2—Si5 2.350(8), Si2—Si6 2.362(9), Si3—Si7 2.375(11), Si3—Si8 2.370(8), Si3—Si9 2.381(6); and selected bond angles (deg): Si2-Si1-Si3 128.34(7), C1-Si1-Si2 113.0(5), C1-Si1-Si3 107.7(4), Si1-Si2-Si4 117.8(3), Si1-Si2-Si5 103.4(3), Si1-Si2-Si6 110.8(4), Si1-Si3-Si7 115.5(4), Si1-Si3-Si8 113.0(4), Si1-Si3-Si9 104.1(3); dihedral angles: Si2-Si1-Si3-Si7 48.9(7), Si2-Si1-Si3-Si8 78.1(6), Si2-Si1-Si3-Si9 166.1(5), Si3-Si1-Si2-Si4 49.6(7), Si3-Si1-Si2-Si5 164.7(5), Si3-Si1-Si2-Si6 80.2(6).



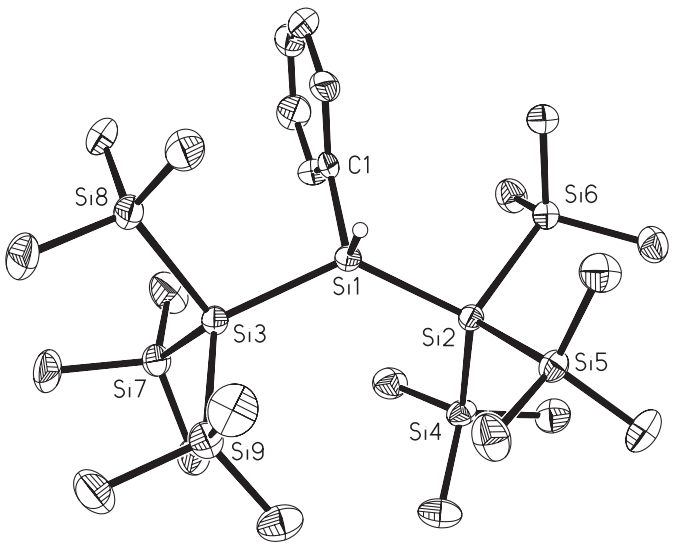


Fig. 2. Molecular structure of **10** in the crystal (ORTEP, 30% probability, H atoms omitted except for Si1 H). Selected bond lengths (Å): Si1—C1 1.891(9), Si1—Si2 2.380(3), Si1—Si3 2.390(3), Si2—Si4 2.359(3), Si2—Si5 2.369(3), Si2—Si6 2.368(3), Si3—Si7 2.371(3), Si3—Si8 2.373(3), Si3—Si9 2.354(4); and selected bond angles (deg): Si2-Si1-Si3 128.66(12), Si1-Si2-Si4 118.69(12), Si1-Si2-Si5 108.18(12), Si1-Si2-Si6 106.93(11), Si1-Si3-Si7 119.89(13), Si1-Si3-Si8 102.32(11), Si1-Si3-Si9 112.81(12); Si2-Si1-Si3-Si7 66.9(2), Si2-Si1-Si3-Si8 173.15(15), Si2-Si1-Si3-Si9 59.7(2), Si3-Si1-Si2-Si4 33.2(2), Si3-Si1-Si2-Si6 153.96(14), Si3-Si1-Si2-Si5 94.37(17).

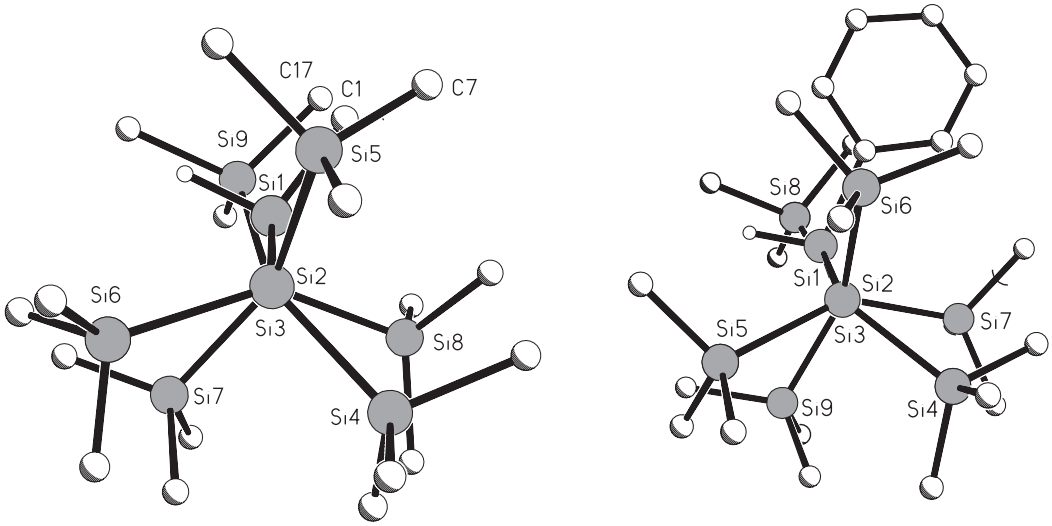
The structures of geminal bis(hypersilyl)silanes



The structures of the products obtained were elucidated by IR, NMR, and MS studies (see Experimental section). As found already for geminal bis(hypersilyl) carbon derivatives (9), in the ^{1}H, ^{13}C, and ^{29}Si NMR spectra of the synthesized bis(hypersilyl) silicon compounds (**8**–**12**) only one signal appeared for all trimethylsilyl substituents, indicating a considerable mobility of these groups in the congested molecules.

X-ray crystal structure analyses were performed for **3**, **10**, and **12**. Unfortunately, the crystal quality of **8** was insufficient for a structure determination. Thus, a direct comparison of the structural parameters of **8** with those of the carbon homologue $[(Me_3Si)_3Si]_2CH_2$ (9*d*) could not be realized. Crystals of **12** contained disordered acetone in special positions (origin of the unit cell), which impedes accurate results. In addition to this, experimental problems with the low-temperature device led to an unfinished ψ scan. So absorption correction calculations on the basis of experimental results could not be performed. Anyhow, the crystal structure of **12** was refined down to $R1 = 0.0661$ for the observed reflections when the structure of the solvent molecule was calculated with both distance and distant restraints as well as a restraint to force the acetone atoms in one plane. Thus, the constitution of **12** was confirmed and, e.g., the central Si-Si-Si angle could be determined to be 130.7°.

For a detailed discussion of molecular structures we have chosen compounds **3** and **10**. As expected, the results of the X-ray analyses of the two compounds, which are illustrated in Figs. 1 and 2, reveal considerable distortions of the molecular skeletons of these polysilanes. The structures are mainly determined by the two extended hemispherical hypersilyl groups, which are separated by a MeSiH or PhSiH unit, respectively, as spacers, causing the angles in the molecular axes of **3** and **10**. As expected, the spatial demand of the $(Me_3Si)_3Si$ substituents forces a widening of the Si-Si-Si angles at the central silicon atoms. In **10**, the small Si1-hydrogen atom and the phenyl ring, whose plain is arranged orthogonal to the line connecting the two central hypersilyl silicon atoms, allow the angle to open to a value of 128.66(12)°. The Si1—Si2 and Si1—Si3 bond distances in **10** (2.380(3) and 2.390(3) Å, respectively) are slightly elongated. The structural parameters obtained for **3** (Si2-Si1-Si3 angle 128.34(7)°, bond distances Si1—Si2 2.374(9) and Si1—Si3 2.360(10) Å, respectively) are comparable with those obtained for **10**, indicating that in these particular compounds the space demand of the methyl and the phenyl group is almost the same. As reported by Marschner (8*g*) for dimethylbis[tris(trimethylsilyl)silyl]silane (**5**), replacement of the hydrogen atom at the central silicon atom of **3** by a further methyl group leads to a decrease of the Si-Si-Si angle to a value of 125.7°, which is in agreement with the picture that increasing space demand of the further substituents at Si1 should reduce the $(Me_3Si)_3Si$-Si-Si-$Si(SiMe_3)_3$ angle. Actually, all the central Si-Si-Si angles of the bis(hypersilyl)silanes mentioned are extraordinarily wide, but increasing bulk of the substituents may lead to even wider angles. Thus, e.g., Lambert et al. (12) and Suzuki et al. (12) found the Si(1)-Si(2)-Si(3) angles in the dendritic polysilane $[(Me_3Si)_3Si(3)\text{-}Si(2)Me_2]_3Si(1)Me$ to amount to a value of 130.4°.

Fig. 3. Projection of the molecular structures of **3** and **10**, looking along the Si2—Si3 axes. Dihedral angles (deg): **3**: Si4-Si2-Si3-Si8 26.11(36), Si5-Si2-Si3-Si8 91.81(40), Si5-Si2-Si3-Si9 36.42(15), Si6-Si2-Si3-Si9 90.49(42), Si6-Si2-Si3-Si7 28.75(42), Si4-Si2-Si3-Si7 86.42(10); **10**: Si4-Si2-Si3-Si7 27.91(13), Si6-Si2-Si3-Si7 90.23(15), Si6-Si2-Si3-Si8 41.42(20), Si5-Si2-Si3-Si8 85.78(16), Si5-Si2-Si3-Si9 32.16(13), Si4-Si2-Si3-Si9 82.50(12).

3 **10**

A direct comparison of the Si-Si-Si angles of **3**, **5**, and **10** with the Si-C-Si angles of carbon centered bis(hypersilyl) compounds is not possible, since derivatives with an identical substitution pattern are not available. But the trend is obvious. Due to shorter Si—C bond distances, the angles at the central carbon atoms are even wider and correlate with the space demand of the further substituents at the carbon atom (e.g., Si-C-Si angles found for $[(Me_3Si)_3Si]_2CHR$: R = H 136.2(2)° (9*d*), R = OH 135.5(2)° (9*b*), R = OMe 132.7(4)° (9*a*), R = NMe_2 132.6(3)° (9*c*), R = OC(O)Me 131.3(2)° (9*e*), R = $N(CH_2)_5$ 128.7(2)° (9*c*)).

The steric strain in the molecules of **3** and **10** leads to considerable deformations of the usually tetrahedral configuration at the central Si atoms of the hypersilyl substituents. Thus, the average MeHSi-Si-$SiMe_3$ angles in **3** are 110.7° or 110.9°, respectively, but the individual angles differ markedly. At positions, where the two hypersilyl hemispheres contact each other, the angles are wider (Si1-Si2-Si4 117.8°, Si1-Si3-Si7 115.5°) and at the opposite positions the Me_3Si groups evade the steric strain making the angle much smaller (Si1-Si2-Si5 103.4°, Si1-Si3-Si9 104.1°). In **10** the situation is quite comparable, the average Si1-Si-Si angles are 111.3° and 111.7°, respectively, the angles Si1-Si2-Si4 (118.7°) and Si1-Si3-Si7 (119.9°) are considerably widened, consequently the angles Si1-Si2-Si6 (106.9°) and Si1-Si3-Si8 (102.3°) are compressed.

Very instructive is a view along the Si2—Si3 axes of **3** and **10**, which again reveals that the structure of the compounds is predominantly determined by the space filling trimethylsilyl groups of the two hypersilyl moieties, the bridging MeSiH and PhSiH groups playing a minor role. No trimethylsilyl group is in gauche conformation with Si1, since this, of course, would lead to an extreme approach of the Me_3Si groups in the anti positions (Fig. 3). At the positions, where the two hypersilyl hemispheres contact each other, the trimethylsilyl groups evade the steric strain by rotating the hypersilyl shells, opening the dihedral angle Si4-Si2-Si3-Si7 in **3** to a value of 86.4°. The dihedral angle Si4-Si2-Si3-Si9 in **10** was found to be 82.5°. Consequently the dihedral angles in the opposite positions, which frame the bridging Si1 atom and its substituents, become very small (**3**: Si5-Si2-Si3-Si9 36.4°; **10**: Si6-Si2-Si3-Si8 41.4°). As a result of that, in **3** the methyl group at Si1 and the neighboring groups of Me_3Si substituents approach to exceptionally short distances (C1—C7 3.31(3), C1—C17 3.51(3) Å). Due to the steric stress in the molecule, the methyl groups at the opposite positions of the hypersilyl hemispheres are also pressed together (C4—C13 3.80(1), C8—C13 3.89(3) Å), resulting in distances significantly shorter than the sum of the van der Waals radii of two methyl groups, which amounts to about 4.00 Å (13). Also in compound **10**, there are short distances between the *ortho* carbon atoms of the phenyl ring and some methyl carbon atoms in the wing groups, ranging from 3.46 Å for C2—C16 to 3.79 Å for C6—C21. Further dihedral angles characterizing the molecular structures of the polysilanes **3** and **10** are given in the captions of Figs. 1 and 2.

Experimental section

All reactions involving organometallic reagents were carried out under purified argon. NMR: Bruker AC 250 or Bruker ARX 300, tetramethylsilane as internal standard. IR: Nicolet 205 FT-IR. MS: Intectra AMD 402 (EI, 70 eV). $(Me_3Si)_3SiLi \cdot 3$ THF was prepared as reported in the literature (14). All yields given refer to amounts obtained after chromatographic separation and purification. Due to

© 2000 NRC Canada

incomplete combustion the results of the elemental analyses were unsatisfactory; therefore HRMS data are given.

Methylbis[tris(trimethylsilyl)silyl]silane (3)

At –78°C, 0.23 g (2.0 mmol) of dichloromethylsilane, dissolved in 20 mL of toluene, were added to a vigorously stirred solution of 1.85 g (4.0 mmol) of $(Me_3Si)_3SiLi \cdot 3$ THF in 20 mL of toluene. After warming up to room temperature, stirring was continued for 2 h and the solution was evaporated in vacuo. Recrystallization of the residue from ethyl acetate gave 0.75 g (71%) of pure **3**. Single crystals were obtained by recrystallization from toluene at –50°C, mp 188–191°C (under partial sublimation). IR (Nujol) $\tilde{\nu}$ (cm^{-1}): 2068 (SiH). MS (*m*/*z*) (%): 538 (1) [M^+], 523 (1) [M^+-CH_3], 464 (88) [M^+-$HSiMe_3$], 217 (100) [M^+-$HSi(SiMe_3)_3$]. ^{1}H NMR (benzene-d_6) δ: 0.35 (s, $Si(CH_3)_3$, 54 H), 0.59 (d, ^3J = 5.2 Hz, $SiCH_3$, 3 H), 4.24 (q, ^3J = 5.2 Hz, SiH, 1 H). ^{13}C NMR (benzene-d_6) δ: –0.4 (SiMe), 3.5 ($SiMe_3$). ^{29}Si NMR (benzene-d_6) δ: –124.7 (*Si*$SiMe_3$), –65.45 (d,^1J = 167.8 Hz, SiH), –9.1 ($SiMe_3$). HRMS calcd. ($C_{19}H_{58}Si_9$): 538.212; found: 538.246.

Bis[tris(trimethylsilyl)silyl]silane (8)

At 0°C, 0.78 g (5.2 mmol) of trifluormethanesulfonic acid were gradually added to a solution of 0.48 g of diphenylsilane in 20 mL of toluene. After warming up to room temperature, the solution was stirred for 3 h and subsequently given at –78°C within 30 min to 2.43 g (5.2 mmol) of $(Me_3Si)_3SiLi \cdot 3$ THF, dissolved in 20 mL of toluene. The mixture was allowed to warm again to room temperature and after stirring for a further 2 h and filtration over silica gel the solvent was removed in vacuo. Chromatography of the residue (silica gel, heptane) gave 0.26 g (19%) of **8**, mp 172–176°C (under partial sublimation). IR (KBr) $\tilde{\nu}$ (cm^{-1}): 2074 (SiH). MS (CI, isobutane as the reactant gas) (*m*/z) (%): 525 (1) [M^+-H], 509 (0.5) [M^+-CH_3], 450 (17) [M^+-$HSiMe_3$], 376 (100) [M^+-2 ($HSiMe_3$)], 303 (52) [M^+- 2($HSiMe_3$)-$SiMe_3$]. ^{1}H NMR (benzene-d_6) δ: 0.35 (s, $SiCH_3$, 54 H), 3.60 (s, SiH_2, 2 H). ^{13}C NMR (benzene-d_6) δ: 2.59 ($SiCH_3$). ^{29}Si NMR (benzene-d_6) δ: = –131.5 (*Si*$SiMe_3$), –107.3 (t, ^1J = 169.5 Hz, SiH_2), – 9.1 ($SiMe_3$). HRMS studies could not be performed. HRMS measurements with chemical ionization were not possible, and under EI conditions no molecular peak was found.

Dibromobis[tris(trimethylsilyl)silyl]silane (9)

A solution of 0.17 g (0.3 mmol) of **8** in 2 mL of bromoform was refluxed for two days. Evaporation and chromatographic purification of the residue (silica gel, heptane) gave 0.08 g (40%) of **9**, sublimation beginning at 160°C. MS (*m*/z) (%): 665 (14) [M^+-CH_3], 608 (9) [M^+-$SiMe_3$], 528 (43) [M^+-$BrSiMe_3$], 354 (46) [M^+-$BrSi(SiMe_3)_3$], 73 (100) [$SiMe_3^+$]. ^{1}H NMR (benzene-d_6) δ: 0.43 (s, $SiCH_3$). ^{13}C NMR (benzene-d_6) δ: 3.68 ($SiCH_3$). ^{29}Si NMR (benzene-d_6) δ: –88.2 (*Si*$SiMe_3$), –7.9 ($SiMe_3$), 32.9 ($SiBr_2$). HRMS calcd. ($C_{17}H_{51}Br_2Si_9$): 665.045; found: 665.028.

Phenylbis[tris(trimethylsilyl)silyl]silane (10)

As described for the preparation of **3**, 1.80 g (3.8 mmol) of $(Me_3Si)_3SiLi \cdot 3$ THF and 0.34 g (1.9 mmol) of dichlorophenylsilane gave, after recrystallization from acetone, 0.82 g (71%) of **10**, mp 223–225°C (under partial sublimation). IR (Nujol) $\tilde{\nu}$ (cm^{-1}): 2065 (SiH). MS (*m*/z) (%): 600 (5) [M^+], 526 (21) [M^+-$HSiMe_3$], 353 (94) [M^+-$Si(SiMe_3)_3$], 279 (100) [M^+-$Si(SiMe_3)_3$-$SiMe_3$], 247 (10) [$Si(SiMe_3)_3^+$]. ^{1}H NMR (benzene-d_6) δ: 0.29 (s, $SiCH_3$, 54 H), 4.83 (s, SiH, 1 H), 7.06–7.08, and 7.67–7.70 (m, arom. H, 5 H). ^{13}C NMR (benzene-d_6) δ: 3.42 ($SiCH_3$), 128.12, 128.71, 137.21, and 138.45 (arom. C). ^{29}Si NMR (benzene-d_6) δ: –123.5 (*Si*$SiMe_3$), –54.7 (d, ^1J = 169.5 Hz, SiH), –9.0 ($SiMe_3$). HRMS calcd. ($C_{24}H_{60}Si_9$): 600.246; found: 600.261.

Bromophenylbis[tris(trimethylsilyl)silyl]silane (12)

0.50 g of **10** were dissolved in 5 mL of bromoform and heated under reflux. The progress of the reaction was monitored by means of ^{1}H NMR spectroscopy. After 3–5 days the conversion was complete. The solution was evaporated and the residue recrystallized from acetone to give 0.4 g (68%) of **12**, mp > 230°C (under partial sublimation). MS (*m*/z) (%): 663 (21) [M^+-CH_3], 605 (8) [M^+-$SiMe_3$], 526 (6) [M^+-$BrSiMe_3$], 433 (100) [M^+-$Si(SiMe_3)_3$]. ^{1}H NMR (benzene-d_6) δ: 0.32 (s, $SiCH_3$, 54 H), 7.00–7.13 and 7.84–7.88 (m, arom. H, 5 H). ^{13}C NMR (benzene-d_6) δ: 3.92 ($SiCH_3$), 128.29, 129.18, 135.05 and 138.40 (arom. C). ^{29}Si NMR (benzene-d_6) δ: –105.2 (*Si*$SiMe_3$), –8.3 ($SiMe_3$), 10.6 (SiBrPh). HRMS calcd. (for M^+-CH_3, $C_{23}H_{56}BrSi_9$): 663.148; found: 663.142.

Crystal structure determination of 3, 10, and 12

The X-ray diffraction results were obtained on a Siemens P4 four circle diffractometer with monochromated Mo-K_α radiation. After taking rotational photos and determining reasonable reduced cells, a data collection was started in routine ω-scan. The structures were solved with direct methods (SHELXTL, Siemens Analytical X-ray Instruments Inc., 1990) and refined with the full-matrix least-squares method of SHELXL-97 (Bruker, SHELXL, 1997, Bruker Analytical X-ray Systems). All non-hydrogen atoms were refined anisotropically whereas the hydrogen atoms were put into theoretical positions and refined according to the riding model. For the presentation of ORTEP plots the Bruker SHELXTL graphical software was used.

Crystallographic data (Table 1) (excluding structure factors) for the structures reported in this paper can be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, Canada K1A OS2 (http://www.nrc.ca/cisti/irm/unpub_e.shtml for information on ordering electronically). This material has also been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC-121792 for **3**, CCDC-121793 for **10**, and CCDC-121793 for **12**. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. (Fax: 44-1223-336033 or e-mail: deposit@ccdc.cam.ac.uk).

A novel route to chlorodimethylsilane

Jerzy J. Chruściel

Abstract: A new efficient laboratory method of preparation of chlorodimethylsilane ($Cl(CH_3)_2SiH$) has been elaborated, which is a modification of the Eaborn et al. method (34) and is based on a *transsilylation reaction of substituted (amino)dimethylhydrosilanes, R_2NSiMe_2H* (R_2 = Me_2, Et_2, $(CH_2)_n$, etc.) with *dimethyldichlorosilane (Me_2SiCl_2)*. The reaction proceeds at reflux, at 70°C, preferably with an excess of Me_2SiCl_2. The most important feature of this novel method is a recovery of intermediate (amino)chlorodimethylsilanes (R_2NSiMe_2Cl), which can be again reduced to R_2NSiMe_2H. *The transsilylation mechanism* has been proven by reaction of (diethylamino)methylphenylsilane with Me_2SiCl_2. The products of this latter reaction are HMePhSiCl and R_2NSiMe_2Cl, thus a disproportionation mechanism has been excluded. New substituted bis(amino)dimethylsilanes ($(R_2N)_2SiMe_2$), (amino)dimethylchlorosilanes (R_2NSiMe_2Cl), and (amino)dimethylhydrosilanes (R_2NSiMe_2H) have been synthesized and characterized by NMR and IR.

Key words: chlorodimethylsilane, $(CH_3)_2SiHCl$, synthesis, new laboratory method, transsilylation mechanism.

Résumé : On a développé une nouvelle méthode de préparation du chlorodiméthylsilane, $Cl(CH_3)_2SiH$, efficace au niveau du laboratoire. Il s'agit d'une modification de la méthode de Eaborn et al. (34) et elle est basée sur une réaction de transsilylation de (amino)diméthylhydrosilanes substitués, R_2NSiMe_2H (R_2 = Me_2, Et_2, $(CH_2)_n$, etc.). Avec le diméthyldichlorosilane, Me_2SiCl_2. La réaction se produit à reflux, à 70°C, de préférence dans un excès de Me_2SiCl_2. La caractéristique la plus importante de cette nouvelle méthode est la récupération des intermédiaires (amino)chlorodiméthylsilanes, $R_2NSiMe_2Cl_2$, qui peuvent être soumis à une nouvelle réduction pour donner du R_2NSiMe_2H. On a démontré le mécanisme de transsilylation par la réaction du (diéthylamino)méthylphénylsilane avec le Me_2SiCl_2. Les produits de cette dernière réaction sont le HMePhSiCl et le R_2NSiMe_2Cl qui permettent d'exclure la possibilité d'une réaction de dismutation. On a synthétisé de nouveaux bis(amino)diméthylsilanes, $(R_2N)_2SiMe_2$, (amino)diméthylchlorosilanes, R_2NSiMe_2Cl, et (amino)diméthylhydrosilanes, R_2NSiMe_2H, que l'on a caractérisés par RMN et IR.

Mots clés : chlorodiméthylsilane, $(CH_3)_2SiHCl$, synthèse, nouvelle méthode de synthèse, mécanisme de transsilylation.

[Traduit par la Rédaction]

Introduction

Chlorodimethylsilane ($(H)Me_2SiCl$) (CDMS) is a very useful and valuable organosilicon monomer and reagent, bearing two different functional groups: ≡Si-Cl and ≡Si-H. The ≡Si-Cl bond can react with Grignard and organolithium reagents, or undergo alcoholysis and hydrolysis reactions. The ≡Si-H group enables preparation of complex derivatives, mainly through hydrosilylation reaction. HMe_2SiCl finds many synthetic applications in organosilicon synthesis and silicone technology (2–6), as well as in general polymer chemistry (7–12). Most often HMe_2SiCl is used in a preparation of 1,1,3,3-tetramethyldisiloxane ($HMe_2SiOSiMe_2H$), other Si-H terminated polysiloxanes (13–20), and multifunctional hydrosiloxanes (e.g., $Si(OSiMe_2H)_4$ (11), octa(hyridodimethylsiloxy)octasilsesquioxane $(HMe_2SiOSiO_{3/2})_8$ (21–23)), or hydropolysilanes (e.g., $Si(SiMe_2SiH)_4$ (24–27) and *o*-(bisdimethylsilyl)benzene (28)).

Yields of HMe_2SiCl in an industrial "direct process" (from elemental silicon and methyl chloride) are poor, usually 0.1–1% (29–31), although, when H_2 was added to the methyl chloride gas phase, yields can be significantly improved up to 8% (32), or 2.2–33% (33), depending on reaction conditions.

Many synthetic methods lead to chlorodimethylsilane, but some are unattractive due to expense and unavailability of intermediates. In the present paper a new laboratory procedure for preparation of HMe_2SiCl is described, which is a modification of the Eaborn et al. (34) method. The key of our method is a transsilylation of substituted (amino)dimethylhydrosilanes R_2NSiMe_2H with dimethyldichlorosilane Me_2SiCl_2.

Received September 21, 1999. Published on the NRC Research Press website on October 20, 2000.

This paper is dedicated to Professor Adrian G. Brook, very distinguished organosilicon and organic chemist, and my briliant teacher, on the occasion of his 75th birthday. In 1982–83 Professor A.G. Brook gave me a chance to join his research group, at the Department of Chemistry of the University of Toronto. In the Lash Miller Chemical Laboratories I had the pleasure to continue studies on a very well known Brook rearrangement, work out some details of its mechanism, and discover a new silyl anion rearrangement (1). I have learned a lot from Professor Adrian G. Brook, who opened for me a world of international science, and I will be always grateful to him.

Experimental

General procedures

All reactions were carried out under an atmosphere of dry nitrogen. Most of the substrates and reaction products were distilled through a Vigreux column (120 cm).

NMR spectra were determined with Tesla BS-487C (80 MHz) and Bruker MSL-300 (300 MHz); ~10% solutions of studied silanes in CCl_4, $CDCl_3$, or CD_2Cl_2 were used. Infrared spectra were recorded for neat samples on a Carl Zeiss Jena 75R spectrometer.

Reagents

Dimethyldichlorosilane (70.5–71.0°C) and methyltrichlorosilane (66°C) were purified by fractional distillation. Diethylamine (POCh, Gliwice, Poland), triethylamine (POCh), pyrrolidine (Aldrich), piperidine (Loba Chem.) were dried with KOH (POCh) and purified by distillation over small amounts of P_2O_5 (POCh). Dimethylamine (Fluka), magnesium (POCh), and lithium aluminium hydride (Aldrich) were used as received. Bromobenzene (POCh) was distilled over CaH_2 (Aldrich). Diethyl ether and tetrahydrofuran were dried with KOH and distilled over fresh sodium wire. Methylphenyldichlorosilane was prepared by a Grignard method (35), from $MeSiCl_3$ and PhMgBr, in ether, and fractionally distilled (bp 103–104°C/20 mmHg).

Bis(diethylamino)dimethylsilane

Bis(diethylamino)dimethylsilane (142.2 g, yield 85%) was prepared from 2.9 mol of diethylamine and 0.7 mol of Me_2SiCl_2, in dry ether (36, 37). Solution of Me_2SiCl_2 was added dropwise to a stirred solution of Et_2NH in 1300 mL of Et_2O, followed by reflux for 7 h. The reaction mixture was left overnight. A precipitate of diethylamine hydrochloride was filtered off and washed with dry ether. The product was fractionally distilled (bp 86°C/20 mmHg).

Preparation of (diethylamino)dimethylchlorosilane

Into a 500 mL four-neck flask, fitted with a condenser and a mechanical stirrer, was placed 116.3 g (0.575 mol) of bis(diethylamino)dimethylsilane. Stirring was turned on and the substrate was cooled down to –5°C. 70 mL (0.578 mol) of Me_2SiCl_2 was added dropwise from an addition funnel, at –5°C, within 2 h. The cooling bath was removed and stirring was continued at room temperature for 6 h. The products were fractionally distilled to give 152.4 g (80% yield) of Et_2NSiMe_2Cl (bp 152°C) (36, 37).

Preparation of (diethylamino)dimethylsilane

(*a*) Into a 500 mL four-neck flask, fitted with a condenser and a mechanical stirrer, was placed 10.63 g (0.28 mol) of $LiAlH_4$ and 250 mL of dry ether. 148.5 g (0.90 mol) of (diethylamino)dimethylchlorosilane in 80 mL of dry ether was added dropwise from an addition funnel, within 1.5 h. The reaction mixture was refluxed for 2.5 h, and cooled to room temperature. Solids were filtered off and washed with dry ether. Fractional distillation of the filtrate gave 94.0 g (80% yield) of Et_2NSiMe_2H (bp 110–111°C).

(*b*) Similarly, from 5.43 g (0.14 mol) of $LiAlH_4$ and 75.7 g (0.46 mol) of (diethylamino)dimethylchlorosilane, with 170 mL of dry ether, after 4 h of reflux and an identical work-up 37.9 g (63% yield) of Et_2NSiMe_2H was obtained.

Reaction of (diethylamino)dimethylsilane with dimethyldichlorosilane

(*a*) Into a 250 mL two-neck flask was placed 74.4 g (0.567 mol) of (diethylamino)dimethylsilane and 74.0 g (0.573 mol) of dimethyldichlorosilane. The reaction flask was connected to a Vigreux column and heated to reflux. A fraction of HMe_2SiCl (containing traces of Me_2SiCl_2) was continously distilled and collected to give 40.8 g (76% yield) of HMe_2SiCl (bp 36°C). Distillation of the reaction flask residue gave 74.8 g (80% yield) of Et_2NSiMe_2Cl (bp 152°C).

(*b*) A similar reaction of 33.0 g (0.252 mol) of (diethylamino)dimethylsilane was carried out with double excess of dimethyldichlorosilane (61 mL, 0.573 mol). 20 mL of Me_2SiCl_2 was added to a flask containing Et_2NSiMe_2H, the reagents were heated to reflux under Vigreux column, and the remaining amount of Me_2SiCl_2 was added dropwise at reflux. Products were recovered by distillation: (*i*) 20.7 g (87% yield) of HMe_2SiCl (bp 36°C); and (*ii*) 37.7 g (90% yield) of Et_2NSiMe_2Cl (bp 152°C) were obtained.

Preparation of bis(pyrrolidino)dimethylsilane

Into a four-neck 2.5 L sulphonation reactor, fitted with a condenser and a mechanical stirrer, was added 126 mL (1.04 mol) of Me_2SiCl_2, 309 mL (2.22 mol) of Et_3N, and 1800 mL of dry ether. 175 mL (2.10 mol) of dry pyrrolidine was added dropwise, within 2 h. A precipitate of triethylamine hydrochloride was filtered off and washed with dry ether (3 × 100 mL). The ether was distilled off and the residue was distilled to give $[(CH_2)_4N]_2SiMe_2$ (73% yield, bp 107–110°C/15 mmHg).

Preparation of (pyrrolidino)dimethylchlorosilane

(*a*) Into a 500 mL four-neck flask, fitted with a condenser and a mechanical stirrer, was placed 90.9 g (0.458 mol) of bis(pyrrolidino)dimethylsilane. The substrate was cooled to –10°C and 56 mL (2.10 mol) of Me_2SiCl_2 was added dropwise, within 2 h. Stirring was continued at –5°C for 4 h and reaction mixture was left overnight. Products were fractionally distilled to give 123.1 g (82% yield) of $(CH_2)_4NSiMe_2Cl$ (bp 80–81°C/40 mmHg).

(*b*) Into a four-neck 1.5 L sulphonation reactor, fitted with a condenser and mechanical stirrer, was added 124 mL (1.02 mol) of Me_2SiCl_2, 139 mL (1.00 mol) of Et_3N, and 900 mL of dry ether. 83.5 mL (1.00 mol) of dry pyrrolidine was added dropwise, within 2 h. Reaction mixture was stirred and refluxed for 2 h, and cooled to room temperature. Triethylamine hydrochloride was filtered off and washed with dry ether (2 × 150 mL). Ether was distilled off and a residue was distilled to give 72.8 g (44% yield) of $(CH_2)_4NSiMe_2Cl$ (bp 60–62°C/15 mmHg).

Preparation of (pyrrolidino)dimethylsilane

Into a 500 mL four-neck flask, fitted with a condenser and a mechanical stirrer, was placed 7.50 g (0.197 mol) of $LiAlH_4$ and 200 mL of dry ether. 64.3 g (0.393 mol) of $(CH_2)_4NSiMe_2Cl$ in 70 mL of dry ether was added dropwise, within 40 min. The reaction mixture was refluxed for 4 h,

© 2000 NRC Canada

cooled to room temperature, and left overnight. Solids were filtered off, washed with dry ether. The filtrate was fractionally distilled to give an ether fraction and 21.8 g (43% yield) of $(CH_2)_4NSiMe_2H$ (bp 47–48°C/40 mmHg).

Reaction of (pyrrolidino)dimethylsilane with dimethyldichlorosilane

Into a 250 mL two-neck flask was placed 18.1 g (0.14 mol) of (pyrrolidino)dimethylsilane and 34 mL (0.28 mol) of dimethyldichlorosilane. The reaction flask was heated to reflux, and HMe_2SiCl (with traces of Me_2SiCl_2) was continously distilled off through a Vigreux columnto give 9.0 g (68% yield) of HMe_2SiCl (bp 36°C). Distillation of the residue gave $(CH_2)_4NSiMe_2Cl$ (17.1 g, 74% yield; bp 80–81°C/40 mmHg).

Preparation of (diethylamino)methylphenylchlorosilane

Into a 1.5 L four-neck reactor, fitted with a condenser and a mechanical stirrer, was placed 116.3 mL (0.72 mol) of methylphenyldichlorosilane and 900 mL of dry ether. 151 mL (1.46 mol) of Et_2NH was added dropwise, within 5 h, followed by reflux for 2 h. On the next day a precipitate of $Et_2NH{\cdot}HCl$ was filtered off (under nitrogen) and washed three times with ether. After removal of ether, the liquid residue was distilled to give 130.2 g (79% yield) of $Et_2NSiMePhCl$ (bp 108–110°C/5 mmHg).

Preparation of (diethylamino)methylphenylsilane

Into a 0.5 L three-neck flask, fitted with a condenser and a mechanical stirrer, was placed 5.50 g (0.145 mol) of $LiAlH_4$ and 90 mL of dry THF. 65.8 g (0.289 mol) of (diethylamino)methylphenylchlorosilane in 70 mL of dry THF was added dropwise, within 30 min. The reaction mixture was refluxed for 4 h, and cooled to room temperature. Solids were filtered off and washed with dry pentane (3 × 30 mL). Solvents were removed and the residue fractionally distilled to give 7.5 g of $MePhSiH_2$ (bp 25–26°C/5 mmHg; n_D^{20} = 1.5051 (Lit. (38) value: 1.5058) and 52.2 g (58% yield) of $Et_2NSiMePhH$ (bp 87–90°C/5 mmHg).

Reaction of (diethylamino)methylphenylsilane with dimethyldichlorosilane

Into a 250 mL two-neck flask was added 13.75 g (0.071 mol) of (diethylamino)methylphenylsilane. 17 mL (0.140 mol) of Me_2SiCl_2 was added dropwise at ~30°C. Reaction mixture was heated to reflux and then fractionally distilled through a Vigreux column. Four fractions were collected and analyzed by means of ^1H NMR (and IR): (1) bp 69–72°C (11.5 g, Me_2SiCl_2); (2) bp 82–86°C/63 mmHg (4.9 g, ~95% of Et_2NSiMe_2Cl and ~5% of HMePhSiCl); (3) bp 97–115°C/65 mmHg (7.2 g, 35% of Et_2NSiMe_2Cl and 65% of HMePhSiCl); (4) bp 130–140°C/64 mmHg (7.0 g, 70% of $Et_2NSiMePhH$ (conversion 64.4%)); and 30% of HMePhSiCl). Contents of the above fractions are based on integrations of their ^1H NMR spectra (80 MHz, in CCl_4).

Analytical data for the products

HMe_2SiCl

Boiling point 36.0°C. IR (neat (cm^{-1})): 2170 (Si-H). ^1H NMR (80 MHz, δ (ppm)), in $CDCl_3$): 0.50 (d, 6H, $(CH_3)_2Si$), 4.88 (sept., 1H, Si-H); in CCl_4: 0.45 (d, J = 3.0 Hz, 6H, $(CH_3)_2Si$), 4.80 (sept., J = 3.0 Hz, 1H, Si-H).

Et_2NSiMe_2Cl

Boiling point 152–154°C. ^1H NMR: 0.38 (s, 6H, $(CH_3)_2Si$), 0.98 (t, J = 7 Hz, 6H, CH_3-C), 2.85 (q, J = 7 Hz, 4H, CH_2-N).

$Et_2NSiMe_2(H)$

Boiling point 111–112°C. IR (neat (cm^{-1})): 2120 (Si-H). ^1H NMR (300 MHz, $CDCl_3$, δ (ppm)): 0.185 (d, 6H, J = 2.79 Hz, $(CH_3)_2Si$), 1.11 (t, 6H, J = 7.14 Hz, CH_3-C), 2.65 (q, 4H, J = 7.15 Hz, CH_2-N), 4.68 (sept., 1H, J = 2.78 Hz, Si-H). ^{13}C NMR: –1.49 (s, CH_3-Si), 15.63 (s, CH_3), 41.00 (s, CH_2-N). ^{29}Si NMR: –7.77 (s).

$Et_2NSiMePhCl$

Boiling point 136–140°C/25 mmHg, 108–110°C/5 mmHg. n_D^{20} 1.5073. IR (neat (cm^{-1})): 3068, 1800–2000, 1588 (Ph), 1426 (Si-Ph), 1253 (Si- CH_3), 2966, 2927, 2866 (C-H aliphat.), 1202, 1166, 1055 (C-N), 1028, 931 (Si-N), 640, 460, 413 (Si-Cl). ^1H NMR (80 MHz, CCl_4, δ (ppm)): 0.79 (s, 3H, CH_3-Si), 1.21 (t, J = 6.4 Hz, 6H, CH_3-C), 3.08 (q, J = 6.4 Hz, 4H, CH_2-N), 7.47–7.65 (m, 3H (Ph, *m*-, *p*-)), 7.8–8.0 (m, C-H (Ph, *o*-)). ^{13}C NMR (300 MHz, $CDCl_3$, δ (ppm)): 1.63 CH_3-Si, 15.12 CH_3-C, 39.37 CH_2-N, 128.06, 130.06, 134.32, 135.14 (Ph). Anal. calcd. (%): C 57.99, H 7.96, N 6.14, Cl 15.56; found (%): C 57.59, 57.59, H 8.02, 8.14, N 5.83, 5.63, Cl 15.16, 15.38.

$Et_2NSiMePh(H)$

Boiling point 115–117°C/21 mmHg, 86–89°C/5 Tr. n_D^{20} 1.4969. IR (neat (cm^{-1})): 3067, 1800–2000, 1591 (Ph), 1428 (Si-Ph), 1252 (Si- CH_3), 2965, 2927, 2864 (C-H aliphat.), 2126, 2085 (Si-H), 1211, 1180, 1065 (C-N), 1028, 931 (Si-N), 1030, 930 (Si-N). ^1H NMR (80 MHz, CCl_4, δ (ppm)): 0.33 (d, J = 3.2 Hz, 3H, CH_3-Si), 0.94 (t, J = 7 Hz, 6H, CH_3-C), 2.82 (q, J = 7 Hz, 4H, CH_2-N), 4.80 (q, J = 3.2 Hz, 1H, Si-H), 7.25 (m, 3H (Ph, *m*-, *p*-)), 7.50 (m, C-H (Ph, *o*-)). Anal. calcd. (%): C 68.33, H 9.90, N 7.24; found (%): C 67.63, 67.56, H 9.86, 9.89, N 6.67, 6.83.

HMePhSiCl

Boiling point 174–176°C, bp 92–95°C/65 mmHg. n_D^{20} 1.5073. IR (neat (cm^{-1})): 2170 (Si-H). ^1H NMR (80 MHz, $CDCl_3$, δ (ppm)): 0.65 (d, J = 3.4 Hz, 3H, CH_3-Si), 5.25 (q, J = 3.4 Hz, 1H, Si-H), 7.35 (m (t), 3H, Ph (*m*-, *p*-), 7.55 (m (d), 2H, Ph (*o*-)).

$[(CH_2)_4N]_2SiMe_2$

Boiling point 107–110°C/15 mmHg. n_D^{20} 1.4682. ^1H NMR (80 MHz, CCl_4, δ (ppm)): 0.24 (s, 6H, $(CH_3)_2Si$), 1.46 (m, 4H, $(CH_2)_2$), 2.73 (m, 4H, $(CH_2)_2N$). ^{13}C NMR (300 MHz, $CDCl_3$, δ (ppm)): –3.33 CH_3-Si, 26.61 $(CH_2)_2$, 46.73 $(CH_2)_2N$. Results and discussion

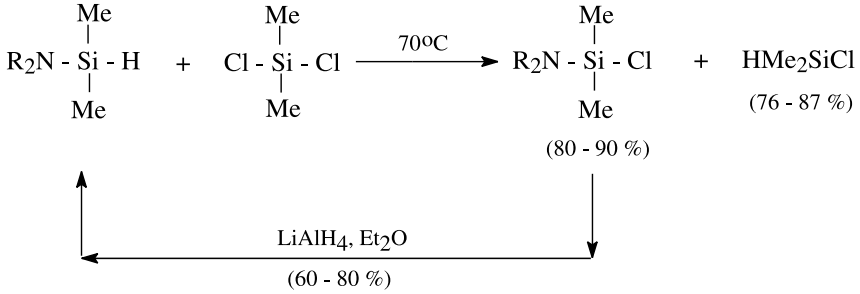
Since yields of chlorodimethylsilane obtained in a direct Rochow and Müller process are very low, many attempts have been made to find new efficient synthetic methods, especially useful on a laboratory scale. HMe_2SiCl has been prepared by the following methods: (*i*) the direct synthesis from elemental silicon and methyl chloride (29–33, 39–44); (*ii*) Grignard reaction between $MeHSiCl_2$ and MeMgBr (45); (*iii*) selective reduction of dimethyldichlorosilane Me_2SiCl_2 (DDS) with Na_3AlH_6, NaH, $NaBH_4$, $LiAlH_4$ (46–49), Et_3Al (50), or $Me_2SiCl(OMe)$ with i-Bu_2AlH (51), and Me_2NSiMe_2Cl with $LiAlH_4$ (followed by cleavage of the intermediate silane with HCl) (34); (*iv*) disproportionation of hydrochlorosilanes (52) or organohydrosilanes and -siloxanes with chlorosilanes (53–59); (*v*) cleavage of $HMe_2SiOSiMe_2H$ with HCl (60, 61), HCl and $AlCl_3$ (62), BCl_3 (63), and polymethylhydrolsiloxanes with Me_2SiCl_2, catalyzed by BF_3, n-Bu_4NCl, BCl_3 and HMPT (64); and with $MeSiCl_3$, Me_2SiCl_2, $PhSiCl_3$, catalyzed by HMPT and HCl (65); (*vi*) photolytic cleavage of polydimethylsilanes (66) and Me_3SiMe_2SiCl (67) with HCl; cleavage of disilanes with HCl towards phosphine–nickel complexes (68) and hydrogenation of chlorodisilanes obtained from the direct process, with copper catalysts (69) and phosphine–nickelocene (and nickel) complexes (70, 71); (*vi*) selective (and quantitative) chlorination of Me_2SiH_2 with $SnCl_4$ (72).

All of these procedures have limitations. Mainly due to safety precautions, the application of metal hydrides is limited to a relatively small scale. According to Eaborn (2) partial reduction of organohalogenosilanes with $LiAlH_4$ is not possible. Reductions of Me_2SiCl_2 with NaH afforded low yields of HMe_2SiCl: 11–17% (46) or 38% (at 150°C) (47). Reduction of Me_2SiCl_2 with Et_3Al, in c-C_6H_{12}, at 500°C, requires very short reaction time (1 s) and gives 17.7% of CDMS (50). Although reduction of DDS with i-Bu_2AlH, carried out at high temperature (at 330°C), gave 76% of CDMS (73). Also reaction of $Me_2Si(OMe)Cl$ with i-Bu_2AlH, at –23°C, gave good, 83% yield of CDMS. Similar reduction of DDS with $NaBH_4$ in HMPT, at 50°C, within 2 h, gave 71% yield of HMe_2SiCl (50). The symmetrical 1,1,3,3-tetramethyldisiloxane cannot be recommended as a substrate for the preparation of chlorodimethylsilane, and $HMe_2SiOSiMe_2H$ is synthesized from HMe_2SiCl. Synthesis of polydimethylsilanes is difficult, and the photolysis is limited to a small scale, requiring a special apparatus. The gaseous dimethylsilane and $SnCl_4$ are expensive substrates as well. The above reasons encouraged us to search for a new laboratory method of synthesis of HMe_2SiCl.



Our new method of preparation of Me_2SiHCl (74, 75) is a modification of the Eaborn et al. method (34), which involves the reduction of the Si—Cl bond to the Si—H bond, in the presence of the Si—N bond:

[1] 

and a subsequent cleavage of of the Si-N bond with gasous hydrogen chloride

[2] 

Our method is based on reaction of (dialkylamino)dimethylhydrosilanes (R_2NSiMe_2H) with dimethyldichlorosilane

[3] 

© 2000 NRC Canada

[4] $$2\,R_2NH + Me_2SiCl_2 + Et_3N \xrightarrow[25\text{ - }35^oC]{Et_2O} Me_2Si(NR_2)_2 + 2\,Et_3N{\cdot}HCl$$

As a single step, the yield of chlorodimethylsilane was in the range 76–87%, with respect to Et_2NSiMe_2H. The overall yield of four-step (or three-step) reaction, including synthesis of Et_2NSiMe_2Cl (see rxns. [4]–[6]), its reduction to (diethylamino)dimethylsilane, followed by reaction (3) with Me_2SiCl_2, ranged from 45 to 58%. However, intermediate Et_2NSiMe_2Cl and other (dialkylamino)dimethylchlorosilanes R_2NSiMe_2Cl were recovered, in a high yield (80–90%), and may be used again for synthesis of $HSiMe_2Cl$, after reduction with $LiAlH_4$. When we are considering the recovery of R_2NSiMe_2Cl, the overall yields of HMe_2SiCl are much higher (within the range of 150–240% (!!!)), than yields calculated for the single step reaction (3).

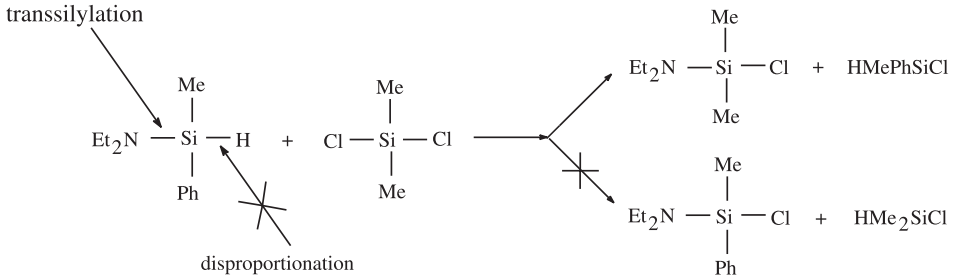
The starting (amino)chlorosilanes can be prepared either in two steps (36, 37)

[5] $$Me_2Si(NR_2)_2 + Me_2SiCl_2 \xrightarrow[-5\text{ - }0^oC]{Et_2O} \underset{\sim 85\ \%}{2\,R_2N\text{-}Me_2Si\text{-}Cl}$$

or in one step (36, 37)

[6] $$R_2NH + Me_2SiCl_2 + Et_3N \xrightarrow[-5\text{ - }0\ ^oC]{Et_2O} R_2N\text{-}Me_2Si\text{-}Cl$$

Alternatively a secondary amine can be used as an HCl acceptor.



(Dialkylamino)chlorodimethylsilanes were reduced with excess $LiAlH_4$ in dry ether (or THF) at reflux. Yields of R_2NSiMe_2H depend on reaction time, and amount of reducing agent. Longer reaction times lead to lower yields, presumably due to reduction of Si—N bond; for Et_2NSiMe_2H: 80% after 2.5 h and 63% after 4 h (crude yields). Yields of reduction of $(CH_2)_4NSiMe_2Cl$ with $LiAlH_4$ were lower than in reduction of Et_2NSiMe_2Cl. Presumably a steric hinderance in this case diminishes the cleavage of the Si—N bond as a side reaction. In the case of reduction of $Et_2NSiMePh(Cl)$, small amounts of $MePhSiH_2$ were isolated. It has been reported (76), that (dimethylamino)trichlorosilane and bis(dimethylamino)dichlorosilane are reduced to monosilane SiH_4, as a result of the cleavage of Si—N bonds.

The final step of the synthesis of HMe_2SiCl, reaction of substituted (amino)dimethylchlorosilanes with Me_2SiCl_2, was carried out at reflux (~70°C), using a fractionation Vigreux column. During dropwise addition of Me_2SiCl_2 to Et_2NSiMe_2H, crude HMe_2SiCl was distilled off. When stoichiometric amounts of both substrates were used the reaction began at reflux and it was quite vigorous (a bleeding of the column appeared); thus 76% of CDMS was obtained. With excess Me_2SiCl_2, the yield of HMe_2SiCl reached 87%. Other substituted (amino)dimethylsilanes (R_2 = Me_2, n-Bu_2, $(CH_2)_5$), can be used for the synthesis of HMe_2SiCl, in the same manner.

Reaction mechanism

The Si—N bond (bond energy: 335 kJ/mol (77)) is slightly weaker than that of the Si—H bond (377 kJ/mole (78)). Thus it seems that reaction of (amino)dimethylsilanes ($R_2NSiMe_2(H)$) with Me_2SiCl_2 proceeds through a transsilylation mechanism, with a cleavage of the Si—N bond, rather than through a *disproportionation mechanism*, which would require breaking of the Si—H bond, in the aminosilane substrate. To prove this mechanism, $Et_2NSiMePhH$ was reacted with Me_2SiCl_2 to yield methylphenylchlorosilane (HMePhSiCl) and Et_2NSiMe_2Cl

[7]

The formation of HMePhSiCl confirms that the reaction of $Et_2NSiMePh(H)$ with Me_2SiCl_2 proceeds through the transsilylation mechanism, with the cleavage of the Si—N bond. The alternative disproportionation process, which would require breaking of the Si—H bond, would give $Et_2NSiMePhCl$ and $HSiMe_2Cl$, as reaction products. $HSiMe_2Cl$ was not detected in products of the above reaction. Moreover in disproportionation reactions of chlorosilanes with hydrosilanes the presence of various catalysts (e.g., $AlCl_3$ or H_2PtCl_6) is necessary. So far we have not conducted comprehensive mechanistic studies of reaction of (amino)hydrosilanes with chlorosilanes. It seems quite obvious, that this interesting and useful reaction is a next example of the nucleophilic displacement at silicon and may be catalyzed by traces of amine hydrochlorides or (amino)silanes hydrochlorides, which could be formed in the presence of traces of moisture, during the course of synthesis.

Conclusions

(1.) The new efficient laboratory method of the synthesis of HMe_2SiCl has been described, based on reaction of (dialkylamino)chlorodimethylsilanes (R_2NSiMe_2H) with dimethyldichlorosilane.

(2.) The main features of this novel method are as follows: (*a*) the intermediate products (dialkylamino)dimethylchlorosilanes (R_2NSiMe_2Cl) are recovered in high yields and are reused, in the synthesis cycle by reduction with $LiAlH_4$ to give R_2NSiMe_2H; (*b*) a very simple procedure and good yields of HMe_2SiCl are obtained (usually above 80%).

(3.) The reaction of substituted (amino)dimethylchlorosilanes with Me_2SiCl_2 proceeds through a nucleophilic substitution (transsilylation mechanism), and was confirmed by reaction of $Et_2NSiMePhH$ with Me_2SiCl_2. Products of this reaction are: HMePhSiCl and Et_2NSiMe_2Cl.

(4.) New compounds, not described in a literature, have been prepared: (*i*) bis(pyrrolidino)dimethylsilane $[(CH_2)_4N]_2SiMe_2$, from pyrrolidine and Me_2SiCl_2, in ether, in the presence of Et_3N; (*ii*) (pyrrolidino)dimethylchlorosilane $(CH_2)_4NSiMe_2Cl$, from reactions of bis(pyrrolidino)dimethylsilane or pyrrolidine with Me_2SiCl_2, in ether (in the presence of Et_3N, in the latter case); (*iii*) (diethylamino)methylphenylchlorosilane, from diethylamine and $MePhSiCl_2$, in ether; (*iv*) (diethylamino)methylphenylsilane, by reduction of $Et_2NSiMePh(Cl)$ with $LiAlH_4$, in THF.

(5.) (Pyrrolidino)dimethylsilane was synthesized by reduction of (pyrrolidino)dimethylchlorosilane $(CH_2)_4NSiMe_2Cl$ with $LiAlH_4$, in ether.

Adducts of sila-, germa-, and stannaethenes $Me_2E=C(SiMe_3)_2$ (E = Si, Ge, Sn) with anthracene: syntheses, structures, thermolyses[1]

Nils Wiberg, Susanne Wagner, Sham-Kumar Vasisht, and Kurt Polborn

Abstract: The [4 + 2] cycloadducts of $Me_2E=C(SiMe_3)_2$ (E = Si, Ge, Sn) and anthracene are prepared by reaction of an excess of anthracene in benzene with the [2 + 2] cycloadduct of $Me_2Si=C(SiMe_3)_2$ and $Ph_2C=NSiMe_3$ at 130°C, with $Me_2Ge(OPh)$-$CLi(SiMe_3)_2$ at 100°C, and with Me_2SnBr-$CNa(SiMe_3)_2$ at 80°C, respectively. The mentioned adducts act as sources for the ethenes $Me_2E=C(SiMe_3)_2$ above 100°C, the intermediate formation of which has been demonstrated by trapping experiments with 2,3-dimethylbutadiene (formation of a [4 + 2] and an ene reaction product). The half life time of the anthracene adducts with E = Si, Ge, and Sn in the presence of DMB (= 2,3-dimethylbutadiene) in benzene on thermolysis at 130°C (first order reactions) is found to be 141, 12, and 0.3 h, respectively. In the absence of DMB, thermolysis of the cycloadducts leads in benzene as reaction medium exclusively to the dimers of the $Me_2E=C(SiMe_3)_2$ intermediates. In toluene as reaction medium ene products of $Me_2E=C(SiMe_3)_2$ are observed in addition to the dimers. The ene products are not isolable as such, but only after migration of the $Me_2E–CH(SiMe_3)_2$ substituents. The formed derivatives $C_6H_5CH_2EMe_2CH(SiMe_3)_2$ of toluene in part give a second ene reaction with another $Me_2E=C(SiMe_3)_2$ molecule. X-ray structure analyses of the mentioned sources in fact prove the latter to be normal [4 + 2] cycloadducts of $Me_2E=C(SiMe_3)_2$ and anthracene.

Key words: silaethene, germaethene, stannaethene, [4 + 2] anthracene adducts, [4 + 2] cycloadditions and reversions, ene reactions, X-ray structure analyses.

Résumé : On a préparé les cycloadduits [4 + 2] du $Me_2E=C(SiMe_3)_2$ (E = Si, Ge, Sn) avec l'anthracène en faisant réagir un excès d'anthracène, en solution dans le benzène, avec respectivement le cycloadduit [2 + 2] du $Me_2Si=C(SiMe_3)_2$ et le $Ph_2C=NSiMe_3$ à 130°C, avec le $Me_2Ge(OPh)$-$CLi(SiMe_3)_2$ à 100°C et avec le Me_2SnBr-$CNa(SiMe_3)_2$ à 80°C. À des températures supérieures à 100°C, les produits mentionnés agissent comme sources d'éthènes $Me_2E=C(SiMe_3)_2$ dont on a démontré la formation par des expériences de piégeage à l'aide de 2,3-diméthylbutadiène qui donne lieu à la formation d'un produit d'addition [4 + 2] ainsi que d'un produit de réaction ène. On a trouvé que les temps de demi-vie des adduits de l'anthracène avec E = Si, Ge et Sn en présence de DMB (= 2,3-diméthylbutadiène), en solution dans le benzène, lors d'une thermolyse à 130°C (réactions du premier ordre) sont respectivement de 141, 12 et 0,3 h. En absence de DMB, la thermolyse des cycloadduits dans le benzène comme milieu réactionnel conduit exclusivement aux dimères des intermédiaires $Me_2E=C(SiMe_3)_2$. Lorsque le milieu réactionnel est le toluène, on observe aussi des produits de réaction ène, en plus de la formation des dimères. Il n'est pas possible d'isoler les produits ène comme tels, uniquement après la migration des substituants Me_2E-$CH(SiMe_3)_2$. Une partie des dérivés qui se forment dans le toluène, $C_6H_5CH_2EMe_2CH(SiMe_3)_2$, donne lieu à une deuxième réaction ène, avec une autre molécule $Me_2E=C(SiMe_3)_2$. Une analyse des structures déterminées par diffraction des rayons X pour les sources mentionnées prouve en fait que ces derniers sont des cycloadduits [4 + 2] normaux des $Me_2E=C(SiMe_3)_2$ avec l'anthracène.

Mots clés : silaéthène, germaéthène, stannaéthène, adduits [4 + 2] de l'anthracène, cycloadditions et cycloréversions [4 + 2], réactions ène, détermination de structures par diffraction des rayons X.

Scheme 1. Generation of **1**, **2**, **3** by thermal salt elimination.

Introduction

In the past years we attempted to generate silaethene $Me_2Si=C(SiMe_3)_2$ (**1**), germaethene $Me_2Ge=C(SiMe_3)_2$ (**2**) and stannaethene $Me_2Sn=C(SiMe_3)_2$ (**3**) as short-lived reaction intermediates, which immediately dimerize to $(\mathbf{1})_2$, $(\mathbf{2})_2$, and $(\mathbf{3})_2$. If a solution of PhLi in ether is added to a cold solution of $Me_2EX\text{-}CBr(SiMe_3)_2$ (E = Si, Ge, Sn; X = Br, F, OPh) in ether, **1**, **2**, and **3** will be formed (1–3). According to Scheme 1, the compounds $Me_2EX\text{-}CBr(SiMe_3)_2$ react by exchange of bromine bonded to carbon for lithium; thus the sila-, germa-, and stannaethene sources $Me_2EX\text{-}CLi(SiMe_3)_2$ (**1**·LiX, **2**·LiX, **3**·LiX)[4] are formed. The latter decompose via thermal salt elimination to ethenes **1**, **2**, and **3.** The reaction rate is found to increase in the order **1**·LiX < **2**·LiX < **3**·LiX and depending on X in the order X = OPh < F < Br (1, 2, 3).

Thus, salt elimination takes place for **1**·LiBr at –78°C during hours (1), for **2**·LiBr at –78°C during minutes (2), for **1**·LiF at +8°C during hours (1), and for **2**·LiOPh at –40°C during one hour (2). The reactive intermediates **1**, **2**, and **3** react with their precursors $Me_2EX\text{-}CLi(SiMe_3)_2$ via the insertion products $Me_2EX\text{-}C(SiMe_3)_2\text{-}EMe_2\text{-}CLi(SiMe_3)_2$ to $(\mathbf{1})_2$, $(\mathbf{2})_2$, and $(\mathbf{3})_2$ (Scheme 1, (4)).

The intermediate formation of **1**, **2**, and **3** could be proved by trapping experiments among others, with organic dienes and enes (formation of Diels–Alder and ene reaction products (5–7)). Due to the high dimerization tendency (even growing in the direction **1**, **2**, **3**, see above) and the reduced reactivity of dienes and enes at lower temperatures, the cycloadditions and ene reactions have to be carried out with an excess of the trapping reagent and not at too low reaction temperatures (see Experimental).

The less reactive dienes and enes are by no means effective trapping reagents for **1**, **2**, and **3** even when the relevant ethenes are released from more stable sources **1**·LiX, **2**·LiX, and **3**·LiX. In the latter case it is advantageous to use "stores" of **1**, **2**, and **3**, which are formed by reaction of the ethenes from **1**·LiX, **2**·LiX, and **3**·LiX with appropriate reactants, able to fix the unsaturated compounds at low temperatures and able to set them free at slightly higher temperatures.

An example are the adducts **1**·$Ph_2C=NSiMe_3$, which can be generated from **1** (from **1**·LiF) and benzophenonimine $Ph_2C=NSiMe_3$ at room temperature via [2 + 2] and [4 + 2] cycloadditions (Scheme 2, first equation). Above 60°C the cycloadducts decompose reversibly into **1** and comparatively unreactive[5] $Ph_2C=NSiMe_3$ (8). Unfortunately it is impossible to "store" **2** and **3** with $Ph_2C=NSiMe_3$. Meanwhile we succeeded in synthesizing the [4 + 2] cycloadducts **1a**, **2a**, and **3a** from **1**, **2**, **3** and anthracene (**a**). They act as "stores" for silaethene as well as germaethene and stannaethene, and are able to decompose above 100°C via thermal cycloreversion into the unsaturated compounds **1**, **2**, and **3** which dimerize in a fast reaction (Scheme 2, second equation).

Syntheses of the anthracene adducts 1, 2, and 3

The adducts **1a**, **2a**, and **3a** must be synthesized at higher temperatures because of the low reactivity of the ethenes **1**, **2**, **3** towards anthracene. Due to the decreasing reactivity in the order **3**, **2**, **1**, the applied reaction temperature is higher for **1** than for **2**, and for **2** higher than for **3**. The adduct **3a** is prepared from $Me_2SnBr\text{–}CBr(SiMe_3)_2$ and sodium (formation of **3** via **3**·NaBr, see Schemes 1 and 2) in the presence of excess anthracene at 80°C using toluene as solvent (molar ratio $Me_2SnBr\text{–}CBr(SiMe_3)_2$:sodium:anthracene = 1:2:20; benzophenone is added to the reaction mixture for activation of sodium; nearly quantitative formation of **3a**). Compound **2a** can be prepared by adding a –50°C cold solution of **2**·LiOPh in *tert*-butylbenzene to a 100°C hot solution of anthracene (added in excess) in *tert*-butylbenzene (molar ratio **2**·LiOPh to anthracene = 1:2; ca. 50% yield of **2a** besides $(\mathbf{2})_2$, see Schemes 1 and 2). The adduct **1a** is synthesized by heating a solution of **1**·$Ph_2C=NSiMe_3$ and an excess of anthracene in benzene at 130°C for 14 h (molar ratio **1**·$Ph_2C=NSiMe_3$ to anthracene = 1:2, nearly quantitative formation of **1a**, see Scheme 2).

In this context it should be mentioned that the rate constants for the formation of the anthracene adducts increase in the order **1a** < **2a** < **3a** (see above), as do the rate constants for the thermal cycloreversions of the adducts, leading to **1**, **2**, **3** and anthracene (ratio of the rate constants about 1:10:100; see below). Thus, going from **1** over **2** to **3**, both activation energies for the formation of the source and for the decomposition of the source are decreasing. Therefore, the absolute reaction enthalpies (equivalent to the difference in both activation energies) for the presumably exothermic formation of the "sources" are obviously very similar. In contrast to **2a** and **3a**, the adduct **1a** shows a low tendency towards cycloreversion even at 130°C. Therefore, it is favorable to use the adducts **1**·$Ph_2C=NSiMe_3$, **2a**, and **3a** as "sources" for **1**, **2**, and **3** (5–7) to perform reaction studies for sila-, germa-, and stannaethenes at temperatures between 100 and 130°C.

[4] The also possible (but unwanted) exchange of X bonded to silicon, germanium, or tin for phenyl under formation of $Me_2EPh\text{–}CBr(SiMe_3)_2$ is only important for $Me_2EX\text{–}CBr(SiMe_3)_2$ with X = Br at reaction temperatures above –78°C (E = Si, Ge) and at –78°C (E = Sn).
[5] $Ph_2C=NSiMe_3$ slowly and irreversibly traps **1** by formation of the insertion product $Ph_2C=N\text{–}SiMe_2\text{-}C(SiMe_3)_3$ (8).

Scheme 2. Generation of **1**, **2**, **3** by thermal cycloreversion.

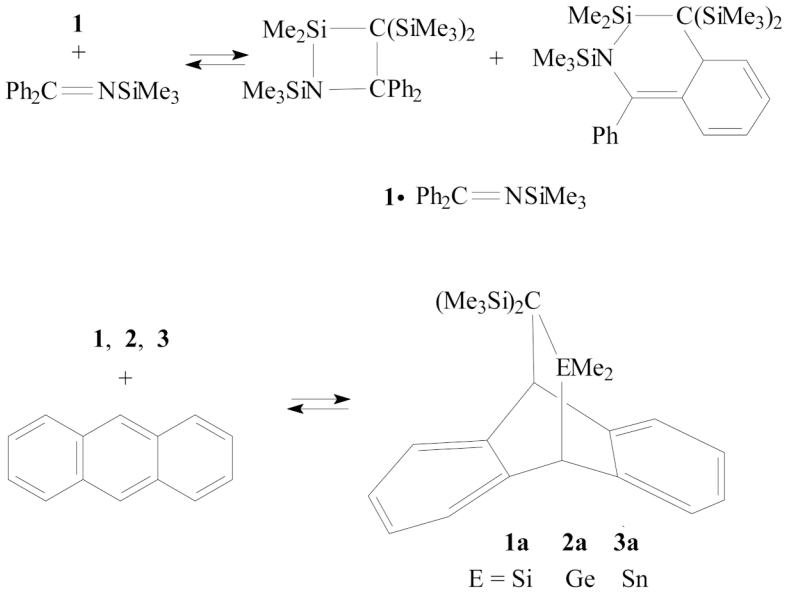

Fig. 1. Kinetic (first order presentation) of the thermolyses of **3a** in the absence or presence of DMB (mol ratio **3a**:DMB = 1:10) in C_6D_6 at 130°C.

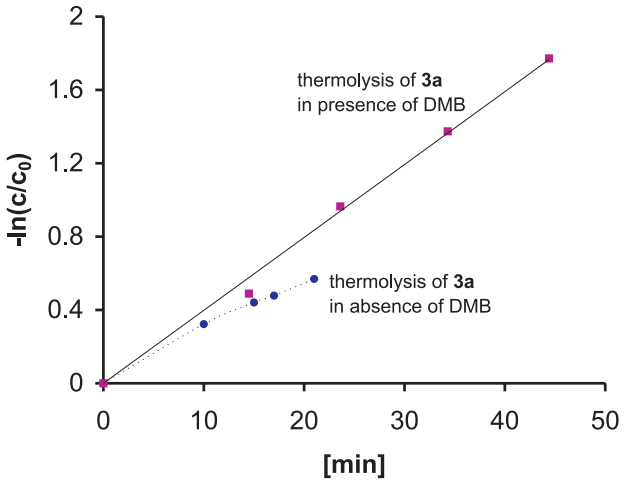

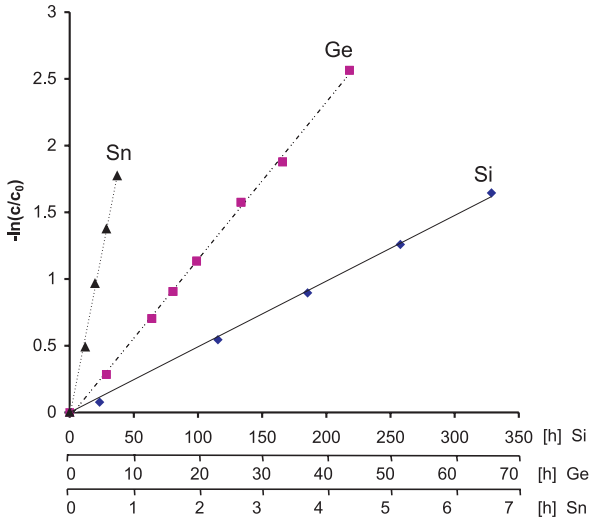

Fig. 2. Kinetic (first order presentation) of the thermolyses of **1a, 2a,** and **3a** in the presence of DMB (mol ratio adduct: DMB = 1:10) in C_6D_6 at 130°C.

Thermolyses of 1a, 2a, and 3a

It is difficult to determine the reaction order and the rate constants for the thermolysis of **1a**, **2a**, and **3a** in benzene, leading to dimers $(\mathbf{1})_2$, $(\mathbf{2})_2$, $(\mathbf{3})_2$, and anthracene. The reason for this fact is the increasing rate of the reverse reaction (that is to say, the rate for the adduct formation from **1**, **2**, **3**, and anthracene) due to the increase of free anthracene in the reaction mixture in the course of the reaction (Scheme 2, second equation). If ln (c/c_0) (c = adduct concentration at time t, c_0 = sum of concentration of adduct and dimer) is plotted against time t in the sense of a first order reaction, a graph with a significant decrease in the ascent will be obtained instead of a straight line (Fig. 1). If the decomposition of **1a**, **2a**, and **3a** is carried out in the presence of a suitable trapping reagent like DMB (= 2,3-dimethylbutadiene), which removes the sila-, germa-, and stannaethene **1**, **2**, and **3** from the adduct equilibrium (Scheme 2, second equation), the thermolysis of the adducts takes place according to a first order reaction as expected (Fig. 2). At the starting point the ascents of first order plots of adduct thermolysis in the presence and the absence of DMB are similar (Fig. 1).

In the presence of DMB, the thermal cycloreversion reactions of the adducts **1a**, **2a**, and **3a** in benzene at 100–130°C lead to [4 + 2] cycloadducts **4** and ene reaction products **5** (Scheme 3). Rate constants and half life times for these thermolyses are shown in Table 1.

Using toluene as solvent instead of benzene for the 130°C thermolyses of **1**·$Ph_2C{=}NSiMe_3$, **2a**, and **3a**; the ene products of **1**, **2**, and **3** with toluene are formed to our surprise, together with the dimers $(\mathbf{1})_2$, $(\mathbf{2})_2$, and $(\mathbf{3})_2$. The highly reactive compounds **1**, **2**, and **3** force the chemically quite

Scheme 3. Thermolyses of **1a**, **2a**, **3a** in the presence of DMB.

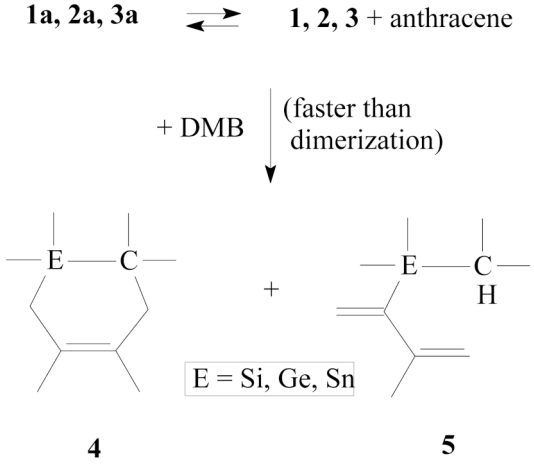

Table 1. Rate constants k and half life times $\tau_{1/2}$ of the thermolyses of **1a, 2a**, and **3a** in C_6D_6 at variable temperatures in the presence of DMB (mol ratio adducts: DMB = 1:10).

		k (s^{-1})	$\tau_{1/2}$ (h)
1a	(130°C)	1.37×10^{-6}	141
2a	(130°C)	1.60×10^{-5}	12
3a	(130°C)	6.60×10^{-4}	0.3
	(100°C)	2.44×10^{-5}	7.9

unreactive toluene to act as an ene reagent. Certainly **1**, **2**, and **3** (generated from **1**·Ph_2C=$NSiMe_3$, **2a**, **3a**) first form the ene products **6** (Scheme 4). These are only intermediates, which finally react to the toluene derivatives **8** and **10**. The products **8** are obtained from **6** via rearrangement of Me_2E–$CH(SiMe_3)_2$ groups, whereas there are three possible ways that may lead to **10** as the product (Scheme 4): (*i*) Products **6** rearrange to the non-isolable products **7** (according to experimental studies a rearrangement of **8** to **7** does not occur), whereby the latter reacts with **1**, **2**, or **3** via ene products **9** to isolable compounds **10** (as no traces of products **7** were found, reaction path (*i*) is less probable). (*ii*) Products **10** are formed by reaction of **8** with **1**, **2**, or **3** via the ene products **11** (according to preliminary studies these reactions do not occur, therefore reaction path (*ii*) is less probable). (*iii*) Products **6**, which certainly are very reactive intermediates, form directly with **1**, **2**, or **3** the ene products **10**.

Table 2 shows the yields of the products after complete thermolysis of **1**·Ph_2C=$NSiMe_3$, **2a**, and **3a** at 130°C in toluene. It reveals that if complete educt thermolysis needs a long time, a decrease in the yields of dimers $(\mathbf{1})_2$, $(\mathbf{2})_2$, and $(\mathbf{3})_2$ will be observed. This fact can be explained as follows: the stationary concentration of intermediates **1**, **2**, and **3** decreases with decreasing rate for the decomposition of the sources **1a**, **2a**, **3a**. As a consequence, the ene reactions of **1**, **2**, and **3** with toluene (which take place according to a first order reaction) are more dominant than the dimerization reactions (which represents a second order reaction). This important result indicates that the formation of $(\mathbf{1})_2$, $(\mathbf{2})_2$, and $(\mathbf{3})_2$ — via the thermal cycloreversion of **1**·Ph_2C=$NSiMe_3$, **1a**, and **2a**, respectively — takes place through a direct dimerization of **1**, **2**, and **3** (compare however the formation of dimers in the course of salt elimination of **1**·LiX, Scheme 1).

Scheme 4. Thermolyses of **1a**, **2a**, **3a** in toluene (in addition to **8** and **10**, the dimers $(\mathbf{1})_2$, $(\mathbf{2})_2$, $(\mathbf{3})_2$ are formed).

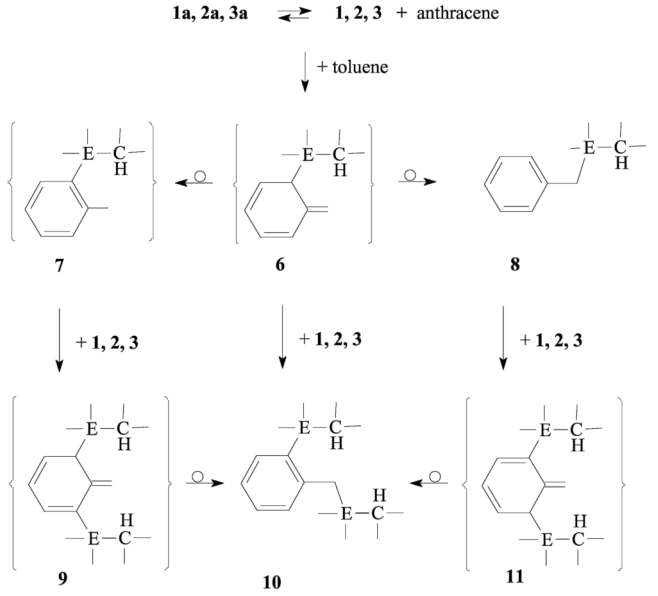

Table 2. Relative yields of dimers $(\mathbf{1})_2$, $(\mathbf{2})_2$, $(\mathbf{3})_2$, and products **8**, **10** [mole %] after complete thermolysis of 0.08 molar solutions of **1**·Ph_2C=$NSiMe_3$, **2a** and **3a** in toluene at 130°C.

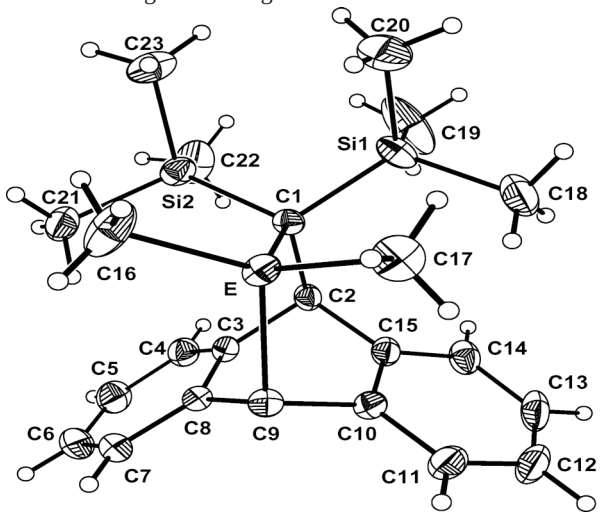
Sources	T (°C)	t (d)	dimers	**8**	10
1·Ph_2C=$NSiMe_3$	130	9	37%	57%	6%
2a	130	44	12%	49%	39%
3a	130	1	83%	13%	4%

Of course, both the ratio of yields of dimers to ene reaction products and the ratio of yields of **8** to **10**, in addition depend on the relative reactivity of ethenes **1**, **2**, or **3** towards themselves, toluene and toluene derivatives **6**, **7**, and **8**, respectively. Obviously, on going from toluene to **6**, **7**, or **8**, the ene reactivity has significant effect in the case of the germaethene **2,** a smaller effect in the case of the stannaethene **3** and the smallest effect in the case of the silaethene **1**, regarding the ratio of yields of **8** to **10** (Table 2). Nevertheless, for direct formation of **10** from **6** – being the most favoured reaction course – the stationary concentrations of **1**, **2**, or **3** are important, as the transformations of **6** into **8** and **10**, respectively, are zero order in the first and first order in the second case concerning the mentioned ethenes.

Structures of 1a, 2a and 3a



The anthracene adducts **1a**, **2a**, and **3a** precipitate from benzene as colourless, moisture- and air-insensitive crystals, which melt at 144, 136, and 140°C, respectively, and are thermolabile above 100°C. Figure 3 shows their molecular structure in the crystal determined by X-ray structure analysis.

Fig. 3. View of the molecular structures of **1a**, **2a**, and **3a** (E = Si, Ge, Sn) in the crystal (ORTEP plot; 25% thermal probability ellipsoids; local symmetry of the molecules $\approx c_n$) (for clarity hydrogen atoms are not shown) and atom numbering scheme. For selected bond lengths and angles see Table 3.

In Table 3, selected bond length and angles are given. It is evident from Fig. 3 that the anthracene part is bent roof-shaped at the central C-atoms in **1a**, **2a**, and **3a**. Both parts of the roof are planar (each angular sum at C3, C8, C10, and C15 is about 360°). The ridge is bridged with a Me_2E–$C(SiMe_3)_2$ group (Fig. 4). The exchange of silicon for germanium and of germanium for tin practically doesn't change most of the bond lengths and angles in **1a**, **2a**, and **3a,** except the E—C bond length and C-E-C bond angles (Fig. 5).

Experimental

All experiments were carried out in the absence of air and moisture. According to literature procedures were prepared: **1**·$Ph_2C{=}NSiMe_5$ (8), $Me_2Ge(OPh)$-$CBr(SiMe_3)_2$ (2), Me_2SnBr-$CBr(SiMe_3)_2$ (3). The NMR-spectra were recorded on multinuclear instruments Jeol GSX 270 and Jeol EX 400. The product seperation was done by preparative HPLC on Waters 600 (column 21.2 mm × 250 mm; Zorbax C18; flow 21 mL/min.; detection: UV at 230 nm and refractometer). Mass spectrometry (EI): Varian CH7; found and calculated isotopic patterns were in perfect agreement.

Thermolyses of 1·LiBr, 2·LiBr, 3·LiBr in the presence of DMB at low temperatures

To a solution of *x* mmol Me_2EBr-$CBr(SiMe_3)_2$ and *y* mmol DMB in ether, *x* mmol PhLi in ether are added dropwise at temperature T (Table 4). After warming up to ambient temperature the types and yields of products formed were identified by ^{1}H NMR (Table 4) and by comparison of

Synthesis of 1a

A solution of 0.132 g (0.28 mmol) **1**•$Ph_2C=NSiMe_3$ and 0.100 g (0.56 mmol) anthracene in 2.4 mL benzene was heated for 14 h at 130°C. According to ^{1}H NMR, 94% **1a**, 2% $(\mathbf{1})_2$ and 4% $Ph_2C=N-SiMe_2-C(SiMe_3)_3$ were formed. The reaction mixture was treated with 0.5 mL MeOH – 1.0 mL *t*BuOMe, and separation was done by HPLC using MeOH and *t*BuOMe as mobile phase (0–8 min: 100% MeOH, 8–20 min with gradient to 80% MeOH – 20% *t*BuOMe, 20–25 min with gradient to 100% MeOH). Retention time: 5.1 min (anthracene), 9.2 min (**1a**), 14.7 min ($Ph_2C=N–SiMe_2–C(SiMe_3)_3$).

*9,10-Dihydro-9,10-[11,11-dimethyl-12,12-bis(trimethylsilyl)-11-silaethano]-anthracen (**1a**):* colourless solid, mp 144°C. ^{1}H NMR (C_6D_6, iTMS) δ: –0.083 (s; 2 $SiMe_3$), 0.085 (s; $SiMe_2$), 3.51 (s, SiCH), 4.56 (s; CCH), 6.90–7.10 (m; =CH). $^{13}C\{^1H\}$ NMR (C_6D_6, iTMS) δ: 1.91 ($SiMe_2$), 4.52 (2 $SiMe_3$), 12.51 (Si_3C), 43.27 (SiCH), 50.68 (CCH), 124.5/125.4/126.0/126.4 (8 =CH-), 143.4/143.5 (4 =C<). ^{29}Si NMR (C_6D_6, eTMS) δ: 1.68 ($SiMe_2$), 3.16 (2 $SiMe_3$). MS: *m*/*z* 394 (M^+). Anal. calcd. for $C_{23}H_{34}Si_3$: C 69.98, H 8.68; found: C 69.54 H 8.46.

Synthesis of 2a

A solution of 1.17 mmol $Me_2Ge(OPh)–CLi(SiMe_3)_2$ in $tBuC_6H_5$ (synthesized by reaction of 1.17 mmol $Me_2Ge(OPh)-CBr(SiMe_3)_2$ with 1.17 mmol *n*BuLi in Et_2O at –78°C, ether replaced by $tBuC_6H_5$ at –78°C) at –50°C, was added dropwise (over a period of one hour) to a solution of 0.456 g (2.56 mmol) anthracene in 20 mL $tBuC_6H_5$, which was heated to 100°C. According to ^{1}H NMR, **2a** and $(\mathbf{2})_2$ were formed in the molar ratio 1.2:1, besides $Me_2GeR–CH(SiMe_3)_2$ (*R* = OPh, *n*Bu) (2). The reaction mixture was allowed to cool to room temperature, 0.3 mL Me_3SiCl (to form Me_3SiOPh of LiOPh) were added, and all volatile

© 2000 NRC Canada

fractions (tBuC$_6$H$_5$, Me$_3$SiCl, Me$_3$SiOPh) were condensed in oil pump vacuum at 30°C. The residue was dissolved in 8 mL benzene and insoluble LiBr was removed. The solution was concentrated to 4 mL, and 1.5 mL MeOH – 2.5 mL tBuOMe were added. Some hours later anthracene and (**2**)$_2$ had crystallized partially and were removed by decantation. The further separation of the reaction mixture was done by HPLC using MeOH as mobile phase. Retention times: 6.0 min (anthracene), 11.4 min (**2a**), 41.6 min ((**2**)$_2$).

*9,10-Dihydro-9,10-[11,11-dimethyl-12,12-bis(trimethylsilyl)-11-germaethano]-anthracene (**2a**)*: colourless solid, mp 136°C. ^{1}H NMR (C$_6$D$_6$, iTMS) δ: –0.102 (s; 2 SiMe$_3$), 0.232 (s; GeMe$_2$); 3.66 (s; GeCH), 4.69 (s; CCH), 6.90–7.10 (m; =CH–). ^{13}C{^{1}H} NMR (CDCl$_3$, iTMS) δ: 2.19 (GeMe$_2$), 3.96 (2 SiMe$_3$), 13.57 (Si$_2$C), 42.38 (GeCH), 50.19 (CCH), 124.0/124.5/125.6/126.5 (8 =CH–), 142.1/143.2 (4 =C<). ^{29}Si NMR (CDCl$_3$, eTMS) δ: 3.49 (2 SiMe$_3$). MS: *m*/*z* 440 (M$^+$).

Synthesis of 3a

A mixture of 0.23 g (10.0 mmol) sodium metal, 9.10 g (50.0 mmol) benzophenone and 17.80 g (100 mmol) anthracene in 200 mL toluene was stirred and heated to 100°C for 1/2 hour to obtain a deep blue coloured solution. The reaction mixture was cooled to 80°C and a solution of 2.33 g (5.00 mmol) of Me$_2$SnBr-CBr(SiMe$_3$)$_2$ in 50 mL toluene was added over a period of two hours. According to ^{1}H NMR 88% **3a**, 10% (**3**)$_2$ and 2% **8** were formed. The reaction mixture was cooled down to 0°C, unsoluble compounds (NaBr, anthracene) were separated, solvent was removed and benzophenone was sublimed out at 60°C and 10^{-3} mbar over 2 days. The residue was treated with 5 mL MeOH – 10 mL tBuOMe and separation of the reaction mixture was done by HPLC using MeOH and tBuOMe as mobile phase (0–8 min: 100% MeOH, 8–14 min with gradient to 80% MeOH – 20% tBuOMe, 20–25 min with gradient to 100% MeOH). Retention times: 5.0 min (anthracene), 8.4 min (**3a**), and 18.5 min ((**3**)$_2$).

*9,10-Dihydro-9,10-[11,11-dimethyl-12,12-bis(trimethylsilyl)-11-stannaethano]-anthracene (**3a**)*: colourless solid, mp 140°C. ^{1}H NMR (C$_6$D$_6$, iTMS) δ: –0.098 (s; 2 SiMe$_3$), 0.166 (s; SnMe$_2$), 3.92 (s, SnCH), 4.90 (s; CCH), 6.83–7.15 (m; =CH). ^{13}C{^{1}H} NMR (C$_6$D$_6$, iTMS) δ: – 4.18 (SnMe$_2$), 3.87 (2 SiMe$_3$), 16.93 (SnSi$_2$C), 39.33 (SnCH), 50.60 (CCH), 123.6/123.8/125.7/127.3 (8 =CH-), 141.0/143.5 (4 =C<). ^{29}Si NMR (C$_6$D$_6$, eTMS) δ: = 3.01 (2 SiMe$_3$). ^{119}Sn NMR (C$_6$D$_6$, eTMS) δ: = –3.14 (SnMe$_2$). MS: *m*/*z* 486 (M$^+$). Anal. calcd. for C$_{23}$H$_{34}$Si$_2$Sn: C 57.06, H 7.03; found: C 56.73 H 6.82.

Thermolysis of 3a in benzene at 130°C

A sealed NMR tube, containing 0.029 g (0.06 mmol) of **3a** in 0.6 mL C$_6$D$_6$, was heated at 130°C. The progress of the reaction was monitored by ^{1}H NMR after 10, 15, 17, 21 min. The intensities of the ^{1}H NMR signals as resulting from the evaluation of the integrals were determined for **3a** and the dimer of **3** as follows: 10 min: 72% **3a**, 28% (**3**)$_2$; 15 min: 64% **3a**, 36% (**3**)$_2$; 17 min: 62% **3a**, 38% (**3**)$_2$; 21 min: 57% **3a**, 43% (**3**)$_2$. In the further course of the reaction (**3**)$_2$ precipitates.

Thermolysis of anthracene adducts 1a, 2a, 3a in presence of DMB at 100°C and 130°C

Sealed NMR tubes containing 0.016 g (0.04 mmol) of **1a** and 0.045 mL (0.40 mmol) DMB in 0.5 mL C$_6$D$_6$ (**A**); 0.018 g (0.04 mmol) of **2a** and 0.045 mL (0.40 mmol) DMB in 0.6 mL C$_6$D$_6$ (**B**); 0.029 g (0.06 mmol) of **3a** and 0.068 mL (0.60 mmol) DMB in 0.6 mL C$_6$D$_6$ (**C**); 0.029 g (0.06 mmol) of **3a** and 0.081 mL (0.72 mmol) DMB in 0.6 mL C$_6$D$_6$ (**D**); were heated at 130°C (**A**, **B**, **C**) and 100°C (**D**). The progress of the reaction was monitored by ^{1}H NMR. The intensities of the ^{1}H NMR signals as resulting from the evaluation of the integrals were determined for **1a**, **2a**, **3a**, **4**, and **5**. To determine the reaction order, –ln (c/c_0) was plotted against time t, with c being the ^{1}H NMR signal area of anthracene adducts and c_0 being the sum of ^{1}H NMR signal areas of anthracene adducts + **4** + **5**. For the plots, rate constants, and half life times see Table 1 and Fig. 2.

Thermolysis of 1·Ph$_2$C=NSiMe$_3$ in toluene

A solution of 0.075 g (0.16 mmol) **1**·Ph$_2$C=NSiMe$_3$ in 2.0 mL toluene was heated at 130°C for 9 d in a sealed, evacuated NMR tube. The ^{1}H NMR spectrum indicated complete conversion to Ph$_2$C=N–SiMe$_2$–C(SiMe$_3$)$_3$ (59%), (**1**)$_2$ (15%), **8** (23%), and **10** (3%). After removal of volatile constituents, the residue was treated with 1.0 mL tBuOMe – 0.5 mL MeOH and separation was done by HPLC using MeOH as mobile phase. Retention times: 10.2 min (**8**), 18.1 min (Ph$_2$C=N–SiMe$_2$–C(SiMe$_3$)$_3$), 34.4 min (**10**), and 44 min ((**1**)$_2$).

*Benzyldimethylsilyl-bis(trimethylsilyl)methane (**8**, E = Si)*: colourless liquid. ^{1}H NMR (C$_6$D$_6$, iTMS) δ: –0.750 (s, Si$_3$CH), 0.078 (s; 2 SiMe$_2$), 0.148 (s; 2 SiMe$_3$), 2.17 (s; SiCH$_2$), 6.99–7.15 (m; *o*-/*p*-/*m*-CH of Ph). ^{13}C{^{1}H} NMR (C$_6$D$_6$, iTMS) δ: 0.645 (SiMe$_2$), 2.28 (Si$_3$C), 3.35 (2 SiMe$_3$), 28.76 (SiCH$_2$), 124.3/128.2/128.5/140.4 (*p*-/*o*-/*m*-/i-C of Ph). ^{29}Si NMR (C$_6$D$_6$, eTMS) δ: –0.15 (2 SiMe$_3$), 0.68 (SiMe$_2$). MS: *m*/*z* 308 (M$^+$).

*1-[1,1-Dimethyl-2,2-bis(trimethylsilyl)-1-silaethyl]-2-[2,2-dimethyl-3,3-bis(trimethylsilyl)-2-silapropyl]-benzene (**10**, E = Si)*: colourless solid, mp 96°C. ^{1}H NMR (C$_6$D$_6$, iTMS) δ: = –0.458 (s, Si$_3$CH), –0.041 (s, Si$_3$CH), 0.148 (s; 2 SiMe$_3$), 0.199 (s; 2 SiMe$_3$), 0.199 (s; SiMe$_2$), 0.521 (s; SiMe$_2$), 2.56 (s; SiCH$_2$), 7.06 (t; J = 7 Hz; 1 CH of Ph), 7.12 (d; J = 7 Hz; 1 CH of Ph), ? Thermolysis of 8 in benzene

A solution of 0.022 g (0.07 mmol) **8** (E = Si) in 0.6 mL benzene was heated at 160°C for 5 d and at 170°C for 11 d. According to ^{1}H NMR spectrum no reaction (formation of **7**) occurred.

Thermolysis of 8 and 1·Ph_2C=$NSiMe_3$ in benzene

A solution of 0.008 g (0.026 mmol) **8** and 0.016 g (0.034 mmol) **1**·Ph_2C=$NSiMe_3$ in 0.6 mL C_6D_6 was heated at 130°C for 9 d. According to ^{1}H NMR spectrum no formation of **10** occurred.

Crystal structures of 1, 2 and 3

Single crystals were crystallized from benzene as colourless plates. For structure determinations a Nonius CAD4 diffractometer was used. All structures were solved by SHELXS86 and refined with SHELXL93. The non-hydrogen atoms were refined anisotropically. The H atoms were considered as a riding model. Crystallographic parameters and details of the data collection are summarized in Table 5.[6]

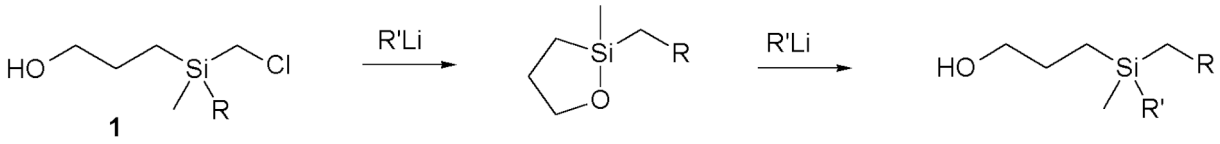
Alkoxides of *o*-silyl benzyl alcohols in cleavage reactions: approaches to benzyl and silyl anion equivalents

Paul F. Hudrlik, Jose O. Arango, Yousef M. Hijji, Cosmas O. Okoro, and Anne M. Hudrlik

Abstract: The alkoxides of *o*-silyl benzyl alcohols **4** undergo cleavage reactions under mild conditions allowing transfer of a benzyl or silyl group to an electrophile. Reactions **3a** → **8**, and **3c** or **4c** → **11** illustrate their potential as benzyl and silyl anion equivalents.

Key words: silyl migration, benzyl anion equivalent, silyl anion equivalent, β-silyl ketone, γ-hydroxysilane.

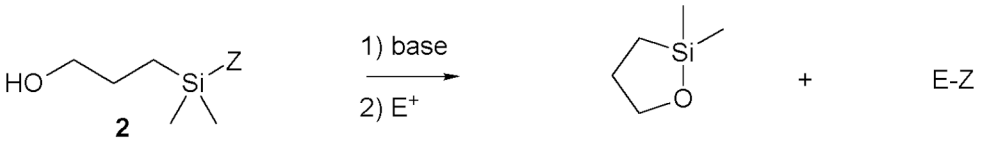
Résumé : Les alcoolates d'alcools benzyliques *o*-silylés (**4**) subissent des réactions de clivage dans des conditions douces qui permettent d'effectuer le transfert d'un groupe benzyle ou silyle vers un électrophile. Les réactions **3a** → **8** et **3c** ou **4c** → **11** illustrent leur potentiel comme équivalents des anions respectivement benzyle et silyle.



Mots clés : migration d'un silyle, équivalent de l'anion benzyle, équivalent de l'anion silyle, β-silylcétone, γ-hydroxysilane.

Introduction

Reactions involving nucleophilic attack at silicon have been used in organic synthesis for the removal of protecting groups (1), for the formation of multiple bonds (elimination reactions) (2), and for the generation of anionic intermediates (3). We have been interested in the use of intramolecular nucleophilic attack for some of these reactions. Organosilicon compounds with a protected internal nucleophile could, in principle, be carried through a synthetic sequence, and later activated (deprotected) to form a more readily cleaved silicon group.



We have previously found that the γ-oxidopropyl group on silicon is effective as an internal nucleophile. We have reported the use of γ-hydroxysilanes **1** in rearrangement reactions (eq. [1]) (4*a*), and of γ-hydroxysilanes **2a**,**b** in cleavage reactions (for generation of benzyl and allyl anion equivalents) (eq. [2]) (4*b*).

We felt that the use of a more rigid *ortho*-substituted aromatic ring in a γ-hydroxysilane such as **4** should facilitate the cleavage reactions. We report that this appears to be the case, and that these reactions can be used for the generation of benzyl and silyl anion equivalents.

Results and discussion

o-Silyl benzyl alcohol **4a** was prepared from *o*-bromobenzyl alcohol by treatment with $PhCH_2SiMe_2Cl$ and triethylamine (to give silyl ether **3a** in 87% yield) followed by treatment of **3a** with lithium wire in ether to give **4a** (92%) (5). Lithium alkoxide **5a** (Scheme 1), a presumed intermediate in the rearrangement of **3a** to **4a**, appears to be relatively stable in ether, but undergoes a facile cleavage reaction in the presence of THF. Treatment of benzyl silyl ether **3a** with *n*-BuLi in ether at room temperature resulted in disappearance of **3a** after 1.5 h, with appearance of alcohol **4a** (analysis of aliquots (with aqueous workup) by GC). Addition of THF to the reaction mixture resulted in almost complete disappearance of **4a** within 1 h with the appearance (after aqueous workup) of toluene and a product assigned as oxasilacyclopentane **7** by the mass spectrum [*m*/*z* 164 (18%, M^+), 149 (100%, M^+ – Me)]. By contrast, treatment of the acyclic analog **2a** with *n*-BuLi–THF resulted in no reaction in 1 day (although cleavage of the benzyl group was observed under more polar conditions, e.g., KH–ether or NaH–THF) (4*b*).

A mechanistic rationale appears in Scheme 1. Treatment of **3** with RLi or of **4** with base should lead to alkoxide **5**. Lithium alkoxide **5a** appears to be stable in ether, although in the presence of THF it yields oxasilacyclopentane **7**, most likely via pentacoordinate intermediate **6**. In the case of **3a**, presumably an anionic intermediate such as **6** or Z^- was trapped with water to form toluene, and could in principle be trapped with a number of electrophiles, allowing **3** and **4** to be used to generate anion equivalents.

We were able to demonstrate that the **3a**–**4a** system can serve as a benzyl anion equivalent by treating silyl ether **3a** with Li in ether (2 h) followed by benzophenone in THF (12 h, room temperature). Benzyldiphenylcarbinol (**8**) was isolated in 57% yield after chromatography (not optimized). In contrast, the analogous reaction with the acyclic γ-hydroxysilane **2a** required the use of a more polar solvent (HMPA) (4*b*).

Evidence for the intermediacy of oxasilacyclopentane **7** in the cleavage reactions was obtained by trapping with MeLi. Treatment of γ-hydroxysilane **4c** (5) with KH–THF–0°C fol-

© 2000 NRC Canada

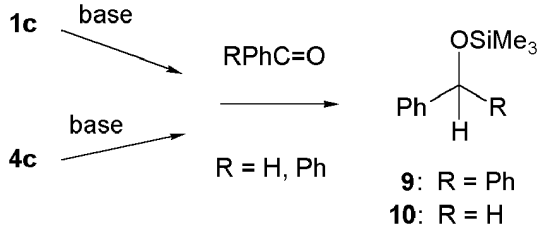
lowed by excess MeLi–ether (15 h, room temperature) gave γ-hydroxysilane **4d** (5, 7) in 82% yield. Initial attempts to isolate and more fully characterize oxasilacyclopentane **7** led to samples which appeared pure by GC and GC/MS, but had sizeable OH signals in the IR, suggesting the oxasilacyclopentane might be forming a dihydroxy compound during workup or partially forming oligomers.

To isolate oxasilacyclopentane **7**, we decided to use γ-hydroxy(allyl)silane **4b** (5) as a substrate because the expected by-product, propene, would be volatile. Compound **4b** was prepared by treatment of silyl ether **3b** with Li–Et_2O (5). Treatment of **4b** with KH in ether (1 h, room temperature), followed by removal of solvent under vacuum (no aqueous workup) and bulb-to-bulb distillation (room temperature, oil pump vacuum) gave a product with an ^{1}H NMR spectrum expected for **7** (singlets at δ 0.40 and 5.15, and a multiplet at 7.2–7.6 in a ratio of 6:2:4), but with an IR spectrum having a rather large OH (3438 cm^{-1}). Because we felt the allylmetallic species generated in this reaction might be causing oligomerization of oxasilacyclopentane **7**, we added 1,2-dibromoethane as a trapping agent. Treatment of **4b** with *t*-BuLi (1.1 equiv) in THF (0°C, 1.5 h) followed by 1,2-dibromoethane (removal of cold bath, 30 min) followed by removal of solvent (no aqueous workup) and distillation gave a sample of **7** having an IR spectrum which did not have the OH peak. The ^{1}H NMR spectrum was essentially identical to that above, except for considerable amounts of dibromoethane (as well as small amounts of ether and THF); the GC showed two major peaks corresponding to dibromoethane (26%) and oxasilacyclopentane **7** (70%).

We were especially interested to study the possibility of using these reactions to generate silyl anion equivalents. Silylmetallic reagents (8) such as trimethylsilyllithium and phenyldimethylsilyllithium have found considerable use in synthesis, but existing methods for the preparation of silylmetallic reagents have disadvantages. Trimethylsilyllithium is most often prepared from the reaction of hexamethyldisilane with MeLi in HMPA (9), which is highly polar, nonvolatile, and a suspected carcinogen. Trimethylsilyllithium can also be made from silylmercury compounds which are undoubtedly highly toxic. Phenyldimethylsilyllithium is easily prepared by the reaction of the disilane (or the silyl chloride) with lithium, but this type of reaction cannot be used for tri*alkyl*silylmetallic reagents (8), and has been found to fail with a number of substituted aryldimethylsilyl groups (10). We are interested in developing general methods to generate trimethylsilyl- and other silylmetallic reagents in solvents which are not highly polar, nonvolatile, or toxic.

Compounds **2c**, **3c**, and **4c** were prepared as potential substrates for generation of silyl anion equivalents. Alcohol **2c** was prepared from $Me_3SiSi(Me_2)F$ by treatment with allylmagnesium bromide (54% yield) followed by hydroboration-oxidation of the product (64% yield). Silyl ether **3c** was prepared from *o*-bromobenzyl alcohol by treatment with $Me_3SiSi(Me)_2Cl$ and triethylamine in 92% yield.

Alcohol **4c** was prepared via rearrangement of **3c** (eq. [3]) with lithium or magnesium followed by aqueous workup. This transformation was studied with several different conditions, and the yields have been improved over those reported (5). Use of magnesium turnings in ether–THF gave good (72%) yields of **4c**, but the Grignard reaction was hard to initiate and keep going. Use of activated (Rieke) magnesium (11) in THF (room temperature) resulted in a facile reaction to give 89% crude yield of a product which appeared to be pure **4c**. Use of lithium wire (containing 1% sodium) in ether (0°C → room temperature) resulted in 78–92% yields of **4c**. In preliminary experiments, lithium powder (~0.5% Na) was also found to give **4c** in a similar manner.



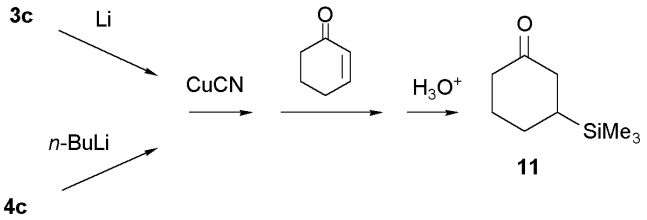
The lithium wire procedure was convenient, and was the procedure we used to prepare alcohol **4c**. In all cases, the progress of the reaction was followed by GC or GC/MS of aliquots before aqueous workup of the entire reaction. The pentamethyldisilyl ether of benzyl alcohol (hydrolysis product of the intermediate from the metal-exchange reaction) could be seen in small amounts in some of the early aliquots from the reactions with lithium wire, and in larger amounts in early aliquots from the reactions with magnesium and activated magnesium.

Relative reactivities of the γ-hydroxysilanes were studied in reactions which were followed by GC and GC/MS of aliquots using an internal hydrocarbon standard (with aqueous workup). γ-Hydroxysilane **4c** was considerably more reactive to cleavage than the acyclic analog **2c** (and **2c** was less reactive than the corresponding benzyl compound **2a**). For example, with NaH in THF at room temperature, reaction of **4c** was complete by 30 min, while reaction of **2c** was complete by 4 h (and reaction of **2a** by 30 min (4*b*)). With KH in Et_2O at room temperature, cleavage reactions of **2a** and **4c** were complete within 3–5 min, and that of **2c** was mostly complete by 90 min.

As mentioned above, the lithium alkoxide of **4a** (generated from **3a**) appeared to be stable in ether, but disappeared within an hour upon the addition of THF. The lithium alkoxide of **4c** was more stable; 70% of alcohol **4c** remained one hour after treatment of **4c** with MeLi in THF. Treatment of alcohol **2c** with MeLi–THF for 22 h resulted in no reaction (after workup).

To study the possible utility of these substrates as silyl anion equivalents, alcohols **2c** and **4c** were treated with base and bromo silyl ether **3c** was treated with lithium wire to generate the corresponding alkoxides (**5** in the case of **3c** and **4c**), and then they were treated with electrophiles, sometimes in a more polar solvent.

Compounds **2c** and **4c** were each treated with base followed by Ph_2C=O or PhCHO. The products were the Me_3Si ethers of benzhydrol (**9**) and of benzyl alcohol (**10**), respectively, presumably from trapping of the Me_3Si group followed by Brook (12) rearrangement. Benzhydrol and benzyl alcohol were also present in the product mixtures, presumably from hydrolysis of the silyl ethers.



© 2000 NRC Canada

For example, treatment of alcohol **4c** with KH–THF and benzaldehyde (mixed at 0°C, then room temperature, 1 h) gave a mixture of silyl ether **10**, benzyl alcohol, and oxasilacyclopentane **7** in GC area ratios of 13%, 33%, and 47%, respectively. Silyl ether **10** (13) was isolated by chromatography in 39% yield. Treatment of **4c** with KH–THF followed by benzophenone similarly gave a mixture containing silyl ether **9**. Use of MeLi–THF followed by benzophenone in THF–HMPA (mixed at 0°C, then room temperature, 15 h) gave a similar mixture from which silyl ether **9** (13) was isolated in 35% yield.

When silyl ether **3c** was treated with lithium wire in ether followed by benzyl bromide in THF, and when alcohol **4c** was treated with *n*-BuLi followed by benzyl bromide or chloride in THF, little or no benzyltrimethylsilane was formed. However, when **4c** in THF was treated with MeLi followed by benzyl bromide in THF–HMPA (0°C, 1 h; room temperature, 14 h), benzyltrimethylsilane was formed, along with comparable amounts of oxasilacyclopentane **7** and benzyl bromide, and small amounts of bibenzyl.

The generation of anionic intermediates for a conjugate addition reaction was studied using both silyl ether **3c** and alcohol **4c**. As mentioned above, silyl ether **3c** could be converted to alcohol **4c** (or alkoxide **5c**) with either lithium or magnesium. Since both copper and zinc reagents are known to promote conjugate addition reactions (14), we have studied several combinations of these reagents with **3c** and 2-cyclohexenone to try to effect conjugate addition to form 3-trimethylsilylcyclohexanone (**11**). β-Silyl ketones such as **11** are of interest (for a recent method for preparing β-silyl ketones via silylcopper reagents see ref. 15) because of the directing effect of the silyl group on reactions such as the Baeyer–Villiger reaction (16), the Beckman fragmentation reaction (9*b*, 17), and alkylation reactions (18).

Reactions of silyl ether **3c** with lithium, CuCN, and cyclohexenone gave moderate yields of silyl ketone **11**. The corresponding reactions with activated magnesium instead of lithium gave no evidence for the formation of **11**. The reactions of **3c** with lithium, Et_2Zn, and cyclohexenone gave small amounts of silyl ketone **11** in two reactions. In most cases (Mg–CuCN and Li–Et_2Zn reactions) alcohol **4c** and oxasilacyclopentane **7** were major products.

The best procedure of those we tried used lithium wire and CuCN. An ice-cooled solution of **3c** in ether was treated with lithium wire until conversion to alkoxide **5c** was complete (from GC or GC/MS analysis of aliquots); the resulting solution was cannulated away from the unreacted lithium into a flask containing about 0.5 equiv of CuCN and ether or THF. Cyclohexenone in THF was added at low temperature (–90 to –75°C), and the solution was allowed to gradually warm to room temperature. The progress of the reaction was followed by analysis of aliquots. Two major products were seen in the GC and GC/MS, oxasilacyclopentane **7** and silyl ketone **11**. Silyl ketone **11** was generally not observed at low temperatures, but began to appear above 0°C. Two reactions were run in the presence of tridecane as an internal standard, and in two other reactions tridecane was added to a portion of the crude product. The yields of silyl ketone **11** at completion were determined by GC to be 61–65%.

Following the progress of the reaction by aliquots appeared to be important. In one case the reaction time (3–4 days) was longer than the others (~1 day), and a reaction in which 1.2 equiv of CuCN was used was faster (~7 h), but the GC yields at completion were all about the same.

The use of alcohol **4c** as a precursor to silyl ketone **11** was also investigated. Reactions of **4c** with *n*-BuLi followed by cyclohexenone were carried out using CuCN and Et_2Zn. The use of CuCN gave good yields of silyl ketone **11**. (An attempt to improve the reaction using Me_3SiCl as an additive (19) led to the trimethylsilyl ether of alcohol **4c**.) The use of Et_2Zn instead of CuCN resulted in mostly recovered **4c**; in one reaction silyl ketone **11** was formed in 14% yield by GC.

The role of copper in these reactions was demonstrated by the reaction of **4c** with *n*-BuLi in ether followed by cyclohexenone in THF. The major product was oxasilacyclopentane **7**; there was no evidence for silyl ketone **11**, the 1,2-addition product (1-trimethylsilyl-2-cyclohexenol (20)), or its Brook rearrangement product, the trimethylsilyl ether (21) of 2-cyclohexenol.

In the best procedure, the reactions were run in a very similar manner to those with silyl ether **3c** and lithium wire followed by CuCN: An ice-cooled ether solution of alcohol **4c** was treated with *n*-BuLi, 0.5–0.6 equiv of CuCN, cooled to about –78°C, then cyclohexenone in THF was added. The mixture was gradually warmed to room temperature following the reaction by GC and (or) GC/MS of aliquots. GC and GC/MS showed only oxasilacyclopentane **7** and silyl ketone **11** as major products. In one reaction, the crude product was purified by chromatography, yielding silyl ketone **11** in 50% yield. In another reaction, tridecane was added as an internal standard, and GC yields were determined. As in the case with the reactions of silyl ether **3c** with lithium wire and CuCN, silyl ketone **11** did not begin to appear in the aliquots until the reaction temperature rose above 0°C (e.g., 11% yield of **11** at 14°C, 8.75 h after addition of cyclohexenone). At reaction completion, the GC yield of silyl ketone **11** was 73%.

In summary, we have found that easily available *o*-silyl benzyl alcohols **4** and their precursor silyl ethers **3** can be used to generate alkoxides **5** which undergo facile cleavage reactions. Alcohols **4** and silyl ethers **3** are therefore of potential use for the generation of anionic intermediates.

Experimental section

General procedures

All reactions were carried out under a nitrogen or argon atmosphere, and liquids were transferred with nitrogen- or argon-flushed syringes. The verb "concentrated" refers to removal of the solvent by a rotary evaporator. Column chromatography was carried out as flash chromatography (22)

© 2000 NRC Canada

using 200–425 mesh silica gel. Nuclear magnetic resonance (NMR) spectra were obtained in $CDCl_3$ (^1H at 300 MHz and ^{13}C at 75 MHz) and chemical shifts are reported in δ using $CHCl_3$ (δ 7.26) for ^1H NMR, and $CDCl_3$ (δ 77.00) for ^{13}C NMR as internal standard. Methylene chloride (δ 5.32) was used as an internal standard for ^1H NMR for compounds containing aromatic hydrogens. Gas chromatography (GC) analyses were carried out with a flame ionization detector and using helium as the carrier gas using a Shimadzu GC-14A instrument with a 15 m × 0.32 mm × 25 μm cross-linked methyl silicone gum capillary column, and the following temperature program: 50°C (5 min), 10°C/min to 230°C (15 min) unless otherwise noted. Most reactions were followed by GC or GC/MS of aliquots (using the aqueous workup of the reaction). GC yields were determined using tridecane calibrated with an authentic sample (9) of 3-trimethylsilylcyclohexanone (**11**). In a few cases where noted, GC analyses were carried out with a Hewlett-Packard HP 5880 instrument with 12.5 and 25 m cross-linked polymethyldisiloxane capillary columns and the following temperature program: 50°C (1 min), 10°C/min to 250° (5 min).

Materials

Chloropentamethyldisilane was prepared by a procedure of Ishikawa et al. (23) and was purchased from Gelest. Anhydrous ether and tetrahydrofuran (THF) were distilled from sodium and benzophenone. Lithium wire contained 1% sodium. 2-Cyclohexenone was dried over magnesium sulfate and fractionally distilled under reduced pressure. Triethylamine was distilled from calcium hydride.

*3-Hydroxypropylpentamethyldisilane (**2c**)*

Allylpentamethyldisilane (24) was prepared from fluoropentamethyldisilane (25) and allylmagnesium bromide, and had IR, ^1H NMR, and mass spectra corresponding to those reported (24).

To an ice-cooled solution of 2.43 g (14 mmol) of allylpentamethyldisilane in 10 mL of THF was added 42 mL (42 mmol) of BH_3·THF (1.0 M in THF) dropwise. The ice bath was replaced with a water bath, and the mixture was stirred for 24 h. The mixture was recooled in ice, and the following additions were made: (1) 10 mL of H_2O, (2) 10 mL of 3 M NaOH, (3) 10 mL of 30% H_2O_2 (dropwise). The resulting mixture was heated at 50°C for 3 h, cooled to room temperature, and then 9.0 g of K_2CO_3 was added. The mixture was stirred an additional 5 min, then the layers were allowed to separate, and the aqueous layer was extracted with ether (2 × 10 mL), and the combined organic layers were washed with saturated $NaHCO_3$, dried ($MgSO_4$), concentrated, chromatographed (50 g of Florisil, ether:petroleum ether (3:7)), and Kugelrohr distilled (oven temperature 70°C, oil pump vacuum) to give 1.72 g (64%) of 3-hydroxypropylpentamethyldisilane (**2c**) (26): IR (film) 3340 (b), 2956, 1461, 1246 (m), 1069, 834 cm^{-1}; mass spectrum *m*/*z* (relative intensity, tentative assignment) 190 (M^+, not visible), 147 (5, $(Me_3SiOSiMe_2)^+$), 133 (20), 131 (20, $Me_3SiMe_2Si^+$), 117 (60, $Me_2Si^+CH_2CH_2CH_2OH$), 75 (100, $(Me_2SiOH)^+$). GC analysis (HP 5880, dodecane = 6.42 min) showed one peak at 6.13 min (100%). The ^1H NMR spectrum is the same as that reported (26).

*Reaction of silyl ether 3a with lithium and benzophenone: Formation of benzyldiphenylcarbinol (**8**)*

To a solution of 0.20 g (0.60 mmol) of silyl ether **3a** (5) in 5 mL of anhydrous ether was added 0.1 g (14 mmol) of lithium wire (flattened and washed with petroleum ether). The reaction was stirred at room temperature for 2 h (following the progress by GC analysis of an aliquot). Then 0.12 g (0.66 mmol) of benzophenone was added, and the reaction mixture was stirred at room temperature for 30 min (aliquots showed little or no reaction). Then 5 mL of THF was added, and the progress of the reaction was followed by aliquots taken after 5 min, 30 min, and 12 h. The reaction mixture was then added to saturated $NaHCO_3$ and extracted twice with ether. The organic layer was dried ($MgSO_4$), concentrated, and chromatographed on 20 g of silica gel using 8:2 pet ether:ether giving 0.094 g (57%) of benzyldiphenylcarbinol (**8**) as a white solid: mp 88–89°C (lit. (27) mp 89–90°C).

*o-Bromobenzyloxypentamethyldisilane (**3c**)*

A solution of 6.30 g (33.7 mmol) of *o*-bromobenzyl alcohol, 14 mL of triethylamine, and 110 mL of anhydrous ether was cooled in an ice bath, and 5.80 g (34.8 mmol) of pentamethylchlorodisilane in 15 mL of anhydrous ether was added dropwise. The mixture was stirred at room temperature for about 2 h, and then added to 170 mL of aqueous $NaHCO_3$ overlaid with 50 mL of ether. The organic layer was washed with water (4 × 30 mL), dried ($MgSO_4$), concentrated, and placed under oil pump vacuum (3 mm, 4 h). Chromatography on silica gel (26.7 × 4.4 cm) using petroleum ether gave 10.2 g (92%) of silyl ether **3c** (5): IR (neat) 3066, 2950, 2891, 1443, 1375, 1247, 1090, 1026, 837, 806, 749 cm^{-1}; ^1H NMR δ 0.17 (s, 9 H), 0.34 (s, 6 H), 4.76 (s, 2 H), 7.15 (crude t, *J* = 7 Hz, 1 H), 7.37 (crude t, *J* = 7 Hz, 1 H), 7.5–7.6 (m, 2 H); ^{13}C NMR (assignments by DEPT) δ –2.01 (CH_3), –0.75 (CH_3), 64.99 (CH_2), 121.08 (C), 127.23 (CH), 127.62 (CH), 128.15 (CH), 131.98 (CH), 140.12 (C). GC analysis showed one major peak at 15.3 min (100%). The mass spectrum was equivalent to that reported (5).

*o-Pentamethyldisilylbenzyl alcohol (**4c**)*

A solution of 10.77 g (33.9 mmol) of *o*-bromobenzyloxypentamethyldisilane (**3c**) in 130 mL of anhydrous ether was cooled in an ice bath. Lithium wire was wiped with paper towels to remove oil, weighed, placed between weighing papers, flattened with a hammer, and cut into small pieces. To the above solution 2.18 g (314 mmol) of the lithium was added. Typically, the reaction was stirred at ice temperature until the slurry turned from slightly turbid to light brown-yellow or until GC or GC/MS indicated the reaction had begun. Then the ice bath was removed, and the reaction was stirred at room temperature until GC and (or) GC/MS indicated the reaction was complete (and the reaction mixture had turned cloudy gray). In this case, the reaction was stirred at ice temperature 1.5 h after the addition of lithium, and 1 h after removal of the ice bath. The reaction mixture was transferred to a beaker, and the remaining lithium pieces were quickly removed. The mixture was then immediately poured into 120 mL of aqueous $NaHCO_3$ overlaid with 50 mL of ether. The organic layer was dried ($MgSO_4$), concentrated, placed under oil pump vacuum (0.75 mm,

© 2000 NRC Canada

2.5 h), and chromatographed on silica gel (35 × 4.4 cm) using petroleum ether:ether (1:0, 7:3, and then 1:1) giving 6.82 g (84%) of alcohol **4c**. The IR, ^{1}H NMR, ^{13}C NMR, and mass spectra were equivalent to those reported (5).

*Reaction of silyl ether **3c** with lithium, CuCN, and 2-cyclohexenone*: *Formation of 3-trimethylsilylcyclohexanone (**11**)*

A solution of 1.10 g (3.47 mmol) of silyl ether **3c** and 40 mL of anhydrous ether was cooled in an ice bath, and 0.22 g (31.7 mmol) of lithium wire (for handling, see the synthesis of **4c**) was added. The progress of the reaction was followed visually and by GC/MS as described for the synthesis of **4c**. In this case, the reaction was stirred in an ice bath for 35 min, and then the ice bath was removed and stirring was continued (total 2 h). The reaction mixture was transferred via cannula into an ice-cooled mixture of 0.20 g (2.23 mmol) of CuCN in 40 mL of THF. The resulting dark brown slurry was stirred for 35 min at ice temperature, and then cooled to –75°C. After 15 min, 0.6 mL (6.2 mmol) of cyclohexenone in 20 mL of THF was added dropwise. The slurry was kept at –80°C for 1 h, then allowed to warm up gradually to room temperature, and the progress of the reaction was monitored by GC/MS and GC analysis of aliquots. After 21 h, the mixture was added to 160 mL of aqueous NH_4Cl overlaid with 50 mL of ether. The organic layer was dried ($MgSO_4$) and concentrated. The GC analysis showed peaks at 7.91 min (59%, oxasilacyclopentane **7**), 9.35 min (29%, silyl ketone **11**), and 16.32 min (12%), and the GC/MS showed two peaks in the GC chromatogram having mass spectra corresponding to **7** (major) and **11**. The product was placed under oil pump vacuum (2.5 mm, 0.5 h) giving 1.65 g of a light brown crude product. The IR, ^{1}H NMR, and ^{13}C NMR were consistent with the presence of predominantly **7** and **11**. A portion of the product was mixed with tridecane in ether, and the GC yield of **11** was calculated to be 65%.

An analogous reaction was done in which the reaction mixture was cannulated into CuCN in ether rather than in THF. GC analysis of the crude product showed two major peaks at 7.99 min (57%, **7**) and 9.45 min (43%, **11**). The spectra were all consistent with predominantly **7** and **11**. A portion of the crude product was mixed with tridecane in ether, and the GC yield of silyl ketone **11** was calculated to be 62%.

A similar reaction was done in which the standard was present when the aliquots were taken (and 1.2 equiv of CuCN were used), and GC yields were calculated at various reaction times: 0.76 g (2.39 mmol) of silyl ether **3c** in 45 mL of anhydrous ether, 0.25 g (36 mmol) of lithium wire, 0°C for 2.5 h; mixture transferred via cannula into an ice-cooled mixture of 0.25 g (2.79 mmol) of CuCN, 0.074 g of tridecane, and 15 mL of anhydrous ether (0°C for 35 min), then cooled to –90°C for 20 min; cyclohexenone (0.55 mL, 5.68 mmol) in 35 mL of THF added, –80 to –85°C for about an hour, and then mixture warmed gradually to room temperature, monitoring progress of the reaction by GC and GC/MS of aliquots. GC yields are given in Table 1.

After 10.3 h, the reaction was quenched by adding it to aqueous NH_4Cl overlaid with ether, the organic layer was dried ($MgSO_4$), and the GC yield of **11** was determined to be 62%. After removal of solvent, the spectra (IR, ^{1}H NMR, ^{13}C NMR, GC/MS) were all consistent with the presence of oxasilacyclopentane **7**, silyl ketone **11**, and tridecane, and the GC analysis showed peaks at 7.93 min (31%, **7**), 9.38 min (16%, **11**), and 11.22 min (10%, tridecane).

Table 1. GC yields of aliquots.

Time (h)	Temp (°C)	% GC yield of **11**
1.1	–83	0
4.1	5	33.0
7.3	16	61.0
9.8	15	60.6

Table 2. GC yields of aliquots.

Time (h)	Temp (°C)	% GC yield of **11**
0.5	–80	0
3.5	–7	0
6.75	9	3.2
8.75	14	11.3
11.25	16	39.8
21.75	22	73.1

*Reaction of alcohol **4c** with n-BuLi, CuCN, and 2-cyclohexenone: Formation of 3-trimethylsilylcyclohexanone (**11**)*

A solution of 1.05 g (4.40 mmol) of alcohol **4c** in 100 mL of anhydrous ether was cooled in an ice bath and 3.9 mL (6.24 mmol) of *n*-butyllithium (1.6 M in hexane) was added. The reaction mixture was stirred and cooled in an ice bath for about 0.5 h at which time the slurry turned light yellow. Then 0.23 g (2.6 mmol) of CuCN was added, within 5 min 40 mL of THF was added, and the mixture was stirred at 0°C for 20 min. Then the slurry was cooled to –80°C, and after 35 min, a solution of 0.74 mL (7.64 mmol) of cyclohexenone in 80 mL of THF was added. The reaction mixture was allowed to warm up gradually, and the progress of the reaction was monitored by GC analysis and GC/MS of aliquots. The reaction mixture was quenched after 13 h by adding it to a mixture of 200 mL of aqueous NH_4Cl overlaid with 85 mL of ether, and the organic layer was dried ($MgSO_4$) and concentrated. GC analysis showed two major peaks at 6.17 min (55%, oxasilacyclopentane **7**) and 7.82 min (19%, silyl ketone **11**), and a number of small peaks from 10–25 min. The product was placed under oil pump vacuum (6–7 mm, 2 h). The spectra were consistent with the presence of **7** and **11**. The crude product was chromatographed on silica gel (24 × 2.9 cm). Elution with petroleum ether:ether (4:1) gave 0.372 g (50% yield) of silyl ketone **11** as a colorless liquid: ^{13}C NMR (assignments by APT) δ –3.90 (CH_3), 25.85 (CH_2), 27.82 (CH), 29.75 (CH_2), 41.77 (CH_2), 42.19 (CH_2), 212.41 (C=O); GC/MS *m*/*z* (relative intensity, tentative assignment) 170 (16, M^+), 169 (15), 155 (24, M^+ – Me), 127 (20), 75 (65), 73 (100, Me_3Si^+). The spectra were essentially identical to those of an authentic sample of silyl ketone **11** (9), and the IR and ^{1}H NMR were identical to those reported (15).

An analogous reaction was done in which the standard was present when the aliquots were taken, and GC yields

© 2000 NRC Canada

were calculated at various reaction times: 0.63 g (2.64 mmol) of alcohol **4c** in 45 mL of anhydrous ether and 0.135 g of tridecane, 1.7 mL (3.4 mmol) of *n*-butyllithium (2.0 M in cyclohexane) (0.5 h at 0°C), 0.135 g (1.5 mmol) of CuCN (30 min), cooled to –75°C for 15 min, dropwise addition of 0.45 mL (4.65 mmol) of cyclohexenone in 40 mL of THF, gradual warming to room temperature, monitoring the reaction by GC analysis of aliquots. GC yields are given in Table 2.

After 22.75 h the reaction was quenched by adding it to aqueous NH_4Cl overlaid with ether, the organic layer was dried ($MgSO_4$), and the GC yield of **11** was determined to be 73%. After removal of solvent, the spectra (IR, ^{1}H NMR, ^{13}C NMR, GC/MS) were all consistent with the presence of oxasilacyclopentane **7**, silyl ketone **11**, and tridecane.

The insertion of germylene into the H—H bond; rate constant limits and thermochemistry. Ab initio and DFT calculations on the reactions of GeH_2 and SiH_2 with H_2

Rosa Becerra, Sergey E. Boganov, Mikhail P. Egorov, Valery I. Faustov, Oleg M. Nefedov, and Robin Walsh

Abstract: The technique of laser flash photolysis in the gas-phase has been used to set limits on the rate constants for the bimolecular reaction of germylene (GeH_2) with deuterium (D_2) at both ambient and elevated temperatures (585 K). These limits show that the activation energy for the insertion of GeH_2 into the H—H bond is at least 19 (±6) kJ mol^{-1}. Thermochemical arguments place the activation energy approximately in the range 63–84 kJ mol^{-1}. DFT B3LYP/6–311++G(3df,2pd) and ab initio QCISD(T)/6–311G++(3df,2pd)//QCISD/6–311G(d,p) calculations have been carried out on the potential energy surfaces of reactions $ZH_2 + H_2 \rightarrow ZH_4$ (Z= Ge, Si). Both methods predict the same mechanisms for germylene and silylene insertion which include formation of loose prereaction complexes and transition states of similar structure. The prereaction complex is only about half as strong in the case of germylene (ΔH (298 K) = –9 (–11) kJ mol^{-1}) as in the case of silylene (ΔH (298 K) = –16 (–21) kJ mol^{-1}) (QCISD values cited with B3LYP values in parentheses). The differences in activation energies are even more significant. Germylene insertion has a very high barrier of 58 (56) kJ mol^{-1} compared to that of silylene 13 (6) kJ mol^{-1}. Calculated activation parameters for both reactions are in reasonable consistency with experimental results. Reasons for the enhanced H-H insertion barrier for germylene compared with silylene are discussed.

Key words: laser flash photolysis, germylene, silylene, deuterium, activation energy, thermochemistry, ab initio calculation, DFT B3LYP calculation.

Résumé : On a fait appel à la technique de la photolyse éclair au laser pour déterminer les limites des constantes de vitesse de la réaction bimoléculaire du germylène (GeH_2) avec le deutérium (D_2) à des températures tant ambiantes qu'élevées (585 K). Ces limites montrent que l'énergie d'activation pour l'insertion du GeH_2 dans la liaison H—H est d'au moins 19 ± 6 kJ mol^{-1}. Des arguments thermodynamiques suggèrent que la valeur de l'énergie d'activation est de l'ordre de 63 à 84 kJ mol^{-1}. On a effectué des calculs DFT B3LYP/6–311++G(3df,2pd) et des calculs ab initio QCISD(T)/6–311G ++(3df,2pd)//QCISD/6–311G(d,p) sur les surfaces d'énergie potentielle des réactions $ZH_2 + H_2 \rightarrow ZH_4$ (Z = Ge, Si). Les deux méthodes prédisent les mêmes mécanismes pour la réaction d'insertion du germylène et du silylène; ils comportent la formation de complexes préréactionnels lâches et des états de transition de structure similaire. La force du complexe préréactionnel du germylène est approximativement la moitié (ΔH (298 K) = –9 (–11) kJ mol^{-1}) que dans le cas du silylène (ΔH (298 K) = –16 (–21) kJ mol^{-1}) (dans lesquelles la valeur citée correspond à QCISD et la valeur entre parenthèses aux calculs B3LYP). Les différences dans les énergies d'activation sont plus significatives. La valeur de la barrière pour l'insertion du germylène est très élevée 58 (56) kJ mol^{-1} par comparaison avec celle du silylène 13 (6) kJ mol^{-1}. Les paramètres d'activation calculés pour les deux réactions sont en accord raisonnable avec les résultats expérimentaux. On discute des raisons de la barrière d'insertion H—H plus élevée pour le germylène par comparaison avec le silylène.

Mots clés : photolyse éclair au laser, germylène, silylène, deutérium, énergie d'activation, thermochimie, calculs ab initio, calculs DFT B3LYP.

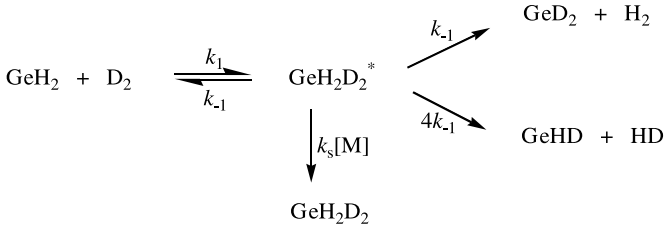
Introduction

Germylene(GeH_2) is thought to be an important intermediate in the chemical vapour deposition (CVD) of semiconductor germanium from GeH_4 (1, 2). It is certainly the key intermediate in the thermal decomposition of GeH_4 (3). Interest in this species has grown, not only because of its involvement in the materials formation process, but also because in recent years it has become accessible to direct monitoring by laser resonant absorption (4–7). Studies in our laboratories have shown that GeH_2 inserts into Ge—H bonds with a negative activation energy which is greater (i.e., more negative) for the Ge—H bond in Et_3GeH (5) than that in GeH_4 (6). In this respect the kinetic and mechanistic behaviour of GeH_2 parallels that of SiH_2 (8–10) which undergoes the equivalent Si—H bond insertion processes. However GeH_2 is less reactive than SiH_2 in its counterpart reactions and shows greater selectivity (alkyl substituents enhance the reactivity of Ge—H bonds to GeH_2 more than of Si—H bonds to SiH_2). This can be explained in terms of the involvement, and binding strengths, of the H bridged complexes formed as intermediates, whose relative stabilities have been calculated by ab initio methods (6).

The question naturally arises of the ability of GeH_2 to insert into the H—H bond, viz.

[1] $GeH_2 + H_2 \rightarrow GeH_4$



This is arguably the simplest insertion reaction of all and is potentially of great significance in CVD systems where H_2 is present. The kinetics of the silylene analogue of [1] were first investigated by Jasinski (11), viz.

[2] $SiH_2 + H_2 \rightarrow SiH_4$

This study made a dramatic impact. Not only was it amongst the earliest of absolute rate measurements for SiH_2, but the rate constant obtained (2.6×10^{-12} cm^3 $molecule^{-1}$ s^{-1} for $SiH_2 + D_2$) was more than 10^4 times greater than expected from earlier indirect experimental measurements (12) or available theoretical calculations (13–16). Thus, this paper caused a significant re-evaluation of the reactivity and thermochemistry of SiH_2.

At the present time there has been no reported (or attempted) measurement of the rate constant of rxn. [1] nor any published calculation of the energy barrier of reaction [1]. Thus unlike for rxn. [2] there is no prior history. The reaction is however ripe for investigation. It is an important point to note that we have chosen to study the deuterium variant of [1], following the logic of Jasinski (11) who studied the deuterium version of [2] (viz. $SiH_2 + D_2$). The reason for this is straightforward; it is to avoid the potential complications arising from studying a third-body assisted association process at pressures below the high-pressure (true bimolecular) limit. The reaction of GeH_2 with D_2 can be described by the mechanism shown in Scheme 1. In this reaction the initial insertion product is vibrationally excited $GeH_2D_2^*$. This species can then either be collisionally stabilized by the third body, or decompose unimolecularly by one of the three pathways shown. Of these three pathways, assuming there are no unexpectedly large isotope effects, reversion to $GeH_2 + D_2$ is only one, and indeed on probability grounds represents only one in six of the possible decomposition channels for $GeH_2D_2^*$. Thus the monitoring of the disappearance of GeH_2 (with its unique isotopic absorption signature) should correspond, to a good approximation, to the rate constant k_1 for the true bimolecular process.

Scheme 1.

We have also carried out ab initio QCISD and DFT B3LYP calculations on the potential energy surfaces of both rxns. [1] and [2]. Silylene insertion [2] was naturally chosen as a reference reaction, not only because of the intrinsic interest in comparing Ge with Si, but also because there is a wealth of experimental (8, 9) and theoretical data (13–17) for [2]. Both reactions may be considered as test systems for comparison of the accuracy of various levels of quantum chemical calculations against kinetic and thermochemical data.

Experimental

Rate measurements

Germylene kinetic studies have been carried out by the laser flash photolysis technique, details of which have been published previously (4–6). Only essential details are therefore included here. GeH_2 was produced by photodecomposition of 3,4-dimethylgerma-cyclopentene-3 (DMGCP) using the 193 nm line of a pulsed excimer laser (Coherent Compex 100). GeH_2 was detected and monitored in real time by use of a single mode dye laser (Coherent 699–21) pumped by an argon ion laser (Coherent Innova 90–5), tuned to a known strong vibration–rotation transition at 17 111.31 cm^{-1} in the visible A ← X absorption band. Experiments were carried out in a variable temperature spectrosil quartz vessel with demountable windows which were regularly cleaned. Signal decays from 3–10 photolysis laser shots (at 60 mJ/pulse) were averaged and found to give good first order linear fits (ln (abs) vs. t plots up to 90% signal decay). These experiments yielded values for the first order rate coefficient, k_{obs}, for removal of GeH_2 in the presence of known partial pressures of D_2. Gas mixtures for study consisted of a few mtorr (1 torr = 133.322 Pa) of DMGCP and various amounts of substrate D_2 (limited by pressures which caused signal quenching). DMGCP was synthesised by us previously (4). Deuterium (British Oxygen Co) was 99.8% pure (0.2% of HD). It contained no GC detectable impurities and was handled carefully to avoid contamination by non-condensibles (air).

Ab initio and DFT calculations

In the ab initio calculations geometry optimisations, vibrational analyses and reaction paths were performed at the frozen core, QCISD/6–311G(d,p) level (18). All the structures obtained here were verified, by examination of the frequency matrix, as minima (all frequencies real) or transition

states (TSs) (one imaginary frequency). Final energies were refined by single point QCISD(T)/6–311G++(3df,2pd) calculations, which are denoted subsequently in this paper as QCISD(T)/6–311G++(3df,2pd)//QCISD/6–311G(d,p). The DFT calculations, including the finding and verification of stationary points, were done with the B3LYP functional (19) using the 6–311++G(3df,2pd) basis. Energies from both levels of theory were corrected to include zero point vibrational energy contributions. For all stationary points we also calculated enthalpies and Gibbs free energies at 298 K. For these other thermodynamic functions, harmonic oscillator and rigid rotor models were used throughout, employing geometries and frequencies (unscaled) from the appropriate set of calculations.

Transition states were confirmed by calculations along the minimum energy paths (intrinsic reaction coordinate, IRC) connecting them with local minima. Most of the calculations carried out here were performed using GAUSSIAN 94 (20) on the SGI POWER CHALLENGE L supercomputer at the computer center of IOC RAS, Moscow.

Results and discussion

Kinetics and thermochemistry

The reaction was studied at 293 K and 585 K at several partial pressures of D_2. The results are shown in Table 1. It is clear from the extremely small variation in values of k_{obs} under the operational conditions that there is very little if any reaction. Even at the maximum pressures of D_2 at each temperature the values of k_{obs} are barely beyond the uncertainties of the measurements without D_2. At intermediate pressures of D_2 the values are consistent. It is certainly possible that the small increases observed could have been caused by as little as 0.01% of an impurity reacting at the collision rate. To obtain an upper limit to the true second-order rate constants, the maximum values of k_{obs} at the highest D_2 pressures were combined with the zero D_2 values and the difference attributed to reaction. This yielded for k_1, maximum values of 1.0×10^{-14} cm^3 $molecule^{-1}$ s^{-1} at 293 K and 1.7×10^{-14} cm^3 $molecule^{-1}$ s^{-1} at 585 K. The difference between these values, which for the reasons given only represent upper limiting values, is not significant, and we therefore saw no point in investigating intermediate temperatures (or further D_2 pressures).

Because these measurements have only given limiting values, the magnitudes of the true rate constants remain to be obtained. Nevertheless each value can be used independently to obtain a lower limiting value for the activation energy $E_a[1]$ through the use of an estimated A factor, $A_1 = 10^{-12.07}$ cm^3 $molecule^{-1}$ s^{-1}. This is obtained by analogy with the measured A factor (8,9) for $SiH_2 + D_2$ (deuterium analogue of rxn. [2]). Use of this value leads to the activation energy values shown in Table 2. Clearly the advantage of the higher temperature study is to have provided a better (higher) limit. While the value of A_1 has been assumed by analogy with A_2, it is worth noting that the values of the A factors for the reverse reactions, A_{-1} and A_{-2}, obtained by study of the thermal decompositions of GeH_4 (3) and SiH_4 (21) respectively, are both $10^{15.5}$ s^{-1}. Since the entropy changes for these isostructural reactions are likely to be close to one another, this adds weight to the assumption of similar forward reaction A factors. The activation energies quoted in Table 2 nevertheless allow for an uncertainty of $10^{\pm 0.5}$ in the estimate of A_1.

Table 2. Limiting values for rate constants and derived activation energies[a] for $GeH_2 + D_2$

Temp (K)	k_1 (cm^3 $molecule^{-1}$ s^{-1})	$E_a[1]$ (kJ mol^{-1})
293	$< 1.0 \times 10^{-14}$	> 10.8 (±3)
585	$< 1.7 \times 10^{-14}$	> 19.2 (±6)

[a]Based on assumed A factor (see text).

There are no previous measurements of this activation barrier by direct means. However this result can be illuminated by consideration of the expected value based on thermochemistry. For the reverse reaction, viz.

[–1] $GeH_4 \rightarrow GeH_2 + H_2$

$\Delta H°$ may be estimated from $\Delta H_f°(GeH_4) = 90.4 \pm 2.1$ kJ mol^{-1} (22) together with $\Delta H_f°(GeH_2) = 237.2 \pm 12$ kJ mol^{-1} by experiment (6), or 250–258 kJ mol^{-1} (6, 23, 24) by theoretical calculation. This puts $\Delta H°[-1]$ in the range 147–168 kJ mol^{-1}; at the lower end from experimental data alone, at the higher end using theoretical information. The thermal decomposition of GeH_4 in static systems is highly perturbed by surface reactions (for previous studies of the kinetics of GeH_4 decomposition see ref. 3). Only one study by Newman et al. (3) in a shock tube in the temperature range 950–1060 K yields reliable kinetic measurements of rate constants of the purely homogeneous rxn. [–1]. Under these conditions the reaction is in its unimolecular fall-off region and RRKM modelling was required to obtain the true infinite pressure value of $E_a[-1]$ for which a figure of 227 kJ mol^{-1} was obtained (error limits are not quoted). If this value is assumed reasonably independent of temperature, then $E_a[1]$ can be

[a]For reagents and products calculated QCISD (B3LYP) parameters are: H_2, *R*(H—H) = 0.744 (0.743); GeH_2, *R*(Ge—H) = 1.592 (1.596), *A*(H-Ge-H) = 91.8 (90.9); GeH_4, *R*(Ge—H) = 1.535 (1.534); SiH_2, *R*(Si—H) = 1.516 (1.523), *A*(H-Si-H) = 92.6 (91.6); SiH_4, *R*(Si—H) = 1.476 (1.480).

obtained via $E_a[1] = E_a[-1] - (\Delta H° - RT)$. From the figures cited this puts $E_a[1]$ in the range 63–84 kJ mol^{-1} (estimated at a temperature of 500 K). Because of the assumptions concerning $E_a[-1]$ the uncertainty must be considered slightly larger than this. Nevertheless this thermochemical estimate is well above the limit set by experiment and therefore shows that unless the thermochemical data are seriously in error, a fast reaction between GeH_2 and H_2 is not to be expected.

Quantum chemical calculations

Apart from the reactants, $GeH_2 + H_2$, and the product, GeH_4, we find two stationary points on the potential energy surface (PES) corresponding to a local minimum and a transition state, both of C_s symmetry. These are shown in Fig. 1. The same set of stationary points was found for the silylene rxn. [2]. For the latter reaction this agrees with earlier studies at the MP4(SDQ)/6–31G*//HF/3–21G level (15), MRD-CI/TZ+P level (16) and MP4/6–311G++(3df,3pd)//MP2/6–311G(2d,2p) level (17). The geometrical parameters of these structures are shown in Table 3, including comparisons with earlier work in the silylene case. The geometries from the B3LYP and QCISD calculations are in good agreement with each other not only for the stable species (reagents and products) but also for the TSs and complexes. The bigger differences found between silylene and germylene complexes reflect the rather loose nature of these structures. The calculated energies are shown in Table 4.

The prereaction complex in the germylene reaction is only about half as strong (ΔH (298 K) = –9 (–11) kJ mol^{-1}) as that in silylene case (ΔH (298 K) = –16 (–21) kJ mol^{-1}). Both here and subsequently the QCISD values are given first, with the B3LYP values following in parentheses. Despite the weakness of these species the interactions of the two fragments are significant enough to stretch the H—H bond (H^4—H^3) by 0.015 (0.030) Å in the germylene complex and by 0.039 (0.062) Å in the silylene complex. [a]Calculated QCISD (B3LYP) total energies of reagents (hartree): H_2, –1.17235 (–1.180013); GeH_2, –2076.57037 (–2078.16115); SiH_2, –290.16762 (–290.643748).

characteristics of the silylene complex are in close similarity to those of the previous highest level of calculation by Gordon et al. (17) although our complex is slightly looser especially in the QCISD calculations.

According to our calculations rxns. [1] and [2] have similar TSs. The distinction between them is only of the degree to be expected from the characteristic differences in Ge—H and Si—H bond lengths. The breaking H^4—H^3 bond of the germylene TS is stretched by 0.472 (0.508) Å compared to 0.373 (0.398) Å for the silylene TS. This implies that the PES maximum in the germylene insertion [1] is shifted towards the product compared to the silylene case [2] in agreement with expectations from Hammond's postulate (25) for a less exothermic process. The TS structure for the silylene insertion [2] found here is very similar to those calculated earlier by Sosa and Schlegel (15) and Gordon et al. (17) but differs somewhat from that of Sax and Olbrich (16) (Table 3). The latter has a much more extended H^4—H^3 bond, which looks (with hindsight) out of keeping with the early nature of the transition state (based on energy). This was probably a deficiency of the calculation.

The values for $\Delta H°$[1] calculated by the QCISD and B3LYP methods are –168 and –157 kJ mol^{-1}, respectively, (Table 4). Both fall within the range –147 to –168 kJ mol^{-1} estimated from thermochemistry and indicated above, and are consistent with our ab initio calculations on the reaction of GeH_2 with GeH_4 (6). The ab initio barrier ($E_a = \Delta E$ + ZPE) of 53 (50) kJ mol^{-1} at 298 K is slightly lower than the thermochemically estimated range of 63–84 kJ mol^{-1} at 500 K. However for the reasons given in the previous section this must be considered quite good agreement. The calculations may be judged by the results for the silylene case for which both methods give the same value of $\Delta H°$[2] of –234 kJ mol^{-1} (Table 4). This compares well with the current best value of –239 ± 3 kJ mol^{-1} (derived from $\Delta H_f°(SiH_4)$ = 34.3 ± 1.2 kJ mol^{-1} (26) and $\Delta H_f°(SiH_2)$ = 273.2 ± 2 kJ mol^{-1} (8, 10)). The QCISD barrier, ΔE[2] of 7 kJ mol^{-1} is slightly higher than the measured E_a of – 2 kJ mol^{-1} (8, 9) but as reasonably close as the previous best calculation of Gordon et al. (17) who also obtained 7 kJ mol^{-1} (the other earlier calculations (13–16) gave significantly higher barriers). Even better agreement for the barrier ΔE[2] was obtained in B3LYP calculations (0 kJ mol^{-1}). It appears that DFT methods, with their markedly lower computational demands, can produce good results for these quite large systems. Thus B3LYP may be considered as the best choice for studying this type of reaction.

The calculations carried out here show that, despite the mechanistic similarity, rxn. [1] has a significant barrier compared with rxn. [2] and so a fast reaction between GeH_2 and H_2, like that between SiH_2 and H_2, is not to be expected. It prompts the question as to why there is a significant increase of activation barrier from [2] to [1]. Sax and Olbrich (16) actually predicted this qualitatively on the basis of a valence-bond configuration mixing (VBCM) model (27, 28) which was employed to explain the differences between the silylene and methylene ($^1A_1$ states) reactions with H_2. The VBCM model involves energy surface mixing with surfaces derived from triplet state species. Despite the slight deficiencies of structure and energy in the calculations mentioned above (16), Sax and Olbrich make their prediction for GeH_2 + H_2 on the basis that the singlet-to-triplet excitation of GeH_2 is ca 17 kJ mol^{-1} higher than that of SiH_2. Whatever the merits of this argument we would point out that our calculations show unequivocally the extra extension of the H—H bond in the TS for rxn. [1] compared to [2] and this is consistent with the need to satisfy the less favourable H···Ge overlap compared to that of H···Si, due to the more diffuse nature of the germanium atomic orbitals. This reasoning also qualitatively supports a more demanding energy requirement for germylene than silylene in reaching the transition state.

The existence of pre-TS complexes of GeH_2 and SiH_2 with H_2 as predicted here, presents a challenge to experiment. The possibility exists of direct spectral observation at low temperatures. In this respect, the germylene complex may be more amenable to isolation than its silylene counterpart,

© 2000 NRC Canada

despite its weaker binding. This is because of the existence of the substantial barrier to formation of GeH_4, in contrast to the low barrier separating the silylene complex from SiH_4. The positive ΔG of complexation at 298 K makes equilibrium detection of either species totally unlikely.

We finish by noting the contrasts between GeH_2 and SiH_2 insertion reactions. Both species insert readily and rapidly into Ge—H bonds (5, 6) and also Si—H bonds (29).[2] Activation energies for these processes are all negative but are more negative for GeH_2 than for SiH_2 insertions although potential energy surfaces show many similarities. For H—H bond insertion, despite some similarity of the potential energy surfaces, GeH_2 requires significant activation whereas SiH_2 does not. For C—H bond insertion, reactions of both GeH_2 and SiH_2 with CH_4 require significant activation. For GeH_2 a recent DFT calculation gives a barrier of 138 kJ mol^{-1} (30), whereas for $SiH_2 + CH_4$ the best estimate of the barrier is 59 kJ mol^{-1} (31).

Dehydrocoupling reactions of hydrosilanes with group 4 metallocenes Cp_2MY_2 (M = Ti, Zr, Hf; Y = F, OPh, NMe_2)

Qingzheng Wang and Joyce Y. Corey

Abstract: Dehydrocoupling polymerization of phenylsilane with group 4 metallocene precatalysts Cp_2MY_2 (M = Ti, Zr, Hf; Y = F, OPh, NMe_2) under comparable conditions has been examined. All nine title metallocenes produced polysilane products which ranged in molecular weight from 1100 to 4400 and exhibited ratios of linear to cyclic products from ~2 to 30. The highest molecular weight polysilanes observed for each metal were obtained from $Cp_2M(NMe_2)_2$ and the highest percentage of linear polysilane was found with $Cp_2Hf(NMe_2)_2$. The near stoichiometric reactions of Cp_2MY_2 with $PhSiH_3$, $PhMeSiH_2$, and Ph_2MeSiH were monitored by ^1H, ^{19}F and ^{29}Si NMR spectroscopy and in all cases exchange products containing Si-Y were identified. Metal hydride species could be observed only with Cp_2TiY_2.

Key words: metallocene, dehydrocoupling, polymerization, hydrosilanes, polysilane.

Résumé : On a étudié la polymérisation par déshydrocouplage du phénylsilane avec des précatalyseurs métallocènes du groupe 4, Cp_2MY_2 (M = Ti, Zr, Hf; Y = F, OPh, NMe_2) dans des conditions comparables. Les neuf métallocènes mentionnés dans le titre ont tous conduit à la formation de polysilanes dont les poids moléculaires varient de 1100 à 4400 et pour lesquels les rapports de produits linéaires à cycliques vont d'environ 2 à 30. Pour chacun des métaux, les poids moléculaires les plus élevés de polysilanes ont été obtenus avec le $Cp_2M(NMe_2)_2$; le pourcentage de polysilane le plus élevé a été obtenu avec le $Cp_2Hf(NMe_2)_2$. La spectroscopie RMN du ^1H, ^{19}F et ^{29}Si a permis de suivre les réactions pratiquement stoechiométriques des Cp_2MY_2 avec $PhSiH_3$, $PhMeSiH_2$ et Ph_2MeSiH; dans chacun des cas, on a pu identifier des produits d'échange comportant la liaison Si-Y. On n'a pu observer des espèces hydrures métalliques qu'avec le Cp_2TiY_2.

Mots clés : métallocène, déshydrocouplage, polymérisation, hydrosilanes, polysilane.

Introduction

Polysilanes exhibit unusual electronic, optical, and chemical properties that have potential technological applications (1). The polymers are traditionally prepared through Wurtz-type coupling of a dichlorosilane by an alkali metal (1). However, the vigorous nature of Wurtz coupling conditions limits the incorporation of some functional groups on the substituents at silicon. Alternative approaches, such as dehydrocoupling (2), ring-opening polymerization of cyclosilanes (3), and anion induced polymerization of masked disilenes (4), have been developed as alternate methods for the synthesis of polysilanes.

Group 4 transition metal catalyzed dehydrocoupling reactions of primary silanes ($RSiH_3$) by metallocenes, Cp_2MR_2 (Cp = η^5-C_5H_5; M = Ti, Zr; R = Me, Ph) were reported in the 1980's by Harrod and co-workers (5). Since then other Group 4 metallocene precursors have been found to be effective including CpCp*M[$Si(SiMe_3)_3$]R (Cp* = η^5-C_5Me_5; M = Zr, Hf; *R* = H, Cl, Me) developed by Tilley and co-workers (2*a*, *e*), Cp_2MCl_2/*n*-BuLi developed by Corey and co-workers (6), and $Cp_2M(OAr)_2$ [M = Ti, Zr; Ar = *p*-XC_6H_4 (X = MeO, Me, Cl, CN)] reported by Corriu and co-workers (7). Recently, we (8*a*) and Marschner's group (8*b*) concurrently discovered that Cp_2MF_2 (M = Ti, Zr) could function as a catalyst precursor for the dehydrocoupling of hydrosilanes. In this report we describe our continued work on the dehydrocoupling of hydrosilanes utilizing Cp_2MY_2 (X = F, OPh, NMe_2) as single component catalysts.

Results

Dehydropolymerization of $PhSiH_3$

After varying induction periods, which occurred when Cp_2MY_2 was added to $PhSiH_3$, gas evolution and color changes were observed followed by dehydropolymerization of the silane (eq. [1]).

[a]The end of the induction period is signaled by gas evolution and the indicated color change (dk = dark, brt. = bright). Reactions were run neat with 1 mol% catalyst precursor and conducted at room temperature after the induction period.

[b]Unless otherwise indicated, polymerization reactions were terminated after 2 days. The molecular weights were determined relative to polystyrene standards; UV detector.

[c]From ref. 8b; condensations performed neat with 1 mol% catalyst precursor, for 1 week. Sample contains about 30% cyclics.

[d]From ref. 8b; 1 mol% catalyst precursor for 3 days. Sample contains <10% cyclics.

[e]From ref. 7; reaction performed neat with 0.1 mol% catalyst precursor for 1 day. Sample contains 25% cyclic.

[f]From ref. 7; reaction performed neat with 0.1 mol% catalyst precursor for 3 days. Sample contains 10% cyclics.

[g]Data obtained after 5 days.

[h]Data obtained after 3 days.

[i]4 mol% Cp_2HfCl_2 (ref. 9*b*).

The reactions of $Cp_2M(OPh)_2$ (M = Ti, Zr, Hf) and Cp_2HfF_2 required heat to initiate catalyst formation but the polymerizations were conducted at room temperature. Reactions of Cp_2MY_2 (1 mol%) with $PhSiH_3$ are summarized in Table 1 as well as the molecular weights of the polysilane products obtained after 48 h.[2] Molecular weight data collected after 24 h and 72 h were similar. When mixtures were examined before the color change and gas evolution occurred, no polysilane oligomers or polymers were observed. Regardless of the nature of Y in Cp_2MY_2 (Y = F, OPh, NMe_2), titanium systems became dark blue and zirconium and hafnium systems became yellow when an active catalyst was generated. In general, conversion of Cp_2HfY_2 to a catalytically active hafnium complex required longer induction periods compared to the corresponding titanium and zirconium complexes. A phenoxide substituent on the metal required a longer induction period relative to the fluoride and the amide.

Of the three classes of complexes (Y = F, OPh, NMe_2) polysilane with the highest MW values were obtained when Y = NMe_2 for all three metals. The amides also exhibited the shortest induction period. The highest linear to cyclic ratio was usually produced with the hafnium complexes and the percent cyclic material followed the sequence Ti > Zr > Hf. These observations are consistent with those reported by Tilley (2*a*, *e*; 10) and demonstrated by Harrod in the reaction of $PhSiH_3$ with Cp_2MCl_2/*x*MeLi (M = Ti, Zr, Hf) (11). The linear/cyclic ratio for the polysilanes produced from the zirconium complexes (Y = F, OPh, NMe_2) exhibited approximately the same value independent of the substituent Y. The ^1H and ^{29}Si spectra of the polysilanes formed from Cp_2MY_2 systems also revealed similar features to those obtained from the previously studied combination, Cp_2MCl_2/2 *n*-BuLi (M = Ti, Zr) (6, 12).

When *p*-$TolSiH_3$ was used as the starting monomer, a longer induction period and (or) a higher temperature was required to initiate the polymerization reaction. A mixture of *p*-tolylsilane and Cp_2TiF_2 (0.5 mol%) required 40 min at 40°C before the onset of the polymerization reaction. The mixture was still fluid after 2 days in contrast to the phenylsilane case (0.5 mol% Cp_2TiF_2) which became very viscous after 1 day. The polymerization of *p*-tolylsilane in the presence of $Cp_2Zr(NMe_2)_2$ (1 mol%) at room temperature provided a product where the linear:cyclic ratio was 2.2, a higher ratio of cyclic products than was observed for phenylsilane under the same conditions.

The reaction of secondary silanes with Cp_2MY_2 occurred relatively slowly. As an example, at 60–85°C only 12% disilane was obtained from Ph_2SiH_2 after 50 hs (2 mol% Cp_2TiF_2). The reaction of $Cp_2Ti(OPh)_2$ and Ph_2SiH_2 provided only 10% disilane after 5 h at 100°C (7).

Exchange reactions of hydrosilanes with Cp_2MY_2

The original motivation in the current study was to utilize excess reacting silane to transfer hydride to the metal center, thus producing a potentially active catalyst for dehydrocoupling of the remaining silane as generally depicted in Scheme 1. To probe the suspected exchange reaction Cp_2MY_2 was mixed with primary, secondary, and tertiary silanes in a Si:M molar ratio of about 4:1 in C_6D_6. Once a color change occurred (either at room temperature or with heating to temperatures indicated in Table 1) the products

[2]MW values are influenced by the mol% catalyst and tend to decrease with increasing concentration of the metal (9*c*).

were analyzed through ^{1}H, ^{19}F, ^{29}Si NMR, and GCMS. Silicon products were identified by comparison to literature data or to authentic samples prepared by literature methods and are summarized in Table 2. In all three types of silanes the substituent originally on the metal complex was found in one or more silicon products and suggested that the exchange between M-Y and Si-H did indeed occur.

The initial product of exchange with the silane might be expected to be Cp_2MHY although such species may react further. If reduction to a paramagnetic M(III) species occurs identification of the metal complex by NMR spectroscopy could be difficult. The formation of a Ti(III) species from Cp_2TiF_2 and $PhSiH_3$ in toluene has been verified by EPR spectroscopy (8*b*). A doublet of triplets (g = 1.9924) was observed which had been assigned previously to $(Cp_2TiH)_2(\mu\text{-}H)$ by Harrod in an earlier study (17). A second radical species was also present in the Cp_2TiF_2–$PhSiH_3$ solution but was not identified (8*b*). We examined the variable temperature ^{1}H NMR spectrum of solutions of Cp_2TiF_2–$PhSiH_3$ in tol-d_8 and observed the same data in the bridging hydride region (upfield of TMS; see Fig. 1) as reported by Harrod for the isolated dimers, $(Cp_2TiSiH_2Ph)_2$ and $[Cp_2Ti(\mu\text{-}H)(\mu\text{-}HSiPh)TiCp_2]$ (Fig. 2) (17*b*).

In an effort to trap one or more of the metal products, PMe_3 was added to the dark-blue mixture from Cp_2TiF_2 and $PhSiH_3$. A deep purple solution formed that exhibited three new resonances in the ^{31}P NMR spectrum between 20 and 28 ppm. The most intense of the new signals appeared at 23.8 ppm and is essentially identical to that reported for $Cp_2Ti(\eta^2\text{-}HSiH_2Ph)PMe_3$ (literature value in tol-d_8, 23.9) (18). The only other system that exhibited resonances in the bridging hydride region occurred in the mixture of $Cp_2Ti(NMe_2)_2$ and $PhSiH_3$.

In another attempt to identify hydride resonances, acetone was added to mixtures of Cp_2MY_2 and $PhSiH_3$. A heptet for O-C*H*Me_2 which would result from the addition of M-H to >C=O (or from the metal activated addition of Si-H to >C=O) could be identified at 4.17 ppm (literature value, 4.11 ppm) (19). Unfortunately, it was not possible to assign any resonances in the original spectrum of Cp_2MY_2–$PhSiH_3$ to M-H. Addition of acetone to the yellow solution produced from $Cp_2Zr(OPh)_2$–$PhSiH_3$ system resulted in the formation of $Cp_2Zr(OCHMe_2)_2$ by comparison to data reported for reaction of Cp_2ZrH_2 with acetone (19).

Discussion

Other substituents that may be removed from the metal center prior to initiation of the dehydrocoupling reaction include the alkyl groups of Cp_2MR_2 [R = Me and CH_2Ph; M = Ti, Zr (the original catalyst precursors studied by Harrod (20))] and $Si(SiMe_3)_3$ in $CpCp^*M[Si(SiMe_3)_3]R$ (R = Me, Cl; Cp* = C_5H_5, (21), C_5Me_5 (2*a*, *e*, 21)). The rate of removal of M-$Si(SiMe_3)_3$ by $PhSiH_3$ is considerably faster than that of M-CH_3 by $PhSiH_3$. This results in varying induction periods for the dehydrocoupling reaction in the case of Cp_2MMe_2. After addition of $PhSiH_3$ to $CpCp^*Hf[Si(SiMe_3)_3]R$ (R = Cl, Me), $HSi(SiMe_3)_3$ and $CpCp^*Hf[SiH_2Ph]R$ are formed initially followed by

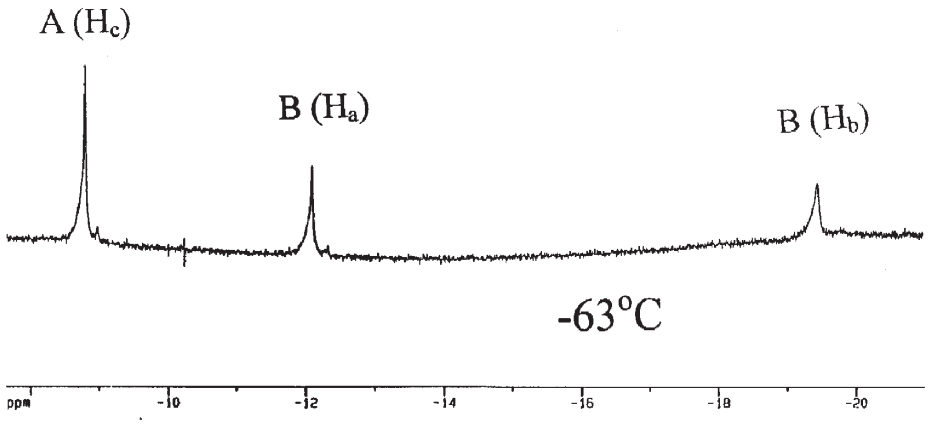
Fig. 1. Bridging hydride region generated from Cp_2TiF_2–$PhSiH_3$ in tol-d_8 at –63°C. Signal labeled A (–8.8 ppm) is assigned to the dimer $[Cp_2Ti(H_cSiHPh)]_2$ and those labeled B are assigned to $[Cp_2Ti(\mu\text{-}H)(\mu\text{-}HSiPh)TiCp_2]$ according to ref. 13*b*.



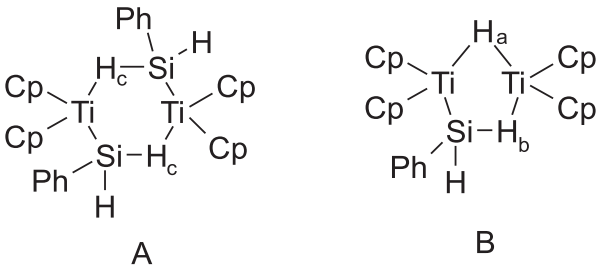


Fig. 2. Titanium hydride dimers.

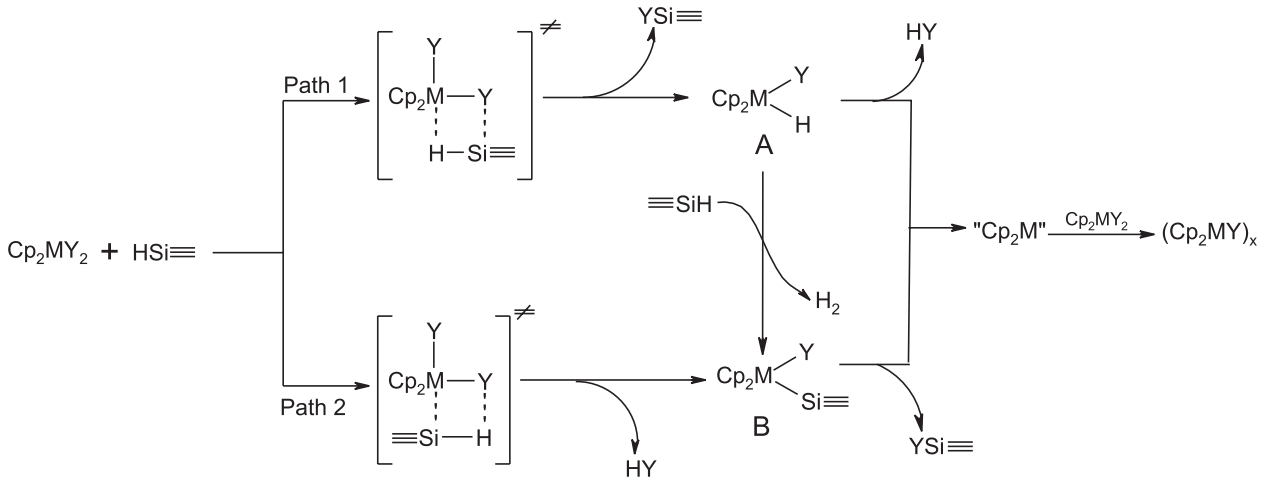
decomposition or reaction of the later with excess $PhSiH_3$ to give $[CpCp^*HfHR]_2$ (22). Observations with the slow coupling system involving hafnium complexes led Tilley to conclude that metal hydrides are the actual catalysts in dehydropolymerization.



With the less sterically hindered Cp substituents in Cp_2TiMe_2, reaction with $PhSiH_3$ produced three hydride bridged dimers of Ti(III) after the induction period. The concentrations of the Ti(III) species could be monitored by NMR spectroscopy. Quantitative yields of $Cp_2(\mu\text{-}HSiHPh)(\mu\text{-}H)TiCp_2$ were initially produced along with CH_4, $PhMeSiH_2$ and polysilane. The original metal dimer then partially converts to the two dimers, $[Cp_2Ti(\mu\text{-}HSiHPh)]_2$ and $[Cp_2Ti(H)]_2(\mu\text{-}H)$ until an equilibrium was reached in which $[Cp_2Ti(\mu\text{-}HSiHPh)]_2$ dominated (23). In the presence of PEt_3 as a trapping agent, high yields of the paramagnetic monomer, $Cp_2Ti(PEt_3)(SiH_2Ph)$, were isolated (23*e*). From kinetic studies of Cp_2TiMe_2-catalyzed reactions, it was concluded that the probable catalytic species was $Cp_2Ti(SiH_2Ph)H$ possibly formed from reaction of the originally formed dimer with $PhSiH_3$. Such a Ti(IV) species has not yet been isolated although the η^2-SiH complex, $Cp_2Ti(\eta^2\text{-}HSiH_2Ph)PMe_3$, has been isolated by Buchwald and co-workers (24). In contrast, the Zr(IV) dimer, $Cp_2Zr(SiMePhH)(\mu\text{-}H)_2(PhH_2Si)ZrCp_2$, (23*a*) precipitated from the reaction of Cp_2ZrMe_2 and $PhSiH_3$. For both Cp_2TiMe_2 and Cp_2ZrMe_2 the Me group originally on the metal is transferred to the silicon center although several different processes are possible by which this occurs (23). Hydride bridged Zr(IV) dimers as well as phosphine adducts of Zr(IV) have been isolated and crystallographically characterized from addition of Ph_2SiH_2 and PMe_3 to the combination of Cp_2ZrCl_2/2*n*-BuLi (25).

In the present study it has been demonstrated that F, OPh, and NMe_2 bound to the metal site in group IV metallocenes can be transferred to primary, secondary, and tertiary hydrosilanes. By implication, hydride is transferred to the metal although it was not possible to identify unequivocally the resonances in the ^1H NMR spectrum that could be attributed to either bridging or terminal hydrides except in the case of Cp_2TiF_2. However, since all nine metallocenes (Cp_2MY_2) were able to dehydrocouple $PhSiH_3$, it is probable that a metal hydride was generated. All three titanium systems appeared to generate Ti(III) species as indicated by the dark blue colored solutions that formed although this is not necessarily the only oxidation state in the solution. It is less likely, but not impossible, that M(III) species are produced in the zirconium and hafnium cases as well. No observable radicals detectable by EPR spectroscopy were reported in the reaction of Cp_2ZrF_2 and $PhSiH_3$ (8*b*).

It is possible that exchange of substituents between Cp_2MY_2 and the hydrosilane occurs initially through a σ-bond metathesis step. There are two possibilities as illustrated in the two transition states depicted in Scheme 2. In Path 1 the hydride from the silicon is transferred to the metal and the substituent on the metal forms a bond to silicon. In Path 2, silicon forms a bond to the metal and HY is eliminated. We originally selected the Y substituents on the basis of those that would form strong bonds to silicon (such as F). This suggests that Path 1 would be favored over Path 2 (Scheme 2). Since CH_4 is eliminated when $PhSiH_3$ is added to $Cp_2M(CH_3)_2$, Path 2 must be followed (in part) when Y = CH_3 (13*a*). Similarly, in Tilley's system, if the reacting Y represents a small silyl group (the nonreacting Y was Me or Cl), Path 1 would provide the observed $CpCp^*MYH$ (Y = Me, Cl) (18*c*). A second metathesis from A to B replaces MH with MSi. Reductive elimination from A or B would produce M(II) and could lead further to M(III) species although reductive elimination of HF, HOPh, or $HNMe_2$ has little precedence. It is interesting to note that the reaction of

© 2000 NRC Canada

Scheme 2.

$R'_3SiZr(NR_2)_3$ (R′ = Me, $SiMe_3$) gives $R'_3SiZrH(NR_2)_2$ which in turn reacts with an aminosilane to return to $R'_3SiZr(NR_2)_3$ (15).

In this study a major difference in the type of substituent on the reacting metallocene compared to the earlier systems examined by Harrod and by Tilley is that the Y substituents (F, OPh, NMe_2) all form stronger bonds to silicon than do either carbon or another silicon. In addition, all these substituents contain lone pairs. The presence of such lone pairs could promote the formation of dimers (or oligomers) through M-Y-M bridges. This was elegantly demonstrated recently by Xue in the the reaction of $Zr(NMe_2)_4$ with Ph_2SiH_2 where a novel trinuclear complex of "$HZr(NMe_2)_3$" was isolated (15). In the metallocene systems, such bridges could also connect metals in different oxidation states. Elimination of HY (Path 2) could lead to adducts such as $Cp_2MY{\cdot}HY$ (particularly with HOPh or $HNMe_2$).[3] If a number of monomeric or oligomeric metal complexes form, it would be fortuitous to isolate crystalline metal products from the near stoichiometric reactions.

Although Cp_2MHCl (A in Scheme 2) is known for Zr, and Hf (and possibly for Ti (22*c*)), Cp_2MHF, $Cp_2MH(OPh)$, and $Cp_2MH(NMe_2)$ do not appear to have been reported. A few examples of monomeric Cp^*_2MHY (M = Hf, Y = Cl, NMe_2; M = Zr, Y = F) do exist (26). This suggests that a study of $Cp^*_2MY_2$ or of other substituted metallocenes complexes with hydrosilanes may provide a less complex system in which to identify intermediate products which could not be identified with Cp_2MY_2 reactants. In general, however, metallocenes with overly substituted rings are not good dehydrocoupling catalysts (2*c*, 9*b*).

Conclusion

Metallocenes, Cp_2MY_2, with electronegative Y substituents such as F, OPh, and NMe_2 function as single component catalysts for the dehydrocoupling of $PhSiH_3$. The molecular weights of the polysilane products are comparable to those produced from the previously studied combination catalyst system, Cp_2MCl_2–2*n*-BuLi, and in most cases exceed those produced from this system. An induction period was observed for Cp_2MF_2 and $Cp_2M(OPh)_2$ but essentially none was found with $Cp_2M(NMe_2)_2$. The amide system also produced the highest molecular weights for all three metals.

Reactions of Cp_2MY_2 with primary, secondary, and tertiary silanes on a near stoichiometric scale shows that one or more Y groups could be transferred from the metal to the silicon center. The formation of Y-SiRR′R′′ suggests that hydride was transferred to the metal center during the induction period to form a metallocene hydride species that functioned as the actual catalyst for the dehydrocoupling reaction. However, efforts to observe these MH systems by NMR spectroscopy or by trapping reactions (with PMe_3) were not successful even in reactions of tertiary silanes where dehydrocoupling has not been observed. During the induction period, reduction of Ti(IV) to Ti(III) also occurred and Ti(III) hydride dimers analogous to those reported in the literature were identified spectroscopically (^{1}H NMR). It is possible that reactions of metallocenes with bulkier cyclopentadiene substituents would lead to MH-containing products that could be trapped as monomers and crystallographically characterized.

The single reagent precatalysts exhibit certain disadvantages over the two component precatalyst system, Cp_2MCl_2–2*n*-BuLi, the components of which are commercially available. Since none of the Cp_2MY_2 (M = F, OPh, NMe_2) are commercially available additional synthetic steps from Cp_2MCl_2 are required. The metallocene (Cp_2TiF_2) has the attractive advantage of being air and water stable in contrast to all the other catalyst systems that have been discussed. The facile reaction of an NMe_2 group in $Cp_2M(NMe_2)_2$ and the higher molecular weight polysilane products that are produced suggest that such substituents could be usefully developed in new catalyst systems. On the other hand, the results described in this report also suggest that the development of precatalysts for dehydrocoupling that do not contain Cp-substituents must take into consideration the possible removal of coordinated O-based or N-based ligands by reacting hydrosilanes. Developing such catalysts will be a challenge in the future.

[3] Formation of $Cp_2TiH{\cdot}NH_3$ has been proposed in the catalytic loop for the reaction of $PhSiH_3$ and NH_3 (23*f*).

Experimental

General methods

All reactions were carried out under an atmosphere of nitrogen in sealed Schlenk flasks that were flame-dried before use. Solvents were freshly distilled under nitrogen from sodium/benzophenone prior to use. ^{1}H, ^{29}Si, and ^{19}F NMR spectra were recorded using a Varian Unity 300 (^{1}H and ^{29}Si referenced to TMS) and an XL-300 (^{19}F, referenced to $CFCl_3$). Unless otherwise stated, the solvent for NMR data collection was benzene-d_6. GPC data were collected using an SSI 222D HPLC pump to elute the samples through a bank of 10^4, 10^2, and 500 Å Waters 78 × 300 mm Ultrastyragel columns in HPLC grade THF solvent. A Linear UV-vis detector set to 254 nm was used for the detection of the polymers. Molecular weights are reported with respect to polystyrene standards.

The following compounds were prepared according to literature procedures: Cp_2MF_2 (M = Ti (27), Zr (28), Hf (28)), $Cp_2M(OPh)_2$ (M = Ti, (29) Zr, (30) Hf (31)), $Cp_2M(NMe_2)_2$ (M = Ti (32), Zr (32), Hf (32)), $PhSiH_3$ (33), (p-$CH_3C_6H_4$)SiH_3 (34), $PhMeSiH_2$ (35), Ph_2SiH_2 (36), $PhSiF_3$ (13), PhMeSiHF (13), $PhMeSiF_2$ (13), PhMeSiH(OPh) (37), $PhMeSi(OPh)_2$ (37), $Ph_2MeSi(OPh)$ (37), and HPhMeSiSiMePhH (38). Ph_2MeSiH was a commercial sample.

General procedures for the dehydropolymerization of $PhSiH_3$

A mixture of Cp_2MY_2 (0.08 mmol, 1 mol%) and $PhSiH_3$ (~1 mL, 8 mmol) in a 25 mL Schlenk tube was magnetically stirred at the indicated temperatures for a period of time until the color of the mixture changed and gas evolution was observed (Table 1). The reaction mixture was cooled immediately to room temperature and was continually stirred for two or more days. To obtain an NMR sample, an aliquot from the reaction mixture was added to a dried, N_2-filled NMR tube containing C_6D_6. For the GPC sample an aliquot was removed, added to THF and air passed through the solution. Solutions were filtered before injection onto the GPC columns. Molecular weight data are also summarized in Table 1.

General procedure for NMR studies

Under a nitrogen atmosphere a mixture of Cp_2MY_2 (0.06 mmol) and hydrosilanes (0.25 mmol; approximate ratio of Si:M = 4:1) in a NMR tube was placed in an oil bath of desired temperature and periodically shaken until the color change described in Table 1 was observed. The solvent C_6D_6 was added to the tube by syringe and the spectrum was obtained. Trapping reagents (acetone or PMe_3; stoichiometry relative to the metal) were added to selected samples and the NMR spectrum again was obtained. In selected cases, excess acetone or PMe_3 were added but no new information was obtained.[4]

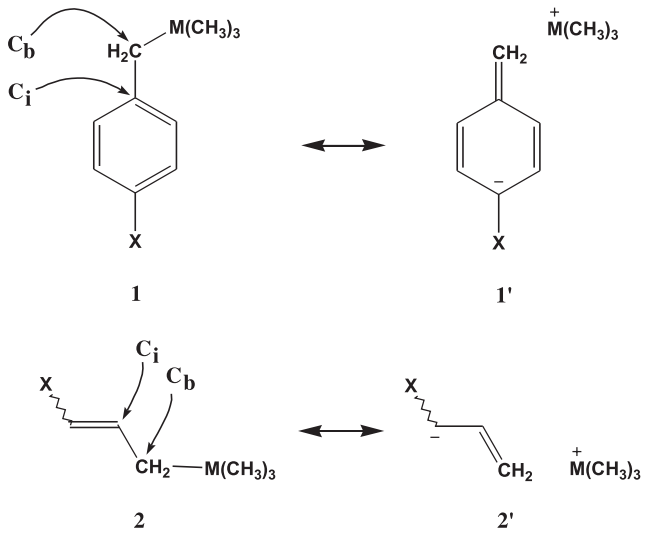
Neutral hyperconjugation and one-bond couplings between heavy atoms

Joseph B. Lambert, Catherine E. Shawl, and Ernani Basso

Abstract: The relationship has been examined between bond order and one-bond couplings involving heavy atoms, as modulated by neutral hyperconjugation. Two systems have been studied in which either an aromatic ring or a double bond can influence, through hyperconjugation, the α and β bonds (respectively, C—C and C—M in =C-C-M). Hyperconjugation may be modulated by substituents on the aromatic ring or double bond or by placement of different atoms (M = C, Si, Ge, or Sn) at the β position. The α bond exhibits no relationship between coupling constant and neutral hyperconjugation, but the β bond shows a strong relationship.

Key words: hyperconjugation, germanium, σ-π conjugation, silicon, tin.

Résumé : On a examiné la relation entre l'ordre de liaison et les couplages à travers une liaison impliquant des atomes lourds, tels que modulée par l'hyperconjugaison neutre. On a étudié deux systèmes dans lesquels l'hyperconjugaison permet d'influencer un noyau aromatique ou une double liaison, soit les liaisons α et β (respectivement C—C et C—M dans =C-C-M). On peut moduler l'hyperconjugaison en fixant divers substituants sur le noyau aromatique ou en plaçant divers atomes (M = C, Si, Ge ou Sn) en position de la double liaison. Pour la liaison α, il n'existe aucune relation entre la constante de couplage et l'hyperconjugaison neutre; toutefois, pour la liaison β, il existe une grande relation.



Mots clés : hyperconjugaison, germanium, conjugaison σ-π, silicium, étain.

Introduction

The donation of σ electrons to π orbitals has been termed hyperconjugation or double-bond, no-bond resonance (1, 2). Valence structures **1** and **1′** illustrate hyperconjugation within neutral aromatics and structures **2** and **2′** illustrate the phenomenon within neutral alkenes. As the structures suggest, hyperconjugation is associated with important changes in bond order. These changes have been well documented in positively charged systems. Thus hyperconjugation is not doubted as the underlying cause for the stabilization of carbocations by alkyl groups and, to an even greater extent, stabilization of carbocations by electropositive elements such as silicon at the β position (3, 4). Electron demand in charged systems thus brings about large kinetic and thermodynamic effects.

Because the effects are much smaller or even negligible in neutral systems, neutral hyperconjugation has been a more controversial subject than charged hyperconjugation (2). There have been no systematic crystallographic studies that would provide unambiguous evidence for neutral hyperconjugation. A theoretical study has concluded that neutral hyperconjugation can alter bond lengths in hydrocarbons by about 0.015 Å (5). The systems studied had been selected because of structural anomalies suggested by crystallography. Even in these systems, however, the bond length changes were rather small.

We suggested that one-bond coupling constants between heavy atoms might provide a novel approach to assessing neutral hyperconjugation (6). The hypothesis is that these one-bond couplings reflect the bond order changes induced by neutral hyperconjugation in structures **1** and **2**. Thus in

the aromatic case, neutral hyperconjugation should enhance the coupling between the ipso and the benzylic carbons ($^1J(C_i\text{-}C_b)$ in **1**) and diminish the coupling between the benzylic carbon and the β atom M ($^1J(C_b\text{-}M)$). In the alkenic case **2**, the allylic carbon replaces the benzylic carbon in these couplings.

As the ionic resonance structures (**1′** and **2′**) indicate, neutral hyperconjugation should be enhanced by electron-withdrawing groups X (which stabilize the negative charge) or by electron-donating atoms M (which stabilize the positive charge). We previously explored the phenomenon in the aromatic series (6) and concluded that neutral hyperconjugation is unimportant when M is carbon but increases in significance down the 14th column, from silicon to germanium to tin. This study involved measurement of one-bond $^{13}C\text{-}^{13}C$ couplings by the INADEQUATE method and direct measurement of one-bond $^{13}C\text{-}^{29}Si$ and $^{13}C\text{-}^{119}Sn$ couplings.

In the course of this study, we measured 71 $^{13}C\text{-}^{13}C$ coupling constants and all the corresponding chemical shifts (6). We found that the chemical shifts and the couplings between aromatic carbons provided little or no information on hyperconjugation. The one-bond couplings to the benzylic carbon, however, did reflect neutral hyperconjugation, but only for the atoms (M) below carbon. Subsequently, Kamieńska-Trela (7) found that two of these couplings were mismeasured. We concurred with this observation (8), and suggested that two others also had been mismeasured because of peak overlap in the INADEQUATE spectra in each case. These were the $^1J(C_i\text{-}C_b)$ for the four carbon compounds, that is, **1** with M = C and X = MeO, Me, H, and NO_2. We now have remeasured all the $C_i\text{-}C_b$ and $C_b\text{-}M$ couplings for molecules **1**. In addition, we have prepared several examples from the alkene series **2** and measured the analogous couplings. We report these measurements herein and assess the results in terms of the relationship between one-bond couplings and neutral hyperconjugation.

Results and discussion

We have prepared the aromatic series **1** anew with M = C and X = MeO, Me, H, and NO_2; with M = Si and Sn and X = MeO, Me, H, and CN; and with M = Ge and X = MeO, Me, and H. We have prepared the alkene series **2** with M = C and X = MeO (*cis* and *trans*), Me (*trans*), H, and CN (*cis* and *trans*); with M = Si and X = Me; and with M = Ge and X = H (in this case the group on M is butyl rather than methyl). The newly measured couplings are given in Tables 1–3. All $^{13}C\text{-}^{13}C$ couplings were obtained by the INADEQUATE method, and all $^{29}Si\text{-}^{13}C$ and $^{119}Sn\text{-}^{13}C$ couplings were measured directly. In each case the $^{13}C\text{-}^{13}C$ couplings were measured twice, as they appear in the INADEQUATE spectra for each coupled carbon. Except for the four cases already mentioned (7, 8), all $^{13}C\text{-}^{13}C$ couplings were very close to those previously measured in the aromatic series, but the results must be reinterpreted in light of the four corrected measurements.

According to the double-bond, no-bond resonance structure for the aromatic series (**1′**), the bond order between the ipso and benzylic carbons should increase with increased electron-withdrawing nature of X and electron-donating nature of M. The $^1J(C_i\text{-}C_b)$ coupling, however, does not reflect this trend. In any given M series (C, Si, Ge, Sn for constant X), the trend begins with the highest value for C, continues with the lowest value for Si, and then rises slightly for Ge and Sn, for example, 45.1, 41.7, 43.7, 43.9 Hz for X = MeO. If this coupling constant reflected increased neutral hyperconjugation from C to Sn, the value should have increased monotonically. The variation in fact follows a simple dependence on the electronegativity of M. The Pauling–Allred electronegativities (9) for C, Si, Ge, and Sn respectively, are 2.55, 1.90, 2.01, and 1.96. Thus a prime factor controlling this coupling constant is the electron density provided through the σ framework rather than neutral hyperconjugation.

Table 1. One-bond couplings (Hz) in the aromatic series **1**.

X	M	$^1J(C_i\text{-}C_b)^a$	$^1J(C_b\text{-}M)$
MeO	C	45.1 (45.1, 45.1)	33.9
	Si	41.7 (41.5, 41.9)	47.3
	Ge	43.7 (43.9, 43.4)	
	Sn	43.9 (43.9, 43.8)	309
Me	C	44.3 (44.5, 44.1)	33.9
	Si	41.0 (40.8, 41.2)	46.7
	Ge	42.7 (42.7, 42.6)	
	Sn	43.2 (42.9, 43.4)	301
H	C	43.9 (43.9, 43.9)	32.9
	Si	40.9 (40.8, 41.0)	46.3
	Ge	42.8 (42.7, 42.9)	
	Sn	42.7 (42.4, 42.9)	288
CN	Si	40.3 (40.3, 40.3)	43.3
	Sn	42.6 (42.4, 42.7)	252
NO_2	C	42.8 (42.9, 42.7)	33.1

[a]Respectively, the mean, the coupling measured from the CH_2 (C_b) signal and the coupling measured from the C_{ipso} (C_i) signal.

For the X series with constant M, this same coupling constant, $^1J(C_i\text{-}C_b)$, decreases with increased electron withdrawal, for example, 45.1, 44.3. 43.9, 42.8 Hz for M = C and X = MeO, Me, H, NO_2. The values decrease for other M to a lesser extent, contrary to the expectation for neutral hyperconjugation, which should increase with larger M. This effect again is along the lines expected for electron withdrawal through the σ framework. Thus variation of the C-C coupling between the ipso and benzylic carbons appears to depend primarily on σ (inductive) rather than π (neutral hyperconjugative) effects. This conclusion is contrary to our earlier study, which was misled by the incorrect values of 36.0 Hz measured for the four C systems, thereby generating a monotonic increase from C to Sn for a given X series.

According to resonance structure **1′**, the bond order between the benzylic carbon and M should decrease with increased electron-withdrawing nature of X and electron-donating nature of M. This prediction cannot be tested for the M series with constant X, as the identity of the coupling partners changes, from C-C to C-Si to C-Sn. The only test therefore is for the X series with constant M. For M = C $^1J(^{13}C\text{-}^{13}C)$ is 33.9, 33.9, 32.9, and 33.1 Hz for X = MeO, Me, H, and NO_2. This invariance suggests no dependence on either neutral hyperconjugation or inductive effects of X. For the carbon series, neutral hyperconjugation must be negligible according to this coupling constant probe, and the X

[b]Respectively, the mean, the coupling measured from the =**C**H-CH_2 signal, and the coupling measured from the CH-**C**H_2M signal.
[c]The alkyl group on germanium is butyl rather than methyl.

group is too far away to manifest an effect through the σ framework. For M = Si, ^1J(^{13}C-^{29}Si) is 47.3, 46.7, 46.3, and 43.3 Hz for X = MeO, Me, H, and CN. This monotonic decrease with increasing electron withdrawal is the expectation for both neutral hyperconjugation and induction. Since induction had no effect in the C series, it is doubtful that it should suddenly bring about a significant effect in coupling constants that are only some 30% larger for the Si series. Consequently, there is a strong likelihood that neutral hyperconjugation is causing this coupling variation.

There is no germanium nuclide for which couplings to carbon can be measured. For M = Sn, ^1J(^{13}C-^{119}Sn) is 309, 301, 288, and 252 Hz for X = MeO, Me, H, and CN. As with Si, this trend is in agreement with either inductive or neutral hyperconjugative effects. As inductive effects should be constant for the series C, Si, Sn, this large increase in the modulation of the coupling is explicable only by neutral hyperconjugation. This coupling therefore appears to be strongly sensitive to hyperconjugation and demonstrates that the effect increases remarkably from C to Si to Sn. The large sensitivity of ^1J(C_b-M) to neutral hyperconjugation compared with ^1J(C_i-C_b) can be attributed to the closeness of M to the C_b-M bond and the greater distance of X to the C_i-C_b bond.

We have more limited data in the alkene series, with a full set only for M = C. Of particular interest is the coupling between the doubly bonded carbons, ^1J(C=C). The analogous couplings in the aromatic series (6) are those between adjacent aromatic carbons. We found little dependence of these couplings on M. Thus for X = H in the aromatic series **1**, the values of ^1J(C_m-C_p) were 55.9 Hz for the entire series of M = C, Si, Ge, and Sn. The values of ^1J(C_o-C_m) for this series were 56.6, 57.2, 57.2, and 57.2 Hz for X = Me, and the values of ^1J(C_i-C_o) were 57.0, 57.3, 57.3, and 57.3 Hz for X = MeO. The only variation of any size was for ^1J(C_m-C_p), which is most affected by direct connection to X, for example, for M = C, 67.6, 56.9, and 55.9 Hz for X = MeO, Me, H. The coupling ^1J(C=C) between the two sp^2 atoms in the alkene series is structurally analogous to ^1J(C_m-C_p), in the sense that the X group is attached to one of the coupled carbons. The variation with X is somewhat similar: for M = C, 81.9, 74.5, and 69.2 Hz for the same substituents, X = MeO, Me, H, indicating greater double bond character for C_m-C_p with electron donation.

Effects of neutral hyperconjugation must then be sought from other couplings. The values of ^1J(=C-CH_2), analogous to ^1J(C_i-C_b) in the aromatic series, for M = C are 45.9, 44.7, 42.3, and 41.7 Hz for X = MeO, Me, H, and CN. This is the identical trend observed in the aromatic series, contrary to neutral hyperconjugation (the coupling should increase with electron withdrawal according to resonance structure **2′**) but in agreement with induction, whereby σ electron withdrawal decreases the coupling. As we have only single values for Si and Ge, we cannot examine this coupling as a function of M.

Table 3. Further one-bond couplings (Hz) in the alkene series **2**, X-CH=CH-CH_2-M(CH_3)$_3$.

X	M	^1J(X-CH=)[a]	^1J(M-CH_3)[a]
trans-Me	C	43.6 (43.5, 43.7)	
trans-Me	Si	43.2 (43.0, 43.4)	65.2
H	C		36.1
cis-CN	C	79.8	36.1
trans-CN	C	78.3	36.1

[a]Respectively, the mean, the coupling measured from the X signal (CH_3 or CN), and the coupling measured from the X-**C**H signal.

In the aromatic series, we found ^1J(C_b-M) to be sensitive to neutral hyperconjugation. The analogous coupling in the alkene series is ^1J(CH_2-M). The only data we have for this series is for M = C for which the values are 36.6, 33.8, 33.8, and 33.2 Hz for X = MeO, Me, H, and CN. There is a possibility that neutral hyperconjugation is having some effect here, as the coupling decreases monotonically with increased electron withdrawal, as expected for resonance structure **2′**. The absolute change, however, is relatively small. Confirmation would have to await preparation of an entire Si or Sn series, which, however, we found synthetically impractical.

The alkene series can exist as either cis or trans isomers, and our syntheses sometimes resulted in stereoisomeric mixtures. The data in Tables 2 and 3 indicate that none of the measured coupling constants exhibits any important dependence on the stereochemistry of the double bond.

Conclusions

The one-bond ^{13}C-^{13}C coupling across the partial double bonds in the aromatic ring and the alkene exhibit significant changes with the nature of the X substituent, but these variations appear to depend primarily on the inductive effect of X. The C-C coupling between the methylene-substituted aromatic or alkenic carbon and the methylene (benzylic, allylic) carbon exhibits small variations with X that also parallel the

© 2000 NRC Canada

inductive effect of X. In the aromatic series, this coupling exhibits small variations with M that parallel the electronegativity of M. The only C-C coupling that exhibits the variation expected for neutral hyperconjugation is that between the allylic methylene carbon and the *tert*-butyl carbon (M = C in the alkene series), and this variation is only 3 Hz. In contrast, the Si-C and particularly the Sn-C couplings in the aromatic series exhibit large variations with change in X that are consistent with neutral hyperconjugation. These couplings are larger to begin with than the corresponding C-C couplings, but the critical consideration probably is the larger magnitude of neutral hyperconjugation in the silicon and tin systems because of the higher polarizability and electropositivity of these elements than carbon.

Experimental section

Aromatic systems **1** were prepared by the methods described earlier (6). 4,4-Dimethyl-1-pentene (**2**, M = C, X = H) and allyltributylgermane (M = Ge, X = H, but with butyl replacing methyl on M) are commercially available. *trans*-5,5-Dimethyl-2-hexene (M = C, X = CH_3) was prepared by the reaction of *tert*-butyllithium with 1,3-butadiene, followed by slow distillation through a Vigreux column (10). 1-Cyano-4,4-dimethyl-1-pentene (M = C, X = CN) was obtained as a *cis*/*trans* mixture by the Wittig reaction of triphenyl(cyanomethyl)phosphonium chloride (from triphenylphosphine and chlorocyanomethane) and 3,3-dimethylbutanal (11). 1-Methoxy-4,4-dimethyl-1-pentene (M = C, X = OMe) was obtained in an analogous fashion with methoxychloromethane as the starting material (11). *trans*-2-Butenyltrimethylsilane was prepared by the reaction of 1-bromo-1-propene with the Grignard reagent (trimethylsilyl)methylmagnesium chloride ($(CH_3)_3SiCH_2MgCl$) in the presence of ($Ni(II)(dppp)Cl_2$) catalyst (12).

Spectra were obtained on a Bruker AMX600 NMR spectrometer with ^{13}C at 150.91 MHz. The standard 1D INADEQUATE pulse was performed, 90°(*x′*)-τ-*180°(y′)*-τ-90°(*x′*) with phase cycling. The GARP decoupling sequence was used, with a 90° pulse of 150 μs. Because the substrates were all liquids, samples were run as 90% solutions with the remaining 10% either $CDCl_3$ or acetone-d_6. The relaxation reagent chromium(acetylacetonate) was added to shorten the delay time between acquisitions, which typically dropped from 10 to 0.5 s. Acquisitions normally required overnight runs with about 50 000 transients. The constant delay time τ in the pulse sequence, $1/4J(^{13}C\text{-}^{13}C)$, was optimized for the coupling constant of interest. For example, for J = 70 Hz τ was 3.57 ms and for J = 35 Hz τ was 7.14 ms. Couplings to ^{29}Si and ^{119}Sn were read directly from the spectra.

Silaheterocycles 36 (1). Trichlorovinylsilane, lithium-*tert*-butyl, and 1,3-enynes: A versatile combination for the competitive formation of silacyclobutanes and silacyclobutenes

N. Auner, M. Grasmann, B. Herrschaft, and M. Hummer

Abstract: Equimolar amounts of trichlorovinylsilane **(9)**, lithium-*tert*-butyl, and 1,3-enynes were reacted to yield the corresponding isomeric silacyclobutanes and silacyclobutenes competitively. As reaction pathway the mixture **9**/^{t}BuLi is discussed to give a silene equivalent, $Cl_2Si{=}CHCH_2{}^tBu$ **(10)**, yielding the four-membered ring silacycles by formal [2 + 2] cycloaddition reactions of **10** with the C=C double or the C≡C triple bond of the 1,3-enyne. The relative ratio of the products formed depends on the polarity of the multiple bonds in the enyne, which is mainly determined by the substituent pattern. Thus, from the organosubstituted 1,3-enynes $R^1C{\equiv}C\text{-}C(R^2){=}CR^3R^4$ (R^1 = Me, Et, $SiMe_3$, Ph; R^2 = H, Me, Ph; R^3=Me, OMe, Ph; R^4=H; and $R^1C{\equiv}C\text{-}R'$ (R′ = 1-cyclohexenyl, cyclohexanevinylidyne)) and **9**/^{t}BuLi the silacyclobutanes **12**, **13**, and **15** and the silacyclobutenes **14**, **16**–**24,** and **27** (from **10** and 3-hexyne) are prepared in a one-step synthesis and isolated from the reaction mixtures. The silacyclobutanes and -butenes are thermally stable and can be distilled under vacuo up to temperatures of about 150°C without decomposition. The experimental results are confirmed qualitatively by semiempiric calculations at the AM-1 level and their analysis using FMO theory. The solid state structure of the silacyclobutene **19** ($C_{17}H_{30}Cl_2Si_2$) has been determined by single crystal X-ray diffractometry. **19** is orthorhombic, space group $P2_12_12_1$, a = 1030.94(2) pm, b = 1244.6(2) pm, c = 1605.5(3) pm, Z = 4.

Key words: neopentylsilene, dichloroneopentylsilene, silacyclobutenes, silacyclobutanes, 1,3-enynes.

Résumé : La réaction de quantités équimoléculaires de trichlorovinylsilane (**9**), de *tert*-butyllithium et de 1,3-énynes conduit à la formation compétitive des silacyclobutanes et silacyclobutènes isomères correspondants. On suggère que la voie réactionnelle du mélange de **9**/^{t}BuLi conduit à un silène équivalent, $Cl_2Si{=}CHCH_2{}^tBu$ (**10**), qui, par une réaction de cycloaddition [2 + 2] avec les liaisons double, C=C, ou triple, C≡C, du 1,3-ényne conduit à la formation de cycles silylés à quatre chaînons. Les rapports relatifs des produits qui se forment dépendent de la polarité des liaisons multiples de l'ényne qui est déterminée principalement par les motifs de substitution. Ainsi, les 1,3-énynes substitués par des groupes organiques ($R^1\text{-}C{\equiv}C\text{-}C(R^2){=}CR^3R^4$ (R^1 = Me, Et, $SiMe_3$, Ph; R^2 = H, Me, Ph; R^3 = Me, OMe, Ph; R^4 = H) et $R^1\text{-}C{\equiv}C\text{-}R'$ (R′ = 1-cyclohexényle; cyclohexavinylidyne)) qui réagissent avec **9**/^{t}BuLi permettent de préparer, en une seule étape, les composés **12**, **13** et **15** ainsi que les silacyclobutènes **14** et **16**–**24** et **27** (qui dérive de **10** et de l'hex-3-yne) et de les extraire des milieux réactionnels. Les silacyclobutanes/butènes sont thermiquement stables et on peut les distiller sous vide jusqu'à des températures d'environ 150°C sans décomposition. Les résultats expérimentaux sont confirmés de façon qualitative par des calculs semiempiriques au niveau AM-1 et par leur analyse à l'aide de la théorie « FMO ». La structure de silacyclobutène (**19**) à l'état solide a été déterminée par diffraction des rayons-X. Le composés **19** est orthorhombique, groupe d'espace $P2_12_12_1$ avec a = 1030,94(2), b = 1244,6(2) et c = 1605,5(3) pm et Z = 4.

Introduction

While synthetic methods for the preparation of silacyclobutanes are well established since more than fourty years (2, 3), much less is known about the chemistry of silacyclobutenes. Although the first multi step syntheses for such compounds were already published starting in 1964 (4), only in 1979 Brook et al. (5) reported the first general route for the formation of a silacyclobutene by silene [2 + 2] cycloaddition reactions: thermolysis or photolysis of pivaloyltris(trimethylsilyl)silane **1** in the presence of 1-phenyl propine as trapping reagent for the intermediate silene **2** yields the sterically crowded silacyclobutene **3** (Scheme 1).

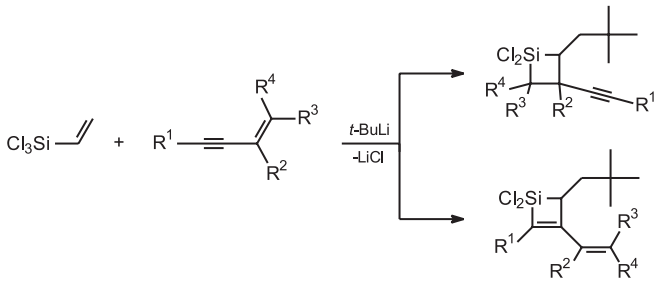
Nearly at the same time Block and Revelle (6) published the flash vacuum pyrolysis (FVP) of dimethyldiallylsilane **4** giving dimethylsilacyclobutene **5** via the intermediate formation and intramolecular rearrangement of 1-silabutadiene **6**. Grobe et al. extended this synthetic method including the formation of the methyl hydrogen substituted derivative **7** and even of the parent silacyclobutene **8** (Scheme 2) (7)[2] starting from the corresponding diallylsilanes.

All synthetic routes to silacyclobutenes reported until 1981 exhibit some common features: they require a multi step synthesis including low yields of products; especially the gas phase reactions described in Scheme 2 lead to complex product mixtures and the isolation of the silacyclobutenes often includes gaschromatographic separation of the thermally not very stable compounds. For the series investigated the thermal stability decreases with increasing hydrogen substitution at the silicon center, $Me_2SiCH{=}CHCH$ > $Me(H)SiCH{=}CHCH$ > $H_2SiCH{=}CHCH$.[2] Moreover, the variation of the organo substituents at the ring carbon atoms is difficult and no silicon chlorinated compound was reported, consequently excluding following reactions using the silicon functionality. Similar arguments hold for the syntheses of silacyclobutanes: Although the ring closure of γ-halopropylhalogenosilanes proved to be a facile entry to silacyclobutanes, the preparation of differently substituted starting γ-halopropylsilanes very often includes multi-step syntheses and suffers from low product yields especially in that case when different functional groups in α- and β-positions are required.

In 1981 we reported a preparatively facile one step synthesis of silicon dichloro substituted silacyclobutenes using vinyltrichlorosilane (**9**), lithium-*tert*-butyl and differently organo- and silyl substituted acetylenes as trapping agents for the intermediate formed dichloroneopentylsilene, $Cl_2Si{=}CHCH_2{}^tBu$ (**10**) (8). Using this synthetic method, the variation of the substitution pattern at the silicon and carbon four-membered ring moiety can easily been performed (9) and the yields of silacyclobutenes are sufficiently high; especially silacyclobutene **11** ($Cl_2SiCH(Ph){=}CH(Ph)CHCH_2Bu^t$) can be isolated nearly quantitatively from mixtures of vinyltrichlorosilane **9**, ^{t}BuLi and tolane. Notably, these silacyclobutenes exhibit an outstanding thermal[3] and chemical stability (10): using the chlorine functionality at silicon, **11** can be easily incorporated into silicones (10), polycarbosilanes,[4] polyorganosiloxanes (11), and polysilanes[5] containing the "closed" four-membered ring subunit as building block and thus transferring extraordinary physical and chemical properties into the polymeric backbones (12). For the formation of high molecular weight polymers the intermolecular linkage of the four-membered ring moieties is required requesting carbon carbon functionalities such as alkenyl- and alkinyl groups at the silacyclobutenes and -butanes carbon atoms; preliminary results reported for silacyclobutanes show that the four-membered rings can be linked together by hydrosilylation reactions (10).

In this paper we report on the preparatively facile competitive synthesis of silacyclobutanes and -butenes containing carbon and silicon functionalities using mixtures of vinyltrichlorosilane, lithium-*tert*-butyl and 1,3-enynes as reaction partners (Scheme 3).

Results and discussion



Preparation of 1,3-enynes and their reactions with mixtures of $H_2C{=}CHSiCl_3/{}^t$BuLi

The synthesis of most of the 1,3-enynes $HC{\equiv}C(R^2)C{=}CR^3R^4$ used in this experimental study is basically described in the literature (13). We focused on a series of compounds which (*i*) could easily been obtained in good yields from readily available starting materials and (*ii*) could easily been transferred into their organo substituted derivatives

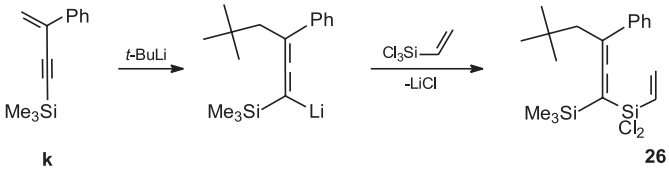


Scheme 4.

$R^1C{\equiv}C(R^2){=}CR^3R^4$. The C,H acidity of the hydrogen substituted precursors does not allow the use of Li-*tert*-butyl as reaction partner for the vinyl group of the starting trichlorovinylsilane **9**. In a general experimental procedure equimolar amounts of Li-*tert*-butyl were slowly added to equimolar mixtures of vinyltrichlorsilane **9** and the corresponding 1,3-enynes listed in Table 1. *n*-Pentane was used as solvent and the reactions were performed at room temperature. Mixing the reactions partners, in most cases LiCl elimination started immediately. The reaction is completed after stirring the solutions for some hours at room temperature. After filtration the silicon carbon four-membered ring compounds can be isolated by vacuum distillation as colourless, highly viscous liquids or as white crystalline solids. The reactions performed from vinylchlorosilane **9**, ^{t}BuLi and the 1,3-enynes **a** to **k** are summarized in Table 1 and clearly prove the extraordinary cycloaddition potential of the dichloroneopentylsilene **10**.

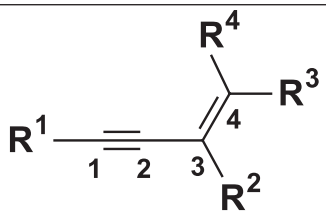
From Table 1 (and Table 4, Exp. section) it becomes obvious that: (*i*) the formation of silacyclobutanes and -butenes occurs regio- but not stereo-specific; (*ii*) the reaction of the C1 phenyl substituted enyne **a** with the **9**/^{t}BuLi mixture exclusively leads to the formation of silacyclobutane **12**; (*iii*) the reactions of the C1 trimethylsilyl substituted enyne **b** and the C1 ethyl substituted derivative **c** with the **9**/^{t}BuLi mixture result in the competitive formation of 1,1-dichloro substituted silacyclobutanes (**13**, **15**) and -butenes (**14**, **16**); (*iv*) the reactions with the C1 trimethylsilyl- and methyl substituted 1,3-enynes **e** to **j** yield the 1,1-dichlorosilacyclobutenes **18**–**23** exclusively; (*v*) the reaction of the **9**/^{t}BuLi mixture with (but-1-ene-3-yne)trimethylsilane **d** is exceptional: besides dichlorosilacyclobutene **17**, the 1,2 addition product **25** (Scheme 4) is formed in yields ranging from 7 up to 22% in different runs. Only small amounts of silacyclobutene **24** are obtained from the reaction with the C3 phenyl substituted enyne **k**. The formation of the main product **26** obviously results from a coupling reaction of an allenylic α-silyllithio species and trichlorovinylsilane **9** as discussed in Scheme 5; and (*vi*) all compounds are formed in good yields: except **25** and **26** no other side products can be detected by gaschromatographic investigations on the product mixtures. The overall yields listed in Table 4 are generally diminished by the high temperatures required for the vacuum distillation to purify the viscous and oily silacycles.

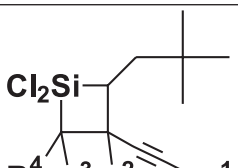
Scheme 5.

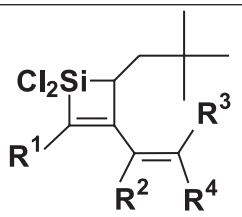
Summarizing the experimental work, the results clearly prove that the 1,2-addition of the lithium organyl to the vinyl group of the chlorosilane **9** dominates the usually favored 1,4 addition to conjugated carbon–carbon multiple bonds of 1,3-enynes in non polar solvents and at room temperature. In order to understand the directive influence of the substituents at the 1,3-enynes on the LiR addition and to predict the product formation "silacyclobutane vs. silacyclobutene" qualitatively, semiempiric calculations at the AM-1 level (14)[6] were performed and analyzed using FMO theory.

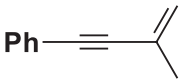
For simplification of the product forming pathway it is assumed that due to the chlorine substitution at silicon highly polar dichloroneopentylsilene **10** is formed by addition of ^{t}BuLi to vinyltrichlorosilane **9** followed by subsequent 1,2-LiCl elimination. The participation of lithiated species for the product formation is neglected.

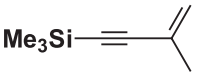
For a rough estimation of the cycloaddition behaviour of **10** the FMO model is used.[6] Silene reactions are usually highly exothermic and should react via early transition states. Consequently the reactivity can be derived by discussion of the electron distribution in the starting material. The reactivity of the 1,3-enynes **a**–**k** is qualitatively estimated by inspecting the frontier orbitals based on the data listed in Table 2. Silene **10** is not included into the calculations because no reliable results might be expected[7] from semiempiric calculations with standard parameters. The question, whether silene **10** reacts with the double and (or) the triple bond of the 1,3-enyne is answered by the polarization of the multiple bonds. The order of polarization is given by the ratio of the HOMO orbital coefficients c_1/c_2 and c_4/c_3 at the carbon atoms C1, C2, C3, and C4 (Table 2): the polarization is getting larger the stronger it deviates from one.

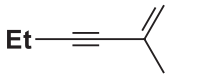


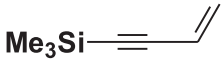


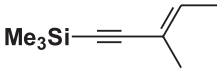


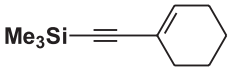


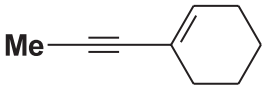


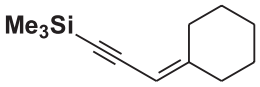


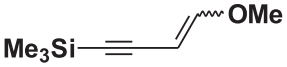


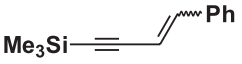


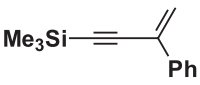












Usually the reactions of dienes and alkynes with neopentylsilenes are regiospecific, but not stereospecific (22). Refering to the eigenvektor coefficients of the LUMO this

[6] All calculations were done with: Hyperchem® 3.0, 1996. Hypercube, Inc. 419 Phillip Street, Waterloo, ON N2L 3X2, Canada.

[7] The geometry of **10** calculated at the AM1 level strongly deviates from that calculated for similar substituted silenes by ab initio methods (21). Thus, the Si=C bond distance is by more than 10 pm smaller than the experimentally measured and with ab initio methods calculated value of about 170 to 175 pm. Consequently, the HOMO–LUMO interaction between enophile and enyne cannot be determined precisely. Nevertheless, knowing the order of magnitude of the eigenvektor coefficients of the HOMO–LUMO interaction, the most favorable conformation of the reactants in the transition state is predictable; preferably the orientation occurs in such a way that bonding results from those atoms with the biggest (smallest) coefficients.

becomes understandable: the biggest coefficient is found at the silicon and compared to the parent silene, $H_2Si{=}CH_2$, the two silicon chlorine substituents of silene **10** even result in an additional increase of the orbital coefficent c_{Si}. Consequently, the resulting regiochemistry of the silacyclobutanes and silacyclobutenes might be explained by an electrophilic attack of silicon at the C1 ($c_1 > c_2$: formation of silacyclobutenes) and C4 ($c_4 > c_3$: formation of silacyclobutanes) of the 1,3-enyne, respectively. According to that the product formation from equimolar mixtures of $Cl_3SiCH{=}CH_2$ (**9**), ^{t}BuLi and 1,3-enynes (Tables 1 and 2) becomes predictable: (*i*) A strong polarization of the C3=C4 double bond and a weak polarization of the C1≡C2 triple bond (e.g., enyne **a**) results in a selective formation of silacyclobutanes; (*ii*) if both multiply bonded centers are polarized, a competitive formation of silacyclobutanes and silacyclobutenes (e.g., enyne **b** and **c**) is expected and experimentally found; and (*iii*) A strong polarization of the C1≡C2 triple bond and an only weak one of the C4=C3 double bond as exhibited by the enynes **d**, **e**, **f**, **g**, **h**, **i**, **j**, and **k**, yield in a selective formation of silacyclobutenes.

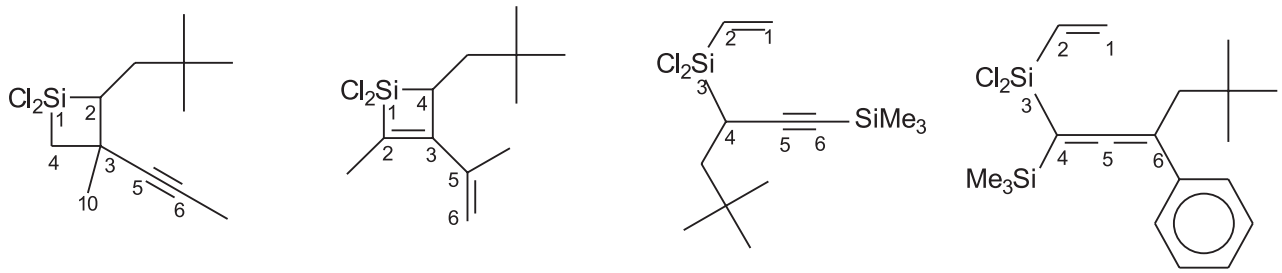
The experimental results listed in Table 1 and the calculations (Table 2) fit very well together: from an estimation of the polarization of the carbon carbon multiple bonds in 1,3-enynes the silacyclobutane/butene formation and their regiochemistry is clearly predictable using **9**/^{t}BuLi mixtures as synthetic equivalent for silene **10**.

Spectroscopic characterization of the reaction products

Although the *E*/*Z* isomeric silacyclobutanes and the regioisomeric silacyclobutenes/butanes can not be separated by distillation, the mixtures are fully characterized by the usual analytical and spectroscopical methods. The relative ratio of the formal [2 + 2] cycloadducts is determined gaschromatographically or by comparison of the intensities of the resonance signals of the *tert*-butyl groups in the ^{1}H NMR spectrum of the sample. Although the NMR data for the silacyclobutanes and silacyclobutenes obtained are completely listed in the Experimental Part, some characteristic ^{29}Si and ^{13}C NMR spectroscopic shifts are given in Table 3 and the data sets for the 2-neopentyl-1-silacyclobutane/butene moieties are examplarily discussed in detail.

As expected each isomer *E* and *Z* of the silacyclobutanes **12a**, **b**; **13a**, **b**; and **15a**, **b** shows two isolated spin systems in the ^{1}H NMR spectrum.[8] In agreement to the corresponding correlations in the ^{1}H^{1}H COSY NMR experiments, the diastereotopic protons H4 are split into two dublets each by geminal couplings (^2J = 12.81–15.82 Hz), while H2 shows a dublet of dublets by two vicinal couplings (^3J = 11.68–12.43, ^3J = 1.89–3.40 Hz) to both of the diastereotopic protons H7 of the neopentyl group. Each of the methylene protons H7 couples to a dublet of dublets due to vicinal coupling to H2 and the geminal coupling. These couplings are characteristic for the silacyclobutane moieties and prove the regiospecific [2 + 2] addition of dichloroneopentylsilene **10** to the 1,3-enynes **a**–**c**. The spin correlations of the exocyclic ethyl group of **15a**, **b** are identified by the ^{1}H^{1}H COSY NMR spectrum. The quaternic acetylenic carbon atoms are assigned according to the literature (17).

For proof of the NMR assignment, a diastereoisomeric mixture of the *E*/*Z*-isomeric dimethyl substituted silacyclobutane **12a′**, **b′** was exemplarily separated by column



[8] By GC/MS the two *E*/*Z*-stereo isomeric silacylobutanes can be detected as a low boiling isomer **a** and a higher boiling isomer **b** (**a** having a shorter retention time compared to **b**). For compound **12a′**, **b′** the two isomers could be separated but not been assigned to *E* and *Z* configurated silacyclobutane **12**. However, separation was successfully performed with the silacyclobutane **33a**, **b**. In this case the low boiling compound is the *Z*-isomer, **b** is the higher boiling *E*-isomer. As there is no distinctive *E*/*Z*-assignment for the two isomers of the silacyclobutanes **12**, **13**, and **15**, they are differentiated as isomers **a** and **b**.

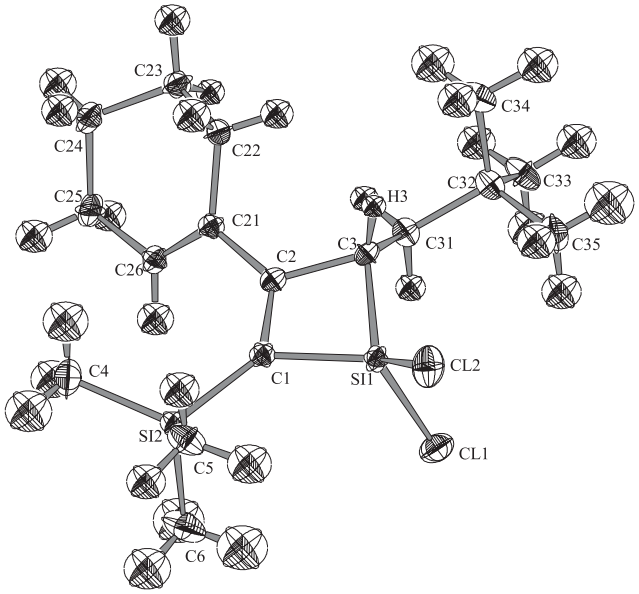
Numbering of the atoms:

chromatography (eluent: *n*-hexane, ratio **a′**:**b′** = 61:39). The methylation of the chlorinated precursor **12a**, **b** was performed using Grignard Reagent (eq. [1]).

Although the NMR data set was determined for both isomers **a** and **b** separately and is in excellent agreement with the data obtained for the isomeric mixtures, a distinctive assignment to the *E* or *Z* configuration of **12** failed.

As expected, the ^1H NMR spectra of the silacyclobutenes **14**, **16**–**21**, ***E***/***Z*-22**, and ***E***/***Z*-23** show two separate spin systems. Both diastereotopic protons H7 exhibit a dublet of dublets each, resulting from geminal (^3J = 13.56–13.94 Hz) and vicinal couplings (^3J = 10.27–12.06, ^3J = 1.13–3.37 Hz). Similarily, for the ring protons H4 a dublet of dublets is detected, caused by vicinal couplings to the protons H7. Compared to the corresponding δ H2 of the silacyclobutanes (δ = 1.90–2.62 ppm), δ H4 of the silacyclobutenes is characteristically shifted to lower fields (δ = 2.51–2.96 ppm). The spin system of the exocyclic ethyl group of **16** is identified by the $^1H^1H$ COSY NMR spectrum. The second spin sequence corresponds to the olefinic protons H6: for the silacyclobutenes **14** and **16** they appear at the lowest field. Only the protons H6 of **14** are splitted into a dublet by geminal coupling, the allylic coupling to the protons of the methyl group R^2 is detected for only one of the diastereoisomers. The protons H6 of **16** exhibit a multiplet and show no coupling to R^2.

According to the rule $J_{trans} > J_{cis}$ for vicinal couplings of alkenes (17), the *E*- or *Z*- configurations of the exocyclic double bonds in ***E***/***Z*-22** and ***E***/***Z*-23** are assigned by the value of the vicinal coupling constants of H5 and H6: thus, the relative isomeric ratio for ***E***/***Z*-22** = 84:16 and for ***E***/***Z*-23** = 24:76.[9]



The silacyclobutenes **19**, **20**, and **21** show the characteristic couplings for the strongly low field shifted protons H4 and the diastereotopic methylene protons; the data are given in the Experimental Part. The protons of the cyclohexenyl substituents in **19** and **20** exhibit two multiplets attributed to the protons at C8/C9 and C7/C10 by $^1H^{13}C$ correlation. An assignment of the methylene protons of the cyclohexylidene ring of **21** is difficult even using the $^1H^{13}C$ correlation method: the two multiplets of H7/H11 and H8/H9/H10 detected in the proton NMR spectra are assigned to the carbon atoms C7/C11 and C8/C9/C10.

The ^{29}Si NMR spectroscopy proved to be an excellent tool for a fast decision between silacyclobutanes and silacyclobutenes formed in the reaction mixtures: both classes of compounds exhibit characteristic and relatively narrow ranges of the chemical shift. Thus, ^{29}Si resonance signals for

[9] Obviously the *E*/*Z* isomeric ratios in both silacyclobutenes are very different compared to those of the 1,3-enynes used [*E*/*Z*-(4-phenylbut-3-ene-1-inyl)-trimethylsilane, **i**: *E*/*Z* = 55:45; and *E*/*Z*-(4-methoxy-but-3-ene-1-inyl)trimethyl-silane, **j**: *E*/*Z* = 92/8]; related to the exocyclic double bonds the formation of the *Z*-isomeric silacyclobutenes is favoured. Assuming that there is no inversion of configurations performing the distillation (bp ***E***/***Z*-22**: 74°C/10^{-3} mbar; ***E***/***Z*-23:** 81–84°C/7 × 10^{-5} mbar) it becomes evident that the *Z*-isomeric enynes preferably react with the mixtures of $Cl_3SiCH{=}CH_2$/^{t}BuLi.

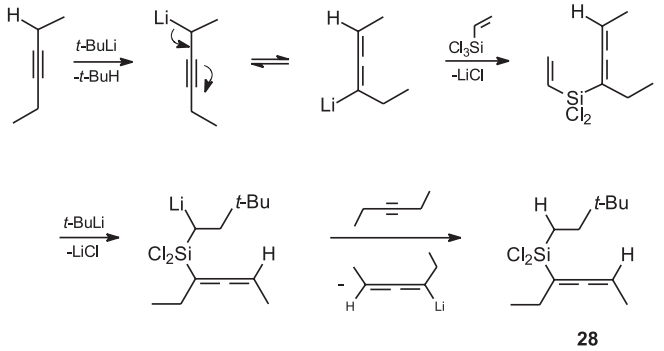
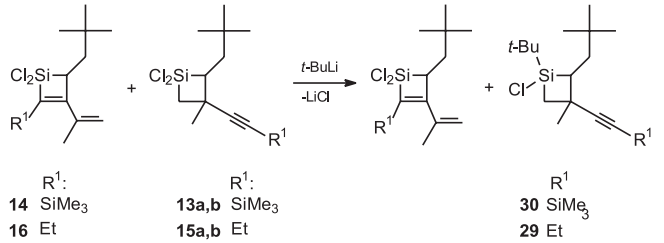
Fig. 1. Molecular structure of 1,1-dichloro-2-trimethylsilyl-3-cyclohex-1-enyl-4-neopentyl-1-sila-cyclobut-2-ene (50% envelopes). Bonding distances (Å) and angles (°):
Cl1—Si1 2.0629(6), Cl2—Si1 2.0656(6), Si1—C1 1.835(1), Si1—C2 2.237(1), Si1—C3 1.871(1), Si2—C1 1.867(1), Si2—C4 1.867(2), Si2—C5 1.880(2), Si2—C6 1.881(2), C1—C2 1.372(2), Si1-C1-C2 87.18(8),C1-C2-C3 110.54(10), C2-C3- Si1 80.90(7), C3-Si1-C1 81.13(1).



the silacyclobutanes are found between 14 and 21 ppm (18), while the shielding effect of the endocyclic double bond in 1,1-dichlorosilacyclobutenes causes a shift to higher field (δ^{29}Si ≈ –5 to 0 ppm) (8, 9). The δ^{29} silicon shifts determined for the silacyclics described in this paper fit very well into these ranges and are listed in Table 3.

X-ray structure analysis of the silacyclobutene 19



From the crude reaction mixture crystalline **19** was isolated. After recrystallization from *n*-pentane a suitable single crystal was investigated by X-ray structure analysis (Fig. 1).

The silacyclobutene **19** crystallizes in the non-centrosymmetric chiral space group $P2_12_12_1$ (no. 19) with a complete dissymmetric molecule as asymmetric unit. For refinement a racemic twin with a *R*:*S* ratio of 0.25 was assumed. With respect to the over-optimistic standard deviations the central, markedly distorted SiC four-membered ring is almost planar (interplanar angle of the planes Si2-C1-C2-C3 and Si2-C1-C2-C21: 5.25 (3)°). The bond lengths and angles are largely determined by the influence of the two chlorine substituents at the Si atom and the shortness of the endocyclic C=C double bond. Due to the chlorine substituents the Si1—C1 and Si1—C3 bond length — in comparison to the structural parameters of other silacyclobutanes (19) — are clearly shortened to 1.835(1) and 1.871(1) Å respectively, and consequently the endocyclic angle at Si1 is widened to 81.13(1)°, whereas the C=C bond distorts the angle Si1-C1-C2 to 87.18(8)°. As a result there are two external angles of 134.8(2)° and 137.9(2)° at C1. The silacyclobutene C1=C2-bond is with 1.372(2) Å slightly longer than the C=C-double bond of the cyclohexenyl substituent (1.340(1) Å). The Si—Cl bonds also differ slightly with 2.0628(6) and 2.0655(5) Å. Within the unit cell no exceptionally short intermolecular contacts are detected. As expected the molecular structure of **19** shows great similarities to that of 1,1-dichloro-2-trimethylsilyl-3-phenyl-4-neopentyl-1-silacyclobut-2-ene published recently (8).

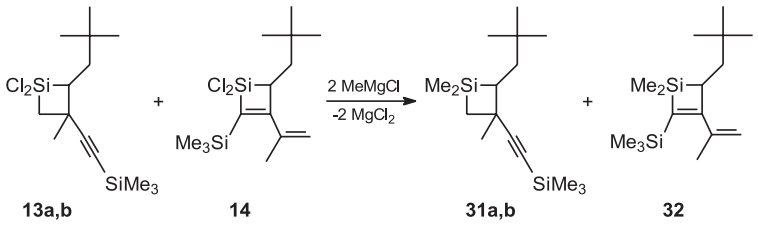
Scheme 6.

Scheme 7.

Formation of side products from mixtures of trichlorovinylsilan, Li-*tert*-Bu, and 1,3-enynes

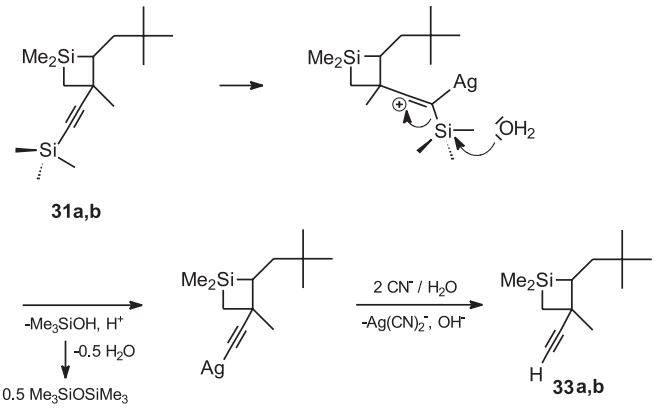
From the reaction of vinylchlorosilane **9**, Li^{t}Bu, and the 1,3-enyne **d**, the "open" isomer **25** of silacyclobutene **17** was isolated in 7–22% yield from several runs. This can easily been understood following the reaction sequence shown in Scheme 4.

In competition to the silacyclobutene formation (**17**), the lithium organyl is added to the enyne double bond in an 1,2 fashion followed by a chlorosilane coupling reaction giving **25**.



In the reaction of vinylchlorosilane **9**, ^{t}BuLi and (3-phenyl-but-3-ene-1-enyne)-trimethylsilane **k**, compound **26** is formed competitively to silacyclobutene **24** (**26**:36%, **24**:9%) and results from an 1,4-addition of ^{t}BuLi to the 1,3-enyne to give a lithiated allenyl derivative. Coupling reaction with chlorosilane **9** yields **26** (Scheme 5).

In this case the side reaction clearly dominates over the silacyclobutene formation. The reaction pathway discussed in Scheme 5 is confirmed by the reaction of the mixture **9**/^{t}BuLi with a *di*alkyl substituted alkyne such as 3-hexyne. From that a 1,2-dichloro-2,3-diethyl substituted silacyclobutene (**27**) and the allenylsilane **28** are isolated. The reaction sequence giving **28** is shown in Scheme 6: deprotonation of 3-hexyne gives a lithiated allenylsilane; chlorovinylsilane coupling yields a dichloroallenylsilane which can not be isolated and serves as starting material to give **28** (19%) after ^{t}BuLi-addition, followed by subsequent deprotonation of 3-hexyne.



Silacyclobutene **27** can be separated as a pure liquid (yield: 30%) by reacting the mixture **27, 28** with bromine:

© 2000 NRC Canada

Scheme 8.

Scheme 9.

while the allenylsilane **28** adds bromine to the carbon double bonds immediately, the silacyclobutene does *not* react; it is isolated from the reaction mixture by distillation, the brominated silane remains as a residue (see Exp. section).

Silacyclobutene/butane separation from isomeric product mixtures

With respect to their comparable boiling points a silacyclobutene/butane separation of the isomeric mixtures **13a**, **b**/**14** and **15a**, **b**/**16** by distillation is impossible; due to the dichlorosilyl functionality even a gaschromatogaphic separation failed. However, for a successful "chemical" separation the two mixtures are reacted with silacyclobutane equivalent molar amounts of ^{t}BuLi each giving the mono-*tert*-butylated silacyclobutanes **29** and **30** nearly quantitatively; notably, the silacyclobutenes **14** and **16** do not react under comparable conditions (Scheme 7). The silacyclobutenes are then easily separated by distillation, the silacyclobutanes **29** and **30** remain as high boiling residues.[10] Electronic and steric reasons might be responsible for the selective substitution of only *one* silacyclobutane Si-Cl function: although the ethyl substituent at C2 of **16** is sterically less demanding than the trimethylsilyl group in **14**, even in that case only the mono substitution to give **29** took place. Nevertheless, methylation of the mixture **13a**, **b**/**14** by methyl Grignard Reagent gives the dimethyl substituted product mixture **31a**, **b**, and **32** (Scheme 8).

Loosing the dichlorosilyl functionality this clean reaction opens possibilities for derivatization and separation: reacting a mixture of **31a**, **b**, and **32** under the conditions of the Arens–Schmidt reaction (desilylation by use of $AgNO_3$/KCN (20)) yields the stereoisomeric silacyclobutane **33a**, **b**, while the silacyclobutene **32** is not affected. The metallated trimethylsilyl—alkyne bond in **31a**, **b** is quantitatively and selectively cleaved by use of a double molar amount of an aqueous solution of cyanide as shown in Scheme 9 and described in the Experimental part.

The high stereospecificity of the Schmidt–Arens reaction is surprising: by addition of an ethereal ethanolic solution of silver nitrate equimolar to the higher boiling isomer **31b**, this isomer is selectively desilylated (95% de). Notably, only after completion the trimethyl—silyl bond of the low boiling isomer **31a** is cleaved. The configuration of **31a** was assigned to be the *Z* isomer by NOE difference NMR spectroscopy; consequently **31b** represents the *E*-isomer. From the experimental results it is obvious that the attack of the silver atoms on the alkinyle triple bond of the *E*-isomer **31b** is kinetically preferred over that at the *Z*-isomer **31a**.

Experimental part

General remarks

All manipulations were performed under purified argon using standard Schlenk techniques. Solvents were dried by refluxing under nitrogen with the appropriate drying agent and were distilled prior before use. $CDCl_3$ was dried with molecular sieves, while [D6]benzene was dried with potassium/sodium and distilled prior to NMR sample preparation. NMR spectra: Bruker AM 300 (^{29}Si), DPX 300 (^{1}H, ^{13}C) and AMX 600 (^{1}H, ^{13}C), ^{1}H and ^{13}C NMR chemical shifts (δ) were internally referenced (δ (C*H*Cl$_3$) = 7.24, δ (*C*DCl$_3$) = 77.00, δ (C_6D_5H) = 7.15, δ (C_6D_6) = 128.00); ^{29}Si NMR spectra were measured using either the INEPT pulse sequence or the inversed gated decoupling technique, the ^{29}Si NMR shifts were externally referenced to TMS. GC: Varian Chromstar 3400 (15 m × 0.32 mm, 1µ film, Fison J & W scientific DB 1 column). GC/MS: Chrompack CP 9000 (capillary column CP-SIL/5CB-MS, diameter 0.25 mm, 12.5 m length) coupled with a Finnigan MAT Ion Trap Detector 800 (electron impact, space current 3000 µA, ionisation energy 70 eV, ion-source temperature 250°C), for chemical ionization methanol was used. Elemental analyses: Microanalytical Laboratory of the Department of Chemistry, Humboldt-University, Berlin. Leco CHNS-932. Trichlorovinylsilane was distilled from sodium carbonate prior before use. *tert*-Butyllithium was used as 1.7 M solution in pentane. All other chemicals were used as purchased by Aldrich and Fluka.

Preparation of 1,3-enynes

2-Methyl-4-phenyl-but-1-ene-3-yne (**a**) was prepared according to ref. 21 (yield 59%) and following the general

[10]Due to very complex isomeric mixtures (from eight expected stereoisomers, four can be detected by GC/MS) a listing of the NMR and mass spectroscopic data for **29** and **30** is avoided.

procedures described in ref. 17. For the syntheses of the 1,3-enynes **b**, **d**, **e**, **f**, **g**, **h**, **i**, **j** see ref. (17), **k** was synthesized according to ref. 21 and **c** is commercially available.

General procedure for the preparation of silacyclobutanes and silacyclobutenes

Trichlorovinylsilane (**9**, 50 mmol, 8.1 g) and the corresponding 1,3-enyne (50 mmol) are dissolved in 150 mL of *n*-pentane. Then 29.4 mL of 1.7 M ^{t}BuLi/*n*-pentane (50 mmol) are added dropwise over a period of 15 min. Generally, the solution warms slightly, and after 4 h stirring at room temperature the solution is separated from the precipitated LiCl by filtration. The solvent and an access of the 1,3-enyne is removed by destillation. Finally, the oily residue is distilled at 10^{-2} mbar for purification.

The syntheses carried out following this procedure are listed in Table 4.

[a]The silacyclobutanes and silacyclobutenes as well as the by-products are colourless, viscous liquids; only **19** was isolated as a crystalline solid.

[b]The *cis*/*trans* isomeric ratios **a**/**b** are given in parentheses.

[c]The *E*/*Z* isomeric ratios **a**/**b** corresponding to the exocyclic double bond of the silacyclobutenes are given in parentheses. The mixtures of isomers were subjected to elemental analysis (see Experimental section).

X-ray structure determination of 1,1-dichloro-2-trimethylsilyl-3-cyclohex-1-enyl-4-neopentyl-1-silacyclobut-2-ene

A crystal of the approximate dimensions 0.5 × 0.6 × 0.6 mm was mounted on a glass fibre tip glued with silicon grease and transfered to the goniometer. The crystal was cooled to 100 K (Oxford CryoStream, U.K.) for all subsequent manipulations. The intensity data collection was performed by means of a one-circle diffraktometer (Stoe IPDS, Darmstadt, FRG) equipped with a image plate (IP: ⌀ = 180 mm, BaFBr(Eu^{2+}), scanning head: He–Ne laser (632 nm), photomultiplier (400 nm), resolution (max.) 150 μm), a sealed fine focus X-ray tube (MoKα radiation, λ = 0.71073 Å) and a graphite monochromator. The indexing procedure for estimating the initial lattice constants used 158 reflections ($I > 12\sigma_I$) out of a total of 260 recorded reflections (5 frames, φ-increment: 72°, 50 kV, 40 mA). The raw intensities (data collection: 21 h, 200 frames, 0° < φ < 240°, φ-increment: 1.2°, 50 kV, 30 mA, 5.1° < 2θ < 63.4°, 23613 reflns: 3 overlapped, 43 overloaded, 23 565 reflns merged (R_{int} = 0.0903), 7690 unique, 6963 observed ($I > 2\sigma_I$)) were corrected for Lorentz and polarization effects. To refine the lattice constants 5000 reflections (φ = 174°, 6.8° < 2θ < 63.3°, 12.0 < I/σ_I < 1020.8) were chosen from the data set. Atom form factors (22) for neutral atoms were implemented in the used program system. Direct Methods (SHELXS86 (23)) were applied to the data set to gain an initial model of the molecular structure. After four cycles of Difference Fourier Syntheses (24) and subsequent Least Squares Refinement the structure model was completed. All second row elements were allowed to refine anisotropically, the next 30 strongest electron densities taken from the Fourier map occured in most plausible positions for hydrogen atoms and were refined isotropically. After the final refinement cycle no meaningful electron densities remained. Details of the crystal structure analysis are given in Table 5. Crystallographic data (excluding structure factor listings) for the

*Preparation of silacyclobutene **27** and separation from **28***: The preparation of **27** followed the general procedure given in the Experimental section. From the equimolar mixture of H_2C=$CHSiCl_3$/^{t}BuLi/3-hexyne (50 mmol each), **27** (3.98 g, 15 mmol, 30%) and **28** (1.75 g, 9.5 mmol, 19%) were obtained as a mixture of colorless liquids, bp 64–68°C, 10^{-2} mbar. The analysis was performed from the mixture; Anal. calcd. (found) for $C_{12}H_{22}Cl_2Si$ (265.29): C 52.31 (52.08), H 8.15 (8.32), Cl 22.06 (22.21).

*Separation of **27** from **28***: To a mixture of 6.63 g (25 mmol) of **27**/**28**, solved in 30 mL CCl_4, 1.82 g (11.42 mmol) Br_2, solved in 20 mL of CCl_4, were slowly added at –10°C. The reaction was controlled by its color lost and by IR spectroscopy (**28**: $\nu_{C=C=C}$: 1938 cm^{-1}). After the bromine color remains and the band at 1938 cm^{-1} has disappeared, the solvent is removed and the residue is distilled under vacuo. While brominated **28** remains as high boiling residue, the silacyclobutene **27** was isolated as a pure liquid.

*1,1-dichloro-2,3-diethyl-4-neopentyl-1-silacyclobut-2-ene (**27**)*: ^{1}H NMR ($CDCl_3$) δ: 0.93 (s, 9H, H7), 1.00, 1.04 (tr, ^3J = 7.53 Hz, 3H, H8, H10), 1.43 (dd, ^2J = 13.57 Hz, ^3J = 11.68 Hz, 1H, H5), 1.53 (dd, ^2J = 13.57 Hz, ^3J = 2.64 Hz, 1H, H5), 2.13, 2.14 (q, ^3J = 7.53 Hz, ^5J = 0.76 Hz, 2H, H8, H10), 2.49 (dd, ^3J = 11.68 Hz, ^3J = 2.64 Hz, 1H, H4). ^{13}C NMR ($CDCl_3$) δ: 11.17, 13.93 (C9, C11), 20.04, 21.51 (C8, C10), 29.41 (C7), 30.44 (C6), 40.05 (C4), 40.42 (C5), 146.89, 162.17 (C2, C3). ^{29}Si NMR ($CDCl_3$) δ: –2.9. MS (70 eV), *m/z* (%): 305 (4.4) (M^+ –15), 291 (22.3) (M^+ -Et), 263 (34.9) (M^+ – ^{t}Bu), 250 (24.5) (M^+ – 2Cl).

*6,6-dichloro-5,9,9-trimethyl-6-siladecadi-3,4-ene (**28**)*: IR: 1938 cm^{-1} ($\nu_{C=C=C}$); ^{1}H NMR ($CDCl_3$) δ: 0.87 (s, 9H, H9), 1.00 (dd, ^3J = 7.54 Hz, ^3J = 7.54 Hz, 3H, H11), 1.13 (m, 2H, H6), 1.37 (m, 2H, H7), 1.68 (d, ^3J = 7.16 Hz, 3H, H1), 2.08 (dq, ^2J = 13.94 Hz, ^3J = 7.54 Hz, 1H, H10), 2.36 (dq, ^2J = 13.94 Hz, ^3J = 7.54 Hz, 1H, H10), 5.15 (pn, ^3J = 7.16 Hz, ^5J = 3.01 Hz, ^5J = 4.15 Hz, 1H, H2). ^{13}C NMR ($CDCl_3$) δ: 13.14 (C11), 14.61 (C6), 21.67 (C10), 27.04 (C1), 28.69 (C9), 30.88 (C8), 36.07 (C7), 85.35 (C2), 95.86 (C4), 208.55 (C3). ^{29}Si NMR ($CDCl_3$) δ: 18.1.

*Methylation of **13a**, **b**/**14** and performance of the Arens–Schmidt reaction*: The mixture **13a**, **b**/**14** was reacted with a double molar amount of methyl Grignard reagent. Silacyclobutane **31a**, **b** and silacyclobutene **32** were obtained nearly quantitatively (93%) as a mixture of colorless liquids, bp 48–49°C/10^{-2} mbar. Both compounds were characterized by GC/MS methods. The isomeric mixture was then reacted under the conditions of the Arens–Schmidt reaction (29). To a solution of 19.78 g (70.5 mmol) of **31a**, **b**/**32** (28.9 mmol of **32**; 24.7 mmol of **31a** and 16.9 mmol of **31b**: the molar ratio was determined from the intensities of the resonance signals of the *tert*-butyl groups in the ^{1}H NMR spectrum of the sample), solved in 100 mL of ether and 50 mL of ethanol, 2.87 g (16.9 mmol) of $AgNO_3$, solved in a mixture of 20 mL of water and 40 mL of ethanol, were added. Immediately a brown solid precipitated. After 10 min of stirring at room temperature 4.16 g NaCN (85 mmol), solved in 40 mL of water, were added. The reaction solution was extracted three times with ether, the organic layer was separated, washed with aequous NaCl solution, and dried over $MgSO_4$. After removal of the solvent the residue was distilled at 1 mbar. The compound isolated contained 98% of ***E*-33** and 2% of the *Z*-isomer. Treating the residue then with a solution of 4.21 g (24.8 mmol) $AgNO_3$, the *Z*-isomer of **31** is obtained in 98%, while the amount of ***E*-31** is 2% (bp 58°C/1 mbar). Repeating the distillation of the residue gave pure **32** (bp 48–49°C/10^{-2} mbar).

The one- and two-photon photochemistry of benzylsilacyclobutanes, acyclic benzylsilanes, and 1,1,2-triphenylsilacyclobutane

William J. Leigh and Thomas R. Owens

Abstract: The photochemistry of several α-silylbenzyl compounds has been investigated in hexane and in methanol solution. Direct photolysis of 1-benzyl-1-methylsilacyclobutane (**1**) in methanolic hexane solution produces 1-propyl-1-methyl-2,3-benzosilacyclobutene (**6**) in quantitative yield, by a sequential two-photon process involving the photoactive isotoluene derivative 1-methylene-6-(1-methylsilacyclobutyl)-2,4-cyclohexadiene (**13a**), which has been identified on the basis of its ^{1}H NMR and UV absorption spectra. In contrast, direct irradiation of 1-benzyl-1-phenylsilacyclobutane (**2**) under similar conditions results in the formation of a complex mixture of products consistent with the competing formation of 1-benzyl-1-phenylsilene and benzyl- and 1-phenylsilacyclobutyl radicals. The silene is a transient which has been detected directly by laser flash photolysis of **2** (λ_{max} = 315 nm, $\tau \sim 4.5$ μs). Free radical formation is shown to be due to secondary photolysis of a second primary product, 1-methylene-6-(1-phenylsilacyclobutyl)-2,4-cyclohexadiene (**13b**), which has also been detected and identified by static UV absorption (λ_{max} = 335 nm) and ^{1}H NMR spectroscopy. In a reaction with some analogy to the acid-catalyzed desilylation of allylsilanes, both **13a** and **13b** can be intercepted in neutral or acidic methanol solution to yield toluene and 1-methyl- or 1-phenyl-1-methoxysilacyclobutane, respectively. Direct photolysis of benzyldimethylphenylsilane (**4**) also leads to the formation of the corresponding isotoluene derivative, while benzyltrimethylsilane (**3**) exhibits negligible photoreactivity. The endocyclic benzylsilane 1,1,2-triphenylsilacyclobutane (**5**) is shown to undergo competing [2 + 2]-cycloreversion and [1,3]-silyl migration to yield a bicyclic isotoluene analogue, which reacts rapidly with methanol to yield the acyclic methoxysilane reported previously to be the main product of photolysis of this silacyclobutane in methanol solution. Relative quantum yields for isotoluene formation from photolysis of **1**–**4** and absolute rate constants for methanolysis of several of these compounds under neutral and acidic conditions have also been determined.

Key words: photochemistry, organosilicon, benzylsilane, silacyclobutane, silene, kinetics, isotoluene.

Résumé : On a étudié la photochimie de plusieurs composés α-silylbenzyles en solutions dans l'hexane ou dans le méthanol. La photolyse directe du 1-benzyl-1-méthylsilacyclobutane (**1**), en solution méthanolique d'hexane, conduit à la formation de 1-propyl-1-méthyl-2,3-benzosilacyclobutène (**6**) avec un rendement quantitatif; la réaction se produit par un processus séquentiel à deux photons impliquant le dérivé photoréactif isotoluène, 1-méthylène-6-(1-méthylsilacyclobutyl)cyclohexa-2,4-diène (**13a**) que l'on a identifié sur la base de son spectre RMN du ^{1}H et de son spectre d'absorption UV. Par ailleurs, l'irradiation directe du 1-benzyl-1-phénylsilacyclobutane (**2**) dans des conditions semblables conduit à un mélange complexe de produits qui pourraient résulter d'une compétition entre la formation des radicaux 1-benzyl-1-phénylsilène, et benzyl- et 1-phénylsilacyclobutyles. Le silène est une espèce transitoire que l'on a détectée directement par photolyse éclair à l'aide d'un laser du produit **2** (λ_{max} = 315 nm, $\tau \sim 4{,}5$ μs). On a démontré que la formation du radical libre est due à une photolyse secondaire d'un deuxième produit primaire, la 1-méthylène-6-(1-phénylsilacyclobutyl)cyclohexa-2,4-diène (**13b**) que l'on a aussi détecté et identifié par absorption UV statique (λ_{max} = 335 nm) et spectroscopie RMN du ^{1}H. Dans une réaction qui présente une certaine analogie avec la désilylation acidocatalysée des allylsilanes, on peut intercepter les composés **13a** ainsi que **13b**, en solutions méthanoliques tant neutre qu'acide, pour obtenir du toluène et respectivement du 1-méthyl- et du 1-phényl-1-méthoxysilacyclobutane. La photolyse directe du benzyldiméthylphénylsilane (**4**) conduit aussi à la formation du dérivé isotoluène correspondant alors que la photoréactivité du benzyltriméthylsilane (**3**) est négligeable. On a démontré que le benzylsilane endocyclique, 1,1,2-triphénylsilacyclobutane (**5**), est soumis à des réactions en compétition de cycloréversion [2 + 2] et de migration de silyle [1,3] qui conduisent à un analogue isotoluène bicyclique qui réagit rapidement avec le méthanol pour fournir le méthoxysilane acyclique reconnu antérieurement comme le produit principal de la photolyse de ce silacyclobutane en solution dans le méthanol. On a aussi déterminé les rendements quantiques

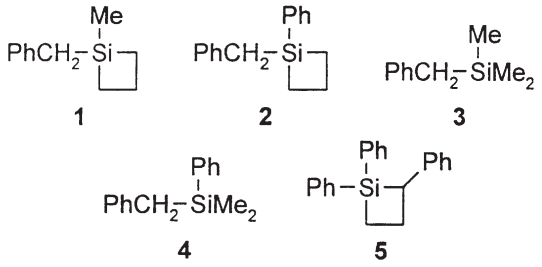
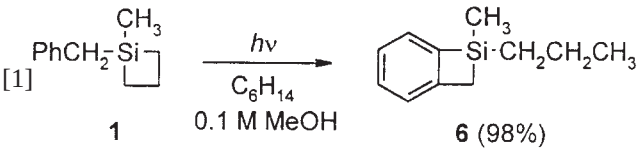
pour la formation de l'isotoluène par photolyse des composés **1**–**4** ainsi que les constantes de vitesse absolues de méthanolyse de plusieurs de ces composés dans des conditions neutres et acides.



Mots clés : photochimie, organosilicium, benzylsilane, silacyclobutane, silène, cinétique, isotoluène.

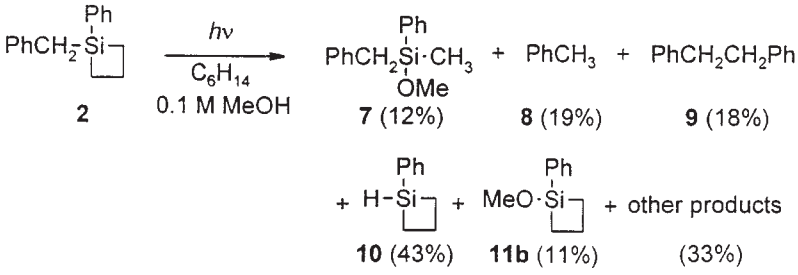
Introduction

Silacyclobutanes are well-known photochemical and thermal precursors to transient Si=C containing compounds ("silenes") (1–8), and are tremendously useful in experiments aimed at detecting these reactive intermediates directly and studying the kinetics and mechanisms of their various characteristic reactions (9–17). Photochemical silene formation proceeds with useful efficiencies from silacyclobutanes bearing a wide range of substituents at silicon, ranging from compounds in which the silacyclobutane ring is the primary chromophore (e.g., 1,1-dialkylsilacyclobutanes) to those in which the lowest excited state is localized more in the substituent (e.g., 1-arylsilacyclobutanes). The only known exception to this generalization is alkoxy-substituted derivatives; substituents of this type, either directly at silicon or on the aromatic rings of phenylated derivatives, renders the silacyclobutane moiety inert to photocycloreversion (13, 17).



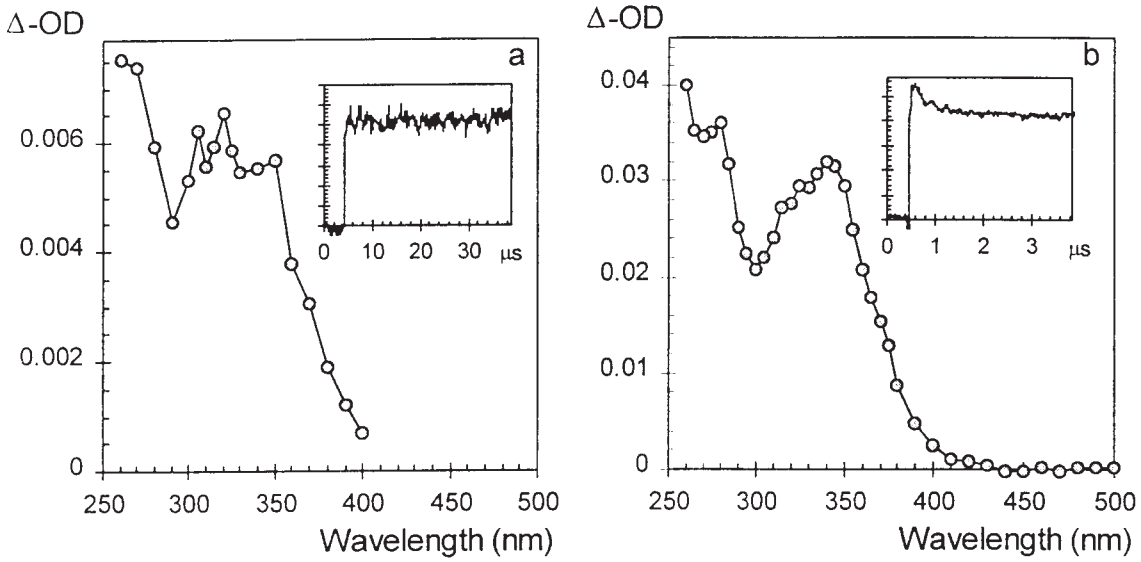
Recent work in our laboratory has been directed at exploring the versatility of arylsilacyclobutanes as photochemical silene precursors, through systematic variation of the structure and photophysical properties of the aryl chromophore (18). These studies have also afforded new detail on the mechanism of silene photoextrusion from arylsilacyclobutanes. For example, the reaction proceeds from the lowest excited singlet state, probably via a 1,4-biradical intermediate that partitions between silene and the ground state of the silacyclobutane. If this mechanism is correct, then the overall quantum yield for reaction will be a function of two factors. The first is the partitioning of the silacyclobutane excited singlet state between Si—C bond cleavage and nonproductive decay via internal conversion, intersystem crossing, and fluorescence; this tends to not vary dramatically as a function of aryl substituent, at least within the series of compounds that we have studied to date. The second is the partitioning of the biradical intermediate between silene and starting material. This does appear to vary as a function of substituent at silicon, most likely due to substituent-induced variations in the conformational properties of the biradical.

In this paper, we describe the results of a study of the photochemistry in solution of two 1-benzylsilacyclobutanes (**1** and **2**). These two compounds exemplify two different photophysical situations – one in which the benzyl group is the primary chromophore in the molecule (**1**) and one in which the role of primary chromophore is shared between it and the silacyclobutane ring via a second phenyl group attached to silicon (**2**). Previous work suggests that benzylsilanes generally exhibit very low photoreactivity upon direct excitation in condensed phases (19). We thus wondered whether benzylsilacyclobutanes might show similar reactivity toward silene photoextrusion as is possessed by other simple silacyclobutane derivatives, with minimal complications from competing reactions due to the benzylic substituent. It quickly became clear that this is not the case, prompting us to expand our studies to include three additional benzylsilane derivatives, two of which have been studied previously: benzyltrimethylsilane (**3**) (19), benzyldimethylphenylsilane (**4**), and 1,1,2-triphenylsilacyclobutane (**5**) (4, 9, 20).



Results and discussion

Direct photolysis of 1-benzyl-1-methylsilacyclobutane (**1**; 0.05 M) in deoxygenated hexane solution containing methanol (0.1 M) with the light from a low pressure mercury lamp (254 nm) affords the single product **6** in quantitative (>98%) yield (eq. [1]). The same product was formed, again quantitatively, when the photolysis was conducted in the absence of methanol.



In contrast, photolysis of **2** as a deoxygenated 0.05 M solution in hexane containing 0.1 M methanol led to the more complex mixture of products shown in eq. [2]. Alkoxysilane **7** is the product expected from trapping of 1-benzyl-1-phenylsilene (**12**) by methanol, while **8**–**10** are most likely the products of hydrogen abstraction or coupling of benzyl

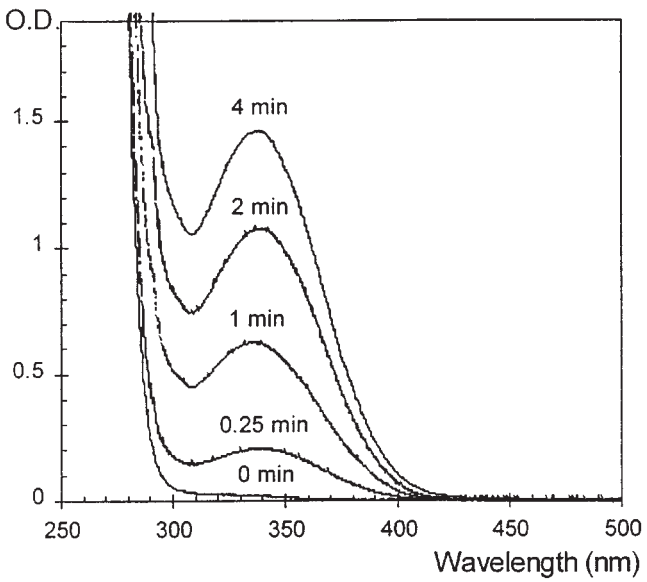
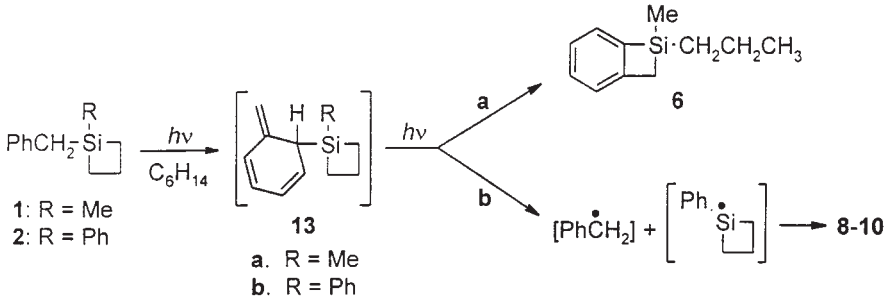
Fig. 1. UV absorption spectra, recorded by laser flash photolysis of deoxygenated hexane solutions of (*a*) 1-benzyl-1-methylsilacyclobutane (**1**; 0.002 M), 10–15 μs after the pulse and (*b*) 1-benzyl-1-phenylsilacyclobutane (**2**; 0.001 M), 3–3.5 μs after the pulse. The inserts show typical traces, recorded at 335 nm.



and phenylsilacyclobutyl radicals. Several other products were also formed, in yields which were too low to enable identification. The mass balance was ~93% at 20% conversion of **2**.

Flash photolysis of a deoxygenated hexane solution of **1** (0.007 M) with a KrF excimer laser (248 nm) led to the formation of a weakly absorbing species which was stable over 10 ms, the longest timescale able to be monitored with our system. The UV spectrum recorded 10–15 μs after laser excitation is shown in Fig. 1*a*, along with a ΔOD vs. time profile. No short-lived transient species could be detected at any monitoring wavelength between 260–600 nm from this compound. Similar experiments with **2** (0.008 M) led to the results shown in Fig. 1*b*: the formation of a long-lived species which exhibits a similar spectrum to that observed from **1**, on which is superimposed a weak transient absorption which decayed with pseudo-first order kinetics ($\tau \sim 4.5$ μs). Subtraction of the spectrum of the long-lived species from the spectrum recorded immediately after the laser pulse revealed an absorption centered at 310–315 nm, which can be associated with the short-lived transient species. The lifetime of this transient was shortened upon addition of methanol to the solution; a plot of k_{decay} vs. [MeOH] according to eq. [3] was linear, with slope $k_{MeOH} = (9 \pm 2) \times 10^7$ M^{-1} s^{-1}. The spectrum and sensitivity of the lifetime of this transient to the presence of methanol are consistent with its assignment to 1-benzyl-1-phenylsilene (**12**). Neither of the long-lived species formed from **1** and **2** were affected detectably by the addition of up to 0.1 M methanol, over the 10 ms timescale.

$$[3] \qquad k_{decay} = k_o + k_{MeOH}[MeOH]$$



The stable species produced in the flash photolysis experiments with **1** and **2** could also be detected by static UV absorption spectroscopy, and by ^{1}H NMR spectroscopy when the reactions were carried out in cyclohexane-d_{12}. For example, the static UV spectrum of a 0.017 M solution of **1** as a function of photolysis time is shown in Fig. 2. The ^{1}H NMR spectra of a cyclohexane-d_{12} solution of this compound after

Fig. 2. Static UV absorption spectra of a 0.017 M solution of **1** in hexane solution after various time intervals of photolysis with 254-nm light, illustrating the formation of isotoluene **13a** (λ_{max} = 335 nm).

photolysis for similar periods of time showed the growth of a broad singlet at δ 3.18 ppm and a number of resonances in the vinylic region which integrate to a total of six protons relative to the signal at δ 3.18. These signals grow in during the early stages of the photolysis and then remain roughly constant in relative intensity upon continued irradiation, and can thus be identified as arising from the same initially-formed product that is responsible for the 335 nm UV absorption. On the basis of these data, we assign the structure of this product to 1-methylene-6-(1-methylsilacyclobutyl)-2,4-cyclohexadiene (**13a**; eq. [4]). The spectral data observed agree very well with those reported for other

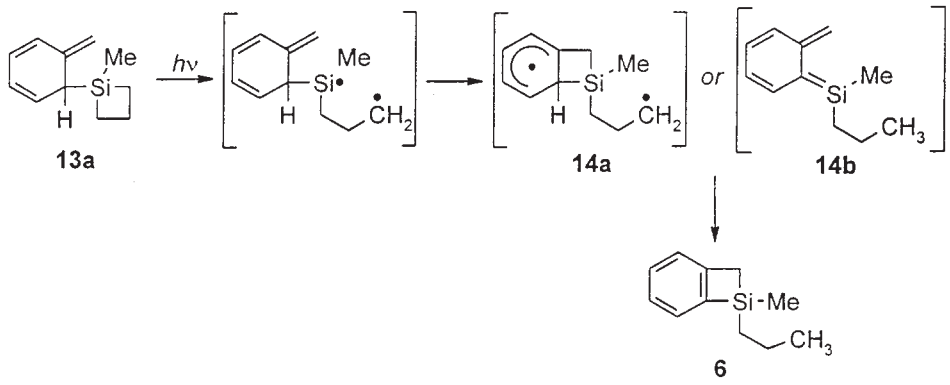
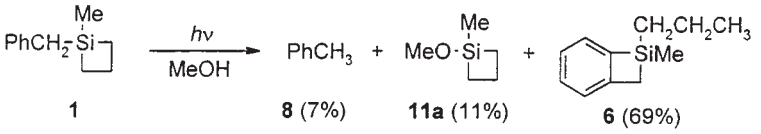
[4] 

isotoluene derivatives (21–24). Compounds of this type are surprisingly quite stable in non-nucleophilic solvents.

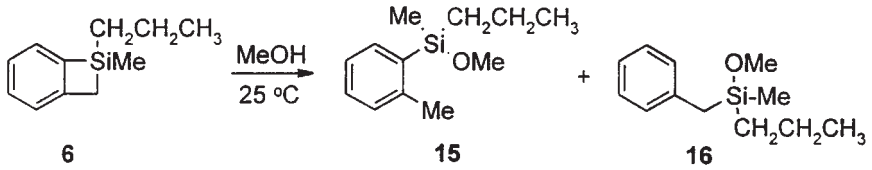
In the case of **1**, these experiments indicated **13a** to be the sole primary photolysis product, building up steadily in concentration over a conversion range of 0–15% to a level roughly 6% of that of the starting material, after which it decreased in parallel with **1** upon continued photolysis. Compound **6** could only be detected in significant yields after the formation of **13a** had nearly reached its initial plateau, suggesting that it is a secondary product resulting from photolysis of the latter species. This was verified by photolyzing a solution of **1** with 248 nm light to ca. 10% conversion, and then continuing the photolysis with 337 nm light; this caused **13a** to disappear, with concomitant formation of **6** and no further consumption of **1**, consistent with the fact that the latter is nonabsorbing above ~280 nm.



Similar experiments with **2** indicated that only alkoxysilane (**7**), ethylene, and a product identifiable as isotoluene **13b** are formed upon photolysis in hexane or cyclohexane-d_{12} solution to low (<ca. 10%) conversions. Again, the isotoluene derivative could be detected by both static UV and ^{1}H NMR spectroscopy, and products **8**–**10** were found to be produced only after the concentration of **13b** rose to ~5% of that of **2**. Alternating 248 and 337 nm irradiation experiments verified that **8**–**10** are formed as a result of secondary photolysis of **13b**.



The formation of **13a**, **b** as the major primary products of photolysis of **1** and **2** indicates that the photochemistry of these compounds is in both cases dominated by reactivity specific to the benzyl chromophore rather than the silacyclobutane moiety, unlike the case with other silacyclobutanes that have been studied. Silene formation competes significantly only in **2**, where the silacyclobutane ring bears a second phenyl chromophore which competes effectively with the benzyl group for direct light absorption. The reactive excited states in both **1** and **2** are most likely the lowest singlet states, since our flash photolysis experiments indicate that **13a**, **b** are both formed within the duration of the laser pulse (~25 ns), consistent with either a concerted sigmatropic rearrangement or a singlet radical-pair recombination mechanism for their formation. No evidence for the competing formation of benzyl radicals in the primary photochemical event could be obtained by flash photolysis in either case, which provides strong evidence against a mechanism for the formation of **13** which involves the triplet excited states of **1** and **2**. For that matter, no evidence for benzyl radical formation could be obtained either in two-laser flash photolysis experiments with **2**, where the second (337 nm) laser pulse was delivered 5–10 μs after **13b** was formed by the primary (248 nm) pulse. Since product studies clearly indicate that free benzyl radicals *must* be formed upon secondary photolysis of **13b**, this result merely suggests that the quantum yield for photolysis of the intermediate is exceedingly low. This is also indicated by the fact that only slight irreversible bleaching of the 335 nm absorption due to **13b** could be detected in these experiments. Flash photolysis experiments carried out with optically matched (at 248 nm) solutions of **1** and **2** indicated that the quantum yield for formation of **13b** from **2** is only slightly higher than that for formation of **13a** from **1** (Φ_{13b}/Φ_{13a} ~ 1.3). This suggests that the main effect of replacing the methyl substituent in **1** with phenyl (in **2**) is to promote silene formation in minor amounts, via [2 + 2]-cycloreversion of the silacyclobutane ring. The spectra shown in Fig. 1 were recorded with solutions which were not optically-matched, and with different excitation laser intensities.



Interestingly, the identity of the second silyl substituent has a far more substantial effect on the photochemistry of the corresponding isotoluene derivatives **13a**, **b**. The formation of **6** from **13a** can be formulated in terms of a nonconcerted mechanism involving rearrangement of the 1,4-biradical intermediate formed by cleavage of the one of the endocyclic silacyclobutyl Si—C bonds (eq. [5]). If this mechanism is correct, then the photochemistry of **13a** initially follows a course typical of 1-substituted methylsilacyclobutanes (18). Unlike other methylsilacyclobutane-derived 1,4-biradicals however, that derived from **13a** has available two possible reaction pathways that are both likely to be less energetically demanding than cleavage to the corresponding silene and ethylene: rearrangement to yield the more stable cyclohexadienyl biradical **14a** which can then aromatize to **6** via intramolecular disproportionation, or intramolecular abstraction of the cyclohexadienyl proton to form an *ortho*-silaxylylene intermediate (**14b**) followed by electrocyclic ring closure. We favour the former mechanism, on the basis of the fact that none of the expected trapping product of **14b** was observed in the photolysis of **1** in 0.3 M MeOH solution; however, its possible intermediacy in the formation of **6** from **13a** cannot be rigorously ruled out.

The photochemistry of **13b**, on the other hand, is evidently initiated by preferential cleavage of the weaker of the *exocyclic* silacyclobutyl Si—C bonds, yielding benzyl- and phenylsilacyclobutyl radicals. To our knowledge, no other examples of exocyclic Si—C bond cleavage are known in silacyclobutane photochemistry. One possible explanation for the difference in the photochemistry of **13a** and **13b** is that the latter has available to it a conformer in which a reasonable degree of π-overlap is possible between the methylenecyclohexadienyl and phenyl rings; this could lead to preferential weakening of the exocyclic Si—C bond due to charge-transfer interactions between the two moieties in the lowest excited singlet state. While no evidence for such interactions could be obtained from the UV absorption spectra

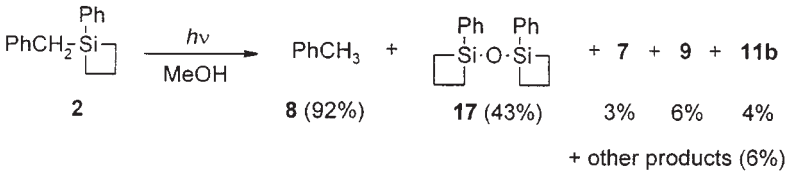
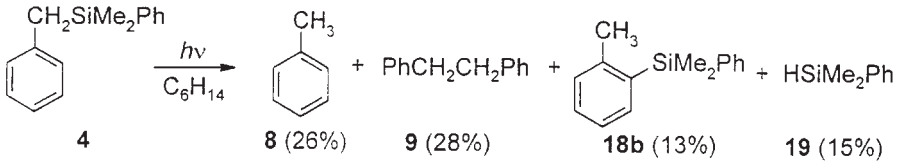
[6] 

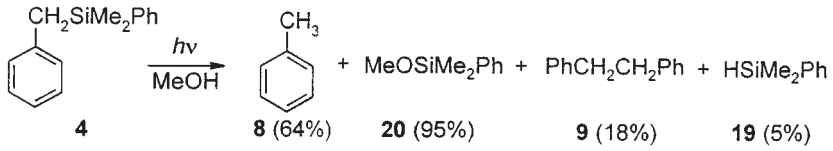
[7] 



of the two compounds, the vinylic resonances in the ^{1}H NMR spectrum of **13b** appear at consistently lower fields than those in the spectrum of **13a**, indicative of significant deshielding of the vinyl protons by the phenyl ring. Neither compound appears to undergo the 4π electrocyclic ring closure that is typical of other isotoluene derivatives that have been studied (24), to any detectable extent.



To gain additional evidence for the primary involvement of **13a**, **b** in the photochemistry of **1** and **2**, we examined the photolyses of the latter two compounds in neat methanol solution. One of the common properties of isotoluene derivatives is their sensitivity towards acid-catalyzed aromatization, the exact course of which (isomerization vs. solvolysis) depends on the nature of the substituents at the *bis*-allylic position of the methylenecyclohexadienyl ring (21, 24). Judging from the well-known reactivity of allylsilanes toward acid-catalyzed desilylation (25, 26), the present compounds should be expected to react readily with aliphatic alcohols to yield toluene and the corresponding methoxysilacyclobutane. Thus, it seemed very likely that the formation of the secondary products of photolysis of **1** and **2** might be suppressed in methanol solution due to interception of the primary products (**13**) by reaction with the solvent. This might also explain the formation of methoxyphenylsilacyclobutane (**11b**) in trace amounts in the photolysis of **2** in hexane containing 0.1 M methanol (eq. [2]).



As expected, photolysis of **1** in neat methanol produced **6** (69%), toluene (**8**; 7%), and 1-methoxy-1-methylsilacyclobutane (**11a**; 11%), as shown in eq. [6]. The reaction mixture was actually somewhat more complicated than this, because like other benzosilacyclobutenes (27), **6** reacts rapidly in methanol solution, in this case to yield two methoxysilanes in a 8:1 ratio. These were tentatively identified as **15** and **16**, respectively, on the basis of ^{1}H NMR and GC/MS evidence (eq. [7]). The actual amount of **6** detected in the photolysis mixture therefore varied depending on the time taken between photolysis and GC analysis. The yields of **8** and **11a** increased to a combined yield of ~73% upon photolysis of a methanol solution of **1** containing 0.1 M HCl, and as expected (27), the relative yields of **15** and **16** changed to 1.4:1. Evaporation of the solvent after photolysis of a hexane solution of **1** to ca. 10% conversion and redissolution of the mixture in methanol confirmed that the formation of toluene (**8**) and 1-methoxy-1-methylsilacyclobutane (**11a**) are due to reaction of **13a** with the alcohol. Monitoring of this reaction by UV spectroscopy revealed that the isotoluene disappears with pseudo-first order kinetics and a rate constant of $k_{\mathbf{-13a}} = (1.10 \pm 0.05) \times 10^{-3}$ s^{-1} in neutral methanol solution at 25°C. In methanol containing 0.1 M HCl, disappearance of **13a** was too rapid for a rate constant to be measured by conventional UV absorption spectroscopy.

Steady state photolysis of **2** in deoxygenated methanol solution led to the formation of two main products, toluene (**8**) and disiloxane **17**, and only traces of bibenzyl (**9**) and the silene-derived methoxysilane **7** (eq. [8]). The mass balance in this experiment was ~92% after ca. 40% conversion of **2**. Disiloxane **17** most likely arises from condensation of **11b** due to the presence of small amounts of water in the solvent, a process which can be expected to proceed more readily in **11b** than in **11a** under neutral (as well as acidic) conditions (28). As before, evaporation of the solvent after photolysis of a hexane solution of **2** to ca. 10% conversion and redissolution of the mixture in methanol resulted in the disappearance of the 335 nm UV absorption due to **13b** and the formation of **8** and **17**. The reaction is complete within ~5 s under these conditions, but was found to be too slow for a rate constant to be obtained by flash photolysis. Thus, while an absolute rate constant for the reaction of **13b** with methanol could not be easily determined, it is clearly at least

[8] 

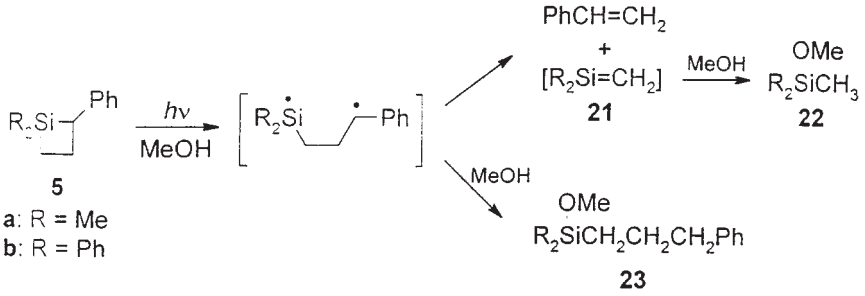
[9] 

[10] 

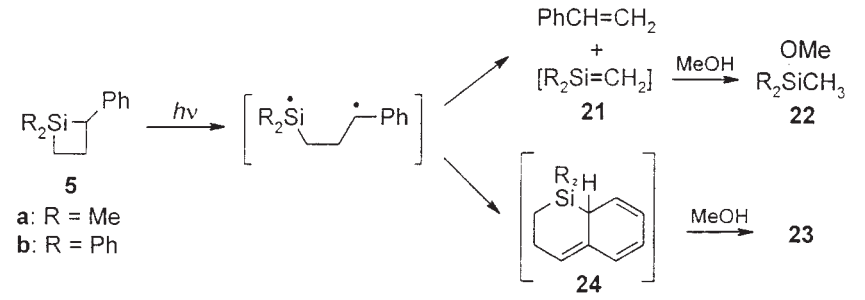
two orders of magnitude greater than that for reaction of **13a** under similar conditions. The much higher reactivity of **13b** toward dark reaction with methanol more effectively lowers its steady-state concentration during the photolysis of **2** in this solvent, resulting in much lower yields of secondary photolysis products relative to what is observed in hydrocarbon solvents, compared to **13a**.

While the photoisomerization of **1** and **2** to the corresponding isotoluene derivatives has precedent in the photochemistry of other benzyl compounds (24), it has not been reported previously for benzylsilanes. Benzyltrimethylsilane (**3**) was first reported to be inert to photolysis in solution (20), but Kira et al. (19) later found that extended photolysis of the compound in hydrocarbon solution leads to the inefficient formation of *ortho*-tolyltrimethylsilane (**18a**), which they suggested to arise from a minor reaction of benzyl and trimethylsilyl radicals produced by homolysis of the benzyl carbon-silicon bond in the benzylsilane. More recently, spectroscopic evidence for the formation of free benzyl radicals upon photolysis of **3** in an ethanol matrix at 77 K has been reported by Hiratsuka et al. (29).

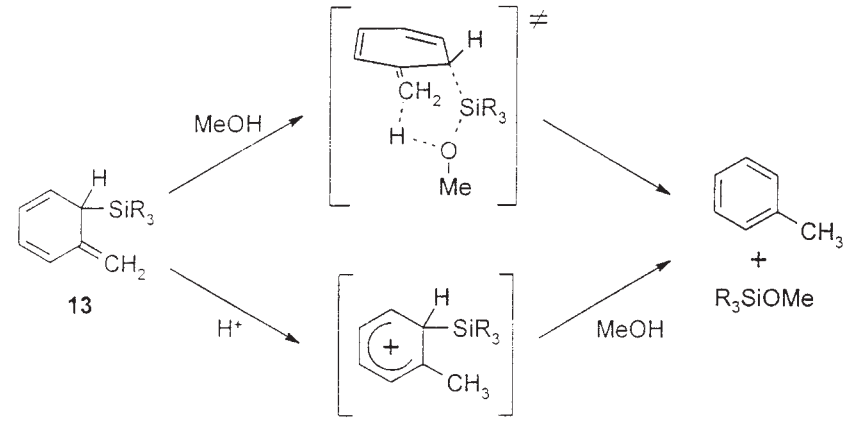
c. R = Me
d. R = Ph



13



We also find that the parent benzylsilane exhibits very low photoreactivity in solution at room temperature. Extended photolysis of **3** in hexane with 254 nm light produces very weak UV absorptions on the long-wavelength edge of the absorption band due to **3**, but the ^{1}H NMR spectrum of the mixture shows no evidence of vinylic resonances consistent with the formation of isotoluene **13c** in detectable amounts. The quantum yield for formation of this product from **3** is thus no greater than ~5% of that for the formation of **13a** from **1** under similar conditions.



On the other hand, photolysis of benzyldimethylphenylsilane (**4**) in hexane results in the fairly efficient formation of a long-wavelength absorbing species which can be identified as the isotoluene derivative **13d** on the basis of its UV and ^{1}H NMR spectra. This compound, the only detectable product at low (<5%) conversion of **4**, is formed with a similar quantum yield to that for formation of **13b** from **2**. It also behaves similarly to **13b** with respect to secondary photolysis and reaction with methanol. For example, eqs. [9] and [10] show the product mixtures obtained from photolysis of **4** in deoxygenated hexane and methanol solutions, respectively, to 40–50% conversion of the starting material. Interestingly, a product tentatively identified as *ortho*-tolyldimethylphenylsilane (**18b**) could be detected in significant yield by GC/MS analysis of the hexane photolyzate. It is barely resolved from **4** under our GC/MS conditions, and coelutes with **4** under those employed for our GC/FID analyses. A closer inspection of the product mixture from photolysis of **2** in hexane revealed that an analogous isomeric product is formed in this case as well, but in yields of less than 10%. These products are most likely formed by a free radical pathway initiated by hydrogen abstraction from **13b/d** by benzyl radicals, since they are not formed in detectable yields in methanol solution, where the steady state concentration of **13** is substantially lower due to reaction with the solvent. As was found with **13b**, dissolution of **13d** in neutral methanol results in its immediate disappearance and the concomitant formation of **8** and **20**. It is possible that the higher photoreactivity of **4** compared to **3** with respect to isotoluene formation is due to similar factors as those suggested above to explain the different photoreactivities of **13a**, **b**. However, we are at a loss to explain why the methylsilacyclobutyl derivative **1** is also more reactive than **3** toward this photorearrangement.

The results reported above provide a reasonable explanation for one or two unusual aspects of the photochemistry of 2-phenylsilacyclobutanes (**5**) which have been reported previously (4, 9, 20). Both 1,1-dimethyl-2-phenyl- and 1,1,2-triphenylsilacyclobutane (**5a** and **5b**, respectively), yield styrene and the corresponding silene **21a**, **b** upon photolysis in methanol solution, as evidenced by the formation of the methoxysilane (**22**) expected from trapping of the silene by the solvent (eq. [11]) (4, 20). Also formed are the methoxysilanes **23a**, **b**, which were originally ascribed to nucleophilic trapping of the 1,4-biradical/zwitterion formed

[12] 

[13] 

by cleavage of a single carbon—silicon bond in the excited state of the silacyclobutane (eq. [11]. The formation of these products was offered as the first evidence for a stepwise reaction mechanism for the formal [2 + 2]-photocycloreversion of silacyclobutanes (4, 20).

Our results for **1**–**4** suggest that a more likely explanation for the formation of **23** is that it arises from reaction of methanol with the isotoluene derivative (**24**) formed by [1,3]-silyl migration into the *ortho*-position of the 2-phenyl ring in **5** (eq. [12]). The isotoluenes **24a**, **b** would be expected to be stable enough that they should build up to significant concentrations, at least in non-nucleophilic solvents. However, their secondary photolysis should result mainly in reversion to the biradical precursor, so no additional products that might have signalled their presence would be expected.

In fact, we have already published evidence consistent with this interpretation, although we failed to recognize it at the time (9). Laser flash photolysis of **5b** in isooctane leads to the formation of a transient species identified as 1,1-diphenylsilene (**21b**), whose absorptions (λ_{max} = 325 nm) are superimposed on those due to a species which is stable over the timescale of our experiment and exhibits λ_{max} ~ 335 nm. We originally reported that this species did not persist over a timescale of several minutes, but this conclusion was based on examination of photolyzed solutions containing small amounts of methanol. In fact, inspection of photolyzed hexane or cyclohexane-d_{12} solutions of **5b** in the absence of added methanol reveals that the species is quite stable, and exhibits a ^{1}H NMR spectrum consistent with isotoluene **24b**. The compound reacts within ~5 s upon dissolution in neutral methanol to yield the previously reported methoxysilane **23**.

The three phenylsilyl-substituted isotoluenes (**13b**, **13d**, and **24b**) all react with methanol under neutral conditions at least two orders of magnitude faster than the trialkylsilyl derivative **13a**. This difference in reactivity, which has been documented previously in other systems (25, 30), suggests that desilylation proceeds by an S_N2 mechanism under these conditions, probably with simultaneous protonation at the exocyclic double bond of the leaving group (eq. [13]).

On the other hand, little difference in reactivity as a function of substitution at silicon is observed in acidic methanol solution. For example, **13a**, **13b**, **13d**, and **24b** were all found (by laser flash photolysis) to have lifetimes in the 12–17 ms range in methanol containing 0.3 M HCl. This suggests that under acidic conditions, the rate-determining step for reaction is protonation of the exocyclic double bond,

Table 1. Pseudo-first order rate constants for decay of isotoluenes in methanol and methanol containing 0.3 M HCl at 23°C.

	k_{decay} (s^{-1})			
	13a	**13b**	**13d**	**24b**
MeOH	0.0011±0.0001	>0.2	>0.2	>0.2
0.3 M HCl–MeOH	85 ± 1	61 ± 2	77 ± 1	58 ± 4

the rate of which is not expected to depend on substitution at silicon. The resulting β-silyl-substituted cyclohexadienyl carbenium ion then undergoes rapid methanol-assisted desilylation (30) to yield toluene and the corresponding methoxysilane. The pseudo-first-order rate constants for decay of the four isotoluenes in methanol and methanol containing 0.3 M HCl are summarized in Table 1.

Summary and conclusions

The direct photolysis of benzylsilanes in solution results mainly in the formation of the corresponding 6-silylisotoluene derivatives, which are sufficiently stable in hydrocarbon solvents that they build up in concentration and start to compete with the precursor for light absorption after conversions of only 5–6%. Secondary photolysis of the isotoluene derivatives is responsible for the formation of most of the products of benzylsilane photolysis that are detected chromatographically. Isotoluene formation results formally from a photochemically allowed [1,3]-sigmatropic rearrangement, although a singlet radical pair recombination mechanism cannot be ruled out, and is generally more efficient in benzyldialkylphenylsilanes than in benzyltrialkylsilanes. Phenyl substitution at silicon also affects the photochemistry of the corresponding 6-silylisotoluene derivative, promoting Si—C bond homolysis to yield benzyl and silyl free radicals. The isotoluene derivatives undergo rapid desilylation in neutral or acidic methanol solution, which allows the formation of secondary photolysis products to be suppressed. The rate of solvolysis under neutral conditions is at least two orders of magnitude greater for the phenylsilyl derivatives, suggesting that it proceeds by an S_N2 mechanism in neutral methanol. The rates are accelerated by up to five orders of magnitude in methanol containing 0.3 M HCl and show no dependence on silyl substituent, consistent with protonation being the rate determining step for isotoluene desilylation under acidic conditions. The photochemical [1,3]-rearrangement also occurs in "masked" benzylsilanes such as 1,1,2-triphenylsilacyclobutane and accounts for the formation of silacyclobutane-ring-opening products in the photolyses of 2-phenylsilacyclobutanes in methanol solution.

Experimental

^1H, ^{13}C, and ^{29}Si NMR spectra were recorded using Bruker AC200, Bruker AC300, or DRX500 NMR spectrometers. Infrared spectra were recorded on a BioRad FTS-40 FT/IR spectrometer and are reported in wavenumbers (cm^{-1}). Ultraviolet absorption spectra were recorded on Cary–Varian Model 50 or Model 400 spectrometers. Gas chromatographic separations employed a Hewlett–Packard 5890 gas chromatograph equipped with a 3396A integrator, flame ionization detector, a conventional splitless injector (heated), and a DB-1 fused silica capillary column (15 m × 0.2-mm; Chromatographic Specialties, Inc.). Low resolution mass spectra were recorded using a Hewlett–Packard 5890 gas chromatograph equipped with a HP-5971A mass selective detector and a DB-5 fused silica capillary column (30 m × 0.25 mm; Chromatographic Specialties, Inc.). High-resolution electron impact mass spectra and exact masses were determined using a VGH ZABE mass spectrometer.

Radial chromatographic separations were carried out using a Chromatotron® (Harrison Research, Inc.), with 2 or 4 mm silica gel 60 thick layer plates using hexane as the eluant.

Hexanes and methanol (BDH Omnisolv), cyclohexane-d_{12} (Cambridge Isotope Laboratories), benzyl bromide (Aldrich), benzyltrimethylsilane (**3**, Aldrich), dimethylphenylsilane (**19**, Aldrich), and chlorodimethylphenylsilane (Aldrich) were used as received from the suppliers. Tetrahydrofuran (BDH) was distilled from sodium. 1-Chloro-1-methylsilacyclobutane (31), 1-chloro-1-phenylsilacyclobutane (32), and benzyldimethylphenylsilane (**4**) (33) were prepared as previously described. 1,1,2-Triphenylsilacyclobutane (**5**) (9), 1-methoxy-1-methylsilacyclobutane (**11a**) (17), 1-phenylsilacyclobutane (**10**) (18), and dimethylmethoxyphenylsilane (**20**) (18) were available from previous studies. Benzylmethoxymethylphenylsilane (**7**) was prepared by reaction of benzylmethylphenylsilane with methanol in the presence of $PdCl_2$ (17).

1-Benzyl-1-methylsilacyclobutane (**1**) (34) was synthesized as follows. Magnesium filings (2.55 g, 0.105 g-atom) were placed in a 500 mL 2-neck round bottom flask fitted with an addition funnel, reflux condenser with nitrogen inlet, and magnetic stirrer. The entire apparatus was flame-dried under nitrogen and after cooling, anhydrous diethyl ether (100 mL) and 1-chloro-1-methylsilacyclobutane (4.0 mL, 2.75 g, 0.0299 mol) were added. Benzyl bromide (3.3 mL, 2.29 g, 0.0136 mol) was dissolved in anhydrous ether (50 mL) and added dropwise over a 30 min period with stirring. The mixture was stirred for 48 h at room temperature, during which time it turned a light gray color. Ice water (30 mL) was added slowly, and the resulting mixture was then filtered. The filtrate was placed in a 500 mL separatory funnel, the aqueous layer was removed, and the ether solution was washed with cold water (3 × 50 mL). After drying with anhydrous magnesium sulfate and filtering, the solvent was removed on a rotary evaporator to afford a slightly yellow oil (2.01 g). Compound **1** (1.04 g, 0.006 mol, 29%) was isolated as a colourless oil in >99% purity by radial chromatography on silica gel using hexane as eluant, and identified on the basis of the following spectroscopic data: ^1H NMR, δ = 0.289 (s, 3H), 1.03 (m, 2H), 1.09 (m, 2H), 2.08 (m, 2H), 2.36 (s, 2H), 7.13 (m, 3H), 7.26 (d, 1H), 7.28 (d, 1H); ^{13}C NMR, δ = –1.79, 13.8, 17.85, 22.68, 26.56, 31.61, 124.16, 128.02, 128.29, 128.60, 139.40; ^{29}Si NMR, δ = 18.85; 3082(s), 3062(s), 3027(s), 2964(m), 2926(w), 2798(m), 1934(m), 1868(m), 1801(m), 1600(s), 1494(s), 1452(s), 1410(m), 1250 (s), 1206(s), 1152(s), 1121(m), 1055(s), 1031(s), 903(s), 873(s), 755(s), 698(m), 653(s); UV (λ_{max}) = 220, 260 nm; MS (EI), *m/z* (I) = 176 (27), 148 (100), 133 (68), 119 (18), 107 (17), 105 (28), 91 (40), 85 (95), 65 (38), 43 (47); HRMS calcd. for $C_{11}H_{16}Si$: 176.1022; found: 176.1025.

1-Benzyl-1-phenylsilacyclobutane (**2**) was synthesized and purified by a similar procedure to the one given above for **1**. It was isolated as a colourless oil and identified on the basis of the following spectroscopic data: ^{1}H NMR, δ = 0.90 (s), 0.98 (t), 1.33 (m, 2H), 1.96 (m, 2H), 2.64 (t, 2H), 7.17 (m, 3H), 7.29 (m, 3H), 7.46 (m, 2H), 7.63 (m, 2H); ^{13}C NMR, δ = 12.88, 18.05, 22.68, 25.32, 31.59, 124.40, 127.88, 128.30, 128.36, 129.51, 133.67, 137.20,138.74; ^{29}Si NMR, δ = 12.00; 3067(w), 3025(m), 2969(m), 2924(w), 1954(m), 1881(m), 1816(m), 1600(s), 1493(s), 1428(s), 1395(m), 1207(s), 1184(s), 1152(m), 1117(m), 1056(s), 1030(s), 999(s), 924(s), 902(s), 858(m), 820(s), 801(s), 766(m), 735(s), 697(w); UV (λ_{max}) = 262, 222; MS (EI), *m*/*z* (I) = 238 (33), 210 (25), 161 (25), 147 (48), 132 (60), 105 (100), 93 (60), 91 (67), 65 (25), 53 (55); HRMS calcd. for $C_{16}H_{18}Si$: 238.1179; found: 238.1177.

Compound **6** was isolated from a semi-preparative scale photolysis of a hexane solution of 1-benzyl-1-methylsilacyclobutane (**1**, 0.22 g, 1.25 mmol) in hexane (20 mL). The solution was placed in a quartz photolysis tube, sealed with a rubber septum, deoxygenated with dry argon, and then irradiated in a Rayonet reactor fitted with seven RPR-2537 lamps The photolysis was monitored periodically by GC, and terminated after ca. 95% conversion of **1** (59 hs). After evaporation of the solvent, the single product was isolated by radial chromatography, further purified by silica gel column chromatography (hexane as eluent), and identified as 1-methyl-1-propyl-3,4-benzosilacyclobutene (**6**; 0.023 g, 0.125 mmol, 10%) on the basis of the following spectroscopic data: ^{1}H NMR, δ = 0.43 (s, 3H), 0.93 (t, 2H), 0.97 (t, 3H), 1.48 (m, 2H), 2.11 (d, 1H), 2.14 (d, 1H), 7.13 (d, 1H), 7.16 (d, 1H), 7.24 (d, 1H), 7.30 (d, 1H); ^{13}C NMR, δ = –2.173, 17.39, 17.66, 18.35, 19.08, 126.12, 126.82, 130.30, 130.57, 145.71, 150.95; ^{29}Si NMR, δ = 10.82; IR (neat), 3078(m), 2969(m), 2938(w), 2875(m), 2360(m), 2313(m), 1718(s), 1703(s), 1671(s), 1625(s), 1546(s), 1531(s), 1500(s), 1422(s), 1407(m), 1375(s), 1281(s), 1250(m), 1125(m), 1063(m), 1047(m), 812(s), 750(w); MS (EI), *m*/*z* (I) = 176(8), 161(3), 134(14), 119(15), 105(4), 85(43), 56(76), 57(74), 43(91), 41(100); HRMS calcd. for $C_{11}H_{16}Si$: 176.1022; found: 176.0995.

Steady state photolysis experiments were carried out in a Rayonet reactor fitted with 6–10 RPR-2537 lamps, on argon-saturated solutions contained in quartz tubes. In some cases, KrF excimer (248 nm) or nitrogen (337 nm) lasers, operated at 0.5 Hz with the intensity reduced using neutral density filters, were employed as excitation sources. Product yields were estimated in small scale runs, from the GC peak areas relative to that of an internal standard (usually decane). These were not corrected for differences in FID response factors.

The products of photolysis of **1** in deoxygenated methanol solution containing 0.1 M HCl were identified by GC/MS and GC coinjection with authentic samples. The major product of dark reaction of **6** with methanol was tentatively identified as methylmethoxy(*o*-tolyl)(1-propyl)silane (**15**; 76%) by ^{1}H NMR and GC/MS, on the crude mixture obtained from stirring a sample of **6** (0.1 g) in methanol (5 mL) for fourteen hours at 25°C, followed by evaporation of the solvent and redissolution in $CDCl_3$. The ^{1}H NMR spectrum of the compound exhibited singlets at δ 0.41 ($SiCH_3$), 2.46 (*o*-tolyl CH_3), and 3.41 (OCH_3) and resonances assignable to the *n*-propyl group (δ 0.90 (t, 2H), 0.95 (t, 3H), 1.38 (m, 2H)), and the following mass spectrum: *m*/*z* (I) = 208 (4), 193 (2), 165 (100), 151 (12), 135 (33), 119 (12), 105 (18), 91 (11), 59 (20). Both the photolysis and dark reaction mixtures also contained a second minor isomer in the same yield relative to **15** (1:8) which was tentatively identified as benzylmethylmethoxy(1-propyl)silane (**16**, 21%) on the basis of its mass spectrum: *m*/*z* (I) = 208 (17), 165 (15), 151 (10), 133 (12), 117 (90), 91 (30), 75 (100), 59 (30)). The latter clearly shows the fragmentation pattern expected for a benzylsilane.

The products of steady state photolysis of **2**–**4** in hexane, hexane containing 0.1 M methanol, or neat methanol were identified by GC coinjection with authentic samples. In the few cases where these were not available, tentative identification was made on the basis of GC/MS. For example photolysis of **2** in hexane yielded an isomer in ~10% yield, which was barely resolved from **2** under our GC/MS conditions. It exhibited the following mass spectral data: MS, *m*/*z* (I) = 226 (7), 211 (100), 195 (7), 181 (10), 165 (15), 148 (67), 133 (15), 105 (22), 91 (10). An analogous product was formed in ~35% yield from photolysis of **4** in hexane solution, and tentatively identified as dimethylphenyl(*o*-tolyl)silane (**18b**) *m*/*z*: (I) = 226 (7), 211 (100), 195 (7), 181 (10), 165 (15), 148 (67), 133 (15), 105 (22), 91 (10). Disiloxane **17** from photolysis of **2** in methanol solution was identified on the basis of its ^{1}H NMR (δ 1.45 (m, 8H), 1.67 (m, 2H), 2.06 (m, 2H), 7.41 (m, 6H), 7.61 (m, 4H)) and mass spectrum: *m*/*z* (I) = 310 (3), 282 (25), 269 (100), 254 (50), 241 (78), 227 (27), 197 (36), 195 (28), 181 (39), 119 (27), 105 (59), 93 (16), 78 (19) (35).

The isotoluene derivatives **13a**, **b**, **d**, and **24b** were detected by UV absorption and ^{1}H NMR spectroscopy on the crude mixtures from 254-nm photolysis of **1**–**5** (0.01–0.02 M) to 5–10% conversion in hexane or cyclohexane-d_{12}. The four compounds exhibited identical UV spectra (λ_{max} = 335 nm; see Fig. 1 for **13a**) and the following ^{1}H NMR spectra: **13a** (from **1**; silacyclobutyl Hs excluded), δ = 0.49 (s, 3H), 3.18 (m, 1H), 4.12 (s, 1H), 4.46 (s, 1H), 5.74 (m, 3H), 5.97 (d, 1H, *J* = 8.7 Hz); **13b** (from **2**; phenyl and silacyclobutyl Hs excluded), δ = 3.34 (m, 1H), 4.42 (s, 1H), 4.58 (s, 1H), 5.60 (m, 1H), 5.72 (m, 2H), 5.94 (d, 1H, *J* = 6.3 Hz); **13d** (from **4**; phenyl Hs excluded), δ = 3.33 (m, 1H), 4.41 (s, 1H), 4.76 (s, 1H), 5.82 (m, 1H), 5.86 (m, 2H), 6.14 (d, 1H, *J* = 7.4 Hz); **24b** (from **5**; phenyl Hs excluded), δ = 3.20 (m, 1H), 4.55 (m, 1H), 5.75 (m, 1H), 5.94 (m, 2H), 6.08 (d, 1H, *J* = 7.5 Hz). Photolysis of a 0.01 M solution of **3** under the same conditions resulted in the appearance of weak edge absorptions in the 300–340 nm range, even after photolysis for roughly 5 times longer than the other compounds. The ^{1}H NMR spectrum of the photolysate (after evaporation of the solvent and redissolution in cyclohexane-d_{12}) showed no evidence of absorptions in the 3–6 ppm range.

Nanosecond laser flash photolysis experiments employed the pulses (248 nm; ca. 25 ns; 70–140 mJ) from a Lambda Physik Compex 120 excimer laser filled with F_2–Kr mixtures in neon, and a microcomputer-controlled detection system (36). The laser beam was unfocussed, and its intensity was reduced to 10–15 mJ at the cell using a series

© 2000 NRC Canada

of stainless steel wire meshes as neutral density filters. Solutions were prepared at concentrations such that the absorbance at the excitation wavelength was ca. 0.7 (~8×10^{-4} M), and were flowed continuously through a 3 × 7 mm Suprasil flow cell connected to a calibrated 100 mL reservoir. Nitrogen was bubbled continuously through the reservoir throughout the experiments.

Addition reactions of a dialkyl- and a diarylsilylene to cyanides RCN: Different pathways? (1)

Manfred Weidenbruch, Frank Meiners, and Wolfgang Saak

Abstract: Di-*tert*-butylsilylene, generated by photolysis of hexa-*tert*-butylcyclotrisilane, reacts with the triple bond of adamantane-1-carbonitrile to furnish the 1,3-diaza-2,5-disilacyclohexa-3,6-diene **5**. However, treatment of 2,2-dimethylpropanenitrile with dimesitylsilylene affords the azadisilacyclobutene ring system **6**. The structures of **5** and **6** were determined by X-ray crystallography.

Key words: silicon, silylene, silaheterocycles, X-ray crystallography.

Résumé : Le di-*tert*-butylsilylène, obtenu par photolyse de l'hexa-*tert*-butylcyclotrisilane, réagit avec la triple liaison de l'adamantane-1-carbonitrile pour conduire à la formation du 1,3-diaza-2,5-disilacyclohexa-3,6-diène, **5**. Toutefois, si on soumet le 2,2-diméthylpropanenitrile au même traitement, il y a formation du système cyclique **6** de l'azadisilacyclobutène. Les structures des composés **5** et **6** ont été déterminées par diffraction des rayons X.

Mots clés : silicium, silylène, hétérocycles silylés, diffraction des rayons X.

Introduction

Dialkyl- and diarylsilylenes, R_2Si:, are versatile and reactive intermediates that undergo numerous addition and insertion reactions. When the substituent R is relatively small the primary products are usually unstable, with rearrangement and other subsequent reactions occurring spontaneously (2). In contrast, the reactions of sterically encumbered silylenes follow a more simple course. For example, treatment of some cyanides with di-*tert*-butylsilylene furnished the diazadisilacyclohexadiene derivatives **1** and **2** (Scheme 1); the structure of the latter has been confirmed by X-ray crystallography (3).

The reaction pathway proposed for the formation of the six-membered ring compounds **1** and **2** involves an initial [2 + 1] cycloaddition of the silylene to the C≡N triple bond followed by a σ-dimerization of the highly strained, three-membered ring intermediate. Indirect support for this proposal was provided by the reactions of di-*tert*-butylsilylene with phosphaalkynes from which the phosphasilirenes **3** were isolated. In these compounds the C=P double bonds are markedly longer than the corresponding C=N bonds so that the three-membered ring system is probably less strained and thus shows no tendency to undergo σ-dimerization (4). It was, therefore, most surprising to find that the analogous reactions of dimesitylsilylene with the phosphaalkynes furnished the phosphadisilacyclobutene derivatives **4**. The appealing hypothesis that two silylene molecules initially dimerize to give $Mes_2Si{=}SiMes_2$ (5) which would then undergo a subsequent [2 + 2] cycloaddition cannot be verified experimentally, since mixtures of the disilene with the phosphaalkyne showed no signs of a reaction. (6)

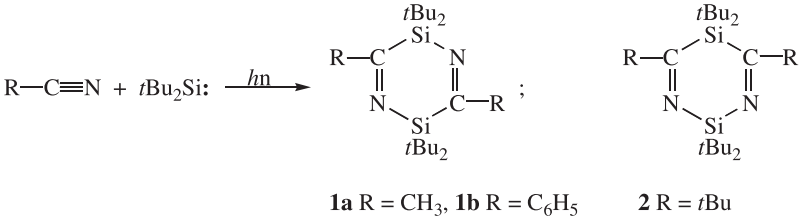
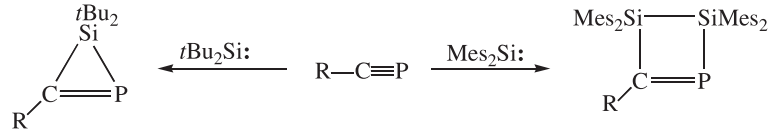
Results and discussion



To test whether the formation of the different products in the reactions of a dialkyl- and a diarlysilylene with phosphaalkynes (4, 6) may have possibly been the result of different reaction pathways, we have reinvestigated the reactions of silylenes with cyanides R-C≡N and now report the results which lend support to this hypothesis (Scheme 2).

For the cyanide partner we selected 1-adamantanecarbonitrile because its alkyl group has even higher steric requirements than the *tert*-butyl group of 2,2,-dimethylpropanenitrile (7). After photolysis of the former nitrile in the presence of hexa-*tert*-butylcyclotrisilane (8), that smoothly furnishes di-*tert*-butylsilylene under these conditions, yellow crystals were isolated in 54% yield. The analytical and spectral data of this product are indicative for the formation of the 1,3-diaza-2,5-disilacyclohexadiene derivative **5**. For example, the ^{29}Si NMR spectrum of this product contains two signals at –20.82 and –35.69 ppm, demonstrating the presence of two silicon atoms in differing environments.



The structure of the obtained product was confirmed by X-ray crystallography (Fig. 1) albeit with some noteworthy aspects. Compound **5** crystallizes as two independent molecules with four of each occupying the unit cell. The six-membered ring is completely planar and possesses a C_2-axis passing through the two silicon atoms. The most surprising features of the molecular structure are the unusually long endocyclic Si—C bonds which, with 2.012(2) (molecule 1) and 2.032(2) Å (molecule 2) are among the largest yet known and, for example, are appreciably longer than the stretched Si—C bonds in the sterically crowded 1,3-disilacyclobutanes (9) and even the corresponding bonds in **2** (2.005(3) Å). The

6 R = *t*Bu

reason for this is the direct adjacency of the *tert*-butyl and the adamantyl groups, the mutual repulsions of which forcibly stretch these bonds. We cannot as yet explain why just the cyanides with spatially demanding substituents should react to give the ring systems **2** or **5**, respectively, instead of **1** in which only three organic groups would be directly adjacent.

Attempts to confirm the differing reaction behavior of dialkyl- and diarylsilylenes by means of the reaction of dimesitylsilylene with adamantanecarbonitrile have not yet resulted in any uniform products. The mass spectrum of the reaction mixture, however, does suggest the probable existence of a four-membered ring product of the type **6** in the mixture. On the other hand, photolysis of 2,2-dimethylpropanenitrile with dimesitylhexamethyltrisilane (10), which decomposes on irradiation to afford hexamethyldisilane and dimesitylsilylene, resulted in the formation of colorless crystals in 43% yield. The analytical and spectral data of this product are indicative for the four-membered ring structure **6**.

Again the structure of the isolated product was confirmed by X-ray crystallography (Fig. 2). The only conspicuous feature of this structure is that the Si—Si bond length of 2.365(1) Å is only slightly larger than the normal bond length of 2.34 Å in spite of the adjacency of the four mesityl groups. The 2,3-disila-1-azetidine ring skeleton of compound **6** has been obtained previously by the addition of tetra-*tert*-butyldisilene to the extremely sterically crowded tri-*tert*-butylsilyl cyanide. (11) We have thus examined the question as to whether dimesitylsilylene may have first dimerized to the disilene $Mes_2Si{=}SiMes_2$ before undergoing

the [2 + 2] cycloaddition to furnish product **6**. However, no signs of any reaction between this disilene and 2,2-dimethylpropanenitrile were observed either under photochemical or thermal conditions. Thus, the formation of **6** must be attributed to a two-fold reaction of dimesitylsilylene with 2,2-dimethylpropanenitrile.

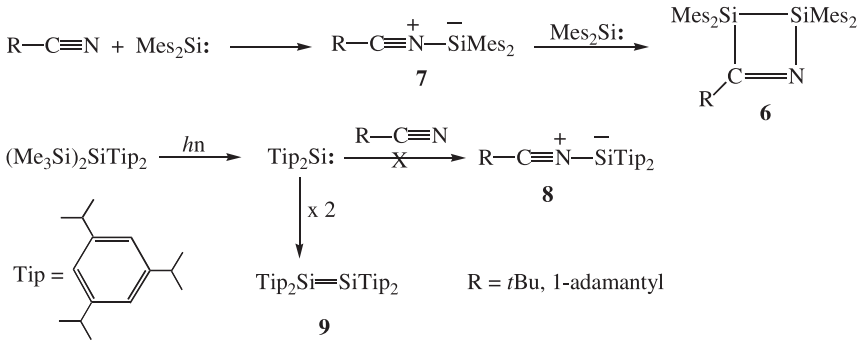
Scheme 3.



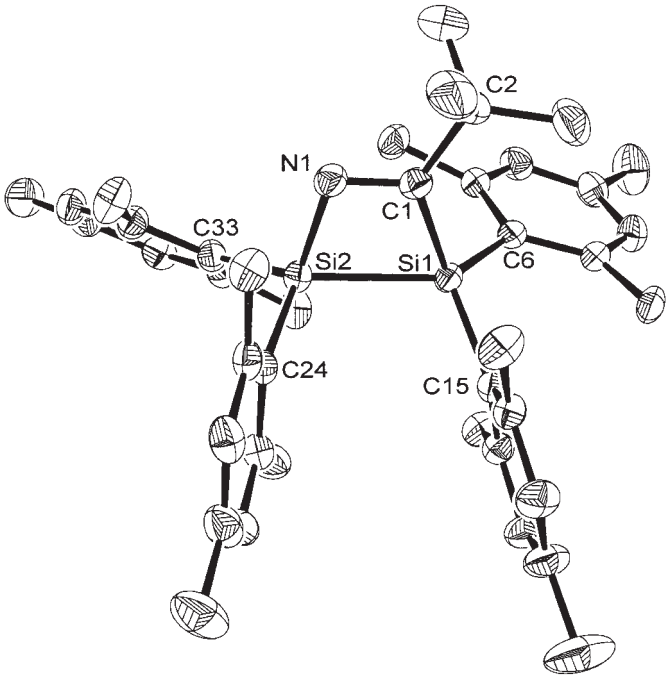


Fig. 2. Molecular structure of **6** in the crystal (hydrogen atoms omitted). Ellipsoids are drawn at 50% probability. Selected bond lengths (Å) and angles (°): Si1—Si2 2.365(1), Si1—C1 1.948(3), Si2—N 1.807(2), C1—N 1.295(4), Si1-Si2-N 77.62(8), Si2-N-C1 104.6(2), N-C1-Si1 107.9(2), C1-Si1-Si2 69.24(8).

Together with the results of previous investigations, (3, 4, 6) the observations described here clearly support the hypothesis that the additions of dialkyl- and diarylsilylenes to cyanides and phosphaalkynes probably proceed by different mechanisms. Thus, the reactions of the weakly nucleophilic di-*tert*-butylsilylene seem to be initiated by [2 + 1] cycloadditions which, in the case of the phosphaalkynes, furnish the stable, three-membered ring products **3** while, in the case of the cyanides, a subsequent σ-dimerization occurs to afford the six-membered ring products **2** or **5**. The more electrophilic dimesitylsilylene, on the other hand, appears to react initially to form an ylide **7** by addition to the free electron pair of the nitrogen atom, followed by addition of a second silylene molecule and ring closure to afford **6** (Scheme 3). However, the formation of a three-membered ring of type **3** (with N instead of P), followed by the addition of a second silylene molecule across the double bond to form a bicyclo[1.1.0]butane derivative as an intermediate cannot be completely excluded. Movement of two bonds from this intermediate then could give **6**. Attempts to trap the postulated ylide **8** by use of the sterically highly overcrowded bis(2,4,6-triisopropylphenyl)silylene were unsuccessful; the disilene **9** (12) and the respective cyanide were isolated from these reactions. In this case the dimerization of the silylene to **9** seems to proceed more rapidly than the possible addition to the nitrogen atom of the cyanide.

Experimental section

General procedures

All reactions were carried out in oven-dried glassware under an atmosphere of dry argon. Photolyses were carried out by using a high-pressure mercury immersion lamp (Heraeus TQ 150). The ^{1}H and ^{13}C NMR spectra were obtained on a Bruker AMX 500 spectrometer using C_6D_6 as solvent. The ^{29}Si NMR spectra were recorded on a Bruker AMX 300 spectrometer. Mass spectra were taken on a Finnigan MAT 95 instrument. Elemental analyses were performed by Analytische Laboratorien, D-51779 Lindlar, Germany.

*4,6-Diadamantyl-2,2,5,5-tetra-tert-butyl-1,3-diaza-2,5-disilacyclohexa-1,3-diene (**5**)*: A solution of hexa-*tert*-butylcyclotrisilane (0.75 g, 1.8 mmol) and adamantanecarbonitrile (0.31 g, 1.9 mmol) in *n*-hexane (80 mL) was irradiated for 6 h at room temperature. After this time the reaction was shown to be complete by the disappearance of the cyclotrisilane (TLC monitoring). The resulting yellow solution was concentrated, cooled at –20°C, and filtered. The isolated yellow needles were recrystallized from a minimum amount of *n*-pentane to provide 0.29 g (54% yield) of yellow, cuboid crystals of **5**: mp 260–268°C (dec). ^{1}H NMR: 1.27 (s, 18 H), 1.28 (s, 18 H), 1.68 (q, 12 H), 2.02 (s, 6 H), 2.15 (d, 12 H). ^{13}C NMR: 19.47, 21.00, 29.33, 29.76, 33.31, 37.36, 42.14, 52.82, 214.84 (*C*N). ^{29}Si NMR: –20.8, –35.7. Mass spectra (CI, isobutane) *m/z*: 606 (MH^+, 10%). Anal. calcd. for $C_{38}H_{66}N_2Si_2$: C 75.18, H 10.96, N 4.62; found: C 74.92, H 11.05, N 4.56.

*4-tert-Butyl-2,2,3,3-tetrakis(2,4,6-trimethylphenyl)-2,3-disila-1-azetine (**6**)*: A solution of 2,2-dimesitylhexamethyltrisilane (1.0 g, 2.4 mmol) and 2,2-dimethylpropanenitrile (0.40 g, 4.8 mmol) in *n*-hexane (80 mL) was irradiated for 5 h at room temperature. After this time the reaction was shown to be complete by the disappearance of the trisilane

Crystallographic analyses of 5 and 6

Crystal data and numerical data of the structure determinations are given in Table 1. In each case, the crystal was mounted in an inert oil. Data collection was performed with an STOE-IPDS area-detector using graphite-monochromated Mo Kα (λ = 0.71073 Å) radiation. The structures were solved by direct phase determination and refined by full-matrix least-squares against F^2 with the SHELXL-97 program system (13). Hydrogen atoms were placed in calculated positions, and all other atoms were refined anisotropically.[2]

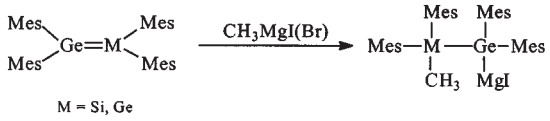
The photolysis of Si,Si-di-*tert*-butyltetramesitylsiladigermirane in the presence of methylmagnesium iodide

Mini S. Samuel, Kim M. Baines, and Donald W. Hughes

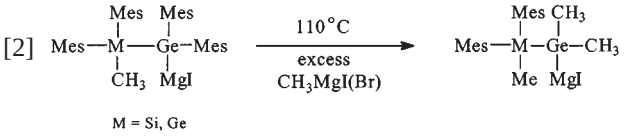
Abstract: The photolysis of Si,Si-di-*tert*-butyltetramesitylsiladigermirane in the presence of methylmagnesium iodide at 15°C has been investigated. Five products were isolated and identified from the complex product mixture: mesityldimethylgermane, dimesitylmethylgermane, (di-*tert*-butylmethylsilyl)mesitylmethylgermane, *meta*-(di-*tert*-butylmethylsilyl)toluene, and *para*-(di-*tert*-butylmethylsilyl)toluene. The characterization of these compounds and proposed mechanisms for their formation will be discussed.

Key words: germasilene, Grignard reagents, germylmagnesium compounds.



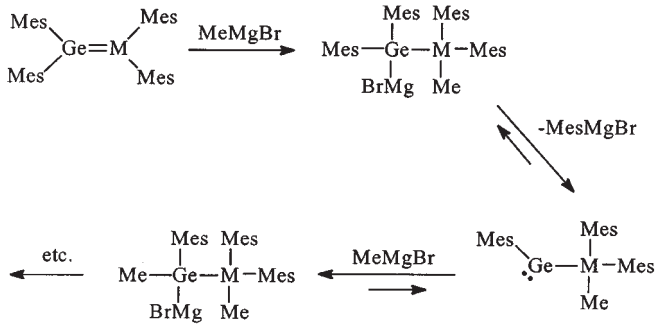
Résumé : Opérant à 15°C, on a étudié la photolyse du Si,Si-di-*tert*-butyltétramésitylsiladigerminane en présence d'iodure de méthylmagnésium. À partir du mélange complexe de produits, on a isolé et identifié cinq produits: mésityldiméthylgermane, dimésitylméthylgermane, (di-*tert*-butylméthylsilyl)mésitylméthylgermane, *méta*-(di-*tert*-butylméthylsilyl)toluène et *para*-(di-*tert*-butylméthylsilyl)toluène. On discute de la caractérisation de ces produits et des mécanismes proposés pour leur formation.

Mots clés : germasilène, réactifs de Grignard, composés germylmagnésium.



[Traduit par la Rédaction]

Introduction



In a recent publication, we reported on a novel route to germyl Grignard reagents by the addition of methylmagnesium halide to $Mes_2Ge{=}GeMes_2$ and $Mes_2Si{=}GeMes_2$ at low temperature (Mes = 2,4,6-trimethylphenyl) (1). The addition to the germasilene is completely regioselective with the alkyl group adding to the silicon atom (eq. [1]).

[1] 

Furthermore, we discovered that thermolysis of the germyl Grignard reagents in the presence of excess MeMgX lead to a facile ligand exchange reaction in which the mesityl groups on the germanium bonded to the magnesium were exchanged for methyl groups (eq. [2]). A mechanism involving the α-elimination of MesMgX followed by the addition of MeMgX to the intermediate germylene has been proposed to explain the observed ligand exchange (Scheme 1). Evidence for the formation of the germylene was provided by trapping the intermediate with 2,3-dimethylbutadiene.

[2] 

Scheme 1.

To our knowledge, this novel ligand exchange in germyl Grignard reagents has no precedent in the literature. Considering the recent interest in the generation and chemistry of both germyl (2) and silyl (3) Grignard reagents and the importance of germylenes as intermediates in organogermanium chemistry, it was desirable to investigate not only

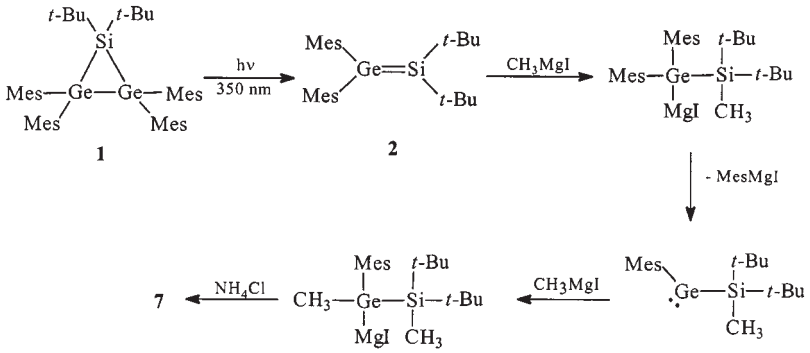
the generality of the Grignard addition to germasilenes as a novel approach for the synthesis of germyl Grignard reagents but also the generality of the ligand exchange reaction. For this reason, the addition of methylmagnesium iodide to $(t\text{-Bu})_2Si{=}GeMes_2$, generated photochemically from Si,Si-di-*tert*-butyltetramesitylsiladigermirane, was investigated.

Results

The photolysis of Si,Si-di-*tert*-butyltetramesitylsiladigermirane **1** has been shown to give di-*tert*-butyldimesitylgermasilene and dimesitylgermylene, regioselectively (eq. [3]) (4). Although stable solutions of tetramesityldigermene and tetramesitylgermasilene can be prepared by photolysis of hexamesitylcyclotrigermane and hexamesitylsiladigermirane, respectively, at –78°C in the presence of triethylsilane, this methodology cannot be used to generate a solution of Si,Si-di-*tert*-butyldimesitylgermasilene; germasilene **2** undergoes photodissociation to yield dimesitylgermylene **3** and di-*tert*-butylsilylene **4**, both of which can be trapped by triethylsilane (eq. [4]) (4). As a result, the study of the reactivity of Si,Si-di-*tert*-butyldimesitylgermasilene must be carried out in the presence of the trapping reagent.

Si,Si-di-*tert*-butyltetramesitylsiladigermirane is unreactive toward methylmagnesium iodide in the dark. Photolysis of Si,Si-di-*tert*-butyltetramesitylsiladigermirane **1** dissolved in toluene, in the presence of excess methylmagnesium iodide at 15°C, yielded a complex product mixture. Through preparative thin layer and centripetal chromatography, five products, **5**, **6**, **7**, and **8** were isolated and identified in a ratio of approximately 5:1:2:3, respectively, and were estimated to account for 75% of the crude product mixture. Although the major products from the reaction mixture were identified, there were several minor unidentified products (eq. [5]).



Compounds **5**, **7**, and **8** were isolated in quantities of 19, 3.5, and 4.5%, respectively, (as determined by assuming that formation of each of these compounds occurred independently of the others), and were characterized by ^1H, ^{13}C, and ^{29}Si NMR, IR, and mass spectrometry. Compound **6** could not be isolated free of compound **7**, and thus, compound **6** was independently synthesized and fully characterized.

Compound **5** was isolated in yields ranging from 14 to 23%. The identification was based on comparison of the ^1H NMR spectral data to literature values (5).

The volatility of **6** largely contributes to the fact that it could not be obtained in pure form; it was difficult to isolate it during the work-up and purification stages. Since **6** could not be isolated, the structural assignment is based upon data obtained from a ^1H NMR spectrum of a mixture of **6** and **7**. To confirm the structure of **6**, it was independently synthesized from $MesGeH_3$ by stepwise deprotonation using *tert*-butyllithium followed by methylation using methyl iodide. We were unable to synthesize **6** in one step from $MesGeH_3$ as has been reported in the literature (eq. [6]) (6).

© 2000 NRC Canada

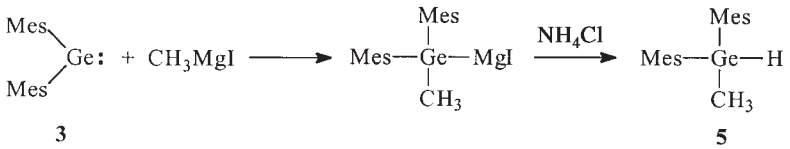
Scheme 2.

The ^{1}H NMR spectrum of compound **7** revealed the presence of two nonequivalent *tert*-butyl groups, one mesityl group, a doublet at 0.63 ppm (^3J = 4.4 Hz, 3H), a quartet at 4.70 ppm (^3J = 4.4 Hz, 1H) and a methyl singlet at 0.23 ppm. The ^{29}Si/^{1}H heteronuclear multiple bond correlation (HMBC) spectrum showed correlations between the signal at 10.9 ppm in the ^{29}Si dimension to the singlets at 1.08, 0.93, and 0.23 ppm in the ^{1}H dimension. These data together with the molecular ion at 366 amu, support our assignment of the structure of compound **7**.

From the ^{1}H, ^{13}C NMR, and mass spectra, compound **8** was determined to be an isomeric mixture of (di-*tert*-butylmethylsilyl)toluenes in a ratio of 3:1. The multiplet at 7.54 ppm in the ^{1}H NMR spectrum of **8** appears to be one half of a typical AA′XX′ pattern associated with 1,4-disubstituted benzenes, and thus, the minor component of the mixture was assigned as the para isomer. Examination of the multiplicity of the remaining four signals in the aromatic region of the ^{1}H NMR spectrum and the correlations observed in the 2-D COSY spectrum indicated that the major component of the mixture was the *meta*-substituted isomer. This was based on the observation that all the signals in the aromatic region, with the exception of the signal at 7.51 ppm, were split by a coupling of 7.5–8.0 Hz. Confirmation of the assignment of the *meta*- and *para* isomers of **8** was made using COSY, ^{13}C-^{1}H, and ^{29}Si-^{1}H HSQC and HMBC experiments, TOCSY and standard spin decoupling experiments. Full details can be found in the supplementary material.[2]

Discussion

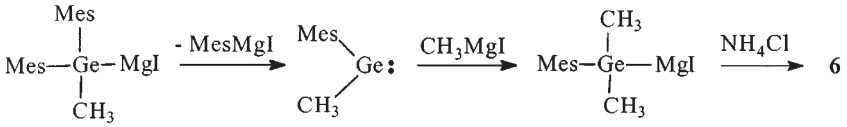
Despite the low isolated yields of the compounds reported herein and the complexity of the reaction mixture, we believe we can add to our understanding of the addition of Grignard reagents to germasilenes and the subsequent behaviour of the newly formed germyl Grignard reagents.



Following what we have previously proposed (see Scheme 1) (1), compound **7** is believed to arise from attack of the Grignard reagent on the silicon atom of the germasilene followed by an α-elimination of mesitylmagnesium iodide. Methylmagnesium iodide could then add to the resulting silylgermylene, giving **7** after hydrolysis (Scheme 2). The regioselectivity of the addition is the same as that of tetramesitylgermasilene: the alkyl portion of the Grignard reagent adds only to the silicon atom of the germasilene. The other regioisomer was not detected.

The mechanism for the formation of compound **8** is indeed intriguing. There is ample precedence for the addition of silyl radicals to aromatic compounds (7, 8). Thus, the most reasonable explanation for the formation of **8** is from the addition of the di-*tert*-butylmethylsilyl radical to toluene followed by loss of a hydrogen atom. The source of the silyl radical is unknown. It is possible that the germyl Grignard reagent, *t*-Bu$_2$MeSiGeR$_2$MgI, undergoes homolysis of the Si-Ge bond. Alternatively, the silyl radical may be derived from *t*-Bu$_2$MeSiMgBr. The germasilene **2** is known to photodissociate to give *t*-Bu$_2$Si: and Mes$_2$Ge: (4). Addition of MeMgI to the silylene may give *t*-Bu$_2$MeSiMgBr which may decompose to give the silyl radical. Further work is required to learn more about the nature of this reaction.

Compound **5** has previously been observed in the photolysis of both hexamesitylcyclotrigermane and -siladigermirane in the presence of excess methylmagnesium iodide followed by hydrolysis. The formation of compound **5** is most likely the result of addition of methylmagnesium iodide to dimesitylgermylene followed by hydrolysis to the germane (eq. [7]).



Compound **6**, on the other hand, is believed to arise from dimesitylmethylgermylmagnesium iodide by elimination of mesitylmagnesium iodide to yield mesitylmethylgermylene

[8] 

and subsequent addition of methylmagnesium iodide to give $MesMe_2GeMgI$, which upon hydrolysis gives **6** (eq. [8]).

Thermolysis of hexamesitylcyclotrigermane in the presence of excess methylmagnesium bromide leads to the formation not only of $Mes_2MeGeGeMe_2H$, but also mesitylene and trimethylgermane (1). Trimethylgermane is believed to be derived from *two* successive α-eliminations of mesitylmagnesium halide from $Mes_2MeGeMgX$ followed, each time, by addition of methylmagnesium iodide. Mesitylmethylgermylene, the first formed intermediate germylene, was trapped with 2,3-dimethylbutadiene to give the germacyclopentene, providing convincing evidence for the proposed mechanism (1). The isolation of compound **6** provides further evidence for the formation of this intermediate germylene.

Compounds **6** and **7**, which are believed to originate from the α-elimination of MesMgI from germyl Grignard reagents, have been observed in the photolysis of Si,Si-di-*tert*-butyltetramesitylsiladigermirane with excess methylmagnesium iodide at 15°C. This is in contrast to the previously studied systems (1), where ligand exchange products were observed well above room temperature (~105°C). The difference in the ease of the proposed α-elimination of the Grignard reagents may be the result of the need to relieve steric congestion in the case of the bulkier di-*tert*-butylmethylsilyl-substituted germylmagnesium halide. However, at 15°C the elimination of a second equivalent of MesMgI does not appear to take place, allowing for the formation of **6** and **7** rather than the products of complete ligand exchange.

In summary, the addition of Grignard reagents to germasilenes to give germyl Grignard reagents and the α-elimination of mesitylmagnesium halide from mesitylgermylmagnesium halides to give the germylenes do appear to be general reactions.

Experimental

All experiments were carried out in flame-dried glassware under an inert argon atmosphere. Toluene, diethyl ether and THF were freshly distilled from sodium–benzophenone. Methylmagnesium iodide was prepared from commercially available methyl iodide (BDH) and magnesium (Lancaster Chemical Co.), stored under argon and the concentration was determined by titration, prior to use. Mesitylgermane was prepared following the published procedure (9). Chromatography was carried out using a Chromatotron (Harrison Research) or on conventional silica gel preparative plates. Photolyses were carried out at 350 nm using a Rayonet Photochemical Reactor.

An acidic work-up entails the separation of the aqueous and organic phases following quenching of the reaction mixture. The aqueous phase was extracted with four portions of an organic solvent (hexanes for the photolyses and diethyl ether for the synthesis of $Me_2MesGeH$) and the extracts were combined with the organic phase. The organic phase was dried over anhydrous magnesium sulfate and then filtered to remove the solid.

NMR spectra were recorded on a Varian Gemini 200, an XL-300, a Varian Gemini 300 or a Bruker Avance DRX-500 using benzene-d_6 as a solvent. The 2-D spectra were acquired using standard techniques. IR spectra were recorded (cm^{-1}) as thin films on a Perkin-Elmer 2000 FT IR spectrometer. A Finnegan MAT model 8230 mass spectrometer, with an ionizing voltage of 70 eV, was used to obtain electron impact mass spectra (recorded in mass-to-charge units, *m*/*z*, with ion identity and peak intensities relative to the base peak in parentheses).

Photolysis of Si,Si-di-*tert*-butyltetramesitylsiladigermirane in the presence of excess methylmagnesium iodide

A solution of $(t\text{-}Bu)_2SiGe_2Mes_4$ (100 mg, 0.131 mmol) and freshly prepared methylmagnesium iodide (3 mL, 84 mmol in Et_2O) in toluene (15 mL) was photolyzed for 16 h at 15°C. Following the photolysis, the reaction mixture was quenched with aqueous ammonium chloride, followed by an acidic work-up. Removal of the solvent in vacuo yielded an oily residue (106.5 mg), which contained several compounds including dimesitylmethylgermane **5** (5), mesityldimethylgermane **6**, (di-*tert*-butylmethylsilyl)mesitylmethylgermane **7** and a mixture of the *meta*- and *para*-isomers of (di-*tert*-butylmethylsilyl)toluene **8**. Separation of the components was accomplished using preparative thin layer chromatography (Chromatotron) with hexanes:CH_2Cl_2 (8:2) as the eluent. Compounds **5**, **7**, and **8** were isolated in 19% (16.25 mg), 3.5% (1.65 mg), and 4.5% (1.5 mg) yields, respectively. Compound **6** could not be separated from **7**.

Preparation of mesitylmethylgermane

Tert-butyllithium (1.7 M in hexanes, 5 mmol) was added to a solution of crude mesitylgermane (0.480 g, 2.5 mmol) in THF (10 mL) at –50°C. The orange-yellow mixture was allowed to stir at –50°C for 10 min before the addition of methyl iodide (1.77 g, 13 mmol). After 20 min at –50°C, the reaction mixture was warmed to room temperature and allowed to stir for 1 hour. The reaction mixture was then quenched with 1 M HCl, followed by an acidic work-up. Removal of the solvent in vacuo yielded a yellow oil. Isolation and purification of **9** was accomplished by Kugelrohr distillation (60°C, 2 mm Hg) which yielded 131.85 mg (24% yield) of **9** as a clear, colourless oil.

*Mesitylmethylgermane (**9**)*: IR (thin film, cm^{-1}): 2064 (s, Ge-H); ^{1}H NMR (ppm): 6.74 (s, 2 H, Mes **H**), 4.53 (q, 2 H, *J* = 3.9 Hz, Ge-**H**), 2.32 (s, 6 H, Mes *o*C**H**$_3$), 2.11 (s, 3 H, Mes *p*C**H**$_3$), 0.34 (t, 3 H, *J* = 3.9 Hz, Ge-C**H**$_3$); ^{13}C NMR (ppm): 143.30, 138.44, 131.6 (Mes **C**), 128.5 (Mes **C**H), 24.00 (Mes *o*C**H**$_3$), 21.10 (Mes *p*C**H**$_3$), –6.78 (Ge-**C**H$_3$); MS (*m*/*z*): 210 (M$^+$, 21), 193 (MesGe, 64), 121 (MesH$_2$, 100), 105 (MeGeH, 43), 91 (M$^+$ – Mes, 26); High resolution MS: calcd. for $C_{10}H_{16}Ge$: 210.0464; found: 210.0451.

Preparation of mesityldimethylgermane

Tert-butyllithium (1.7 M in hexanes, 0.85 mmol) was added to a solution of mesitylmethylgermane (0.131 g, 0.63 mmol) in THF (5 mL) at –50°C. The orange-yellow mixture was allowed to stir at –50°C for 10 min before the addition of methyl iodide (0.45 g, 3.2 mmol). After 20 min at –50°C the reaction mixture was warmed to room temperature and allowed to stir for 1 h. The reaction mixture was then quenched with 1 M HCl, followed by an acidic work-up. Removal of the solvent in vacuo yielded a yellow oil. Isolation and purification of **6** was accomplished by Kugelrohr distillation (85°C, 2 mm Hg) which yielded 42.4 mg (30% yield) of **6** as a clear, colourless oil.

*Mesityldimethylgermane (**6**)*: IR (thin film, cm^{-1}): 2050 (s, Ge-H); ^{1}H NMR (ppm): 6.75 (s, 2 H, Mes **H**), 4.85 (septet, 1 H, *J* = 3.7 Hz, Ge-**H**), 2.34 (s, 6 H, Mes *o*C**H**$_3$), 2.13 (s, 3 H, Mes *p*C**H**$_3$), 0.42 (d, 6 H, *J* = 3.7 Hz); ^{13}C NMR (ppm): 143.27, 138.19, 134.01 (Mes **C**), 128.79 (Mes **C**H), 24.11 (Mes *o*C**H**$_3$), 21.04 (Mes *p*C**H**$_3$), –2.18 (Ge-**C**H$_3$); MS (*m*/*z*): 224 (M$^+$, 26), 209 (M$^+$ -CH$_3$, 100), 191 (MesGe, 12), 119 (Mes, 32), 105 (M$^+$ – Mes, 19), 89 (GeCH$_3$, 29); High resolution MS: calcd. for $C_{11}H_{18}Ge$: 224.0620; found: 224.0608.

Improved simple synthesis of cyclic sulfates from trimethylsilyl chlorosulfonate

Alan R. Bassindale, Ibrahim Katampe, and Peter G. Taylor

Abstract: Reaction of iodosobenzene and trimethylsilyl chlorosulfonate followed by removal of the solvent and trimethylchlorosilane gives phenyliodosulfate. This can be used without further purification to prepare cyclic sulfates from alkenes, including vinylsilanes. Previous results have shown that if the trimethylchlorosilane is not removed, sultones are formed and a possible explanation of this behaviour is given.

Key words: silicon, vinylsilanes, cyclic sulfate, phenyliodosulfate.

Résumé : La réaction de l'iodosobenzène et du chlorosulfonate de triméthylsilyle, suivie de l'élimination du solvant et du triméthylchlorosilane, conduit à la formation du phényliodosulfate. On peut l'utiliser sans purification subséquente pour préparer des sulfates cycliques à partir d'alcènes, y compris les vinylsilanes. Des résultats antérieurs ont montré qu'il y a formation de sultones si l'on n'enlève pas le triméthylchlorosilane; on propose une explication pour ce comportement.

Mots clés : silicium, vinylsilanes, sulfate, phényliodosulfate.

Introduction

Cyclic sulfates are vicinally substituted electrophiles (for reviews see ref. 1). Like epoxides, they have a unique role in organic synthesis: they simultaneously activate and protect adjacent functionalized carbon atoms for nucleophilic attack. They are usually superior to their acyclic counterparts because their cyclic nature renders competing elimination processes stereoelectronically unfavourable (2). Cyclic sulfates have been shown by Sharpless and his group to react readily with a wide variety of nucleophiles with apparent complete selectivity (3) to give aziridines and amino alcohols as shown in Scheme 1.

We are interested in the preparation of silylaziridines from simple precursors such as vinyl silanes. Thus, the synthesis of aziridines from the corresponding cyclic sulfates seemed very attractive. However, the preparation of silyl substituted cyclic sulfates is not straightforward. Unfortunately in our hands traditional methods of preparation of silyl substituted cyclic sulfates, such as from the corresponding diol, usually resulted in desilylated products. Xu and co-workers (4), however, was successful in preparing one silylated cyclic sulfate by this method and subsequently converting it to the corresponding 2-trialkylsilyl aziridine. In this paper we report an alternative synthesis of cyclic sulfates based on the reaction of iodosobenzene with trimethylsilyl chlorosulfonate to give phenyliodosulfate. This reagent reacted with vinyl silanes to give the corresponding silyl substituted cyclic sulfate which could subsequently be converted to aziridines.

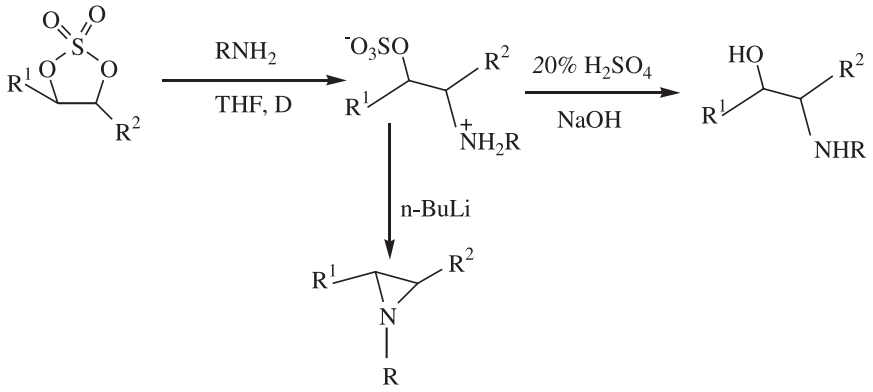
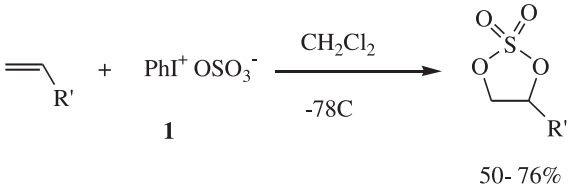
Results and discussion

Ethylene cyclic sulfate and the 4-butyl derivative have previously been prepared in 70–85% yield by the reaction of the corresponding olefin with the hypervalent organoiodine complex, phenyliodosulfate **1**, as shown in Scheme 2 (5).



The authors prepared the phenyliodosulfate by the reaction of sulfur trioxide with iodosobenzene. However, the preparation and handling of dry sulfur trioxide is not always straightforward and thus we looked for alternative ways of preparing phenyliodosulfate. We found that the reaction of iodosobenzene with trimethylsilyl chlorosulfonate at –78°C followed by warming to room temperature and removal of the solvent and trimethylsilyl chloride, gave the reagent **1** in good yield (procedure A). This could then be stored for further reaction; however, we found it more convenient to proceed with a "one pot" synthesis and to immediately react the iodosulfate, without further purification, with vinyltrimethylsilane. This gave the corresponding cyclic sulfate in a reasonable yield as listed in Table 1.

Alternatively, trimethylsulfonyl chloride could be added to 1,4-dioxane at low temperature and the solvent removed to give a sulfur trioxide – 1,4-dioxane adduct (6). Further reaction of this with iodosobenzene gave phenyliodosulfate which could be used as before to give the cyclic sulfate. This second procedure (procedure B) gave slightly improved yields, as shown in Table 1.



The addition of 1,4-dioxane to trimethylsulfonyl chloride lead to the equilibrium found in Scheme 4.

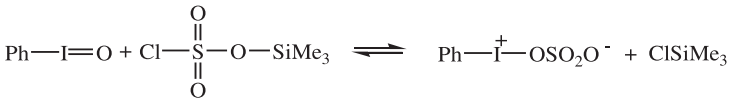
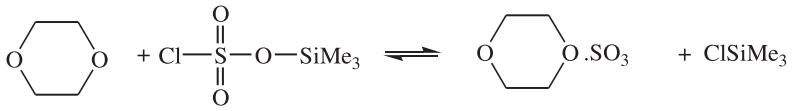
Scheme 1.



Scheme 2.



Presumably removal of the trimethylchlorosilane shifts the equilibrium in favour of the sulfur trioxide – 1,4-dioxane complex. We have previously found that direct reaction of iodosobenzene with trimethylsilyl chlorosulfonate at –78°C followed by addition of the alkene, without removal of the trimethylsilyl chloride generates the corresponding sultone (7) as shown in Scheme 5.

We suggest that the iodosobenzene – trimethylsilyl chlorosulfonate system exists as a series of equilibria as shown in Scheme 6.

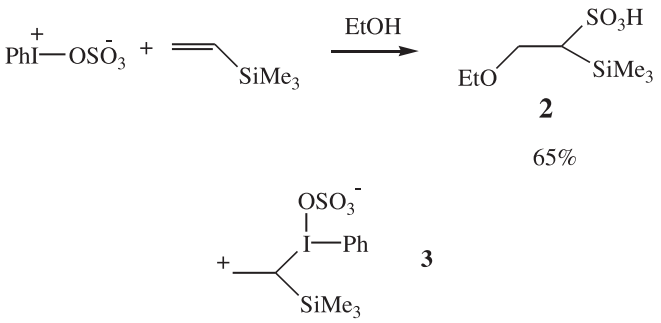
Table 1. Yields of cyclic sulfates obtained from reaction of an alkene with phenyliodosulfate.



Alkene	Cyclic Sulfate	Procedure	Yield
		A	64%
		B	76%
		B	65%
		B	66%
		B	50%

At –78°C generation of sulfur trioxide, rather than the phenyliodosulfate, is favoured, such that addition of the alkene results in sultone formation. Alternatively, both species may be available for reaction; however, sulfur trioxide is more reactive than phenyliodosulfate, leading to the preferential formation of the sultone. In the absence of the alkene, warming to room temperature and removal of the trimethylsilyl chloride leads to formation of the phenyliodosulfate. The boiling points of trimethylsilylchloride and hexamethyldisiloxane are 58 and 101°C respectively, suggesting that the equilibria may be driven by preferential loss of the trimethylsilyl chloride. However, we may also expect loss of sulfur trioxide to favour generation of the hexamethyldisiloxane and the iodosobenzene dichloride. We would suggest that at room temperature the equilibria favour the formation of the phenyliodosulfate.

Reaction of phenyliodosulfate with vinyltrimethylsilane leads to the corresponding cyclic sulfate. However, if the reaction is carried out in the presence of ethanol, an ethoxy group ends up β to the trimethylsilyl group, giving the sulfonic acid **2**, as shown in Scheme 7.

In this case addition of the phenyliodosulfate occurs in two steps via the formation of the more stable β-silyl carbocation **3**. Formation of the cyclic sulfate followed by ring opening with ethanol is unlikely because it should yield the corresponding α-ethoxy trimethylsilyl compound. In this case the geometry of the ring prevents hyperconjugative stabilisation of the incipient carbocation. Nucleophilic attack α to the silicon is likely as observed with α-silylepoxides and aziridines (8).

Scheme 7.

In conclusion, the formation of phenyliodosulfate from iodosobenzene and trimethylsilyl chlorosulfonate provides a route to cyclic sulfates that avoids the use of sulfur trioxide. The preparation of the cyclic sulfate can be carried out in one pot and provides a route into trimethylsilyl substituted aziridines which we are at present exploring (9).

Experimental

Melting points were determined on a Buchi 510 melting point apparatus and are uncorrected. Infrared spectra were obtained as Nujol mulls or thin films using sodium chloride plates or as KBr discs on a Nicolet 205 FT-IR spectrometer. NMR spectra were recorded as solutions in deuteriochloroform with tetramethylsilane as internal standard on a JEOL EX 400 NMR spectrometer. Mass spectra were obtained using a VG20–250 quadrupole instrument equipped with an Ion Tech fast atom bombardment (FAB) gun.

*Iodosobenzene sulfate (**1**)*: To a slurry of iodosobenzene (10) (5.50 g, 25 mmol) in dry dichloromethane (100 mL), at –78°C under a nitrogen atmosphere, was added trimethylsilyl chlorosulfonate (3.0 mL, 20 mmol) with continuous stirring to produce a clear yellow solution. The reaction mixture was allowed to slowly warm up to room temperature and allowed to stir at this temperature for another 30 min before removal of the solvent under vacuum, to give a very moisture-sensitive yellow solid: mp 110°C (dec.). Physical properties were in agreement with published data (5).

Trimethylsilylethene-1,2-sulfate: *Procedure A*: To a slurry of iodosobenzene (2.20 g, 10 mmol) in dry dichloromethane (50 mL), at –78°C under a nitrogen atmosphere was added trimethylsilyl chlorosulfonate (1.5 mL, 10 mmol) with continuous stirring to produce a clear yellow solution. The solution was allowed to slowly warm up to about –10°C and then subjected to vacuum distillation until all the solvent had been removed to leave a yellow powder. Dry CH_2Cl_2 (50 mL) was immediately added and the mixture re-cooled to –78°C. To this was added vinyltrimethylsilane (1.5 g, 15 mmol). The reaction mixture, which turned colourless, was allowed to warm up to room temperature and stirring continued at this temperature for another 1 h. Removal of the solvent from the reaction mixture using a rotary evaporator gave a black residue. Purification of the crude product over silica gel using hexane–dichloromethane as the eluent gave 1-trimethylsilylethylene-1, 2- sulfate (1.9 g, 64%) as a white solid: IR (Nujol): 2960, 2930, 2857, 1376, 1254, 1202, 943, 843 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ: 0.00 (s, 9H, $SiMe_3$), 4.38 (m, 1H, CHSi), 4.50 (m, 2H, CH_2); ^{13}C (100 MHz, $CDCl_3$) δ: 4.52 ($SiMe_3$), 72.19 (CH_2), 76.68 (CH); (EI) *m*/*z* 181 (M^+-O_2, 1%), 165 (1%), 153 (1%), 147 (12%), 101 (61%), 80 (10%), 75 (33%), 73 (100%), 64 (12%), 59 (37%), 48 (9%), 45 (33%), 43 (19%), 28 (10%). Anal. calcd. for $C_5H_{12}SiSO_4$: C 30.6, H 6.2, S 16.3; found: C 30.7, H 5.7, S 16.2.

Procedure B: To 1,4-dioxane (1.32 g, 15 mmol,) in dry dichloromethane (25 mL), under a nitrogen atmosphere at –5°C was added dropwise trimethylsulfonyl chloride (1.5 mL, 10 mmol). The reaction mixture was allowed to warm up to room temperature and the solvent removed under vacuum to leave a white crystalline moisture-sensitive solid. To this was added dry dichloromethane (50 mL) and the mixture re-cooled to –78°C before addition of iodosobenzene. The mixture was allowed to warm up to 0°C and vinyltrimethylsilane (1.5 g, 15 mmol) was added dropwise. The reaction mixture was allowed to warm up to room temperature and stirring continued at this temperature for another 1 h. Removal of the solvent from the reaction mixture using a rotary evaporator gave a black residue. Purification of the crude product over silica gel using hexane–dichloromethane as the eluent gave 1-trimethylsilylethylene-1,2- sulfate **(**2.2 g, 76%) as a white solid.

1-Dimethylphenylsilylethene-1,2-sulfate: Reaction of iodosobenzene sulfate, generated in situ as described in Procedure B, with (1.62 g, 10 mmol) of vinyldimethylphenylsilane gave 1-dimethylphenylsilyl-ethylene-1, 2-sulfate (0.7 g, 65%) as a white solid; IR (Nujol): 2960, 1375, 1254, 1200, 1119, 935, 852, 832 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ: 0.52 (s, 3H, SiMe), 0.53 (s, 3H, SiMe), 4.52 (dd, 1H, *J* = 8.8, 12.0 Hz, CH_2), 4.56 (dd, 1H, *J* = 6.4, 8.8 Hz, CH_2), 4.86 (dd, 1H, *J* = 6.4, 12 Hz, CH), 7.54 (m, 5H, Ph); ^{13}C NMR (100 MHz, $CDCl_3$) δ: –6.5 ($SiMe_2$), –5.5 ($SiMe_2$), 72.37 (CH_2), 77.48 (CHSi), 128.7, 130.99, 131.75, 134.00 (Ph); (EI) *m*/*z* 258 (M^+, 51%), 257 (30%), 123 (51%), 96 (94%), 80 (100%), 64 (22%). This product was very unstable and hence could not be characterized further.

1-n-*butylethene-1,2-sulfate*: Addition of 1-hexene (1.3 g, 15 mmol), to iodosobenzene sulfate, generated as described above (Procedure B), gave after purification 1-*n*-butylethene-1,2-sulfate (1.8 g, 66%); IR (Nujol): 2962, 2936, 1469, 1387, 1212, 1191, 997, 832 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ: 0.95 (t, 3H, *J* = 6.8 Hz, CH_3), 1.26–2.1 (m, 6H, $(CH_2)_3$), 4.33 (dd, 1H, *J* = 5.3, 12.2 Hz, CH_2O), 4.75 (dd, 1H, *J* = 7.5, 12.2 Hz, CH_2O), 5.12 (m, 1H, CHO); ^{13}C NMR (400 MHz, $CDCl_3$) δ: 13.83 (CH_3), 22.15, 26.56, 32.12 $(CH_2)_3$, 72.86 (CH_2O), 83.30 (CHO); (EI) *m*/*z* 181 (MH^+, 2%), 164 (7.8%), 149 (3%), 139 (3.4%), 129 (6%), 123 (10%), 100 (13%), 87 (16%), 83 (100%), 82 (69%), 81 (19%), 71 (20%). Anal. calc. for $C_6H_{12}SO_4$: C 40.0, H 6.7; found: C 40.6, H 6.8.

Cis-*1,2- dibutylethene cyclic sulfate*: Addition of *cis*-5-decene (0.70 g, 5 mmol) to iodosobenzene sulfate, generated as described above (Procedure B), gave after purification 1,2-*n*-dibutylethylene cyclic sulfate (0.6 g, 50%). The physical properties were in agreement with published data (3).

*1-Trimethylsilyl-2-ethoxyethane sulfonic acid (**2**)*: To a slurry of iodosobenzene (2.20 g, 10 mmol) in dry dichloromethane,(50 mL) at –78°C under a nitrogen atmosphere was added trimethylsilyl chlorosulfonate (1.5 mL, 10 mmol) with continuous stirring to produce a clear yellow solution. The solution was allowed to slowly warm up to about –10°C and then subjected to vacuum distillation. When all the solvent had been removed, a yellow powder remained. A further 50ml of dry CH_2Cl_2 "spiked" with ethanol was added and the mixture re-cooled to –78 °C. To this was added vinyltrimethylsilane (1.5 g, 15 mmol) and the reaction mixture, which turned colourless, was allowed to warm up to room temperature and stirring continued at this temperature for another 1 h. Removal of the solvent from the reaction mixture using a rotary evaporator gave a black residue. Purification of the crude product over silica gel using hexane–dichloromethane as the eluent gave an oil (2.2 g, 65%). IR (neat): 2986, 1388, 1254, 1192, 923, 848 cm^{-1}; ^1H NMR (400 MHz, $CDCl_3$) δ: 0.00 (s, 9H, $SiMe_3$), 1.42 (t, 3H, *J* = 6.8 Hz, CH_3), 3.64 (m, 2H, OCH2CH3), 3.87 and 4.02 (dd, 1H, *J* = 6.4, 12.8 Hz and dd, 1H, *J* = 3.6, 12.8 Hz, CH_2-),

Reactions of the stable bis(amino)silylene Si[{N(CH$_2$*t*Bu)}$_2$C$_6$H$_4$-1,2] with group 3 or lanthanide metal organic compounds. Crystal structures of [Ln(η^5-C$_5$H$_5$)$_3$Si{[N(CH$_2$*t*Bu)]$_2$C$_6$H$_4$-1,2}]·C$_7$H$_8$ (Ln = Y or Yb)

Xiaoping Cai, Barbara Gehrhus, Peter B. Hitchcock, and Michael F. Lappert

Abstract: Treatment of the thermally stable aminosilylene Si[{N(CH$_2$*t*Bu)}$_2$C$_6$H$_4$-1,2] [≡ Si(NN)] with a tris(cyclopentadienyl)- group 3 or -lanthanide metal compound LnCp$_3$ (Cp = η^5-C$_5$H$_5$ and Ln = Y or Yb) in toluene at ambient temperature afforded the first earliest transition or f-block metal–silylene complexes [LnCp$_3${Si(NN)}]·C$_7$H$_8$ (Ln = Y (**1**) or Yb (**2**)), characterized by NMR spectroscopy and X-ray crystallography: complex **1** (monoclinic, space group $P2_1/c$ (no. 14), a = 15.641(5), b = 15.895(7), c = 14.876(5) Å, β = 112.93(3), Z = 4, $R1$ = 0.067 for 6194 observed data), and **2** (monoclinic, space group $P2_1/c$ (no. 14), a = 15.635(3), b = 15.795(2), c = 14.842(2) Å, β = 112.87(2), Z = 4, $R1$ = 0.044 for 9829 observed data). The Ln atom in each of the isoleptic complexes **1** and **2** has distorted trigonal monopyramidal geometry, with the approximately trigonal silicon atom in the apical position. The Ln—Si bond length is 3.038(2) (**1**) or 2.984(2) Å (**2**). Variable temperature ^{29}Si{^{1}H} NMR spectra in toluene-d_8 show that each complex readily dissociates (Y > Yb) into its factors; at 188 K, the ^{29}Si{^{1}H} signal for (**1**) was a doublet centred at δ 119.5, $^1J(^{29}\text{Si}\text{-}^{89}\text{Y})$ = 59 Hz.

Key words: crystallography, NMR, silylene, yttrium, ytterbium, organometallic complexes.

Résumé : La réaction de l'aminosilylène thermiquement stable Si[{N(CH$_2$*t*Bu)}$_2$C$_6$H$_4$-1,2] [≡ Si(NN)] avec un composé comportant un groupe tris(cyclopentadiényl) attaché à un métal du groupe 3 ou à un lanthanide, LnCp$_3$ (Cp = η^5-C$_5$H$_5$ et Ln = Y ou Yb), dans du toluène à la température ambiante, a permis d'obtenir les premiers complexes de silylène attaché à un métal prémier de transition ou du bloc f, [LnCp$_3${Si(NN)}]·C$_7$H$_8$ (Ln = Y (**1**), ou Yb (**2**)), qui ont été caractérisés par spectroscopie RMN et par diffraction des rayons X. Le complexe **1**, monoclinique, groupe d'espace $P2_1/c$ (no. 14), avec a = 15,641(5), b = 15,895(7) et c = 14,876(5) Å, β = 112,93(3)°, Z = 4 et $R1$ = 0,067 pour 6194 données observées. Le complexe **2**, monoclinique, groupe d'espace $P2_1/c$ (no. 14), avec a = 15,635(3), b = 15,795(2) et c = 14,842(2) Å, β = 112,87(2)°, Z = 4 et $R1$ = 0,044 pour 9829 données observées. Dans chacun des complexes isoleptiques **1** et **2**, l'atome Ln présente une géométrie monopyramidale trigonale déformée dans laquelle l'atome de silicium trigonal est approximativement en position apicale; la longueur de la liaison Ln—Si est de 3,038(2) (**1**) et de 2,984(2) (**2**) Å. Les spectres RMN du ^{29}Si{^{1}H} à température variable, dans le toluène-d$_8$, montrent que chacun des complexes peut facilement se dissocier (Y > Yb) en ses composants; à 188 K, le signal ^{29}Si{^{1}H} du composé **1** est un doublet centré à un δ de 119,5 avec un $^1J(^{29}\text{Si}\text{-}^{89}\text{Y})$ = 59 Hz.

Mots clés : cristallographie, RMN, silylène, yttrium, ytterbium, complexes organométalliques.

[Traduit par la Rédaction]

Introduction

Compounds containing a group 3 or lanthanide metal atom (Ln) bound to silicon are exceedingly rare and invariably have involved a tetravalent organosilyl ligand [SiXX′X″]$^-$ bound to a Ln(II) or Ln(III) metal, as in [Yb(η^5-C$_5$H$_5$){Si(SiMe$_3$)$_3$}(THF)$_2$] (1*a*), [Sm(η^5-C$_5$H$_5$)$_2${SiH(SiMe$_3$)$_2$}]$_2$ (1*b*), or [Yb(SiPh$_3$)$_2$(THF)$_4$] (1*c*).

Another class of silicon-containing ligands which has recently attracted attention, in the context of lower oxidation state d^6, d^8, or d^{10} metal complexes, is a neutral silylene SiX$_2$ (with or without a stabilizing neutral base bound to

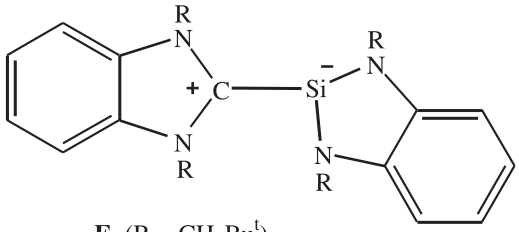
D

silicon). Among these are those derived from the thermally stable silylenes **A** (2), **B** (3), and **C** (4); the silylene **D** is somewhat less robust than its unsaturated analog **A** (5). The transition metal complexes which had previously been reported were derivatives of Cr(0), Mo(II), Fe(0), Ru(II), Ni(0), Ni(II), Pt(0), Pt(II), and Au(I): [Cr(CO)$_2$(C$_6$H$_3$Me$_3$-1,3,5)(**A**)] (6), [Mo(Cp)$_2$ (**A**)] (7), [Fe(CO)$_4$(**A**)] (6), [Ru(η^5-C$_5$H$_5$)(PMe$_3$)$_2$(SiX$_2$)]$^+$ [X = SEt (8*a*), SC$_6$H$_4$Me-4 (8*b*) or Ph], [Ni(CO)$_2$(**A**)$_2$] (9), [Ni(PPh$_3$)(**B**)$_3$] (10), *trans*-[Pt{Si(NN)Cl}$_2${Si(NN)}$_2$] (10), *trans*-[PtH{P(C$_6$H$_{11}$-c)$_3$}$_2${Si(SEt)$_2$}]$^+$ (11*a*), [PtH{P(Pr^i)$_2$CH$_2$}$_2${Si(C$_6$H$_2$Me$_3$-2,4,6)$_2$}]$^+$ (11b), [Pt{P(C$_6$H$_{11}$-c)$_3$}$_2${ Si(C$_6$H$_2$Me$_3$-2,4,6)$_2$}] (12), and [AuCl(**C**)] (13).

Of the above silylene–transition metal complexes, only those derived from one of the silylenes **A**–**C** were directly accessible from the parent silylene SiX$_2$. Two methods of synthesis have been employed: (*i*) a nucleophilic displacement of carbon monoxide (**A** or **C**), or (**B**) cycloocta-1,4-diene (COD), or a tertiary phosphine (**A** or **B**) from an appropriate transition metal precursor; and (*ii*) for **B**, displacement of PPh$_3$ and concomitant reductive Cl atom elimination, eq. [1]. The methods for the silylene Si[{N(CH$_2$Bu^t)}$_2$C$_6$H$_4$-1,2] [≡ Si(NN)] (**B**) are illustrated in eqs. [1]–[4] (10).

[1] $$[Ni(COD)_2] + 4\ Si(NN) \rightarrow [Ni\{Si(NN)\}_4] + 2\ COD$$

[2] $$[NiCl_2(PPh_3)_2] + 4\ Si(NN) \rightarrow [Ni(PPh_3)\{Si(NN)\}_3] + Si(NN)Cl_2 + PPh_3$$



[3] $$[NiCl_2(PPh_3)_2] + 5\ Si(NN) \rightarrow [Ni\{Si(NN)\}_4] + Si(NN)Cl_2 + 2\ PPh_3$$

[4] $$[PtCl_2(PPh_3)_2] + 4\ Si(NN) \rightarrow \textit{trans}\text{-}[Pt\{Si(NN)Cl_2\{Si(NN)\}_2] + 2\ PPh_3$$

The isolation and mode of formation of the above silylene–transition metal complexes is consistent with the notion that silylenes probably are rather "soft" ligands and hence bind strongly to low oxidation state (M(0), M(I), or M(II)) soft Lewis acid metal (M) centers.

The present work represents an extension of a previous study (10) of the coordination chemistry of the silylene Si(NN) **B** to the earliest transition and the lanthanide metals, collectively abbreviated as Ln. As for the former, yttrium was chosen as a representative group 3 metal, in part because of its possession of an NMR-friendly nucleus, ^{89}Y, I = 1/2, 100% natural abundance; for the latter, ytterbium was selected, in part because it more than any other Ln metal shows a facile Ln(III) → Ln(II) reduction. The Ln metal complexes are ubiquitously found in the +3 oxidation state and are regarded as having rather "hard" metal centers, showing a preference for binding to hard Lewis acids. For example, LnCp$_3$ complexes form 1:1 adducts with tetrahydrofuran or ammonia, but more rarely with carbon monoxide, an alkene, or a tertiary phosphine.

The data here presented are also complementary to our studies of the role of the silylene **B** as a ligand in main group element chemistry. However, the present indications are that **B** behaves more akin to a Lewis acid than base in the complex 1,2-C$_6$H$_4$[N(CH$_2$*t*Bu)]$_2$C$^+$-$^-$Si[N(CH$_2$*t*Bu)]$_2$C$_6$H$_4$-1,2 **E** (14).

E (R = CH$_2$Bu^t)

Experimental section

General techniques

All operations and manipulations were carried out under purified argon, by conventional Schlenk techniques. Solvents were dried and degassed before use. The silylene Si(NN) (3) and the tris(cyclopentadienyl)metal complexes LnCp$_3$ (15) were obtained by published procedures. Other chemicals were purchased and purified by standard techniques. Microanalyses were carried out by Medac Ltd. (Brunel University). The NMR spectra were recorded in benzene-d_6 or toluene-d_8 using Bruker Instruments: Bruker DPX 300 (^{1}H and ^{13}C) and AMX 500 (^{29}Si), and referenced internally to residual solvent resonances (data in δ). Electron impact mass spectra were taken from solid samples using a Kratos MS 80 RF instrument. Melting points were taken in sealed capillaries and are uncorrected.

Synthesis of the crystalline complex 1

A solution of Si(NN) (0.48 g, 1.76 mmol) in toluene (10 mL) was slowly added to a suspension of YCp$_3$ (0.25 g, 0.88 mmol) in toluene (30 mL) at 0°C. The cloudy solution was stirred for one day at room temperature. After filtration, the filtrate was concentrated and cooled (–25°C) yielding colorless crystals of complex **1** (0.35 g, 61.4%), mp 75–80°C. MS: 284 [YCp$_3$]$^+$, 219 [YCp$_2$]$^+$, 274 [Si(NN)]$^+$, 217 [Si(NN) – CMe$_3$]$^+$, 147 [Si(NN) – CH$_2$*t*Bu-CMe$_3$]$^+$, 93 [C$_7$H$_8$H]$^+$, 66 [CpH]$^+$, 57 [CMe$_3$]$^+$. ^{1}H NMR (C$_6$D$_6$, 300.13 MHz, 298 K, δ): 7.12, 7.10, 7.06 (phenyl, 5H), 7.02

© 2000 NRC Canada

(phenyl, 4H, s), 5.92 (Cp, 15H, s), 3.56 (CH_2, 4H, s), 2.10 (Me, 3H, s), 0.89 (CMe_3, 18H, s). ^{13}C NMR (C_6D_6, 75.46 MHz, 298 K, δ): 111.19 (Cp), 21.38 (Me), 137.82, 129.27, 128.00, 125.64 (phenyl), 28.74 (CMe_3), 33.28 (CMe_3), 54.50 (CH_2), 141.24, 111.02, 118.75 (phenyl). $^{29}Si\{^1H\}$ NMR (C_7D_8, 99.33 MHz, 188 K, δ): 119.5 (d, $^1J(^{29}Si\text{-}^{89}Y)$ = 59 Hz), 93.5. For some variable temperature $^{29}Si\{^1H\}$ NMR spectral data, see the discussion. Anal. calcd. for $C_{38}H_{49}N_2SiY$ (%): C 70.1, H 7.59, N 4.30; found (%): C 69.5, H 7.55, N 4.68.

Synthesis of of the crystalline complex 2

A solution of Si(NN) (0.22 g, 0.82 mmol) in toluene (10 mL) was added slowly to a suspension of the dark green $YbCp_3$ (0.15 g, 0.41 mmol) in toluene (20 mL) at 0°C. The cloudy solution was stirred overnight at room temperature. After filtration, the filtrate was concentrated and cooled (–25°C) affording deeper green crystals of complex **2** (0.24 g, 80%), mp 61–65°C. MS: 643 $(M)^+$, 369 $[YbCp_3]^+$, 304 $[YbCp_2]^+$, 239 $[YbCp]^+$, 276 $[Si(NN)H_2]^+$, 91 $[C_7H_8]^+$, 66 $[CpH]^+$. ^1H NMR (C_6D_6, 300.13 MHz, 298 K, δ): 10.18 (CH_2, 2H, s), 8.92 (CH_2, 2H, s), 8.68 (phenyl, 4H, s), 7.08, 6.99, 6.90 (phenyl, 5H), 3.22 (CMe_3, 18H, s), 2.01 (Me, 3H, s), –61.56 (Cp, 15H, s). ^{13}C NMR (C_6D_6, 75.46 MHz, 298 K, δ): –124.81 (Cp), 20.48 (Me), 137.35, 128.91, 128.00, 125.38 (phenyl), 31.04 (CMe_3), 36.91(CMe_3), 62.05 (CH_2), 149.13, 114.55, 121.07 (phenyl). Anal. calcd. for $C_{38}H_{49}N_2SiYb$ (%): C 62.1, H 6.72, N 3.81; found (%): C 60.2, H 6.74, N 3.97.

Lack of reaction between $LaCp_3$ and Si(NN)

A solution of Si(NN) (0.41 g, 1.50 mmol) in toluene (10 mL) was added slowly to a suspension of $LaCp_3$ (0.25 g, 0.75 mmol) in toluene (30 mL) at 0°C. Unlike in the preparation of **1** or **2**, for which the sparingly soluble $LnCp_3$ largely dissolved upon addition of Si(NN), the almost insoluble $LaCp_3$ appeared not to dissolve. The mixture was heated to 80–90°C for 24 h, then filtered. The precipitate was dried under vacuum to yield a white powder (0.2 g), which was shown by its ^1H NMR spectrum and X-ray crystal data to be the $LaCp_3$ starting material.

X-ray crystallographic analysis of $[YCp_3\{Si(NN)\}]\cdot C_7H_8$ (1) and $[YbCp_3\{Si(NN)\}]\cdot C_7H_8$ (2)

Crystallographic data for complexes **1** and **2** are displayed in Table 1. Crystallographic data collection was carried out on an Enraf–Nonius CAD4 diffractometer using Mo-K_α radiation, λ = 0.71073 Å. The crystal was coated with a layer of hydrocarbon oil, attached to a glass fiber, and cooled to 173(2) K. The structures were solved by direct methods (SHELXS-97) (16) and refined on all F^2 by the full-matrix, least-squares procedure (SHELXL-97) (17).

Results and discussion

Treatment of a tris(cyclopentadienyl)metal complex $LnCp_3$ (Ln = Y or Yb) with an excess of the thermally stable bis(amino)silylene Si[{N(CH_2*t*Bu)}$_2$$C_6H_4$-1,2] [≡Si(NN)] at ambient temperature afforded (eq. [5], forward reaction) the first of the earliest (group 3–5) transition (Y) or lanthanide (Yb) metal–silylene complexes, the crystalline $[LnCp_3\{Si(NN)\}]\cdot C_7H_8$ (Ln = Y (**1**) or Yb (**2**)).

$$[5] \quad LnCp_3 + Si(NN) \overset{PhMe}{\rightleftarrows} [LnCp_3\{Si(NN)\}]\cdot PhMe$$

The colorless (Y) or green (Yb) crystals of each of the complexes **1** or **2** were thermally stable in the solid state, mp 75–80°C (Y) or 61–65°C (Yb) without obvious decomposition. The EI mass spectrum showed the parent molecular ion only for the Yb complex **2**, indicating that the latter is thermally more robust than **1**.

In toluene-d_8 solution, however, it was evident from variable temperature $^{29}Si\{^1H\}$ NMR spectroscopic measurements that there was Ln(III)—Si(II) bond dissociation (eq. [5], back reaction). This occurred more readily for Ln = Y than Ln = Yb and, as appropriate for an equilibrium process, was temperature-dependent. Thus, at 298 K, the proportion of the diamagnetic complex **1** to its factors was 1:14; at 188 K, it was 6:10; while at 338 K essentially the sole silicon-containing species in solution was the free silylene, δ 97.4. For the case of the paramagnetic Yb(III) complex **2**, no free silylene was detected at 298 K (nor at temperatures down to 238 K), while at 343 K a significant silylene signal at δ 94.6 was present. Despite the evident kinetic lability of the Ln(III)—Si(II) bond in a solution of each of **1** or **2**, the magnitude of the coupling constant $^1J(^{29}Si\text{-}^{89}Y)$ = 59 Hz, suggests that there is strong YSi bond orbital overlap. This *J* value may be compared with the $^1J(^{13}C_{sp3}\text{-}^{89}Y)$ = 33 Hz found in $[Y\{\eta\text{-}C_8H_6(SiMe_3)_2\text{-}1,4\}\{CH(SiMe_3)_2\}(THF)]$.[2] The ^{29}Si NMR spectral signal at 188 K was at the higher frequency of δ 119.5 in **1** than the free silylene (δ 93.5); cf. δ 136.5 in $[Ni(PPh_3)\{Si(NN)\}_3]$ (10).

[a]M (1), M(2), and M(3) are the centroids of the C(1)–C(5), C(6)–C(10), and C(11)– C(15) rings, respectively.

The ^{1}H NMR spectrum in benzene-d_6 of the complex **1** showed signals of each of the individual components of the equilibrium mixture of eq. [5] (Ln = Yb): (*i*) the sparingly soluble YCp_3 ($\delta[^1H]$: 5.93 and $\delta^{13}C\{^1H\}$]: 113.9); (*ii*) Si(NN) ($\delta[^1H]$: 7.01, 3.58, and 0.89; $\delta[^{13}C\{^1H\}]$: 141.5, 118.5, 110.7, 54.9, 33.2, and 28.7 (3)); and (*iii*) toluene. We conclude that the rate of exchange at 298 K between **1** and its factors is fast on the NMR time scale. As for the paramagnetic complex **2**, we consider that the rate of exchange at 298 K between **2** and its factors in benzene-d^6 is slow on the NMR time scale. Thus, no signals close to those of Si(NN) were observed and others differed significantly from those found for the sparingly soluble (in C_6D_6) $YbCp_3$: $\delta[^1H]$: –65.7, $\delta[^{13}C\{^1H\}]$: –127.2.

Molecular structures of the crystalline complexes 1 and 2

The molecular structures of the isomorphous, crystalline complexes $[LnCp_3\{Si(NN)\}]\cdot C_7H_8$ (Ln = Y (**1**) or Yb (**2**)) are illustrated in Fig. 1, the unit cell being shown in Fig. 2. Non-hydrogen bond lengths and angles are listed in Table 2. In Table 3 are shown some comparative geometric data for the mononuclear complexes $[YbCp_3]$ (18), $[YbCp_3(THF)]$ (19), $[LuCp_3(THF)]$ (20), **1**, and **2**. Comparison is not so readily made with YCp_3, since this crystalline complex is polymeric $[\{Y(\eta^5\text{-}C_5H_5)_2(\mu\text{-}\eta^2\text{-}C_5H_5)\}_\infty]$ (21), having average Y—C distances for the two $[\eta^5\text{-}C_5H_5]^-$ ligands of 2.67 Å for one ring and 2.75 Å for the other, while the two Y—C distances to the $[\eta^2\text{-}C_5H_5]^-$ ligands are 3.35 ± 0.25 Å. The molecule $[LuCp_3(THF)]$, an f^{14} complex, is taken as a model for the f^{13} Yb(III) analog for which data are not available. Table 4 shows some structural comparison relating to the silicon environment in the crystalline free ligand Si(NN) **B** (3) and its Y (**1**) and Yb (**2**) tris(cyclopentadienyl) complexes.

The Ln atom in each of the crystalline complexes **1** and **2** is in a distorted trigonal monopyramidal environment, being almost coplanar with each of the centroids of the three Cp^- ligands; the distorted trigonal silicon atom occupies the apical site. This arrangement is close to that found in the related THF complexes (Table 3), in which the ligating oxygen atoms of the neutral donor is similarily situated. The Ln—Si bond in the yttrium complex **1** of 3.038(2) Å is longer than in the ytterbium analog **2**, 2.984(2) Å (and may be compared with the Yb—Si bond length of 3.158(2) Å in $[Yb(SiPh_3)_2(THF)_4]$ (1*c*)). The ca. 2% longer Y—Si than Yb—Si bond is matched by the comparable trend in the Ln—C or Ln—M bond lengths (Y > Yb).

Conclusions

It has been shown that the bis(amino)silylene Si[{N(CH$_2$*t*Bu)}$_2$C$_6$H$_4$-1,2] [Si(NN)] (**B**) forms well characterized crystalline 1:1-complexes with tris(cyclopentadienyl)metal complexes $LnCp_3$ of formula $[Ln(\eta^5\text{-}C_5H_5)_3\{Si(NN)\}]\cdot C_7H_8$ (Ln = Y (**1**) or Yb (**2**)), by treating $LnCp_3$ with Si(NN) in toluene at ambient temperature. Fig. 1. Cameron representation of the molecular structure of the isomorphous, crystalline complexes $[LnCp_3\{Si(NN)\}]\cdot C_7H_8$ (Ln = Y (**1**) or Yb (**2**)), with the atom numbering system. Thermal ellipsoids correspond to 50% probability.

contrast, under similar conditions, $LaCp_3$ proved to be unreactive. Each of the complexes **1** and **2** in toluene was found to be in equilibrium with its factors, the yttrium complex **1** being the more readily dissociated. We interpret these findings on the three $LnCp_3$ complexes in the following manner. Only the ytterbium complex is a monomer in the crystal, the other two being polymeric, of structure $[\{Ln(\eta^5\text{-}C_5H_5)_2(\mu\text{-}\eta^2\text{-}C_5H_5)\}_\infty]$, and of these the bridge-binding is more effective for lanthanum than yttrium. The thermodynamics of the formation of a silylene-tris(cyclopentadienyl)metal complex $[LnCp_3\{Si(NN)\}]$ requires an additional term for Ln = La or Y than for Ln = Yb, namely ΔG for $[\{LnCp_3\}_\infty]$ depolymerization. This is greater for Ln = La than Ln = Y. Evidently, the ΔG (depolym.) term for Ln = La is sufficiently large to prevent formation of the La(III)-Si(NN) complex, while for Ln = Y it is responsible for making complex **1** more readily prone to Ln—Si bond dissociation than its isoleptic ytterbium analog **2**. On steric grounds, a silylene–Ln complex might have been expected to be favored by a large Ln(III) radius (La > Y > Yb), an effect which is evidently less important.[3]

Metal supported catalysts obtained by sol-gel in the hydrosilylation of phenylacetylene with R_3SiH organosilanes (R_3 = Ph_3, Ph_2Me, and $PhMe_2$)

Rafael Jiménez, Juan Manuel López, and Jorge Cervantes

Abstract: The hydrosilylation reaction of phenylacetylene, generated on the surface of solid catalysts (such as Pt and Ru) supported on inorganic matrices such as MgO obtained by the sol-gel process, yields vinylsilanes as the main products. The products' distribution, specific activity, and turnover reactions were determined for the case of the hydrosilylation reaction of PhC≡CH with R_3SiH (R = Ph_3, Ph_2Me, and $PhMe_2$). For Ph_3SiH and Ph_2MeSiH, the presence of β-*trans* and α isomers is observed. Addition of $PhMe_2SiH$ to phenylacetylene leads to the formation of β (*cis* and *trans*) and α isomers. These catalytic systems provide a new synthetic route to Si—C bond formation.

Key words: Vinylsilanes, sol-gel catalysts, hydrosilylation and phenylacetylene.

Résumé : La réaction d'hydrosilylation du phénylacétylène, effectuée à la surface d'un catalyseur solide tel le Pt ou le Ru fixé sur des matrices inorganiques tel le MgO obtenu selon le procédé de sol-gel, donne des vinylsilanes comme produits majoritaires. On a déterminé, la distribution des produits, l'activité spécifique et les réactions d'échange dans le cas de la réaction d'hydrosilylation du PhC≡CH avec R_3SiH (R = Ph_3, PH_2Me, et $PhMe_2$). On a observé la présence d'isomères β-*trans* et α dans le cas du Ph_3SiH, PH_2MeSiH. L'addition du PH_2MeSiH sur le phénylacétylène conduit à la formation d'isomères β(*cis* et *trans*) et α. Ces systèmes catalytiques fournissent une nouvelle voie de synthèse pour la formation de la liaison Si—C.

Mots clés : vinylsilanes, catalyseur sol-gel, hydrosilylation et phénylacétylène.

Introduction

Catalysts prepared by the sol-gel method show good catalytic activity for a broad range of chemical reactions. Ni–SiO_2 aerogel catalysts have been used for the hydrogenation of toluene to methylcyclohexene (1). Willey et al. (2) studied the selective catalytic reduction of nitric oxide by ammonia over iron oxide-chromia-alumina aerogels. On the other hand, Armor et al. (3) found that Pd–Al_2O_3 aerogel catalysts were highly active toward hydrogenation for the quantitative and selective production of aniline from nitrobenzene. In it has also been found that aerogel catalysts can be used for the nitration of toluene into nitrobenzene (4); the synthesis of methanol from CO_2–H_2 mixtures (5); and the transformation of isobutylene by NO into methacrylonitrile, acrylonitrile, and acetonitrile (6). They also show a good hydrogenation-dehydrogenation activity (7). The sol-gel method provides an useful method of preparing supported metal systems because several reaction parameters can be adjusted to modify the structure of the samples. Ru–MgO has been used in the benzene hydrogenation reaction (8) and in the hydrogenolysis of cyclopentene (9). A high turnover value and considerably smaller deactivation rate have been observed for Ru–MgO, Ru–SiO_2, Ru–Al_2O_3, or Ru–TiO_2. Alumina-supported platinum, prepared by the sol-gel process by Balakrishan and Gonzalez (10), was active in *n*-hexane hydrogenation.

Sol-gel catalysts used in the hydrosilylation reaction

The hydrosilylation reaction represents one of the most important routes to obtain organosilicon compounds. The addition of Si—H bonds to unsaturated compounds can be carried out by free radical chain reactions, or more conveniently by the use of catalysts such as platinum or other transition metals (11, 12). One of the most important features in the development of this reaction is the use of heterogeneous catalysts (13–16). For example, Polizzi et al. (14) reported studies of specific activity, selectivity, and turnover reactions of heterogeneous catalytic systems, prepared by treatment of solids supports such as graphite, γ-Al_2O_3, and carbon with mesitylene solvated platinum atoms. They found that Pt–C, Pt–graphite, and Pt–γ-Al_2O_3 systems are able to promote the hydrosilylation of 1- and 2-hexyne. The hydrosilylation of 1-hexyne with $HSiMeCl_2$ took place at room temperature when the Pt–C was used. However, other systems also show good catalytic activity at 70°C.

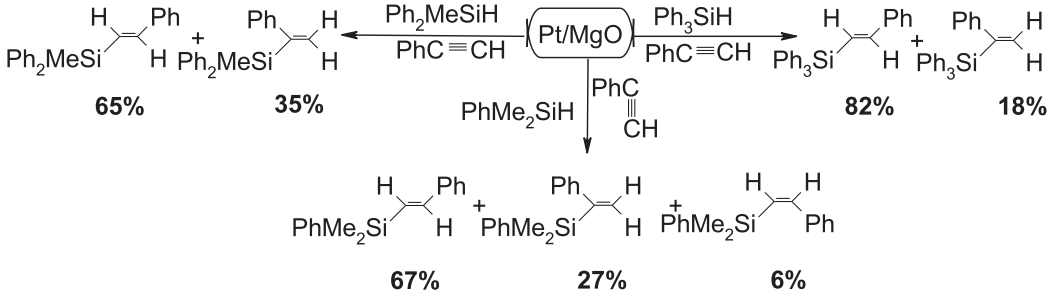
Fig. 1. Hydrosilylation reaction of phenylacetylene promoted by Pt–MgO, 0.5% Pt wt% with Ph_3SiH, Ph_2MeSiH, and $PhMe_2SiH$.



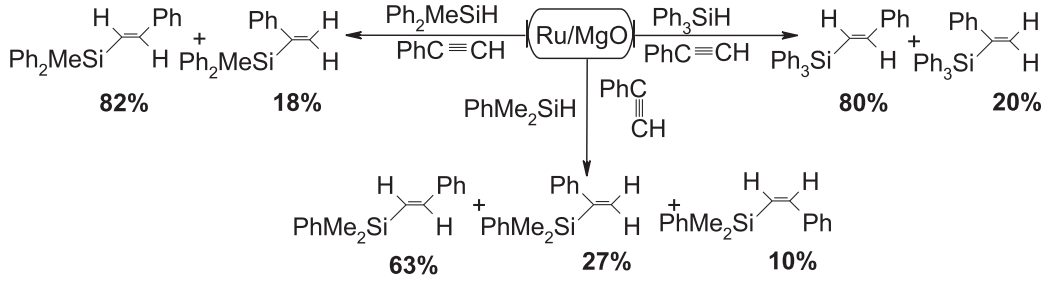


Fig. 2. Hydrosilylation reaction of phenylacetylene promoted by Ru–MgO, 0.5% Ru wt% with Ph_3SiH, Ph_2MeSiH, and $PhMe_2SiH$.

Schubert et al. (17) reported the activity of $Rh(CO)Cl(PR_3)_2$ heterogenised by the sol-gel process in the hydrosilylation of 1-hexene with triphenylsilane.

Considering that there are only a few examples of hydrosilylation reactions catalyzed by heterogeneous systems obtained by sol-gel we have studied this reaction catalyzed by Ru–MgO and Pt–MgO generated by this route. We found that Ru–MgO and Pt–MgO systems are able to promote the selective hydrosilylation of phenylacetylene with Ph_3SiH, Ph_2MSiH, and $PhMe_2SiH$. The reactions and general results are illustrated in Fig. 1 and Fig. 2.

Experimental

The catalysts used (Pt–MgO, 0.5% Pt and Ru–MgO, 0.5% Ru) were prepared by the sol-gel method in the Department of Chemistry at the Universidad Autonoma Metropilitana-Iztapalapa, Mexico. Synthetic methods of these catalytic systems have been described already in the literature (18–22). The BET areas were determined by air adsorption at the temperature of liquid nitrogen. The values reported are 46.3 m^2/g for Pt–MgO and 23.2 m^2/g for Ru–MgO. Catalysts were activated in air at 400, 450, and 540°C during 4 h and then reduced in hydrogen atmosphere for 1 h. The chemicals used were all reagent-grade and available from suppliers such as Aldrich. All the glassware used was treated with a 1 M of KOH in EtOH solution, washed carefully with deionized water and acetone, and dried in an oven at 110°C for several hours. Any contact with other organic materials such as silicon grease was avoided. All reactions were carried out under nitrogen atmosphere.

Liquid hydrosilanes were purified by distillation under nitrogen atmosphere. NMR measurements were performed in $CDCl_3$ solutions using a Varian Gemini 200 MHz spectrometer and a Varian Unity-Plus 300 MHz spectrometer.

General procedure for the preparation of vinylsilanes

In a typical experiment, the previously activated catalyst (25 mg Pt–MgO, 0.5% Pt), were mixed at room temperature with 4.066 mmol of Ph_2MeSiH and 4.473 mmol of phenylacetylene in a 50 mL two-necked flask equipped with a reflux condenser and a thermometer. After the addition was completed, the mixture was stirred and heated at 80–90°C for 2 h. Progress of the reaction was monitored by ^1H NMR spectroscopy and aliquots from the mixture reaction were taken every half and hour. The isomeric ratio of the hydrosilylation products was derived from the areas of olefinic protons. Decrease of the ≡**C-H** bond was comparable with the increase of the vinylic protons signals. The specific activity was calculated as moles of phenylacetylene transformed per g-atom of metal per hour. Products were conveniently purified by distillation or crystallization. For Ph_3SiH with PhC≡CH, the product mixture was washed with CH_2Cl_2–methanol (2:1) solution and crystallized at –5°C to separate the β-*trans* and α-isomer from the solution.

We also studied the turnover reaction for these catalytic systems. The product mixture was separated from the catalyst by decantation and then equal amounts of fresh silane and phenylacetylene were added to the catalyst to start the next hydrosilylation reaction. The decrease in integrals of the ≡**C-H** bond were comparable with the increase of the vinylic protons signals, and then the specific activity was again measured as moles of phenylacetylene transformed per g-atom of metal per hour.

Results and discussion

It is important to discuss the effect of the activation temperature in the observed catalytic activity. In the MgO synthesis by the sol-gel process, hydrolysis is improved by the presence of acid and basic catalysts, leading to $Mg(OH)_2$

$PhMe_2SiH$	2	80–90	67	27	6

Table 2. Reaction conditions and product distribution in the hydrosilylation of phenylacetylene by R_3SiH promoted by Ru–MgO.

R_3SiH	Time (h)	*T* (°C)	Product (%)		
			Trans	*Gem*	*Cis*
Ph_3SiH	2	80–90	80	20	——
Ph_2MeSiH	2	80–90	82	18	——
$PhMe_2SiH$	2	80–90	63	27	10

formation that persists after gelation (23–24). López et al. (18) reported, in MgO synthesis by sol-gel process, hydrolysis is improved by the presence of acid an basic catalysts leading to $Mg(OH)_2$ large formation. We found that if the catalysts were activated at 400°C, reaction time was about 25 h, which is caused by $Mg(OH)_2$ brucite phase, affecting specifically the catalytic activity. When the catalysts were activated at 450 or 540°C, the support crystallized completely as MgO periclase phase, and the reaction time was reduced to only 2 h. This particular behavior has not been completely understood. However, some explanation has been suggested: temperature very easily modifies morphology and crystalline structure, and the hydroxyl groups found in the surface of the support are directly related to the catalytic activity.

The reactivity and products distribution ratio of the hydrosilylation reactions of phenylacetylene using the Pt–MgO and Ru–MgO as catalysts are shown in Fig. 1 and 2. Model reactions used were hydrosilylation of phenylacetylene by Ph_3SiH, Ph_2MeSiH, and $PhMe_2SiH$ under nitrogen atmosphere at constant organosilane:catalyst ratio (4.066 mmol/25 mg). In terms of product distribution, we observe that the hydrosilylation reaction with Ph_3SiH and Ph_2MeSiH using Pt–MgO or Ru–MgO as catalysts generates a mixture of *trans* (63–82%) and *gem* (17–34%) vinylsilanes. In the hydrosilylation reaction of Ph_3SiH with PhC≡CH, the mixture formed by catalyst and Ph_3SiH was heated to 50°C to melt the triphenylsilane before the addition of phenylacetylene. After 2 h, the reagents have been consumed and the reaction products mixture was washed with CH_2Cl_2:methanol (2:1) solution and crystallized at –5°C to separate the β-*trans* (mp 149–152°C) and α-isomer (mp 115–119°C) from the solution. The use of $PhMe_2SiH$ in the hydrosilylation of phenylacetylene with both catalysts resulted in a different ratio of isomers, containing: *trans* (63–67%), *gem* (27%), and *cis* (6–10%) isomers. Results obtained in the two catalytic systems are listed in Tables 1 and 2.

To compare results, Table 3 illustrates the product distribution for the same model reactions using the well known catalytic systems of Karsted, Speier, and Wilkinson (25–28).

Reaction products were characterized by ^1H, ^{29}Si, and ^{13}C NMR spectroscopy, and the properties for the entire set of compounds prepared according to Figs. 1 and 2 are the same as those reported previously (14, 29). The isolated *trans* and *gem* isomers obtained in the hydrosilylation of phenylacetylene with Ph_3SiH and Ph_2MeSiH were identified. In the ^1H NMR spectrum two doublets are seen in 5.6–6.1 ppm region, which are typical signals of an AB spin system (J = 2.8 Hz) and correspond to protons in geminal position.

Table 3. Product distribution for hydrosilylation of phenylacetylene with different catalysts and several hydrosilanes.

Catalysts	R_3SiH	*Trans*	*Gem*	*Cis*	Ref.
Karsted's	Ph_3	78	7	15	25–26
H_2PtCl_6	Ph_3	90	10	0	27
	Ph_2Me	78	22	0	27
	$PhMe_2$	69	31	0	27
$(PPh_3)_3RhCl$	Ph_3	67	6	26	28
	Ph_2Me	83	17	0	28
	$PhMe_2$	19	5	76	28

The signals in the downfield region of 6.6–7.0 ppm are assigned to the AX spin system (J = 19.1 Hz) and indicate vicinal protons of the HC=CH fragment in the *trans* position. According to the ^{29}Si NMR spectrum, negative peaks are observed for all silicon atoms linked to a double bond as is shown in Table 4. All these signals agree with information reported in the literature (14, 29–32). On the other hand, the hydrosilylation reaction of the phenylacetylene with $PhMe_2SiH$ using the two catalytic systems produces a mixture of β-*trans*, *cis*, and α-vinylsilanes. The β-*trans* and α-vinylsilanes were easily identified by ^1H, ^{13}C, and ^{29}Si NMR spectroscopy and compared to those reported elsewhere in the literature (14, 29–33). The *cis* isomer was identified by ^{29}Si NMR; we observed a negative chemical shift value for the silicon atom linked to a double bound at –8.2 ppm.

Specific activity is illustrated in the hydrosilylation of phenylacetylene with Ph_2MeSiH. The Ru–MgO catalysts showed a specific activity of 17989 with 45% of conversion in the first half and hour to 18943 with 96% of conversion in the first hour. 98% of conversion was reached after 2 h of reaction. The Pt–MgO specific activity was 47555 with 75% of conversion in the first half and hour but higher conversion (93%) was achieved after 1 h of reaction. The results are shown in Tables 5 and 6. The same study also revealed that hydrosilylation of phenylacetylene catalyzed by Pt–MgO and Ru–MgO is often accompanied by olefin isomerization. During the first half and hour, *trans–gem* isomerization was observed and measured from ^1H NMR areas of olefinic protons calculated for both catalytic systems. The results summarized in Table 7 shows that isomeric ratio depends on the total reaction time. Turnover reactions are illustrated in the hydrosilylation of phenylacetylene with Ph_2MeSiH using Pt–MgO as catalyst. As it can be seen, after three cycles the specific activity remained unchanged. The catalysts do not lose any activity even after several months.

29542	3	2	64	36

[a]Specific activity is calculated as moles of phenylacetylene transformed/g-atom of Pt per hour.

Conclusions

The supported catalysts Pt–MgO and Ru–MgO, synthesized by the sol-gel process, catalyze selective hydrosilylation of phenylacetylene. A good selectivity and specific activity are observed. Reactions can be run without solvent, products can be easily separated, and the catalyst can be recycled.

The use of heterogeneous catalysts prepared by the sol-gel method appears to offer new options that can be widely used for the synthesis of organosilicon compounds.

We are currently performing studies on the reaction mechanism and the isomerization reaction observed during the hydrosilylation. These results will be help us to understand the applications of these catalytic systems in the hydrosilylation reaction. An investigation of the use of other catalytic systems prepared by sol-gel process are underway.

On the possible formation of Si=O, Si=S, and Si=Se double bonds via the reaction of silylenes with oxirane, thiirane, and selenirane, respectively. An ab initio theoretical study

Yitzhak Apeloig and Stepan Sklenak

Abstract: The reactions between silylene, H_2Si, and the three-membered ring compounds, oxirane (**9**), thiirane (**10**), and selenirane (**11**), which provide possible routes to Si=X (X = O, S, Se) double bonds were studied by ab initio calculations at the MP2 and QCISD correlated levels of theory employing the polarized 6-31G** basis set. The calculations show that the three reactions are all *highly exothermic*, (–61.8, –45.2, –52.9 kcal/mol at MP2/6-31G**//MP2/6-31G** for X = O, S, Se, respectively). In the gas phase, at 0 K, these reactions are predicted to be also spontaneous (i.e., the calculated transition states are lower in energy than the reactants). At 298 K, entropy contributions result in small barriers on the ΔG surface for X = O, S (7.4 kcal/mol for both reactions at QCISD (full)/6-31G**), but for X = Se the reaction remains spontaneous. Thus, the calculations suggest that these reactions are viable routes for the preparation of compounds with Si=X (X = O, S, Se) double bonds. The first step in all the reactions is the barrier-less formation of an encounter-complex between the silylene and the X atom of the precursor. For X = O, S, these complexes are predicted to be sufficiently stable to be observed in a matrix. The reaction steps which follow depend on X; for X = O fragmentation of the silylene–XC_2H_4 complex proceeds in two steps via a *biradical* intermediate, while for X = S and X = Se the fragmentation occurs in *a single step*. The first ab initio calculations for H_2Si=Se are reported.

Key words: silylene, silanone, silanethione, silaneselone.

Résumé : Faisant appel à des calculs ab initio aux niveaux MP2 et QCISD apparentés de la théorie et utilisant l'ensemble polarisé 6-31G**, on a étudié les réactions entre le silylène, H_2Si, et les composés cycliques à trois chaînons oxirane (**9**), thiirane (**10**) et sélénirane (**11**) qui pourraient servir de voies à la formation de doubles liaisons Si=X (X = O, S, Se). Les calculs montrent que les trois réactions sont toutes *très exothermiques* (–61,8, –45,2 et –52,9 kcal/mol au niveau MP2/6-31G**//MP2/6-31G** pour X = O, S et Se respectivement). En phase gazeuse, à 0 K, il est aussi prédit que ces réactions seront spontanées (c'est-à-dire que l'énergie des états de transitions est plus faible que l'énergie des réactifs). À 298 K, les contributions de l'entropie conduisent à de faibles barrières sur la surface du ΔG pour X = O et S (7,4 kcal/mol pour chacune des réactions au niveau QCISD(plein)/6-31G**)); toutefois, pour X = Se, la réaction reste spontanée. Ainsi les calculs suggèrent que ces réactions sont viables pour la préparation de composés comportant une double liaison Si=X (X = O, S, Se). La première étape de toutes ces réactions est une formation sans barrière d'énergie d'un complexe de rencontre entre le silylène et l'atome X du précurseur. Pour X = O et S, il est prédit que ces complexes sont suffisamment stables pour être observés dans une matrice. Les étapes réactionnelles qui suivent dépendent de la nature de X; pour X = O, la fragmentation du complexe silylène–XC_2H_4 se produit en deux étapes par le biais d'un intermédiaire *biradical* alors que pour X = S et X = Se, la fragmentation se produit en *une seule étape*. On rapporte aussi les premiers calculs ab initio pour le H_2Si=Se.

Mots clés: silylène, silanone, silathione, silanesélone.

Introduction

The synthesis of compounds with multiple bonds to silicon is one of the important contemporary challenges in silicon chemistry (1). For many years such compounds were known only as transients and stable compounds with multiple bonds to silicon were isolated only in the last two decades (1). Of the R_2Si=X (X = O, S, Se) family, a stable

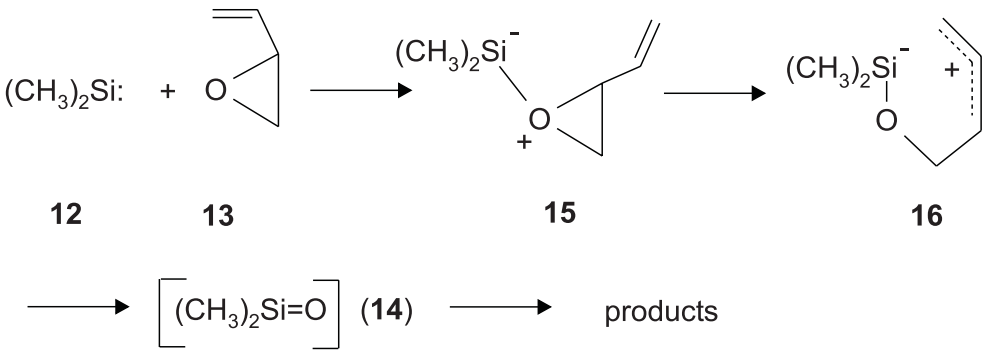
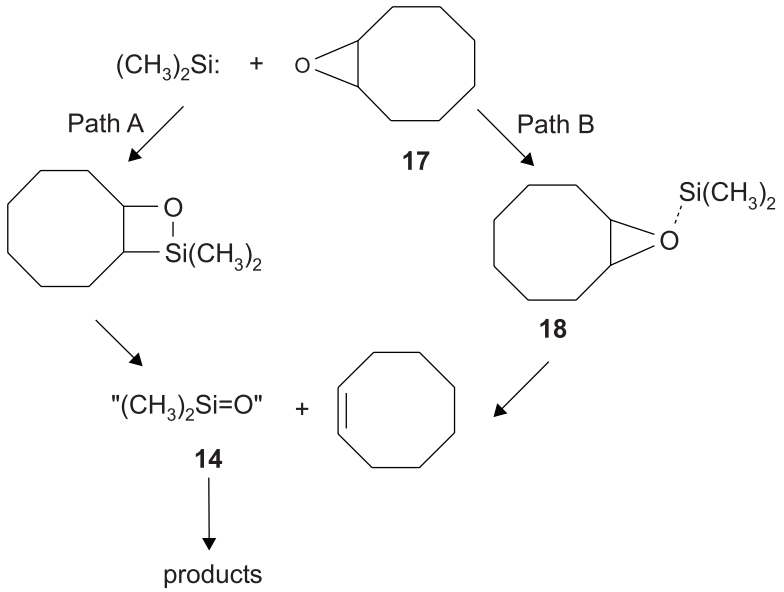
silanethione $R_2Si{=}S$ (**1**) (2) and a stable silaneselone $R_2Si{=}Se$ (**2**), (3) which are kinetically stabilized by the very bulky substituents Dip (2,6-$^i Pr_2C_6H_3$), Tip (2,4,6-$^i Pr_3C_6H_2$), and Tbt (2,4,6–$[(Me_3Si)_2CH]C_6H_2$) were recently isolated by Okazaki and co-workers (2, 3) in two spectacular achievements. All other known silanethiones or silaneselones with a tricoordinated silicon atom are transient species (1, 4, 5). Si=X double bonds can also be stabilized by substituents which can coordinate intramolecularly to the low-coordinated silicon atom. Three such "internally coordinated silanethiones," **3a**, **3b**, and **4**, were recently isolated (6); **3** and **4** have tetracoordinate (6*a*) and pentacoordinate (6*b*) silicon atoms, respectively. An internally coordinated silaneselone (**5**), with a tetracoordinated silicon atom, was also isolated (6*a*). Stable silanones, $R_2Si{=}O$, are not yet known (not even as internally coordinated species as in **3**–**5**), but several transient silanones, including the parent $H_2Si{=}O$ (**6**), (7*a*, *b*) were detected spectroscopically in matrix (7) and in the gas phase (8). The parent silanone $H_2Si{=}O$ (**6**) (1*b*, (for a related theoretical study see ref. 8*c* and 8*e*), 9) and silanethione $H_2Si{=}S$ (**7**) (9*c*, 10) were studied theoretically. In contrast, nothing is currently known, either theoretically or experimentally, on silaneselone $H_2Si{=}Se$ (**8**).



A possible route leading to compounds with a Si=X (X = O, S, Se) double bond is the reaction between a silylene, R_2Si:, and a strained chalcagenide three-membered ring compound, c-C_2H_4X, such as oxirane (X = O, **9**), thiirane (X = S, **10**), or selenirane (X = Se, **11**), as shown in eq. [1].

Several experimental studies of the reaction of silylenes with oxiranes have been reported (11). Tzeng and Weber (11*a*) studied the reaction between dimethylsilylene (**12**) and 2-vinyl oxirane (**13**) and based on the observed products they suggested that dimethylsilanone (**14**) is formed as an intermediate (Scheme 1). The proposed mechanism (Scheme 1) involves the initial formation of a silylene–oxirane ylide intermediate **15**, which opens to an allylic ion-pair (**16**), which dissociates to give $(CH_3)_2Si{=}O$. Although the observed products are consistent with the intermediacy of $(CH_3)_2Si{=}O$, the desired dimethylsilanone (**14**) was not directly observed.



Barton (11*b*) and Goure and Barton (11*c*) studied the reaction of $(CH_3)_2Si$ with cyclooctene oxide (**17**). They concluded (Scheme 2) that the ylide **18** is formed, but they could not establish unequivocally if **18** extrudes $(CH_3)_2Si{=}O$, or whether it acts as a "silanone transfer agent" yielding products which are consistent with the presence of **14**. They also could not differentiate between paths A and B in Scheme 2.

Scheme 1.

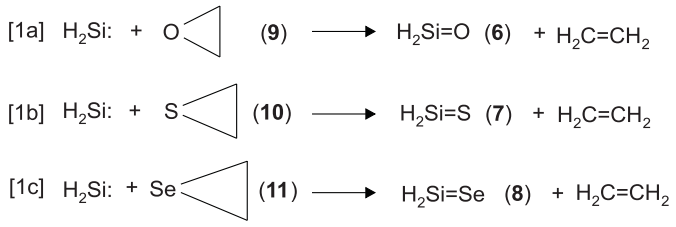
Scheme 2.

Scheme 3.

Ando et al. (11*d*), suggested the intermediacy of dimesitylsilanone ($Mes_2Si=O$, Mes = 2,4,6-$Me_3C_6H_2$) (**21**) in the reaction of Mes_2Si (**19**) with oxiranes and with several 2-substituted oxiranes (Scheme 3).



In a recent study, Walsh and co-workers (11*e*) studied the gas phase reactions of $(CH_3)_2Si$ with oxirane and interpreted their results in terms of the transient formation of $(CH_3)_2Si=O$.

Although a variety of thiiranes, are known (12*a*), only one example of rxn. [1], X = S, between a disilyloxy silylene, $(Me_3SiO)_2Si$ (generated in situ on a reactive silica surface) and a thiirane, was reported, and the intermediacy of a silanethione was suggested (12*b*). There are no reports on the reaction of silylenes with seleniranes; which is not surprising, as the number of available seleniranes is limited. Only one stable tetra-substituted selenirane (13*a*, 13*b*) and two relatively unstable tri-substituted seleniranes (13*c*) are known.

To shed further light on the mechanism of the reactions of silylenes with chalcogenide-3-membered ring compounds and to test whether these reactions are potentially useful for generating Si=X double bonds we have studied rxn. [1] by high-level ab initio molecular orbital calculations. We have attempted to answer questions such as: "Is rxn. [1] exothermic, despite the formation of the high energy $H_2Si=X$? Do large energy barriers separate the reactants from the desired products? Are there lower energy channels leading to other products?." Three major model reactions were studied: i.e., the reactions between H_2Si and oxirane (**9**), thiirane (**10**), and selenirane (**11**), potentially leading to $H_2Si=X$, X = O,

S, Se, respectively, (eqs. [1*a*]–[1*c*]), as well as the reactions of the larger Me_2Si and Mes_2Si (Mes = 2,4,6-$Me_3C_6H_2$-) with oxirane. The computational results and our conclusions about the mechanisms of these reactions are reported in this paper.

Computational methods

Ab initio molecular orbital calculations (14) at the correlated Møller–Plesset MP2 (15) and QCISD (16) levels of theory were performed, using the Gaussian 94 series of programs (17). The fully polarized 6-31G** basis set (18) was used throughout and all electrons were included in the calculations (including for Se). Equilibrium geometries and transition structures were fully optimized at both the MP2(full)/6-31G** and the QCISD(full)/6-31G** (except for H_2Si=Se) levels of theory. Vibrational frequencies at the MP2/6-31G** level were computed for all species, to characterize them as minima, transition structures, or higher order saddle points on the potential energy surface (PES) and for evaluating their zero-point vibrational energies (ZPE). IRC calculations (19) were applied to all the MP2/6-31G** calculated transition structures to secure that they indeed connect the reactants with the desired products.

Enthalpies at 0 K (H°_0) were calculated as the sum of the total energies (either at MP2 or at QCISD) and the corresponding ZPEs calculated at MP2/6-31G**. Entropies (S°_{298}), Gibbs free energies (G°_{298}), and ZPEs at 298 K, were calculated using the ideal gas approximation, as implemented in Gaussian 94 (17). S°_{298} and thus G°_{298} could be calculated directly at the MP2 level. At the QCISD level (where the vibration energies were not calculated) G°_{298} was estimated using the S°_{298} values calculated at MP2/6-31G**.

To simplify the presentation the following designations are used throughout the paper: (*i*) S° and G° (without a subscript) denote these values at 298 K (i.e., $S^\circ = S^\circ_{298}$ and $G^\circ = G^\circ_{298}$, respectively), while ΔH° denotes this value at 0 K; (*ii*) MP2 and QCISD denote such calculations with the 6-31G** basis set using the optimized geometries at the same levels, i.e., MP2 and QCISD denote MP2/6-31G**/ /MP2/6-31G** and QCISD/6-31G**//QCISD/6-31G** calculations, respectively.

Results

The calculated total energies, ZPEs, entropies, and Gibbs free energies of all species involved in eqs. [1*a*]–[1*c*] are listed in Table 1. Selected geometrical parameters of the optimized structures of the reactants and products are shown in Fig. 1, those of the intermediates and the transition states are given in Table 2 and the atom numbering used is shown in Scheme 4. The calculated enthalpies and Gibbs free energies of eqs. [2*a*]–[2*c*] are given in Table 3. The supplementary material includes the calculated vibration frequencies of the $H_2S\cdots XC_2H_4$ complexes.

The effect of the level of theory which was used on the calculated reaction energies is small for X = S, but somewhat more significant for X = O, where the MP2/6-31G** calculations overestimate ΔH° of rxn. [1*a*] by 5 kcal/mol (the difference is even higher for the individual reaction steps) relative to QCISD/6-31G**. In general the QCISD/6-31G** values are believed to be the more reliable and therefore QCISD values are generally used in the discussion (unless stated otherwise). The very small difference between the MP2 and QCISD results for eq. [1*b*] (X = S) suggest that this is the case also for eq. [1*c*] (X = Se), where QCISD calculations are beyond our current capabilities.

Discussion

The calculations reported in this paper apply directly to the isolated molecules in the gas-phase and we wish first to point out some of the consequences of this fact. In connection to the bimolecular reactions discussed in this paper, two types of potential energy surfaces (PES), shown in Fig. 2, should be considered: (*i*) an exothermic multistep reaction in which the energy of the reactants is higher than the energy of all the transition states involved (Fig. 2*a*). Such a reaction is spontaneous at 0 K and is expected to occur extremely rapidly. The encounter-complex is produced in a vibrationally excited state having sufficient internal energy to overcome the activation barrier, $\Delta E(1)$, and to proceed to yield the products; (*ii*) an exothermic multistep reaction in which one of the transition states is higher in energy than the energy of the reactants (Fig. 2*b*). In this case the reaction is not spontaneous and the encounter-complex (or other intermediates) will have a significant life time (depending on the height of the $\Delta E(3)$ barrier), because on average the vibrationnally excited molecules do not have the required energy to cross the $\Delta E(3)$ barrier. An additional energy of at least $\Delta E(3)$ has to be supplied to allow the reaction to proceed to the products.

The situation is different in solution (or in high-pressure gas-phase reactions) because the energy gained in the formation of the first encounter-complex (or intermediate) can be rapidly distributed to the environment and the complex can reach its vibrational ground state. So even in case (*i*) (Fig. 2*a*) the encounter-complex will have a significant lifetime and an additional energy of $\Delta E(1)$ has to be supplied to the system to overcome the barrier separating the first encounter-complex from the products. In case (*ii*) (Fig. 2*b*), the energy required in solution to overcome the activation barrier of $\Delta E(2)$ is higher than for the isolated molecules in the gas-phase ($\Delta E(3)$).

The discussion below applies generally to the gas-phase reactions to which the calculations are directly applicable, but in some cases the conclusions are extended to the liquid phase based on the guidelines discussed above.

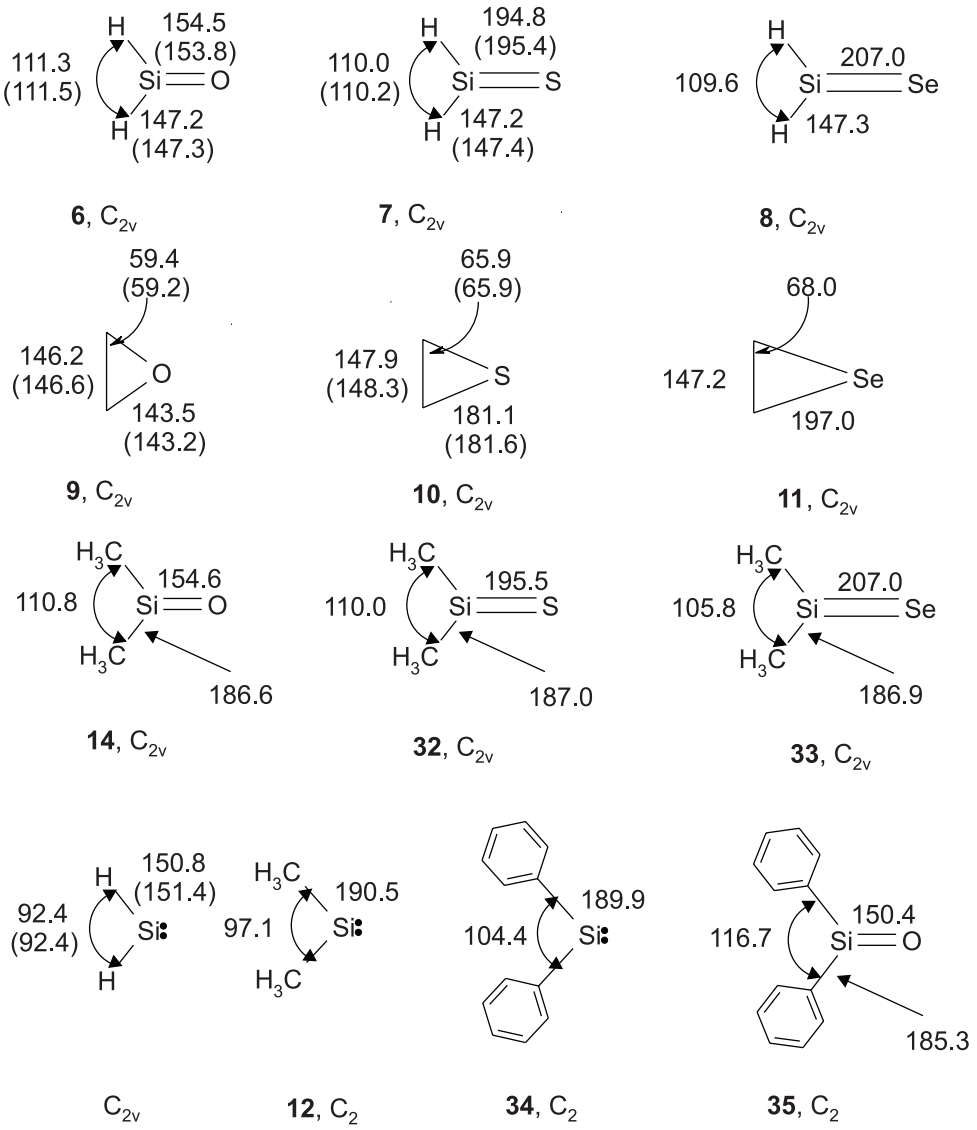
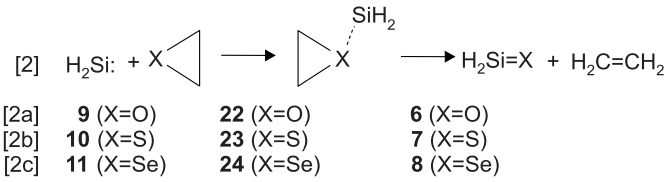
oxirane (eq. [1*a*]), –45.2 for thiirane (eq. [1*b*]) and –52.9 for selenorane (eq. [1*c*]). The calculated reaction enthalpies, $\Delta H°$, are very similar to the $\Delta G°$ values (Table 3). The energies of eqs. [1*a*]–[1*c*] are significantly lower than those calculated for the analogous reactions of singlet methylene, CH_2, ($\Delta H°$ values at MP2, kcal/mol) with oxirane (–110.0), thiirane (–85.8), and selenorane (–80.0). However, although these reactions are highly exothermic, rxns. [1*a*] and [1*b*] are calculated not to occur spontaneously at 298 K even in the gas-phase because significant barriers (ΔG surface) of 7.4 and 7.3 kcal/mol, respectively, separate the reactants from the products. This result has, of course, important experimental consequences which will be discussed below. Only rxn. [1*c*], for X =Se is predicted to occur spontaneously in the gas-phase.

The first step in all three reactions is the attack of H_2Si on the heteroatom X of the three-membered ring to give the corresponding encounter-complex intermediates: (*i*) **22** (X = O, eq. [2*a*]); (*ii*) **23** (X = S, eq. [2*b*]); and (*iii*) **24** ((X = Se, eq. [2*c*]). This step is exothermic and does not involve an energy barrier and it occurs spontaneously both on the enthapy and on the free energy surfaces. However, due to the contribution of entropy this step is much less exothermic (by ca. 9–10 kcal/mol at 298 K) on the ΔG_{298} surface than on the ΔH_{298} surface. The geometries (Table 2) and the electronic nature of the intermediate silylene–XC_2H_4 complexes **22**–**24** are discussed below.



The subsequent reaction steps, leading from the encounter-complex intermediates to the final $H_2Si{=}X + CH_2{=}CH_2$ products, are different for the silylene reaction with oxirane (eq. [2*a*]) and for the reactions with thiirane and selenirane (eq. [2*b*] and eq. [2*c*], respectively), and these reactions are therefore discussed separately.



1. (a) The reaction of silylene with oxirane

The calculated enthalpies and Gibbs free energies (at 298 K) for the reaction between H_2Si and oxirane (rxn. [2*a*]) are shown in Figs. 3*a* and 3*b*, respectively. These figures and the

© 2000 NRC Canada

Fig. 1. Selected optimized geometrical parameters at MP2/6–31G** and QCISD/6–31G** (values in parenthesis) of species of interest. Species **34** and **35** are at HF/6-31G**. Bond lengths are given in pm, bond angles in degrees.

discussion below are based on the QCISD/6-31G** values, which are believed to be the more reliable (the MP2/6-31G** values are given in parenthesis). As pointed out above, rxn. [2*a*], although it is very exothermic, $\Delta G°$ = –56.6 kcal/mol (at QCISD/6-31G**) is predicted not to occur spontaneously at 298 K even in the gas-phase, as it involves a significant barrier (i.e., the PES is of type (*b*) in Fig. 2) on the ΔG surface (Fig. 3*b*). On the other hand at 0 K, where the contribution of entropy is zero (Fig. 3*a*), the reaction is spontaneous (i.e., the PES is of type (*a*) in Fig. 2).

In the first step of the reaction, a donor–acceptor complex between H_2Si and oxirane (**22**), which is kinetically stable, is formed. This step is spontaneous and quite exothermic ($\Delta H°$ = –17 – –20, $\Delta G°$ = –7 – –11 kcal/mol), pointing to a stable complex, which should be detectable spectroscopically at low temperatures. Similar complexes between silylenes and ethers or alcohols have been reported and also characterized spectroscopically (20). The calculated vibrational frequencies of the complexes **22**–**24** are reported in the supplementary material to assist in their future spectroscopic identification. The cleavage of the complex **22** to give the $H_2Si{=}O$ and $H_2C{=}CH_2$ products is also exothermic ($\Delta G°$ = –49.3 kcal/mol), however a significant energy barrier of 14.8 kcal/mol ($\Delta H°$) and 14.9 kcal/mol ($\Delta G°$) (at QCISD/6-31G**, 19.3 and 19.4 kcal/mol, respectively, at MP2/6-31G**) separates **22** from the products. The cleavage of **22** occurs in two steps: in the first step, one of the C—O bonds cleaves via transition state (TS) **26** to give the biradical intermediate **25**, which then fragments (via TS **27**) to produce

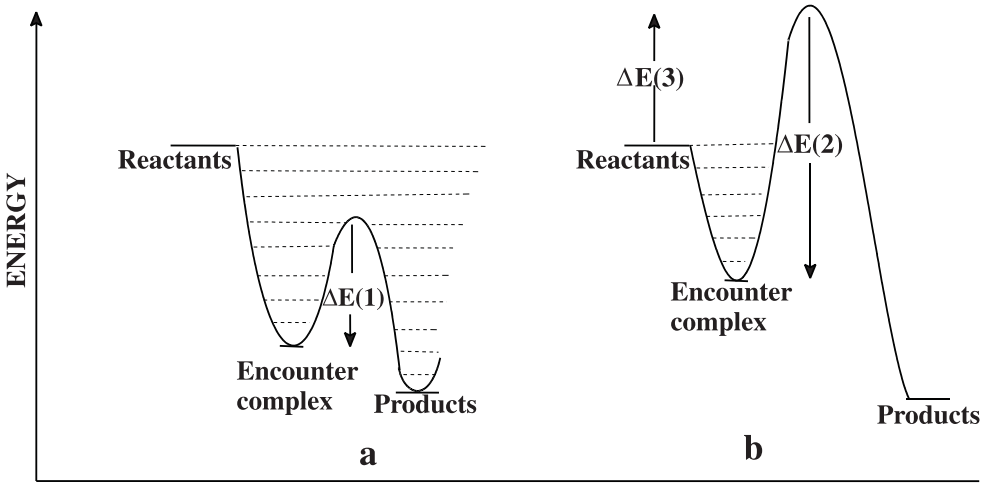
the desired silanone **6** (and ethylene). The biradical intermediate (**25**) lies higher in energy than **22** on both the ΔH and the ΔG surfaces (at QCISD)[2] and as the barrier for its cleavage is only ca. 2 kcal/mol, it is expected to have a very short lifetime.

These computational results are consistent with the only experimental kinetic study of the reaction of dimethylsilylene with oxirane (11*e*). Yet, the high value of the measured rate constant together with the observation of C_2H_4 formation, suggest that the calculated barrier of 14.9 kcal/mol (QCISD) separating **22** from **25** (i.e., TS **26**) is probably too high. This small theoretical–experimental discrepancy may result from real differences in the reactions of H_2Si (used in the calculations) and of $(CH_3)_2Si$ (used experimentally), or from errors in the calculations. B3LYP/6-31G**//B3LYP/6-31G** calculations indeed give a lower barrier of 10.4 kcal/mol for the conversion of **22** to **25** ($\Delta H°$ for the formation of **22** is –16.6 kcal/mol at this level). A more detailed theoretical study of the reaction of $(CH_3)_2Si$ with oxirane, as well as additional experiments are however required to reach a fully consistent theoretical–experimental picture of this reaction.



1. (b) The reaction of H_2Si with thiirane and selenirane

In contrast to the multistep fragmentation of the oxirane–silylene complex **22**, the fragmentation of the analagous S- and Se-complexes (**23** and **24**) to produce the desired products (silanethione **7** or silaneselone **8** (and ethylene), respectively) occurs in a single step via transition states **28** and

[2]At MP2/6–31G** **25** is slightly lower in energy than **22** (Table 1), but based on previous experience with biradicals (e.g., ref. 23) we prefer the QCISD/6–3IG** results.

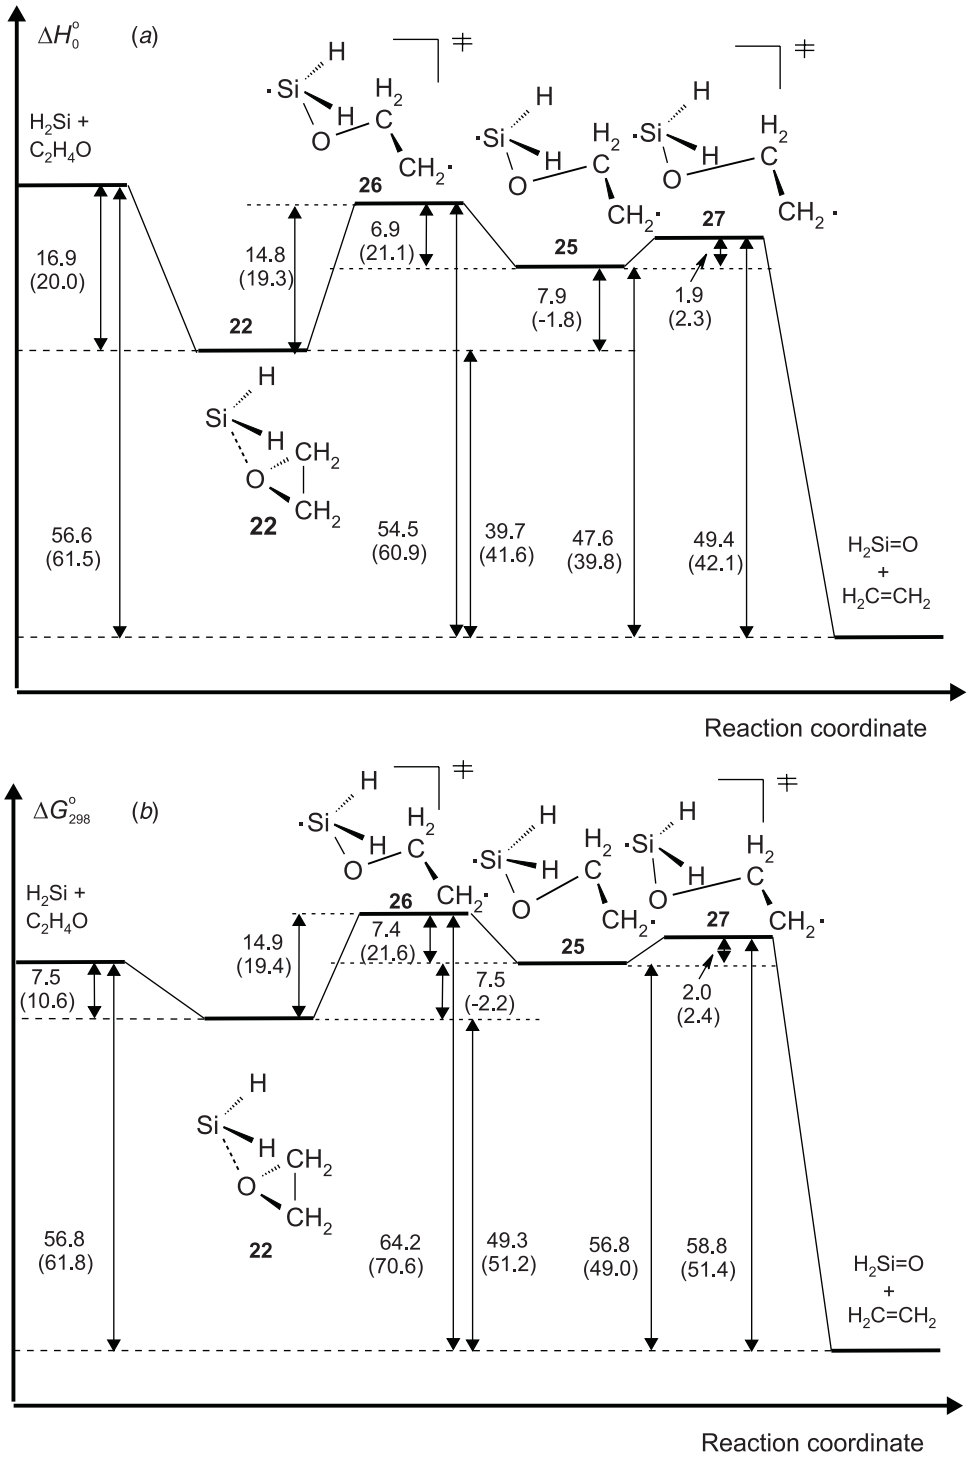
Fig. 2. Schematic potential energy surfaces for an exothermic multi-step bimolecular gas-phase reaction: (*a*) the energy of the reactants is higher than that of the transition state for the conversion of the encounter-complex to products; (*b*) the energy of the reactants is lower than the energy of the transition state for the conversion of the encounter-complex to products.

29, respectively, in which the two C—X bonds are equally elongated.[3]

Reaction [2*b*] and each of its two steps are highly exothermic on both the ΔH and the ΔG surfaces (Fig. 4). Thus, $\Delta H°$ at 0 K for the overall reaction and for the first and second steps are: (QCISD, kcal/mol): –44.2, –16.8, and –27.4, respectively, and $\Delta G°$ = –44.4, –7.6, and –36.8, respectively. However, rxn. [2*b*], similarly to rxn. [2*a*], is spontaneous at 0 K but not at 298 K. The rate-determining step, as in rxn. [2*a*], is the cleavage of the intermediate silylene–thiirane complex **23**. The Gibbs free energy of activation for this step is calculated to be relatively high, ca. 15.0 kcal/mol at both QCISD and MP2 ($\Delta H°$ is very similar, 15.4 kcal/mol).[3] As the complexation energy released in the formation of **23** from the reactants of 7.6 kcal/mol is smaller than the energy required for its fragmentation (14.9 kcal/mol), **23** is predicted to be a long-lived entity even in the gas-phase. This conclusion applies even more strongly to the solution phase, where the energy gained by complexation can be speedily distributed to the environment and therefore it might be possible to observe **23** spectroscopically in matrices (the calculated vibrational frequencies of **23** are given in the supplementary material).



Reaction [2*c*] (Fig. 5) is the only reaction of the three reactions studied here in which no energy barrier exists between reactants and products either on the ΔH or on the ΔG surfaces (i.e., the reaction is of type (*a*) in Fig. 2). Reaction [2*c*] in contrast to rxns. [2*a*] and [2*b*], is therefore predicted to occur spontaneously in the gas-phase, as the barrier for the fragmentation of the silylene–selenirane intermediate **24** ($\Delta G°$ = 7.5 kcal/mol) is significantly lower than the energy released ($\Delta G°$ = –21.8 kcal/mol) upon its formation (Fig. 5). Reaction [2*c*] is predicted to be very facile also in solution as the barrier for the fragmentation of complex **24** is small, only 7.5 kcal/mol.

In summary, the calculations show that rxns. [2*a*]–[2*c*] are highly exothermic, both on the ΔH and ΔG energy surfaces, in the range of –44 – –56 kcal/mol (QCISD/6-31G**) depending on the heteroatom X of the reactant three-membered ring. All reactions proceed via intermediate $H_2Si\cdots XC_2H_4$ donor–acceptor complexes which are formed spontaneously. These complexes are quite stable kinetically (less so for

[3] It is noteworthy that the synchronous single-step fragmentation of the $H_2Si\cdots XC_2H_4$ encounter-complexes, **22–24**, to the corresponding $H_2Si{=}X$ and ethylene is formally a "symmetry-allowed" reaction in a "linear-type" process (see ref. 24). Thus, assuming a linear-type process with C_s-symmetry the relevant occupied orbitals of the reactant (**22**) are: (*i*) the two σ(C—X) bonds — one symmetric (S) and one *anti*-symmetric (A); (*ii*) the Si···X bond (S); (*iii*) and the silylene lone-pair (S). These orbitals correlate with those of the ground state orbitals of the products, $H_2C{=}CH_2 + CH_2{=}X$, i.e., σ(C—X) (S), π(C=X) (S), π(C=C) (S), and the lone-pair on O (A). A close analogy to rxns. [2*a*]–[2*c*] is the abstraction of NR from *N*-alkylaziridines by dichlorocarbenes producing olefins in which the relative configuration of the substituents is retained, indicating a synchronous symmetry-allowed process (see for example ref. 25). However, a closer examination of the reaction reveals that the fragmentation step has, to some extent a "symmetry-forbidden" contribution due to the very high polarity of the $H_2Si{=}X$ molecules which are better described as $H_2Si^+—X^-$ (the calculated charges on X are: –0.96, –0.55, –0.46 for X = O, S, Se, respectively). To better understand this point it is more convenient to analyze the fragmentation reaction in the reverse direction, i.e., as an addition reaction of $H_2Si^+—X^-$ to $CH_2{=}CH_2$. Such a reaction is a symmetry-forbidden $\pi 2s + \omega 2s$ reaction. In agreement with this analysis, the fragmentation reactions of **22**–**24**, although highly exothermic, have significant activation barriers and for X = O, the preferred reaction path is indeed nonconcerted, i.e., it proceeds via a two-step mechanism, as expected for a symmetry–forbidden reaction (a C_s species having two imaginary frequencies and closely corresponding to TS **28** for X = S and to TS **29** for X = Se, is 5.9 kcal/mol higher in energy than the biradicaloid TS **26**) The contribution of the polarity to the degree of symmetry-forbiddeness of the fragmentation reactions is smaller for X = S and Se than for X = O, due to the lower polarity of $H_2Si{=}S$ and $H_2Si{=}Se$ relative to $H_2Si{=}O$, and with these chalcogonites fragmentation occurs in a single step. Another factor contributing to the significant barriers of the fragmentation step is the high degree of electron reorganization required along the fragmentation process (see for example ref. 26).

X = Se) and according to the calculations should be detectable in low-temperature matrices. The cleavage of these complexes is also highly exothermic and in the gas-phase at 0 K it is also spontaneous (i.e., represented by a PES of type (*a*) in Fig. 2). However, at 298 K, even in the gas-phase, the cleavage of the donor–acceptor complex is spontaneous only for X = Se. For X = O and X = S, a significant barrier (ΔG = 7.4 kcal/mol for both reactions) exists and the energy gained in the complexation step is not sufficient to overcome the barrier separating the complex from the products. In solution, where the silylene–XC_2H_4 complexes may have the possibility to relax, the barriers which have to be overcome are larger and become quite significant, i.e., 14.9 kcal/mol for both reactions (at QCISD).

1. (c) The silatane route

Barton (11*b*) and Barton and Goure (11*c*), who studied experimentally the reaction of dimethylsilylene with cyclohexane oxide, pointed out that an alternative mechanism to that shown in Fig. 3, i.e., via the corresponding silaoxetanes (see path A in Scheme 2), could not be excluded. To evaluate the viability of this mechanistic possibility, we have calculated the "silatane route" for the reaction of H_2Si with **9**–**11**, shown in Scheme 5. Our results reveal that the rearrangement of **22** to **30***a* is very sluggish since the calculated barrier $E_a(1)$ is 32.0 kcal/mol. Unfortunately, we could not locate the corresponding transition states connecting the silylene complexes **23**–**24** with the corresponding silatanes **30b**–**30c**, and thus could not compare directly these barriers ($E_a(1)$) with the corresonding barriers for fragmentation of the complexes **23**–**24** to the corresponding $H_2Si{=}X + C_2H_4$, $E_a(4)$ in Scheme 5 ($E_a(4)$ are the barriers to the fragmentation of **22**–**24** given in Figs. 3*a*–3*c*, respectively). However, even without this direct comparison the calculations (at the MP2/6-31G**//MP2/6-31G** level), show clearly (Table 4)

© 2000 NRC Canada

Fig. 5. Calculated reaction scheme (kcal/mol) for eq. [2*c*] at MP2/6–31G**. The relative energies are given in kcal/mol. (*a*) Reaction enthalpies. (*b*) Gibbs free energies at 298 K.

that in solution the silatane route is not a likely mechanism for the production of $H_2Si{=}X$. Thus, the silatanes **30a**–**30c,** even if formed in the reaction, are significantly more stable than the final products of rxn. [2] (i.e., by 31.5, 29.8, 29.9 kcal/mol for X = O, S, and Se, respectively (see $\Delta H(2)$ values in Table 4). Furthermore, the cleavage of the silatanes involves additional activation barriers ($E_a(-2)$ values in Table 4) of 9.9, 11.4, and 8.6 kcal/mol for X = O, S, Se, respectively, so that the overall activation barriers, $E_a(2)$, for the cleavage of the silatanes **30a**–**30c** to the corresponding $H_2Si{=}X$ are 41.4, 41.2, and 38.4 kcal/mol, respectively, (Table 4). Thus, if the silatanes were indeed formed as intermediates in the reactions of silylenes with chalcogenide three-membered rings, they would not be expected to extrude $H_2Si{=}X$ under the reaction conditions used in the literature experiments and therefore they should have been

© 2000 NRC Canada

detected experimentally. At the moment experiments are available only for X = O and in agreement with the above theoretical analysis, silaoxetanes were not detected in solution experiments (11*a*–11*c*, 21)[4]. Also, in gas-phase reactions the silatanes are not expected according to the calculations to be observed experimentally, as the energy released in their production $\Delta H(1)$, far exceeds the energy, $E_a(2)$, required for their fragmentation. This is in agreement with the available gas-phase experiments (11*e*, 21)[4].

Attempts to locate a reaction path connecting directly the reactants with the corresponding silatanes, i.e., a direct insertion of the silylene into the strained C—X bond of the XC_2H_4 molecule (a reaction which is exothermic ($\Delta H(3)$ in Scheme 5) by –97.7, –79.3, and –87.1 kcal/mol (MP2/6–31G**) for X = O, S, and Se, respectively) have failed, but we believe that these pathways are higher in energy than via the silylene–XC_2H_4 complexes.

Our computational results combined with the fact that silaoxetanes were not observed experimentally in these reactions (11) strongly support the conclusion that silaoxetanes are not involved as intermediates in the reactions of silylenes with chalcogenide three-membered rings. The calculations also show that silatanes are not good precursors for the production of Si=X multiple bonds (e.g., via pyrolysis), because the activation barriers for their fragmentation, $E_a(2)$, are high, ca. 38–41 kcal/mol, requiring relatively high reaction temperatures.

2. Reactions of dimethylsilylene and diphenylsilylene with chalcogenide three-membered rings

Do the calculations for the parent H_2Si discussed above apply also to silylenes, which experimentally are used more widely than H_2Si, such as dimethylsilylene and diphenylsilylene? To answer this question we have calculated the reaction enthalpies of rxn. [3] (at MP2/6–31G**//MP2/6–31G**) and of rxn. [4] (at HF/6–31G**//HF/6–31G**). The calculated reaction energies (Table 3) are quite similar to those obtained for the parent rxns. [2*a*]–[2*c*] and although a full scan of the PES was not carried out, this result suggests that alkyl- and aryl-substituted silylenes can also serve as precursors for producing the desired $R_2Si{=}X$ compounds. Of particular interest is the computational prediction that even with the relatively stable Ph_2Si the reaction with oxirane to give $Ph_2Si{=}O$ is still highly exothermic, i.e., by –58.9 kcal/mol. This suggests that it might be possible to use even sterically protected silylenes, such as Mes_2Si and even Tbt_2Si, to produce sterically stabilized silanones, e.g., $Mes_2Si{=}O$ and $Tbt_2Si{=}O$. We encourage experimentalists to test this suggestion.

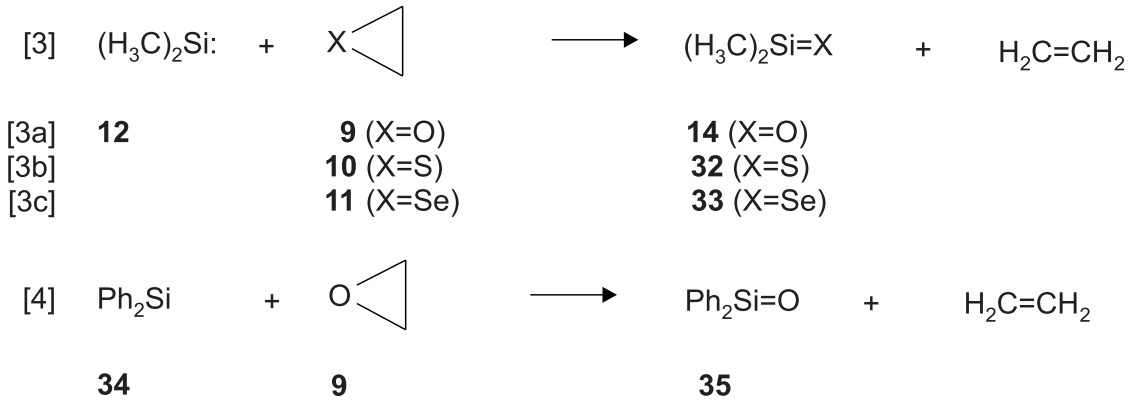

Table 4. Calculated enthalpies and activation energies (kcal/mol) at MP2/6–31G**//MP2/6–31G** for the silatane route (Scheme 5).

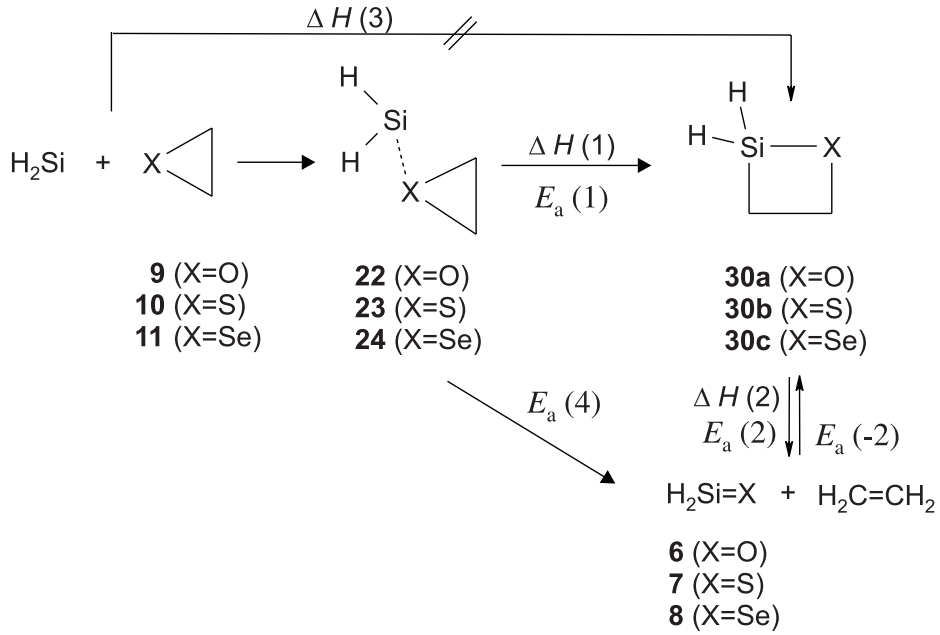
X	$\Delta H(1)$	$\Delta H(2)$	$E_a(2)$	$E_a(-2)$
O	–73.1	31.5	41.4	9.9
S	–54.2	29.8	41.2	11.4
Se	–51.4	29.9	38.5	8.6

Equilibrium geometries

The differences between the QCISD and the MP2 calculated geometries are relatively small (see Fig. 1 and Table 2), and the discussion below is based on the QCISD geometries (except for X = Se, where only MP2 values are available) which are believed to be more reliable.



The doubly bonded compounds: silanone (**6**), silanethione (**7**), and silaneselone (**8**) are all planar, i.e., have C_{2v} symmetry. The calculated Si=X bond lengths (pm) of: 153.8 (X = O), 195.4 (X = S), and 207.0 (X = Se) are all significantly shorter (by ca. 8–9%) than the corresponding Si—X single

[4] For X = O, the silaoxetane **30a** can be formed from the silylene–oxirane complex **22** via ring-closure of the biradical **25**. This ring-closure requires rotation around the Si—O and C—C bonds in **25**. The fact that a silaoxetane was not observed experimentally (11*a*–11*c*, 11*e* indicates that the fragmentation of **25** to $H_2Si{=}O$ and $H_2C{=}CH_2$ is faster than its ring closure to **30a**. This is reasonable, as the activation barrier for the fragmentation of **25** is only ca. 2 kcal/mol and it essentially involves only elongation of the C—O bond, while ring-closure to **30a** requires rotation around two bonds, reducing the dynamic probability of this process (for a discussion of the rates of rotation around C—C bonds in biradicals, see for example ref. 21). The actual substituents used in the experiments, which are significantly larger than H used in the calculations, may further slow down the ring-closure relative to fragmentation. The fact that silaoxetanes were not observed experimentally implies that the free energy of activation for the ring-closure of **25** is by at least 3 kcal/mol higher in energy than that for its fragmentation. For X = S and Se we could not locate the transition state which separates the S–silylene and Se–silylene complexes (**23** and **24**, respectively) from the corresponding silatanes, **30b** and **30c**. We assume that also in these cases these barriers are higher than the corresponding fragmentation barriers to the products (15.4 and 7.5 kcal/mol, respectively), but this point will have to be rechecked when such experiments will become available.

Scheme 5. The silatane route.

bond distances, (166.7, 214.3, 226.6 pm, respectively in H_3SiXH), indicating the multiple bonding nature of the Si=X bond in these molecules. The calculated (H-Si-H) bond angles are: 111.5° (X = O), 110.2° (X = S), and 109.6° (X = Se) and the Si—H bond lengths in all species are 147.3 pm. The calculated QCISD geometry of silanone **6** agrees well with the recently measured experimental values (8*b*) (r(Si=O) = 151.5 pm, r(Si—H) = 147.2 pm, < (H-Si-H) = 112.0°) as well as with the best available calculated geometry at CCSD/TZ2P(f,d)//CCSD/TZ2P(f,d) (8*c*). Substitution of the hydrogens in $H_2Si=X$ by two methyl groups has a minor effect on the geometry of the Si=X.

The calculated charges and geometries of the silylene–XC_2H_4 complexes (Table 2) are consistent with the description of these species as involving a modest donor–acceptor interaction between one of the lone pairs of X (donor) and the vacant 3*p*(Si) orbital (acceptor).[5] Thus, in the encounter complexes **22**–**24**, the calculated total charge transferred from C_2H_4X to the SiH_2 unit (using the Natural Population Analysis at MP2(full)/6–31G**) is: 0.15 el. in **22**, 0.31 el. in **23**, and 0.34 el. in **24**. Consistent with the modest charge transfer is the fact that the Si···X distances in the complexes **22**–**24** are quite long, r(Si—X) = 205.7 (X = O), 239.0 (X = S), and 243.3 (X = Se) pm, in comparison with the corresponding Si—X single bonds in H_3SiXH: 166.7 (X = O), 214.3 (X = S), and 226.6 (X = Se) pm. Similarly, the C—X bond lengths in the complexes are only slightly elongated (by 1–2 ppm) compared to those calculated for the corresponding three-membered ring precursors. The silylene is tilted above the three-membered ring; the Si-X-Y bond angle (where Y is the center of the C—C bond) is 124° for **22,** and ca. 102° for **23** and **24**. Rotation of the silylene around the Si···X axis is facile (barriers of 0.6–2 kcal/mol), with **22** preferring the "inside" conformation (i.e., where the ∠HSiXC dihedral angle is ca. 0°), while **23** and **24** are more stable in the "outside" conformation (e.g., ∠HSiXC is ca. 180°). Although, the geometrical parameters of **22**–**24** indicates a relatively weak complexation, the calculated complexation energies show that these complexes are bound quite strongly; i.e., by 20.0, 20.6, and 31.1 kcal/mol for X = O, S, Se, respectively, (at MP2). This apparent dichotomy between the geometries and the complexation energies reflects the high energies of the Si—X bonds (22).

The transition states for the concerted fragmentation of the silylene–XC_2H_4, X = S, Se intermediates (**28** and **29**, respectively) are structurally similar to those of the corresponding silylene–XC_2H_4 complexes (**23** and **24**, respectively), but they have much shorter Si···X distances (r(Si—X) = 214.4 and 224.5 pm), much longer C—X bonds (r(C—X) = 216.8 and 222.4 pm), significantly shorter C—C bonds (ca. 140 pm) and significantly wider Si-X-C bond angles (ca. 120°), compared to those parameters in the corresponding complexes. Actually, the r(Si—X) distances in **28** and **29** are very close to those of the corresponding Si—X single bonds (214.3 and 226.6 pm for X = S and Se, respectively) and these transition states can be described as occurring relatively "late" along the fragmentation reaction coordinate.

In the silylene–oxirane reaction the intermediate complex **22** undergoes cleavage in two steps: (*i*) first only one of the C—O bonds breaks (via TS **26**) to give the biradical complex **25**; (*ii*) followed by cleavage of the second C—O bond (TS **27**) to give $H_2Si=O$ and ethylene. Along the progression: **22** → **26** → **25** → **27** → **6**, the Si—O bond length is gradually shortened (205.7, 181.0, 169.9, 162.8, and 153.8 pm respectively) and the C—O bond length is gradually elongated (143.2 (**9**), 145.6 (**22**), 185.5 (**26**), 236.0 (**25**), and 244.4 (**27**), pm). The largest differences between the QCISD and MP2 geometries are found for the *biradical* **25** (Table 2).

[5] Silylene–XR_2 complexes are often referred to in the literature as "zwiterionic." According to the calculations this description is not justified and we prefer to refer to them as donor–acceptor complexes.

© 2000 NRC Canada

Conclusions

High level ab initio calculations for the reactions between silylene and oxirane (**9**), thiirane (**10**), and selenirane (**11**) which are possible routes to Si=X double bonds (X = O, S, Se, eqs. [2*a*]–[2*c*]), show that these reactions are highly exothermic ($\Delta H°$ = –61.5, –44.9, and –52.7 kcal/mol for X = O, S, Se, respectively at MP2/6–31G**) and in the gas-phase at 0 K they are also spontaneous. The first step of these reactions involves the barrierless formation of a donor–acceptor complex between the silylene and the X atom of the precursor, C_2H_4X. The reaction steps which follow depend on X. For X = O, fragmentation of the silylene–C_2H_4X complex **22** proceeds in two steps via a biradical intermediate. In contrast, fragmentation of the S (**23**) and the Se (**24**) complexes occurs in a single step. At 298 K in the gas-phase, the contributions of entropy lead for X = O and S, to a small energy barrier (ΔG) of 7.4 kcal/mol on the path between the silylene–XC_2H_4 complex and the products, but for X = Se the reaction is spontaneous also at 298 K. In solution, a barrier of 7.5 kcal/mol separates the silylene complexes from the products also for X = Se and this barrier is somewhat higher (14.9 kcal/mol) for X = O, and S. However, these barriers can be easily surmounted, making these reactions synthetically attractive.

In conclusion, the computational results suggest that the reaction of silylenes with chalcogenide three-membered ring compounds (eq. [1]) is indeed a viable route for the preparation of compounds with a Si=X double-bond (X = O, S, Se), both in the gas-phase and in solution. We call for an experimental testing of this prediction.

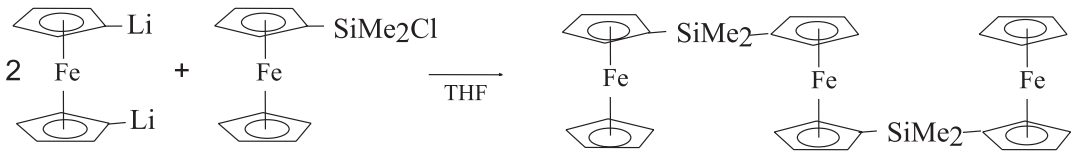
A low temperature reversible phase transition for 1,1′-bis-(ferrocenyldimethylsilyl)ferrocenylene, $(\eta^5\text{-FcSiMe}_2\text{C}_5\text{H}_4)_2\text{Fe}$, an oligomeric model for silyleneferrocenylene polymers

Mikhail Yu Antipin, Ivan I. Vorontsov, Irene I. Dubovik, Vladimir Papkov, Francisco Cervantes-Lee, and Keith H. Pannell

Abstract: We have reinvestigated the solid state structure of 1,1′-*bis*-(ferrocenyldimethylsilyl)ferrocenylene, $(\eta^5\text{-FcSiMe}_2\text{C}_5\text{H}_4)_2\text{Fe}$, Fc = $(\eta^5\text{-C}_5\text{H}_5)\text{Fe}(\eta^5\text{-C}_5\text{H}_4)$. Using a DSC technique we observed a reversible phase transition for this compound at 169(3)K with ΔH = 1.1 kJ/mol, and ΔS = 6.54 J/mol K. A single crystal X-ray diffraction study has demonstrated that this phase change involves a transformation from a high temperature phase, space group $P2_1/c$, Z = 2, to a triclinic low temperature phase, space group $P\bar{1}$, Z = 4. The phase transition involves the loss of the molecular crystallographic center of symmetry and rotations about the terminal and central cyclopentadienyl ring pairs. The results are compared to those reported for ferrocene.

Key words: solid state, phase transition, silyleneferrocenylene.

Résumé : On a réexaminé la structure à l'état solide du 1,1′-*bis*-(ferrocényldiméthylsilyl)ferrocénylène, $[\eta^5\text{-FcSiMe}_2\text{C}_5\text{H}_4)_2\text{Fe}$, Fc = $\eta^5\text{-C}_5\text{H}_5)\text{Fe}(\eta^5\text{-C}_5\text{H}_4)]$. Faisant appel à la technique de l'analyse calorimétrique différentielle (ACD), il a été possible d'observer une transition de phase réversible pour ce composé à 169(3)K, avec un ΔH de 1,1 kJ/mol et un ΔS de 6,54 J/mol K. La diffraction des rayons X par un seul cristal a permis de démontrer que ce changement de phase implique une transformation d'une phase de température élevée, groupe d'espace $P2_1/c$ avec Z = 2, vers une phase triclinique de température plus faible, groupe d'espace $P\bar{1}$ avec Z = 4. La transition de phase implique la perte du centre de symétrie cristallographique moléculaire et des rotations autour les paires de cycles cyclopentadiényles centraux et terminaux. On compare ces résultats avec ceux rapportés pour le ferrocène.



Mots clés : état solide, transition de phase, silylèneferrocénylène.

[Traduit par la Rédaction]

Introduction

The potential of inorganic-based polymers to produce materials with novel electrical, electrooptic and physical properties has been understood for some time (1). Ferrocene is a compound of particular interest since it forms easily handled, thermally stable materials, but has a readily accessible and useful redox system (2). Early attempts to make group 14 [1]-ferrocenophanes often resulted in the formation of oligomeric materials (3); however, more recently the thermal, anionic, and transition metal-catalyzed ring opening of such ferrocenophanes has been shown to produce a range of well-behaved high molecular weight polymers (4–6). Such polymers can be semi-crystalline or amorphous depending upon the various substituents on the group 14 element and the thermal history of the sample.

Models of the structures of such polymers have been published and the structures of oligomeric complexes have been determined by single crystal X-ray diffraction (4, 5). We have published the synthesis and the structure of 1,1′-*bis*-(ferrocenyldimethylsilyl)ferrocenylene, $(\eta^5\text{-FcSiMe}_2\text{C}_5\text{H}_4)_2\text{Fe}$ (**1**), eq. [1] (5*e*):

We also synthesized **1** by the addition of ferrocenyllithium with 1,1′-*bis*-(chlorodimethylsilyl)ferrocene (5*e*) and the Manners group isolated **1** (4*g*), along with other oligomers, from the anion-catalyzed ring opening of [1]-(dimethylsilylene)ferrocenophane. The crystal structure of **1** derived from data obtained at room temperature showed the terminal ferrocenyl groups to be orthogonal to the central group and although the structure was satisfactory, we observed that certain portions of the molecule exhibited very large thermal motions. We have revisited the structure of **1** and now report a low-temperature study which demonstrates that it undergoes a reversible phase change at approximately 160 K. This phase change can also be observed and quantified by differential scanning calorimetry.

Experimental section

Differential scanning calorimetric measurements were performed with a DSM-3 calorimeter (Pushino Biopribar, Russia) using a sample of 18 mg and a heating/cooling rate of 8 K/min.

X-ray diffraction analysis was carried out for single crystal samples with the approximate dimensions 0.20 × 0.20 × 0.35 mm at two temperatures 185 ± 2 (HT) and 135 ± 2 K (LT). Fast cooling in the temperature interval near the phase transition severely reduced the diffraction quality of the crystal (the width of the diffraction maxima increased significantly). Thus, before data collection for the LT-phase at 135 K the sample crystal was cooled slowly (≈ 30 K/h) from 180 to 135 K and this preserved the diffraction quality of the single crystal.

Unit cell parameters and intensities of reflections for both HT and LT phases were measured with two different samples of **1** using 4-circle diffractometer (Siemens P3/PC, MoKα-radiation, λ = 0.71073 Å, graphite monochromator, θ/2θ-scan, 2θ ≤ 50°, scan range in ω = 1.80 deg) equipped with a low-temperature device. To establish precisely the temperature dependence of the unit cell dimensions and the relationship between the two phases during the phase transition, special measurements of the unit cell parameters and unit cell volume were performed at eight temperature points in the temperature interval 200–130 K. During this process the crystal sample was cooled at a rate about 8 K/h.

Both structures were solved with the direct methods and refined by least-squares in the anisotropic approximation for non-hydrogen atoms. Hydrogen atoms were placed at the calculated positions and refined with a riding-model. All calculations were made with a personal computer using SHELXTL PLUS program package. Selected crystal data and results of the refinement for both HT and LT phases are summarized in Table 1. No absorption correction was applied because it was small (μ = 1.54 mm^{-1}) and extinction corrections were found to be negligible.

Atomic coordinates and their displacement parameters for the non-hydrogen atoms in both structures are given in Supplementary Materials, selected bond lengths and bond angles are presented in Table 2. Figure 1 shows a general view of the molecule **1** at 185 K (HT phase) and one of the two independent molecules of **1** in the LT phase in projection on the planes of the central five-membered rings.

Results and discussion

By DSC analysis we established that a phase transition in **1** takes place at the temperature 169 ± 3 K. Upon heating a sample of **1** at a rate of 8 K/min it displayed a small but very sharp endothermic peak centered at 169 K. The cooling runs of the same sample (also at 8 K/min) revealed the expected exothermic event; the DSC traces are presented in Fig. 2.

Table 2. Selected bond lengths (Å) and bond angles (deg) in the structure of (1).[a]

Parameter	185 K	135 K	Room temp.
Bond lengths			
Fe(1)—C(1)	2.054(4)	2.061	2.065(4)
Fe(2)—C(6)	2.052(5)	2.053	2.062(6)
< Fe—C(Cp) > $_{centr}$	2.041	2.045	—
< Fe—C(Cp) > $_{term}$	2.031	2.033	—
Si—C(1)	1.842(5)	1.842	1.861(6)
Si—C(6)	1.866(4)	1.870	1.870(5)
< Si—C(Me) >	1.843(9)	1.863	1.860
Bond angles[b]			
X-Fe(1)-X′	180.0	177.4 / 177.1	—
X-Fe(2)-X′	179.0	172.9–178.6	—
C(1)-Si-C(6)	107.6(2)	108.1	—
Me-Si-Me	108.7(4)	111.1	—

[a]For chemically equivalent bond lengths and angles averaged values are given, for data at 135 K the results are averaged for both independent molecules as well. The mean standard deviation in the Fe—C bond lengths at 135 K is 0.01 Å. Atomic numbering scheme corresponds the data at 185 K. For comparison, available data for the same structure at room temperature from ref. (1) are given.

[b]X and X′ are Cp-ring centroids.

The areas of the *exo*- and the endothermic peaks are essentially identical and analysis provides the enthalpy and entropy of the phase change as 1.1 KJ/mol and 6.54 J/mol K respectively. Such values are typical for phase transitions in molecular crystals (7). In particular it should be noted that a similar phase transition has been reported for solid ferrocene itself at 163.4 K with the enthalpy and entropy parameters of 0.87 KJ/mol and 5.32 J/mol K, respectively, (8).

Two low temperature X-ray diffraction experiments were performed on either side of the transition temperature noted by DSC, i.e., at 185(2) (HT) and 135(2) K (LT). From the unit cell parameters it is clear that the phase transition is accomplished by a doubling of the unit cell volume and the changing of the crystal symmetry. The latter changes from the monoclinic HT phase (space group $P2_1/c$, $Z = 2$, molecules in the inversion centers) to a triclinic LT phase (space group $P\bar{1}$, $Z = 4$, two independent molecules in the unit cell).

The molecular geometry parameters (bond lengths and bond angles) in each of the two crystal phases of **1** have values that are essentially the same as those previously published for the monoclinic modification of **1** measured at room temperature (*4g*, 5*e*). These data are compared in Table 2. For both phases the mean Fe—C distances in the central ferrocenylene fragments are systematically larger than in the terminal ferrocenyl groups. This can be explained by the steric demands of the two bulky Me_2SiFc-substituents. In addition, the corresponding Fe—C_{ipso} bond lengths are also systematically larger than all other Fe—C bonds.

The Si atoms have a distorted tetrahedral coordination, the bong angles C(1)-Si-C(6) being slightly smaller than the corresponding Me-Si-Me angles; however, the scatter of the individual values is rather large. All Si atoms deviate from the mean ring planes by 0.02–0.03 Å in the directions opposite to the Fe atoms. In all the molecules, for both phases of **1,** the endocyclic C-C(Si)-C angles in the rings are smaller (by ~4.0°) in comparison with other similar angles (i.e., 104.6° vs. 108.5°). The terminal ferrocenyl fragments are slightly bent with dihedral ring angles in the range 0.7–4.3° and the angles X-Fe-X′ (X and X′ are centroids of the rings) in the range 172.9–178.6°. The Cp rings of the central ferrocenylene fragment in the monoclinic phase are strictly parallel due to a crystal symmetry. The pseudo-torsion angles Fe-Si-Si-Fe characterizing the relative orientation of the Fc-fragments are equal to 180.0° for monoclinic phase (atoms Fe(1), Si(1), Fe(2), Fe(1a), Si(1a), and Fe(2a) are strictly coplanar), and 175.7°, 172.3° for triclinic phase (angles Fe(1)-Si(1)-Si(2)-Fe(3) and Fe(4)-Si(3)-Si(4)-Fe(6), respectively). The angles Si(1)-Fe(2)-Si(2) and Si(3)-Fe(5)-Si(4) are close to linear (166.9 and 167.5°), so all Fe and Si atoms in the molecule are almost coplanar.

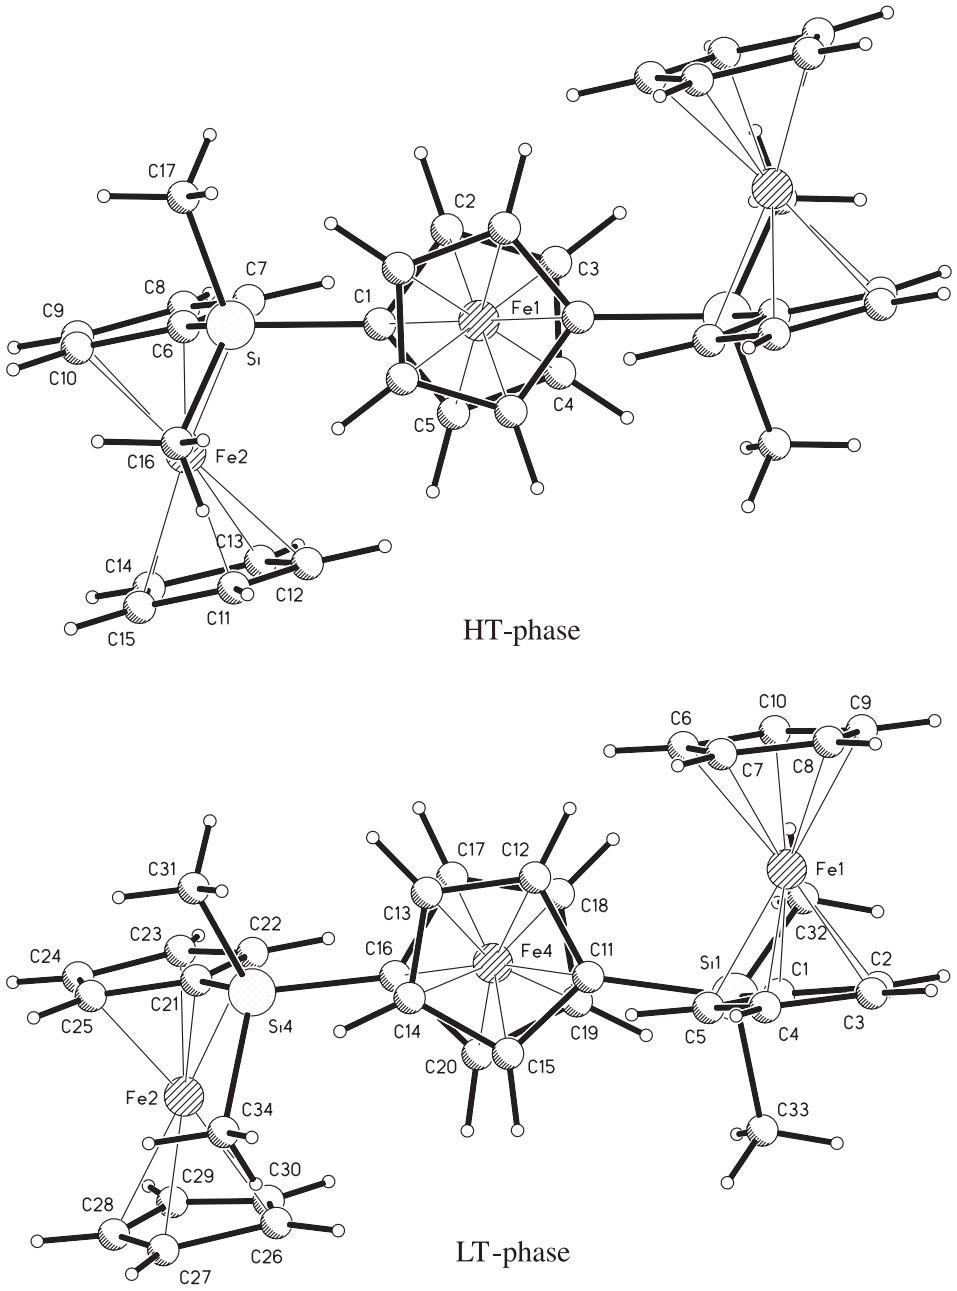

Table 3. Mutual orientation of the 5-member rings (degrees) in monoclinic (HT) and triclinic (LT) phases of (1). Values X and X′ are centroids of the rings and Cp/Cp are interplanar angles.

	HT phase	LT phase
Central rings		
Fe(1) : C(1)-X-X′-C(3a)	36.0	—
Cp / Cp and X-Fe(1)-X′	180.0 and 180.0	—
Fe(2) : C(11)-X-X′-C(19)	—	15.3

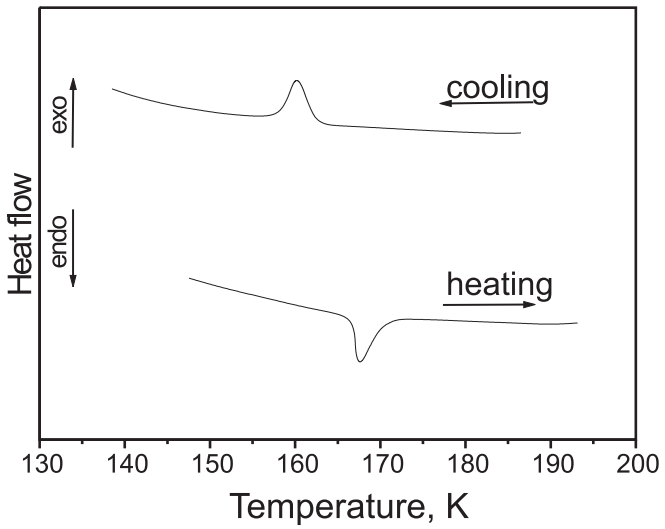
Fig. 1. General view of the molecule **1** in the HT- and LT-phase(one of the two independent molecules) and atomic numbering scheme. Molecules are shown in projection on the central ring planes.

eclipsed, or intermediate) of the cyclopentadienyl groups in the central and terminal ferrocenylene and ferrocenyl fragments. The parameters describing various orientations of rings for both phases are presented in Table 3.

At room temperature and 185 K, in accord with the crystal symmetry, the central ferrocenylene fragment has an ideal staggered conformation of rings, Fig. 1. In the terminal ferrocenyl fragments the orientation of the rings is close to the eclipsed one (torsion angle C(6)-X-X′-C(11) = 6.1°) with a very small ring bending (angle X-Fe(2)-X′ = 179.0°, dihedral angle = 1.3°).

The phase transition is accomplished by a loosening of the molecular and crystallographic center of symmetry, and in the LT phase the central rings have an intermediate orientation between the eclipsed and staggered ones (torsion angles C-X-X′-C = 15.3 and –17.8°, see Table 3), Fig 1. Some small bending of the central Fc-fragment is also observed. In the terminal ferrocenyl fragments the ring orientation is also intermediate (ring rotation angles from 10.3 to –28.3°), and for some of them, in particular for the Fe(3) atom, it is even closer to staggered. Thus, during the phase transition both the central and terminal Fc-fragments have changed a mutual ring orientation.



The present result is close to that exhibited for the parent compound ferrocene, $Fe(C_5H_5)_2$, which has a well-established phase transition at 164 K. This transition occurs from a disordered monoclinic high-temperature phase (space group $P2_1/a$, $Z = 2$) to the low-temperature triclinic one with

two independent molecules in the unit cell. For the high-temperature phase, due to the crystal symmetry, the molecules must possess D_{5d} symmetry. However, this is not the case since an analysis of the atomic anisotropic displacement parameters clearly indicated that the structure is characterized by the static disorder related to a superposition of a few ring orientations in the crystal. It has been shown (9) that two independent molecules in the ordered triclinic low-temperature phase of ferrocene have approximate D_5 symmetry, but are neither eclipsed nor staggered. A very similar situation is observed for **1**. However, our analysis of the high-temperature data for **1** did not reveal clearly the central ring disorder although for both sets of HT data (room temperature and 185 K) there is some extra elongation of the central ring atom thermal ellipsoids.

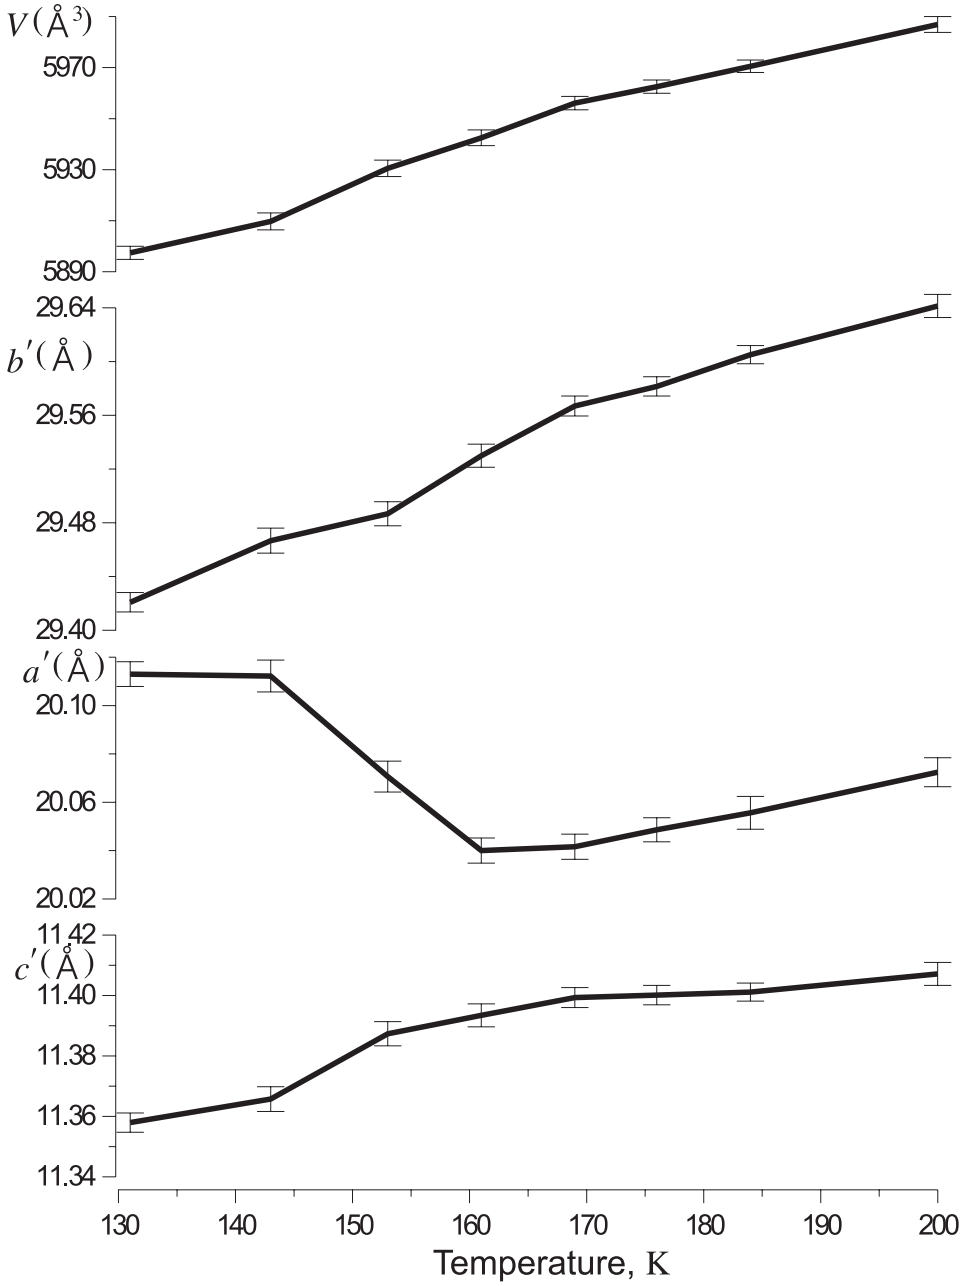
The data on the temperature dependence of the unit cell parameters of **1** are presented in Table 4. For better comparison of the two unit cells their initial parameters (Table 1) were transformed to their similar crystal settings. Thus, the monoclinic HT phase was transformed into a new monoclinic phase ($P2_1/n$) with the a', b', c' axes and the monoclinic angle β' = 118.63(2)°, and the triclinic LT phase was transformed into a *C*-centered triclinic phase with new parameters a' and b' doubled in comparison with those in the HT phase. The corresponding transformation matrices are given below

HT-phase, from β to β' monoclinic setting LT-phase, from triclinic P to triclinic C-centered setting

$$\begin{pmatrix} a' \\ b' \\ c' \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & -1 & 0 \\ -1 & 0 & -1 \end{pmatrix} \begin{pmatrix} a \\ b \\ c \end{pmatrix} \qquad \begin{pmatrix} a' \\ b' \\ c' \end{pmatrix} = \begin{pmatrix} 1 & 1 & 0 \\ -1 & -1 & -2 \\ -1 & 0 & 0 \end{pmatrix} \begin{pmatrix} a \\ b \\ c \end{pmatrix}$$

The temperature dependence of these parameters is presented in Figs. 3 and 4 where the a' and b' values for HT phase were doubled, and the unit cell volume was multiplied by the factor of 4 for a more clear comparison of the data.

It is seen from these data that on cooling the crystal, the $b'$and c' parameters smoothly decrease, while a' attains a minimum at nearly 160 K, and then increases. This behaviour correlates with the estimated temperature of the phase transition at about 159 K. The α' and γ' angles which are very close to ideal value of 90° above the transition point ($\Delta\alpha'$ and $\Delta\gamma'$ are less than 3σ), deviate significantly from this value below the transition point, and at 131 K the corresponding deviations $\Delta\alpha'$ and $\Delta\gamma'$ are equal to 0.35(2) and 0.25(2)°. The β' angle is increased on cooling by 0.56(2)°. In principle, the LT phase could be considered as strongly distorted pseudo-monoclinic *C*-centered, and some non-direct indications were found for it, namely the presence of small number of weak additional reflections at 143 K corresponding to this setting. Nevertheless, our attempts to solve and (or) refine the structure of this phase in the *C*-centered monoclinic space group failed. We believe therefore that the true symmetry of the LT phase is triclinic, and only for easy comparison with the HT-phase it might be transformed to monoclinic *C*-centered one.



Concluding remarks

The phase transition we have observed in **1** is related to the change of C_i-symmetry of the central ferrocenyl fragment at the transition point. In this respect the transition might be similar to those found in 3d and 4d metallocenes, namely ferrocene (9) or decamethylosmocene (10). In the HT phase of decamethylosmocene the Cp* rings are strictly eclipsed (space group $P2_1/m$, Z = 2), and below the transition (in the LT phase crystal space group is $P2_1/c$, Z = 4) there is some small but significant mutual ring rotation that increases gradually on further cooling the sample.

This is probably not the case for **1** where the transition is much closer to that in ferrocene. The fact that during this transition the ring orientation changes, and both central and terminal ferrocenyl fragments are involved in this process, allows one to suggest that transition might result from an

Fig. 3. Temperature dependence of the unit call dimensions in **1**. The values shown for *a*, *b*, *c* and *V* are given as 2*a′*, 2*b′*, *c′* and 4*V* (HT-phase in the β-monoclinic setting, see explanations in the text) at $T > 160$ K (transition temperature), and *a′*, *b′*, *c′* and *V* (LT-phase, C-centered triclinic cell) at $T < 160$ K.

interplay between intermolecular and intramolecular interactions among the ferrocene moieties. The occurrence of a similar transition in higher molecular weight dimethylsilylferrocenylene oligomers and polymer is therefore an interesting issue in further investigation.

The temperature dependence of the unit cell volume in crystal of **1** is also of special interest. As shown in Fig. 3, there is no sharp change in the volume of the doubled cell near the transition point. In this respect the transition appears to proceed nearly continuously although it is accompanied by the well-defined but small sharp change in the enthalpy of the crystal (1.1 kJ/mol).

Preparation and characterization of organic-inorganic hybrid materials incorporating diphosphino moieties. Study of the accessibility of the phosphorus atoms included into the material

Jean-Philippe Bezombes, Claude Chuit, Robert J.P. Corriu, and Catherine Reyé

Abstract: The hydrolysis-polycondensation by the sol-gel process of the aromatic diphosphines $(X_3SiC_6H_4)_2PC_6H_4P(C_6H_4SiX_3)_2$, which are rigid molecules bearing four hydrolysable SiX_3 groups (X = O^iPr, H), leads to new organic-inorganic hybrid materials, characterized by solid state ^{13}C, ^{29}Si, and ^{31}P NMR spectroscopies. The accessibility of the phosphorus centres incorporated into the xerogel obtained from the diphosphine with X = O^iPr has been studied. All the phosphorus atoms reacted quantitatively with H_2O_2, S_8, and CH_3I but only 20% with the more bulky reagent $W(CO)_5$·THF. This result is explained by the rigidity of the inorganic network resulting from the high number of hydrolysable Si-O^iPr groups in the precursor.

Key words : Diphosphines, sol-gel process, xerogels, solid ^{31}P NMR.

Résumé : L'hydrolyse-polycondensation via le procédé sol-gel des diphosphines aromatiques $(X_3SiC_6H_4)_2PC_6H_4P(C_6H_4SiX_3)_2$, molécules rigides portant quatre groupements SiX_3 hydrolysables (X = O^iPr, H), conduit à de nouveaux matériaux hybrides organique-inorganiques qui ont été caractérisés par la RMN à l'état solide du ^{13}C, du ^{29}Si et du ^{31}P. L'étude de l' accessibilité des centres phosphorés incorporés dans le xérogel obtenu à partir de la diphosphine avec X = O^iPr est décrite. Tous les atomes de phosphore réagissent quantitativement avec H_2O_2, S_8, et CH_3I, mais seulement 20% réagissent avec $W(CO)_5$·THF réactif plus volumineux que les précédents. Ce résultat est expliqué par la rigidité du réseau inorganique qui est la conséquence du nombre élevé de groupements hydrolysables Si-O^iPr porté par le précurseur.

Mots clés : diphosphines, procédé sol-gel, xérogels, RMN solide ^{31}P.

Introduction

The sol-gel process allows the preparation of organic–inorganic hybrid materials under smooth conditions (1–4). In a recent publication (5) we described the preparation of phosphines **1**, **2**, and **3** as well as their hydrolysis and polycondensation via the sol-gel process, giving rise to the corresponding xerogels. The accessibility of the phosphorus centres included in these xerogels was investigated by using some classical reactions at phosphorus. We found that the phosphorus centres react quantitatively with H_2O_2, S_8, and MeI, whilst their reactivity towards $W(CO)_5$·THF (6) varied depending on the xerogel studied. We noticed that the phosphorus atoms became more readily accessible when the number of $Si(OR)_3$ groups in the precursor is low. Thus the phosphorus atoms in the xerogel derived from precursor **1** (with two $Si(O^iPr)_3$ groups) reacts more readily with $W(CO)_5$·THF than when included into the xerogels derived from precursors **2** and **3** (with three SiX_3 groups).

As a continuation of this study, we prepared the aromatic diphosphines **4** and **5** (with four SiX_3 groups) and studied their hydrolysis and polycondensation as well as the accessibility of the phosphorus centres included into the xerogel **X4** obtained from the diphosphine **4**. This diphosphine was chosen with rigid substituents around the phosphorus centres as in the case for the phosphines **1** and **2**. This study was undertaken to verify if the high number of $Si(O^iPr)_3$ groups in the precursor **4** gives rise to a low accessibility of the phosphorus centres included into the corresponding xerogel as predicted by our previous study (6).

Results and discussion

1) Preparation of diphosphines 4 and 5 and of phosphine derivatives 7–9.

The diphosphine **4** was prepared in 53% yield by reaction of the previously described functional Grignard reagent **6** (5) with *P,P,P′,P′*-tetrachloro-*p*-phenylenediphosphine (7) in

Scheme 2.

THF (Scheme 1). $LiAlH_4$ reduction of **4** gave the diphosphine **5** in good yield (Scheme 1). Treatment of **4** by methyl iodide, BH_3·THF, and $W(CO)_5$·THF gives rise respectively and quantitatively to the diphosphonium salt **7**, to the diphosphine borane complex **8**, and to the diphosphine tungsten pentacarbonyl complex **9** (Scheme 2).

2) Sol-gel processing of diphosphines 4 and 5 and of diphosphine derivatives 7–9

We previously showed (5) that phosphines **1** and **2** required an acidic catalyst to be hydrolyzed, therefore diphosphine **4** was hydrolyzed and polycondensed with 6 equivalents of water in the presence of 10% of HCl in THF solution (eq. [1] and Table 1). At 30°C, the gelation occurs within 2 h which is close to the gelation time for phosphine **2** (5). Xerogel **X4** was obtained after ageing at 30°C for five days. It was then powdered and washed twice with ethanol, acetone, and diethyl ether and dried in vacuo at 120°C for two hours. The solid state ^{31}P NMR spectrum of **X4** displays only one signal at –5.0 ppm which indicates that no oxidation of the phosphorus atom occurred during the sol-gel process. The solid state ^{13}C NMR spectrum of **X4** displays one signal at 134.4 ppm attributed to the aromatic carbons and two further signals at 24.8 and 66.7 ppm attributed to remaining O^iPr groups. Thus the hydrolysis is incomplete; however the elemental analysis indicates that only about 10% of the $Si(O^iPr)_3$ groups were not hydrolyzed. The solid state ^{29}Si NMR spectrum of **X4** displays two main resonances at –60.5 ppm [substructure T^1, C-$Si(OR)_2OSi$] and –69.1 ppm [substructure T^2, C-$Si(OR)(OSi)_2$]. A minor resonance assigned to the substructure T^3 [C-$Si(OSi)_3$] was observed while substructure T° was absent. The ratio of the T groups was estimated from deconvoluted T peaks (8, 9) at 42% for T^1, 52% for T^2, and 6% for T^3 corresponding to a degree of condensation τ of 55%.[2] Thus while the hydrolysis is important, the polycondensation is rather weak. The absence of any Q signal corresponding to the SiO_4 substructure (region of –100ppm) is noteworthy indicating that the

[2] The degree of condensation was calculated according to the equation: $\tau = [(0.5)(\text{area } T^1) + (1.0)(\text{area } T^2) + (1.5)(\text{area } T^3)]/1.5$.

integrity of the organic moiety had been maintained during the sol-gel process. The surface area (N_2 BET measurement) is of 460 m^2/g, value comparable to that found for the hydrolysis of phosphine **2** (Table 2). The adsorption–desorption isotherms for **X4** indicated that the solid is microporous with a microporous volume of 0.182 mL g^{-1} and mean pore diameter of 15.5 Å.

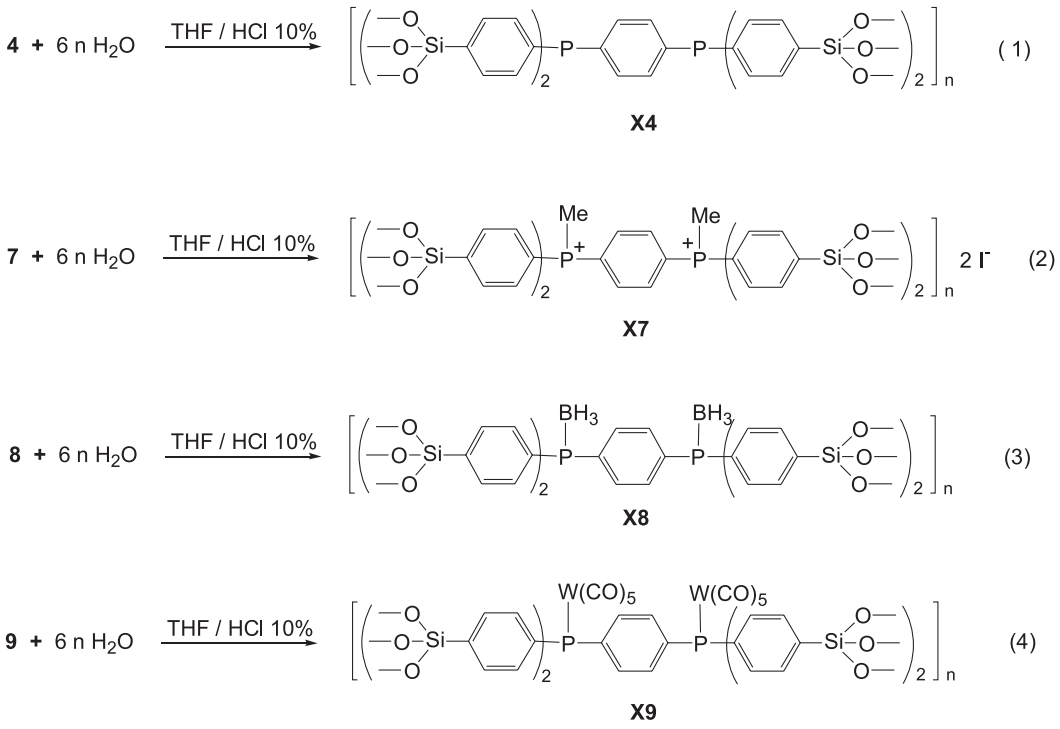
The hydrolysis of diphosphine **5** was performed in THF solution in the presence of a catalytic amount of tetrabutylammonium fluoride (10) with 6 equivalents of water. The reagents were mixed at 0°C and the solution was allowed to warm to 24°C after 8 min. The gel was formed after 30 h. After the usual work-up, xerogel **X5** was obtained. Its N_2 BET surface area was found of 570 m^2 g^{-1}, with a microporous volume of 0.247 mL g^{-1}. There is no oxidation of the phosphorus atoms during the hydrolysis as indicated by the solid state ^{31}P NMR spectrum of **X5** which displays only one signal at –5.1 ppm. The solid state ^{29}Si NMR spectrum of **X5** displays a set of three resonances at –61.6 ppm (substructure T^1), –69.3 ppm (substructure T^2), and –77.0 ppm (substructure T^3); and a broad resonance (–50 to –30 ppm) corresponding to $CSi(H)O_2$ substructures. This is consistent with the FTIR spectrum which shows a Si—H absorption band at 2160 cm^{-1}. No peak corresponding to an SiO_4 substructure was found around –100 ppm indicating that no Si—C cleavage occurred during the sol-gel process.

Phosphorus derivatives **7**–**9** were hydrolyzed and polycondensed under the same conditions as those previously described for phosphine **4** to give xerogels **X7**-**X9** (eqs. [2]–[4] and Table 1). The solid state ^{31}P NMR spectra of xerogels **X7** and **X9** showed that there was neither oxidation nor decomplexation during the polycondensation reactions. In the case of the diphosphine derivative **8** partial decomplexation took place during the hydrolysis. The P—B bond cleavage was estimated by ^{31}P NMR spectroscopy to be about 40% after reaction without drying the xerogel. After heating for one night at 120°C, the cleavage of the P—B bond was increased to 70%. This P—B bond cleavage occurred probably either by hydrolysis or by reaction of the Si-OH present in the xerogel or by both processes. The participation of the Si-OH groups in the cleavage of the P—B bonds is likely as elemental analysis showed that most of the B atoms are incorporated in the xerogel after washing, probably as Si-O-B groups.

Thus the behaviour of diphosphines **4** and **5** and diphosphine derivatives **7**–**9** during the hydrolysis process is very similar to those of phosphines **2** and **3** as well as that of the corresponding derivatives of phosphine **2** (5).

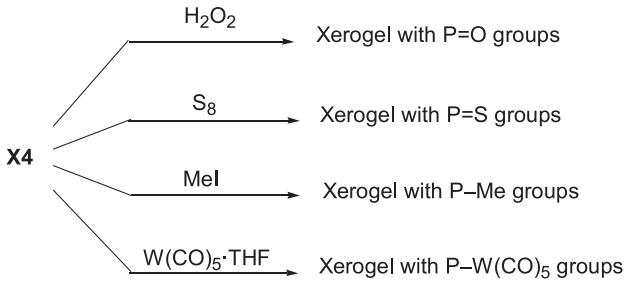
3) Reactivity of the xerogel X4 with H_2O_2, S_8, CH_3I, and $W(CO)_5$·THF

To investigate the accessibility of the phosphorus centers included into **X4**, we treated it with an excess of the following reagents: H_2O_2, S_8, CH_3I, and $W(CO)_5$·THF (Scheme 3).



First we studied the oxidation of the phosphorus centres by reacting **X4** with an aqueous solution of H_2O_2 (60 equiv). The solid state ^{31}P NMR spectrum of the resulting xerogel showed the absence of the signal attributed to the phosphino group (–5.0 ppm) and the presence of a signal at 28.1 ppm assigned to the phosphine oxide centers (5).

X4 was treated with sulphur (13 equiv) in *n*-butanol heated under reflux for 48 h. The solid state ^{31}P NMR spectrum of the resulting xerogel exhibited only a signal at 41.3 ppm assigned to the thiophosphoryl centres (5).



Treatment of **X4** with an excess of methyl iodide for 48 h in toluene heated under reflux gave rise to a xerogel, the solid state ^{31}P NMR spectrum of which displayed a signal at 21.5 ppm, close to that for **X7** (δ = 22 ppm). This signal indicates that all the phosphino groups were transformed into phosphonium salts.

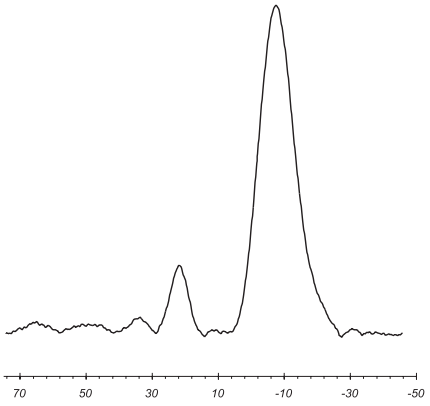
Finally **X4** was treated with an excess of $W(CO)_5$·THF (4 equiv) in THF heated under reflux for 96 h. After the usual work-up, FTIR analysis of the resulting xerogel revealed the presence of the same CO stretching bands as those observed in **X9**, which characterize the expected $LW(CO)_5$. The solid state ^{31}P NMR spectrum of this xerogel displays a weak signal at 22.0 ppm corresponding to about 20% of complexed

© 2000 NRC Canada

Scheme 3.

phosphino centres and a large signal at –7.3 ppm corresponding at about 80% of unchanged phosphino groups (Fig. 1). Thus, most of the phosphino groups in xerogel **X4** are not accessible by $W(CO)_5$·THF under the conditions used for the reaction.

Discussion



All the phosphorus atoms of the xerogel **X4** are accessible to the small reagents H_2O_2, S_8, and CH_3I as was previously observed for the xerogels **X1** and **X2** obtained from the phosphines **1** and **2** respectively (Table 2) (5). In contrast, the reaction with the rather bulky reagent $W(CO)_5$·THF allowed discrimination between the xerogels **X1**, **X2**, and **X4**. Indeed, only 20% of phosphorus atoms included into **X4** were complexed by $W(CO)_5$ while the complexation was complete for **X1** and was 80% for **X2** (Table 3).

In our previous publication (6) we have observed that the average number (N) of Si-O-Si bonds attached to each organophosphorous moiety in the material was an important parameter controlling the accessibility of the phosphino centres. This number N is a function of both the degree of condensation τ of the xerogel and the number f of hydrolysable SiX_3 groups of the precursor ($N = f \times \tau$) (see Table 2). We observed that the greater the N value, the more difficult was the accessibility of the phosphorus centres by the rather bulky reagent $W(CO)_5$·THF. The present study of the accessibility of the phosphorus centres incorporated into **X4** confirms this observation.

We consider that the number of Si—O—Si bonds should have an influence on the mobility of the network of the xerogel. The more important the mobility of the organic moieties, the easier is the penetration and the diffusion of the reagents into the hybrid organic-inorganic material (11, 12). Thus the diffusion of the reagent through **X1**, material in which the average number of Si—O—Si bonds by organic moiety is $N = 3.7$, is much easier than through **X4** in which the organic moieties are more rigid ($N = 6.6$). This interpretation is supported by ^{31}P NMR data of xerogels **X1**, **X2**, and **X4**. Indeed as shown on Fig. 2, the broadening of the ^{31}P NMR signals for xerogels increases with the average number N of Si—O—Si bonds attached to the organic moieties. The less flexible the organophosphorus moieties, the larger is the ^{31}P NMR signal of the phosphorus atoms (13).

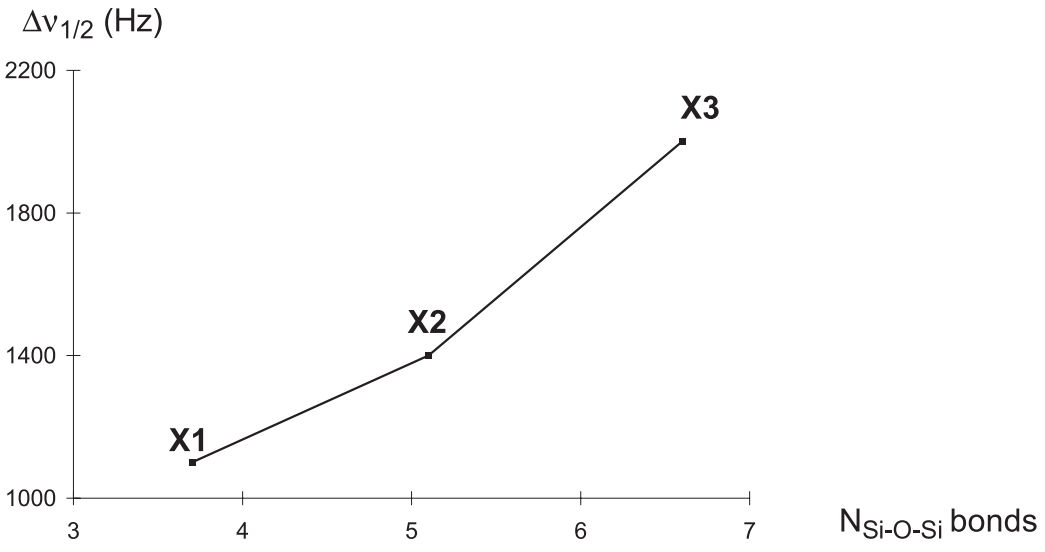
Fig. 1. Solid state ^{31}P NMR spectrum of the xerogel **X4** after reaction with $W(CO)_5$·THF

Thus these NMR data confirm that the mobility of organophosphorous moieties decreases as *N* increases, the phosphorus atoms being less readily accessible to reagents owing to a lower swellability of the matrix.

In conclusion, this study and the preceding one (6) clearly show that the average number *N* of Si—O—Si bonds attached to the organic moiety is an important parameter controlling the accessibility of the phosphorus centers included in an hybrid organic-inorganic material. This shows the importance of the number of the hydrolysable SiX_3 bonds in the organic precursor. This parameter has been well evidenced because the precursors **1**, **2**, as well as **4** all bear rigid groups around the phosphorus centres. It is likely that in the case of phosphines with flexible groups around the phosphorus atoms, the situation is different.

Experimental



All reactions were carried out under argon by using a vacuum line. Solvents were dried and distilled just before use. Melting points were determined with a Gallenkamp apparatus and are uncorrected. IR data were obtained on a Perkin-Elmer 1600 FTIR spectrophotometer by the DRIFT method. The solution NMR spectra were recorded on a Bruker AC-200 (^{29}Si), Bruker DPX-200 (^{1}H and ^{13}C), and Bruker WP 250 SY (^{31}P, ^{11}B). Chemical shifts (δ in ppm) were referenced to Me_4Si (^{1}H, ^{13}C, ^{29}Si), BF_3·THF (^{11}B), or H_3PO_4 (^{31}P). The CP MAS solid state ^{29}Si NMR spectra were recorded on a Bruker FTAM 300 as well as CP MAS ^{13}C solid state NMR spectra in that case by using the TOSS technique. In both cases the repetition time was 5 and 10 s with contact times of 5 and 2 milliseconds. The HPDEC MAS ^{31}P solid state NMR spectra were recorded on a Bruker FTAM 300, a Brucker ASX 200, or a Brucker ASX 400 with repetition time of 5 s. FAB mass spectra (matrix, *m*-nitrobenzyl alcohol (NBA), thioglycerol (GT)) were registered on Jeol JMS-D3000 spectrometer. Specific surface areas were determined by the Brunauer-Emmett-Teller (BET) method on Micromeritics ASAP 2010 and Micromeritics Gemini III 2375 analysers. Elemental analyses were carried out by the Service Central de Micro- Analyse du CNRS.

Table 3. Solid state ^{31}P NMR chemical shifts (δ in ppm) of phosphorus atoms after treatment of the xerogels **X1**, **X2**, and **X4** with $W(CO)_5$·THF. The percent of each signal is indicated in parentheses.

	^{31}P HPDEC MAS NMR

*P,P,P′,P′-tetrakis(4-triisopropyloxysilylphenyl)p-phenylenediphosphine diborane (**8**)*: A molar solution of BH_3·THF in THF (4.1 mL, 4.1 mmol) was added dropwise, at 0°C, to 2.56 g (2.03 mmol) of **4** in THF (10 mL). After stirring one hour at room temperature the solvent was removed to give 2.61 g (2.02 mmol, 99%) of crude **8**. Mp 163.7 (decomp.); ^{1}H NMR (δ, 200 MHz, $CDCl_3$) 1.25 (d, $^{3}J_{H\text{-}H}$ = 6.1 Hz, 78H, Me+BH), 4.31 (spt, $^{3}J_{H\text{-}H}$ = 6.1 Hz, 12H, OCH), 7.54–7.81 (m, 20H, aromatic); ^{13}C NMR (δ, 50 MHz, $CDCl_3$) 25.9 (Me), 66.1 (OCH), 128–138 (aromatic); ^{11}B NMR (δ, 80 MHz, $CDCl_3$) –38.5 (broad signal); ^{29}Si NMR (δ, 40 MHz, $CDCl_3$) –63.5 (d, $^{5}J_{P\text{-}Si}$ = 1.2 Hz); ^{31}P NMR (δ, 100 MHz, $CDCl_3$) 22.1 (broad signal); MS (FAB+, GT) 1263 [$(M - 2BH_3 + H)^+$, 41%]. Anal. calc. for $C_{66}H_{110}O_{12}B_2P_2Si_4$: C 61.39, H 8.53%; found: C 60.86, H 8.35.

*P,P,P′,P′-tetrakis(4-triisopropyloxysilylphenyl)p-phenylenediphosphine bis tungsten pentacarbonyl (**9**)*: A THF solution of $W(CO)_5$·THF (15) (150 mL, 8.55 mmol) was added to 2.61 g (2.07 mmol) of **4**. After stirring for two hours at room temperature, the solvent was evaporated under vacuum. After elimination of excess of $W(CO)_5$·THF by sublimation at 60°C under vacuum, 3.71 g (1.94 mmol, 94%) of crude **9** was obtained. Mp (2-propanol) 203.6 (decomp.); ^{1}H NMR (δ, 200 MHz, $CDCl_3$) 1.25 (d, $^{3}J_{H\text{-}H}$ = 6.1 Hz, 72H, Me), 4.31 (spt, $^{3}J_{H\text{-}H}$ = 6.1 Hz, 12H, OCH), 7.44–7.80 (m, 20H, aromatic); ^{13}C NMR (δ, 50 MHz, $CDCl_3$) 25.9 (Me), 66.1 (OCH), 132.4–138.9 (aromatic), 197.4 (s and d $^{2}J_{P\text{-}C}$ = 6.8 Hz, CO cis), 199.4 (s and d $^{2}J_{P\text{-}C}$ = 22 Hz, CO trans); ^{29}Si NMR (δ, 40 MHz, $CDCl_3$) –63.3 (d, $^{5}J_{P\text{-}Si}$ = 1.2 Hz); ^{31}P NMR (δ, 100 MHz, $CDCl_3$) 21.7 (s d, $^{5}J_{P\text{-}Si}$ = 1.2 Hz); IR (ν/cm^{-1}, CCl_4) 1942, 1980, 2071; MS (FAB+, NBA) 1911 [$(M + H)^+$, 14%], 1587 [$(M - W(CO)_5 + H)^+$, 18%], 1263 [$(M - 2W(CO)_5 + H)^+$, 16%]. Anal. calc. for $C_{76}H_{104}O_{22}P_2Si_4$ W_2: C 47.75, H 5.44%; found: C 47.89, H 5.84.

Xerogel X4: To a THF (3.2 mL) solution of **4** (2.00 g, 1.58 mmol) in a 12.5 mL flask were added dropwise at room temperature 1.6 mL of a 6 M H_2O (9.6 mmol) and 0.1 M HCl (0.16 mmol) solution in THF. The mixture was stirred for 5 min, then the flask was placed in a water-bath at 30°C without stirring. Gelation occurred after 3h. The wet whitish gel was allowed to age for 5 days at 30°C after which it was powdered and washed with ethanol, acetone and ether. The powdering and washing were repeated once and the gel was powdered again and dried in vacuum for 2 h at 120°C to yield 1.14 g of **X4** as a white powder. Specific surface area, ^{31}P, ^{13}C, and ^{29}Si CP-MAS NMR are indicated in Table 1. Elemental anal. calc. for $C_{30}H_{20}O_6PSi_4$: C 55.38, H 3.07, O 14.77, P 9.54, Si 17.23; found: C 51.80, H 5.13, O 20.87, P 8.05, Si 14.15 which corresponds to $C_{33.24}H_{39.51}O_{10\cdot04}P_{2.00}Si_{3.89}$.

Xerogel X5: To a THF (5.7 mL) solution of **5** (1.76 g, 3.10 mmol) in a 20 mL test tube was added dropwise at 0°C in 5 min, under stirring, 3.1 mL of a 6 M H_2O (16.2 mmol) and 0.01 M nBu_4NF (0.03 mmol) solution in THF. The reaction mixture was then kept at room temperature without stirring. A release of dihydrogen was observed until gel formation (30h). The wet gel was left to age for 5 days at room temperature and the solid was subsequently treated as it was described before to give 1.93 g of white xerogel **X5**. Specific surface area, ^{31}P and ^{29}Si CP-MAS NMR are indicated in Table 1. IR (DRIFT) (ν/cm^{-1}) 2159 (Si-H). Elemental anal. calc. for $C_{30}H_{20}O_6PSi_4$: C 55.38, H 3.07, O 14.77, P 9.54, Si 17.23; found: C 53.82, H 4.36, O 15.87, P 9.25, Si 16.70 which corresponds to $C_{30.06}H_{29.22}O_{6.65}P_{2.00}Si_{3.99}$.

Xerogel X7: To a THF (1.3 mL) solution of 2 g (1.29 mmol) of **7** in a 12.5 mL flask were added dropwise at room temperature 1.3 mL of a 6 M H_2O (7.8 mmol) and 0.1 M HCl (0.13 mmol) solution in THF. The reaction mixture was stirred and gel formation occurred after one min. After drying, 1.32g of yellow **X7** was obtained. Elemental anal. calcd. for

$C_{32}H_{26}I_2O_6P_2Si_4$: C 41.11, H 2.78, I 27.20, O 10.28, P 6.64, Si 11.99; found: C 41.30, H 4.80, I 20.45, O 17.50, P 5.80, Si 10.15 which corresponds to $C_{36.79}H_{41.30}I_{1.72}O_{11.69}P_{2.00}Si_{3.87}$.

Xerogel X8: To a THF (1.55 mL) solution of 2.0 g (1.55 mmol) of **8** in a 12.5 mL flask were added dropwise at room temperature 1.55mL of a 6 M H_2O (9.3 mmol) and 0.1 M HCl (0.15 mmol) solution in THF. The reaction mixture was stirred for 5 min and kept at 30°C without stirring. Gel formation occurred after 15 min. However, after about 10 min a slight release of gas was observed so that the cork of the flask was pierced. After ageing, powdering and washing, 1.31 g of white powder was obtained. Drying 2 h at 120°C of 1.01 g of crude xerogel gave 882 mg of **X8**. ^{31}P CP MAS NMR spectra indicated a cleavage of P—B bonds of 50%. Elemental anal. calcd. for $C_{30}H_{26}B_2O_6P_2Si_4$: C 53.10, H 3.83, B 3.24, O 14.16, P 9.14, Si 16.52; found: C 50.47, H 5.17, B 1.95, O 22.01, P 6.20, Si 14.20 which corresponds to $C_{42.06}H_{51.7}B_{1.77}O_{13.76}P_{2.00}Si_{5.07}$. The cleavage of the P—B bond of the crude xerogel is 40%. It is of 70% if the crude xereogel is heated one night at 120°C.

Xerogel X9: To a THF (1.0 mL) solution of 2.0 g (1.05 mmol) of **9** in a 12.5 mL flask were added dropwise at room temperature 1.1mL of a 6 M H_2O (6.6 mmol) and 0.1 M HCl (0.11 mmol) solution in THF. The reaction mixture was stirred for 5 min and kept at 30°C without stirring. Gel formation occurred after 20min. After drying, 1.38 g of light beige **X9** was obtained. IR (DRIFT ν/cm^{-1}, KCl) 1934, 1986, 2072. Specific surface area and ^{31}P CP-MAS NMR data are indicated in Table 1. Elemental anal. calcd. for $C_{40}H_{20}O_{16}P_2Si_4W_2$: C 36.98, H 1.54, O 19.72, P 4.78, Si 8.63, W 28.30; found : C 30.33, H 2.88, O 28.55, P 3.81, Si 7.58, W 26.85 which corresponds to $C_{41.13}H_{46.86}O_{29.03}P_{2.00}Si_{4.40}W_{2.37}$.

Reactivity of X4 with H_2O_2

To a suspension of 325 mg (0.50 mmol) of **X4** in CH_2Cl_2 (20ml) were added dropwise at room temperature 5 mL of a 35% aqueous H_2O_2 solution (60 mmol). After 13 h stirring at room temperature, the suspension was filtered off and the precipitate was washed with water, ethanol, acetone, and diethyl ether. After drying, 296 mg of a white powder were obtained. ^{31}P NMR (δ, 162 MHz, HPDEC MAS) 28.1. S_{BET} < 370 m^2/g. Elemental anal. calc for $C_{30}H_{20}O_8P_2Si_4$: C 52.78, H 2.93, O 18.77, P 9.09, Si 16.42; found: C 47.39, H 4.34, O 26.07, P 7.35, Si 14.85 which corresponds to $C_{33.31}H_{36.61}O_{13.74}P_{2.00}Si_{4.47}$.

Reactivity of X4 with S_8

333 mg (0.51 mmol) of **X4**, 426 mg (13.3 mmol) of sulphur, and 24 mL of *n*-butanol were heated under reflux for 48 h. The hot suspension was then filtered (to remove the excess of sulphur) and the precipitate was washed twice with hot *n*-butanol (2 × 20 mL) then with acetone and diethyl ether. After drying under vacuum for 2 h at 120°C, 346 mg of a whitish solid was obtained. ^{31}P NMR (δ, 120 MHz, HPDEC MAS) 41.3. S_{BET} = 415 m^2/g. Elemental anal. calc. for $C_{30}H_{20}O_6P_2S_2Si_4$: C 50.42, H 2.80, O 13.45, P 8.68, S 8.96, Si 15.69%; found: C 49.91, H, 4.68, O 18.75, P 6.90, S 6.19, Si 13.75%, which corresponds to $C_{37.37}H_{42.00}O_{10.53}P_{2.00}S_{1.74}Si_{4.41.}$

Reactivity of X4 with MeI

334 mg (0.514 mmol) of **X4** and 0.25 mL (4.0 mmol) of methyl iodide were heated under reflux in toluene (10ml) for 48 h. After filtration, the precipitate was washed with ethanol, acetone and diethyl ether, and dried to give 398 mg of a yellow powder. ^{31}P NMR (δ, 162 MHz, HPDEC MAS) 21.4. S_{BET} < 10 m^2/g. Elemental anal. calc. for $C_{36}H_{26}I_2O_6P_2Si_4$: C 41.11, H 2.78, I 27.20, O 10.28, P 6.64, Si 11.99%; found: C 43.40, H 4.53, I 15.32, O 17.25, P 7.30, Si 12.20 which corresponds to $C_{30.72}H_{38.47}$ $I_{1.02}$ $O_{9.16}P_{2.00}Si_{3.70}$.

Reactivity of X4 with $W(CO)_5$·THF

302 mg (0.46 mmol) of **X4** and 70 mL of a 0.057 M THF solution of $W(CO)_5$·THF (4.0 mmol) were heated under reflux and stirring for 96 h. The greenish suspension was then filtered and the precipitate was washed twice with THF (2 × 30 mL) then with ethanol, acetone, and ethyl ether. After drying under vacuum for 2 h at 120°C, 344 mg of a pale green solid was obtained. ^{31}P NMR (δ, 120 MHz, HPDEC MAS) 20.8 (20%), –5 (80%). IR (DRIFT ν/cm^{-1}, KCl) 1935, 1984, 2072. S_{BET} = 380 m^2/g. Elemental anal. calc for $C_{40}H_{20}O_{16}P_2Si_4W_2$: C 36.98, H 1.54, O 19.72, P 4.78, Si 8.63, W 28.35; found: C 43.67, H 3.58, O 23.25, P 5.90, Si 11.80, W 11.80% which corresponds to $C_{38.24}H_{37.62}O_{15.27}P_{2.00}Si_{4.43}W_{0.67}$.

Synthesis and reactivity of the stable silylene *N,N′*-di-*tert*-butyl-1,3-diaza-2-sila-2-ylidene

Michael Haaf, Thomas A. Schmedake, Bryan J. Paradise, and Robert West

Abstract: The synthesis and several reactions of the stable silylene **1** (*N,N′*-di-*tert*-butyl-1,3-diaza-2-sila-2-ylidene) are reported. Overreduction of **1** with alkali metals results in the formation of a dimeric dianion, which can be trapped with a proton source to give the dihydride derivative **9**. In the solid state or in concentrated solutions, **1** undergoes a reversible conversion into the novel tetrameric disilene, **10**. **1** reacts with ethanol, phenol, and water via insertion into the O—H bond, and with iodomethane by insertion into the C—I bond. A reaction of **1** with the diene 2,3-dimethyl-1,3-butadiene affords the silacyclopentene, **15**. This reaction is markedly different from the one found for the unsaturated analog of the silylene, **2**, which catalyzes the conversion of this diene into a highly cross-linked polymer.

Key words: silylene, carbene analog, disilene, divalent compounds, *N*-heterocycles.

Résumé : On a réalisé la synthèse du *N,N′*-di-*tert*-butyl-1,3-diaza-2-sila-2-ylidène (**1**), un silylène stable, sur lequel on a effectué plusieurs réactions. Une surréduction de **1** avec des métaux alcalins conduit à la formation d'un dianion dimère que l'on peut piéger avec une source de proton pour obtenir le dérivé dihydrure **9**. À l'état solide ou en solutions concentrées, **1** subit une conversion réversible en un nouveau disilène tétramère, **10**. Le produit **1** réagit avec l'éthanol, le phénol et l'eau par le biais d'une insertion dans la liaison O—H et avec l'iodométhane par insertion dans la liaison C—I. Une réaction de **1** avec le 2,3-diméthylbuta-1,3-diène conduit à la formation du silacyclopentène, **15**. Cette réaction est très différente de celle qui est observée avec le composé **2**, l'analogue insaturé du silylène, qui catalyse la conversion de ce diène en un polymère hautement réticulé.

Mots clés : silylène, analogue de carbène, disilène, composés bivalents, hétérocycles azotés.

[Traduit par la Rédaction]

Introduction

Silylenes (R_2Si:), the silicon analogs to carbenes in organic chemistry, are key intermediates in numerous thermal and photochemical reactions of organosilicon compounds and hence are extremely important in the field of silicon chemistry (for recent reviews, see ref. (1)). Until recently, silylenes have been observed only at low temperatures in argon or hydrocarbon matrices, disappearing quickly at temperatures above 77 K.

In 1994, syntheses were reported for two novel silylenes, **1** (2) and **2** (3). The unsaturated silylene **2** has truly remarkable thermal stability; it can be sublimed or distilled at 85°C (1 torr, 1 torr = 133.322 Pa), survives heating in toluene at 150°C indefinitely, and decomposes only at its melting point of 220°C. The properties of **2** reflect the electron donation from the nitrogen to the silicon, stabilizing the vacant *p*-orbital on the silicon atom, as well as aromatic delocalization in the six π-electron ring (4, 5). By comparison, silylene **1**, which does not benefit from aromaticity, is significantly less stable, converting into a red product in concentrated solutions or in the solid state at room temperature. Since the synthesis of **1** and **2**, four additional stable silylenes **3a** (6)**, 3b** (7), **4** (8), and **5** (9), have subsequently been reported.

The reactions of **2** (10) and **3a** (11) have been explored and reactions common to these silylenes are shown in eq. [1]. However, no reactions of the saturated analog, **1**, have been reported. Herein we report an improved variation of a previously reported synthesis for silylene **1** (2), several reactions involving insertion of the silylene into a variety of chemical bonds, and a discussion of the novel disilene formed from the saturated silylene in the solid state or in concentrated solutions (12).

Results and discussion

The synthetic pathway for **1** is outlined in eq. [2]. Diamine **6**, formed from dibromoethane and *tert*-butylamine in refluxing hexane, was treated with silicon tetrachloride in the presence of triethylamine (TEA) to give **7**, the five-membered

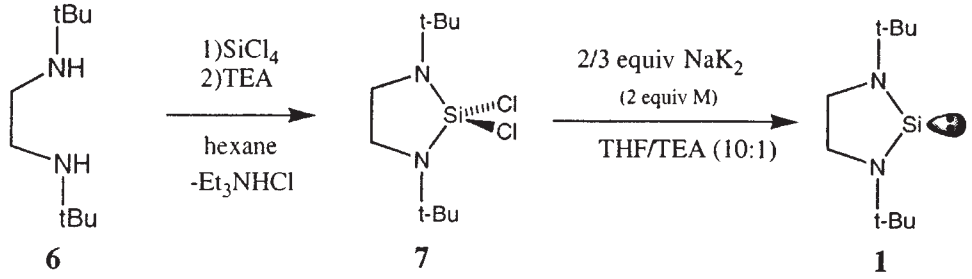
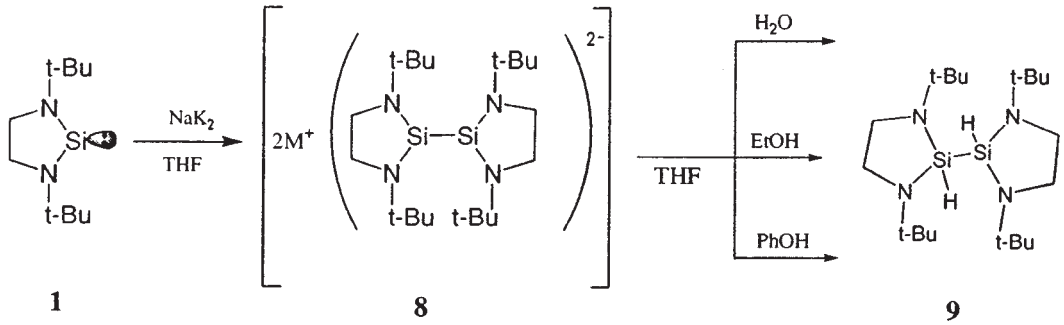
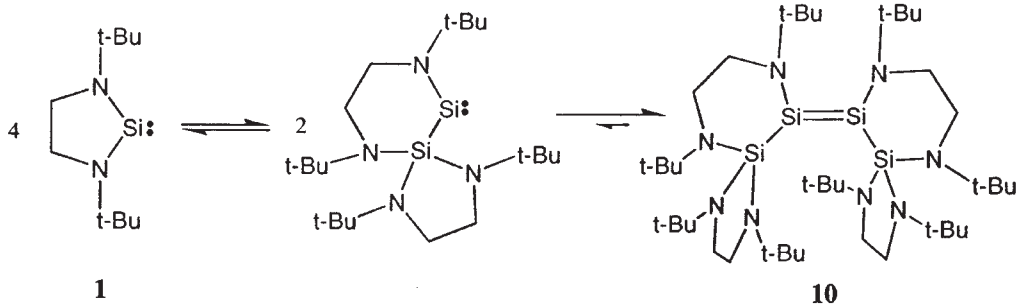
[1]



N-heterocyclic precursor to **1**. Sublimation of the dichloride precursor **7** at 53°C and 0.1 torr (1 torr = 133.322 Pa) affords clear, colorless crystals.



Dechlorination of **7** to produce **1** took place upon treatment with sodium potassium alloy in a 10:1 THF–TEA solution for approximately 3 h.



Although the reduction of **7** can be performed at room temperature with Na–K alloy in neat THF, these reaction conditions often result in the formation of overreduced products, such as the dimeric dianion **8** shown in eq. [3]. Evidently, the reduction of the silylene **1** competes with the reduction of the dichloride **7**, resulting in a lower yield of silylene. The anionic species of the silylene has yet to be fully characterized, but it can be trapped in nearly quantitative yields. Formation of the dihydride **9**, by trapping of the dianion with a proton source, provides evidence for the dimeric nature of the overreduced silylene. The crystal structure of **9** is displayed in Fig. 1.

The presence of triethylamine in the reaction mixture appears to decrease the rate of reduction for the silylene, affording silylene **1** in yields in excess of 95% according to NMR. However, overreduction of the silylene can still take place once the dichloride is used up. Consequently, the reaction must be carefully monitored by ^{1}H NMR and the

[3] 

[4] 

reducing agent must be filtered away from the reaction mixture as soon as all of the dichloride is consumed.

Evaporation of the solvent leaves a red-black residue, which can be sublimed (60°C, 0.1 torr (1 torr = 133.322 Pa)) as colorless crystals of **1**. Although crystals of the unsaturated silylene, **2**, are stable under inert conditions, the crystals of **1** "decompose" over a period of days to a red powdery material, which has been characterized as the novel tetrameric disilene **10** (12; similar insertions into metal–nitrogen bonds have been observed. See for example ref. (13)). Remarkably, the interconversion between **1** and **10** is reversible (eq. [4]). Dissolving crystals of **10** in an inert solvent produces a concentration dependent equilibrium mixture of silylene and disilene, with dilution favoring silylene formation. A 0.013 M solution of disilene in THF will effectively convert to a solution containing 100% silylene over a period of 2 h. Conversely, attempts to crystallize silylene from solution inevitably lead to crystallization of **10**. Unlike **1**, disilene **10** can be stored indefinitely in a dry box and dissolved prior to use.

Reactions of 1

The reactivity of silylene **1** (eq. [5]) appears to be similar in many ways to that of the unsaturated silylene **2** (10). It does not insert into Si—H bonds, nor does it behave as a Lewis acid, even in the presence of relatively strong bases (THF, triethylamine).

However, like the more reactive transient silylenes, **1** does insert into O—H bonds of hydroxyl compounds. With alcohols such as ethanol and phenol, the product formed is the corresponding ethoxysilane **11** (liquid, bp = 38°C, 0.1 torr (1 torr = 133.322 Pa)) or phenoxysilane **12** (Fig. 2). Water reacts with **1** to give disiloxane **13**, presumably through condensation of an intermediate silanol. **1** will also readily insert into the C—I bond of iodomethane to form the corresponding alkyliodosilane, **14**.

Not all reactions of **1** and **2** are identical. Contrary to the unsaturated silylene **2**, which catalyzes the conversion of 2,3-dimethyl-1,3-butadiene into a highly cross-linked, insoluble polymer, the saturated silylene undergoes a 1 + 4 cycloaddition reaction with the diene to give the 1-sila-3-cyclopentene **15**. Clear, colorless crystals of **15** were obtained in nearly quantitative yields by reacting **1** with 2,3-dimethyl-1,3-butadiene. The crystal structure is shown in Fig. 3. The two five-membered rings in **15** are nearly perpendicular (89.5°).

Experimental

All reactions and manipulations were conducted under an argon atmosphere using standard Schlenk techniques.

Dibromoethane, *tert*-butylamine, silicon(IV) chloride, 2,3-dimethyl-1,3-butadiene and phenol, were purchased and used without further purification. All of the reaction solvents were dried and distilled in an inert atmosphere. Lithium and potassium were purchased in mineral oil and washed with hexane or pentane before use.

Proton NMR spectra were recorded on either a Bruker AC-250 or a Bruker AC-300 spectrometer. Silicon-29 NMR spectra were collected on a Bruker 500 MHz spectrometer. Carbon-13 NMR spectra were taken on a Bruker AC-300 spectrometer. Solid state ^{29}Si NMR spectra were determined on a Varian 500 MHz spectrometer or a Bruker 360 MHz spectrometer. All NMR spectra were taken in solutions of deuterated benzene.

Synthesis of *N*,*N*′-di-*tert*-butylethylenediamine (6)

Into a 1 L three-necked round bottom flask fitted with a condenser, a gas inlet, a stopper and a septum, dibromoethane (141 g, 65 mL, 0.75 mol), *tert*-butylamine (274 g, 394 mL, 3.75 mol), hexane (100 mL), and water (100 mL) were added. The reaction mixture was brought to a boil and was allowed to reflux for three days. During this time period, a precipitate formed and two layers became apparent. After refluxing, the mixture was cooled in an ice bath and three portions of 27.0 g of NaOH (81.0 g total) were sequentially added to the reaction mixture. The heat generated from this addition caused the reaction to begin refluxing again. After cooling, the reaction mixture was decanted away from the precipitate and into a separatory funnel. The hexane (top) layer was saved and stored over NaOH. This organic layer was then distilled to remove the hexane and any unreacted dibromoethane or *tert*-butylamine. The distillation was then continued under vacuum and 93 g

(72%) of product **6** was collected (49°C, 0.1 torr (1 torr = 133.322 Pa)) The product was stored over NaOH to keep it dry. ^{1}H NMR δ: 1.014 (s,18H), 2.541 (s, 4H). ^{13}C NMR δ: 29.5, 43.6, 49.8.

Synthesis of *N,N′-di-tert*-butyl-1,3-diaza-2,2-dichloro-2-silacyclopentane (7)

Into a three-necked 2 L flask equipped with a condenser, gas inlet, stopper, stir bar, and septum was added *N,N′*-di-*tert*-butylethylenediamine **6** (20.0 g, 116 mmol) and hexane (250 mL). The solution was stirred at 0°C while $SiCl_4$ (20.0 g, 118 mmol) was added via syringe. The solution was then allowed to warm to room temperature, at which time triethylamine (40 mL) was added. The solution was heated to reflux and left stirring overnight, and was then allowed to cool to room temperature. The reaction mixture was filtered under vacuum and the ammonium salt precipitate was washed with two aliquots of hexane (300 mL each). The hexane filtrate was subsequently concentrated to dryness. The remaining white solid was purified by distillation (90°C, 1 torr (1 torr = 133.322 Pa)), affording 21.0 g (67.2%) of a colorless, crystalline solid. This product can be stored indefinitely under an atmosphere of nitrogen. ^{1}H NMR δ: 1.20 (s, 18H), 2.71 (s, 4H). ^{13}C NMR δ: 29.0, 41.7, 51.8.

Synthesis of *N,N′*-di-*tert*-butyl-1,3-diaza-2-sila-2-ylidene (1)

A solution of *N,N′*-di-*tert*-butyl-1,3-diaza-2,2-dichloro-2-silacyclopentane, **7**, (10 g, 37.1 mmol) in THF (100 mL) was made up in a flame-dried, degassed Schlenk flask. A three-necked, 250 mL flask was equipped with a stir bar, frit, septum, and stopper. On the other end of the frit was placed a 250 mL Schlenk flask equipped with a stir bar and attached to the Schlenk line. The apparatus was rigorously flame-dried and charged with argon. Freshly cut potassium (2.0 g) and sodium (0.6 g) were added to the three-necked flask under a heavy flow of argon. The apparatus was then evacuated, and the flask heated with a heat gun to melt the potassium and sodium chunks to generate NaK_2. The apparatus was again charged with argon, and cooled to room temperature at which point 50 mL freshly distilled THF and 20 mL freshly distilled TEA were added to the flask. The apparatus was then cooled in a dry ice – acetone bath. The solution of **7** in THF was added to the flask, and the apparatus was warmed to room temperature. The reaction was monitored by ^{1}H NMR and filtered when complete (approximately 2–3 h). It is important to filter immediately upon completion for maximal yield. The filtrate was concentrated to give 6 g (80%) of crude product and recrystallized from THF to give crystals of disilene **10** (5.0 g, 68%). ^{1}H NMR (for **1**) δ: 1.269 (s, 18H), 3.140 (s, 4H). ^{13}C NMR δ: 31.68, 46.46, 52.46. ^{29}Si NMR δ: 118.9.

Synthesis of dihydride (9)

A solution of *N,N′-di-tert*-butyl-1,3-diaza-2,2-dichloro-2-silacyclopentane, **7**, (1.0 g, 3.7 mmol) in THF (20 mL) was made up in a flame-dried, degassed Schlenk flask. A three-necked, 250 mL flask was equipped with a stir bar, frit, septum, and stopper. On the other end of the frit was placed a 250 mL Schlenk flask equipped with a stir bar and attached to the Schlenk line. The apparatus was rigorously flame-dried and charged with argon. Freshly cut potassium (1.0 g, 25.5 mmol) and sodium (0.33 g, 14.3 mmol) were added to the three-necked flask under a heavy flow of argon. The apparatus was then evacuated, and the flask heated with a heat gun to melt the potassium and sodium chunks to generate NaK_2. The apparatus was again charged with argon, and cooled to room temperature at which point 30 mL freshly distilled THF was added to the flask. The apparatus was then cooled in a dry ice – acetone bath. The solution of **7** in THF was added to the flask via cannula, and the apparatus was warmed to room temperature. Upon warming the solution turned black. Regular monitoring by ^{1}H NMR indicated a gradual formation and then disappearance of silylene over a 3 h period. Eventually no silylene peaks were observed in the NMR. At this point the solution was filtered. The filtrate was cooled in a dry ice – acetone bath and reacted with 1 equiv of a proton source (water, EtOH, phenol) to produce the dihydride in 95% yield (by NMR). Crystals suitable for X-ray analysis were grown from THF. HRMS : *m/z* 398 [M^+]. Exact mass calcd. for $C_{20}H_{46}N_4Si_2$ *m/z*: 398.3261; found: 398.3210. ^{1}H NMR δ: 1.293 (s, 36H), 2.965 (s, 8H), 5.739 (s, 2H). ^{13}C NMR δ: 29.71, 44.78, 50.73. ^{29}Si NMR δ: –23.9.

Synthesis of tetramer (10)

Disilene **10** was produced by recrystallization of **1** from THF or diethyl ether. Alternatively, crystals of **1** will slowly convert in the solid state to disilene **10**. ^{1}H NMR δ: 1.368 (s, 18H), 1.416 (s, 18H), 1.429 (s, 18H), 1.575 (s, 18H), 2.9–3.1 (m, 16H). ^{13}C NMR δ: 30.16, 30.22, 31.0, 31.20, 42.50, 42.56, 45.41, 51.36, 51.55, 51.67, 55.59, 55.67. ^{29}Si NMR δ: 119.0, –25.0.

Reaction of 1 with ethanol

A dried, degassed Schlenk flask was charged with 0.222 mL of ethanol (3.8×10^{-3} mol) and 10 mL THF, then placed in a dry ice – acetone bath. A solution of **1** (0.075 g (3.8×10^{-3} mol)/50 mL THF) was added and the flask was allowed to warm to room temperature. The ethanol insertion product **11** is a liquid, which can be isolated by fractional distillation (38°C, 0.1 torr (1 torr = 133.322 Pa)) (60%). ^{1}H NMR δ: 1.207 (s, 18H), 1.207 (t, 3H, J = 6.9 Hz), 2.88–2.94 (m, 4H), 3.736(q, 2H, J = 6.9 Hz), 5.090 (s, 1H). ^{13}C NMR δ: 18.41, 29.58, 43.05, 50.50, 56.92. ^{29}Si NMR δ: –44.5.

Reaction of 1 with phenol

A dried, degassed Schlenk flask was charged with 0.475 g of phenol (5.0×10^{-3} mol) and 30 mL THF, then placed in a dry ice – acetone bath. A solution of **1** (1.0 g (5.05×10^{-3} mol)/50 mL THF) was added and the flask was allowed to warm to room temperature. The insertion product **12** was formed in 80% yield by NMR. Recrystallization from THF provided crystals of **12** suitable for X-ray analysis. ^{1}H NMR δ: 1.130 (s, 18H), 2.9–3.0 (m, 4H), 5.354 (s, 1H), 6.7–7.2 (m, 5H). ^{13}C NMR δ: 29.38, 42.81, 50.69, 116.5,121.6, 123.3, 129.9. ^{29}Si NMR δ: –46.6.

Reaction of 1 with water

A dried, degassed Schlenk flask was charged with 0.034 mL of water (1.9×10^{-3} mol) and 10 mL THF, then placed in a dry ice – acetone bath. A solution of **1** (0.075 g

Reaction of 1 with iodomethane

A dried, degassed Schlenk flask was charged with 0.236 mL of freshly distilled iodomethane (3.8×10^{-3} mol) and 10 mL THF, then placed in a dry ice – acetone bath. A solution of **1** (0.075 g, 3.8×10^{-3} mol) in 50 mL THF was added and the flask was allowed to warm to room temperature. The insertion product, **14**, was produced cleanly (90% yield by NMR). ^{1}H NMR δ: 0.390 (s, 3H), 1.176 (s, 18H), 2.8–2.95 (m, 4H). ^{13}C NMR δ: 29.54, 29.68, 42.91, 60.70.

Reaction of 1 with 2,3-dimethyl-1,3-butadiene

A dried, degassed Schlenk flask was charged with 0.414 g of 2,3-dimethyl-1,3-butadiene (5.05×10^{-3} mol) and 30 mL THF, then placed in a dry ice – acetone bath. A solution of **1** (1.0 g, 5.05×10^{-3} mol) in 50 mL THF was added and the flask was allowed to warm to room temperature. The major product was the silacyclopentene, **15** (85% by NMR). Crystals suitable for X-ray analysis were grown from THF. HRMS: *m*/*z* 280 [M^+]. Exact mass calcd. for $C_{16}H_{32}N_2Si$ *m*/*z*: 280.2334; found: 280.2334. ^{1}H NMR δ: 1.173 (s, 18H), 1.55 (s, 4H), 1.756 (s, 6H), 2.940 (s, 4H). ^{13}C NMR δ: 19.44, 29.29, 29.76, 43.63, 50.98, 130.48. ^{29}Si NMR δ: –10.2.

Crystal structure determination

Intensity data for compounds **9** and **12** were collected using a Bruker SMART ccd area detector mounted on a Bruker Platform goniometer equipped with graphite-monochromated Mo Kα radiation. Intensity data for **15** was collected using a Siemens SMART ccd area detector mounted on a Siemens P4 diffractometer equipped with graphite-monochromated Mo Kα radiation. All structures were determined at temperatures below 150 K. The structures of all compounds were solved by direct methods and refined by full-matrix least-squares on F^2 (SHELXTL, Version 5). Hydrogen atoms were initially determined by geometry and refined by a riding model. Non-hydrogen atoms were refined with anisotropic displacement parameters. Compound **12** sits on a crystallographic mirror that includes the silicon and nitrogens. The mirror symmetry causes the phenyl group and the hydrogen on the silicon to be disordered. Restraints on the positional and displacement parameters of the phenyl group were required to achieve convergence in the refinement. Details of the data collection and refinement are given in Table 1.

Acknowledgment

This research was supported by a grant from the National Science Foundation. We thank Douglas R. Powell and Randy K. Hayashi for crystal structure determinations and the National Science Foundation and the University of Wisconsin for funds to purchase the X-ray instrument and computers.

Supporting information available

Tables of crystallographic data, atomic coordinates, thermal parameters, and bond lengths and angles for **9**, **12**, and **15** have been deposited as supplementary material and may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2 (http://www.nrc.ca/irm/unpub_e.shtml for information on ordering electronically).

Crystallographic data for the structure(s) reported in this paper have deposited with the Cambridge Crystallographic Data Centre (CCDC). Copies of the data can be obtained, free of charge, on application to the Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. (Fax: 44-1223-336033 or e-mail: deposit@ccdc.cam.ac.uk).

Professor Adrian G. Brook, FCIC,

**University Professor of Chemistry Emeritus,
University of Toronto**

This Special Issue of *The Canadian Journal of Chemistry* honours the scientific contributions of Adrian Brook. We are pleased to present this collection of papers whose contents indicate the richness and diversity of research areas and themes taken by his many students, research associates, colleagues, and friends in their own careers.

Adrian Brook has enriched the discipline of chemistry in Canada and worldwide through manifold contributions in research, teaching, and administration. From the early days of his independent career, he established an international reputation for work on organosilicon chemistry. His research in the synthesis of a wide variety of functionally substituted organometalloid compounds and the study of their properties is of particular significance. From these fundamental studies evolved important synthetic and other applications, including the use of organosilicon compounds as unusual synthons that take advantage of altered functional reactivity. Particularly noteworthy are: the first synthesis of acylsilanes, compounds whose utility is being increasingly exploited; the synthesis of silylcarbinols and his discovery of their base-catalyzed rearrangement to alkoxysilanes which all chemists recognize as the Brook rearrangement; the photoinduced rearrangement of polysilylacylsilanes leading to the first synthesis, isolation, and characterization of silenes, stable compounds containing a silicon–carbon double bond, a testament of Brook's ingenious and methodical pursuit of a long sought goal which had eluded organometallic chemists. Even as we celebrate his contributions, Brook continues to pursue research on the thermal chemistry and photochemistry of silenes and silene precursors.

Adrian Brook received the Frederick Stanley Kipping Award in Organosilicon Chemistry of the American Chemical Society in 1973 for his work in organosilicon chemistry. The neighbours at his favourite residence, a cottage north of Toronto, were somewhat surprised to observe the sailboat, "Miss Silicone", on the lake after the award had been received. He also received the Chemical Institute of Canada Medal in 1985 and the Izaak Walton Killam Memorial Prize in 1994 for his contributions to organic chemistry.

As a teacher, Brook is well-known for the clarity of his lectures and the high standards he inculcates in his students. As an administrator he brought the same high standards to the positions that he has held, which include the chairmanships of the Research Board of the University of Toronto and of the Chemistry Grants Selection Committee of NRC (currently NSERC).

Brook is an enthusiastic do-it-yourselfer. His *magnum opus* was the construction of a cedar plank cottage on a small Ontario lake using as his only assistants a col-

Professeur Adrian G. Brook, MICC,

**Professeur hors rang émérite de chimie
University of Toronto**

Le présent numéro spécial de la *Revue canadienne de chimie* rend hommage aux contributions scientifiques de M. Adrian Brook. Nous sommes ravis de présenter ce recueil d'articles qui témoigne de la richesse et de la diversité des domaines qu'explorent ses nombreux étudiants, agrégés de recherche, collègues et amis.

Adrian Brook a enrichi la discipline de la chimie au Canada et dans le monde entier grâce à ses précieuses interventions en recherche, en enseignement et en administration. Dès le début de sa carrière de chercheur autonome, il a acquis une réputation internationale d'excellence pour ses travaux sur la chimie des organosiliciés, en particulier sur la synthèse d'un grand nombre de composé organométalloïdes ayant subi une substitution fonctionnelle et sur leurs propriétés. Ces études fondamentales ont été la source d'applications de synthèse et d'autres applications, y compris le recours aux composés organosiliciés comme synthons atypiques en vue de tirer avantage de la réactivité fonctionnelle ainsi modifiée. Parmi ses réalisations les plus notables figurent la première synthèse d'acylsilanes, composés dont l'utilité devient de plus en plus apparente; la synthèse de silylcabinols et la découverte de leur réarrangement par catalyse basique en alkoxysilanes, que tous les chimistes appellent aujourd'hui le « réarrangement de Brook »; et le réarrangement photo-induit des polysilylacylsilanes ayant découlé en la première synthèse, isolation et caractérisation des silènes, composés stables révélant une double liaison silicium–carbone. Ces travaux reflètent l'engagement indéfectible de Brook à atteindre un objectif qui constituait une pierre d'achoppement pour les autres chimistes organométalliques. Au moment de publier le présent recueil qui célèbre ses réussites, Brook poursuivait ses recherches sur la chimie thermique et la photochimie des silènes et de leurs précurseurs.

En 1973, la American Chemical Society a remis à Adrian Brook le prix Frederick Stanley Kipping de chimie des organosiliciés pour ses contributions dans ce domaine. Les voisins de sa résidence de prédilection, un chalet au nord de Toronto, ont dû être fort surpris de constater le nom du bateau d'Adrian, « Miss Silicone », après son retour de la cérémonie de remise des prix! Adrian a aussi vu ses efforts applaudis par la Médaille de l'Institut de chimie du Canada, en 1985, et par le Prix commémoratif Izaak-Walton Killam, en 1994, pour ses contributions à la chimie organique.

À titre d'enseignant, Brook était réputé pour la précision de ses exposés et pour les normes élevées qu'il visait avec ses étudiants. Ces normes ne manquaient pas à l'appel lorsqu'il a assumait des fonctions d'administrateur, y compris la présidence du Conseil d'administration de la recherche de la University of Toronto et du Comité de sélection des boursiers en chimie du CNRC (programme qui relève maintenant du CRSNG).

Brook est un bricoleur enjoué. Le projet dont il est le plus fier à ce chapitre est la construction d'un chalet en cèdre sur la rive d'un petit lac de l'Ontario. Ses seuls assistants dans cette

league (for beams, joists and floor), graduate students (for walls), and his brother and then 10-year-old son (for the roof). The later advent of hydroelectricity at the lake led to exploits in wiring and plumbing. As well, his stable of homemade watercraft include a fibreglass kayak and a sailing pram.

Adrian Gibbs Brook was born in Toronto in 1924. He received B.A. and Ph.D. degrees from the University of Toronto in 1947 and 1950, respectively, his research for the latter being carried out with Professor George F. Wright on oxymercuration chemistry. He was appointed Lecturer in Chemistry at the University of Saskatchewan (1950-51) and then was awarded first a Nuffield Fellowship at the Imperial College of Science and Technology, University of London (1951–53), with Professor R. P. Linstead, and then a Research Fellowship at Iowa State University with Professor Henry Gilman. In 1953, he returned to the University of Toronto as Lecturer in Chemistry, becoming Assistant Professor in 1956, Associate Professor in 1960, and Professor of Chemistry in 1962. During the 1968–74 period, Brook served as Associate Chairman, Acting Chairman, and Chairman of the Department of Chemistry. In 1967, he held a NRC Senior Research Fellowship at Princeton University. He also held Visiting Professorships at the University of Sussex (1974–75), Cambridge University (1982) and Indiana University (1988). In 1977, Brook was elected Fellow of the Royal Society of Canada.

On behalf of all of the contributors and, we have no doubt, chemists worldwide, we are pleased to offer this Special Issue to Adrian Brook and to wish him further discoveries in silicon chemistry.

Michael A. Brook

entreprise ont été un de ses collègues (pour l'installation des poutres, des poutrelles et du plancher), quelques-uns de ses étudiants diplômés (pour l'érection des murs) ainsi que son frère et le fils de ce dernier, qui n'avait alors que dix ans (pour la construction du toit). L'arrivée de l'électricité dans le secteur a marqué un retour aux outils pour Adrian, qui a alors entrepris des travaux de câblage et de plomberie dans son chalet. Constructeur d'esquifs à ses heures, il a à son actif la construction d'un kayak en fibre de verre et d'une prame à voiles.

Adrian Gibbs Brook est né à Toronto en 1924. Il a reçu son baccalauréat et son doctorat de la University of Toronto en 1947 et 1950, respectivement. Son doctorat, supervisé par le professeur George F. Wright, a porté sur la chimie de l'oxymercuration. Il a été nommé maître de conférences en chimie à la University of Saskatchewan (1950–51). Il a ensuite obtenu une bourse Nuffield au Imperial College of Science and Technology, à la University of London (1951–53), auprès du professeur R. P. Linstead, puis une bourse de recherche de la part de la Iowa State University, auprès du professeur Henry Gilman. En 1953, il a regagné la University of Toronto à titre de maître de conférences en chimie. Il y est ensuite devenu professeur adjoint (1956), professeur agrégé (1960) puis professeur de chimie (1962). De 1968 à 1974, Brook a été tour à tour directeur adjoint, directeur intérimaire et directeur du Département de chimie de l'Université. En 1967, il a été nommé chargé de recherche du NRC à la Princeton University. Il a également été professeur invité à la University of Sussex (1974–75), à la Cambridge University (1982) et à la Indiana University (1988). En 1977, Brook a été élu membre de la Société royale du Canada.

Au nom de tous les collaborateurs du présent ouvrage et, nous osons le dire, de tous les chimistes du monde, nous sommes heureux de dédier ce numéro spécial à Adrian Brook. Nous lui souhaitons de faire encore de nombreuses découvertes dans le domaine de la chimie du silicium.

Michael A. Brook

AIM study on the transferability of the oxygen atom in linear ethers

Antonio Vila, Enrique Carballo, and Ricardo A. Mosquera

Abstract: The integrated values of the electron population, electron energy, nucleus–electron potential energy interaction, dipole moment and volume of the oxygen atoms, and the main properties of the O—C bond critical points, were determined by employing the theory of atoms in molecules and 6–31++G**//6–31G* wave functions for a series of 25 unbranched alkyl monoethers. These results were used to assess the degree of approximate transferability of the oxygen atom along this series in terms of the particular alkyl radicals bonded to it. It has been found that a set of six different oxygen atoms is necessary to classify all the computed values. It can be established that the oxygen atoms bonded to propyl and larger radicals can be treated, in practice, as a transferable fragment, while those bonded to at least one smaller radical are specific. Though the total HF energy and the available experimental heats of formation are well fitted by a traditional additivity scheme that distinguishes only among O, CH_2, and CH_3 units, it has been found that the energy properties are influenced by the size of the molecule.

Key words: transferability, AIM theory, ethers.

Résumé : Utilisant la théorie des atomes dans les molécules et des fonctions d'onde 6–31++G**//6–31G*, on a déterminé les valeurs intégrées de la population électronique, de l'énergie électronique, de l'énergie potentielle d'interaction noyau-électron, du moment dipolaire et du volume des atomes d'oxygène ainsi que les propriétés principales des points critiques de la liaison O—C d'une série de 25 éthers monoalkylés et non ramifiés. On a utilisé ces résultats pour évaluer le degré approximatif de transférabilité de l'atome d'oxygène dans cette série en fonction des radicaux alkyles particuliers qui lui sont liés. On a trouvé qu'un ensemble de six atomes d'oxygène différents est nécessaire pour classifier toutes les valeurs calculées. On a pu établir que, en pratique, les atomes d'oxygène liés à des groupes propyle ou plus importants peuvent être traités comme des fragments transférables alors que ceux liés à des groupes à au moins un radical plus petit sont spécifiques. Même si le schéma d'additivité traditionnelle qui ne distingue que des unités O, CH_2 et CH_3 permet d'établir une bonne corrélation entre l'énergie totale selon HF et les chaleurs de formation expérimentales disponibles, on a trouvé que les propriétés d'énergie sont influencées par la taille de la molécule.

Mots clés : transférabilité, théorie des atomes dans une molécule, éthers.

[Traduit par la Rédaction]

Introduction

The transferability of the physical properties of atoms and groups of atoms (especially those known as functional groups) has been a basic idea for the development of chemistry allowing researchers to systematize the reactivity and the physical properties of a huge amount of chemical compounds. It is also employed as the basic concept sustaining many different theoretical or computational methodologies ranging from the straightforward calculation of thermochemical quantities by using the additivity of functional groups or bonds schemes (1), to the employment of solution molecular models to compute thermodynamic properties of liquid mixtures (2). Even such a widespread and powerful methodology as molecular mechanics (3) can be easily related to the functional group concept. In accordance with this practical importance the concept of functional group has been the subject of several recent theoretical research papers (4–9).

Though it has been demonstrated that the perfect transferability is an unattainable limit (10, 11), the development of the theory of atoms in molecules (AIM) (12, 13) has provided the physical basis, methodology, and computational tools required to carry out quantitative analysis of the degree of approximate transferability of atoms and groups of atoms (9, 14, 15). In fact, this theory was applied a long time ago to the study of the methyl and methylene fragments of *n*-alkanes giving rise to the distinction of the methylene group bonded to a methyl group from the remaining methylenes (16, 17). In spite of the increasingly amount of applications of the AIM theory, there are not many series of compounds for which this theory has been

employed to make a detailed study of the variability or approximate transferability of atomic groups containing hetheroatoms. In one recent paper (18) the application of the AIM theory has proportioned a classification of the carbonyl groups presented in these compounds, and has pointed out that the energy of the carbonyl group along a series of aldehydes and ketones exhibited a dependence on the size of the molecule that had not been reported previously. The same trend was also found in another study on protonated ketones (19). In this work we try to confirm if this dependence is also shown for the oxygen atom in other molecular environments. At the same time, the evolution of the atomic and bond properties of the oxygen atom along the series of alkyl monoethers is analyzed aiming to define molecular environments for which an oxygen atom can be considered approximately transferable, along the series of ethers, within the known limits of experimental errors and the accuracy of numerical calculations. The definition of such environments would establish a transferability scheme of general applicability, which would provide rationalization of chemical facts and prediction of physical properties or chemical behaviours. As an example, the definition of transferable fragment in unbranched alkanes and esters done in a previous work and based upon the distances between nuclei and the bond critical points surrounding them were employed to define parameters sets for the Nitta–Chao liquid-state molecular solution theory based on a group contribution model (20). Though this definition was based only on a not very sensitive property, the parameter sets developed according to it improved the prediction of activity coefficients in mixtures alkane + ester by a factor of two and allowed the reproduction of the evolution of these activity coefficients with temperature (21).

Computational details

The calculations of the atomic and bond properties were carried out using the AIMPAC program series (22, 23) with wave functions obtained with the GAUSSIAN 94 program (24) using the 6–31++G** (25) basis set on the geometries optimized with the 6–31G* basis (26). The calculations were carried out on the 25 molecules of unbranched monoethers (CH_3-$(CH_2)_n$-O-$(CH_2)_m$-CH_3) shown in Table 1 and named by their n and m coefficients ($n \leq m$). Table 1 also displays ab initio energies, experimental heats of formation (27–30), virial ratios, and integration errors expressed as differences between total properties and those obtained by summation of properties of the fragments ($\Sigma N(\Omega) - N$ or $\Sigma E(\Omega) - E$) and as the summation of the integrated values of the laplacian of the charge density in all the atomic fragments ($\Sigma L(\Omega)$). The linear relationship between both forms of integration errors previously observed in a series of aldehydes and ketones (18) has also been found here (Fig. 1). For all the compounds concerned, we took into account only the conformer corresponding to the optimization of the antiperiplanar disposition of all the dihedral angles of the main skeleton and the alternate disposition of the terminal methyl groups with regard to the main skeleton. In this work we have studied the following atomic properties for the oxygen atom: (*i*) electron population (N(O)); (*ii*) electronic energy (E(O)); (*iii*) potential

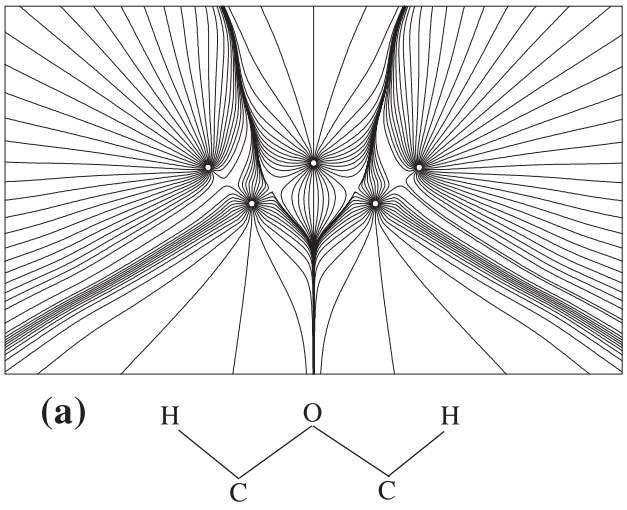
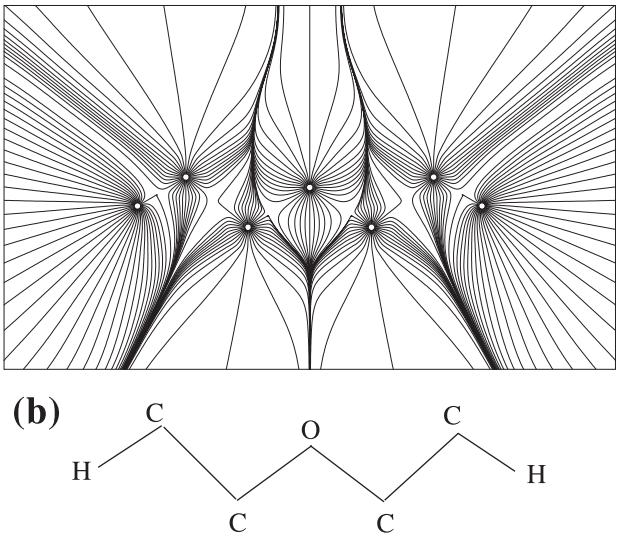
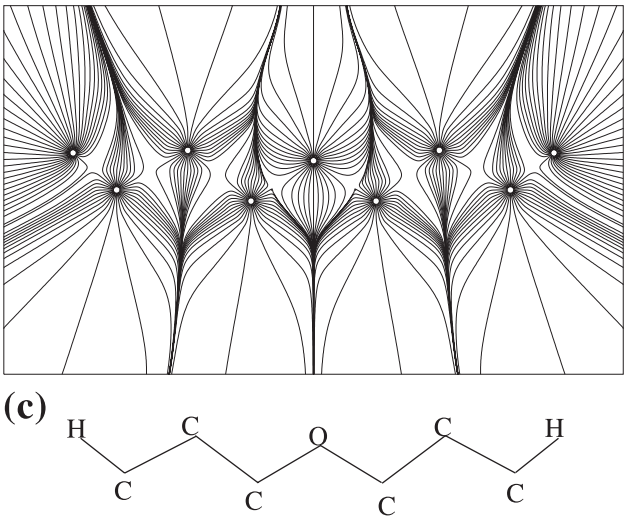
Fig. 1. Linear relationship between $N - \Sigma N(\Omega)$ and $\Sigma L(\Omega)$.



energy of interaction of the nucleus with the electron charge of the fragment (V_{NEO}(O)); (*iv*) dipole moment of the fragment (μ(O)); and (*v*) atomic volume (*v*(O)) of the region delimited by the interatomic surface and the boundary defined by an electron charge density of 0.002 au. We also include the integrated value of the laplacian of the charge density (*L*(O)); this parameter is a measure of the accuracy with which the interatomic surface was determined. Oxygen fragments were also characterized in terms of the properties at the O—C bond critical points, viz. the positive eigenvalue of the Hessian matrix for the electron charge density at this point (λ_3), bond ellipticity (ε) (defined as $\varepsilon = (\lambda_1/\lambda_2) - 1$ where $|\lambda_1| > |\lambda_2|$ are the two negative eigenvalues of the Hessian of the charge density at the bond critical point), charge density at the bond critical point (ρ_c), and distance from the nucleus to the bond critical point (*R*).



Results and discussion



As it could be expected, the geometries obtained for the completely antiperiplanar conformer of the 25 compounds here studied are very similar; it can be mentioned only the well-known difference between O—CH_3 (1.391 Å) and O—CH_2 (1.396 Å) bond length distances as well as the even less significant differences between bond angles (for example the value of the C-O-C bond angle is 113.8° and 114.2° for compounds labelled as **00** and **01**, respectively).

Figure 2 shows the plots of the charge density gradient field in the main plane of the methoxymethane (**00**), ethoxyethane (**11**), and 1-propoxypropane (**22**) molecules. The oxygen atoms are represented by the central lens-shaped fragments. It is clear that the form of the enveloping surface of the gradient lines changes substantially from methoxymethane to ethoxyethane. Thus, the properties of an atom are a function of its boundary surface, its change necessarily results in significant variations of the properties (31). On the other hand, the basins of the oxygen atom display a more similar form in ethoxyethane and 1-propoxypropane molecules, suggesting that the values of the integrated properties in both systems have to be closer.

Note: All values are given in au. $^-$ and $^+$ represent bond properties referring to the bond point between the oxygen atom and the carbon atom bonded to it on the left and right, respectively.

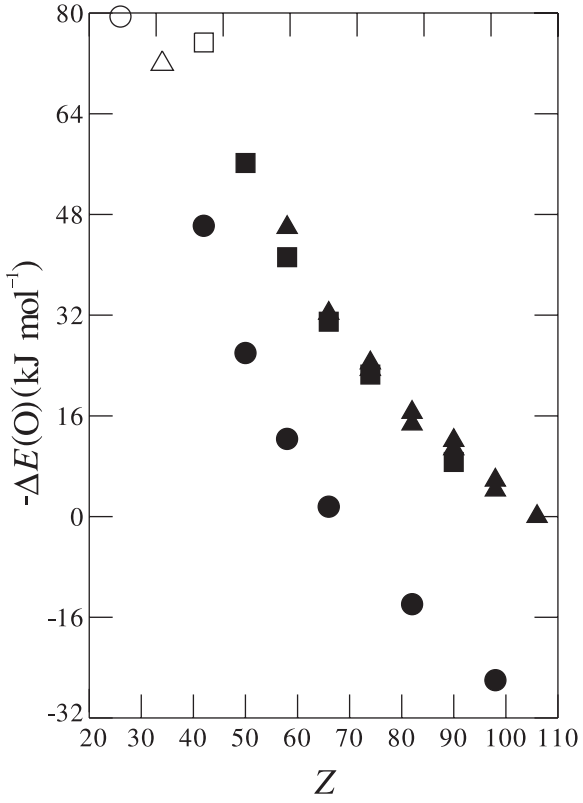

Table 2 presents the main atomic and bond properties computed for the oxygen atom from the HF/6–31++G**//6–31G* wave functions. It can be observed that the values of L(O) never exceed 0.0023 au — what makes them susceptible to be employed to study the transferability of the computed properties — being one order of magnitude larger than those obtained for the carbonyl oxygen in a previous work (18). This fact can be explained bearing in mind that two boundary surfaces have to be determined for oxygen atom in ethers. On the other hand, these larger values of L(O) allow us to employ N(O) vs. L(O) plots to distinguish among different transferable oxygen atoms as it was previously done for carbonyl carbon (18), and carbons of methyl and methilene groups in aldehydes and ketones (32). Though these linear relationships are empirical and they can be only applied along a certain range of $L(\Omega)$ values (typically $L(\Omega)$ values should verify: 10^{-2} au > $|L(\Omega)|$ > 10^{-4} au), the classification of the oxygen atoms provided by them is supported by the remaining properties (as it also happened with the atoms studied in the above mentioned works (18, 32)). In fact, the properties evaluated at bond critical points, which are not affected by integration errors, and which have been proposed to span an abstract space for similarity measures (33), and were used to classify alkyl esters (20), can be successfully classified according to this partition (Table 2). These N(O) vs. L(O) plots, presented in Fig. 3, indicate that the N(O) values can be classified in six groups: three specific values for the smallest molecules (methoxymethane, methoxyethane, and ethoxyethane) and other three values which can be considered transferable within methylethers (n = 0, m > 1), ethyl ethers (n = 1, m > 1), and the remaining dialkyl ethers (n > 1, m > 1). This conclusion can be also obtained at lower computational levels (just as an example of that, Table 3 shows the constancy of the integrated and bond properties of the dialkyl ethers' oxygen computed with smaller basis sets). It can be observed that though the addition of polarization functions over 6–31G basis set yields electron populations of the oxygen that are around 0.28 au larger and the addition of diffuse functions raises them by further 5–6 × 10^{-3} au, the differences among values computed at different levels for every molecule are almost constant. The linear relationship between N(O) and L(O) is maintained for all these computational levels (r coefficients are: 0.98, 0.97 and 0.97 for 6–31G//6–31G, 6–31G*//6–31G* and 6–31++G**//6–31G*, respectively).

Fig. 3. Variation of the electron population (N(O)) for the oxygen fragment with the error integral in the $CH_3(CH_2)_nO(CH_2)_mCH_3$ molecular series, r being the linear correlation coefficient. (○) n = m = 0; (△) n = 0, m = 1; (□) n = m = 1; (●) n = 0, m > 1; (■) n = 1, m > 1; (▲) n, m > 1.

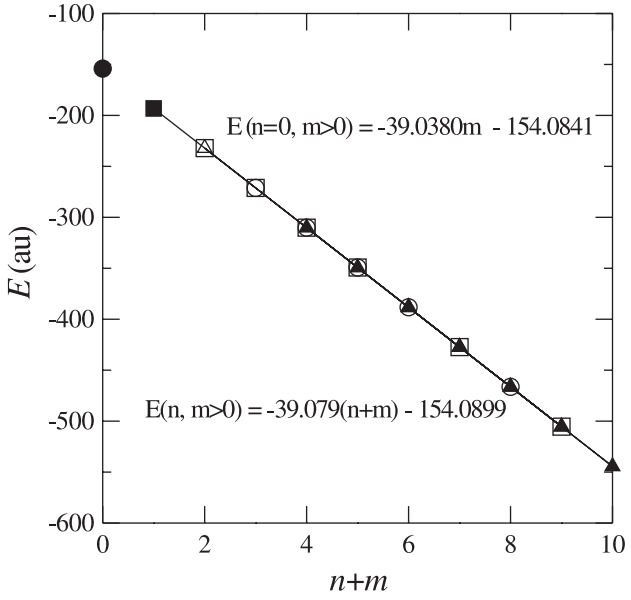
Fig. 4. Plot of the electronic energy (ΔE(O)) for oxygen in $CH_3(CH_2)_nO(CH_2)_mCH_3$ relative to that in $CH_3(CH_2)_3O(CH_2)_7CH_3$ against the total nuclear charge Z of the molecule. (○) n = m = 0; (△) n = 0, m = 1; (□) n = m = 1; (●) n = 0, m > 1; (■) n = 1, m > 1; (▲) n, m > 1.



It has to be remarked that, though the employment of N(O) absolute values to establish this classification can lead to wrong conclusions because of the influence of L(O) over N(O), N(O) absolute values are consistent with the strong electronegativity of the O atom (electron populations are always greater than 9.3 au). Both the transferable values extrapolated to L(O) = 0 (9.3161, 9.3219, and 9.3235 au for methyl ethers, ethyl ethers, and dialkyl ethers, respectively) and the specific values mentioned before indicate that the oxygen electron populations increases with the size of the substituents (methyl, ethyl, or a substituent larger than ethyl).

The evolution of the values of the oxygen energies (E(O)) (Fig. 4), obtained after correcting the electron kinetic energy (T(O)) with the (γ – 1) factor, also support the partition for the O atoms proposed above from N(O) values. As it has been found for carbonyl, methyl, and methylene groups in neutral (18, 32) and protonated (19) aldehydes and ketones, oxygen energies in alkyl ethers are also dependent of the molecule size (expressed by Z, sum of the atomic numbers of the molecule). The possibility that the molecular size effect on E(O) could be an artifact due to the incompleteness of the basis set was studied in a work on alkyl alcohols (34).[2] In no case did the changes observed in that work for the E(O) values modify the relative ΔE(O) by more than a 3% (i.e., for 1-penthanol ΔE(O), referred to 1-dodecanol, changed from –61.1 to –60.8 kJ mol^{-1}). Figure 4 shows the variation of the electronic energy ΔE(O) for oxygen atom relative to that in $CH_3(CH_2)_3O(CH_2)_7CH_3$ (the largest value of E(O) found in the molecules here studied) against the total nuclear charge Z of the molecule. So, E(O) increases with increasing m at fixed n. For example, the oxygen atoms in 1-methoxybutane and 1-methoxypentane, which are so similar as regards all other properties (Table 2), exhibit an energy difference of 13.7 kJ mol^{-1}. If we consider the difference between the energy of the smallest and the largest molecule in every series, it reaches 72.1 kJ mol^{-1} in methyl ethers, 66.6 kJ mol^{-1} in ethyl ethers, and 45.9 kJ mol^{-1} in the remaining dialkyl ethers. As a general result, we have found that oxygen atom is more stabilized for the dialkyl ether isomer than for the ethyl ether one and the latter is more stable than the corresponding methyl ether isomer. It can be concluded from Fig. 4 that it is not possible to establish transferable values for E(O) because of the influence of the molecular size Z on this magnitude. Nevertheless, this fact does not mean that the different models of group contribution traditionally applied to the calculation of energy properties in these systems cannot be employed. In fact, both HF total molecular computed energies and ΔH_f° experimental values can be very well fitted to expressions of the form:

$$E_{HF} = E(CH_2)\cdot(n + m) + E_0$$

where (n + m) represents the number of CH_2 groups in the molecule, $E(CH_2)$ is the CH_2 contribution to the total energy, and E_0 is the sum of the remaining groups contributions (the oxygen atom and the two CH_3 groups). We have considered two independent fittings, with no inclusion of methoxymethane molecule: one for methyl ethers and another one for the remaining molecules (Fig. 5) which allow an excellent reproduction of the HF/6–31++G** energies (Table 1) with maximum discrepancies of 2.2 kJ mol^{-1}

Fig. 5. HF/6–31++G** vs. number of CH_2 groups n + m for molecules in Table 1. (●) n = m = 0; (■) n = 0, m = 1; (△) n = m = 1; (□) n = 0, m > 1; (○) n = 1, m > 1; (▲) n, m > 1.

Table 4. Transferable values of electron population extrapolated to $L(O) = 0$, $[N(O)]_{L(O)=0}$, and mean values of the molar volume ($v(O)$) for the partition proposed in this work.

	$[N(O)]_{L(O)=0}$ (au)	$v(O)$ ($cm^3\ mol^{-1}$)	RMS$[v(O)] \times 10^4$
Methoxymethane	—	7.89	—
Methoxyethane	—	7.88	—
Ethoxyethane	—	7.83	—
Methylethers ($n = 0$, $m > 1$)	9.3161	7.86	3.9
Ethylethers ($n = 1$, $m > 1$)	9.3219	7.85	10.5
Dialkylethers (n, $m > 1$)	9.3235	7.83	11.8

(Fig. 6). Though the difference between the energy of the CH_2 groups for methyl ethers and remaining dialkyl ethers does not reach 1 kcal mol^{-1} according to these fittings, the difference in the intercepts justifies the consideration of two independent fittings for each series. We have also applied the same treatment to the experimental $\Delta H^{\circ}_{f\ exp}$ values available for these compounds (Table 1), though the quality of the fitting decreases (Fig. 7) as it could be expected bearing in mind the magnitude of the experimental errors and the diversity of the experimental methods employed. We have also found that there was no meaningful improvement when three independent fittings were considered for methyl ethers, ethyl ethers, and the remaining dialkyl ethers.

Also, the different evolutions of the values of the potential energy for the nucleus–electron charge interaction in the oxygen fragment ($V_{NEO}(O)$) (Table 2), allow one to distinguish methyl ethers, ethyl ethers, and dialkyl ethers with longer chains than those in the previous series.

The volumes ($v(O)$) of the region bound by the interatomic C-O surfaces and the boundary defined by an electron charge density of 0.002 au are significantly smaller than those obtained for the carbonyl oxygen (18). The evolution of the magnitude along the alkyl ethers indicates the volume decreases slightly in the series: $v(n = 0) > v(n = 1) > v(n > 2)$ as shown in Table 2. Mean values and RMS obtained for each of these series are consistent with the partitioning of the alkyl ethers proposed from the properties we have analyzed above. In Table 4 we present the transferable values of the atomic population extrapolated to $L(O) = 0$ and molar volume for the partition proposed in this work.

Though the values of the dipole moment of the electron charge distribution ($\mu(O)$) for the oxygen fragments are very similar (Table 2), it is clear the charge distribution of the oxygen in methyl ether is more polarized and that a symmetric substitution reduces the value of this magnitude.

Bond properties, which are not affected by the errors and uncertainties involved in the numerical determination of the zero-flux surfaces, clearly reflect the specific character of the oxygen fragments observed from the previous analysis. Table 2 contains the main critical bond properties for C—O bonds. Opposite to what was found for the energetic properties, bond properties do not exhibit any dependence on the total nuclear charge Z.

The ellipticity values obtained for both C—O bonds (ε^+ and ε^-) can be classified also considering three specific pairs of values for (methoxymethane, methoxyethane, and

Note: $^-$ and $^+$ represent bond properties referring to the bond point between the oxygen atom and the carbon atom bonded to it on the left and right, respectively. All values are given in au.

ethoxyethane) and three groups of molecules (the same above defined to classify atomic properties) where the ellipticity values present small oscillations (never larger than 3×10^{-4} au) around certain transferable and clearly different values presented in Table 5. This table also contains the mean values (with RMS and maximum deviations) of the positive eigenvalue of the Hessian matrix of the charge density at the C—O bond critical points (λ_3^+, λ_3^-).The larger value of the O—CH_3 bond can be associated to a smaller dependence on the environment for the properties of this bond (35).

The values obtained for the charge density at the bond critical points display a smaller variation in the series and could be grouped distinguishing only between methyl ethers the remaining alkyl ethers and the specific behaviour of the methoxymethane molecule. In fact the main difference among the values listed in Table 2 correspond to the values of ρ_c for an O—CH_3 bond (0.268 au) and an O—CH_2 bond (0.265 au). The same can be said for the R values (1.798 au and 1.795 au for O-CH_3 and O-CH_2, respectively), which can also be classified according to the partition described for ρ_c. As it has been previously stated by Wiberg and Breneman (36) a large part of the variation in ρ_c is associated with the change in bond length and so O-Et is almost the same as O-R (R > Et). Table 5 includes mean values of R and ρ_c with RMS and maximum deviation for each of the groups considered for previous properties.

Conclusions

To sum up, the different trends followed by the energy properties (which cannot be considered transferable because of a strong dependence with the size of the molecule already reported for aldehydes and ketones), the different linear relationships between N(O) and L(O), and the different values of other integrated properties and the main C—O bond properties, support the consideration of six different oxygen atoms along the series of the unbranched dialkyl ethers. These atoms are the O of: MeOMe, MeOEt, EtOEt, MeOR, EtOR, and ROR′ (R, R′ > Et).

Anhydrous perchlorato complexes of palladium(II): $Pd(ClO_4)_2$, $(ClO_2)_2Pd(ClO_4)_4$, and $(NO_2)_2Pd(ClO_4)_4$. Syntheses and structural analyses

Frédérique Cunin, Frédéric Favier, and Jean Louis Pascal

Abstract: Chlorine trioxide (Cl_2O_6) reacts with $PdCl_2$ to yield "$ClO_2Pd(ClO_4)_3$" which is, in fact, an equimolar mixture of $Pd(ClO_4)_2$ and $(ClO_2)_2Pd(ClO_4)_4$. The chloryl salt decomposes under vacuum to give $Pd(ClO_4)_2$. $(NO_2)_2Pd(ClO_4)_4 \cdot 0.5\ NO_2ClO_4$ is prepared using $Pd(NO_3)_2 \cdot 0.5\ (H_2O, HNO_3)$ as the starting salt. Excess NO_2ClO_4 sublimes easily and pure $(NO_2)_2Pd(ClO_4)_4$ is obtained. $Pd(ClO_4)_2$ and $(NO_2)_2Pd(ClO_4)_4$ crystallize poorly; however, a $P2_1/m$ space group is proposed for the latter. A complete assignment of vibrational modes, and DFT calculations, show that $Pd(ClO_4)_2$ is monomeric with chelating bidentate [ClO_4] groups and Pd is in a square planar environment. In nitryl and chloryl salts, individual anions ($Pd(ClO_4)_4^{2-}$), where unidentate [ClO_4] groups interact partially with the cation or the Pd core, were characterized.

Key words: palladium(II), chlorine trioxide, perchlorato complexes, chelating bidentate, vibrational spectroscopy, DFT calculations, powder X-ray diffraction.

Résumé : Le trioxyde de chlore (Cl_2O_6) réagit avec $PdCl_2$ pour donner « $ClO_2Pd(ClO_4)_3$ ». Ce sel est en fait un mélange équimoléculaire de $Pd(ClO_4)_2$ et de $(ClO_2)_2Pd(ClO_4)_4$. Ce dernier se décompose sous vide dynamique en $Pd(ClO_4)_2$ et Cl_2O_6. $(NO_2)_2Pd(ClO_4)_4 \cdot 0{,}5\ NO_2ClO_4$ est obtenu à partir de $Pd(NO_3)_2 \cdot 0{,}5\ (H_2O, HNO_3)$. NO_2ClO_4 additionnel se sublime facilement et $(NO_2)_2Pd(ClO_4)_4$ pur est isolé. La cristallinité de $Pd(ClO_4)_2$ et $(NO_2)_2Pd(ClO_4)_4$ est médiocre cependant il est possible de proposer le groupe d'espace $P2_1/m$ pour le sel de nitryle. Une attribution complète des modes de vibration et un calcul DFT montrent que $Pd(ClO_4)_2$ est un monomère et que les groupements [ClO_4] sont bidentés chélatants. Pd est dans un environnement plan carré. Les sels de nitryle et de chloryle comportent des anions individuels $Pd(ClO_4)_4^{2-}$ ou les groupements [ClO_4] monodentés interagissent fortement avec les cations ou le centre métallique Pd.

Mots clés : palladium(II), trioxyde de chlore, complexes perchlorato, bidenté chélatant, spectroscopie de vibration, calculs DFT, rayons X sur poudre.

Introduction

In spite of advancing knowledge of perchlorato complexes (1) they still remain an attractive subject of interest (2) in view of their versatile structural properties (1), their potential use as catalysts (3) or electrolytes (4), and as a source of materials such as chlorides, oxides, or oxychlorides (5) or oxygen (6). Perchlorates of precious metals are little studied for reasons less linked to the cost of starting materials than to their difficult synthesis. According to Pearson's HSAB concept (7), the hard base ClO_4^- interacts more readily with hard acids than boundary or soft acids. The latter are mainly found in the platinum group family. Since these metals can exist in high oxidation states they should bind more easily to O^{2-} than ClO_4^-, and O^{2-} can be formed from efficient perchlorating reagents such as anhydrous $HClO_4$ or Cl_2O_6 which are also very strong oxidizers. Since the most stable oxidation state of Pd is II, the synthesis of palladium perchlorato complexes should be easier than that of the other perchlorato complexes of the platinum series. In fact, this has been demonstrated previously when it was shown that $Pd(ClO_4)_2$ and $ClO_2Pd(ClO_4)_3$ could be prepared without the formation of oxides (8). However, their IR spectra did not allow a molecular geometry to be proposed. In this paper, synthesis and structural studies of the above complexes are revisited and a previously unknown perchlorate ($(NO_2)_2Pd(ClO_4)_4$) has been synthesized and analyzed. For the first time, a DFT optimization of the geometry of a perchlorato complex involving a chelating bidentate [ClO_4] group was performed and a complete assignment of vibrational modes is proposed.

Results and discussions

Synthesis

Reaction of a perchlorating reagent with various salts has been described in a recent review (1), where the choice of Cl_2O_6 as perchlorating reagent as well as strategies to improve reactions have been explained.

© 2000 NRC Canada

If a hydrated chloride is used as the starting salt, [Cl] is replaced by [ClO_4] and eliminated as Cl_2 and as the acids that are produced when Cl_2O_6 reacts with water (9). Extra Cl_2O_6 adds to the neutral molecule $M(ClO_4)_n$ (n = oxidation state of M) to give well-characterized salts $(ClO_2)_mM(ClO_4)_{n+m}$ or mixtures $M(ClO_4)_n$, mCl_2O_6, ($0.5 < m < 2$) (1).

With $PdCl_2 \cdot \varepsilon H_2O$ ($\varepsilon \approx 0.1$), the reaction proceeds as follows:

[1] $$PdCl_2 \cdot \varepsilon H_2O + (3 + \varepsilon)Cl_2O_6 \rightarrow ClO_2Pd(ClO_4)_3 + \varepsilon HClO_3\uparrow + \varepsilon HClO_4\uparrow + Cl_2\uparrow$$

[2] $$ClO_2Pd(ClO_4)_3 \underset{\Delta / \text{vacuum}}{\rightarrow} Pd(ClO_4)_2 + Cl_2O_6$$

Nitrate salts behave differently since NO_3^- is transformed into the nitryl cation (NO_2^+) in acidic medium (10, 11) and is replaced simultaneously by ClO_4^- according to:

[3] $$M(NO_3)_n + 2nCl_2O_6 \underset{10°C}{\rightarrow} (NO_2)_nM(ClO_4)_{2n} + 2nClO_2\uparrow + n/2O_2\uparrow$$

$(NO_2)_nM(ClO_4)_{2n}$ is generally formed as the mixture: $NO_2M(ClO_4)_{n+1}/n - 1\ NO_2ClO_4$. Nitryl perchlorate sublimes under vacuum at $T > 60°C$ and pure $NO_2M(ClO_4)_{n+1}$ is obtained. When $T > 100°C$, nitryl perchlorato metallate salts decompose to yield $M(ClO_4)_n$ (1). Well-defined $(NO_2)_nM(ClO_4)_{2n}$ salts are rarely prepared in a single step. Until the present study, only Cu (11) and Hg (12) salts of such stoichiometry had been obtained.

With $Pd(NO_3)_2 \cdot 0.5(H_2O, HNO_3)$ as the starting material, the reactions can be summarized as follows:

[4] $$Pd(NO_3)_2 + 4Cl_2O_6 \underset{10°C}{\rightarrow} (NO_2)_2M(ClO_4)_4 + 4ClO_2\uparrow + O_2\uparrow$$

[5] $$H_2O + HNO_3 + 2Cl_2O_6 \underset{10°C}{\rightarrow} NO_2ClO_4 + 2ClO_2\uparrow + 1/2O_2\uparrow + HClO_3\uparrow + 2HClO_4\uparrow \quad (13)$$

therefore:

[6] $$Pd(NO_3)_2 \cdot 0.5(H_2O, HNO_3) + 5Cl_2O_6 \underset{10°C}{\rightarrow} (NO_2)_2Pd(ClO_4)_4 + NO_2ClO_4 + 5ClO_2\uparrow + 1.25O_2\uparrow + 0.5HClO_3\uparrow + 2HClO_4\uparrow$$

Powder X-ray diffraction analysis

The powder diffraction pattern of $Pd(ClO_4)_2$ is of poor quality, only 14 well-defined lines were found in the 2θ range: 10–50° and at higher angles, the line intensities vanish rapidly, therefore an indexing program such as TREOR 90 (TREOR 90: A semiexhaustive TRial and ErrOR powder indexing program. Basic principles: see ref. 14*a*; for all symmetries: see ref. 14*b*) could not give an accurate determination of the crystallographic symmetry. For $(NO_2)_2Pd(ClO_4)_4$, 24 lines could be used and determination of the unit cell was straightforward. This compound crystallizes with monoclinic symmetry (a = 15.063(4), b = 9.666(1), c = 5.436(2) Å, β = 103.29(2)° (M(24) = 23 av. eps. = 0.0000316) (15); F24 = 35 (0.009554, 72) (16))).

$P2_1/m$ appears as a possible space group. With $Z = 2$, the calculated density is 2.57. It is in the expected range for a such perchlorato complex (17). An X-ray diffraction pattern finger print is given in Table 1 for $Pd(ClO_4)_2$. The indexed X-ray lines for $(NO_2)_2Pd(ClO_4)_4$ are listed in Table 2.

Vibrational analysis

$Pd(ClO_4)_2$

IR and Raman spectra of bis(perchlorato)palladium(II) are shown in Fig. 1. The distribution of lines and their frequencies in the range of the stretching modes (800–1350 cm^{-1}) are consistent with bidentate bonding for the [ClO_4] groups (1). The region containing deformation modes (400–700 cm^{-1}) is very perturbed. Comparison of these data with those found for $Ti(ClO_4)_4$ (18) or $Yb(ClO_4)_3$ (high-temperature form) (2*a*) (Fig. 2) suggests that [ClO_4] is a chelating bidentate group in $Pd(ClO_4)_2$ and that therefore, the complex is a monomeric unit (Fig. 3). This is very surprising because the chloride salt (from which the geometry of perchlorato complexes generally derives (19)) ($PdCl_2$) is a two-dimensional polymer with bridging Cl atoms (20) and because some carboxylate and phosphate complexes, ligands act as bridging entities. $(Pd(OAc)_2$ is a cyclic trimer (21) while $Pd(PO_3)_2$ is built on a three-dimensional network (22)). However, the geometry of $Pd(ClO_4)_2$ is similar to that of $Pd(AlCl_4)_2$ (23). Assignment of bands and lines was improved by a DFT geometry optimization which provided the vibrational frequencies (24). A starting model was built on the basis of the relation $\nu = f$(dCl—O) established elsewhere (1) for a bidentate chelating [ClO_4] group and a square planar geometry around palladium with 4 Pd—O

distances around 2.00 Å. For this closed shell compound ($S = 0$), we searched for a local minimum on the potential energy surface at three levels (HF, B3LYP, and B3PW91). The calculated geometry converged to a deformed square planar environment for Pd and chelating bidentate $[ClO_4]$ groups (Fig. 3) which was independent of the level of theory and basis sets used. Geometrical data are summarized in Table 3. As expected, the higher the level of calculation and the more complex the basis sets, the closer the result of the calculation to the experimental data. The calculated vibrational frequencies (unscaled) are compared with the experimental frequencies in Table 4. A description of vibrational modes is also given. Regardless of the level of theory and basis sets used, the same classification of vibrational energy levels and coupling were obtained. Best agreement was found with B3PW91 hybrid density functional level and selected basis sets for Pd, Cl, and O (LANL2DZ for Pd, cc-pVQZ for Cl and O). Although a maximum symmetry of D_{2h} was expected, assignments correspond to C_{2v} symmetry. In contrast crystal effects which are associated mainly with stretching modes cannot be accounted for. Shifts between experimental and calculated frequencies are consistent with those observed in several solids for which a similar procedure was carried out (25). The stretching modes are located, as expected, at frequencies higher than 800 cm^{-1}. The three groups of lines or bands are close to those observed in other

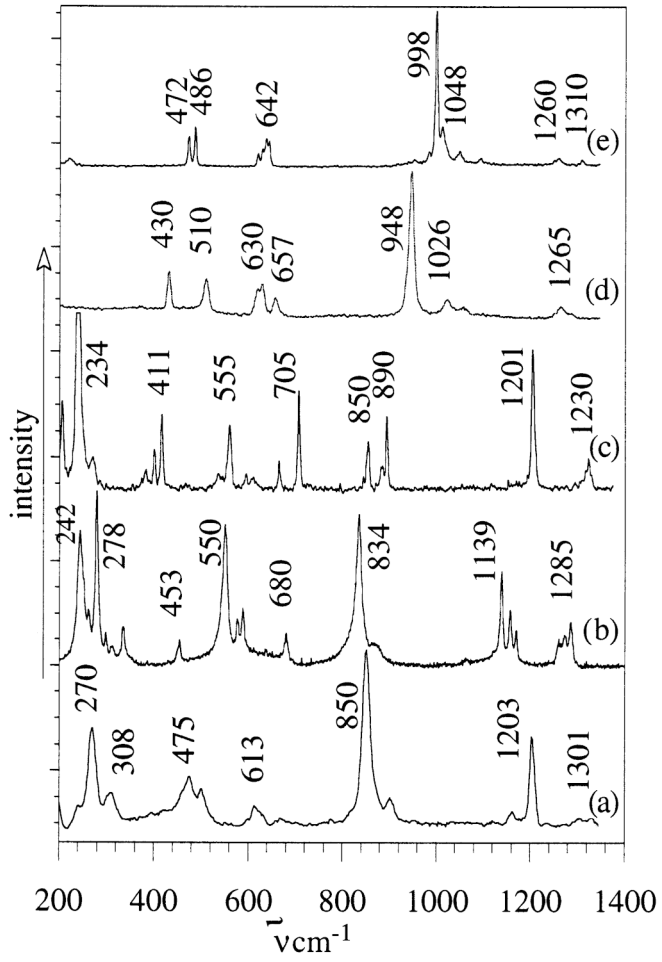
Fig. 1. (*a*) Raman and (*b*) IR spectra of $Pd(ClO_4)_2$.



complexes involving bidentate $[ClO_4]$ (1) (Fig. 2). The most striking feature appears for the deformation modes. Previous results using guidelines from Hathaway and Underhill (26) and from a simple force constant calculation (27), but which did not take into account coupling between ClO_4 and MO_n vibrational modes, led to the following scale: $\rho_r > \rho_w > \delta ClO_t > \rho_t > \delta ClO_b$. Present results show that $\delta ClO_b > \rho_w > \rho_t > \delta ClO_t > \rho_r$, and that these modes are coupled with PdO_4 vibrations. The distribution seems consistent with constraints imposed by the chelation of $[ClO_4]$ groups.

Chloryl- and nitryl-perchloratopalladates

The Raman spectra for these salts are shown in Fig. 4. They are compared with those of $Pd(ClO_4)_2$ and $ClO_2Au(ClO_4)_4$ (2*f*). The ClO_2^+ and NO_2^+ cations are clearly identified by their very strong lines resulting from their symmetric stretching vibrations at 1033 cm^{-1} and 1406 cm^{-1} (1), respectively. The strong line around 1050 cm^{-1}, the broad doublet near 1200 cm^{-1}, and lines in the range 750–900 cm^{-1} are characteristic of perturbed unidentate $[ClO_4]$ groups (28). For the chloryl salt, additional lines appear at 555, 835, 1150, and 1280 cm^{-1}, which are interpreted as characteristic of a bidentate $[ClO_4]$. A close comparison of these lines with those found for $Pd(ClO_4)_2$ show that they are identical. Subtraction of the $Pd(ClO_4)_2$ contribution leads to a clean spectrum of $ClO_2Pd(ClO_4)_3$ in which only unidentate $[ClO_4]$ appears

Fig. 2. Comparison of the Raman spectra of: (*a*) $Fe(ClO_4)_3$ (43); (*b*) $Pd(ClO_4)_2$; (*c*) $Ti(ClO_4)_4$; (*d*) $Yb(ClO_4)_3$ (high-temperature form); and (*e*) $Yb(ClO_4)_3$ (low-temperature form). Shifts in the deformation mode range (400–700 cm^{-1}) distinguish bridging and chelating bonding modes for bidentate (a, b, c) and tridentate (d, e) $[ClO_4]$ groups.

as found in $ClO_2Au(ClO_4)_4$ or $(ClO_2)_2Pt(ClO_4)_6$ (2*f*). Since Pd(II) is generally found in a square planar environment, we can conclude that the chloryl salt is $(ClO_2)_2Pd(ClO_4)_4$ and that the product obtained in a first step is an equimolar mixture of $Pd(ClO_4)_2$ and $(ClO_2)_2Pd(ClO_4)_4$.

X-ray diffraction and vibrational spectroscopic analyses of Cl_2O_6 (27, 29), $(ClO_2)_2Sn(ClO_4)_6$ (28), and $ClO_2Au(ClO_4)_4$ (2*f*) indicate strong anion–cation interactions. This is demonstrated in metal salts by a shift and a splitting of the νClO_b modes (750–920 cm^{-1} range) as well as by the appearance of new lines between 1000 and 1250 cm^{-1}. Only some $[ClO_4]$ interacts with ClO_2^+ leading to pseudo-bidentate $[ClO_4]$ groups (Fig. 5), whereas the remaining $[ClO_4]$ groups are classical unidentate groups (1). These two kinds of bonding modes are distinguished. They appear in Table 5 where their vibrational assignments are given and where couplings found from the DFT optimization of $ClO_2Au(ClO_4)_4$ are included.

The nitryl salt, $(NO_2)_2Pd(ClO_4)_4$, behaves like the chloryl salt, however, the lines assigned to the stretching modes of bridged Cl—O (Cl—O_b) are shifted to higher frequencies,

Fig. 3. Molecular geometry of $Pd(ClO_4)_2$.

indicating stronger interactions between $[ClO_4]$ and a positive center. Generally NO_2^+ is relatively free (17), but in this nitryl salt ν_s NO_2^+ is located at 1406 cm^{-1} instead of at 1396 cm^{-1} (30) and δNO_2^+ is assigned at 596 cm^{-1} (the same position as the line arising from δ_{as} ClO_{3t}) instead of 570 cm^{-1}. This implies weak bonding of the nitryl cation to $[ClO_4]$ with a shortening of N—O bonds and an angular deformation, but this does not account entirely for the large observed shift. A secondary interaction between $[ClO_4]$ and the Pd center probably occurs leading to a pseudo-bidentate $[ClO_4]$ and a strained octahedron around Pd. Such a geometry was suggested in $Au(NO_3)_4^-$ (31). However in $(NO_2)_2Pd(ClO_4)_4$, $O_3ClO_b\cdots Pd$ distances should be shorter than those observed for $O_2NO_b\cdots Au$ (2.86 Å) in $Au(NO_3)_4^-$ or $O_3ClO_b\cdots Au$ (≈2.90 Å) in $Au(ClO_4)_4^-$ and the Pd-O_b-Cl angle lower to support formation of pseudo-bidentate $[ClO_4]$ and to explain the observed frequency shifts in the νClO_b range. Frequency assignments are compared to those of $ClO_2Au(ClO_4)_4$ (2*f*) and $(ClO_2)_2Pd(ClO_4)_4$ in Table 5.

Experimental

Caution: Chlorine trioxide, perchlorato complexes prepared in this work are very hazardous reagents. They can explode spontaneously when mixed with organic compounds. They must be handled with an efficient protective shield. Reactions have to be continuously checked and monitored. Only small amounts of products should be prepared and used.

Starting products

The perchlorating reagent (Cl_2O_6) was prepared and purified as previously described (9). The starting salts were anhydrous $PdCl_2$ (Alpha 99%) and $Pd(NO_3)_2{\cdot}xH_2O$ (Aldrich, $x \approx 2$). To facilitate the reaction between $PdCl_2$ and Cl_2O_6, $PdCl_2$ was dissolved in distilled water (17) then dried under dynamic vacuum (1.33 Pa) to give a slightly hydrated chloride $PdCl_2{\cdot}\varepsilon H_2O$ ($\varepsilon \approx 0.1$). Behaviour of the nitrate salt toward Cl_2O_6 (2*f*) showed that this commercial compound should be written as $Pd(NO_3)_2{\cdot}0.5(H_2O, HNO_3)$ rather than as $Pd(NO_3)_2{\cdot}2H_2O$.

Syntheses

Reactions were performed as previously described on a vacuum line (1) by reacting an excess of Cl_2O_6 with the starting salts for several hours. Weight and Raman spectroscopic tests were carried out regularly to check the progress of the reactions. Products are very hygroscopic and they were handled in a JACOMEX glove box (model B 5531 NMT) filled with ultra-purified and dried N_2.

In a typical reaction, 0.196 g of $PdCl_2$ gave 0.496 g of a brown-black solid which should be formulated as

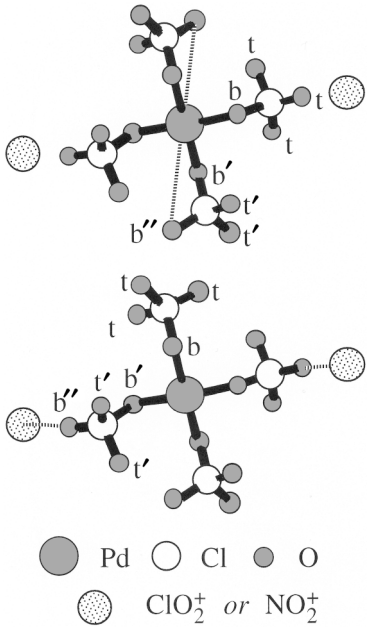
Fig. 4. Raman spectra of (*a*) $Pd(ClO_4)_2$; (*b*) raw $ClO_2Pd(ClO_4)_3$; (*c*) $(ClO_2)_2Pd(ClO_4)_4$; (*d*) $(NO_2)_2Pd(ClO_4)_4$; and (*e*) $ClO_2Au(ClO_4)_4$.



$ClO_2Pd(ClO_4)_3$ (expected: 0.498 g). This compound decomposes over a period of 3 weeks at room temperature under dynamic vacuum (1.33 Pa) to yield a brown solid $Pd(ClO_4)_2$ (anal. calcd.: Pd 34.8, ClO_4 65.2; found: Pd 34.8, ClO_4 66.6). Warming the chloryl salt to 60°C under dynamic vacuum increased the decomposition rate and limited the duration of synthesis of pure $Pd(ClO_4)_2$ to a few hours. In so doing, some of the $Pd(ClO_4)_2$ sublimed, without decomposition, onto the cold part of the reactor as a thin brown metallic film.

When 0.305 g of $Pd(NO_3)_2 \cdot 0.5(H_2O,HNO_3)$ reacted with an excess of Cl_2O_6, 0.752 g of the pale brown solid $(NO_2)_2Pd(ClO_4)_4 \cdot 0.5\ NO_2ClO_4$ (expected: 0.749 g) was obtained after removal of the unreacted Cl_2O_6 under vacuum at room temperature. Extra NO_2ClO_4 was removed above 60°C to yield $(NO_2)_2Pd(ClO_4)_4$. At higher temperature, this nitryl salt sublimed to form thin brown metallic films and microcrystals which were not suitable for X-ray diffraction studies.

Structural studies

Powder X-ray diffraction analysis of $Pd(ClO_4)_2$ and $(NO_2)_2Pd(ClO_4)_4$ were collected at the IMN in Nantes on an INEL PSD PCS 120 diffractometer equipped with a curved

Fig. 5. Molecular geometry of $(A)_2Pd(ClO_4)_4$ (A = ClO_2^+, NO_2^+).

detector. Cu-$K_{\alpha 1}$ radiation (1.54059 Å) was used. $Na_2Ca_3Al_2F_{14}$ was the external standard (a = 10.25012 Å). Finely ground and sieved (0.45 μ) powder was introduced into a thin Lindeman capillary (0.3 mm) that was sealed under dry N_2. TREOR90 (14) was used to determine cell parameters and lattice symmetry. A complete analysis of the observed lines with DTETA (32) and application of extinction rules led to determination of the space groups.

For IR spectroscopy, finely ground solids were pressed between very clean and polished AgCl plates (2*f*). Plates were placed in an airtight holder. Spectra were recorded on a Bomem DA8 FTIR spectrometer. Calibration was performed with a polystyrene film. For Raman analysis, a LABRAM DILOR spectrometer, equipped with a RX40 OLYMPUS microscope, was used. Samples sealed in thin Pyrex capillaries (≈1 mm) were illuminated with an He–Ne laser (6328 Å, 0.12 mW on the sample). Lines of a neon tube were used as standard.

Computational details

All calculations on the complex $Pd(ClO_4)_2$ were carried out with the GAUSSIAN 98 set of programs (24). Palladium was represented using Los Alamos relativistic core potential (ECP) for the 32 innermost electrons and its associated double ζ basis set (33) with or without polarization *f* function (34). Chlorine atoms were also described with the Los Alamos ECPs and their associated double ζ basis set (35) augmented by polarization *d* functions (34). A 6–31G (d,p) was used for the oxygen atoms (36). For calculations at higher levels of theory, chlorine and oxygen atoms were described with the double, triple, or quadruple ζ correlation consistent basis set of Dunning and co-workers (37). Calculations were performed by the Hartree–Fock method or within the framework of density functional theory with two different hybrid functions. The exchange potential was that proposed by Becke (38) and included in part, the exact Hartree–Fock exchange (39). Correlation potentials of Perdew and Wang (40) (B3PW91) and of Lee et al. (41)

(B3LYP) were used. The nature of the optimized structure was assigned by analytical calculations of the vibrational frequencies. Vibrational modes were displayed with the MOLDEN program (42).

Conclusion

Whereas $[ClO_4]$ generally acts as an assembling ligand leading to polymeric channeled or layered structures (1), results on Pd perchlorato complexes show that it can behave differently to give monomeric units which are less frequently encountered in the list of known perchlorato complexes. Such behaviour should improve their reactivity.

Acknowledgment

The authors are grateful to Catherine Deudon of the IMN in Nantes for the powder X-ray data recording. They thank Deborah J. Jones and Bernard Mula for helpful discussion and CNRS for financial support.

A thermodynamic study of aqueous acetonitrile: excess chemical potentials, partial molar enthalpies, entropies and volumes, and fluctuations

Penka V. Nikolova, Sheldon J. B. Duff, Peter Westh, Charles A. Haynes, Yasutoshi Kasahara, Keiko Nishikawa, and Yoshikata Koga

Abstract: We measured vapour pressures of aqueous acetonitrile (abbreviated as ACN) at 6, 20, and 37°C, from which excess chemical potentials of ACN (μ^{E}_{ACN}) were calculated. We also determined excess partial molar enthalpies of ACN (H^{E}_{ACN}) at 6, 20, 30, 37, and 45°C. From these data, excess partial molar entropies of ACN (S^{E}_{ACN}) were calculated at 6, 20, and 37°C. Using density data by Benson's group, excess partial molar volumes of ACN (V^{E}_{ACN}) were evaluated. The response function data by the same group were also used to evaluate amplitude and wavelength of mean-square fluctuations in terms of volume, entropy, and cross between volume and entropy. All the above quantities and their dependence on the mol fraction of solute, i.e., the effect of additional solute on the above quantities were used to study the effect of acetonitrile on the molecular organization of H_2O. It was found that acetonitrile works as a stronger structure-making solute than methanol. Rather its effect on H_2O is about the same as that of propan-1-ol.

Key words: aqueous acetonitrile, interaction functions, fluctuations.

Résumé : On a mesuré les tensions de vapeur de solutions aqueuses d'acétonitrile (ACN) à 6, 20 et 37°C et, à partir des valeurs obtenues, on en a calculé les potentiels chimiques en excès d'ACN (μ^{E}_{ACN}). On a aussi déterminé les enthalpies molaires partielles en excès d'ACN (H^{E}_{ACN}) à 6, 20, 30, 37 et 45°C. À partir de ces données, on a calculé les entropies molaires partielles en excès d'ACN (S^{E}_{ACN}) à 6, 20 et 37°C. En utilisant des données relatives à la densité obtenues par le groupe de Benson, on a calculé les volumes molaires partiels en excès, d'ACN (V^{E}_{ACN}). On a aussi utilisé les données relatives à la fonction de réponse obtenues par ce même groupe pour évaluer l'amplitude et la longueur d'onde des fluctuations quadratiques moyennes en termes de volume, entropie et mélange de volume et d'entropie. Dans le but d'étudier l'effet de l'acétonitrile sur l'organisation moléculaire de H_2O, on a aussi utilisé toutes les valeurs mentionnées plus haut ainsi que leur dépendance sur la fraction molaire du soluté, c'est-à-dire l'effet de soluté additionnel sur les quantités mentionnées plus haut. On a trouvé que, par rapport au méthanol, l'acétonitrile agit comme un soluté provoquant une mise en place plus grande de la structure. Son effet sur H_2O est à peu près égal à celui du propan-1-ol.

Mots clés : acétonitrile aqueux, fonctions d'interaction, fluctuations.

Introduction

As a part of our continuing effort to study binary aqueous solutions by using partial molar quantities and response functions (1–9), we report here the results of our study on aqueous acetonitrile (abbreviated as ACN). Our earlier studies on aqueous alcohols (AL) including methanol (ME) (4, 7) indicated that there are three composition regions in each of which the mixing scheme is qualitatively different from those of other regions. In the most H_2O-rich region, what we

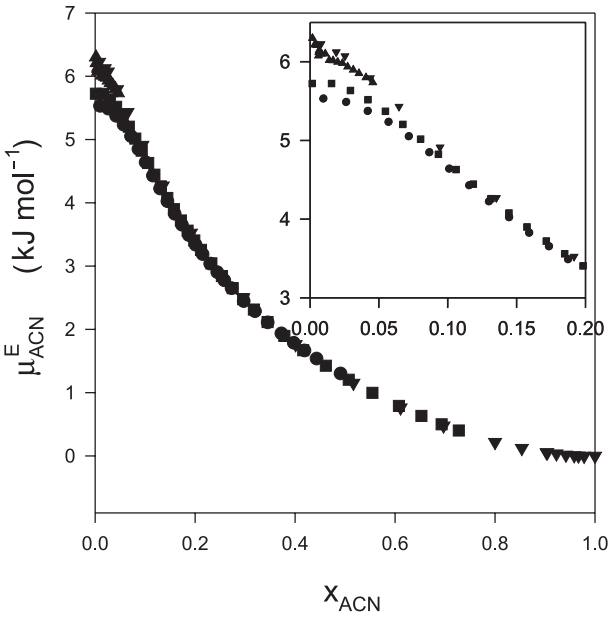
call Mixing Scheme I is operative. Alcohol enhances the hydrogen bond network of H_2O in its immediate vicinity with a concomitant reduction of the hydrogen bond probability of bulk H_2O away from solute. However, the hydrogen bond probability of bulk H_2O is still high enough so that the hydrogen bond network is connected throughout of the entire bulk. Namely, the hydrogen bond network is still bond-percolated.

In the intermediate composition, there is no bond-percolation and the solution consists of two kinds of clusters, each rich in AL or H_2O. We call this Mixing Scheme II. The transition from Mixing Scheme I to II occurs in a certain narrow mol fraction range. We call the starting point of transition X and the end point Y. This is apparent in an anomalous behaviour in the thermodynamic quantities proportional to the third derivatives of Gibbs energy (G) (as demonstrated later on in this paper). The longer the alkyl chain of AL, the stronger the effect of solute. The transition region occurs at a lower mol fraction of AL (x_{AL}) and the interaction between solutes is stronger.

In the AL-rich region, Mixing Scheme III becomes apparent, in which AL molecules cluster. H_2O molecules then interact with AL clusters as a single molecule (1, 2, 4, 7). Thus, the characteristics of liquid H_2O are lost completely in this region.



ME–H_2O mixtures follow this general trend, although the effect of ME is not as dramatic as those of higher alcohols. The transitions of mixing scheme are still observable in ME–H_2O. Point X occurs at x_{ME} = 0.07, Y at x_{ME} = 0.25, and at x_{ME} = 0.45 the transition from Mixing Scheme II to III takes place (4, 7).

Our interest in studying aqueous acetonitrile lies on the effect of change from -OH of ME to -CN on the thermodynamic behaviour of aqueous solutions, on one hand. On the other, our preliminary study on a cellulolytic enzyme in a mixed solvent, ACN–H_2O, shows a strong, step-wise dependence of enzyme function on the mol fraction of ACN (x_{ACN}) hinting at the effect of the change in mixing scheme in the solvent system, ACN–H_2O, on enzyme kinetics. To gain insight in the mixing schemes, we measured the excess partial molar enthalpy of ACN (H^E_{ACN}) and the vapour pressures to calculate excess chemical potential of ACN (μ^E_{ACN}). For density and response functions, there are extensive data by Benson and co-workers (10, 11). We use these data for evaluating partial molar volume, and fluctuation functions (5–7, 12, 13).

Experimental

Acetonitrile (ACROS, nonaqueous titration grade, 99+%) was handled in a dry nitrogen atmosphere. H_2O was distilled three times; the last two times in a Pyrex glass still immediately before use. Excess partial molar enthalpy of ACN (H^E_{ACN}) was determined by a microtitration calorimeter, Calorimetry Science Corp. (Provo, UT) Model 4209, at 20, 30, 37, and 45°C. For 6°C, a homemade titration calorimeter (14), similar to an LKB Bromma model, was used. The uncertainty in H^E_{ACN} is about ±0.05 kJ mol^{-1}. Since the absolute sensitivity of the former calorimeter is higher by some 100-fold, the amount of titre is reduced by the same ratio. As a result, the data increments are much smaller. This turned out to be crucial in detecting anomalous behaviour in a very dilute range (x_{ACN} < 0.01). Vapour pressure was measured by a static method (15).

Fig. 1. Excess chemical potential of acetonitrile (μ^E_{ACN}). Circle (6°C), square (20°C), triangle up (37°C), triangle down (35°C) (17).

Results

The total vapour pressure data (p) corrected by the Gibbs–Konovalov relation (15), for a small temperature variation during the measurement, are listed in Table I, deposited in CISTI.[3] The 37°C data are limited to a dilute range (x_{ACN} < 0.05) since the total pressure reached 100 torr (1 torr = 133.322 Pa), the upper limit of the Baratron gauge used. The partial pressure of ACN (p_{ACN}) and that of H_2O (p_W) were calculated by the Boissonnas method (15), and they are listed in Table I.[3] The excess chemical potential of ACN (μ^E_{ACN}) was calculated as,

$$[1] \qquad \mu^E_{ACN} = RT \ln (p_{ACN}/x_{ACN}p^0_{ACN})$$

where p^0_{ACN} is the vapour pressure of pure ACN at the same temperature (16). The correction term due to nonideality of the gas-phase is negligibly small in comparison with the value calculated by the right hand side of eq. [1]. The resulting μ^E_{ACN} data are also listed in Table I,[3] and plotted in Fig. 1. Also plotted in Fig. 1 are the data by French (17) for 35°C. As is evident in Fig. 1, the temperature dependence of μ^E_{ACN} is small. Our 37°C data are almost identical to the 35°C data by French in the range x_{ACN} > 0.03. The first few

points ($x_{ACN} < 0.03$) calculated by the Boissonnas method are not reliable (18).

The excess partial molar enthalpies of ACN (H^{E}_{ACN}) are listed in Table II[3] and plotted in Fig. 2. In Fig. 2*b* are also plotted the values of TS^{E}_{ACN}, the excess partial molar entropy of ACN times temperature for 6 and 37°C calculated as,

[2] $$TS^{E}_{ACN} = H^{E}_{ACN} - \mu^{E}_{ACN}$$

For 37°C, French's data of μ^{E}_{ACN} at 35°C (17) were used. The excess partial molar volume of ACN (V^{E}_{ACN}) was calculated using the density data by Handa and Benson (10) in the same manner as described elsewhere (19). The resulting V^{E}_{ACN} data were plotted in Fig. 3.

The density (10), the heat capacity, and the speed of sound data by Benson et al. (11) were treated in the same way as in a previous paper on fluctuations in aqueous alcohols (7). Briefly, the following quantities related to mean-square fluctuation were calculated using molar volume (V_m), heat capacity (C_p), isothermal compressibility (κ_T), and thermal expansivity (α_p):

[3] $$^{V}\delta = T\kappa_T$$

[4] $$^{S}\delta = C_p/V_m$$

[5] $$^{SV}\delta = T\alpha_p$$

[6] $$^{V}\Delta = RT\kappa_T/V_m$$

[7] $$^{S}\Delta = RTC_p/V_m{}^2$$

[8] $$^{SV}\Delta = RT\alpha_p/V_m$$

As discussed at some length earlier (7), $^{q}\delta$ (q = *V*, *S*, or *SV*) shows the amplitude of fluctuation in q, while $^{q}\Delta$ contains qualitative information about the wavelength as well as the amplitude of fluctuation in q. The functions calculated by eqs. [3]–[8] are listed in Table III[3] and plotted in Figs. 4–6.

Discussion

Second derivatives of *G*

We discuss first what the data of H^{E}_{ACN}, S^{E}_{ACN}, V^{E}_{ACN}, $^{q}\delta$s, and $^{q}\Delta$s indicate in terms of the nature of ACN–H_2O. The latter quantities are all proportional to the second derivatives of G with respect to a combination of independent variables (p, T, n_{ACN}) in the Gibbs ensemble. The fact that μ^{E}_{ACN} is positive and decreases as x_{ACN} increases (Fig. 1), hints at a possibility of liquid–liquid phase separation (1, 2, 20). The H^{E}_{ACN} and TS^{E}_{ACN} data in Fig. 2 indicate that in the H_2O-rich region, $x_{ACN} < 0.1$, the slopes are positive, i.e., $(\partial H^{E}_{ACN}/\partial x_{ACN}) > 0$ and $(\partial S^{E}_{ACN}/\partial x_{ACN}) > 0$. Together with $(\partial \mu^{E}_{ACN}/\partial x_{ACN}) < 0$, this is a necessary but not sufficient requirement for phase separation with a lower critical solution temperature (LCST) (1, 2, 20). Thus, if there were to be a phase separation in the range $x_{ACN} < 0.1$, it must be that with an LCST. In the range $x_{ACN} > 0.1$, on the other hand, the slopes turn negative $(\partial H^{E}_{ACN}/\partial x_{ACN}) < 0$ in Fig. 2, which hints together with $(\partial \mu^{E}_{ACN}/\partial x_{ACN}) < 0$ a possibility of a phase separation with an upper critical solution temperature

(UCST) (1, 2, 20), although $(\partial S^{E}_{ACN}/\partial x_{ACN})$ is weakly positive. Indeed, there is a UCST at –1°C at x_{ACN} = 0.38 (21). Hence, at temperatures higher than –1°C, the solution in this composition region consists of two kinds of clusters, rich in each component, which would grow to a macroscopic size at –1°C; a typical behaviour of Mixing Scheme II as discussed earlier (1–9). Indeed, our preliminary X-ray scattering measurement shows a sharp increase in the forward scattering intensity near the UCST, suggesting growth of such clusters. In the H_2O-rich region (x_{ACN} < 0.1), on the other hand, a qualitatively different mixing scheme must be operative, since the slopes of H^{E}_{ACN} and TS^{E}_{ACN} do not support a phase separation with UCST. Figure 2 shows that at the infinite dilution H^{E}_{ACN} is negative and TS^{E}_{ACN} is more negative. Also, the slopes $(\partial H^{E}_{ACN}/\partial x_{ACN})$ and $(\partial S^{E}_{ACN}/\partial x_{ACN})$ are both positive which is similar to aqueous alcohols (1, 2, 4). These observations indicate that a typical Mixing Scheme I is operative in ACN–H_2O in this region. Namely, the ACN molecule enhances the hydrogen bond network of H_2O in its immediate vicinity. However, the excess partial molar volume (V^{E}_{ACN}) (Fig. 3), does not show very clearly an initial decrease, although there is a hint at it below x_{ACN} < 0.005. An initial decrease in the partial molar volume would indicate a progressive decrease of the hydrogen bond probability of bulk H_2O away from solutes, typical for Mixing Scheme I of aqueous alcohols (1, 2, 7). The excess partial molar volume of a solute at the infinite dilution is determined basically by the following two effects: (*i*) a negative effect due to size difference between solute and H_2O; and (*ii*) a positive effect due to bulkiness of H_2O depending on the hydrogen bond probability (1, 2, 22). The second effect would be the same for any solute since at the infinite dilution the bulkiness of H_2O, i.e., the hydrogen bond probability, depends only on temperature. Now, the molar volume of pure ACN is 52.9 cm^3 mol^{-1}, while that of ME is 40.8 and that of ethanol (ET) 58.7 cm^3 mol^{-1}. Unless there is some additional direct effect between ACN and H_2O that makes V^{E}_{ACN} a very negative value, it is expected V^{E}_{ACN} at the infinite dilution to be not far away from V^{E}_{ET}. Thus, there could be a sharp initial decrease that has not been detected by the present method used (10), determining density as composition is changed. Dilatometry, by which a change in volume on addition of a solute is directly measured, may be required to detect such a sharp decrease in this very dilute region.

Next, we discuss the behaviours of fluctuation functions (Figs. 4–6) in comparison with those for aqueous alcohols, methanol in particular, dealt with extensively in a previous publication (7). The volume fluctuation density ($^{V}\delta$) (Fig. 4*a*) shows very little decrease on addition of ACN. The amplitude of volume fluctuation in ACN–H_2O depends much less on composition than that for ME–H_2O (7). A decrease in $^{V}\delta$ is consistent with a progressive loss of the hydrogen bond probability of bulk H_2O away from solute. Thus, the effect of reduction of the hydrogen bond probability of bulk H_2O, if any, is apparently little. Alternatively this could be related

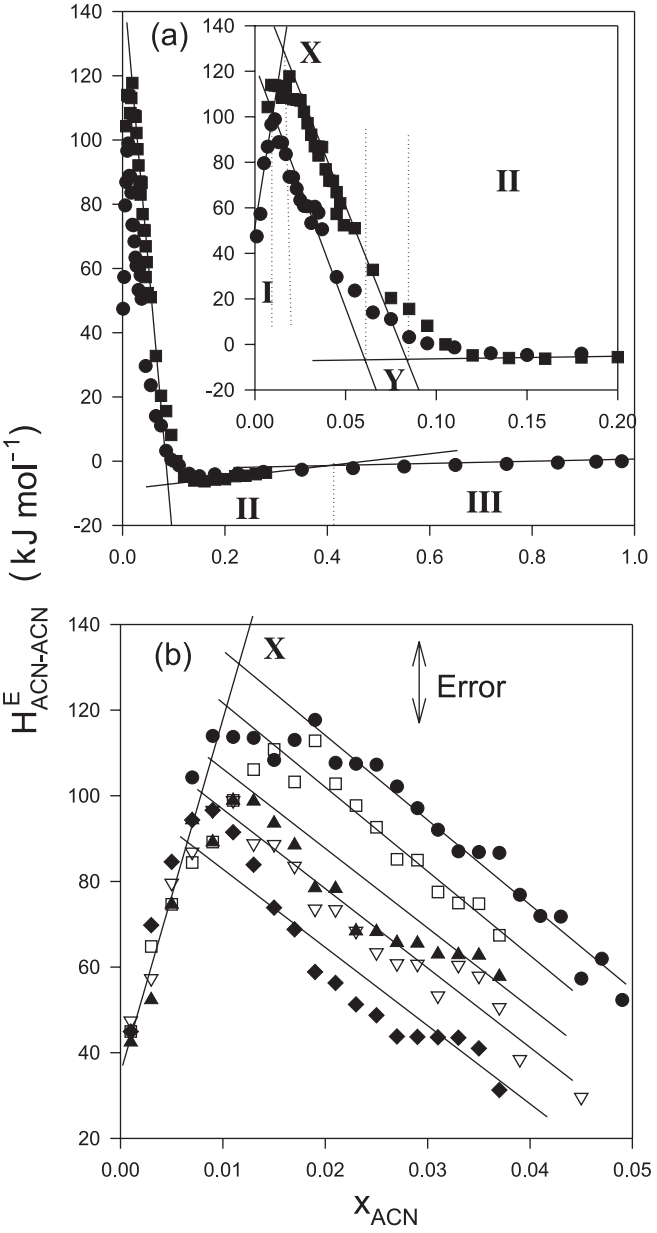
Fig. 6. Entropy–volume cross-fluctuation at 25°C. (*a*) Amplitude of cross fluctuation (Sνδ); (*b*) amplitude and wavelength of cross-fluctuation ($^{SV}\Delta$).

to an apparent lack of an initial decrease in V^{E}_{ACN} in Fig. 3. For the normalized volume fluctuation ($^{V}\Delta$) Fig. 4*b* shows an appreciable decrease to almost the same extent as that for ME–H_2O (7), suggesting that ACN works to decrease the wavelength as well as the amplitude of volume fluctuation. The wavelength of fluctuation is related to collectiveness of fluctuation, which is one of the characteristics of liquid H_2O (7, 13). Thus, ACN does reduce H_2O-likeness of solvent H_2O, just as alcohols (5–7).

The entropy fluctuations (Fig. 5) seem to behave in almost the same manner as those in ME–H_2O (7). Entropy fluctuation is equivalent of enthalpy fluctuation ($< (\Delta S)^2 > = < (\Delta H)^2 > /T^2$) showing fluctuation in the hydrogen bond strength, and hence in the degree of hydrogen bond bending. For higher alcohols than ME, there is an initial increase in $^{S}\delta$, presumably due to an enhanced bending near the hydration structures or the so-called "iceberg." The larger the hydrophobic alkyl moiety, the stronger the effect (7). For ME–H_2O, its effect is not apparent. As is evident in Fig. 5*a*, the effect of ACN on $^{S}\delta$ is almost the same as that of ME. The same is true for $^{S}\Delta$ (Fig. 5*b*). Hence, in terms of the effect on the hydrogen bond bending, or on the hydrogen bond strength, ACN works in the same way as ME.

The entropy–volume cross fluctuations (Fig. 6) shows an initial rapid increase as for ME–H_2O. Namely, a negative contribution to $^{SV}\delta$ and $^{SV}\Delta$ that is characteristic to liquid H_2O diminishes rapidly on addition of either ACN or ME. While the amplitude of volume fluctuation ($^{V}\delta$) is not affected by ACN as much as ME, the amplitude plus the wavelength of volume fluctuation ($^{V}\Delta$) is equally affected. As for entropy fluctuations, both ACN and ME have almost the same effect on H_2O. Now the cross fluctuations show almost the same trend in both ACN–H_2O and ME–H_2O. We are thus in favour of the notion that ACN does affect the molecular organization of H_2O equally as well as alcohols, at least as ME, and that Mixing Scheme I is operative in the most H_2O-rich region.

Third derivatives of *G*



The quantities shown in Figs. 2–6 are all proportional to the second derivatives of *G* with respect to *p*, *T*, or n_{ACN}, or a combination thereof. We now take one more derivative with respect to the amount of ACN (n_{ACN}) to evaluate the effect of additional ACN on the quantity in question (1, 2, 4, 8, 9). Thus, the enthalpic interaction function ($H^{E}_{ACN-ACN}$) is calculated as,

$$[9] \qquad H^{E}_{ACN-ACN} = N(\partial H^{E}_{ACN}/\partial n_{ACN}) = (1 - x_{ACN})(\partial H^{E}_{ACN}/\partial x_{ACN})$$

In evaluating $H^{E}_{ACN-ACN}$, we use a graphical method. As argued to some length earlier (1, 2), a more common practice of numerical method, curve-fitting or some variation thereof, has a tendency of introducing a systematic error in derivatives. Davis et al. (23), recognizing that no single analytic function can fit thermodynamic data of aqueous solutions in the entire composition range, used several analytic functions at separate segments. However, there is arbitrariness in determining a segment boundary. We measured H^{E}_{ACN} accurately and in small increments (Fig. 2), and thus we could take the derivative (eq. [9]) graphically with a reasonable uncertainty, an order of %. Smooth curves are drawn by means of a flexible ruler through all the data points in Fig. 2. The values of H^{E}_{ACN} were read off a smooth curve at the interval of $\delta x_{ACN} = 0.002$ for $x_{ACN} < 0.1$ and at a larger increment for $x_{ACN} > 0.1$, where H^{E}_{ACN} changes slowly. Then, $(\partial H^{E}_{ACN}/\partial x_{ACN})$ is approximated by $(\delta H^{E}_{ACN}/\delta x_{ACN})$. The uncertainty in $H^{E}_{ACN-ACN}$ is estimated as ±10 kJ mol^{-1}, shown in Fig. 7(*b*). This quantity ($H^{E}_{ACN-ACN}$), is the effect of additional ACN on the enthalpic situation of ACN in the system. Thus, as we argued earlier (1, 2), $H^{E}_{ACN-ACN}$ signifies the degree of ACN–ACN interaction in terms of enthalpy. Figure 7 indicates the x_{ACN}-dependence of $H^{E}_{ACN-ACN}$ is similar to the x_{ME}-dependence of H^{E}_{ME-ME} (4). Thus, we assign similarly the regions of Mixing Scheme I, II, and III as shown in Fig. 7. The boundary region between Mixing Scheme I and II, starting at point X and completing at point Y, is also shown in Fig. 7. The loci of points X and Y and the values of $H^{E}_{ACN-ACN}$ are listed in Table 1. In Table 1 are also listed equivalent values for aqueous alcohols (7). We recall that in a series of alcohols, the larger the hydrophobic alkyl moiety, the stronger the effect on H_2O, the smaller the value of mol fraction at point X and the larger the value of enthalpic interaction function. It is striking that ACN appears to work as a stronger hydrophobic solute than ME. In terms of the locus of point X, it is stronger than 2-butoxyethanol, while in terms of the value of $H^{E}_{ACN-ACN}$, it seems to lie between ethanol and propan-1-ol.

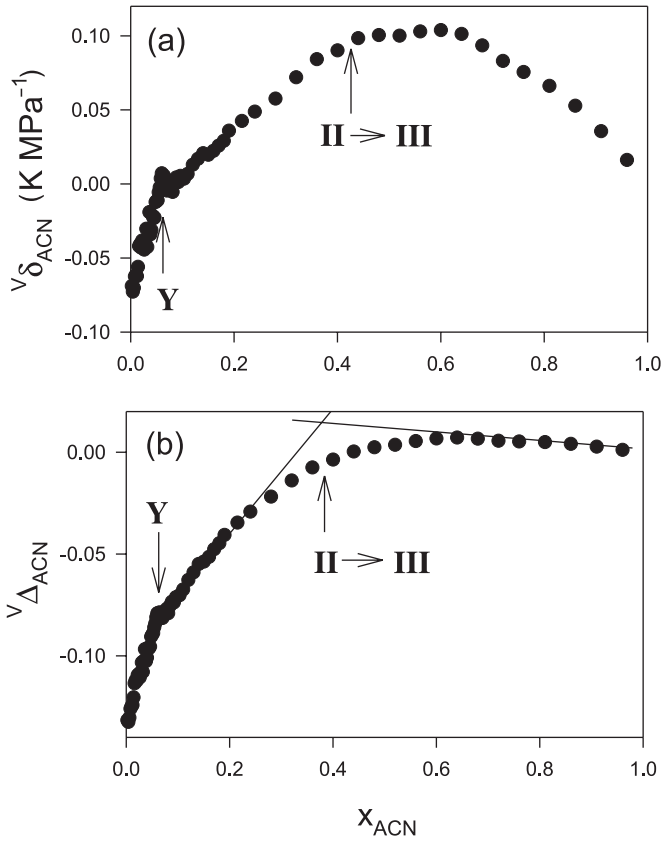
Fig. 7. Enthalpic interaction between acetonitrile molecules ($H^{E}_{ACN-ACN}$). (*a*) Circle (37°C), square (6°C); (*b*) filled diamond (45°C), hollow triangle down (37°C), filled triangle up (30°C), hollow square (20°C), filled circle (6°C).

We also calculate the partial molar fluctuation functions (eq. [5]–[7]) as,

[10] $${}^{q}\delta_{ACN} = N(\partial^{q}\delta/\partial n_{ACN}) = (1 - x_{ACN})(\partial^{q}\delta/\partial x_{ACN})$$

[11] $${}^{q}\Delta_{ACN} = N(\partial^{q}\Delta/\partial n_{ACN}) = (1 - x_{ACN})(\partial^{q}\Delta/\partial x_{ACN})$$

where $q = V, S,$ or $SV,$ specifying volume, entropy, and cross (entropy–volume) fluctuations. These quantities show the effect of additional ACN on the respective fluctuations. They are plotted in Figs. 8–10.



The partial molar volume fluctuations of alcohols in aqueous alcohols start off negative, and progressively increase to about zero at point Y (7). There is no sign of anomaly at point X (7). For ACN–H_2O (Fig. 8) the situation is the same,

Table 1. Loci of mixing scheme boundaries and the value of enthalpic interaction function (H^{E}_{A-A} at point X, A = ACN, ME, ET, or 1P).

	Temp. (°C)	X	H^{E}_{A-A} (kJ mol^{-1})	Y	II → III

although the absolute value of $^{V}\delta_{ACN}$ at the infinite dilution is smaller than the counter part of alcohol, even of ME. However, both $^{V}\delta_{ACN}$ and $^{V}\Delta_{ACN}$ show an anomalous break in slope at point Y (x_{ACN} = 0.07). For alcohols–H_2O, it is propan-1-ol (1P) that shows a bend at point Y, and there is no apparent anomaly at point Y for ME–H_2O, and ET–H_2O (7). For *tert*-butanol (TBA–H_2O) and 2-butoxyethanol (BE–H_2O), $^{V}\Delta_{TBA}$ (6) and $^{V}\Delta_{BE}$ (5) show anomalous behaviours not only at point Y but also at X. This observation hints that the larger the hydrophobic moiety, the more apparent the anomaly at point Y and X, and that the effect of ACN on $^{V}\delta_{ACN}$ and $^{V}\Delta_{ACN}$ in this regard is equivalent to that of propan-1-ol.

Fig. 9. Partial molar entropy fluctuations of acetonitrile at 25°C. (*a*) Amplitude ($^{S}\delta_{ACN}$); (*b*) amplitude and wavelength ($^{S}\Delta_{ACN}$).

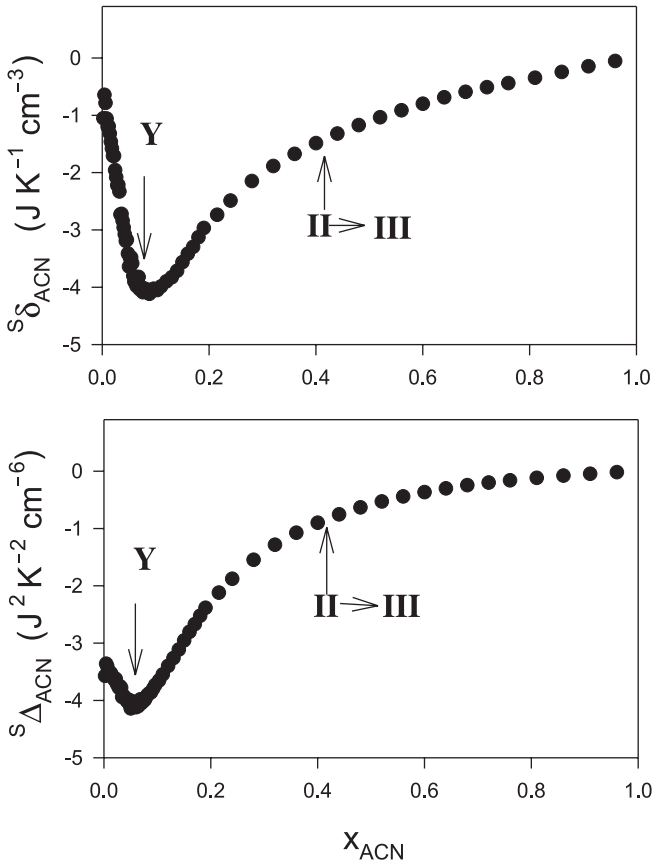

Figure 9*a* shows that $^{S}\delta_{ACN}$ starts at a value very close to zero, similar to ME (7), continues to decrease linearly to point Y and then turns around. There is no indication of anomaly at point X. It is again 1P–H_2O that has a conspicuous anomaly at point X and Y in $^{S}\delta_{1P}$ (7). For ET and ME, both points, X and Y, are obscure (7). For 1P, $^{S}\delta_{1P}$ stays constant to point X, and then drops sharply to point Y (7). For the present case, there is no sign of point X, but $^{S}\delta_{ACN}$ starts to decrease immediately. The situation for the normalized fluctuation is similar and $^{S}\Delta_{ACN}$ (Fig. 9*b*) starts to decrease immediately without a sign of point X. Thus, in terms of entropy fluctuation, ACN seems to start driving the system to point Y without going through point X.

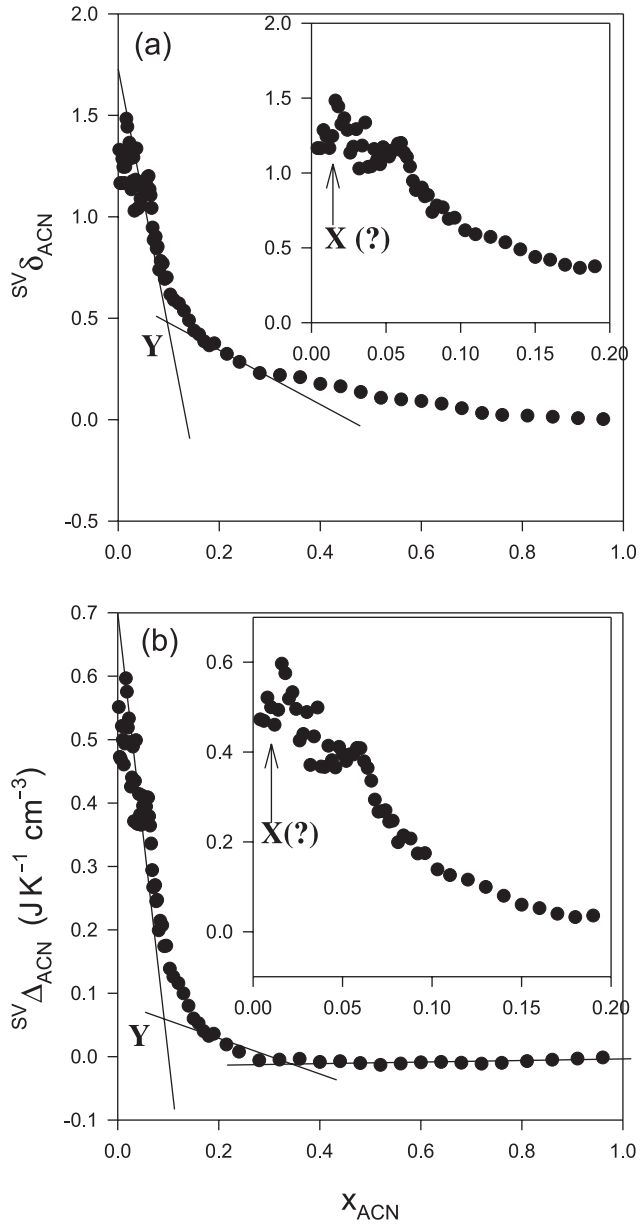
The peculiarity of H_2O and aqueous solutions manifests itself in the cross entropy–volume fluctuations, since there is a characteristic negative contribution in $< (\Delta S)(\Delta V) >$ (5–7, 13). Earlier, it was pointed out that the x_{AL}-dependence of $^{SV}\delta_{AL}$ and $^{SV}\Delta_{AL}$ is the same as that of the enthalpic interaction function (H^{E}_{AL-AL}) (6, 7). In particular, $^{SV}\Delta_{AL}$ and H^{E}_{AL-AL} are identical with a scaling factor on the ordinate (6, 7). Here, subscript AL stands for alcohol, ME, ET, 1P, TBA, and BE. Indeed, the x_{ACN}-dependence of $^{SV}\delta_{ACN}$ and $^{SV}\Delta_{ACN}$ (Fig. 10) looks similar to that in Fig. 7 ($H^{E}_{ACN-ACN}$) except that the existence of point X is not perfectly unequivocal, due to inevitable uncertainty in determining α_p by using density data at two temperatures. Dilatometry, in which the volume change due to temperature rise is directly measured, is required for an attempt to resolve the existence of X in

Fig. 10. Partial molar cross-fluctuations of acetonitrile at 25°C. (*a*) Amplitude ($^{SV}\delta_{ACN}$); (*b*) amplitude and wavelength ($^{SV}\Delta_{ACN}$).



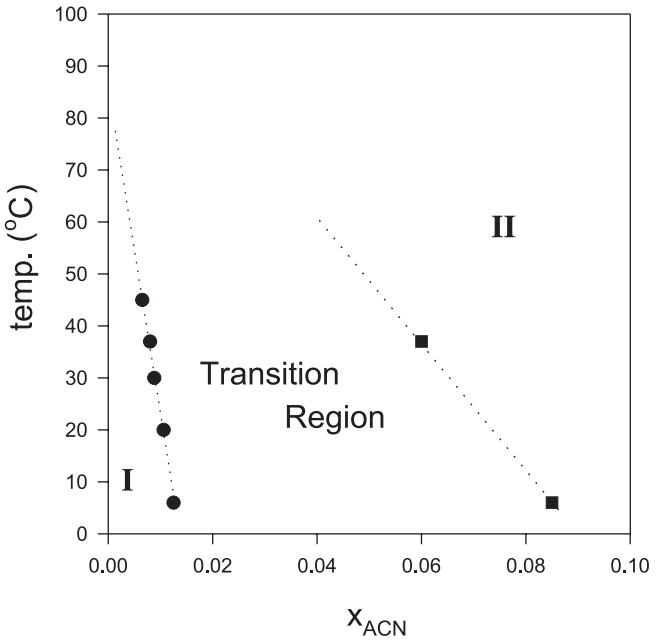


Fig. 10. We point out, however, the values of $^{SV}\delta_{ACN}$ and $^{SV}\Delta_{ACN}$ at a presumed point X in Fig. 10 are the same as those of $^{SV}\delta_{1P}$ and $^{SV}\Delta_{1P}$ for 1P–H_2O.

Turning back to Fig. 7, high sensitivity of the titration calorimeter that we used was the key to obtain many data points in a very dilute region ($x_{ACN} < 0.01$), which made locating points X and Y possible in $H^{E}_{ACN-ACN}$ plots. The loci of X and Y thus obtained are plotted in Fig. 11 as functions of temperature. In the figure, the region between X and Y is the transition region. The transition from Mixing Scheme I to II starts at point X and ends at Y. Beyond point Y is the region where Mixing Scheme II is operative. Extrapolation of the data points in Fig. 11 hints, though not quite conclusively, that the region of Mixing Scheme I disappears above about 80°C, and above this temperature Mixing Scheme II is operative right from $x_{ACN} = 0$. According to Stanley and

© 2000 NRC Canada

Fig. 11. The loci of the transition region from Mixing Scheme I to II.

Teixeira's (24) estimate, at about 80°C the hydrogen bond probability of H_2O decreases to 0.39, which is the bond percolation threshold of ice Ih lattice. Namely, above 80°C the hydrogen bond network of liquid H_2O is no longer bond-percolated. This suggests that in Mixing Scheme I in Fig. 11 the hydrogen bond network of H_2O is percolated and that ACN–H_2O also has Mixing Scheme I as typical as aqueous alcohols. In turn, Fig. 11 provides other evidence, though circumstantial, of the loss of percolation at about 80°C for pure liquid H_2O, together with the similar graphs for TBA–H_2O and BE–H_2O (1, 2).

Conclusion

We conclude that in ACN–H_2O there are three qualitatively different mixing schemes are operative, Mixing Scheme I, II, and III, just as in aqueous alcohols (1, 2, 4, 7). However, the effect of ACN on H_2O is stronger than that of ME. In terms of the locus of the transition from Mixing Scheme I to II, ACN appears to be stronger than BE, while the strength of the enthalpic interaction is equivalent to 1P. The equivalence to 1P is also apparent in the behaviours of volume, entropy, and cross (entropy–volume) fluctuation functions.

The above conclusion is pending, however, on future direct determination by dilatometry of V^{E}_{ACN} and α_p at a very dilute region, $x_{ACN} < 0.01$. Furthermore, there are still many unresolved issues. (1) Why does $^{V}\delta$ show an extremely slow decrease, while $^{V}\Delta$ behaves similar to alcohols? (2) Why is the locus of point X smaller than that for BE, while all other indications are that ACN's effect on H_2O is the same as 1P? (3) Why is ACN much stronger in its effect on H_2O than ME? Clearly, answers to all the above and other questions ought to be sought in the function of the -CN group as opposed to the -OH of alcohols. Further elucidation of these questions may be possible in studies of aqueous solution of cyanide with a higher alkyl group.

Interactions of 6-aminopurine (adenine) in water and aqueous urea solutions

J.D. Pandey, S. Haroon, Krishna K. Dubey, Madhulika Upadhyaya, Ranjan Dey, and K. Misra

Abstract: Density (ρ), ultrasonic velocity (*U*), viscosity (η), and absorbance (*A*) of adenine in water, 1 M, 3 M, and 6 M aqueous urea solutions have been measured in the presence (and absence) of different concentrations of salts, i.e., NaCl, KCl, and $CaCl_2$. From these measured values, the apparent molar volume (ϕ_v), experimental slope (S_v), apparent molar compressibility (ϕ_K), viscosity coefficients A and B of Jones–Dole equation, specific acoustic impedance (*Z*), hydration number (S_n), internal pressure (P_i), molar absorptivity (ε), hypochromicity (*h*), and oscillator strength (*f*) have been calculated at 298.15 K. The increasing and (or) decreasing trends of all these parameters indicate a strong interaction of urea in moderate concentration (1 M and 3 M) with adenine especially at the hydrophilic/polar and ionic sites, particularly by hydrogen bonding. However, the interaction at hydrophobic sites are relatively weaker. Higher concentrations of urea (6 M) have more denaturation effect. The π–π interactions (stacking) in adenine are more prominent in concentrated solutions and are also strengthened by the presence of cations up to an optimum concentration of salts (cut-off point). The self-association of urea and adenine is more significant in concentrated aqueous solutions and becomes negligible on dilution.

Key words: interaction, adenine, urea, density, viscosity, and ultrasonic velocity.

Résumé : On a mesuré la densité (ρ), la vélocité ultrasonique (*U*), la viscosité (η) et l'absorbance (*A*) de l'adénine dans l'eau et dans des solutions aqueuses à 1 M, 3 M et 6 M d'urée, en présence et en absence de sels (tels que NaCl, KCl et $CaCl_2$) à diverses concentrations. Sur la base de ces valeurs mesurées, on a calculé le volume molaire apparent (ϕ), la pente expérimentale (S_v), la compressibilité molaire apparente (ϕ_k), les coefficients de viscosité A et B de l'équation de Jones–Dole, l'impédance acoustique spécifique (*Z*), le nombre d'hydratation (S_n), la pression interne (P_i), l'absorptivité molaire (ε), l'hypochromicité (*h*) et la force de l'oscillateur (*f*) à 298,15 K. Les tendances à l'augmentation/diminution de tous ces paramètres indiquent la présence d'une forte interaction de l'urée avec l'adénine aux concentrations modérées (1 M et 3 M), particulièrement au niveau des sites ioniques et hydrophiles/polaires principalement par le biais de liaisons hydrogènes. Toutefois, l'interaction au niveau des sites hydrophobes est relativement faible. Des concentrations plus élevées d'urée (6 M) ont un effet de dénaturation. Les interactions π–π (empilement) de l'adénine sont plus importantes en solutions concentrées et elles sont aussi renforcées par la présence de cations jusqu'à des concentrations optimales de sels (point de rupture). L'autoassociation de l'urée et de l'adénine est aussi plus importante en solutions aqueuses concentrées et elle devient négligeable par dilution.

Mots clés : interaction, adénine, urée, densité, viscosité, vélocité ultrasonique.

Introduction

Molecular interactions in general and protein–nucleic acid interactions in particular are of immense importance in understanding the life processes. Despite exhaustive researches being carried out in this field during the last two decades we do not have a clear idea about the geometry of repressor–operator recognition. Simultaneous observations of two associated macromolecules makes this study rather highly complex.

The most plausible solution to this problem is to study model compounds using both theoretical and experimental approaches. Urea with its highly polar >C=O and -NH_2 functional groups can be the best model substitute for peptide bond of proteins. In earlier work (1, 2) thermodynamic studies of urea and its derivatives in water and in water–dioxan solutions at different temperatures have been carried out.

Aqueous urea solutions have been widely reported to be nucleic acid denaturants. The effects of urea on the secondary structure of nucleic acids has been investigated by some workers (3). Hemmes et al. (4) have reported that urea concentration larger than 7 M effectively eliminated stacking in a model of 6-methyl purine. On the basis of partial molar heat capacities and volumes, studies (5), it has been found that urea in high concentrations (3–6 mol kg^{-1}) showed

strong hydrophilic–hydrophilic ionic group interactions of nucleic acid bases, nucleosides, and nucleotides, thereby supporting its denaturing characteristics. Various types of interactions are encountered in biomolecules, the predominant being π—π bond, hydrogen bond, and ionic interactions.

Base–base interaction through hydrogen bonding has been investigated by thermodynamic methods to derive association constants as well as enthalpies and entropies for this process. Stacking interactions are mainly due to π-electrons resulting in dispersion and dipole induced dipole forces and hydrophobic bonding.

The role of water in these interactions is extremely important. Hydration of proteins and nucleic acids is mainly responsible for stabilization of their secondary and tertiary structure (4–6) and is responsible for the conformational transitions of DNA. The bases are known to self-assemble into ordered structures by active participation of water molecules. High relative humidity favours the B-form of DNA and reduced humidity leads to transitions from B-form to C or A and with specific sequences to D and Z-DNA. Nucleic acid–water interactions have been studied by a number of workers (7–9). We have reported earlier the interaction of nucleic acid components in water–dioxan mixtures (10–12) and also of urea and its derivatives in water (13).

The concentration of ions significantly effects the conformational changes in both, i.e., DNA and (or) RNA and proteins. Besides phosphate oxygen, metal ions also coordinate with ribose hydroxyls, base ring nitrogens, and keto substituents. Since metal ions like Na^+, K^+, and Ca^{++} are present in the body in millimolar concentrations, proteins and nucleic acids occur as complexes coordinated with these metal ions. Therefore, the interaction between these two macromolecules is greatly affected by the presence of these metal ions.

To explicitly study the contribution of purine and (or) pyrimidine bases of DNA towards their interaction with urea, the purine base viz., adenine has been investigated separately in water, aqueous urea solutions of different concentrations, without metal ions, and in the presence of different concentrations of metal ions, e.g., Na^+, K^+, and Ca^{2+}. Ultrasonic, volumetric, and viscometric techniques have been used in addition to spectroscopic (UV) technique. Ultrasonic velocity, density, and viscosity data have been used to deduce a number of interesting and important thermodynamic parameters viz., apparent molar volume, apparent molar compressibility, viscosity coefficients A and B of the Jones–Dole equation, apparent hydration number, internal pressure, acoustic impedance, and molar absorptivity, hypochromicity, and oscillator strength, etc. Interestingly, the use of all these parameters reported in this paper yielded comparable results which is certainly a step forward in the direction of solving the complexities involved in such macromolecular interactions at unimolecular level.

Materials and methods

Ultrasonic velocity, density, and viscosity for all the systems were measured at 298.15 ± 0.01 K over the entire composition range (i.e., three solutions in 0.1–0.5 M range).

Ultrasonic velocity (U) was measured using a variable path ultrasonic interferometer (frequency 2 MHz). Density was measured with the help of a standard double capillary pycknometer technique used by other workers (14, 15). Viscosity was measured by a calibrated Ubbelhode type viscometer, UV absorption was recorded on 220 S Hitachi UV–vis spectrophotometer. Temperature was maintained by a SB-16 shaking thermostatic bath with an accuracy of ±0.01 K. The uncertainties in the measurements of velocity and density were within $\pm 1 \times 10^{-2}$ ms^{-1} and $\pm 1 \times 10^{-4}$ g cm^{-3}, respectively. Uncertainties in the measurements of viscosity and ε values were within $\pm 1 \times 10^{-2}$ g cm^{-1} ms^{-1} and 1×10^{-6} unit, respectively. Time was measured by a calibrated stopwatch. The details of the experimental procedures and method of calibration have been reported earlier (16).

Adenine was purchased from Sigma Chemical Co. U.S.A. and used after drying under vacuum for 12 h. Salts (NaCl, KCl, $CaCl_2$) and urea were obtained from E. Merck, India and were used after drying in an air oven and kept dry over CaO and P_2O_5 in a dessicator. Purity of all the chemicals was checked by TLC. All the solutions were prepared by weight in double-distilled and degassed water.

Solutions of urea and adenine were prepared in concentrations of 2×10^{-2} M, individually. 1 M stock solutions of NaCl, KCl, and $CaCl_2$ were prepared separately and these were diluted to make solutions in the range of 0.1–0.5 M.

Experimental values of density (ρ), ultrasonic velocity (U), and viscosity (η) along with the computed values of apparent molar compressibility (ϕ_k), apparent molar volume (ϕ_v) and Jones–Dole parameters ($\eta_{rel}^{-1}/\sqrt{m}$) and hydration number (S_n) of adenine–water, adenine–1 M, 3 M, and 6 M urea have been recorded in Table 1. The same parameter for equimolar mixtures of adenine (10^{-4} M) – aqueous urea (10^{-4} M) in the presence of varying concentration (0.1–0.5 M) of the salts NaCl, KCl, and $CaCl_2$ have been presented in Table 2. The partial molar volume (ϕ_v^0), experimental slope (S_v), apparent molar compressibility (ϕ_k^0), and viscosity coefficient A and B of the Jones–Dole equation for all the systems under the present investigation have been depicted in Table 3. Computed values of internal pressure (P_i), acoustic impedance (Z) of adenine–water and adenine–1 M, 3 M, and 6 M aqueous urea at different concentrations (0.1–0.5 mol L^{-1}) of salts, i.e., NaCl, KCl, and $CaCl_2$ are presented in Table 4.

Absorbance (A), molar absoptivity (ε), hypochromicity (h), and oscillator strength (f) of all the systems under the present study have been listed in Table 5.

The systems chosen for the present investigation are: (1) adenine in water; and (2) adenine in 1 M, 3 M, and 6 M aqueous urea with and without the presence of different concentrations of salts, i.e., NaCl, KCl, and $CaCl_2$.

Ultrasonic velocity (U), density (ρ), viscosity (η) data of various solutions have been employed to deduce a number of useful parameters viz., apparent molar volume (ϕ_v), partial molar volume (ϕ_v^0), apparent molar compressibility (ϕ_k), partial molar compressibility (ϕ_k^0), viscosity interaction coefficient A and B of the Jones–Dole equation, apparent hydration number (S_n), acoustic impedance (Z), and internal pressure (P_i) using the following equations (17),

$$K_s = (U^2\rho)^{-1}$$

$$\phi_v = \frac{M_{soln}}{\rho} - \frac{\rho - \rho_0}{m\rho\rho_0}v$$

Results and discussion

In the present study, the hydration cosphere, i.e., the region occupied by water that is significantly affected by the presence of solute molecule viz. adenine (**1**) and urea is extremely important. When the cospheres of both these molecules, i.e., adenine and urea overlap due to their proximity caused by van der Waals hydrogen bonding or electrostatic interactions, some of the cosphere material is displaced, causing changes in thermodynamic parameters (5, 18–20). The hydrogen bonding capability of water leads to its interactions with adenine acid groups such as O and N atoms that are hydrogen bonding acceptors and protons that are hydrogen bonding donors. It also leads to extensive though imperfect and transitory hydrogen-bonded network in water itself. Formation or disruption of such networks leads to a decrease or increase, respectively, in the entropy (*S*), thus affecting the thermodynamics of processes that affect water hydrogen bonding. Introduction of a hydrophobic residue like adenine base in water leads to the formation of hydrogen-bonded water cluster and leads to negative ΔS. This is partially responsible for low solubility of adenine base in water and consequently for its tendency to self-associate by stacking in aqueous solution (21). A structure breaking species such as urea disrupts water hydrogen bonding and thereby increases the entropy of the system. The large dipole moment of water

makes it a good solvent for ions. Cations interact favourably with the O and anions interact with H atoms. Since, a high dipole moment leads to a high dielectric constant, ε, coulumbic interactions between ions, whose energy is $E = q_1q_2/\varepsilon r$ (where q_1 and q_2 are the ion charges and r is their separation) will be weaker in water ($\varepsilon \approx 80$) than in organic

solvents ($\varepsilon \approx 2$). Moreover, in the present case the adenine moiety is interacting with highly polar urea molecule and the properties of water as a solvent for ions becomes crucial. However, this effect may be more important if in place of adenine more ionic adenosine or adenylic acid are used.

The ϕ_v values for adenine in water and 1 M, 3 M, and 6 M urea solutions are positive and increase regularly with dilution, indicating the decrease in stacking interactions. These values are highest for adenine in 6 M urea, indicating maximum denaturation (Table 1).

The effects of salts NaCl, KCl, and $CaCl_2$ on ϕ_v values can be observed from the results reported in Table 2. The calculated values of ϕ_v gradually decrease with increase in concentration of each salt, indicating that these salts do contribute to the strengthening of interactions between adenine and urea. The values of partial molar volumes are highest for the adenine–urea–$CaCl_2$ system as compared to adenine–urea–KCl and adenine–urea–NaCl systems, indicating the interaction strengthening contribution of salts in the order $CaCl_2$ > KCl > NaCl.

Table 2 shows the values of ϕ_v calculated from the intercept of the linear plot of ϕ_v against the square root of the concentration. The plot is in accordance with Masson's equation. The increase in S_v values (Table 3) is indicative of stronger solute–solvent interaction. In case of adenine in aqueous urea (1 M, 3 M, and 6 M) this value decreases with an increase in concentration of urea and is minimum in 6 M urea indicating the disruption of adenine water interaction

with urea. The presence of salts apparently increases S_v values and the contribution of $CaCl_2$ is maximum as compared to KCl and NaCl.

Degree of hydration of DNA and (or) RNA plays an important role in their conformational transitions. The solvation parameter (S_n) is responsible in deciding the "effective" density gradient and therefore, the relative molecular weights. Hydration number also varies with the nature and concentration of salts. High values of apparent hydration number are indicative of strong solute–solvent interactions. This is evident from the results obtained in the present study (Table 1). It is observed that in the case of the adenine–water system, the value of S_n decreases with dilution. Since the stacking interactions in the case of purine bases having flat aromatic rings, i.e., adenine are mainly hydrophobic in nature, it is maximum in concentrated solutions and decreases with dilution. This may also be due to water molecules forming a cage around $-N^+H_3$ of adenine. However, stacking interactions are not important. Similarly, when urea is added the polar interactions increase and there is a broad gamut of intermolecular interactions. However, maximum values of η are observed in adenine – 3 M urea, while these decrease in 6 M urea. It may be due to a higher degree of denaturation in more concentrated urea solutions. The molecules of urea, such that they correspond to those of the cages in the ice-like structure of water, arrange themselves in the aqueous urea environment so that >C=O groups are located in the structures existing in water, whereas the $-NH_2$ groups are enclosed in clathrates and are unable to interact with added solute molecules. Hence, in the systems, urea–water and adenine–urea–water, the concentration dependence of the apparent hydration number (S_n) also depends on the number of cages not occupied by the $-NH_2$ group of urea. Finally, these observations can be interpreted by the cosphere overlap model developed by Gurney (22).

Negative values of apparent molar compressibility (ϕ_K) in all systems studied are indicative of the loss of structural compressibility of the solvent molecules due to increased population of bonded water molecules in the aqueous urea. The ϕ_K values for adenine–water systems decreases with decrease in concentration. In aqueous urea this value increases for adenine in comparison to pure water. However, the highest value of ϕ_K are obtained in adenine – 1 M urea solution. These values increase on increasing concentration of salts, the highest values being obtained with $CaCl_2$. The sequence of increase is in the order $CaCl_2$ > KCl > NaCl.

The B coefficient of the Jones–Dole equation (Table 3) has positive values for all the systems indicating a strong alignment of the solvent molecules with solute. This B coefficient is known to be sensitive to the nature of solute–solvent interaction. Comparatively higher values of B coefficient are observed for the adenine–urea–$CaCl_2$ system as compared to adenine–urea–KCl, while, adenine–urea–NaCl values are still lower. Thus Ca^{2+} causes stronger interactions as compared to K^+ or Na^+.

A coefficient is positive for adenine in 6 M urea solution indicating the structure-breaking (denaturation) behaviour of urea (Table 3). The values of A coefficient for adenine–urea is negligibly small as compared to aqueous adenine. Although the values of A coefficient are positive in the presence of salts, there is no significant variation. This indicates that solute–solute interactions in these systems are unimportant.

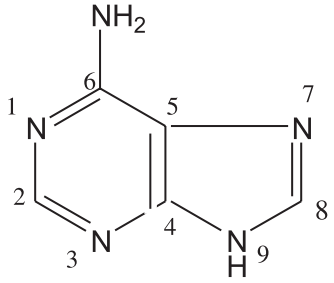
The viscosity values (Table 1) show a regular trend in case of all systems, i.e., decrease with dilution whereas it shows a small upward trend with decrease in concentration of urea.

The "cut-off" point for increasing viscosity is 0.3 M concentration of the salts (Table 2). Evidently, the solute–solvent interaction increases beyond this concentration considerably and, therefore, the viscosity decreases due to denaturation. The system which become more viscous at the highest salt concentration contain NaCl or KCl. Systems having $CaCl_2$ always show a decrease in viscosity after a certain point. This can be explained due to the larger ionic size and higher charge on Ca^{2+} as compared to Na^+ and K^+. NaCl and KCl ionize to form two ions each while $CaCl_2$ produces three ions. Moreover, smaller ions have a better chance of electrostatic bonding than a larger ion. The strength of these ionic bonds also differ because of the size and number of orbitals in these atoms. In the present case it appears that the higher concentrations of ions enhance the denaturing capacity of urea, although in some cases it is not

© 2000 NRC Canada

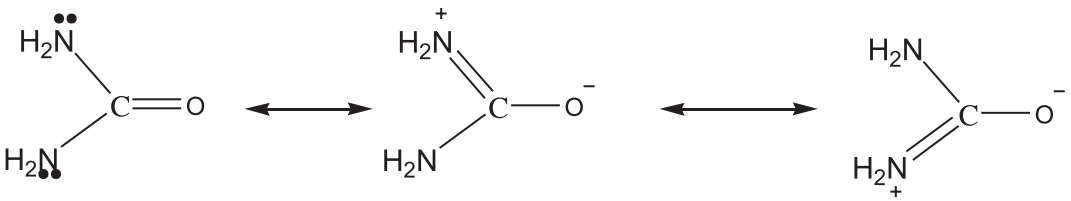
quite apparent. Urea appears to act as denaturant even in very dilute solutions.

Internal pressure (P_i) is an important parameter for study of solute–solvent interaction of biomolecules. The higher values of P_i indicate strong solute–solvent interactions. Table 4 shows that P_i values for the adenine–water system are higher as compared to those in 1 M, 3 M, and 6 M urea solutions at 298.15 K. Values of P_i in 1 M urea solutions are higher as compared to those in 3 M and 6 M urea solutions. P_i values decrease with decrease in solute concentration. Apparently, the solute–solvent interactions are stronger for adenine in water than in urea solutions and among different concentration of urea solutions. Such interactions become stronger in 1 M urea and weak in 6 M urea solution.



The values of internal pressure change significantly with a slight change in concentration of salts (Table 4). These values were found to decrease with an increase in concentration of NaCl, KCl, $CaCl_2$ in adenine–urea salt. A dissolving electrolyte is known to lower the compressibility of the solvent due to the influence of the electrostatic field of the ions on the surrounding solvent molecules and thus the total P_i of the solution increases. Contrary to this in the present study the internal pressure decreases with increase in concentration of salt. This anomalous behaviour can be accounted for, due to several reasons viz.: (*i*) the denaturing effect of urea on adenine, bringing about abnormal changes in both the molecules. The presence of salts further affects this denaturation; (*ii*) different neutral salts may have striking effects on the stacking interactions of adenine; (*iii*) the hydrogen bonding between urea and adenine are affected by salts; (*iv*) cohesive forces may be loosened; and (*v*) the upsurge in various types of interactions may take place in the system.

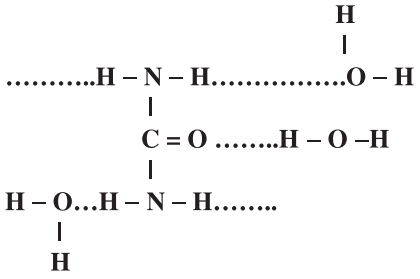
Specific acoustic impedance (Table 2) is another parameter used during the present study for revealing the nature of interactions in the medium. The *Z* value has a greater significance as a characteristic property of the medium than either density (ρ), ultrasonic velocity (*U*), individually. Its value has been found to decrease with dilution in the case of adenine–water and adenine–water–urea systems, and with increasing concentration of salts. However, the changes are not very significant.



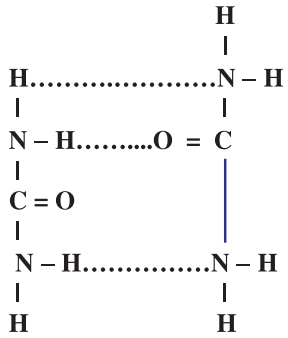
To confirm the findings of the solute–solvent interactions of nucleic acids components viz. adenine in water and urea–water systems by the use of various thermodynamic parameters presented, in this paper, the UV spectral studies were also carried out and measured values of absorbance (*A*) and calculated values of molar extinction coefficient (ε) were used as parameters. UV spectra of nucleic acids are sensitive to base stacking affects and hypochromicity (reduction in UV absorption) is specific for base composition and conformational transitions. UV spectra are effected by any modification in the purine and (or) pyrimidine base, e.g., protonations and (or) deprotonations or hydrogen bonding or any change in electronic state of the π electrons.

As shown in Table 5, the absorbance value (*A*) of adenine shows considerable variation with concentration, the trend being a decrease in *A* values with decrease in concentration of the solution which is in accordance with Lambert–Beer law, ε value being specific for π electron system are fairly constant for a particular set. In 1 M, 3 M, and 6 M urea solution, the ε values for adenine indicate a regular decrease with increase in urea concentration indicating strong interactions of adenine with urea.

Adenine (**1**) is planar, aromatic, and has strong π–π* transitions. The exocyclic amino group can act as a weak acid and therefore as a donor for the hydrogen bond. The N1, N3, and N7 positions of adenine can act as proton acceptors. Urea is a resonance hybrid having the following canonical forms (**2**):

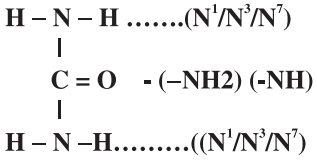


1



2

© 2000 NRC Canada



It can therefore act as both a proton acceptor and a proton donor. The possibilities of hydrogen bond formation between urea–water (**2**a), urea–urea (**2**b), and urea–adenine (**2**c) are shown below

2a

2b

2c

The equilibrium constant for self-association of two urea molecules in water is very low, i.e., the association constant (M^{-1}) of the urea dimer is 0.04 and for the benzene dimer (van der Waals interaction) in water the $K_{benzene}$ (M^{-1}) value is 0.442.

In aqueous solution, adenine forms hydrogen bonds with water. When urea is added, complete loss of structure is observed due to hydrogen bonding between urea and water. Due to the very low concentration of adenine used, the interactions between these molecules are not so important. Interaction between urea and polar hydrophilic and (or) ionic sites of adenine through overlap of hydration cosphere lead to increased hydrogen bonding interactions. This increase in hydrogen bonding with increase in urea concentration as solvent is reflected in increased hypochromicity and, therefore, indicating stronger solute–solvent interactions. It can be seen from Table 5 that due to the increase in concentration of urea from 1 to 3 M there is a decrease in molar absorptivity of adenine by a factor of 49.49 mol cm^{-1} and for the increase in urea concentration from 3 to 6 M, there is a decrease in molar absorptivity of 40.63 mol cm^{-1}. It may be due to H-bonding at $-NH_2$ and >NH groups of adenine with urea and also due to the extended π electron cloud present in adenine, responsible for hydrophobic interaction.

Interesting observation has been made in the case of adenine–urea salt systems. The absorbance and molar absorptivity values fall initially with increasing concentration of NaCl and KCl salts in the case of adenine but after a certain limit start rising, while with $CaCl_2$ these values regularly fall and there is no cut-off point. A decrease in *A* and ε values is an indication of stronger interaction. It is evident that interaction increases with an increase in concentration of NaCl, KCl until a saturation point is reached after which it starts decreasing. This optimum concentration of salt is about 0.35–0.4 mol λ^{-1} for equimolar solution of adenine (10^{-4} M) and urea (10^{-4}M). In case of $CaCl_2$, the values regularly decrease indicating a comparatively stronger interaction. The cut-off point can be explained due to the fact that as the salt concentration goes on increasing, higher numbers of Na^+, K^+, and Ca^{2+} ions are released in the system which counteract with the charges already present. In case of Ca^{2+} there are two counter ions for each cation. Another reason may be that the cations help in binding the extended π electron systems in adenine and more availability of cations helps in increasing π–π interaction. However, beyond a certain extent the interaction decreases because of the limited interaction sites.

Hypochromicity values (Table 5) also show a similar trend as *A* and ε, i.e., increase up to a certain concentration of NaCl, KCl and thereafter decrease, while in the case of $CaCl_2$ these values continuously increase with increasing concentration of salt. Since, increase in *h* values indicates a more extended chromophore. This can be explained by stronger interactions between π–π electrons of the adenine base. The cations increase these interactions by getting sandwiched in between the electron clouds.

Oscillator strength (Table 5) depends upon the ε values and decides whether the transitions are allowed or forbidden. The values either decrease or first increase and then decrease with the increase in concentration of salt. This trend indicates that the interaction goes on increasing, or initially increases and then decreases as the concentration of salts is increased.

Conclusion

All the thermodynamic and spectroscopic parameters used under the present study for the interpretation of interactions of adenine in water, aqueous urea, and in the presence of salts i.e., NaCl, KCl, and $CaCl_2$ leads to parallel conclusions. The trend is the same in all cases. The interaction of urea with adenine is dependent on the concentration of urea and presence of salts.

In adenine there are hydrophobic (delocalized π electrons) as well as hydrogen bond donor ($-NH_2$/-NH) and (or) acceptor (N1, N3, N7) sites (**2**c) responsible for base pairing with complementary bases, i.e., thymine in DNA and uracil in RNA. The hydration cospheres around adenine molecules having both hydrophobic and hydrophilic sites in the adenine–water system result in a transitory and rather imperfect

© 2000 NRC Canada

hydrogen-bonded network of water. The hydrophobicity of adenine being responsible for the π–π stacking interactions, which are effected by the presence of metal ions, being strongest in presence of Ca^{2+} ions. However, the hydrophilic sites on adenine result in an increase in entropy of the system by disrupting the hydrogen-bonded network. The highly polar urea molecule can interact with polar and (or) hydrophilic sites on adenine (especially -NH_2 / -NH) and also with the hydrophobic sites, although the former are much more important than the latter. The stacking π–π interactions due to hydrophobicity of the purine base are more evident by the study of absorption spectroscopy. The measured absorbance values of ε, *h*, and *f* indicate a strong π–π stacking interaction which is strong in the presence of cations like, Na^+, K^+, and Ca^{2+} up to a certain optimum concentration of salts after which it falls.

The self-association in urea and adenine resulting in the corresponding dimers is more important in relatively concentrated solutions. In more dilute solutions salts play an important role and the role of water becomes crucial. Urea acts as a denaturant in concentrated solutions since it disrupts intermolecular hydrogen bonds between adenine and water and itself interacts at the hydrophobic and (or) hydrophilic polar and ionic sites of the adenine moiety.

Syntheses and electrochemical characterization of heteroleptic cyclopentadienyl–bis(dithiolene) complexes of niobium and tantalum

I.V. Jourdain and F. Guyon

Abstract: Diamagnetic niobium and tantalum complexes of general formula [M(η^5-C_5Me_5)(dithiolene)$_2$] have been prepared (M = Nb, dithiolene = dddt^{2-} (5,6-dihydro-1,4dithiine-2,3-dithiolate) (**1**); M = Ta, dithiolene = dddt^{2-} (**2**); M = Nb, dithiolene = dddt^{2-} and dmit^{2-} (1,3-dithiole-2-thione-4,5-dithiolate) (**3**)). All these complexes exhibit temperature-dependent ^{1}H NMR spectra which result from a fluxional behavior of the dithiolene ligands. Their redox properties have been investigated by cyclic voltammetry and reversible oxidation processes involving the dithiolene ligands have been evidenced for the complexes **1** and **2**.

Key words: niobium, tantalum, dithiolene, voltammetry cyclic, variable-temperature ^{1}H NMR.

Résumé : On a préparé des complexes diamagnétiques du niobium et du tantale de formule générale [M(η^5-C_5Me_5)(dithiolène)$_2$] [M = Nb, dithiolène = dddt^{2-} (5,6-dihydro-1,4-dithiine-2,3-dithiolate) (**1**); M = Ta, dithiolène = dddt^{2-} (**2**); M = Nb, dithiolène = dddt^{2-} et dmit^{2-}(1,3-dithiole-2-thione-4,6-dithiolate) (**3**)]. Les spectres RMN ^{1}H de chacun de ces complexes varient avec la température en raison d'un comportement dynamique des ligands dithiolènes. Les propriétés redox ont été par voltampérométrie cyclique et, pour chacun des complexes **1** et **2**, a été mis mettre en évidence un processus d'oxydation réversibles impliquant les ligands dithiolènes.

Mots clés : niobium, tantale, dithiolène, voltampérométrie cyclique, RMN ^{1}H à température variable.

Introduction

Coordination chemistry of sulfur-rich dithiolenes such as dmit^{2-} (1,3-dithiole-2-thione-4,5-dithiolate) or dddt^{2-} (5,6-dihydro-1,4dithiine-2,3-dithiolate) has attracted considerable interest in the past two decades (1) since the discovery of (TTF)[Ni(dmit)$_2$]$_2$ the first molecular superconductor containing a transition metal complex (2). For our part, we have been interested in the synthesis of heteroleptic complexes bearing both such dithiolene and cyclopentadienyl ligands with regards to the elaboration of novel conducting or magnetic materials. Our attention was mainly concentrated on complexes of general formula [M(cp)$_2$(dithiolene)] (cp = η-C_5H_5). We have shown that the radical cations [M(cp)$_2$(dithiolene)]$^{+}$ (M = Mo and W) organize in the solid-state into various supramolecular structures from quasi-regular chains to spin ladder with relatively strong antiferromagnetic interactions (3). However, in those paramagnetic species the spin density on the metal is far from negligible. This restricts the strength of the intermolecular interactions which result from dithiolene–dithiolene interactions via short S···S contacts. Thus we turned our effort to the synthesis of compounds in which the spin density is fully supported by the dithiolene ligand. For example, this property was expected in the oxidative form of the M(cp)$_2$(dithiolene) complexes of group 4 metals (d^0), but any oxidation process in these series ended up with the destruction of the molecules (4). So, the modification of these complexes by substituting cyclopentadienyl for electron-rich dithiolene seems a prerequisite to realize our goal. In that respect, the heteroleptic complexes M(cp)(dithiolene)$_2$ of group 5 metals (d^0) are particularly promising. Compounds of this class are very scarce in the literature, only two studies involving the synthesis of three complexes of vanadium (5) and tantalum (6) have been published. Note that their redox properties have not been investigated. Another consideration which led us to choose this family as precursors of molecular materials is the report by Fourmigué and Coulon (7) on an ordered three-dimensional antiferromagnetic ground state in the Mo(cp*)(dmit)$_2$ (cp* = η^5-C_5Me_5) complex.

Here, we describe the syntheses, characterization, and the electrochemical properties of M(cp*)(dddt)$_2$ (M = Nb and Ta) and Nb(cp*)(dmit)(dddt) complexes. The use of cp* instead of the unsubstituted cp ligands was settled to favor the formation of stable radical cation. Indeed the stabilizing effect of higher oxidation states by using cp* is well established (8).

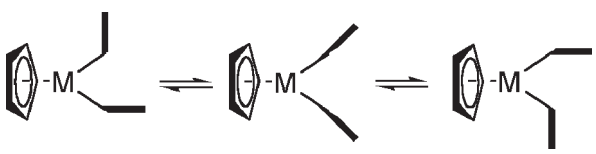
Results and discussion



The synthesis of M(cp*)(dddt)$_2$ (M = Nb (**1**) and Ta (**2**)) was achieved by nucleophilic substitution of halides from the highly air sensitive precursors M(cp*)Cl$_4$ (M = Nb and Ta) by two equivalents of the dithiolene Na$_2$dddt. The reactivity of Ta(cp*)Cl$_4$ proved to be inferior to that of Nb(cp*)Cl$_4$ and the complex (**2**) was isolated in low yield (<10%). All our attempts to prepare the analogous M(cp*)(dmit)$_2$ remained unsuccessful. However we were able to isolate Nb(cp*)(dddt)(dmit) (**3**) by treating successively Nb(cp*)Cl$_4$ by one equivalent of Na$_2$dddt and one equivalent of Na$_2$dmit. To the best of our knowledge, this compound represents the first example of a mixed bis(dithiolene) in the class of heteroleptic cyclopentadienyl–dithiolene complexes. The formation of the intermediate Nb(cp*)(dddt)Cl$_2$ was evidenced by the ^{1}H NMR spectrum which shows two signals integrating four and 15 protons, respectively.

All the bis(dithiolene) complexes were identified by elemental analysis and ^{1}H NMR spectroscopy (Table 1). The IR spectra are poor of distinctive bands except the $\upsilon_{C=S}$ vibration in **3** at 1060 cm^{-1}. An interesting feature is the temperature-dependence of the ^{1}H NMR spectra (Fig. 1). At low temperature, two symmetric signals are observed for the protons of the dddt ligands which coalesce at higher temperatures. Such behaviour is consistent with a fluxional process of the ligands which has been already reported in Ta(cp*)(S$_2$C$_2$H$_2$)$_2$ by Nakamura and co-workers (6). These observations are in agreement with the *exo–endo* geometry observed in the isoelectronic [Ti(cp)(dithiolene)$_2$]$^-$ (4, 9). Indeed this geometry involves the presence of two conformers in equilibrium in which the dithiolene ligands are not equivalent. At high temperature, the interconversion between the two conformers is fast and the ^{1}H NMR spectra correspond to an averaged hypothetical C_{2v} conformer.

dddt ligand. Indeed the SCH_2CH_2S protons exhibit a AA′BB′ pattern at low temperature whereas they appear as a singlet at higher temperature.

Scheme 3.

Note that the *exo–endo* geometry has been rationalized with the aid of molecular orbital considerations and extended Hückel calculations in the case of Ta(cp*)$(S_2C_2H_2)_2$ and [Ti(cp)(dithiolene)$_2$]$^-$ complexes (4, 6).

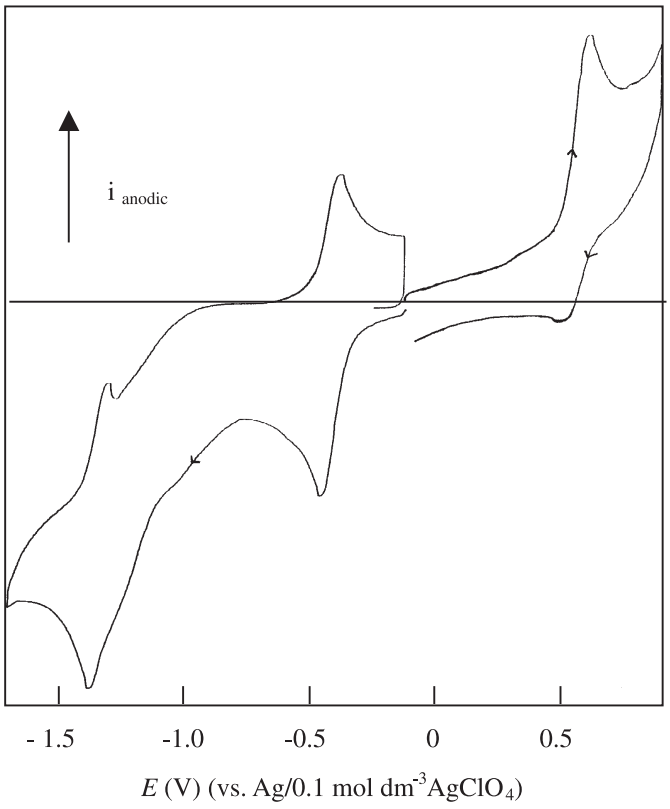

Fig. 2. Cyclic voltammogram of Nb(cp*)(dddt)$_2$ (**1**). Scan rate 100 mV s^{-1}.

Cyclic voltammetry experiments were performed in MeCN for complexes **1**–**3** to study their redox properties (Table 2). The cyclic voltamogramm of **1** and **3** are presented in Figs. 2 and 3. Each complex exhibits one reversible reduction wave corresponding to the formation of the d^1 species. The reduction occurs at lower potential in the case of the tantalum compound and is limited to one electronic process in the range investigated (–2 V/+1 V vs. Ag/Ag^+), whereas another reversible reduction process is observed in the case of niobium complexes. This second monoelectronic wave is attributed to the couple Nb^{IV}/Nb^{III}. The substitution of one dddt ligand by one dmit ligand induces a potential shift of about 0.2 V toward more anodic potentials of each electrochemical process involving the metal. This may be a consequence of the global electron impoverishment of the resulting complex. The electron-rich character of the dddt ligand appears also in the oxidative process which should derived from one electron oxidation of the dithiolene ligands. Indeed, for a scan rate of 100 mV/s, the ratio of peak currents $i_{p,a}/i_{p,c}$ are equal to 1 for the complexes **1** and **2** whereas this value is lower than 0.5 for compound **3**. The

formation of a stable radical cation requires also complexes bearing two dddt ligands. Contrary to what is observed in reduction, the nature of the metal has no significant effect which confirms that the oxidation involves the dithiolene ligands.

Further studies will concern the isolation of the species $[Mcp^*(dddt)_2]^{+\cdot}$ (M= Nb or Ta) by using electrocrystallization technique. Interesting magnetic properties may be expected from these radicals in the solid-state since the spin density is assumed to be strongly localized on the dithiolene ligands.

Experimental

General data

All reactions were carried out under an atmosphere of dry argon using standard Schlenk techniques. Solvents were dried and distilled just prior to use under nitrogen. The compounds $M(\eta^5\text{-}C_5Me_5)Cl_4$ were prepared according to the literature method (M = Nb (10) and Ta (11)) and characterized by ^1H NMR spectroscopy. IR spectra were measured with a Bruker IFS45 WHR FTIR spectrophotometer on KBr pellets. NMR spectra were recorded in $CDCl_3$, with TMS as an internal standard, on a Bruker 200 MHz spectrometer. Elemental analysis were performed at the Service Central d'Analyse, CNRS, Vernaison, France.

Synthesis of $Nb(\eta^5\text{-}C_5Me_5)(dddt)_2$ (1)

A solution of $Nb(\eta^5\text{-}C_5Me_5)Cl_4$ (0.5 mmol) in dichloromethane (40 mL) is added to a suspension of Na_2dddt (8*b*) (1 mmol) in dichloromethane (10 mL) at 0°C. After allowing the mixture to warm to room temperature, it was stirred for 15 h, then filtered, and the filtrate was concentrated under vacuum. Chromatography (SiO_2, $CHCl_3$) afforded a purple crystalline solid, yield: 135 mg, 45%. IR (υ (KBr)/cm^{-1}): 2985, 2955 (C-H), 1450 (C=C). Anal. calcd: C 36.7, H 3.9, S 43.6; found: C 36.0, H 3.9, S 43.8%.

Synthesis of $Ta(\eta^5\text{-}C_5Me_5)(dddt)_2$ (2)

A solution of $Ta(\eta^5\text{-}C_5Me_5)Cl_4$ (0.5 mmol) in dichloromethane (40 mL) is added to a suspension of Na_2dddt (1 mmol) in dichloromethane (10 mL) at 0°C. The cooling bath was removed, allowing the mixture to warm to room temperature and stirring was continued for 15 h in refluxing dichloromethane. The green solution was then filtrered and the filtrate was concentrated under vacuum. Chromatography (SiO_2, $CHCl_3$) afforded a green solid, yield; 25 mg, 8%. IR (υ (KBr)/cm^{-1}): 2985, 2950 (C-H), 1450 (C=C). Anal. calcd: C 34.5, H 3.7, S 41.0; found: C 33.8, H 3.6, S 39.8%.

Synthesis of $Nb(\eta^5\text{-}C_5Me_5)(dddt)(dmit)$ (3)

A solution of $Nb(\eta^5\text{-}C_5Me_5)Cl_4$ (0.5 mmol) in dichloromethane (40 mL) is added to a suspension of Na_2dddt (0.5 mmol) in dichloromethane (10 mL) at 0°C. After allowing the mixture to warm to room temperature, it was stirred for 15 h, then filtered, and the filtrate was concentrated under vacuum. After washing with three portions of hexane (10 mL), the green solid obtained (m = 0.132 g) is reacted with Na_2dmit (12) (70 mg, 0.29 mmol) in refluxing dichloromethane (30 cm^3) during 15 h. After filtration, the brown-red solution is concentrated under vacuum. Chromatography (SiO_2, $CHCl_3$) afforded a yellow-brown solid, yield: 130 mg, 42%. IR (υ (KBr)/cm^{-1}): 2985, 2950w (C-H), 1450 (C=C), 1060 (C=S). Anal. calcd: C 34.9, H 3.4, S 46.6; found: C 34.7, H 3.4, S 44.3%.

Electrochemical measurements

Cyclic voltammetry experiments were performed with a radiometer PGP 201 potentiostat. The electrolyte consisted of 0.1 M $N^nBu_4PF_6$ solution in acetonitrile dried on molecular sieves. A three-compartment cell was used with a platinum working electrode (diameter 2 mm), a platinum counter electrode, and an Ag – 0.1 mol dm^{-3} $AgClO_4$ reference electrode. Experiments were performed under argon flow. After each measurement the reference electrode was checked against the ferrocene–ferricinium couple (+0.025 V).

An approximate ab initio method based on the DIM model

John M. Cullen

Abstract: Using a second quantized formulation, an approximate diatomics in molecules (DIM) theory is presented in which all three- and four-centered electronic integrals are neglected. To ameliorate the effects of this approximation, the DIM one electron operator is constructed so that the true ab initio first-order density matrix and total energy are reproduced at the Hartree–Fock level. The resulting model was extensively tested for a variety of basis sets for its capability of capturing both the dynamic and nondynamic components of the electron correlation energy as well as the energies of excited electronic states. A modified method in which the DIM one-electron operator is formed from the initial extended Hückel guess of the Hartree–Fock orbitals was also found to produce excellent results.

Key words: DIM, electron correlation energy, excited states, semiempirical.

Résumé : Faisant appel à une deuxième formulation quantifiée, on propose une approximation de la théorie des molécules diatomiques (« DIM ») dans laquelle on néglige les intégrales électroniques à trois et à quatre centres. Afin d'améliorer les effets de cette approximation, on construit l'opérateur à un électron de la « DIM » de façon à ce que la vraie matrice de densité du premier ordre ainsi que l'énergie totale ab initio soient reproduites au niveau Hartree–Fock. On a vérifié le modèle qui en résulte de façon extensive pour une variété d'ensembles de base pour évaluer sa capacité de capturer les composantes dynamiques et non dynamiques de la corrélation d'énergie de l'électron ainsi que les énergies des états électroniques excités. On a aussi trouvé qu'il est possible d'obtenir d'excellents résultats à l'aide d'une méthode modifiée dans laquelle l'opérateur à un électron de la « DIM » est formé à partir d'évaluations initiales des orbitales de Hartree–Fock, faites sur la base de la théorie étendue de Hückel.

Mots clés : molécules diatomiques (« DIM »), énergie de corrélation des électrons, états excités, semi-empirique.

[Traduit par la Rédaction]

Introduction

Possibly one of the most underrated methods in quantum chemistry is the diatomics in molecules (DIM) approach originated by Ellison (1). This theory begins with the recognition that the two-body nature of the nonrelativistic molecular electronic Hamiltonian allows one to express the operator as a sum of diatomic and atomic terms (for reviews of DIM method see ref. 2). Unlike standard quantum chemical methods no electronic integral evaluations are performed. There is no hierarchy of procedures as found in molecular orbital methods to include electron correlation. Instead a Hamiltonian-like matrix is constructed from overlap integrals and eigenvalues of the isolated atomic and diatomic fragments. Diagonalization gives results which automatically include electron correlation. The calculation of excited electronic states becomes as easy to obtain as the ground state. The multireference nature of the DIM wave function also ensures accurate results for molecular geometries in which chemical bonds are being broken or formed.

Though the DIM formulation is exact for a complete set of electronic eigenstates of the constituent atoms and diatomics, for an incomplete set the results are nonvariational. In fact results of DIM calculations can be quite sensitive to the basis set used (see for example ref. 3). Unfortunately the size of the atomic and diatomic eigenstate basis needed for reliable results precludes most molecular applications. A notable exception has been the successful work done on argon gas clusters interacting with one or two open-shell atoms or ions (4). To curtail the large basis set requirement, recent work (5) has focused on incorporating electrostatic terms into the DIM Hamiltonian and using a second-order perturbation expansion to include the effects of less dominant terms in the polyatomic basis set.

In this paper we take a different tack expanding out in second quantized form the molecular electronic Hamiltonian by the method of increments (6) to obtain an approximate DIM model in which all three- and four-centered electronic integrals vanish. Using a modified one-electron operator which reproduces the exact Fock matrix, calculations were performed at the Moller–Plesset second-order perturbation (MP2), generalized valence bond (GVB), and configuration interaction of all single excitations (CIS) levels to test the accuracy of this model for predicting the dynamic electron correlation, nondynamic electron correlation, and electronically excited state energies respectively. A faster computational form of the DIM one-electron operator based on an initial extended Hückel guess of the Hartree–Fock molecular

© 2000 NRC Canada

orbitals was also tested and found to work surprisingly well. Before presenting theory and results we comment on the relationship of our model to the linearized class of quantum chemical methods.

Today groups such as those led by Scuseria (7, 8) and Head-Gordon (9) are recasting standard quantum chemical methods such as density functional theory and Hartree–Fock theory into procedures which computationally scale linearly with system size. For the most part this is being accomplished through the use of fast multipole moment expansions (10, 11) and exploiting the local nature of the first-order density matrix (12). For a double ζ basis set typically these linear algorithms do not become more effective over traditional ones until the problem size has exceeded 300 atomic orbitals (11). This is a result of the large prefactor for the integral generation and subsequent Fock matrix construction step. In comparison standard matrix diagonalization routines which are often used in these linear programs scale with the cube of the system size. Because these latter methods have relatively small prefactors, they do not become computational bottlenecks until the molecular size exceeds 3000 atomic orbitals (7).

To compare our approximate ab initio DIM approach to these theories we first examine the case of small molecules where linearized programs offer no advantage over the traditional methods. Using the ratio of the number of two electron integrals generated by both programs as a rough measure of the relative computational times we find at the 6-31G double ζ level, that for benzene (66 orbitals), the standard ab initio procedure already uses eleven times more two-electron integrals than our DIM method. By the time we have reached buckminsterfullerene (540 orbitals) this ratio has increased to 157:1. Though the number of two-electron integrals grows roughly quadratically with molecular size for both ab initio and our DIM model, the scaling is N^2 where N is the number of atomic orbitals in the ab initio case (7*b*), and m^2, where m is the number of atoms in the molecule in the DIM case. For very large molecules the methods used to linearize standard quantum chemical programs could also be applied to our DIM model.

Theory

The second quantized form of the molecular electronic Hamiltonian consisting of m atoms and n electrons is

$$[1a] \qquad H = \sum_{i,j}^{N} h_{ij}\, a_i^{+} a_j + \frac{1}{2} \sum_{i,j}^{N} \sum_{k,l}^{N} (ij|kl) a_i^{+} a_k^{+} a_l a_j$$

Here sums are over the orthonormal basis set of N atomic spin orbitals which span the entire molecule. The one- and two-electron matrix elements are defined by the usual expressions

$$[1b] \qquad h_{ij} = \langle \phi_i \left| -\frac{1}{2}\nabla^2 - \sum_{K}^{m} \frac{Z_K}{|R_k - r|} \right| \phi_j \rangle$$

$$[1c] \qquad (ij|kl) = \langle \phi_i(r_1)\, \phi_k(r_2) \left| \frac{1}{r_{12}} \right| \phi_j(r_1)\, \phi_l(r_2) \rangle$$

For an isolated atom "A" embedded within the molecule, the Hamiltonian is similarly given by

$$[2a] \qquad H_{\mathrm{A}}^{0} = \sum_{i,j \in \mathrm{A}}^{N} h_{ij}\, a_i^{+} a_j + \frac{1}{2} \sum_{i,j \in \mathrm{A}}^{N} \sum_{k,l \in \mathrm{A}}^{N} (ij|kl) a_i^{+} a_k^{+} a_l a_j$$

where now sums are over the subset of orbitals associated with atom A and these are only orthogonalized within this local subset. As a zero-order approximation the molecule can be considered as being composed of collection of the m isolated atoms. Then the resulting Hamiltonian of this system is then

$$[2b] \qquad H^{0} = \sum_{\mathrm{A}}^{m} H_{\mathrm{A}}^{0}$$

To improve upon this approximation we now consider the interaction of pairs of atoms within the molecule. The Hamiltonian of a diatomic fragment consisting of atoms A and "B" is

$$[3a] \qquad H_{\mathrm{AB}}^{1} = \sum_{i,j \in \mathrm{AB}}^{N} h_{ij}\, a_i^{+} a_j + \frac{1}{2} \sum_{i,j \in \mathrm{AB}}^{N} \sum_{k,l \in \mathrm{AB}}^{N} (ij|kl) a_i^{+} a_k^{+} a_l a_j$$

Again only those orbitals associated with the atoms A and B are included and orthogonalized to each other. To extract the diatomic interactions from the atomic ones we define

$$[3b] \qquad \Delta H_{\mathrm{AB}}^{1} = H_{\mathrm{AB}}^{1} - H_{\mathrm{A}}^{0} - H_{\mathrm{B}}^{0}$$

Included in $\Delta H_{\mathrm{AB}}^{1}$ are one-centered atomic terms which result from the reorthogonalization that occurs when the separate sets of atomic orbitals on atoms A and B are joined to form one orthonormal set. Therefore the approximate molecular Hamiltonian to first-order can be written as

$$[4a] \qquad H_1 = \sum_{\mathrm{A}}^{m} H_{\mathrm{A}}^{0} + \sum_{\mathrm{A>B}}^{m} \Delta H_{\mathrm{AB}}^{1}$$

Substituting eq. [3*b*] for $\Delta H_{\mathrm{AB}}^{1}$ yields

$$[4b] \qquad H_1 = \sum_{\mathrm{A}}^{m} H_{\mathrm{A}} + \sum_{\mathrm{A>B}}^{m} H_{\mathrm{AB}}^{1} - \frac{1}{2} \sum_{\mathrm{A} \neq \mathrm{B}}^{m} (H_{\mathrm{A}}^{0} + H_{\mathrm{B}}^{0}) = \sum_{\mathrm{A>B}}^{m} H_{\mathrm{AB}}^{1} - (m-2) \sum_{\mathrm{A}}^{m} H_{\mathrm{A}}^{0}$$

In comparison to this result the original DIM Hamiltonian (1) is given by

$$[5] \qquad H_{\mathrm{DIM}} = \sum_{\mathrm{A>B}}^{m} H_{\mathrm{AB}} - (m-2) \sum_{\mathrm{A}}^{m} H_{\mathrm{A}}$$

where H_{A} and H_{AB} are the usual Hamiltonians consisting of differential kinetic and classical potential energy terms for the isolated atom A and the isolated diatomic molecule composed of atoms A and B, respectively. Formally eq. [5] is exact and for a finite orthonormal atomic orbital basis the second quantized form will contain all three- and four-centered integrals. For a common set of atomic orbitals spanning the molecule, the calculation of fragment Hamiltonian matrix elements will not only involve basis

© 2000 NRC Canada

functions within the fragment but also basis functions or so-called ghost orbitals external to the fragment. Normally DIM methods ignore these latter orbitals and a variational calculation will not necessarily produce an upper bound to the exact energy. This omission however, can either be minimized by the use of extensive basis sets for the internal spaces of the respective atomic and diatomic fragments, or accounted for by explicit incorporation into the Hamiltonian of three-body empirical potentials (4, 5).

Equation [4*b*] which is developed from a perturbative-like expansion contains only one- and two- centered electronic integrals over an atomic orbital basis which is only approximately orthogonal. For diatomic molecules this model becomes exact. Our test calculations on polyatomics further show a cancellation of errors between those made from the neglect of three- and four-centered electronic integrals and the assumption of othogonality of the atomic orbital basis. These results however systematically overestimate chemical binding energies and produce optimized molecular geometries with chemical bond lengths predicted too short. Since the intended use of our model Hamiltonian is for applications where electron correlation plays a significant role, it can be improved with exact results obtained within the same calculation at the Hartree–Fock level. Therefore we reformulate the DIM one-electron operator to reproduce the exact Hartree–Fock energy as well as the exact Fock density within a symmetrically orthogonalized atomic orbital (OAO) basis set, i.e.,

$$[6a] \quad P^{\mathrm{OAO}}_{\mathrm{exact}} = P^{\mathrm{DIM}}$$

$$[6b] \quad E^{\mathrm{exact}}_{\mathrm{HF}} = E^{\mathrm{DIM}}_{\mathrm{HF}}$$

To satisfy eq. [6a] we set

$$[7a] \quad f^{\mathrm{DIM}} = f^{\mathrm{OAO}}_{\mathrm{exact}} + \sigma I$$

Here I, f^{DIM}, and $f^{\mathrm{OAO}}_{\mathrm{exact}}$ are the identity matrix, corresponding DIM and exact Fock operators, respectively. Expanding out eq. [7*a*] results in

$$[7b] \quad h^{\mathrm{DIM}} = h^{\mathrm{OAO}} + (g^{\mathrm{OAO}} - g^{\mathrm{DIM}}) + \sigma I$$

where matrices h^{OAO}, g^{OAO} and h^{DIM}, g^{DIM} are the two-electron contributions to the respective Fock operators. In the closed shell case over the atomic orbital basis, $\{\chi_m\}$, g takes the form

$$[7c] \quad g_{\mu\nu} = \sum_{\lambda\sigma}^{N} P_{\lambda\sigma}\left[(\mu\nu|\lambda\sigma) - \frac{1}{2}(\mu\sigma|\lambda\nu)\right]$$

In similar fashion expanding out eq. [6*b*] leads to

$$[8a] \quad \frac{1}{2} TrP^{\mathrm{OAO}}_{\mathrm{exact}}(2h^{\mathrm{OAO}} + g^{\mathrm{OAO}}) = \frac{1}{2} TrP^{\mathrm{DIM}}(2h^{\mathrm{DIM}} + g^{\mathrm{DIM}})$$

Substitution of eqs. [6*a*], [7*b*] produces

$$[8b] \quad \sigma = \frac{1}{2n} TrP^{\mathrm{OAO}}_{\mathrm{exact}}(g^{\mathrm{DIM}} - g^{\mathrm{OAO}})$$

where n is the number of electrons in the molecule. Another possibility is to directly use the ab initio Fock operator as our DIM one-electron operator in the molecular orbital basis, however for multireference electron correlation treatments of the ground and excited states we would need to make an intermediate transformation to the MO basis and ensure that our programs use the two-electron integrals in normal product form.

For open shell molecules we shall only consider high-spin cases in this initial paper. One can partition the Fock matrix into its α- and β-spin components. Over a canonical molecular orbital basis this yields

$$[9a] \quad f^{\alpha}_{ii} = h_{ii} + \sum_{j}^{N_\alpha}[(ii|jj) - (ij|ij)] + \sum_{j}^{N_\beta}(ii|jj)$$

$$[9b] \quad f^{\beta}_{ii} = h_{ii} + \sum_{j}^{N_\beta}[(ii|jj) - (ij|ij)] + \sum_{j}^{N_\alpha}(ii|jj)$$

where N_α and N_β are the number of occupied and -spin molecular orbitals with, $N_\alpha > N_\beta$. To have a spin independent one-electron DIM operator we define the Fock operator

$$[10a] \quad f_{ii} = h_{ii} + \sum_{j}^{N_\beta}[2(ii|jj) - (ij|ij)] + \sum_{j=N_\beta+1}^{N_\alpha}\left[(ii|jj) - \frac{1}{2}(ij|ij)\right]$$

Then

$$[10b] \quad f^{\alpha}_{ii} = f_{ii} - \frac{1}{2}\sum_{j=N_\beta+1}^{N_\alpha}(ii|jj)$$

$$[10c] \quad f^{\beta}_{ii} = f_{ii} + \frac{1}{2}\sum_{j=N_\beta+1}^{N_\alpha}(ii|jj)$$

Therefore this is equivalent to choosing an average Fock operator (i.e., $f = 1/2(f^{\alpha} + f^{\beta})$). Equations [8*b*] and [7*b*] then can be used in these high-spin cases with the density matrix generalized to

$$[10d] \quad P_{\mu\nu} = \sum_{j}^{N_\alpha} c^{\alpha}_{\mu j} c^{\alpha}_{\nu j} + \sum_{j}^{N_\beta} c^{\beta}_{\mu j} c^{\beta}_{\nu j}$$

Results and discussion

Moller–Plesset second-order (MP2) perturbation calculations were performed for a range of Pople-type basis sets (see for example ref. 13) over a variety of molecules to test the capability of our ab initio DIM model to capture the dynamic electron correlation energy, responsible for the London or van der Waals forces in a molecule. These results are compared with exact values in Table 1 where energies are reported in millihartrees (mH) and all molecular geometries set to their 6-31G(d) MP2 optimized values. Due to the two-body nature of our model Hamiltonian and the approximate nature of the orthonormal basis used, one might expect that errors should increase in cases where atoms are crowded in as found in cyclic molecules or when atomic orbitals from multiple centers overlap to a significant extent as in the case

[a]All energies are in millihartrees relative to the Hartree–Fock value for each given basis set.

of basis sets having diffuse functions. Comparing the linear vs. cyclic types of molecules in Table 1 shows that with the exception of the 6-311G(d,p)++ results in cases such as benzene, borazine, pyrimidine, and trioxane, there really is no significant increase in error. The root mean square (RMS) errors made by the DIM method to the exact results for the 6-31G, 6-31G(d), 6-31G(2d), 6-311G(d,p) basis sets are 2.3, 5.0, 2.5, 4.0 mH, respectively, while the RMS error for the 6-311G(d,p)++ basis is 9.7 mH. The last basis with its diffuse orbitals appears problematic for our model. In comparison, the RMS relative errors are 1.0, 0.96, 0.45, 0.54,and 1.3% for the corresponding basis sets ranging from 6-31G to 6-311G(d,p)++. These results are similar to those found by the resolution of the identity methods for computing MP2 energies when they were first introduced (14, 15). It may be possible to "tune" the basis to minimize these errors, the 6-31G(2d) results when compared to the 6-31G(d) values demonstrate this possibility.

We can also extract from Table 1 electron correlation contributions to conformational energy differences as well as to chemical reaction enthalpies.[2] Focusing on results at the 6-311G(d,p) level and using the notation ΔE^{exact} (ΔE^{DIM}) we find that the MP2 electron correlation energy favors staggered ethane by 0.5 (0.3) kJ mol^{-1} over the eclipsed conformer. Similarly *cis*-2-butene is favored by 0.7 (1.3) kJ mol^{-1} over *trans*-2-butene. For the isomerization of propene into cyclopropane and acetonitrile into methylisocyanide there is, respectively, a 18.7 (15.5) kJ mol^{-1} contribution in favor of cyclopropane and 36.1 (38.3) kJ mol^{-1} for acetonitrile. The formation of the Lewis adduct trifluoroboronamine over the reactants ammonia and trifluoroboron is also favored by an electron correlation contribution of 13.4 (21.8) kJ mol^{-1}. Finally the gas phase energy difference between acetate, H^+, and acetic acid, known as the absolute acidity (see for example ref. 13), has an MP2 contribution of 4.0 (4.9) kJ mol^{-1} at the 6-311G(d,p) level and for the more anion appropriate 6-311G(d,p)++ basis, 21.5 (21.0) kJ mol^{-1}. These cases demonstrate that errors in the DIM computed dynamic electron correlation energy are generally small, much smaller than the basis set incompletion errors occurring at the 6-311G(d,p) level. Similar results were also found at the coupled cluster singles, doubles level of theory.

In contrast to the dynamic electron correlation energy, the nondynamic electron correlation energy arises from constraining spin paired orbitals in the restricted Hartree–Fock (RHF) wave function to have the same spatial function. As a chemical bond is stretched or twisted this constraint causes the Hartree–Fock energy to rise more rapidly than the true energy. The remedy is to replace the single Slater determinant representation of the RHF wave function with a multideterminant spin adapted one. The generalized valence bond (GVB) approach accomplishes this in a computationally simple and quick way (16, 17). In Table 2, GVB as well as RHF results are presented for ethylene in which first the π bond is broken as one CH_2 group is twisted perpendicular to the other and then both carbon–carbon π and σ bonds are simultaneously stretched to twice their equilibrium distance. Agreement between the exact GVB energies and those generated by the DIM Hamiltonian with the one-electron operator constructed at the Hartree–Fock level is within a millihartree.

To complete the examination of our DIM model to post Hartree–Fock treatments, vertical excitation energies computed at the configuration interaction singles (CIS) level of theory are presented in Table 3. The 6-31G and 6-31G+ basis sets are identical to those employed by Foresman et al.

[2]For comparison later to experiment we report ethalpies in kJ mol^{-1} where 1 mH = 2.626 kJ mol^{-1}. Typically quantum calculations strive for an accuracy with experiment of a kcal mol^{-1} which corresponds to 4.184 kJ mol^{-1}.

C—C bond stretched 1.5 × R_0	223.21	153.73	223.21	153.98	223.19	154.33
C—C bond stretched 2.0 × R_0	424.70	257.78	424.70	258.35	424.42	259.09

[a]Energies are in atomic units for the equilibrium geometry and in millihartrees relative to this reference for all other molecular geometries.
[b]The HDIM method uses a density matrix generated from the initial extended Hückel guess to construct the DIM one-electron operator.

(18), however our molecular geometries for formaldehyde and ethylene differ slightly since we use 6-31G(d) MP2 optimized coordinates. In the case of formaldehyde these differences are for the CO bond: 0.0089 Å; CH bond: 0.0003 Å; and CHO angle: 0.24°. Examining the sensitivity of the vertical excitation energies to these molecular geometry variations at the 6-31G+ level shows that the Foresman results are 0.04 eV higher for the valence state $^1A_2$ n-π* transition and 0.08 eV lower for the Rydberg $^1B_2$ n-3s transition. Examining our exact results with the DIM computed values for the same transitions and basis set yields excitation energies which are 0.03 eV higher for the $^1A_2$ n-π* case and 0.09 eV lower in the $^1B_2$ n-3s transition. Therefore these errors are comparable to the errors made from the uncertainties in the molecular geometry. Overall, inspection of Table 3 reveals good agreement between the DIM and exact computed values. However when excited states lie close to one another as for example, in the case of $^1B_1$ π-3s, $^1B_2$ π-3p Rydberg transitions in pyrrole (for the calculated value see ref. 29), reversals in the ordering of the states can occur.

In place of the converged Fock–Dirac density matrix used to generate the one-electron operator in our DIM model Hamiltonian, the initial guess density matrix generated from an extended Hückel calculation was also used. The results with this modified DIM Hamiltonian, which we denote as HDIM are displayed in Table 4. Compared to the exact energies computed with the same basis set the agreement at the Hartree–Fock level is surprisingly good with RMS errors of 2.8, 2.0, and 2.4 mH for the corresponding 6-31G, 6-311G(d,p), and 6-311G(d,p)++ basis sets. This good agreement also holds when bonds are stretched or twisted as seen in the ethylene case of Table 2, where the HDIM RHF energies lie within 0.3 mH of the exact RHF values. The corresponding errors at the GVB level are 1.5 mH or less showing the capability of the HDIM model to capture accurately the nondynamic electron correlation energy. In comparison, the computed MP2 dynamic electron correlation results have, with the exception of the 6-31G basis, errors slightly larger than seen in our original DIM model but still quite acceptable when compared to the basis set incompletion errors that occur at these levels. In Table 4 we find RMS errors for the respective 6-31G, 6-311G(d,p), and 6-311G(d,p)++ basis sets of 4.8, 4.3, and 10.5 mH.

Using the notation ΔE^{exact} (ΔE^{HDIM}) we compare the total 6-311G(d,p) conformational energy differences as well as reaction enthalpies to experiment. Because zero-point energies are not taken into account and 6-31G(d) MP2 optimized molecular geometries are used, one can only hope for semi-quantitative accuracy. In the case of staggered vs. eclipsed ethane, the RHF energy difference is 12.9 (13.1) kJ mol^{-1} while the contribution from MP2 electron correlation is 0.5 (0.3) kJ mol^{-1}. Both exact and HDIM calculations yield an identical 13.4 kJ mol^{-1} energy gap compared to the experimental

Table 3. Comparison of vertical excitation energies computed at the CIS level.[a]

[a]RHF energies are in au, MP2 energies are in mH relative to their respective HDIM, exact RH*F* values. Errors are mH for both RHF and MP2 results.

value of 12.1 kJ mol^{-1} (31). Similarly, the *cis*/*trans*-2-butene conformational energy difference is 6.7 (7.5) kJ mol^{-1} at the RHF level and 6.0 (6.3) kJ mol^{-1} at the MP2 level compared to the estimated experimental value of 4.2 kJ mol^{-1} (32). For the isomerization of acetonitrile to methylisocyanide, the experimental enthalpy of reaction is 99 kJ mol^{-1} (33). At the RHF and MP2 levels energy differences of 79.3 (79.4) kJ mol^{-1} and 36.1 (36.9) kJ mol^{-1}, respectively, produce a total of 115.4 (116.4) kJ mol^{-1}. In contrast to this overestimation, the experimental isomerization energy of propene to cyclopropane of 35.1 kJ mol^{-1} (34) is underestimated with computed RHF and MP2 contributions of 37.7 (35.5) kJ mol^{-1} and –18.7 (–15.8) kJ mol^{-1} yielding a net energy of 19.0 (19.7) kJ mol^{-1}. Finally, the formation of trifluoroboron from ammonia and BF3 is predicted to be 81.8 (85.4) kJ mol^{-1} at the RHF level and when MP2 electron correlation contributions are added in, 95.2 (108.2) kJ mol^{-1}. Experimentally the gas-phase reaction enthalpy is unknown. The best theoretical estimate is 80.3 kJ mol^{-1} (35).

Results of the determination of equilibrium geometries by numerically minimizing the energy with respect to the molecular coordinates are presented in Table 5. A comparison between exact and HDIM values shows excellent agreement both at the RHF and MP2 6-311G(d,p) levels of theory with bond distances predicted to within 0.002 Å and bond angles to within 0.3°. Also included in Table 5 are three examples of open shell systems, the lowest lying triplet states of ethylene (CH_2 groups twisted 90° to one another) and cyclopropenylidene as well as the doublet methyl radical (planar D_{3h} conformation). Even though our one-electron DIM operator is constructed from densities of an averaged Fock operator, eqs. [10*a*]–[10*c*], geometries and energies show similar accuracies as found in the closed shell molecules.

The only dihedral angle reported in Table 5 is for hydrogen peroxide where there is 0.2° agreement at the RHF level but a 2.4° difference at the MP2 level. One reason for this is as seen from Table 4 is that the HDIM MP2 errors are larger than the RHF errors for hydrogen peroxide. However, a more significant factor is likely the shallow H_2O_2 torsional potential well causing a deterioration in the accuracy of the numerical optimization used. The error in the BC bond distance in borane carbonyl also is an exception to the 0.002 Å accuracy found in most compounds. There is a substantial 0.015 Å deviation at the Hartree–Fock level which would seem to indicate that the extended Hückel guess used to generate the initial density matrix employed in the construction of our HDIM one-electron operator is not sufficiently accurate. However the computed exact and HDIM RHF energies differ by only 0.6 mH. Therefore, it is likely our numerical minimization is again suspect in this weakly bound intermolecular complex.

Occasionally, one comes across molecules where the HDIM method fails to be sufficiently accurate. Two examples are pyrrole and C_{60} at the 6-31G level. In the case of buckminsterfullerene, the exact RHF calculation which requires just under 3 billion two-electron integrals yields an energy of –2270.9496 Hartrees. In comparison, the HDIM calculation uses 19 million two-electron integrals but the predicted RHF energy of –2271.0205 Hartrees is in error by 70.9 mH. However, the converged density matrix can be used to reconstruct a more accurate DIM one-electron operator from eqs. [7*b*] and [8*b*]. Repeating the Hartree–Fock step

produces a new energy of –2270.9790 Hartrees reducing the error to 29.4 mH. A second iteration yields –2270.9565 Hartrees further reducing the error to 6.9 mH.

Conclusions

Molecular applications of the diatomics in molecules (DIM) method often prove impractical due to the large basis set size of atomic and diatomic eigenstates needed to obtain reliable and accurate results. We have presented a semiempirical DIM theory which sidesteps this problem by using a second quantized approach. In this method all three- and four-centered electronic integrals are discarded. This is equivalent to ignoring the overlaps between atomic and diatomic fragments. To compensate for this approximation, the one-electron DIM operator is constructed to reproduce the density matrix and energy in a Hartree–Fock calculation. The resulting method is found to reproduce accurately the energies from both the dynamic and nondynamic electron correlation as well as excited stated states. A modified model in which the DIM one-electron operator is formed from the initial extended Hückel guess density matrix was also examined and found to work surprisingly well.

In this initial work no attempt has been made at the post Hartree–Fock level to take advantage of the reduced number of two-electron integrals which formally scale as m^2, where m is the number of atoms. Even so, our DIM MP2 energies computed over a canonical molecular orbital basis, using the segmented integral transformation algorithms of the GAMESS program (38) are three to four times faster than the exact MP2 results for the same basis computed in the same fashion. More suitable electron correlation treatments for our DIM model would be to use the atomic orbital (AO) based MP2 and coupled cluster approaches of Scuseria and Ayala (8). Alternatively, due to the orthogonal AO basis used in our model, transforming integrals to a strictly localized one- and two-centered molecular orbital basis (39) would scale as m^2 and allow localized electron correlation treatments.

For the future we plan to examine the possibility of reducing computational times of the DIM one- and two-centered orthogonal AO two-electron integrals by constructing interpolation tables to directly reproduce these integrals for a given basis set as a function of internuclear separation. Transformations would still be required to rotate these results from their local frames into the external molecular frame. Also in the case of our HDIM model we would like to improve the extended Hückel starting guess of Hartree–Fock molecular orbitals which is used to form the density matrix that in turn is used to form g^{DIM} and g^{OAO} in eqs. [7] and [8] which in turn is used to construct our DIM one-electron operator. Because these starting guesses are projections of a minimum AO basis set onto our larger target basis, it may be possible to form g^{OAO} by first building the g matrix over the two-electron integrals of the minimum basis set rather than the two-electron integrals of our target AO basis, then projecting these results onto the symmetrically orthogonalized target atomic orbital basis.

Dew points of ternary methane + water + methanol. Measurement and correlation

Sofía T. Blanco, Inmaculada Velasco, Evelyne Rauzy, and Santos Otín

Abstract: A water and methanol dew point generation device has been built up and tested. Experimental measurements of dew point for ternary methane + water + methanol were carried out between 1.01×10^5 Pa to 97.84×10^5 Pa and the temperature range from 248.71 to 282.93 K. A EOS–CR method (equation of state – chemical reticular) reproduces very accurately the experimental curves independently of the pressure and temperature ranges.

Key words: dew point, experimental method, equation of state, excess function.

Résumé : On a mis au point et évalué un appareil permettant de générer le point de rosée de l'eau et du méthanol. On a déterminé expérimentalement le point de rosée du mélange ternaire méthane + eau + méthanol entre $1{,}01 \times 10^5$ et $97{,}84 \times 10^5$ Pa et à des températures entre 248,71 et 282,93 K. Une méthode « EOS–CR » (équation d'état chimique réticulaire) permet de reproduire avec beaucoup de précision les courbes expérimentales quelles que soient les variations de pression et de température.

Mots clés : point de rosée, méthode expérimentale, équation d'état, fonction d'excès.

Introduction

Methanol is one of the main additives added to natural gases. This chemical is used firstly as a hydrate inhibitor and secondly as a secant after hydraulic tests, which constitute one of the first phases in the starting of gas transport pipelines. In both of two submitted applications, methanol is found with water in natural gases. To know the influence of these two components in vapour–liquid equilibrium of natural gases, water and methanol dew points in methane have been generated and the conditions of them determinated. Taking into account that natural gas is composed of more than 90% methane, the study of the methane + water + methanol system constitutes an approximated knowledge of natural gas + water + methanol behaviour.

A water and methanol dew point generation device has been built up and tested to determine the experimental dew points of methane + water + methanol mixtures. The results obtained on these mixtures between 1.01×10^5 and 97.84×10^5 Pa and temperatures from 248.71 to 282.93 K are presented here.

The demand for reliable calculation procedures to estimate these dew points in natural gases is becoming more and more important. Therefore the experimental results obtained on the ternary system were analyzed in terms of an EOS–CR method, which reproduces very well the experimental dew point curves.

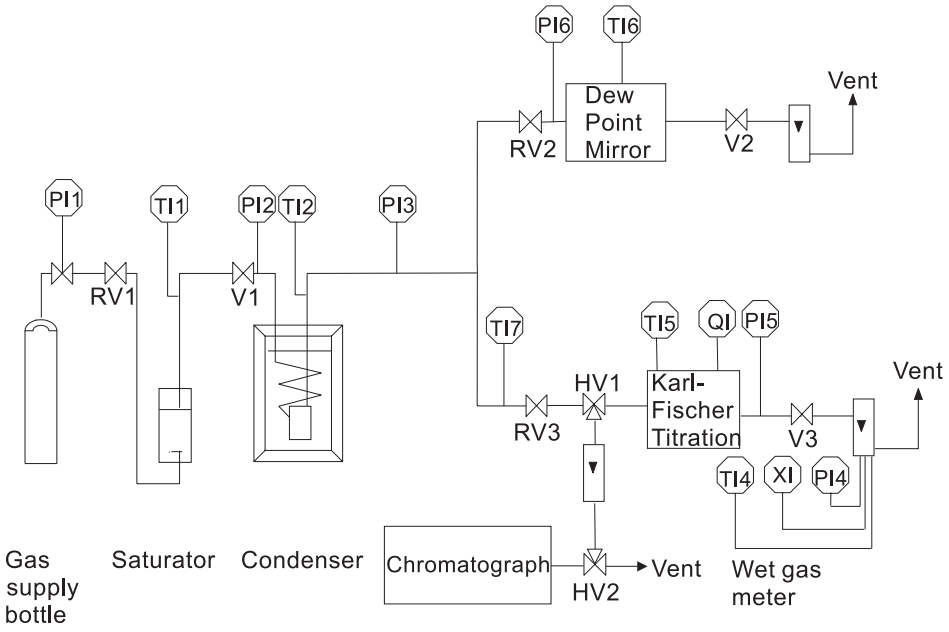
Experimental

Apparatus

The experimental method used for this work is based on the generation of saturated gases with water and methanol by condensation of these compounds in one temperature-controlled condenser with continuous gas flow at specified pressures. The concentrations of water and methanol in the gas are measured at the outlet of the dew point generation system, using a Karl Fischer titration, according to the standard method ISO 10101 (1) at atmospheric pressure, and a gas chromatography analysis, respectively. By doing so, the water and methanol contents reference values of the gaseous phase are obtained. The dew point values are measured by means of a chilled mirror instrument. The chilled mirror instrument input pressure is set using a regulator valve, when the apparatus reaches a stable value of dew temperature, both pressure and temperature are recorded. In this way, the values of the temperature and pressure of the dew point curve of the mixture generated are obtained.



Operating procedure

The dew point pressure values range from 1.01×10^5 Pa to 97.84×10^5 Pa and the temperature values range from 248.71 to 282.93 K. The methane gas was supplied by Air Liquide with the specified purity of 99.95 vol.% and was used without further treatment.

The dew point generation device used for our experimental data collecting is presented in Fig. 1. After controlled expansion (PI1), the gas is saturated with water and methanol vapour by flowing through a liquid mixture of these compounds in an isolated saturator held at laboratory temperature. The condensation temperature of water and methanol is then achieved in a controlled-temperature stainless steel condenser.

Fig. 1. Experimental apparatus used in this work. RV: control valve; V: ball valve; HV: three-way valve; TI: temperature measurement; PI: pressure measurement; QI: coulometric measurement; XI: volume measurement.

To avoid any recondensation, the expansion before the Karl–Fischer titrator inlet is made using a heated valve (RV3). To analyze the contents of water and methanol and to carry out the dew point measurements the following instrumentation is used: (*i*) Mitsubishi CA 06 Karl–Fischer titrator, coupled with an Elster wet gas meter Type Gr. 00, E51, 0.2% accuracy; (*ii*) HP 5890 gas chromatograph with TCD detector adjusted to maximum sensitivity; (*iii*) MBW dew point instrument model DP3-D. The cooling of the mirror is achieved by a Peltier cooling device with automatic mirror check. The uncertainty on the dew temperature is better than ±0.4 K; and (*iv*) pressure transmitter with a maximum error of 0.2% in the calibrated range.

Previously to the study of methane + water + methanol, the performance of both analysis methods and experimental procedures was determined. Repeatability and reproducibility of the Karl–Fischer titration, the gas chromatography analysis, and the dewpoint generation were calculated according to ISO 5725 (2) after repetitive measurements. The results obtained in the performance evaluation are presented in Table 1. Reference conditions for volume are 273.15 K and 1.01325×10^5 Pa. The test was achieved on a water and methanol dew point of 283.15 K and 5×10^5 Pa in pure nitrogen. The reliability tests results are taken as consistency criteria; the maximum acceptable standard deviation of measurements is derived from the repeatability value, and the maximum acceptable discrepancy with measurements from external laboratories is derived from the reproducibility value.

Results

The water and methanol contents in the vapour phase and the dew point curve of the mixtures generated at the dew point generation system were determined and the results of the experiments are collected on Table 2.

Repeatability (n)	15.96	316.7
Reproducibility (n)	36.32	294.0

Theory

Introduction

Classical models such as UNIQUAC or NRTL yield good results for vapour–liquid equilibrium of binary systems under low pressures containing one self-associating compound such as alcohol, but are not suitable for high-pressure phase equilibrium calculations.

In this work, EOS–CR is used and is derived from the excess function equations of state model (3) and founded on the zeroth approximation on the quasireticular model. The values of dew temperature and composition of the vapour phase for the studied system are calculated by means of this theoretical method using the experimental values of pressure obtained in the present work.

To know the ability of this method to predict the dew point curves of the ternary system in the temperature and pressure studied ranges, the comparison between experimental and calculated values is carried out obtaining very good results.

Description of the model

To represent the vapour–liquid equilibrium of mixtures containing one self-associating component, we use a model founded on the zeroth approximation of Guggenheim's reticular model, which answers two conditions: (*i*) the

Helmholtz energies of pure components are calculated by equations of state; (*ii*) the excess functions are defined at constant packing fraction, the latter described by $v°/v$, $v°$ being the molar close-packed volume and v the molar volume. It is assumed that it is possible to define a "covolume" b proportional to $v°$, which enables evaluation of the packing fraction by the ratio $\eta = b/v$. If the packing fraction for the pure components and for the mixture is assumed to be the same, then:

$$[1] \qquad \eta = \frac{b}{v} = \frac{b_1}{v_1} \qquad (i = 1, \ldots p)$$

The equation of state used in this model is the translated Peng–Robinson cubic equation of state (4, 5) of the form:

$$[2] \qquad P = \frac{RT}{\bar{v} - \bar{b}} - \frac{a(T)}{\bar{v}(\bar{v} + \gamma\bar{b})}$$

where P and T are the system pressure and temperature, R is the gas constant, $\bar{v}$ is a translated molar volume called the pseudo-molar volume and $\bar{b}$ is the pseudo covolume and it is calculated as follows for each component of the mixture:

$$[3] \qquad \bar{b} = 0.045572\frac{RT_c}{P_c}$$

where T_c and P_c are the critical temperature and pressure, respectively, for each component.

The parameter a in eq. [2] is the attractive parameter and is a function of the temperature; the equations used for its calculation are the proposed by Carrier (6) and Carrier et al. (7).

The molar Helmholtz energy of a mixture, A, may be written as follows:

$$[4] \qquad A = A^{id} - RT \ln (1 - \eta) - \sum_{i=1}^{p} \frac{x_i a_i}{b_i} Q(\eta) + A^E_{res}$$

where A^{id} is the ideal mixture molar Helmholtz energy, a_i is the attractive parameter of the translated Peng–Robinson cubic equation of state for the component i (4, 5), b_i is the molar covolume for the component i, A^E_{res} is the residual excess Helmholtz energy which will be explained later, and $Q(\eta)$ is expressed as follows:

$$[5] \qquad Q(\eta) = \int_0^\eta \frac{Q'(\eta)}{\eta}\, d\eta$$

where

$$[6] \qquad Q'(\eta) = \frac{\eta}{1 + \gamma\eta}$$

and

$$\gamma = 2(\sqrt{2} + 1)$$

The value used for the parameter γ is characteristic of the equation of state under consideration, in our case the translated Peng–Robinson cubic equation of state (4, 5).

The residual excess Helmholtz energy (A^E_{res}) is separated into two terms (eq. [7]): (*i*) the physical interactions between different compounds are represented by the physical term (A^E_{fis}) using the eq. [8] (8); (*iii*) the molecular associations

[a] This work.

are described by the chemical term ($A^{\mathrm{E}}_{\mathrm{qui}}$). For its calculation, the CREE model (Chimique Réticulaire Equation d'Etat) is used, which is a continuous association model defined by Rauzy and Berro (9, 10).

$$[7] \qquad A^{\mathrm{E}}_{\mathrm{res}} = A^{\mathrm{E}}_{\mathrm{fis}} + A^{\mathrm{E}}_{\mathrm{qui}}$$

where the physical part, $A^{\mathrm{E}}_{\mathrm{fis}}$, is written by means of a formalism which enables to separate the composition and packing fraction variables:

$$[8] \qquad A^{\mathrm{E}}_{\mathrm{fis}} = E(T,x)\,Q(\eta)$$

For the first factor on the right hand side of eq. [8] the following equations are used (8):

$$[9] \qquad E(T,x) = \frac{1}{2q_{\mathrm{m}}}\left[\sum_{i=1}^{p} q_i x_i \left[\sum_{j=1}^{p} q_j x_j K_{ij}\right] + \sum_{i=1}^{p} q_i x_i \left[\sum_{j=1}^{p} q_j^{1/3} x_j L_{ji}^{1/3}\right]\right]$$

with

$$K_{ij} = \frac{E^1_{ij} + E^2_{ij}}{2}$$

$$[10] \qquad L_{ij} = E^2_{ij} - E^1_{ij}$$

$$L_{ij} = -L_{ji}$$

$$[11] \qquad q_{\mathrm{m}} = \sum_{i=1}^{p} q_i x_i$$

and

$$q_i = \delta_i b_i$$

where the subscripts i and j are referred to the components i and j of the mixture with p components, q_i is the molecular surface of the component i and it is supposed that $q_i/q_j = (b_i/b_j)\delta$, being an adjustable parameter. K_{ij} and L_{ij} are two binary interaction parameters between components i and j, which depend on the terms of the binary interchange energy (E^1_{ij} and E^2_{ij}) calculated using a group contribution method as follows (8):

$$[12] \qquad E^1_{ij} = -\frac{1}{2}\sum_{k=1}^{N}\sum_{l=1}^{N}(\alpha_{ik} - \alpha_{jk})(\alpha_{il} - \alpha_{jl})\,A^1_{kl}(T)$$

with

$$A^1_{kl} = {}_1A^0_{kl}\left(\frac{T^\circ}{T}\right)^{{}_1B^0_{kl}}$$

$$[13] \qquad E^2_{ij} = -\frac{1}{2}\sum_{k=1}^{N}\sum_{l=1}^{N}(\alpha_{ik} - \alpha_{jk})(\alpha_{il} - \alpha_{jl})\,A^2_{kl}(T)$$

with

$$A^2_{kl} = {}_2A^0_{kl}\left(\frac{T^\circ}{T}\right)^{{}_2B^0_{kl}}$$

where ${}_1A^0_{kl}$, ${}_1B^0_{kl}$, ${}_2A^0_{kl}$ and ${}_2B^0_{kl}$ are group interaction parameters. In this work, these parameters for the interchange energy between methane and methanol are obtained using the experimental results of vapour–liquid equilibrium for methane + methanol system from the literature (11). New values for ${}_2A^0_{kl}$ and ${}_2B^0_{kl}$ group interaction parameters for the binary interchange energy E^2_{ij} between methane and water are obtained using dew point experimental results available in Enagás, S. A. The values for these parameters used in later calculations of this work are presented in Table 3.

The chemical contribution to the residual molar excess Helmholtz energy of a mixture ($A^{\mathrm{E}}_{\mathrm{qui}}$) is based on the self-association model of Rauzy and Berro (9, 10) where the alcohol (methanol in this work) is assumed to form continuous linear hydrogen-bounded polymers M_1, M_2, …, M_i, … by successive chemical reactions:

$$M_1 + M_1 \xleftrightarrow{k_{\mathrm{M}}} M_2$$

$$M_2 + M_1 \xleftrightarrow{k_{\mathrm{M}}} M_3$$

$$\vdots$$

$$M_i + M_1 \xleftrightarrow{k_{\mathrm{M}}} M_{i+1}$$

described by a single equilibrium constant (k_{M}) of the form:

$$[14] \qquad k_{\mathrm{M}} = \frac{\eta RT}{[b(1-\eta)]}\exp\left(\frac{-\Delta A}{RT}\right)\exp\left(\frac{\beta Q(\eta)}{RT}\right)$$

The self-association Helmholtz energy (A) is obtained as follows:

$$[15] \qquad \Delta A = \Delta U^\circ + C_{\mathrm{T}}(T - T^\circ) - T\left(\Delta S^\circ + C_{\mathrm{T}}\ln\left(\frac{T}{T^\circ}\right)\right)$$

The values of U°, C_{T} are from the literature (8) but a new value for S° of –127.767 J K^{-1} mol^{-1} is obtained in this work using the experimental data of vapour–liquid equilibrium of methane + methanol system from the literature (11).

The chemical contribution to the residual molar excess Helmholtz energy ($A^{\mathrm{E}}_{\mathrm{qui}}$) of a mixture with p components where the component M is self-associated is calculated as:

$$[16] \qquad A^{\mathrm{E}}_{\mathrm{qui}} = A_{\mathrm{qui}} - A^{\mathrm{id}}_{\mathrm{qui}}$$

[17] $$A_{qui} = (x_M - X)\Delta A$$

[18] $$A_{qui}^{id} = x_M(1 - X_p)\Delta A$$

and

[19] $$X = \frac{X_1}{1 - k_M X_1}$$

where X_1 is the monomer molar fraction that is expressed as:

[20] $$X_1 = \frac{(1 + 2k_M x_M) - (1 + 4k_M x_M)^{1/2}}{2k_M^2 x_M}$$

The water self-association is not accounted for and the same for cross-association between water and methanol.

Discussion

The pressure and temperature values ranges studied in this work include *P–T* conditions in which methane gas hydrate is stable and can be obtained from the gas phase. However, the presence of methanol in the studied mixtures avoids the formation of hydrates and, on the other hand, the generation of hydrates in the device produces the quick interruption of gas flow, not observed in this work.

The experimental dew point curves and calculated with the ESO–CR method are represented in Fig. 2–5, as it can be seen in them an increase of contents of water and methanol in the mixtures of the system studied leads to a displacement of the dew point curves to higher values of dew temperatures and pressures.

After comparing the experimental and calculated dew point curves in Figs. 2–5, it can be concluded that the EOS–CR method used in this work reproduces very accurately the dew point curves independently of the pressure and temperature ranges. The mean deviations obtained are between 0.21 and 2.26 K. For each mixture studied in the present work the calculated values for molar fraction of both water and methanol in vapour phase are exactly the same as the experimental values.

Rate and equilibrium constants for formation and hydrolysis of 9-formylfluorene oxime: diffusion-controlled trapping of a protonated aldehyde by hydroxylamine

R.A. More O'Ferrall, D.M. O'Brien, and D.G. Murphy

Abstract: Equilibrium constants K_{add} = 440 and K_{ox} = 3.0 × 10^8 for formation of a carbinolamine adduct and oxime, respectively from 9-formylfluorene and hydroxylamine, and pK_a = –1.62 for protonation of the oxime, have been evaluated at 25°C in aqueous solution, based on measurements in hydroxylamine buffers, acetic acid buffers, and dilute HCl. Rate constants for hydrolysis of the oxime have been measured in the acidity range pH 4–12 M $HClO_4$. At the highest acidities, a reaction pathway via protonated carbinolamine has been identified: evidence is presented that the reverse of this reaction involves rate-determining attack of hydroxylamine upon protonated 9-formylfluorene. By assuming that the attack of hydroxylamine is diffusion-controlled, with rate constant 3 × 10^9 M^{-1} s^{-1}, a pK_a for *O*-protonation of the aldehyde (–4.5) is derived. Taking account of the equilibrium constant for enolization of 9-formylfluorene (K_E = 16.6), a pK_a for for *C*-protonation of the enol tautomer (–5.7) may also be obtained. Comparison of this pK_a with that of the enol of acetophenone shows that the enol of 9-formylfluorene is less basic by a factor of 10^{10}. By combining pK_as for protonation of the aldehyde and oxime with measured or estimated equilibrium constants for addition of water, hydroxide ion, and hydroxylamine to 9-formylfluorene, it is also possible to obtain values of pK_R = –5.3, 4.1, and 12.25 for the protonated 9-formylfluorene, protonated oxime, and 9-formylfluorene, respectively. The usefulness of pK_R in providing a general measure of equilibrium constants for electrophile–nucleophile combination reactions is discussed.

Key words: oxime, formyfluorene, hydrolysis, protonation, diffusion-control.

Résumé : En se basant sur des mesures faites en solutions aqueuses, à 25°C, dans des tampons d'hydroxylamine ou d'acide acétique et dans des solutions diluées de HCl, on a établi les valeurs des constantes d'équilibre pour la formation de l'adduit carbinolamine (K_{add} = 440) et de l'oxime ((K_{ox} = 3,0 × 10^8) entre le 9-formylfluorène et l'hydroxylamine ainsi que le pK_a (= –1,62) de la protonation de l'oxime. On a mesuré les constantes de vitesse d'hydrolyse de l'oxime dans les domaines d'acidité allant de pH 4 à 12 M, $HClO_4$. Aux acidités les plus élevées, on a identifié la présence d'une voie réactionnelle impliquant la carbinolamine protonée: on présente des données suggérant que l'étape déterminante de la réaction inverse implique une attaque de l'hydroxyle sur le 9-formylfluorène protoné. En faisant l'hypothèse que l'attaque de l'hydroxylamine est soumise à un contrôle par la diffusion, on en déduit que sa constante de vitesse est de 3 × 10^9 M^{-1} s^{-1} et que le pK_a de la *O*-protonation de l'aldéhyde est de –4,5. Si l'on tient compte de la constante d'équilibre de l'énolisation du 9-formylfluorène (K_E = 16,6), on a aussi obtenu une valeur de pK_a (–5,7) pour la *C*-protonation de l'éther énolique. Une comparaison de ce pK_a avec celui de l'énol de l'acétophénone montre que l'énol du 9-formylfluorène est moins basique par un facteur de 10^{10}. En combinant les valeurs de pK_a de protonation de l'aldéhyde et de l'oxime avec les constantes de vitesse mesurées ou évaluées pour l'addition de l'eau, de l'ion hydroxyde et de l'hydroxylamine au 9-formylfluorène, on peut aussi obtenir les valeurs de pK_R = –5,3, 4,1 et 12,25 respectivement pour le 9-formylfluorène protoné, l'oxime protoné et le 9-formylfluorène. On discute de l'utilité des pK_R comme mesure générale des constantes d'équilibre pour les réactions de combinaison électrophile–nucléophile.

Mots clés : formylfluorène, hydrolyse, protonation, contrôle par diffusion.

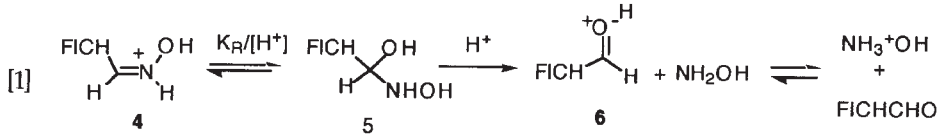
Introduction

The main features of the mechanism of formation and hydrolysis of oximes are now fairly well understood based on studies extending over more than 30 years (1–13). Nucleophilic attack of hydroxylamine upon an aldehyde or ketone yields initially a carbinolamine adduct which undergoes acid- or base-catalysed dehydration to form the oxime; depending on the pH either formation or reaction of the adduct may be rate-determining. Less well understood, however, is the structural dependence of rate and equilibrium constants for these reactions (2). Thus for oximes of aldehydes measurements have focused largely on aromatic aldehydes (1–6), presumably because these are easily prepared and show a strong UV absorbance convenient for monitoring the reactions. Studies of aliphatic aldehydes have either been less comprehensive (7, 8) or have involved reactions of *N*-alkyl or *N*-aryl hydroxylamines leading to nitrones (9).

In this paper we report measurements for formation and hydrolysis of the oxime of the (aryl-substituted) aliphatic aldehyde, 9-formylfluorene (**1**). This aldehyde is unusual in that it exists in aqueous solution predominantly as its enol tautomer **2** (14). The chromophore associated with the enol eases kinetic and equilibrium measurements, while the availability of rate and equilibrium constants for enolization and hydration (14) allows reactions of the enol to be transformed to those of the aldehyde.

1 **2** **3**

The main aim of the study was to obtain rate and equilibrium constants for overall formation of the oxime **3** and for the individual steps of this reaction. Of particular interest were the protonation and hydration of the oxime. Measurement of the equilibrium constant K_R for the hydration reaction, shown in the first steps of eq. [1], identifies the protonated oxime **4** as a carbocation and allows comparisons of its stability with that of other carbocations (15).



Also of interest are the mechanism and equilibria asssociated with hydrolysis of the oxime in acidic media. It is proposed that in strongly acidic solutions the carbinolamine intermediate **5** is subject to protonation and reacts initially to form hydroxylamine and the *O*-protonated 9-formylfluorene (**6**). If this is correct, and we assume that the reverse reaction, attack of hydroxylamine on the protonated aldehyde, is diffusion-controlled, rate constants for the forward and reverse reactions can be combined to assign an equilibrium constant for conversion of protonated oxime to protonated aldehyde. This in turn leads to values of K_a and K_R for the conjugate acid of 9-formylfluorene.

Results

Hydrolysis of the oxime

Formation and hydrolysis of the oxime of 9-formylfluorene have been studied as forward and reverse reactions. The hydrolysis occurs at a convenient rate for measurement in the pH range 0–4 and in concentrated solutions of HCl and $HClO_4$. The reaction is much slower than keto–enol tautomerization of 9-formylfluorene and except at highest acid concentrations, where the tautomeric equilibrium is displaced in favour of the aldehyde, it could be monitored by the appearance of the chromophore of the enol. A repetitive scan for the conversion of oxime to enol is shown in Fig. 1, and demonstrates that the product has the distinctive chromophore of fluorene. In Fig. 2, a pH profile for the hydrolysis is shown with logs of first-order rate constants (k_{obs}) plotted against pH – X, where X is the usual solvent free energy parameter (16) measuring the effect of a strong acid medium upon the protonation of an aniline base. The X-function was formulated by Cox and Yates (17) for correlating measurements of rate and equilibrium constants in aqueous mixtures of strong acids. Thus plots of log ($k_{obs}/[H^+]$) against $-X$ are normally linear and are characterized by a slope m^*. The value of pH – X also provides a convenient formal extension of pH equivalent to the "acidity function" H_o. In principle, correlations based on X should be independent of the nature of the acid but it is evident from the figure that hydrolysis of the oxime shows significant divergence between $HClO_4$ (open circles) and HCl (closed circles) at high acidities; similar relative effects of HCl and $HClO_4$ have been observed in the hydrolysis of triaryl carbocations (18). Values of k_{obs}, X (18), and pH are listed in Table S1.[2]

It can be seen from Fig. 2 that the hydrolysis reaction is acid-catalyzed above pH 2. Below pH 2 it approaches pH independence, and after passing through a weak max decreases with increasing acidity at high acid concentrations (>5 M $HClO_4$). This rather complex behaviour receives a fairly straightforward interpretation in terms of the expected mechanism of hydrolysis which, as we will see, is confirmed by studies of the reverse reaction forming the oxime. A similar acidity dependence has been described by Gregory and Moodie (10) for hydrolysis of the oxime of acetophenone.

(FlCH_2 denotes fluorene)

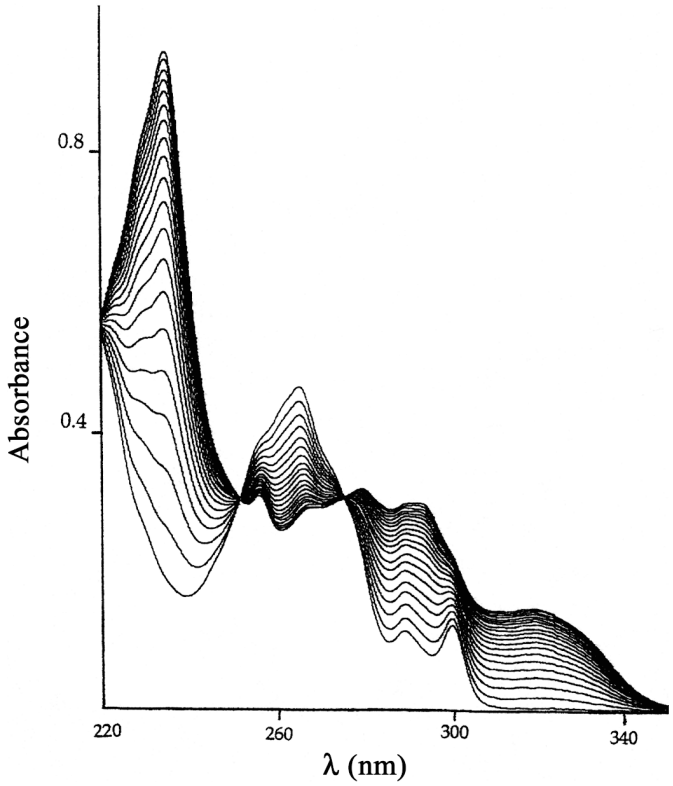
Fig. 1. Repetitive scan of spectra during hydrolysis of the oxime of 9-formylfluorene (3×10^{-5} M) in 0.1 M $HClO_4$.



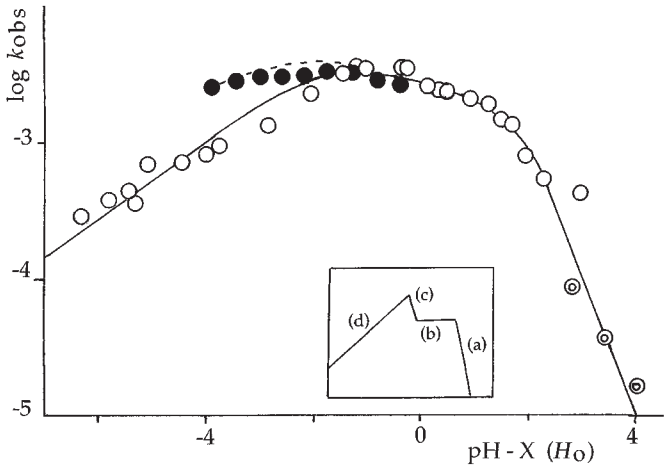


Fig. 2. Dependence of log k_{obs} upon pH – X (pH or H_0) for hydrolysis of the oxime of 9-formylfluorene in $HClO_4$ (○), aqueous chloroacetic acid buffers (◎), and HCl (●) at 25°C. The inset shows schematically limiting acidity dependences inferred.

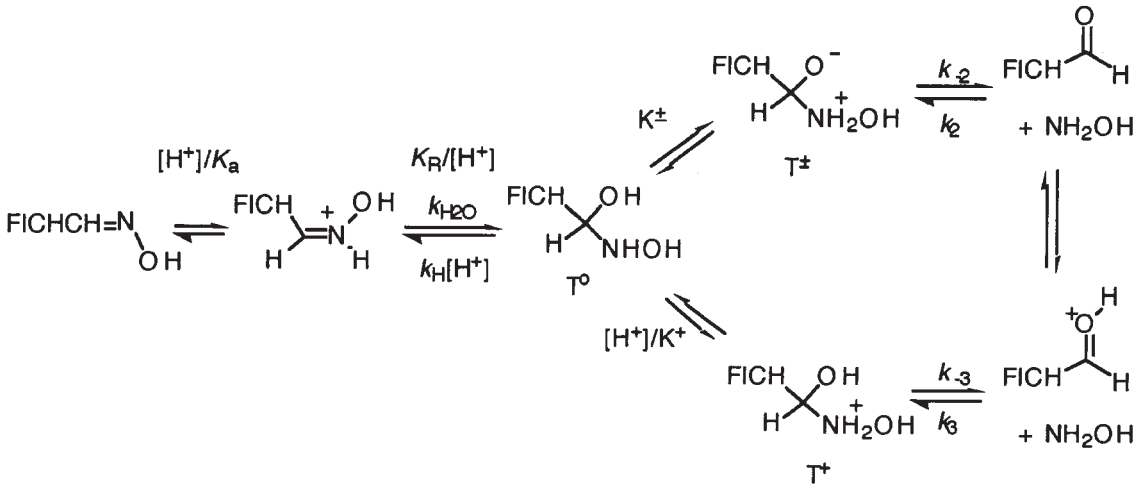

The sequence of steps expected to occur in the hydrolysis reaction is shown in Scheme 1 (10). It comprises: (*i*) rapid protonation of the oxime (with equilibrium constant K_a); (*ii*) attack of H_2O on the protonated species to form a carbinolamine intermediate; and (*iii*) reaction of the carbinolamine to form the product aldehyde via zwitterionic and (or) protonated intermediates $T^{\pm}$ and T^+, respectively.

In Scheme 1, rate constants for attack of water on the protonated oxime and for reaction of the zwitterionic and *N*-protonated forms of the adduct are denoted k_{H_2O}, k_{-2}, and k_{-3}, respectively; k_H is the rate constant for acid-catalyzed reversion of carbinolamine to protonated oxime. Negative subscripts are used for rate constants to retain positive values for oxime formation. By analogy with previous studies (1–6) the acid-dependent reaction at high pH corresponds to the k_{H_2O} step being rate-determining, while the transition to pH independence around pH 2 indicates that the k_{-2} step has become rate-determining. The weak max in the pH profile should correspond to protonation of the oxime and the transition from reaction via $T^{\pm}$ to reaction via T^+ as an intermediate.

It should be noted that, in principle, protonation of the oxime could be associated with the break in the pH dependence at either pH – X = –1.5 or +2. Evidence that it is the former comes from measurements of the UV spectra of the oxime prior to hydrolysis which show a significant change in the acid concentration range (3–6 M $HClO_4$). The spectrum of the oxime is dominated by the chromophore for fluorene but shows an end absorption and a weaker than normal long-wavelength peak at 300 nm ($\varepsilon = 1.1 \times 10^4$). The end absorption disappears between 1.0 and 2.5 M and the peak at 300 nm decreases with a satisfactorily defined isosbestic point (290 nm) between 3.0 and 6.0 M $HClO_4$. The latter

Scheme 1.

change is attributed to protonation; the former may reflect changes in solvation similar to those occurring prior to protonation of aliphatic carbonyl compounds (19). The protonation is also associated with a small increase and shift to shorter wavelengths of the peak at 260 nm. A plot of log K_a, calculated from the absorbance changes at 300 nm at different acid concentrations, against $-X$ has an intercept giving an aqueous pK_a = –1.5 and a slope m^* = 0.91. As discussed below, it is likely that these values correspond to an equilibrium mixture of *syn*- and *anti*-forms of neutral and protonated oxime. It is difficult to determine whether the protonated species is the oxime or oxime plus carbinolamine (T^+). An estimate of the pK = –2.12 for conversion of T^+ to the oxime, included in an appendix to this paper, suggests that the protonated oxime and T^+ are not very different in stability. Strictly speaking, therefore, the measured pK_a is an apparent value representing an equilibrium mixture of protonated species. Correcting for this, using the estimated pK for T^+, yields pK_a = –1.62 for the protonated oxime, although this value is clearly subject to some uncertainty.

The assumption that the reaction in strong acids is proceeding with the formation of T^+ as an intermediate is consistent with a reverse reaction in which attack of hydroxylamine upon the aldehyde is acid-catalyzed. This reaction has been well-characterized for aromatic aldehydes reacting with hydroxylamine, methoxylamine, and a range of weakly basic amines by Jencks and co-workers (2) and Sayer et al. (3). In principle reaction of the protonated oxime, which will be the reactant species in strongly acidic media (possibly in equilibrium with a fraction of T^+), should be independent of acid concentration. In practice it can be seen in Fig. 2 that there is a significant decrease in rate with increasing acid concentration, which is more pronounced in $HClO_4$ than HCl. We believe that this decrease is a result of a medium effect reflecting a reduced solvation requirement for the transition state compared with the reactant. For the closely analogous hydrolysis of the oxime of *p*-chlorobenzaldehyde, the reverse reaction, in which the oxime is formed from the aldehyde, is independent of acid concentration in strongly acidic media under conditions that the hydroxylamine reactant is fully protonated (3). This implies that hydrolysis of the protonated *oxime* of *p*-chlorobenzaldehyde is also independent of acid concentration.

Strictly speaking the decrease in rate with increasing acid concentration in Fig. 2 does not exclude the possibility of rate-determining loss of NH_2OH from the zwitterionic form of the tetrahedral intermediate $T^{\pm}$, a reaction which would be inversely dependent on stoichiometric acid concentration. However, comparison with the hydrolysis of *p*-chlorobenzaldehyde-*N*-phenyl imine (20), a reaction which almost certainly does proceed via $T^{\pm}$, shows that a plot of log k vs. X implies a much sharper decrease in rate with increasing acid concentration ($m^* \cong 1.3$) than for the oxime of 9-formylfluorene (m^* = 0.3). Moreover, reaction via $T^{\pm}$ would be expected to show a fairly large "normal" solvent isotope effect (k_{H_2O}/k_{D_2O} = 2–3) as a consequence of the preequilibrium deprotonation of the (protonated) oxime reactant in strongly acidic media. The experimentally observed isotope effect, k_{H_2O}/k_{D_2O} = 1.3, is not consistent with this.

An alternative acid-independent reaction (for hydrolysis of the protonated oxime) could involve deprotonation of T^+ to form $T^{\pm}$ (2, 3). However, this mechanism is viable only when expulsion of hydroxylamine from $T^{\pm}$ is faster than reprotonation to form T^+. This is not expected of $T^{\pm}$ intermediates derived from aliphatic aldehydes because such intermediates should be relatively stable; nor is it likely at high acid concentrations. The scope of the T^+ mechanism and different modifications of the $T^{\pm}$ mechanism for hydrolysis and formation of oximes and other imines has been summarised by Sayer and co-workers (3). (Although, as will be discussed below, we differ from these authors in believing that loss of NH_2OH from T^+ is a stepwise process and not a concerted one).

Returning to Fig. 2, the line drawn through the points is based on a best fit of rate constants and m^* values for rate-determining expulsion of NH_2OH from the zwitterionic and protonated carbinolamine intermediates ($T^{\pm}$ and T^+ in Scheme 1) at low pH and hydration of the protonated oxime at high pH. Each m^* corresponds to the slope of a plot of log ($k_{obs}/[H^+]$) vs. X (or, for acid-independent reactions, log k_{obs} vs. X) in concentrated solutions for the appropriate reaction step or mechanism; details are given in the experimental section. The limiting acidity dependences assigned in different acid regions are shown schematically in the inset to the figure and are labelled (*a*)–(*d*) in the direction of increasing acid concentration. For protonation of the oxime m^* and K_a were taken as their equilibrium values (above). The transition from reaction via the zwitterionic ($T^{\pm}$) to protonated (T^+) tetrahedral intermediate is presumed to occur just before the onset of protonation of the oxime. This is not well-defined by the results for $HClO_4$ but is suggested by the near constancy of the rate in hydrochloric acid solutions in the range 3–11 M (filled circles). As noted above, the weak but distinctive decrease in rate constants at high concentrations of $HClO_4$ implies a transition state with greater solvation demands than the protonated oxime (16). This is consistent with the expected structure of the transition state for reaction of T^+ which should lead to relocation of charge to the solvation sensitive hydrogen-bearing oxygen atom, as shown in **7**. Indeed, it will be argued below that for 9-formylfluorene oxime the bond to nitrogen is completely broken and the charge fully transferred to oxygen. The decrease in log k_{obs} at high acid concentrations corresponds to an m^* value (slope of log k_{obs} vs. X) of –0.3.

7

A source of uncertainty in the pH profile is the influence of *syn*- and *anti*-tautomerism of the oxime on the hydrolysis reaction. The NMR spectrum of the oxime indicates that its configuration is *syn* and this form must be the reactant at high pH. However, below pH 2 where nucleophilic attack of water on the protonated oxime becomes reversible, *syn–anti* tautomerization should be faster than hydrolysis. Nucleophilic catalysis of *syn–anti* tautomerization of aldehyde oximes has been studied previously by Cocivera et al. (7). The equilibrium ratio of isomers is expected to be about 1:2

© 2000 NRC Canada

$$[2]\qquad k_{obs} = \frac{k_{H2O}k_{-2}K^{\pm}}{(k_H[H^+] + k_{-2}K^{\pm})(1 + K_a/[H^+])} + \frac{k_{H2O}k_3}{(1 + K_a/[H^+])k_HK^+}$$

$$(a)\quad \frac{k_{H2O}[H^+]}{K_a} = 0.10[H^+] \qquad (b)\quad \frac{k_{H2O}k_{-2}K^{\pm}}{k_HK_a} = 2.5 \times 10^{-3}$$

$$(c)\quad \frac{k_{-3}k_{H2O}[H^+]}{k_HK^+K_a} = 6.0 \times 10^{-4}[H^+] \qquad (d)\quad \frac{k_{H2O}k_3}{k_HK^+} = 1.1 \times 10^{-2}$$

(21) and establishing this equilibrium should slow the reaction. However, it was not possible to separate the effect on the rate of isomerization from that of the subsequent (presumed) change from the $T^{\pm}$ to T^+ reaction pathway, and it is assumed that the rate constant for the pH-independent process below pH 2 represents reaction of the equilibrated isomers. In principle the onset of tautomerization should be detectable as a perturbation of first-order kinetics in the hydrolysis reaction. However, no significant departure from first-order kinetics was detected, and this is probably a consequence of the similarity of spectra, lack of pronounced difference in reactivities of the two isomers, and possibly rapidity of isomerization.

If *syn–anti* tautomerism is neglected the appropriate rate expression to fit the experimental dependence of first-order rate constants for hydrolysis (k_{obs}) on acid concentration in the limit of low acid concentrations is given by eq. [2]. In this equation the notation for rate and equilibrium constants follows that of Scheme 1. The equilibrium constants K^+ and $K^{\pm}$ refer to formation of the tetrahedral intermediates T^+ and $T^{\pm}$, respectively from the carbinolamine adduct (T°). Limiting rate expressions corresponding to the different sections of the pH – *X* profile ((*a*)–(*d*)) are indicated below the equation together with the numerical values used to obtain the best fit. For the reactions in concentrated acid solutions the expressions were modified by inclusion of *m** values. However, as noted above, these modifications are described in the experimental section and here *m** values are summarized only.

Thus the region (*a*) in Fig. 2 is well fitted by $k_{H_2O}/K_a = 0.10$. If the pK_a of the protonated oxime is assigned its independently measured value of –1.62 we then derive $k_{H_2O} = 4.2\ s^{-1}$. The value of *m** for the protonation was assumed to be the same as its equilibrium value (0.9) and the same value was assumed for the acid-catalyzed expulsion of NH_2OH from T° (via T^+). The analysis is rather insensitive to choice of the latter *m** or to dissection of *m** = 1.2 implied for the equilibrium conversion of T° to protonated oxime into kinetic values for the forward and reverse constants k_H (*m** = –0.8) and k_{H_2O} (*m** = 0.4).

The limiting rate constant accommodated by the pH profile in region (*b*) was 2.5×10^{-3}. Correction of this for the contribution of $k_{H_2O}/K_a = 0.10$ and $k_H = 8.5 \times 10^4$, evaluated from the reverse oxime forming reactions in hydroxylamine buffers, yields $k_{-2}K^{\pm} = 2.1 \times 10^3\ s^{-1}$. For the reaction at the highest acidities (*d*), extrapolation to *X* = 0 yields values of $k_{H_2O}k_{-3}/k_HK^+ = 1.1 \times 10^{-2}\ s^{-1}$ for $HClO_4$ and 9.0×10^{-3} for HCl. The difference in the values reflects the divergence of rate constants between the two acids at high acid concentrations, which appears to be due partly to a different dependence of *X* upon stoichiometric acid concentration and possibly to small differences in *m** values between the two acids. Taking 1.0×10^{-2} as an average value for this rate constant yields $k_{-3}/K^+ = 200\ s^{-1}$. In principle, at more moderate acidities (*c*), where the oxime is unprotonated, the rate expression for region (*d*) is modified by dividing by $K_a/[H^+]$; however, as already implied, region (*c*) makes little impact on the pH profile.

As a general comment, although it might appear that the pH and X dependence of Fig. 2 is relatively featureless and should offer considerable flexibility in choice of the several rate constants and *m** values implicated in the fit, in practice the rate constants defined by regions (*a*) and (*b*) and even (*d*) are sharply constrained. Probably the main uncertainty resides in the pK_a for protonation of the oxime, arising partly from the possible formation of T^+ as well as protonated oxime.

In addition to measurements for HCl in H_2O rate constants were measured for DCl in D_2O. There was little variation in the isotope effect with acid concentration, with values of k_{H_2O}/k_{D_2O} in the range 1.25–1.35 between 1 M and 6 M acid concentration (Table 1). These isotope effects should correspond to regions (*d*) and (*b*) of the pH profile, i.e., to reaction of the protonated oxime by the T^+ pathway and of the neutral oxime via the $T^{\pm}$ pathway, as discussed below. The smallness of the variation may reflect a rough coincidence of the pH at which the change between $T^{\pm}$ and T^+ pathways occurs and the pK_a of the protonated oxime. Similar isotope effects have been found for the hydrolysis of acetophenone oxime (10).

Formation of oxime from 9-formylfluorene

Hydrolysis of the oxime of 9-formylfluorene was monitored by the appearance of the chromophore of the enol. The reverse oximation could be monitored by its disappearance. The reaction was studied by introducing a small amount of enol from a stock solution in acetonitrile into aqueous solutions containing hydroxylamine. In acetonitrile the enol is the only isomer detectable by NMR, and it was presumed that at low concetrations of hydroxylamine (in aqueous solution) the enol exists in rapid equilibrium with a few percent

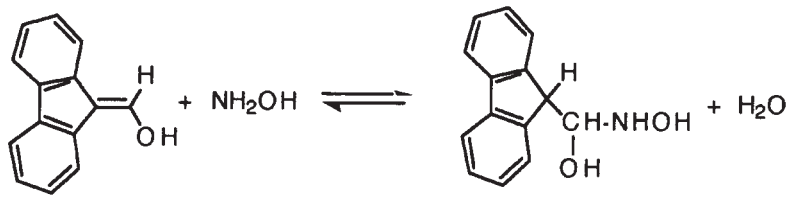
of aldehyde (K_E = [enol]/[aldehyde] = 16.6) (14). At higher concentrations of NH_2OH, where oxime formation is rapid, conversion of the enol to aldehyde becomes rate determining in the oximation reaction. At low pH and low concentrations of NH_2OH competing hydration of the aldehyde may also occur, giving at equilibrium, together with the aldehyde and enol, about 30% of hydrate (K_h = 5.6 for the aldehyde). By use of these equilibrium constants measured rate constants could be adjusted so that rate constants refer specifically to reaction of the aldehyde.

Several measurements of rate and equilibrium constants for reaction of the enol with hydroxylamine were undertaken: (*i*) the equilibrium conversion of enol to carbinolamine adduct in aqueous hydroxylamine buffers; (*ii*) the corresponding equilibrium between enol and oxime in aq. HCl in the presence of hydroxylammonium chloride; (*iii*) rates of formation of the oxime in hydroxylamine and acetic acid buffers (in which dehydration of the carbinolamine intermediate is rate determining); and (*iv*) rates of formation of the oxime in dilute aq. HCl and $HClO_4$ (for which the rate-determining step is attack of hydroxylamine upon the 9-formylfluorene).

Enol–carbinolamine equilibrium

Injection of a small quantity of a 10^{-2} M stock solution of the enol of 9-formylfluorene into hydroxylamine buffers led to a rapid buffer concentration-dependent drop in absorbance consistent with the formation of an aldehyde–hydroxylamine adduct **5** as shown in eq. [3]. This initial drop in absorbance was followed by a slower decrease attributed to the reaction forming the oxime. Initial absorbances were extrapolated to times of mixing and yield an effective equilibrium constant K = 25.0 between **5** and the equilibrated enol and aldehyde species (and hydroxylamine). This may be corrected to K_{add} = 440 for the aldehyde by division by 0.057 (= $1/(1 + K_E)$), the fraction of aldehyde present at equilibrium. Under the conditions of the reaction conversion of the aldehyde to hydrate is expected to be slow, so this species is not included in the equilibration.

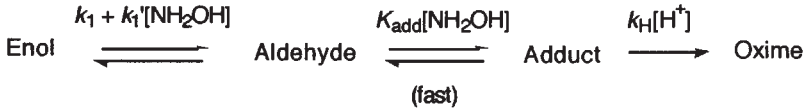
Fig. 3. Plot of k_{obs} against [NH_3OH^+] for oxime formation from 9-formylfluorene enol in aqueous hydroxylamine buffers at 25°C with [acid]/[base] buffer ratios 1:1 (◎), 4:1 (●), 9:1 (○). The inset shows measurements at low buffer concentrations with rate constants (k_{obs}) corrected for carbinolamine adduct formation; [acid]/[base] buffer ratios 3:7 (○), 1:4 (●), 1:9 (◎).



Oxime formation in hydroxylamine buffers

In hydroxylamine buffers, 9-formylfluorene is converted to its oxime with strong buffer catalysis, predominantly by the acidic component of the buffer. This is apparent from the plot of first-order rate constants at different buffer concentrations and buffer ratios against [NH_3^+OH] for the more acidic buffers investigated in Fig. 3. The measured rate constants are listed in Table S2.[2]

From the figure it can be seen that the buffer plots are curved. This curvature occurs at too low a concentration of hydroxylamine to be attributed solely to conversion of the enol reactant to the hydroxylamine adduct of the aldehyde,



[3]

5

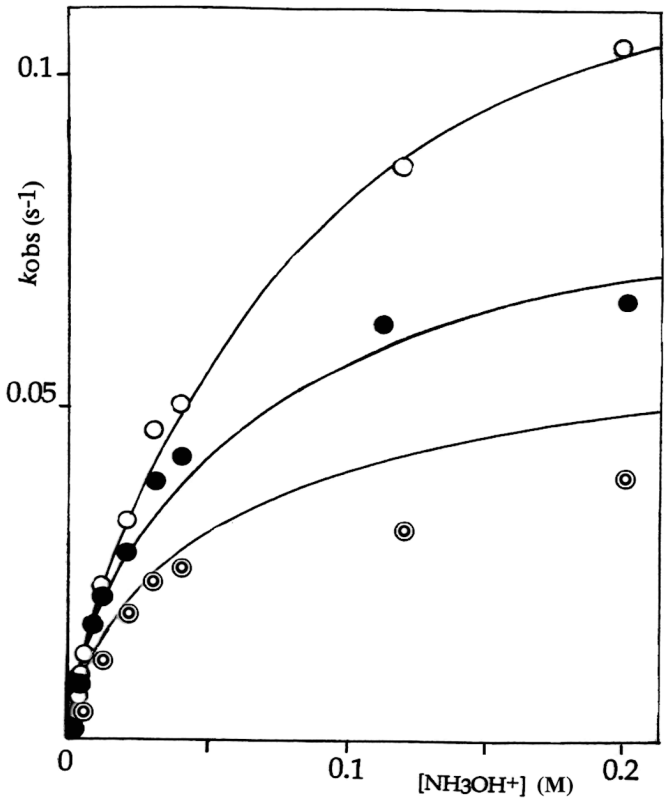
Scheme 2.

and it is apparent that there is a change in rate-determining step from dehydration of the adduct at low hydroxylamine concentrations to conversion of the enol to aldehyde at high concentrations. The curvature is not more pronounced because conversion of the enol to aldehyde is catalyzed by the basic component of the buffer, NH_2OH.

The curves drawn in Fig. 3 represent a best-fit of rate constants to a kinetic expression based on Scheme 2, in which k_H is the rate constant for acid-catalyzed dehydration of the adduct and k_1 and k_1' are rate constants for uncatalyzed and hydroxylamine-catalyzed ketonisation of the enol of 9-formylfluorene. This expression is given in the experimental section of the paper. The dependence of the rate of the overall reaction upon $[NH_3OH^+]$ arises from the combination of $k_H[H^+]$ for dehydration with $K_{add}[NH_2OH]$ from the preceding rapid equilibrium.

The analysis yields the rate constants k_H and k_1'. The value of k_1' was 3.1 which fits satisfactorily a Bronsted plot for general base-catalyzed ketonization of the enol (14). Values of k_1 and K_{add} were those determined previously (k_1 = 0.254/16.6 =.0153) (14) or as described above (K_{add} = 440).



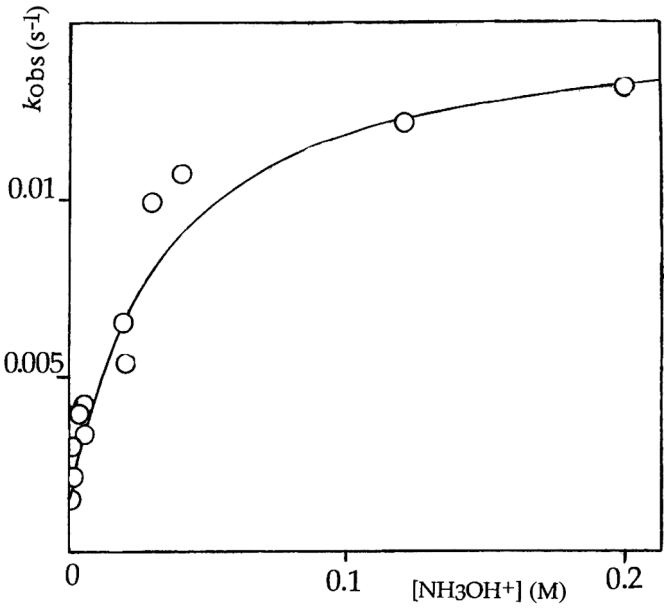
In practice the value of k_H was best determined from the slope of a linear plot of k_{obs} against $[NH_3OH^+]$ at high concentrations of NH_2OH, i.e., for basic hydroxylamine buffers with a high ratio of $[NH_2OH]$:$[NH_3OH^+]$. Under these conditions the k_H step is fully rate-determining and the slope of the plot is given by $k_H K_a K_{add}/K_E$, where K_a is the ionization constant of NH_3OH^+ (pK_a = 6). This plot is shown as an inset in Fig. 3. Values of k_{obs} are corrected for partial conversion to adduct by multiplying by $\{1 + (K_{add}/K_E)[NH_2OH]\}$. The value of k_H obtained was 8.5×10^4 M^{-1} s^{-1}. The lack of dependence of this value upon buffer ratio indicates that there is no appreciable catalysis by NH_3OH^+.

Oxime formation in acetic acid buffers

Similar measurements to those in hydroxylamine buffers were made in 1:1 acetic acid buffers with concentrations of the buffer components 0.025, 0.05, and 0.1 M. First-order rate constants (k_{obs}) for different stoichiometric concentrations of hydroxylamine hydrochloride are listed in Table S3[2] and plotted against $[NH_3OH^+]$ in Fig. 4. The figure shows more pronounced kinetic saturation at high concentrations of NH_3OH^+ than Fig. 3. This reflects the lower concentration of NH_2OH present at lower pH and hence weaker catalysis of ketonization at high concentrations of NH_3OH^+, when this step becomes rate-determining.

The kinetic expression describing the reaction in acetic acid buffers was similar to that in hydroxylamine buffers save that the initial ketonization step is catalyzed by acetate ion ($k_1 + k_1'[NH_2OH] + k_1''[AcO^-]$) and a small allowance is made for catalysis of dehydration by acetic acid. The dependence of the rate of ketonization upon concentration of acetate ion accounts for the strong dependence of the limiting rate constants at high concentrations of NH_3OH^+ seen in Fig. 4 upon buffer concentrations since under these conditions the ketonization step becomes rate-determining.

Fig. 4. Plot of k_{obs} against $[NH_3OH^+]$ for oxime formation from 9-formylfluorene enol in 1:1 aqueous acetic acid buffers at 25°C. [AcOH] = [AcO^-] = 0.1 M (○), 0.05 M (●), and 0.025 M (◎).



The lines drawn through the points in the figure are based on the same rate and equilibrium constants as for the hydroxylamine buffers but with k_1'' = 1.00 for the acetate-catalyzed ketonization, which compares reasonably well with the previously determined value of 0.88 (14). Account was taken of the change in concentrations of acetic acid and acetate ion at the relatively high concentrations of NH_3OH^+. A contribution of 20% to the rate from general acid-catalyzed dehydration in the 0.1 M acetic acid buffers (and proportionately less at lower concentrations) was assumed, taking Reimann and Jencks (1) study of *p*-chlorobenzaldehyde as a guide for this small correction. The fit to the data is satisfactory, except at the lowest concentration of acetic acid buffers; there it appears that the contribution of the water reaction and catalysis by hydroxylamine to the ketonization of 9-formylfluorene has been slightly overestimated relative to that of the acetate ion.

Oxime formation in aq. HCl

Measurements were also made of oxime formation in solutions of 0.05 M HCl. First-order rate constants are shown

© 2000 NRC Canada

Fig. 5. Plot of k_{obs} against [NH_3OH^+] for oxime formation from 9-formylfluorene enol in 0.05 M HCl at 25°C.

in Table S4[2] and are plotted against [NH_3OH^+] in Fig. 5. Pronounced kinetic saturation at high concentrations of NH_3OH^+ is again observed and as before can be attributed to a change in rate-determining step from oxime formation to ketonization. However, in this case the slowness of the reaction at low concentrations of NH_3OH^+ also signals a change in rate-determining step relative to higher pHs in the oximation reaction. The same change is apparent in the reverse hydrolysis reaction from the break in pH dependence between pH 1 and 3 seen in Fig. 2. In the oxime-forming direction this corresponds to the well-known transition from rate-determining dehydration of the hydroxylamine adduct at high pH to attack of hydroxylamine on the aldehyde at low pH (1–6).

In 0.05 M HCl the low concentration of hydroxylamine in equilibrium with hydroxylamine hydrochloride also renders the overall oxime forming reaction appreciably reversible if the concentration of NH_3OH^+ falls below 0.02 M. Taking account of this a kinetic expression for the reaction may be based on the reaction steps shown in Scheme 3.

In Scheme 3, k_2 is the rate constant for the attack of hydroxylamine upon the aldehyde. The rate constant for the reverse reaction is k_2/K_{ox} where K_{ox} = ([oxime]/[NH_2OH][FlCHCHO]) is the equilibrium constant for oxime formation from the aldehyde. The rate constant for the uncatalyzed enolization is k_1 and, as before, K_E is the keto–enol tautomeric constant. The line drawn through the data points in Fig. 5 corresponds to $k_1 = 0.0135\ s^{-1}$, $k_2 = 4.8 \times 10^5\ L\ mol^{-1}\ s^{-1}$, and intercept $k_2/K_{ox} = 1.6 \times 10^{-3}\ s^{-1}$.

Scheme 3 is oversimplified in that it neglects hydration of the aldehyde. At low pH the hydration reaction is acid-catalyzed and, in contrast to the reaction in hydroxylamine or acetic acid buffers, water now competes effectively with the low concentration of hydroxylamine present in trapping the aldehyde. In Fig. 5 it was assumed that equilibration is complete; therefore the measured value of k_2 (4.8×10^5) has been corrected for the presence of an equilibrium concentration of the hydrate in addition to the enol. Equilibration is probably incomplete at high concentrations of NH_3OH^+ and the value of $k_o = 0.0135\ s^{-1}$ compares with an independently measured value of 0.0170 for the enol alone. The latter value would be reduced to 0.0120 in the presence of an equilibrium concentration of hydrate, and it may be significant that the value measured here falls between these extremes.

Scheme 3.

The oxime-enol equililibrium

Evaluation of the intercept in Fig. 5 and its identification with the rate constant for the reverse reaction of hydrolysis of the oxime k_2/K_{ox} allows us to evaluate an equilibrium constant for oxime formation (from the aldehyde) as $K_{ox} = 3.0 \times 10^8\ L\ mol^{-1}$. The value for the intercept (k_2/K_{ox}) is confirmed by measurements for the hydrolysis reaction in Fig. 2. This is the rate constant stemming from the break in the pH profile and change in rate-determing step below pH 2 corresponding to $k_{H_2O}k_{-2}K^{\pm}/k_HK_a$ (= k_2/K_{ox}). Although subject to a rate-enhancing medium effect in strong acid media, the rate constant extrapolated to dilute acid has the value of 2.5×10^{-3}, which is in acceptable agreement with 1.6×10^{-3} from Fig. 5 considering the uncertainties in extracting this rate constant from the experimental measurements in both cases. This agreement also provides confirmation that the break in the pH profile close to pH 2 in Fig. 2 does not correspond to the pK_a of the oxime.

The equilibrium between oxime and enol is also reflected in the incomplete conversion of enol to oxime. This indeed provides a more direct measurement of the equilibrium constant for this reaction. Because measurements are made at low pH, the equilibrium encountered experimentally (after correction for conversion of the enol to aldehyde) is that shown in eq. [4] and is sensitive to concentrations of both H^+ and NH_3OH^+. Analysis of measurements of enol absorbance as a function of concentration of H^+ and NH_3OH^+ gives a value of $K_{ox} = 2.2 \times 10^8\ M^{-1}\ s^{-1}$. In principle this value is preferred to that derived above (3.0×10^8) based on the slope and the intercept of the plot on Fig. 5 which is only approximately corrected for competition between oxime formation and hydration of the 9-formylfluorene.

However, yet another value of K_{ox} can be obtained from

rate constants for the reaction at higher pH where acid-catalyzed dehydration of the aldehyde–hydroxylamine adduct is rate-determining in the oxime forming direction. For the H^+-catalyzed reaction, we can write Scheme 4, in which the forward rate constant is k_HK_{add} and the reverse rate constant is k_{H_2O}/K_a. The value of k_{H_2O}/K_a is again obtainable from the pH profile for hydrolysis of the oxime at the highest pHs measured as $0.10\ M^{-1}\ s^{-1}$. The forward rate constant comes from the measurement of oxime formation in hydroxylamine buffers and yields a value of $k_HK_{add} = 3.7 \times 10^7$. The equilibrium constant is then given by

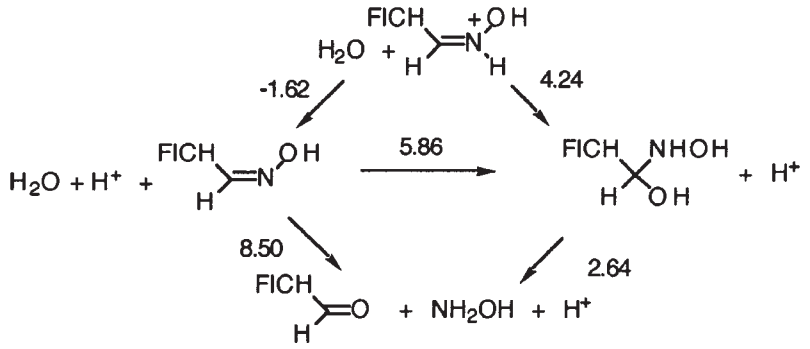
[n]Because of over determination of rate and equilibrium constants, values of k_H and k_{H_2O} are adjusted relative to those determined experimentally.

[p]Rate constant for acid-catalyzed reaction of aldehyde or ketone with NH_2OH.

[q]Diffusion rate constant; the brackets indicate that this is an estimated value (cf. ref. (46)).

$k_H K_{add} K_a / k_{H_2O} = 3.7 \times 10^8$. This is in relatively poor agreement with 2.2×10^8 from direct monitoring of the equilibrium. However, it is possible that the larger value from the pH profile arises because reaction there is believed to involve hydration of the (possibly less reactive) *syn*-oxime whereas in the equilibrium measurements we should be dealing with an equilibrated mixture of *syn*- and *anti*-isomers.



In practice we have taken $K_{ox} = 3.0 \times 10^8$. Since this does not correspond precisely to the ratio of experimentally determined forward and reverse rate constants, $k_{H_2O}/K_a = 0.1$ and $k_H K_{add} = 3.7 \times 10^7$, we have assigned "best" values of k_H and k_{H_2O} consistent with this value of K_{ox} which involve a minimum correction of the experimental values, i.e., $k_{H_2O}/K_a = 0.11$ and $k_H K_{add} = 3.3 \times 10^7$. With $pK_a = -1.62$ and $K_{add} = 440$, these yield $k_{H_2O} = 4.6 s^{-1}$ and $k_H = 7.5 \times 10^4$. These are the rate constants shown in the first column of Table 2. Corresponding values of $k_{-2}K^{\pm}$ and k_{-3}/K^+ are 1.4×10^3 and 160 s^{-1}, respectively. The value of $k_2 = 6.0 \times 10^5$ in Table 2 comes from the average of values of $k_2 K_{ox}$ (2.0×10^{-3}) together with $K_{ox} = 3 \times 10^8$.

Discussion

Equilibrium measurements for the formation and hydrolysis of the oxime of 9-formylfluorene provide access to equilibrium constants for the elementary reactions summarized in Scheme 5. The equilibrium constants are shown as negative logs (p*K*s), and, following Guthrie et al. (22), the p*K*s are expressed to two decimal places to avoid round-off errors. The arrows in the scheme indicate the direction of reactions to which the constants refer. Three of the equilibrium constants, those for formation of the oxime and carbinolamine adduct and for ionization of the protonated oxime, have been measured directly, and because the equilibria can be written as thermodynamic cycles (Scheme 5) two additional equilibrium constants, for addition of water to the oxime (pK = 5.86) and for the reaction of water with the protonated oxime (pK_R = 4.24), can be inferred. The p*K*s for these equilibria are summarized in Table 2. Also shown are values for the few oximes for which a comparable range of equilibrium constants can be evaluated. Apart from 9-formylfluorene, the table includes the oximes of acetone (5, 12), acetophenone (10), and *p*-chlorobenzaldehyde (1, 3).

Scheme 5.

A principal focus of the following discussion will be rate and equilibrium constants for electrophile–nucleophile combination reactions. Examples of these from Scheme 5 include the reactions of the protonated oxime with water and of 9-formylfluorene with hydroxylamine. Reactions of electrophiles with nucleophiles have been extensively discussed in the literature (23–25), but here attention will be confined to: (*i*) the use of the equilibrium constant K_R to measure the relative stability and affinity of electrophiles and nucleophiles; and (*ii*) the possibility of deriving values of pK_a and pK_R for the conjugate acid of 9-formylfluorene.

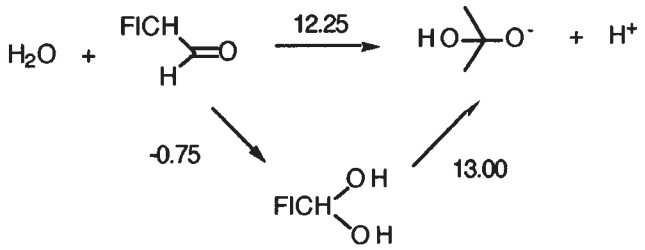
pK_R and stabilities of nucleophiles and electrophiles

Use of the equilibrium constant K_R as a measure of carbocation stability (15) is based on the reaction of the carbocation with water shown in eq. [5].

$$[5]\qquad R^+ + H_2O \overset{K_R}{\rightleftharpoons} ROH + H^+ \qquad K_R = \frac{[H^+][ROH]}{[R]}$$

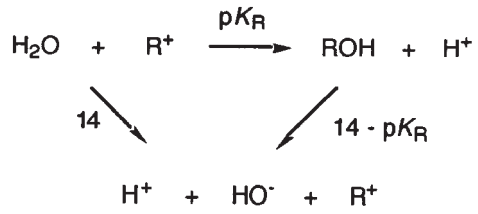
Some years ago, Hine (23) suggested use of the equilibrium constant K_c to characterize the general reaction of electrophiles with nucleophiles shown in eq. [6].

$$[6]\qquad E^+ + N^- \overset{K_c}{\rightleftharpoons} EN \qquad K_c = \frac{[EN]}{[E^+][N^-]}$$



It was pointed out by Bunting (26) that when the nucleophile is a hydroxide ion, K_c and K_R provide equivalent measures of electrophile stability. Thus, Bunting reexpressed equilibrium constants for pseudo-base formation from reaction of hydroxide ion with a range of heterocylic cations as pK_R values, by using the relationship $K_R/K_c = K_w$ (where K_w is the autoprotolysis constant of water).

The same analysis can be applied to addition of hydroxide ion to a carbonyl group. This is illustrated by and provides a value of K_R for 9-formylfluorene. The appropriate equilibrium is shown in eq. [7].

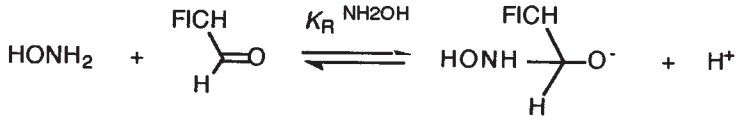


$$[7]\qquad H_2O + \text{>C=O} \overset{K_R}{\rightleftharpoons} HO\text{-C<}\,O^- + H^+$$

For most aldehydes K_R can be obtained from a direct measurement of K_c (27). For 9-formylfluorene, however, reaction in aqueous sodium hydroxide yields not the required hydroxide adduct but an enolate anion. K_R is then best obtained from the thermodynamic cycle of Scheme 6 which relates pK_R to the equilibrium constants for hydration of the aldehyde and ionisation of the hydrate to its monoanion.

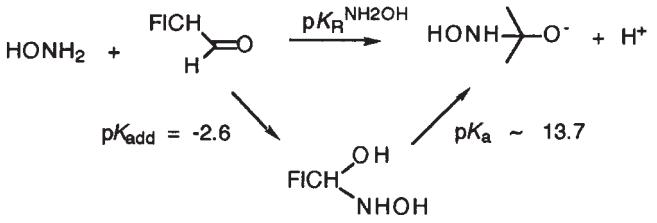
Scheme 6.

Scheme 7.



In this cycle the equilibrium constant for hydrate formation is known (K_h = 5.6) and the pK_a of the hydrate may be estimated as 13.0 from a Taft relationship for gem diols by taking σ^* = 0.41 for the fluorenyl group, on the assumption that this is the same as for Ph_2CH (28). Then, from pK_a = 13.57 for the hydrate of acetaldehyde (29) and ρ^* = 1.45 (30), we obtain pK_R = pK_h + pK_a = 12.25.

Again following arguments of Hine (23), we can write a further cycle of p*K*s as in Scheme 7 to show that pK_R measures the relative affinity (Lewis basicity) of a proton (H_3O^+) and an electrophile (R^+) towards hydroxide ion. This is apparent from the lower arms of the cycle which correspond to values of log K_c for reactions of H^+ and R^+ with hydroxide.



Hine (23) also used K_c to compare affinities (Lewis basicities) of electrophiles for nucleophiles other than hydroxide ion. For any nucleophile, we can again derive a value of "K_R" using the relationship $K_R/K_c = K_a$, where K_a is the ionization constant of the conjugate acid of the nucleophile. Thus in eq. [8] we write the equilibrium for reaction of 9-formylfluorene with hydroxylamine and denote the equilibrium constant $K_R^{NH_2OH}$.

A value for $pK_R^{NH_2OH}$ can be obtained in the same way as pK_R by combining equilibrium constants for formation and

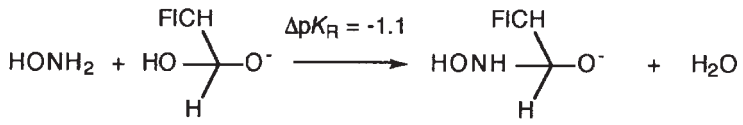
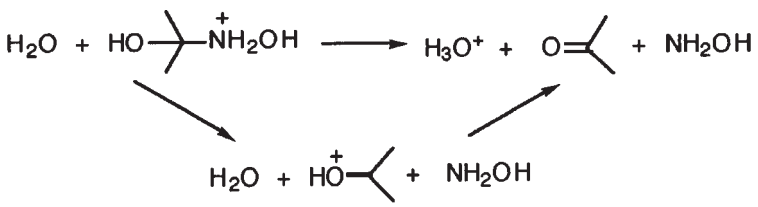
[8] 



Scheme 8.



ionization of the carbinolamine adduct as shown in Scheme 8. The equilibrium constant for adduct formation pK_{add} is 2.64 and that for ionization may be estimated from pK_R = 13 for 9-formylfluorene hydrate by adding $\rho^*\Delta\sigma^*$, where ρ^* = 1.45 (30) and $\Delta\sigma^*$ is the difference in values of σ^* for OH and NHOH. Unfortunately the effect of NHOH on the ionization of an alcohol has not been determined directly and there is some doubt as to the value of σ^* to use. We took a value of 1.1 which may be compared with values of 1.2 for PhNH and 0.62 for NH_2 used recently by Guthrie et al. (22) for estimating pK_as of tetrahedral intermediates and with a value of 1.61 for OH based on the ionization constants of ethanol and formaldehyde hydrate. This gives pK_a = 13.7 and $pK_R^{NH_2OH}$ = 11.06. Jencks and co-workers (31) used σ_I = 0.18 for NHOH which implies a value of σ^* ~ 0.9 which is comparable with ours.

The difference between pK_R values of 9-formylfluorene with respect to the two nucleophiles (HO^- and $HONH^-$) indicates a difference in relative "carbon" and hydrogen basicities, $\Delta pK_R = pK_R^{NH_2OH} - pK_R^{H_2O} = -1.15$. The negative value implies that hydroxide ion has a smaller affinity for the carbonyl group relative to a proton (bound to water) than the hydroxylamide ion (eq. [9]). Identification of ΔpK_R as a measure of carbon basicity again follows Hine (23, 32). Although the difference between the nucleophiles in this instance is small, differences for other nucleophiles are much larger (32).

An advantage of using K_R rather than K_c to characterize equilibria for nucleophile–electrophile combination reactions is that K_R can sometimes be determined when K_c cannot, e.g., evaluation of K_c for NH_2OH in eq. [8] would require knowledge of the ionization constant of NH_2OH. On the other hand, K_c is required for investigating rate equilibrium correlations (23) so both equilibrium constants are of interest. In the light of current preoccupation with reactions between electrophiles and nucleophiles (25) it is possible that Hine's analysis has received less attention than it deserves (24).

[9] 

Scheme 9.

The mechanism of hydrolysis in strong acid

We may also derive values of pK_a and pK_R for the conjugate acid of 9-formylfluorene. To do so, however, it is necessary to consider the mechanism of hydrolysis of the oxime in strongly acidic media. As noted above, at high acid concentrations this reaction occurs exclusively via the protonated tetrahedral intermediate T^+ (Scheme 1). Twenty-five years ago, Jencks and co-workers (2), Sayer and co-workers (2, 3), and Sayer and Conlon (33) concluded that the reaction takes place by a concerted mechanism in which breaking of the C—N^+ bond occurs simultaneously with deprotonation of T^+ to form the hydroxylamine and aldehyde products in a single step. After reexamining the experimental data, however, and in the light of new measurements, we conclude that the mechanism is stepwise, with C—N bond-breaking preceding proton transfer and an *O*-protonated aldehyde being formed as a reactive intermediate. The alternative mechanisms are shown in the upper and lower pathways of Scheme 9.

Jencks and Sayer advanced two main arguments in favour of a concerted reaction. Firstly, they suggested that aldehydes were too weakly basic for their conjugate acids to be discrete intermediates in the acid-catalyzed oxime forming and hydrolysis reactions. Secondly, they argued that a stepwise mechanism was unlikely on the grounds that the rate of reaction in the oxime forming direction was insensitive to substituent effects in the aldehyde.

The first of these arguments was based on an estimate of the basicity of aldehydes which has since been revised. Thus, Reiman and Jencks (1) and Sayer regarded –8 as a reasonable value for the pK_a of *p*-chlorobenzaldehyde, which is more than three units more negative than the value accepted today. At the time (1972), the qualitative magnitudes

© 2000 NRC Canada

of pK_as of carbonyl compounds (34) were still under discussion. Indeed, more recently, Toullec (35) has argued in favour of the larger negative values on the grounds that they are consistent with α-hydroxy and α-alkoxy carbocations having similar stabilities. If the ketones were 3–4 orders of magnitude more basic than supposed by Jencks and Sayer (2), a substantially greater stability would be implied for the α-hydroxycarbocations, which Toullec (35) considered unlikely.

However, it is now clear that the large negative pK_as for aldehydes were based on an inadequate extrapolation of equilibrium measurements in strongly acidic media to aqueous solution. Methods for correcting equilibrium constants (and measurements of UV–vis spectra used to monitor the equilibria) for medium effects in concentrated solutions of strong acids are now well understood (16, 36, 37). This means that pK_as, at least of compounds in which conjugation of the carbonyl group and the aromatic ring provides an intense π-π* chromophore for reliably monitoring the extent of protonation (such as pK_a = –3.87 for acetophenone (36, 37) and –4.5 for benzaldehyde (38)), can no longer be considered in doubt. It also seems clear that the large difference in stabilities of carbocations containing α-hydroxy and α-alkoxy substituents derives from the stabilization conferred by aqueous solvation of a hydroxyl group conjugated to the charge centre (39). This stabilization is not available to the alkoxy group.

The basis of Jencks's and Sayer's (2) second argument, that the rates of acid-catalyzed oxime-forming reactions are insensitive to substituents in the carbonyl reactant, is illustrated by rate constants for acid-catalyzed attack of *O*-methyl hydroxylamine upon *p*-methoxy, *p*-chloro, and *p*-nitro benzaldehydes. For these reactions Jencks and Sayer obtained values of 1 500, 2 070, and 1 930 M^{-1} s^{-1}, respectively (2). They concluded that the rate constants for attack of hydroxylamine on the *protonated* benzaldehydes, which are obtained by correction of the experimental rate constants for the extent of protonation of the aldehyde, were too *sensitive* to the structure of the aldehyde to represent reactions which should be close to diffusion control.

However, if we widen the range of structures of ketones and aldehydes to include acetone (5, 12), acetophenone (10), and 9-formylfluorene, this insensitivity to substituents is no longer apparent. We find that rate constants for their acid-catalyzed reactions vary by 250-fold, as is indicated by values of k_H' listed in Table 2. Explicit values of the rate constants for attack of NH_2OH on the protonated conjugate acids of these compounds are considered below, and it is argued that they show a rational dependence on the structure of the substrate.

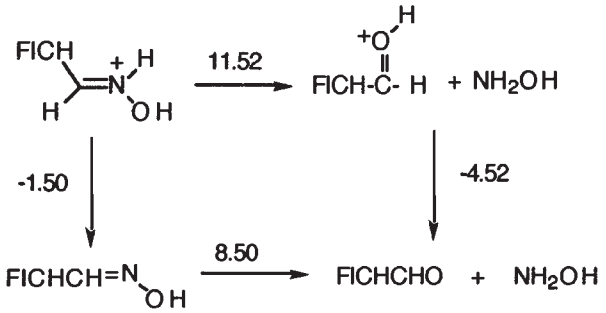
Further evidence cited by Sayer et al. (3) in support of the concerted mechanism, was the observation of general acid catalysis in oxime-forming reactions. However, because the T^+ pathway is normally observed only at fairly high concentrations of strong acid, most studies demonstrating general acid catalysis pertain to the alternative acid-catalyzed mechanism occurring at higher pH and involving rate-determining formation of T^+ through trapping of the zwitterionic tetrahedral intermediate $T^\pm$ by protonation (40).

At this point, we might conclude that there is little evidence to support the concerted reaction in Scheme 9. However, Brown and Guthrie and co-workers (41) have recently inferred such a mechanism for the H_3O^+-catalyzed hydrolysis of acetanilides. They monitored C—N^+ bond-breaking in the protonated tetrahedral intermediate formed from attack of water on the protonated anilide by measuring the extent of oxygen isotope exchange occurring in the reactant in competition with hydolysis. Their principal evidence that the reaction of T^+ is concerted came from the measurement of a solvent isotope effect (k_{H_2O}/k_{D_2O}) close to 1.0 for ^{18}O exchange. This strongly implicated the contribution of a primary isotope effect k_H/k_D = 2.5 to compensate an expected solvent isotope effect in the opposite direction arising from protonation of the anilide by H_3O^+ in a preequilibrium (42).

The isotope effect for hydrolysis of the oxime of 9-formylfluorene is also close to unity: k_{H_2O}/k_{D_2O} = 1.3. However, a fundamental difference from the hydrolysis of the anilides is that the reactants are not the oxime and H_3O^+, but the *protonated* oxime (Scheme 5). In contrast to the anilides, therefore, there is no preequilibrium protonation so the value of k_{H_2O}/k_{D_2O} points to the *absence* of a primary isotope effect in the reaction. We found that the magnitude of k_{H_2O}/k_{D_2O} does not change appreciably on going to lower acid concentrations, where the oxime is no longer protonated. However, reaction then occurs via the $T^\pm$ pathway of Scheme 1 and is not subject to catalysis by H_3O^+. Again therefore an inverse solvent isotope effect is not to be expected.

It is not clear why the mechanisms for reaction via T^+ in the hydrolysis of anilides and oximes should differ. Possibly that the greater acidity of the protonated carboxylic acid than protonated aldehyde as a reactive intermediate, coupled with a less acidic medium, implies a greater preference for concerted proton transfer in the reaction of anilides than oximes.

pK_R and pK_a for protonated 9-formylfluorene



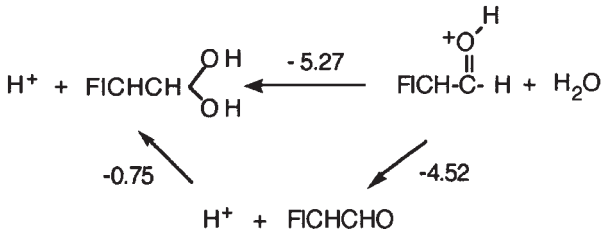
Summarizing the above arguments, we conclude, on the basis of the isotope effect, and the fact that the reaction takes place at acidities at which the extent of protonation of the aldehyde renders its conjugate acid a viable intermediate, that C—N bond-breaking of T^+ derived from the 9-formylfluorene oxime is unlikely to be concerted with proton transfer.

If this conclusion is correct the immediate products of the reaction of T^+ are protonated 9-formylfluorene and hydroxylamine. If formation of these products is rate-determining, then by the principle of microscopic reversibility the rate-determining step of the reverse reaction is attack of hydroxylamine on the protonated 9-formylfluorene. It follows that we can infer a pK_a for the protonated aldehyde if we make the assumption that its reaction with hydroxylamine is diffusion-controlled.

An experimental rate constant for the reaction in the oxime-forming direction can be deduced by combining the rate constant for the acid-catalyzed hydrolysis with the equilibrium constant for the overall reaction. This rate constant corresponds to k_3/K_a where k_3 is the rate constant for attack of hydroxylamine on, and K_a is the acid dissociation constant of, the protonated aldehyde (Scheme 1). If k_3 corresponds to a diffusion-controlled reaction then, since the magnitude of rate constants for diffusion are known, K_a can be determined.

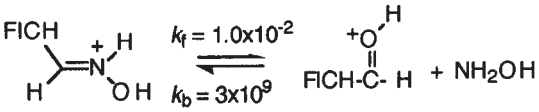
© 2000 NRC Canada

Scheme 10.



What evidence is there that attack of hydroxylamine on the protonated aldehyde is diffusion-controlled? Diffusion control for reactions of carbocations with nucleophiles has been invoked most commonly for azide (43) or sulphur (44) anions. NH_2OH is a reactive α-nucleophile which is more basic and more reactive towards methyl iodide than azide ion (45). Although its N^+ value is somewhat lower than that of azide (5.1 compared with 7.5 (24)) it is still large. Its rate constant for reaction with 9-formylfluorene itself is 3.4×10^5. It is very likely that the increase in reactivity conferred by protonation of the carbonyl group would increase this by the factor of 10^4 required to achieve the expected diffusion rate constant of 3×10^9 M^{-1} s^{-1} for attack of a neutral molecule upon an ion in aqueous solution (46).

This argument is reinforced below by assessing the activating effect of protonation of 9-formylfluorene on nucleophilic attack in the case of water as a nucleophile. However, further evidence for diffusion control comes from examination of rate constants for acid-catalyzed attack of hydroxylamine on other protonated ketones and aldehydes for which pK_as are known. Again the experimental rate constant corresponds to a ratio of the rate constant for attack by hydroxylamine to the ionization constant of the protonated ketone (k_3/K_a). Now, however, we deduce the magnitude of the rate constant from knowledge of the equlibrium constant rather than vice versa.



Rate constants (k_3) for attack of hydroxylamine on protonated acetone, acetophenone, and *p*-chlorobenzaldehyde and the pK_as on which they are based are shown in Table 2. The rate constants are rather large. For acetophenone and acetone they are 1.6×10^6 and 3.9×10^6 respectively and for *p*-chlorobenzaldehyde 5.8×10^8. As expected the aldehyde is more reactive than the ketones. The order of reactivities is confirmed if we deduce a value for *p*-methoxybenzaldehyde by assuming that the ratio of acid-catalyzed rate constants for reactions of hydroxylamine and methoxylamine (2) are the same for the *p*-methoxy and *p*-chlorobenzaldehydes. The value obtained, 1.1×10^8, is somewhat less than for *p*-chlorobenzaldehyde and is again consistent with expected relative stabilities of the carbonyl compounds.

It is clear that the rate constant for the *p*-chlorobenzaldehyde is within an order of magnitute of the value of 3×10^9 for diffusion. 9-Formylfluorene should be significantly more reactive than an aromatic aldehyde and we conclude that any error from assuming that the reaction of hydroxylamine with the protonated aldehyde is diffusion-controlled must be small.

Scheme 11.

If we assume that the reaction of hydroxylamine with protonated 9-formylfluorene does indeed occur at the diffusion limit we can combine the rate constant for diffusion (3×10^9) with the experimental rate constant $k = 1.0 \times 10^{-2}$ for the forward, weakly acid-dependent, hydrolysis reaction occurring in concentrated acid solutions, to obtain an equilibrium constant for the hydrolysis reaction. As shown in eq. [10], the reactant in this equilibrium is the protonated oxime, which is the predominant form of the oxime existing at the acid concentrations at which the T^+ reaction path prevails.

[10] 

Thus we derive an equilibrium constant between protonated 9-formylfluorene and protonated oxime of $1.0 \times 10^{-2}/3 \times 10^9 = 3.3 \times 10^{-12}$ (pK = – 11.52). As shown in Scheme 10, this can be combined in a cycle with equilibrium constants for protonation and formation of the oxime to derive pK_a = –4.52 for the protonated 9-formylfluorene. (The apparent pK_a = –1.50 for protonation of the oxime to yield a mixture of protonated oxime and protonated carbinolamine is used in Scheme 10). The pK_a of the 9-formylfluorene may be compared with directly measured values of pK_a = –4.4 and –5.0 for protonated benzaldehyde and *p*-chlorobenzaldehyde, respectively (38).

An alternative way of deriving K_a is by converting the hydrolysis rate constant 1.0×10^{-2} M^{-1} s^{-1} into a rate constant for the reverse acid-catalyzed attack of hydroxylamine upon 9-formylfluorene and identifying this rate constant with k_3/K_a where k_3 is again the rate constant (3×10^9) for diffusion-controlled attack of hydroxylamine on protonated aldehyde. Correcting for the contribution from k_3 then yields the value of K_a.

The pK_a for protonation of 9-formylfluorene so obtained may be further combined with an equilibrium constant for hydration of the aldehyde to yield a value of pK_R = –5.27 for the protonated aldehyde by taking advantage of the cycle of Scheme 11. This value is compared with pK_R values for protonated *p*-chlorobenzaldehyde, acetone and acetophenone in Table 2. It is noteworthy that the pK_R for 9-formylfluorene is considerably more negative than that for *p*-chlorobenzaldehyde (–2.9) even though the pK_as of the two compounds are practically the same. The trend in pK_R values is similar to that of the protonated oximes, for which pK_Rs are also shown in Table 2.

Finally, we derive $pK_R^{NH_2OH} = -7.14$ for the protonated 9-formylfluorene based on the cycle of Scheme 12. The pK_R

Scheme 12.

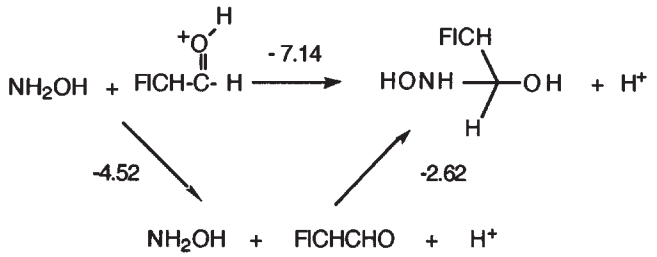

Table 3. Values of pK_R for 9-formylfluorene, its conjugate acid, and protonated oxime in water at 25°C.

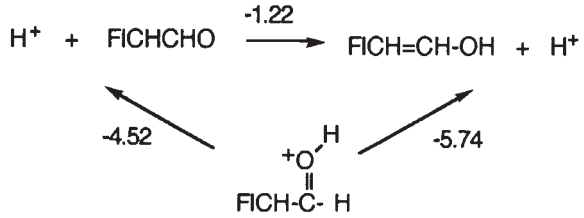
	pK_R	p$K_R^{NH_2OH}$
FlCHCH=OH^+	–5.27	–7.14
FlCHCH=NH^+OH	4.10	—
FlCHCH=O	12.25	11.1



values for 9-formylfluorene, its conjugate acid, and protonated oxime are summarized in Table 3.

We return now to the question of diffusion control of attack by NH_2OH on the protonated 9-formylfluorene and compare the activating effect of protonation upon attack by water and attack by hydroxylamine. In a previous study of the hydration reaction a rate constant for catalysis by H_3O^+ was measured as 12.5 M^{-1} s^{-1}. Combining this with K_R = 3.7×10^5 yields a rate constant $k_{H_2O} = 3.4 \times 10^6$ s^{-1} for attack of water on the protonated 9-formylfluorene. This may be compared with $k = 2.86 \times 10^{-2}$ s^{-1} for hydration of the unprotonated aldehyde. The ratio of these rate constants, 1.2×10^8, measures the activating effect of protonation of the carbonyl oxygen atom upon nucleophilic attack by water. Such a ratio has been called by Stewart and Srinivasan (47) a proton activating factor (paf).

It should be noted that the evaluation of paf implies that attack of water occurs on a fully protonated carbonyl group whereas it has usually been considered that in the acid-catalyzed hydration of aldehydes attack of water is concerted with proton transfer from H_3O^+ (48). Strictly speaking, therefore, 1.2×10^8 should be an upper limit for the activation of water attack. The possibility of concertedness and the difficulty of distinguishing this from direct reaction with water exists for other carbocation reactions. However, Ritchie (24) has shown that relative rates of reactions of electrophiles with H_2O are often correlated with those of nucleophiles not reacting by a concerted pathway, such as hydroxide ion. It seems likely therefore that the qualitative significance of the comparison of rates of reaction of water with those of NH_2OH remains valid.

By assuming that reaction of NH_2OH with the protonated aldehyde is indeed diffusion-controlled ($k = 3 \times 10^9$ M^{-1} s^{-1}) an activation factor for NH_2OH may be calculated from the value of $k_2 = 6.0 \times 10^5$ for attack of NH_2OH on the unprotonated aldehyde (Table 2) to give a value of paf = 5×10^3. This is more than 10^4 times smaller than the value for water. An unexpectedly slow reaction between a nucleophile and a carbocation is commonly used as an argument for diffusion control (44). Put another way, the ratio of rate constants for attack of NH_2OH and H_2O on the unprotonated 9-formylfluorene (2.1×10^7) is much larger than the corresponding ratio (900) for attack on the protonated compound, even though the reaction of hydroxylamine is assumed to be diffusion-controlled. A low selectivity between water and a reactive nucleophile is again an established argument for diffusion control. The measured ratio of 900 may also be compared with a value of $>10^5$ predicted by the N^+ relationship.

Scheme 13.

Finally, we note that in principle the limiting rate constant for NH_2OH might even exceed that for diffusion if, as seems likely, the encounter complex with protonated aldehyde is generated by proton tranfers to and from 9-formylfluorene and NH_3OH^+ already associated within a solvent cage. However, it seems unlikely that this would increase the rate sufficiently to affect the estimated pK_a of the protonated 9-formylfluorene by more than a few tenths of a log unit.

Protonation of the enol of 9-formylfluorene

We may now use the pK_a for protonation of 9-formylfluorene to complete the cycle of equilibria associated with the enolization and ionization of its aldehyde tautomer shown in Scheme 13. This cycle allows us to assign a pK_a = –5.74 to the *C*-protonated enol. This pK_a is of interest for comparison with corresponding values for the enols of acetone and acetophenone. These may be derived in the same way as for 9-formylfluorene by combining keto–enol tautomeric constants measured by Chiang et al. (49) and Kresge and co-workers (49, 50) (7.90 for acetophenone and 8.33 for acetone) with the pK_as of the ketones measured by Bagno (36) (–3.87 for acetophenone and –3.06 for acetone). We then obtain as pK_as for the enols of acetophenone and acetone 4.03 and 5.27, respectively. Thus, these enols are more basic than the enol of formylfluorene by factors of 10^{10} and 10^{11}.

The exceptionally low basicity of the enol of 9-formylfluorene partly reflects the greater stabilizing effect on the protonated species of the α-methyl or α-phenyl substituent of the ketones than hydrogen of the aldehyde. Another factor is the electron-withdrawing effect of the fluorenyl group. However, these also influence the basicities of the keto tautomers, and the most important factor specifically affecting the enol is undoubtedly the influence of the fluorenyl group on the stability of the enolic double bond (51). Thus K_E = 16.6 for 9-formylfluorene is more than 10^9-fold greater than that of K_E for acetone or acetophenone. Accordingly the difference in basicity of the enols is much greater than that of their keto tautomers.

Summary

The pK_as for protonation of 9-formylfluorene and its enol represent the principal results of this study. The pK_a of the aldehyde tautomer is derived from measurements of rate constants for formation and hydrolysis of its oxime and

© 2000 NRC Canada

depends on evidence: (*i*) that the mechanism of acid-catalyszd formation involves attack of hydroxylamine on the protonated aldehyde (rather than concerted attack and protonation); and (*ii*) that this reaction is diffusion-controlled. The value of the pK_a = –4.5 (and pK_R = –5.2) is consistent with p*K*s of other aldehydes based on measurements of protonation equilibria in concentrated solutions of strong acids (38).

The study also yields values of pK_a and pK_R for the protonated oxime and equilibrium constants for the reaction of hydroxylamine with 9-formylfluorene to form the tetrahedral adduct and the oxime itself. Such a set of equlibrium constants has not previously been obtained for an aldehyde group bound to an aliphatic carbon atom.

Experimental

The kinetics of reactions described in this paper were monitored spectrophotometrically using Phillips PU 8600, Perkin–Elmer Hitachi 124, or Spectronic Genesys 2PC UV–vis spectrophotometers. Measurements of pH were made with a Radiometer PHM 26 or Metronohm pH meter 744. Solutions of strong acids or buffers were prepared from commercial reagents usually of AR quality. The acids were standardized with solutions of NaOH prepared from Merck "Titrisol" ampoules. Reactions were carried out in aqueous solutions using doubly distilled water.

9-Formylfluorene was prepared as previously described (14, 52) and purified by Kugelrohr distillation to give a pale yellow oil. To prepare the oxime, 9-formylfluorene (1.57 g, 8.4 mmol) was dissolved in ethanol (20 mL). Sodium (0.195 g, 8.4 mmol) in ethanol (3.5 mL) was added, followed by hydroxylamine hydrochloride (0.59 g, 8.4 mmol) in water (3.5 mL) to give a light brown solution and white precipitate. The mixture was heated at 60°C for 1 h to give a clear solution from which a water soluble white precipitate formed after leaving overnight in a freezer. Addition of water (50 mL) led to precipitation of the oxime which was filtered and dried. Careful recrystallization gave white needles, mp 160–165°. ^{1}H NMR (CD_3CN) δ: 5.66 (d, *J* = 7.0 Hz, 1H), 6.60 (d, *J* = 7.0 Hz, 1H), 7.3 – 7.9 (m, 8H), 9.23 (s, 1H) (in $CDCl_3$, the peak at 9.23 was broadened and shifted upfield to δ 8.2). ^{13}C NMR ($CDCl_3$) δ: 44.4, 120.0, 125.5, 127.5, 127.9, 141, 142.5, 150.5. Anal. calcd. for $C_{14}H_{11}NO$: C 80.36, H 5.36, N 6.61; found: C 80.35, H 5.3, N 6.69.

Based on the work of Karabatsos and Taller (21), it was expected that the oxime that crystallized was the *syn*-isomer. This was confirmed by the magnitude of the chemical shift of the vinyl hydrogen when compared, e.g., with *syn*- and *anti*-oximes from phenylacetaldehyde (21). No conversion to the *anti*-isomer was observed after leaving the NMR solution for several days. However, excessive heating of solutions during recrystallization produced a product with a broad melting range which was presumed to be a mixture of *syn*- and *anti*-oximes.

Equilibrium measurements

Protonation of 9-formylfluorene

A pK_a for the protonated oxime was obtained from measurements of (small) changes in absorbance in the UV spectrum in solutions of perchloric acid in the concentration range 2.5–8.0 M. Below 2.5 M there was interference from a significant end absorption from the oxime. Absorbances were measured following injection of 10 μL of a 10^{-2} M solution of the oxime in acetonitrile into 2 mL of different concentrations of aq $HClO_4$. Measured absorbances at the indicated acid concentrations were: 0.40 (3.01 M), 0.36 (3.76 M), 0.337 (4.14 M), 0.32 (4.35 M), 0.322 (4.51 M), 0.314 (4.70 M), 0.305 (5.08 M), 0.29 (5.64 M). The pK_a was obtained as the intercept of a plot of –log *K* against *X* based on eq. [11], in which 0.27 and 0.45 are absorbances for ionized and unionized oxime, respectively (which were interpolated by assuming that log *K* depends linearly upon the medium acidity function *X*) and *A* is the measured absorbance at the acid concentration [H^+] (16–18).

$$[11] \quad -\log K = -\log\left\{\frac{(A - 0.27)[H^+]}{(0.45 - A)}\right\} = m^*X + pK_a$$

The plot gave m^* = 0.9 and pK_a = –1.50 with an error estimated qualitatively as ±0.2. The pK_a is confirmed by the fact that it yields a satisfactory fit of calculated to experimental rate constants in the pH – *X* profile for hydrolysis of the oxime (Fig. 2). However, it should be noted that protonation of the oxime may be associated with partial hydration to form the protonated carbinolamine (T^+). The pK_a used in the text (–1.62) includes a correction for this described in the appendix.

Formation of carbinolamine

An equilibrium constant for the addition of hydroxylamine to 9-formylfluorene was measured by injecting a small amount of a solution of the substrate in acetonitrile (typically 20 μL) into 2 mL of aq hydroxylamine buffer and measuring the absorbance at 319 nm. The absorbance decreased with time, but an initial value A_I was extrapolated to the time of injection. This and the limiting absorbance (A_{max}), referring to a solution without added hydroxylamine, are related to the ratio of concentrations of carbinolamine and enol (and aldehyde) as shown in eq. [12].

$$[12] \quad \frac{A_{max} - A_I}{A_I} = \frac{[\text{carbinolamine}]}{[\text{enol}] + [\text{aldehyde}]}$$

Combination of eq. [12] with the equilibrium constant for formation of carbinolamine from equilibrated enol and aldehyde, K_{eff} (eq. [13]), gives eq. [14], which shows that $1/A_I$ may be plotted against [NH_2OH] to give $1/A_{max}$ as intercept and K_{eff}/A_{max} as slope.

$$[13] \quad K_{eff} = \frac{[\text{carbinolamine}]}{([\text{enol}] + [\text{aldehyde}])[NH_2OH]}$$

$$[14] \quad \frac{1}{A_I} = \frac{1}{A_{max}} + \frac{K_{eff}\,[NH_2OH]}{A_{max}}$$

Two sets of measurements were carried out. The first with [NH_2OH]/[NH_3OH^+] = 1 gave the following absorbances (A_I) at the indicated concentrations of NH_2OH: 0.34 (0.025 M), 0.45 (0.01 M), 0.49 (0.005 M), 0.52 (0.0025 M), 0.53

© 2000 NRC Canada

(0.00125 M). The second with $[NH_2OH]/[NH_3OH^+]$ = 9 gave: 0.24 (0.04 M), 0.39 (0.009 M), 0.47 (0.0045 M). The average value of K_{eff} derived from the two sets of data was 25, with an estimated error of ±2. The corresponding equilibrium constant for formation of the carbinolamine from the aldehyde was obtained from $K_{add} = K_{eff}(1 + K_E)$ where K_E is the keto–enol equilibrium constant (=16.6). This gave K_{add} = 440.

Formation of oxime

An equilibrium constant was also measured for the complete reaction of enol with hydroxylamine to form oxime. In practice the equilibrium was approached both from the oxime-forming direction and the reverse direction of oxime to enol. Because the equilibrium strongly favours the oxime, measurements were made in solutions of HCl, in which the hydroxylamine is fully protonated. Practically speaking the equilbrium studied corresponds closely to that of eq. [4] and, taking account of the presence of the small fraction of aldehyde, has an equilibrium constant K given by eq. [15]. In this equation the ratio of concentrations of oxime to enol plus aldehyde may be replaced by $(\Delta A_{max} - \Delta A)/\Delta A$ where ΔA is the change in absorbance between the oxime initially present and the equilibrium concentration of oxime and enol (plus aldehyde and hydrate) and ΔA_{max} is the value of ΔA for complete conversion of the oxime to "enol". Making this substitution the value of K could be determined from a plot of $1/\Delta A$ vs. $[NH_3OH^+]/[H^+]$ based on rearrangement of eq. [15] to eq. [16].

$$[15] \qquad K = \frac{[\text{carbinolamine}]}{([\text{enol}] + [\text{aldehyde}] + [\text{hydrate}])[NH_3OH^+]}$$

$$[16] \qquad \frac{1}{\Delta A} = \frac{1}{\Delta A_{max}} + \frac{K}{\Delta A_{max}} \frac{[NH_3OH^+]}{[H^+]}$$

From this plot, a value of K = 9.9 was obtained based on the following sets of measurements of ΔA at different concentrations of acid and $[NH_3OH^+]$. For $[H^+]$ = 0.2 M values of ΔA and $[NH_3OH^+]$ were: 0.559, 0.02 M; 0.591, 0.016 M; 0.630, 0.012 M; 0.683, 0.01 M; 1.145, 0 M. For $[H^+]$ = 0.1 M they were 0.551, 0.01 M; 0.627, 0.008 M; 0.733, 0.005 M; 1.137, 0.0 M. For $[H^+]$ = 0.05 M they were: 0.512, 0.005 M; 0.566, 0.004 M; 0.642, 0.003 M; 0.703, 0.002 M; 1.064, 0.0 M.

Similar measurements were made at 319 nm with the enol and protonated hydroxylamine as reactants. At this wavelength, the oxime does not absorb and the ratio [oxime]/[enol] at equilibrium is given by $(A_I - A_F)/A_F$, where A_I and A_F are absorbances at the beginning and completion of the reaction. Measured values of A_I and A_F (in that order) at different concentrations of NH_3OH^+ in 0.1 M HCl were as follows: 0.428, 0.145, 0.02 M; 0.435, 0.25, 0.008 M; 0.430, 0.390, 0.001 M. These gave an average value of K = 9.4 and the combined results gave K = 9.7. The value of K is related to K_{ox} for oxime formation from the aldehyde tautomer of 9-formylfluorene by $K_{ox} = K/(0.044 \times K_a)$ where $K_a = 10^{-6}$ is the ionization constant of NH_3OH^+ and 0.044 is the ratio of the concentration of the aldehyde tautomer to the combined concentrations of aldehyde, enol, and hydrate (9). The derived value is $K_{ox} = 2.20 \times 10^8$.

Kinetic measurements

Hydrolysis of the oxime

Rate constants for hydrolysis of the oxime in acidic media were monitored from the spectrum of the enol product at 234, 260, and 270 nm (Fig. 1). In solutions of HCl, care had to be taken to avoid oxidation to fluorenone with the formation of a characteristic peak at 260 nm. In concentrated solutions of $HClO_4$, there was a shift in the equilibrium between keto and enol tautomers in favour of the keto isomer. The reaction was then monitored from a decrease in absorption of the peak for the protonated oxime at 270 nm.

In principle microscopic rate constants for the hydrolysis reaction could be obtained from a best fit of eq. [2] based on Scheme 1 to the pH-dependence of log k_{obs} shown in Fig. 2. In practice measurements were made mainly with concentrated solutions of HCl or $HClO_4$. Log k_{obs} is then correlated not by pH but pH – X, where X measures the acidity of the medium based on the protonation of weakly basic anilines (12, 13) and account must be taken of the acidity dependence of limiting rate constants in different acidity ranges. In practice, therefore, the line drawn through the points in Fig. 2 is based on the modified form of eq. [2] shown as eq. [17].

The limiting kinetic expressions for different reaction paths and numerical values of their composite rate coefficients extrapolated to aqueous solution are those shown below eq. [2]. In eq. [17] the dependence of these rate coefficients upon X in strong acids is described by multiplying microscopic rate or equilibrium constants by 10^{m^*X} where m^* is the slope of a plot of the log of the limiting rate constant against $-X$ (16, 17). The constants to which these m^* refer are shown in Scheme 14, which is an abbreviated form of Scheme 1 with the oxime and protonated oxime denoted Ox and OxH^+, respectively, and rate and equilibrium constants k and K replaced by $k \times 10^{-m^*X}$ or $K \times 10^{-m^*X}$.

Assignments of values of m^* include the measured value of 0.9 for the dissociation constant of the protonated oxime and $m^* = m_2^* + m_4^* - m_3^* = 0.3$ for the measured limiting dependence of log k_{obs} upon $-X$ at the highest concentrations of $HClO_4$. If we take m_4^* for the acidity dependence of k_{-3}/K^+ (the reaction of T° via T^+) as –0.9, the same as for the protonation of the oxime, and m^* for the corresponding reaction of T^o via $T^\pm$ as 0, then the implied value of m^* for reaction of the protonated oxime via the $T^\pm$ pathway is 1.2, which is close to the value (1.3) previously observed for the hydrolysis of the *N*-phenylimine of *p*-chlorobenzaldehyde (20). Finally, m_2^* and m_3^* are assigned by noting that $m_2^* - m_3^* = 1.2$ and giving m_2^* and m_3^* the arbitrary but reasonable values of 0.4 and –0.8. These values provide the satis-

$$[17] \qquad k_{obs} = \frac{k_{H2O}k_{-2}K^\pm 10^{m_2^*X}}{(k_H 10^{m_3^*X}[H^+] + k_{-2}K^\pm)(1 + K_a 10^{m_1^*X}/[H^+])} + \frac{k_{H2O}k_{-3}10^{(m_4^* + m_2^* - m_3^*)X}}{k_H K^+(1 + K_a 10^{m_1^*X}/[H^+])}$$

© 2000 NRC Canada

Scheme 14.

$$H^+ + Ox \underset{}{\overset{[H^+]/K_a 10^{m_1^* X}}{\rightleftharpoons}} OxH^+ \underset{k_H 10^{m_3^* X}[H^+]}{\overset{k_{H2O}10^{m_2^* X}}{\rightleftharpoons}} T^{\circ} \xrightarrow{k_{-2}K^{\pm} + (k_{-3}/K^+)10^{m_4^* X}[H^+]}$$

factory fit to the measurements for $HClO_4$ shown in Fig. 2. However, the dominant influences on the acidity dependence are the measured limiting value, which is established at X – pH < –2, and the fact that X approaches zero at pH > 0. The flexibility in assignments of m^* values is: (*i*) more limited than appears therefore; and (*ii*) confined to reactions making little contribution in the strong acid region such as the reaction via $T^{\pm}$.

For HCl, slighly different values of m* were used: $m_1^* = m_4^* = 0.8$, $m_2^* = 0.45$, and $m_3^* = -0.55$. The rate and equilibrium constnats were the same as for $HClO_4$ except for the limiting rate constant extrapolated from high acidities ($k_{H_2O}k_{-3}/k^H K^+$) being 9×10^{-3} instead of 1.1×10^{-2} s^{-1}.

The solvent isotope effect upon hydrolysis of the oxime was based on the measurements of rate constants at the concentrations of DCl shown in Table 1. When combined with interpolated rate constants at the same concentrations of HCl the following isotope effects (k_{H_2O}/k_{D_2O}) at the indicated acid concentrations were obtained.

$$k_{H_2O}/k_{D_2O} = 1.3 \text{ (4.8–6.1 M)}$$
$$= 1.25 \text{ (1.2–2.4 M)}$$

Oxime formation in hydroxylamine buffers

The dependence of k_{obs} upon concentration of NH_3OH^+ in hydroxylamine buffers at different buffer ratios is shown in Fig. 3 and Table S2.[2] The lines drawn through the points in Fig. 3 are based on a kinetic expression derived from Scheme 2 which allows for a change in rate-determining step from H^+-catalyzed dehydration of the carbinolamine adduct of 9-formylfluorene and hydroxylamine at low buffer concentrations to ketonization of the enol at high buffer concentrations. This expression is shown in eq. [18] and con-

$$[18] \qquad k_{obs} = \frac{ax(b + Rcx)}{ax + (b + Rcx)}$$

tains parameters a, b, and c which may be defined in terms of the symbols for rate and equilibrium constants of Schemes 1 and 2, as $a = k_H K_{add} K_a / K_E$, $b = k_1'$, $c = k_1$, $x = [NH_3OH^+]$, and $R = [NH_2OH]/[NH_3OH^+]$ (and where k_1' is the rate constant for ketonization catalysed by NH_2OH). As noted above, at high concentrations of NH_2OH a correction is applied for partial conversion of the enol of 9-formylfluorene to the carbinolamine adduct by replacing a by $a/(1 + K_{eff}[NH_2OH])$ where $K_{eff} = K_{add}/(1 + K_E) = 25$ is the apparent equilibrium constant for adduct formation from the enol (14).

A value of $a = 2.25$ was obtained from the limiting slope of the plot of k_{obs} against $[NH_3OH^+]$ for relatively basic buffers shown in the inset of Fig. 3. In this plot the correction for adduct formation is applied by multiplying k_{obs} by $(1 + K_{eff}[NH_2OH])$ as described. The value of a allowed evaluation of k_H. It was also used, together with independently determined values of k_1 (.0153) and K_{add} (440) and a value of $k_1' = 3.1$ based on a best-fit to the data at high concentrations of NH_3OH^+, in fitting the curved buffer plots shown in Fig. 3.

Oxime formation in acetic acid buffers

The behaviour observed in acetic acid buffers in the presence of hydroxylammonium chloride was similar to that in hydroxylamine buffers. The dependence of k_{obs} upon $[NH_3OH^+]$ and the concentration of acetic acid buffer was also fitted to eq. [18] but with b replaced by $k_1 + k_1''[AcO^-]$ where k_1 and k_1'' are rate constants for uncatalyzed and acetate-catalyzed ketonization of the enol of 9-formylfluorene, respectively. The term a was also modified to allow for a 20% contribution from general acid catalysis of dehydration of the carbinolamine intermediate by acetic acid at 0.1 M concentration. This was based on previous work for *p*-chlorobenzaldehyde (1) but has little influence on the results. Otherwise the parameters used in eq. [18] were the same for acetic as for hydroxylamine buffers. When calculating concentrations of buffer components and hydroxylamine, allowance had to be made for modification of added concentrations of hydroxylamine hydrochloride, acetic acid, and acetate ion through equilibration according to eq. [19].

$$[19] \qquad CH_3COOH + NH_2OH \overset{K}{\rightleftharpoons} CH_3COO^- + NH_3OH^+$$

The concentration of NH_2OH (x) from mixing $NH_3OH^+Cl^-$ and a 1:1 acetic acid buffer to give formal concentrations A and B, respectively is given by eq. [20]. In this equation the equilibrium constant K is given by the ratio of acid dissociation constants of the acetic acid buffer and NH_3OH^+. Values of x and the concentration of acetate ion $(A - x)$ and acetic acid $(B - x)$ were obtained by solution of eq. [20] as a quadratic.

$$[20] \qquad \frac{(A - x)(B - x)}{x \quad (B + x)} = K$$

To correct for ionic strength, K was replaced by $K' = K \times 10^y$ where $y = I^{1/2}/(1 + 1.6I^{1/2})$ and I is the ionic strength.

Oxime formation in aq. HCl

The dependence of first-order rate constants for oxime formation in 0.05 M aq HCl shown in Table S4[2] and Fig. 4 is described by eq. [21], which is based on and uses the symbols of Scheme 3. The equation takes account of the reversibility of the reaction at low concentrations of NH_2OH

$$[21] \qquad k_{obs} = \frac{k_1 k_2 [NH_2OH]}{k_1 K_E + k_2 [NH_2OH]} + k_2/K_{ox}$$

© 2000 NRC Canada

and also of the difference in rate-determining step for the oxime-forming reaction from that for the measurements with acetic acid or hydroxylamine buffers. However, it does not take account of the competing hydration reaction which equilibrates enol and hydrate at low concentrations of hydroxylamine. The concentration of hydroxylamine used in the equation was calculated as $K_a[NH_3OH^+]/[H^+]$ where K_a is the acid dissociation constant of NH_3OH^+.

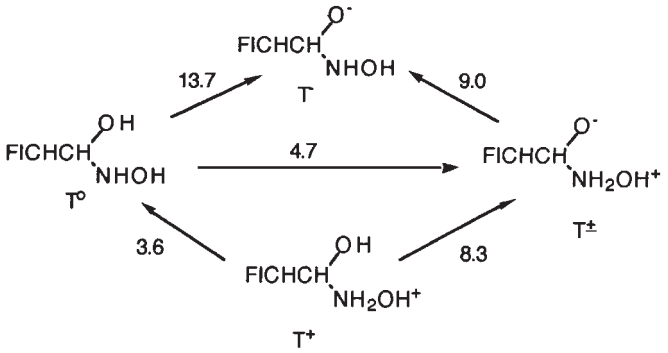
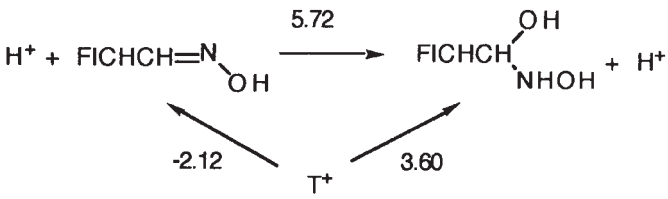
APPENDIX



Following Sayer and Jencks (40) and Guthrie (22), the set of rate and equilibrium constants for formation and hydrolysis of the oxime shown in Scheme 1 can be completed by estimating equilibrium constants for formation of cationic and zwitterionic forms of the carbinolamine adduct T^+ and $T^{\pm}$. As these estimates are of lower precision than measurements of rate and equilibrium constants in the body of the paper they are presented in an appendix.

The relationships between the carbinolamine adducts of 9-formylfluorene T°, T^-, T^+, and $T^{\pm}$ are summarized in Scheme 1. The pK_a for ionization of T° to T^- has already been estimated as 13.7. We can estimate a pK_a for conversion of T^+ to T° based on pK_a = 6.1 for $CH_3NH_2OH^+$ by correcting for the substituent effects of the OH group and fluorenyl group present in T^o (for which σ* = 1.31 and 0.41, respectively). Thus, if ρ* for the ionization of substituted methylamines is 1.4 (28), the required pK_a is calculated as 6.1 – (1.31 + 0.41) × 1.4 = 3.6.



To evaluate a pK_a for conversion of T^+ to $T^{\pm}$ we begin with Hine and Kokesh's (53) estimate of pK_a = 9.98 for the ionization of $MeNH_2^+CH_2OH$ to $MeNH_2^+CH_2O^-$ based on the measured ionization constant for $Me_3N^+CH_2OH$ of 9.33 (54). If we replace the methyl group on $MeNH_2^+CH_2OH$ by OH and presume that ρ* is the same as if NH_2^+ was replaced by CH_2, then from σ*= 0.62 and –0.1 for CH_3 and CH_2OH[28], we obtain pK_a = 9.98 – 1.45(0.62 – 0.1) = 8.85 for $HONH_2^+CH_2OH$. Finally, correcting for the substituent effect of the fluorenyl group, taking σ* = 0.41 for Ph_2CH as usual, we obtain pK_a = 8.85 – 1.45 × 0.41 = 8.25 for T^+. This allows completion of the cycle shown below (Scheme A1).

A noteworthy feature of this cycle is that the proton activating factor (PAF), i.e., effect of protonation of nitrogen upon ionization of the hydroxyl group (47) is given by log PAF = 5.4. This value is roughly consistent with other estimates of pK_as of tetrahedral intermediates for which log PAF values of 3.6 (22), 4.7 (40), 4.8 (31), and 5.3 (2, 22) have been recorded, including in particular the value 5.3 for the adduct of methylhydroxylamine and three substituted benzaldehydes (2). It seems likely that the greatest uncertainty in pKs in the cycle is ±0.5 log units.

Scheme A1.

Scheme A2.

If we combine the pK_a for conversion of T^+ to T° with the equilibrium constant between T° and the oxime, we obtain an effective ionization constant for conversion of T^+ to the oxime, pK_a^{eff} = 2.12, as shown in Scheme A2. This value is used to correct the experimentally measured value of –1.50 for conversion of the oxime to protonated oxime and T^+ to a pK_a = –1.62 for protonation specifically of the oxime.

The equilibrium constants of Scheme A1 can be used to derive rate constants for reaction of T^+ in the hydrolysis of the oxime from the measurements of $k_{-2}K^{\pm} = 1.4 \times 10^3$ and $k_{-3}/K^+ = 160$ based on the pH-profile of Fig. 2 and shown under eq. [2]. Thus the rate constant k_{-2} for expulsion of NH_2OH from T± is calculated as 2.8×10^8 and the corresponding reaction from T^+ is $k_{-3} = 4.0 \times 10^{-2}$ s^{-1}.

Preparation, X-ray structure, and dynamic solution behaviour of *N*,*N*′,*N*″-tris(2,6-diisopropylphenyl)-guanidine, and its reaction with molybdenum carbonyl

Robyn E. Boeré, René T. Boeré, Jason Masuda, and Gotthelf Wolmershäuser

Abstract: The reaction of *N*,*N*′-bis(2,6-diisopropylphenyl)carbodiimide with lithium 2,6-diisopropylanilide, quenching with water and recrystallization from heptane produces the symmetric guanidine $[DipNH]_2C{=}NDip$ which crystallizes in the triclinic system, space group $P\bar{1}$, a = 10.6513(11), b = 10.8997(11), c = 16.2961(17) Å, α = 80.524(12), β = 78.921(13), γ = 70.060(12)°, V = 1735.2(3) Å^3, Z = 2. The molecule crystallizes with three perpendicular 2,6-diisopropylphenyl groups, which surround and shield the central CN_3 unit, and provide (almost) three-fold symmetry around the central atom. Its dynamic solution behaviour has been studied by VT NMR between –90 and +180°C, and is consistent with three distinct barriers to N—C_{Ar} rotation. Preliminary estimates of the Gibbs free energy of activation for the lower two barriers are 56 ± 2 and 73 ± 2 kJ mol^{-1}. Reaction of the title compound with $Mo(CO)_6$ in refluxing *n*-heptane produces $[DipNH]_2C{=}NDip{\cdot}Mo(CO)_3$, a complex in which $Mo(CO)_3$ is η^6-coordinated to one of the diisopropylphenyl rings.

Key words: crystal structure, diisopropylaniline, guanidine, bulky ligands.

Résumé : La réaction du *N*,*N*′-bis(2,6-diisopropylphényl)carbodiimide avec le 2,6-diisopropylanilure, suivie d'un piégeage avec de l'eau et d'une recristallisation à partir de l'heptane permet d'isoler la guanidine symétrique $[DipNH]_2C{=}NDip$ qui cristallise dans le système triclinique, groupe d'espace $P\bar{1}$, avec a = 10,6513(11), b = 10,8997(11) et c = 16,2961(17) Å, α = 80,524(12), β = 78,921(13) et γ = 70,060(12)°, V = 1735,2(3) Å^3 et Z = 2. La molécule cristallise avec trois groupes 2,6-diisopropylphényles perpendiculaires qui entourent et protègent l'unité CN_3 centrale et qui assurent une symétrie pratiquement ternaire autour de l'atome central. On a étudié son comportement dynamique en solution à l'aide de la RMN à température variable entre –90 et 180°C et il est en accord avec trois barrières distinctes pour la rotation autour de la liaison N—C_{Ar}. Sur la base d'évaluations préliminaires, les énergies libres d'activation de Gibbs des deux barrières les plus faibles sont respectivement de 56 ± 2 et 73 ± 2 kJ mol^{-1}. La réaction des composés mentionnés dans le titre avec du $Mn(CO)_6$ dans l'heptane au reflux conduit à la formation de $[DipNH]_2C{=}NDip{\cdot}Mo(CO)_3$, un complexe dans lequel le $Mo(CO)_3$ est η^6-coordiné à l'un des noyaux diisopropylphényles.

Mots clés : structure cristalline, diisopropylaniline, guanidine, ligands encombrants.

[Traduit par la Rédaction]

Introduction

We have recently reported the synthesis of a series of superamidines (**1**) and their molybdenum carbonyl adducts (**2**) (1, 2), which contain the sterically demanding 2,6-diisopropylphenyl (Dip) substituent on nitrogen. The reactions of carbodiimides with nucleophiles is a well-established organic synthetic route for the preparation of amidines, and in particular for amidinate anions used in coordination chemistry (3), and we are interested in exploring this route to amidines and related compounds bearing Dip substituents using the known *N*,*N*′-bis-(2,6-diisopropylphenyl)carbodiimide.

There is currently a strong interest in the use of guanidines (4) and guanidinate anions (5, 6) as ligands in coordination chemistry. Symmetrically trisubstituted guanidines are the nitrogen analogues of carbonic acid. In this work we report on the preparation of a guanidine (**3**) with a Dip substituent on all three nitrogen atoms using the carbodiimide route. Thermal reaction of the guanidine with $Mo(CO)_6$ leads to a single product (**4**) in which $Mo(CO)_3$ is coordinated in an η^6 fashion by one of the Dip groups, which is the dominant reaction previously observed for Dip-substituted amidines (1, 2).

Fig. 1. ORTEP diagram (50% probability) of the structure of **3** as found by X-ray crystallography, with the atom numbering scheme. Hydrogen atoms on carbon are omitted for clarity. The occupancy of H(1) is 30%, and of H(2) 70%.

Results and discussion

Synthesis and structure of 3

Bis-(2,6-diisopropylphenyl)carbodiimide was prepared from *N*,*N*′-2,6-diisopropylphenylisocyanate according to a literature method (7). Attempts to prepare the guanidine by direct addition of the carbodiimide with 2,6-disopropyl aniline in refluxing toluene or xylenes failed, although this is precisely how *N*,*N*′,*N*″-triphenylguanidine is prepared (5). However, when the lithium anilide is prepared in situ in THF (rxn. [1]), it reacts quantitatively with the carbodiimide (rxn. [2]), to provide, after quenching, the desired guanidine (rxn. [3]).

[1] $DipNH_2 + n\text{BuLi} \rightarrow DipNH^-Li^+ + n\text{BuH}$

[2] $DipNH^-Li^+ + DipN{=}C{=}NDip \rightarrow [DipN]_2CNHDip^-Li^+$

[3] $[DipN]_2CNHDip^-Li^+ + H_2O \rightarrow [DipNH]_2C{=}NDip + LiOH$

The guanidine **3** is easily purified by recrystallization from acetonitrile, which removes coloured impurities. Since these crystals tend to retain solvent, we performed a second recrystallization from *n*-heptane to give solvent-free colourless crystals that have been fully characterized by elemental analysis, mass spectrometry, and solution NMR.

The structure of **3** has been determined in the solid state by X-ray diffraction (Figs. 1 and 2, Tables 1 and 2). The side view of the structure shown in Fig. 1 is particularly instructive, showing the three Dip groups arranged almost perpendicular to the planar central CN_3 unit. A similarly rotated aryl group disposition was observed previously in the structure of 2-(2,6-dichlorophenyl)-1-methylguanidine, and seems to be a feature of *ortho*-disubstituted aryl amidine or guanidine derivatives (8). Figure 2 shows the central triazamethane unit in **3** with directly attached atoms. Noteworthy is the similarity of all the C—N distances [from 1.316(2) to 1.357(2) Å]. A representative C=N bond distance has been established as 1.283(3) Å (9), and a value close to this has been obtained for the neutral guanidine (*E*)-*N*,*N*′-dicyclohexyl-4-morpholinecarboxamidine for which the C=N distance was measured as 1.276(3) Å (10). The related C—N single bonds in the latter guanidine were measured as 1.414(2) and 1.381(2) Å. Häfelinger and Kuske (11) have defined the parameter $\Delta_{CN} = d(C{-}N) - d(C{=}N)$ for the central N-C-N linkage found in all amidines (including guanidines). We have previously found that two almost identical Dip-substituted amidine structures, (**1**, R = 4-$CH_3C_6H_4$ and R = 4-$CH_3OC_6H_4$) possessed the very different Δ_{CN} values of 0.027(6) and 0.057(3) (1). In the former case, i.e., where the difference in interatomic distance in the supposed "double" and "single" bonds was very small, we were able to detect the presence of two N—H hydrogen atom positions, and refined a disorder model with 72 and 28% occupancy of the two structures. We propose that a similar positional disorder is operative in the crystal structure of **3**, for which $\Delta_{CN} = 0.032(6)$ Å. Indeed, peaks corresponding

Fig. 2. ORTEP diagram of the central triazamethane fragment in **3** with directly attached atoms. The disordered H atoms were located on a difference Fourier map, and correspond to positional disorder in the crystal packing of the molecule.

to the three N—H hydrogen atom locations were observed on a difference Fourier map, and their occupancies were allowed to vary. Convergence was achieved with H(3) as 100, H(2) 70, and H(1) 30%. In a structure so large we do not put a great deal of weight in the refinement of these occupancies, and our disorder model is based primarily on the metric parameters. As Fig. 2 clearly shows, the atoms in the triazamethane fragment are well-defined with almost spherical thermal ellipsoids.

Tautomeric disorder was postulated (without location of the H atoms) in the 2-(2,6-dichlorophenyl)-1-methylguanidine mentioned above (8). In this system, the three C···N distances are 1.364(5), 1.339(4), and 1.308(4) Å, only a slightly larger range than that found in the structure of **3**. These authors conclude only that the tautomer that identifies the 1.308(4) Å distance as the C=N bond "is predominant." In **3**, unlike our previously determined amidine structure (**1**, R = 4-$CH_3C_6H_4$) (1), the tautomeric forms are degenerate, and the apparent bond length averaging can be achieved by simple positional disorder in the crystal packing, as shown in the following graphic:

What these results emphasize is that the large Dip groups dominate the crystal packing and small variations in position of the remaining atoms can be tolerated with little cost to the lattice energy.

Scheme 1.

Reaction of 3 with $Mo(CO)_6$

The reaction of **3** with $Mo(CO)_6$ in refluxing *n*-heptane, conditions that were identical to our previous reactions of superamidines with molybdenum carbonyl (1, 2), resulted in a slow reaction that deposited yellow crystalline solid at the reflux temperature. Careful cooling of the solution resulted in the formation of essentially pure **4**, which has been characterized by solution IR, NMR and mass spectroscopies, and combustion analysis. The similarity in the NMR and IR spectroscopic parameters with those observed previously for type **2** complexes strongly suggests that the metal is coordinated in an η^6 fashion to the aromatic ring of one of the Dip groups. A parent ion for the complex is observed in the high-resolution mass spectrum. In the ^{1}H NMR spectrum, the aromatic C—H signals of *one* of the three Dip rings (a pseudo doublet and a pseudo triplet) are shifted ~1.5 ppm upfield as a consequence of π-coordination to the molybdenum atom. One of the two N—H signals is shifted ~2 ppm downfield (as observed for **2**), while the other retains a chemical shift similar to that in free **3**. The ν(C≡O) bands in the solution IR spectra are diagnostic of a "piano stool" coordination geometry for the $Mo(CO)_3$ group. Almost certainly it is the *imino* Dip group that attaches to the metal, as seen in all the superamidine complexes. Moreover, among the three X-ray structures previously determined for type **2** complexes, the ligand environment is extremely similar, and we note that this same arrangement can be obtained in **4** with the ligand in the conformation obtained for **3** in the solid state. This proposed structure is indicated in Scheme 1.

If we compare the solution IR data of **4** with those of **2** (Table 3), a distinct pattern emerges (1, 2). The electron withdrawing CF_3 group in **2** (R = CF_3) despite being three bonds removed from the diisopropylphenyl ring, nevertheless reduces the electron density at the ring. This leads to weaker back-bonding to Mo, and hence to about 5 cm^{-1} higher ν(C≡O) frequencies than in the methyl- and aryl-substituted amidine complexes **2** (R ≠ CF_3). In **4**, where an electron-donating DipNH group is attached to the amidine backbone, the ν(C≡O) frequencies are about 3 cm^{-1} lower in energy than in the methyl- and aryl-substituted amidine complexes **2** (R ≠ CF_3) consistent with stronger back-bonding by a more electron-rich aromatic ring.

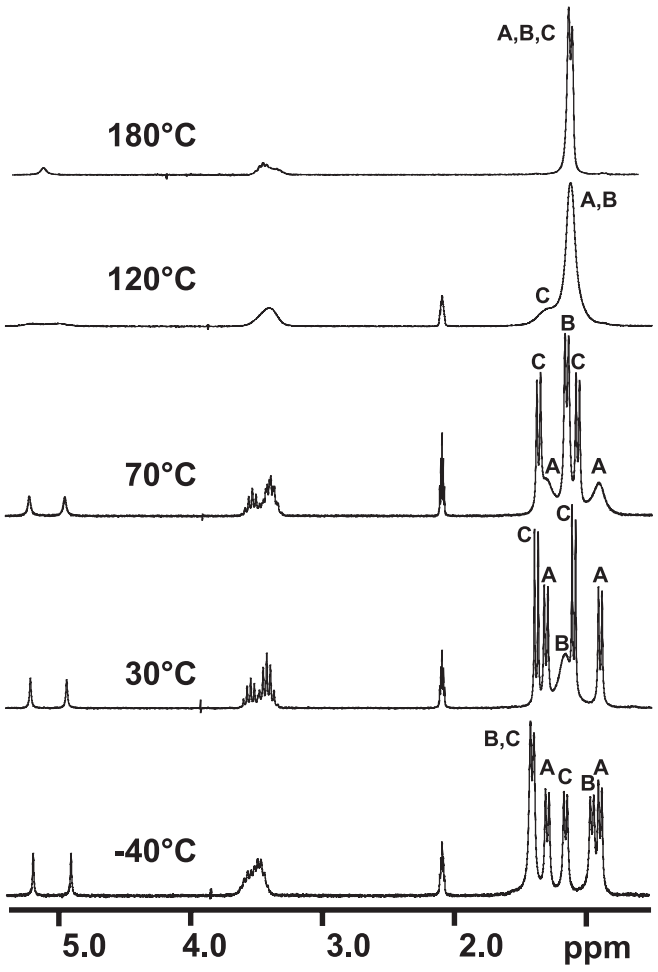
[a] *n*-Heptane solution in 0.2 mm NaCl solution cell.
[b] $CHCl_3$ solution in 0.2 mm NaCl solution cell; these weak bands are not observed in *n*-heptane because of limited solubility of the complexes.



The large difference in NH environments observed for **4** in the NMR spectrum (δ 5.06 and 7.28) is also seen in solution IR spectra. Thus there is a broad band at 3272 cm^{-1} quite similar to the NH bands found in **2**, but there remains a sharp NH stretch at 3403 cm^{-1} for the additional DipNH group. In summary, the spectroscopic evidence for similarity with the previously characterized superamidine adducts strongly supports the proposed structure of **4** shown in Scheme 1.

Dynamic processes in solution

The room temperature ^1H NMR spectra of both the guanidine **3** and its metal complex **4** contain exchange-broadened signals as well as many sharp peaks. The room temperature ^{13}C spectrum of **3** also contains exchange-broadened peaks. Thus, there is some sort of dynamic process operative in both the guanidine and its complex with $Mo(CO)_3$. In this respect, the Dip-substituted guanidine differs from the Dip-substituted amidines **1** and their metal complexes **2**. The predominant isomers of **1** and the sole isomers of **2** have sharp, nonexchanging room temperature NMR signals. We have undertaken a preliminary VT-NMR study of the ^1H NMR spectra of **3** to try and sort out the complexities in the spectra. No attempt has been made to analyze the VT ^{13}C spectra of this compound; the RT spectrum is reported in the experimental section. Metal complex **4** is far too unstable in $CDCl_3$ solution to allow for VT-NMR studies.

The room temperature ^1H NMR spectrum of **3** in $CDCl_3$ solution as reported in the experimental section, or in $CD_3C_6D_5$ as shown in Fig. 3 at 30°C, is quite complex. Two very distinct NH proton signals, each integrating to one, are observed at δ 5.00 and 4.76. The isopropyl CH protons occur as three different septets, two of which have almost coincident chemical shifts, upfield of the remaining set. The most unusual feature is the isopropyl CH_3 protons, which exist as four sharp doublets in a 1:1:1:1 ratio, as well as a large exchange-broadened singlet between the inner two sharp doublets. These data strongly suggest that **3** exists in solution as a single isomer in which some sort of internal exchange is occurring that is slow on the NMR timescale. The NMR parameters of **3** closely resemble the predominant *Z-anti* isomer found for **1** (this conformation is that drawn in Scheme 1). This is the predominant solid-state form when H-bonding is not involved, as well as the lowest energy isomer by gas-phase computation (AM1 method) (1). Moreover, this is the geometry uniquely adopted by the $Mo(CO)_3$ adducts **2** in the solid-state and in solution (1, 2). Indeed, the solid-state structure of **3** can be considered as an amidine in the *Z-anti* geometry, with an additional DipNH group attached as the "R" group on the C atom of the backbone.

Fig. 3. NMR spectra of **3** at various temperatures (–40°C to +120°C in $CD_3C_6D_5$, 180°C in 1,2-$Cl_2C_6H_4$). Spectra were monitored at 10 degree intervals, and in the intervening spectra to those displayed here, smooth transitions between the peaks were observed.

© 2000 NRC Canada

Our VT-NMR spectroscopic study was conducted in a variety of solvents, namely CD_2Cl_2 and $CDCl_3$ for the low-temperature range, $CD_3C_6D_5$ for the intermediate, and 1,2-$Cl_2C_6H_4$ for the high-temperature range. There is indeed some solvent dependence of the chemical shifts of the signals, but the general process seems to be the same, and is clearly of an intramolecular nature. The solvent that covers the widest temperature range is $CD_3C_6D_5$. We independently checked the low-temperature range of this solvent by using the less viscous deuterated halocarbons, and find that essentially the same effects occur in all solvents studied. For simplicity we discuss the dynamic NMR behaviour using the data collected in $CD_3C_6D_5$ (except at the highest temperatures beyond the boiling point of this solvent, where 1,2-$Cl_2C_6H_4$ is used.)

Consider the representative NMR spectra presented in Fig. 3. At –40°C, rotational exchange of the Dip groups is frozen out, and in $CD_3C_6D_5$ solution there are five sharp methyl doublets in 2:1:1:1:1 ratio corresponding to two sets of two symmetry equivalent methyl groups of the imino Dip groups labeled "C" in the figure (δ 1.15 and 1.41), as well as two sets of two for each of the *amino* Dip groups, labeled "A" (δ 0.89 and 1.29) and "B" (δ 0.95 and 1.41). These data are consistent with three different Dip environments and a single plane of symmetry in the molecule, as seen in the solid-state structure. The shift equivalence of the deshielded B and C resonances is accidental (in CD_2Cl_2 their shifts are different). We note also that over the temperature range –90 to +80°C, the NH resonances remain sharp and distinct, with remarkably temperature-independent chemical shifts. This also agrees with the structure of **3** shown in Fig. 1 in which there are two different kinds of NH environments [i.e., H(2) and H(3)], and supports the notion that there is only a single geometrical isomer in solution over the whole temperature range that we have studied. There are of course several possible conformations that **3** may adopt in solution. We have modeled several of these by gas-phase AM1 calculations, and find that the geometry found in our crystal structure is indeed the lowest energy isomer we could find, lying 26.5 kJ mol^{-1} below the next higher form. Since this structure is fully consistent with the dynamic NMR data we will for the sake of argument consider this to be the isomer in solution, though we recognize that the actual solution geometry has not been proven.

Rotation of an amino Dip group exchanges the "inner" and "outer" methyl groups of the ^{i}Pr substituents, which appear to possess quite distinct shielding environments. On warming to 30°C, the two doublets labeled B have coalesced to a broad singlet at δ 1.15, indicating slow rotation of a single amino Dip group. This leaves four sharp doublets labeled A and C now in a 1:1:1:1 ratio for the shielded and deshielded methyl groups of the remaining amino and imino Dip groups, respectively. Spectra were obtained at 10 deg. intervals, and the changes in peak intensities and locations between the selected spectra presented in Fig. 2 underwent smooth transitions in the intermediate stages. At 70°C the coalesced signal B has grown into a sharp doublet at δ 1.14 (effectively the average of the two separate signals at –40°C) due to the four methyl groups on the rapidly rotating Dip substituent, while the second amino Dip CH_3 signals have collapsed into two exchange-broadened singlets labeled A. The two doublets C remain sharp, which we assign to the more rigid imino ring. Thus there are again five different CH_3 environments, integrating in a 1:1:2:1:1 ratio. At 120°C, line broadening of the NH signals to produce two extremely broad lines has (finally) set in, indicating the onset of slow NH tautomerism. This exchange process interconverts the amino and imino Dip sites, breaking down the rigidity of the latter. Now wholesale exchange of all the CH_3 *and* the CH environments sets in, the latter signals having remained sharp at lower temperatures, and all resonances are either coalesced or almost coalesced. Finally, at 180°C, NH tautomerism and rotation of the Dip groups are all fast on the NMR time-scale, and a simple high-symmetry spectrum containing a single Dip environment occurs. These changes are also reflected in the aromatic region, but we have not interpreted the observed patterns in detail; they are partly obscured by the residual toluene signals, and have thus been omitted from Fig. 3 for the sake of clarity.

An important piece of additional evidence for the interpretation of the dynamic phenomena put forth above for **3** is the RT spectrum in $CDCl_3$ of the metal complex **4**. The NMR signals that are sharp are virtually identical to those obtained for the two Dip groups of the type **2** amidine complexes, i.e., a coordinated imino and an uncoordinated amino group (1, 2). The CH_3 resonances of the third DipNH group are exchange-broadened at RT. This suggests that one amino DipNH group is undergoing slow rotation on the NMR time-scale, while the other is not, and that it must be the DipNH group on the amidine backbone that is dynamic. Sample instability has prevented us from performing the same kind of VT studies with **4** that were done with **3**. Ligand fluxionallity in a Pt{COD} complex of the dianion of *N*,*N*′,*N*″-triphenylguanidine has recently been reported, but the mechanism of intramolecular motion in this complex is not directly comparable to that observed in **4** (6).

A preliminary estimate of the activation energies for some of these dynamic processes can be obtained from the half-height line widths of the NMR signals at the coalescence temperature, using the classical expression of Gutowsky and Holm (12). Eyring absolute rate theory (13) leads to a value of $\Delta G^{\ddagger} = 56 \pm 2$ kJ mol^{-1} for the interconversion of the A set of signals, which we have attributed to the rotation of one of the Dip groups about an N—C_{Ar} bond. Similarly, $\Delta G^{\ddagger} = 73 \pm 2$ kJ mol^{-1} for the interconversion of the B set of signals. The final process that interconverts A, B, and C signals at the highest temperature is too complex to analyze by simple coalescence-point measurement. Although a full understanding of the dynamic processes that operate in **3** will require complete line-shape analysis and spectral simulation, we note that similar free energies of activation have been measured for hindered rotation about P—C_{Ar} bonds bearing the related bulky supermesityl substituent. Thus in Mes*P=C=PMes*, $\Delta G^{\ddagger} = 59 \pm 1$ kJ mol^{-1} (14), while in Mes*As=C=PMes*, $\Delta G^{\ddagger} = 57$ kJ mol^{-1} (15).

In conclusion, an *N*,*N*′,*N*″-trisubstituted guanidine bearing super-bulky Dip substituents has been prepared by the carbodiimide route, and shows interesting conformational effects due to hindered rotation in solution as shown by NMR spectroscopy. It forms a piano stool complex with $Mo(CO)_3$, in which the imino aryl ring acts as a six-electron donor to the organometallic fragment.

Experimental section

Starting materials and general procedures

All experimental procedures were performed under a nitrogen atmosphere using modified Schlenk techniques. 2,6-Diisopropylaniline and *n*-butyllithium (Aldrich) were commercial products and used as received. Bis-2,6-diisopropylphenylcarbodiimide was prepared using the published procedure (7). Solvents were reagent grade, or better, and were used as received (acetonitrile) or dried and distilled under a nitrogen atmosphere from $LiAlH_4$ (*n*-heptane) and sodium–benzophenone (tetrahydrofuran). ^1H and ^{13}C NMR spectra were recorded on a Bruker AC250/Tecmag Macspect spectrometer operating at 250.13 and 62.90 MHz, respectively. The ^1H and ^{13}C chemical shifts δ (ppm) for $CDCl_3$ solutions are referenced to TMS, while $CD_3C_6D_5$ solutions were referenced to the residual CHD_2 signal at δ 2.09. VT-NMR spectra were recorded using the Bruker VT accessory, and temperatures are considered accurate to ±2° below RT and ±1° above RT. IR spectra were recorded on a Bomem MB-100 spectrometer as KBr pressed pellets (solids) or in NaCl solution cells. Mass spectra were undertaken in the Department of Chemistry, University of Alberta and elemental analyses by MHW Laboratories, Phoenix, AZ.

Preparation of *N,N′,N″*-tris(2,6-diisopropylphenyl)guanidine (3)

A solution of 0.495 g (2.75 mmol) 2,6-diisopropylaniline in 10 mL of anhyd THF was treated with 3.03 mmol of 2.25 M *n*BuLi in hexanes at 0°C, and stirred for an additional 20 min at the same temperature. After warming to RT, 1.00 g (2.75 mmol) of *N,N′*-bis(2,6-diisopropylphenyl)carbodiimide in 6 mL of THF was added dropwise to the orange solution, whereupon the mixture was refluxed for 2 h. After cooling to RT, 1 mL H_2O was added, the mixture dried with anhyd $MgSO_4$ and evaporated to dryness. Crystallization from CH_3CN afforded 1.05 g (1.94 mmol, 70.5% yield) of **3**, mp 261–262°C. Additional product could be won from the mother liquor, but this tended to be slightly discoloured. Analytical material and data crystals were obtained by recrystallization from *n*-heptane. MS (70 eV): *m/z* 539.42351 (M^+ within 0.8 ppm, 100%), 524 ($M - CH_3^+$, 8%); 496 ($M - {}^iPr^+$, 92%). IR (KBr) cm^{-1}: ν(N-H) 3407, 3398; ν(C=N) 1646. ^1H NMR ($CDCl_3$): δ 0.98 (d, *J*(H-H) = 6.8 Hz, 12H), 1.09 (br s, 12H), 1.31 (d, *J*(H-H) = 6.8 Hz, 6H), 1.36 (d, *J*(H-H) = 6.8 Hz, 6H), 3.26 (sept, *J*(H-H) = 6.8 Hz, 2H), 3.31 (sept, *J*(H-H) = 6.8 Hz, 2H), 3.46 (sept, *J*(H-H) = 6.8 Hz, 2H), 4.77 (s, 1 H), 5.00 (s, 1 H), 6.93–7.30 (m, 9H). ^{13}C NMR δ: 22.55, 23.00, 24.31 (br), 24.88, 26.04, 28.66, 28.80, 28.89, 122.54, 123.07, 124.09, 127.30, 128.76, 132.47, 133.92, 141.15, 144.15, 145.63, 147.09, 147.92. Anal. calcd. for $C_{37}H_{53}N_3$ (539.9): C 82.32, H 9.90, N 7.78%; found: C 82.12, H 9.89, N 7.93%.

Preparation of *N,N′N″*-tris(2,6-diisopropylphenyl)guanidinotricarbonylmolybdenum(0) (4)

A mixture of **3** (0.482 g, 0.895 mmol) and $Mo(CO)_6$ (0.236 g, 0.895 mmol) was heated in *n*-heptane (24 mL) to reflux. After 18 h, a solid precipitate formed. On cooling, the solid was filtered off, and recrystallized from a minimum quantity of boiling heptane, hot filtering, and cooling to –35°C to give small, bright yellow crystals of **4** which were analytically pure. Yield: 0.17 g, (0.24 mmol, 26%), mp 210°C dec. ^1H NMR ($CDCl_3$) δ: 0.91 (d, *J*(H-H) = 6.8 Hz, 6H), 1.1 (br s, 12H), 1.20 (d, *J*(H-H) = 6.8 Hz, 6H), 1.29 (d, *J*(H-H) = 6.8 Hz, 6H), 1.39 (d, *J*(H-H) = 6.8 Hz, 6H), 2.87 (sept, *J*(H-H) = 6.8 Hz, 2H), 3.11 (sept, *J*(H-H) = 6.8 Hz, 2H), 3.49 (sept, *J*(H-H) = 6.8 Hz, 2H), 5.06 (s, 1 H), 5.50 (d, *J*(H-H) = 6 Hz, 2 H), 5.77 (t, *J*(H-H) = 6 Hz), 1 H), 7.06–7.37 (m, 6H), 7.28 (s, 1 H). ^{13}C NMR spectrum not obtained due to sample instability. MS (70 eV) reported on ^{98}Mo isotopomers: *m/z* 721.31377 (M^+ within 1.8 ppm, 2%), 635.31446 ($M - 3CO - 2H^+$ within 0.2 ppm, 17%); 539 (ligand$^+$, 62%), 496 (ligand–$^iPr^+$, 100%). IR (KBr) (cm^{-1}): ν(N-H) 3400, 3252 br; ν(C≡O) 1952, 1882, 1833; ν(C=N) 1635. Anal. calcd. for $C_{40}H_{53}MoN_3O_3$ (719.83): C 66.74, H 7.42, N 5.84%; found: C 67.00, H 7.16, N 5.95%.

X-ray analysis

The crystal structure of **3** was determined using a Stoe IPDS diffractometer. 277 Frames with an angle increment of 1.3° were measured. Therefore the full φ range of 360° was covered and each reflection was thus measured twice. Experimental details are summarized in Table 1. The structure was solved by direct methods using SHELXS-97 (16) and refined by full-matrix least-squares on F^2 using SHELXL-97 (17) using all reflections. The non-hydrogen atoms were refined anisotropically, and although most of the H atoms on C were located on the difference map, they were refined using a riding model (C—H = 0.95 Å). For CH_3 groups, a geometrically fixed trigonal pyramidal unit was fitted to the electron density for H by refining a torsion angle that defined the rotation of the group on the C—C bond (a standard procedure in SHELXL). The H atoms attached to N were refined freely. Isotropic *U* values were bound to 1.2 times the *U* values of the corresponding N atoms. Disorder is encountered with respect to the position of one such H atom. The disorder ratio was freely refined (the sum was fixed to 1). The refinement converged with occupancy of 0.3 for the hydrogen attached to N(1) and 0.7 for N(2). Crystallographic data (excluding structure factors) for the structures in this paper have been deposited.[2]

Electronic structure calculations

All calculations were performed using the AM1 method as implemented in HyperChem 5.1 running on a Pentium III computer under Windows NT 4.0 (18).

[2] A detailed structure report including atom positions and the anisotropic temperature factors has been deposited. Copies of materials on deposit may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON, Canada K1A 0S2 (http://www.nrc.ca/cisti/irm/unpub_e.shtml for information on ordering electronically). Crystal data, atomic coordinates, bond lengths and angles, and hydrogen coordinates of the structure(s) reported in this paper have been deposited with the Cambridge Crystallographic Data Centre. Copies of the data can be obtained, free of charge, on application to the Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, U.K. (Fax: 44-1223-336033 or e-mail: deposit@ccdc.cam.ac.uk).

Synthesis and characterization of two new "pincer" complexes of zinc(II). The X-ray crystal structures of the five coordinate complexes [$ZnCl_2$\{η^3-*NN′N*-2,6-$(R_2NCH_2)_2C_5H_3N$\}] (R = *n*-Bu or Me)

Ignacio del Río, Robert A. Gossage, Milja S. Hannu, Martin Lutz, Anthony L. Spek, and Gerard van Koten

Abstract: The potentially terdentate *NN′N* donor ligand 2,6-bis[di-(*n*-butyl)aminomethyl]pyridine (**1**) does not form a stable, isolable Ru complex using any standard Ru starting materials. This is in contrast to the dimethylamino derivative **2**. In the presence of Zn metal as a reducing agent, the treatment of hydrated ruthenium trichloride with **2** leads instead to the isolation of a diamagnetic Zn(II) complex (**3**) of general formula [$ZnCl_2$(**1**)]. Analysis of **3** (NMR, X-ray) reveals the complex to be a mononuclear Zn halide compound containing ligand **1** in an η^3-*NN′N* bonding motif. The Zn atom is found to be five-coordinate and in a geometry best described as midway between trigonal bipyramidal and square pyramidal in structure. Similar experiments using **2** produce an analogous Zn species (**4**) which has likewise been fully characterized (NMR, X-ray) and found to be similar to **3** although the metal is in a distinctly square pyramidal environment. These compounds are viewed as relatives of the class of Zn "pybox" catalysts.

Key words: pincer complexes, zinc(II) compounds, X-ray crystal structure.

Résumé : Lorsqu'on le met en présence de dérivés du ruthénium appropriés, le ligand donneur, potentiellement terdentate *NN′N*, 2,6-bis[di(butyl)aminométhyl]pyridine (**1**) ne forme aucun complexe stable ou isolable du Ru. Ceci est en opposition avec le comportement du dérivé diméthylamino, **2**. En présence de Zn métallique comme agent de réduction, le traitement du trichlorure de ruthénium hydraté avec du produit **2** conduit plutôt à un complexe diamagnétique de Zn(II), de formule générale [$ZnCl_2$(**1**)] que l'on peut isoler. L'analyse de ce complexe (**3**) par RMN et diffraction des rayons X indique que le complexe est un composé mononucléaire d'halogénure de zinc contenant un ligand **1** dans un motif de liaison η^3-*NN′N*. On a observé que le zinc est pentacoordonné et qu'une structure intermédiaire entre une bipyramide trigonale et une pyramide à base carrée est la meilleure façon de décrire sa géométrie. Des expériences semblables avec le complexe **2** conduisent à la formation d'une espèce analogue contenant du zinc (**4**) que l'on a aussi caractérisée par RMN et diffraction des rayons X; on a trouvé que ce complexe est semblable à **3**, même si le métal se trouve dans un environnement à pyramide à base carrée bien caractérisée. On considère que ces composés sont apparentés aux catalyseurs de la classe « pybox ».

Mots clés : complexes en forme de pince, composés du Zn(II), structure cristalline par diffraction des rayons X.

Introduction

The use of multidentate ligands in the stabilization of transition metal fragments is an important aspect of modern inorganic and organometallic synthesis. Of the large number of ligands that are currently known, the group of potentially terdentate ligands referred to as the "pincer" class of ligands (Fig. 1) has been yielding a rich body of interesting and novel chemistry (1). In particular, pincer complexes of the platinum group metals have been used in a number of diverse applications which include molecular sensor technology (1, 2) and in the modelling of reaction intermediates (1, 3). Several other properties, many of which have direct industrial relevance, have also been reported for metal complexes containing a pincer ligand. These aspects include a number of catalytic organic transformations involving C—C (4), C—N (5), and C—halogen bond formation (6), in addition to the polymerization of activated olefins via ROMP[3] or ATRP[4]. One of our areas of interest revolves around the inorganic chemistry of Ru containing a neutral, potentially terdentate *NN′N*-donor ligand derived from 2,6-bis(aminomethyl)pyridine (**1**: R = *n*-Bu; **2**: R = Me, Fig. 1). We have previously shown that **2** can be used to produce a number of useful Ru containing starting materials and reagents for the catalytic and stoichiometric activation of a variety of substrates including olefins, amines, and sulphur containing compounds (5, 7–10). We wished to expand our investigations to include Ru pincer complexes containing **1**. However, our attempts to coordinate this particular pincer ligand to a Ru metal centre have instead led to the isolation of a new *NN′N* complex of Zn(II). The incorporation of a Zn metal atom was the result of a failed attempt to produce a reactive source of Ru(II) (i.e., Ru(III) reduced via Zn) in situ in the presence of **1**. From this result, we have expanded this Zn chemistry and have fully characterized (NMR, X-ray) two novel Zn complexes, incorporating ligands **1** or **2**. In contrast to the plenitude of work involving platinum group metal pincer compounds (1–3, 5–9), relatively little is known about the Group XII transition metal chemistry of these ligands (1). This work has obvious relevance to Zn pybox (Fig. 1) complexes and their derivatives (pybox = [2,6-bis{oxazolin-2-yl}pyridine]) (11*a*). Several halide and pseudohalide complexes of Zn(II) in the presence of a pybox ligand are known to be potent enantioselective catalysts (e.g., Diels–Alder, aldol reactions, etc.) (11*b*, 11*c*) and surmised to have the general formula [$ZnX_2(\eta^3$-*NN′N*-pybox)]. In addition, complexes of this general class have recently been used as models for hydrolytic metallo-enzymes (11*d*).

Fig. 1.

Experimental section

General

All synthetic manipulations were carried out under inert atmosphere (Schlenk) techniques. Solvents were dried and degassed by standard methods. Diethyl ether was predried with NaOH and distilled from sodium–benzophenone; halocarbons were distilled from CaH_2 and hydrocarbon solvents and tetrahydrofuran (THF) was distilled from sodium–benzophenone. NMR spectra (^{1}H, ^{13}C, and ^{31}P) were recorded on a Bruker AC-200 or AC-300 spectrometer at RT (RT = room temperature). Chemical shifts (^{1}H and ^{13}C) are reported in ppm referenced to external $SiMe_4$ ($\delta_{H\ or\ C}$ = 0.00) and coupling constants (*J*) are given in Hz. Elemental analyses were performed by Kolbe Microanalytisches Laboratorium, Mülheim, Germany. The compounds $[RuCl_2(PPh_3)_3]$ (12), $[RuCl_2(nbd)]_n$ (nbd = 1,5-norbornadiene) (13), and 2,6-bis(dimethylaminomethyl)pyridine (**2**) (14) were synthesized according to previously published procedures. All other reagents and solvents were used as received from commercial sources.

Synthesis of 2,6-bis(di-*n*-butylaminomethyl)pyridine (1)

A sample of HBr (0.210 L, 48% in water) was added dropwise to a precooled solution (0°C) of 2,6-pyridinedimethanol (15.99 g, 43.0 mmol) in 500 mL of acetic anhydride. After addition was complete, the flask was removed from the ice bath and the mixture stirred overnight at 100°C. The resulting brown solution was cooled again to 0°C and a white precipitate formed. The solid was filtered, washed with ethylacetate (2 × 50 mL), and then dried under reduced pressure to give 29.0 g (73%) of a white solid presumed to be the HBr salt of 2,6-bis(bromomethyl)pyridine. A 150 mL portion of di-*n*-butylamine was added to a 15.0 g (4.44 mmol) portion of the above salt suspended in 150 mL of benzene. The mixture was then heated to reflux temperature for 48 h. Pentane was then added to the resulting light brown suspension to precipitate any salts. The solid was removed by filtration and washed with ether (3 × 20 mL). Volatile components of the combined organic fractions were then removed under reduced pressure to give 10.9 g (69%) of **1** which was deemed to be of sufficient purity (>95%: NMR) for further use. ^{1}H NMR ($CDCl_3$): 7.45 (t, 1H, py-*H*,

[3] ROMP = Ring Opening Metathesis Polymerization (7*a*).
[4] ATRP = Atom Transfer Radical Polymerization (6*b*, 7*b*).

J = 7.6), 7.23 (d, 2H, py-*H*), 3.56 (s, 4H, CH_2), 2.37–2.32 (m, 8H, NCH_2), 1.38–1.29 (m, 8H, CH_2), 1.24–1.14 (m, 8H, CH_2), 0.77–0.72 (m, 12H, CH_3). ^{13}C NMR ($CDCl_3$): 160.1 (*o*-C, py), 136.4 (*m*-C, py), 120.5 (*p*-C, py), 60.9 (NCH_2), 54.3 (CH_2), 29.6 (CH_2), 20.7 (CH_2), 14.1 (CH_3).

Synthesis of [{η^3-*NN′N*-2,6-bis(di-*n*-butylaminomethyl)pyridine} zinc(II) chloride] (3)

Method A

A solution of hydrated ruthenium trichloride (0.35 g, 3.44 mmol) and **1** (1.64 g, 4.54 mmol) was dissolved in EtOH (25 mL) and heated to 40°C in the presence of excess Zn powder for a period of 48 h. The resulting black suspension was centrifuged, the green-brown layer was then removed, and a black solid portion was isolated. This material was dissolved in 30 mL of dichloromethane, filtered, and the solution concentrated to a volume of about 5–10 mL. Pentane (10 mL) was then added and the resulting precipitated solid was collected and dried in vacuo to afford crude **3** in the form of a brown-grey solid (1.51 g, 88%).

Method B

A solution of anhyd zinc dichloride (0.13 g, 0.95 mmol) and **1** in EtOH (25 mL) was stirred at RT for 12 h. The liquid layer was removed from the resulting white suspension and the remaining solid was then dried under reduced pressure. The white solid thus obtained was dissolved in 5 mL of dichloromethane and filtered. The resulting light grey solution was mixed with 10 mL of pentane to precipitate **3** in the form of a white solid (yield: 0.30 g, 57%). ^{1}H NMR ($CDCl_3$): 7.88 (t, 1H, py-*H*, *J* = 7.2), 7.27 (d, 2H, py-*H*), 3.86 (s, 4H, CH_2), 2.80–2.72 (m, 8H, NCH_2), 1.59–1.43 (m, 8H, CH_2), 1.33–1.15 (m, 8H, CH_2), 0.92–0.84 (m, 12H, CH_3). ^{13}C NMR ($CDCl_3$): 158.6 (*o*-C, py), 141.1 (*m*-C, py), 122.4 (*p*-C, py), 57.5 (NCH_2), 52.5 (CH_2), 26.0 (CH_2), 21.0 (CH_2), 14.3 (CH_3). Anal. calcd. for $C_{23}H_{43}N_3Cl_2Zn$ (497.89): C 55.48, H 8.71, N 8.44; found: C 55.39, H 8.65, N 8.39.

Synthesis of [{η^3-*NN′N*-2,6-bis(dimethylaminomethyl)pyridine} zinc(II) chloride] (4)

Method A

A solution of hydrated ruthenium trichloride (0.52 g, 5.12 mmol) and **2** (1.61 g, 8.33 mmol) was dissolved in EtOH (25 mL) and stirred at RT in the presence of excess Zn powder for a period of 12 h. The resulting black suspension was centrifuged, the brown-black layer was then removed and a black solid portion was isolated. This material was dissolved in 30 mL of dichloromethane, filtered, and the solution concentrated to a volume of about 5–10 mL. Pentane (10 mL) was then added and the resulting precipitated solid was collected and dried in vacuo to afford crude **4** in the form of a light yellow solid (0.31 g, 17%).

Method B

A solution of zinc dichloride (0.41 g, 3.0 mmol) and **2** in EtOH (25 mL) was stirred at RT for 12 h. The yellow liquid layer was removed from the resulting suspension and the remaining solid was then dried under reduced pressure. The white solid thus obtained was dissolved in 5 mL of dichloromethane and the yellow solution was filtered thereafter. The mixture was then treated with a 10 mL portion of pentane to precipitate **4** in the form of a white solid (yield: 0.37 g, 37%). ^{1}H NMR ($CDCl_3$): 7.92 (t, 1H, py-*H*, *J* = 7.9), 7.29 (d, 2H, py-*H*), 3.77 (s, 4H, CH_2), 2.49 (s, 12H, CH_3). ^{13}C NMR ($CDCl_3$): 155.5 (*o*-C, py), 141.5 (*m*-C, py), 122.8 (*p*-C, py), 65.2 (NCH_2), 46.5 (CH_3). Anal. calcd. for $C_{11}H_{19}N_3Cl_2Zn$ (329.57): C 40.09, H 5.81, N 12.75; found: C 40.15, H 5.75, N 12.66.

Crystal structure determinations

General

Intensities were measured on a Nonius Kappa CCD diffractometer with rotating anode (Mo-Kα, λ = 0.71073 Å) at a temperature of 150 K. The structures were solved with direct methods (SHELXS-97 (15)) and refined with the program SHELXL-97 (16) against F^2 of all reflections up to a resolution of $(\sin\theta/\lambda)_{max}$ = 0.65 Å^{-1}. Non-hydrogen atoms were refined freely with anisotropic displacement parameters, hydrogen atoms were refined freely with isotropic parameters. The drawings, calculations, and checking for higher symmetry were performed with the PLATON package (17).

Crystal structure determination of 3

Formula: $C_{23}H_{43}Cl_2N_3Zn$; fw = 497.87; colourless-brownish plate, 0.25 × 0.25 × 0.11 mm^3; monoclinic, *C*2/*c* (no. 15), *a* = 13.1705(1) Å, *b* = 9.1163(1) Å, *c* = 21.7754(2) Å, β = 92.0916(6)°, *V* = 2612.75(4) Å^3, *Z* = 4, ρ = 1.266 g cm^{-3}, analytical absorption correction (PLATON (17), μ = 1.158 mm^{-1}, 0.73–0.88 transmission). Results and discussion

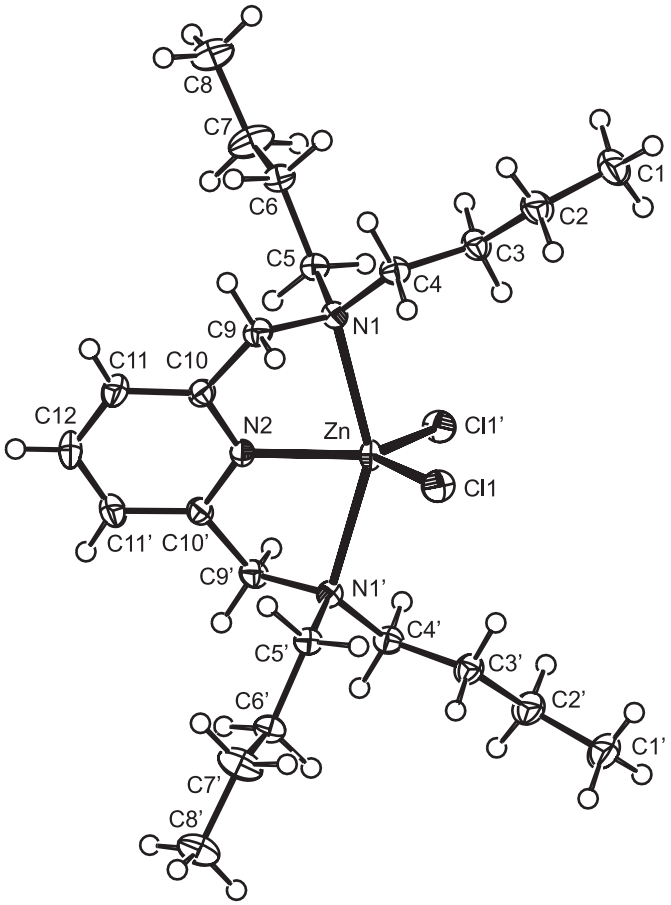
Our desire to use a Bu derivative of the *NN′N* ligand (i.e., **1**) was a direct consequence of the observation that several of our catalysts containing ligand **2** have low-solubility characteristics in organic solvents. Thus, derivative **1** was synthesized to evaluate its potential as a ligand for metal complexation where the resulting species will ideally present more favourable solubility properties. In addition, the trialkyl *N*-donor atoms of **1** are expected to have a stronger (Lewis) basic character when compared with the analogous *N*-atoms of **2**. Thus, one can evaluate the effect of increased ligand basicity on complexation behaviour, stability, and catalytic performance. Ligand **1** was produced according to a



© 2000 NRC Canada

modified version of a simple two-step procedure (18). The treatment of 2,6-pyridinedimethanol with aq HBr, followed by heating in the presence of excess $HNBu_2$, gives **1** in 51% overall yield (see Experimental section).

The typical synthesis of Ru complexes containing **2** involves the reaction of the ligand with 1 equiv of $[RuCl_2(PPh_3)_3]$ in a halocarbon solvent. However, the treatment of **1** with this Ru precursor (CH_2Cl_2 or $C_2H_4Cl_2$ as solvent) gave no reaction at RT (NMR). Heating of these mixtures to reflux temperature gave a complicated mixture of products (NMR) including both starting materials, free PPh_3, and a number of other phosphine containing complexes in an inseparable mixture. The use of a hydrocarbon solvent such as toluene gave only starting materials at both RT and upon addition of heat. We then attempted the use of the polymeric form of $[RuCl_2(nbd)]$ as the Ru starting material. Unfortunately, this also gave a complex mixture upon treatment with **1**, using either toluene or THF as solvent. Following these failures, we attempted the use of hydrated $RuCl_3$ as the source of Ru under reducing conditions (Zn metal in EtOH) in the presence of **1**. To our surprise, a new complex was formed which appeared to contain the reducing agent (i.e., Zn) and not a Ru metal centre. Elemental analysis indicated a formula which corresponds to $[ZnCl_2(\mathbf{1})]$ (i.e., **3**). Although the yield of **3** was low, heating of the mixture to 40°C gave **3** in over 88% isolated yield. Complex **3** can also be produced in moderate yield from anhyd zinc dichloride (EtOH, reflux, 12 h) in the absence of ruthenium halide source. The ^1H and ^{13}C NMR spectra of **3** indicates a high degree of molecular symmetry and the diamagnetic nature of this inorganic Zn complex. The ^1H NMR spectrum reveals a singlet resonance assigned to the benzylic methylene protons of the *NN′N* ligand fragment (δ_H = 3.86 ppm) and a corresponding ^{13}C resonance for the corresponding benzylic carbon (δ_C = 57.5 ppm). These results cannot distinguish between an η^3-*NN′N*, or η^1-N_{py} binding motif of **1** to the metal centre nor the possibility that a multinuclear complex has been formed.

Therefore, a single crystal X-ray structure determination of **3** was carried out to confidently assign the structural properties of this compound. A suitable crystal was obtained by the slow evaporation of a dichloromethane solution of the complex which had been layered by a blanket of pentane and THF. The solid-state molecular structure of **3** is depicted in Fig. 2. The list of relevant bond lengths and angles appears in Table 1. The coordination sphere around the Zn atom is best described as midway between trigonal bipyramidal (TBP) and square pyramidal (SQP) in structure. The τ-value for estimating the distortion from these two extremes was found to be 0.47 (the τ-values range from 1.0 for a true trigonal bipyramidal geometry to 0.0 for an idealized square pyramidal structure. See ref. 19). However, the compound is not on a true Berry pseudo-rotation pathway between these two ideal geometries. Thus, a numerical description such as the τ-value is very approximate (19). Since complex **3** has an exact C_2 symmetry plane in the solid-state, the Zn atom is in the plane formed by the three N atoms. The bond lengths between the metal and the N and halogen ligands are typical for a complex that is formally Zn(II) and can be compared with that of other Zn complexes containing the 3N-2X (X = halogen or pseudo-

Fig. 2. Representation of the solid-state structure of **3**.

halogen) ligand set. These include such complexes as $[ZnCl_2(\eta^3\text{-terpy})]$ (terpy = 2:6,2′,2″-terpyrdine) (20*a*) and others (crystallographically characterized examples of the general formula $[ZnX_2(\eta^3\text{-}NN'N'')]$ can be found in ref. 20*b*–20*j*; for a discussion of the bond length properties of coordination complexes, including Zn(II) compounds, see ref. 21; for a general discussion on the coordination properties of zinc(II) ions see ref. 22). Complex **3** may also be viewed as an analogue of compounds having the general formula $[ZnX_2(\eta^3\text{-pybox})]$. Such complexes have recently found application in a variety of Lewis acid-catalyzed asymmetric organic transformations including Diels–Alder reactions (11*b*), aldol (Mukaiyama) reactions (11*b*), and for the enantioselective addition of enol silanes to ketomalonate (11*c*).

The robust nature of **3** was demonstrated by the following experiments. No reaction was observed (NMR) when a solution of **3** was heated to reflux temperature under a nitrogen atmosphere in a CCl_4 (12 h), acetonitrile (12 h), benzene (48 h), or toluene (48 h) solution. No spectral changes were observed when a RT solution of **3** is treated with a basic trialkyl phosphine (e.g., PMe_3) or a phosphite (e.g., $P[OMe]_3$), even in the presence of excess $AgBF_4$. However, treatment of **3** with an ether solution of HCl resulted in some decomposition of the material (a black precipitate was noted). Compound **3** was also found to be unstable to the presence

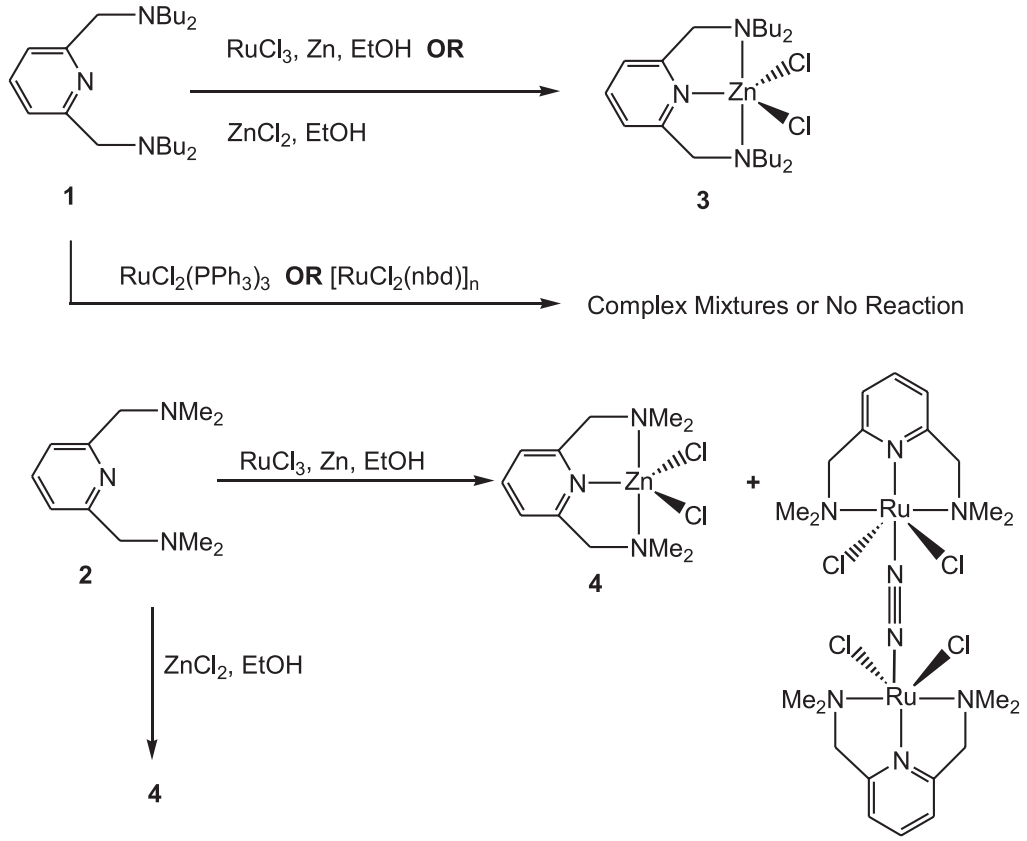
of sulphur dioxide or phenylacetylene[5] when a silver salt was present ($AgBF_4$ or AgOTf). Under these conditions, the bis HX salt (X = BF_4 or OTf) of ligand **1** can be isolated from the reaction mixture[6].

Despite our failure to produce the desired Ru complexes by the above route, we were intrigued as to the possibility of forming the related Zn(II) complex using the prototypical *NN′*N ligand **2** described earlier. Thus, treatment of a solution of anhyd zinc dichloride with a solution of **2** in EtOH solution gave complex **4** in 37% isolated yield. Interestingly, treatment of a solution of **2** with Zn metal in the presence of hydrated ruthenium trichloride under a nitrogen atmosphere leads to the formation of both **4** (17%) and the known complex $[RuCl_2(NN'N)]_2(\mu\text{-}N_2)$ (15%: NMR) (5b). Thus, it appears that the higher nucleophilicity of the nitrogen atoms in **1**, when compared with ligand **2**, may be detrimental to forming stable Ru(II) species.

Fig. 3. Representation of the solid-state structure of **4**.

As in the case of **3**, an X-ray structural determination of **4** was also carried out. The compound has a somewhat similar molecular structure when compared with **3** (i.e., a mononuclear complex (Fig. 3)). However, the Zn atom in **4** is more accurately described as being in a slightly distorted square pyramidal environment (τ = 0.16 (19)). Also, compound **4** has an approximate, non-crystallographic C_s (mirror) symmetry and hence the Zn atom, unlike in **3**, is not in the plane formed by the three N atoms (a deviation of 0.726(1) Å). The important bond lengths and angles for complex **4** can be found in Table 1. The *NN′N* pincer ligand is in a typical geometry (5*b*–5*c*, 7*b*, 8–10). Compound **4** was also found to be stable to prolonged heating (12 h) under a nitrogen atmosphere in CCl_4 solution.



Conclusions

Attempts to synthesise Ru complexes under standard conditions (5*b*, 5*c*) with the basic *NN′N* ligand **1** leads to complex mixtures or a complete absence of any reaction. The former result may be due to the more basic nature of the trialkylamine donor atoms when compared with the complimentary ligand **2**. Treatment of hydrated $RuCl_3$ with **1** in the presence of Zn metal in EtOH solution leads to a thermally stable compound (**3**), which is an *NN′N* complex of Zn(II). Complex **3** and its methyl analogue **4** can also be produced in moderate yields using anhyd zinc chloride as the metal source (Scheme 1). Both **3** and **4** have been characterized by elemental analysis, NMR, and by a single crystal X-ray structure determination.[7] The latter results show that both

[5] Our interest in the activation of SO_2 and PhC≡CH stems from earlier work (2, 8, 10).

Scheme 1.

compounds are mononuclear, five coordinate Zn species but the geometry about the metal is notably different between the two species. Compound **3** is best described as midway between TBP and SQP geometry while compound **4** has a slightly distorted SQP geometry about the metal centre. These results clearly emphasize that subtle changes in ligand structure can have a large effect on metal geometry, even with the two closely related cases of pincers **1** and **2**. This observation may have a profound impact on catalytic applications, especially as both **3** and **4** may be viewed as simple relatives to the Zn pybox systems which are known to be mediators of regio- and enantio-selective organic reactions (11*a*–11*c*).

Determination of the acidity constant of isothiocyanic acid in aqueous solution

Y. Chiang and A.J. Kresge

Abstract: Changes in absorbance of the thiocyanate ion (SCN^-) at λ = 220 nm, measured in concentrated aqueous perchloric acid solution, were analyzed using a titration curve expression containing the X_o excess acidity function; this provided the acidity constant K_a = 19.2 ± 1.1 M, pK_a = –1.28 ± 0.03, for isothiocyanic acid (SCNH).

Key words: isothiocyanic acid (acidity of), thiocyanate ion (basicity of), acid–base titration in concentrated aqueous acids, X_o excess acidity function, Cox–Yates method.

Résumé : Utilisant une expression pour la courbe de titrage contenant la fonction d'acidité en excès X_α, on a analysé les changements d'absorbance de l'ion thiocyanate (SCN^-) à λ = 220 nm, mesurés dans une solution concentrée d'acide perchlorique aqueux; cette analyse nous a permis d'évaluer la constante d'acidité, K_a = 19,2 ± 1,1 M (pK_a = –1,28 ± 0,03) de l'acide isothiocyanique (SCNH).

Mots clés : acide isothiocyanique (acidité), ion thiocyanate (basicité), titrage acide–base dans des acides concentrés aqueux, fonction d'acidité en excès X_α, méthode de Cox–Yates.

The thiocyanate ion (SCN^-) is a strong nucleophile, useful for studies of nucleophilic displacement and carbocation–nucleophile combination reactions. Analysis of quantitative data obtained in such studies, carried out in aqueous solution under conditions of acid catalysis, requires accurate knowledge of the acid dissociation constant of the conjugate acid of SCN^-. The literature contains reports of a number of determinations of this constant, but there is little agreement among the results obtained: a recent compilation, for example, lists nine values, but these differ by three orders of magnitude (1).

The thiocyanate ion has a strong UV absorption max at λ = 220 nm, which is replaced by another, somewhat weaker, max at λ = 235 nm as the ion is protonated. We used this spectral change to determine the acidity constant of the conjugate acid of SCN^- in aqueous solution. The thiocyanate ion is only weakly basic, and measurements had to be made in concentrated acid solutions. The data so obtained were then extrapolated to a dilute solution standard-state using the X_o excess acidity function (2). This scale appears to be the best function currently available for this purpose (3), and we believe that its use here eliminated many of the difficulties experienced in previous attempts to determine this acidity constant.

The thiocyanate ion is an ambident species that bonds to hard metals through its nitrogen atom and to soft metals through its sulfur (1). No definitive determination of the site of protonation of SCN^- in aqueous solution appears to have been made, but, since the proton is a hard species, it seems likely that SCN^- bonds with H^+ in aqueous solution on its nitrogen atom, forming isothiocyanic acid, as shown in eq. [1]. This conclusion is supported by the fact that isothiocyanic acid rather than the isomeric thiocyanic acid (HSCN) is the species present in the gas-phase (4).

[1] $SCN^- + H^+ \rightleftarrows SCNH$

Experimental section

Absorbance measurements were made at λ = 220 nm in perchloric acid solutions over the concentration range $[HClO_4]$ = 0.1–8.3 M using NaSCN as the source of thiocyanate ion. A Cary 2200 spectrometer, whose cell compartment was thermostated at 25.1 ± 0.05°C, was employed. Measurements were made in triplicate at some 20 different perchloric acid concentrations. The stoichometric concentration of thiocyanate ([SCN] + [SCNH]) in these solutions was held constant at 5×10^{-4} M.

The data so obtained are summarized in Table S1.[2]

Results and discussion

The conventional way of converting measurements made in concentrated acid solutions into acidity constants refer-

Fig. 1. Absorbance data for the protonation of thiocyanate ion in aqueous perchloric acid solution at 25°C plotted according to eq. [4].

enced to the usual infinitely dilute standard-state is to extrapolate values of I, where I is the ratio of concentrations of protonated (SH^+) to unprotonated (S) forms of the substrate, down an appropriate acidity function. Values of I are generally calculated from absorbance measurements made at constant total substrate concentration ($[SH^+] + [S]$) using the relationship shown in eq. [2] where A_{SH} and A_S are the limiting absorbances of solutions

$$[2] \qquad I = \frac{[SH^+]}{[S]} = \frac{A_S - A}{A - A_{SH}}$$

containing only SH^+ or S, respectively, and A is the absorbance of solutions containing both SH^+ and S. When the extrapolation is done using the X_o acidity function, the quantity extrapolated is $\log (I/[H^+])$ (5). Since the limiting value of X_o in dilute solution is zero, the pK_a is then obtained as the y-intercept at $X_o = 0$, as shown in eq. [3]. The quantity m in this equation is a slope parameter that

$$[3] \qquad \log (I/[H^+]) = pK_a + mX_o$$

takes into account the fact that the acidity function appropriate to the system under investigation may not be X_o, but that it will in that case be a simple multiple of X_o.

This method has the advantages inherent in a linear extrapolation, e.g., analysis of the experimental data can be done by simple linear least-squares fitting. It suffers, however, from the fact that the limiting absorbances A_{SH} and A are used to calculate each value of I, and accurate knowledge of these quantities is consequently required. Values of I, moreover, are less reliable the farther they are from unity (6), and measurement should either be confined to a region not too distant from $I = 1$, or $\log (I/[H^+])$ values should be weighted appropriately.

These difficulties may be avoided by using a least-squares fitting function in which A is the sole dependent variable and A_{SH} and A_S are parameters to be determined by the fit. Such an expression, eq. [4] has the form of a titration curve; it can be derived by combining eqs. [2] and

$$[4] \qquad A = \frac{A_{SH}[H^+]10^{mX_o} + A_S K_a}{[H^+]10^{mX_o} + K_a}$$

[3] and then solving for A. The resulting function has two independent variables, $[H^+]$ and X_o, and four parameters to be determined by the fit: K_a, A_{SH}, A_S, and m. Analysis of experimental data using this function requires nonlinear least-squares fitting, but, with the current widespread availability of powerful desktop computers and appropriate software, that is not a problem. This method has the advantages of not requiring prior knowledge of A_{SH} and A_S, not being restricted to a narrow range of experimental data, and, since all values of A are likely to have similar uncertainties (7), not requiring special weighting of the data.

As Fig. 1 demonstrates, the present experimental data conform to the expression of eq. [4] quite well. Least-squares analysis using Grafit software gave $K_a = 19.2 \pm 1.1$ M, $pK_a = -1.28 \pm 0.03$, $A_{SH} = 0.131 \pm 0.004$, $A_S = 0.897 \pm 0.004$, and $m = 0.851 \pm 0.027$.

The acidity constant determined here is consistent with $pK_a = -1.1 \pm 0.3$ obtained by Raman spectroscopy (8). This agreement, however, must be considered to be fortuitous, for the data obtained in the previous work were analyzed, not by extrapolating down an acidity function, but rather by applying activity coefficients estimated using a method of dubious validity.

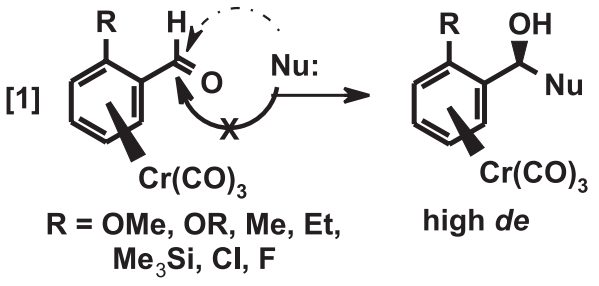
Asymmetric synthesis based on chiral (arene)tricarbonylchromium acetal complexes. Addition reactions to the *ortho*-formyl complex

M. Kevin McKay and James R. Green

Abstract: The addition reactions of organolithium and Grignard reagents to chiral, enantiomerically pure *ortho*-formyl (arene)tricarbonylchromium acetal complex (**2**) have been studied. The diastereoselectivity of the addition process is fair in the absence of an additional Lewis acid, and good in the presence of $Ti(O^iPr)_4$. The nature of the newly formed chiral centre, and studies on the possible nature of the nucleophilic species suggest that the Lewis acid acts through monodentate coordination to the aldehyde carbonyl, and thereby alters the carbonyl rotamer population more heavily in favour of the *s-trans* conformation. Nucleophilic attack then occurs on the face *anti-* to that bearing the $Cr(CO)_3$ unit.



Key words: (arene)tricarbonylchromium complexes, asymmetric synthesis, carbonyl additions, Lewis acids.

Résumé : On a étudié les réactions d'addition de réactifs organolithiens et de Grignard sur le complexe chiral, énantiomériquement pur *ortho*-formyl(arène)tricarbonylchrome acétal (**2**). La diastéréosélectivité du processus d'addition est correcte en l'absence d'un acide de Lewis additionnel et elle est bonne en présence de $Ti(O^iPr)_4$. La nature du centre chiral qui se forme et les études sur la nature possible de l'espèce nucléophile suggèrent que l'acide de Lewis agit par le biais d'une coordination monodentate du groupe carbonyle de l'aldéhyde et que celle-ci modifie la population des rotamères du groupe carbonyle de façon à favoriser la conformation *s-trans*. L'attaque nucléophile se produit alors sur la face *anti-* par rapport à celle qui porte l'unité $Cr(CO)_3$.

Mots clés : complexes (arène)tricarbonylchrome, synthèse asymétrique, additions sur des carbonyles, acides de Lewis.

The chemistry of (arene)tricarbonylchromium complexes has been the subject of considerable attention in organic synthesis, due to the relative ease of preparation of compounds of this class, the change in electronic properties of the arene ring upon complexation, and the presence of a large functional group (the $Cr(CO)_3$ unit) on one face of the ring (1). Recently, much of the focus of work in this area has been concerned with the chemistry of chiral and enantiomerically pure versions of these complexes. In particular, the enantiopure complexes have seen wide application in the chemistry of nucleophilic attack on the arene ring (2), in stereoselective functionalization of prochiral centres adjacent or near the ring (3), and in enantioselective catalysis (4). A former bottleneck to research in this area, namely that of reliable access to enantiomerically enriched complexes, has been eliminated to a large degree by several important recent advances (5, 6, 7). Among these developments is the diastereoselective ortho lithiation of tartrate-derived benzaldehyde acetal tricarbonylchromium complex **1**, which allows highly selective *ortho* functionalization of the pro-(*R*) site (ca. 90% de) (5*a*). As a result, we consider the framework in **1** to be promising in the field of asymmetric synthesis, and therefore the systematic investigation of the reactions of prochiral centres attached to the ring in these systems is warranted. We have shown that homobenzylic ketones derived from **1** a capable of undergoing highly diastereoselective reductions at very low temperatures (8).

In the field of *ortho*-disubstituted arenetricarbonylchromium complexes, study of the additions to the arylaldehyde function has become the most important measure of the system in asymmetric synthesis (3*a*). A substantial number of types of nucleophiles have been shown to participate in the addition process. These include alkyl-, aryl-, and alkynylmetals (9), enolates and their equivalents (10), nitronate anions (11), Reformatsky reagents (10*a*, 12), α-halo carbonyl enolates (13), and active methylene compounds (14). In most cases the diastereoselectivity of addition is good to excellent at the benzylic site, and is consistent with a predominant *s-trans* conformation of the aldehyde function, and nucleophile addition *anti-* to the face bearing the $Cr(CO)_3$ fragment (eq. [1]). In the vast majority of these cases, however, the

ortho-substituent is simple and, saving the aryl ether complexes, not containing any Lewis basic centres. In contrast, Koide and Uemura's (15) work on complexes containing an *ortho*-benzamide function has shown more complex behaviour, where the degree and disposition of asymmetry in alkylmetal additions varies greatly with the metal counterion and the presence of additional Lewis acids.

Extension of these studies to the compound based on the arylaldehyde system derived from **1**, namely **2**, would give ether-alcohols **3**, with a 1,6-dioxygen relationship. Other classes of enantiomerically pure ether-alcohols which are capable of making seven membered chelates with transition metal fragments have seen recent use in enantioselective catalysis of protonation reactions (16), enol silane isomerizations (17), and aldol type condensations (18, see also ref. 19). Therefore, we have chosen the *ortho*-benzaldehyde complex **2** for study in its addition reactions with a variety of nucleophiles. The results are contained in this report.

The diastereomerically and enantiomerically pure *ortho*-formyl complex **2** was prepared by adaptation of the previously reported procedure (5*a*). Lithiation of the chiral acetal **1** under the literature conditions (–35°C, slow addition of BuLi, 4.5 h total) followed by addition of *N*-methylformanilide afforded **2** in 78% yield after aqueous workup, a slight increase from the yields resulting from the use of DMF as the electrophile (70%). In addition, the ^{1}H NMR spectrum of the crude reaction products employing *N*-methylformanilide showed no evidence for the presence of the minor diastereomer **2′**, and therefore we consider the diastereoselectivity for this transformation to be >94% de.

With ready access to **2**, conditions were investigated for optimization of the addition reactions; methyllithium was chosen as a representative nucleophile for this process. Addition of methyllithium to **2** was investigated in Et_2O and THF, and at several reaction temperatures.[2] Reaction was most straightforwardly evidenced by a change in solution colour from dark orange to yellow, indicative of destruction of the conjugation between the aldehyde carbonyl and the arene ring, and was rapid under most sets of conditions. For example, based on this very approximate parameter, reaction was instantaneous at –35°C and –78°C, and required approximately 1 min at –110°C (in Et_2O). The stereoselectivity of the process was evaluated by the ^{1}H NMR spectra of the crude reaction products; most diagnostic was the acetal proton of addition product **3a**, which resonated at 6.02 in the major diastereomer, and at 6.26 in the minor diastereomer (**3a′**).

Between the two solvent systems, greater diastereoselectivity was observed in Et_2O (4.6:1 at –78°C) relative to THF (2.9:1 at –78°C). Diastereoselectivity also increased with decreasing reaction temperature; in Et_2O, this varied from 2.4:1 at –35°C to 4.6:1 at –78°C, and to 4.9:1 at –110°C.

The possibility of a significant effect of the presence of Lewis acids on the addition reaction was also investigated. BF_3–OEt_2, $Ti(O^iPr)_4$, $Ti(O^nPr)_4$, and $ZnCl_2$ (3 equiv relative to **2**) were investigated for their effect. The presence of BF_3–OEt_2 or $ZnCl_2$ were deleterious to the addition reaction with MeLi; BF_3–OEt_2 caused complete decomplexation of **2**, while $ZnCl_2$ gave partial decomplexation of **1** and partial transformation to **3a**. We have previously observed ready decomplexation of (arene)tricarbonylchromium complexes bearing this acetal unit in the presence of Lewis- or protic acid reagents containing halide ion (5*a*, 20). Conversely, in the presence of both $Ti(O^iPr)_4$ and $Ti(O^nPr)_4$, decomplexation of **2** was negligible, and the diastereoselectivity of the addition process improved substantially at –78°C.[3] In view of the lower viscosity of $Ti(O^iPr)_4$, this Lewis acid was chosen for all addition reactions; the diastereoselectivity of the MeLi/$Ti(O^iPr)_4$ combination in Et_2O at –78°C was 16:1 or 88% de (75% yield of diastereomerically and enantiomerically pure **3a**, Table 1).

With optimized conditions of MeLi addition reactions delineated, the basic transformation was expanded to a wider range of nucleophiles. Representative organolithium and organomagnesium halides were chosen for investigation based on ready availability, and included *n*-BuLi, *t*-BuLi, 1-lithio-1-hexyne, phenyllithium, EtMgBr, *n*-PrMgBr, *i*-PrMgCl, phenylmagnesium bromide, and 1-thienylmagnesium bromide. In each case, aldehyde **2** was subjected to $Ti(O^iPr)_4$ mediated addition of the nucleophile at –78°C in Et_2O. While the nucleophiles derived from smaller organic units reacted noticeably more rapidly than those of the aryl

[2] Methyllithium addition to the analogue of **2** lacking the $Cr(CO)_3$ unit occurred in total stereorandom fashion.
[3] In the presence of $Ti(O^iPr)_4$, the reaction became very sluggish at –110°C.

nucleophiles and 2° and 3° alkylmetals, consumption of **2** was complete after 3 h in all cases except for the *t*-BuLi case. With *t*-BuLi, very little conversion had occurred after the 3 h time period, and the reaction was allowed to gradually warm to room temperature overnight prior to workup.

The results are summarized in Table 1. In general, addition products **3a–c, e–i** were obtained in good chemical yield and in diastereomerically and enantiomerically homogeneous form following chromatographic purification. Diastereoselectivities of addition were good (82–94% de) and were in general consistent across the nucleophiles examined. In three cases, the results deserve specific comment. In the one case where the organolithium and the organomagnesium reagent derived from the same organic unit (entries 8 and 9), the organolithium reagent was observed to give slightly higher de. This trend is the converse of that observed previously in organometallic addition reactions to *o*-trimethylsilylbenzaldehyde complexes (9*c*), and stands in complete contrast to change in direction of asymmetry observed in the additions to *o*-diethylcarbamoylbenzaldehyde complexes reported recently by Koide and Uemura (15). In the case of hexynyllithium nucleophile, the initial addition products were quite clean; these, however, underwent extensive decomplexation upon attempted chromatographic purification. Repeated precipitation from petroleum ether gave pure material, with a compromise of the isolated yield of **3g** (42%). Finally, *i*-PrMgCl did not give the addition product, but rather the product of aldehyde reduction, namely **3d** (21).

With the presence of several Lewis basic groups in the vicinity of the aldehyde carbonyl, the disposition of the addition process was open to question. Fortunately, the *n*-BuLi/Ti(O^i-Pr)$_4$ addition product, **3e**, gave crystals from petroleum ether suitable for X-ray diffraction (Fig. 1, Table 2). This revealed the major diastereomeric product to possess the (*S*)-configuration at the benzylic carbinol carbon. The analogous stereochemical assignments have therefore been made to the other addition products (**3a–c, e–i**). Additional support for uniformity in the stereochemical assignments may be derived from the ^{1}H NMR spectra of the crude adducts, as the acetal hydrogen atoms of the major diastereomers resonated further upfield than those of the minor diastereomer in all cases. These additions are also consistent with the dominant mode of nucleophilic additions to simpler *ortho*-substituted benzaldehyde–Cr(CO)$_3$ complexes (3*a*).

There are several alternative possibilities for the role played by Ti(O^{i}Pr)$_4$ in the addition process. For example, the Lewis acid could complex to the carbonyl oxygen, could complex to one or several oxygen atoms of the acetal unit, or could react with the nucleophile to give a different nucleophilic species. In the case of Ti(O^{i}Pr)$_4$, the "different" nucleophilic reagent may conceivably be the titanium ate complex, formally [RTi(O^{i}Pr)$_4$]$^-$ (the nature of these ate complexes have not been determined rigourously, see ref. 22), or the organotitanium triisopropoxide, RTi(O^{i}Pr)$_3$. To evaluate the latter set of possibilities, CH$_3$Ti(O^{i}Pr)$_3$ was prepared by the addition of MeLi to ClTi(O^{i}Pr)$_3$ (23). Addition of this reagent to **2** under the standard addition conditions gave no **3a** and predominantly recovered **2** (84% recovery). In a similar fashion, the ate complex [CH$_3$Ti(O*i*-Pr)$_4$]$^-$Li$^+$ was prepared by the addition of Ti(O^i-Pr)$_4$ to MeLi in Et$_2$O at –30°C. Addition of this ate complex to **2** under the standard addition conditions gave no addition products, and starting material **2** was recovered (75% recovery).

Fig. 2. Lewis acid coordination to **2**.

In view of the lack of reactivity of $MeTi(O^iPr)_3$ and $[CH_3Ti(O^iPr)_4]^-Li^+$, the most economical interpretation of the reaction characteristics features monodentate coordination of $Ti(O^iPr)_4$ to the aldehyde oxygen lone-pair (**4**), in the plane of the carbonyl and the arene. Nucleophilic attack then occurs on the face of arylaldehyde *anti-* to the $Cr(CO)_3$ unit (Fig. 2). Bidentate or tridentate coordination of $Ti(O^iPr)_4$ to the carbonyl and acetal oxygen(s) is considered unlikely in that it would then require attack of the nucleophile *syn-* to the $Cr(CO)_3$ unit to obtain the observed major diastereomer of **3**. Similarly, there is no evidence in these systems of out-of-plane Lewis acid coordination and resultant reversal of facial selectivity, as has been observed in conjugate additions to aryl enone chromium complexes (24). The increased stereoselectivity observed in the presence of the Ti Lewis acid in the current case most likely stems from the resultant effective increase in size of the carbonyl oxygen and therefore an increase in the bias for the *s-trans* conformer drawn in Fig. 2 (***s-trans* 4**). This is the more commonly established role of Lewis acids in related additions (9*c*). Coordination of an additional molecule of $Ti(O^iPr)_4$ to the acetal unit of **2** cannot be ruled out with certainty.

This work, in conjunction with our work on reductions of homobenzylic ketones, demonstrates the utility of tartrate-derived benzaldehyde acetal tricarbonylchromium complexes in the induction of chirality in side chain alkyl functions. Further work on materials derived from this study will be reported in due course.

Experimental section

General methods

All solvents were used after distillation from the appropriate drying agent. Diethyl ether and tetrahydrofuran were distilled from benzophenone ketyl immediately prior to use. *n*-BuLi, *s*-BuLi, *t*-BuLi, MeLi, and PhLi were obtained from Aldrich Chemical Co., Ltd. Their titres were determined using 2,5-dimethoxybenzyl alcohol (25) or diphenylacetic acid as standards (26). $ClTi(O^iPr)_3$ and $MeTi(O^iPr)_3$ were prepared according to literature methods (27). Melting points are uncorrected. Flash chromatography followed the protocol described by Still et al. (28).

NMR spectra were run at 300 MHz or 500 MHz for ^1H, and 75 MHz or 125 MHz for ^{13}C, in $CDCl_3$ solution at 25°C; chemical shifts are given in ppm and coupling constants (*J*) are given in Hz. Mass spectra were run at the Chemistry and Biochemistry Mass Spectrometry Facility, University of Windsor.

All reactions were performed under nitrogen or argon unless otherwise noted.

*(1′R,2′*S,*4*R,*5*R*)-[4,5-Bis(1-methoxy-1-methylethyl)-2-(2′-formyl)phenyl)-1,3-dioxolane]tricarbonylchromium(0) (2)*

To a solution of acetal **1** (1.500 g, 3.49 mmol) in diethyl ether (150 mL) at –35°C was added *n*-BuLi (3.78 mL, 2.21M, 8.364 mmol, 2.4 equiv) over 90 min. The solution was kept at –35°C for 3h, at which point *N*-methylformanilide (1.03 mL, 8.36 mmol, 2.4 equiv) was added. The reaction mixture was stirred for a further 1 h. Standard aqueous workup afforded a red viscous oil, which was subjected to column chromatography using petroleum ether:ethyl acetate (5:1) as the eluent to afford **2** (1.246 g, 78%) as a red crystalline solid, mp 104–105°C (hexanes). $[\alpha]_D$ = 296° (c 0.6, Et_2O). IR (KBr) ν_{max} (cm^{-1}): 1984, 1924, 1692. ^1H NMR δ: 9.91 (s, 1H), 6.42 (s, 1H), 6.06 (d, 1H, *J* = 6.5), 5.60–5.68 (m, 2H), 5.26 (t, 1H, *J* = 6.0), 4.22, (d, 1H, *J* = 3.3), 4.05 (d, 1H, *J* = 3.3), 3.22 (s, 3H), 3.13 (s, 3H), 1.31 (s. 3H), 1.14 (s, 3H), 1.12 (s, 3H), 1.03 (s, 3H). ^{13}C NMR δ: 230.2, 187.3, 110.9, 99.7, 94.1, 93.7, 92.3, 88.7, 86.8, 85.1, 83.2, 75.4, 49.4, 49.3, 22.1, 21.2, 20.9, 19.4. MS *m/e*: 458 (M^+). HRMS *m/e* calcd. for $C_{21}H_{26}CrO_8$ (M^+): 458.1032; found: 458.1031.

Standard nucleophilic addition procedure

To a solution of *o*-formyl complex **2** (0.075–0.100 g) in Et_2O (10 mL) at –78°C was added $Ti(O^iPr)_4$ (3 equiv), and the solution allowed to stir for 20 min. The nucleophile

© 2000 NRC Canada

(3 equiv) was added dropwise by syringe and stirring was continued for 3 h at –78°C. The reaction was quenched by the addition of distilled water (ca. 2 mL), and a standard aqueous work-up resulted in a crude product whose ^{1}H NMR spectrum was examined to determine the diastereomeric ratio.

*(1′*R*,2′*S*,4*R*,5*R*)-[4,5-Bis(1-methoxy-1-methylethyl)-2-(2′-(*S*-1-hydroxyethyl)phenyl)-1,3-dioxolane]tricarbonylchromium(0) (**3a**) (methyl derivative)*

o-Formyl complex **2** (0.0983 g, 0.215 mmol) was subjected to the standard procedure with MeLi (0.43 mL, 1.5 M in Et_2O, 0.64 mmol) as the nucleophile. A standard aqueous work-up resulted in a crude product whose ^{1}H NMR spectrum revealed a resonance at δ 5.99 (**3a**) and 6.26 (**3a′**) with a relative integral of 15.6:1 (88% de). Purification by silica gel chromatography using petroleum ether:ethyl acetate (5:1) as eluent gave **3a** (0.076 g, 75%) as a yellow solid, mp 77–78°C (pentane). $[\alpha]_D$ = –36° (c 0.5, Et_2O). IR (KBr pellet) ν_{max} (cm^{-1}): 3436, 1966, 1886. ^{1}H NMR δ: 6.01 (s, 1H), 5.76 (d, 1H, *J* = 6.0), 5.66 (d, 1H, *J* = 6.1), 5.34 (m, 2H), 4.82 (m, 1H), 4.16 (d,1H, *J* = 3.2), 3.98 (d, 1H, *J* = 3.2), 3.22 (s, 3H), 3.16 (s, 3H), 2.02 (s, 1H), 1.48 (d, 3H, *J* = 6.3), 1.26 (s, 3H), 1.17 (s, 3H), 1.13 (s, 3H), 1.03 (s, 3H). ^{13}C NMR δ: 232.8, 117.5, 105.5, 99.6, 92.3, 91.6, 90.0, 88.9, 84.6, 82.6, 75.4, 64.4, 49.4, 49.3, 25.7, 22.3, 21.1, 19.1. MS *m*/*e*: 474 (M^+). HRMS *m*/*e* calcd. for $C_{22}H_{30}CrO_8$ (M^+): 474.1346; found: 474.1357.

*(1′*R*,2′*S*,4*R*,5*R*)-[4,5-Bis(1-methoxy-1-methylethyl)-2-(2″-(*S*-1-hydroxypropyl)phenyl)-1,3-dioxolane]tricarbonylchromium(0) (**3b**) (ethyl derivative)*

o-Formyl complex **2** (0.0890 g, 0.194 mmol) was subjected to the standard procedure with EtMgBr (0.49 mL, ca. 1.2 M in Et_2O, 0.58 mmol) as the nucleophile. A standard aqueous work-up resulted in a crude product whose ^{1}H NMR spectrum revealed a resonance at 6.00 (**3b**) and 6.26 (**3b′**) with a relative integral of 12.4:1 (85% de). Purification by silica gel chromatography using petroleum ether:ethyl acetate (5:1) as eluent gave **3b** (0.069 g, 73%) as a yellow oil, $[\alpha]_D$ = –40.4° (c 0.54, Et_2O). IR (NaCl, neat) ν_{max} (cm^{-1}): 3452, 1966, 1892. ^{1}H NMR δ: 6.00 (s, 1H), 5.77 (d, 1H, *J* = 5.9), 5.61 (d, 1H, *J* = 5.9), 5.33 (m, 2H), 4.61 (br d, 1H, *J* = 8.2), 4.17 (d, 1H, *J* = 3.1), 3.98 (d, 1H, *J* = 3.1), 3.23 (s, 3H), 3.17 (s, 3H), 1.94 (s, 1H), 1.90 (m, 1H), 1.67 (m, 1H), 1.31 (s, 3H), 1.14 (s, 3H), 1.12 (s, 3H), 1.05 (s, 3H), 1.03 (t, 3H, *J* = 7.3). ^{13}C NMR δ: 232.8, 116.7, 105.9, 99.5, 92.2, 91.7, 90.3, 89.2, 84.6, 82.6, 75.4, 69.2, 49.5, 49.3, 32.4, 22.4, 21.2, 19.2, 10.4. Addition of $CH_3Ti(O^iPr)_3$ to o*-formyl complex **2***

To a solution of the *o*-formyl complex **2** (0.100 g, 0.218 mmol) in diethyl ether (10 mL) at –78°C was added $CH_3Ti(O^iPr)_3$ (1.64 mL, 0.40 M in Et_2O, 0.66 mmol) in a dropwise manner. The reaction was allowed to proceed for 3 h, at which time H_2O (10 mL) was added. A standard aqueous work-up afforded a red residue which was subjected silica gel chromatography (petroleum ether:ethyl acetate, 5:1) to afford starting material **2** (0.084 g).

Addition of the ate complex $[CH_3Ti(O^iPr)_4Li]$ to o*-formyl complex **2***

To a solution of MeLi (0.66 mL, 1.0 M, 0.66 mmol) in Et_2O (10 mL) at –30°C was added $Ti(O^iPr)_4$ (0.19 mL, 0.66 mmol, 3 equiv) in a dropwise fashion. After 30 min, the solution was cooled to –78°C, and *o*-formyl complex **2** (0.100 g, 0.218 mmol) was added as a solution in Et_2O (2.0 mL). The solution allowed to stirred for 3 h, at which point distilled water (10 mL) was added. A standard aqueous work-up afforded a red residue which was subjected silica gel chromatography (petroleum ether:ethyl acetate, 5:1) to afford starting material **2** (0.075 g).

X-ray analysis of 3e

Yellow plates of **3e** were obtained from petroleum ether at –10°C. Accurate cell dimensions and a crystal orientation matrix were obtained on a Rigaku AFC5R diffractometer by a least-squares fit of the scattering angles of 25 reflections in

© 2000 NRC Canada

the range $10.5° < 2\theta < 22.9°$. Intensity data were collected by the ω-2θ method using a scan speed of 16° min^{-1}, scan width 1° above $K\alpha_1$ / 1° below $K\alpha_2$, and monochromatic MoK_α radiation in the range $4.5° < 2\theta < 50.0°$.

The intensities of 2778 unique reflections were measured of which 681 had $F_o^2 > 3\sigma(F_o^2)$. Data were corrected for Lorentz polarization and absorption effects. The structure was solved by direct methods and expanded using Fourier techniques. The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included but not refined. Scattering factors were those of Cromer and Waber (29) and allowance was made for anomalous dispersion. All calculations were performed using teXsan.

Material on deposit

The ^{13}C NMR spectra of **2** and **3a**–**i** and the details of the X-ray structural characterization of **3e** (details of data collection and refinement, tables of atomic coordinates, anisotropic displacement parameters, bond distances and angles) (29 pages) have been deposited as supplementary material.[4]

Acknowledgements

We are grateful for the research support of the Natural Sciences and Engineering Research Council of Canada (NSERC) and the University of Windsor. We wish to thank the Windsor Molecular Structure Centre (WINMOL) for the crystallographic structural work on **3e**. We wish to thank the Wayne State University Central Instrumentation Facility for mass spectral work on **3i**.

Potentiometric study of cadmium(II) and lead(II) complexation by a cross-linked poly(acrylic acid). Comparison with the linear analogue

Catherine Morlay, Yolande Mouginot, Monique Cromer, Michelle Chatelut, and Olivier Vittori

Abstract: Cadmium(II) or lead(II) complex formation with an insoluble cross-linked poly(acrylic acid) was investigated in dilute aqueous solution ($NaNO_3$ 0.1 M, 25°C). Potentiometric titrations were carried out to determine the stability constants of the MA and MA_2 complex species formed. The Bjerrum's method, modified by Gregor et al. (1955), for the study of polymeric acids was used. The results obtained showed that lead(II) was more readily bound to the polymer. PbA_2 was the predominant species; the global stability constant log B_{102} was equal to 7.4. With cadmium(II), none of the complex species MA or MA_2 was predominant (log B_{102} = 6.0). Finally, the comparison of these results with those of our previous studies showed that the insoluble cross-linked poly(acrylic acid) and its hydrosoluble linear analogues present similar complexing properties towards cadmium(II), lead(II), copper(II), and nickel(II).

Key words: insoluble cross-linked poly(acrylic acid), cadmium(II), lead(II), complexation, potentiometry.

Résumé : La complexation du cadmium (II) et du plomb (II) par un acide polyacrylique réticulé insoluble a été étudiée en solution aqueuse diluée ($NaNO_3$ 0,1 M, 25°C). Les titrages potentiométriques réalisés ont permis de déterminer les constantes de stabilité des complexes de type MA et MA_2. La méthode de Bjerrum, modifiée par Gregor et al. (1955) pour l'étude des polyacides, a été utilisée. Les résultats obtenus montrent que le plomb (II) est mieux retenu par le polymère. L'espèce PbA_2 est prédominante ; sa constante globale de stabilité log B_{102} vaut 7,4. Avec le cadmium (II), aucune des formes MA ou MA_2 n'est prédominante (log B_{102} = 6,0). Enfin, la comparaison de ces résultats avec ceux de nos précédentes études montre que cet acide polyacrylique réticulé insoluble et ses analogues linéaires solubles présentent des propriétés complexantes similaires vis-à-vis des ions cadmium (II), plomb (II), cuivre (II) et nickel (II).

Mots clés : acide polyacrylique réticulé insoluble, cadmium (II), plomb (II), complexation, potentiométrie.

Introduction

Some insoluble cross-linked polymers, called superabsorbents, present many industrial applications which are linked to their important water-absorbing capacity (10 to several hundred times their dry weight) (1–3). Although the bulk of the research and development effort has been placed on disposable absorbent products, numerous other applications have been developed (water-retention of soils for agricultural applications, water-absorbing construction materials, electronics and cabling, food packaging, thickeners (2, 3)). Some interesting new applications of superabsorbents are emerging, for example in the cosmetic industry, to develop new sensors or for the controlled release of substances such as pharmaceuticals, pesticides, or fertilizers (3).

In our previous studies of metal complexation with linear hydrosoluble poly(acrylic acids) (HPAAs) of high molecular weight, we showed that HPAAs were able to trap different metal ions (4–7). There is some literature relative to this field of research but there is a complete lack of data for their insoluble cross-linked analogues, i.e., superabsorbents of a carboxylic nature.

The aim of this work was to study the metal complexation of an insoluble cross-linked PAA, Aquakeep® SAP X 50 R superabsorbent, under precise conditions of pH, ionic strength, and concentrations and to compare these results with those obtained with HPAAs, their hydrosoluble linear analogues. The metal ions considered, cadmium(II) and lead(II), are highly pollutant substances. This work was carried out in dilute aqueous solution using protometry as an investigation means. Observations of the polymer beads were also realized using scanning electron microscopy (SEM).

Theory

Molar concentration has little meaning for polymer compounds (4). Thus, we shall define for polycarboxylic acids the total content of titratable acid functions of the sample

Gelling time	85 s	

under study (C_A) expressed in equiv. L^{-1}. C_A corresponds to the total reactive site (potentially complexing site) concentration of the polymer introduced in the analysis cell as used next for the complexation study.

Metal complexation by Aquakeep® was studied during the alkali titration of the protonated polyacid (HA) in the presence of metal ions (M). We chose to examine concentration ratios of complexing sites to metal ions ($R = C_A/C_M$, C_M: total metal ion concentration in the analysis cell) in aqueous solution higher than unity. The system under study could then be considered as a simple binary system and the formation of monomolecular complexes was only examined.

The Bjerrum (8) approach, modified by Gregor et al. (9) for the analysis of complexes formed with macromolecules, was used. The average coordination number ($\bar{r}$) can be calculated for every experimental point of the ligand titration curve in the presence of metal ions. The successive stability constants K_1 and K_2 as well as the global stability constants β_{102} and B_{102} for the formation of the MA_2 species were determined using the formation curves $\bar{r}$ vs. –log ([HA]/[H]) (or p([HA]/[H])); the values of p([HA]/[H]) were read for $\bar{r}$ = 0.5, 1.0, and 1.5. The mathematical treatment of the experimental data implies that the acid–base properties of the polymer (i.e., the variation of the apparent protonic dissociation constant K_A^H with pH) have been previously studied. All the definitions and assumptions needed for this work have been described in previous papers (4, 5, 10). We limited our investigations to the MA and MA_2 species. As explained earlier by Gregor et al. (9), it is not possible to estimate complexation constants of greater than second-order as the formation curves are subject to several uncertainties for $\bar{r} > 2.0$.

Experimental

Reagents

The poly(acrylic acid) used was Aquakeep® SAP X 50 R superabsorbent (Elf-Atochem Co. (Levallois-Perret, France)). All the experiments were carried out using the same batch of polymer which was stored in a polyethylene flask, at room temperature (20°C) and in the dark. It was used without any further treatment. Its main characteristics are presented in Table 1.

Metal ion stock solutions (2×10^{-2} M) were prepared from cadmium nitrate and lead nitrate (Fluka Chemika, Switzerland) and standardized using an EDTA disodium salt solution (Merck, Germany). For potentiometric titrations, a 0.1 M sodium hydroxide (Prolabo) solution was prepared and standardized with a 5×10^{-2} M (weighted amount) potassium monohydrogenophtalate (Fluka Chemika) solution. The standardized NaOH solution was kept free of carbonate using a carbon dioxide trap containing NaOH beads and fitted on the flask cap. A standardized 0.1 M solution was prepared from concentrated nitric acid (Prolabo). The stock solution of supporting electrolyte, $NaNO_3$ (Fluka Chemika), was 1 M. The other solutions prepared were described previously (10).

Table 2. Instrumental parameters used for the potentiometric study.

Instrumental parameter

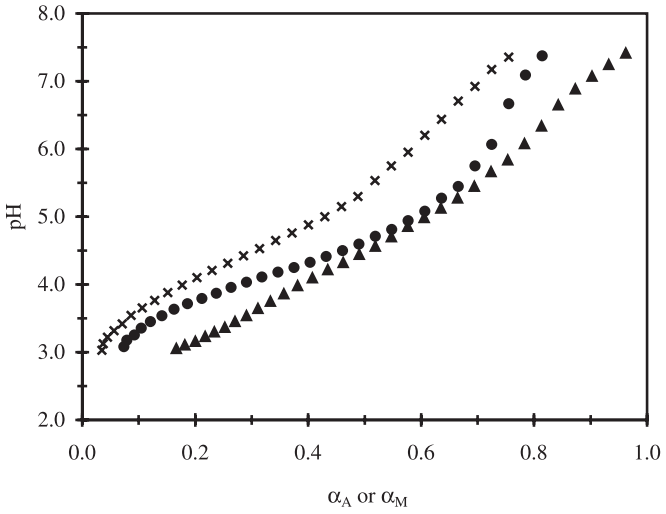
Volume increments (μL): Min	100
Max	200
Stability criterion or maximum increment delay	0.01 pH unit min^{-1} 300 s
Inflexion detection	Incremental

Apparatus and procedure

The apparatus description and use to perform the potentiometric analyses were presented earlier (10). The instrumental parameters chosen are shown in Table 2.



Aquakeep® (50.0 ± 0.1 mg) was introduced under a moderate agitation (vigorous enough to ensure a rapid homogenization and to avoid the settlement of the polymer beads, around 450 rpm) in the analysis cell containing a given volume of distilled water and 5 mL of a 1.0 M $NaNO_3$ solution. The polymer beads were left to swell for 20 min. An excess (5 mL) of the 0.1 M HNO_3 standardized solution was then added to allow the protonation of all the carboxylate groups. The reaction time was 20 min. Finally, a known volume of the metal ion stock solution was introduced in the analysis cell and a further 20 min. waiting time was respected. The sample total volume was 50 mL and metal ion final concentrations were $C_M = 2 \times 10^{-3}$ or 8×10^{-4} M for cadmium(II) and $C_M = 8 \times 10^{-4}$ or 4×10^{-4} M for lead(II).

The titration with the standardized carbonate-free 0.1 M NaOH solution was started after an initial nitrogen bubbling of 20 min. The pH of the sample was stable when the titration started. The measurements were performed at 25.0 ± 0.1°C, under a moderate agitation and under a nitrogen atmosphere. All the samples were treated in the same way. Each titration lasted nearly 5 h. The reproducibility of both cadmium(II) and lead(II) complexation was determined by carrying out the same experiment twice.

The Aquakeep® beads were observed using a scanning electron microscope (SEM) HITACHI model S 800. Aquakeep® (10.0 ± 0.1 mg) was introduced in a 100 mL 0.1 M $NaNO_3$ sample containing the studied metal ion at 8×10^{-4} M final concentration. An Aquakeep® blank was prepared without any metal ion. All samples were left 10 h under a moderate agitation and then filtrated. The Aquakeep® beads were dried at room temperature.

Fig. 1. Curves of pH vs. the dissociation coefficient of Aquakeep® in the absence (α_A, *x*) or in the presence (α_M) of metal ion for very close values of $R = C_A/C_M$ (● Cd(II), R = 8.4; ▲ Pb(II), R = 8.2; C_A = 6.7 mequiv. L^{-1}).

Results and discussion

The previous potentiometric study of the acid–base properties of Aquakeep® (10), showed that the polymer exhibits both a weak and a very weak acidity (specific values: 6.7 ± 0.1 and 2.1 ± 0.1 mequiv. g^{-1}, respectively). The weak acidity of Aquakeep® is characterized by a pK_m^H value of 5.40 ± 0.05. This study also showed that the carboxylic groups accounting for the very weak acidity of Aquakeep® dissociate at pH values above 7.5. As explained in the Theory section, the formation curves can be used only for $\bar{r} \leq 2.0$; consequently, in this study of metal complexation, we had to treat the experimental data contained in the 2.8–6.0 pH range. The very weak acidity of Aquakeep® was thus not considered. In the following, C_A represents the weak acidity content introduced in the analysis cell (C_A = 6.7 ± 0.1 mequiv. L^{-1} for 50.0 ± 0.1 mg of Aquakeep®).

Two ligand to metal ratios ($R = C_A/C_M$) were examined for each metal ion. R values were 3.4 and 8.4 for cadmium(II). Because of the shape of the formation curves obtained, we had to use a higher value of R for lead(II); the R values were 8.2 and 16.3. C_A was kept constant.

Calculations were made, using the formula proposed by Baes and Mesmer (11), to investigate the possible formation of metal hydroxides during the alkali titration of the weak acidity of Aquakeep®. Taking into account the value of C_M, we verified that neither soluble nor insoluble metal hydroxides were significantly formed up to a pH value of 7.5.

Qualitative study of complexation

Figure 1 shows the evolution of pH vs. the dissociation coefficient of Aquakeep® in the absence (α_A) or in the presence (α_M) of metal ions and for the same concentration ratio examined for cadmium(II) or lead(II) (R around 8.3). For any pH located in the pH range where complexation takes place, α_M is higher than the corresponding α_A. Moreover, by comparison with the curve obtained with the ligand alone, the "ligand + metal ion" titration curves show a supplementary release of protons (curves not shown) which is attributed to the formation of metal complexes. For R around 8.3, the complexation occurs significantly from pH = 4.0 for cadmium(II) and from pH = 3.0 for lead(II). Moreover, complexation appears to be more significant with lead(II) than with cadmium(II). These qualitative results are similar to those previously reported for the complexation study of HPAAs (5).

The SEM observation shows that, compared to the blank, the spherical structure of the Aquakeep® beads which have been in presence of metal ions has completely collapsed (Fig. 2). The cluster arrangement has also disappeared.

Quantitative study of complexation

Figure 3 shows the formation curves $\bar{r}$ vs. p([HA]/[H]) obtained in the presence of cadmium(II) or lead(II), respectively, and for the different C_A/C_M ratios considered. The maximum pH range investigated was 2.8–6.0. The formation curves obtained for lead(II)–Aquakeep® systems present a decrease of their slope for the average coordination number $\bar{r}$ in the 1.5–2.0 range (for R = 8.2, $\bar{r}$ = 2.0 corresponds to pH = 3.85 and α_M = 0.35). This plateau means that the corresponding PbA_2 complex species is thus the predominant species formed in that region compared to the PbA species. Concerning the cadmium(II)–Aquakeep® systems, the formation curve obtained for R = 8.4 do not present any plateau for $\bar{r}$ in the 0–2 range (for R = 8.4, $\bar{r}$ = 2.0 corresponds to pH = 4.60 and α_M = 0.48), which means that none of the two complex species CdA or CdA_2 becomes predominant in all that domain of $\bar{r}$.

Elsewhere, the formation curves obtained for both cadmium(II) or lead(II) – Aquakeep® systems present an important slope for $\bar{r}$ about 1 (for cadmium(II) and R = 8.4, $\bar{r}$ = 1.0 corresponds to pH = 3.97 and α_M = 0.27; for lead(II) and for R = 8.2, $\bar{r}$ = 1.0 corresponds to pH = 2.97 and α_M = 0.16). One may conclude that, for one metal ion, the stability constants of the MA and MA_2 species are quite close and that, as a consequence, both species exist with comparable concentrations in the corresponding pH domain.

Finally, the value of $\bar{r}$ still increases above $\bar{r}$ = 2.0. This suggests that in that region some other complexes may possibly be formed besides the MA_2 complex species but their precise nature cannot be found from the formation curves (9).

The same observations were formulated previously for the complexation of cadmium(II) or lead(II) with HPAAs (5) because the shapes of the formation curves were identical for each of the metal ions studied, respectively.

The values of log b_r were obtained by a graphical interpolation of the formation curves. The corresponding values of the complexation constants K_1, K_2, β_{102}, and B_{102} as well as the pH and pK_A^H values for which K_1, K_2, and B_{102} were determined are presented in Tables 3 and 4 for cadmium(II) and lead(II). The apparent dissociation constant of the ligand $K_A{}^H$, was determined from the curve pK_A^H vs. pH previously established (10). The experimental error on the values of log K (log K_1 or log K_2) was estimated at ±0.1. The experimental error on the values of log β_{102} or log B_{102} was estimated at ±0.2.

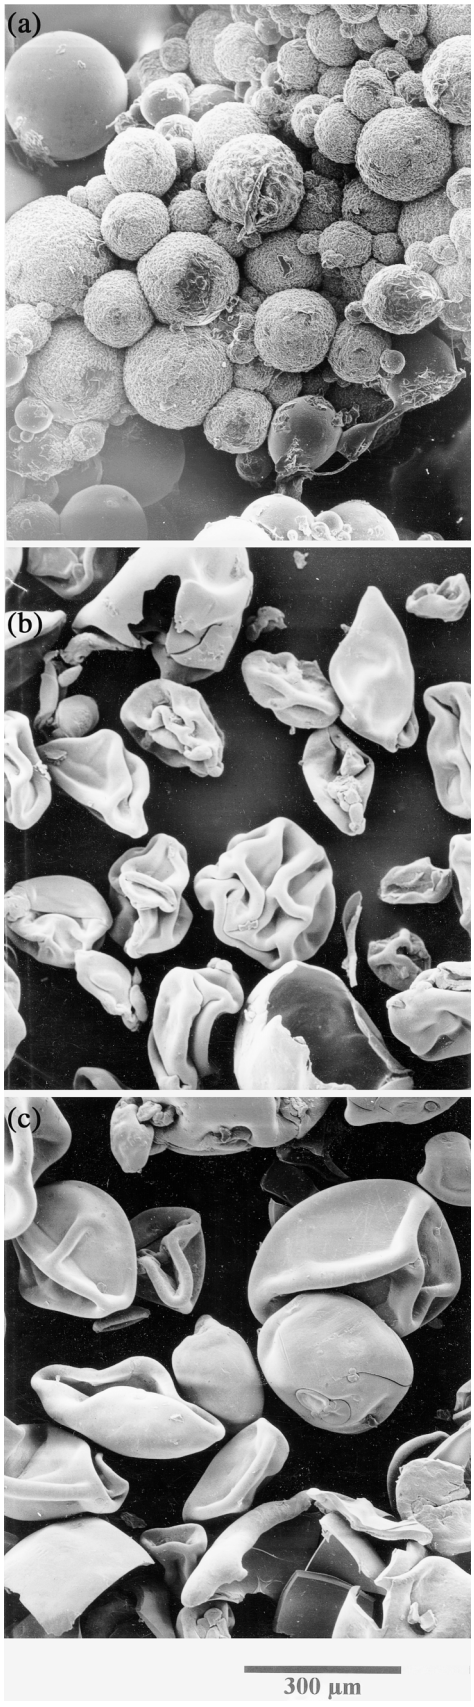

Fig. 3. Formation curves obtained for the Aquakeep®–Cd(II) systems (○ R = 3.4; ● R = 8.4; C_A = 6.7 mequiv. L^{-1}) and for the Aquakeep®–Pb(II) systems (△ R = 8.2; ▲ R = 16.3; C_A = 6.7 mequiv. L^{-1}).

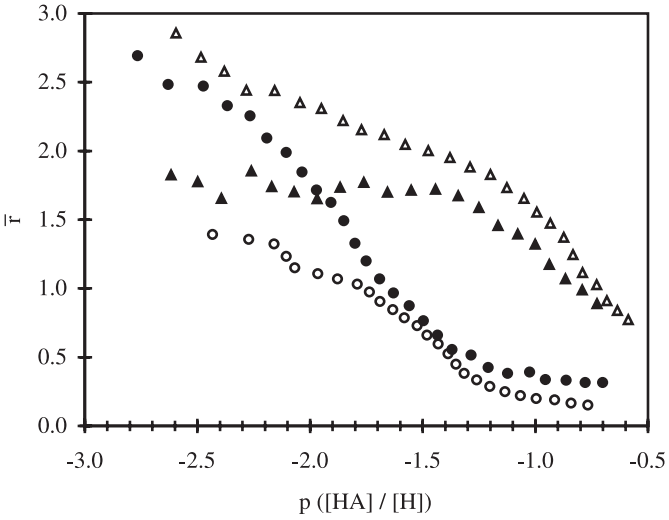

Table 3. Stability constants log K_1 and log K_2 and corresponding pH and pK_A^H values obtained for the Cd(II)–Aquakeep® and Pb(II)–Aquakeep® systems with different values of $R = C_A/C_M$ (C_A = 6.7 mequiv. L^{-1}).

	Cd(II)		Pb(II)	
R	3.4	8.4	8.2	16.3
log K_1[a] ($\bar{r}$ = 0.5)	3.2	3.3	(3.8)	(3.9)
pH	3.78	3.51	—	—
pK_A^H[b]	4.60	4.56	—	—
log K_2[a] ($\bar{r}$ = 1.5)	(2.8)	2.9	3.6	3.4
pH	—	4.25	3.25	3.45
pK_A^H[b]	—	4.75	4.55	4.55
log β_{102}[c]	—	6.2	—	—

[a]The error on log K_1 and log K_2 was estimated at ±0.1.
[b]The error on pK_A^H was estimated at ±0.01.
[c]The error on log β_{102} was estimated at ±0.2.

Because of the shape of the formation curves, it was not possible to determine the value of all the stability constants K_1, K_2, and thus β_{102}. In our previous work on HPAAs (5), we observed that the values of log β_{102} and log B_{102} were not significantly different. Making this assumption with Aquakeep®, we can estimate the missing values of the stability constants; these values are mentioned in brackets in Table 3. It appears that all the values of Table 3 are in very good agreement with those previously determined with HPAAs (5).

To more globally compare the complexing properties of HPAAs and Aquakeep®, Table 5 gives the log B_{102} values obtained with both types of polymer and with the four metal ions we studied, i.e., copper(II), nickel(II), cadmium(II), and lead(II) (5, 10). We can draw the following conclusions: (*i*) for a given metal ion, the values of log B_{102} are in very good agreement; and (*ii*) for both polymers the conditional stability constants of the complexes formed increase in the following order: Ni(II) < Cd(II) < Cu(II) < Pb(II).

log B_{102} [b]	6.0	6.0	7.4	7.3

[a]The error on pK_A^H was estimated at ±0.01.

[b]The error on log B_{102} was estimated at ±0.2.

Table 5. Values of log B_{102} obtained with HPAA and Aquakeep®.

	Cu(II)	Ni(II)	Cd(II)	Pb(II)
HPAA[a]	6.6 (6.3)	5.4 (6.6)	6.1 (6.4)	7.1 (13.1)
	6.4 (12.6)	5.3 (13.2)	5.9 (12.9)	7.0 (26.1)
Aquakeep®	6.9 (3.3)[b]	5.3 (3.4)[b]	6.0 (3.4)[c]	7.4 (8.2)[c]
	6.5 (8.3)[b]	5.3 (8.6)[b]	6.0 (8.4)[c]	7.3 (16.3)[c]

Note: In both cases, the error on log B_{102} was estimated at ±0.2. The values of $R = C_A/C_M$ are given in brackets.

[a]Average mol wt = 2.5×10^5, C_A = 5.3 mequiv. L^{-1} (from ref. 5).

[b]C_A = 6.7 mequiv. L^{-1} (from ref. 10).

[c]This study.

We did not find any data in the literature relative to the complexation of cadmium(II) or lead(II) with a cross-linked poly(acrylic acid) or even with a resembling polymer (such as a cross-linked poly(methacrylic acid) for example). We did not consider studies relative to natural substances or natural waters as the complexing material in this case is not well defined and not comparable with our study.

Conclusion

The aims of this study were, first, to assess the binding properties of an insoluble cross-linked poly(acrylic acid) towards cadmium(II) and lead(II) in dilute aqueous solution and, secondly, to compare these results to those previously obtained in the same conditions with two linear hydrosoluble poly(acrylic acids) of high molecular weight (5).

The results obtained showed that both linear and cross-linked PAAs present very similar complexing properties towards the four metal ions we examined. Furthermore, the binding properties of both types of polymer increased, depending on the metal ion, in the following order: Ni(II) < Cd(II) < Cu(II) < Pb(II). Finally, as mentioned in a previous paper (5), compared to their monomer analogues (simple carboxylic acids such as glutaric or acetic acids), polymeric acids, cross-linked or linear, are better complexing agents.

Acknowledgments

We wish to thank the Elf-Atochem Co. who kindly provided the Aquakeep® SAP X 50 R superabsorbent.

Bis(trimethylsilyl)methanesulfonyl and tris(trimethylsilyl)methanesulfonyl chlorides and their reactions by way of sulfenes[1,2]

James F. King, Kim M. Baines, Matthew R. Netherton, and Vinod Dave

Abstract: Bis(trimethylsilyl)methanesulfonyl and tris(trimethylsilyl)methanesulfonyl chlorides (**2c** and **2d**, respectively), have been prepared for the first time. Reactions of **2d** with nucleophiles give products evidently derived from bis(trimethylsilyl)sulfene (**1c**). Reaction of **2c** with piperidine gives the same piperidide as that from **2d**, presumably via **1c** formed by dehydrochlorination of **2c**, whereas water and fluoride ion yield products consistent with their formation via trimethylsilylsulfene (**1b**) formed from **2c** by attack at silicon with loss of the trimethylsilyl and chloro groups. No evidence for any enhanced stability in **1c** was found.

Key words: sulfonyl chlorides, sulfenes, silylsulfonyl chlorides, silylsulfenes, desilylation.

Résumé : Les chlorures de bis(triméthylsilyl)méthanesulfonyle et de tris(triméthylsilyl)méthanesulfonyle, respectivement **2c** et **2d**, ont été préparés pour la première fois. Les réactions de **2d** avec des nucléophiles conduisent à des produits qui, de toute évidence, dérivent du bis(triméthylsilyl)sulfène (**1c**). La réaction de **2c** avec la pyridine donne naissance au même pipéridure que celui obtenu à partir de **2c**, vraisemblablement par le biais de **1c** qui se formerait par déshydrochloration de **2c**; toutefois, les réactions avec l'eau et l'ion fluorure conduisent à des produits qui correspondraient à une formation via le triméthylsilylsulfène **1b** formé par une attaque au niveau du silicium avec perte des groupes triméthylsilyle et chloro. On n'a pas détecté de données suggérant que **1c** jouit d'une stabilité accrue.

Mots clés : chlorures de sulfonyle, sulfènes, chlorure de silylsulfonyle, silylsulfènes, désilylation.

[Traduit par la Rédaction]

Introduction

Over a number of years we have investigated the reactions of sulfonyl compounds, with a particular focus on those that lead to and from sulfenes (**1**) (2, 3). A significant component of this study in recent years has been the examination of the mechanisms of hydrolysis of alkanesulfonyl chlorides (**2**) and related compounds (4–8). Included in this latter work is a study of the hydrolysis of trimethylsilylmethanesulfonyl chloride (**2b**) (6), in which we observed that the only discernible mode of reaction of water or fluoride anion in an aqueous medium was by way of attack at the silicon atom with ultimate formation of products derived from sulfene (**1a**). The reaction in water was clearly following the pathway found by Block and Aslam (9) in the reaction of **2b** with cesium fluoride in acetonitrile. With aqueous hydroxide ion, silicophilic attack to form **1a** was the major pathway (65%), with proton removal leading to trimethylsilylsulfene (**1b**), a minor (35%) route (6). The trimethylsilyl group appeared to be mildly activating relative to an alkyl group in sulfene formation by dehydrohalogenation; k_{EOH} at 1°C for **2b** (reaction via **1b**) was found to be 6.0×10^2 M^{-1} s^{-1}, whereas the corresponding reactions of ethanesulfonyl, propanesulfonyl, and butanesulfonyl chlorides (by dehydrochlorination with hydroxide anion) have slightly lower rate constants (respectively, 5.47×10^2, 5.10×10^2, 4.47×10^2 M^{-1} s^{-1}) even at 25°C (4).

Within this context it was of interest to inquire about the corresponding chemistry of the unknown bis- and tris(trimethylsilyl)methanesulfonyl chlorides (**2c** and **2d**, respectively) and to determine by what means and how readily these materials might yield the sulfenes **1b** and **1c**. A potential bonus in the proposed study was the possibility that bis(trimethylsilyl)sulfene (**1c**) might be sufficiently stable or at least slow enough to react so that some kind of direct observation of sulfene **1c** at room temperature might be possible. Sulfenes as commonly generated are very short-lived species, and the parent sulfene itself (**1a**) has only been observed in matrices at low temperatures (e.g., 77 K); at the time this study began, all previous attempts to generate a

sulfene directly observable by NMR spectrometry, for example, had failed (see ref. 3 for details).[4] In support of the possibility that **1c** might be directly observable we recalled that trimethylsilylketene is evidently more stable than most simple ketenes (see ref. 14 and sources cited), and to the extent that sulfenes are analogues of ketenes, one may naively imagine similar behaviour with trimethylsilylsulfenes. Trimethylsilylsulfene itself (**1b**) had been found to react very rapidly under the conditions of its formation (6, 9), but the possibility remained that the doubly substituted sulfene (**1c**) might react more slowly.[5]

This paper reports the preparation of bis(trimethylsilyl)methanesulfonyl and tris(trimethylsilyl)methanesulfonyl chlorides (**2c** and **2d**), and a brief study of some of their reactions with nucleophiles and bases leading to products formed through intermediate sulfenes.

Results and discussion

The preparation of **2b** reported by Baukov et al. (16) involved reaction of the trimethylsilylmethyl Grignard reagent with sulfur dioxide followed by treatment with chlorine. Since preparations of both the bis- and tris(trimethylsilyl)methyllithium species had been described earlier (17, 18) they were, in our view, promising intermediates for the proposed syntheses. Zwanenburg and coworkers (19–21) had already reported that α-silylated organolithium species on treatment with sulfur dioxide at low temperature followed by warming to room temperature led to the corresponding sulfine, $R^1R^2C{=}SO$, postulated to arise from a Peterson elimination of Me_3SiO^- from the intermediate silylated sulfinate salt, $Me_3SiR^1R^2C\text{-}SO_2^-Li^+$. It seemed likely that sulfine formation could be avoided if the sulfinate salt were treated with chlorine prior to allowing the mixture to warm up. This was indeed found to be the case. As may be seen in Scheme 1, warming of the sulfinate gave the sulfine (**3**) whereas addition of chlorine to the cold sulfinate yielded the sulfonyl chloride (**2d**) in 71% yield. Similar treatment of bis(trimethylsilyl)methyllithium with sulfur dioxide followed by addition of chlorine at low temperature produced bis(trimethylsilyl)methanesulfonyl chloride (**2c**). The structures, **2c** and **2d**, follow from the mode of synthesis, full agreement of spectra and analyses with expectation, and the reactions summarized in Scheme 2.

Reaction of **2d** with cesium fluoride and neopentyl alcohol in acetonitrile following the procedure of Block and Aslam (9) for the generation of sulfene (**1a**) from **2b**, gave a product showing a ^1H NMR spectrum in full accord with the neopentyl ester (**4a**) (and which is very similar to that of the methyl ester prepared as indicated below). This product is, of course, that expected from silicophilic attack of fluoride

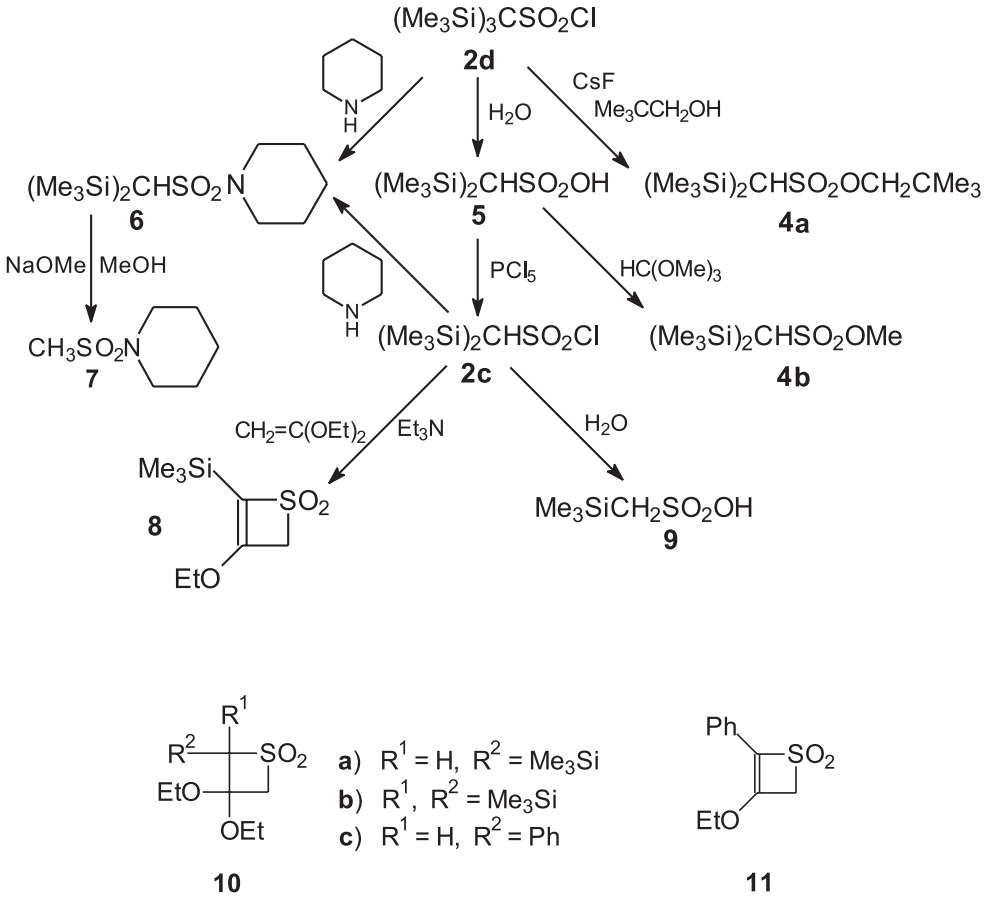
to yield bis(trimethylsilyl)sulfene (**1c**), followed by trapping of the sulfene with the alcohol. All attempts to observe **1c** by NMR spectrometry were unsuccessful; **2d** with CsF and CD_3CN in the absence of added sulfene traps showed in the ^{19}F NMR spectrum a decet appropriate to Me_3SiF, but neither ^1H nor ^{13}C NMR spectra showed any signals clearly assignable to **1c**.

With water, **2d** gave bis(trimethylsilyl)methanesulfonic acid (**5**), presumably also via **1c** which is trapped in the normal way by water. The structure (**5**) was confirmed by conversion with phosphorus pentachloride to the same sulfonyl chloride (**2c**) as that obtained above from bis(trimethylsilyl)methyllithium, sulfur dioxide, and chlorine. Esterification of **5** with trimethyl orthoformate by the method of Just and co-workers (22) gave methyl bis(trimethylsilyl)methanesulfonate (**4b**).



Further corroboration of this general picture was provided by the formation of the same sulfonpiperidide (**6**) by reaction of either **2d** or **2c** with piperidine. With **2d**, which lacks the α-hydrogen, piperidine reacts at one of the silicon atoms to form **1c**, but with **2c** the preferred mode of attack is

[4] After this work began we learned of the report by Skrypnik and Lyashchuk (10) that reaction of Arduengo's carbene (11) with sulfur dioxide gives a crystalline sulfene which is: (*i*) stable at low temperature; and (*ii*) at a "temperature above 25–30°C leads to a rapid decomposition … with SO_2 loss." Mention of this report requires a caveat concerning the reliability of work from this laboratory. Dixon and Arduengo and coworkers (12) re-examined a closely related report by Lyashchuk and Skrypnik (13) on the analogous formation of a ketene by reaction of the Arduengo carbene with carbon monoxide. The American authors: (*i*) were unable "to duplicate the experimental result reported by Lyashchuk and Skrypnik,"; and (*ii*) carried out extensive ab initio calculations, finally concluding that "no evidence is found for the existence of a stable ketene product [in this system]." (12). We had previously investigated two earlier reports by Skrypnik and co-workers of experimental results which appeared difficult to reconcile with previous experience, and found that the results reported by the Ukrainian workers were in both instances different from ours (ref. 3, pp. 708 and 710).

[5] It should be pointed out that the stabilization of trimethylsilylketene has been ascribed (14, 15) to hyperconjugation involving donation from the C—Si bond into the carbonyl system, and that no analogous hyperconjugation is possible with the sulfonyl analogues (**1b** or **1c**).

Scheme 2.

evidently at the α-proton with elimination of HCl to form the same sulfene (**1c**) which then yields **6**. With water, on the other hand, the normal reaction of **2c** (as had already been observed with **2b** (6, 23)), is silicophilic attack to yield the sulfonic acid with one fewer trimethylsilyl groups, i.e., **9**, presumably via **1b**; the acid was identical to that previously obtained as the minor product in the reaction of **2b** with hydroxide ion (6).[6] Further evidence for the formation of the sulfene by elimination of HCl with an amine was provided by the isolation (albeit in low yield) by treatment of **2c** with triethylamine and diethyl ketene acetal, of a product assigned structure **8** on the basis of its spectra and mode of synthesis. Formation of **8** may be readily imagined to take place by way of the initial bis(trimethylsilyl)sulfene – ketene acetal adduct (**10b**), formed in the same way as **10a** from the reaction of the triethylamine and the same ketene acetal with trimethylsilylmethanesulfonyl chloride, as reported by Shipov et al. (24). Loss of alkoxide in the formation and reactions of sulfene cycloadducts has been reported (25–27), with perhaps the closest analogue being Truce and Norell's conversion (25) of **10c** into **11** by the action of sodium ethoxide in dry ethanol. The formation of a carbanion from attack of a nucleophile on the trimethylsilyl group is well-known, and the ease of such cleavage with α-trimethylsilylsulfonyl compounds is strikingly shown by the reaction of **6** with 0.2 M sodium methoxide in methanol; 5 min at room temperature was sufficient to remove both trimethylsilyl groups to form methanesulfonpiperidide (**7**).

The present experiments taken with previous studies (6) reveal a consistent pattern in the reactions of these sulfonyl chlorides with nucleophiles. Water and fluoride anion are strongly silicophilic but not very basic, the result is that these reagents attack at silicon with formation of the sulfene lacking one trimethylsilyl group, and thence to derived products. With piperidine, which is a stronger base, attack at an α-hydrogen (where present) leads to the sulfene with the same number of trimethylsilyl groups, but where there is no α-hydrogen the silicophilic attack readily takes place. This behaviour is to be compared with that noted earlier for **1b** with: (*i*) triethylamine which led, in the presence of an enamine or a ketene acetal, to the enamine cycloadducts expected from **2b** (23); and (*ii*) hydroxide in which the major product is that of silicophilic attack (to give **2a**) and the minor product that of dehydrohalogenation (to give **2b**); the balance in favour of silicophilic attack of hydroxide is consistent with the stronger Si—O bond vs. Si—N.

[6] Note that a conceivable alternative route from **2c** to **9**, namely via a simple hydrolysis of **2c** to give **5** followed by desilylation of **5** to form **9**, is excluded by the observation that **5** is stable to these reaction conditions. The possibility that **2d** reacts by initial hydrolysis to $(Me_3Si)_3CSO_2OH$ followed by desilylation is not rigorously excluded by the present work but in view of the evidence in this and previous studies for sulfene formation by desilylation by the action of water or amines on **2b** and **2c**, it would seem perverse to propose a non-sulfene process from **2d**.

Experimental

Instruments and general procedures are as previously described (1); where not otherwise noted NMR spectra are of $CDCl_3$ solutions.

Tris(trimethylsilyl)methanesulfonyl chloride (2d)

Excess SO_2 (~10 mL) was condensed into dry THF (5 mL) at –78°C under an atmosphere of argon. A solution of $(Me_3Si)_3CLi$ (18) (10 mmol in THF) was added over 5 min; the solution became pale green. Immediately following the addition, a stream of dry Cl_2 was passed through the solution until it became colourless. The volatile material was removed at the rotary evaporator, and the residual solid taken up in petroleum ether (bp 35–60°C). The mixture was filtered through a sintered glass funnel, and the solvent evaporated leaving a white solid (2.34 g, 71%), mp 131°C (dec.). IR (film) ν_{max} (cm^{-1}): 1338 (vs), 1259 (vs), 1149 (vs), 834 (vs, br), 680 (s). ^1H NMR δ: 0.43. ^{13}C NMR δ: 63.7, 2.9. ^{29}Si NMR δ: 3.36. Exact mass calcd. for $C_{10}H_{27}ClO_2SSi_3$: 330.0728; found: 330.0723. Anal. calcd. C 36.36, H 8.18, Cl 10.60, S 9.69; found: C 36.33, H 8.23, Cl 10.69, S 9.27.

Bis(trimethylsilyl)sulfine (3)

To excess SO_2 (~5 mL) in dry THF (10 mL) at –78°C under argon was added $(Me_3Si)_3CLi$ (3 mmol in 7 mL of THF) over 2 min as above, and the solution allowed to come to room temperature, (turning from pale green to pale yellow). Saturated aq NH_4Cl (20 mL) was added and the mixture extracted with ether (3 × 20 mL). The solvent was removed yielding an orange oil (372 mg). Kugelrohr distillation (50°C, 1 torr (1 torr = 133.322 Pa)) yielded **3** as a colourless liquid (246 mg, 41% from $(Me_3Si)_3CH$). ^1H NMR δ: 0.31 (s, 9H), 0.25 (s, 9H). ^{13}C NMR δ: 194.7, 0.24, 0.20. ^{29}Si NMR δ: –3.48, –4.37. A sample of the sulfine was further purified by preparative thick layer chromatography on silica gel eluting with hexanes:benzene (1:1) yielding a colourless oil. Exact mass calcd. for $C_7H_{20}OSSi_2$ (M + 1): 207.0695; found (CI): 207.0687. Zwanenburg (21) refers to preparation of **3** in a table without further description.

Bis(trimethylsilyl)methanesulfonyl chloride (2c)

(i) From bis(trimethylsilyl)methyllithium

To stirred excess SO_2 (~25 mL) at –70°C was added a solution of $(Me_3Si)_2CHLi$ in ether (25 mL) (kindly supplied by F. Guérin and D.H. McConville) over 1 min, and the solution stirred for 15 min. To this solution, still at –70°C, Cl_2 gas was bubbled in and the solution allowed to stir at –70°C for 30 min. The volatile material was evaporated under reduced pressure and the residual oily solid taken up in petroleum ether (bp 35–60°C) and the mixture filtered through a sintered glass funnel. Removal of the solvent gave **2c** as a colourless solid, mp 71–73°C. IR ν_{max} (cm^{-1}): 1370 (s), 1198 (s). ^1H NMR δ: 3.26 (s, 1H), 0.34 (s, 18H). ^{13}C NMR δ: 63.4, 0.7. ^{29}Si NMR δ: 2.83. Anal. calcd. for $C_7H_{19}ClO_2SSi_2$: C 32.47, H 7.34, Cl 13.70, S 12.36; found: C 33.09, H 7.67, Cl 13.12, S 12.37.

(ii) From bis(trimethylsilyl)methanesulfonic acid (5)

A mixture of **5** (5 mg, 0.02 mmol) anhydrous ether (2 mL) and phosphorus pentachloride (15 mg, 0.07 mmol) was stirred at room temperature for 2 h. The volatile material was evaporated under reduced pressure, the residue taken up in petroleum ether, the mixture filtered, and the solvent evaporated as above, to yield a colourless solid showing the same ^1H and ^{13}C NMR spectra as those obtained from **2c** prepared as above.

Reaction of 2d with cesium fluoride and neopentyl alcohol

To a mixture of neopentyl alcohol (90 mg, 1 mmol) and cesium fluoride (71 mg, 0.5 mmol) in dry acetonitrile (7 mL) at 0°C under an atmosphere of dry argon was added **2d** (150 mg, 0.45 mmol) in acetonitrile (2 mL) in one portion. The mixture became pale brown in colour. After 2 h, the mixture was warmed to room temperature and stirred for an additional 1.5 h, whereupon the solvent was removed under reduced pressure and the residue taken up in CH_2Cl_2. Water was added and the mixture extracted with several small portions of CH_2Cl_2. The organic extracts were combined, dried over $MgSO_4$, and the solvent removed on the rotary evaporator yielding a pale brown waxy solid (92 mg). The ^1H NMR spectrum and mode of preparation are consistent with structure **4a**: δ: 3.80 (s, 2H), 2.39 (s, 1H), 0.97 (s, 9H), 0.27 (s, 18H).

Hydrolysis of tris(trimethylsilyl)methanesulfonyl chloride (2d)

$(Me_3Si)_3CSO_2Cl$ (**2d**) (160 mg, 0.485 mmol) was added to a solution of THF (1 mL) in water (5 mL). The solid dissolved quickly with evolution of heat. After 1 h, the solution was extracted with hexane (3 × 2 mL). The water was removed from the aqueous layer under reduced pressure (Rotovap) giving a brownish waxy solid. Hexane was added to the solid, giving a clear organic layer with dark coloured aqueous drops; the latter were discarded and the hexane removed under reduced pressure yielding **5** as white crystals (90 mg, 77%). ^1H NMR (D_2O) δ: 10.2 (br s), 2.46 (s, 1H), 0.26 (s, 18H). ^{13}C NMR δ: 45.5, 0.5. ^{29}Si NMR δ: 1.51.

Bis(trimethylsilyl)methanesulfonpiperidide (6)

(i) From tris(trimethylsilyl)methanesulfonyl chloride (2d)

Excess piperidine (1 mL, 10 mmol) was added dropwise to a solution of **2d** (200 mg, 0.61 mmol) in CH_2Cl_2 (5 mL), and the mixture stirred for 2 h. Water (10 mL) was added and the mixture extracted with ether (3 × 10 mL). The organic layers were combined, dried ($MgSO_4$), and the solvent removed on the rotary evaporator yielding an orange waxy solid. Column chromatography on silica gel (eluting with 35% ether in petroleum ether), followed by preparative thick layer chromatography gave the sulfonamide (**6**) (120 mg, 64%) as white needles, mp 72–73°C. IR ν_{max} (cm^{-1}): 1291 (s), 1277 (s); 1249 (s), 1128 (s), 851 (vs). ^1H NMR δ: 3.10 (m, 4H), 2.55 (s, 1H), 1.56 (m, 6H), 0.23 (s, 18H). ^{13}C NMR δ: 46.1, 44.3, 25.4, 23.9, 1.0. ^{29}Si NMR δ: 0.44. Exact mass calcd. for $C_{12}H_{29}NO_2SSi_2$: 307.1458; found: 307.1446.

(ii) From bis(trimethylsilyl)methanesulfonyl chloride (2c)

A solution of piperidine (100 mg, 1 mmol) in chloroform (0.5 mL) was added to a stirred solution of **2c** (32 mg, 0.1 mmol) in chloroform (1.0 mL) at 0°C and the mixture stirred at 0°C for 30 min and at room temperature for 1 h.

© 2000 NRC Canada

Chloroform was added and the mixture washed with water. The organic layer was dried and the solvent removed yielding **6** (30 mg) identical (mp, TLC, ^{1}H and ^{13}C NMR spectra) to the **6** prepared as above from **2d**.

Desilylation of bis(trimethylsilyl)methanesulfonpiperidide (6)

A solution of sodium methoxide (10 mL) (from Na, 50 mg, 2 mmol) was added to a solution of **6** (29 mg, 0.09 mmol) in methanol and the mixture stirred for 5 min. Water (5 mL) was added and the mixture extracted with small portions of ether. The ether extracts were combined, dried, and the solvent removed yielding methanesulfonpiperidide (**7**) (13 mg, 89%) as a white solid showing ^{1}H and ^{13}C NMR spectra identical to those of a sample of **7** prepared earlier from piperidine and **2a**, mp 48–49°C (28), lit. (29) mp 48.5–50°C. ^{1}H NMR δ: 3.16, (m, 4H), 2.74 (s, 3H), 1.66 (m, 4H), 1.54 (m, 2H). ^{13}C NMR δ: 46.8, 34.5, 25.4, 23.8.

Methyl bis(trimethylsilyl)methanesulfonate (4b)

A solution of **5** (10 mg, 0.04 mmol) in trimethyl orthoformate (0.5 mL) was heated for 18 h (22). Volatile materials were evaporated under reduced pressure leaving methyl bis(trimethylsilyl)methanesulfonate (**4b**) as a colourless solid, mp 52–53°C. IR ν_{max} (cm^{-1}): 1262 (s), 1297 (s), 1167 (s). ^{1}H NMR δ: 3.70 (s, 3H), 2.40 (s, 1H), 0.25 (s, 18H). ^{13}C NMR δ: 52.5, 43.5, 0.5. ^{29}Si NMR δ: 1.89. Exact mass calcd. for $C_8H_{23}O_3SSi_2$ (M + 1): 255.0906; found (CI): 255.0901.

Reaction of bis(trimethylsilyl)methanesulfonyl chloride (2c) with ketene diethyl acetal

Sulfonyl chloride (**2c**) (200 mg, 0.77 mmol) in ether (2 mL) was added with a positive pressure of argon over 2 min to a stirred solution of Et_3N (82 mg, 0.77 mmol) and ketene diethyl acetal (30) (95 mg, 0.8 mmol) in dry ether (3.0 mL) at 5°C. A white solid precipitated immediately; stirring was continued for 30 min at 5°C and then for 6 h at room temperature. The precipitate was removed by filtration through a sintered glass funnel and the solvent from the filtrate removed under reduced pressure leaving a viscous oil (214 mg). Preparative thick layer chromatography (twice, initially with hexanes:ethyl acetate (94:6) R_f = 0.35, then benzene:ether (95:5) developing twice, R_f = 0.38) gave a colourless oil (9 mg) showing the following spectra consistent with structure **8**: ^{1}H NMR δ: 4.55 (s, 2H), 4.04 (q, 2H), 1.38 (t, 3H), 0.28 m (s, 9H). ^{13}C NMR δ: 165.0, 132.9, 69.9, 69.3, 14.9, –0.7. Exact mass calcd. for $C_8H_{16}O_3SSi$: 220.0588; found: 220.0587.

Acknowledgements

We thank the Natural Sciences and Engineering Research Council of Canada (NSERC) for financial support in the form of an operating grant, and Drs. F. Guérin and D.H. McConville for the generous gift of a supply of bis(trimethylsilyl)methyllithium.

Synthesis and X-ray structure of 1,2,2,2-tetrakis(3-methoxyphenyl)ethanone

LeRoy H. Klemm and Timothy J.R. Weakley

Abstract: Photochemical reductive dimerization of 3,3′-dimethoxybenzophenone (**1b**) gave the symmetrical benzopinacol 1,1,2,2-tetrakis(3-methoxyphenyl)ethane-1,2-diol (**2b**), which was rearranged to the benzopinacolone 1,2,2,2-tetrakis(3-methoxyphenyl)ethanone (**3b**) by means of I_2 in boiling glacial HOAc. The structure of **3b** was indicated by ^{1}H NMR and determined definitively by X-ray crystallography. The crystals are monoclinic, space group $P2_1/c$, a = 12.250(2), b = 9.6997(12), c = 20.866(2) Å, β = 95.319(11)°, Z = 4, R = 0.053 for 4523 independent reflections. The structure establishes that the migrating 3-methoxyphenyl group retains bonding through its number 1′ carbon atom to the parent C_2-unit during the rearrangement process.

Key words: X-ray structure, pinacol–pinacolone rearrangement, chemical bonding.

Résumé : La réaction de dimérisation photochimique réductrice de la 3,3′-diméthoxybenzophénone (**1b**) fournit le benzpinacol symétrique 1,1,2,2-tétrakis(3-méthoxyphényl)éthane-1,2-diol (**2b**) qui se réarrange en benzopinacolone 1,2,2,2-tétrakis(3-méthoxyphényl)éthanone (**3b**) sous l'influence d'I_2 dans de l'acide acétique glacial bouillant. La structure du composé **3b** a été établie par RMN du ^{1}H et déterminé d'une façon définitive par diffraction des rayons-X. Les cristaux sont monocliniques, groupe d'espace $P2_1/c$ Å, β = 95,319°, Z = 4, R = 0,053 pour 4523 réflexions indépendantes. La structure permet de conclure que, durant le processus de réarrangement, le groupe 3-méthoxyphényle qui migre maintient sa liaison avec l'atome de carbone 1′ jusqu'à ce qu'il soit relié à l'unité C_2.

Mots clés : diffraction des rayons X, réarrangement pinacol–pinacolone, liaison chimique.

[Traduit par la Rédaction]

Introduction

The rearrangement of benzopinacol (**2a**) to benzopinacolone (**3a**) was described in 1877 (1). Convenient experimental procedures for the synthesis of **2a** from benzophenone (**1a**) and its conversion to **3a** were reported by Bachmann (2), who also investigated the relative migratory apititudes of various substituted phenyl groups (3–5). Comparison of the isolated yield of the isomeric ketones from rearrangement of diols **4a** and **4b** gave the order *p*-methoxyphenyl >>>phenyl > *m*-methoxyphenyl (3, 4, 6, 7) in migratory aptitude. A variety of Brönsted and Lewis acidic catalysts have been used for the pinacol rearrangement (1–3, 6, 8). For most symmetrical aromatic pinacols Bachmann and Ferguson (4) effected the transformation by refluxing 2–4 g of the diol, e.g., **4d**, with a mixture of AcCl, HOAc, and benzene for 2–4 days. However, this treatment was ineffective for rearranging the *m*-methoxyphenyl compounds **4a** and **4c**, which required "a more powerful reagent," viz. a solution of 0.05 g of I_2 in 15 mL of HOAc, plus refluxing for only 15–30 min. In contrast, compound **2d**, bearing the highly activating *p*-methoxy groups, is easily rearranged to **3d** under either of these reaction conditions, or even by heating in HOAc alone at 100°C for 10 min (7, 9). The less reactive parent benzopinacol (**2a**) undergoes rearrangement by heating with acid chlorides or aqueous acids, as well as by the I_2–HOAc method (2, 10). A solution of **2a** in HOAc alone required heating at 180–200°C in a sealed tube to accomplish rearrangement (1).

Consultation of the literature indicated that neither the benzopinacol **2b** nor the ketone **3b**, bearing four *m*-methoxyphenyl groups, had been reported. Since we had compound **1b** available from another project (11), we proceeded to ascertain: (*i*) if Scheme 1 could be completed by the Bachmann procedure; and, if so, (*ii*) if the aryl group on migrating from C-1 to C-2 would retain its bonding position to the molecule via carbon C-1′ i.e., if the *m*-methoxyphenyl group would undergo ipso-rearrangement exclusively (12).

Specifically, the known ketone **1b** was converted into diol **2b** (42% yield) and rearranged nearly quantitatively following closely the Bachmann procedures (2). Structural location of the methoxy groups in the resultant benzopinacolone was indicated by ^{1}H NMR and established definitively by X-ray crystallography of the isolable, purified product.[2]

Experimental

IR spectra were determined on KBr wafers by means of a Nicolet 5-DXB FTIR spectrophotometer. ^{1}H NMR spectra were recorded on a General Electric QE-300 instrument. Mass spectra were obtained at 70 eV by Dr. Richard Wielesek of this laboratory on a VG 12-250 instrument. Elemental analyses were conducted by Desert Analytics, Tucson, AZ.

Purification of 3,3′-dimethoxybenzophenone (1b)

This compound, available from a previous synthesis (11), was redistilled as a light yellow oil, bp 170–172°C (1.3 mm). EIMS *m*/*z* (%): 243 (18), 242 (M^+, 100), 211 (M^+ – MeO, 17), 135 ($MeOC_6H_4C{=}O^+$, 72), 107 ($MeOC_6H_4^+$, 15), 92 (27). ^{1}H NMR (in $CDCl_3$, δ): 7.45–7.3 (m, 6 aromatic H), 7.2–7.1 (m, 2 aromatic H), 3.87 (s, 6H, 2 MeO).

Preparation of 1,1,2,2-tetrakis(3-methoxyphenyl)ethane-1,2-diol (2b)

A solution of **1b** (7.08 g, 29.2 mmol), glacial HOAc (4 drops), and 2-propanol (100 mL) was exposed to midsummer sunlight in a tightly corked round-bottomed flask for 8 days. The colorless needles which formed were collected by filtration and rinsed with cold 2-propanol (2.97 g of **2b**, 42%), mp 153.5–156°C, raised to 157.5–158.5°C on recrystallizations from petroleum ether (30–60°C):acetone (1:1). EIMS *m*/*z* (%): 468 ($M^+ - H_2O$, <0.1), 242 ($(MeOC_6H_4)_2C{=}O^+$, 41), 135 ($MeOC_6H_4C{=}O^+$, 100), 109 (33), 107 ($MeOC_6H_4^+$, 35). FTIR (cm^{-1}): 3535 (OH), 1603, 1583, 1483, 1430, 1290, 1231 (OMe). ^{1}H NMR (in acetone-d_6, δ) 7.2–6.9 (m, 12 aromatic H), 6.67 (split d, J = 3.4 Hz, 4 aromatic H), 4.79 (s, 2 OH), 3.58 (s, 12H, 4 MeO). Anal. calcd. for $C_{30}H_{30}O_6$: C 74.06, H 6.21; found: C 74.26, H 6.11.

Preparation of 1,2,2,2-tetrakis(3-methoxyphenyl)ethanone (3b)

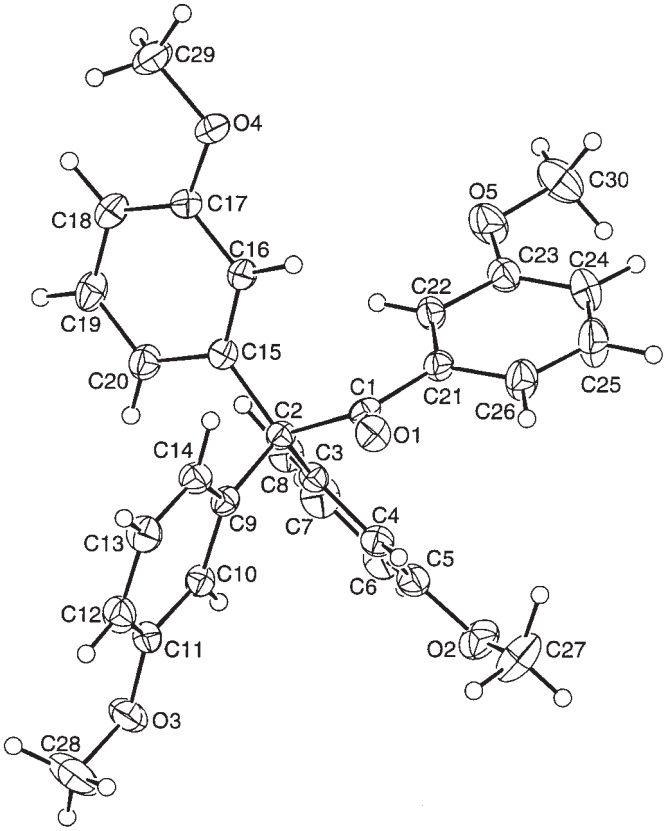
A solution of **2b** (1.85 g, 3.81 mmol) and iodine (0.11 g, 0.41 mmol) in glacial HOAc (20 mL) was refluxed for 15 min and poured into a mixture of ice, water, and excess $NaHSO_3$. The cream-colored precipitate coagulated to a brittle solid on standing. The pulverized solid was washed with water and dried in air (1.8 g of **3b**, 100%), mp 100–104°C, converted to colorless prisms on recrystallization from Et_2O–petroleum ether and then from 95% ethanol, mp 108.5–109.5°C. FTIR (cm^{-1}): 1686 (C=O), 1597, 1292, 1256, 1236 (MeO). EIMS *m*/*z* (%): 468 (M^+, 0.4), 334 (31), 333 ($(MeOC_6H_4)_3C^+$, 100), 135 ($MeOC_6H_4C{=}O^+$, 33), 107 ($MeOC_6H_4^+$, 17). ^{1}H NMR (in $CDCl_3$, δ): 7.3–6.7 (m, 16 aromatic H), 3.68 (s, 9H, 3 MeO), 3.62 (s, 3H, MeO). Anal. calcd. for $C_{30}H_{28}O_5$: C 76.90, H 6.02; found: C 76.87, H 5.95.

X-ray analysis of 3b

A crystal suitable for X-ray analysis was obtained by recrystallization of the preceding **3b** from absolute ethanol. A colorless prism was mounted on a fiber. The orientation parameters and cell dimensions were obtained at 22°C from the setting angles of an Enraf–Nonius CAD-4 diffractometer (Mo Kα radiation, λ 0.71073 Å) for 25 centered reflections in the range of 11.6–13.7°θ. Data were collected by ω-2θ scans (ω width (0.85 + 0.35 tan θ)°, speed 4.1° per min) in the θ range 1.5–25.5°; *h* 0→14, *k* 0→11, ℓ –25→25. A SIR92 E-map (13) showed all of the non-hydrogen atoms. Hydrogen atoms were located and refined isotropically. The TeXsan program suite (14), incorporating complex atomic scattering factors, was used in all calculations.

Results and discussion

The ^{1}H NMR of **3b** shows a singlet for three equivalent MeO groups at δ 3.68 and for one MeO group at δ 3.62, consistent with the structure shown.



The crystallographic data for **3b** are given in Table 1; selected bond lengths and angles, in Table 2; and selected torsion angles, in Table 3. An ORTEP drawing is shown in Fig. 1.

It is apparent from Fig. 1 that the 3-methoxyphenyl group has undergone ipso-rearrangement during the benzopinacol →benzopinacolone transformation. The quantitative yield of crude **3b** from this reaction and a high recovery of analytically pure crystals of narrow melting range indicate that no more than a few percent (if any) of a structural isomer of **3b** could have formed.

The selected data in Table 2 illustrate limited variability in corresponding bond lengths in the aryl groups attached to C-1 and C-2. However, there is a 9° variation (from 105.7–114.7°) in the angles centered on C-2, perhaps due to crowding in the molecule around this tetra-substituted carbon.

© 2000 NRC Canada

Fig. 1. ORTEP (30% probability ellipsoids) plot for **3b.**

Notable in Table 3 is the fact that in every case the MeO group is only slightly twisted (1.2–9.0°) out of coplanarity with its benzene ring. However, in three of the cases the methyl portion of the MeO group is oriented toward the *para* carbon on the ring, while in the fourth case (C27) it is oriented toward the *ortho* carbon on its ring.

ARTICLES

Colin W. Clarke and David N. Glew Aqueous nonelectrolyte solutions. Part XVI. Formula of deuterium sulfide D-hydrate and its dissociation thermodynamic functions **1**

Pierre Blais, Tristram Chivers, Andrew Downard, and Masood Parvez Synthesis and X-ray structures of amidinate, oxoamidate, and thioamidate complexes of boron **10**

John M. Roscoe, Alain R. Bossard, and Margaret H. Back A kinetic modeling study of ethylene pyrolysis **16**

Arthur Camerman, Donald Mastropaolo, Peter Nickel, Andrew Hempel, and Norman Camerman Structure of 8-[4′-(3″-nitrobenzamido)-benzamido]naphthalene-1,3,6-trisulfonate (NF-033), and molecular basis of its cellular toxicity **26**

Hironori Ohtsu, Reiko Tanaka, Yasuko In, Shunyo Matsunaga, Harukuni Tokuda, and Hoyoku Nishino New abietane diterpenoids from the cones of *Larix kaempferi* **31**

Noham Weinberg and Kurt Mislow On chirality measures and chirality properties **41**

Note of appreciation

The quality of the papers in this journal depends a great deal on the efforts of those who agree to act as critical readers of manuscripts. The editors gratefully acknowledge the following, who helped us between November 1, 1999 and October 31, 2000:

Abd-El-Aziz, A.S.
Abu Irhayem, E.
Acree, W.E.
Adam, W.
Adams, R.D.
Agosta B.
Agosta, W.C.
Albright, J.
Allara, D.L.
Allen, P.
Alper, H.
Alvarez-Cisneros, C.
Amyes, T.L.
Andersen, R.A.
Anderson, H.
Angelici, R.J.
Apeloig, Y.
ApSimon, J.W.
Armstrong, D.A.
Arndtsen, A.
Arnold. J.
Aroca, R.
Atherton, M.J.
Aube, J.
Bach, R.D.
