$$[17] \quad \Delta G_a = \langle \psi_a(\boldsymbol{X})\rangle_s \equiv E_a$$

Recapitulation

The total solvation Gibbs energy change is

$$[18] \quad \Delta G^{\bullet} = \Delta G_c + \Delta G_a = \Delta G_c + E_a = -T\Delta S_x + E_a$$

It is given by the balance between two contrasting terms: ΔG_c, which is always positive and increases with the solute size, and E_a, which is always negative and increases, in absolute value, with the solute size. Their relative magnitude is the principle factor here. It is worth noting that this equation corresponds to that obtained by means of perturbative approaches using a hard-sphere fluid as the reference system (18). The derivation outlined above, however, originally devised by Lee (6), is more robust and convincing from a theoretical point of view (i.e., there is no need to consider a reference system of hard spheres). In any case, eq. [18] has to be considered of general validity (19), and is used in the present study to understand the solubility of nonpolar compounds in different solvents.

The total enthalpy change upon solvation is

$$[19] \quad \Delta H^{\bullet} = E_a + \Delta H_r$$

where E_a, the average solute–solvent interaction energy, is the enthalpic term for the perturbing potential. The term $\Delta H_r \equiv \Delta H_c + \Delta H_{ar}$ is the enthalpy change due to structural-solvent reorganization, which happens as a response to full perturbation.

The total entropy change upon solvation is given by

$$[20] \quad \Delta S^{\bullet} = \Delta S_r = \Delta S_x + \Delta S_{nx}$$

This change is due to solvent reorganization, because the solute molecule is fixed in space, adopting the standard state proposed by Ben-Naim (3), and its internal degrees of freedom are assumed to be unchanged on transfer. The excluded-volume effect for cavity creation is, however, the entropic part of the perturbing potential, and not a solvent response (14, 15); the ΔS_x term is the corresponding entropy

© 2002 NRC Canada

contribution. Solvent molecules further reorganize around the solute in response to the full perturbation (both volume exclusion and turning on solute–solvent interaction). ΔS_{nx} represents this non-excluded volume contribution to the total entropy change upon solvation. Finally, the following compensation relation:

[21] $T\Delta S_{nx} = \Delta H_r$

is operative for the solvent response.

Calculation procedure

The Gibbs energy cost to create a cavity is calculated with the following equation provided by scaled particle theory (SPT) (20, 21):

[22] $$\Delta G_c = RT\,[K_0 + K_1(\sigma_2/\sigma_1) + K_2(\sigma_2/\sigma_1)^2 + K_3(\sigma_2/\sigma_1)^3]$$

where $K_0 = -\ln(1-\xi)$; $K_1 = u = 3\xi/(1-\xi)$; $K_2 = u\,(u+2)/2$; and $K_3 = \xi P v_1/RT$.

In these equations, R is the gas constant; ξ is the volume packing density of pure solvent, which is defined as the ratio of the physical volume of a mole of solvent molecules over the molar volume of the solvent, v_1 (i.e., $\xi = \pi\sigma_1^3 N_{Av}/6v_1$); σ_1 and σ_2 are the hard-sphere diameters of the solvent and solute molecules, respectively; and P is the pressure. There is still debate, however, on what is the correct pressure to use in eq. [22]: the experimental value of the real liquid or the value of the corresponding hard-sphere fluid (22, 23). According to the above theoretical approach, ΔG_c is the work to create the cavity in the real liquid, not in the corresponding hard-sphere fluid. Therefore, as already claimed by other authors (21, 24, 25), P has to be the experimental value (1 atm), which is the hydrostatic pressure over the liquid. This value is used in all the SPT calculations.

The cavity size is defined as the diameter of the spherical region from which any part of any solvent molecules is excluded (i.e., it corresponds to the size of the solute molecule). It is well known that the SPT results are very sensitive to the σ values selected for both solvent and solute (26). For this reason, customary hard-sphere diameters are used for the solutes and solvents, which are listed in the second column of Table 4. For water, $\sigma = 2.75$ Å (27) is used, which is close to the location of the first peak in the oxygen–oxygen pair-correlation function of water (28). It should represent the distance of closest approach between two H-bonded water molecules. For the other four solvents, ethanol, benzene, *c*-hexane, and *n*-hexane, the σ values determined by Wilhelm and Battino (4) are used. They should be reliable; for instance, in the case of benzene, $\sigma = 5.26$ Å, which is close to the maximum of the ring center – ring center pair-correlation function of liquid benzene (29). In addition, the experimental values of the liquid densities at 25°C are used for all solvents (4, 30).

Ben-Naim (3) pointed out that SPT, as applied to real solvents, is not a true molecular theory because experimental values of the molecular diameter and molar volume are used as input data in the calculations. This, however, may be one of the reasons for its wide applicability, since some structural information on the liquid is implicitly taken into account. The application of SPT relies on treating molecularly detailed solutes as effective hard spheres, which is clearly an approximation. Nevertheless, both surface-area-based models (31) and statistical mechanically founded force fields (32), able to account for the subtleties of treating a molecular solute, seem to validate the spherical approximation.

The E_a term accounts for the van de Waals interactions of nonpolar molecules in the five solvents. It is estimated using a simple formula devised by Pierotti (21). He assumed that the solute–solvent dispersive interactions are represented by the Lennard–Jones potential and that the solvent density around the solute is uniform and equal to that of pure solvent. The formula of Pierotti (21) is:

[23] $E_a = -(64/3)\xi\,\varepsilon_{12}(\sigma_{12}/\sigma_1)^3$

where $\sigma_{12} = (\sigma_1 + \sigma_2)/2$, $\varepsilon_{12} = (\varepsilon_1\varepsilon_2)^{1/2}$, and ε_1 and ε_2 are the Lennard–Jones potential parameters for the solvent and solute, respectively, which measure the magnitude of the maximum attractive potential energy. Notwithstanding the simplifying assumptions, this formula is sound from a physico-chemical point of view, and should perform satisfactorily (33).

In benzene, *c*-hexane, and *n*-hexane the van der Waals interactions of nonpolar solutes consist purely of dispersive contributions. For these solvents, the ε_1/k values determined by Wilhelm and Battino (4) are used: 531 K for benzene, 573 K for *c*-hexane, and 517 K for *n*-hexane. In water and ethanol the van der Waals interactions of nonpolar solutes consist of both dispersive and dipole-induced dipole contributions. It is assumed that the latter can be absorbed into the parameterization of the dispersive contribution. This assumption is reasonable because both terms depend on the inverse sixth power of distance (34), and is usually employed in molecular mechanics force fields (35). The dipole-induced dipole contribution is taken into account by increasing the ε_1/k value of water and ethanol. Specifically, for water $\varepsilon_1/k = 100$ K instead of 85 K (21) is used, and for ethanol $\varepsilon_1/k = 330$ K instead of 324 K is used (4).

The ε_2/k values used for noble gases and alkanes are listed in the third column of Table 4. They do not correspond exactly to literature values; this should not be a problem because of the discrepancies that exist between the ε_2/k values obtained by different procedures (4). In addition, the ε_2/k values of noble gases are close to those reported by Pierotti (21); the values for the aliphatic hydrocarbons are lower than those reported by Abraham and Nasehzadeh (36), but in accordance with those quoted by Hirschfelder and co-workers (37).

It should be emphasized that both ΔG_c and E_a are not measurable quantities and that only their sum can be tested against experimental $\Delta G^\bullet$ data (38). In this paper, estimates of ΔG_c and E_a are obtained using several assumptions whose validity cannot be taken for granted. Computer simulations are also based on assumptions, where the results may be biased by the parameter values selected for the potential energy functions. The consistency of the assumptions can be checked by comparing the sum $\Delta G_c + E_a$ with the experimental $\Delta G^\bullet$ data. This procedure has been applied to this work.

Values for ΔH_r are obtained via eq. [19], where the E_a estimates are subtracted from the experimental $\Delta H^\bullet$ values.

This procedure is appealing because it is very difficult to obtain a reliable estimate of ΔH_r, using both theoretical relations and computer simulations. This is because ΔH_r is the difference in the two large and fluctuating quantities: the enthalpy of the solvent after the solute insertion and that of the pure solvent. For the same reason, the values for ΔS_{nx} are obtained by means of eq. [20], where the ΔS_x estimates, calculated using eq. [9], are subtracted from the experimental ΔS^* values.

Analysis of the direct perturbation

The values of ΔG_c for noble gases and aliphatic hydrocarbons in the five solvents, calculated using eq. [22], are listed in the third column of Tables 5–9. It is readily evident that the work of cavity creation is larger in water than in the other four solvents. For instance, for methane, ΔG_c(in kJ mol^{-1}) = 21.1 in water, 17.3 in benzene, 16.0 in *c*-hexane, 15.6 in ethanol, and 13.4 in *n*-hexane; for *i*-butane, ΔG_c(in kJ mol^{-1}) = 41.7 in water, 32.6 in benzene, 29.8 in *c*-hexane, 29.6 in ethanol, and 24.6 in *n*-hexane. It is interesting to note that the order of ΔG_c corresponds to that of the surface tension of the five liquids. (The values for surface tension at 25°C, in dyne cm^{-1}, are 71.99 for water, 28.22 for benzene, 24.65 for *c*-hexane, 21.97 for ethanol, and 17.89 for *n*-hexane (39).) This agrees with the well-established correlation between the work of cavity creation and the surface tension of the liquid at room temperature (40). It must be noted, however, that the

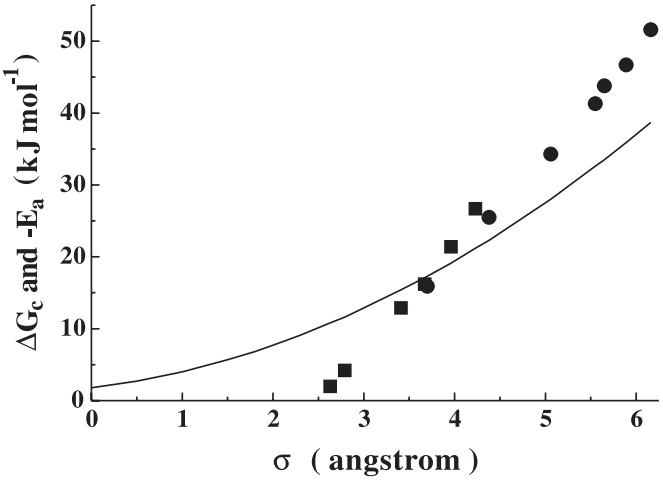

Fig. 8. Trend of ΔG_c in *c*-hexane at 25°C as a function of the solute's size, calculated by means of eq. [22]. The estimates of $-E_a$, calculated by means of eq. [23], for noble gases (■) and aliphatic hydrocarbons (●) in *c*-hexane are also shown.

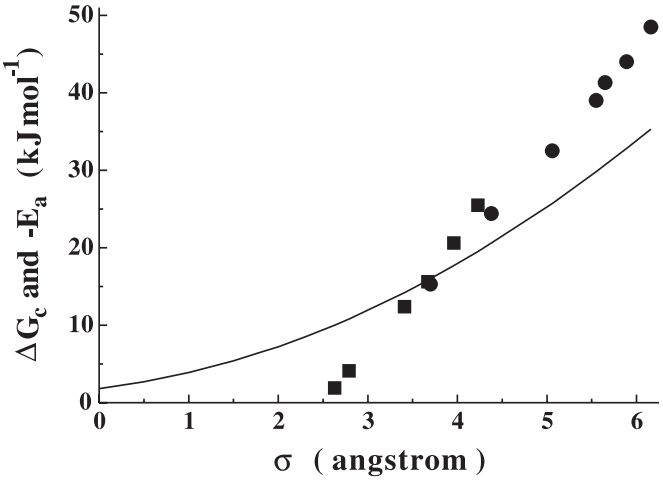

temperature dependence of ΔG_c in water does not agree with the macroscopic surface tension, i.e., with increasing temperature, the former exhibits a maximum (33), whereas the latter decreases monotonically (39). This implies a crossover from molecular cavities to macroscopic surfaces, which is perhaps buried in the non-trivial temperature dependence of the Tolman length (24, 41).

Analysis of the SPT formula shows that, at a fixed temperature and cavity radius, the magnitude of ΔG_c is determined by two geometrical properties of the solvent (6, 39): the size of its molecules (σ) and its volume-packing density (ξ). The work of cavity creation increases on decreasing the value of σ for a given ξ, and on increasing the value of ξ for a given σ. In general, the effect of the smallness of σ is dominant, and ΔG_c is larger in water compared with other solvents (6, 42–44). (Recall that the size of a water molecule is the smallest among all common solvents, i.e., it corresponds to the size of an oxygen atom.) It is worth noting that Lazaridis (45) recently claimed that it is the large cohesive energy density of liquid water, due to H-bonds, that are the fundamental cause of hydrophobicity and not the small size of water molecules. But this analysis seems to be a bit artificial, considering that the ΔG_c values determined in an isotropic single-site model of water, which lacks the attractive interactions due to H-bonds but retains the small molecular size, prove to be larger than those determined in water models, which take into account the presence of H-bonds (46).

In general, detailed computer simulations have confirmed the SPT predictions (47–50). At room temperature, the fractional-free volume is larger in water than in common organic liquids, as approximately indicated by the ξ values: 0.363 for water, 0.439 for ethanol, 0.513 for benzene, 0.517 for *c*-hex-

© 2002 NRC Canada

ane, and 0.497 for *n*-hexane (i.e., approximate because the ξ values refer to the packing of spheres, whereas the actual molecules are not spheres). Pohorille and Pratt (47) show, however, that this fractional-free volume is partitioned in a specific manner in each liquid, depending on the characteristic length scale of the liquid itself, i.e., the size of its molecules. As a consequence, the distribution of cavity sizes is significantly sharper in water than in other solvents (47), and the actual volume accessible to a solute is smaller in the former than in the latter. In addition, the contact density predicted by SPT, even though lower than that computed for TIP4P water, show a similar dependence on solute size (48). This quantitative discrepancy may be due to the directional nature of H-bonds, a feature neglected in SPT. The major role of the squeezing force exerted by water molecules on the cavity surface is, however, correctly explained by SPT. In conclusion, ΔG_c is larger in water than in common organic solvents because the empty space is partitioned in smaller packets due to the smaller size of water molecules (6, 49, 50).

The estimates of E_a, calculated using eq. [23], and the values for the sum $\Delta G_c + E_a$ are listed in the fourth and fifth columns of Tables 5–9, respectively. Good agreement with the experimental $\Delta G^•$ data for both noble gases and alkanes in ethanol, benzene, *c*-hexane, and *n*-hexane is seen. It is also observed for noble gases and methane in water, but not for large alkanes in water (see Table 5). For the latter, the estimates of E_a calculated using Pierotti's formula are too large; i.e., see the numbers reported in the second line of the fourth column of Table 5 from ethane to *n*-pentane. In particular, the calculated E_a values for neopentane and *n*-pentane are so large that they overwhelm the ΔG_c values from SPT. This result is clearly not correct, because experimental measurements unequivocally show that $\Delta G^•$ is a large positive quantity. Pierotti's formula, therefore, seems to fail for large alkanes in water.

The problem, however, is not in the formula itself, but the parameters that are used. Specifically, the ε/k values reported in the third column of Table 4 for large alkanes do not work well for water. This could be due to the fact that each water molecule, being very small, interacts only with a single methyl or methylene group and does not "feel" all of the electron density of an alkane molecule. This situation does not occur in the other four solvents, because their molecules have a size comparable or larger than that of all the solutes considered. It also does not happen for noble gases and methane in water for two physical reasons: first, these solutes are not large in comparison with a water molecule, except xenon and radon; second, they are spherical, and thus each water molecule in the hydration shell interacts with all the electrons of the solute.

If this reasoning is correct, Pierotti's formula should also work well for large alkanes in water by fixing a unique and constant ε/k value, which is intermediate in value, between methane and ethane. In fact, by using $\varepsilon/k = 210$ K for all the alkanes except methane, eq. [23] gives the values reported in the first line of the fourth column of Table 5 from ethane to *n*-pentane. When the latter are combined with the ΔG_c estimates from SPT, agreement with the experimental $\Delta G^•$ data is good. These E_a values are reliable because they are close to the solute–water interaction energies calculated at room temperature by Jorgensen et al. (16) for seven alkanes in TIP4P water by means of large-sample Monte Carlo simulations.

It is important to note that the magnitude of the van der Waals energetic contribution is different in each of the five solvents. The absolute value of E_a for each solute shows the following order: benzene > *c*-hexane > ethanol > *n*-hexane > water. For instance, in the case of methane, E_a (in kJ mol^{-1}) = –15.9 in benzene, –15.3 in *c*-hexane, –13.8 in ethanol, –13.2 in *n*-hexane, and –12.7 in water; in the case of *i*-butane, E_a (in kJ mol^{-1}) = – 41.3 in benzene, –39.0 in *c*-hexane, –38.0 in ethanol, –33.1 in *n*-hexane, and –32.1 in water.

Using a detailed continuum model approach, Floris and Tomasi (51) found that the magnitude of the dispersive energy follows the order: benzene > *c*-hexane > water, which is in accordance with the above findings. This is due to (*i*) the larger polarizability of the molecules of the organic solvents compared with water molecules; and (*ii*) the larger volume-packing density of the former compared with the latter. For large alkanes in water, however, the difference is amplified by the mechanism suggested above, i.e., given its small size, a single water molecule interacts with only a small part of an alkane molecule, whereas a single benzene molecule interacts with the whole alkane molecule. The size of solvent molecules is, therefore, a characteristic length scale of the solvent for both ΔG_c and E_a.

Since the calculations satisfactorily reproduce the experimental $\Delta G^•$ data, an understanding of the size dependence of the solubility of nonpolar compounds in the five different solvents is achievable. For this purpose, plots of ΔG_c and $-E_a$ vs. the hard-sphere diameter of noble gases and alkanes in the five solvents were constructed. The plot for water, shown in Fig. 5, indicates that the work of cavity creation dominates the solvation process, making the $\Delta G^•$ values large and positive for all of the solutes considered. Moreover, the $\Delta G^•$ values for noble gases decrease on increasing the molecular diameter because E_a increases in magnitude more rapidly than ΔG_c; the contrary is true for the large alkanes. The plots for ethanol, benzene, and *c*-hexane are shown in Figs. 6–8, respectively. (A plot for *n*-hexane is not shown because it is qualitatively similar.) These plots emphasize that the solvation process is dominated by ΔG_c up to $\sigma \approx 4.0$ Å. For $\sigma >$ 4.0 Å, the E_a term is larger in magnitude than ΔG_c, rendering the total Gibbs energy change negative. In benzene an increase in solute size results in an increase in ΔG_c, but the increase is smaller and slower than E_a. This supports the existence of critical sizes for solutes, above which the $\Delta G^•$ values are negative. This is also true for ethanol, *c*-hexane, and *n*-hexane.

General features emerge from the analysis of helium, the smallest extreme solute, and *n*-pentane, the largest one. The values of $\Delta G^•$ (in kJ mol^{-1}) at 25°C for He in the five solvents are positive and not dramatically different among each other: 11.5 in water, 8.5 in ethanol, 9.6 in benzene, 8.9 in *c*-hexane, and 7.5 in *n*-hexane. The corresponding ΔG_c and E_a estimates (in kJ mol^{-1}) are, respectively, 12.4 and –1.3 in water, 9.6 and –1.6 in ethanol, 10.8 and –2.0 in benzene, 10.0 and –1.9 in *c*-hexane, 8.6 and –1.7 in *n*-hexane. Clearly the difference among the five solvents is the ΔG_c term, which is larger in water than in the other four solvents. The E_a term plays no significant role because of the very small

© 2002 NRC Canada

polarizability of the helium atom. On the other hand, the value of $\Delta G^{\bullet}$ (in kJ mol^{-1}) at 25°C for *n*-C_5H_{12} in water is dramatically different compared with those in the other four solvents: 9.9 in water, –10.1 in ethanol, –13.1 in benzene, and –13.8 both in *c*-hexane and *n*-hexane. The corresponding ΔG_c and E_a estimates (in kJ mol^{-1}) are, respectively, 50.0 and –39.7 in water, 35.2 and –48.2 in ethanol, 38.7 and –51.6 in benzene, 35.3 and –48.5 in *c*-hexane, 29.1 and –41.0 in *n*-hexane. As expected, the ΔG_c term is larger in water than in the other four solvents, and there is also a difference in the E_a values. The two terms in eq. [18], therefore, account for the fundamental difference between water and common organic solvents for the solvation of alkanes.

Analysis of the solvent response

The standard solvation enthalpy changes are now analyzed. The E_a estimates for all solutes in the four solvents are larger in magnitude than the $\Delta H^{\bullet}$ values. For methane (in kJ mol^{-1}), E_a = –12.7, whereas $\Delta H^{\bullet}$ = –10.9 in water; in ethanol, E_a = –13.8, whereas $\Delta H^{\bullet}$ = –2.1 ; in benzene, E_a = –15.9, whereas $\Delta H^{\bullet}$ = 0.3; in *c*-hexane, E_a = –15.3, whereas $\Delta H^{\bullet}$ = –0.9; in *n*-hexane, E_a = –13.2, whereas $\Delta H^{\bullet}$ = –0.7. The van der Waals interactions of nonpolar solutes are so large that the purely structural solvent reorganization are, therefore, an endothermic process in all the solvents considered. The ΔH_r values, determined by eq. [19], which uses the experimental $\Delta H^{\bullet}$ values and the E_a estimates, are listed in the sixth column of Tables 5–9, and show that ΔH_r is small in water but large in the other solvents. For instance, in the case of methane, ΔH_r (in kJ mol^{-1}) = 1.8 in water, 11.7 in ethanol, 16.2 in benzene, 14.4 in *c*-hexane, and 12.5 in *n*-hexane; in the case of *i*-butane, ΔH_r (in kJ mol^{-1}) = 10.2 in water, 21.9 in ethanol, 28.2 in benzene, and 15.8 in *n*-hexane. In this regard, the purely structural solvent reorganization involves different intermolecular interactions in these solvents, i.e., van der Waals interactions in benzene, *c*-hexane, and *n*-hexane; H-bonds in water; and both types of interactions in ethanol.

In fact, this result is expected because a significant part of ΔH_r is due to the enthalpy change upon cavity creation, which, according to SPT (6, 21), is directly proportional to the thermal expansion coefficient of the solvent. The latter quantity, at room temperature, is very small for water with respect to all other solvents; at 25°C, $\alpha = 0.257 \times 10^{-3}$ K^{-1} for water compared with $\approx 1.2 \times 10^{-3}$ K^{-1} for common organic solvents (6, 21). These values can be rationalized by the statistical mechanical definition of $\alpha \equiv \langle \delta H\, \delta V \rangle / kT^2 \langle V \rangle$, where $\delta H = H - \langle H \rangle$, $\delta V = V - \langle V \rangle$, and the angle brackets represent ensemble average values (52). The thermal expansion coefficient is, therefore, directly proportional to the ensemble correlation between the fluctuations of enthalpy and those of volume. It is small in the case of water because there is little correlation between the enthalpy fluctuations and the volume fluctuations as a consequence of the strength of H-bonds, i.e., volume changes cause very little alteration in the number of H-bonds. On the other hand, α is large for common organic solvents because there is significant correlation between the enthalpy fluctuations and the volume fluctuations in view of the weakness of the van der Waals interactions and their strong dependence on the distance among interacting particles. This physical reasoning is also supported by the results of detailed computer simulations on water models and Lennard–Jones liquids (53).

The small positive values of ΔH_r for nonpolar solutes in water imply that there is no significant breakage of H-bonds. Water molecules in the hydration shell, exploiting their tetrahedral functionality, are able to form as many H-bonds as water molecules in the bulk, by straddling the surface of nonpolar groups (44). In fact, they point in two or three tetrahedral bonding directions (both the OH covalent bonds and the lone-pair directions) tangential to the surface of the occupied space, giving rise to disordered clathrate cages. This geometrical arrangement has been established by direct-neutron scattering and X-ray absorption spectroscopy measurements (54, 55). Similar results emerged from computer simulations (56), confirming the plasticity of the H-bonded network of water.

The two terms of the solvation entropy change are calculated by eqs [9] and [20]; the values obtained are listed in the seventh and eighth columns of Tables 5–9. The ΔS_x contribution is large and negative for all solutes in the five solvents. It is, however, significantly larger in water than in the others as a consequence of the difference in the ΔG_c estimates. For methane, ΔS_x (in J K^{-1} mol^{-1}) = –70.8 in water, –52.3 in ethanol, –58.0 in benzene, –53.7 in *c*-hexane, – 44.9 in *n*-hexane. These values unequivocally indicate that the excluded-volume effect is the physical cause explaining why the standard solvation entropies are negative for almost all the nonpolar solutes in the five solvents considered (see Table 3). The ΔS_{nx} contribution is always positive, i.e., the purely structural solvent reorganization leads to an entropy increase. This term is small in water but large in the other four solvents reflecting the behaviour of the ΔH_r contribution since the phenomenon of enthalpy–entropy compensation is operative.

Conclusion

The analysis performed shows that the solubility of nonpolar solutes in different solvents is always determined by the balance between the work spent to create the cavity and the work gained to turn on the solute–solvent interactions. The combination of SPT to estimate ΔG_c, with a simple formula to evaluate E_a allows one to rationalize the different size dependence found for the solubility of noble gases and alkanes in water compared with common organic solvents. The shortcomings of the calculation procedure adopted cannot detract from the general qualitative correctness of the results obtained.

Assigning structures to diastereomeric aliphatic α,α′-dibromo ketones

Masood Parvez, S.M. Humayan Kabir, Ted S. Sorensen, Fang Sun, and Brian Watson

Abstract: X-ray crystal structures are reported for two symmetrical aliphatic α,α′-dibromo ketones: a *meso* diastereomer of 3,5-dibromo–2,2,6,6-tetramethylheptan-4-one, and a *rac* isomer of 4,6-dibromo–2,2,3,3,7,7,8,8-octamethylnonan-5-one. Using these secure assignments and a previously confirmed structure for the diastereomers of 2,4-dibromopentan-3-one, we show in this study that gas–liquid chromatography (GLC) retention times (*meso* > *rac*) can be used to confidently assign the diastereomers for a range of symmetrical and unsymmetrical aliphatic α,α′-dibromo ketones. ^{1}H NMR chemical shifts for the >CHBr hydrogen(s) can also be corroboratively used for assignment purposes ($\delta_{racH} > \delta_{mesoH}$).

Key words: α,α′-dibromo ketones, X-ray crystal structures, GLC retention times, isomer assignment

Résumé : Faisant appel à la diffraction des rayons X, on a déterminé les structures de deux α,α′-dibromocétones aliphatiques symétriques, un diastéréoisomère *méso* de la 3,5-dibromo-2,2,6,6-tétraméthylheptan-4-one et un isomère racémique de la 4,6-dibromo-2,2,3,3,7,7,8,8-octaméthylnonan-5-one. En se basant sur ces attributions certaines ainsi que sur une preuve de structure rapportée antérieurement pour les diastéréoisomères de la 2,4-dibromopentan-3-one, on démontre que les temps de rétention relatifs, en c.p.g., *méso* > *rac*, peuvent être utilisés avec confiance pour attribuer les configurations des diastéréoisomères pour un ensemble α,α′-dibromocétones aliphatiques symétriques et non-symétriques. Les déplacements chimiques en RMN du ^{1}H des hydrogènes >CHBr peuvent aussi être utilisés à des fins de corroboration des attributions, $\delta_{racH} > \delta_{mésoH}$.

Mots clés : α,α′-dibromocétones; diffraction des rayons X; structures; temps de rétention en c.p.g; attribution de structures d'isomères.

[Traduit par la Rédaction]

Introduction

Several years ago we reported (1, 2) the stereospecific conversion of a symmetrical acyclic α,α′-dibromo ketone (3,5-dibromo-2,2,6,6-tetramethylheptane-4-one) (**1**) to *cis*-2,3-di-*tert*-butylcyclopropanone (**2**). Dibromo ketone **1** was a crystalline single diastereomer, prepared directly in solution from the ketone and bromine, as previously described in the literature (3).

[1]

1 **2**

The question naturally arose as to whether the stereospecificity in the above reaction resided in the starting material (**1** *rac* vs. **1** *meso*), or in some later step in the overall mechanism. Unlike the diastereomeric mixtures found in many other α,α′-dibromination reactions, there was no evidence for a second diastereomer in the preparation of **1**.

There have been numerous reports in which symmetrical α,α′-dibromo ketones have been prepared, but where no consideration of stereochemistry needed to be taken into account. Föhlisch and Gottstein (4), however, made secure assignments for 2,4-dibromopentan-3-one, based on the reduction of the *rac* isomer to a single alcohol product, since in their studies it was important to assign the dibromo ketone stereochemistry.

The present paper extends and generalizes on these *rac* vs. *meso* assignments, and includes an X-ray structure of the di-*tert*-butyl system **1** (*meso* isomer). It also includes a predictive *rac* assignment in another system, which was subsequently verified by a second X-ray structure. We also discuss the stereochemical assignments for several unsymmetrical α,α′-dibromo ketones.

Results and discussion

Table 1 contains a summary of the relevant experimental data related to the *meso* vs. *rac* assignments for the symmetrical dibromo ketones. The first part of the table is based on gas–liquid chromatography (GLC) retention times and the

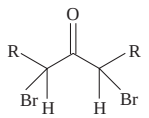
second on ^{1}H NMR chemical shifts for the >CHBr hydrogen. Note that the retention-time NMR-shift assignments are correlated, usually because one diastereomer in the mixture is dominant or because a complete or partial chromotographic separation of diastereomers was employed. The Föhlisch assignment for **3** (R = CH_3) is highlighted in bold as are the two X-ray structures reported in this work.



3

No data is given for the somewhat variable *meso–rac* product ratio observed for the direct bromination of the ketones in chlorinated hydrocarbon solvents. Since the HBr co-product of the reaction catalyzes *meso–rac* interconversion, the precise experimental procedure used undoubtedly plays a role in determining this ratio (kinetic vs. thermodynamic control). For entries 1–4 in Table 1, significant quantities of both diastereomers were obtained by direct bromination of the ketone. Somewhat inexplicably, however, only a single diastereomer for R = *t*-Bu was obtained (as previously noted). A small percentage of the other isomers could be obtained,[2] however, by direct bromination of the *cis*-cyclopropanone **2**. For entries 6–8 in Table 1, both diastereomers are obtained by direct bromination of the ketone.

In all cases, the *rac* and *meso* isomers have virtually identical mass-spectral fragmentation patterns. Hence, the identity of the peaks due to the α,α′-dibromo ketones are readily apparent in a GLC–MS determination, even when small amounts of the α,α-dibromo or tribromo impurities are present.

Early in the study, an X-ray crystal structure of the R = *t*-Bu isomer was obtained, and as is apparent from the ORTEP diagram (Fig. 1), this isomer has the *meso* configuration. Incorporating this information into Table 1, along with the Föhlisch R = CH_3 assignment, leads to the tentative conclusion that the *meso* isomer has the longer GLC retention time, and with the exception of R = *i*-Pr, it also has the higher-field chemical shift for the >CHBr hydrogen.

The Table 1 predictions could be readily tested because a pure crystalline shorter-retention-time isomer of R = $-C(CH_3)_2C(CH_3)_3$ could be obtained by column chromotography (first eluting fraction). The ORTEP X-ray crystal structure of this isomer is shown in Fig. 2, and indeed has the assigned (Table 1) *rac* stereochemistry. We therefore feel confident that all of the entries in Table 1 have the proper designated configurations.

It is possible that a chiral GLC column could be used to confirm the *rac* vs. *meso* assignments in Table 1. In unsym-

[2]Crystallographic information has also been deposited with the Cambridge Crystallographic Data Centre (CCDC No. 170983 for **3**, R = *t*-Bu; 170984 for **3**, R =  ($-C(CH_3)_2C(CH_3)_3$)).

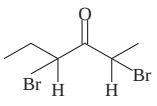
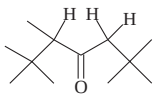
metrical dialkyl ketones, however, both diastereomers are racemates. Nevertheless one would expect that the diastereomer assignments would follow those of the symmetrical examples, i.e., the *meso* pair (*RS*(*SR*)) would have a longer GLC retention time and a higher-field ^{1}H NMR chemical shift for >C*H*Br than the racemic pair *RR*(*SS*).

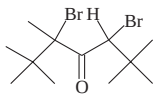
Dibromination of 3-hexanone produces two isomers (**4**) with distinct GLC-retention behaviour (8.5 and 9.3 min, ratio 0.91), similar to the symmetrical examples in Table 1. Likewise, the longer- retention-time isomer has, on average, higher-field ^{1}H NMR shifts for the >CHBr hydrogens than the shorter retention diastereomer (δ 4.555 (dd) and 4.755 (q) vs. 4.74 (t) and 4.93 (q), respectively). Thus these isomers can be assigned as follows: the shorter-retention-time lower-field ^{1}H's to 2*R*,4*S*(2*S*,4*R*); and the longer-retention-time higher-field ^{1}H's to 2*R*,4*R* (2*S*,4*S*). Similarly, dibromination of the unsymmetrical ketone **5**, in which two alkyl groups are present on one α-carbon, one large (*t*-Bu), and one small (CH$_3$), again results in two diastereomers of **6**. The ^{1}H NMR shifts for >CHBr (a single ^{1}H peak) occur



4



5



6

at δ 4.91 (longer-retention-time isomer) and at δ 5.22 (shorter-retention-time isomer), which is consistent with the assignment of 3*R*,5*S*(3*S*,5*R*) for the former and 3*R*,5*R*(3*S*,5*S*) for the latter. This assignment is based on the reasonable assumption that the steric interactions in A will somewhat resemble those in B.

X-ray structures

Tables 2 and 3 contain X-ray parameters[2] for the structure determination of **3**, R = *t*-Bu, and **3**, R = -C(CH$_3$)$_2$C(CH$_3$)$_3$. The R = *t*-Bu crystal contains two independent molecules in the asymmetric unit, but the conformations of these are similar. One molecule is shown as an ORTEP diagram (Fig. 1) and is clearly a *meso* configuration. The methyl moieties of the *t*-Bu groups are staggered with respect to the >CHBr bonds. The most important features of this structure are, however, the Br1-C2-C1-O1 and Br2-C7-C1-O1 dihedral angles (56.5° and –110.8° respectively), and the Br1-C2-C7-Br2 dihedral angle of – 44.6°. Thus the two separate $C^{\delta+}$–$Br^{\delta-}$ dipoles are significantly aligned when the structure as a whole is taken into consideration. Individually, they are both almost perpendicular to the $>C^{\delta+}=O^{\delta-}$ dipole.

The R = -C(CH$_3$)$_2$C(CH$_3$)$_3$ crystal contains two independent molecules in the asymmetric unit of a centrosymmetric space group, again with very similar conformations. The structure for (4*S*,6*S*) is shown in Fig. 2, and as we had already predicted from the GLC–NMR data in Table 1, it is a *rac* configuration.

The methyl groups of the -C(CH$_3$)$_2$C(CH$_3$)$_3$ substituents are internally staggered, and are also staggered with respect to the >CHBr atoms. The Br1-C2-C1-O1 and Br2-C10-C1-O1 dihedral angles are –93.8° and –92.9°, respectively, and the

Largest diff. peak and hole (e Å^{-3})	0.47 and –0.49

dihedral angle Br1-C2-C7-Br2 is 165.0°. Thus, in the molecule as a whole, the two $C^{\delta+}$–$Br^{\delta-}$ dipoles are nearly opposed, and both are nearly perpendicular to the $>C^{\delta+}=O^{\delta-}$ dipole.

The polarity behaviour of *cis*- and *trans*-2,6-dibromocyclohexanones (*cis* more polar than *trans*) has been discussed (5) in terms of the fixed orientation of the two $C^{\delta+}$–$Br^{\delta-}$ dipoles. In contrast, acyclic dibromoketones have free rotation around all of the bonds, but it seems clear that the *meso* conformations must have at least partially aligned $C^{\delta+}$–$Br^{\delta-}$ dipoles in the molecule as a whole, while the *rac* isomers involve some net cancellation of the two $C^{\delta+}$–$Br^{\delta-}$ dipoles. While it is somewhat dangerous to infer solution conformations from crystal structures, it should be noted that the two $C^{\delta+}$–$Br^{\delta-}$ dipoles are partially aligned in the more polar *meso* structure, compared with a cancellation of these dipoles in the *rac* structure, i.e., the crystal structure conformations sufficiently account well for the expected solution conformations.

There have been previous X-ray crystal structures of α,α′-dibromo ketones, but these have involved cyclic or bicyclic structures that do not have much conformational flexibility, the exception being a structure of dibromocyclododecanone (6).

Other possible *rac* vs. *meso* assignment parameters

The reduced polarity of the *rac* isomer is not confined to GLC retention times. In **3**, R = CH_3, the pure *rac* isomer can be obtained from a fractional distillation as the first fraction(4). TLC and flash chromotography will also separate the *rac* and *meso* isomers. We also looked at some of the ^{13}C NMR chemical shifts of the >CHBr carbons in the diastereomeric sets, but these do not correlate with the Table 1 assignments on a consistent basis.

Conclusions

Based on the two X-ray structures of α,α′-dibromo ketones, and a previous assignment of the the 3-pentanone system, it is clear that a combination of the GLC retention-time behaviour and the ^1H NMR chemical shifts (>CHBr) can be used to reliably assign the diastereomeric configuration of these compounds.

Experimental

^1H NMR spectra (δ values) were obtained in $CDCl_3$ at 200 MHz, using a Brucker ACE-200 spectrometer. All GLC–MS data was obtained on a Hewlett–Packard model 5890 gas chromatograph equipped with a model 5971 mass-selective detector. Split-mode injection was used employing 25 m × 0.25 mm i.d capilliary columns (DB5, DB17, or OV101). The intent of the Table 1 data is to show the large-retention-time differences for the diastereomeric pairs, under conditions where the retention times were in the range of 8–20 min.

α,α′-Dibromo ketones

Entries 5–8 in Table 1 involve compounds prepared in previous studies from this laboratory (2,7). Compound **3**, R = CH_3 (4), Et (8), *i*-Pr (8), and compound **4** (9) have been reported, often with no mention of diastereomeric possibilities. Compound **6** has also been reported (2). 4,6-Dibromononan-5-one (**3**, R = *n*-Pr) was prepared as a mixture of diastereomers, by adding Br_2 in CCl_4 at 20°C to a solution of 5-nonanone in CCl_4. For dibromides **3** (R = *i*-Pr) and **4**, the corresponding pure *rac* diastereomer was obtained by column chromatography (SiO_2). Our own preparations for entries 1–4 in Table 1 invariably contained small amounts of α,α-dibromo and tribromo impurities, which could be detected by GLC–MS.

X-ray structures

Compound 3 (R = t-Bu)

Pertinent data concerning the crystal structure determination of **3** (R = *t*-Bu) is summarized in Table 2.

Data Collection

A colorless prismatic crystal of $C_{11}H_{20}Br_2O$ having approximate dimensions of 0.42 × 0.40 × 0.39 mm was mounted on a glass fiber. All measurements were made on a Rigaku AFC6S diffractrometer using Mo Kα radiation monochromatized with a Zr filter.

The data were collected at a temperature of –103 ± 1°C using the ω–2θ scan technique to a maximum 2θ value of 50.0°. Omega scans of several intense reflections, made prior to data collection, had an average width at half height of 0.22°. Scans of (0.84 + 0.34 tan θ)° were made at a speed of 4.0° min^{-1} (in omega). The weak reflections ($I < 10.0\ \sigma(I)$) were re-scanned (maximum 4 scans) and the counts were accumulated to ensure good-counting statistics. Stationary background counts were recorded on each side of the reflection. The ratio of peak-counting time to background-counting time was 2:1. The diameter of the incident beam collimator was 1.0 mm, the crystal-to-detector distance

© 2002 NRC Canada

was 400 mm, and the aperture was 9.0 × 13.0 mm (horizontal × vertical).

Structure solution and refinement

The structure was solved by direct methods (10) and expanded using Fourier techniques (11). The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included at geometrically idealized positions and were not refined. The final cycle of full-matrix least-squares refinement was based on 1836 observed reflections ($I > 3.00\sigma(I)$) and 253 variable parameters and converged (largest parameter shift was 0.01 times its esd) with unweighted and weighted agreement factors of

$$[1] \qquad R = \sum \left| \frac{|F_0| - |F_c|}{F_0} \right| = 0.043$$

$$[2] \qquad R_w = \sqrt{\left(\sum w \frac{(|F_0 - F_c|)^2}{wF_0^2} \right)} = 0.041$$

The standard deviation of an observation of unit weight was 1.75. The weighting scheme was based on counting statistics and included a factor ($p = 0.015$) to downweight the intense reflections. Plots of $\Sigma w(|F_0| - |F_c|)^2$ vs. $|F_0|$, reflection order in data collection, $\sin\theta/\lambda$, and various classes of indices showed no unusual trends. The maximum and minimum peaks on the final difference Fourier map corresponded to 0.48 and –0.63 e Å^{-3}, respectively.

Neutral-atom scattering factors were taken from Cromer and Waber (12). Anomalous dispersion effects were included in F calcd. (13); the value for Δ and $\Delta f''$ were those of Creagh and McAuley (14). The values for the mass-attenuation coefficients are those of Creagh and Hubbel (15). All calculations were performed using the teXscan (16) crystallographic software package from the Molecular Structure Corporation.

Compound 3 (R = -C(CH$_3$)$_2$C(CH$_3$)$_3$)

Pertinent data concerning the crystal structure determination of **3** (R = -C(CH$_3$)$_2$C(CH$_3$)$_3$) is summarized in Table 3.

Data collection

A colorless prismatic crystal of $C_{17}H_{32}Br_2O$ was coated with paratone 8277 oil (Exxon) and mounted on a glass fibre. All measurements were made on a Nonius KappaCCD diffractrometer with graphite-monochromated Mo Kα radiation. Cell constants obtained from the refinement (17) of 8589 reflections in the range $1.0 < \theta < 27.5°$ corresponded to a primitive monoclinic cell. The space group was determined uniquely from the systematic absences. The data were collected (18) at –100(1)°C using the $\omega-\varphi$ scans to a maximum θ value of 27.5°. The data were corrected for Lorentz and polarization effects and for absorption using multi-scan methods (17). Since the crystal did not show any sign of decay during data collection, a decay correction was deemed unnecessary.

Structure solution and refinement

The structure was solved by the direct methods (10) and expanded using Fourier techniques (11). The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included at geometrically idealized positions and were not refined. The final cycle of full-matrix least-squares refinement using SHELXL97 (19) converged (largest parameter shift was <0.001 times its eds) with unweighted and weighted agreement factors, $R = 0.028$ [$I > 2\sigma(I)$] and $wR = 0.067$ (all data), respectively and goodness of fit, $S = 0.99$. The weighing scheme was based on counting statistics and the final difference Fourier map was essentially featureless. Figures 2 and 3 were plotted with the aid of ORTEPII (20).

Aqueous nonelectrolyte solutions. Part XVIII. Equilibrium pressures of two methane hydrates with water. Formulae and dissociation thermodynamic functions for the structures I and II methane hydrates

David N. Glew

Abstract: Literature data for the saturation pressure $P(hl_1g)$ of methane hydrate with water, at 102 temperatures between –0.29 and 46.87°C, are properly represented by two distinct equations, with a quadruple point $Q(h_1h_2l_1g)$ transition temperature at 26.7°C with standard error (*SE*) 0.9°C and 55.5 MPa with *SE* 5.3 MPa. The structure I type methane hydrate phase h_1 is stable below 26.7°C and the structure II type methane hydrate phase h_2 is stable above 26.7°C. Between –0.29 and 25.54°C, 85 equilibrium pressures of methane hydrate with water are best represented, with *SE* 1.33% on a single pressure measurement, by a four-parameter thermodynamic equation. The corresponding equilibrium methane fugacities are represented, with *SE* 0.94% on a fugacity determination, by a five-parameter equation. Between 26.98 and 46.87°C, 17 equilibrium methane hydrate pressures with water are best represented, with *SE* 2.22% on a pressure measurement, by a three-parameter equation. Composition of the equilibrium aqueous phase is evaluated using methane fugacity with the solubility equation including a Poynting correction. Literature data between –2.22 and –14.10°C, for the saturation pressure $P(h_1s_1g)$ of structure I methane hydrate with ice, are properly represented by a two-parameter equation, with *SE* 1.1% on a single pressure measurement. Standard enthalpy change for structure I methane hydrate dissociation into ice and methane gas is found to be $\Delta H^{ot}(h_1 \rightarrow s_1g) = 18058$ J mol^{-1} with *SE* 608 J mol^{-1} at –8.28°C. The quadruple point $Q(h_1s_1l_1g)$ is estimated at –0.290°C with *SE* 0.0064°C and at 2.527 MPa with *SE* 0.053 MPa. Using the classical thermodynamic method, as described for deuterium sulfide D-hydrate, methane hydrate equilibrium fugacities define 85 equilibrium constants $Kp(h_1 \rightarrow l_1g)$ between –0.29 and 25.54°C for dissociation of structure I hydrate h_1 into liquid water l_1 and methane gas. Temperature dependence of ln $Kp(h_1 \rightarrow l_1g)$ is well-represented by a three-parameter thermodynamic equation that gives both estimates and their standard errors for (*i*) $\Delta H^{ot}(h_1 \rightarrow l_1g)$ and $\Delta Cp^{ot}(h_1 \rightarrow l_1g)$, the standard enthalpy and heat capacity changes, respectively, for hydrate h_1 dissociation, and for (*ii*) $n = r$, the approximate formula number of the hydrate $CH_4 \cdot nH_2O$ at each experimental temperature. The formula $CH_4 \cdot 6.205H_2O$ with *SE* $0.066H_2O$ is found for the structure I methane hydrate h_1 with water at quadruple point $Q(h_1s_1l_1g)$ –0.29°C; an approximate formula $CH_4 \cdot 5.759H_2O$ with *SE* $0.077H_2O$ is found at quadruple point $Q(h_1h_2l_1g)$ 26.7°C. Between 26.98 and 46.87°C, the 17-equilibrium constants $Kp(h_2 \rightarrow l_1g)$ for dissociation of structure II methane hydrate h_2 into liquid water l_1 and methane gas are represented by a constrained three-parameter thermodynamic equation. For structure II methane hydrate the formula $CH_4 \cdot 5.822H_2O$ with *SE* $0.064H_2O$ is found at quadruple point $Q(h_1h_2l_1g)$ 26.7°C and the formula $CH_4 \cdot 5.699H_2O$ with *SE* $0.064H_2O$ at 46.87°C. Molar volumes and cohesive energy densities of the methane hydrates are compared with equilibrium compressed water.

Key words: clathrate hydrates of methane, two methane gas hydrates, formula of structure I methane hydrate, thermodynamics of clathrate hydrate dissociation, dissociation equilibrium constants of structure I methane hydrate, standard enthalpy and heat capacity changes for dissociation of structure I methane hydrate, methane hydrates' transition temperature, formula of structure II methane hydrate, dissociation equilibrium constants of structure II methane hydrate, standard enthalpy change for dissociation of structure II methane hydrate, methane hydrates' cohesive energy density.

Résumé : Les données retrouvées dans la littérature pour la pression de saturation, $P(hl_1g)$ de l'hydrate de méthane avec l'eau, à 102 températures entre –0,29 et 46,87°C, peuvent être représentées correctement par deux équations distinctes, avec une température de transition à point quadruple, $Q(h_1h_2l_1g)$, à 26,7°C et une erreur standard (*ES*) de 0,9°C et une pression de 55,5 avec une *ES* de 5,3 MPa; avec une structure d'hydrate de méthane de type I, phase h_1, stable en-dessous de 26,7°C et une structure d'hydrate de méthane de type II, phase h_2, stable au-dessus de 26,7°C. Entre –0,29 et 25,54°C, la meilleure représentation de 85 pressions d'équilibre de l'hydrate de méthane avec l'eau est donnée par une équation thermodynamique à quatre paramètres, avec une *ES* de 1,33% sur une mesure de pression particulière; les fugacités correspondantes de l'équilibre du méthane sont représentées par une équation à cinq paramètres, avec une *ES*

Received 18 July 2001. Published on the NRC Research Press Web site at http://canjchem.nrc.ca on 10 April 2002.

de 0,94%. Entre 26,98 et 46,87°C, la meilleure représentation des 17 pressions d'équilibre de l'hydrate de méthane avec l'eau est donnée par une équation à trois paramètres, avec une *ES* de 2,22%. La composition de la phase aqueuse en équilibre est évaluée en utilisant la fugacité du méthane avec l'équation de solubilité et en y incluant la correction de Poynting. Les données de la littérature entre –2,22 et –14,10°C pour la meilleure représentation de la pression de saturation $P(h_1s_1g)$ de l'hydrate de méthane de structure I avec la glace est donnée par une équation à deux paramètres, avec une *ES* de 1,1% sur une mesure particulière de pression. On a trouvé que le changement d'enthalpie standard pour la dissociation de l'hydrate de méthane de structure I en glace et en méthane gazeux, $\Delta H^{ot}(h_1 \rightarrow s_1g) = 18058$ avec une *ES* de 608 J mol^{-1} à –8,28°C. On a évalué que le point quadruple se situe à une température de –0,290° avec une *ES* de 0,0064°C et une pression de 2,527 avec une *ES* de 0,053 MPa. Utilisant la méthode thermodynamique classique décrite pour le sulfure de deutérium et l'hydrate D, les fugacités d'équilibre de l'hydrate de méthane définissent 85 constantes d'équilibre $Kp(h_1 \rightarrow l_1g)$ entre –0,29 et 25,24°C pour la dissociation de l'hydrate h_1 de structure I en molécule d'eau liquide, l_1, et de méthane gazeux. La relation de ln $Kp(h_1 \rightarrow l_1g)$ avec la température est bien représentée une équation thermodynamique à trois paramètres qui fournit des évaluations, ainsi que leurs erreurs standards, pour (*i*) $\Delta H^{ot}(h_1 \rightarrow l_1g)$ et $\Delta Cp^{ot}(h_1 \rightarrow s_1g)$, les changements d'enthalpie standard et de capacité calorifique pour la dissociation de l'hydrate h_1, et pour *(ii)* $n = r$, le nombre de formule approximatif de l'hydrate $CH_4 \cdot nH_2O$ à chaque température expérimentale. Pour l'hydrate de méthane h_1 de structure I, on a trouvé que la formule est $CH_4 \cdot 6{,}205H_2O$, avec une *ES* de $0{,}066H_2O$, avec un point quadruple, $Q(h_1s_1l_1g)$, à –0,29°C; on a aussi détecté une formule approximative de $CH_4 \cdot 5{,}759H_2O$, avec une *ES* de $0{,}077H_2O$, avec un point quadruple, $Q(h_1h_2l_1g)$, à 26,7°C. Entre 26,98 et 46,87°C, la meilleure représentation des 17 constantes d'équilibre $Kp(h_2 \rightarrow l_1g)$ pour la dissociation de l'hydrate de méthane de structure II, h_2, en eau liquide et en méthane gazeux est donnée par une équation à trois paramètres contraints. Pour l'hydrate de méthane de structure II, on a trouvé que la formule est $CH_4 \cdot 5{,}822H_2O$, avec une *ES* de $0{,}064H_2O$, avec un point quadruple, $Q(h_1h_2l_1g)$, à 26,7°C et une formule de $CH_4 \cdot 5{,}699H_2O$, avec une *ES* de $0{,}064H_2O$, à 46,87°C. On a aussi comparé les volumes molaires et les densités de l'énergie cohésive des hydrates de méthane avec celles de l'équilibre de l'eau comprimée.

Mots clés : clathrate d'hydrates de méthane, deux hydrates du méthane gazeux, formule de l'hydrate de méthane de type I, thermodynamique de la dissociation du clathrate d'hydrate, constantes d'équilibres pour la dissociation de l'hydrate de méthane de structure I, changements d'enthalpie standard et d'entropie pour la dissociation de l'hydrate de méthane de structure I, température de transition des hydrates de méthane, formule de la structure de l'hydrate de méthane de structure II; constantes d'équilibre de dissociation de l'hydrate de méthane de structure II, changement d'enthalpie standard pour la dissociation de l'hydrate de méthane de structure II, densité de l'énergie cohésive des hydrates de méthane.

[Traduit par la Rédaction]

Introduction

Literature on the methane clathrate gas hydrate is large and extends from the pioneering pressure measurements of Villard in 1888 up to the calorimetric and spectroscopic studies of the present time (1–23). An excellent modern review of the clathrate hydrates of natural gases by Sloan (24) provides the background for the present work and has encouraged us to revisit methane hydrate (9).

Initially the data sets of methane hydrate measurements are examined separately, subsequently the data sets are combined to provide statistically valid models for all measurements.

Methane hydrate temperatures are converted to ITS-90 as described (25) and two digits are retained after the decimal point.

The temperature dependence of univariant equilibrium properties such as the total methane hydrate pressure $P(hl_1g)$, the hydrate methane fugacity $f_2(hl_1g)$, and the methane hydrate dissociation equilibrium constants $Kp(h \rightarrow l_1g)$ and $Kp(h \rightarrow s_1g)$ are represented by well-conditioned, unbiased, thermodynamic equations, similar to eq. [1*a*], which are fully described elsewhere (26).

The methane hydrate pressures (1–3, 6, 7, 10, 12–14, 17, 22) are combined with accurate aqueous methane solubility data including the Poynting correction (16) and the IUPAC equation of state for methane fugacity (27) to define the equilibrium composition of the aqueous phase l_1. The equilibrium constants for dissociation of the structures I and II methane hydrates use auxiliary properties of water (28–31).

Classical thermodynamic equations are used to define the dissociation equilibrium constant and formula for a methane hydrate of variable composition, as described in detail for the structure I deuterium sulfide D-hydrate and hydrogen sulfide hydrate (32–34).

All regression equations are evaluated using the method of weighted least-squares (35) and a predicted estimate is qualified by its standard error, written *SE*. Residuals for individual data sets from regression models for the combined data sets are qualified by their root mean-squared deviations, written *RMS*.

Results and discussion

Pressures of methane hydrate with aqueous liquid

The dependence on temperature of the total pressure $P(hl_1g)$ for methane hydrate with water is examined by individual data set first for internal consistency and then for attainment of equilibrium.

Because of the lack of agreement between the hydrate pressures from various data sets, each data set is fitted separately by eq. [1*a*] using the method of least-squares with unit

© 2002 NRC Canada

weights. In general, the lower the observed methane pressure at a given temperature, the nearer the measurement is to equilibrium.

Using this simple lower-pressure criterion, the four measurements of data set GRCK70 (13) are clearly shown to be nearest to thermodynamic equilibrium. To achieve proper phase equilibrium Kobayashi and co-workers (13) found it necessary to use the vigorous mixing of rolling stainless steel balls to triturate the methane hydrate slurry with the aqueous liquid. The earlier study of data set MSK64 (10) achieved equilibrium measurements for methane hydrate at higher pressures using a dynamic pressure–temperature variation method. Data sets D&F40 (2) and V74 (14) also exhibit lower methane hydrate pressures and are taken to be in equilibrium.

Using the lower-pressure criterion, the other seven data sets (1, 3, 6, 7, 12, 17, 22) of hydrate measurements are found to be near to, but not at equilibrium. It is found that the gentle rocking of a cell gauge for a short duration (6, 7, 12, 22), and the occasional stirring of a Caillitet tube (3, 17), are inadequate to achieve phase equilibrium for methane hydrate with its aqueous liquid.

The methane hydrate pressures of Villard (1) are consistently higher than those of the modern data sets with better phase agitation (2, 3, 6, 7, 10, 12–14, 17, 22). Six sets of modern measurements show slightly but significantly higher pressures than the four sets of equilibrium measurements (2, 10, 13, 14).

Individual data sets of pressure measurements below 26.7°C for methane hydrate, phase h_1, in contact with aqueous liquid, phase l_1, are represented by the general unbiased thermodynamic equation,

$$[1a] \quad \ln P(h_1l_1g) = b0 + b1.u1 + b2.u2 + b3.u3$$

which equation is mathematically equivalent (26) to the ill-conditioned thermodynamic equation

$$[1b] \quad \ln P(h_1l_1g) = A + B/T + C \ln T + DT.$$

Table 1 shows the results for representation of individual data sets of methane hydrate pressures by eq. [1*a*]. Column one lists abbreviated name(s) of the author(s) and the year of publication of the data set, together with the literature reference. Columns two and three list the temperature range of the hydrate measurements and their number *n*. Column four lists the estimate of the standard error of ln $P(h_1l_1g)$, abbreviated to *SE*(ln *P*), for a single hydrate pressure measurement, and the coefficient of determination R^2 for the least-squares fit of the data by eq. [1*a*]. Columns five to seven of Table 1 show the parameter estimates (*b*0, *b*1, *b*2) with their *SE* estimates, evaluated (26) at reference temperature θ = 25°C ≡ 298.15 K, for the 11 separate data sets.

No individual data set requires more than three parameters for a proper representation of the observed pressures, and all estimates of *b*1 and *b*2 are positive. The upper 11 rows of Table 1, for data at temperatures below 26.7°C, show values of *b*1 between 34.2 and 40.5 with values of *b*2 between 112.7 and 208.9. These parameters are characteristic of pressure measurements from the structure I type (36, 37) methane hydrate, which we define as phase h_1. Ideally all values of *b*1 should be equal and all values of *b*2 should be equal.

Estimates for the standard error, *SE*(ln *P*), of a single measurement vary from a minimum of 0.0028 for the most precise data set D&F40 (2), to a maximum of 0.0211 for the equilibrium data set MSK64 (10); standard errors of the other data sets are in the range between 0.0112 and 0.0186. Values of R^2 are greater than 0.9980 and indicate reasonable fits of the pressure data by eq. [1*a*].

In the 12th row of Table 1 parameters are shown for the fit of the combined set of 85 pressure measurements from the 11 data sets (1–3, 6, 7, 10, 12–14, 17, 22) plus one pressure datum evaluated in this work at the ice quadruple point, –0.29°C. This equation provides the best model with three parameters for the equilibrium pressure of methane hydrate with water below 26.7°C. The seven biases between the non-equilibrium data sets (1, 3, 6, 7, 12, 17, 22) and the four equilibrium data sets (2, 10, 13, 14) are removed in the weighted least-squares regression analysis. For the 85 data combined, the parameter and (*SE*) estimates are *b*1, 39.863 (0.241) and *b*2, 205.29 (5.12), values which confirm the reliability of the internal temperature differences within the data sets V1888 and J&R65 (1, 12). This contrasts with their large positive data set biases for *b*0 of 0.1072 (1) and 0.0456 (12), or biases of about +11.3% and +4.7% on their reported pressures. The overall *SE*(ln *P*) 0.0143 indicates a *SE* of 1.44% on a single pressure measurement of unit weight; this *SE* is significantly larger than the expected 0.1–0.4% using the upper 75% range of a precision Bourdon-type metal-tube pressure gauge. This relatively large *SE* estimate for pressure measurement indicates error contributions arising from other unknown factors, together with the inadequacy of eq. [1*a*] with three parameters. The coefficient of determination R^2 = 0.9998 indicates a good fit of the 85 data by eq. [1*a*].

When the combined 85 methane hydrate pressures are fitted by eq. [1*a*] without data set biases, the overall *SE*(ln *P*) estimate is 0.0291, giving a *SE* estimate of 2.95% on a single hydrate pressure measurement with 82 degrees of freedom. This model shows the data sets GRCK70, MSK64, D&F40, and V74 (13, 10, 2, 14) with large negative residuals and the data sets V1888, K&K49, and J&R65 (1, 6, 12) with large positive residuals. When the combined 85 hydrate pressures are fitted by eq. [1*a*], constrained to pass through the mean of the four measurements of data set GRCK70 (13), the overall *SE*(ln *P*) estimate is increased to 0.0477, giving a *SE* estimate of 4.88% for a single hydrate pressure measurement. Clearly these two models without data set biases do not provide an accurate representation of the equilibrium pressure for methane hydrate with water below 25.54°C.

Two methane hydrates

The seven methane hydrate pressure measurements of data set MSK64 (10) between 17.05 and 24.99°C are not continuous with the 13 higher-pressure measurements between 26.98 and 46.87°C.

The 13 hydrate pressure measurements between 15.49 and 25.54°C from data sets M&C61, MSK64, and GRCK70 (7, 10, 13) are represented by eq. [1*a*] with *SE*(ln *P*) 0.0243 on a single measurement, with parameter and (*SE*) estimates *b*0, 3.8046 (0.0108) and *b*1, 37.517 (0.531) and with R^2 0.9978. The 15 pressure measurements between 26.98 and 46.87°C from data sets M&C61 and MSK64 are represented by eq. [1*a*] with *SE*(ln *P*) 0.0243 on a single measurement, with

parameters and (*SE*)s *b*0 3.8454 (0.0124) and *b*1 30.498 (0.280) and with R^2 0.9989. The point of intersection of the low- and the high-temperature equations indicates a quadruple point $Q(h_1h_2l_1g)$ transition temperature at 26.7°C with *SE* 0.9°C and a transition pressure of 55.5 MPa with *SE* 5.3 MPa for equilibrium of the low-temperature structure I methane hydrate phase h_1 with a different methane hydrate phase h_2 stable at higher temperature.

The bottom row of Table 1 shows the three parameters for the equation representing the 13 pressures of data set MSK64 (10) between 26.98 and 46.87°C for the high-temperature methane hydrate h_2. The significantly smaller values of the parameters *b*1 28.572 (1.310) and *b*2 56.04 (33.07) for the methane hydrate above 26.7°C indicate that it contains less water per mol of methane and is different from structure I methane hydrate (36–38) stable below 26.7°C.

The different methane hydrate h_2, stable above 26.7°C, explains why the authors (10) noted that above 68.9 MPa the methane hydrate–equilibrium locus became somewhat more concave down toward the temperature axis than had been expected. It also explains why the predicted (6) pressure of 275.8 MPa for methane hydrate at 37.78°C was too high, and was found experimentally (10) to be 165.5 MPa at 37.78°C.

Evaluation of equilibrium model for $P(h_1l_1g)$ for methane hydrate with water between −0.29 and 26.7°C

Table 2 presents 85 evaluations of $P(h_1l_1g)$ MPa, the equilibrium methane pressure for structure I methane hydrate h_1 in contact with water-rich liquid l_1 between −0.29 and 25.54°C.

The equilibrium pressure evaluations are defined by the best-weighted least-squares fit of the 85 corrected pressure measurements that are continuous from −0.29 to 25.54°C and are represented by eq. [1*a*] with four parameters.

Data sets D&F40 (2), MSK64 (10), GRCK70 (13), and V74 (14) are taken to be in thermodynamic equilibrium. The continuous equilibrium model for ln $P(h_1l_1g)$ with zero bias is defined to pass through the data-mean value of (the 13 ln $P(h_1l_1g)$ values of data set D&F40, plus the seven ln $P(h_1l_1g)$ values at lowest temperature of data set MSK64, plus four times the four ln $P(h_1l_1g)$ values of data set GRCK70, plus the seven ln $P(h_1l_1g)$ values of data set V74).

The seven other data sets (1, 3, 6, 7, 12, 17, 22) show positive data-set biases ln (P_u/P) taken to be constant for each data set, above the continuous ln $P(h_1l_1g)$ model. The logarithm of the observed equilibrium pressure $P(h_1l_1g)$ is defined by eq. [2]

$$[2] \qquad \ln P(h_1l_1g) = \ln P_u(h_1l_1g) - \ln (P_u/P)$$

in which the data-set bias, ln (P_u/P), is subtracted from the logarithm of the observed uncorrected pressure $P_u(h_1l_1g)$ MPa.

The 85 uncorrected ln $P_u(h_1l_1g)$ data are fitted first by eq. [1*a*], the seven mean values of data-set bias ln (P_u/P) are evaluated and the 85 first-approximation equilibrium values of ln $P(h_1l_1g)$ are obtained from eq. [2]. The first-approximation equilibrium values are refitted by eq. [1*a*], the seven first-approximation data-set biases are evaluated, and the 85 second-approximation equilibrium values are obtained from eq. [2], and so on. This is continued for 18 cycles to convergence of better than 1×10^{-9} on each of the seven data-set biases.

The best fit of the final 85 ln $P(h_1l_1g)$ MPa equilibrium evaluations by eq. [1*a*] gives a *SE* estimate of 1.33% on a single equilibrium pressure datum of unit weight with 71 degrees of freedom. The coefficient of determination R^2 is 0.99982. Parameter and (*SE*) estimates at 25°C are the following: *b*0, 3.8093 (0.0059); *b*1, 41.713 (0.560); *b*2, 311.95 (30.0); *b*3, 1217.2 (338). The value of *b*3 could arise by random chance with a probability of less than 0.05%. The number of degrees of freedom for this weighted least-squares regression is 85 minus the 4 model parameters, minus the 3 low-weighted data, minus the 7 data-set biases, leaving the difference of 71.

We note that the three parameters (*b*1, *b*2, *b*3) for the temperature variation of methane hydrate pressure are positive at 25°C, as found for deuterium sulfide D-hydrate (32) and for hydrogen sulfide hydrate (34).

In Table 2 column one gives the observed hydrate temperature *t* (°C) (ITS-90) and column two indicates the data set.

Column three shows $w^{1/2}$, the square root of the weight of the measurement. Three data are assigned the low weight

© 2002 NRC Canada

$w^{1/2}$ = 0.001 because they deviate from the fitted model by more than 15-times their computed standard errors; this weighting reduces the degrees of freedom by three and ensures that these measurements do not bias the final representative model. The 11 measurements of data set V1888 (1) are assigned the weight $w^{1/2}$ = 0.5 because they are assessed to be four times less reliable than the modern measurements, which use improved phase agitation and automatic thermostatic control of the hydrate temperature. The remaining 71 measurements are given unit weight.

Column four gives the observed uncorrected hydrate pressure $P_u(h_1l_1g)$ MPa from the literature, uncorrected for bias of the data set from equilibrium conditions, and column five shows its calculated value.

Column six gives the observed equilibrium pressure $P(h_1l_1g)$ MPa, corrected for data-set bias from equilibrium conditions, and column seven shows its calculated value from eq. [1*a*] using the four best parameters.

Column eight lists the data-set bias from equilibrium conditions ln (P_u/P), which is the logarithm of the ratio of (uncorrected pressure/equilibrium pressure). The seven data-set biases are determined in the least-squares evaluation of the best model for the equilibrium methane pressure $P(h_1l_1g)$ as a continuous function of temperature over the data range −0.29 to 25.54°C.

The *RMS* (root mean squared) deviations of the unweighted residuals of ln $P(h_1l_1g)$ from eq. [1*a*] for the individual data sets are slightly larger than the (*SE*)s shown in Table 1 for the separate regressions. The *RMS* deviations for weighted (unweighted) residuals of ln $P(h_1l_1g)$ from eq. [1*a*] with four parameters are the following: V1888, 0.0116 (0.0232); D&F40, 0.0098; RBH40, 0.0077; K&K49, 0.0085; M&C61, 0.0174; MSK64, 0.0249; J&R65, 0.0134; GRCK70, 0.0141; V74, 0.0135 (0.0210); dRPLD83, 0.0052 (0.0185); and AFS91, 0.0071 (0.0182).

The very consistent equilibrium data set D&F40 (2), shows a relatively large *RMS* residual estimate of 0.0098, contributed mainly by a data set bias of 0.0091 combined with a very low internal standard deviation of 0.0028. Similarly the equilibrium data set GRCK70 (13), shows a large *RMS* residual estimate of 0.0141, contributed mainly by a data set bias of −0.0129 combined with a low internal standard deviation of 0.0056.

It should be noted that the total real error on each hydrate pressure measurement is equal to the square root of the sum of its data-set bias squared plus its random error squared.

Data set V1888 (1) shows the largest average data-set bias of ln (P_u/P) = 0.0789 above the equilibrium model, corresponding with observed uncorrected pressure measurements an average of 8.2% larger than their equilibrium values. This large bias, probably arising from lack of agitation, combined with an uncertain bias of the temperature scale, contributed to our final assignment of weight $w^{1/2}$ = 0.5 for each measurement of data set V1888.

The data set K&K49 (6), comprised of two measurements, shows a bias of 0.0624 above the equilibrium model, corresponding with observed uncorrected pressure measurements an average of 6.4% larger than the equilibrium values based on data sets (2, 10, 13, 14). This bias difference clearly highlights the nearer approach to equilibrium of the dynamic pressure–temperature variation method introduced by Kobayashi and co-workers (10) in MSK64.

The remaining five data sets (3, 7, 12, 17, 22) show data-set biases of between 0.0252 and 0.0397, with observed uncorrected pressure measurements between 2.6 and 4.0% larger than their equilibrium values.

Evaluation of equilibrium model for $f_2(h_1l_1g)$ for methane hydrate with water between −0.29 and 26.7°C

Table 3 presents 85 evaluations of $f_2(h_1l_1g)$ MPa, the equilibrium methane fugacity for structure I methane hydrate h_1 in contact with water-rich liquid l_1 between −0.29 and 25.54°C.

The equilibrium fugacity evaluations are defined by the best weighted least-squares fit of the 85 corrected fugacity measurements that are continuous from −0.29 to 25.54°C and are represented by eq. [1*a*] with five parameters and with ln $f_2(h_1l_1g)$ replacing ln $P(h_1l_1g)$.

Data sets D&F40, MSK64, GRCK70, and V74 (2, 10, 13, 14) are taken to be in thermodynamic equilibrium. The continuous equilibrium model for ln $f_2(h_1l_1g)$ with zero bias is defined to pass through the data mean value of (the 13 ln $f_2(h_1l_1g)$ values of data set D&F40, plus the seven ln $f_2(h_1l_1g)$ values at lowest temperature of data set MSK64, plus four times the four ln $f_2(h_1l_1g)$ values of data set GRCK70, plus the seven ln $f_2(h_1l_1g)$ values of data set V74).

The seven other data sets (1, 3, 6, 7, 12, 17, 22) show positive data-set biases, ln (f_{2u}/f_2), taken to be constant for each data set, above the continuous ln $f_2(h_1l_1g)$ model. The logarithm of the observed equilibrium fugacity ln $f_2(h_1l_1g)$ is defined by eq. [3]

$$\ln f_2(h_1l_1g) = \ln f_{2u}(h_1l_1g) - \ln (f_{2u}/f_2) \qquad [3]$$

in which the data-set bias ln (f_{2u}/f_2) is subtracted from the logarithm of the observed uncorrected fugacity $f_{2u}(h_1l_1g)$.

The observed uncorrected methane fugacity $f_{2u}(h_1l_1g)$ MPa is evaluated from the IUPAC fugacity equation for methane (27) using the observed uncorrected hydrate pressure $P_u(h_1l_1g)$ MPa and the observed thermodynamic temperature T (K) corrected to IPTS-68.

The 85 uncorrected ln $f_{2u}(h_1l_1g)$ data are fitted first by eq. [1*a*], the seven mean values of data-set bias ln (f_{2u}/f_2) are evaluated and the 85 first-approximation equilibrium values of ln $f_2(h_1l_1g)$ are obtained from eq. [3]. The first-approximation equilibrium values are refitted by eq. [1*a*], the seven first-approximation data-set biases are evaluated, and the 85 second-approximation equilibrium values are obtained from eq. [3], and so on. This is continued for 22 cycles to convergence of better than 1×10^{-9} on each of the seven data-set biases.

The best fit of the final 85 ln $f_2(h_1l_1g)$ equilibrium evaluations by eq. [1*a*] gives a *SE* estimate of 0.94% for a single equilibrium $f_2(h_1l_1g)$ observation of unit weight with 70 degrees of freedom. The coefficient of determination R^2 is 0.99989. Parameter and (*SE*) estimates at 25°C are the following: *b*0, 3.4550 (0.0047); *b*1, 42.185 (0.748); *b*2, 688.60 (71.0); *b*3, 8692.6 (1850); *b*4, 36663 (14100). The value of *b*4 could arise by random chance with a probability of about 0.65%, and could arise "not" by chance with a probability of 99.35%, with an odds on chance of being significant of about 154:1.

The *RMS* deviations of residuals for ln $f_2(h_1l_1g)$ from eq. [1*a*] for individual data sets are usually slightly smaller than those found for ln $P(h_1l_1g)$. The *RMS* deviations for weighted (unweighted) residuals of ln $f_2(h_1l_1g)$ from eq. [1*a*] with five parameters are the following: V1888, 0.0073 (0.0145); D&F40, 0.0082; RBH40, 0.0040; K&K49, 0.0088; M&C61, 0.0070; MSK64, 0.0198; J&R65, 0.0060; GRCK70, 0.0076; V74, 0.0117 (0.0201); dRPLD83, 0.0038 (0.0182); and AFS91, 0.0066 (0.0136).

The consistent equilibrium data set D&F40 (2), shows a *RMS* residual estimate of 0.0082, contributed mainly by a data set bias of 0.0067 together with an internal standard deviation of 0.0049. Similarly the equilibrium data set GRCK70 (13), shows a *RMS* residual estimate of 0.0076, contributed mainly by a data set bias of −0.0069 combined with a very small internal standard deviation of 0.0032.

The arrangement of Table 3 is similar to Table 2. Column eight shows values of the seven data-set biases ln (f_{2u}/f_2), evaluated together with the best weighted least-squares fit of the 85 equilibrium methane fugacities. The data-set biases for the best fugacity equation are slightly smaller than those for the best pressure equation. The five-parameter fugacity equation and the four-parameter pressure equation are mutually consistent and lie well within the real error limits of the pressure measurements.

Properties of gas and aqueous phases with methane hydrate

Intensive properties of the gas and aqueous phases in equilibrium with methane hydrate are assessed. The gas phase fugacity of methane for methane hydrate $f_2(h_1l_1g)$ is taken to be that of pure methane at equilibrium total pressure $P(h_1l_1g)$, because the water vapour pressure is less than 0.023% of the total pressure, while the accuracy of the methane hydrate pressures is not better than 1.3%. The methane fugacity is evaluated directly from the IUPAC fugacity equation (27).

The equilibrium methane solubility mol fraction in water x_2^{l1} is evaluated from the methane fugacity $f_2(h_1l_1g)$ divided by the Henry law constant H_2^P, which includes the Poynting

correction at pressure $P(h_1l_1g)$; the solubility equation is from Rettich et al. (16). The equilibrium x_2^{l1} of methane in phase l_1 is listed in column eight of a later table.

Methane hydrate–ice–gas (h_1s_1g) equilibrium

Table 4 presents seven measurements of $P(h_1s_1g)$, the total pressure of structure I methane hydrate h_1 in contact with ice I_h s_1, at temperatures between –2.22 and –14.10°C. Column two lists the data sets and column three their references. Column four shows the observed $P(h_1s_1g)$ MPa, and column five the $P(h_1s_1g)$ calculated from the best (26) equation

$$[4] \qquad \ln P(h_1s_1g) = 9.2645 - 2275/T$$

with thermodynamic temperature T (K) (ITS-90). This equation gives a *SE* estimate of 1.1% for a single measurement of $P(h_1s_1g)$ and a *SE* estimate of 79 K on the parameter –2275. Column six shows the percentage difference of observed minus calculated pressures.

Seven hydrate pressure measurements between –29.95 and –82.95°C (15, 23) show significant positive-pressure deviations above eq. [4], of +4.7% at –30°C increasing to more than +20% below –75°C; these measurements are excluded from the regression to reduce possible bias of eq. [4].

Data set, denoted QPsol, is the quadruple point $Q(h_1s_1l_1g)$, evaluated at methane hydrate pressure from eq. [4] together with the fusion properties of ice (29–31) in equilibrium with its saturated aqueous solution of methane (16, 28).

Column seven in Table 4 shows the methane fugacity $f_2(h_1s_1g)$ abbreviated to f_2, evaluated using the IUPAC fugacity equation (27) at pressure $P(h_1s_1g)$ and at temperature T (K) corrected to IPTS-68.

Quadruple point $Q(h_1s_1l_1g)$

The quadruple point $Q(h_1s_1l_1g)$ is determined from first principles, by successive approximations, using the freezing-point depression (29–31) of ice at hydrate pressure $P(h_1s_1g)$ in equilibrium with an aqueous methane solution (16) having mol fraction x_1^{l1} of water. We find the estimated ice freezing-point depression for $t(h_1s_1l_1g)$ is –0.290°C with *SE* 0.0064°C and the estimated pressure $P(h_1s_1l_1g)$ is 2.527 MPa with *SE* 0.053 MPa, which is in agreement with the –0.30°C and 2.523 MPa by Falabella (15). The quadruple point temperature of –0.20°C given by de Roo et al. (17) is in error by 0.11°C, the effect of neglecting the methane solubility in water; their quadruple point pressure of 2.523 MPa agrees with Falabella (15).

Equilibrium constant for dissociation of methane hydrate into ice and methane gas

Thermodynamic equations from ref. 33 are used here without derivation since all have been discussed for the determination of the formula of deuterium sulfide D-hydrate.

Consider the standard dissociation of one gram mol (gram-molar mass) of methane hydrate h_1 of formula $CH_4{\cdot}nH_2O$ into n mol of ice s_1 plus one mol of methane gas g. The equilibrium constant $Kp(h_1{\rightarrow}s_1g)$ for this process is defined by the equation

$$[5] \qquad \ln Kp(h_1{\rightarrow}s_1g) = \ln f_2(h_1s_1g) + n(1/RT)\int_{0.1}^{P(h_1s_1g)}(V_1^{s1} - V_1^{h1})dP$$

in which $f_2(h_1s_1g)$ is the fugacity of methane, n the hydrate formula number, V_1^{s1} the molar volume of ice, and V_1^{h1} the molar volume of water in structure I hydrate, at total pressure $P(h_1s_1g)$ and thermodynamic temperature T (K). Values for $f_2(h_1s_1g)$ are given in Table 4 and the gaseous standard state is 1.0 MPa fugacity. The standard state of the condensed phases is 0.1 MPa pressure. Formula number $n = 6.2$ is assigned and is equal to its equilibrium value at $Q(h_1s_1l_1g)$. The molar volume of ice, its coefficient of expansion, and compressibility are from Lide (29).

The standard molar volume of water in structure I hydrate, V_1^{oh1} is evaluated from the methane D-hydrate lattice spacing 1.177 ± 0.001 nm at 5.2 K (38), expanded to 1.178 nm for the methane hydrate. Methane hydrate is taken to have the same coefficient of expansion as ethylene oxide hydrate between 18 and 260 K (39), and the same compressibility as ice (29). At pressure 0.1 MPa the standard molar volumes of structure I hydrate water V_1^{oh1} are 22.26, 22.31, and 22.35 $cm^3\ mol^{-1}$ at –14.10, –6.66, and –0.29°C, respectively.

The seven values of $\ln Kp(h_1{\rightarrow}s_1g)$ MPa between –2.22 and –14.10°C are best (26) represented by the equation

$$[6] \qquad \ln Kp(h_1{\rightarrow}s_1g) = 8.8110 - 2172/T$$

with thermodynamic temperature T (K). This equation gives a *SE* estimate of 1.05% for a single determination of $Kp(h_1{\rightarrow}s_1g)$ and a *SE* of 73 K on the parameter –2172. The coefficient of determination R^2 is 0.9944.

The standard enthalpy change derived for hydrate dissociation $\Delta H^{ot}(h_1{\rightarrow}s_1g)$ is 18058 J mol^{-1} with *SE* 608 J mol^{-1} methane at –8.28°C. This estimate of standard enthalpy change agrees with the calorimetric value 18130 J mol^{-1}

with *SE* 270 J mol^{-1} methane at 0°C reported by Handa (18). The agreement of these two values for the standard enthalpy change confirms that the structure I methane hydrate pressure measurements between –2.22 and –14.10°C (3, 4, 23) are in thermodynamic equilibrium with ice. Hydrate pressures reported (15, 23) between –30 and –75°C do not agree with the values of the standard enthalpy change.

Definition of equilibrium constant for dissociation of structure I methane hydrate into water and methane gas between –0.29 and 26.7°C

Consider the standard dissociation of one gram mol of methane hydrate of formula $CH_4 \cdot nH_2O$ phase h_1 into n mol of pure water l_1 plus one mol of gaseous methane g. The equilibrium constant $Kp(h_1 \rightarrow l_1 g)$ for this process is defined by the equation

$$[7] \quad \ln Kp(h_1 \rightarrow l_1 g) = \ln f_2(h_1 l_1 g) + n \ln x_1^{11} + n(1/RT) \int_{0.1}^{P(h_1 s_1 g)} (V_1^{11} - V_1^{h1}) dP$$

in which V_1^{l1} is the molar volume of water at pressure $P(h_1 l_1 g)$ and temperature T (K). Equilibrium values of $P(h_1 l_1 g)$ are given in column six of Table 2, equilibrium values of $f_2(h_1 l_1 g)$ are given in column six of Table 3, and equilibrium values for $x_1^{11} = (1 - x_2^{11})$ are from x_2^{11} in column eight of Table 5. The formula number $n = 6.0$ is assumed initially, but this value changes with convergence and varies with temperature along the $(h_1 l_1 g)$ equilibrium line. The molar volume of water is from Haar et al. (28). At 0.1 MPa, the standard structure I hydrate water molar volumes V_1^{oh1} are 22.45 and 22.55 cm^3 mol^{-1} at 13.10 and 26.7°C, respectively.

© 2002 NRC Canada

Values of the 85 equilibrium constants ln $Kp(h_1 \rightarrow l_1g)$ MPa between −0.29 and 26.7°C are best (26) represented by the three-parameter thermodynamic equation,

[8*a*] $\ln Kp(h_1 \rightarrow l_1g) = d0 + d1.u1 + d2.u2$

which is mathematically equivalent to

[8*b*] $\ln Kp(h_1 \rightarrow l_1g) = A' + B'/T + C' \ln T$

Formula of methane hydrate at quadruple point $Q(h_1s_1l_1g)$

The formula of methane hydrate is evaluated by the method of Scheffer and Meyer (40) who first derived eq. [9] for *n*,

[9] $\Delta H^{oq}(h_1 \rightarrow l_1g) - \Delta H^{oq}(h_1 \rightarrow s_1g) = n\Delta H^{oq}(s_1 \rightarrow l_1)$

which is exact at −0.29°C of the quadruple point $Q(h_1s_1l_1g)$, with the equilibrium standard enthalpy changes denoted by superscript q.

Substitution into eq. [9], of 55 356 J mol^{-1} with *SE* 289 J mol^{-1} CH_4 for $\Delta H^{oq}(h_1 \rightarrow l_1g)$ from this work, of 18129 J mol^{-1} with *SE* 270 J mol^{-1} CH_4 for $\Delta H^{oq}(h_1 \rightarrow s_1g)$ from Handa (18), and of 6000 J mol^{-1} with *SE* 4 J mol^{-1} H_2O for $\Delta H^{oq}(s_1 \rightarrow l_1)$, evaluated from Osborne (31) and Giauque and Stout (30), yields $n = 6.205$ with *SE* 0.066 for the formula of structure I methane hydrate at $Q(h_1s_1l_1g)$ −0.29°C.

Using this method for hydrogen sulfide hydrate gives $n = 6.119$ with *SE* 0.029 (34) and for deuterium sulfide D-hydrate $n = 6.115$ with *SE* 0.018 (33) at their $Q(h_1s_1l_1g)$ quadruple points. The formula for methane hydrate at $Q(h_1s_1l_1g)$ is seen to be slightly richer in water than the formulae for the two sulfide hydrates.

A Student t-test of the formula difference [(6.205 − 6.119)/0.068] gives $t = 1.26$ with more than 40 degrees of freedom. The value of *t* indicates that this formula difference could arise by random chance with a probability of about 11%, could "not" arise by random chance with a probability of 89%, that is, the odds on this difference being significant is about 8:1.

The present study shows that the methane hydrate formula $CH_4 \cdot 5.765H_2O$ at 0°C reported earlier by us (9) is incorrect. The $\Delta H^{oo}(h_1 \rightarrow l_1g)$ is too small by 1707 J mol^{-1} and the $\Delta H^{oo}(h_1 \rightarrow s_1g)$ is too large by 920 J mol^{-1} leading to a total error on their difference of 2627 J mol^{-1} and a methane hydrate formula deficit of $0.433H_2O$.

The hydrate formula number *n* determined by Diepen and co-workers (17) at their $Q(h_1s_1l_1g)$ varies from 5.5 to 6.9, with a mean value of 6.3 and with three individual values of 6.1, 6.1, and 6.2: these are in rough agreement with our estimate of 6.205 with *SE* 0.066 at −0.29°C.

The equilibrium methane hydrate formula $CH_4 \cdot 6.205 \pm 0.066H_2O$ found at $Q(h_1s_1l_1g)$ −0.29°C contains significantly more water than the ice-free calorimetric sample $CH_4 \cdot 6.00 \pm 0.01H_2O$ prepared by direct synthesis under 2.6-times excess methane pressure at 253 K by Handa (18). Both formulae are probably correct and provide a clear confirmation of the variable stoichiometry of the structure I methane hydrate.

A similar positive difference of hydrate formula is reported by Davidson et al. (41) in their study on xenon hydrate. A xenon hydrate $Xe \cdot 6.286 \pm 0.030H_2O$ was found in equilibrium with water and xenon gas at 273 K, and a hydrate of formula $Xe \cdot 5.90 \pm 0.05H_2O$ was prepared under 27-times excess xenon pressure at 253 K (42).

Our equilibrium methane hydrate formula at the quadruple point $Q(h_1s_1l_1g)$ differs significantly from the NMR sample (20), conditioned for ~3 months at −40°C and then for one week at −13°C, presumably under excess methane pressure, and then measured as $CH_4 \cdot 6.05 \pm 0.06H_2O$ at −80°C. The variable stoichiometry of methane hydrate is again confirmed.

Our methane hydrate formula number at $Q(h_1s_1l_1g)$ agrees roughly with the NMR derived results of Collins et al. (43) who reported $H_2Se \cdot 6.21 \pm 0.13H_2O$ at 275 K, $D_2Se \cdot 6.21 \pm 0.18D_2O$ at 270 K, and $CO \cdot 6.22 \pm 0.24H_2O$ at 220 K.

Formula of structure I methane hydrate at temperatures between −0.29 and 26.7°C

We now extend eq. [9], valid at $Q(h_1s_1l_1g)$, for use at higher temperature *t* (°C) to evaluate an approximate formula number, defined as *r*, using the thermochemical identity eq. [10]

[10] $\Delta H^{ot}(h_1 \rightarrow l_1g) - \Delta H^{ot}(h_1 \rightarrow s_1g) = r\Delta H^{ot}(s_1 \rightarrow l_1)$

where superscript q in eq. [9] is replaced by t in eq. [10]. Values of $\Delta H^{ot}(h_1 \rightarrow s_1g)$ and $\Delta H^{ot}(s_1 \rightarrow l_1)$ at *t* are equal to their values at the quadruple point, plus the integral of their heat capacity changes from the quadruple point.

The first term in eq. [10] is derived from the 85 $Kp(h_1 \rightarrow l_1g)$ measurements (1–3, 6, 7, 10, 12–14, 17, 22) of this work.

The second term $\Delta H^{ot}(h_1 \rightarrow s_1g) = \Delta H^{oo}(h_1 \rightarrow s_1g) + \Delta Cp^{oo}(h_1 \rightarrow s_1g)t = (18130 + 4t)$ varies linearly with *t* (°C), where $\Delta H^{oo}(h_1 \rightarrow s_1g)$ is 18130 J mol^{-1} with *SE* 270 J mol^{-1} and $\Delta Cp^{oo}(h_1 \rightarrow s_1g)$ is 4 J mol^{-1} deg^{-1} with *SE* 3 J mol^{-1} deg^{-1}, taken directly from Handa (18).

The final term in eq. [10] is the standard molar enthalpy change for fusion of metastable ice H_2O s_1 into liquid water H_2O l_1 at *t* (°C). This is evaluated using the Taylor's series expansion

[11] $$\Delta H^{ot}(s_1 \rightarrow l_1) = \Delta H^{oo}(s_1 \rightarrow l_1) + \Delta Cp^{oo}(s_1 \rightarrow l_1)t + d\Delta Cp^{oo}(s_1 \rightarrow l_1)/dt(1/2)t^2 + d^2\Delta Cp^{oo}(s_1 \rightarrow l_1)/dt^2(1/6)t^3$$

at the normal freezing point 0°C, with $\Delta H^{oo}(s_1 \rightarrow l_1) = 6009$ J mol^{-1} with *SE* 4 J mol^{-1} (31). The standard molar heat capacity change and its temperature derivatives for fusion are evaluated at 0°C using (*i*) the heat capacities of ice between −74 and −2.6°C by Giauque and Stout (30); and (*ii*) the tabulated heat capacities of liquid water between 0 and 80°C by Haar et al. (28).

Method for evaluation of dissociation equilibrium constant of methane hydrate and its formula number *r*

The phase rule requires that the equilibrium water–methane two-component three-phase (h_1l_1g) system is univariant and that the intensive properties of the three equilibrium phases are continuous functions of temperature. In particular, the equilibrium hydrate composition and its component H_2O–CH_4 mol ratio $n = r$ is a continuous function of temperature only.

$Q(h_1h_2l_1g)$	26.7	58377	367	112	23	5.759	0.077

A method is given to evaluate the approximate formula number *r* for the structure I methane hydrate $CH_4 \cdot rH_2O$ and its dissociation equilibrium constant $Kp(h_1 \rightarrow l_1 g)$ at each experimental temperature on the univariant $(h_1 l_1 g)$ equilibrium line, between quadruple point $Q(h_1 s_1 l_1 g)$ at −0.29°C and quadruple point $Q(h_1 h_2 l_1 g)$ at 26.7°C.

The method of convergence to a stable solution depends on the temperature continuity of *r*, the approximate hydrate formula number. Initially we assume that $n = r = 6.0$ in eq. [7] for all measurements, giving a first approximation for the logarithm of the equilibrium constant, abbreviated ln *Kp*(1st). The ln *Kp*(1st) values are fitted as a proper function of temperature (26) by the method of least squares (35) to yield the best thermodynamic equation of the form of eq. [8*a*]. These measurements use two temperature variables (*u*1 *u*2) with $x = (T - 298.15)/298.15$, and define (26) three thermodynamic function parameters (*d*0, *d*1, *d*2) and their standard errors at 298.15 K.

Derived from (*d*1, *d*2) of eq. [8*a*], the first approximation standard enthalpy changes $\Delta H^{ot}(h_1 \rightarrow l_1 g)$, abbreviated ΔH(1st), for each measurement at its temperature *t* are substituted into eq. [10], to give a first approximation formula number *r*(1st).

Values of *r*(1st) are substituted for *n* in eq. [7] for each measurement to provide a second approximation for the logarithm of the equilibrium constant ln *Kp*(2nd); the ln *Kp*(2nd) values are refitted by eq. [8*a*], thence to obtain second approximation ΔH(2nd) values; these are substituted for $\Delta H^{ot}(h_1 \rightarrow l_1 g)$ in eq. [10] to give *r*(2nd) values, which are recycled for *n* in eq. [7], and so on. Iterations for 32 cycles give the converged values of $Kp(h_1 \rightarrow l_1 g)$ and of *r*, which are presented in Tables 5 and 6.

Values of equilibrium constant for dissociation of structure I methane hydrate into water and methane gas between –0.29 and 26.7°C

Table 5 lists 85 determinations between –0.29 and 25.54°C of the equilibrium constant, $Kp(h_1 \rightarrow l_1 g)$, for dissociation of structure I methane hydrate to liquid water and methane gas with $n = r$. Standard thermodynamic function changes refer to dissociation of one mol of $CH_4 \cdot rH_2O$ h_1 at 0.10 MPa to form r mol of pure water l_1 at 0.10 MPa plus one mol of methane g at 1.0 MPa fugacity.

Column one of Table 5 indicates the data set and column two lists the hydrate temperature. Column three lists the square root of the weights used. Column four lists $Kp(h_1 \rightarrow l_1 g)$ MPa observed and column five gives $Kp(h_1 \rightarrow l_1 g)$ calculated from the converged eq. [8*a*]. Column six shows the percentage differences between observed and calculated equilibrium constants, which yield an overall *SE* of 0.79% for a single $Kp(h_1 \rightarrow l_1 g)$ determination of unit weight with 72 degrees of freedom. Column seven shows the percentage error on the estimated equilibrium constant defined by eq. [8*a*]. Column eight of Table 5 lists the equilibrium mol fraction x_2^{11} of methane in the aqueous phase l_1.

Further investigation shows that the methane hydrate measurements are sufficiently accurate to evaluate only ($d0$, $d1$, $d2$) in eq. [8*a*], but are insufficiently accurate to define any value for $d3$.

The three parameters of the best converged eq. [8*a*] with their (*SE*)s are $d0 = 2.9516$ (0.0029), $d1 = 23.473$ (0.133), and $d2 = 13.46$ (2.82). The coefficient of determination R^2 is 0.99989.

The value of the least significant parameter $d2$ could arise by pure chance at a probability level of less than 0.05%. Estimates of $d1$ and $d2$ for structure I methane hydrate are 88 and 70%, respectively, of those found for hydrogen sulfide hydrate (34).

The *RMS* deviations of the residuals for ln $Kp(h_1 \rightarrow l_1 g)$ from eq. [8*a*] for the individual data sets are generally smaller than those for ln $P(h_1 l_1 g)$ and are about equal to those for ln $f_2(h_1 l_1 g)$. The *RMS* deviations for weighted (unweighted) residuals of ln $Kp(h_1 \rightarrow l_1 g)$ from eq. [8*a*] with three parameters are the following: V1888, 0.0063 (0.0126); D&F40, 0.0081; RBH40, 0.0066; K&K49, 0.0064; M&C61, 0.0073; MSK64, 0.0148; J&R65, 0.0073; GRCK70, 0.0079; V74, 0.0077 (0.0173); dRPLD83, 0.0037 (0.0167); and AFS91, 0.0056 (0.0120).

The very consistent equilibrium data set D&F40 (2), shows a *RMS* residual estimate of 0.0081, contributed mainly by a data set bias of 0.0071 combined with a low internal standard deviation of 0.0034. Similarly the equilibrium data set GRCK70 (13), shows a *RMS* residual estimate of 0.0079, contributed mainly by a data set bias of –0.0065 combined with a low internal standard deviation of 0.0044.

At 26.7°C with *SE* 0.9°C the estimate of equilibrium constant $Kp(h_1 \rightarrow l_1 g)$ is 21.87 MPa with *SE* 1.59 MPa, evaluated from eq. [8*a*].

The *SE* estimate of 0.79% for a single $Kp(h_1 \rightarrow l_1 g)$ datum of unit weight given by the best three-parameter eq. [8*a*] is seen to be about 60% of the *SE* estimate 1.33% for a single $P(h_1 l_1 g)$ measurement of unit weight given by the best four-parameter eq. [1*a*].

Standard enthalpy change $\Delta H^{ot}(h_1 \rightarrow l_1 g)$ and formula number r for structure I methane hydrate

Table 6 presents estimates and *SE*s for the standard enthalpy change $\Delta H^{ot}(h_1 \rightarrow l_1 g)$, for the standard heat capacity change $\Delta Cp^{ot}(h_1 \rightarrow l_1 g)$ and the approximate formula number r for the standard dissociation of structure I methane hydrate into water and methane gas. We note that the results listed in Tables 5 and 6 are biased estimates, except for those at –0.29°C, the ice quadruple point $Q(h_1 s_1 l_1 g)$, where eq. [10] is exact.

At higher temperatures a small bias may arise because it is assumed in eq. [10] that $\Delta H^{ot}(h_1 \rightarrow s_1 g) = (18130 + 4t)$ J mol^{-1} and that $\Delta Cp^{ot}(h_1 \rightarrow s_1 g)$ is a constant 4 J mol^{-1} deg^{-1} over the temperature range –0.29 to 25.54°C, where it is probable that $\Delta Cp^{ot}(h_1 \rightarrow s_1 g)$ may vary with temperature. The effect of this bias is assessed using the upper *SE* limit of (4 + 3) J mol^{-1} deg^{-1} for $\Delta Cp^{ot}(h_1 \rightarrow s_1 g)$ from (18). Evaluation of r at 25.54°C, using eq. [10] with $\Delta H^{ot}(h_1 \rightarrow s_1 g) = (18130 + 7t)$ at t (°C), gives a converged $r = 5.768$ with *SE* 0.074; a result not significantly different from that given in Table 6.

A second bias may arise because $\Delta H^{ot}(s_1 \rightarrow l_1)$ is given by the Taylor's series eq. [11] over the extrapolated temperature range –0.29 to 25.54°C. Classical error theory (35) indicates that the *SE* on r at 25.54°C, due to errors on the Taylor's series parameters of eq. [11], is less than 0.0004 and is not significant.

The *SE*s on the standard enthalpy changes for r at 25.54°C are 341 J mol^{-1} on $\Delta H^{ot}(h_1 \rightarrow l_1 g)$, 281 J mol^{-1} on $\Delta H^{ot}(h_1 \rightarrow s_1 g)$, and 8 J mol^{-1} on $\Delta H^{ot}(s_1 \rightarrow l_1)$.

The methane hydrate formula number n determined by method 1 of Galloway et al. (13) between 9.99 and 15.55°C has a mean value of 6.01 with *SE* 0.14, in approximate agreement with our mean value of 5.96 with *SE* 0.052 found using their four-equilibrium hydrate pressures. Unfortunately their temperature coefficient for n is of the wrong sign, which precludes a closer comparison.

In Table 6 the value of r decreases monotonously with increasing temperature and approaches its theoretical lower limit of 5.75, for a structure I hydrate (36–38), at a temperature above 25.54°C and very near to the quadruple point $Q(h_1 h_2 l_1 g)$ temperature of 26.7°C.

This requires a continuous increase with temperature in the number of methane guest molecules per unit cell of $46H_2O$, from 7.414 with *SE* 0.079 at –0.29°C, to 7.966 with *SE* 0.101 at 25.54°C, to about 7.987 with *SE* 0.107 at 26.7°C. Although these numbers may be slightly biased, the overall effect of increasing temperature remains unchanged. This shows that an increased fraction of cavities must be occupied by methane guests to stabilize the structure I hydrate lattice against thermal collapse up to $Q(h_1 h_2 l_1 g)$ at 26.7°C.

At 25.54°C and 48.6 MPa methane pressure the equilibrium hydrate lattice has 0.42% of empty cavities and 99.58% of occupied cavities with *SE* 1.26%. At 26.7°C and 55.5 MPa methane pressure the estimated hydrate lattice composition has 0.16% of empty and 99.84% of occupied cavities with *SE* 1.34%. These lattice compositions are less than, close to, and not significantly different from the theoretical formula limit $CH_4 \cdot 5.75H_2O$, for a cubic structure I methane clathrate hydrate.

This limiting hydrate composition found at 26.7°C, independently supports the discontinuity of the hydrate pressures

of data set MSK64 (10) and defines the $Q(h_1h_2l_1g)$ transition from the structure I methane hydrate phase h_1 stable below 26.7°C, to a different methane hydrate phase h_2 stable above 26.7°C.

At a temperature just above 26.7°C we expect that phase h_2 is a structure II methane clathrate hydrate similar to the structure II hydrates reported for Ar and Kr (38) and for O_2 (44).

Evaluation of equilibrium model for $P(h_2l_1g)$ for methane hydrate with water between 26.98 and 46.87°C

Table 7 presents 17 evaluations of $P(h_2l_1g)$, the equilibrium methane pressure for methane hydrate h_2 in contact with water-rich liquid l_1 between 26.98 and 46.87°C.

Column one of Table 7 indicates the data set and column two shows the hydrate temperature. Column three gives $w^{1/2}$, the square root of the assigned weight. Column four shows the observed equilibrium methane hydrate pressure $P(h_2l_1g)$ MPa, column five gives $P(h_2l_1g)$ calculated from eq. [1*a*], and column six shows the percent difference. Column seven lists the estimated percentage *SE* on the calculated hydrate pressure.

The measurement at 28.82°C of data set K&K49 is assigned the low weight $w^{1/2} = 0.001$ because its residual is greater than nine times its computed *SE*; the low weight eliminates bias of the regression model by this possibly deviant measurement.

The 13 measurements of data set MSK64 (10) are assumed to be in thermodynamic equilibrium and bias free, the two measurements of data set K&K49 (6) use the bias $\ln (P_u/P) = 0.0624$ and the two measurements of data set M&C61 (7) use the bias $\ln (P_u/P) = 0.0252$, the same biases found in Table 2. The equilibrium pressures, taken to be continuous between 26.98 and 46.87°C, are properly represented by their weighted least-squares fit by eq. [1*a*] with three parameters.

The best fit of the 17 $\ln P(h_2l_1g)$ equilibrium pressures by eq. [1*a*] gives a *SE* estimate of 2.2% on a single equilibrium pressure measurement of unit weight with 11 degrees of freedom. The coefficient of determination R^2 is 0.99983. The parameter and (*SE*) estimates at 25°C are the following: *b*0, 3.8527 (0.0163); *b*1, 28.835 (1.21); *b*2, 50.86 (31.7). The value of *b*2 could arise by random chance with a probability of about 7.5%, and could "not" arise by chance with a probability of 92.5%, giving an odds on chance of being significant of about 12:1.

We note that the estimates of the parameters *b*1 and *b*2 for methane hydrate h_2 are both positive and are significantly smaller than the 39.863 and 205.29 found for the structure I methane hydrate.

The *RMS* deviations for the weighted (unweighted) residuals of $\ln P(h_2l_1g)$ from eq. [1*a*] with three parameters are the following: K&K49, 0.0126 (0.0546); M&C61, 0.0105; and MSK64, 0.0218.

Column eight of Table 7 lists the equilibrium methane fugacity $f_2(h_2l_1g)$ MPa for methane hydrate h_2 with water. Measurements of data set MSK64 (10) are bias free, the two measurements of data set K&K49 (6) use the bias $\ln (f_{2u}/f_2) = 0.0467$ and the two measurements of data set M&C61 (7) use the bias $\ln (f_{2u}/f_2) = 0.0255$, the same biases given in Table 3. The observed uncorrected methane fugacity $f_{2u}(h_2l_1g)$ MPa is evaluated from the IUPAC fugacity equation for methane (27) using the observed uncorrected hydrate pressure $P_u(h_2l_1g)$ (MPa) and the observed thermodynamic temperature *T* (K) corrected to IPTS-68.

Equilibrium constant for dissociation of structure II methane hydrate into water and methane gas between 26.7 and 46.87°C

The equilibrium constant $Kp(h_2 \rightarrow l_1g)$ for dissociation of methane hydrate h_2 into pure water l_1 and methane gas g is the same as eq. [7] with h_1 replaced by h_2. Values of the equilibrium methane hydrate fugacity $f_2(h_2l_1g)$ and equilibrium pressure $P(h_2l_1g)$ are from columns eight and four, re-

spectively, of Table 7. Values of $x_1^{11} = (1 - x_2^{11})$ are evaluated from the equilibrium aqueous methane solubility (16).

The standard molar volume of water in structure II methane hydrate V_1^{oh2} is evaluated from the oxygen D-hydrate lattice spacing of 1.707 ± 0.001 nm at 5.7 K (44), expanded to 1.708 nm for the methane hydrate. Structure II methane hydrate is taken to have the same coefficient of expansion as tetrahydrofuran hydrate between 18 and 260 K (45) and the same compressibility as ice (29). At standard pressure of 0.1 MPa, the structure II methane hydrate water molar volumes V_1^{oh2} are 22.96, 23.01, and 23.06 cm^3 mol^{-1} at 26.7, 37.15, and 46.87°C, respectively.

Temperature dependence of ln $Kp(h_2 \rightarrow l_1 g)$ MPa between 26.98 and 46.87°C is represented by a constrained three-parameter equation eq. [12]

$$[12] \quad \ln Kp(h_2 \rightarrow l_1 g) = d0 + d1(u1 + (d2/d1).u2) = d0 + d1(u1 + f.u2)$$

in which the constraint factor $f = (d2/d1)$ is assigned a constant value. Equation [12] is evaluated by the method of least-squares and is converged as a two-parameter equation, with $d0$ $d1$ unknown, using the combined temperature variable $(u1 + f.u2)$. The best value of f is determined to give the minimum *SE* for ln $Kp(h_2 \rightarrow l_1 g)$. The variability of the input measurements and the consequent large *SE* of $d2$ precluded use of an unconstrained three-parameter equation for ln $Kp(h_2 \rightarrow l_1 g)$.

The method of evaluation of the best model for the 17 $Kp(h_2 \rightarrow l_1 g)$ equilibrium constants is similar to that used for the structure I hydrate. Equation [7] initially uses $n = 6.0$ for all measurements but this changes with convergence. Equation [12] replaces [8*a*], and $d1$ and f values are used to determine the value of $\Delta H^{ot}(h_2 \rightarrow l_1 g)$ at each temperature. Equation [10] is used to determine r, with $\Delta H^{ot}(h_2 \rightarrow s_1 g)$ taken to be a constant 18130 J mol^{-1} with *SE* 270 J mol^{-1} for structure II methane hydrate. Equation [11] is used unchanged. After converging four models, each of 24 cycles, the best estimate of f is 0.7320 with *SE* 0.632.

Table 8, with the same arrangement as Table 5, shows best estimates of equilibrium constants $Kp(h_2 \rightarrow l_1 g)$ between 26.98 and 46.87°C. Differences between observed and calculated equilibrium constants yield an overall *SE* of 1.04% for a single $Kp(h_2 \rightarrow l_1 g)$ determination of unit weight with 12 degrees of freedom.

The two parameters of the best converged eq. [12] with their (*SE*)s are the following: $d0 = 2.9020$ (0.0048) and $d1 = 23.585$ (0.110). The estimate of $d2 = f.d1$ is 17.26 with an external *SE* estimate of 14.91. The coefficient of determination R^2 is 0.99993.

The *RMS* deviations for the weighted (unweighted) residuals of ln $Kp(h_2 \rightarrow l_1 g)$ from eq. [12] with two parameters are the following: K&K49, 0.0083 (0.0274); M&C61, 0.0041; and MSK64, 0.0104.

At 26.7°C with *SE* 0.9°C the estimate of equilibrium constant $Kp(h_2 \rightarrow l_1 g)$ is 21.25 MPa with *SE* 1.55 MPa, evaluated from eq. [12].

After some difficulty co-converging eqs. [7] and [12] for the structure II methane hydrate, we are surprised and reassured by the final good fit of the equilibrium constants, considering the extreme changes of the equilibrium methane fugacities above 40°C.

Standard enthalpy change $\Delta H^{ot}(h_2 \rightarrow l_1 g)$ and formula number r for structure II methane hydrate with water

Table 9, with the same arrangement as Table 6, presents estimates and *SE*s for the standard enthalpy and heat capacity changes $\Delta H^{ot}(h_2 \rightarrow l_1 g)$ and $\Delta Cp^{ot}(h_2 \rightarrow l_1 g)$ and for the ap-

proximate formula number *r* for standard dissociation of structure II methane hydrate into water and methane gas. The constrained standard heat capacity change estimate is listed with zero *SE*.

At quadruple point $Q(h_1h_2l_1g)$ 26.7°C the formula of structure II methane hydrate is $CH_4 \cdot 5.822H_2O$ with *SE* $0.064H_2O$. This hydrate is in equilibrium with a structure I hydrate of formula $CH_4 \cdot 5.759H_2O$ with *SE* $0.077H_2O$. The formula difference of $0.063H_2O$ at 26.7°C is not significant compared with either the individual or the combined *SE*s. It is noted that the structure II methane hydrate at 37.15°C has the formula $CH_4 \cdot 5.750H_2O$ with *SE* $0.064H_2O$, at a significant higher temperature 10.45°C and pressure 97.2 MPa than the structure I methane hydrate.

In Table 9 the value of *r* decreases monotonously with increasing temperature and approaches the theoretical lower limit of 5.667, for a structure II hydrate (36–38), at some temperature above 46.84°C.

This requires a continuous increase with temperature in the number of methane guests per unit cell of $136H_2O$, from 23.36 with *SE* 0.26 at 26.7°C, to 23.87 with *SE* 0.27 at 46.87°C. Although these numbers may be slightly biased, the overall effect of increasing temperature remains unchanged. An increased fraction of cavities must be occupied by methane molecules to stabilize the structure II hydrate lattice against thermal collapse with increase of temperature from 26.7 to 46.87°C.

Expressed in terms of structure II hydrate lattice sites occupied by methane molecules, at 26.7°C there are 2.67% of empty and 97.33% of filled sites with *SE* 1.07%, and at 46.87°C there are 0.56% of empty and 99.44% of filled sites with *SE* 1.12%.

Quadruple point $Q(h_1h_2l_1g)$ and metastable quadruple point $Q(h_2s_1l_1g)$

Structure I methane hydrate undergoes a transition at 55.5 MPa and 26.7°C because all lattice sites are filled by methane and no empty site is available for additional methane. Additional volume is obtained by transition into the more open structure II hydrate water lattice, which can encage 1.47% more methane per mol lattice water.

Methane does not form a structure II hydrate with water at –0.29°C and 2.53 MPa because an approximate 70% occupancy by methane of the pentagonal dodecahedral sites of structure II is insufficient to stabilize a structure II methane hydrate of formula $CH_4 \cdot 7.083H_2O$. By contrast, under the same conditions the structure I methane hydrate has all six tetrakiadecahedral sites fully occupied by methane and the two pentagonal dodecahedral sites are at least 70.7% occupied by methane with *SE* 3.9%, stabilizing the structure I methane hydrate of formula $CH_4 \cdot 6.205H_2O$. As the equilibrium methane pressure and temperature are increased, methane completely fills the two pentagonal dodecahedral sites of structure I giving the extreme formula $CH_4 \cdot 5.75H_2O$ at 26.7°C and 55.5 MPa. Under these higher methane pressure conditions, the slightly smaller pentagonal dodecahedra of the structure II hydrate are at least 95.99% filled by methane with SE 0.40%, giving the structure II methane hydrate of formula $CH_4 \cdot 5.822H_2O$. Thus, it is seen that the methane "help gas" must occupy substantially more than 70% of the pentagonal dodecahedra to stabilize the structure II methane hydrate with methane in the large hexakiadecahedral sites.

Extrapolation of $P(h_2l_1g)$ to 0°C gives a methane gas pressure of 4.11 MPa with *SE* 1.00 MPa for formation of metastable structure II methane hydrate with water, having a for-

© 2002 NRC Canada

Table 10. Cohesive energy density of water and the methane hydrates

t (°C)	$P(hl_1g)$ (MPa)	V_1^{l1} (cm^3 mol^{-1})	p_i^{l1} (MPa)	a (nm)	V_1^{h} (cm^3 mol^{-1})	$p_i^{MT\,h}$ (MPa)	$p_i^{CH_4\,h}$ (MPa)
–0.29	2.53	18.00	2501	1.195	22.34	2283	2682

46.87	397	16.17	2303	1.701	21.80	2055	2551
46.87	397	16.17	2303	1.707	22.04	2032	2523

mula $CH_4{\cdot}6.113H_2O$ with *SE* $0.064H_2O$, with at least 89.05% occupancy of the dodecahedral sites by methane with *SE* 1.46%. The long extrapolation to 0°C is not very accurate, but the pressure should be correct within six *SE*s.

We note that the meta-stable structure II methane hydrate at 0°C has a higher methane pressure and a formula containing less water than the stable equilibrium structure I methane hydrate.

The meta-stable quadruple point $Q(h_2s_1l_1g)$ is estimated at –0.46°C with *SE* 0.11°C and at 3.93 MPa with *SE* 1.0 MPa.

Strictly, we need an equilibrium datum for $P(h_1h_2g)$ near 0°C, which is accessible by experiment, and which we estimate to be less than 40 MPa and more than 4.11 MPa methane pressure. Since the excess methane pressure required to form structure II methane hydrate from water is relatively small at 0°C, we expect that structure II methane hydrate will be produced by direct synthesis from ice with excess methane under higher methane pressure than used (18) for structure I methane hydrate. Even if structure I methane hydrate is formed first, it should equilibrate to form structure II methane hydrate with the excess methane gas at higher pressure.

Cohesive energy density of water and the methane hydrates

It is instructive to compare the cohesive energy density of the two equilibrium methane hydrates with their empty hydrate water lattices and with compressed water under the same conditions of temperature and pressure. The cohesive energy density of compressed water is evaluated from steam tables (28) as the specific enthalpy of vaporization of the liquid divided by its specific volume. Results are presented in Table 10. The cohesive energy density evaluated as J cm^{-3} is identical with the internal pressure listed in MPa.

For compressed water at –0.29°C and an external pressure of 2.53 MPa the cohesive-internal pressure of water p_i^{l1} is 2501 MPa, this value mainly reflects the strength of the hydrogen bonds in liquid water. With temperature increase to 46.87°C and external pressure to 397 MPa the water internal pressure p_i^{l1} is 2303 MPa, this is still 92% of the value at –0.29°C and indicates the relatively strong hydrogen bonds in water at 46.87°C.

Columns one and two in Table 10 give the equilibrium temperature and total pressure $P(hl_1g)$ for the methane hydrates at their quadruple points $Q(h_1s_1l_1g)$ and $Q(h_1h_2l_1g)$ and at the highest temperature of data set MSK64 (10). Column five lists the equilibrium-hydrate cubic-lattice spacing a in nm, and column six shows the equilibrium hydrate water molar volume V_1^{h} in cm^3 mol^{-1}. Column 7 is the internal pressure, $p_i^{MT\,h}$ in MPa, of the empty hydrate water lattices, and column eight is the internal pressure, $p_i^{CH_4\,h}$ in MPa, of the equilibrium methane hydrates.

At –0.29 and 26.7°C we find that 24 and 27% expansions of the liquid water volume are required to form the empty water lattice of structure I hydrate, this expansion reduces the water internal pressures by 8.7 and 8.3%, or by 218 and 203 MPa, respectively. Similarly at 26.7 and 46.87°C, liquid water expansions of 29% and 35%, are required to form the empty water lattice of structure II hydrate, this reduces the water internal pressures by 10.0 and 10.8%, or by 243 and 248 MPa, respectively. Despite these relatively large expansions the empty-hydrate water lattices have cohesive-internal pressures between 8.8 and 9.8 times larger than the 233 MPa internal pressure of liquid methane at 100 K (27).

The cohesive energy density of the equilibrium methane hydrates shown in column eight is found to be 7.2 and 10.3% greater than water for structure I hydrate at –0.29 and 26.7°C, respectively, and 8.2 and 10.8% greater than water for structure II hydrate at 26.7 and 46.87°C, respectively. The difference of column eight minus column seven gives the enhancement of stability due to the equilibrium methane within the two hydrate lattices. We note that the overall attractive methane–water enhancement of internal pressure runs from 399 to 453 MPa for structure I hydrate and from 443 to 496 MPa for structure II hydrate, and that the stability enhancement increases with equilibrium temperature and pressure. The encaged gaseous methane at these internal pressures has an estimated (27) methane molar volume of 33.32 and 33.05 cm^3 mol^{-1} in the structure I hydrate and 33.20 and 32.81 cm^3 mol^{-1} in the structure II hydrate; the lattice water partial molar volumes are correspondingly reduced to 16.97 and 16.63 cm^3 mol^{-1} in the structure I hydrate and to 17.09 and 16.04 cm^3 mol^{-1} in the structure II hydrate.

If the internal pressure enhancement for structure I hydrate is divided by an average coordination number 23 and that for structure II is divided by 22.667, the individual water–methane contributions are 17.3, 19.7 and 19.5, 21.9 MPa, respectively, from –0.29 to 46.87°C, which may be compared with the 19.4 MPa for methane–methane interactions assuming 12-fold coordination in liquid methane at 100 K.

It would appear that the filling of the "free volume" of each hydrate water molecule at separations between 0.278 and 0.454 nm, by three or four methane molecules, without breaking water–water H-bonds is responsible for the increased cohesive energy density of the methane hydrates relative to compressed water.

We may regard the formation of the methane gas hydrates as the efficient "pumping up" of the strongly self-adhering

© 2002 NRC Canada

water with individual methane molecules, and the data in Table 10 indicate the stabilization of the pumped up methane hydrate water lattices. In the equilibrium methane hydrates each water molecule has four nearest water neighbours, with 3 or 4 next-nearest neighbours which are methane, and then second nearest water molecules. It is the additional 3 or 4 next-nearest methane neighbours, giving the 7 or 8 coordination of each water molecule, that provide the extra attractive cohesive energy density of the methane hydrates. Equally the encaged methane guests provide the repulsive volume that efficiently fills the 4 regions between the H-bonds to nearest water neighbours.

We find that the equilibrium structure I hydrate lattice spacing a and hydrate water molar volume V_1^{h1} show the very small expansions of 0.054 and 0.162%, respectively, with temperature increase from –0.29 to 26.7°C; this clearly shows the balance between lattice thermal expansion and lattice compressibility.

We note that the highest external pressure of 397 MPa at 46.87°C is sufficient to reduce the structure II lattice spacing a to 1.701 nm and the hydrate water molar volume V_1^{h2} to 21.80 cm^3 mol^{-1}; this appears to be reasonable since the external pressure is now 80% of the internal pressure increment 496 MPa due to the encaged methane guests.

The last row of Table 10 shows the structure II hydrate internal pressures estimated using the lattice spacing a 1.707 nm, evaluated from the lattice spacing at 250 MPa and 25°C by Chou et al. (46). The hydrate water molar volume V_1^{h2} 22.04 cm^3 mol^{-1} at 46.87°C and 397 MPa remains smaller than at 26.7°C and 55.5 MPa. The hydrate lattice internal pressures $p_i^{MT\,h}$ of 2032 MPa and $p_i^{CH_4\,h}$ of 2523 MPa, are slightly reduced and the internal pressure increment due to the encaged methane guests becomes 491 MPa; these estimates are substantially the same as those given in row four of Table 10. Our estimate of the cubic structure II methane hydrate lattice spacing at about 250 MPa and 25°C is a = 1.7110 nm; 0.28% smaller than the value measured by Chou et al. (46).

Addendum after the referee's comments

We thank the referee for valuable suggestions and for the most recent references on the methane hydrates at high pressure.

After this work had been submitted for publication I was made aware of the elegant high-pressure studies by Chou et al. (46, 47), who had grown single crystals of structure II methane hydrate, in which the structure was confirmed by synchrotron X-ray diffraction analysis (46), and had indicated the structure II methane hydrate stability range in a phase diagram indicating invariant points.

This work is complementary to that of Chou et al. (46, 47) and provides independent and confirmatory estimates for (*i*) the equilibrium stability range and formulae of structure I methane hydrate with water and methane gas between quadruple point $Q(h_1s_1l_1g)$ at –0.29°C and 2.53 MPa and quadruple point $Q(h_1h_2l_1g)$ at 26.7°C and 55.5 MPa, and for (*ii*) the equilibrium stability range and formulae of structure II methane hydrate with water and methane gas between $Q(h_1h_2l_1g)$ at 26.7°C and 55.5 MPa and 46.87°C and 397 MPa. The reliability of this study depends on the accuracy of the primary (hl_1g) P–T measurements (1–4, 6, 7, 10, 12–14, 17, 22, 23): the accuracy on pressure is better than 1.5% and on temperature it is better than 0.10°C. Furthermore, (hl_1g) measurements, with phase mixing for long time periods in a thermostat, more closely attain equilibrium than unstirred condensed-phase measurements.

In Fig. 4. of reference 47 invariant point A is listed at 1.2 MPa and 0°C, whereas we find $Q(h_1s_1l_1g)$ at 2.53 MPa and –0.29°C. Invariant point C is listed at 137 MPa and 35.3°C, whereas we find $Q(h_1h_2l_1g)$ at 55.5 MPa and 26.7°C. The pure water isochore BC is listed (47) at 1046.8 kg m^{-3} cutting the ice Ih curve at –8.7°C and 99 MPa; we find the water isochore through $Q(h_1h_2l_1g)$ at density 1020.1 kg m^{-3} (28), which extrapolates to the ice Ih curve at about –3.5°C and 40 MPa. There is no evidence given to prove that the pure water isochore BC represents the equilibrium three-phase ($h_1h_2l_1$) curve, nor that the ice point B at –8.7°C is the equilibrium quadruple point $Q(h_1h_2s_1l_1)$.

The studies of methane hydrate by Dyadin et al. (48, 49) and by Nakano et al. (50), between 59 MPa at 27.6°C and 414 MPa at 46.65°C agree with the $P(h_2l_1g)$ measurements of Marshall et al. (10) for the equilibrium of structure II methane hydrate with water and methane gas.

Sampling variance as a function of single-increment size for estimation of bitumen in an oil-sand core

Zhi Gao and Byron Kratochvil

Abstract: The relationship between sampling variance and single-increment size for bitumen content in oil sand was investigated for a previously collected data set of 1468 contiguous 1-cm^2 IR measurements on a 15-m core. A variogram study showed that bitumen in the 15-m core is highly regionalized with a range of influence of 20 cm. For increment sizes lower than this range, the sampling variance as a function of increment size fits a logarithmic function but does not fit Visman's reciprocal function, which was also confirmed for a second oil-sand core with a range of influence of 100 cm. Visman's equation does, however, give good results for larger increment sizes. Computer randomization of the data reveals that Visman's equation is valid for either local or overall random distributions. Characterization by fractal dimension showed that Visman's equation is applicable to populations with higher fractal dimensions (equal or close to 2), whereas a logarithmic relationship is more applicable to populations with lower fractal dimensions.

Key words: Sampling, geostatistics, variogram, Visman's equation, oil sand.

Résumé : Utilisant un ensemble de données recueillies antérieurement pour 1468 mesures IR contiguës de 1 cm^3, sur une carotte de 15 m, on a étudié la relation entre la variance d'échantillonnage et des augmentations unitaires de leur taille pour le contenu en bitume de sables bitumineux. Une étude sous la forme de variogramme montre que le bitume, dans une carotte de 15 m, est fortement régionalisé avec un intervalle d'influence de 20 cm. Pour des augmentations de tailles inférieures à cette plage, la variance de l'échantillonnage en fonction des augmentations de la taille s'accommode bien dans une fonction logarithmique, mais elle ne peut pas être représentée par la fonction réciproque de Visman, ce qui a été confirmé par une deuxième carotte de sable bitumineux, avec un intervalle d'influence de 100 cm. Toutefois, l'équation de Visman donne de bons résultats pour augmentations de la taille plus importantes. Une distribution au hasard des données à l'aide d'un ordinateur révèle que l'équation de Visman est valide pour des distributions aléatoires locales ou globales. Une caractérisation par dimension fractale montre que l'équation de Visman peut être appliquée à des populations de dimensions fractales plus élevées (égales ou s'approchant de 2) alors qu'une relation logarithmique peut s'appliquer mieux à des populations de dimensions fractales plus faibles.

Mots clés : échantillonnage; géostatistiques; variogramme; équation de Visman; sable bitumineux.

Introduction

The overall analytical uncertainty of an analyte in a population is a combination of sampling and measurement errors. For bitumen in an oil-sand core, measurement is usually by Soxhlet extraction (1) or near-infrared diffuse-reflectance spectroscopy (2, 3). Both methods have reasonable analytical precision. As a result, the major part of the analytical uncertainty in bitumen analyses usually arises from sampling. Many factors affect sampling precision, but the primary factor is that bitumen is highly segregated in an oil-sand core. Additional factors include difficulties with sample collection, subsampling operations, and sample storage and handling in general. Due to the heterogeneous nature of oil sand, small samples do not give adequate sampling precision (3). On the other hand, large samples are more costly to obtain, process, and store. A better understanding of the relationship between sampling variance for bitumen and sample size would, therefore, be useful.

Among sampling equations (4), those of Ingamells (5) and Gy (6) are often applied to well-mixed particulate materials. Visman's equation for segregated populations is primarily empirical (7, 8). Although successfully used in some cases, its breadth of applicability has been questioned (9), and it should not be arbitrarily used.

This paper considers the relationship between single-sample increment size and sampling variance, using as a database a set of earlier measurements of bitumen content in an oil-sand core at 1-cm resolution by near-infrared diffuse-reflectance spectroscopy (3).

Experimental

The oil-sand analytical data used in this study was obtained by K. Donkor and reported earlier (3). A brief summary of the experimental details provided in that paper is repeated here. The original core, approximately 20 m long and 7 cm in diameter, was provided by Syncrude Canada from a region of the Athabasca oil-sand deposit near Fort McMurray, Alberta, Canada. A 15-m section, selected as typical of grade variations over a vertical transect within the deposit, was frozen and sawed in half longitudinally. This provided a uniformly textured flat surface for analysis by near-infrared diffuse-reflectance spectrometry. Spectra were recorded over the range of 1200–2400 nm at a rate of 5 scans per second with a resolution of 1 nm. The 15-m core was scanned at 1-cm intervals along its length in a 1-cm-wide strip, about 1.5 cm from one edge of the core casing. Fifty scans were taken and averaged for each reading of the 1-cm^2 sampling area for both samples and standards. All spectra were digitized and stored on a computer hard disk for processing. Standards were prepared by removal of 1- to 2-g samples from 96 1-cm^2 sections of the core and analyzed for bitumen by toluene extraction, evaporation of the solvent, and weighing. Calibration models were optimized by both principal-component regression and partial least-squares statistical data processing. Both models gave satisfactory results (residual values less than 1%).

All sample-increment sizes are expressed here in one dimension. For example, a L-cm increment represents a rectangle L cm in length and 1 cm in width. Thus the bitumen content in a L-cm increment sample is calculated as the average of L contiguous 1-cm^2 measurement units. Variation in the density of the oil sand was neglected for the purposes of this study. The relative standard deviation of the infrared analytical measurements was of the order of 0.2%, which is sufficiently small to be neglected in calculating sampling standard deviations from the data (2).

Results and discussion

Distribution of bitumen content as a function of increment size

The profile of bitumen content in the oil-sand core, at 1-cm resolution (1-cm increments), is shown in Fig. 1*a*. The upper 5 m of the core is generally more segregated than the middle 5 m, and the middle part is more segregated than the lower 5 m. Increasing the increment size changes the apparent bitumen distribution (Fig. 1*b–d*): the larger the increment size, the more homogeneous the distribution appears to be. Sampling precision therefore increases with increase in increment size. Quantification of this relationship for single increments collected from this population is investigated in the following sections.

Visman's equation

The sampling equation proposed by Visman relates sampling variance (s^2) to sample size through a random variability term (A/w) and a segregation term (B)

Table 1. Fit of Visman's equation to the relationship between sampling variance of bitumen content and sample size over 15-m length of oil-sand core and three 5-m subsections (100 points included in each fitting with increment sizes of 1, 2, …, 100 cm).

Oil-sand core	Sampling constants		Correlation coefficient, R
	A (1×10^{-4})	B (1×10^{-4})	
0–15m	4.00±0.31	1.07±0.04	0.792
0–5m	9.27±0.78	1.39±0.10	0.769
5–10m	2.21±0.12	0.21±0.02	0.878
10–15m	0.29±0.02	0.21±0.01	0.827

$$[1] \qquad s^2 = \frac{A}{Nw} + \frac{B}{N}$$

where w is the size of each increment, A and B are constants, and N is the number of increments collected from a population. Equation [1] shows that for a given increment size the sampling variance is proportional to the reciprocal of the number of increments. For $N = 1$, s^2 is the single-increment sampling variance. Figure 2 shows the sampling variance of bitumen content as a function of increment size for the entire core and for three 5-m sections, using eq. [1] to fit the relationship. Values calculated for A and B are shown in Table 1. From the correlation coefficients, it can be seen that Visman's equation does not work well under these conditions.

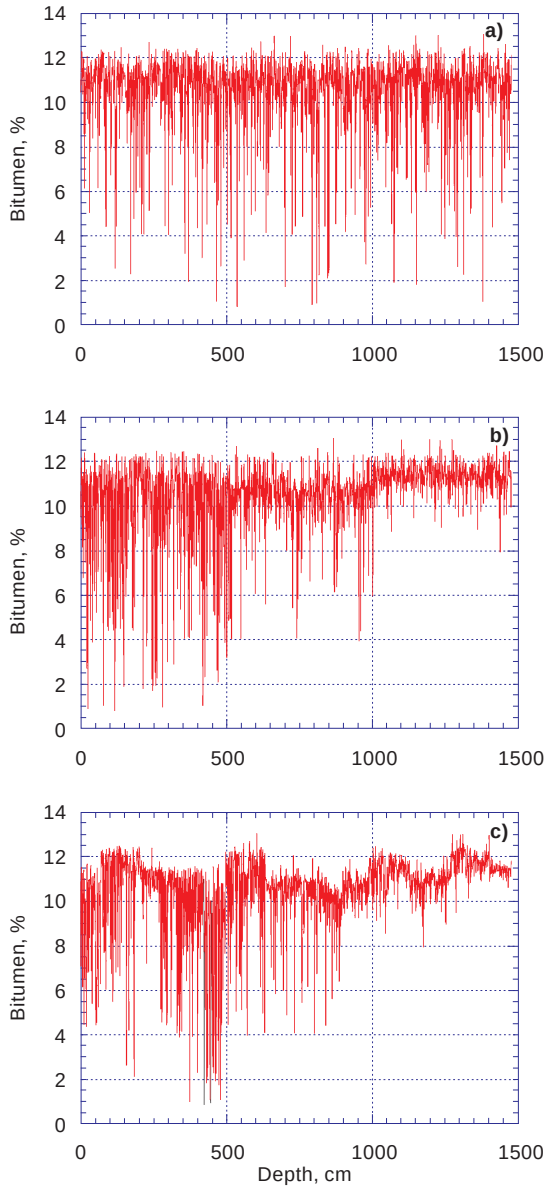
In Visman's equation, the constants A and B are usually estimated by a two-point method:

$$[2] \qquad A = \frac{w_{Lg} w_{Sm} (S^2_{Sm} - S^2_{Lg})}{w_{Lg} - w_{Sm}}$$

$$[3] \qquad B = S^2_{Lg} - \frac{A}{w_{Lg}}$$

where w_{Lg} and w_{Sm} are large and small increment sizes, respectively, and S^2_{Lg} and S^2_{Sm} are the corresponding sampling variances. This method can be misleading, however, because it will always give estimates for A and B even though the relationship between sampling variance and sample size may not follow Visman's equation. For a population such as the one considered here, an ideal equation should apply to all increment sizes with good correlation. As shown in Table 2, then, different values of w_{Lg} and w_{Sm} give different values for A and B. We conclude that Visman's equation is not generally applicable to this oil-sand core. Of interest, however, is to determine those distributions where Visman's equation is applicable and, if possible, to find a sampling expression that better fits populations such as the one under study.

Fig. 3. Bitumen distributions for regionally randomized core data. (*a*) Population I; (*b*) Population II; (*c*) Population III.



Different distributions of bitumen yield different populations, which affect sampling statistics. To assess this, the bitumen values for the 15-m core were redistributed into three different populations by computer (using the random-generation function in Microsoft Excel) and the applicability of Visman's equation to each was investigated. In Population I (Fig. 3*a*) the bitumen content was randomized over the whole core. In Population II (Fig. 3*b*) the initial oil-sand

40–100	15.32 ± 0.34	0.59 ± 0.01	0.9864

*All possible points were included in the fitting, e.g., sample sizes of 1–10 cm mean 1, 2, … 10 cm.

core was divided into three sections (0–5 m, 5–10 m, and 10–14.68 m) and the bitumen content within each section was randomly distributed. In Population III (Fig. 3*c*) the initial oil-sand core was divided into 22 sections of 70 cm each (68 cm for the last section) and the bitumen content within each section was randomly distributed.

In Population I, where the bitumen is randomly distributed, the estimated Visman sampling constants for seven repetitions lie in the range of $(3.57–3.63) \times 10^{-4}$ with an average of 3.59×10^{-4} for *A*, and $(–0.21–0.22) \times 10^{-4}$ with an average of $–0.001 \times 10^{-4}$ for *B*. The correlation coefficients of the sampling variance as a function of increment size lie in the range of 0.9993–0.9998, with an average of 0.9996. The increment sizes used for the fitting are $L = 1, 2, \ldots, 100$ cm. These results show that in this case the sampling variance ($N = 1$) as a function of increment size fits Visman's equation well, with the segregation constant *B* approximately equal to zero, as expected for a random distribution. Changing the increment size over the range of 1–100 cm does not significantly affect the fitted results.

For Population II, the relationship between sampling variance and increment size fits Visman's equation well for small increment sizes, but as shown in Table 3, not so well for larger ones.

For Population III, sampling variance as a function of increment size again fits Visman's equation for small increment sizes (Table 4) but, similar to Population II, not for larger ones. The correlation coefficient drops with increasing large increment size (w_{Lg}) for a given small increment size (w_{Sm}), and vice versa. The range of increment sizes used to calculate the constants *A* and B can, therefore, significantly affect their values.

An alternate approach to estimation of Visman's sampling constants *A* and *B*

In this section we derive equations to estimate the constants *A* and *B* based on an assumed population distribution.

© 2002 NRC Canada

Consider a population divided into r sections, with the analyte randomly distributed within each section. If the increment size is very small relative to the size of the section from which it is taken, the theoretical random-sampling variance for a single increment can be estimated by

$$[4]\quad \sigma^2 = \frac{1}{N}\sum_{i=1}^{r}\sum_{j=1}^{N_i}(c_{ij}-\bar{c})^2 = \frac{1}{N}\sum_{i=1}^{r}\sum_{j=1}^{N_i}c_{ij}^2 - (\bar{c})^2$$

$$= \frac{1}{N}\sum_{i=1}^{r}N_i\left(\frac{1}{N}\sum_{j=1}^{N_i}c_{ij}^2 - (\bar{c}_i)^2\right) + \frac{1}{N}\sum_{i=1}^{r}N_i(\bar{c}_i)^2 - (\bar{c})^2$$

$$= \frac{1}{N}\sum_{i=1}^{r}N_i\sigma_i^2 + \frac{1}{N}\sum_{i=1}^{r}N_i(\bar{c}_i)^2 - (\bar{c})^2$$

where i is the serial number of sections, j is the serial number of increments from each section, N is the total number of increments, N_i is the number of increments taken from section i, c_{ij} is the analyte concentration in increment ij, $\bar{c}_i$ is the mean concentration of analyte in section i, $\bar{c}$ is the mean concentration of analyte in the overall population, and σ_i^2 is the theoretical single-increment variance for section i.

Since $N_i/N = f_i$, the fraction of section i in the population, when N and N_i are very large, eq. [4] gives

$$[5]\quad \sigma^2 = \sum_{i=1}^{r}f_i\sigma_i^2 + \sum_{i=1}^{r}f_i(\bar{c}_i-\bar{c})^2$$

Since Ingamells' sampling constant $K_{si} = 10^4\sigma_i^2 w/(\bar{c}_i)^2$ (5), eq. [5] becomes

$$[6]\quad \sigma^2 = \frac{1}{w}\sum_{i=1}^{r}10^{-4}K_{si}f_i(\bar{c}_i)^2 + \sum_{i=1}^{r}f_i(\bar{c}_i-\bar{c})^2$$

Letting

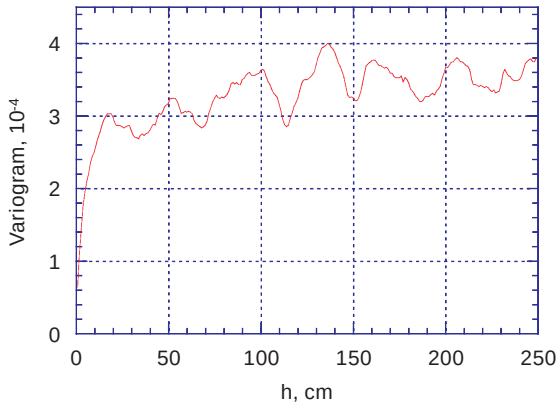
$$[7]\quad A = \sum_{i=1}^{r}10^{-4}K_{si}f_i(\bar{c}_i)^2$$

and

$$[8]\quad B = \sum_{i=1}^{r}f_i(\bar{c}_i-\bar{c})^2$$

eq. [6] becomes Visman's sampling equation (eq. [1]) when $N = 1$. Since all the quantities on the right-hand sides of eqs. [7] and [8] are constants for a given population, A and B are constants. A is characterized by the randomness of analyte within sections, and B by the difference between sections. From eqs. [7] and [8], the sampling constants for Population I were calculated to be $A = 3.59 \times 10^{-4}$ and $B = 0$; for Population II, $A = 3.13 \times 10^{-4}$ and $B = 0.47 \times 10^{-4}$; and for Population III, $A = 2.64 \times 10^{-4}$ and $B = 0.99 \times 10^{-4}$, all of which are in good agreement with experimental results for all increment sizes for Population I and for relatively small increment sizes for Populations II and III (Tables 3 and 4). We therefore conclude that Visman's equation is valid for segregated populations with randomly distributed values within subsections (or locally random distribution in general) and for increments of relatively small size.

Fig. 4. Semivariogram of bitumen content in oil-sand core (0–15 m).



Evaluation of variogram approach

We have shown that Visman's equation is not applicable to sampling of the oil-sand core studied here because the bitumen is not randomly distributed at the local level. An alternative approach to characterize the relationship between sampling variance and increment size is therefore needed.

Geostatisticians commonly describe spatial correlation between sampling points by use of a semivariogram (10) or, for simplicity, a variogram ($\gamma(h)$) (11, 12) as follows:

$$[9]\quad \gamma(h) = \frac{1}{2n}\sum[c(x+h)-c(x)]^2$$

Here, $c(x)$ and $c(x + \mathrm{h})$ denote analyte content for sampling points x and x + h, and n is the number of pairs of sampling points distance h apart. Figure 4 shows the semivariance as a function of sampling interval h for the 15-m core studied. It shows that for $h \leq 20$ cm, $\gamma(h)$ monotonically increases with increase of sampling interval h, which indicates that points close to each other have more similarity than those far apart. For $h = 20$ cm, $\gamma(h)$ tends toward a plateau, with irregular variations over the sampling interval. This indicates that the bitumen in the 15-m core studied is highly regionalized, with a range of influence of 20 cm. At a scale larger than 20 cm, the bitumen distribution exhibits randomness; the sampling properties are therefore expected to be different for different sampling scales.

Evaluation of a logarithmic relationship between sampling variance and increment size

De Wijs (10) proposed a geostatistical dispersion model that relates log variance with log of sample size. Converting the bitumen contents in the oil-sand core into logarithmic values, we found that log variance as a function of increment size fitted de Wijs's equation very well. Although log variance is a useful parameter for geological study, for the purpose of evaluating the bitumen content in oil-sand core variance is still the commonly used parameter to reflect the sampling uncertainty, which (other than the logarithmic values) is calculated directly from the initial analyte contents. We therefore investigated the simpler expression

$$[10]\quad s^2 = K_1 - K_2 \log L$$

© 2002 NRC Canada

Table 5. Fit of logarithmic equation to the relationship between sampling variance of bitumen content and increment size over 15-m length of oil-sand core, three 5-m subsections and three randomized populations (50 points included with sample sizes of 1, 2, … 50 cm).

	Sampling constants		
Oil-sand core	K_1 (1×10^{-4})	K_2 (1×10^{-4})	Correlation coefficient, R
0–15m	3.58 ± 0.04	1.46 ± 0.02	0.988
0–5m	7.33 ± 0.11	3.45 ± 0.07	0.983
5–10m	1.45 ± 0.03	0.71 ± 0.02	0.969
10–15m	0.39 ± 0.01	0.10 ± 0.01	0.987
Population I	1.51 ± 0.11	0.83 ± 0.07	0.786
Population II	1.78 ± 0.09	0.73 ± 0.06	0.790
Population III	2.22 ± 0.07	0.78 ± 0.04	0.886

to relate sampling variance with increment size for the oil-sand core, where s^2 refers to variance calculated directly from initial bitumen content. Table 5 lists the fitted results of sampling constants using eq. [10], along with the correlation coefficients for the overall core population for the three 5-m subsections and for the idealized populations described earlier. The results confirm that eq. [10] gives a reasonable fit to the real oil-sand core, but not to the randomized populations I, II, or III. Considering different sampling scales, we found that for $L \leq 20$ cm (L = 1, 2, … 20 cm), eq. 10 becomes $s^2 = 3.78 \times 10^{-4} - 1.62 \times 10^{-4} \log L$ with $r = 0.993$, and for $L > 20$ cm (L = 21, … 100 cm), $s^2 = 2.80 \times 10^{-4} - 1.02 \times 10^{-4} \log L$ with $r = 0.991$. The equation for $L \leq 20$ cm does not differ much from the fitted result for increment sizes of 1–100 cm for the 15-m core (Table 5) because the points for small sample sizes contribute the most to regression results calculated by least squares. For larger increment sizes ($L \geq 20$ cm), the relationship fits Visman's equation better: $s^2 = 0.629 \times 10^{-4} + [(20.02 \times 10^{-4})/L]$ (r = 0.997, L = 20, 21, … 100 cm).

We conclude, therefore, that eq. [10] is more applicable for small increment sizes (L = 20 cm), which correspond to highly regionalized distribution, whereas Visman's equation is more applicable to large increment sizes ($L > 20$ cm), which correspond to relatively random distribution.

An additional test of eq. [10] was made by applying it to data obtained on an independent 4-m section of core, which was also analyzed with near-infrared diffuse-reflectance spectrometry (2). Bitumen content at 1-cm resolution for this core was in the range of 0–20%, for an average of 10.56%. A variogram for this core shows an increase with increase in sampling interval (h) up to 100 cm. For increment size $L \leq 100$ cm, the relationship between sampling variance and increment size fits eq. [10] well: $s^2 = 21.92 \times 10^{-4} - 7.66 \times 10^{-4} \log L$ (r = 0.986, L = 1, 2, …, 100 cm). It does not, however, fit Visman's equation: $s^2 = (18.47 \times 10^{-4})/L + 7.97 \times 10^{-4}$) ($r$ = 0.694, L = 1, 2, …, 100 cm). These results further verify that eq. [10] is applicable to the core for increment sizes smaller than the range of influence.

Fractal analysis of bitumen distribution in the oil-sand core

The preceding discussions reveal that whether Visman's equation or eq. [10] is applicable to a population depends on the distribution of the population. It is necessary, therefore, to characterize the distribution of a population prior to selecting the equation for sampling. Many geological structure or element distributions in geological or environmental areas exhibit self-similarity which can be characterized by fractal dimension (13–15). In this theory, a complicated environmental or geological data series can be depicted by a simple number called fractal dimension (D), which is related to the variogram expression by the following equation (14, 15):

$$[11] \quad \frac{d \log \gamma(h)}{d \log h} = 4 - 2D \qquad (h \rightarrow 0)$$

For a spatial-data series, since D is calculated by eq. [11] for $h \rightarrow 0$, fractal dimension is a parameter that reflects the local heterogeneity, or consistency, of a population (16). Data series that have a small fractal dimension imply that samples close to each other are more likely to be similar in composition, and heterogeneity can be found only over a longer range of scale. On the other hand, larger fractal dimension implies that samples close to each other are likely to be different in composition, and heterogeneity is dominant over a shorter range of scale. A fractal dimension of 2 as calculated by eq. [11] refers to a population with totally random distribution.

The fractal dimension for bitumen content distributed in the oil-sand core investigated here is estimated as 1.60. For the three 5-m sections of the core, the upper section (0–5 m) has a fractal dimension of 1.58, the middle section 1.61, and the lower section 1.82. These results show that the more random the population, the higher the fractal dimension would be. This conclusion is consistent with eq. [11]. The estimated fractal dimensions for ideal Populations I, II, and III are 2, 1.99, and 1.98, respectively.

By correlating the fractal dimension with the sampling equation, we therefore conclude that Visman's equation is more applicable to populations with higher fractal dimensions (equal or close to 2), whereas eq. [10] is more applicable to populations with lower fractal dimensions.

Conclusion

A study of the relationship between single-increment sampling variance and sample size for bitumen content in a 15-m length of an oil-sand core showed that a logarithmic equation is more useful for increment sizes lower than the range of influence in which the bitumen content is highly regionalized, and Visman's equation is more useful for larger increment sizes in which the bitumen content is relatively distributed. A random redistribution by computer of the initial bitumen content along the core showed that

© 2002 NRC Canada

Visman's equation is applicable to populations with local or overall random distributions. Characterization of the populations by the theory of fractal dimension reveals that Visman's equation is valid for populations with higher fractal dimensions (equal or close to 2), whereas eq. [10] applies for populations with lower fractal dimensions.

An ab initio study of conformations and sigmatropic shifts in triazene and its mono-, di-, and trimethyl derivatives

Cory C. Pye, Keith Vaughan, and Julie F. Glister

Abstract: A computational study of triazene, methyltriazene, dimethyltriazene, and trimethyltriazene is presented. A number of different conformers are analyzed and rationalized using hyperconjugation and steric interaction arguments. The transition states for rotation, inversion, and proton and methyl shifts (including water-mediated) are found and the barriers determined.

Key words: triazene, ab initio, methyltriazene, 1,3-proton shift.

Résumé : On présente une étude théorique du triazène, du méthyltriazène, du diméthyltriazène et du triméthyltriazène. On a analysé un certain nombre de conformères différents qui ont été rationalisés sur la base de l'hyperconjugaison et d'arguments stériques. On a localisé les états de transition pour la rotation, l'inversion ainsi que pour les déplacements d'hydrogènes et de méthyles (y compris ceux qui s'effectuent sous l'influence de l'eau) et on en a déterminé les barrières.

Mots clés : triazène, calculs ab initio, méthyltriazène, déplacement-1,3 de proton.

[Traduit par la Rédaction]

Introduction

Triazene (NH_2-N=NH) is the fundamental reactive site in a number of molecules possessing antitumour properties, such as Dacarbazine, Temozolomide, and Mitozolomide (1–3). In addition, nitrogen–nitrogen bonds, found in high-energy compounds, are an important area of fuel and explosives research and new reports in this area still appear (4–10). Triazene itself, however, remains an elusive molecule, with reports sporadically appearing in the literature. Mass spectrometric evidence for triazene first appeared from a fast-flow apparatus in which hydrazine is subjected to an electrodeless discharge. The ionization energy was reported to be 9.6 ± 0.1 eV (11, 12). Triazene is also postulated to be an intermediate in the decomposition of hydrazine in aqueous solution by pulse radiolysis. After initial production of the hydroxyl radical, the following kinetic pathway was proposed, with protonated forms appearing at lower pH.

[1] $OH^{\bullet} + N_2H_4 \rightarrow H_2O + N_2H_3^{\bullet}$

[2] $2N_2H_3^{\bullet} \rightarrow N_4H_6$

[3] $N_4H_6 \rightarrow N_3H_3 + NH_3$

Triazene then decomposes with first-order kinetics. The pK_a of triazene was determined to be 7.0 ± 0.2 (13). In another study, the decomposition of triazene was shown to be dependent on the total phosphate buffer concentration, suggesting a second pathway for decomposition involving phosphate (14). The first and second pK_a of protonated triazene were determined to be 4.95 and 11.37, respectively. The isomer cyclotriazane (triaziridine) was found as a silver-ion complex after sorption of ammonia onto a completely silver-ion exchanged zeolite A and an X-ray structure was reported. The mass spectrum indicates that N_3H_3 can be degassed from the complex (15). The gas phase structure could be *cis*- or *trans*-triaziridine, the acyclic isomer azimine, which could be formed from triaziridine by ring opening, or *cis*- or *trans*-triazene, which could be formed from azimine via a 1,2-hydrogen shift.

Triazene and its isomers have also been studied by theoretical means. In a survey of all three-membered rings involving C, N, and O, the *cis* (C_{3v}) and *trans* (C_s) forms of triaziridine were examined using HF/STO-3G geometries and single-point Hartree–Fock calculations using the 4-31G and 6-31G* basis sets (16). Dipole moments and orbital energies were provided. In a HF/STO-3G study of substituted diazenes, the *trans* form of triazene was shown to be 20 kJ mol^{-1} more stable than the *cis* form (17). An approximate barrier of 312 kJ mol^{-1} was found between the two via an inversion mechanism at the central nitrogen, which was lower in energy than a rotation mechanism. Seven isomers of N_3H_3 were studied at the HF/3-21G, HF/6-31G, and HF/6-31G**//HF/3-21G levels (18). The two forms of triaziridine were higher in energy than the three forms of azimine, which were in turn higher in energy than the two forms of triazene. It is thus clear that triazene is the thermodynamically stable form. In addition, the transition states for conversion between the triaziridine forms, between the triazene forms, the 1,2-hydrogen shifts interconverting azimine and triazene, and the 1,3-hydrogen shift in triazene were investigated. This work was extended to the HF/6-31G* geometric

and single-point HF and MP2/6-31G** energy levels (19) by the same authors, who also looked at barriers for double-proton transfer and amine rotation. Others have extended this work to the correlated level (MP2/DZP, CCSD-T/DZP) and supplied vibrational frequencies (20). Planar triazene was studied at the HF/3-21G* level in relation to double-bond conjugation in second- and third-period elements (21). Schmiedekamp et al. (22) investigated the protonation of triazenes at the HF/3-21G, HF/6-31G*//HF/3-21G, and MP3/6-31G*//HF/3-21G levels and later, with a multitude of basis sets at the HF, MP2-MP4, QCISD, and NL-DFT levels (23).

This paper comprises a computational examination of triazene itself, with a focus on conformational energetics and its rationalization, and the 1,3-proton shift. These results help us to interpret the following study of all methylated forms of triazene, which in principle can also undergo a methyl shift. It is intended that these studies will lay groundwork for future studies of triazene drugs used in chemotherapy, which are believed to act as methylating agents. A computational study of triazene drugs and smaller model systems is in progress and will be published separately.

Method

Calculations were performed using Gaussian 98 (24), using the 6-31G* (25) and 6-31+G* (26) basis sets. The MP2 calculations use the frozen-core approximation. The geometries were optimized using a stepping-stone approach, in which the geometries at the levels HF/STO-3G, HF/3-21G, HF/6-31G*, HF/6-31+G*, MP2/6-31G*, and MP2/6-31+G* were sequentially optimized.[2] Default optimization specifications were normally used. After each level, where possible, a frequency calculation was performed at the same level and the resulting Hessian was used in the following optimization. *Z*-matrix coordinates constrained to the appropriate symmetry were used as required to speed up the optimizations. If symmetry constraints led to a transition state or hilltop, instead of a minimum, this would show up as the presence of one or more imaginary frequencies not belonging to the totally symmetric irreducible representation. The Hessian was evaluated at the first geometry (opt = CalcFC) for the first level in a series to aid geometry convergence.

Results and discussion

Triazene

Conformational possibilities

Triazene itself can exist in either a *cis* or *trans* geometry about the N=N double bond (see Fig. 1).[3] For each of these isomers, there can exist three possible structures with C_s symmetry. The structures, whose hydrogens on the tricoordinate nitrogen are in the σ-plane, are labelled #1 and #4 for the *trans* and *cis* isomers, respectively. There are four structures whose hydrogens are bisected by the symmetry plane. Two of these are in an anticlinal arrangement with respect to the N=N double bond (*trans* (#2) and *cis* (#5)), and two are in a synclinal arrangement (*trans* (#3) and *cis* (#6)). None of these structures at any level was a minimum-energy structure. All possessed an imaginary frequency of irreducible representation A''. Of these structures, #1 and #4 were the lowest energy *trans* and *cis* structures, respectively. For these, the imaginary frequency corresponded to an NH_2 wagging motion. Desymmetrizing structures #2 and #3 invariably resulted in a *trans* structure with no symmetry (C_1 #1, see Fig. 1), while #5 and #6 led to the analogous *cis* structure (C_1 #2, see Fig. 1). The relative energies of the various *trans* and *cis* isomers relative to the most stable *trans* and *cis* isomers are given in Tables 1 and 2. The amine prefers this arrangement presumably because of the strong stabilizing hyperconjugation interaction between the nonbonding orbital of the sp^3 nitrogen and the π* orbital of the N=N bond.

The *trans* C_1 structure was the lowest in energy at all levels. We hypothesize that the repulsion between the sp^2 nitrogen lone pairs in the *cis* form destabilizes this structure. This is evident by the increase in the energy difference when

[2] A reviewer suggested that we elucidate the effect of adding polarization functions to hydrogen on N–H bond breaking. We re-examined *trans*-triazene and its transition state for proton transfer for the four highest levels investigated. Four single point calculations were done for each molecule, namely, HF/6-31G**//HF/6-31G*, HF/6-31+G**//HF/6-31+G*, MP2/6-31G**//MP2/6-31G*, and MP2/6-31+G**//MP2/6-31+G*. The barrier to proton transfer was about 11 kJ mol^{-1} lower at the HF level, but only 5 kJ mol^{-1} lower at the MP2 level. To examine trends in barriers in the substituted triazenes, the effect of the hydrogen polarization functions would most likely be consistent. Including them in, for example, Dacarbazine, would entail much additional computational expense, especially if geometry optimizations and frequency calculations were to be considered.

[3] The total electronic energies and the ZPE-uncorrected versions of the following tables are found in the supplementary material. diffuse functions are added to the basis set, which give a better description of the lone pairs.

The C_s structures studied are assumed to be transition states for various transformations of the C_1 structures. The planar species #1 and #4 can be seen as transition states for the inversion of the sp^3 nitrogen of the C_1 structures to their mirror images, while the four remaining C_s structures, #2, #3, #5, and #6, can be seen as transition states for the transformations of the C_1 structures to their mirror images via rotation about the N–N single bond. These energies show that the inversion of the amine group is a more favorable reaction pathway than rotation since the barrier is lower. These barriers would be of importance in determining the high-resolution vibrational spectra because of hydrogen permutations and inversion doubling, especially with regard to tunnelling, and also to configurational stability for amines with chiral nitrogens.

Note: relative to C_1 *trans*-triazene.

It is of interest to compare the energies of triazene with that of other isomers, namely, triaziridine and azimine (see Fig. 2). We confirm the literature results (20) that the triazenes are more stable than the azimines, which, in turn, are more stable than the triaziridines (see Table 3).

Proton transfer via 1,3-hydrogen shift

Triazenes with an available proton on a nitrogen atom are able to undergo a proton transfer. Two possible structures of the transition state were studied. The first structure investigated possessed C_{2v} symmetry (see Fig. 1). This structure possessed two imaginary frequencies, indicating that it is not a true transition state. The first imaginary frequency was of irreducible representation B_2 and corresponded to the desired process, the proton transfer. The second imaginary frequency was of irreducible representation A_2 and corresponded to an out-of-plane amino hydrogen motion. To obtain the true transition state for the proton transfer, desymmetrization to a C_2 point group gave the structure shown in Fig. 1. This structure was coincident with the HF/3-21G and HF/6-31+G* representation and very close in energy to the HF/6-31G*

representation of the C_{2v} structure. This structure possessed only one imaginary frequency of irreducible representation *B*, corresponding to the proton transfer. The activation barriers for this process for the C_{2v} and C_2 structures are shown in Table 4. This barrier is high, indicating that this process is not favored at room temperature in the gas phase.

In aqueous solution, water may facilitate the proton transfer by catalyzing the reaction. Triazene itself is stabilized by hydration to the effect of about 40 kJ mol^{-1}. Two different transition structures were tried with C_s and C_{2v} symmetry. At the lower levels, the C_{2v} structure was higher in energy than the C_s structure, and possessed two imaginary frequencies, the smaller of the two corresponding to an out-of-plane motion of the hydrogen to give the C_s structure. The C_{2v} structure was not investigated further.

The activation barriers decrease by a factor of two (see Table 5). To understand the reason for this, we consider the structures of hydrated triazene and the associated transition

state for a water-assisted proton transfer in the *trans*-C_1 structure, as presented in Fig. 1. The N-N-N angle (MP2/6-31+G*) in *trans*-triazene is 112.4° (cf. experimental values in related compounds of 112.8–114.6° (28, 29)), while in the transition state it is 101.6°, resulting in a bending of 11.2°. In the hydrated forms, the corresponding angles are 115.0° and 113.3°, a change of only 1.7°. It is clear that a large part of the activation energy is removed if the triazene unit does not have to deform much to reach the transition state (27, 30).

Methyltriazenes

Conformation and isomerism

A methyl group can be located at either the 1- or the 3-position of either *cis*- or *trans*-triazene to give a total of four isomers. The results on triazene itself suggest that the amino group has a preferred orientation with respect to the double bond, and this does not change upon methyl substitution. Also, the *trans* structures remain more stable than the corresponding *cis* structures by approximately the same amount as in triazene itself. For *cis*- and *trans*-3-methyltriazene, the methyl group can take one of two possible minimum-energy conformations about the N–N bond corresponding to substitution of the two different hydrogens. These possibilities are enumerated in Fig. 3 and their relative energies are given in Table 6.

The orientation of the methyl group in *trans*-1-methyltriazene can be rationalized using hyperconjugation arguments. The methyl group has a moderately strong σ_{CH} donor and a moderately weak acceptor σ^*_{CH}. The N=N fragment has a strong lone-pair donor, a moderate σ_{NN} donor, a strong π^*_{NN} acceptor, and a moderate σ^*_{NN} acceptor. The strong lone pair donates into the σ^*_{CH}. In the *cis* isomer, the same interactions are possible, but the opposite orientation is preferred, suggesting that the hypercongugation preference is overridden by a steric interaction between one of the amine hydrogens and the methyl hydrogen in the less preferred conformation.

If we assume that the same interactions control the orientation about the N–N single bond as in triazene itself, we can then rationalize the stability of the conformers in the *trans* isomer by looking at the donation of the strong lone pair of the central nitrogen into either acceptor σ^*_{NH} or acceptor σ^*_{NC}. The latter should be the better acceptor, therefore the lone pair should be *trans* to the N–C bond, i.e., an *s-cis* conformation. In the *cis* structure, the steric interaction between the *cis* hydrogen and the methyl group cancels the hyperconjugation effect, causing the conformers to be closer in energy.

Proton and methyl transfer

trans-1-Methyltriazene can, in principle, undergo a 1,3-proton shift to give *trans*-3-methyltriazene in the *s-trans* conformation. Similarly, the *s-cis* conformer of 3-methyltriazene can undergo a degenerate 1,3-methyl shift. The transition state for these processes are shown in Fig. 3 and the barriers given in Table 7. There is no systematic difference between barriers to 1,3-proton shifting in triazene and in 1-methyltriazene. The barriers for methyl shifting are approximately 100 kJ mol^{-1} greater than those of the hydrogen shifting. It is clear that extremely high temperatures would be required to observe these processes in methyltriazene.

Again, water can catalyze the 1,3-hydrogen shift, as seen for triazene. The structures for water bound to *trans*-1-methyltriazene (*trans*-3-methyltriazene *s-trans*) and the 1,3-proton shift transition state are given in Fig. 3 and the relative energies are given in Table 8. The hydration energies of 1-methyltriazene are slightly less than those of triazene, by up to 3 kJ mol^{-1}. There are no systematic differences between the proton-shift barriers in triazene and in methyltriazene. The difference in energy between 1-methyltriazene and 3-methyltriazene, *s-trans* conformer, narrows somewhat as water is added, which suggests that the latter is better stabilized by water (by 2–4 kJ mol^{-1}).

Dimethyltriazenes

For dimethyltriazene, the methyl groups may be attached in either a 1,3- or 3,3- fashion. For the 1,3-dimethyl form, the methyl attached to the 3 position can be in one of two conformations, *s-cis* or *s-trans*. Along with the *cis–trans*

isomers about the double bond, this gives a total of four distinct possibilities for 1,3-dimethyltriazene. There are also two additional possibilities, *cis*- and *trans*-3,3-dimethyltriazene, for a total of six minimum-energy geometries, as shown in Fig. 4. The relative energies are presented in Table 9.

If the difference between the *trans s-cis* and *s-trans* conformers are compared between 3-methyltriazene and 1,3-dimethyltriazene, the same general trends are noted to within about 2 kJ mol^{-1}. Methyl substitution does seem to stabilize the *s-cis* conformation more (or destabilizes the *s-trans* conformation more) than the other isomer by 1.2–1.8 kJ mol^{-1}. The difference in energy between the *cis* and *trans* isomers of 1,3-dimethyltriazene parallels the difference for 1-methyltriazene. The main difference is the high energy of *cis*-1,3-dimethyltriazene *s-cis*. This is clearly due to a steric interaction between the methyl groups. This interaction is so strong that the amine moiety rotates significantly out of the position it normally would have in triazene, breaking some of the amine lone-pair antibonding-π hypercongugation.

Proton and methyl transfer

trans-1,3-Dimethyltriazene in the *s-trans* conformation can undergo a degenerate proton shift. The same molecule in the *s-cis* conformation can also undergo a methyl shift to form *trans*-3,3-dimethyltriazene. The structures of these transition states are shown in Fig. 4 and the activation energies for these processes are given in Table 10. The barriers for proton migration are all about 5–13 kJ mol^{-1} lower than methyltriazene. For methyl migration, at the HF level, the barriers are higher by between 5–10 kJ mol^{-1}, but at the

1,3,3-Trimethyltriazene

The only isomers of 1,3,3-trimethyltriazene are the *cis* and *trans* forms, whose structures are given in Fig. 5 and whose relative energies are given in Table 12. One very clear point to be made here is the difference between the *cis* and *trans* structures. This energy difference is much greater than that of triazene, by 20–30 kJ mol^{-1}. The steric interaction between the methyls is very significant in the *cis* form, causing one of the methyl groups to rotate severely out of its optimal hyperconjugation arrangement. The difference in energy between the *cis* and *trans* structures may be predicted to within about 3 kJ mol^{-1} by looking solely at the dimethyl case, i.e., by taking the difference in energy between the

© 2002 NRC Canada

cis-1,3-dimethyltriazene *s-cis* and *trans*-1,3-dimethyltriazene *s-cis* forms. Another way to predict these values is to add the value for *cis–trans* isomerization of triazene to that of rotating the amine moiety of *cis*-triazene to structure C_s #5. This method underestimates the value by 10–15 kJ mol^{-1}.

The barriers to methyl migration are also shown in Table 12. In general, the methyl barriers are lower than in dimethyltriazene. This effect is much more pronounced at the MP2 level.

Conclusions

The most stable form of triazene is the *trans* isomer. In the absence of steric interactions, the amine adopts a non-symmetric arrangement, which places the lone pair parallel to the π system. The barrier to inversion at the amine is much lower than the barrier to rotation about the nitrogen–nitrogen single bond. The barrier to proton transfer is high, but is cut in half when a water molecule mediates the transfer. The most stable form of methyltriazene is *trans*-1-methyltriazene. Methyl substitution does not affect systematically the proton shift barriers. The barrier to the 1,3-methyl shift is much higher than that of the 1,3-hydrogen shift. Similar conclusions regarding the hydrogen and methyl shift were reached for di- and trimethyltriazene.

Experimental and theoretical study of the photochemical and thermal decomposition of maleic and dichloromaleic anhydrides

A. Ionescu, N. Piétri, M. Hillebrand, M. Monnier, and J.P. Aycard

Abstract: The photochemical and thermal behavior of maleic anhydride **1a** and dichloromaleic anhydride **1b**, in cryogenic matrix were investigated by means of FT-IR spectroscopy. The ketenylcarbenes represent the key intermediate in the decomposition processes of the anhydrides, even if they were not observed experimentally. The yields of the different products depend on the thermal or photochemical reaction conditions. The main photochemical products obtained from **1a** were cyclopropenone and acetylene, whereas the major products from **1b** were dichlorocyclopropenone and dichloroacetylene, along with small quantities of dichloropropadienone. The thermal reaction leads to dichloropropadienone, CO, and CO_2. MO calculations performed at the HF/6–31G*//HF/6–31G* level support the experimental mechanisms.

Key words: photolysis, thermolysis, ab initio calculations, cryogenic matrix, ketenylcarbenes.

Résumé : Le comportement photochimique et thermique de l'anhydride maléique **1a** et dichloromaléique **1b**, piégées en matrices cryogéniques est suivi par spectroscopie IRTF. Les intermédiaires clés dans le processus de décomposition des anhydrides sont des céténylcarbènes qui ne sont pas observés expérimentalement. La proportion des différents produits formés dépend des conditions de réaction. Les produits majoritaires obtenus photochimiquement à partir de l'anhydride maléique **1a** sont la cyclopropénone et l'acétylène tandis que l'anhydride dichloromaléique **1b** produit également une faible quantité de dichloropropadiénone. La décomposition thermique de l'anhydride dichloromaléique entraîne la formation de dichloropropadiénone, CO et CO_2. Les états de transitions des différentes réactions ont été modélisés en HF/6–31G*//HF/6–31G*.

Mots clés : photolyse, thermolyse, calculs ab initio, matrices cryogéniques, cétènes-carbenes.

Introduction

For many years our laboratory has been interested in the identification of highly reactive intermediate species produced by photochemical processes in cryogenic matrices (1). Attention was paid to the chemistry and reactivity of some conjugated carbenes, such as the ketenyl (2) and allenyl carbenes (3). Both carbenes can undergo several reactions, including ring closure, hydrogen or chlorine migration, and (or) CO elimination (ketenylcarbenes), which are the precursors of stable compounds. The presence of mono- or disubstituted ketenylcarbenes was postulated in the thermal and photochemical decomposition reactions of some cyclobutenediones and substituted maleic anhydride (4–9).

In our previous study (2) on the matrix photochemical decomposition of 3,4-dichloro-1,2-cyclobutenedione, both dichlorocyclopropenone (1896 cm^{-1}) and dichloropropadienone (2200 and 2260 cm^{-1}) were identified by FT-IR spectroscopy. A kinetic survey of the time evolution of the reaction reveals a ratio of about 13:1 for the respective formation rate constants — cyclopropenone is the major product. Under continuous irradiation, both compounds decomposed to dichloroacetylene (2232, 990, and 846 cm^{-1}). The mechanism of the reaction assumed the presence of the *syn*- and *anti*-dichloroketenylcarbenes, but attempts to identify them have failed.

In the case of difluoromaleic anhydride (R, R′ = F), Brahms and Dailey (4) reported that pyrolysis leads to difluoropropadienone, whereas photochemical decomposition predominantly gives difluorocyclopropenone. In contrast with this behaviour, the pyrolysis of the fluoromaleic anhydride (R = H, R′ = F) yields fluoroacetylene (7). For the two fluoromaleic anhydrides, irradiation initially produces cyclopropenones and, with time, produces the corresponding alkynes. In both cases, a ketenylcarbene was postulated as an intermediate, but only in the matrix photolysis of the fluoromaleic anhydride (7) was evidence found to support the presence of the fluoro–ketenylcarbene. The carbene was characterized by the IR bands at 2168, 1321, and 1102 cm^{-1}, the first value being the most intense.

Fig. 1. Evolution of the FT-IR spectra of maleic anhydride **1a** isolated in an argon matrix at 10K during different irradiation times. (*a*) Spectrum after deposition t = 0 min; (*b*) t = 152 min; (*c*) t = 2800 min.

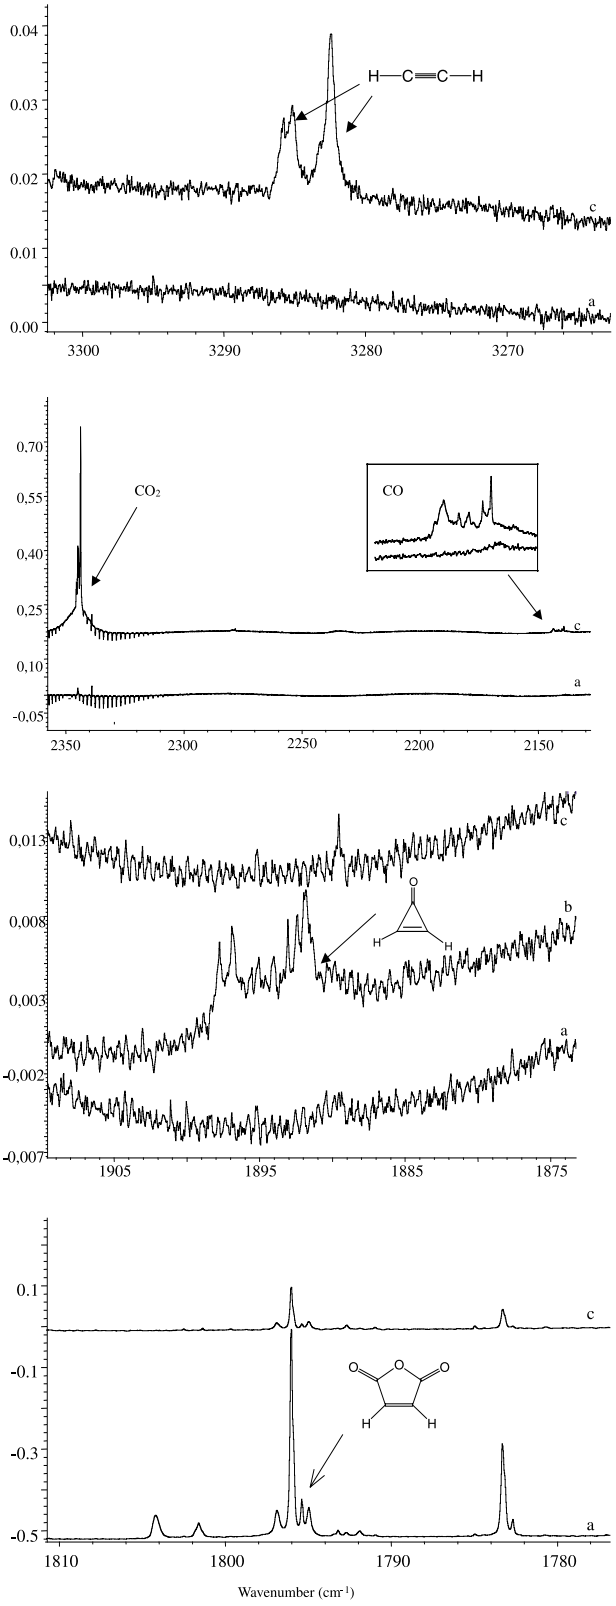

Fig. 2. Evolution of the FT-IR spectra of dichloromaleic anhydride **1b** isolated in an argon matrix at 10 K during different irradiation times. (*a*) Spectrum after deposition, t = 0 min; (*b*) t = 35 min; (*c*) t = 568 min.

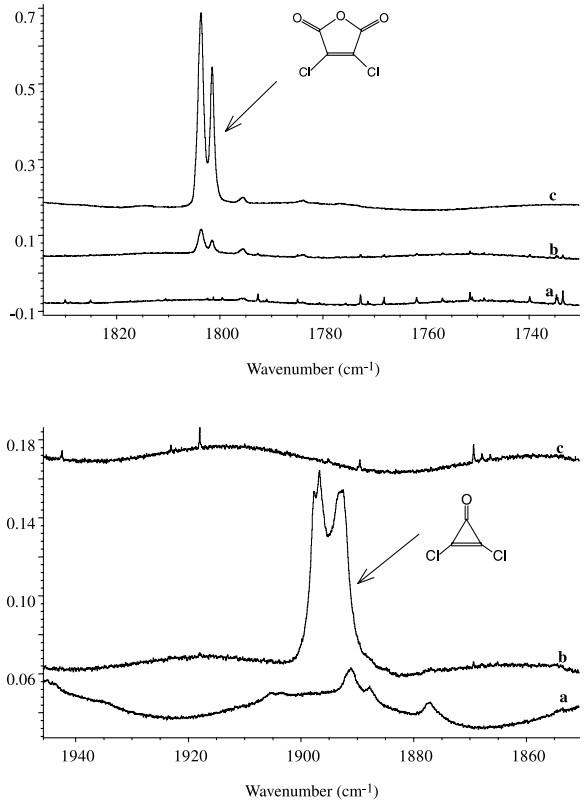


Taking into account the results of Dailey and co-workers (4, 7), it seems that the photolysis and thermolysis of maleic and dichloromaleic anhydrides could be a convenient method to confirm the presence and the role of the ketenylcarbenes in the reaction mechanism.

An extensive theoretical study on the formation of ketenylcarbenes starting from bisketenes, and of their reactivity in subsequent reactions of ring closure and further decarbonylation, was done by Tidwell and co-workers (10). In this study, they outlined the role of the substituents on the relative stability of the ketenes and the cyclopropenones.

In the present study, we report experimental and theoretical results on the photochemical and thermal decomposition of unsubstituted **1a** and dichloro derivative **1b** to provide more information on the different possible reaction pathways. In addition, ab initio MO calculations were performed to explain the chemical pathways.

Experimental

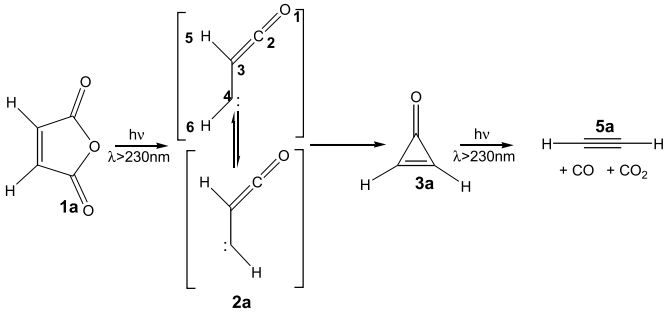
Dichloromaleic and maleic anhydride, supplied by Aldrich, were used after purification by vacuum sublimation.

Matrix-isolation experiments

The matrices were obtained by spraying anhydride–argon mixtures (1:750 and 1:360) onto a gold-copper plate cooled to 20 K in a closed-cycle helium refrigerator. The IR spectra were recorded at 10 K by reflectance with a Nicolet Series II

© 2002 NRC Canada

Scheme 1.



750 FT-IR in the 4000–400 cm^{-1} spectral range with a resolution of 0.12 cm^{-1}. The UV spectra were recorded in hexane and in the 200–600 nm range on an Unicam UV4 spectrometer. The spectrum of maleic anhydride shows an absorption band at 224 nm. In the case of the dichloromaleic anhydride, two absorption bands were observed at λ = 214 and 269 nm.

Irradiation techniques

Irradiation was carried out using an Osram 200 W high-pressure mercury lamp equipped with a quartz envelope. The broad band was filtered at λ > 230 nm. The light intensity was the same in all experiments and the irradiation area was wider than the surface used to record the spectrum.

MO calculations

Ab initio calculations at the HF/6–31G*//HF/6–31G* level were performed using the program Gamess (11). The critical points on the energy surface, minimum and saddle points, were characterized by the Hess matrix.

Ab initio calculations (on the lowest excited electronic states) using single-excitation CI (CI-single) at the 6–31G* level were also performed.

Results and discussion

Photolysis of maleic anhydride

The behavior of maleic anhydride (**1a**) with UV irradiation (λ > 230 nm) is shown in the IR spectra presented in Fig. 1. Broad-band irradiation (λ > 230 nm) of the matrix-isolated maleic anhydride causes a decrease in the absorption bands (the most intense located at ν = 1795.9 cm^{-1}) and the appearance of new bands in different areas of the spectrum.

The bands at 2139.1–2143.5 and 2343.8 cm^{-1} were assigned to CO and CO_2, respectively, while the intense bands at 3285.2 and 3282.4 cm^{-1} (due to the different matrix sites) and the less intense band at 742.3 cm^{-1} were assigned to acetylene (12).

Analysis of the spectra shows weak absorption bands at 1896.0–1891.9, 1628.7–1626.7, and 1035.8 cm^{-1}, which initially increase in intensity and then decrease after prolonged irradiation (Fig. 1). These bands, assigned to cyclopropenone, demonstrate the intermediary presence of this compound (13). The photochemical process is described in Scheme 1.

Table 1. Experimental vibrational frequencies of products obtained from photolysis of the dichloromaleic anhydride **1b**.

Observed frequencies (cm^{-1})

Photolysis of dichloromaleic anhydride

The time evolution of the IR spectrum of the matrix-irradiated (λ > 230 nm) dichloromaleic anhydride (**1b**) is presented in Fig. 2, and the vibrational frequencies used for the identification of the products are listed in Table 1.

During irradiation, the bands of **1b** (1803.7, 1624.9, 1247.2, 1205.0, 1006.8, 934.1, 885.9, 727.8, 701.5 cm^{-1}) gradually diminish in intensity and completely disappear after 568 min.

With time, three new band systems with different intensities were observed in the 2400–2100 cm^{-1} region. The two most intense bands were assigned to CO (2142.7 cm^{-1}) and CO_2 (2345.6 cm^{-1}), while the band at 2281.1 cm^{-1}, of lower intensity, was assigned to dichloropropadienone (2).

The analysis of the whole range of frequencies revealed that a group of bands at 1895.7 (the most intense), 1626.5, and 1036.4 cm^{-1} have the same kinetic behavior: initially they increased in intensity and then they decreased in intensity. These bands were assigned to dichlorocyclopropenone (2), and correspond to the $\nu_{C=C}$, $\nu_{C=O}$, ν_{C-C} + β_{C-C-C} vibrations, respectively. With time, these bands disappeared and a band at 993.1 cm^{-1}, assigned to the most intense vibration mode of dichloroacetylene (2), gradually increased in intensity. The time evolution of the integrated absorbancies of the products is shown in Fig. 3. The experimental data are reported in Scheme 2. The relative intensities of the bands indicate that the major photochemical products are dichlorocyclopropenone and dichloroacetylene.

Thermolysis

The thermolysis of dichloromaleic anhydride at 450°C leads to the bands of the dichloropropadienone, CO, and CO_2 (Fig. 4). The reaction mechanism is also given in Scheme 2. The presence of CO in the matrix cage suggests formation of dichlorocyclopropenone. This compound, however, which is unstable in these temperature conditions, was not observed.

On heating maleic anhydride at 450°C, no spectral changes were observed. Apparently the thermal energy supplied was not sufficient for decomposition of the molecule.

Theoretical results

The experimental conditions used (irradiation of both compounds in their absorption-band regions) indicate that

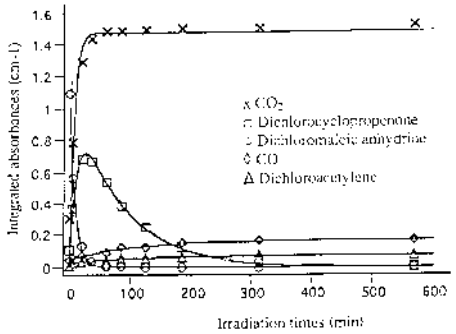
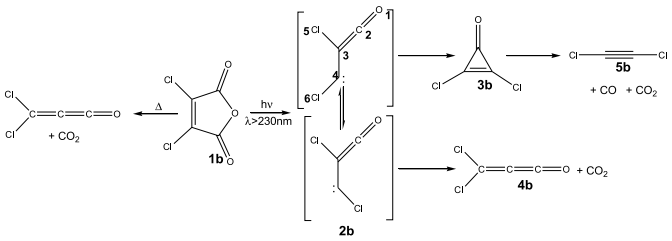
Fig. 3. Evolution of integrated absorbance during photolysis of dichloromaleic anhydride **1b** at $\lambda > 230$ nm. The band at 2281.1 cm^{-1}, assigned to dichloropropadienone, is too small to follow its evolution.



Scheme 2.



the first-excited singlet was populated. The energies of the Frank–Condon first-excited states depend on the number of included configurations and (or) the number of the required states. Their average value was approximately the energy of the experimental radiation, attesting that the singlet state was populated. We cannot tell if the energy furnished to the system is also sufficient to overcome the transition barriers in the excited state; we have considered that a radiationless deactivation process to the ground state could be taking place. Consequently, the reaction was based on the potential energy surface of the ground state.

Formation of ketenyl carbenes

The first step in the decomposition (either photochemical or thermal) of both anhydrides is CO_2 elimination, which yields ketenylcarbenes **2a** and **2b**. The localized transition states (TS1, Fig. 5) for this process are planar and have activation energies of 68.1 and 62.9 kcal mol^{-1} for **1a** and **1b**, respectively.

The differences between the lengths of the broken bonds in the anhydrides and the corresponding transition states for the CO_2 elimination are listed in Table 2. It may be seen that the bond breaking is asynchronous. In the transition state TS1, the increase of the O-C-O angle supports CO_2 formation.

After this first step, it is likely that an equilibrium mixture of *syn*- and *anti*-ketenylcarbene is present, as reported by Dailey (7).

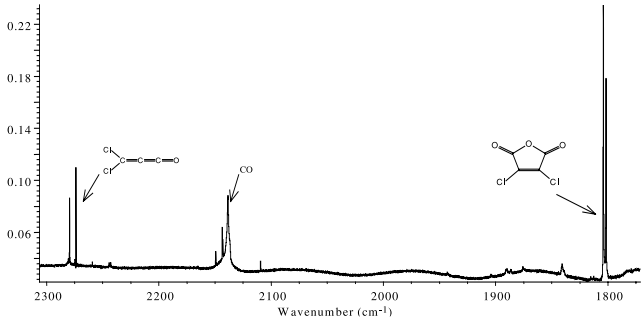

Fig. 5. Relevant optimized parameters (distances, Å; angles, deg) for the transition states of the CO_2 elimination from **1a** and **1b** (values in parentheses) and activation energies (kcal mol^{-1}) calculated with HF/ 6–31 G* basis set.

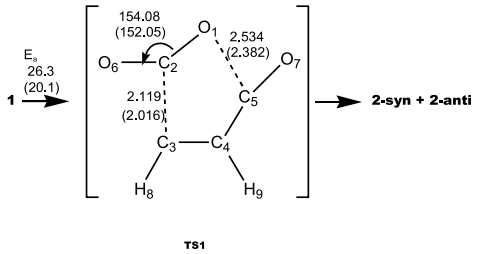

Reactivity of ketenyl carbenes

The previously discussed experimental data show that both ketenylcarbenes **2a** and **2b** undergo subsequent reactions leading to the corresponding cyclopropenone, propadienone, and alkyne.

The ketenylcarbenes **2a** and **2b** were optimized at the HF/6–31G*//HF/6–31G* level in the singlet and triplet states for both the *syn* and *anti* conformations (Table 3). For the unsubstituted ketenylcarbene, it was found that the ground state is a triplet for both conformers, whereas for dichloroketenylcarbenes, both conformers have singlet ground states, with the *syn* conformer more stable.

The optimized geometries reflect the features generally predicted for the singlet and triplet states of the *syn*-carbene conformers, i.e., an X-C-Y angle ($H_6C_4C_3$ (Scheme 1) and $Cl_6C_4C_3$ (Scheme 2)) of 109–115° for the singlet states and 130–131° for the triplet state. At the MP2 level, no minimum could be located for *syn*-**2a** or *syn*-**2b** due to spontaneous ring closure to cyclopropenone. The same results were observed by Tidwell and co-workers (10) for other *syn*-ketenylcarbenes.

Table 4 contains the compounds and transition-state energies modeled at the HF/6–31G* set level. The relevant geometric parameters of the transition states and the activation barriers for reactions of the *syn*- and *anti*-ketenylcarbenes are presented in Fig. 6.

Ring closure and cyclopropenone stabilities

With regard to the experimental data, the most important process (TS2) is the ring closure leading to the formation of cyclopropenones (**3**), which starts from the *syn*-

ketenylcarbene conformers. The calculated energy barriers for this pathway are very low: 2.4 kcal mol^{-1} for *syn*-**2a** and 3.1 kcal mol^{-1} for the *syn*-**2b**.

The formation of acetylene in the decomposition reaction of **1a** and the accumulation of dichloroacetylene during prolonged irradiation of **1b** raises the question of the stability of the cyclopropenones. Two pathways to be considered are (*i*) concerted decarbonylation of the cyclopropenones leading directly to the alkynes; (*ii*) ring opening of cyclopropenones followed by decarbonylation of the *syn*-ketenylcarbenes, which are in competition with ring closure.

The optimized transition states (TS3) for the first process predicted high activation energies, 46.9 kcal mol^{-1} for **3a** and 53.9 kcal mol^{-1} for **3b**. These values indicate that there is a somewhat higher probability for the formation of the alkyne for unsubstituted carbene **2a** in comparison with substituted carbene **2b**. This is in agreement with the experimental findings.

For the second pathway, a larger activation energy was calculated for the ring opening of **3a** than for **3b**, 26.3 vs. 20.1 kcal mol^{-1}. (The transition state (TS2) is the same for the ring-closing and ring-opening reactions.) The transition states found for the CO elimination from the *syn*-ketenylcarbenes were identical (structure and energy) with those located in the previous path for the decarbonylation of cyclopropenones (TS3). This means that energetically both paths are equivalent.

Decarbonylation of the anti conformers

Assuming the *anti* conformers are present, they could be a source of the alkynes. The decarbonylation reaction starting from the *anti*-ketenylcarbenes and leading to the alkynes is characterized by the transition state TS4. The geometries of TS4 reflect the main features of the transition states for decarbonylation reactions in the ketenyl group, i.e., $r_{C\text{-}CO}$ values in the range 1.6–1.8 Å and C-C-O angles in the range 145–155°. There is a correlation between the activation energy and the length of the breaking C—CO bond in the TS4—the value in carbene **2a** ($r_{C\text{-}CO}$ = 1.680 Å (E_a = 17.6 kcal mol^{-1})) is lower than that found for Cl,Cl-disubstituted ketenylcarbene **2b** ($r_{C\text{-}CO}$ = 1.71 Å (E_a = 25.8 kcal mol^{-1})). The differences in the activation energies for the decarbonylation process indicate that the CO elimination is highly favored for **2a**.

1,2–Substituent migration

This reaction is specific to the *anti*-ketenylcarbenes and may explain the formation of propadienones. The high probability of 1,2-halogen or 1,2-hydrogen migration in carbene chemistry is due to the interaction of the electrons of the migrating group with the vacant carbene orbital (14). This occurs only in cases in which the electrons of the migrating atom are located in an orbital quasi-parallel with the carbene vacant orbital. In such cases the overlap of orbitals is ensured and the repulsive interaction avoided.

For the singlet state **2a** and **2b**, the double-occupied carbene orbital is located in the molecular plane, whereas the first vacant orbital is a π orbital with a high degree of localization on the carbene and the ketene C=O group. It is therefore unlikely that such a migration, which might explain the formation of propadienone, can be favored, even assuming a nonplanar transition state.

The calculated results reveal that the activation energies are indeed very high; the larger value predicted for **2b** is in agreement with the assumption that the electronic repulsion between the chlorine lone pair and the carbene in-plane electrons prevents the migration. The structure of TS5 and the activation energies are similar to those found by Dailey (7) for the 1,2-fluorine migration in the fluoro-ketenylcarbene (E_a = 50 kcal mol^{-1}). It is apparent that the nature of the substituent does not have a large influence on this process.

An enhanced possibility for a 1,2 migration reaction could be expected starting from the triplet state, for which the carbene in-plane orbital is only single occupied, implying a decrease in electronic repulsions. The results in Fig. 6 indicate that for triplet ^{3}***anti*-2a** the 1,2-migration remains a high-energy process. For the triplet chlorine-disubstituted ketenylcarbene (^{3}***anti*-2b**), however, the 1,2-migration in the triplet state is a possible pathway and, therefore, the presence

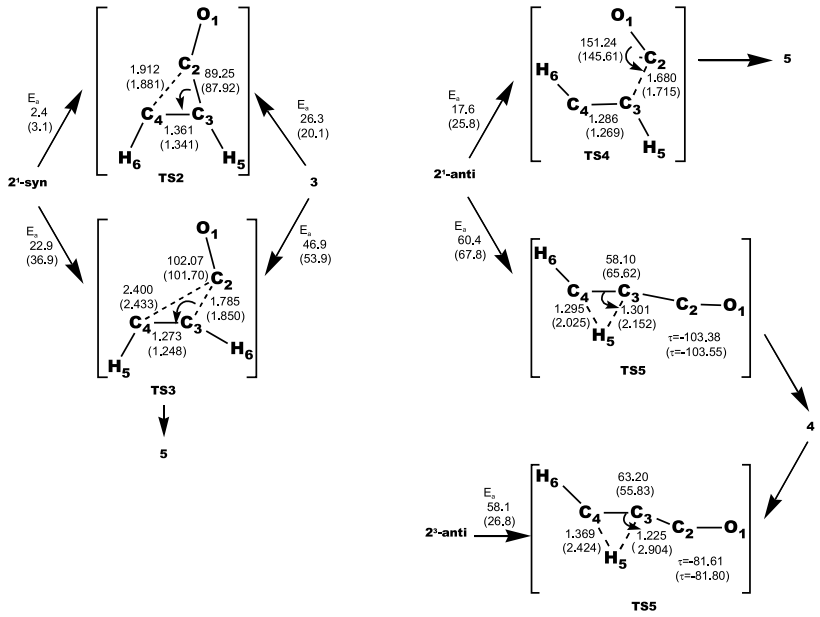
Fig. 6. Relevant optimized parameters (distances, Å; angles, deg) for the transition states of the reactions of the *syn*- and *anti*-ketenyl carbenes **2a** and **2b**, respectively, (values in parentheses) and activation energies (kcal mol^{-1}) calculated with HF6–31G* basis set (τ=$H_5C_3C_4H_6$).



of small quantities of dichloropropadienone can be explained.

Summary

During the photolysis of maleic anhydride, only cyclopropenone, acetylene, CO, and CO_2 are observed as products. The transition-state structure calculations are consistent with these results. In fact, the cyclization process is spontaneous (2.4 kcal mol^{-1}) from *syn*-ketenylcarbene. From the *anti*-ketenylcarbene, decarbonylation is easier (17.6 kcal mol^{-1}) than the 1,2 migration process (63.5 kcal mol^{-1}). These results explain why the propadienone was not experimentally observed.

Photochemically, matrix-isolated dichloromaleic anhydride **1b** is converted to a mixture of *anti*- and *syn*-ketenylcarbene. The *syn* conformer undergoes rapid ring closure to dichlorocyclopropenone, while for the *anti* isomer there is competition between two possible pathways with similar activation barriers (25–26 kcal mol^{-1}) if we consider the 1,2-migration in the triplet state. The presence of small quantities of dichloropropadienone and dichloroacetylene can, therefore, be explained. The formation of the latter could also be produced from the *syn*-ketenylcarbene via dichlorocyclopropenone, a pathway which is calculated to have a lower barrier (37 kcal mol^{-1}).

The reaction mechanism is the same for the thermolysis and photolysis of dichloromaleic anhydride. The predicted facile ring opening to *syn*-ketenylcarbene (20.1 kcal mol^{-1}) explains the failure to isolate dichlorocyclopropenone in the matrix when **1b** was pyrolyzed at 450°C. (Dichlorocyclopropenone is not stable under these conditions.) Although the IR absorption bands seem intense, it is difficult to determine the quantity of dichloropropadienone produced because we cannot compare the relative intensities between this compound and the dichloropropenone, since the latter is not observed.

Excess molar enthalpies of mixtures of methyl derivatives of polyethylene glycol with 1-alkanol at 298.15 K and 101.3 kPa

M.E.F. de Ruiz Holgado, J. Fernandez, M.I. Paz Andrade, and E.L. Arancibia

Abstract: Excess molar enthalpies (H^E) of the binary mixtures containing tetraethylene glycol dimethyl ether (TEGDME) or polyethylene glycol 350 monomethyl ether with a 1-alkanol (1-propanol, 1-butanol, or 1-pentanol) at 298.15 K and atmospheric pressure were measured using a Calvet microcalorimeter. All the H^E experimental values were positive and increase as the 1-alkanol length increases. The results are discussed qualitatively in terms of molecular interactions. The UNIFAC and DISQUAC group contribution models have been used to compare the predicted and the experimental values.

Key words: excess enthalpy, 1-alkanol, polyether, binary system.

Résumé : On présente les enthalpies molaires d'excès, H^E, des mélanges binaires de l'éther diméthylique du tétraéthylèneglycol ou de l'éther monométhylique du polyéthylèneglycol 350 avec un alcan-1-ol (propan-1-ol, butan-1-ol ou pentan-1-ol), à 298,15 K, à pression atmosphérique et mesurées à l'aide du microcalorimètre Calvet. Les valeurs de H^E de chacun des mélanges sont toutes positives et elles augmentent avec une augmentation de la longueur de la chaîne des alcanoles. On discute les résultats en fonction des interactions moléculaires. On a utilisé les modèles de contribution de groupes UNIFAC et DISQUAC pour comparer les résultats théoriques et expérimentaux.

Mots clés : enthalpie en excès, alcan-1-ol, polyéther, système binaire.

Introduction

In the last few years, interest in the thermophysical properties of polyethers and polyglycols with alkanols has increased. In the case of mixtures with methanol, these studies were undertaken to characterize new absorbent–refrigeration pairs, which could improve cycle performance (1, 2). Furthermore, mixtures containing ethers (-O- group) and alcohols (-OH group) are interesting because they are used as gasoline additives for their octane-enhancing and pollution-reducing properties (3).

In this work, excess enthalpies of tetraethylene glycol dimethyl ether (TEGDME) or polyethylene glycol 350 monomethyl ether (PEGMME) with an 1-alkanol (1-propanol, 1-butanol, or 1-pentanol) were determined to analyze the molecular interactions in the mixing process. The experimental results obtained for these mixtures were used to test the predictions of UNIFAC and DISQUAC models. For UNIFAC, we have used the Tassios et al. version, which uses the parameters of Dang and Tassios (4), the Larsen et al. version, which uses their parameters (5), and the Gmehling et al. version (6), which uses the parameters published in ref. 7. The parameters for the DISQUAC model (8) were determined by Delcros et al. (9). For mixtures containing PEGMME, we did not applied the DISQUAC model because not all of the required interaction parameters were available.

Experimental

1-Propanol, 1-butanol, and 1-pentanol were obtained from Merck (pro-analysis >99%) and TEGDME was obtained from Aldrich (99%). PEGMME (Sigma, 350 average molecular weight) was analyzed by gas chromatography and mass spectrometry, the mean molecular weight was 340.25 g mol^{-1}. All chemicals were used without further purification and were also kept over molecular sieves (4 Å). Density measurements (ρ) at 298.15 K and atmospheric pressure are given in Table 1, together with some values taken from the literature (Pal et al. (10), Carmona et al. (11), Reddick et al. (12), Shan and Asfour (13), and Aralaguppi et al. (14)).

Excess molar enthalpies (H^E) were determined with a standard Calvet microcalorimeter (1 μW precision) linked to a Philips voltmeter PM2525. The calorimeter is equipped with a batch-mixing cell with a small (<2%) vapour space. The microcalorimeter was calibrated electrically using a

stabilized current source (EPJ-30, Setaram). More details of the apparatus and procedure have been described elsewhere (15).

Binary mixtures were prepared using a Mettler balance H51 (precision ±1 × 10^{-5} g) and air-tight stoppered bottles. The possible error in the mol fractions is estimated to be less than ±10^{-4}. Calibration of the calorimeter was performed using cyclohexane–hexane at 298.15 K. The results were compared with the literature (16) and agreed within ±1%.

Results and discussion

Tables 2 and 3 show the experimental values of H^E (J mol^{-1}) for the six binary mixtures studied in the present work. For each binary mixture, a Redlich–Kister function was used to correlate the experimental values.

$$[1] \qquad H^E = x_1 x_2 \sum_{i=1,\ldots n} A_i (2x_1 - 1)^{i-1}$$

The parameters A_i, and their standard deviation, obtained by a linear least-squares fitting procedure, are given in Table 4, together with the standard deviations (σ). The number of coefficients determined in each case were obtained using an *F*-test.

The root-mean-square deviations presented in this paper were computed using the following expression:

$$[2] \qquad \sigma = \left[\frac{\sum_{i=1}^{N} (H^E_{\text{exp}} - H^E_{\text{pred}})^2}{N - n} \right]^{1/2}$$

where N is the number of the experimental data points and n is the number of A_i coefficients.

Figures 1 and 2 show the measured values of H^E plotted against x_1, the mol fraction of glycol derivatives, together with the fitted curves. In Fig. 1, we have also included for comparison the excess enthalpies of TEGDME + methanol measured by Lopez et al. (17). The excess enthalpies of TEGDME + alkanol are positive, increasing with the length of the alkanol, and the $H^E(x)$ curves are slightly asymmetrical with a maximum in the polyether-poor region. The endothermicity of these mixtures shows that breaking the hydrogen bonds in the alkanol and the dipole–dipole interactions in the polyethers are energetically more important than the formation of hydrogen bonds between the unlike molecules.

$A_5 \pm \sigma(A_i)$	1580 ± 360	—	2050 ± 560
$\sigma(H^E)$	10	16	15

Figures 1 and 3 show that the excess enthalpies increase more from methanol to 1-propanol than from 1-propanol to 1-pentanol. This is in agreement with the H^E values of 2,5-dioxahexane and 3,6-dioxaoctane with alkanols (18–20). Excess volumes of polyether + alkanol mixtures present similar trends with the alkanol length, but for the shorter alkanols the excess volumes are negative because of the free-volume effect (11). Furthermore, if we compare our H^E results with those of the shorter glymes 2,5-dioxahexane (19) and 2,5,8-trioxaundecane (20) with alkanols, it can be concluded that the excess enthalpies increase as the number of OCH_2CH_2 groups increase.

Figure 2 shows that the excess enthalpies of PEGMME + alkanol systems are positive, increasing when the alcohol size increases. The $H^E(x)$ curves are quite asymmetrical with the maximum in the PEGMME-poor region. The breaking of the hydrogen bonds of both the alcohol and glycol derivatives, together with the formation of hydrogen bonds between the unlike molecules, is taking place in the mixing process. The endothermicity of these mixtures shows that the breaking of the hydrogen bonds is energetically more important that the formation of new hydrogen bonds, similar to the TEGDME mixtures.

In the application of the three versions of UNIFAC, there are three options for choosing the number and type of the different functional groups, because of the symmetry of the ether group (-O-). Thus, the types of molecules of TEGDME (CH_3O-$(CH_2$-$CH_2O)_4CH_3$) that can be considered are, option #1: $2CH_3O$, $5CH_2$, and $3CH_2O$. This option has been used by Delcros et al. (9) in the application of the Gmehling et al. version. Option #2: $1CH_3$, $4CH_2$, $4CH_2O$ and $1CH_3O$, in which the authors of the different versions of the UNIFAC model propose this option. Option #3: $2CH_3$, $3CH_2$, and $5CH_2O$, which was suggested by López et al. (17).

PEGMME 350 used in the present study is a commercial mixture of monomethyl polyethylene glycol ether (CH_3-$(OCH_2$-$CH_2)_n$OH with n = 5–9). Gas chromatography and mass spectrometry analysis yielded a molecular weight of 340.25 g mol^{-1} and pseudo n-value of 6.996. A value of n = 7.00 was assumed for the application of the group-contribution models, and we used option #1 ($1CH_3O$, $8CH_2$, $6CH_2O$, and 1OH) and option #2 ($1CH_3$, $7CH_2$, $7CH_2O$, and 1OH). Option #3 is not feasible because there is only one CH_3 group in the CH_3-$(OCH_2$-$CH_2)_7$OH molecule.

In Fig. 3, we have plotted the UNIFAC predictions with the different options for $H^E(x = 0.5)$ for TEGDME + 1-alkanol mixtures. The Larsen et al. version gives the poorest predictions (up to 85% of deviation for mixtures with methanol), while option #3 gives the best results. In the Tassios et al. version, the predictions for the longer alkanols can be considered good for options #2 and #3. In this version, however, methanol is not an independent group, and consequently, the predictions of Tassios et al. are poorest for

Fig. 1. H^E at 298.15 K and atmospheric pressure for TEGDME (1) + 1-alkanol (2) mixtures vs. x_1. Solid lines: results from the smoothing eq. [1] with the coefficients listed in Table 4. Experimental data: methanol (●) (14); 1-propanol (■); 1-butanol (▲); 1-pentanol (▼).

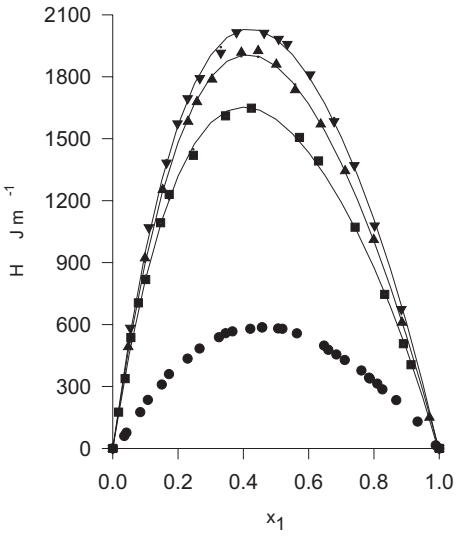

Fig. 2. H^E at 298.15 K and atmospheric pressure for PEGMME (1) + 1-alkanol (2) mixtures *vs.* x_1. Solid lines: results from the smoothing eq. [1] with the coefficients listed in Table 4. Experimental data: 1-propanol (■); 1-butanol (▲); 1-pentanol (▼).

Fig. 3. Experimental and theoretical H^E (x = 0.5) at 298.15 K of the systems TEGDME + $C_nH_{2n+1}OH$ vs. n, the number of carbon atoms of the 1-alkanol. Experimental data: (○) DISQUAC model; (◆) UNIFAC model, version (*a*) Tassios et al., (*b*) Larsen et al., (*c*) Gmehling et al. Option #1 (■); #2 (▲); #3 (▼).

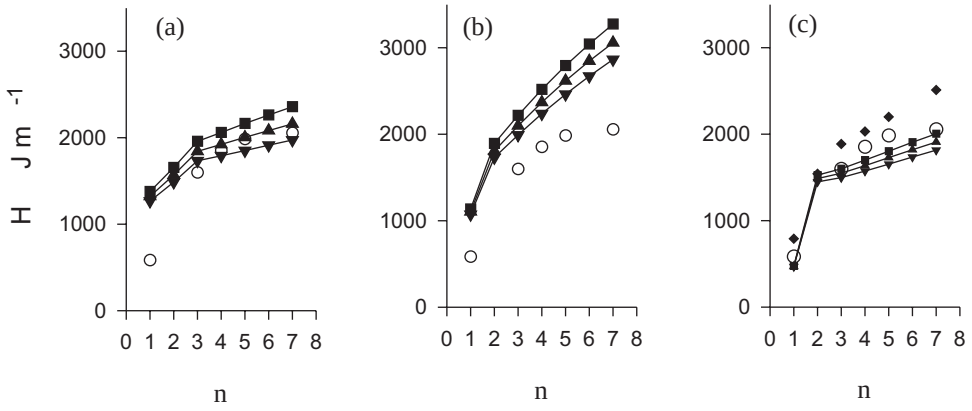

Fig. 4. Experimental and theoretical H^E (x = 0.5) at 298.15 K of the systems PEGMME + $C_nH_{2n+1}OH$ vs. n, the number of carbon atoms of the 1-alkanol. Experimental data: (○) UNIFAC model, version (*a*) Tassios et al., (*b*) Larsen et al., (*c*) Gmehling et al. Option #1 (■); #2 (▲).

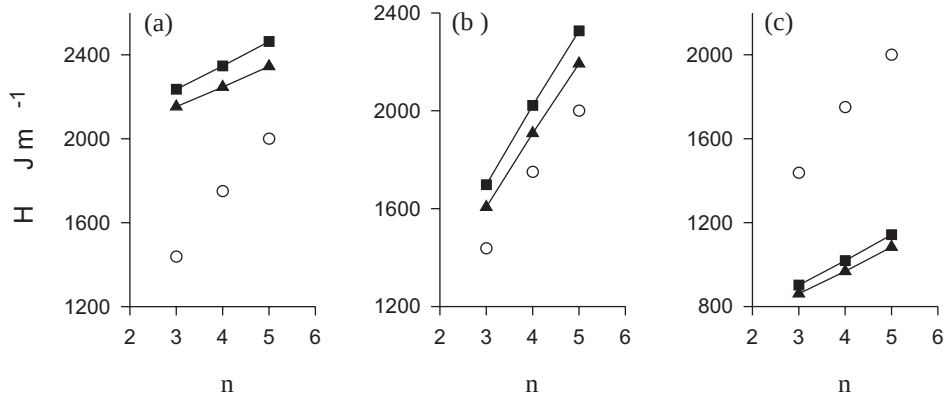

mixtures containing methanol. The Gmehling et al. version gives the best predictions because it correctly predicts both the trend of the excess enthalpies with the alkanol length and magnitude. The Gmehling et al. predictions, in contrast with the Tassios et al. and Larsen et al. versions, are quite independent of the options for choosing the type and number of groups. The symmetry of the $H^E(x)$ curves is well predicted with both the Gmehling et al. and Larsen et al. versions.

For the DISQUAC model, the parameters of González et al. (21) are used for alkanol–alkane interactions, while the parameters of Kehiaian et al. (22) are used for ether–alkane interactions and the parameters of Delcros et al. (9) are used for ether–alkanol interactions. Figure 3*c* shows that the DISQUAC model adequately reproduces the shape of the $H^E(x)$ curves with respect to the alkanol size. For the TEGDME + alkanol mixtures the global mean deviation of $H^E(x = 0.5)$ is around 19%.

Figures 4*a–c* shows the UNIFAC predictions for monomethyl polyethylene glycol ether + alkanol. Using the Larsen et al. version, the mean deviations for these mixtures are 10 and 17% for options #1 and #2, respectively. For the Tassios et al. version, the deviations are 38% for option #1 and 32% for option #2. The deviations using the Gmehling et al. versions are 41% for option #1 and 44% for option #2. Some of the interaction parameters needed to apply the DISQUAC model to this type of system are not available.

Conclusions

Data on H^E at 298.15 K and atmospheric pressure for TEGDME or polyethylene glycol 350 monomethyl ether + alkanols (from propanol to pentanol) are reported. Our results for H^E (x = 0.5) of TEGDME + alkanol follow a regular trend with those reported in the literature for mixtures with methanol and heptanol. In the comparison with the predictions with the UNIFAC model, the Gmehling version gives the best predictions for TEGDME + alkanol, whereas the Larsen version gives the best predictions for PEGMME + alkanol.

Excess molar volumes and viscosities of binary mixtures of some polyethers with propylamine at 298.15 K

Amalendu Pal and Rakesh Kumar Bhardwaj

Abstract: Excess molar volumes (V^{E}_{m}) and dynamic viscosities (η) have been measured as a function of composition for binary liquid mixtures of propylamine with 2,5-dioxahexane, 2,5,8-trioxanonane, 2,5,8,11-tetraoxadodecane, 3,6,9-trioxaundecane, and 5,8,11-trioxapentadecane at 298.15 K. The excess volumes are positive over the entire range of composition for the systems propylamine + 2,5-dioxahexane, and + 3,6,9-trioxaundecane, negative for the systems propylamine + 2,5,8,11-tetraoxadodecane, and + 5,8,11-trioxapentadecane, and change sign from positive to negative for the remaining system propylamine + 2,5,8-trioxanonane. From the experimental data, deviations in the viscosity ($\Delta\ln\eta$) and excess energies of activation for viscous flow (ΔG^{*E}) have been derived. These values are positive for all mixtures with the exception of propylamine + 2,5-dioxahexane.

Key words : excess volume, viscosity, binary mixtures.

Résumé : On a mesuré les volumes molaires en excès (V^{E}_{m}) et les viscosités dynamiques (η) en fonction de la composition pour des mélanges liquides binaires de propylamine avec du 2,5-dioxahexane, du 2,5,8-trioxanonane, du 2,5,8,11-tétraoxadodécane, du 3,6,9-trioxoaundécane et du 5,8,11-trioxapentadécane, à 298,15 K. Les volumes en excès sont positifs sur toute la plage de compositions pour les systèmes propylamine + 2,5-dioxahexane et + 3,6,9-trioxoaundécane, ils sont négatifs pour les systèmes propylamine + 2,5,8,11-tétraoxadodécane et + 5,8,11-trioxapentadécane et ils changent de signe, de positif à négatif, pour le dernier système, celui de la propylamine + 2,5,8-trioxanonane. Utilisant les données expérimentales, on a dérivé les déviations dans la viscosité ($\Delta\ln\eta$) et dans les énergies d'activation en excès pour l'écoulement visqueux (ΔG^{*E}). Ces valeurs sont positives pour tous les mélanges, excepté celui de la propylamine + 2,5-dioxahexane.

Mots clés : volume en excès, viscosité, mélanges binaires.

[Traduit par la Rédaction]

Introduction

In recent years, we have been actively engaged in a systematic study of the thermodynamic, acoustic, and transport properties of some binary mixtures of polyethers with organic solvents (1–4), especially in terms of evaluation of various thermodynamic properties and functions that give a better understanding of the molecular interactions. Previously (5), we reported excess molar volumes and viscosities for binary mixtures of some alkoxyethanols with propylamine. From these results it was observed that there exist specific interactions between amine and alkoxyethanol, including the self association of both the amine and alkoxyethanol molecules, which influence the properties of the mixtures. As an extension of our studies and to understand the molecular interactions between amines and polyethers, here we report new experimental data for the excess molar volumes (V^{E}_{m}) and viscosities (η) of binary solvent mixtures containing 2,5-dioxahexane, 2,5,8-tetraoxanonane, 2,5,8,11-tetraoxadodecane, 3,6,9-trioxaundecane, and 5,8,11-trioxapentadecane with propylamine over the whole composition range at 298.15 K and atmospheric pressure. A survey of the literature reveals that binary mixtures of alkoxyethanols or amines with alkanol (6–11) and different amines with straight chain ethers (12) have mainly been studied. Recently, a few studies involving excess volumes and excess heat capacities of (polyethers + alkane or esters) (13–15), excess volumes and excess enthalpies of (alkanol + polyethers) (16–18) and excess volumes of (1–propanol, *n*-hexanol, or branched alkanols + polyethers) (19–21) have been reported. There is, however, no systematic study on the behavior of propylamine with polyethers.

(Acros, 99 mol%) was used without further purification. Prior to measurements, however, all liquids were degassed and stored over with molecular sieves. The purities of the liquids were checked by measuring and comparing the densities and viscosities at 298.15 K with their corresponding literature values (24–30) as shown in Table 1. Densities (ρ) of pure solvents were measured with a bicapillary pycnometer. The pycnometer was calibrated at 298.15 K with doubly distilled water. The sensitivity of the pycnometer corresponded to a precision in density, 1×10^{-2} kg m^{-3}. The reproducibility of the density estimates was found to be within 1×10^{-1} kg m^{-3}. The mol fraction of each mixture was obtained with an uncertainty of 1×10^{-4} from the measured masses of the components. All masses were corrected for buoyancy.

The excess molar volumes were measured using a continuous-dilution dilatometer similar to that described by Dickinson et al. (31). The details pertaining to calibration, experimental set-up, and measuring procedure have been previously described (32). The measured excess molar volumes were reproducible to $\pm 0.003 \times 10^{-6}$ m^3 mol^{-1}. Each run covered just over half of the range of the ether mol fraction (x_1) so as to give an overlap between two runs.

Kinematic viscosities ν (= η/ρ) of the pure liquids and the mixtures were measured at 298.15 K with a calibrated Ubbelohde suspended-level viscometer. The detailed procedure has been previously reported (33, 34). The viscometer is filled with liquid or liquid mixtures, and its limbs are closed with Teflon caps, taking precautions to minimize evaporation losses. The flow-time measurements were made with an electronic stopwatch having a readability of ±0.01 s. Four- or five-flow times were averaged to evaluate the viscosity at each composition. The caps of the limbs are removed during the measurement of flow times. The measured kinematic viscosities were converted to dynamic viscosities (η) by multiplication with the density. The reproducibility of the viscosity was within ±0.003 mPa s. All measurements were carried out in a well-stirred water bath at a temperature controlled to ±0.01 K.

Results

Tables 2 and 3 give the experimental results of the excess molar volumes and viscosities at 298.15 K at various mol fractions. The plots of excess molar volumes ($V^{\mathrm{E}}_{\mathrm{m}}$) and viscosities (η) against the mol fraction of the polyether are given in Figs. 1 and 2. For compact and smooth representation of the results, the measured viscosities were fitted to a polynomial of type

$$[1] \qquad \eta = \sum_{i=0}^{n} a_i x_1^i$$

by the method of least squares with each point equally weighted. The values of coefficients a_i and standard deviations σ are listed in Table 4*a*.

From the measured values of the excess molar volumes, the densities of liquid mixtures were computed using the equation

$$[2] \qquad \rho = (x_1M_1 + x_2M_2)/(V^{\mathrm{E}}_{\mathrm{m}} + x_1V^*_1 + x_2V^*_2)$$

where M_1 and M_2 represent molar masses. The accuracy in ρ due to the estimated accuracy in excess molar volume ($\pm 0.003 \times 10^{-6}$ m^3 mol^{-1}) is 1×10^{-1} kg m^{-3}.

The deviation of the viscosity has been calculated from the following relationship (35, 36):

$$[3] \qquad \Delta \ln \eta = \ln \eta - (x_1 \ln \eta_1 + x_2 \ln \eta_2)$$

where x_1 and x_2 are the mol fractions, η is the dynamic viscosity of the mixture, and η_1 and η_2 are the viscosities of components 1 and 2, respectively.

The excess energies of activation for viscous flow were obtained with the following expression:

$$[4] \qquad \Delta G^{*\mathrm{E}} = RT\,[\ln(\eta V) - x_1 \ln(\eta_1 V^*_1) - x_2 \ln(\eta_2 V^*_2)]$$

where V, V^*_1, and V^*_2 are the molar volumes of the mixture and of the pure components 1 and 2, respectively. R and T are the gas constant and temperature, respectively. The

Fig. 1. Experimental excess molar volumes for propylamine (2) + 2,5-dioxahexane (1) (○); 2,5,8-trioxanonane (1) (Δ); 2,5,8,11-tetraoxadodecane (1) (□); 3,6,9-trioxundecane (1) (●); 5,8,11-trioxapentadecane (1) (⊗). Continuous curves were calculated from eq. [5].

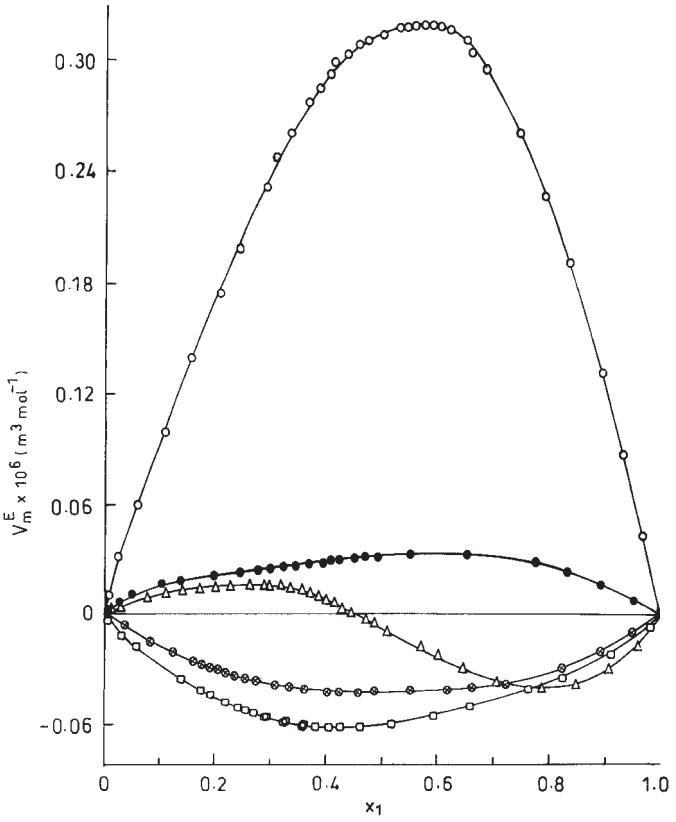

Fig. 2. Experimental viscosities for propylamine (2) + 2,5-dioxahexane (1) (○); 2,5,8-trioxanonane (1) (Δ); 2,5,8,11-tetraoxadodecane (1) (□); 3,6,9-trioxaundecane (1) (●); 5,8,11-trioxapentadecane (1) (⊗). Continuous curves were calculated from eq. [1].

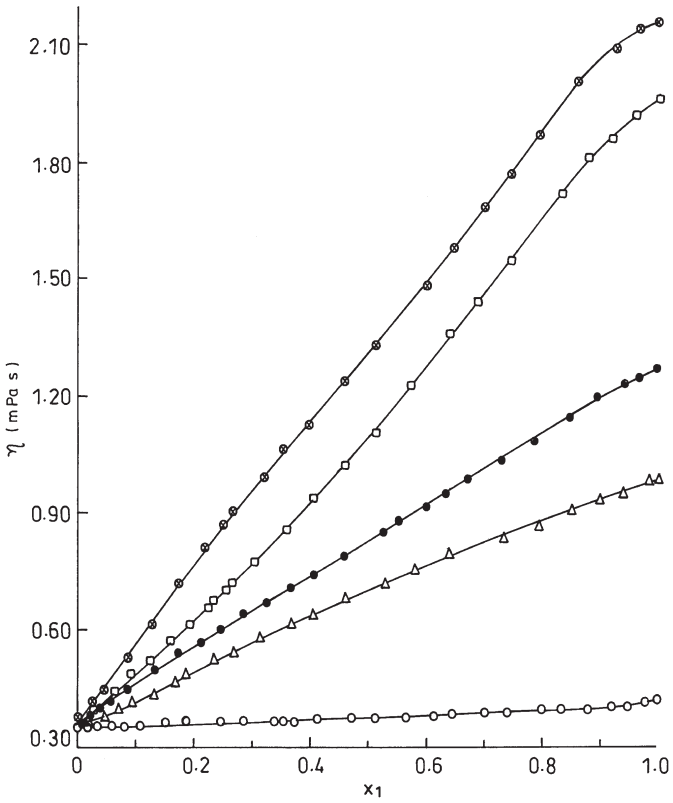

derived densities, viscosities, and excess energies of activation for viscous flow for the different binary mixtures at 298.15 K are given in Table 3.

The values of V_m^E, $\Delta \ln \eta$, and ΔG^{*E} for all mixtures were represented mathematically by the Redlich–Kister polynomial.

$$[5] \qquad Y(x) = x_1 x_2 \sum_{i=0}^{n} a_i (x_1 - x_2)^{i-1}$$

Values of the coefficients a_i and standard deviation σ are summarized in Table 4*b*. For all mixtures, $\sigma(V_m^E) \leq 0.003$, in accord with the precision attainable with the dilatometer

used. Literature values for V^E_m or η for these mixture are not available for comparison.

Comparison of experimental results with several empirical laws of mixing

Several relations have been proposed to evaluate the dynamic viscosity (η) of liquid mixtures by using several chemical laws of mixing representative of the viscosity of binary mixtures with an adjustable empirical parameter. The literature contains many laws of mixing, which can be defined according to the number of adjustable parameters used to account for the deviation from an ideal mixture. Thus, there are laws based on parameters of zero, one, two, three, and so forth

The equation of Kendall and Monroe (37), which has no adjustable parameters, is expressed as

$$[6] \qquad \eta = (x_1\eta_1^{1/3} + x_2\eta_2^{1/3})^3$$

The equations of Grunberg–Nissan (38), Tamura and Kurata (39), Hind (40), and Katti and Chaudhry (41) have one adjustable parameter. The single-parameter Grunberg–Nissan equation (38) reads

$$[7] \qquad \ln \eta = x_1 \ln \eta_1 + x_2 \ln \eta_2 + x_1x_2G_{12}$$

where G_{12} is a parameter proportional to the interchange energy. Tamura and Kurata (39) developed the following expression for the viscosity of binary mixtures:

$$[8] \qquad \eta = x_1\phi_1\eta_1 + x_2\phi_2\eta_2 + 2(x_1x_2\phi_1\phi_2)^{1/2}T_{12}$$

where T_{12} is the interaction parameter and ϕ_1 and ϕ_2 are the volume fractions. Hind et al. (40) proposed the following equation:

$$[9] \qquad \eta = x_1^2\eta_1 + x_2^2\eta_2 + 2x_1x_2H_{12}$$

where H_{12} is attributed to unlike-pair interactions. Katti and Chaudhry (41) derived the following equation:

$$[10] \qquad \ln (\eta V) = x_1 \ln (\eta_1 V_1^*) + x_2 \ln (\eta_1 V_1^*) + x_1x_2W_{vis}/RT$$

where W_{vis} is an adjustable parameter. The two-parameter Heric and Brewer equation (42) is of the form

$$[11] \qquad \ln \nu = x_1 \ln \nu_1 + x_2 \ln \nu_2 + x_1 \ln M_1 + x_2 \ln M_2 + \ln (x_1M_1 + x_2M_2) + x_1x_2[\alpha_{12} + \alpha_{21}(x_1 - x_2)]$$

where α_{12} and α_{21} are adjustable parameters and ν_i is the kinematic viscosity of pure component *i*. The two-parameter

Fig. 3. Experimental viscosity deviations for propylamine (2) + 2,5-dioxahexane (1) (○) ; 2,5,8-trioxanonane (1) (Δ); 2,5,8,11-tetraoxadodecane (1) (□); 3,6,9-trioxaundecane (1) (●); 5,8,11-trioxapentadecane (1) (⊗). Continuous curves were calculated from eq. [5].

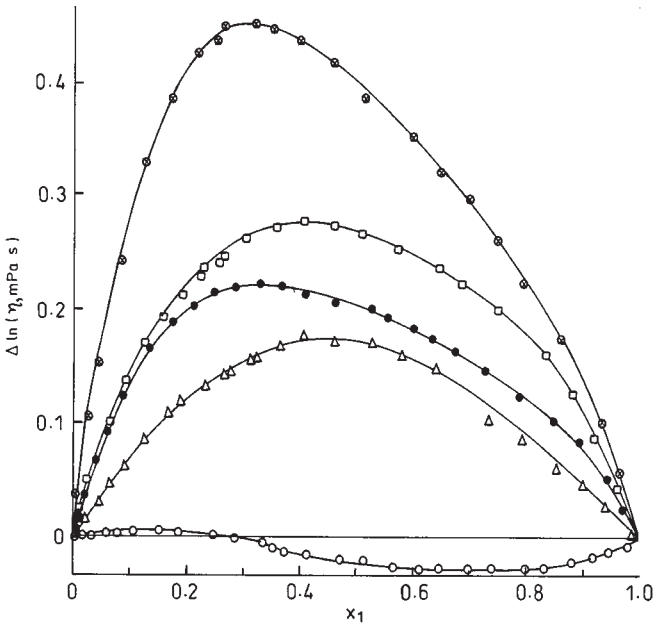

Fig. 4. Experimental excess energies of activation for viscous flow for propylamine (2) + 2,5-dioxahexane (1) (○); 2,5,8-trioxanonane (1) (Δ); 2,5,8,11-tetraoxadodecane (1) (□); 3,6,9-trioxaundecane (1) (●); 5,8,11–trioxapentadecane (1) (⊗). Continuous curves were calculated from eq. [5].

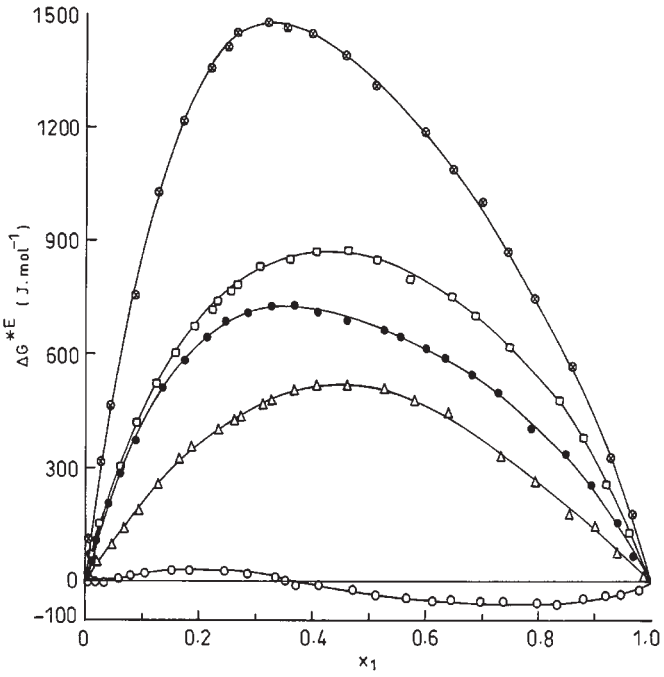

McAllister equation (43), based on Eyring's theory of absolute reaction rates (44), and the three-body interaction model is

$$[12]\quad \ln \nu = x_1^3 \ln \nu_1 + 3x_1^2x_2 \ln Z_{12} + 3x_1x_2^2 \ln Z_{21} + x_2^3 \ln \nu_2 - \ln [x_1 + x_2(M_2/M_1)] + 3x_1^2x_2 \ln [(2 + M_2/M_1)/3] + 3x_1x_2^2 \ln [(1 + 2M_2/M_1)/3] + x_2^3 \ln (M_2/M_1)$$

The four-body model gives

$$[13]\quad \ln \nu = x_1^4 \ln \nu_1 + 4x_1^3x_2 \ln Z_{1112} + 6x_1^2x_2^2 \ln Z_{1122} + 4x_1x_2^3 \ln Z_{2221} + x_2^4 \ln \nu_2 - \ln [x_1 + x_2(M_2/M_1)] + 4x_1^3x_2 \ln [(3 + M_2/M_1)/4] + 6x_1^2 2x_2^2 \ln [(1 + M_2/M_1)/2] + 4x_1x_2^3 \ln [(1 + 3M_2/M_1)/4] + x_2^4 \ln (M_2/M_1)$$

where Z_{12}, Z_{21}, Z_{1112}, Z_{1122}, and Z_{2221} are interaction parameters and M_i is the molecular mass of pure component *i*. The three-parameter Auslaender eq. [45] is of the form

$$[14]\quad \nu_1(x_1 + B_{12}x_2)(\nu - \nu_1) + A_{21}x_2(B_{21}x_2 + x_2)(\nu - \nu_2) = 0$$

where B_{12}, A_{21}, and B_{21} are the parameters representing binary *1 – 2* interactions. The correlating capability of eqs. [6]–[14] was tested by calculating the standard percentage deviation (σ%) between the experimental and the calculated viscosity using the following relation:

$$[15]\quad \sigma(\%) = [1/(p - k)\ \Sigma(100(\eta_{exp} - \eta_{cal})/\eta_{exp})^2]^{1/2}$$

where *p* represents the number of experimental points and *k* the number of numerical coefficients in the respective equations.

Discussion

From Fig. 1, it can be seen that V_m^E is large and positive for the 2,5-dioxahexane + propylamine mixtures at 298.15 K over the entire range of composition. For the same value of x_1, the magnitude of the V_m^E decreases with each additional -OC_2H_4- group in the parent molecule 2,5-dioxahexane. The behavior is similar to that of V_m^E for 2-methoxyethanol or propylamine with *n*-alkoxyethanol (5, 7, 46, 47), ethyl acetate with (mono and poly) ethers (14), and alkanols with polyethers (19, 27, 48), where V_m^E decreases with the increasing number of oxygen atoms in the ether chain. In Fig. 1, it can also be observed that V_m^E increases in the sequence 5,8,11-trioxapentadecane > 3,6,9-trioxundecane > 2,5,8- trioxanonane. This behavior may be compared with that of V_m^E for 2-(2-methoxyethoxy)ethanol, 2-(2-ethoxyethoxy)ethanol, or 2-(2-butoxyethoxy)ethanol with propylamine (5). The behavior of these mixtures is very complex and the overall values of V_m^E are attributable to the result of several opposing and diverse effects (49, 50): (*i*) a disruption of liquid order on mixing and unfavorable interactions between unlike molecules, which contribute positively to V_m^E; (*ii*) a volume decrease caused by the differences in molecular volumes and free volumes and possible interstitial accommodation of propylamine within larger molecules. Upon increasing the size of the polar-head group of the polyether, the interactions between unlike molecules become more important; V_m^E decreases and becomes more negative for the

larger polyethers. In the same homologous series, the algebraic values of V^E_m at $x_1 > 0.8$ for the three binary systems with propylamine vary in the following order: 5,8,11-trioxapentadecane < 2,5,8-trioxanonane < 3,6,9-trioxaundecane. The negative contribution to V^E_m for the 5,8,11-trioxapentadecane systems is caused by stronger interactions between unlike molecules giving higher negative values compared with those of the other two mixtures.

Figure 2 shows that η increases with the ether mol fraction (x_1) for all of the mixtures studied. The deviation in the viscosity (Δln η) and the excess energies of activation for viscous flow (ΔG^{*E}) are represented in Figs. 3 and 4. All of the mixtures show positive deviations from mol fraction linearity, except for the 2,5-dioxahexane + propylamine system at low ether mol fractions. Similar behavior is observed for ΔG^{*E}. The magnitude of η, Δln η, and ΔG^{*E} increase with increasing size of the polar-head group and with increasing alkyl chain length of polyether. The positive values of ΔG^{*E} are attributed to the large size and cohesive-energy difference between the two unlike molecules. The positive Δln η and ΔG^{*E} values are an indication of specific interactions (51, 52). Indeed, we observe positive deviations in the viscosity that regularly increase as the size or viscosity of the polyether is increased. This reveals that the strength of specific interaction is not the only factor influencing the viscosity deviation of liquid mixtures. The molecular size and shape of the components also play important roles.

The results of the correlating eqs. [6]–[14] are compiled in Tables 5 and 6. The fitting precision of eq. [6] (no adjustable parameters) and eqs. [7]–[10] (one adjustable parameter) are presented in Table 5. Table 6 gives the fitting results for the two-parameter Heric–Brewer equation (eq. [11]), the McAllister three-body model (eq. [12]), the three-parameter McAllister four-body model (eq. [13]), and the Auslaender equation (eq. [14]). The values of the different fittings parameters in eqs. [7]–[14] and the percentage standard deviation listed in Tables 5 and 6 were obtained from the experimental viscosity data using least squares with equal weights assigned to each point.

The values of σ are in the range from 1.3 to 20.3% for eq. [6] (no adjustable parameters); from 0.9 to 9.2% for the single-parameter fitting eqs. [7]–[10]; from 0.2 to 3.5% for the two-parameter eqs. [11] and [12]; and from 0.2 to 3.5% for the three-parameter eqs. (13] and [14]. Table 5 shows that, because of lower values of σ%, the equations of Tamura and Kurata (eq. [8]), and Hind et al. (eq. [9]), the behavior of the binary mixture satisfactorily compares with the equations of Grunberg–Nissan (eq. [7]) and Katti and Chaudhary (eq. [10]). The equations of Kendall and Monroe (eq. [6], with no adjustable parameters) has higher values of σ% than those of the single-parameter eqs. [7]–[10]. Use of the two-parameter eqs. [11] and [12] significantly reduces the σ% values below that of the single-parameter eqs. [8] and [9], except with 3,6,9-trioxaundecane and 5,8,11-trioxapentadecane. For all of the systems studied here, the three-parameter equation of McAllister (eq. [13]) gives very good results. The values of σ% are in the range of only 0.2–0.4%. Use of the three-parameter equation of Auslaender (eq. [14]), however, gives higher σ% values than that of the three-parameter equation of McAllister (eq. [13]).

From this study it can be concluded that all of the correlating equations considered are effective in the empirical fitting of viscosity data for (polyether + propylamine) mixtures. This is not surprising in view of the number of adjustable parameters in each equation, where a very large variability of the experimental measurements with composition of the solvent mixtures is observed. Thus it become very difficult to suggest any general rule in establishing the effectiveness of one fitting over the other. The comparisons are, however, more suitable with the same number of adjustable parameters. Thus the equations having one adjustable parameter (Tamura and Kurata, and Hind et al.) show a good correlating ability over the equation of Grunberg–Nissan and Katti and Chaudhry.

© 2002 NRC Canada

With respect to the three-parameter equations, it should be noted that the McAllister equation (eq. [13]) gives the best fit of the experimental values. Furthermore, the reproducibility of the experimental point is similar to those obtained by applying the two-parameter equations of Heric-Brewer and McAllister (eq. [11] and 12]).

Thermodynamics of mixtures containing a very strongly polar compound. Part II. Solid–liquid equilibria for sulfolane + nitrile systems and characterization of the sulfolane–nitrile and sulfolane–1-alkyne interactions in terms of DISQUAC

Urszula Domanska and Juan Antonio Gonzalez

Abstract: Equilibrium temperatures for solid–liquid transitions of mixtures formed by sulfolane and ethanenitrile, propanenitrile, butanenitrile, or pentanenitrile were measured by a dynamic method. The solid–liquid equilibria phase diagrams show positive deviations from Raoult's law, except for the system with ethanenitrile, which is nearly ideal. The sulfolane–nitrile and sulfolane–1-alkyne interactions have been characterized in terms of the DISQUAC group contribution model. DISQUAC properly represents a complete set of thermodynamic properties: solid–liquid equilibria, molar excess enthalpies, and natural logarithms of activity coefficients. DISQUAC predictions are valid over a wide temperature range.

Key words: solid–liquid equilibria, thermodynamics, mixtures, interactions.

Résumé : Faisant appel à une méthode dynamique, on a mesuré les températures d'équilibre de transitions solide–liquide de mélanges formés de sulfolane et d'éthanenitrile, de propanenitrile, de butanenitrile ou de pentanenitrile. Les diagrammes de phase pour les équilibres solide–liquide présentent des déviations positives par rapport à la loi de Raoult, excepté pour le système de l'éthanenitrile qui est pratiquement idéal. Les interactions sulfolane–nitrile et sulfolane–alk-1-yne ont été caractérisées en fonctions du modèle DISQUAC de contribution des groupes. Le modèle DISQUAC représente assez bien un ensemble complet de propriétés thermodynamiques: équilibre solide-liquide, enthalpies molaires en excès ou logarithmes naturels des coefficients d'activité. Les prédictions découlant du modèle DISQUAC sont valides sur un large éventail de températures.

Mots clés : équilibre solide–liquide, thermodynamique, mélanges, interactions.

[Traduit par la Rédaction]

Introduction

We are engaged in a systematic study of solutions containing a component with a very high dipolar moment (μ) in the gas phase, e.g., propylene carbonate (μ = 4.94 D (1)), 1-methyl-2-pyrrolidinone (μ = 4.09 D (1)), dimethyl sulfoxide (DMSO; μ = 4.06 D (1)), or sulfolane (μ = 4.80 D (1)).

Sulfolane is a globular molecule in which only the negative end of its large dipole moment is exposed (2, 3) and thus it cannot act as a proton acceptor–donor (4, 5). Also, because of the steric hindrance of its globular shape, sulfolane does not easily interact with other molecules (2, 3, 6, 7). Below its melting point (301.60 K (1)), it is also a weakly structured substance (8). This conclusion may be drawn from the insensivity to temperatures of its dipole moment in the liquid phase and below the melting point (9, 10) — that is, in the stability range of the mesophase crystal (crystal I) (11), in which molecules can freely rotate, until a transition temperature (288.6 K (2, 8)) is gained at which an ordinary nonrotational phase (crystal II) is formed.

Due to these properties, mixtures of sulfolane are very interesting from a theoretical point of view. Systems with benzene, CCl_4, or 1,4-dioxane are almost regular (12) since volumes or dielectric constants on mixing scarcely exhibit noticeable deviations from ideal values (13–16). The activity coefficients of components obtained from solid–liquid equilibrium measurements are also close to 1 (14–16). Nevertheless, solid–liquid equilibrium phase diagrams for sulfolane + CCl_4 or 1,4-dioxane mixtures indicate the presence of complexes (15, 16). Their formation has been attributed more to favourable packing rather to strong interactions (15, 16). On the other hand, sulfolane is almost insoluble with many

organic liquids, such as *n*-alkanes, cycloalkanes, or long chain 1-alkanols (17–22). These systems show strong positive deviations from Raoult's law.

In this work, we report solid–liquid equilibrium measurements for sulfolane + nitrile systems. Moreover, we characterize solutions with these compounds and sulfolane + 1-alkyne mixtures in terms of DISQUAC (23, 24), an extended-group contribution model based on the rigid-lattice theory developed by Guggenheim (25). Previously, we have reported solid–liquid and liquid–liquid equilibria data on sulfolane + 1-alkanol mixtures (26). Binary systems formed by sulfolane and one organic solvent, such as alkane, benzene, toluene, CCl_4, or 1-alkanol have been also characterized in terms of DISQUAC (26).

Experimental

Materials

Sulfolane was supplied by Aldrich (98% reagent) and was twice vacuum distilled at a pressure below 2.7 kPa to yield a colourless and odourless product. To minimize the contact of this deliquescent reagent with moist air, the product was kept in sealed bottles in a dessicator. Ethanenitrile (99.93% HPLC), propanenitrile (99%), butanenitrile (>99%), and pentanenitrile (99.5% GC) from Aldrich, were stored over molecular sieves (4 Å) and used without further purification.

Procedure

The solubilities were determined using a dynamic method described elsewhere (27). The mixtures of solute and solvent were prepared by mass, with weighings accurate to 0.0002 g. Conversion to molar quantities was based on the relative atomic mass table issued by IUPAC (28). The mixtures were well stirred using a magnetic stirrer and heated very slowly with a heating rate that did not exceed 2 K h^{-1} near the equilibrium temperature. The temperature at which the last set of crystals disappeared was taken as the temperature of the solution–crystal equilibrium. The temperature was measured using a calibrated platinum-resistance thermometer (Authoterm2 by Gallenkamp), with an accuracy of 0.01 K. The reproducibility of the measurements was better than 0.1 K, which corresponded to an estimated error in mol fraction of Δx = 0.001.

Results

Experimental solid–liquid equilibrium temperatures of the sulfolane(1) + nitrile(2) systems considered in this work are collected in Tables 1– 4. There are no data in the literature for comparison. The sulfolane(1) + ethanenitrile(2) system presents an eutectic point (determined graphically (29)): x_{1e} = 0.253, T_e = 217.03 K. This solution is nearly ideal (Fig. 1). The remaining mixtures show positive deviations from Raoult's law, which increase with the size of the nitrile (Fig. 2).

DISQUAC

Assessment of geometrical parameters

When DISQUAC is applied, the total relative molecular volumes (r_i), surfaces (q_i), and molecular surface fractions (α_{si}), of the compounds present in the mixture are usually calculated additively on the basis of the group volumes (R_G) and surfaces (Q_G), recommended by Bondi (30). As volume and surface units, the volume R_{CH_4} and Q_{CH_4} of methane are arbitrarily taken (31). For the sulfolane group, r_{c-SO_2} = 1.18574; q_{c-SO_2} = 0.89655 (26). The geometrical parameters for other groups referred to in this work are given elsewhere (31–33).

Equations

The equations used to calculate molar Gibbs energies (G^E_m) and molar excess enthalpies (H^E_m) are the same as in other applications (34). The interactional terms in the excess thermodynamic properties G^E_m and H^E_m contain a DIS and a QUAC contribution, which are calculated independently by classical formulas and then simply added. The degree of nonrandomness is thus expressed by the relative amounts of dispersive and quasichemical terms

$$[1] \qquad G^E_m = G^{E,COMB}_m + G^{E,DIS}_m + G^{E,QUAC}_m$$

$$[2] \qquad H^E_m = H^{E,DIS}_m + H^{E,QUAC}_m$$

where $G^{E,COMB}_m$ is the Flory–Huggins combinatorial term (31, 35). For the QUAC contribution, the reference value z = 4 was chosen for the coordination number.

The temperature dependence of the interaction parameters g_{st}, h_{st}, and c_{pst} has been expressed in terms of the DIS and QUAC interchange coefficients (34), $C^{DIS}_{st,1}$ and $C^{QUAC}_{st,1}$, where s and t are the two groups present in the solution (s ≠ t); and l = 1 (Gibbs energy; $C^{DIS/QUAC}_{st,1} = g^{DIS/QUAC}_{st}(T_0)/RT_0$); l = 2 (enthalpy; $C^{DIS/QUAC}_{st,2} = h^{DIS/QUAC}_{st}(T_0)/RT_0$); and l = 3 (heat capacity; $C^{DIS/QUAC}_{st,3} = c^{DIS/QUAC}_{stp}(T_0)/R$). T_0 = 298.15 K is the scaling temperature.

The equation of the solid–liquid equilibrium curve of a pure-solid component 1, including one first-order transition (as in the case of sulfolane (2, 8)) is (29, 36):

$$[3] \qquad -\ln x_1 = (\Delta H_{fus1}/R)\,[1/T - 1/T_{fus1}] + (\Delta H'_{trs1}/R)\,[1/T - T'_{trs1}] + \ln \gamma_1$$

Conditions at which eq. [3] is valid have been specified elsewhere (37). In eq. [3], x_1 is the mole fraction and γ_1 the activity coefficient of component 1 in the solvent mixture, at temperature T. In this work, DISQUAC is used to calculate γ_1. $\Delta H_{fus\,1}$ and $T_{fus\,1}$ are the molar enthalpy of fusion and the the melting temperature, respectively, of component 1, while $\Delta H'_{trs1}$ and T'_{trs1} represent the molar enthalpy of transition and transition temperature, respectively. For sulfolane, ΔH_{fus1} = 1428 J mol (1), T'_{trs1} = 288.6 K (2,8), and $\Delta H'_{trs1}$ = 7860 J mol^{-1} (38). For nitriles, ΔH_{fus} values were taken from ref. 1.

Estimation of DISQUAC interaction parameters

The general procedure applied for the fitting of the DISQUAC interaction parameters has been explained in detail in the first article of this series (26) and will not be repeated. Some remarks are given below. Sulfolane + nitrile or 1-alkyne mixtures are characterized by the following four types of surfaces: type *a*, CH_3 or CH_2 in nitriles or 1-alkynes; type *c*, *c*-CH_2 in sulfolane; type *w*, *c*-SO_2 in sulfolane; type *s*, *s* = *n*, CN in nitriles or *s* = *y*, HC≡C in 1-alkynes. We therefore have six types of contacts: (*a*, *c*), (*a*, *w*), (*c*, *w*), (*a*, *s*) (*c*, *s*), and (*s*, *w*) with *s* = *n* or *y*.

Because sulfolane is a five-membered ring, the (*a*, *c*) contacts must be fitted to experimental data for cyclopentane +

≥1-Octyne	2.00	–1.75	3.00	–5.30

[a] l = 1, Gibbs energy; l = 2, enthalpy.
[b] Type *c*, *c*-CH_2 in cyclopentane or sulfolane; type *n*, CN in alkanenitriles
[c] Type *w*, *c*-SO_2 in sulfolane.
[d] Type *y*, HC≡C in 1-alkynes.

n-alkane systems, which are described only by dispersive parameters (26). In our previous work (26), the interchange coefficients for the (*a*, *w*) and (*c*, *w*) contacts were determined assuming that $C^{DIS}_{ac,1}$ (l = 1, 2, 3) = 0. This is reasonable in view of the low values of the excess functions of cyclopentane + *n*-alkane systems (26). Here, we have proceeded in a similar manner.

The interaction parameters for the (*a*, *n*) contacts are known from experimental data for nitrile + *n*-alkanes mixtures (33). The $C^{DIS/QUAC}_{cn,1}$ coefficients should be determined using data for nitrile + cyclopentane systems (see above). Unfortunately, for this class of solutions there are no data available in the literature. We therefore estimated the mentioned coefficients (Table 5) taking into consideration the liquid–liquid equilibria measurements for nitrile + alkane mixtures (39–41), and assuming, as in many other applications (42–54) that $C^{QUAC}_{an,1} = C^{QUAC}_{cn,1}$. These coefficients are well known from the DISQUAC analysis of nitrile + (*n*-alkane or cyclohexane) systems (33).

The interaction parameters for the (*a*, *y*) and (*c*, *y*) contacts have been previously estimated by us on the basis of experimental data for 1-alkyne + (*n*-alkane or cyclohexane) mixtures (32).

Now, the $C^{DIS/QUAC}_{cw,1}$ and $C^{DIS/QUAC}_{wy,1}$ (l = 1, 2, 3) coefficients must be determined. The former were obtained using experimental data for sulfolane + nitrile systems; the latter were calculated from data for sulfolane + 1-alkyne mixtures (Table 5). Due to the lack of H^E_m measurements at different temperatures for the solutions under study, the third DIS and QUAC coefficients were neglected.

Results and discussion

DISQUAC predictions for the mixtures are compared with experimental data in Tables 6–8. Graphical comparison are shown in Figs. 1–4.

In view of these results, we can conclude that DISQUAC favorably represents the thermodynamic properties of the mixtures under study. It is noteworthy that the same interaction parameters can be used to describe solutions with isomeric nitriles (Table 7). The model can be applied over a rather wide range of temperature. Note the good results obtained for solid–liquid equilibria of sulfolane(1) + nitrile(2) systems are at very low temperatures (Table 6). DISQUAC predicts eutectic points (Table 6). For the mixture with ethanenitrile, $x_{1e} = 0.261$ and $T_e = 218.03$ K, which compare well with the experimental values ($x_{1e} = 0.253$, $T_e = 217.03$ K).

The modified UNIFAC model (55, 56) has been applied to characterize mixtures formed by sulfolane and nitrile, or by sulfolane and 1-alkynes assuming that sulfolane is an homogeneous molecule (57). DISQUAC, however, substantially improves the results for sulfolane + nitrile systems, because the UNIFAC parameters were determined using only H^E data for the solutions (57).

Discussion

It is interesting to compare experimental results of mixtures containing sulfolane, DMSO, or acetonitrile. These

compounds have different dipole moments, but similar effective dipole moments (Table 9). This quantity is defined as (58–62)

$$[4] \qquad \mu = [\mu^2 N_A/(4\pi\varepsilon_o\ V k_B T)]^{1/2}$$

where N_A is Avogadro's number, k_B is Boltzmann's constant, ε_o is the permittivity of vacuum, and V is the molar volume. The effective dipole moment is a very useful property for characterizing the impact of polarity on bulk properties. Moreover, it gives an indication of the ratio between dipolar and nonpolar interactions (63).

For ethanenitrile(1) + *n*-hexane(2), the upper critical solution temperature (UCST) is 350.15 K (39). For sulfolane(1) + *n*-hexane(2), the UCST must be much higher. Note that the liquid–liquid equilibrium temperature at $x_1 = 0.013$ is 373.15 K (18). DISQUAC predicts 476.6 K for the UCST and 475 K for DMSO(1) + *n*-hexane(2) (64).

On the other hand, for ethanenitrile(1) + ethanol(2), H^E_m ($x_1 = 0.5$; 298.15 K) = 1496 J mol^{-1} (65). For sulfolane(1) + ethanol(2), H^E_m ($x_1 = 0.5$; 303.15 K) = 1971 J mol^{-1} (66), and for DMSO(1) + ethanol(2), H^E_m ($x_1 = 0.5$; 298.15 K) = 411 J mol^{-1} (67). These data reveal that sulfolane–alkane and sulfolane–1-alkanol interactions are very weak. The positive and relatively low H^E_m values of sulfolane + nitrile or 1-alkyne systems (except for the solution with ethanenitrile, Table 7) might be attributed to strong interactions between unlike molecules. The excess enthalpy of this class of solutions and the observed increase in H^E_m for sulfolane + nitrile mixtures when the effective dipole moment of the nitrile

1-Hexyne	303.15		1.58	1.75	1.87
	313.15		1.55	1.73	1.86
1-Heptyne	303.15		2.13	2.09	2.10
	313.15		2.08	2.05	2.08
1-Octyne	303.15		2.64	2.48	2.32
	313.15		2.62	2.42	2.30

decreases have, however, been mainly ascribed to the breaking of the dipole–dipole interactions between nitrile molecules in presence of sulfolane (68, 69). The solid–liquid equilibrium measurements carried out in this work also show that sulfolane + nitrile systems present positive deviations from Raoult's law. Note that the mixture with ethanenitrile is nearly ideal.

Finally, it should be noted that the excess molar volumes (V_m^E) of sulfolane + nitrile or 1-alkyne systems are large and negative. At equimolar composition and 303.15 K, $V_m^E = -0.726$ cm^3 mol^{-1} and –1.36 cm^3 mol^{-1} for the systems with butanenitrile (70) and 1-heptyne (71), respectively. In addition, V_m^E decreases with increasing temperature (6, 70). It has been proposed by assuming that, in the case of mixtures with nitriles, nitrile–nitrile interactions predominate over weak sulfolane–nitrile interactions (6, 70) as well as in terms of packing effects (6, 70).

It is therefore possible to conclude that sulfolane may play the role of an almost inert diluent and thus limits its action to a disturbing effect of the other component; this is probably due to the steric hindrance of this globular molecule (2, 3, 6, 7, 17, 26, 68, 70).

Conclusions

Equilibrium temperatures for solid–liquid transitions of mixtures formed by sulfolane and ethanenitrile, propanenitrile, butanenitrile, or pentanenitrile mixtures are reported. The solid–liquid equilibrium phase diagrams show positive deviations from Raoult's law, except for the system with acetonitrile, which is nearly ideal.

DISQUAC interaction parameters are given for binary systems of sulfolane with nitriles or 1-alkynes. DISQUAC reasonably represents a complete set of thermodynamic properties (solid–liquid equilibria, molar excess enthalpies, natural logarithms of activity coefficients at infinite dilution) over a wide temperature range.

Sulfolane may play the role of an almost inert diluent — probably due to the steric hindrance of this globular molecule.

Ryanoids and related compounds — Isolation and characterization of 11 new minor ryanoids from the plant *Ryania Speciosa* Vahl

Luc Ruest, Marco Dodier, Hélène De Sève, Christian Lessard, and Pascal Mongrain

Abstract: In a search for minor ryanoids from the plant *Ryania Speciosa* Vahl, we recently characterized 11 new members of that family of natural compounds. Most of them represent ryanodine (**1**) and dehydroryanodine (**2**) with a modified stage of oxidation in ring C. A second member of the new 4-deoxy series has been identified.

Key words: minor natural ryanoids, ryanodine, dehydroryanodine, deoxyryanoids.

Résumé : En cherchant à identifier les ryanoïdes mineurs de la plante *Ryania Speciosa* Vahl, nous avons caractérisé récemment onze nouveaux membres de cette famille de produits naturels. La plupart de ces composés représentent la ryanodine (**1**) et la déhydroryanodine (**2**) avec un degré d'oxydation modifié dans le cycle C. Un deuxième membre de la série 4-déoxyryanoïde a été identifié.

Mots clés : ryanoïdes mineurs naturels, ryanodine, déhydroryanodine, déoxyryanoïde.

Introduction

Ryanodine (**1**) (Scheme 1) is known to be a potent modulator of the sarcoplasmic reticulum calcium release channel (1). After ryanodine's structure elucidation by Wiesner (2), groups (3–14) have reported that this complex polycyclic, polyhydroxylic compound was not the sole insecticidal component in the plant *Ryania Speciosa* Vahl. In a recent review on the pharmacology of ryanodine and related compounds (1), 18 structurally related compounds, the ryanoids, were reported. More recently (13), four other minor ryanoids have been identified. These structures have been elucidated by extensive NMR analysis and also by X-ray diffraction. These natural compounds represent a very interesting family of molecules, in which the parent structure is slightly modified by the different orientations of the functional groups and the nature of the functional groups. Most of the natural ryanoids would be relatively difficult to obtain by multistep transformations of ryanodine (**1**) or 9,21-didehydroryanodine (**2**), the two most abundant ryanoids in that plant. The total synthesis of ryanodol (**3**) (15) and 3-epiryanodine (not shown) (16) from ryanodol (**3**) have been reported.

The biological activities of these metabolites and of several of their derivatives have been studied (1, and refs. therein). A number of hypotheses have been formulated on the effects of specific structural moieties on the binding affinity of these compounds in the ryanodine binding site (1, 17–29).

In a search for other members of this family, we have very recently identified new ryanoids **4**–**14** (Fig. 1) in the extracts of the plant. Compound **5** represents a second known member of a novel series — the 4-deoxyryanoids (13). These 11 metabolites are very minor components, each one representing ~0.1–5.0 ppm quantities (w/w) of the dried powdered wood, compared with approximately 500–800 ppm for **1** and **2**. With the 11 new ryanoids, this family of natural compounds presently has 32 identified metabolites.

Results and discussion

The discovery of the new ryanoids came after the usual separation of the known major compounds (1). In this paper, we will present, for each new compound, the arguments (mainly NMR data) that led us to propose the nature, the position, and the orientation of the substituents. In the experimental section, we will list the new compounds in order of their increasing polarity on silica gel, when mixtures of chloroform and methanol are used as the solvent.

The ^{1}H NMR spectrum of diester **4** shows two series of pyrrole aromatic hydrogens together with the usual singlet at δ 5.53 for the C3 hydrogen and a doublet (J = 10.5 Hz) at δ 5.44 for the C10 hydrogen. Synthetically, acylation of ryanodine (**1**) (Scheme 1) with α-pyrrole carboxylic acid and dicyclocarbodiimide (30) afforded compound **4** in low yield (10%).

The ^{1}H NMR spectrum of compound **5** shows that the C21 hydrogens (at δ 4.91) are magnetically equivalent and that they are coupled (J = 1.8 Hz) with the axial hydrogen at C8 (allylic coupling). The configuration at C10 was deduced by irradiating the equatorial C8 hydrogen (at δ 2.20): this

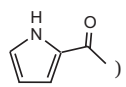
2: 9,21-Didehydroryanodine



operation resulted in a 20% enhancement of the signal at δ 4.26 (W coupling), indicating the equatorial orientation of that hydrogen.

For compound **6**, the C10 hydrogen appears as a broad singlet at δ 3.27. The intensity of this signal was increased 30% by irradiating at δ 1.54 (equatorial C8 hydrogen). This result is consistent with a W coupling and an equatorial orientation of the C10 hydrogen. The absence of the usual multiplet for the C9 hydrogen, together with the downfield shift of the C9 methyl group (now a singlet at δ 1.35), indicates the presence of a hydroxyl group at position 9. The equatorial orientation of the C9 methyl group was deduced by the absence of W coupling between the methyl group and the axial C8 hydrogen. An axial methyl group at that position indeed shows a W coupling with axial hydrogens at the C8 and (or) C10 positions (vide infra for compound **14**).

The ^{1}H NMR spectrum of ryanoid **7** is consistent with the proposed structure: the axial hydroxyl groups at positions 8 and 9 account for a broad singlet at δ 3.73 (this is the equatorial hydrogen at C8) and a methyl singlet at δ 1.39 that overlaps the CH_3-C1 signal (this is the equatorial methyl group at C9). The signal at δ 3.35 is increased by 50% upon

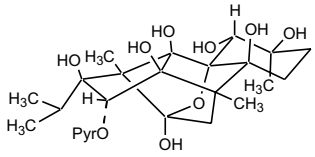
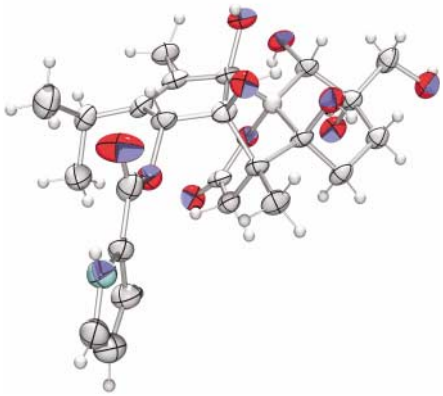
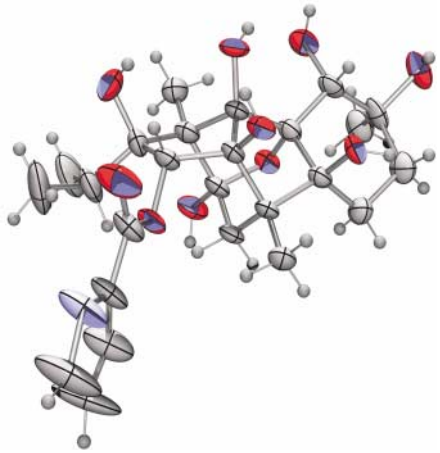
11: 9,21-Dihydroxy-anhydroryanodine



14: 9β-Hydroxyryanodine





irradiation of the signal at δ 3.73. This increment shows a significant coupling between these two hydrogens due to a mutual W orientation. Ryanoid **8** shows the usual ^{1}H NMR signals of the anhydro-9,21-dehydroryanodine series, with the C3 hydrogen as a quartet at δ 6.20 and narrow multiplets at δ 5.45 and 5.25 for the C21 hydrogens. The axial orientation of the hydroxyl group at position 8 is revealed by the small coupling constants between $H_{eq}C8$ (δ 4.63) and H_2C7 (J = 2.3 and 3.7 Hz). The axial orientation of HC10 was revealed by a COSY experiment, which clearly showed an allylic coupling with both C21 hydrogens. No W coupling between HC10 and HC8 was observed under selective irradiation.

Compound **9** represents the second known member of the 4-deoxyryanoid series (13). An unusual doublet (J = 8.4 Hz) at δ 5.65 for the C3 hydrogen suggests the presence of a vicinal hydrogen at C4 — this new hydrogen signal appears at δ 3.20 as a doublet of doublets (J = 8.4 and 1.5 Hz). The small coupling constant (1.5 Hz) is due to a mutual W orientation of HC4 with one hydrogen at C14, which also appears as a doublet of doublets at δ 1.71. A narrow multiplet at δ 3.99 accounts for the equatorial hydrogen at C8, and the axial hydrogen at C10 appears as a doublet (J = 10.7 Hz) at δ 3.97, in accordance with an equatorial orientation of the methyl group at C9.

Ryanoid **10** is the "ryanodine version" of compound **8**. The axial orientation of the hydroxyl group at C8 is revealed by a narrow signal at δ 4.54, which represents the equatorial hydrogen at that position. This is confirmed by the small coupling constants of that hydrogen with the C7 hydrogens appearing at δ 2.24 and 1.65. Our assigned stereochemistry at C10 follows the same arguments used for compound **8** — strong allylic coupling between axial HC10 and H_2C21, and no W coupling with the equatorial C8 hydrogen.

New compound **11** belongs to the anhydroryanodine series, with HC3 (m) at δ 6.17, the C1 methyl group at δ 1.87, and the C14 methylene as two doublets (J = 19.7 Hz) at δ 3.44 and 2.58. The unequivalent hydrogens at C21 appear as two sharp doublets (J = 10.8 Hz) centered at δ 3.44, suggesting the presence of two hydroxyls at positions 9 and 21. The very sharp singlet at δ 4.46 is consistent with an axial hydrogen at C10 (no W coupling with the C8 equatorial hydrogen nor with the C21 hydrogens) and an equatorial orientation of the hydroxymethyl at C9. In Fig. 2 the ORTEP view for this natural crystalline ryanoid confirms the deductions made by the preceeding NMR analysis.

Compound **12** shows a doublet (J = 10.4 Hz) at δ 4.07, which is consistent with a diaxial relationship between HC10 and HC9. An ABX pattern centered at δ 3.66 represents the equatorial H_2C21 bearing a hydroxyl group. The remaining signals in the ^{1}H NMR spectrum are easily assigned.

The ^{1}H NMR spectrum of ryanoid **13** shows an olefinic hydrogen at δ 5.62 (broad singlet) near the HC3 signal (δ 5.63). Irradiation at δ 5.62 produced a noticeable sharpening of the broad doublets at δ 4.25 and 4.08, which thus represents a hydroxymethyl group attached to C9. It also revealed vicinal coupling, with two doublets of doublets located at δ 2.66 and 1.84 that represent H_2C7. In addition, this irradiation revealed the position and orientation of the axial allylic HC10: it appears as a broad singlet at δ 4.86 and is partly obscured by the solvent signal, which appears at δ 4.87. This broad singlet is enhanced by 15% upon the same irradiation, which allows us to deduce a β pseudoaxial orientation for HC10. Identification of the other signals in ^{1}H NMR spectrum of compound **13** was not a problem.

New ryanoid **14**, actually the most polar known ryanoid, was shown to be the epimer of known 9-hydroxyryanodine

© 2002 NRC Canada

(11). Its ^{1}H NMR spectrum shows, in particular, a singlet (δ 4.21) whose intensity is enhanced by 15% upon irradiation of the methyl singlet appearing at δ 1.35. Alternatively, irradiation of the singlet at δ 4.21 enhanced the intensity of this methyl group by 25% (W coupling). This situation clearly illustrates the diaxial relationship between HC10 and CH_3-C9. The ORTEP view of this crystalline material (Fig. 2) corroborates the proposed structure deduced from ^{1}H NMR analysis.

The biological activities of the new ryanoids and their affinities for ryanodine binding sites are currently under analysis in the laboratories of Professor William Welch, Department of Biochemistry, University of Nevada, Reno, Nevada.

Experimental

Melting points were recorded on a Reichert hot stage apparatus and are uncorrected. Mass spectra (MS) and peak matching (HRMS) data were determined at 70 eV on a VG Micromass ZAB-1F spectrometer. The ^{1}H (300 MHz) NMR spectra were recorded on a Bruker AC-300 instrument (with CHD_2OD as internal standard centered at δ 3.30). The usual abbreviations have been used to indicate the multiplicity of the proton signals. Analytical and preparative thin layer chromatography were performed with glass plates (0.25 or 0.5 mm) precoated with silica gel 60F-250 (Merck). The typical solvent was 5–15% of methanol in chloroform, to which 0.5–2.0% of commercial 40% aqueous methylamine may be added. For some special cases, we also used mixtures of ethyl acetate in hexane (40–80%). Column chromatography (flash) was performed with Merck silica gel (200–400 mesh). High performance liquid chromatography (HPLC) used a Waters model 510 instrument equipped with a Vydac C18 reverse-phase preparative column (15 μm, 2.5 × 25 cm) and a Waters 484 tunable UV detector set at 254 nm. The typical solvent for HPLC preparative separation was 40% methanol in water. All reactions were performed under argon atmosphere and in solvents purified by standard methods. Reaction mixtures were extracted with at least five portions of distilled ethyl acetate. Solutions in organic solvents were washed with brine, dried over anhydrous sodium sulfate, filtered, and then stripped of solvents with a rotatory evaporator connected to a water aspirator.

Isolation of the new ryanoids

Extraction of powdered Ryania wood was done as previously described (11). The isolation of each of the new ryanoids was done as described above. After numerous chromatographic separations and purification operations, we isolated each of the new ryanoids **4**–**14** in quantities of approximately 3 to 100 mg, starting from a lot of ~100 g of crude extract (obtained from ~ 100 kg of dry powder wood). The presentation of these new ryanoids follows their *increasing polarities* — the first compound (**4**) in the following is therefore the least polar one. Occasionally, polarities relative to already known ryanoids (1, 4, 6, 12, 13) will be given to locate these new compounds by thin layer chromatography.

New ryanoids less polar than ryanodine (1)

*3,10-Di-*O*-Pyrrolecarbonylryanodol (10-*O*-pyrrolecarbonylryanodine) (4)*

By TLC analysis, compound **4** is slightly less polar than the known Ester A (8β-hydroxy-10-*O*-methyl-10-epiryanodine), (1, 4, 6) but slightly more polar than 4-deoxyester A (13). Amorphous solid: ^{1}H NMR (CD_3OD) δ: 7.03, 6.86, 6.23 and 6.96, 6.91, 6.19 (two series of doublets of doublets for pyrrole rings hydrogens), 5.57 (s, 1H, HC3), 5.44 (d, J = 10.5 Hz, 1H, HC10), 2.58 (d, J = 13.8 Hz, 1H, H_AC14), 2.23 (m, 1H, HC13), 2.22–2.05 (m, 2H, $H_{ax}C7$, HC9), 1.98 (d, J = 13.8 Hz, 1H, H_BC14), 1.62 (m, 2H, $H_{eq}C7$, $H_{ax}C8$), 1.33 (m, 1H, $H_{eq}C8$), 1.31 (s, 3H, CH_3C1), 1.08 (d, J = 6.7 Hz, 3H, H_3C18), 0.91 (s, 3H, CH_3C5), 0.86 (d, J = 6.6 Hz, 3H, CH_3C9), 0.71 (d, J = 6.4 Hz, 3H, H_3C19). MS *m*/*z*: 475 ([M – $C_5H_5O_2N$]$^+$). HRMS calcd. for $C_{25}H_{33}NO_8$ ([M – $C_5H_5O_2N$]$^+$): 475.2206; found: 475.2201.

Synthesis of diester 4 from ryanodine

At ambient temperature, a solution of dicyclohexylcarbodiimide (230 mg, 1.11 mmol) in dry dichloromethane (3 mL) was transferred (canula) to a solution of ryanodine (133 mg, 0.27 mmol), pyrrole-2 carboxylic acid (128 mg, 1.15 mmol), 4-dimethylaminopyridine (1 mg), and triethylamine (5 μL) in dry THF (5 mL) (30). After 40 h, the reaction mixture was poured into aqueous sodium bicarbonate and extracted. The crude product was chromatographed to give a low yield (17 mg, 10%) of diester **4** together with unreacted starting ryanodine (93 mg).

10-Epi-9,21-didehydroryanodine (5)

This compound was obtained from the extracts by HPLC techniques combined with careful multi-elution preparative thin layer chromatography using a mixture of chloroform–methanol (95:5) as the solvent. It is slightly more polar than ester A (1, 4, 6), but less polar than the known 3-*O*-benzoylryanodol (13); mp 198–200°C. ^{1}H NMR (CD_3OD) δ: 7.03, 6.86, and 6.23 (3 dd for pyrrole ring hydrogens), 5.67 (s, 1H, HC3), 4.91 (d, J = 1.8 Hz, 2H, H_2C21), 4.26 (s, 1H, $H_{eq}C10$; this signal is increased by ~20% upon irradiation at 2.20 ppm), 2.65 (m, 1H, $H_{ax}C8$), 2.58 (d, J = 13.8 Hz, 1H, H_AC14), 2.18 (m, 3H, HC13, $H_{ax}C7$ and $H_{eq}C8$), 1.87 (d, J = 13.8 Hz, 1H, H_BC14), 1.50 (m, 2H, $H_{eq}C7$), 1.33 (s, 3H, CH_3C1), 1.07 (d, J = 6.8 Hz, 3H, H_3C18), 0.91 (s, 3H, CH_3C5), 0.73 (d, J = 6.4 Hz, 3H, H_3C19). MS *m*/*z*: 492 ([M + H]$^+$). HRMS calcd. for $C_{25}H_{34}NO_9$, MH$^+$): 492.2233; found: 492.2243.

*9α-Hydroxy-10-*O*-methyl-10-epiryanodine (6)*

This compound was obtained as above after HPLC techniques combined with careful multi-elution preparative thin layer chromatography using a mixture of chloroform–methanol (97:3) as the solvent. It is slightly more polar than the known ester B (1, 4), but less polar than ester C_2 (1, 4); mp 212–215°C. ^{1}H NMR (CD_3OD) δ: 7.02, 6.85, and 6.23 (3 dd for pyrrole ring hydrogens), 5.66 (s, 1H, HC3), 3.63 (s, 3H, OCH_3), 3.27 (s, 1H, $H_{eq}C10$; this signal is increased by ~30% upon irradiation at 1.54 ppm), 2.58 (d, J = 13.8 Hz, 1H, H_AC14), 2.21 (m, 1H, HC13), 2.04 (m, 1H, $H_{ax}C8$), 1.88 (m, 1H, $H_{ax}C7$), 1.84 (d, J = 13.8 Hz, 1H, H_BC14),

1.54 (m, 1H, $H_{eq}C8$), 1.39 (s, 3H, CH_3C1), 1.35 (s, 3H, CH_3C9) (this signal shows no enhancement by irradiation at δ 2.04), 1.31 (m, 1H, $H_{eq}C7$), 1.07 (d, *J* = 6.8 Hz, 3H, H_3C18), 0.89 (s, 3H, CH_3C5), 0.72 (d, *J* = 6.4 Hz, 3H, H_3C19). MS *m/z*: 505 ($[M - H_2O]^+$). HRMS calcd. for $C_{26}H_{35}NO_9$ ($[M - H_2O]^+$): 505.2312; found: 505.2322.

8*β,*9*α-*Dihydroxy-10*-O-*methyl-10-epiryanodine (7)

This compound was obtained as above after HPLC techniques combined with careful multi-elution preparative thin layer chromatography using a mixture of chloroform–methanol (97:3) as the solvent. It is slightly more polar than the known ester G (3-*O*-nicotinoylryanodol) (1), but less polar than 10-*O*-acetylryanodol (13). Amorphous solid; ^{1}H NMR (CD_3OD) δ: 7.03, 6.86, and 6.23 (3 dd for pyrrole ring hydrogens), 5.64 (s, 1H, HC3), 3.73 (br s, 1H, HC8), 3.55 (s, 3H, CH_3-O-C10), 3.35 (s, 1H, HC10; this signal is increased by 50% upon irradiation at 3.73), 2.63 (d, *J* = 13.9 Hz, 1H, H_AC14), 2.43 (dd, *J* = 12.0 and 3.4Hz, 1H, $H_{ax}C7$), 2.21 (m, 1H, HC13), 1.90 (d, *J* = 13.7 Hz, 1H, H_BC14), 1.69 (dd, *J* = 12.0 and 1.5 Hz, 1H, $H_{eq}C7$), 1.39 (s, 6H, CH_3C1 and CH_3C9), 1.08 (d, *J* = 6.8 Hz, 3H, H_3C18), 0.95 (s, 3H, CH_3C5), 0.74 (d, *J* = 6.4 Hz, 3H, H_3C19). MS *m/z*: 539 ($[M]^+$). HRMS calcd. for $C_{26}H_{37}NO_{11}$: 539.2366; found: 539.2379.

8*β-*Hydroxy-9,21-didehydroanhydroryanodine (8)

This compound was obtained as above after HPLC techniques combined with careful multi-elution preparative thin layer chromatography using a mixture of chloroform–methanol (95:5) as a solvent. It is slightly more polar than 10-*O*-acetylryanodol (13), but less polar than ester D (1, 4, 6); mp 180–185°C (dec.). ^{1}H NMR (CD_3OD) δ: 7.05, 6.85, and 6.24 (3 dd for pyrrole ring hydrogens), 6.19 (m, 1H, HC3), 5.43 (apparent t, *J* = 2.0 Hz, H_AC21), 5.26 (apparent t, *J* = 2.0 Hz, H_BC21), 5.19 (br s, 1H, $H_{ax}C10$), 4.63 (br s, 1H, $H_{eq}C8$), 3.46 (d, *J* = 19.8 Hz, 1H, H_AC14), 2.76 (m, 1H, HC13), 2.54 (d, *J* = 19.8 Hz, 1H, H_BC14), 1.89 (dd, *J* = 14.5 and 2.3 Hz, 1H, $H_{eq}C7$), 1.88 (d, *J* = 2.2 Hz, 3H, CH_3C1), 1.68 (dd, *J* = 14.5 and 3.7 Hz, 1H, $H_{ax}C7$), 1.07 (d, *J* = 7.1 Hz, 3H, H_3C18), 1.01 (s, 3H, CH_3C5), 0.98 (d, *J* = 7.0 Hz, 3H, H_3C19). MS *m/z*: 471 ($[M - H_2O]^+$). HRMS calcd. for $C_{25}H_{29}NO_8$: 471.1893; found: 471.1896.

New ryanoids more polar than ryanodine (1)

4-Deoxy-8*β-*hydroxyryanodine (9)

This compound was obtained as above after HPLC techniques combined with careful multi-elution preparative thin layer chromatography using a mixture of chloroform-methanol (90:10) as the solvent. It is slightly more polar than 9-hydroxyryanodine (11), but less polar than 19-hydroxyryanodine (1, 12). Amorphous solid; ^{1}H NMR (CD_3OD) δ: 7.00, 6.84, and 6.21 (3 dd for pyrrole ring hydrogens), 5.65 (d, *J* = 8.4 Hz, 1H, HC3), 3.99 (br s, 1H, $H_{eq}C8$), 3.97 (d, *J* = 10.7 Hz, 1H, HC10), 3.20 (dd, *J* = 8.4 and 1.5 Hz, 1H, HC4), 2.40 (m, 1H, HC13), 2.34 (d, *J* = 13.6 Hz, 1H, H_AC14), 2.16 (dd, *J* = 13.7 and 3.3 Hz, 1H, $H_{ax}C7$), 2.00 (m, 1H, HC9), 1.71 (dd, *J* = 13.6 and 1.5 Hz, 1H, H_BC14), 1.52 (dd, *J* = 13.4 and 2.3 Hz, 1H, $H_{eq}C7$), 1.34 (s, 3H, CH_3C1), 1.14 (apparent t, *J* = 7.1 Hz, 6H, H_3C18 and CH_3C9), 0.82 (d, *J* = 6.4 Hz, 3H, H_3C19), 0.80 (s, 3H, CH_3C5). MS *m/z*: 450 ($[M - C_3H_7]^+$). HRMS calcd. for $C_{22}H_{28}NO_9$ ($[M - C_3H_7]^+$): 450.1764; found: 450.1756.

8*β-*Hydroxy-9,21-didehydroryanodine (10)

This compound was obtained as above after HPLC techniques combined with careful multi-elution preparative thin layer chromatography using a mixture of chloroform–methanol (88:12) as solvent. It is slightly more polar than the known 18-hydroxy-9,21-didehydroryanodine (1, 12). Amorphous solid; ^{1}H NMR (CD_3OD) δ: 7.01, 6.86, and 6.23 (3 dd for pyrrole ring hydrogens), 5.65 (s, 1H, HC3), 5.30 and 5.15 (two apparent t, *J* = 2.0 Hz, 1H each, H_AH_BC21), 4.95 (br s, 1H, HC10), 4.54 (br s, 1H, $H_{eq}C8$), 2.60 (d, *J* = 13.8 Hz, 1H, H_AC14), 2.24 (dd, *J* = 13.6 and 4.3 Hz, 1H, $H_{ax}C7$), 2.23 (m, 1H, HC13), 1.85 (d, *J* = 13.8 Hz, 1H, H_BC14), 1.64 (dd, *J* = 13.6 and 2.0 Hz, 1H, $H_{eq}C7$), 1.40 (s, 3H, CH_3C1), 1.09 (d, *J* = 6.7 Hz, 3H, H_3C18), 0.95 (s, 3H, CH_3C5), 0.73 (d, *J* = 6.4 Hz, 3H, H_3C19). MS *m/z*: 471 ($[M - 2H_2O]^+$). HRMS calcd. for $C_{25}H_{29}NO_8$ $[M - 2H_2O]^+$): 471.1893; found: 471.1901.

9*α,*21-Dihydroxyanhydroryanodine (11) (X-ray)

This compound was obtained as above after HPLC techniques combined with careful multi-elution preparative thin layer chromatography using a mixture of chloroform–methanol (85:15) as the solvent. It is slightly more polar than compound **10**; mp: 210–214°C (dec., MeOH–CH_2Cl_2). ^{1}H NMR (CD_3OD) δ: 7.06, 6.87, and 6.25 (3 dd for pyrrole ring hydrogens), 6.17 (m, 1H, HC3), 4.46 (s, 1H, HC10), 3.59 (d, *J* = 10.8 Hz, 1H, H_AC21), 3.44 (d, *J* = 19.7 Hz, 1H, H_AC14), 3.32 (d, *J* = 10.8 Hz, 1H, H_BC21), 2.76 (m, 1H, HC13), 2.58 (d, *J* = 19.7 Hz, 1H, H_BC14), 2.18 (m, 1H, $H_{ax}C8$), 1.87 (d, *J* = 2.3 Hz, 3H, CH_3C1), 1.80 (m, 1H, $H_{ax}C7$), 1.61 (m, 1H, $H_{eq}C8$), 1.49 (m, 1H, $H_{eq}C7$), 1.08 (d, *J* = 7.1 Hz, 3H, H_3C18), 0.99 (d, *J* = 7.0 Hz, 3H, H_3C19), 0.98 (s, 3H, CH_3C5). MS *m/z*: 489 ($[M - H_2O]^+$). HRMS calcd. for $C_{25}H_{31}NO_9$: 489.1999; found: 489.2010. This material was analyzed by X-ray diffraction (see Fig. 2).

21-Hydroxyryanodine (12)

This compound was obtained as above after HPLC techniques combined with careful multi-elution preparative thin layer chromatography using a mixture of chloroform–methanol (85:15) as the solvent. It is slightly more polar than compound **11**. Amorphous solid: ^{1}H NMR (CD_3OD) δ: 7.02, 6.87, and 6.23 (3 dd for pyrrole ring hydrogens), 5.62 (s, 1H, HC3), 4.07 (d, *J* = 10.4 Hz, 1H, HC10), 3.74 (dd, *J* = 10.6 and 4.1 Hz, 1H, H_AC21), 3.56 (dd, *J* = 10.6 and 6.3 Hz, 1H, H_BC21), 2.56 (d, *J* = 13.7 Hz, 1H, H_AC14), 2.26 (m, 1H, HC13), 2.10 (m, 1H, $H_{ax}C7$), 1.93 (d, *J* = 13.7 Hz, 1H, H_BC14), 1.92 (m, 1H, HC9), 1.60 (m, 2H, $H_{ax}C8$ and $H_{eq}C7$), 1.39 (s, 3H, CH_3C1), 1.30 (m, 1H, $H_{ax}C8$), 1.10 (d, *J* = 6.7 Hz, 3H, H_3C18), 0.89 (s, 3H, CH_3C5), 0.74 (d, *J* = 6.4 Hz, 3H, H_3C19). MS *m/z*: 491 ($[M - H_2O]^+$). HRMS calcd. for $C_{25}H_{33}NO_9$ ($[M - H_2O]^+$): 491.2155; found: 491.2158.

9β-Hydroxyryanodine (14) (X-ray)

This compound was obtained as above after HPLC techniques combined with careful multi-elution preparative thin layer chromatography using a mixture of chloroform–methanol (80:20) as the solvent. It is slightly more polar than compound **13**; mp 165–168°C (dec.). ^{1}H NMR (CD_3OD) δ: 7.03, 6.86, and 6.23 (3 dd for pyrrole ring hydrogens), 5.63 (s, 1H, HC3), 4.21 (s, 1H, HC10; this signal is increased by 15% upon irradiation at 1.35), 2.56 (d, J = 13.7 Hz, 1H, H_AC14), 2.25 (m, 1H, HC13), 2.10 (m, 1H, $H_{ax}C8$), 2.02 (m, 1H, $H_{ax}C7$), 1.88 (d, J = 13.7 Hz, 1H, H_BC14), 1.51 (m, 1H, $H_{ax}C7$), 1.39 (s, 3H, CH_3C1), 1.35 (s, 3H, H_3C9), 1.31 (m, 1H, $H_{eq}C8$), 1.09 (d, J = 6.8 Hz, 3H, H_3C18), 0.89 (s, 3H, CH_3C5), 0.74 (d, J = 6.4 Hz, 3H, H_3C19). MS *m/z*: 491 ($[M - H_2O]^+$). HRMS calcd. for $C_{25}H_{33}NO_9$ ($[M - H_2O]^+$): 491.2155; found: 491.2148. This material was analyzed by X-ray diffraction (see Fig. 2).

Acknowledgments

We are grateful to Professor W. Welch, Department of Biochemistry, University of Nevada, Reno, who allowed us to do this work as subcontracts of projects funded by the National Science Foundation (NSF) and the American Heart Association (AHA). We also thank Professor Alan J. Williams, Department of Cardiac Medicine, Imperial College School of Medicine at NHLI, London, U.K., for a research contract from the British Heart Foundation. We also thank the Université de Sherbrooke for financial support from the Fonds de Recherche à Allocation Interne (FRAI). We wish to thank Dr. N. Pothier, Mr. G. Boulé, and Mr. M. Drouin, Département de Chimie, Université de Sherbrooke, for their technical assistance (NMR spectroscopy, mass spectrometry, and X-ray diffraction analysis).

Catalytic reduction of benzoate esters and lactones in the presence of $PhMeSiH_2$ and a titanocene-based catalyst

Ronghua Shu, John F. Harrod, and Anne-Marie Lebuis

Abstract: $PhMeSiH_2$ reduces ethyl benzoate in the presence of a Cp_2TiMe_2 (Cp = η^5-cyclopentadienyl) catalyst to give $PhMeSi(OEt)(OCH_2Ph)$ (**1**). Small to moderate amounts of toluene are also produced, depending on the reaction conditions. Under 40 psi of H_2 the same reaction gives quantitative reduction of the ester to toluene. PhCHO is reduced, under the same conditions as the ester, to a mixture of $PhMeSi(OCH_2Ph)_2$ and toluene in proportions similar to that observed with the ester. A stoichiometric reaction of $PhMeSiH_2$, PhCOOEt, and Cp_2TiMe_2 resulted in the formation of known $[Cp_2Ti(OEt)]_2$ (**2**) in 75% isolated yield. A mechanism is proposed in which the C=O of the ester inserts into a Ti–H bond. A Ti-mediated transfer of the ethoxy group from the resulting (α-ethoxy)benzyloxytitanium intermediate to silicon produces PhMeSi(OEt)H and PhCHO. **1** is generated via hydrosilation of PhCHO by PhMeSi(OEt)H. Both β- and γ-butyrolactones react with $PhMeSiH_2$ in the presence of a catalytic amount of Cp_2TiMe_2 to produce copolymers $-[O\text{-}PhMeSi\text{-}O(CH_2)_3CHR]_n-$ (R = H, **3**; R = Me, **4**) ($M_w \approx 1 \times 10^3$; $M_w/M_n \approx 1.3$). A mechanism analogous to that proposed for the ethyl benzoate reduction is proposed. A reaction of $PhMeSiH_2$ and γ-butyrolactone with a stoichiometric amount of Cp_2TiMe_2 in the presence of tetrahydofuran (THF) produces $Cp_2Ti(\mu\text{-}H)(\mu\text{-}\eta^1,\eta^5\text{-}C_5H_4)Ti(OC_4H_8)Cp$ **(5)** (65% isolated yield) whose structure is determined by X-ray crystallography.

Key words: hydrosilation, esters, lactones, titanocene, catalysis.

Résumé : En présence d'un catalyseur de Cp_2TiMe_2 (Cp = η^5-cyclopentadiényle), le $PhMeSiH_2$ réduit le benzoate d'éthyle en conduisant à la formation de $PhMeSi(OEt)(OCH_2Ph)$, **1**. Suivant les conditions expérimentales utilisées, il y a aussi formation de faibles quantités de toluène. À une pression de H_2 de 40 << psi >>, la même réaction conduit à une réduction quantitative de l'ester en toluène. Dans les mêmes conditions de réduction, le PhCHO fournit un mélange de $PhMeSi(OCH_2Ph)_2$ et de toluène dont les proportions sont semblables à celles observées avec l'ester. Une réaction stoechiométrique de $PhMeSiH_2$, PhCOOEt et de Cp_2TiMe_2 conduit à la formation du $[Cp_2Ti(OEt)]_2$, **2**, déjà connu, avec un rendement isolé de 75%. On propose un mécanisme dans lequel le C=O de l'ester s'insère dans une liaison Ti-H. Un transfert du groupe éthoxy, sous l'influence du Ti, de l'intermédiaire (α-éthoxy)benzoyloxytitane vers le silicium conduit à la formation de PhMeSi(OEt)H et de PhCHO. Le produit **1** est généré par le biais d'une hydrosilation du PhCHO par le PhMeSi(OEt)H. Les β- et γ-butyrolactones réagissent toutes les deux avec le $PhMeSiH_2$, en présence d'une quantité catalytique de Cp_2TiMe_2 pour conduire à la formation de copolymères $-[O\text{-}PhMeSi\text{-}O(CH_2)_3CHT]_n-$ (R = H, **3**; R Me, **4**) ($M_w \approx 10^3$; $M_w/M_n \approx 1{,}3$). On propose un mécanisme semblable à celui suggéré pour la réduction du benzoate d'éthyle. Une réaction du $PhMeSiH_2$ avec la γ-butyrolactone et une quantité stoechiométrique de Cp_2TiMe_2 dans du tétrahydrofurane (THF) conduit à la formation de $Cp_2Ti(\mu\text{-}H)(\mu\text{-}\eta^1,\eta^5\text{-}C_5H_4)Ti(OC_4H_8)Cp$, **5** (rendement de 65% en produit isolé) dont on a déterminé la structure par diffraction des rayons X.

[Traduit par la Rédaction]

Introduction

Titanocene derivatives have been widely applied as catalysts for the hydrogenation and hydrosilation of carbonyl compounds (1). Hydrosilation of ketones (2) has received the most attention, but Buchwald and co-workers have also developed procedures for the reduction of both lactones (3) and esters (4). A variety of esters, including those containing bromo-, phenoxy-, amino-, alkenyl- or cyclopropyl-groups, as well as α,β-unsaturated esters, can be reduced with triethoxysilane and catalytic amounts of titanocene dichloride, preactivated with butyllithium (4*a*). This procedure can also be used for the selective reduction of methyl esters in the presence of *tert*-butyl esters. For substrates containing a terminal olefin, or an epoxide, a more hindered titanocene dichloride species, such as ethylene-1,2-bis(tetrahydroindenyl)titanium dichloride ($[EBTHI]TiCl_2$), is required. Other procedures involving safer and cheaper reagents, such as poly(methylhydrosiloxane) instead of $(EtO)_3SiH$ and EtMgBr instead of *n*-BuLi, were also reported (4*c*).

Most of the reported work on the hydrosilation of esters and lactones, catalyzed by titanocene derivatives, has been focused on its use for synthesis of alcohols, while little is known of the mechanism or the nature of the intermediates in the reactions. On the other hand, our interest in hydrosilation chemistry has been focused on the organosilicon products and the titanocene intermediates (5). In the present paper, we describe a detailed analysis of the intermediates and products for some titanocene catalyzed hydrosilations of esters and lactones. The results of these studies provide the first direct evidence for the participation of Cp_2Ti in a catalytic hydrosilation reaction catalyzed by Cp_2TiMe_2. Our interest in these reactions evolved from an earlier study of hydrosilation–hydrogenation of pyridine carboxylic esters (6).

Results and discussion

Reduction of ethyl benzoate under hydrosilation conditions

To remove the complications arising from the presence of the ring nitrogen in isonicotinate esters, we re-investigated the reduction of ethyl benzoate under hydrosilation conditions (eq. [1] — this equation is not balanced but shows the observed reactants and products). Under most conditions studied, benzyloxysilane (**1**) was the major product. Toluene was generally a minor product, but was the only product when the reaction was carried out under a hydrogen atmosphere.

[1] $$PhCOOEt + PhMeSiH_2 \xrightarrow{Cp_2TiMe_2} \underset{\mathbf{1}}{MePhSi(OCH_2Ph)(OEt)]} + PhMe$$

The results of a number of reactions carried out under a range of conditions are summarized in Table 1. It is difficult to derive any conclusion from the results under Ar due to the scatter in the data. Nevertheless, it is reasonable to conclude that the C–O bond reduction is favored by higher temperatures and by the presence of H_2.

An isolated sample of **1** did not react with $PhMeSiH_2$ in the presence of Cp_2TiMe_2. Reactions of benzaldehyde and anisole were also briefly studied as substrates for the reaction with $PhMeSiH_2$ in the presence of Cp_2TiMe_2. A reaction of benzaldehyde at room temperature for 1 h, with a ratio of PhCHO–$PhMeSiH_2$–Cp_2TiMe_2 of 1:2:0.15, gave roughly equal amounts of $PhMeSi(OCH_2Ph)_2$ and $PhCH_3$. Under the same conditions, anisole gave only a trace of product ($PhCH_3$, ca. 0.5%). After an additional 4 h at 60°C, the yield of $PhCH_3$ increased to ca. 10%.

A reaction of $PhMeSiH_2$, PhCOOEt, and Cp_2TiMe_2 in a molar ratio of 2:1:1 gave a 75% isolated yield of the known ethoxy titanocene(III) dimer, $[Cp_2Ti(OEt)]_2$ (**2**, ref. 7). This pale green complex reacts slowly with $PhMeSiH_2$ at room temperature to give a blue product that exhibits a catalytic activity similar to that of Cp_2TiMe_2 for reduction of PhCOOEt to **1**, but with no detectable production of toluene.

Reactions of lactones with $PhMeSiH_2$ and Cp_2TiMe_2

Both γ- and β-butyrolactone reacted with $PhMeSiH_2$ in the presence of a Cp_2TiMe_2 catalyst to yield the ring-opened copolymers **3** (eq. [2]) and **4** (eq. [3]), respectively.

Table 1. Yields of toluene from reactions of ethyl benzoate with $PhMeSiH_2$ and Cp_2TiMe_2 under various conditions.

Cp_2TiMe_2/PhCOOEt (%)	*T* (°C)	Yield of toluene (%)[a]
5	20	5
10	20	10
20	20	19
30	20	11
40	20	13
10	0	2
20[b]	20	4
20[c]	20	3
20	40	40
20[d]	40	100

Note: Except where indicated, reactions were run under Ar with 10 mol% catalyst, based on $PhMeSiH_2$. All reactants were added to the reactor at the same time. Conversions were quantitative and the balance of the product was **1**.

[a]Based on ^1H NMR integration.

[b]Ethyl benzoate was added dropwise after the reaction of $PhMeSiH_2$ and Cp_2TiMe_2 was complete.

[c]$PhMeSiH_2$ (0.10 mL, 0.7 mmol) was added to the mixture of Cp_2TiMe_2 (0.088 g, 0.43 mmol) and ethyl benzoate (0.30 mL, 2.13 mmol). After the solution color changed from orange to dark violet blue an additional 0.50 mL of $PhMeSiH_2$ was added dropwise to the mixture.

[d]The reaction was run under 40 psi H_2.

The polymers were recovered in ca. 30% yields, as amorphous white solids, by precipitation of the reaction mixtures with excess methanol. Molecular weights, determined by GPC, were in the range of 2–4 × 10^3 D, with polydispersities in the range of 1.2–1.3. The balance of the reaction products was not fully characterized, but from their IR and NMR spectra appeared to be a mixture of lower molecular-weight oligomers of the same structure as the isolated solid.

Stoichiometric reactions of Cp_2TiMe_2, $PhMeSiH_2$, and either γ- or β-butyrolactone, in a molar ratio of 1:2:1 in hexane–THF (15:2 v/v), yielded dark grayish-brown crystals. Given the reaction of ethyl benzoate, described above, and the known oxophilicity of Ti, a product containing Ti–O bonds was expected. To our surprise, a structure determination by X-ray crystallographic analysis showed the product to be **5** (Fig. 1).

Molecule **5** contains two inequivalent Ti atoms. One, Ti1, is coordinated to a η^5-C_5H_5 ligand, a bridging η^5-C_5H_4 ligand, and a THF molecule. The other, Ti2, is η^1-bonded to the bridging C_5H_4 ligand and to two η^5-C_5H_5 ligands. More importantly, a hydrogen-atom bridge, located in the difference map, connects the two Ti atoms. The mean distance

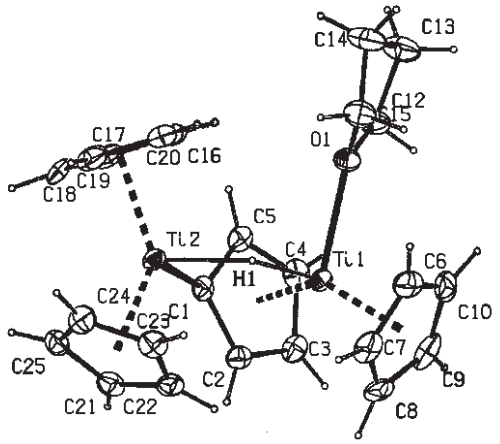
Fig. 1. The structure of **5**, showing thermal ellipsoids at the 30% probability level.



between the titaniums and the carbon atoms of the η-C_5H_5 rings (2.388 Å) and the distance between C1 and Ti1 (2.207(5) Å) agree with the assignment that three of the C_5 rings are coordinating to Ti1 and Ti2 in η^5-mode, while the fourth bridging ring is coordinating η^5 to Ti1 and η^1 to Ti2. The formula of **5** ($C_{24}H_{28}OTi_2$) corresponds to a dimer of Cp_2Ti coordinated to a molecule of THF. The crystal structure also reveals that in the lattice there is half a molecule of THF per formula unit of **5**.

The values of the molecular parameters for **5** (a number of which are compared in Table 2) are essentially the same as those reported by Pez (8) for compound **5′**, which differed only in the absence of the hydride bridge. We believe these compounds to be the same. Small differences in the parameter values are attributed to the fact that our data were collected at –60°C, while those of Pez were collected at 23°C. In addition, our measurements were carried out with Cu Kα radiation in order to favour detection of the hydride, while Pez used Mo Kα radiation. In a preliminary study, we also failed to detect the bridging hydride using Mo Kα radiation. Finally, there is a slight difference due to the fact that the Pez structure is reported in the monoclinic space group *I*2/*a*, which is a non-conventional orientation of the *C*2/*c* group used by us.

Solutions of **5** in THF are strongly paramagnetic. NMR spectra of such solutions are very broad and strongly shifted, and give essentially no clue to the structure. Their EPR spectra also consist of a very broad single peak, which gives no structural information. Pez also concluded that his compound was paramagnetic on the basis of the temperature dependence of the ^{1}H NMR chemical shift. The originally proposed structure, without a bridging hydrogen atom, is an odd- electron count system and therefore would be expected to have one unpaired electron. Addition of the bridging hydrogen atom results in an even-electron count and the molecule is expected to be diamagnetic. A simple rationalization of these observations is that **5** dissociates in the weakly coordinating THF solvent to give a titanocene(II) complex (**6**), as in eq. [4]. Although Cp_2TiL_2 complexes are well known for strong-field ligands such as PR_3 (9) and CO (10), the ground states of such complexes are normally spin singlets. The bipyridyl complex is unusual, in that it has a spin-triplet ground state, interpreted to be the result of a Ti(III) coordinated to a bipyridyl radical anion ligand (11). It is not unreasonable however to assume that a Ti(II)-centered triplet ground state could be preferred with a σ-bonding weak-field ligand such as THF that coordinates through O. Indeed, both theoretical (12) and experimental (13) results support the conclusion that the ground state of *uncomplexed* Cp_2Ti is a triplet. We are continuing to study the magnetochemistry and EPR properties of solutions of **5** in order to resolve this question.

[4] 
5 **6**

The two titanium atoms in **5** can be formally assigned either as Ti(II) and Ti(IV), or both as Ti(III). This oxidation-state ambiguity, and the structural motif of a hydride bridge accompanying another more-complex bridging group, is now a common feature of titanocene chemistry (6, 14–16).

The mechanism of ester hydrosilation–reduction

Earlier studies of hydrosilation–reduction of esters (17) and lactones (18) in the presence of titanocene-based catalysts were carried out from the perspective of their usefulness in organic synthesis. In no case was the intermediate organosilicon compound identified or isolated. Nevertheless, a reasonable mechanism involving addition of a Ti–H bond across the carbonyl group, followed by release of the alkoxy silicon product was proposed. A similar mechanism is shown in Scheme 1.

The cycle shown in Scheme 1 rationalizes all of the features of the hydrosilation reaction. There is ample evidence from earlier studies for the generation of Cp_2TiH by reaction of Cp_2TiMe_2 with a hydrosilane (5*a* and refs. therein). Step **a** is a plausible insertion of C=O into a Ti–H bond. The

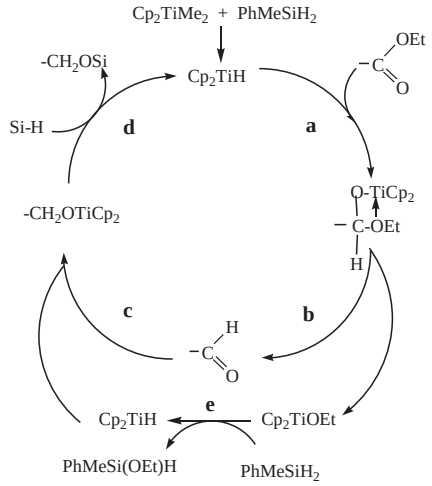
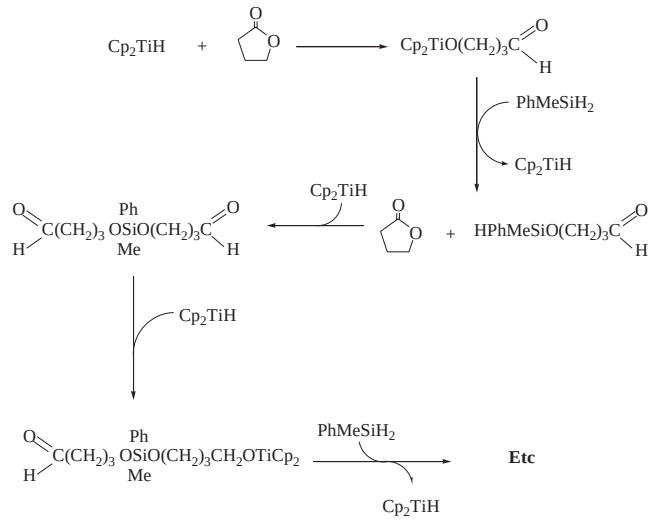


Scheme 2. A cycle for the titanocene-hydride catalyzed co-polymerization of γ-butyrolactone–$PhMeSiH_2$.



observation that a stoichiometric reaction of Cp_2TiMe_2, $PhMeSiH_2$, and PhCOOEt gives **2** in high yield is explained by the assumption that the initially formed (1-phenyl-1-ethoxy)methoxy titanocene is unstable with respect to transfer of the ethoxy group to the Ti, perhaps by an initial intramolecular coordination of the EtO oxygen to the metal. The intermediate benzaldehyde was not detected under catalytic conditions, perhaps because of an additional rapid reaction. It was however shown that benzaldehyde is reduced under these conditions to give $PhMeSi(OCH_2Ph)_2$ (presumably by step **c**) and toluene in proportions similar to those observed in the reaction with PhCOOEt. For the benzaldehyde reaction, there is no possibility of EtO transfer to the Si and hence it raises the question as to why the observed product in the ester reaction (step **d**, Scheme 1) is $PhMeSi(OEt)(OCH_2Ph)$ rather than $PhMeHSi(OCH_2Ph)$, or $PhMeSi(OCH_2Ph)_2$. A problem is also presented by the fact that $PhMeSiH_2$ does react with $[Cp_2Ti(OEt)]_2$ (step **e** Scheme 1), and the latter is also a precatalyst for the hydrosilation of PhCOOEt. Neither of these reactions, however, are fast enough to account for the rate of the Cp_2TiMe_2 catalyzed hydrosilation of PhCOOEt.

Both of these problems would be resolved if the slowness of the reaction of **2** with $PhMeSiH_2$ was due to a slow dissociation of the dimer, which masks the intrinsic reactivity of monomeric $Cp_2Ti(OR)$. The assumption of the production of a highly reactive monomeric $Cp_2Ti(OEt)$ in step **c** permits the rapid recycling of this intermediate through loop **d**, to allow for the transfer of the EtO group to silicon and regeneration of the catalyst, Cp_2TiH. Finally, once the reaction is underway, the Si–H in the σ-bond metathesis in step **d** would have to be mainly PhMe(EtO)SiH, rather than $PhMeSiH_2$.

Although the steps in the catalytic loop of Scheme 1 can explain the features of the hydrosilation reaction of PhCOOEt, they fail to explain the complete reduction (deoxygenation) to toluene. The fact that toluene is the only product when the reaction is carried out under moderate pressure of H_2 suggests that high concentrations of Ti–H favour complete deoxygenation. Reactions of hydrosilanes with Cp_2TiMe_2 produce a mixture of $CpTiSiR_3$ and Cp_2TiH, which have been isolated and characterized as bridged dimers (5*b*, 15). The balance between the amounts of silyl and hydride complexes is a function of the silane concentration, with the silyl species being favored by high silane concentration. It is also likely that H_2 is in equilibrium with these species as shown in eq. [5] (although this has never been unequivocally demonstrated). The fact that $PhMeSi(OEt)(OCH_2Ph)$ does not react under the catalytic reduction conditions excludes it as an intermediate in the production of toluene. On the other hand, the similarity of the products from the PhCOOEt and PhCHO reductions suggests that $Cp_2Ti(OCH_2Ph)$ is a plausible intermediate in the production of toluene.

[5] $Cp_2TiH + R_3SiH \rightleftharpoons Cp_2TiSiR_3 + H_2$

The mechanism of lactone–silane co-polymerization

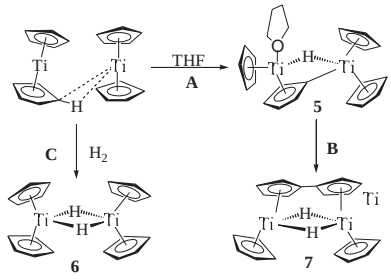
A plausible mechanism for the titanocene-hydride mediated co-polymerization of γ-butyrolactone and $PhMeSiH_2$ is shown in Scheme 2. This scheme couples two of the steps proposed in Scheme 1 for the reduction of ethylbenzoate; namely, the addition of Cp_2TiH to an aldehyde and a σ-bond metathesis between Ti–O and Si–H to give Si–O and Ti–H. In this case the ring-opening step is an intramolecular version of steps **a** and **b** in Scheme 1. In the lactone reactions no cleavage of C–O bonds was observed.

The mechanism of formation of 5

Compound **5** is expected to be formed from the dimerization of bis(η^5-cyclopentadienyl)Ti. The manner in which the latter species may be generated by reaction of Cp_2TiMe_2 with a hydrosilane has been discussed at length elsewhere (5*b* and refs. therein). It is our belief that titanocene(II), or its dimer (**5**) is normally present in reactions involving Si–H and Cp_2TiMe_2, but its detection in solution is precluded by its electronic structure. (Its paramagnetism interferes with NMR measurements and a triplet ground state can be very difficult to observe by EPR.)

© 2002 NRC Canada

Scheme 3. In **A**, one molecule of Cp_2Ti inserts into a C–H bond of a second molecule. In **B**, a second intramolecular insertion of Ti into a C–H bond of the Cp_2Ti unit of **5** occurs, followed by coupling of the two C_5H_4 fragments. In **C**, a molecule of H_2 reacts with two Cp_2Ti molecules, perhaps by initial formation of the Cp_2TiH_2, followed by reaction with the second Cp_2Ti molecule.



It has also been postulated that titanocene, as a result of its carbene-like character, will insert into X–H bonds and, in the absence of other choices, it will insert into one of its own C–H bonds (19). Pez (8) recognized this possibility when he first isolated and characterized **5**. A second similar-intramolecular insertion takes **5** to the hydride-bridged fulvalenyl dititanium complex (**7**), originally reported by Bercaw and co-workers (20) and structurally characterized by Troyanov et al. (21). The relationship between the various titanocene hydrides is shown in Scheme 3.

Conclusions

The titanocene-catalyzed hydrosilation of esters to the alkoxide level can be rationalized by a conventional Ti–H mediated reduction of the ester, followed by alkoxide transfer to Si. Further reduction to the hydrocarbon level occurs under unusually mild conditions, particularly in the presence of a hydrogen atmosphere. Although the mechanism is not known, it is likely that this reaction occurs via X–H (X = H or Ti) induced C–O cleavage of a benzyloxy-Ti complex.

Experimental

General manipulations and materials

All manipulations were performed under an atmosphere of nitrogen or argon using Schlenk techniques. Dry oxygen-free solvents were employed throughout. Glassware was flame-dried or oven-dried before use. γ-Butyrolactone and (±)-β-butyrolactone were purchased from Aldrich and distilled prior to use. Ethyl benzoate, benzaldehyde, and benzyl alcohol were purchased from Aldrich and purified by distillation over calcium hydride before use. Dimethyltitanocene (22) and phenylmethylsilane (23) were prepared by the procedures described in the literature.

Benzylmethyl ether was prepared by a Williamson synthesis using the following procedure: sodium (2.3 g, 0.1 mol) was added in small pieces to benzyl alcohol (11 g, 0.1 mol) in ether (50 mL). After the sodium had dissolved, CH_3I (16 g, 0.11 mol) was added dropwise from a syringe. A white solid precipitated during the addition of CH_3I. The suspension was stirred for 1 h and then dilute HCl (5 mL concentrated HCl in 30 mL H_2O) was added dropwise. The organic phase was washed with distilled water three times and then dried with $MgSO_4$. Pure benzylmethyl ether was obtained in 80% isolated yield by distillation.

^{1}H NMR spectra were recorded on a Varian XL-200, Varian XL-300, Gemini-200, or Unity-500 spectrometer using an internal solvent as a reference. ^{13}C NMR spectra were recorded on a Unity-500 spectrometer using C_6D_6 (128.0 ppm) as a reference. GPC analyses were run with THF as solvent and calibrated relative to polystyrene standards.

Reaction of ethyl benzoate with $PhMeSiH_2$ catalyzed by Cp_2TiMe_2

$PhMeSiH_2$ (0.20 mL, 1.4 mmol) and ethyl benzoate (0.10 mL, 0.70 mmol) were added to Cp_2TiMe_2 (14 mg, 0.07 mmol). After a while, the solution color changed to dark blue then brown with vigorous gas evolution. After stirring at room temperature for 1 h, quantitative conversion of ethyl benzoate to a mixture of toluene and **1** was observed by ^{1}H NMR (molar ratio 1:9). ^{1}H NMR (300 MHz, C_6D_6) for **1**: 0.34 (s, 3H, Si-C*H*$_3$), 1.15 (t, 3H, OCH_2CH_3), 3.70 (q, 2H, OCH_2CH_3), 4.78 (m, 2H, $PhCH_2O$-), 6.9–8.0 (m, Ph-*H*).

All of the experiments to obtain the data in Table 1 were carried out following the above general procedure, with the exception of the last entry, which was carried out in a stirred mini-autoclave rather than a Schlenk tube and with all of the reactants scaled up by a 10-fold.

Preparation of $[Cp_2Ti(\mu\text{-}OEt)]_2$

$PhMeSiH_2$ (0.70 mL, 4.9 mmol) and ethyl benzoate (0.40 mL, 2.5 mmol) were added to a solution of Cp_2TiMe_2 (0.50 g, 2.4 mmol in 40 mL toluene and 10 mL benzene). The solution turned dark green with precipitation of green crystals of $[Cp_2Ti(\mu\text{-}OEt)]_2$, which were filtered, washed with hexane, and dried in vacuo (0.40 g, 75% isolated yield). The identity of the product was confirmed by comparison of its IR spectrum and X-ray diffraction pattern to those of an authentic sample (7).

Reaction of ethyl benzoate and $PhMeSiH_2$ in the presence of $[Cp_2Ti(\mu\text{-}OEt)]_2$

$PhMeSiH_2$ (0.34 mL, 2.60 mmol) was added to $[Cp_2Ti(\mu\text{-}OEt)]_2$ (50 mg, 0.11 mmol). The mixture was stirred at room temperature for 24 h (during this time the formation of some 1,2-dimethyl-1,2-diphenyldisilane was observed by ^{1}H NMR). Ethyl benzoate (0.17 mL, 1.06 mmol) was then added. Gas evolution was observed in 5 min, while the solution changed from green to yellow-green. Conversion (86%) of the ester to **1** was obtained in 12 h. No toluene was detected by ^{1}H NMR.

Reaction of benzaldehyde and $PhMeSiH_2$ in the presence of Cp_2TiMe_2

$PhMeSiH_2$ (0.40 mL, 3.06 mmol) and benzaldehyde (0.20 mL, 1.97 mmol) were added to Cp_2TiMe_2 (55 mg, 0.28 mmol) at room temperature. After a while, the solution color changed to purple then dark blue accompanied by gas evolution. After 1 h toluene was observed in a 50% yield (based on ester, by ^{1}H NMR). The reaction mixture was diluted with C_6D_6 (1.0 mL) and saturated with gaseous HCl to destroy the presumed $Cp_2Ti(OCH_2Ph)$. Volatiles were

© 2002 NRC Canada

removed under vacuum and collected in an NMR tube. The resulting mixture contained toluene and $PhCH_2OH$ in roughly equal amounts, as shown by spiking the mixture with authentic samples.

Reaction of $PhCH_2OMe$ and $PhMeSiH_2$ in the presence of Cp_2TiMe_2

$PhMeSiH_2$ (0.60 mL, 4.20 mmol) and $PhCH_2OMe$ (0.30 mL, 2.46 mmol) were added to Cp_2TiMe_2 (0.10 g, 0.48 mmol). The solution color changed from orange to dark blue, accompanied by gas evolution. After stirring at 60°C for 4 h, toluene was detected in the solution by ^1H NMR in an amount equivalent to 10% of the reactant ether.

In the absence of Cp_2TiMe_2, reactions of $PhCH_2OMe$ with $PhMeSiH_2$ or $(EtO)Me_2SiH$ at 60°C for 12 h yield no toluene.

Reaction of γ-butyrolactone and $PhMeSiH_2$ catalyzed by Cp_2TiMe_2

γ-Butyrolactone (0.30 mL, 3.9 mmol) and $PhMeSiH_2$ (0.60 mL, 4.2 mmol) were added to a solution of Cp_2TiMe_2 (0.05 g, 0.24 mmol in 1 mL THF). After thorough mixing, the solution was stirred for 10 h at 80°C. The product was added dropwise to 10 mL of well-stirred dry methanol; 0.3 g of a white precipitate were obtained. The compound was assigned as $-[OSiPhMeO(CH_2)_4]_n-$ based on ^1H and ^{13}C NMR spectra. GPC analysis indicated a $M_w = 4.9 \times 10^3$, $M_w/M_n = 1.3$. ^1H NMR (300 MHz, C_6D_6) δ: 0.40 (s, 3H, Si-CH_3), 1.7 (m, 4H, $CH_2(CH_2)_2CH_2$), 3.75 (m, 4H, $CH_2(CH_2)_2CH_2$), 7.0–8.0 (m, 5H, Ph-*H*). ^{13}C NMR (500 MHz, C_6D_6) δ: –5 (1C, SiCH_3), 29 (2C, $CH_2(CH)2CH$), 62 (2C, $CH_2(CH_2)_2CH_2$), 130, 134 (6C, C_6H_5).

Reaction of (±)-β-butyrolactone and $PhMeSiH_2$ in the presence of Cp_2TiMe_2

(±)-β-Butyrolactone (0.30 mL, 3.7 mmol) and $PhMeSiH_2$ (0.55 mL, 3.8 mmol) were added to a solution of Cp_2TiMe_2 (0.05 g, 0.24 mmol, in 1 mL THF). After thorough mixing, the solution was stirred for 8 h at 80°C. The product was added dropwise to 10 mL of well-stirred methanol. A white precipitate (0.28 g) was obtained. The compound was identified as $-[OSiPhMeO(CH_2)_2CH(CH_3)]_n-$ based on its ^1H NMR spectrum. GPC analysis indicated a $M_w = 1.8 \times 10^3$ with $M_w/M_n = 1.2$. ^1H NMR (300 MHz, C_6D_6) δ: 0.40 (s, 3H, Si-CH_3), 1.1 (m, 3H, $CH_2CH_2CH(CH_3)$), 1.4 (m, 2H, $CH_2CH_2CH(CH_3)$), 3.6 (m, 2H, CH_2 $CH_2CH(CH_3)$), 3.9 (m, 1H, $CH_2CH_2CH(CH_3)$), 7.1–7.9 (m, 5H, Ph-*H*).

Sythesis of crystalline $C_{26}H_{32}O_{1.5}Ti_2$ (5)

γ-Butyrolactone (0.02 mL, 0.26 mmol) and $PhMeSiH_2$ (0.07 mL, 0.49 mmol) were added to a Cp_2TiMe_2 in hexane–THF solution (50 mg, 0.24 mmol, in 15 mL hexane and 2 mL THF). After thorough mixing, the flask was left undisturbed for 24 h. Dark gray plates of **5** (33 mg) crystallized from the solution (65% isolated yield). Anal. calcd. for $C_{26}H_{32}O_{1.5}Ti_2$: C 67.86, H 6.96, O 4.35, Ti 20.84; found: C 67.58, H 6.75. The low CH analysis is probably due to loss of lattice THF during sample isolation. The IR spectrum of **5** showed the same features as that of the compound described by Pez (8). Despite several attempts, we were not able to assign an IR band due to the bridging hydride of **5**, or to its deuterated analogue, prepared with $PhMeSiD_2$.

Collection of X-ray data and structure determination of 5

Data were collected on a crystal of **5** of dimensions of 0.52 × 0.29 × 0.01 mm mounted in a glass capillary under argon.[2] *Crystal data*: $C_{24}H_{28}O_1Ti_2 \cdot 1/2C_4H_8O_1$; FW = 456.299; monoclinic, *C*2/*c*; a = 31.232(13), b = 7.998(3), c = 19.603(9) Å, β = 116.78(3)°; Z = 8, Z' = 1; D_c = 1.387 g cm^{-3}. Data were collected on a CAD4 diffractometer using Cu Kα radiation. In all, 29561 reflections were measured, of which 4145 unique (R_{int} 14.9%) reflections were used for structure solution and refinement. Data were corrected for absorption (μ = 63.48 cm^{-1}; transmission range: 0.2708–0.9287). Final agreement factors: R_1: (obsd./all) 0.059/0.094; wR_2: 0.143/0.157. The structure was solved by SHELXLS-96 (24) and refined in SHELXL-96 (25). All nonhydrogen atoms are anisotropic. Hydrogen atoms are calculated except the bridging hydride, which was located in the difference map and refined isotropically with the restraint that both Ti–H distances be similar.

Solution and solid-state characterization of a dicopper receptor for large substrates

Greg J.E. Davidson, Andrew J. Baer, Adrien P. Côté, Nicholas J. Taylor, Garry S. Hanan, Yasutaka Tanaka, and Masashi Watanabe

Abstract: Ligand **2** contains two metal-binding domains separated by a rigid spacer and assembles into a dicopper receptor with a large central cavity with no evidence of catenation.

Key words: copper complex, coordination, X-ray crystallography, molecular recognition.

Résumé : Le ligand **2** contient deux groupement pour coordonner des métaux séparer par un espaceur rigide et s'auto-assemble avec le cuivre(II) pour former un récepteur avec un grand cavité centrale avec aucune evidence pour la formation de caténane.

Mots clés : complex de cuivre, coordination, crystallographie rayons-X, reconnaissance moléculaire.

Introduction

The metal-directed self-assembly of discrete supramolecular structures, e.g., triangles (1), squares (2), and grids (3), has attracted considerable interest in recent years. When properly designed, discrete supramolecular structures may serve as metalloreceptors for small organic and bio-organic molecules (4). A key advantage of metallomacrocycles over similarly sized organic receptors is the higher yields associated with metal-directed self-assembly compared with conventional macrocycle synthesis (5). One drawback, however, is that dimetallic receptors have a tendency to form interlocking rings depending on their concentration and the size of the receptor site (6). Although templation of the metalloreceptor around a guest molecule(s) may eliminate catenation, it may in turn diminish or eliminate further guest binding by occupying the receptor site.

Since metalloreceptors capable of binding functionalized substrate can perform catalysis and behave as artificial enzymes (7), receptors for larger substrate would increase the diversity of possible substrate and, therefore, products obtained. Early work with dimetallic receptors proved the importance of metal-directed self-assembly; however, it focused on systems with small receptor sites (8). Thus the binding of substrates larger than a single heterocycle was precluded, and the formation of catenanes was impossible. Although reports of dimetallic receptors with large cavities have recently appeared in the literature, no confirmation of host–guest binding in the solid state was presented (9). Herein we present solution and solid-state evidence for the assembly of a dimetallic receptor with a large cavity that displays no evidence of catenation, yet requires no template for its formation.

Results and discussion

The organic framework for our dimetallic receptor is based on *m*-terphenyl, synthesized by the uncatalyzed reaction of aryllithium or arylmagnesium reagents with *m*-dichlorobenzene (the Hart reaction) (10). The Hart reaction allows facile entry into large substructures suitable for further functionalization, since R groups may be readily incorporated in the ligand framework (Scheme 1). Thus, 4,4′-bis(bromomethyl)-1,1′:3′,1″-terphenyl (**1**) was synthesized from 4,4′-dimethyl-1,1′:3′,1″ -terphenyl by radical bromination with NBS in 67% yield (11). Allowing **1** to react with two equivalents of potassium acetylacetonate in *tert*-butanol afforded ligand **2** in 91% yield after extraction with methanol (Scheme 1).[2] In solution, ligand **2** exists in its keto and enol forms. Integration of the two methyl peaks at 2.12 and 2.17 ppm supports an approximate 1:1 of the two forms. A singlet and doublet for H-3 and H-3′, respectively, and a triplet for H-2, also supports this assignment. In the IR region, both O–H and C–O stretches confirm the keto–enol formulation.

The dicopper receptor is readily synthesized in near quantitative yield from **2** and $Cu(NH_3)_4SO_4$ in a biphasic H_2O–$CHCl_3$ reaction mixture (8).[3] Upon layering **2** in chlo-

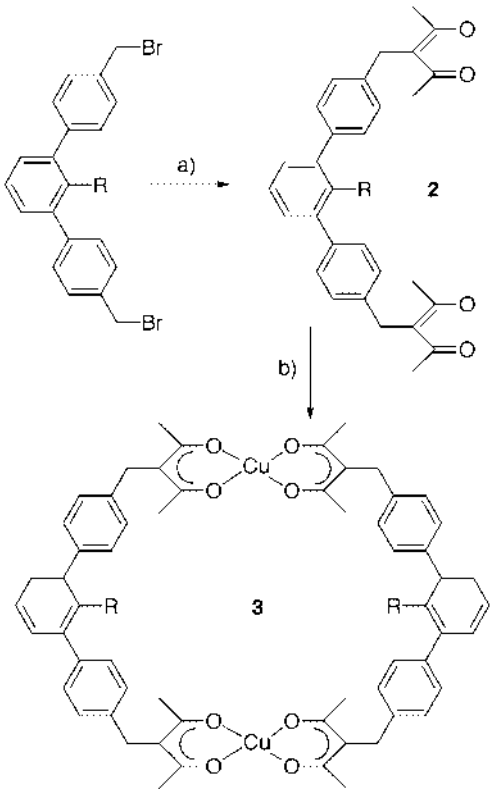
Scheme 1. Synthesis of ligand **2** and metallomacrocycle **3** (R = H). Reagents and conditions: (*a*) KO-*t*-Bu and 2,4-pentanedione in *t*-BuOH; (*b*) $Cu(NH_3)_4SO_4 \cdot H_2O$ in H_2O–$CHCl_3$.

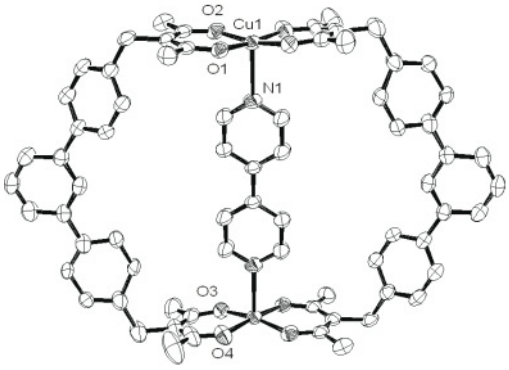


roform with $Cu(NH_3)_4SO_4$ in H_2O, the organic-soluble olive-green $Cu_2\mathbf{2}_2$ complex (**3**) is produced (Scheme 1). The IR spectrum of **3** confirms the presence of metal-bound acetylacetonate moieties, while electrospray mass spectrometry verified the molecular structure of complex **3**. Since the complex is charge neutral, the molecular ion was obtained as the Na^+ adduct of the complex.[3]

The electronic absorption spectrum of **3** contains an absorption band at 644 nm associated with metal-based *d–d* transitions. The addition of nitrogen-containing bases to a chloroform solution of **3** produces a turquoise solution and a concomitant shift in the metal-based transition to higher energy. (An isosbestic point in the titration is an indication of a two-species system.) A more detailed binding study with 4,4′-bipyridine reveals a binding constant of 250 M^{-1}. Monoaza guests, such as pyridine and substituted pyridines, bind much more poorly to the dicopper complex, with binding constants of ≈1.

X-ray quality crystals of **3** as its 4,4′-bipyridine adduct (**4**) are obtained by slow evaporation of a 1:1 mixture of 4,4′-bipyridine and **3** in $CHCl_3$ (Scheme 1, Fig. 1).[4] The solid-state structure of **4** clearly delineates the size of the cavity

Fig. 1. X-ray crystal structure of **4** showing 50% probability ellipsoids for all nonhydrogen atoms. H atoms and $CHCl_3$ have been omitted for clarity. Only the N, O, and Cu of the asymmetric unit are labelled. Selected bond distances (Å) and angles (°): Cu(1)—N(1): 2.338(5); Cu(1)—O(1): 1.926(4); Cu(1)—O(2): 1.921(4); Cu(1)—O(3): 1.921(5); Cu(1)—O(4): 1.912(4); O(1)-Cu(1)-O(2): 91.61(17)°; O(3)-Cu(1)-O(4): 90.8(2)°.



produced by the assembly of the complex: the Cu—Cu distance is 11.8 Å, while the cross-cavity distance, measured from the central benzene 2-positions, is 14.0 Å, and the peripheral phenyl groups are separated by 12.6 Å. The metal ions are not only directing the assembly of the receptors, but they are also binding the substrate, 4,4′-bipyridine, into their primary coordination sphere. The Cu—N bond length is 2.338 Å, and the Cu—O bond lengths vary between 1.912 and 1.926 Å. The Cu(II) ions are pulled slightly out of the basal plane (0.15 Å), maintaining a typical metal–metal distance for 4,4′-bipyridine bridged-metal ions. The angle at the benzyl carbon that connects the acetylacetonate and terphenyl moieties is distorted from a tetrahedral geometry to 115°. The unit cell is over 2500 $Å^3$; ten chloroform molecules are also present.

The large hexagonal cavity delineated by the two terphenyl groups and the $Cu(acac)_2$ moieties encompasses a volume of approximately 400 $Å^3$ when extended to the acetylacetonate methyl groups (Fig. 2). Crystallization solvent (10 × $CHCl_3$) is also found within this cavity. The $Cu(acac)_2$ moieties are approximately perpendicular to the central phenyl ring, whereas the two other phenyl rings are tilted away from the plane. Molecular modelling based on the $Cu_2\mathbf{2}_2$ framework suggests that the $Cu(acac)_2$ moities are sufficiently bulky to preclude catenane formation in **4**. This bodes well for the use of this framework in secondary sphere coordination studies, since R groups such as -CO_2H, -CO_2Me, and -$CONH_2$ may be readily introduced using existing methodology (Scheme 1). Furthermore, extending the cavity volume may also be possible by introducing bulkier aliphatic groups to the metal-binding acetylacetonate

Gas-phase pyrolysis of thiopheneacetic acids, thienylethanols, and related compounds — protophilicity of ring π-electrons and relative acidities of hydrogen-bond donors of hydroxyl groups

Ibtehal A. Al-Juwaiser, Nouria A. Al-Awadi, and Osman M.E. El-Dusouqui

Abstract: Based on kinetic data of thermal gas-phase elimination reactions, the following Arrhenius log A (s^{-1}) and E_a (kJ mol^{-1}) values, respectively, are obtained: 10.76 and 153.5 for 3-thiopheneacetic acid (**1**), 10.08 and 149.4 for 2-thiopheneacetic acid (**2**), 12.04 and 207.1 for 2-(3-thienyl)ethanol (**3**), 11.55 and 203.3 for 2-(2-thienyl)ethanol (**4**), 10.91 and 123.4 for 2-thiopheneglyoxylic acid (**5**), 11.05 and 223.8 for 1-(2-thienyl)propan-1-one (**6**), and 10.33 and 149.8 for 3-thiophenemalonic acid (**7**). The products of these pyrolytic reactions were either carbon dioxide or formaldehyde in addition to methylthiophene or thiophenecarboxaldehyde. Both positional and molecular reactivities of the substrates and related compounds are compared, and the results are rationalized on the basis of a reaction pathway involving a concerted six-membered transition state.

Key words: thiophenes, gas-phase, pyrolysis, kinetics, mechanism.

Résumé : Sur la base de données cinétiques de réactions d'élimination thermiques en phase gazeuse, on a déterminé les valeurs suivantes d'Arrhenius suivantes log A (s^{-1}) et E_a (kJ mol^{-1}) pour respectivement l'acide 3-thiophèneacétique (**1**, 10,76 et 153,5), l'acide 2-thiophèneacétique (**2**, 10,08 et 149,4), le 2-(thién-3-yl)éthanol (**3**, 12,04 et 207,1), le 2-(thién-2-yl)éthanol (**4**, 11,55 et 203,3), l'acide 2-thiophèneglyoxylique (**5**, 10,91 et 123,4), la 1-(thién-2-yl)propan-1-one (**6**, 11,05 et 223,8) et l'acide 3-thiophènemalonique (**7**, 10,33 et 149,8). Les produits de ces réactions de pyrolyse sont le bioxyde de carbone ou le formaldéhyde ainsi que le méthylthiophène ou le thiophènecarboxaldéhyde. On a comparé les réactivités positionnelles ainsi que moléculaires des substrats examinés ici ainsi que celles de composés apparentés et on rationalise les résultats en se basant sur une voie réactionnelle impliquant un état de transition concerté à six chaînons.

Mots clés : thiophènes, phase gazeuse, pyrolyse, cinétique, mécanisme.

[Traduit par la Rédaction]

Introduction

Thiophene is classified as an electron-rich (π-excessive) heteroaromatic compound, with its aromaticity between that of furan and benzene, and reactivity towards electrophiles ca. 10^3- to 10^5-fold higher relative to benzene (1, 2). The structural effects associated with the 2,3-conjugative interaction and the high 2:3-bond order superimposed upon an intrinsic 2 > 3 positional reactivity serve to explain the relative rates and partial rate factors obtained in electrophilic aromatic substitution reactions of thiophene and its N, O, and Se analogues and monosubstituted derivatives (3–5). Hammett substituent-replacement constants reported for both solution and gas-phase reactions suggest that the 2- and 3-thienyl ring systems act as electron withdrawing and electron donating groups, respectively (6). An electron withdrawing effect would be expected to augment the electrophilic nature of the hydroxyl hydrogen of both the alcohol and carboxylic acid moieties of substituted thiophenes. The present study involves thiophenes substituted at the 2- and 3-positions with groups in which terminal O-H moieties serve as H-bond donor acids, and where a protonic hydrogen is available for intramolecular electrophilic H-exchange processes. Reactions of this nature, for which a concerted six-membered transition state (TS) is postulated, are expected to have favourable conformations and effective intramolecular pre-organization. A representative example is the thermal gas-phase elimination reaction of 2-thiopheneglyoxylic acid, the final product of which is 2-thiophenecarboxaldehyde (Scheme 1).

Previous studies on comparable reactions have lead to the conclusion that, during the development of the TS of the elimination process, either bond **a**, **b**, or **d** (Scheme 1) could be effectively displaced further away from the reacting site compared with the other two bonds, or that a combined

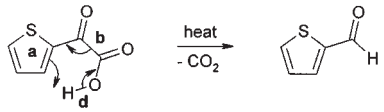
Scheme 1. Reaction pathway, concerted six-membered TS, and final product of thermal gas-phase elimination.



effect on the observed reactivity involves either two or all three of the bonds (7–11). The effect of the double bond (**a**) is associated with the lability (protophilicity) of its π-electrons, the effect of **b** depends on bond polarity, and that of **d** results from the relative acidity of the H-bond donor and the magnitude of the positive charge developing on the hydrogen. In addition, an important factor in these elimination reactions is the relative thermodynamic stability of the incipient moieties leading to the products (10*a*, *c*). It is noteworthy that a six-membered TS has also been proposed for decarboxylation reactions of heteroarylacetic acids in aqueous media (12).

Results and discussion

Kinetics

The kinetic data of the gas-phase elimination reactions of the seven compounds (**1**–**7**) under study are given in Table 1. Each rate constant represents an average from a set of three values obtained in three separate kinetic runs; all three values were measured at the same temperature. The agreement between the rate-constant values in each set is within ±2%. Each elimination process was monitored until 90–95% of reaction was completed. The temperature range (54 ± 7 K) over which each compound was investigated is a prerequisite for reliable kinetic studies (9–11). Arrhenius parameters were obtained using the results from Table 1. The Arrhenius plots were linear over the temperature range studied, with correlation coefficients of the order of 0.990 ± 0.009. For example, for 3-thiopheneacetic acid (**1**) at 53.5 K the correlation coefficient is 0.9994. Arrhenius log A (s^{-1}), $\Delta S^{\#}$ (J mol^{-1} K^{-1}), the energy of activation (E_a, kJ mol^{-1}), and the first-order rate constants (k, s^{-1}) of the elimination reactions at 600 K are recorded in Table 2. The values of log A (s^{-1}) show a narrow range for each set of compounds (10.5 ± 0.4 for the acids and 11.8 ± 0.2 for the alcohols), but a wider range for the E_a (kJ mol^{-1}) values, an indication of dependence of the reaction on E_a. This seems to be a common feature of polar thermal gas-phase elimination processes (13). The values for $\Delta S^{\#}$ (J mol^{-1} K^{-1}) are negative and relatively large, which might be the result of considerable pre-organization leading to the formation of the six-membered TS postulated for such gas-phase reaction pathways (7). It is to be noted that an earlier but independent preliminary study by our group on the present substrates gave almost identical reaction rate factors at 450 K; however, only the rates for pyrolysis at 600 K are reported here.

Reaction products

Reaction products for complete pyrolysis were obtained for all substrates except 1-(2-thienyl)-1-propanone, since its complete pyrolysis required temperatures beyond the operating temperatures of the reactors. Pyrolyses were carried out either in a flow reactor or in a sealed-tube pyrolyzer at temperatures comparable with those used in the kinetic investigations. The reactions were allowed ample residence time to ensure maximum pyrolysis. The constituents of the pyrolysates were analyzed using GC–MS, FT-IR, and ^1H NMR techniques. Conversion of the acid and alcohol starting materials into reaction products was monitored in part by observing the absence of the characteristic FT-IR absorption peaks of the substrates. Pyrolysis of 2-thiopheneacetic acid (**2**) and 2-(2-thienyl)ethanol (**4**) gave 2-methylthiophene (*m*/*z*: $M^{\bullet+}$ = 98 and base peak at 97; the corresponding values for their precursor substrates are $M^{\bullet+}$ = 142 and $M^{\bullet+}$ = 128, respectively). On the other hand, pyrolysis of 3-thiopheneacetic acid (**1**) and 2-(3-thieny)ethanol (**3**) produced 3-methylthiophene with *m*/*z* values identical to those of their 2-substituted analogues. Differentiation between 2-methylthiophene and 3-methylthiophene was derived from their respective ^1H NMR spectra (2-methylthiophene ($CDCl_3$) δ: 3.2–3.5 (s, 3H, CH_3), 6.8–7.7 (m, 3H, HAr); 3-methylthiophene ($CDCl_3$) δ: 2.1–2.3 (s, 3H, CH_3), 6.9–7.5 (m, 3H, HAr)). Pyrolysis of 2-thiopheneglyoxylic acid (**5**) gave 2-thiophenecarboxaldehyde (*m*/*z*: $M^{\bullet+}$ = 112, and fragment ions at 111 and 83; ν_{max}: 1655 (C=O); and δ ($CDCl_3$): 7.3–8.3 (m, 3H, HAr), 10.0 (s, 1H, HCO)). It is noteworthy

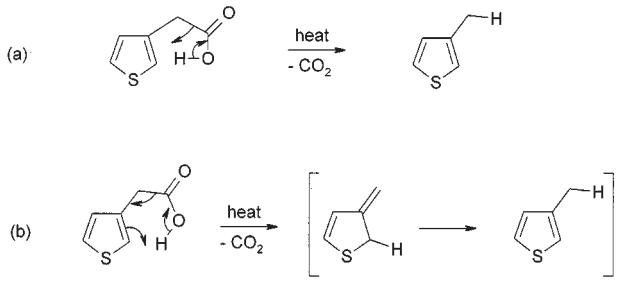
Scheme 2. Concerted four-membered TS (*a*) and six-membered TS (*b*) for pyrolysis of 3-thiopheneacetic acid.



that 3-thiophenemalonic acid (**7**) gave pyrolysis products and a rate constant similar to those of 3-thiopheneacetic acid, an indication that the latter seems to be the primary decomposition product, which then pyrolyzes further into 2-methylthiophene and CO_2.

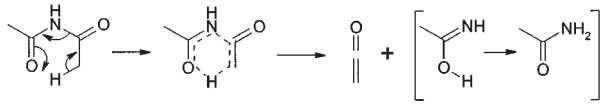
Reaction pathway and molecular reactivity

The present results for substrates **1**–**7** suggest a homogeneous unimolecular first-order elimination process. Moreover, the magnitudes of the Arrhenius-parameter values are in the range expected for such reactions (7, 13–16). The homogeneous nature and the lack of reactor-surface effects were proven by increasing the available surface area for reaction using tubes packed with glass helices. An increase of ca. 50% in surface area produced no noticeable change in the reaction rates. Kinetic runs were also conducted in the presence and absence of cyclohexene (free-radical scavenger). The rates, however, remained the same within experimental error. Additional analysis of the pyrolysates gave no indication of a radical-based reaction product.

Product formation can be rationalized either (*i*) on the basis of a mechanism involving a concerted four-membered TS or (*ii*) by a pathway with a concerted six-membered TS. The two mechanisms are shown in Scheme 2 for the gas-phase elimination reaction of 3-thiopheneacetic acid.

Although it is much simpler to explain product formation using the four-membered TS mechanism (Scheme 2*a*), theoretical and experimental evidence favour the six-membered TS (Scheme 2*b*). This evidence includes the following: (*i*) the conformation of the cyclic six-membered structure is known to be much more stable compared with the highly strained four-membered counterpart. (*ii*) The development of the six-membered TS requires a more facile intramolecular transfer of the electrophilic hydrogen to the protophilic thiophene ring positions, which are amenable to electrophilic attack. (*iii*) Theoretical ab initio calculations on the mechanism of similar thermal gas-phase elimination reactions gave results based on a six-membered TS that agree well with experimental values. In addition, these calculations have replaced the proposed four- and five-membered TS with five- and six-membered structures, respectively (17, 18).

Scheme 3. Calculated reaction mechanism for thermal gas-phase elimination of diacetamide.



The theoretical studies used analytical gradients at the MP2//RHF/6–31G* level of theory, optimization routines, and microcanonical probability fluxes through TS to map PES and to calculate activation barriers and rate constants for the thermal reactions. The compounds whose elimination reactions were assigned a concerted six-membered TS include diacetamide, β-hydroxyketones, acetic anhydride, and methyl benzoylformate (17). Concerted five-membered TS were calculated for the pyrolysis of pyruvic acid, benzoyl formic acid, 3-hydroxy-3-methyl-2-butanone (α-oxoacids and α-hydroxyketone), and a large number of α-substituted carboxylic acids (17, 18). The theoretical calculations further confirm that the development of the TS involves intramolecular hydrogen transfer to a protophilic site and concomitant formation and breaking of the other bonds in the concerted structure. Typically, the reaction pathway calculated for the thermal gas-phase elimination reaction of diacetamide shown in Scheme 3 reproduces the cyclic six-membered TS, which accounts for the kinetic values and the reaction products reported in the experimental study of this substrate (17*a*, 19).

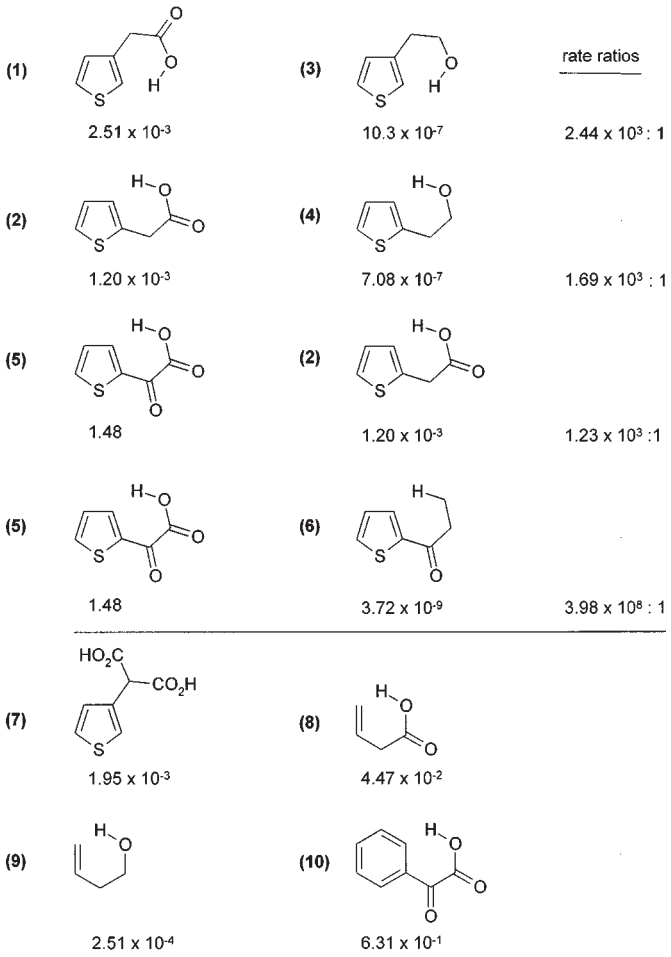
The six-membered TS mechanism (Scheme 2*b*), presently adopted to account for the kinetic results and reaction products of the thiophene compounds (**1**–**7**), has also been proposed for the thermal elimination reaction of 3-butenoic acid (**8**), 3-buten-1-ol (**9**), and the π-deficient 2-(2-ethoxy)pyridine systems (7, 15). The values of the Arrhenius parameters reported for the latter systems are comparable to those obtained in the present study.

The gas-phase molecular and positional reactivities of the thiophene compounds (**1**–**7**) and related systems (**8**–**10**) given in Scheme 4 allow for the following comparisons to be made:

(*i*) the thiopheneacetic acids **1**, **2** are more reactive than their thienylethanol analogues (**3**, **4**) by a factor ca. 2×10^3.

© 2002 NRC Canada

Scheme 4. Rate coefficients (k, s^{-1}) at 600 K and selected rate ratios for pyrolysis of present substrates (**1**–**7**) and related compounds (**8**–**10**).



This large difference in molecular reactivity is ascribed to a more acidic H-bond (bond **d**, Scheme 1) and to the magnitude of the positive charge developing on the incipient hydrogen of the OH group of substrates **1**, **2**. The difference in reactivity becomes much larger (a factor of 4×10^8) when the O–H moiety of **5** is compared with a C–H bond of related ketone **6**.

(*ii*) 2-Thiopheneglyoxylic acid (**5**) is 1.2×10^3 more reactive than 2-thiopheneacetic acid (**2**). This is a consequence of the effect of the relative bond polarity (bond **b**, Scheme 1) on molecular reactivity, and on the repulsion between the positive charge on the carbon atoms of the adjacent carbonyl groups of **2**, which result in a more polar bond (**b**) in **2**.

(*iii*) Aliphatic 3-butenoic acid (**8**) and 3-buten-1-ol (**9**) are both more reactive than their heteroaromatic thienyl counterparts (3- and 2-thiopheneaceatic acid (**1**, **2**) and 1-(3-thienyl)- and 1-(2-thienyl)ethanol (**3**, **4**), respectively). The rate factors involved are, respectively, 18 and 37 for the former, and 244 and 355 for the latter pair of analogues. This pattern of relative reactivities indicates that although the thiophene ring is π-excessive in nature, its π bonds (bond **a**, Scheme 1) are still less protophilic than the aliphatic π bonds. Comparative protophilicity of bond **a** also explains why the rate of the elimination reaction of 3-buten-1-ol ($k = 2.5 \times 10^{-4}$ s^{-1} at 600 K, protophilic alkene π bond) is much lower than that of 4-hydroxy-2-butanone ($k = 1.5 \times 10^{-2}$ s^{-1} at 600 K, protophilic carbonyl moiety) (15). The effect of aromaticity on molecular reactivity is demonstrated when thiopheneglyoxylic acid (**5**) is shown to be twofold more reactive than benzoylformic acid (**10**); the latter being the more aromatic in nature (20).

(*iv*) 3-Thiopheneacetic acid (**1**) is more reactive than its 2-isomer (**2**) by a factor of ca. 2, whereas the corresponding relative rate factor for the thienylethanols (**3** and **4**) is 1.5. These rate factors, though moderate, are nevertheless consistent with the accepted intrinsic 2 > 3 positional reactivities of π-excessive five-membered aromatic heterocycles (4, 5). In the present systems, the protonic H of the group at the 3-position is reacting with the more protophilic π-bond at the nuclear 2-position.

(*v*) 3-Thiophenemalonic acid (**7**) has two equivalent carboxylic acid groups that are equally susceptible to decarboxylation during pyrolysis, whereas 3-thiopheneacetic acid (**1**) only has one such group. Statistically, **7** would be expected to be twice as reactive as **1**; however, the rate constants of the elimination reaction of the two acids are comparable (2.0×10^{-3} s^{-1} and 2.5×10^{-3} s^{-1}, respectively). The reason that the higher reactivity expected for **7** is not observed might be due to intramolecular H-bonding involving the two acid groups, with an adverse effect on the molecular reactivity of acid **7**.

Experimental

Materials, techniques, and instrumentation

The acids, alcohols, and ketone (**1**–**7**) under investigation are commercially available from Aldrich. The substrates and the constituents of their pyrolysates were characterized using GC–MS, FT-IR, and ^{1}H NMR spectroscopy. Instrumentation included a Finnigan Mat INCOSXL for GC–MS studies, a PerkinElmer 2000 for the FT-IR, and a Bruker AC80 for the NMR analysis. Kinetic runs were conducted in a Chemical Data System (CDS) custom-made pyrolyzer comprising an insulated aluminium block fitted with a platinum-resistance thermometer and a thermocoupler connected to a Comark microprocessor thermometer. The temperature of the aluminium block was controlled by a digital Eurotherm 093 precision temperature regulator. It is to be noted that aluminium was chosen for its low temperature gradient and resistance to elevated temperatures. HPLC analysis of kinetic runs was carried out on a Bio-rad Model 2700 coupled with a Bio-rad 1740 UV–vis detector.

Kinetic measurements and product analysis

Procedures for kinetic measurements and data treatment and analysis of pyrolysates using flow-reactors have been described in detail elsewhere (9*a*, 10*b*, 19). Reaction products were obtained in sealed-tube pyrolyzers. Acetonitrile was used as the solvent for both kinetic and reaction product studies, and either benzene or 1,2,3-trichlorobenzene as the internal standard in the quantitative chromatography measurement of the extent of the reaction.

A facile methodology for the synthesis and detection of N7-guanine adduct of sulfur mustard as a biomarker

Mula Kameswara Rao, Pinaki S. Bhadury, Mamta Sharma, Rajinder S. Dangi, Appanabhotla S.B. Bhaskar, Syed K. Raza, and Devendra K. Jaiswal

Abstract: A simple and convenient method has been developed for the synthesis of a N7-guanine adduct of sulfur mustard (SM), which can serve as an efficient biomarker for alleged exposure to SM. The adduct obtained in high yields (~78%) was characterized on the basis of its physical properties and spectral data. In addition, HPLC and LC–MS conditions have been standardized for the detection of the adduct in both in vitro and in vivo samples, which is useful for retrospective detection of exposure to SM in biological samples.

Key words: sulfur mustard, biomarker, N7-guanine adduct, in vitro, in vivo, HPLC, LC–MS, electrospray, 2D NMR.

Résumé : On a développé une méthode simple et pratique de synthétiser l'adduit de la N7-guanine avec la moutarde au soufre (MS) qui peut servir de biomarqueur efficace dans les cas supposés d'exposition à la MS. L'adduit qui a été obtenu avec des rendements élevés (environ 78 %) a été caractérisé sur la base de données physiques et spectroscopiques. De plus, on a développé des conditions standards de chromatographie liquide à haute performance (CLHP) et de spectrométrie de masse couplée à la chromatographie liquide (SM–CL) pour la détection de l'adduit dans des échantillons in vitro ainsi que in vivo; celles-ci seront très utiles pour la détection rétrospective d'expositions à la MS dans des échantillons biologiques.

Mots clés : moutarde au soufre, biomarqueur, adduit de la N7-guanine, in vitro, in vivo, CLHP, SM–CL, électronébulisation, RMN 2D.

[Traduit par la Rédaction]

Introduction

Sulfur mustard (SM) is a carcinogen because of its ability to alkylate DNA (1, 2). The primary site of alkylation is the N7 position of guanine (3, 4) resulting in the formation of N7-[2-[(2-hydroxyethyl)thio]ethyl]guanine (**V**). This is the most abundant adduct arising out of alkylation of DNA with SM (4, 5). The adduct can be formed in the skin, blood, and urine of animals allegedly exposed to SM and can, therefore, serve as a biomarker for the retrospective detection of exposure to SM in alleged exposure to the agent (6, 7). Attempts have, therefore, been made to develop a synthetic method for the preparation of synthetic standard of N7-guanine–SM adduct to be used as reference material for its detection in real biological samples obtained from the patients allegedly exposed to SM.

The reported method for the synthesis of N7-guanine–SM adduct from guanosine-5′-monophosphate (GMP) and SM involves a cumbersome procedure with poor yields (15%) (3). Furthermore, in these studies, attempts were not made to understand the underlying chemistry and structures of the intermediates formed during the reaction. We have developed a simplified and improved methodology for the synthesis of N7-guanine–SM adduct, based on the techniques adopted for the methylation of certain purine nucleosides (8). In this paper, we discuss the mechanism, the probable structures of the pH-sensitive intermediates, and the underlying chemistry behind the improved and facile synthesis of the adduct, which has been fully characterized on the basis of its physical properties and its spectral data. Furthermore, a methodology for the detection of the adduct by HPLC and LC–MS with electrospray ionization has also been standardized, and has been successfully applied for the analysis of the adduct obtained from in vitro and in vivo samples.

Results and discussion

We have developed a simplified and improved methodology for the synthesis of the N7-guanine–SM adduct. This method is analogous to the techniques adopted for the methylation of certain purine nucleosides (8). It is well documented that alkylation of guanosine using methyl iodide generates N7-methyl guanosine as an iodide salt. This salt on treatment with concentrated aqueous ammonia is converted into a water-soluble betaine 7-methyl guanosine intermediate. It should be noted that this internal betaine (which is not a salt) is characteristic of N7-alkylated guanosine derivatives. Both N7-methyl guanosine and its iodide salt, i.e.,

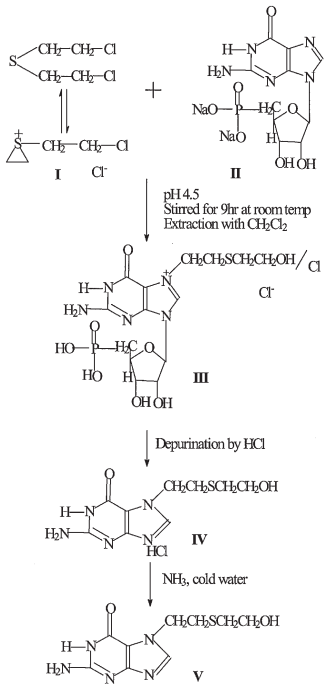
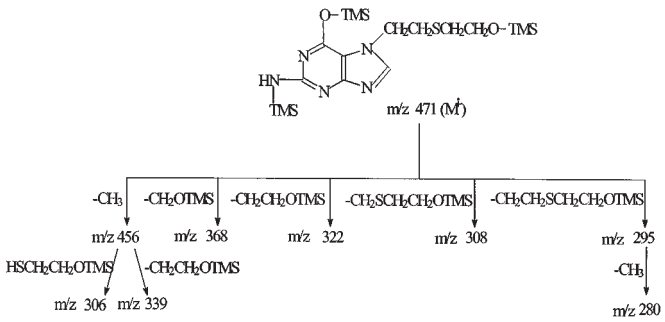


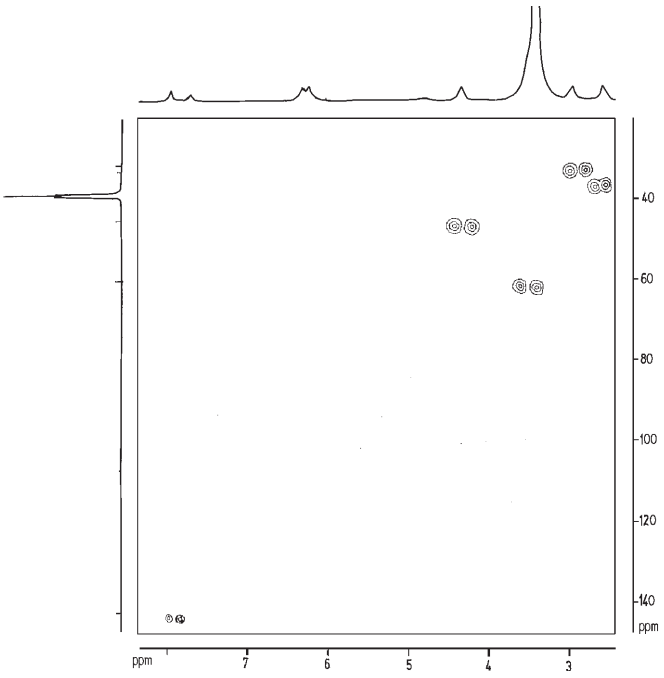
Scheme 2. Fragmentation mechanism under electron impact (EI) conditions.



N7-methyl guanine hydro iodide, can be hydrolyzed or depurinated by acid to yield 7-methyl guanine.

Using the same analogy, we reacted sulphur mustard (SM, **I**) with guanonsine-5′-monophosphate (GMP) (**II**) in aqueous medium to generate the chloride salt of N-7-[2-[(2-hydroxy/chloro-ethyl)thio]ethyl]guanosine monophosphate (**III**). This salt was formed via the interaction between the N7 nitrogen atom of the purine base and sulphur mustard, presumably existing as a sulfonium species, through a S_Ni rearrangement. The pH of the reaction mixture was maintained at 4.5. The hydrochloride salt was then purified by careful extraction with dichloromethane to remove the organic impurities, mainly thiodiglycol. The salt thus obtained was subjected to direct depurination by hydrochloric acid to afford the hydrochloride salt of the desired N7-guanine–SM adduct (**IV**). Since GMP was totally consumed as indicated by HPLC and the organic impurities removed by extraction, the aqueous extract, containing soluble hydrochloride of N7-guanine–SM adduct, was neutralized with ammonia resulting in the formation of the free insoluble organic base (N-7-[2-[(2-hydroxyethyl)thio]ethyl]guanine, **V**), which was precipitated out and collected (Scheme 1).

Fig. 1. 2D COSY (HETCOR) spectrum of N7-guanine–SM adduct.



Experiments showed that hydrolysis was achieved at the salt stage (Scheme 1, ensuring the absence of any unreacted GMP) and that this method of hydrolysis did not involve any binding or retention of the product on the column. Furthermore, since this type of hydrolysis does not contain any inorganic salts or thiodiglycols, the purification technique employing sephadex G-10 column as used in earlier methods was also avoided. This resulted in the development of a synthetic method that not only is drastically simplified but also results in excellent yields of the final product. The purity of the final product was confirmed by HPLC (99%).

It should be noted that, the solvent, the pH, and the substrate play a major role in the selective synthesis of the N7-monoalkylated guanine adduct of sulphur mustard. The selection of GMP over guanosine is based on its solubility in water — pH 4.5 has been found to be the most effective for exclusively obtaining the N-7 adduct. Alkylation at position 9 through other tautomeric forms of the imidazole ring or the formation of a dialkylated product in the ring or a mixture of both is avoided by blocking position 9 with a sugar moiety. Moreover, under this steric model, N7 is the only position favoured for alkylation that is not involved in hydrogen bonding in the Watson–Crick model of DNA (4). At pH 4.5, not only is the nucleophilicity of N-7 nitrogen maintained, but depurination of GMP is also avoided. On the other hand, at an alkaline pH, SM is converted into thiodiglycol via the interaction of nucleophilic water with an intermediate sulphonium species. Thus alkylation of water is preferred over N7-purine at alkaline pH and hence reaction conditions at pH 4.5 are preferred. In addition, an excess of SM is added to avoid the formation of a di-adduct of purine and SM.

Fig. 2. Direct-probe EI (above) and CI (below) mass spectra of the silylated N7-guanine–SM adduct.

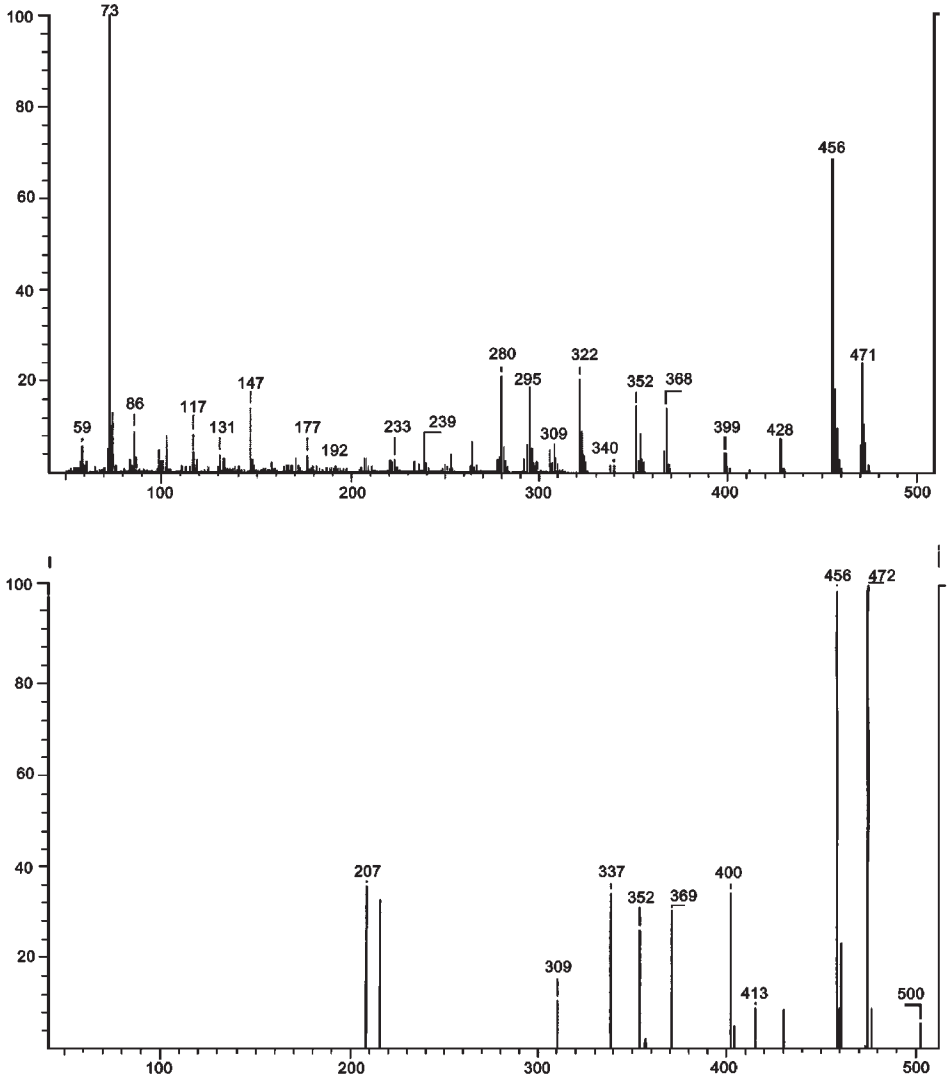

Fig. 3. Reverse-phase HPLC chromatogram for the N7-guanine–SM adduct dissolved in DMSO. The adduct eluted at 3.9 min.

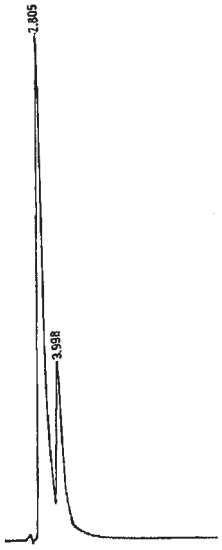

The adduct has been characterized on the basis of its physical properties and its spectral data. The melting point, the UV absorbance, and ^{1}H and ^{13}C NMR data of the adduct were in full agreement with the reported values (5). In addition, we also recorded the 2D NMR spectrum (Fig. 1) of the adduct, which clearly showed long-range coupling (4 Hz and 3 Hz for C-8 and C-5, respectively) between N7-CH_2 and C-8 and C-5 carbons. This long-range coupling is indicative of CH_2 being attached to the N7 position of the guanine. The adduct was not amenable to GC–MS even after derivatization (3, 12, 13). Since the compound was pure, analysis by direct probe MS was attempted. The adduct however failed to give a reasonable spectrum under these conditions. Analysis of the silylated derivative of the adduct with a direct probe, however, provided a spectrum showing a strong molecular-ion peak at *m*/*z* 471 (Fig. 2). The molecular weight of the adduct was further confirmed by recording a CI-MS spectrum of the compound, which showed an $[M + H]^{+}$ ion peak at *m*/*z* 472 (Fig. 2). Fragment ions in EI-MS were observed at *m*/*z* 456, 399, 368, 352, 322, 339, 295, 280, 264, 239, 177, 147, 131, 117, 103, and 73. The genesis of the formation of some of the significant ions is shown in

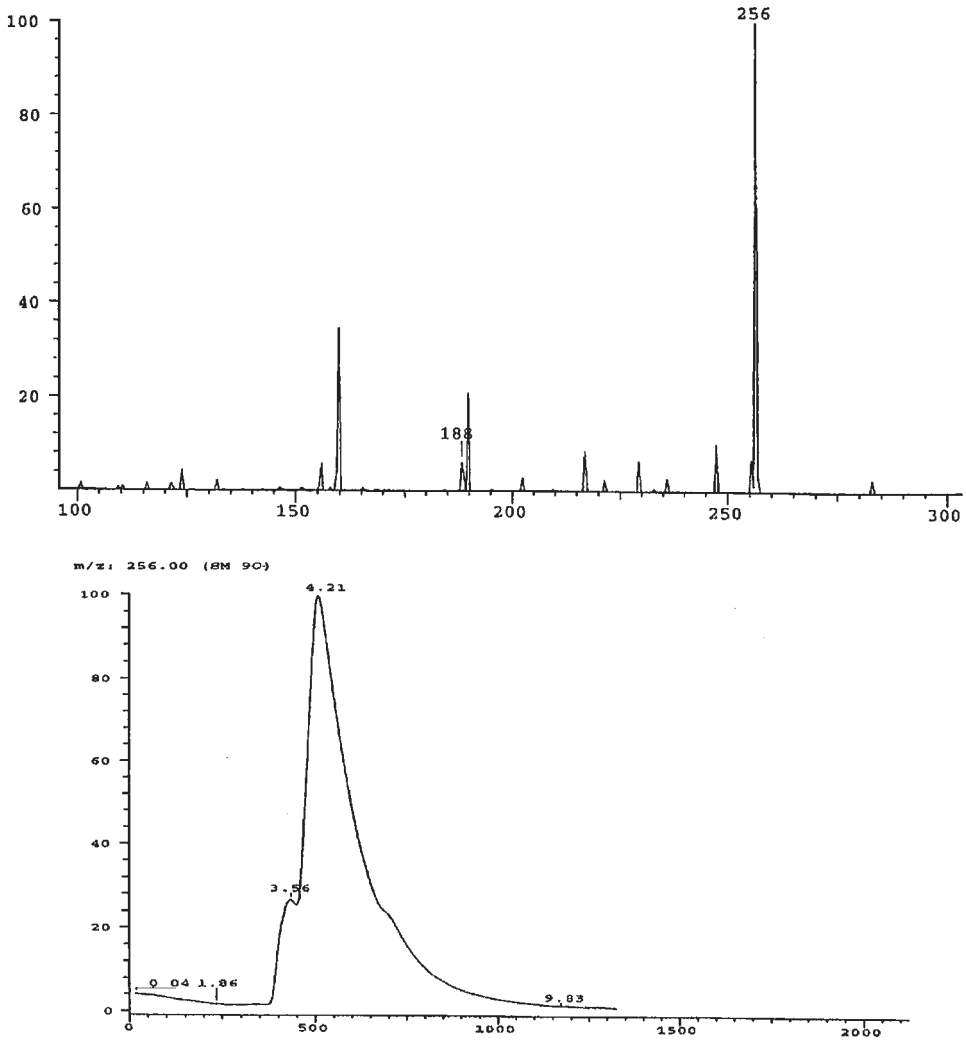
Fig. 4. ESI-MS spectrum (top) of the N7-guanine–SM adduct showing a $[M + H]^+$ peak at *m*/*z* 256 and ion chromatogram (bottom) for the adduct at *m*/*z* 256.



Scheme 2. The mechanism proposed has been confirmed by performing MS–MS experiments in daughter-ion mode.

A method based on HPLC and LC–MS using electrospray ionization has also been optimized for easy detection of the adduct. HPLC analysis was performed on a PG C-18 column using 25 mM NH_4HCO_3 in 20% methanol (v/v) (pH 8) as the mobile phase at a flow rate of 1 mL min^{-1}. The adduct was detected by UV at 280 nm. The adduct was well separated under these conditions and showed an excellent response. The results were reproducible (Fig. 3). The adduct was also subjected to LC–MS analysis using electrospray ionization and gave an $[M + H]^+$ ion peak at *m*/*z* 256 (Fig. 4). The detection limit achieved using LC–ESI-MS was 10 ng.

The HPLC and LC–MS methods developed for the synthetic standard has been successfully used for the detection of adduct in various in vitro and in vivo samples. The adduct formed in vitro by reacting calf thymus DNA with SM has been analyzed by HPLC using the same conditions as optimized for synthetic standard. The results are shown in Fig. 5. These samples were also analyzed by direct-probe MS after silylation, and LC–MS and the spectra matched well with those obtained from the synthetic standard.

For in vivo samples, SM was given percutaneously to rats. Liver and spleen were collected after 7 days. The DNA content in these tissues was estimated for the analysis of N7-guanine–SM adduct and was found to be 38 μg in spleen and 56 μg in liver. Previously, our laboratory showed that there is time- and dose-dependent DNA damage in various organs after percutaneous or inhalation exposure of SM (14). We observed persistent DNA damage in liver, spleen, and thymus even after 7 days exposure and liver was the major organ affected in terms of DNA damage by either dermal or inhalation exposure. In the present study, N7-guanine–SM adduct was detected in both types of tissues 7 days after a single dermal exposure (Fig. 6).

Conclusion

The method developed for the synthesis of N7-guanine–SM adduct as a biomarker for the verification of alleged exposure to SM is simple and convenient. The purification stages

do not employ Q-sepharose or sephadex G-10 and hence the yields are much better than those previously reported. The chemistry behind the synthesis was explained in detail. A detection methodology based on HPLC and LC–MS with electrospray ionization was also developed for the easy detection of adduct, which is useful when monitoring the biomarker in biological samples obtained from the patients allegedly exposed to SM.

Experimental

Chemicals

Sulphur mustard (2,2′-bis(2-chloroethyl)sulphide, SM) is a carcinogen and cytotoxic agent. All operations involving this compound should be carried out only in a well-ventilated fume cupboard by experienced personnel. Guanosine monophosphate (disodium salt), CT DNA, and the enzymes used for the hydrolysis of DNA adduct were purchased from Sigma (St. Louis, MO). The solvents used were from E. Merck (India).

Synthesis of sulfur mustard

Sulfur mustard used in this study was synthesized in our laboratory according to the standard procedure (9) and found to be 99% pure by GC.

Synthesis of N7-[2-[(2-hydroxyethyl)thio]ethyl]guanine

A solution of guanosine-5′-monophosphate (GMP) disodium salt monohydrate (814 mg, 2 mmol) in water (20 mL) was adjusted to pH 4.5 with 1 N HCl. The mixture was transferred into a two-necked flask (100 mL) and stirred at room temperature for 5 min. One end of the flask was connected to a U-shaped tube filled with active carbon. Sulfur mustard (0.50 mL, 4 mmol) was then added into the reaction mixture by means of a micropipette in one shot through the second neck of the flask. The pH of the reaction mixture immediately decreased due to the liberation of HCl, which was readjusted to 4.5 with 0.1 N NaOH solution. The reaction mixture was stirred vigorously at room temperature and continuously monitored by HPLC for the complete consumption of GMP. The reaction mixture was then neutralized with 0.1 N NaOH solution and stirred for an additional 10 min. The organic impurities (mainly thiodiglycol) were then removed by careful extraction with dichloromethane (3 × 20 mL). The aqueous extract containing the chloride salt of the GMP–SM adduct was concentrated on a speed vacuum lyophiliser. The adduct was then dissolved in 1 N HCl (50 mL) and subjected to direct depurination on a boiling water bath for 2 h. The resulting adduct was a soluble hydrochloride. The reaction mixture was then concentrated to a small volume (10 mL) under reduced pressure and neutralized with ammonia. The free insoluble organic base (N7-guanine–SM adduct) immediately precipitated out from the reaction mixture. The material was filtered under suction, washed repeatedly with cold water, and dried in a vacuum desiccator. The isolated yield of the adduct was 400 mg (~78%). Melting point: >280°C (dec.). UV λ_{max} (nm, pH 7): 284. ^{1}H NMR (DMSO-d_6) δ: 10.79 (br s, H, NH), 7.93 (s, 1H, H-8), 6.17 (s, 2H, NH_2), 4.89 (t, 1H, OH), 4.32 (t, 2H, CH_2OH), 3.52 (t, 2H, CH_2OH) 2.94 (t, 2H, $NCCH_2S$), 2.56 (t, 2H, SCH_2COH). ^{13}C NMR (DMSO-d_6) δ: 160.1 (C_4), 154.7 (C_6), 153.2 (C_2), 143.5 (C_8), 107.9 (C_5), 60.8 (CH_2OH), 46.0 (NCH_2), 33.8 (SCH_2COH), 32.2 ($NCCH_2S$). EI-MS *m/z* (%): 471 (M^+, 24), 456 (65), 399 (6.6), 368 (18), 352 (18), 339 (7), 322 (22.6), 308 (7.9), 306 (5.3), 295 (18.6), 280 (24), 264 (6.6), 239 (8), 177 (6.6), 147 (17.3), 131 (8), 103 (9.3), 73 (100). CI-MS *m/z* (%): 472 ($[M + H]^+$, 100), 456 ($[M - 15]^+$).

In-vitro SM–CT DNA adduct formation

A solution of double stranded calf thymus DNA (1 mg mL^{-1} in phosphate-buffered saline) was treated with

© 2002 NRC Canada

SM in acetone (1 mM) for 24 h at 37°C. The G + C content obtained in 1 mg CT DNA was 40%, which is similar to the published G + C content (42%) (10, 11). The reaction was stopped by precipitating DNA from the reaction medium on ice with a mixture of 3 M sodium acetate and ice cold ethanol (0.1:3 v/v) and centrifuging for 15 min at 3000 rpm. The supernatant was removed and the pellet was washed with ice cold 70% aqueous ethanol and the wash was added to the supernatant. The pellet was air dried for 15 min and dissolved in 50 mM Tris buffer. The DNA was then enzymatically hydrolyzed (10) at 37°C overnight using nuclease P1 (24 U mL^{-1}), alkaline phosphatase (3 U mL^{-1}), DNase (10 U mL^{-1}), and phosphodiesterase (0.3 U mL^{-1}). The enzymatic hydrolysis was stopped by heating the sample at 100°C for 5 min, followed by centrifugation and filtration to remove the denatured enzyme proteins. Acidic hydrolysis of the reaction mixture was also performed by adding 0.1 N HCl to the alkylated DNA in Tris buffer and the sample was heated at 75°C for 20 min to release the purine bases. The sample was then cooled to room temperature and the pH was adjusted to 7.2 with potassium hydroxide solution and stored at 4°C until analysis. The samples in each case were concentrated by speed-vacuum lyophilization prior to analysis by HPLC and LC–MS. The sample was dried, silylated, and analyzed by direct-probe MS. The yield of the adduct based on guanine residue in the CT DNA and the SM added was 24%.

In-vivo formation of N7-guanine–SM adduct

The tissues selected for the in vivo formation of N7-guanine–SM adduct were spleen and liver. Female albino rats of weight range of 230–250 g were used in this study. SM dose was 3 mg kg^{-1} dissolved in PEG 300, and applied (100 μL) percutaneously after clipping the hairs on the back. Animals were observed for 7 days. On 7th day animals were sacrificed, the liver and spleen were quickly excised in cold PBS, and stored at –70°C. Genomic DNA was isolated from tissue sample using QIAamp DNA mini kit (QIAGEN GmbH, Germany). Genomic DNA was collected in deionized water and DNA content was estimated using spectrofluorimetry. The DNA content estimated for the analysis of N7-G–SM adduct was 38 μg in spleen and 56 μg in liver. Acid hydrolysis was employed for the release of adduct from the backbone of DNA (10). After hydrolysis samples were centrifuged at 500 × *g* for 20 min, supernatants collected and freeze dried. Just before HPLC analysis samples were redissolved in acidic methanol (50 μL), centrifuged again at 500 × *g* . Clear supernants were injected in to HPLC.

Instrumentation

HPLC analysis was carried out on a reverse-phase C-18 column using Shimadzu LC-6A. The mobile phase used was 25 mM NH_4HCO_3 in 20% methanol (v/v) (pH 8) at a flow rate of 1 mL min^{-1}. The UV detection was at 280 nm. ^1H, ^{13}C, and 2D NMR spectra were recorded on a Bruker Avance 400 MHz spectrophotometer. Chemical shifts are given in ppm relative to TMS. The solvent signal at 2.51 ppm (residual DMSO in DMSO-d_6) served as a reference for ^1H NMR spectroscopy, whereas the solvent signal at 39.59 ppm (DMSO-d_6) was used as a reference for ^{13}C NMR spectroscopy. UV spectra were recorded on a Speccord 200 (Analytical Jena, Carl Zeiss Technology, Germany). Direct-probe MS (EI and CI) and LC–MS experiments were carried out on a TSQ 7000 mass spectrometer (Finnigan Mat, U.K.) using electrospray ionization in positive-ion mode. The samples in LC–MS were introduced through HP 1100 HPLC system using PG C-18 column with 25 mM NH_4HCO_3 in 20% methanol (v/v) (pH 8) as the mobile phase at a flow rate of 1 mL min^{-1}. The sheath gas (nitrogen) pressure was 60 psi and the capillary temperature was set at 200°C. The spray needle was held at 4.5 KV. MS–MS experiments in daughter-ion mode was performed by using argon as the collision gas at a pressure of 2 torr.

Medium-size cyclophanes. Part 60[1]: Synthesis and conformational studies of 9-substituted [3.3]metacyclophane-2,11-diones and conversion to the corresponding [3.3]metacyclophanes

Takehiko Yamato, Koji Tsuchihashi, Noriko Nakamura, Mai Hirahara, and Kan Tanaka

Abstract: Various *syn*- and *anti*-9-substituted [3.3]metacyclophane-2,11-diones are obtained by the coupling reaction of the corresponding 2,6-bis(bromomethyl)benzenes (**3**) with 2,6-bis[2-cyano-2-(toluenesulfony)ethyl]-4-*tert*-butyl-1-substituted benzenes (**4**) in dimethylformamide (DMF) with an excess of sodium hydride. Depending on the substituents at positions 1 and 4 on **3**, different yields (inversion of selectivity) of *anti*-**5** and *syn*-**5** were achieved.

Key words: metacyclophanes, cyclization, conformation, CH–π interaction, through-space interaction, charge-transfer-type interaction.

Résumé : Le couplage des 2,6-bis(bromométhyl)benzènes correspondants (**3**) et des 2,6-bis[2-cyano-2-toluènesulfonyl)éthyl]-4-*tert*-butylbenzènes substitués en position 1 (**4**) effectué dans le diméthylformamide (DMF) avec un excès d'hydrure de sodium permet d'obtenir diverses [3.3]métacyclophane-2,11-diones portant des substituants *syn*- et *anti*- en position 9. Les rendements (avec inversion de sélectivité) en composés *anti*-**5** et *syn*-**5** varient avec la nature des substituants dans les positions 1 et 4 des divers 2,6-bis(bromométhyl)benzènes (**3**).

Mots clés : métacyclophanes, cyclisation, conformation, interaction CH–π, interaction à travers l'espace, interaction de type transfert de charge.

[Traduit par la Rédaction]

Introduction

The synthesis and stereochemical aspects of conformationally mobile [3.3]MCPs (MCP= metacyclophane) have been of interest for the past decade, with particular attention (2) paid to dithia[3.3]MCPs, which possess an *anti*-stepped conformation. The pioneering conformational investigation of 2,11-dithia[3.3]MCPs was reported by Vögtle and Schunder (3). While Shinmyozu and co-workers (4) reported the first preparation and conformational behavior of carbocyclic [3.3]MCPs **1** and their analogues. The [3.3]MCP **1** exist in the crystal state in a *syn* geometry with the trimethylene chains in a chair–chair arrangement (Fig. 1). The preferred geometry of **1** in solution is also *syn* on the basis of the ^{1}H NMR spectrum, in which **1** shows a strong temperature-dependent phenomenon at low temperatures (5, 6).

Shinmyozu and co-workers (4) prepared [3.3]MCP **1** using (*p*-tolylsulfonyl)methyl isocyanide (TosMIC) as the cyclization reagent, followed by a Wolff–Kishner reduction (4). They also performed studies on the *syn–anti* conversions in other [3.3]MCPs, especially in relation to the size of the substituents such as halogens (7). Like the parent compound, 9-halo[3.3]MCPs prefer the *syn* conformation but the corresponding 2,11-diones favour the *anti* arrangement. Even one internal halogen substituent is sufficient to allow the isolation of a discrete *syn* or *anti* isomer. Although the effect on the ratio of *syn* and *anti* conformers of [3.3]MCPs was reported, it is still not clear what the effects are — including not only the properties of the internal substituents, but also the presence of unsymmetrically substituted benzene rings arising from charge-transfer-type interactions between two benzene rings, as well as the steric effects of substituents at the 6 and 15 positions.

All of the previous compounds are internally unsubstituted [3.3]MCP-2,11-diones and it is surprising that there are very few reports (8) on the preparation of 9-methyl- or 9-methoxy-analogues despite the fact that the chemical shift of the internal substituents, such as the methyl and the methoxy group, provides a convenient probe for ^{1}H NMR studies of any possible conformational changes. We report here the synthesis and stereochemical assignments of 9-substituted [3.3]MCP-2,11-diones and conversion to the

corresponding [3.3]MCPs by Wolff-Kishner reduction. The substituent effects on the formation of the *syn*- and *anti*-conformations are discussed.

Results and discussion

Vögtle and co-workers reported (9) the preparation of carbocyclic [3$_n$]MCPs using TosMIC (10) as the cyclization reagent, which was applied in a new cyclization procedure without phase-transfer conditions (Scheme 1) (11).

This strategy can be employed for the preparation of [3.3]MCP containing two benzene rings. The preparation of [3.3]MCPs using the TosMIC method is, however, difficult because of its low yield as well as the difficulty of the product separation from the other macrocyclic oligoketones, i.e., trimer and tetramer. It has, therefore, been very difficult to obtain sufficient amounts of the above compounds to investigate their chemical behavior.

Scheme 3.

[a]Isolated yields.
[b]Ratios of *anti*-to-*syn* determined by ^{1}H NMR spectroscopy at 20°C.

We therefore have selected the stepwise cyclization of the TosMIC adduct **4** with 2,6-bis(bromomethyl)-4-*tert*-butyl-1-substituted benzenes (**3**) to prepare the desired cyclic dimer **5**. The starting compounds, 2,6-bis(bromomethyl)-4-*tert*-butyl substituted benzenes (**3**), are easily prepared by bromomethylation of 4-*tert*-butyltoluene (**2a**) and 4-*tert*-butylalkoxybenzenes (12) using the *tert*-butyl group as a positional protecting group on the aromatic ring (Scheme 2) (13). Although TosMIC adduct **4c** was obtained in 78% yield by the reaction of **3c** with TosMIC as a mixture of two isomers, i.e., *meso* and *dl*, the attempted separation of these isomers of **4c** pure failed.

The cyclic diketones (**5**) were synthesized by coupling **3** with TosMIC adduct **4c** under highly diluted conditions in DMF with an excess of sodium hydride as shown in Scheme 3. We have improved the addition procedure in Vögtle's method (9) — thus, to a suspension of NaH in DMF was added dropwise a solution of **3** and TosMIC adducts **4c** in DMF at room temperature. This method not only improves the yield of the desired ketones but also makes the handling of the base (solid NaH) easier (Table 1). The ^{1}H NMR spectrum of **5** shows two kinds of methoxy protons, each as a singlet. By careful column chromatography (silica gel, Wako C-300), the two conformers, *anti*-**5** and *syn*-**5**, are

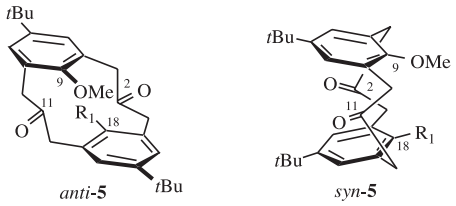
Table 2. ^{1}H NMR spectral data for 6,15-di-*tert*-butyl-9-methoxy[3.3]MCP-2,11-diones **5a**.



Compound	Methoxy protons	Protons of internal substituent (R_1)		Benzene protons	*tert*-Butyl protons
anti-**5a**	3.26	H	5.29	7.08, 7.19	1.27, 1.36
anti-**5b**	3.15	Me	0.94	7.19, 7.21	1.27, 1.35
anti-**5c**	3.15	OMe	—	7.14	1.31
anti-**5d**	3.13	OEt	0.98, 3.26	7.15	1.30, 1.32
anti-**5e**	3.12	OPr	0.79, 1.35,[a] 3.17	7.14, 7.15	1.30, 1.32
syn-**5b**	3.43	Me	2.50	6.64, 6.70	1.07, 1.14
syn-**5c**	3.52	OMe	—	6.68	1.08
syn-**5d**	3.54	OEt	1.37	6.66, 6.67	1.07
syn-**5e**	3.54	OPr	1.18, 1.85,[a] 3.50	6.67	1.08

Note: Determined in $CDCl_3$ by using $SiMe_4$ as a reference and expressed in ppm given.
[a]Midpoint value of multiplet.

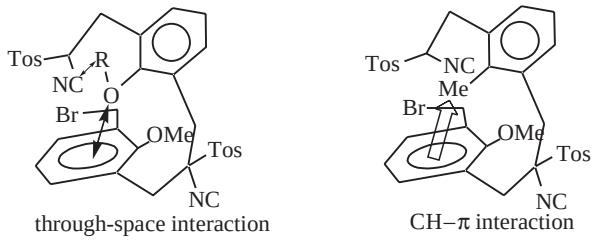
separated. They are thermally stable and do not interconvert at 150°C in DMSO solution and at 400°C in the solid state.

The structures of **5** have been elucidated by elemental analyses and spectral data. For instance, the mass spectral data for *anti*-**5c** (M^+ = 436) strongly support cyclic dimeric structure. The IR spectrum of *anti*-**5c** shows the absorption of the carbonyl stretching vibration around 1706 cm^{-1}. The ^{1}H NMR spectrum (in $CDCl_3$) of *anti*-**5c** exhibits a set of doublets at δ = 3.22 and 3.73 (*J* = 14.7 Hz) for the Ar*CH*$_2$CO*CH*$_2$Ar methylene protons and a singlet for the internal methoxy group at an upfield shift δ = 3.15 from that of anisole (δ = 3.75) due to the ring current of the opposing aromatic ring (13*a, b*, 14). This observation strongly suggests that compound *anti*-**5c** adopts the *anti*-conformation.

In contrast, the methoxy protons of *syn*-**5c** are observed at δ 3.52. Furthermore, the aryl hydrogens can clearly be seen to be shielded (δ 6.68) by the adjacent ring, a common consequence of a face-to-face benzene ring (14, 15). Also the *tert*-butyl protons were observed at higher field (δ 1.09) compared with that of the *anti*-**5c** (δ 1.31) due to the strong shielding effect of the benzene ring. These observations strongly suggest that compound *syn*-**5c** adopts *syn*-conformation. Similarly, the assignments of structures for other *anti* and *syn* conformers were readily apparent from their ^{1}H NMR spectra. The chemical shifts (δ) of the internal methoxy protons, the protons of internal substituents at the 18 position, aromatic protons, and the *tert*-butyl protons of *anti*- and *syn*-9-methoxy[3.3]MCP-2,11-diones **5a**–**e** are compiled in Table 2.

Dependent on R_1 and R_2 of 2,6-bis(bromomethyl)-1-substituted benzenes (**3**), different yields (inversion of selectivity) of *anti*-**5** and *syn*-**5** were formed. Thus, the 18-unsubstituted analogue is exclusively formed in the *anti*-conformer, but other 18-methyl- and 18-alkoxy-analogues are formed in a mixture of *syn*- and *anti*-conformers. Interestingly, the 18-methyl analogue decreases the ratio of *syn*-to-*anti* conformers of [3.3]MCP-2,11-diones. The effect of the bulkiness of the alkyl group in alkoxy substituents on the ratio of *syn*-to-*anti* conformers was not, however, observed.

Fig. 2. Reaction intermediate for the cyclization to form [3.3]MCP-2,11-diones.



These findings suggest that in the case of the 18-methyl analogue the aromatic π–π interaction of two opposite benzene rings and the steric crowdedness at internal positions 9 and 18 may inhibit the formation of the *syn*-conformer in the [3.3]MCP-2,11-diones system and in turn the CH–π interaction (16) between methyl groups, and the opposite aromatic π-electrons may favour the formation of *anti*-conformer in the cyclization process. The CH–π interaction involving aliphatic CH moieties is well documented (16*a*) as either a conformation-controlling intramolecular process or a crystal-structure controlling intermolecular force, especially for inclusion complexes of calixarene derivatives (16*b–h*). In contrast, in the case of the 18-alkoxy analogue, the through-space interaction between the nonbonding electron pairs of the oxygen atom of the alkoxy groups and the opposite aromatic π-electrons of the *anti*-conformer may disfavour the formation of the latter (Fig. 2).

On treatment of 2,6-bis(bromomethyl)anisole (**3f**) with **4c** a preferential formation of *syn*-[3.3]MCP-2,11-dione (*syn*-**5f**) in the ratio of 95:5 was observed, which is different from the result of that of **5c** (the *syn*-to-*anti* ratio; 70:30). This result might be attributed to the bulkiness of the *tert*-butyl groups, which would inhibit the formation of *syn*-**5c**. Accordingly, the ratio of *syn* conformer is observed to increase with decreasing bulkiness of the substituents at the 15-position, as shown in Fig. 3. Furthermore, the effect on the

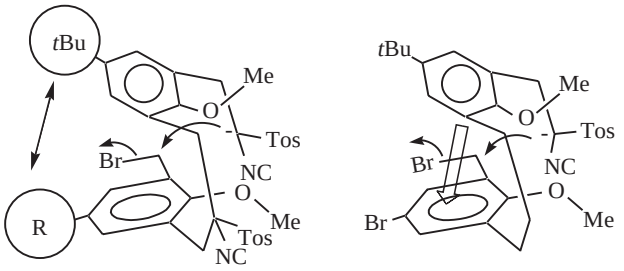
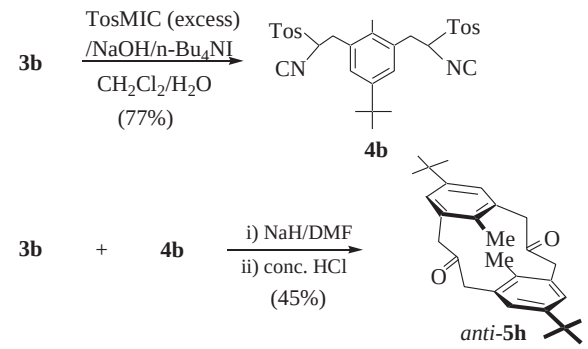
Fig. 3. Steric effect and π–π stacking charge-transfer-type interaction on the reaction intermediate for the cyclization to form *syn*-[3.3]MCP-2,11-diones.



Scheme 4.



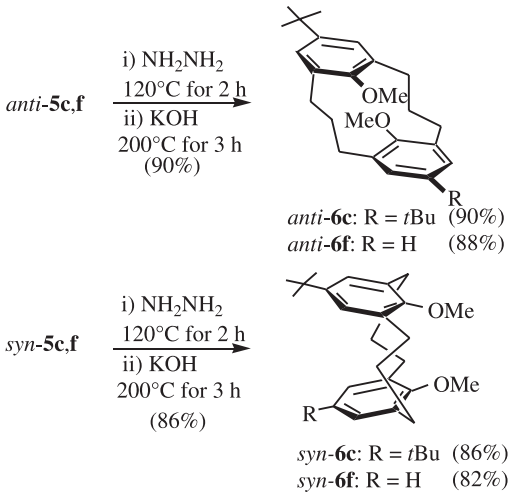
ratio of *syn*-to-*anti* conformers of MCP-2,11-diones might be also governed by charge-transfer-type interactions between the two benzene rings in the case of unsymmetrically substituted benzene rings. In fact, in the case of *syn*-6-bromo-15-*tert*-butyl-9,18-dimethoxy[3.3]MCP-2,11-dione (**5g**) the *syn*-conformer was exclusively formed due to π–π stacking charge-transfer-type interactions, as shown in Fig. 3.

To study in more detail the effects on the reaction intermediates in the cyclization to form [3.3]MCP-2,11-diones attributable to through-space interactions, we have attempted to investigate the cyclization of the TosMIC adduct **4b** with 2,6-bis(bromomethyl)-4-*tert*-butyltoluene (**3b**). Thus, the cyclization of **3b** and **4b**, carried out under the same conditions as described above, afforded exclusively the *anti*-[3.3]MCP-2,11-dione (*anti*-**5h**) in 45% yield (Scheme 4). No formation of the *syn*-conformer was observed. This result strongly suggests that the CH–π interactions play an important role in the *syn*–*anti* conformer distribution during the cyclization reaction.

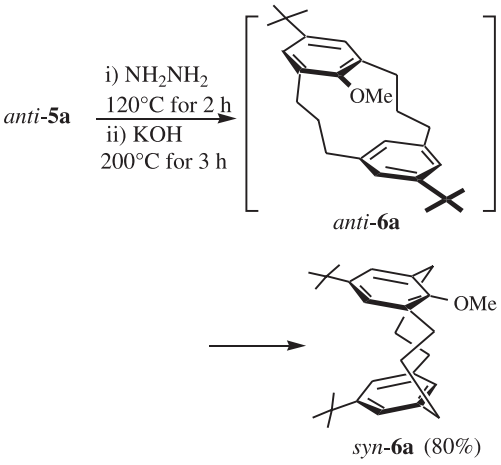
In conclusion, we have demonstrated for the first time a through-space interaction between the nonbonding electron pairs of the oxygen atom of the methoxy group and the opposite aromatic π-electrons, which may disfavour formation of the *anti*-conformer during the coupling reaction of the corresponding 2,6-bis(bromomethyl)alkoxybenzenes and TosMIC adduct **4c** to preferentially afford *syn*-9-methoxy[3.3]MCP-2,11-diones (**5**).

The Wolff-Kishner reduction of *syn*- and *anti*-diketone **5c** afforded the desired *syn*- and *anti*-6,15-di-*tert*-butyl-9,18-dimethoxy[3.3]MCP (**6c**) in 86 and 90% yields, respectively. Similar results were obtained in the case of reduction of **5f** to afford **6f**. No *syn*–*anti* isomerization was observed under the reaction conditions used (Scheme 5).

Scheme 5.



Scheme 6.



In contrast, attempted Wolff-Kishner reduction of *anti*-diketone **5a**, carried out under the same reaction conditions as **5c**, led to *syn*-9-9-methoxy[3.3]MCP *syn*-**6a** in 80% yield (Scheme 6). No formation of the corresponding *anti* conformer has been observed under the reaction conditions used. This finding strongly suggests that the ring inversion to the thermodynamically more stable *syn* conformation is possible in the 9-methoxy[3.3]MCP **6a**. On the other hand, as previously mentioned, we have reported that of *anti*-**5a** is thermally stable and does interconvert at 150°C in DMSO solution and at 400°C in the solid state. Although a detailed mechanistic conclusion to rationalize the present observation of *anti*-to-*syn*-conversion is not clear, one might assume the similar behaviour that the [3.3]MCP **1** exists in the *syn* geometry with a chair–chair arrangement of the trimethylene chains. Further studies on the chemical properties of the two conformers *syn*- and *anti*-**5** and **6** are now in progress.

Experimental

All melting points (Yanagimoto MP-S1) were uncorrected. ^{1}H NMR spectra were recorded on a Nippon Denshi JEOL FT-270 spectrometer. Chemical shifts are reported as δ values (ppm) relative to internal Me_4Si. Mass spectra were obtained

© 2002 NRC Canada

on a Nippon Denshi JMS-01SG-2 mass spectrometer at an ionization energy of 70 eV using a direct-inlet system through GLC; *m*/*z* values reported include the parent ion peak. Infrared (IR) spectra were obtained on a Nippon Denshi JIR-AQ2OM spectrophotometer as KBr disks. Elemental analyses were performed by Yanaco MT-5. Gas–liquid chromatograph (GLC) analyses were performed by Shimadzu gas chromatograph, GC-14A; silicone OV-1, 2 m; programmed temperature rise, 12°C min^{-1}; carrier gas nitrogen, 25 mL min^{-1}.

Materials

The preparations of 2,6-bis(bromomethyl)-4-*tert*-butylbenzene (**3a**), 2,6-bis(bromomethyl)anisole (**3f**), and 2,6-bis(bromomethyl)-4-bromoanisole (**3g**) were previously described (17).

Bromomethylation of 4-*tert*-butyltoluene (2a)

A mixture of **2a** (37 g, 0.23 mol), paraformaldehyde (45 g, 1.5 mol), acetic acid (55 mL), H_3PO_4 (85%, 110 mL), and concentrated HBr (48%, 164 mL) was heated at 85–90°C with vigorous stirring for 14 h, and then the reaction mixture was extracted with benzene (3 × 200 mL). The combined extracts were neutralized with a 10% aqueous Na_2CO_3 solution, washed with water, dried with Na_2SO_4, and the solvent was evaporated in vacuo to leave a residue, which was chromatographed on silica gel with hexane as the eluent to give a colorless solid. Recrystallization from hexane afforded 2,6-bis(bromomethyl)-4-*tert*-butyltoluene (**3b**) (63.6 g, 82%) as colorless prisms, mp 89–91°C. ^{1}H NMR ($CDCl_3$) δ: 1.30 (s, 9H), 2.41 (s, 3H), 4.54 (s, 4H), 7.30 (s, 2H). MS *m*/*z*: 332, 334, 336 (M^+). Anal. calcd. for $C_{13}H_{18}Br_2$: C 46.73, H 5.43; found: C 46.72, H 5.52.

Compounds **3c**, **3d**, and **3e** were similarly prepared. The yields are listed in Scheme 2.

*2,6-Bis(bromomethyl)-4-*tert*-butylanisole (3c)*

Colorless prisms (hexane), mp 88–89°C. ^{1}H NMR ($CDCl_3$) δ: 1.31 (s, 9H), 4.01 (s, 3H), 4.56 (s, 4H), 7.36 (s, 2H). MS *m*/*z*: 348, 350, 352 (M^+). Anal. calcd. for $C_{13}H_{18}Br_2O$: C 44.60, H 5.18; found: C 45.30, H 4.99.

*2,6-Bis(bromomethyl)-4-*tert*-butylethoxybenzene (3d)*

Colorless prisms (hexane), mp 65–66°C. ^{1}H NMR ($CDCl_3$) δ: 1.31 (s, 9H), 1.51 (t, *J* = 7.32 Hz, 3H), 4.16 (q, *J* = 7.32 Hz, 2H), 4.56 (s, 4H), 7.36 (s, 2H). MS *m*/*z*: 362, 364, 366 (M^+). Anal. calcd. for $C_{14}H_{20}Br_2O$: C 46.18, H 5.54; found: C 45.95, H 5.39.

*2,6-Bis(bromomethyl)-4-*tert*-butylpropoxybenzene (3e)*

Colorless prisms (hexane), mp 108.5–109.5°C. ^{1}H NMR ($CDCl_3$) δ: 1.13 (t, *J* = 7.32 Hz, 3H), 1.31 (s, 9H), 1.85–2.00 (m, 2 H), 4.05 (t, *J* = 6.83 Hz, 2H), 4.56 (s, 4H), 7.36 (s, 2H). MS *m*/*z*: 376, 378, 380 (M^+). Anal. calcd. for $C_{15}H_{22}Br_2O$: C 47.64, H 5.86; found: C 47.98, H 5.89.

Preparation of the TosMIC adduct 4

Typical procedure

To a mixture of 20% aqueous NaOH (40 mL) and CH_2Cl_2 (50 mL) was added *n*-Bu_4NI (700 mg, 1.9 mmol) followed by a solution of TosMIC (8 g, 41 mmol) in CH_2Cl_2 (50 mL). After the reaction mixture was stirred at room temperature for 30 min, a solution of dibromide **3b** (4.0 g, 11 mmol) in CH_2Cl_2 (50 mL) was added. The reaction mixture was stirred at room temperature for 2 h, quenched with water (100 mL), and extracted with CH_2Cl_2 (3 × 100 mL). It was washed with water (100 mL), dried with Na_2SO_4, and concentrated in vacuo to leave a residue. To this residue methanol (100 mL) was added and left overnight in the refrigerator to give 2,6-bis[2-cyano-2-(toluenesulfonyl)ethyl]-4-*tert*-butyltoluene (**4b**) (4.90 g, 77%) as pale brown prisms, mp 176°C (dec.). IR (KBr) υ_{max} (cm^{-1}): 2135 (CN). ^{1}H NMR ($CDCl_3$) δ: 1.26, 1.27 (each s, 9H), 2.26, 2.27 (each s, 3H), 2.50 (s, 6H), 3.00–4.52 (m, 6H), 7.16 (s, 2H), 7.46 (d, *J* = 8.3 Hz, 4H), 7.92 (d, *J* = 8.3 Hz, 4H). MS *m*/*z*: 436 (M^+). Anal. calcd. for $C_{31}H_{34}N_2O_4S_2$: C 66.16, H 6.09, N 4.98; found: C 65.95, H 6.06, N 4.73.

Compound **4c** was similarly prepared in 78% yield.

*2,6-Bis[2-cyano-2-(toluenesulfony)ethyl]-4-*tert*-butylanisole (4c)*

Pale brown prisms (hexane), mp 150–151°C (dec.). IR (KBr) υ_{max} (cm^{-1}): 2134 (CN). ^{1}H NMR ($CDCl_3$) δ: 1.26, 1.27 (each s, 9H), 2.49, 2.50 (each s, 6H), 2.87, 2.99 (each dd, *J* = 11.7 and 13.7 Hz, 2H), 3.66, 3.77 (each dd, *J* = 2.9 and 13.7 Hz, 2H), 3.76, 3.80 (each s, 3H), 4.73, 4.83 (each dd, *J* = 2.9 and 11.7 Hz, 2H), 7.19, 7.20 (each s, 2H), 7.44, 7.46 (each d, *J* = 8.3 Hz, 4H), 7.87, 7.93 (each d, *J* = 8.3 Hz, 4H). MS *m*/*z*: 578 (M^+). Anal. calcd. for $C_{31}H_{34}N_2O_5S_2$: C 64.34, H 5.92, N 4.84; found: C 64.56, H 5.87, N 4.73.

Stepwise cyclization of TosMIC adduct 4 and dibromide 3

Typical procedure

To a suspension of NaH (2.1 g, 51 mmol) in DMF (150 mL) a solution of **3c** (4.7 g, 8.5 mmol) and **4c** (5.0 g, 8.5 mmol) in DMF (35 mL) was added dropwise over a period of 6 h. After the suspension was stirred for an additional 5 h at room temperature, it was quenched with ice water (300 mL). The reaction mixture was extracted with CH_2Cl_2 (3 × 100 mL), washed with water (200 mL), dried with Na_2SO_4, and concentrated in vacuo to 15 mL. Conc. HCl (15 mL) was added, and the solution was stirred for 15 min. The organic layer was again extracted with CH_2Cl_2 (3 × 100 mL), washed with water (2 × 100 mL), dried with Na_2SO_4, and concentrated and condensed under reduced pressure. The residue was chromatographed on silica gel using $CHCl_3$ as eluents to give crude *anti*-**5c** and *syn*-**5c** as a pale yellow solid. Recrystallization from hexane afforded *anti*-**5c** (592 mg, 16%) and *syn*-**5c** (1.37 g, 37%).

anti-*6,15-Di*-tert-*butyl-9,18-dimethoxy[3.3]metacyclophane-2,11-dione (*anti-*5c)*

Colorless prisms (hexane), mp 210–211°C. IR (KBr) υ_{max} (cm^{-1}): 1706 (C=O). ^{1}H NMR ($CDCl_3$) δ: 1.31 (s, 18H), 3.15 (s, 6H), 3.22 (d, *J* = 14.7 Hz, 4H), 3.73 (d, *J* = 14.7 Hz, 4H), 7.14 (s, 4H). MS *m*/*z*: 436 (M^+). Anal. calcd. for $C_{28}H_{36}O_4$: C 77.03, H 8.31; found: C 76.66, H 8.37.

syn-*6,15-Di*-tert-*butyl-9,18-dimethoxy[3.3]metacyclophane-2,11-dione (*syn-*5c)*

Colorless prisms (hexane), mp 22–23°C. IR (KBr) υ_{max} (cm^{-1}): 1701 (C=O). ^{1}H NMR ($CDCl_3$) δ: 1.08 (s, 18H), 3.28 (d, *J* = 12.7 Hz, 4H), 3.52 (s, 6H), 4.24 (d, *J* = 12.7 Hz,

Kinetics of glycoluril template-directed Claisen condensations and mechanistic implications

Mohammad Rahimizadeh, Karen Kam, Stephen I. Jenkins, Robert S. McDonald, and Paul H.M. Harrison

Abstract: Eight *N*-acetyl-*N*-aroyl-glycolurils were prepared and found to undergo efficient *tert*-butoxide-promoted Claisen-like condensation between the two acyl moieties. The kinetics for formation of each of the *N*-(aroylacetyl)glycoluril products were monitored by UV spectroscopy. The reactions exhibited pseudo-first-order kinetics in substrate in the presence of excess base. For the parent benzoyl compound the observed first-order rate constant (k_{obs}) was linearly dependent on the concentration of the base, *tert*-butoxide. A Hammett plot of the resulting apparent second-order rate constants (k_{app}) vs. σ for each of the eight aroyl derivatives was linear and had a positive ρ value 1.04 ± 0.04), demonstrating that the substituent on the aromatic ring exerts a significant effect upon the condensation reaction. The corresponding plot for three [D_3]acetyl analogues was also linear, but the slope was reduced by 20% relative to the protonated compounds. The isotope effect (k^{H}_{app}/k^{D}_{app}) thus increased from 1.4 (benzoyl) to 2.6 (*p*-nitrobenzoyl). The results are consistent with a three-step mechanism in which both deprotonation of the acetyl entity and the ensuing nucleophilic attack of the resulting enolate on the benzoyl group are partially rate-determining steps. The tetrahedral intermediate thus produced rapidly collapses to the product. For the [D_3]acetyl benzoyl derivative, exchange of substrate deuterium with solvent hydrogen due to reprotonation of the enolate intermediate occurs at a rate that is similar to that of condensation, but the enolate partitions towards the product when electron withdrawing groups are present in the aroyl ring. Thus, despite the presence of a large excess of co-solvent *tert*-butanol, the efficiency with which the enolate undergoes condensation remains high. The clean kinetics observed allows further exploration of the details of this intramolecular Claisen-like condensation process.

Key words: Claisen condensation, glycoluril, kinetics, Hammett, mechanism.

Résumé : On a préparé huit *N*-acétyl-*N*-aroylglycolurils et on a observé que les deux portions acyles subissent facilement une condensation de type Claisen, catalysée par l'ion *tert*-butylate. La cinétique de formation de chacun des *N*-(aroylacétyl)glycolurils produits a été suivie par spectroscopie UV. En présence d'un excès de base, les réactions présente une cinétique de pseudo-premier ordre en substrat. Pour le composé benzoylé fondamental, la constante de vitesse du premier ordre observée (k_{obs}) varie de façon linéaire avec la concentration du *tert*-butylate utilisé comme base. La courbe de Hammett des constantes de vitesse du deuxième ordre apparentes qui en résultent (k_{app}) en fonction de σ est linéaire pour chacun des huit dérivés aroylés et la valeur de ρ est légèrement positive (1,04 ± 0,04) ce qui démontre que le substituant du noyau aromatique exerce un effet important sur la réaction de condensation. La courbe correspondante pour les trois analogues [D_3]acétylés est aussi linéaire, mais la pente est réduite de 20% par rapport à celle des composés protiés. L'effet isotopique (k^{H}_{app}/k^{D}_{app}) augmente donc de 1,4 (benzoyle) à 2,6 (*p*-nitrobenzoyle). Les résultats sont en accord avec un mécanisme en trois étapes dans lequel la déprotonation de l'entité acétyle ainsi que l'attaque nucléophile subséquente de l'énolate qui en résulte sur le groupe benzoyle sont les étapes partiellement cinétiquement limitantes. L'intermédiaire tétraédrique ainsi produit se décompose rapidement en produit. Pour le dérivé [D_3]acétyle benzoyle, l'échange de deutérium du substrat avec l'hydrogène du solvant causé par la reprotonation de l'intermédiaire énolate se produit à une vitesse similaire à celle de la condensation, mais l'énolate se partitionne vers le produit quand le noyau aroyle comporte des groupes électroattracteurs. Ainsi, malgré la présence d'un large excès du *tert*-butanol qui agit comme solvant, l'efficacité avec laquelle l'énolate donne lieu à une condensation demeure élevée. Les cinétiques bien définies observées permettent d'explorer plus à fond les détails du processus de condensation intramoléculaire de type Claisen.

Mots clés : condensation de Claisen, glycoluril, cinétique, Hammett, mécanisme.

Introduction

The fatty acids (1, 2) and polyketides (1, 3) are two large and diverse groups of natural products. Both sets of metabolites are assembled in vivo by sequential "head-to-tail" condensations of acyl units in a series of Claisen-like condensation steps on the surface of multifunctional fatty acid- (FAS) or polyketide synthases (PKS) (1–3). Synthetically, these compounds are frequently accessed by a sequence of aldol condensations, often mediated by catalysts and (or) chiral auxiliaries. Another approach involves using Claisen-like condensations to mimic the biosynthetic assembly process (4). In this context, we developed a method using a glycoluril auxiliary: two acyl units are attached to the N-1 and N-6 positions of 3,4,7,8-tetramethylglycoluril (**1**, Scheme 1) to give **2**. An ensuing intramolecular base-promoted Claisen-like condensation furnishes β-ketoacylglycolurils **3** under relatively mild conditions and in high yield (5–7).

Furthermore, the resulting β-ketoacylglycolurils **3** can be chemically modified through a sequence of reactions, which is analogous to those that occur on FAS or PKS. The ensuing product can then undergo repetitive cycles of acylation, condensation, and functional group manipulations, resembling the head-to-tail assembly of acyl units by FAS or PKS (6–8). Thus, **1** acts as a functional small-molecule model of some of the features of these giant enzymes.

A study of the mechanism of the condensation reaction of **2** to give **3** would provide further insight into the effects that contribute to the efficiency of the process. As part of our earlier studies, we showed that when the 1-acetyl-6-[D_3]acetyl analogue **2b** was treated with lithium *tert*-butoxide, the base preferred to remove protium over deuterium by a factor of 4.6:1 (7). We invoked a primary kinetic isotope effect (KIE) and proposed a slow proton removal followed by fast intramolecular trapping of the resulting enolate by the other acceptor acyl entity, in accord with our strategy for the design of **1**. Subsequent work, however, showed that changing the reaction conditions caused a small but significant change in the magnitude of the isotope effect, suggesting that deprotonation may not be the sole rate-limiting step (unpublished data).

We have not previously been able to quantify the rate of transformation of diacylglycolurils **2** into **3**, and thus little is known about the critical carbon–carbon bond-forming step. To re-examine the rate-limiting step(s), to further probe the details of the mechanism of this intriguing process, and to provide a quantitative measure of the efficiency of the condensation and the factors that govern it, we chose the acetyl benzoyl glycoluril **2c** for monitoring the progress of the condensation reaction by UV spectroscopy. Herein, the results of this experiment as well as further quantitative studies of the effects of substituents on the aroyl ring, and of deuterium substitution in the acetyl group in **2c**, are described. Mechanistic implications are then discussed, and the results compared with those from the literature for intramolecular Claisen and aldol condensations.

Results

Treatment of monoacetylglycoluril **4a** (7) with *n*-BuLi in THF, then benzoyl chloride, using the method previously reported for preparation of diacylglycolurils readily afforded acetyl benzoylglycoluril **2c** in 92% yield (Scheme 1). Compound **2c** was fully characterized by X-ray crystallography, as will be described elsewhere (9). In a similar manner, a range of *meta*- and *para*-substituted acetyl aroyl glycolurils (**2d**–**j**) were prepared from the appropriate acid chloride. In all cases, little apparent difference in ease of reaction was observed when compared with the aliphatic diacylglycolurils that we have previously reported (5–8). Deuterated monoacetylglycoluril **4b** was prepared from **1** and $(CD_3CO)_2O$, or from **1** and *n*-BuLi–CD_3COCl, as has been previously described for the protonated analogue (7). Conversion of **4b** to **2k**, **2l**, and **2m** followed as for **2c**, **2e**, and **2g**, respectively.

Treatment of **2c** with lithium *tert*-amylate or potassium *tert*-butoxide under preparative conditions in THF at 0°C resulted in rapid rearrangement to product **3c**, the result of an intramolecular Claisen-like condensation, in 98% isolated yield. The structure of **3c** was also unambiguously confirmed by X-ray crystallographic analysis (9). Each of the compounds (**2d**–**g**) was also subjected to the same condensation

Scheme 1. Reagents and conditions: (*i*) $(CX_3CO)_2O$, reflux or *n*-BuLi, THF, reflux then CX_3COCl, rt; (*ii*) *n*-BuLi, THF, 0°C then RCOCl, 0°C to rt; (*iii*) 50:50 *t*-BuOH:THF, 0°C, then *n*-BuLi, 0°C to rt.

[a]Second-order rate constant, calculated from observed rate constant and base concentration (see text).
[b]Determined by treatment of synthetic **3** with potassium *tert*-butoxide (5–10 equiv.).
[c]Determined from a preliminary kinetic run.
[d]Not determined, compound was not prepared.
[e]Value obtained during comparison of **2c**–**j**.
[f]Value obtained during comparison of **2k**–**m** with protonated analogues. See text for discussion of the discrepancy between these values.
[g]Kinetics observed at 337 nm.
[h]Values as for protonated analogs.

conditions to afford β-ketones **3d**–**g** (Table 1). In each case, condensation proceeded within minutes, and no detectable side-products were observed. All the compounds for subsequent kinetic work were recrystallized under identical conditions to those for **2c** and **3c**. Furthermore, although the chemical yields for formation of **2c** and **3c** were improved through a degree of optimization of conditions, no attempt was made to optimize the yields for the remaining compounds. Thus, the reported yields of recrystallized material are not indicative of the efficiency of either step. Each product **3c**–**g** was found by NMR to be a mixture of the tautomeric keto and enol forms. These reactions thus proceed analogously to those of the aliphatic acyl derivatives and similarly provide good yields with no detectable side-products. The results clearly show that the template-directed condensation may be extended with high efficiency to aroyl groups.

Preliminary experiments to evaluate conditions for monitoring the kinetics of these intriguing condensations were conducted with **2c**. It was found that the solid potassium *tert*-butoxide base was not readily soluble in THF, while the substrate was poorly soluble in *tert*-butanol. For this reason, we chose a mixed solvent system of 50:50 v/v *tert*-butanol–THF for kinetics experiments. Both **2c** and potassium *tert*-butoxide were readily soluble in this mixture at concentrations of interest, i.e., up to several millimolar. All stock solutions were prepared in rigorously dried solvents. Control UV spectra of a 1–2 × 10^{-4} M solution of each substrate **2c**–**j** in this solvent were recorded. Similarly, control spectra for each of the products **3c**–**g** were obtained. Finally, control spectra of each of the putative enolates resulting from deprotonation of products **3c**–**g** were obtained by treatment of the solutions of **3c**–**g** in situ with a five- to tenfold excess of base. The λ_{max} values were determined for each species (Table 1 and *Experimental*). For **3h**–**j**, the enolate λ_{max} was determined by scanning the solution within the UV cell after a preliminary kinetic experiment. It was found that the starting solutions **2c**–**j** showed essentially no absorbance at the λ_{max} of the deprotonated products.

For the first kinetics experiments, a solution of **2c** in a stoppered quartz cuvette was treated with a freshly prepared solution of potassium *tert*-butoxide (5–10 equiv.) in the standard solvent. After magnetic mixing within the cuvette, the increase in absorbance at the predetermined λ_{max} of the presumed enolate of the product was monitored with time until no further change was observed. Formation of product was then confirmed by recording the UV spectrum of the final solution, which showed a λ_{max} identical to within 2–3 nm to that of the authentic deprotonated product. Attempts to monitor the disappearance of starting material were unsuccessful because both the starting and the final solutions were found to absorb in the same region. These experiments show that the reaction proceeds within minutes at 25°C under these conditions.

The absorbance values at λ_{max} vs. time were fit to the equation for pseudo-first-order kinetics by the spectrometer computer, giving the pseudo-first-order rate constant k_{obs}. For each run, excellent fits were obtained ($\sigma < 0.001$). Errors in rate constants were, therefore, estimated from variance in replicate runs (≤10%). A series of experiments was next performed on **2c** in which the concentration of base was varied. A plot of k_{obs} vs. [base] was found to be linear over the range examined (Fig. 1); no curvature was observed, implying that saturation did not occur, at least at the low concentrations used in this study. The reaction is, therefore, first order for both **2c** and base. The overall second-order rate constant (k_{app}) was then determined by division of k_{obs} by the concentration of base, as determined during stock solution preparation.

Each of the substituted compounds **2d**–**j** was monitored by the same procedure. In all cases, excellent fits were obtained for pseudo-first-order kinetics ($\sigma < 0.001$). The rate law is, therefore, first order for substrate concentration for all substrates **2c**–**j**. Values of k_{app} were then obtained as for

Fig. 1. Plot of apparent pseudo-first-order rate constant k_{obs} for formation of **3c** from **2c** vs. concentration of potassium *tert*-butoxide base. The line was generated by linear regression (R^2 = 0.9635).

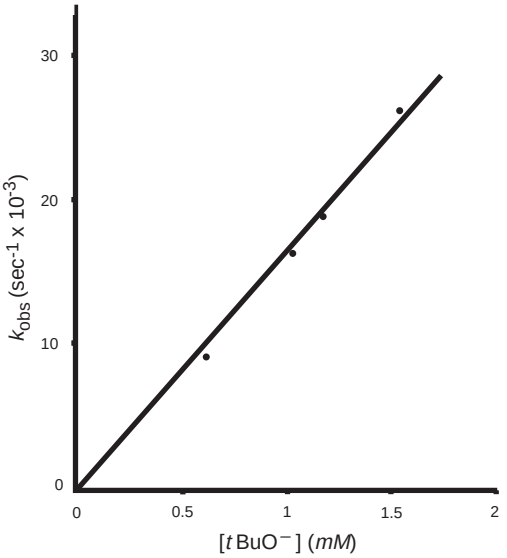

Fig. 2. Successive scans performed on the acetyl *p*-methylbenzoyl glycoluril **2f**. UV spectra were recorded sequentially at a scan rate of 600 nm min^{-1}. The direction of change in absorbance with time is indicated by the arrows. The peak due to the enolate **8f** of product **3f** at 336 nm was used to monitor reaction progress in further kinetic runs.

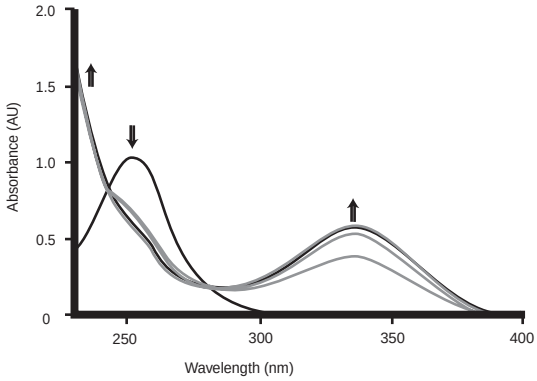
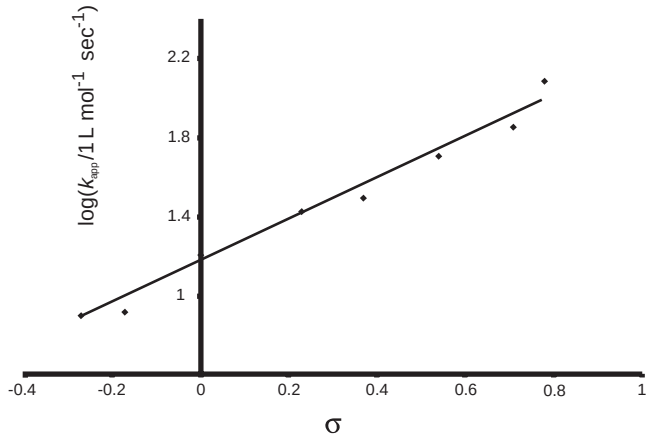


2c, with the assumption that the reactions are all first order for base concentration. A series of successive scans was performed during the reaction of both **2c** and **2f**. A smooth increase in absorption with time at the λ_{max} of the product enolate as well as at low wavelengths, accompanied by a net decrease in absorbance at intermediate wavelengths, was found (Fig. 2). The scans clearly show two isosbestic points for each of the reactions monitored.

The results of the experiments on **2c**–**j** may be shown in the form of a Hammett plot (Fig. 3) (10). When log k_{app} is plotted against the substituent constant σ (11), a linear relationship is seen, with positive slope ρ = 1.05 ± 0.05.

In a separate series of experiments, the rates of condensation for **2c**, **2e**, **2g**, **2k**, **2l**, and **2m** were compared under identical conditions. When the values for k_{app} are plotted on

Fig. 3. Hammett plot showing the logarithm of the observed bimolecular rate constant (log k_{app}) plotted against the substituent constant σ for the eight acetyl aroyl glycoluril substrates **2c**–**j** that were studied. Linear regression gives a slope ρ = 1.05 ± 0.05 and R^2 = 0.9952.



a Hammett plot, it was found that protio-compounds **2c**, **2e**, and **2g** again correlated well with the Hammett equation, in this case with ρ = 1.55 ± 0.02. When the corresponding deuterated substrates **2k**–**m** were investigated by the same UV spectroscopic method, they were also found, at first approximation, to obey pseudo-first-order kinetics. Each data set could be fit to predicted curves to give values of k_{app}, although the errors were higher for these fits than for the protonated analogues. The deviation from the first-order fit was highest for **2k**, less for **2l**, and negligible for **2m**. The resulting values of log K_{app} also varied in a linear manner with σ on the Hammett plot, and gave a slope ρ = 1.20 ± 0.06, a value significantly different from the former plot for the protio analogues (Fig. 4). The apparent isotope effect on k_{app} (k^H_{app}/k^D_{app}) varied from 1.4 for the benzoyl moiety (**2c** vs. **2k**), to 2.6 for *p*-nitrobenzoyl acetyl glycoluril (**2g** vs. **2m**).

When a typical data set for **2k** was analyzed in greater detail, a small deviation from pseudo-first-order behaviour was observed. It was found that the value of the parameter *n* as determined by curve fitting to the equation d[**3k**]/dt = *n*[**2k**] increased as the time at which curve fitting was initiated increased. This result is illustrated in Fig. 5, where the value of *n* is plotted against the start time for curve fitting; in each case the curve was fit to the same stop time, a time where the absorbance had essentially reached a steady value (8 min). By contrast, a similar analysis of the protonated analogue revealed that the value of *n* remained essentially constant regardless of which part of the absorbance-time curve was analyzed; thus this reaction is truly first order and *n* = k_{obs} (Fig. 5). The [D_3]acetyl *m*-chlorobenzoyl derivative **2l** followed a similar but less dramatic trend, with *n* increasing from 0.027 to 0.038 sec^{-1}. The [D_3]acetyl *p*-nitrobenzoyl derivative **2m** gave an absorbance-time plot that fit much better to first-order kinetics and no significant change in *n* with time was observed. The changing values of *n* imply that another process must be included in the deuterated compounds; this is interpreted as isotope exchange (see *Discussion*).

Fig. 4. Hammett plots showing log k_{app} plotted against σ for three acetyl aroyl glycoluril substrates **2c**, **2e**, and **2g**; and for the trideutero isotopomers **2k**, **2l**, and **2m**. Linear regression gives slopes ρ = 1.55 ± 0.02 and 1.20 ± 0.06 for the two respective series. Correlation coefficients R^2 are 0.9994 and 0.9901, respectively. The isotope effect, k^H_{app}/k^D_{app}, is given by the difference in rate between pairs of points for the same substituent, and varies from 1.4 for the benzoyl moiety (σ = 0), to 2.6 for the 4-nitrobenzoyl case (σ = 0.77).

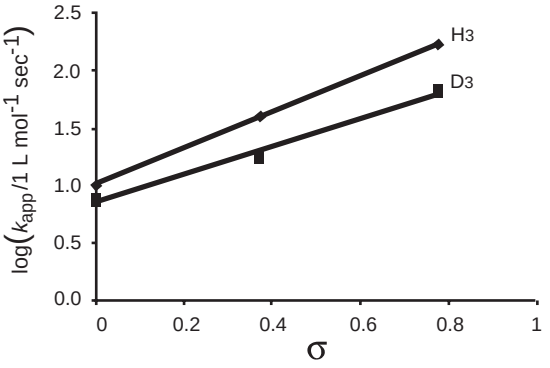

Fig. 5. For [D_3]acetyl benzoyl glycoluril **2k**, different values of parameter *n* are obtained when the absorbance vs. time data are analysed over different portions of the curve. The data were fit between different starting times *t* and an arbitrary but constant final time at which the absorbance remained essentially unchanged. The resulting values of *n* from the equation d[**3k**]/dt = *n* [**2k**] are then plotted against start time *t* (▲). Comparison of the calculated curves and the experimental data showed that this procedure emphasized the data around, and hence gave a good fit at, time *t*. By contrast, a corresponding analysis for [H_3]acetyl benzoyl glycoluril **2c**, gave values for *n* which were independent of *t* (■), and $n = k_{obs}$. The starting concentration for **2c** and **2k** was 28.8 μM; [KO-*t*-Bu] = 1.43 mM.

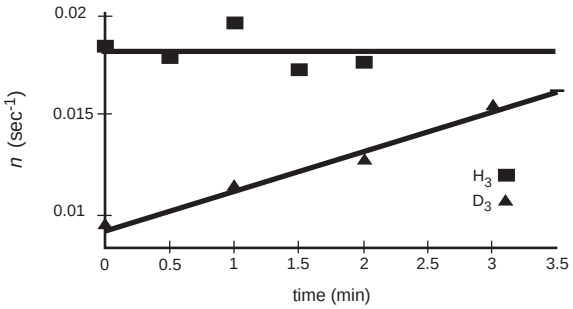

Discussion

A minimal scheme for the condensation reaction of diacylglycolurils **2** to give β-ketoacylglycolurils **3**, in accord with the classical mechanism for Claisen (12, 13) and Dieckmann (14) condensations, is presented in Scheme 2. A potentially reversible deprotonation of **2** by the *tert*-butoxide base forms enolate **5**. Rate constants k_1 and k_{-1} characterize this step. Intramolecular nucleophilic attack forms tetrahedral intermediate **6** with rate constant k_2, while k_{-2} reflects the potential reverse reaction. Intermediate **6** collapses to the amide anion of the product β-ketoacylglycoluril **7**, and finally, proton transfer generates enolate **8** of product **3**. It is the rate of formation of **8** that is monitored in the kinetics experiments. Product **3** is formed during acidic work-up, but is fully deprotonated by the excess base present in the reactions, as shown by the change in the UV spectra of authentic **3c**–**g** when treated with potassium *tert*-butoxide under the conditions of the kinetics experiments. The presence of isosbestic points during analysis of reaction progress by scanning kinetics illustrates that there is no significant build-up of intermediates as the reaction proceeds. Consideration of pK_a values for **5**–**8** suggests that each of the forward steps connecting these species would be thermodynamically favorable, and hence effectively irreversible. In addition, the proton transfer step of **7** to **8** is likely to be rapid, leaving step(s) 1 and (or) 2 as the most likely possibilities for the rate-limiting steps. Indeed, these ideas are fully consistent with the experimental data described below.

The observation of a clear, positive ρ value in the Hammett plot of rate constant k_{app} for **2c**–**k** vs. the substituent constant σ shows that the aromatic system must be involved in a rate-limiting step. The rates for formation of **8** increase over a range of more than tenfold from the electron donating *p*-OMe group to the electron withdrawing *p*-NO_2 group. The relationship is linear, suggesting no fundamental change in mechanism as the substituent is varied. The simplest explanation of the results involves invoking step 2 as at least partially rate limiting. When the aroyl substituent is electron withdrawing, it activates the electrophilic carbonyl group and enhances the rate constant k_{app} relative to the benzoyl compound **2c**. Conversely, electron donating substituents in the aromatic ring reduce k_{app} through loss of resonance between the carbonyl and aromatic π systems in the transition state leading to **6**. Although k_1 might be influenced by the aroyl substituent through steric effects, and marginally through electronic effects at the anomeric carbon C-7, which we have previously invoked to explain the geometry of diacylglycolurils (15–17), it seems improbable that these effects can explain the good fit to the Hammett equation and the magnitude of the Hammett constant ρ.

The electron withdrawing and electron donating substituents may influence the rate constant for step 2 in either of two ways: activating or deactivating the carbonyl group to nucleophilic attack, or altering the conformation of the aroyl entity, for example by altering the twist angle τ around the amide N–C bond (15–17). The crystal structure shows that for the parent system **2c**, the amidic twist of the benzoyl group is substantial (9). It is possible that the twist may be further influenced by the aromatic substituent as more electron donation allows greater C=O π stability despite a putatively larger twist and hence less resonance stabilization of the aroyl carbonyl group by nitrogen. A study of how the substituents influence τ through X-ray crystallography is currently underway to resolve this issue and determine if τ has an influence on transition state structure and energy.

While the results with deuterated substrates **2k**–**m** reconfirm the sensitivity of k_{app} to the benzoyl substituent, they also demonstrate a substantial isotope effect in this reaction. The magnitude of this effect for the *p*-nitrobenzoyl compounds (2.6) is indicative of a primary kinetic isotope effect, and suggests that in this case the reaction is sensitive to the

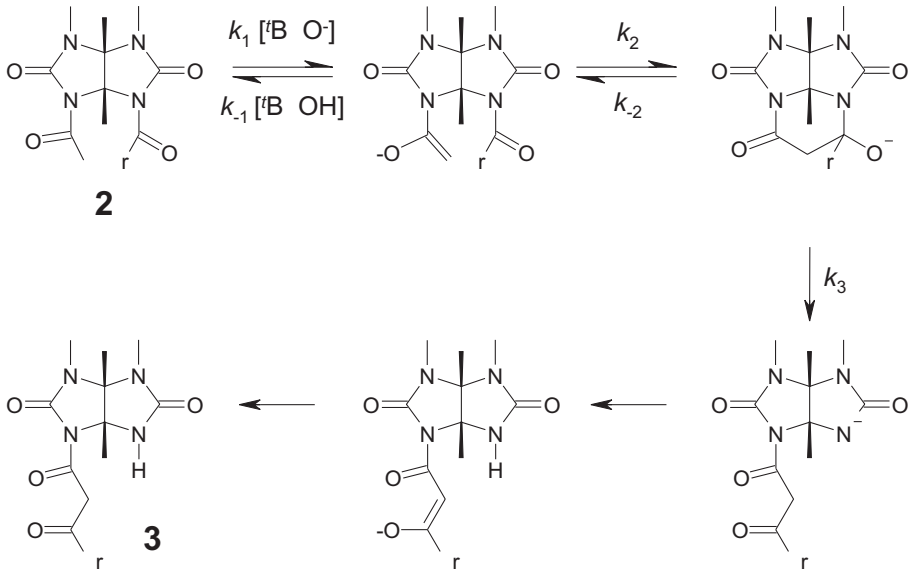
Scheme 2. Proposed mechanism for intramolecular Claisen-like condensation of **2** to give **3**.



rate of deprotonation as well as to the substituent on the aroyl ring. This set of results may be rationalized by invoking a mechanism in which both steps 1 and 2 are partially rate limiting and thus k_1[**2**][base] ≈ k_2[enolate]. The other results are consistent with this interpretation: as the substituent becomes less electron-withdrawing, the rate becomes dominated by step 2 and therefore it is less sensitive to step 1 and hence to the isotopic substitution. Nonetheless, a substantial and reproducible isotope effect remains even in the acetyl benzoyl case. Conversely, substitution with deuterium slows step 1 and the sensitivity of step 2 to the aroyl substituent is reduced, resulting in a lower ρ value for the deuterated series compared with the protonated analogues. Furthermore, comparison of the two independent Hammett plots for the protonated series shows that ρ varies with the conditions. In the former series, ρ ≈ 1, while the second determination gives ρ ≈ 1.5. This change in Hammett slope is consistent with the difference in base concentration between the two experiments (5–10 × 10^{-4} vs. 1.43 × 10^{-3} M). At the lower base concentration used in the former experiments, bimolecular step 1 is slower, step 2 becomes less dominant in determining the rate, and the overall rate of reaction is less sensitive to the aromatic substituent.

In prior work with **2b** (7) it was concluded that step 1 was at least primarily rate limiting because of the presence of a significant primary kinetic isotope effect as the base discriminates between abstraction of hydrogen from the acetyl entity versus deuterium from the CD_3 group. This result now becomes consistent with the overall mechanism as presented, if the preparative reaction of **2b** proceeds under conditions where step 1 is dominant. The kinetic experiments contrast with this earlier preparative work in several ways, each of which might contribute to this influence on the rate-limiting step. First, the structure of the substrate has changed. Second, the absolute concentration of substrate has been dramatically reduced for the kinetics work. Third, the solvent has changed from THF with a trace of excess *tert*-butanol to a 50:50 mixture of these two solvents; as a result, all of the base is in solution, a situation which does not occur in the preparative work. Fourth, there is a relatively larger molar excess of base in the kinetics experiments. Finally, the temperature has been changed from 0 to 25°C. Thus, although the lower concentration of substrate in the kinetics work will dramatically reduce the rate of the bimolecular step 1 relative to unimolecular step 2, this may be compensated by the reduction of k_2 due to any or all of the greater stability of the benzoyl group over acetyl; the higher relative concentration of base and its availability in solution, accelerating step 1; stabilization of intermediates and transition states by the polar protic alcohol co-solvent; and the higher temperature accelerating the bimolecular step. Although the current experiments do not yet allow for a definitive answer to the question of how each of these effects influence the reaction, experiments to resolve these issues become possible as a result of the ability to quantitate the rates described in this paper, and are now underway.

While a further study is needed to perform a complete mathematically correct analysis of the deviation from first-order kinetics for the deuterated acetyl benzoyl compound **2k**, the current data are fully consistent with a slow exchange of deuterium for hydrogen in the substrate. The increase in parameter *n* (formally k_{obs} in a pure first-order reaction) with time as the process progresses would result from the reprotonation of the substrate enolate intermediate **5** by solvent *tert*-butanol, yielding first mono-, then di-, and then tri-protioacetyl substrate. As the reaction proceeds, the original trideutero substrate is depleted and partially deuterated substrates form; these react at a greater rate due to the isotope effect. Near the end of the reaction, the value of *n* approaches, but still does not reach, that for **2c**. The results show that most molecules overall react through loss of deuterium, and hence the first-order approximation used to evaluate k_{app} for this compound is valid. On this basis, qualitative information on the rate of enolate reprotonation, k_{-1}, may be obtained. The time needed for *n* to increase by 33% of the difference between its initial value and the constant value for **2c** is approximately 1.5 min. Assuming that this time approximates the average time required to exchange

© 2002 NRC Canada

one deuteron for a proton, it may be compared with the half-life for the overall condensation reaction (1.75 min) as measured by k_{app}. Thus molecules of the enolate of **2c** partition roughly equally between protonation to regenerate substrate and condensation to generate product, and k_{-1}[*t*-BuOH] ≈ k_2. This analysis illustrates the remarkable efficiency of trapping of the enolate by the proximal electrophilic carbonyl group — despite the availability of solvent *tert*-butanol as a proton donor, the enolate still has a strong tendency to condense to give product. A similar analysis for **2l** shows that the half-life for deuterium exchange is approx. 1.3 min, essentially unchanged from the value for **2k**. This is consistent with the aromatic substituent exerting little effect on the deprotonation–reprotonation step, as expected and discussed above. By contrast, the half-life for condensation in **2l** is reduced to 0.63 min. Hence, the substituent accelerates the rate of step 2 relative to **2k**, and the enolate partitions towards condensation by approx. 2:1 over reprotonation. For **2m**, step 2 is still further accelerated and reprotonation only rarely occurs; thus the plot of absorbance vs. time fits well to the equation for pseudo-first-order kinetics.

It should be noted that the results cannot rigorously exclude a concerted deprotonation–condensation process (i.e., steps 1 and 2 in Scheme 2 are concerted), although similar concerted mechanisms have been excluded in both chemical enolization (18) and enzymatic mechanistic (19, 20) studies. In such a process, both a variable isotope effect and a substituent effect in the aroyl ring would be expected, as the extent of C–H bond breaking and C–C bond making in the transition state varies with substrate structure. The tetrahedral intermediate **6** would, however, have to partition between retro-Claisen reaction to give **2** and conversion to **7** in order to explain the deuterium exchange in the substrate (i.e., $k_{-2} \approx k_3$); this is counter to the thermodynamic stability arguments (above).

Ashby and Park (21) proposed a mechanism involving a single electron transfer (SET) followed by coupling of the resulting radical anion–radical pair for the C–C bond-forming step of the Claisen-like condensation of pinacolone enolate with ethyl *p*-nitrobenzoate, although this mechanism was refuted by Arnett and co-workers (22). In the present case, the good correlation with σ suggests a polar one-step mechanism (23); there was a significantly worse correlation of our data with σ^+ (R^2 = 0.895, data not shown), a parameter which has been shown to give a better correlation than σ for SET reactions such as reduction of aceto- and benzophenones (24). The data for **2g** also lie on the Hammett line, suggesting that there is no change in mechanism for the *p*-nitro compound compared with other members of the series. We conclude that there is no reason to invoke a SET in the conversion of **2** to **3**.

The magnitude and sign of the Hammett slope ρ for the current data set also favorably compare with published values for intermolecular additions of ketone enolates to aroyl esters (ρ = 2–3) (25) or ketones (ρ = 1–2.2) (26, 27), under conditions where the second C–C bond-forming step is slow. For the latter, aldol condensations, the classic work of Bell and co-workers (28, 29) showed that, as in the current case, one or both of the ketone deprotonation and condensation steps may be rate limiting. Furthermore, Guthrie and Guo (30) and Richard and co-workers (31) examined intramolecular aldol condensations in exquisite kinetic detail, and concluded that either step may be rate limiting. Notably, in their study of the intramolecular aldol condensation of 2-(2-oxopropyl)benzaldehyde, Richard and Nagorski (32) observed that the extent of enolate reprotonation to effect reversal of step 1 depended on the acidity of the proton donor and the relative rates k_{-1} and k_2, a result which compares with the explanation offered herein for the deviation from first-order kinetics observed with **2k**. Thus, the current study correlates with a substantial body of mechanistic data from the literature, which supports a general mechanism for addition of enolates to carbonyl compounds, and extends this work to the Claisen-like conversion of **2** into **3**.

It should be pointed out, however, that the current work does not offer any direct evidence for tetrahedral intermediate **6**, or its protonated analogue. It is not possible to rigorously exclude collapse of **6** (step 3) as the rate-limiting step, because the value of ρ in such a scheme would be an aggregate of the effect on both earlier steps and on step 3, making it hard to predict (33). We are currently exploring this reaction further to clarify these details.

Overall, the data give a clear and fully consistent picture of the events occurring as compounds **2** are converted to **3** by base. For these compounds, the rates of deprotonation and condensation are comparable, as seen by the presence of an isotope effect in deprotonation and a substituent effect in the condensation step(s). Additionally, enolate reprotonation (step 1) and condensation are competitive in some cases. As the substituent is changed and (or) hydrogen is replaced by deuterium in the acetyl group, the relative importance of deprotonation vs. condensation, and of enolate reprotonation vs. condensation change in a consistent and rational manner. This analysis supports the classic mechanism for the Claisen condensation in this case, and has various implications for structural variation of the substrate, and the effect of variations in conditions (e.g., *tert*-butanol solvent concentration on rate, the effect of base concentration on the magnitude of the isotope effect); these aspects are currently being explored.

Conclusion

That each acyl aroyl glycoluril underwent efficient condensation on the preparative scale, irrespective of the presence of electron withdrawing or electron donating substituents, shows that the glycoluril-directed condensation process is rugged, and can tolerate various substituents. It is shown that conditions can be arranged under which the condensation of diacylglycolurils to give β-ketoacylglycolurils proceeds with clean bimolecular kinetics and short half-lives. This work shows that both the deprotonation of substrate and a condensation step, probably the second, key C–C bond formation process, are partially rate limiting. Once formed, the enolate partitions approximately halfway between condensation and reprotonation by solvent under these conditions. These two observations imply roughly equal rates for substrate deprotonation, enolate reprotonation, and enolate condensation steps in **2c**; as the substrate structure is changed, the rate of each step alters in a consistent and rational manner. Hence, the door is opened to find conditions in which a single step may be made fully rate

© 2002 NRC Canada

determining, thus allowing further studies of these key steps of the reaction. Such results may lead to better understanding of the mechanistic details, geometric requirements and transition state structure for enolate addition reactions onto carbonyl groups.

Experimental

General

THF was dried over potassium–benzophenone, then distilled. *tert*-Butanol was dried over calcium oxide and distilled. All glassware was dried in the oven and cooled under an atmosphere of dry nitrogen. All solvent transfers were by syringe. Quartz UV cells bearing a screw cap and septum were from Aldrich; they were dried by evacuation over phosphorus pentoxide in the desiccator.

UV spectroscopy was performed on a Cary 500 spectrophotometer with the temperature controlled to 25°C. NMR spectra were recorded on a Bruker AM-200 spectrometer. IR spectra were recorded on a Biorad FTS-40 spectrophotometer, or on the probe of an ASI in situ reaction monitoring system. Mass spectra were determined on a Finnigan 4500 mass spectrometer.

General procedure for kinetic determinations

Stock solutions of each pre-dried acetyl aroyl glycoluril (**2c**–**m**) were prepared under argon by dissolution of a carefully determined mass (ca. 20 mg) in 1:1 v/v anhydrous THF–*tert*-butanol in a dried volumetric flask (25 mL). Serial dilution was employed to give final concentrations of 5–10 × 10^{-5} M. Stock solutions of the condensation products were prepared similarly, giving final concentrations of 1–10 × 10^{-5} M. Stock solutions of potassium *tert*-butoxide were prepared in the same manner by dissolution of a carefully determined mass (ca. 20 mg) in the same solvent (25 mL). Final concentrations were 2–5 × 10^{-3} M.

To a dried quartz UV cell equipped with a magnetic stir bar and a septum, and which had been purged with dry nitrogen, was added 2.0 mL of stock solution of **2** by syringe. The reference cell contained 1:1 v/v anhydrous THF–*tert*-butanol. After equilibration of the temperature to 25°C within the spectrophotometer, the UV spectrum was recorded in scanning mode. Base solution (0.1–0.5 mL) was added by syringe with rapid stirring. The reaction was monitored, beginning within 5 s, either by following the absorbance at a set wavelength with time, or in some cases by rapid scanning of the spectrum. The observation wavelengths used were: **2c**, **2d**, and **2k**: 335; **2e** and **2l**: 337; **2f**: 336; **2g** and **2m**: 404; **2h**: 339; **2i**: 341; and **2j**: 348 nm. After there was no further change in absorbance, the UV spectrum of the final solution was recorded.

The absorbance–time plot was analyzed on the spectrometer computer by a best-fit approach for pseudo-first-order kinetics. The resulting values of k_{obs} were converted to k_{app} by dividing by the calculated base concentration within the sample. Standard deviations in k_{app} which were generated by the program were evaluated in each experiment; these were always small (<0.001) for **2c**–**j**, and thus errors in k_{app} were calculated from variations between replicate experiments.

General procedure for preparation of acetyl aroyl glycolurils 2c–m

To a solution of **4a** or **4b** in anhydrous THF (15 mL per mmol **4**), which had been cooled to 0°C, was added 1.05 equivalents of *n*-butyllithium in hexane (1.6 M). The mixture was stirred for 15 min, then the aroyl chloride (1.2 equiv.) was added and stirring was continued for 1 h. After quenching with 1 M $NaHSO_4$ (3 mL per mmol **4**), most of the THF was removed on the rotary evaporator and the aqueous residue was extracted three times with $CHCl_3$. The combined organic layers were washed with an equal volume of water and then brine, dried over Na_2SO_4, filtered, and concentrated. The product was purified by recrystallization from $CHCl_3$–hexanes.

Acetyl benzoyl glycoluril 2c

Compound **4a** (708 mg, 2.95 mmol) and benzoyl chloride (410 μL) gave 855 mg (92%) of pure **2c** as a yellowish foam. UV (THF) λ_{max} (nm) (ε, M^{-1} cm^{-1}): 242 (6 300). IR (NaCl disks, cm^{-1}): 3020 (C-H str.), 1728 (C=O), 1408, 1333, 1216, 1114. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.51–7.42 (m, 3H, *m*-, *p*-C_6H_5), 7.37–7.24 (m, 2H, *o*-C_6H_5), 3.00 (3H, s, N-CH_3), 2.82 (s, 3H, N-CH_3), 2.47 (s, 3H, O=C-CH_3), 2.03 (s, 3H, CH_3), 1.53 (s, 3H, CH_3). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 170.04 (C=O), 169.91 (C=O), 153.14 (C=O), 152.61 (C=O), 135.02, 132.00, 129.04 (2C), 127.51 (2C, benzoyl), 80.03, 78.04 (*C* bridgehead), 27.04, 25.18, 20.92, 19.09, 15.01. EI-MS *m*/*z*: 344 [M^+], 301, 229, 126, 105 (base), 77, 56. HRMS calcd. for $C_{17}H_{20}N_4O_4$: 344.1484, found: 344.1492.

Acetyl 4-methoxybenzoyl glycoluril 2d

Compound **4a** (960 mg, 4 mmol) and 4-methoxybenzoyl chloride (715 mg) gave 920 mg (61%) of **2d**; mp 182–183°C. UV (50:50 THF–*t*-BuOH) λ_{max} (nm) (ε, M^{-1} cm^{-1}): 273 (14 400). IR ($CHCl_3$ cast, cm^{-1}): 3018 (Ar-H str.), 2941 (C-H str.), 1721 (C=O), 1698 (C=O), 1603, 1329, 1254, 1167. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.53 (d, *J* = 7 Hz, 2H, Ar*H*), 6.85 (d, *J* = 7 Hz, 2H, Ar*H*), 3.81 (s, 3H, OCH_3), 3.05 (s, 3H, N-CH_3), 2.86 (s, 3H, N-CH_3), 2.47 (s, 3H, O=C-CH_3), 2.04 (s, 3H, CH_3), 1.58 (s, 3H, CH_3). EI-MS *m*/*z*: 374 [M^+], 346, 135 (base), 77, 56, 43. HRMS calcd. for $C_{18}H_{22}N_4O_5$: 374.1590, found: 374.1587.

Acetyl 3-chlorobenzoyl glycoluril 2e

Compound **4a** (720 mg, 3 mmol) and 3-chlorobenzoyl chloride (577 mg) gave 485 mg (43%) of **2e**; mp 154–156°C. UV (50:50 THF–*t*-BuOH) λ_{max} (nm) (ε, M^{-1} cm^{-1}): 237, 287 (11 000, 2 200). IR ($CHCl_3$ cast, cm^{-1}): 3018 (Ar-H str.), 2944 (C-H str.), 1725 (C=O), 1702 (C=O), 1573, 1407, 1329, 1115, 1094, 942. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.22–7.46 (m, 4H, Ar*H*), 3.02 (s, 3H, N-CH_3), 2.83 (s, 3H, N-CH_3), 2.49 (s, 3H, O=C-CH_3), 2.02 (s, 3H, CH_3), 1.55 (s, 3H, CH_3). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 170.34 (2 O=C), 153.01, 152.65 (urea C=O), 136.87, 133.73, 132.01, 129.15, 128.92, 127.26 (aroyl), 80.14, 78.16 (*C* bridgehead), 27.09, 26.82, 25.12, 19.25, 15.24. EI-MS *m*/*z*: 378, 380 [M^+], 336, 156, 141, 139, 135, 126, 111, 56, 43 (base). HRMS calcd. for $C_{17}H_{19}{}^{35}ClN_4O_4$: 378.1095, found: 378.1089.

Acetyl 4-methylbenzoyl glycoluril 2f

Compound **4a** (720 mg, 3 mmol) and 4-methylbenzoyl chloride (437 μL) gave 590 mg (55%) of **2f**; mp 111–114°C dec. UV (50:50 THF–*t*-BuOH) λ_{max} (nm) (ε, M^{-1} cm^{-1}): 253 (13 500). IR ($CHCl_3$ cast, cm^{-1}): 3010 (Ar-H str.), 2944 (C-H str.), 1721 (C=O), 1702 (C=O), 1609, 1407, 1329, 1277, 1115, 1094. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.42 (d, *J* = 8 Hz, 2H, Ar*H*), 7.14 (d, *J* = 8 Hz, 2H, Ar*H*), 3.04 (s, 3H, N-CH_3), 2.85 (s, 3H, N-CH_3), 2.47 (s, 3H, O=C-CH_3), 2.34 (s, 3H, ArCH_3), 2.04 (s, 3H, CH_3), 1.57 (s, 3H, CH_3). EI-MS *m*/*z*: 358 [M^+], 330, 243, 126, 119 (base), 91, 56, 43. HRMS calcd. for $C_{18}H_{22}N_4O_4$: 358.1641, found: 358.1618.

Acetyl 4-nitrobenzoyl glycoluril 2g

Compound **4a** (720 mg, 3 mmol) and 4-nitrobenzoyl chloride (555 mg) gave 277 mg (24%) of **2g**; mp 212–218°C dec. UV (50:50 THF–*t*-BuOH) λ_{max} (nm) (ε, M^{-1} cm^{-1}): 269 (12 500). IR ($CHCl_3$ cast, cm^{-1}): 3018 (Ar-H str.), 2946 (C-H str.), 1727 (C=O), 1710 (C=O), 1605, 1524 (NO_2), 1407, 1333, 1115, 1094. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 8.45 (d, *J* = 8 Hz, 2H, Ar*H*), 7.65 (d, *J* = 8 Hz, 2H, Ar*H*), 3.05 (s, 3H, N-CH_3), 2.85 (s, 3H, N-CH_3), 2.55 (s, 3H, O=C-CH_3), 2.05 (s, 3H, CH_3), 1.60 (s, 3H, CH_3). EI-MS *m*/*z*: 389 [M^+], 347, 240, 141, 126 (base), 56, 43. HRMS calcd. for $C_{17}H_{19}N_5O_6$: 389.1335, found: 389.1355.

Acetyl 3-nitrobenzoyl glycoluril 2h

Compound **4a** (720 mg, 3 mmol) and 3-nitrobenzoyl chloride (577 mg) gave 493 mg (42%) of **2h**; mp 192–194°C. UV (50:50 THF–*t*-BuOH) λ_{max} (nm) (ε, M^{-1} cm^{-1}): 259 (sh, 10 900), 225 (sh). IR ($CHCl_3$ cast, cm^{-1}): 3018 (Ar-H str.), 2944 (C-H str.), 1725 (C=O), 1706 (C=O), 1615, 1530 (NO_2), 1331, 1115, 1092. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 8.31 (ddd, *J* = 8, 2, 1 Hz, 1H, Ar*H*), 8.27 (dd, *J* = 2, 1 Hz, 1H, Ar*H*), 7.82 (ddd, *J* = 8, 2, 2 Hz, 1H, Ar*H*), 7.54 (ddd, *J* = 8, 8, 1 Hz, 1H, Ar*H*), 3.07 (s, 3H, N-CH_3), 2.86 (s, 3H, N-CH_3), 2.51 (s, 3H, O=C-CH_3), 2.05 (s, 3H, CH_3), 1.60 (s, 3H, CH_3). EI-MS *m*/*z*: 389 [M^+], 374, 272, 150, 135 (base), 126, 56, 43. HRMS calcd. for $C_{17}H_{19}N_5O_6$: 389.1335, found: 389.1345.

Acetyl 4-chlorobenzoyl glycoluril 2i

Compound **4a** (720 mg, 3 mmol) and 4-chlorobenzoyl chloride (420 μL) gave 1.07 g (94%) of **2i**; mp 186–188°C. UV (50:50 THF–*t*-BuOH) λ_{max} (nm) (ε, M^{-1} cm^{-1}): 250 (11 900). IR ($CHCl_3$ cast, cm^{-1}): 3014 (Ar-H str.), 2943 (C-H str.), 1721 (C=O), 1702 (C=O), 1590, 1329, 1279, 1115, 1090. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.43 (d, *J* = 8 Hz, 2H, Ar *H*), 7.30 (d, *J* = 8 Hz, 2H, Ar*H*), 3.04 (s, 3H, N-CH_3), 2.84 (s, 3H, N-CH_3), 2.48 (s, 3H, O=C-CH_3), 2.02 (s, 3H, CH_3), 1.57 (s, 3H, CH_3). EI-MS *m*/*z*: 378, 380 [M^+, base], 352, 350. HRMS calcd. for $C_{17}H_{19}{}^{35}ClN_4O_4$: 378.1095, found: 378.1074.

Acetyl 4-(trifluoromethyl)benzoyl glycoluril 2j

Compound **4a** (1.05 g, 4.36 mmol) and 4-(trifluoromethyl)benzoyl chloride (1 g) gave 222 mg (12%) of **2j**; mp 193–195°C. UV (50:50 THF–*t*-BuOH) λ_{max} (nm) (ε, M^{-1} cm^{-1}): 238, 276 (sh) (12 400, 1 090). IR ($CHCl_3$ cast, cm^{-1}): 3018 (Ar-H str.), 2943 (C-H str.), 1725 (C=O), 1708 (C=O), 1407, 1332, 1297, 1111, 1065, 1017, 936, 851. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.62 (m, 4H, Ar*H*), 3.08 (s, 3H, N-CH_3), 2.88 (s, 3H, N-CH_3), 2.53 (s, 3H, O=C-CH_3), 2.08 (s, 3H, CH_3), 1.61 (s, 3H, CH_3). EI-MS *m*/*z*: 412 [M^+, base], 370, 297, 172, 125, 56, 43. HRMS calcd. for $C_{18}H_{19}F_3N_4O_4$: 412.1358, found: 412.1368.

[D_3]Acetyl benzoyl glycoluril 2k

Compound **4b** (see below, 176 mg, 724 μmol) and benzoyl chloride (91 μL) gave 83.3 mg (33%) of **2k**. ^{1}H NMR as for **2c**, except that the resonance due to the acetyl group was absent. EI-MS *m*/*z*: 347 [M^+, base], 319, 229, 105, 43.

[D_3]Acetyl 3-chlorobenzoyl glycoluril 2l

Compound **4b** (134 mg, 550 μmol) and 3-chlorobenzoyl chloride (96 mg) gave 160 mg (71%) of **2l**. ^{1}H NMR as for **2e**, except that the resonance at 2.49 ppm due to the acetyl group was absent. EI-MS *m*/*z*: 381, 383 [M^+, base], 337, 263, 139, 127, 84, 56, 49.

[D_3]Acetyl 4-nitrobenzoyl glycoluril 2m

Compound **4b** (243 mg, 1.0 mmol) and 4-nitrobenzoyl chloride (185 mg) gave 82 mg (21%) of **2m**. ^{1}H NMR as for **2g**, except that the resonance at 2.55 ppm due to the acetyl group was absent. EI-MS *m*/*z*: 392 [M^+, base], 348, 150, 127, 56, 46.

Benzoylacetyl glycoluril 3c with KO-*t*-Bu

To a solution of compound **2c** (100 mg, 0.29 mmol) in THF (10 mL) at 0°C was added potassium *tert*-butoxide (43 mg, 1.3 equiv.), and the mixture was stirred for 30 min. The reaction mixture was quenched over 3 h with ammonium bicarbonate, then filtered through celite. Solvent was removed in vacuo to give **3c** as a foam (98 mg, 98%). UV (50:50 THF–*t*-BuOH) λ_{max} (nm) (ε, M^{-1} cm^{-1}): 240, 313 (9 650, 6 950); when treated with excess KO-*t*-Bu: λ_{max} = 335 (15 800). IR (NaCl disks, cm^{-1}): 3020 (C-H), 1728 (C=O), 1408, 1333, 1216, 1114. ^{1}H NMR (200 MHz, $CDCl_3$, 2.6:1 mixture of keto–enol tautomers) δ: 8.10–7.40 (m, 5H, Ar*H*), 6.11 (br s, 1H, N*H* enol), 6.09 (br s, 1H, N*H* keto), 4.94 (d, *J* = 16 Hz, 1H, O=C-C*H*H keto), 4.05 (d, *J* = 16 Hz, 1H, O=CCH*H* keto), 3.02 (s, 3H, N-CH_3 enol), 2.92 (s, 3H, N-CH_3 keto), 2.86 (s, 3H, N-CH_3 enol), 2.84 (s, 3H, N-CH_3 keto), 1.79 (s, 3H, CH_3 keto), 1.76 (s, 3H, CH_3 enol), 1.56 (s, 3H, CH_3 enol), 1.55 (s, 3H, CH_3 keto). ^{13}C NMR (125 MHz, $CDCl_3$, keto and some enol signals) δ: 193.67 (O=*C*-Ph), 167.91 (C=O), 167.23 (C=O), 152.79 (C=O), 136.06, 133.73, 131.58, 128.73, 128.16, 126.48, 88.24, 78.80, 48.15, 28.10, 26.44, 20.05, 19.32, 15.71. EI-MS *m*/*z*: 344 [M^+], 272, 198, 125, 105 (base), 77, 56. HRMS calcd. for $C_{17}H_{20}N_4O_4$: 344.1484, found: 344.1492. Anal. calcd. for $C_{17}H_{20}N_4O_4$: C 59.24, H 5.85, N 16.27; found C 59.16, H 6.05, N 16.58.

General procedure for preparative condensations of acetyl aroyl glycolurils 2d–g giving 3d–g

The acetyl aroyl glycoluril was dissolved in anhydrous THF and *t*-BuOH, and the mixture cooled to 0°C. A solution of *n*-butyllithium in hexane (1.6 M) was added and the mixture was stirred for 30 min at 0°C then for 30 min at room temperature. The reaction mixture was quenched with

© 2002 NRC Canada

1 M $NaHSO_4$ (5 mL), then organic solvents were removed on the rotary evaporator, and the residue extracted with $CHCl_3$. The extracts were dried, filtered, concentrated, and where needed, purifed from unreacted starting material by flash column chromatography in 1% then 2% MeOH–$CHCl_3$.

4-Methoxybenzoylacetyl glycoluril 3d

Compound **2d** (930 mg, 2.49 mmol) in THF (12 mL) and *t*-BuOH (8 mL) with *n*-BuLi (2 mL) gave 275 mg (30%) of **3d**; mp 187–191°C dec. UV (50:50 THF–*t*-BuOH) λ_{max} (nm) (ε, M^{-1} cm^{-1}): 271, 326 (10 800, 4 900); when treated with excess KO-*t*-Bu: λ_{max} = 271, 335 (7 300, 14 400). IR ($CHCl_3$ cast, cm^{-1}): 3327 (br, OH and NH str.), 2999, 2944 (C-H str.), 1710 (C=O), 1673 (C=O), 1601, 1408, 706. ^{1}H NMR (200 MHz, $CDCl_3$, keto form ca. 75%) δ: 7.84 (d, *J* = 9 Hz, 2H, Ar*H* keto), 7.78 (d, *J* = 9 Hz, 2H, Ar*H* enol), 7.30 (d, *J* = 9 Hz, 2H, Ar*H* enol), 7.15 (s, 1H, C*H*=C enol), 6.88 (d, *J* = 9 Hz, 2H, Ar*H* keto), 6.15 (br s, 1H, N*H* enol), 6.11 (br s, 1H, N*H* keto), 4.88 (d, *J* = 16 Hz, 1H, O=C-C*H*H keto), 4.00 (d, *J* = 16 Hz, 1H, O=CCH*H* keto), 3.81 (s, 3H, OCH_3 keto), 3.79 (s, 3H, OCH_3 enol), 2.99 (s, 3H, N-CH_3 enol), 2.90 (s, 3H, N-CH_3 enol), 2.89 (s, 3H, N-CH_3 keto), 2.81 (s, 3H, N-CH_3 keto), 1.75 (s, 3H, CH_3 keto), 1.72 (s, 3H, CH_3 enol), 1.57 (s, 3H, CH_3 enol) 1.52 (s, 3H, CH_3 keto). EI-MS *m*/*z*: 374 [M^+], 176, 135 (base), 56. HRMS calcd. for $C_{18}H_{22}N_4O_5$: 374.1590, found: 374.1573.

3-Chlorobenzoylacetyl glycoluril 3e

Compound **2e** (82 mg, 217 μmol) in THF–*t*-BuOH (50:50, 15 mL) with *n*-BuLi (0.53 mL) gave 60.6 mg (74%) of **3e**; mp 148–151°C dec. UV (50:50 THF–*t*-BuOH) λ_{max} (nm) (ε, M^{-1} cm^{-1}): 323 (7 960); when treated with excess KO-*t*-Bu: λ_{max} = 325, 348 (sh) (17 800). IR ($CHCl_3$ cast, cm^{-1}): 3430, 3316 (br, OH and NH str.), 3015 (Ar-H str.), 2935 (C-H str.), 1708 (br, C=O), 1407, 1214, 1109, 746. ^{1}H NMR (200 MHz, $CDCl_3$, keto form ca. 66%) δ: 7.66–8.05 (m, 2H, Ar*H*), 7.24–7.55 (m, 2H, Ar*H*), 6.23 (br s, 1H, N*H* enol), 6.18 (br s, 1H, N*H* keto), 4.87 (d, *J* = 16 Hz, 1H, O=C-C*H*H keto), 4.02 (d, *J* = 16 Hz, 1H, O=C-CH*H* keto), 3.03 (s, 3H, N-CH_3 enol), 2.92 (s, 3H, N-CH_3 keto), 2.86 (s, 3H, N-CH_3 enol), 2.84 (s, 3H, N-CH_3 keto), 1.78 (s, 3H, CH_3 keto), 1.76 (s, 3H, CH_3 enol), 1.57 (s, 3H, CH_3 enol), 1.55 (s, 3H, CH_3 keto). EI-MS *m*/*z*: 378, 380 [M^+], 308, 306, 141, 139, 125, 111, 56, 43 (base). HRMS calcd. for $C_{17}H_{19}{}^{35}ClN_4O_4$: 378.1095, found: 378.1095.

4-Methylbenzoylacetyl glycoluril 3f

Compound **2f** (90 mg, 250 μmol) in THF–*t*-BuOH (50:50, 15 mL) with *n*-BuLi (0.53 mL) gave 62 mg (69%) of **3f**; mp 202–203°C. UV (50:50 THF–*t*-BuOH) λ_{max} (nm) (ε, M^{-1} cm^{-1}): 322 (8 900); when treated with excess KO-*t*-Bu: λ_{max} = 331 (17 800). IR ($CHCl_3$ cast, cm^{-1}): 3325 (br, OH and NH str.), 3005, 2927 (C-H str.), 1715 (C=O), 1607, 1406, 1328, 1104, 803. ^{1}H NMR (200 MHz, $CDCl_3$) (keto form ca. 75%) δ: 7.79 (d, *J* = 8 Hz, 2H, Ar*H* keto), 7.72 (d, *J* = 8 Hz, 2H, Ar*H* enol), 7.24 (m, 2H, Ar*H* keto and enol, enol C*H*=C), 6.12 (br s, 1H, N*H* enol), 6.02 (br s, 1H, N*H* keto), 4.94 (d, *J* = 16 Hz, 1H, O=C-C*H*H keto), 4.02 (d, *J* = 16 Hz, 1H, O=CCH*H* keto), 3.02 (s, 3H, N-CH_3 enol), 2.92 (s, 3H, N-CH_3 keto), 2.86 (s, 3H, N-CH_3 enol), 2.85 (s, 3H, N-CH_3 keto), 2.39 (s, 3H, ArCH_3 keto), 2.37 (s, 3H, ArCH_3 enol), 1.79 (s, 3H, CH_3 keto), 1.75 (s, 3H, CH_3 enol), 1.56 (s, 3H, CH_3 enol), 1.55 (s, 3H, CH_3 keto). ^{13}C NMR (50 MHz, $CDCl_3$, keto and some enol signals) δ: 168.11, 152.82, 144.42, 133.71, 129.43 (2C), 129.24, 128.30 (2C), 126.52, 87.58, 78.80, 48.05, 27.11, 26.46, 21.64, 19.34, 15.73. EI-MS *m*/*z*: 358 [M^+], 330, 119 (base), 91, 56, 43. HRMS calcd. for $C_{18}H_{22}N_4O_4$: 358.1641, found: 358.1628.

4-Nitrobenzoylacetyl glycoluril 3g

Compound **2g** (195 mg, 501 μmol) in THF–*t*-BuOH (50:50, 20 mL) with *n*-BuLi (0.41 mL) gave 67.9 mg (35%) of **3g**; mp 167–169°C. UV (50:50 THF–*t*-BuOH) λ_{max} (nm) (ε, M^{-1} cm^{-1}): 271, 335 (11 200, 4 800); when treated with excess KO-*t*-Bu: λ_{max} = 286, 404 (15 000, 4 000). IR ($CHCl_3$ cast, cm^{-1}): 3395 (br, OH and NH str.), 2942 (C-H str.), 1705 (br, C=O), 1593, 1523, 1105, 759. ^{1}H NMR (200 MHz, $CDCl_3$, ca. 50% keto form) δ: 8.08–8.16 (m, 2H, enol and keto Ar*H*), 7.80–7.93 (m, 2H, enol and keto Ar*H*), 6.0 and 5.9 (br s, 1H, enol and keto N*H*), 4.75 (d, *J* = 16 Hz, 1H, O=CCH*H* keto), 3.95 (d, *J* = 16 Hz, 1H, O=CCH*H* keto), 2.91, 2.79, 2.74 and 2.72 (s, 6H, keto and enol N-CH_3), 1.66, 1.64, 1.45, and 1.43 (s, 6H, keto and enol C-CH_3). EI-MS *m*/*z*: 389 [M^+, weak], 150, 125, 56.

[D_3]Monoacetylglycoluril 4b

Method A: Glycoluril **1** (0.5 g, 2.5 mmol) and [D_6]acetic anhydride (5 mL) were heated at reflux for 20 h. Work-up as previously described (7) gave [D_3]monoacetylglycoluril **4b** (50 mg, 9%).

Method B: Glycoluril **1** (2 g, 10 mmol) in THF (200 mL) was treated with *n*-BuLi (7.0 mL of 1.6 M solution in hexane) and [D_3]acetyl chloride (1.07 mL, 15 mmol) was added as previously described (7). Work-up as previously reported gave [D_3]monoacetylglycoluril **4b** (0.64 g, 26%). ^{1}H NMR data were as previously reported for **4**, except that the resonance due to the acetyl group was absent.

Acknowledgments

The authors gratefully acknowledge financial support from NSERC. M.R. was supported on sabbatical leave by Ferdowsi University, Iran. R.M. acknowledges the Committee for Research and Publication at Mount St. Vincent University (MSVU) for financial support. We also wish to thank Verna MacKinnon for many initial kinetic trials during her honours research project at MSVU.

Selective reduction and chemical modification of oxidized lipase cysteine mutants

Eva M.K. Hedin, Shamkant A. Patkar, Jesper Vind, Allan Svendsen, Karl Hult, and Per Berglund

Abstract: Thirteen single-cysteine mutants of the 33 kDa fungal triacylglycerol lipase *Thermomyces* (formerly *Humicola*) *lanuginosa* lipase (TLL, EC 3.1.1.3) were produced and characterized for the purpose of site-directed chemical modification with spectroscopic reporter groups. All cysteine mutants were found to be predominantly blocked by oxidation to disulfides with endogenous cysteine during production. The fraction of lipase molecules with free sulfhydryl groups was analyzed by labeling with *N*-biotinylaminoethyl methanethiosulfonate, followed by a novel dot-blot method based on biotin–streptavidin interactions. A non-invasive method for the reduction of the introduced cysteine was elaborated for this protein containing three native disulfide bridges. The site-specifically reduced TLL mutants were then labeled with the sulfhydryl-specific reagents 2-(5-dimethylaminonaphth-1-ylsulfonamido)ethyl methanethiosulfonate or (1-oxyl-2,2,5,5-tetramethyl-Δ^3-pyrroline-3-methyl) methanethiosulfonate, and studied by fluorescence and electron spin resonance (ESR) spectroscopy.

Key words: lipase, cysteine mutant, selective reduction, chemical modification, methanethiosulfonate.

Résumé : Dans le but d'obtenir des modifications chimiques orientées vers les sites au contact de groupes rapporteurs, on a préparé et caractérisé 13 mutants de la lipase fongique du triacétylglycérol, la lipase *Thermomyces* (antérieurement *Humicola*) *lanuginosa* (TLL, EC 3.1.1.3), de masse 33 kDa, qui ne comportent qu'une seule cystéine. On a trouvé que, durant la production, tous les mutants à la cystéine sont bloqués principalement par une oxydation en disulfures avec la cystéine endogène. On a analysé la fraction de molécules de lipase comportant des groupes sulfhydryles libres en les marquant avec du méthanethiosulfonate de *N*-biotinylaminoéthyle, suivi d'une nouvelle méthode à point sur papier buvard qui est basée sur les interactions entre la biotine et la streptavidine. On a élaboré une méthode non invasive de réduction de la cystéine introduite pour la protéine qui contient trois ponts disulfures d'origine. Par la suite, les mutants de TLL réduits spécifiquement en fonction du site ont été marqués avec des réactifs spécifiques aux sulfhydryles, le méthanethiosulfonate de 2-(5-diméthylaminonapht-1-ylsulfamido)éthyle ou de (1-oxyl-2,2,5,5-tétraméthyl-Δ^3-pyrroline-3-méthyle) et on les a étudiés par fluorescence et par spectroscopie de résonance paramagnétique électronique (RPE).

Mots clés : lipase, mutant à cystéine, réduction sélective, modification chimique, méthanethiosulfonate.

[Traduit par la Rédaction]

Introduction

The combination of site-directed mutagenesis and covalent chemical modification has, during the last decades, emerged as a powerful tool in the study of protein structure, function, and dynamics. Introducing probes, such as fluorescent groups or spin labels, at predetermined sites in a protein enables detailed information on protein structure and interactions to be obtained through spectroscopic studies (1, 2). For example, advances in the field of site-directed spin labeling and electron spin resonance (ESR) spectroscopy have allowed the elucidation of protein topology and function for several proteins (3–5), as well as of protein–membrane interactions (6, 7). With the technique of chemical modification of mutated proteins (CMM technology), enzymes with new functionalities or enhanced activities have also been prepared (for a review, see ref. 8). An example of altering the activity and specificity of an enzyme by this approach is reported by Jones and co-workers (9), in which the introduction of various alkyl- and aryl-side chains in the S_1 and S'_1 specificity pockets of subtilisin *Bacillus lentus* cysteine mutants created enzymes with greater activity than the wild-type enzyme.

The success of studying proteins using CMM technology is ultimately dependent on the specificity of the chemical-modification reaction. Although chemical modification can be targeted to various amino-acid side chains, it often results in multiple labeling due to the occurrence of several copies of the target amino acid. Cysteine, however, is very rarely present as free cysteine in protein structures, and possesses a unique reactivity among the amino acids. Consequently, the

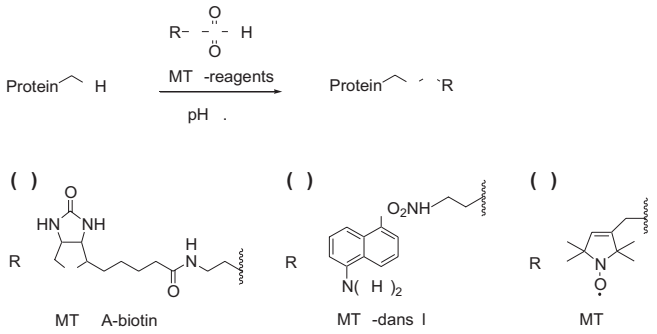
Scheme 1.



introduction of cysteine by mutagenesis at a preselected site in a protein, in combination with sulfhydryl-specific labeling reagents, has emerged as a highly specific modification process that is extensively employed. Several classes of reagents exist for the modification of cysteine (reviewed in ref. 10), of which the methanethiosulfonate (MTS) reagents have surfaced as the most specific, and are routinely used (10, 11). The MTS reagents react specifically and quantitatively with sulfhydryl groups under mild reaction conditions with no large excess of reagent required, and their reactivity is independent of the nature of the group to be attached (12, 13).

Unfortunately, due to the intrinsic reactivity of cysteine, it is prone to oxidation, especially when introduced at surface-exposed parts of a protein, which may result in disulfide formation with endogenous sulfur-containing compounds or in protein dimerization (14, 15). As a result, reduction of cysteine disulfides must often precede any chemical modification. An interesting study was recently reported, in which several single-cysteine mutants of subtilisin were produced, and the oxidation state of the introduced cysteine was analyzed by mass spectrometry (MS), employing protein digestion and sub-digestion techniques (15). In particular, a striking correlation was found between oxidation and surface accessibility of the cysteines. Most of the cysteine mutants that had been oxidized, however, were also found to contain a small fraction of free sulfhydryl groups.

In the present study, we report the detection and quantitation of free sulfhydryl groups in recombinant single-cysteine mutants of a triacylglycerol lipase. Specifically, the oxidation state of the introduced cysteine was studied for this lipase that contains three native disulfide bridges. Furthermore, a procedure for selective and non-invasive reduction of the oxidized recombinant proteins has been developed, to enable site-specifically labeled lipases as the end product. This was performed on a series of single-cysteine mutants of *Thermomyces* (formerly *Humicola*) *lanuginosa* lipase (TLL). This 33 kDa fungal glycosylated triacylglycerol lipase (EC 3.1.1.3) is a well-characterized enzyme with interesting industrial applications (16), and displays classical interfacial activation (17). TLL has been cloned, overexpressed, and purified (16, 18), and several high-resolution crystal structures of TLL have been reported (19, 20). Furthermore, the dynamics and the kinetic behaviour of TLL have been well characterized (18, 21–24), although the mechanistic details of interfacial activation have not yet been elucidated. In this paper, 13 TLL single-cysteine mutants are presented, in which the cysteine has been introduced at the surface of the enzyme. The cysteine variants were studied through labeling with different MTS reagents (Scheme 1). A dot-blot method for the detection of free sulfhydryl groups in the protein (employing reagent **A**) was developed and evaluated. This method requires only small quantities of protein and is based on the strong ligand interaction between biotin and streptavidin. A selective reduction method for the oxidized TLL cysteine mutants is then presented, which distinguishes between the three structural disulfide bridges in TLL and the introduced cysteine. The selectively reduced TLL mutants were labeled with spectroscopic probes (**B** and **C**, Scheme 1), which afforded varying degrees of label insertion in each of the different mutants. The labeled mutants were studied by fluorescence- and ESR spectroscopy. The correlation between spectral signatures, yield of label insertion, and local structural features at the mutation site is discussed, as is the applicability of the dot-blot method and the optimized selective-reduction method.

Results

Preparation of functional TLL mutant proteins

Thirteen single-cysteine mutants of TLL were produced for the purpose of site-directed labeling with various spectroscopic probes. The mutations were made on the surface of TLL by replacement of a selected residue with cysteine. Every target site was preselected to provide a coverage around the surface of the molecule, using the TLL X-ray structure for reference. A structure of TLL in the open conformation, complexed with an *n*-dodecyl (C12) phosphonate inhibitor, was used (the TLL-C12 atomic coordinates were provided by Lawson et al., ref. 25). The TLL mutants created can be divided into two groups. In the first group, only single-cysteine mutations were made, which afforded 11 different mutants with a cysteine introduced at one of the following positions: P42C (proline 42 exchanged for cysteine), G61C, K74C, D96C, T123C, D137C, T192C, R209C, T231C, I252C, and T267C. The second group included two variants where, in addition to the cysteine mutation, three tryptophans were removed, leaving only the tryptophan residing in the lid of TLL (Trp-89). This was done for the purpose of fluorescence spectroscopy studies to allow Trp-89 to be monitored without any interference from the other tryptophans. Furthermore, these mutants had the glycosylation site removed, which yielded two TLL variants containing the following mutations: G61C/W117F/W221H/W260H/N33Q and R209C/W117F/W221H/W260H/N33Q (which henceforth shall be referred to as "G61C-singleW" and "R209C-singleW," respectively).

The ribbon structure in Fig. 1 shows the relative positions of all single-point cysteine mutations prepared in TLL, with the substituted amino acids highlighted in yellow. In addition, the four tryptophans are indicated, of which Trp-89, together with the rest of the α-helical lid, is colored green. The catalytic triad (Ser-146, His-258, Asp-201), which is next to the lid, is displayed in cyan/red. Five cysteine mutations were placed around the lid and the active site (T267C, I252C, R209C, D96C, and G61C). A ring of residues were mutated around the lower third of the molecule (P42C, T231C, T192C, and T123C), and opposite to the active site,

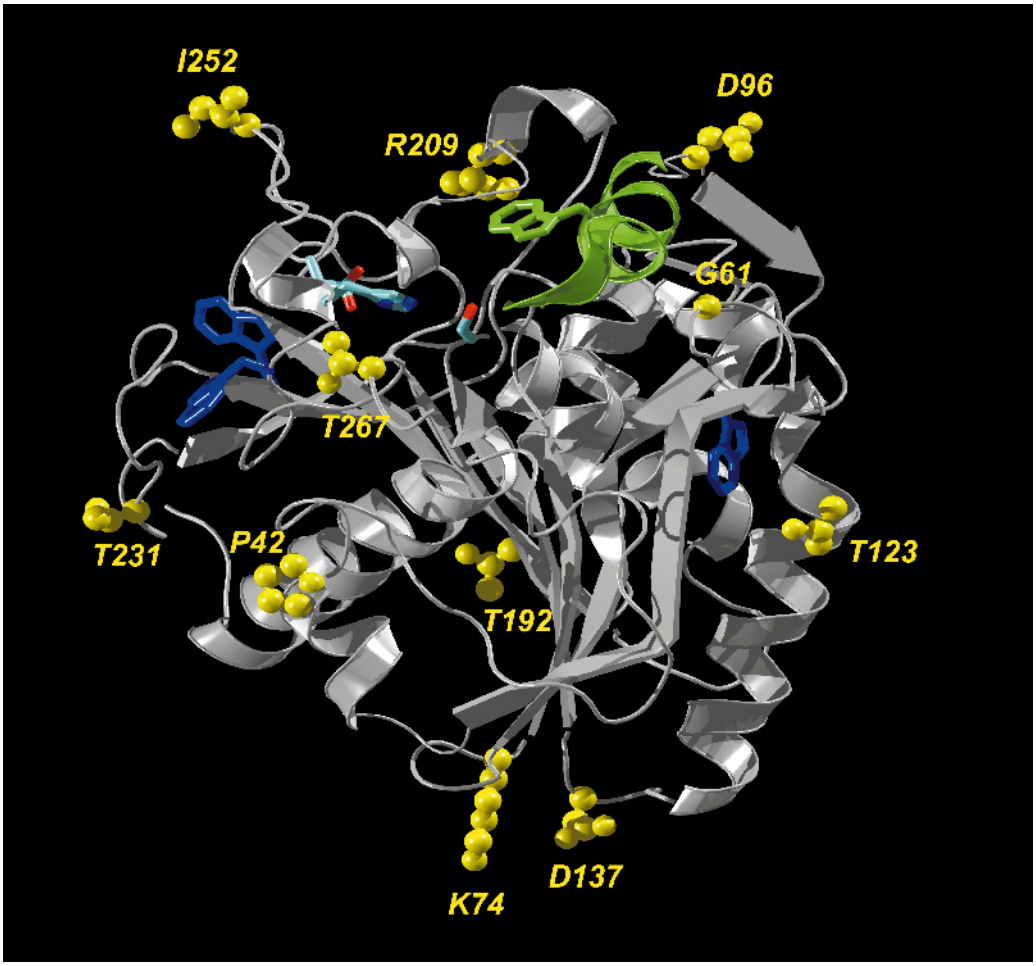
Fig. 1. A ribbon representation of *Thermomyces lanuginosa* lipase, showing the open conformation (the complexed *n*-dodecyl (C12) phosphonate inhibitor has been omitted in this figure for clarity). The relative positions of all single-point cysteine mutations are shown, where the substituted residues are marked in yellow spacefill (single amino-acid codes used). In addition, the four tryptophans in TLL are indicated, the lid is highlighted in green and the catalytic triad in cyan/red. The TLL-C12 atomic coordinates were kindly provided by Lawson and Brzozowski (25). The figure was generated using VMD (39) and POV-Ray.



two mutations were placed close to each other but positioned at the turns of two different hairpin loops (K74C and D137C). Although all of these mutations are at the surface of TLL, some are situated on more exposed and flexible segments of the protein, such as loops, whereas others are located on the surface of α-helices and β-sheets.

All created TLL proteins produced one band of approximately 33 kDa on SDS-PAGE. The tryptophan fluorescence spectra of the variants containing only the single-cysteine mutation were effectively identical to that of the wild-type enzyme. This was also the case for G61C-singleW and R209C-singleW, indicating the strong contribution to the total TLL tryptophan fluorescence by Trp-89 in the lid, in agreement with previously reported work (21). The specific hydrolytic activity of the TLL mutants was measured on an emulsion of glyceryl tributanoate using a pH-stat method (16). All mutants displayed high hydrolytic activity comparable to that of the wild-type enzyme, where G61C-singleW and R209C-singleW were the least active (Table 1). The specific activity of the TLL mutants varied between 53–118% of that of the wild-type enzyme. As seen in Table 1, the mutants I252C and T267C have slightly lower activity than the rest of the single-cysteine mutants, which may be due to the proximity of the mutation to the lid and the active site in TLL. Finally, it should also be noted that the specific activity of the mutants was found to vary slightly between different batches. Altogether, the above data show that the mutations performed on TLL did not significantly perturb the protein structure or activity.

Detection of free protein-sulfhydryl groups by the dot-blot method

In the present study, a dot-blot method for the detection of free protein-sulfhydryl groups was developed. This method requires only small quantities of protein (50–200 μL) at concentrations of 1–3 mg mL^{-1}, and is based on the strong ligand interaction between biotin and avidin or streptavidin. Accordingly, the produced TLL cysteine mutants were labeled with the sulfhydryl-specific reagent MTSEA–biotin (**A**, Scheme 1) and purified by dialysis. The biotinylated proteins were then applied on a nitrocellulose membrane by a Bio-Dot® microfiltration apparatus, together with a series of biotinylated protein standards. The membrane was subsequently incubated with a streptavidin-AP (alkaline

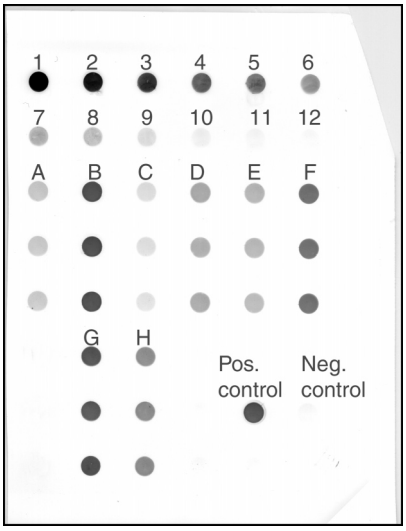
G61C	6660 ± 10
K74C	7480 ± 60
D96C	7120 ± 400
T123C	7640 ± 520
D137C	7130 ± 300
T192C	6070 ± 140
R209C	7640 ± 10
T231C	6050 ± 340
I252C	5360 ± 230
T267C	4090 ± 280
G61C-singleW	3540 ± 40
R209C-singleW	3890 ± 10

Note: Activity mesured by the pH-stat method on a 16 mM emulsion of glyceryl tributanoate. The error in each sample was estimated from the standard deviation of triplicate measurements.

[a]A lipase unit (LU) equals one μmol of released titratable acid per min.

phosphatase) conjugate at 30°C and developed with the substrate BCIP–NBT (5-bromo-4-chloro-3-indolyl phosphate – nitro blue tetrazolium), which afforded dots of varying intensities, proportional to the AP activity. The intensities of the developed dots were analyzed by densiometry. The densiometrically determined quantities of the TLL biotin content were normalized by protein concentration, which revealed the amount of free cysteine for each variant. The "biotinylated" TLL wild-type control always gave a negative result in the dot-blot assay (data not shown). A representative dot-blot membrane is shown in Fig. 2. The results from the dot-blot quantitation are summarized in the second column of Table 2. As seen, the dot-blot method showed that for all TLL cysteine variants analyzed, the sulfhydryl group of the introduced cysteine was predominantly blocked. Four variants contained only 1–2% of free cysteine (mol of free cysteine per mol of protein, in percent), three contained around 15%, and one variant displayed 37% free cysteine (T231C). Nevertheless, these results are not unexpected for cysteine mutations positioned on the surface of a protein (15). The dot-blot method was evaluated by comparison with three other methods of sulfhydryl detection: titration with Ellman's reagent (DTNB, 26), labeling with a dansyl fluorescent probe (**B**, Scheme 1), and labeling with a nitroxide spin label (**C**, Scheme 1). The population of variants labeled with **B** or **C** was then estimated by fluorescence spectroscopy or ESR spectroscopy against dansyl- and nitroxide-standard solutions, respectively. The results obtained by the different methods, including the dot-blot method, are compared in Table 2. It is generally seen that the four independent techniques agree well in determining the free sulfhydryl content of the TLL cysteine mutants, even though very low contents were measured in most cases. As indicated by the majority of the methods, only two of the 11 TLL variants contained any substantial fraction of free cysteine (10–15%), whereas the rest contained 5% or less. It is also noted that the dot-blot method appeared to overestimate the biotin content in two cases (P42C and T231C), but was otherwise in good agreement with the other methods.

Fig. 2. The dot-blot method performed on biotinylated TLL cysteine variants. Dots number 1–12 are standards (biotinylated BSA) with the following biotin concentrations: 730, 360, 180, 90, 45, 23, 11, 6, 3, 1.4, 0.7, and 0.4 nM. The biotinylated TLL variants are applied in triplicates vertically (protein concentrations in parenthesis) in the following order: A, D96C (340 nM); B, K74C (650 nM); C, T123C (290 nM); D, T267C (590 nM); E, I252C (500 nM); F, P42C (300 nM); G, T231C (250 nM); and H, R209C (180 nM). Positive control: biotinylated Rat-IgM. Negative control: I252C (not biotinylated).



On the other hand, Ellman's reagent underestimated the free sulfhydryl content in R209C.

Selective reduction of blocked TLL cysteine mutants

All methods indicated that the sulfhydryl groups of the TLL cysteine mutants were predominantly blocked from reaction. Electrospray MS revealed that this was due to oxidation by disulfide coupling to free cysteine (presumably during protein expression, ref. 15). It was, therefore, desirable to increase the yield of labeled proteins by prior reduction of the oxidized cysteine on the enzyme surface. Since the native protein contains three disulfide bridges, however, a procedure for selective reduction of the surface cysteine had to be elaborated. This was done in two steps:

(*i*) the limiting reduction conditions were analyzed on the wild-type enzyme by varying the concentration of reducing agent (DL–dithiothreitol, DTT). In addition, reduction on a column was tested (Reduce-Imm™ column, Pierce). The reactions were performed at pH 8.5 and 8.0, for reduction in solution and on the column, respectively. The effect of the reduction was assessed by Ellman's reagent, activity measurements, and dansyl labeling. Table 3 shows the results from the reduction experiments on the wild-type enzyme. As can be seen, non-invasive reduction conditions for TLL were found only as low as with 0.1 mM DTT. For any higher concentrations of DTT, the decrease in residual specific activity and the presence of free sulfhydryl groups suggest that disulfide bridges were reduced to some extent. This is also supported by the insertion of dansyl seen after reduction with higher DTT concentrations, and the further decrease of the already diminished activity after labeling. Reduction on the column afforded fractions with different quantities of

free sulfhydryl content as analyzed by Ellman's reagent. It seems peculiar that substantial dansyl insertion was seen also after reduction with 0.1, 0.5, and 1 mM DTT, which is contradicted by the findings with Ellman's reagent and the specific activity. The fluorescence noted may originate from hydrophobically attached dansyl reagent still present after purification. Interestingly, this was not observed with the unreduced wild-type control.

(*ii*) A systematic variation of several parameters, such as pH, DTT concentration, time of reduction, and inert reaction atmosphere was performed on the wild-type enzyme and a cysteine mutant (G61C) in parallel. Furthermore, efforts were made to remove all residual dansyl reagent after the reaction. The results from this second optimization are summarized in Table 4. The optimal reduction conditions were found where the dansyl insertion in G61C was as close to quantitative as possible, with minimal insertion into the wild-type enzyme. This was encountered at pH 7.7 with a DTT concentration of 0.3 mM and a reduction time of 30 min, affording a 36% yield of dansyl insertion for the mutant. Table 4 shows that the effect of increasing the pH by one unit approximately equaled a 10-fold increase in DTT concentration. Furthermore, increasing the reduction time apparently allowed the DTT to act on the disulfide bridges, which was seen for both the wild-type and the mutant enzymes. This implies a kinetic discrimination between the structural cysteines and the cysteine introduced at the protein surface. The most harsh reduction conditions attempted, at pH 8.5 with 10 mM DTT for 90 min, reduced all disulfide bridges as well as the blocked surface cysteine in the mutant, resulting in 7 dansyl groups incorporated per enzyme. Other variables, such as performing the reactions under an atmosphere of N_2 or adding the DTT to the dialysis buffer, were found to be of less importance. These optimized conditions for selective reduction and labeling allowed the production of various selectively and site-directed labeled TLL mutants containing different functional groups, with no or minimal (1–2%) insertion of label in the wild-type controls.

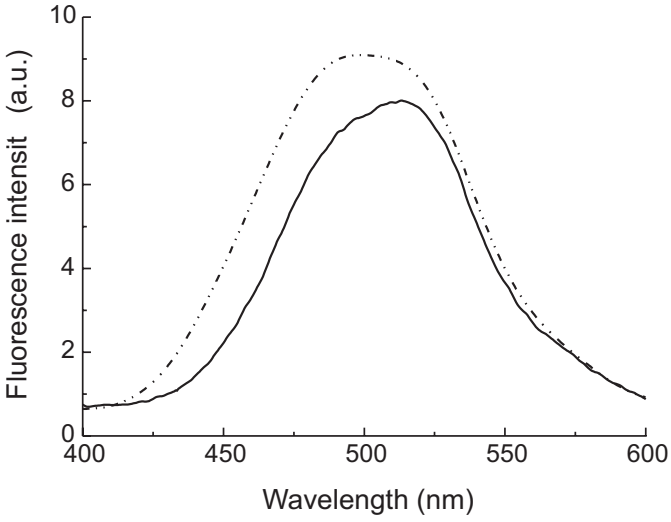
with the fluorescent reagent MTS–dansyl (**B**, Scheme 1). The dansyl labeling was performed on a few of the single-cysteine variants, and on the cysteine variants containing only one tryptophan (G61C-singleW and R209C-singleW). Interestingly, the latter mutants required milder reduction conditions, and the DTT concentration had to be reduced threefold. This is consistent with the lowered resistance to thermal denaturation observed for G61C-singleW and R209C-singleW, displaying a T_m of 62.1 and 60.3°C, respectively, compared with 75.0°C for the wild-type enzyme, at pH 7.0. This decrease in stability after removal of the three tryptophans has been previously reported in studies of thermal and chemical denaturation of similar TLL tryptophan variants without the cysteine mutation (27, 28). Generally, the yield of dansyl insertion (after reduction and labeling) for the mutants employed was around 30%, as determined by fluorescence spectroscopy. An accurate determination of the dansyl content was difficult to obtain, however, since the quantum yield for the attached dansyl is unknown and its extinction coefficient is quite low for detection through UV spectroscopy (approximately 4200 cm^{-1} M^{-1} in methanol, 29). Furthermore, it has been reported that the quantum yield of a fluorophore may decrease as much as 60% by covalent attachment to a protein (29) and, moreover, the local environment of the label position in each TLL mutant will differ, effecting further variations in the quantum yield. The fluorescence spectra of dansyl-labeled TLL K74C and G61C-singleW are shown in Fig. 3. The emission maxima were 518 and 498 nm for the two variants, respectively. This 20 nm blue shift in dansyl emisson for G61C-singleW, compared with K74C, is in good agreement with the relative positions of the cysteine mutation in the two variants. K74C is positioned on the turn of a hairpin loop, exposed to the aqueous surroundings, whereas G61C is proximal to a β-sheet quite close to the lid in TLL, and should be more restricted in the protein structure.

The dansyl-labeled TLL mutants were analyzed by SDS-PAGE and a Western blot, which was developed with antibodies directed against dansyl. A representative gel and

Fig. 3. Fluorescence emission spectra of dansyl-labeled *Thermomyces lanuginosa* lipase variants K74C (solid line) and G61C-singleW (broken line). The spectra were recorded with the excitation set at 340 nm. The protein concentrations were 15 and 20 μM (K74C and G61C-singleW, respectively) in 20 mM HEPES, pH 7.0.



Western blot are shown in Fig. 4, with the dansyl-labeled mutants G61C-singleW, R209C-singleW, and two controls from the labeling reaction. The controls were singleW (the tryptophan mutant without the cysteine mutation) and the wild-type enzyme. Each protein was prepared in both a reducing and a non-reducing loading buffer before application on the gel (panel A). As seen, the bands appear somewhat higher than 33 kDa. It is also seen that the non-reduced proteins have migrated slightly farther on the gel. Upon illumination of the gel with UV light (302 nm), only the labeled cysteine mutants loaded in the non-reducing buffer displayed dansyl fluorescence (panel B). A Western blot was performed (panel C), where the membrane was incubated

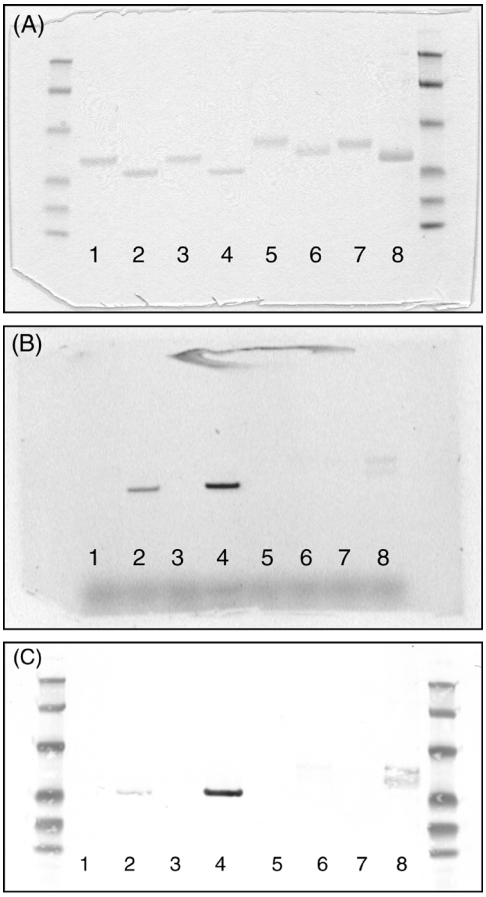
Fig. 4. SDS-PAGE and Western blot performed on dansyl-labeled *Thermomyces lanuginosa* lipase variants and wild-type (wt) enzyme showing the Coomassie-stained gel (panel A), fluorescent dansyl bands of the UV-illuminated gel (panel B), and the Western blot developed with anti-dansyl IgG (panel C). The dansyl-labeled proteins were loaded on the gel in the following order (prepared in reducing and non-reducing loading buffers, respectively): 1, G61C-singleW reduced; 2, G61C-singleW not reduced; 3, R209C-singleW reduced; 4, R209C-singleW not reduced; 5, singleW-control reduced; 6, singleW-control not reduced; 7, wt-control reduced; 8, wt-control not reduced. Molecular weight markers (from top): 112, 81, 49.9, 36.2, 29.9, and 21.3 kDa.



with antibodies directed against dansyl (anti-dansyl rabbit IgG) and with a secondary antibody-AP conjugate (anti-rabbit goat IgG-AP). The membrane was developed with BCIP–NBT, which afforded positive bands only for the non-reduced labeled cysteine mutants, consistent with the UV-illuminated gel. A weak signal was seen for the wild-type control in lane 8, however, which indicates that there was a slight unspecific insertion of dansyl in this control (but not in the singleW-control). Nevertheless, the lack of fluorescence in the UV-illuminated gel suggests that this dansyl content was insignificant. It is also seen in panel C that G61C-singleW only displayed a weak band on the blot, but was clearly fluorescent on the gel (panel B), indicating a steric restriction for the antibody in binding to the dansyl at position G61. The results from the SDS-PAGE and Western blot confirmed that the dansyl was covalently attached to the protein via a disulfide bond.

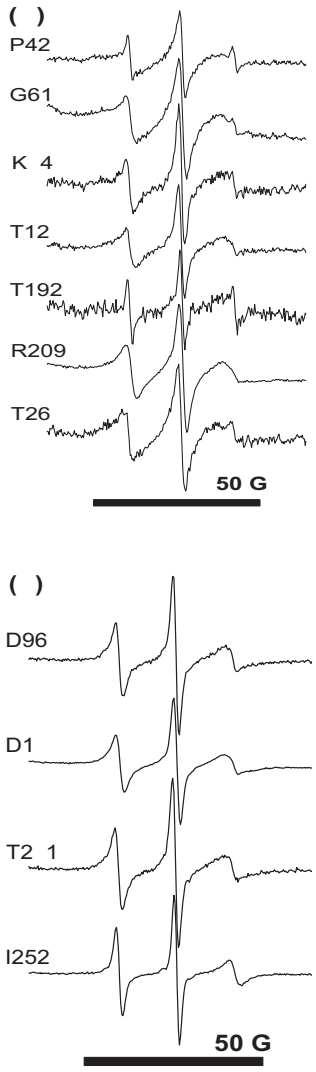
Spin-labeled TLL variants

Eleven TLL single-cysteine mutants were specifically reduced and labeled with the nitroxide spin-label reagent MTSL (**C**, Scheme 1). The degree of spin-label insertion was estimated by continuous wave (CW) ESR spectroscopy against nitroxide standard solutions. The yield of spin-label insertion varied between 10–100% for the different mutants. Table 5 shows the degree of spin-label incorporation, the residual specific activity after the labeling, and the secondary structure at the mutation site. As seen in Table 5, there was no severe effect of the spin labeling on the activity of the lipases, and in some instances there was even a slight increase of activity (I252C, T267C), which may be ascribed to the reduction of covalent dimers.[2] The variations in spin-label incorporation was consistent with the relative steric accessibility of the cysteines (30, 31) but did not correspond with the variations in the residual specific activity. First derivative CW ESR spectra for the spin-labeled mutants are presented in Fig. 5, where the spectral amplitude has been normalized by the central resonance line. The variants are arranged according to low and high spin-label insertion (panels A and B, respectively), where the high spin-label insertion provided a better signal-to-noise ratio. All spectra are distinctive for moderately immobilized nitroxides with rotational correlation times (τ_R) of approximately 1 ns (2, 4), which is equivalent with rapid internal motion of the nitroxide side chain, caused by unrestricted bond rotation when attached to the protein surface. It can be seen in the

[2] In addition to being oxidized by linkage to a free cysteine, a small content of covalent dimers was seen for some TLL cysteine mutants on SDS-PAGE.

© 2002 NRC Canada

Fig. 5. First derivative CW ESR spectra retrieved in the X-band at 9.75 GHz of site-specific spin-labeled *Thermomyces lanuginosa* lipase cysteine variants, grouped according to low spin-label insertion (panel A) and high spin-label insertion (panel B). The resonance amplitudes were normalized with respect to the central $m_{I=0}$ resonance line. The scale of the magnetic field is indicated by a bar and the identity of the variants is specified in the figure.



linewidth, however, that the spectra in panel A display more constrained nitroxide mobility, whereas the spectra in panel B reflect more rapid isotropic motion.[3] This is characteristic for spin-label side chains on the surface of α-helices or β-sheets (panel A), while the narrower line widths (panel B) are characteristic of spin-label side chains attached to highly flexible protein segments, such as hairpin loops (4). Altogether, this points toward a correlation between cysteine steric accessibility in the protein and the yield of spin-label insertion. In conclusion, the different lineshapes of the ESR spectra and the variable incorporation of spin label in each of the different TLL mutants were found to correlate well with the local structural features near the cysteine mutations.

Discussion

In the present study, 13 single-cysteine mutants of TLL were created that were fully functional and displayed specific hydrolytic activities comparable to that of the wild-type enzyme. This is consistent with previous work that has shown that single or multiple mutations on the surface of proteins do not perturb protein structure and function (3, 32, 33). Substitution of three tryptophans in the TLL variants G61C-singleW and R209C-singleW, however, caused a decrease in activity and resistance to thermal denaturation, in good agreement with previous studies on similar TLL mutants (27, 28).

It is recognized that cysteines introduced at surface-exposed parts of proteins are prone to oxidation, and furthermore, that for such proteins only a small fraction of unoxidized cysteines may exist (14, 15). Presumably, unwanted oxidation takes place during fermentation or purification (34, 35). When producing cysteine mutant proteins, it may be desirable to detect post-translational modifications of the cysteine at an early stage. Early detection could enable changes in fermentation conditions to be made, such as employing expression systems with reducing conditions (bacterial periplasmatic expression) or modulating the pH. Alternatively, one might choose to use the small fraction of free cysteines in the batch, if present in acceptable amounts. In the present paper, a dot-blot method for the quantitation of free protein-sulfhydryl groups was developed. This method has a picomole detection limit and should, therefore, be convenient to use as a diagnostic tool in the production of recombinant proteins. The method could present an alternative to using Ellman's reagent, which, although useful, requires substantial amounts of protein (1–3 mL, approximately 10 μM), where the detection limit is set by the extinction coefficient of the produced thiolate anion. The method could also be useful with glycosylated proteins, for which the oxidation state of the sulfhydryl groups is complex to detect and quantify by mass spectrometry due to the glycosylation patterns. The dot-blot method was found to be sensitive and accurate in protein sulfhydryl determination.

All TLL cysteine mutants created were found to be oxidized to a major extent. Through a careful optimization of the reduction conditions, however, it was shown that the oxidized surface cysteine could be selectively reduced, in varying degrees for the different mutants, without damaging any of the native disulfide bridges. It is unambiguous that creating cysteine mutants is more suitable with a protein that contains no disulfide bridges; however, this would severely limit the scope of proteins that can be studied.

Several of the selectively reduced TLL variants were labeled with a fluorescent probe (dansyl) or a spin label (a nitroxide). It was verified by SDS-PAGE and Western blot that the dansyl group was covalently attached to the protein via a disulfide bridge. In addition, it was shown that the reduction and labeling had little or no effect on the activity of the lipases. By means of the selective reduction, the spin labeling afforded insertion between 10–100%. The quantitative yield achieved for I252C suggests that the reduction conditions were optimized. Furthermore, the correlation found

[3] It should be noted that only qualitative information in the ESR spectra was used to draw conclusions on protein structure. A more detailed analysis of the lineshapes by simulation was not attempted in the present paper.

© 2002 NRC Canada

between spin-label insertion and ESR spectral linewidths suggested a dependency on cysteine steric availability for the yield of labeling, which has previously been seen (30, 31).

In conclusion, the development of a novel dot-blot method enabled the detection and quantitation of oxidized sulfhydryl groups in lipase cysteine mutants, with a high sensitivity. A process for selective reduction of the oxidized surface cysteine enabled the production of specifically labeled and functional proteins. The methods presented in this paper should prove useful in the production and modification of other related cysteine-mutant proteins.

Experimental

General

Unless stated otherwise, all chemical reagents (DTT, Ellman's reagent, BCIP–NBT, anti-rabbit goat IgG alkaline phosphatase conjugate, biotinylated BSA), organic solvents, and buffers were purchased from Sigma–Aldrich Sweden AB (Stockholm, Sweden). PD-10 desalting columns were purchased from Amersham Pharmacia Biotech (Uppsala, Sweden). Streptavidin-AP was purchased from Roche Diagnostics Scandinavia AB (Bromma, Sweden). The ReduceImm™ column and Slide-A-Lyzer® dialysis cassettes (10 kDa molecular weight cut-off) were purchased from Pierce (Boule Nordic AB, Stockholm, Sweden). MTSL, MTSEA–biotin, and MTS–dansyl were purchased from Toronto Research Chemicals Inc. (Ontario, Canada), and anti-dansyl rabbit IgG from Molecular Probes Europe BV (Leiden, The Netherlands).

Construction, fermentation, and purification of TLL lipase variants

All *Thermomyces lanuginosa* lipase variants were constructed by the USE method according to the manufacturer (Stratagene). The template was pAHL (WO lipase patent number EP 305.216), and the selection oligos were P-GAATGACTTGGTTGACGCGTCACCAGTCAC (changing the ScaI site into the MluI site in the Amp gene) and P-TCTAGCCCAGAATACTGGATCAAATC (changing the ScaI site in the lipase gene without changing the amino acids). The variants were sequenced across the whole gene, transformed into *Aspergillus oryzae* and fermented as reported previously (36). The fermentation supernatant was sterile-filtered using 0.22 μm EKS filters (Seitz-Schenk, Waldstetten, Germany), solid NaCl was added to a final concentration of 1 M, and the supernatant was filtered again using 0.45 μm Millipore filters (Millipore, Molsheim, France). The succeeding chromatographic steps were carried out using an ÄKTA explorer (Amersham Pharmacia Biotech). Hydrophobic interaction chromatography was performed using Decyl Agarose 6XL (Affinity Chromatography Ltd, Freeport, Isle of Man) packed in a XK50 column (Amersham Pharmacia Biotech). The column was equilibrated with a buffer consisting of 50 mM Tris-acetate and 1 M NaCl at pH 7.0, after which the supernatant was applied. Elution was made with ultrapure water (resistivity, $\rho \geq 18.2$ MΩ cm^{-1}). Fractions with high absorbance at 280 nm were pooled and assayed for lipase activity using the pH-stat method (described below). Pools displaying activity were diluted with ultrapure water to a final conductivity of <4 mSi and the pH was adjusted to 7.5. Anion-exchange chromatography was performed with Fast Flow Q-Sepharose (Amersham Pharmacia Biotech) packed in an XK50 column and equilibrated with 50 mM Tris-acetate, pH 7.5. The pools containing activity were applied on the column and eluted with a linear salt gradient using the 1 M NaCl Tris-buffer.

Characterization of TLL lipase variants

The purity of the produced TLL proteins was verified by SDS–PAGE. The protein concentration was determined from the absorbance at 280 nm using an extinction coefficient of 35 920 cm^{-1} M^{-1} (18 850 cm^{-1} M^{-1} for the tryptophan mutants) based on amino acid composition (37). The specific hydrolytic activity was measured by the pH-stat method on an emulsion of glyceryl tributanoate (a modification of the method described in ref. 16), where one lipase unit is defined as one μmol of released titratable acid per min. The assay was performed at pH 7.0 and 25°C on a sonicated (Branson Sonifier W-250; 10 W min^{-1} for 30 mL substrate) 16 mM emulsion of glyceryl tributanoate (0.5% w/v) in a 2% aqueous solution of gum arabicum and 0.2 M $CaCl_2$. Typically, 10 μL of enzyme (1 μM) was added to 1.5 mL stirred emulsion and the activity was monitored using an ABU91 Autoburette together with a TIM900 Titralab station and software TimTalk 9, v1.4 (Radiometer, Copenhagen, Denmark). The tryptophan–cysteine variants and wild-type enzyme were analyzed by differential scanning calorimetry (DSC) using a MicroCal (Tm) VP microcalorimeter (MicroCal, Northampton, MA, U.S.A.), using 1.3 mg mL^{-1} TLL in 50 mM HEPES–NaOH, pH 7.0. The scan rate was 90°C h^{-1}.

The dot-blot method

The TLL cysteine mutants (200 μL, 1.5–3 mg mL^{-1} in 100 mM Tris-HCl, pH 8.5) were incubated with MTSEA–biotin (**A**, Scheme 1, 25–50 μL, 5.5 mM in DMF) in Eppendorf tubes and rotated slowly end-over-end for 1 h. The reaction mixture was purified by dialysis against 20 mM HEPES–NaOH, pH 7.0 (three buffer exchanges) at 4°C. A nitrocellulose membrane (0.45 μm, Bio-Rad Laboratories AB, Sundbyberg, Sweden) was pre-wet in Tris-buffered saline (TBS; 20 mM Tris-HCl, 150 mM NaCl, pH 8.0) for 10 min and fitted onto a Bio-Dot® Microfiltration Apparatus (Bio-Rad) according to the manufacturer's instructions. A dilution series of biotinylated bovine serum albumin (BSA, approximately 9 mol of biotin per mol BSA) was prepared in TBS ranging from 0.04 to 73 μM biotin. All samples (standards, controls, or biotinylated TLL variants) were diluted (1:100) in TBS. The samples were loaded in the applicator, 100 μL per well, and applied to the membrane by gravitation (vacuum not used), after which the wells were washed several times with TBS. The membrane was dried, then treated with the blotting procedure, performed with gentle rocking at 30°C as follows: Blocking of membrane in a 2% solution of nonfat milk powder in TBS for 30 min, washing with 0.1% Tween 20 in TBS (3 × 5 min), incubation with the streptavidin–AP conjugate (diluted 1:20 000 in TBS–Tween) for 90 min, washing again, and lastly, development with BCIP–NBT (5-bromo-4-chloro-3-indolyl phosphate and nitro blue tetrazolium) prepared according to the

© 2002 NRC Canada

manufacturer (Sigma). The membrane was dried and scanned. The intensities of the dots were quantified against the standards by densiometric analysis, using the public domain NIH Image software (developed at the U.S. National Institutes of Health and available on the Internet at http://rsb.info.nih.gov/nih-image/). It should be mentioned that application by manual auto pipet was also performed with the dot-blot method (3 μL undiluted protein applied per dot), which afforded similar results in quantifying the biotinylated TLL variants (data not shown).

Selective reduction of oxidized TLL cysteine mutants

In the first optimization, reduction was performed for 60 min on the TLL wild-type enzyme (1.5–2 mg mL^{-1} in 100 mM Tris-NaOH, pH 8.5) by adding DTT from freshly prepared stocks (in the same buffer) of appropriate concentrations (250 μL stock solution added to 2.5 mL protein) to the gently stirred protein in a round bottom flask. The following final DTT concentrations were employed: 0.1, 0.5, 1, 10, 25, and 50 mM. The reaction was terminated by gel filtration on a PD-10 desalting column equilibrated with deoxygenated Tris buffer, and the proteins were further purified by dialysis against the same buffer (three buffer exchanges) under an atmosphere of nitrogen. Reduction with the Reduce-Imm™ column was performed with 10 mM DTT at pH 8.0 in a 20 mM sodium phosphate buffer containing 2 mM EDTA, according to the protocol (Pierce). Wild-type enzyme (1 mL, 5.6 mg mL^{-1}) was incubated on the column for 60 min after which ten 1-mL fractions were collected and analyzed without further purification. The reduced and purified (or eluted) proteins were assayed with Ellman's reagent (10 mM DTNB freshly prepared in the phosphate buffer) by adding 100 μL reagent to 1 mL protein solution (10 μM) and measuring the absorption at 412 nm using a Cary 50 Bio UV-vis spectrophotometer (Varian AB, Solna, Sweden) for 15–30 min. The concentration of free sulfhydryl groups was determined using an extinction coefficient of 14 150 cm^{-1} M^{-1} (at pH 8.0).

The second optimization of reduction conditions was performed on the wild-type enzyme and the variant G61C in parallel (1.0 mg protein per mL). DTT was added from a freshly prepared stock either to the protein solution (as described in the previous paragraph) or to the dialysis buffer, against which the protein was dialyzed. The reduction was performed either at pH 8.5 (in 100 mM Tris-NaOH), at pH 7.0 (in 20 mM HEPES–NaOH or 20 mM sodium acetate), or at pH 7.7 (in 50 mM Tris-acetate and 2 mM EDTA) for 30–100 min. The protein was purified by dialysis against Tris buffer, with or without an atmosphere of nitrogen.

Site-directed labeling of TLL variants with spectroscopic probes

Chemical labeling with the fluorescent probe MTS–dansyl and the nitroxide spin-label MTSL (**B** and **C**, Scheme 1, respectively) was performed with or without prior reduction of the TLL single-cysteine mutants. TLL wild-type or the mutant singleW were used as controls in all reactions. The labeling reagent was added to the protein (1–3 mg mL^{-1} in 100 mM Tris-NaOH, pH 8.5, or 50 mM Tris-acetate, 2 mM EDTA, pH 7.7); 45 or 15 molar equivalents, from a freshly prepared stock in ethanol or acetonitrile (for MTSL and MTS–dansyl, respectively). The final content of organic solvent in the sample was 1.5% (v/v). MTSL remained totally soluble under these conditions, while MTS–dansyl had the tendency to partially precipitate and was, therefore, spun down after the reaction. After 1 h the reaction mixture was subjected to gel filtration on a PD-10 column preequilibrated with 20 mM HEPES–NaOH, pH 7.0 and was further purified by extensive dialysis against the same buffer at 4°C. The entire reaction with MTS–dansyl was performed with minimal exposure to light.

The dansyl-labeled variants (1 μg per band, each sample prepared in reducing (containing 50 mM DTT) and nonreducing Novex LDS loading buffers) were analyzed by SDS-PAGE, using a Novex NuPAGE™ precast 4–12% Bis Tris gel (1.0 mm × 10 well) and a Novex MES running buffer, performed in a Novex XCell II™ Mini-Cell electrophoresis equipment (Labora Chemicon, Sollentuna, Sweden). Low-range prestained SDS-PAGE molecular-weight standards (Bio-Rad) were used. After separation at 200 V and 35 min, the gels were analyzed for fluorescence on a Gel Doc 2000 gel documentation system, illuminated with UV light at 302 nm and employing the Quantity One imaging software (Bio-Rad). The gels were then Coomassie stained (50% (v/v) methanol, 10% (v/v) acetic acid, and 0.1% (w/v) Coomassie Brilliant Blue R-250 in ultrapure water) or subjected to a Western blot. The proteins were transferred with a Trans-Blot SD semidry transfer cell (Bio-Rad) at 15 V for 15 min onto a nitrocellulose membrane (0.45 μM, Bio-Rad), using a Towbin transfer buffer (25 mM Tris, 19.2 mM glycine, 20% (v/v) methanol, pH 8.3). The immunoblot was performed at 30°C as follows: Blocking of the membrane with a 5% (w/v) solution of nonfat milk powder in TBS for 30 min, incubation with anti-dansyl rabbit IgG (12.5 μg mL^{-1} in TBS containing 5% milk, 0.1% (w/v) Tween 20, and 33 μg TLL wild type) for 90 min, washing of the membrane with 0.1% Tween 20 in TBS (3 × 5 min), incubation with anti-rabbit goat IgG-AP conjugate (diluted 1:20 000 in TBS containing 5% milk, 0.1% Tween 20 and 7 μg TLL wild type) for 90 min, washing (4 × 5 min), and development with BCIP–NBT.

Fluorescence spectroscopy

Fluorescence spectra were recorded on a PerkinElmer LS50B spectrofluorimeter at room temperature, using slit widths of 10 nm and a scan range of 500 nm min^{-1}. The tryptophan emission spectra were recorded with the excitation set at 280 nm, and the dansyl emission spectra were recorded with the excitation set at 340 nm. Protein concentrations were 1–20 μM (in 20 mM HEPES–NaOH, pH 7.0). The yield of dansyl incorporation for the TLL variants was quantified against dansyl standards in acetonitrile, and normalization by protein concentration. A Bradford assay (Pierce) was used for reconfirmation of the protein concentration of the dansyl-labeled variants.

ESR spectroscopy

The ESR spectra were recorded on a Bruker EMX EPR spectrometer with a 12 kW 10″ magnet in the X-band at 9.75 GHz, using a Bruker ER 4102 ST standard cavity and a microwave power up to 10 mW. The spectra were recorded at room temperature using 1 G, 100 kHz magnetic field

© 2002 NRC Canada

modulation for phase-sensitive detection, which ensures a well-defined signal. The line broadening due to overmodulation is less than 10% (38). All measurements were performed under critical coupling conditions and the spectra were recorded several times for improvement of signal-to-noise ratio. Quartz tubes (i.d. = 1 mm) were used and the sample size was 50 μL. The spin-label incorporation for the enzymes (15 μM in 20 mM HEPES–NaOH, pH 7.0) was determined by quantitation against nitroxide standard solutions and normalization by protein concentration.

Acknowledgments

This work was supported by the European Commission (contract number BIO4-CT972365). We thank Dr. Pernille Høyrup for helping us with the ESR measurements. Dr. Harry Brumer III is thanked for help in preparing the molecular graphics figure of *Thermomyces lanuginosa* lipase.

Chemo-enzymatic synthesis of trimeric sialyl Lewis^x pentadecasaccharide

Yeuk Chuen Liu, Hong Li, Albin Otter, Vivekanand P. Kamath, Markus B. Streiff, and Monica M. Palcic

Abstract: The enzymatic synthesis of trimeric sialyl Lewis^x pentadecasaccharide (**6**), a 15-mer, from a trimannoside precursor required six different glycosyltransferase enzymes and four nucleotide donor sugars. Three *N*-acetylglucosaminyl residues were transferred from UDP-*N*-acetylglucosamine to a trimannoside by *N*-acetylglucosaminyltransferases I, II, and V, respectively. Galactosylation using β(1→4) galactosyltransferase and UDP-galactose gave three *N*-acetyllactosamine units in nonasaccharide **4**. Sialylation of **4** with α(2→3) sialyltransferase and CMP-*N*-acetylneuraminic acid was followed by fucosylation with α(1→3) fucosyltransferase and GDP-fucose giving the 15-mer **6** in mg quantities. Compound **4** was also converted to a trimeric Lewis^x dodecasaccharide 12-mer with α(1→3) fucosyltransferase and GDP-fucose and to a trimeric α-2,6-sialyl *N*-acetyllactosamine dodecasaccharide 12-mer with α(2→6) sialyltransferase and CMP-*N*-acetylneuraminic acid.

Key words: glycosyltransferases, pentadecasaccharide, sialyl Lewis^x.

Résumé : La synthèse enzymatique du pentadécasaccharide trimère sialyl Lewis^x (**6**), un 15-mère, a été réalisée à partir d'un trimannoside en utilisant six glycosyltransférases différentes et quatre nucléotides comme donneurs de sucre. Trois résidus *N*-acétylglucosaminyles ont été transférés de la UDP-*N*-acétylglucosamine à un trimannoside par les *N*-acétylglucosaminyltransférases I, II et V respectivement. La galactosylation utilisant une β(1→4) galactotransférase et du UDP-galactose ont conduit à trois unités de *N*-acétyllactosamine dans le nonasaccharide **4**. Le sialylation de **4** à l'aide de la α(2→3) sialyltransférase et d'acide CMP-*N*-acétylneuraminique a été suivie d'une fucosylation à l'aide de la α(1→3) fucosyltransférase et de GDP-fucose conduisant à quelques milligrammes du 15-mère **6**. Le composé **4** a aussi été transformé en dodécasaccharide trimère 12-mère de Lewis^x à l'aide de la α(1→3) fucosyltransférase et de GDP-fucose et en un α-2,6-sialyl *N*-acétylactosamine dodécasaccharide trimère 12-mère à l'aide de α(2→6) sialyltransférase et d'acide CMP-*N*-acétylneuraminique.

Mots clés : galactotransférase, pentadécasaccharide, sialyl Lewis^x.

[Traduit par la Rédaction]

Introduction

Interest in the preparation of oligosaccharides and their analogs stems from demonstrations of their roles in diverse biological recognition events (1). Cell-surface oligosaccharides are attachment sites for the binding of bacteria, viruses, toxins, and hormones and they also are involved in cell–cell adhesion. Characteristic changes in complex carbohydrates also occur during cellular differentiation, development, and malignant transformation. Oligosaccharides are required not only for basic glycobiology research but also for developing leads to new therapeutics for the treatment of infectious diseases, inflammation, and cancer (2).

The chemical synthesis of oligosaccharides is well established. It is, however, a multistep endeavor requiring the preparation of selectively protected building blocks, their coupling and then deprotection to obtain the desired stereochemistry and regiochemistry in the final product (3). Biocatalytic approaches for oligosaccharide production are increasingly being used employing engineered cells or isolated enzymes, either glycosyltransferases or glycosidases (4). Glycosyltransferases catalyze the transfer of a monosaccharide from a donor (usually a nucleotide donor) to saccharide, protein, or lipid acceptors (5). These transfers are regiospecific and stereospecific thus eliminating the need for the protection and deprotection steps required in chemical synthesis.

The tetrasaccharide sialyl Lewis^x (α-Neu5Ac(2→3)β-Gal(1→4)[α-Fuc(1→3)]β-GlcNAc-) is an example of a biologically important oligosaccharide. It is found on the termini of glycoproteins where it binds to selectins, a class of calcium-dependent carbohydrate-binding proteins (6).

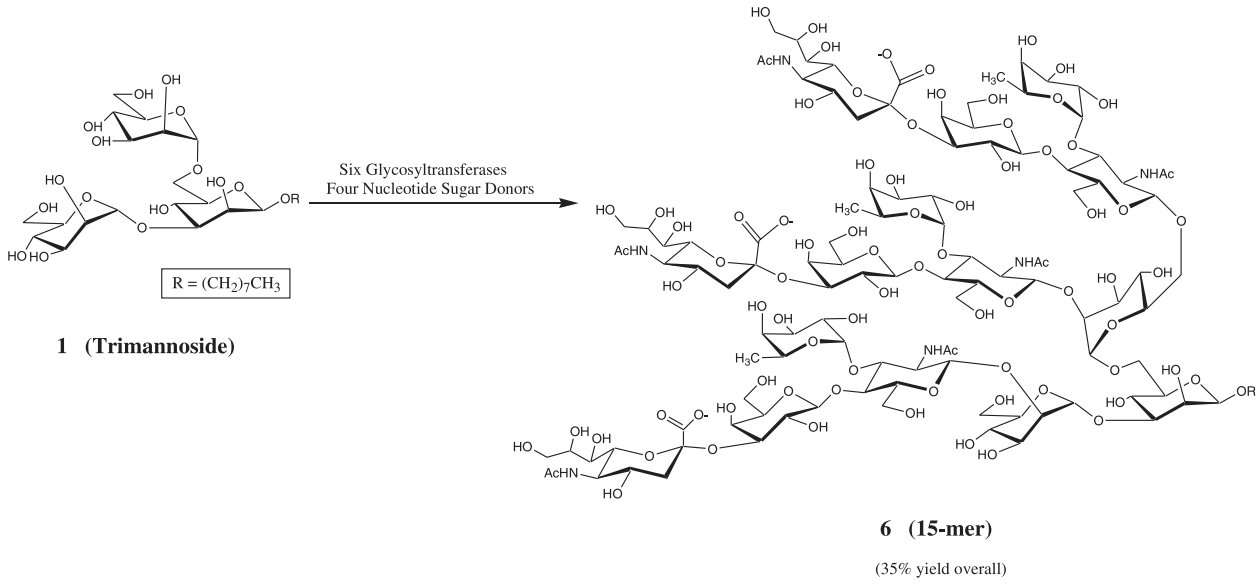
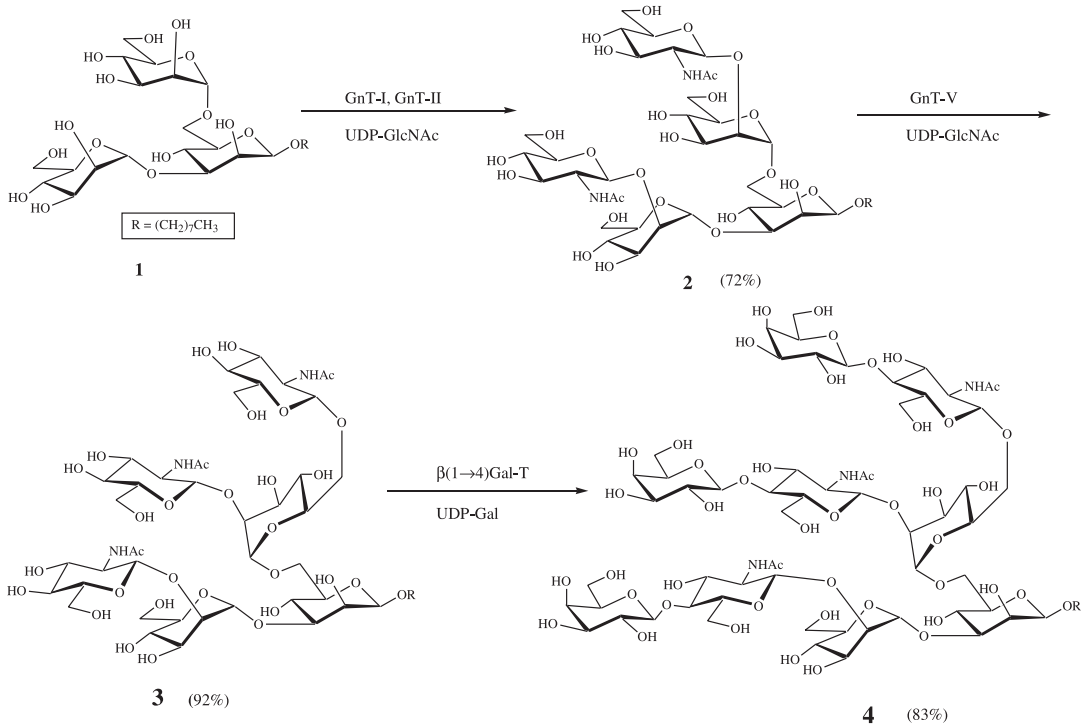
Scheme 1.



Scheme 2.



Selectins are found on vascular cell surfaces where they mediate leukocyte capture to endothelial cells, an early step in the inflammatory response. The use of sialyl Lewis^x to inhibit the interaction of E-selectin with it's physiological ligand represents a potential treatment for inflammatory disorders. Monovalent carbohydrate–protein interactions are, however, usually weak interactions with dissociation constants typically in the mM range. High affinity binding has been achieved by multivalent presentation of carbohydrate ligands including sialyl Lewis^x (6, 7). In this paper we report the chemo-enzymatic synthesis of a multivalent (trimeric) sialyl Lewis^x containing pentadecasaccharide (**6**) (Scheme 1) for use in probing selectins and other carbohydrate-binding proteins. This is a natural multivalent sequence found on asparagine-linked oligosaccharides in glycoproteins.

Results and discussion

The enzymatic synthesis of trimeric sialyl Le^x **6** from trimannoside **1** required six glycosyltransferase enzymes and four different nucleotide donor sugars (Schemes 2 and 3). Trimannoside **1** is easily prepared by chemical synthesis (8) and is the conserved core present on all *N*-linked oligosaccharides. In the natural structures, a chitobiose unit is present rather than the octyl group. The hydrophobic octyl moiety facilitates the isolation of reaction products by solid-phase

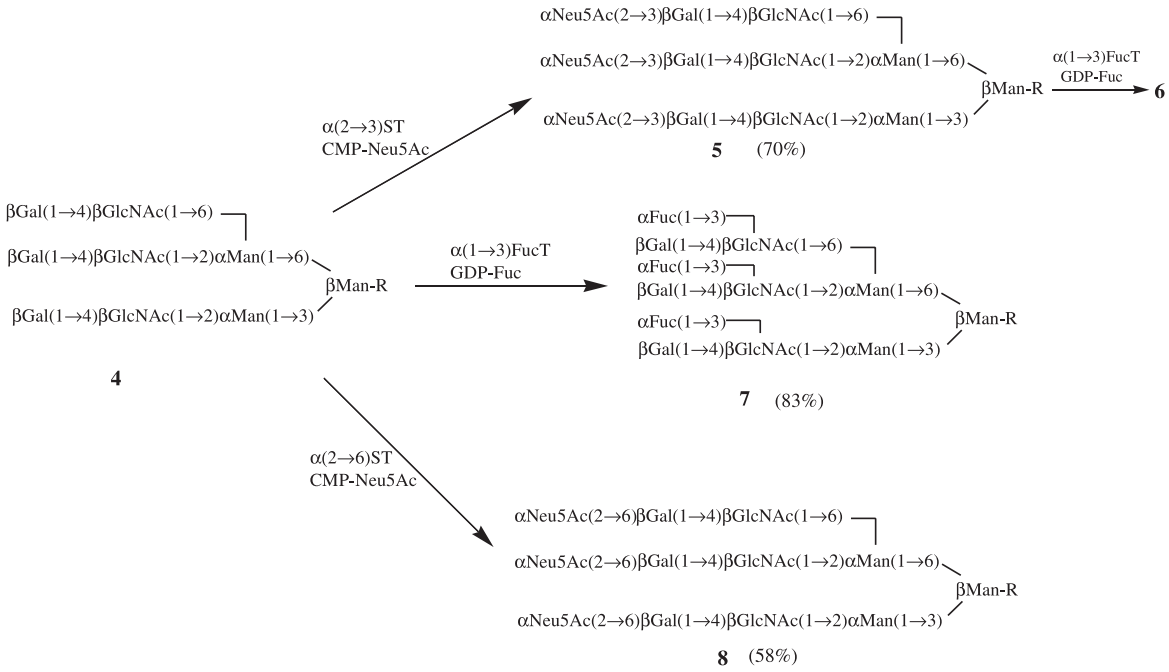
Scheme 3.



extraction on reverse-phase cartridges as well the monitoring of reaction progress by MALDI mass spectrometry (9).

Each of the *N*-acetylglucosamine residues is transferred from UDP-GlcNAc to a specific mannose by a different *N*-acetylglucosaminyltransferase enzyme. *N*-acetylglucosaminyltransferase I (GnT-1) first transfers GlcNAc to the α-1,3-Man branch, which is followed by *N*-acetylglucosaminyltransferase II (GnT-II) transfer to the α-1,6-Man arm (Scheme 2). While the isolated yield of the GnT-I and GnT-II product **2** was 70%, this yield is variable and will depend on the purity of the original trimannoside (8). Although the chemical synthesis of the trimannoside is straightforward, a mixture of trimannosides is produced, only one of which is a substrate for GnT-I enzyme. The conversion of the trimannoside **1** to pentasaccharide **2** was likely quantitative since unreacted starting material was not a substrate for either GnT-1 or GnT-II when re-assayed with these enzymes. Compound **3** was obtained in good yield after the *N*-acetylglucosaminyltransferase V (GnT-V) reaction.

Unlike the strict branch specificity of the *N*-acetylglucosaminyltransferases, galactosylation using β(1→4) galactosyltransferase (Gal-T) and UDP-Gal will give all three *N*-acetyllactosamine residues in nonasaccharide **4**. This is a key compound, because it can be employed not only for probing galactose and *N*-acetyllactosamine binding proteins such as galectins (10), but it can also be further elaborated to trimeric sialosides and fucosides.

Sialylation of **4** with recombinant rat liver α(2→3) sialyltransferase (ST) and CMP-Neu5Ac was followed by fucosylation with milk α(1→3) fucosyltransferase (Fuc-T) and GDP-Fuc giving mg quantities of the trimeric sialyl Lewis^x **6** (Scheme 3). Compound **6** was obtained in 35% yield after the six enzyme reactions starting from trimannoside **1**. The ^{1}H NMR spectrum of the final product is shown in Fig. 1, where the characteristic resonances for fucose (δ 1.17 and 4.83, methyl and H-5, respectively) and sialic acid (δ 1.80 and 2.77, for H-3$_{ax}$ and H-3$_{eq}$, respectively) are clearly seen. No peaks corresponding to partially glycosylated intermediates were observed in any of the electrospray mass spectra. This indicated essentially complete glycosylation as verified by the integration in the ^{1}H NMR spectra. Assignments for anomeric protons given in the experimental section are in agreement with literature values. Mammalian biosynthesis requires that sialylation precede fucosylation since **7**, the product of the fucosyltransferase reaction, is not a substrate for rat sialyltransferase. In addition to α-2,3-sialylLacNAc, compound **4** was also converted to Lewis^x **7** and to α-2,6-sialyl *N*-acetyllactosamine **8** (Scheme 3). These were produced on mg scale, which is sufficient material for use in glycobiology applications to inhibit sialosides on cellular receptors for influenza and other viruses (11).

In summary, the trimeric sialyl Lewis^x containing 15-mer **6** and its precursors were conveniently obtained in highly purified form because the glycosyltransferases employed are regiospecific and stereospecific. The hydrophobic octyl aglycon facilitated the purification processes by solid-phase extraction using reverse-phase cartridges. Since glycosyltransferase enzymes are becoming increasingly commercially available and more are being cloned and overexpressed, multistep syntheses such as those described here could easily be scaled up to the gram scale.

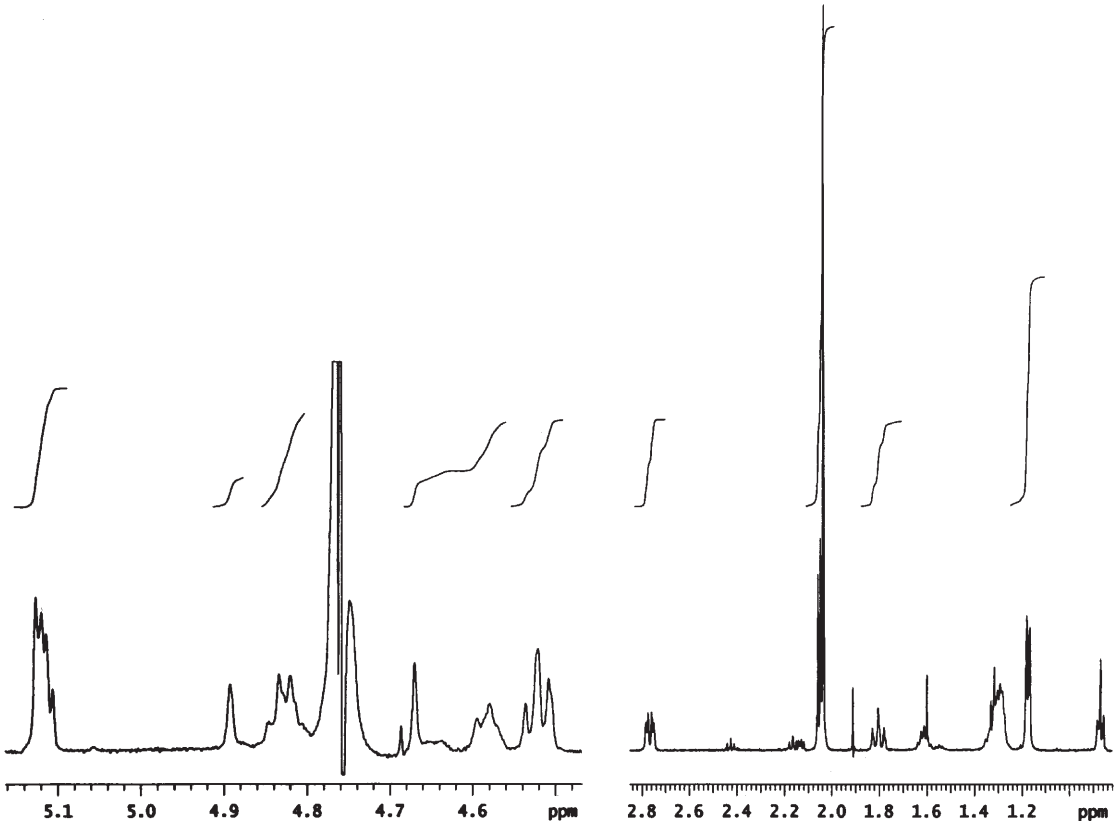
Experimental

General

Trimannoside **1** was chemically synthesized as previously reported (8). Uridine 5′-diphosphate-*N*-acetylglucosamine (UDP-GlcNAc, disodium salt) and cytidine 5′-monophosphate-*N*-acetylneuraminic acid (CMP-Neu5Ac, sodium salt) were from the Sigma Chemical Co. Sequencing-grade calf intestine alkaline phosphatase and UDP-galactose (UDP-Gal,

© 2002 NRC Canada

Fig. 1. The ^{1}H NMR spectrum (500 MHz, deuterium oxide) of sialyl Lewis^x 15-mer **6**.



dipotassium salt) were obtained from Boehringer-Mannheim, and guanosine 5′-diphosphate-fucose (GDP-Fuc, disodium salt) was from Calbiochem. A mixture of *N*-acetylglucosaminyltransferase I and II (GnT-I and GnT-II) was isolated from rabbit liver acetone powder (Sigma) by modification of literature procedures (12). Briefly, a 1% Triton X-100 extract of 150 g of the acetone powder was applied to a UDP-hexanolamine affinity column equilibrated with 50 mM sodium cacodylate buffer, pH 6.5, containing 10 mM $MnCl_2$ and 1% of Triton X-100. The column was washed with equilibration buffer until the column eluant contained background levels of protein. GnT-I and GnT-II were both eluted from the column with equilibration buffer containing 3 M NaCl. The following enzymes were isolated and assayed by previously reported methods: recombinant human *N*-acetylglucosaminyltransferase V (GnT-V) (13), bovine milk $\beta(1\rightarrow4)$ galactosyltransferase (9), recombinant rat liver $\alpha(2\rightarrow3)$ sialyltransferase (9, 14), rat liver $\alpha(2\rightarrow6)$ sialyltransferase (15), and human milk $\alpha(1\rightarrow3)$ fucosyltransferase (9, 14). A unit of enzyme activity is the amount that catalyzes the formation of 1 μmol of product per min. Millex GV filters (0.22 μm) and Sep-Pak Plus C_{18} cartridges were from Millipore. The cartridges were preconditioned immediately before use by washing with 20 mL HPLC-grade methanol and then 20 mL of Milli-Q water. Centriprep concentrators were obtained from Amicon. TLC was performed on silica gel 60-F254 (Merck, Darmstadt) with detection by charring with 5% phenol–H_2SO_4. Iatrobead, a beaded silica gel 6RS-8060 was obtained from Iatron Laboratories Tokyo. ^{1}H NMR spectra were recorded in D_2O with a Varian Unity 500 spectrometer at 500 MHz. Only partial NMR data are reported, the remaining data were in accordance with the proposed structures. Chemical shifts in ppm are relative to external acetone at 2.225 ppm. Due to the complex nature of the molecules, spectral overlap is common and therefore ranges for chemical shifts are given where appropriate. The fast atom bombardment mass spectra (FAB-MS) were recorded on a modified Kratos AEI MS-9 instrument using Cleland's matrix and electrospray (ESI-MS) on a Micromass ZabSpec hybrid Sector-TOF. A Kratos Kompact MALDI I was used to monitor enzyme reaction progress (9).

Synthesis of pentasaccharide 2

A mixture (30 mL) containing trimannoside **1** (50 mg, 81 μmol), UDP-GlcNAc (100 mg, 150 μmol), 27 mU GnT-I, 16 mU GnT-II, alkaline phosphatase (40 U), 50 mM sodium cacodylate buffer, pH 6.5, 1% Triton X-100, and 10 mM $MnCl_2$ was incubated for ten days at rt. UDP-GlcNAc (35 mg, 54 μmol) was added daily for six days. Additional enzyme (5 mU of GnT-I and 4 mU of GnT-II) was added after six days. The reaction mixture was filtered through a Millex filter and divided into four portions, each of which was applied to two Sep-Pak C_{18} cartridges in tandem. The cartridges were washed with Milli-Q water (100 mL) and then the product was eluted with HPLC grade MeOH (35 mL). The combined methanol eluants were evaporated to dryness under reduced pressure. The residue was dissolved in CH_2Cl_2–MeOH (9:1), applied to an Iatrobead column (15 g), and eluted with CH_2Cl_2–MeOH (9:1) to remove Triton X-100 detergent. Product eluted with CH_2Cl_2–MeOH–H_2O (65:35:6), the fractions containing product were

© 2002 NRC Canada

combined and evaporated to dryness. The residue was dissolved in Milli-Q H_2O, filtered through a Millex filter, and the filtrate was lyophilized to dryness giving **2** as a white powder (60 mg, 72% yield). ^{1}H NMR δ: 5.13 (br s, Manα1,3-H1), 4.92 (br s, Manα1,6-H1), 4.67 (s, Manβ-H1), 4.58 (d, *J* = 8.6 Hz, GlcNAcα1,3-H1)[a], 4.56 (d, *J* = 8.2 Hz, GlcNAcα1,6-H1)[a]. [a]The two GlcNAc resonances might be interchanged. FAB-MS calcd. *m/z* for $[M + Na]^+$ $C_{42}H_{74}N_2O_{26}Na$: 1045.4; found: 1045.2.

Synthesis of hexasaccharide 3

A mixture containing pentasaccharide (**2**, 25 mg, 24 μmol), UDP-GlcNAc (16 mg, 25 μmol), GnT-V (10 mU), alkaline phosphatase (20 U), and *N*-acetyl glucosamine (10 mg) in 25 mL of 50 mM sodium cacodylate buffer, pH 7.0, was incubated at 37°C for 3 days. Additional UDP-GlcNAc (16 mg) was added after 24 and 48 h. The reaction mixture was filtered through a Millex filter, divided into four portions, and each portion was applied to three Sep-Pak C_{18} cartridges in tandem for isolation as described for the preparation of **2**. The residue was further purified by Iatrobead column chromatography (6 g) using CH_2Cl_2–MeOH (7:3) for column loading and CH_2Cl_2–MeOH–H_2O (40:40:8) for product elution. The fractions containing product were evaporated to dryness, dissolved in water, filtered, and lyophilized giving **3** as a white powder (27 mg, 92% yield). ^{1}H NMR δ: 5.14 (br s, Manα1,3-H1), 4.88 (br s, Manα1,6-H1), 4.68 (s, Manβ-H1), 4.60 (d, *J* = 8.5 Hz, GlcNAcα1,3-H1)[a], 4.56 (d, *J* = 8.5Hz, GlcNAcα1,6-H1)[a], 4.50 (d, *J* = 8.1 Hz, GlcNAcα1,6-H1′). [a]The three GlcNAc resonances might be interchanged. FAB-MS calcd. *m/z* for $[M + Na]^+$ $C_{50}H_{87}N_3O_{31}Na$: 1248.5; found: 1248.3.

Synthesis of nonasaccharide 4

A mixture containing hexasaccharide (**3**, 12 mg, 9.8 μmol), UDP-Gal (20 mg, 31 μmol), β(1→4) galactosyltransferase (2 U), alkaline phosphatase (30 U) in 3 mL of 20 mM sodium cacodylate buffer, pH 7.1, and 20 mM $MnCl_2$ was incubated at rt for 25 h. Additional UDP-Gal (10 mg) was added after 18 h. The reaction mixture was divided into five portions, each of which was applied to three Sep-Pak C_{18} cartridges in tandem for isolation as described for **2**. The residue was dissolved in H_2O, filtered through a Millex filter, and the filtrate was lyophilized to dryness. Compound **4** was obtained as white powder (14 mg, 83% yield). ^{1}H NMR δ: 5.14 (d, *J* = 1.4 Hz, Manα1,3-H1), 4.89 (d, *J* = 1.2 Hz, Manβ-H1), 4.68 (s, Manβ-H1), 4.62 (d, *J* = 8.2 Hz, GlcNAcα1,3-H1), 4.58 (d, *J* = 8.0 Hz, 2 GlcNAcα1,6-H1), 4.48 (d, *J* = 7.8 Hz, 1 Gal-H1), 4.47 (d, *J* = 7.8 Hz, 2 Gal-H1), 4.19 (Manα1,3-H2)[b], 4.15–4.12 (Manα1,6-H2[b] and Manβ-H2), 3.92 (Manα1,3-H3), 3.83 (Manα1,6-H3), 3.75 (Manβ-H3), 2.06–2.04 (s, 3 NAc-CH3). [b]The typical dd (ca. 3.4 and 1.8 Hz) coupling pattern for Man-H2 is visible but precise values cannot be measured due to spectral overlap. FAB-MS calcd. *m/z* for $[M + Na]^+$ $C_{68}H_{117}N_3O_{46}Na$: 1734.7; found: 1734.9.

Synthesis of dodecasaccharide 5

A mixture containing nonasaccharide (**4**, 10.0 mg, 5.8 μmol), CMP-Neu5Ac (11 mg, 17 μmol), α(2→3) sialyltransferase (120 mU), alkaline phosphatase (20 U) in 1 mL of 50 mM sodium cacodylate buffer, pH 6.5, and 20 mM $MnCl_2$ was incubated at 37°C for 3 days. Additional CMP-Neu5Ac was added — 12 mg after 20 h and 6 mg at 38 and 58 h. α(2→3) Sialyltransferase (45 mU) was added after 58 h. The reaction mixture was filtered through a Centriprep concentrator (30 000 D cut-off), divided into five portions, each of which was applied to three Sep-Pak C_{18} cartridges in tandem. The cartridges were washed with water (60 mL) and then the product was eluted in 50% MeOH–H_2O (60 mL). The combined MeOH fractions were evaporated to dryness, the residue was dissolved in H_2O, filtered through a Millex filter, and the filtrate was lyophilized. Compound **5** was obtained as a white powder (10.5 mg, 70% yield). ^{1}H NMR δ: 5.14 (br s, Manα1,3-H1), 4.91 (br s, Man α1,6-H1), 4.69 (s, Manβ-H1), 4.64–4.54 (3 GlcNAc-H1 and 3 Gal-H1), 2.76 (dd, *J* = 12.5 and 4.5 Hz, 3 NeuNAc-H3eq), 1.81 (t, *J* = 12.5 Hz, 3 NeuAc-H3ax). ESI-MS *m/z* calcd. for $[M + 2Na]^+$ $C_{101}H_{166}N_6O_{70}Na_2$: 2628.9; found: 2629.1.

Synthesis of pentadecasaccharide 6

A mixture containing dodecasaccharide (**5**, 5.5 mg, 2.1 μmol), GDP-Fuc (3.7 mg, 5.7 μmol), α(1→3) fucosyltransferase (80 mU), and alkaline phosphatase (20 U) in 50 mM sodium cacodylate buffer (5 mM $MnCl_2$, 25% glycerol, pH 6.5, 1 mL) was incubated at rt for 30 h. Additional GDP-Fuc was added after 10 h (3.8 mg) and 20 h (1.6 mg). The reaction mixture was filtered through a Centriprep concentrator (30 000 D cut-off), the filtrate was diluted with water to 1% glycerol, and divided into five portions, each of which was applied to three tandem Sep-Pak C_{18} cartridges for isolation as described for the preparation of **5**. Compound **6** was obtained as a white powder (5.6 mg, 90% yield). ^{1}H NMR δ: 5.14–5.10 (3 Fuc-H1 and 1 Manα1,3-H1), 4.90 (br s, Manα1,6-H1), 4.85–4.80 (br q, 3 Fuc H-5), 4.67 (s, Manβ-H1), 4.66–4.56 (3 GlcNAc-H1), 4.54–4.50 (3 Gal-H1), 2.77 (dd, *J* = 12.5 and 4.5 Hz, 3 NeuNAc-H3eq), 2.07–2.02 (s, 6 NAc-CH3), 1.80 (t, *J* = 12.5 Hz, 3 NeuNAc-H3ax), 1.17 (d, *J* = 6.5 Hz, 3 Fuc-H6). ESI-MS *m/z* calcd. for $[M + 2Na]^+$ $C_{119}H_{196}N_6O_{82}Na_2$: 3067.1; found: 3066.9.

Synthesis of dodecasaccharide 7

A reaction mixture containing nonasaccharide (**4**, 2 mg, 1.2 μmol), GDP-Fuc (1.8 mg, 2.8 μmol), α(1→3) fucosyltransferase (40 mU), and alkaline phosphatase (20 U) in 50 mM sodium cacodylate buffer (5 mM $MnCl_2$, 25% glycerol, pH 6.5, 1.2 mL) was gently stirred at rt for 30 h. Additional GDP-Fuc was added after 8 h (1.8 mg) and 20 h (1 mg). The reaction mixture was filtered through a Centriprep concentrator (30 000 D cut-off), the filtrate was diluted with Milli-Q water to 1% glycerol, divided into three portions, each of which were applied to three Sep-Pak C_{18} cartridges in tandem for isolation as described for the preparation of **5**. Compound **7** was obtained as a white powder (2.2 mg, 83% yield). ^{1}H NMR δ: 5.16–5.12 (3 Fuc-H1 and 1 Manα1,3-H1), 4.88 (br s, Manα1,6-H1), 4.87–4.83 (br q, 3 Fuc-H5), 4.68 (s, Manβ-H1), 4.60–4.56 (3 GlcNAc-H1), 4.47–4.42 (3 Gal-H1), 1.18 (d, *J* = 6.5 Hz, 3 Fuc-H6). ESI-MS *m/z* calcd. for $[M + Na]^+$ $C_{86}H_{147}N_3O_{58}Na$: 2172.9; found: 2173.1.

Synthesis of dodecasaccharide 8

A reaction mixture containing nonasaccharide (**4**, 2.0 mg, 1.2 μmol), CMP-Neu5Ac (2.3 mg, 3.6 μmol), α(2→6)

Biomimetic reactions in organic synthesis: Semi-pinacol rearrangements of some spirocyclic epoxyalcohols derived from Juliá–Colonna asymmetric epoxidations

Bernhard Hauer, Jamie F. Bickley, Julien Massue, Paula C. A. Pena, Stanley M. Roberts, and John Skidmore

Abstract: Epoxy *tert*-alcohols have been prepared from (*E*)-enones in a two-step approach consisting of Juliá–Colonna asymmetric epoxidation followed by Grignard alkylation of the epoxyketone. On treatment with sub-stoichiometric amounts of $Yb(OTf)_3$ these *trans*-epoxyalcohols underwent efficient stereoselective semi-pinacol rearrangement to afford *anti*-α-phenyl-β-hydroxy-ketones (aldols). Under the same conditions, spirocyclic epoxyalcohols derived from 1-tetralone and 1-benzosuberone undergo either ring contraction (via semi-pinacol rearrangement) or fragmentation. A mechanistic rationale is presented to explain the formation of the various products.

Key words: Juliá–Colonna reaction, asymmetric epoxidation, epoxy *tert*-alcohols, semi-pinacol rearrangement.

Résumé : Faisant appel à l'approche en deux étapes de Juliá–Colonna impliquant une époxydation asymétrique suivie d'une alkylation de Grignard de l'époxycétone, on a préparé des époxy *tert*-alcools à partir de (*E*)-énones. Le traitement de ces *trans*-époxyalcools avec des quantités sous-stoechiométriques d'$Yb(OTf)_3$ provoque un réarrangement semi-pinacolique stéréosélectif et efficace qui conduit aux *anti*-α-phényl-β-hydroxycétones (aldols). Dans les mêmes conditions, les époxyalcools spirocycliques obtenus à partir de la 1-tétralone et de la 1-benzosubérone donnent lieu soit à une contraction de cycle (par le biais d'un réarrangement semi-pinacolique) ou à une fragmentation. On propose un mécanisme qui permet de rationaliser la formation des divers produits.

Mots clés : réaction de Juliá–Colonna, époxydation asymétrique, époxy *tert*-alcools, réarrangement semi-pinacolique.

Introduction

Epoxides are among the most widely used functional groups in modern synthetic chemistry. This reflects the existence of numerous reliable, highly enantioselective methods for epoxidation, and the wealth of chemistry that epoxides can undergo, allowing a wide range of compounds to be prepared in an efficient and stereoselective manner (1). Amongst the reactions of epoxides, rearrangements have been widely used as key steps in the synthesis of biologically active targets and natural products. Several different modes of epoxide rearrangement have been identified (2); in substrates where the epoxide is flanked by an alcohol, or a silyl-protected alcohol, treatment with a suitable Lewis acid can lead to a semi-pinacol rearrangement (3), in which 1,2-migration of one of the alcohol substituents opens the epoxide, generating an α-substituted-β-hydroxyketone (aldol) in a stereoselective manner. Various Lewis acids have been used, in stoichiometric quantities, to facilitate this rearrangement, including $TiC1_4$ (4), $BF_3{\cdot}OEt_2$ (3, 5, 6), $Ti(i\text{-}PrO)_2C1_2$ (5), $Ti(i\text{-}PrO)_3C1$ (7), and $SnC1_4$ (8). Until recently, catalytic variants of this rearrangement required a silyl-protected epoxyalcohol, using either TMSI or TMSOTf as the Lewis acid (9). Our recent report (10) and that of Tu et al. (11) have shown, however, that rare-earth triflates and $ZnBr_2$ are capable of catalyzing semi-pinacol rearrangements of unprotected epoxyalcohols.

Some of the epoxy *tert*-alcohol substrates used in semi-pinacol rearrangements may be prepared in enantiomerically enriched form by a five-step Sharpless AE–oxidation–alkylation–oxidation–alkylation strategy (4, 5). An alternative approach to prepare such substrates is the use of a polyleucine-catalyzed asymmetric epoxidation of an enone (Juliá–Colonna epoxidation) (12–14) followed by a

diastereoselective Grignard alkylation of the resultant epoxyketone (15, 16). This method entails conversion of achiral enones **1** into optically active epoxides **2**, which are transformed with high stereoselectivity into enantiomerically enriched diastereomerically pure epoxyalcohols **3**. We have shown that such epoxyalcohols are efficiently rearranged to afford aldols **4** in reactions catalyzed by rare-earth triflates (Scheme 1) (10).

Recent work has extended the Juliá–Colonna epoxidation to cyclic enones possessing an exocyclic olefin unit; thus epoxidation of ketones **5** using urea–H_2O_2 and DBU in the presence of poly-L-leucine affords spirocyclic epoxides **6** in 63–85% yield and 59–94% ee (Scheme 2) (17).

It was anticipated that alkylation of spirocyclic epoxyketones **6** would afford epoxy alcohols **7** (step b) in which the aromatic ring is the group with the highest migratory aptitude in a semi-pinacol rearrangement unless stereochemical constraints become dominant. Thus, treatment of 1,2,3,4-tetrahydronaphthalene epoxyalcohols (**7**, *n* = 1) with rare-earth triflates was expected to result in ring contraction to afford indans (**8**, *n* = 1) bearing a quaternary chiral center (step c); such systems are not readily accessible, in enantiomerically enriched form, using conventional methodology. We report herein the outcome of Lewis acid catalyzed rearrangements of compounds of type **7**.

Results

E-3,4-Dihydro-2-propylidene-2*H*-naphthalen-1-one (**5a**) was converted into the epoxide **6a** in 75% yield and 85% ee employing silica-supported poly-L-leucine as the catalyst with urea–H_2O_2 (UHP) as the oxidant and sub-stoichiometric quantities of BEMP as the base (Scheme 3). Using similar reaction conditions,indanone epoxide **6b** was prepared from enone **5b** with good stereoselectivity (74% yield, 81% ee), whilst the epoxidation of alkylidene–benzosuberone **5c** under these conditions proved to be very slow and to generate racemic product **6c** (62% yield). This result contrasts with our previously reported asymmetric epoxidation of **5c** (under different conditions), which generated the product in 74% yield and 59% ee. The synthesis of epoxide **6d** (76% yield and 84% ee) was reported previously, employing poly-L-leucine as the catalyst, UHP as the oxidant in isopropyl acetate containing DBU (17). The alternative use of sub-stoichiometric quantities of BEMP as the base and silica-supported poly-L-leucine as the catalyst led to a quantitative yield of **6d** having the same optical purity.

Epoxyketones **6a**–**d** were alkylated with methylmagnesium bromide to afford the epoxyalcohols **7a**–**d**, respectively; compounds **6a** and **6d** were also reacted with phenylmagnesium bromide to afford the tertiary alcohols **7e** and **7f** (Scheme 4 and Table 1).

All the ketones gave the appropriate product as a single diastereoisomer. The operation of a Cram-chelate mode of

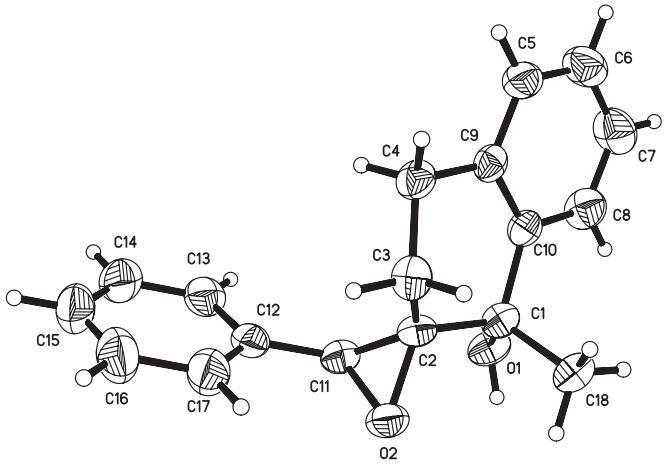
addition (16) was confirmed by X-ray analysis of the epoxyalcohol **7d** (Fig. 1).[2]

To effect the desired semi-pinacol rearrangement, tertiary alcohol **7a** was treated with Yb $(OTf)_3$ (20 mol %) in dichloromethane for 1 h. The formation of the expected methyl ketone **8a** (Scheme 5) was supported by NMR spectroscopy (three-proton singlet at δ 2.03 inter alia) and by a strong signal at 1693 cm^{-1} in the IR spectrum. Under the same reaction conditions, indan-epoxide **7b** gave a complex mixture, whereas treatment of the benzosuberan-epoxide **7c** with $Yb(OTf)_3$ gave the ring-contracted product **8c** in 60% yield.

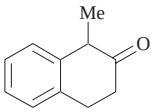
Similarly, treatment of **7e** with $Yb(OTf)_3$ (20 mol %) in dichloromethane, followed by purification of the crude product by chromatography over silica gel led to the isolation of a rearranged product. The structure of the isolated product **8e** (58% yield) was initially suggested by IR spectroscopy (λ_{max} = 1661 cm^{-1}), corroborated by NMR spectroscopy, and firmly established by X-ray crystallography (Fig. 2). As expected, the epoxide ring opening had occurred with inversion of configuration.

Treatment of alcohol **7f** with $Yb(OTf)_3$ (20 mol %) gave a mixture of products from which the indan-1-yl phenyl ketone (**9**) was isolated in 63% yield (Scheme 6). Ketone **9** is most probably formed by retroaldol fragmentation of the initially formed ring-contracted product **8f**. To try to provide proof for this hypothesis, the reaction was repeated but quenched after a much shorter period of time. Purification of the crude material led to the isolation of a major product — the ^1H NMR spectrum of which was closely analogous to those of the ring-contracted products **8a** and **8e**. FAB mass spectrometry displayed a molecular-ion peak corresponding to compound **8f**. This material was unstable (decomposing readily but cleanly to ketone **9** and benzaldehyde), which prevented more extensive characterization. With this additional evidence, however, it seems highly likely that the well-precedented semi-pinacol rearrangement forms during the first part of the reaction.

Fig. 1. X-ray crystal structure of compound **7d**.



Surprisingly, epoxyalcohol **7d** did not produce ring-contracted material, but instead, formed two major products, 1-methyl-2-tetralone (**10**) (40% yield) and benzaldehyde, which were identified by ^1H NMR and by comparison with authentic materials (10).



10

Discussion

Indans **8a** and **8e** are clearly formed by the expected ring-contraction process, whilst the fragmentation product **9** is assumed to be generated from indan **8f**. The fact that indan-epoxide **7b** fails to undergo ring contraction is presumably due to a high-energy transition state caused by ring strain. The key stereoelectronic requirement for the semi-pinacol rearrangement is that the migrating group should be anti-periplanar to the breaking C–O bond. Note that compound **7e** undergoes ring contraction rather than phenyl migration. Although no crystal structure data are available for **7e**, inspection of the X-ray crystal structure of the analogous methyl substituted epoxyalcohol **7d** (Fig. 1) suggests an origin for the selectivity. Thus whilst the dihedral angle between the epoxide C–O and the methyl group C–C [O(2)-

Scheme 6. Reagents and conditions: (*i*) $Yb(OTf)_3$, CH_2Cl_2, room temp.

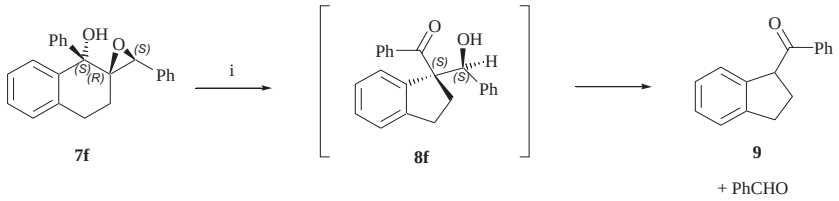

Fig. 2. X-ray crystal structure of compound **8e**.

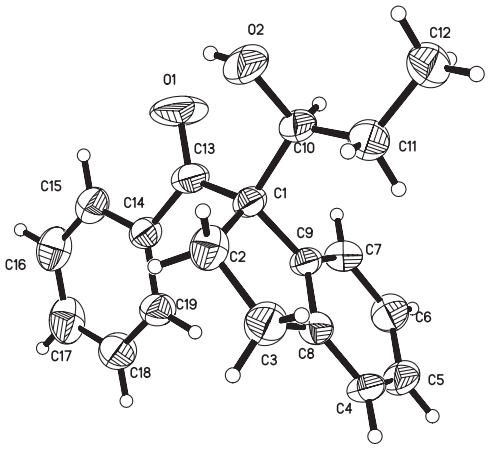

C(2)-C(1)-C(18)] is 61.0°, the dihedral angle between the epoxide C–O and the migrant C–C [O(2)-C(2)-C(1)-C(10)] is 178.45°, i.e., anti-periplanar. The required alignment of the migrating C–C with the C–O s^* of the epoxide dictates the outcome of these semi-pinacol rearrangements.

The mechanism by which 1-methyl-2-tetralone (**10**) is formed from epoxyalcohol **7d** is less clear; two possibilities are outlined in Scheme 7. Coordination of the $Yb(OTf)_3$ to the epoxide moiety should assist ring opening to reveal benzylic carbocation **11** (Scheme 7, path a). It is possible that this cation can rearrange via oxetane **12** to generate tertiary benzylic carbocation **13**. This would readily undergo a fragmentation reaction to generate benzaldehyde and the enolate (**14**) of 1-methyl-2-tetralone. An alternative approach to benzylic carbocation **13** is via a Lewis acid-catalyzed Payne rearrangement generating epoxyalcohol **15** followed by epoxide opening (Scheme 7, path b).

Work is in progress to try to distinguish between these two possibilities and the outcome of these experiments will be reported in a full paper.

Conclusions

Application of Juliá–Colonna asymmetric epoxidation followed by Grignard alkylation has been used to prepare epoxyalcohols in enantiomerically enriched form, both from acyclic enones and from cycloalkanones bearing exocyclic olefin units. The spirocyclic epoxyalcohols prepared from the latter substrates undergo either ring contraction or fragmentation processes, depending on the substituents present and the size of the ring. $Yb(OTf)_3$ has been shown to be an excellent catalyst for epoxyalcohol semi-pinacol rearrangements.

Discriminating between dispersion and lyoprotection effects in biocatalysis in organic media

Francesco Secundo, Giacomo Carrea, and Francesco Maria Veronese

Abstract: The increment of activity and solubility in 1,4-dioxane of lipase B from *Candida antarctica*, lipase from *Pseudomonas cepacia*, and subtilisin, were investigated as a function of the methoxypoly(ethylene glycol)–protein (PEG–protein) ratio employed during lyophilization. Both activity and solubility markedly increased as the PEG–protein ratio was increased. The increment of activity at low PEG–protein ratios, however, was much higher than that of solubility. These data suggest that the PEG-induced activation effect is due mainly to a lyoprotection effect rather than to relaxation of diffusional limitations.

Key words: hydrolases, activity, dispersion, lyoprotection, circular dichroism.

Résumé : On a étudié l'augmentation de l'activité et de la solubilité de la lipase B de la *Candida antartica*, de la lipase de *pseudomonas cepacia* et de la subtilisine dans le 1,4-dioxane en fonction du rapport méthoxypoly(éthylèneglycol)/protéine (PEG/protéine) utilisé lors de la lyophilisation. L'activité ainsi que la solubilité augmentent toutes les deux de façon remarquable avec une augmentation du rapport PEG/protéine. Toutefois, l'augmentation de l'activité à des rapports PEG/protéine faibles est beaucoup plus grande que celle de la solubilité. Ces données suggèrent que l'effet d'activation induite par le PEG résulte principalement d'un effet de lypoprotection que d'une relaxation des limitations diffusionnelles.

Mots clés : hydrolases, activité, dispersion, lyoprotection, dichroïsme circulaire.

[Traduit par la Rédaction]

Introduction

Biocatalysis in non-aqueous media has been widely studied and employed, as shown by its numerous applications in the areas of synthesis, food, and even analysis (1–3). Although this methodology has numerous advantages, its main drawback is the lower catalytic efficiency of enzymes in organic solvents than in aqueous solutions. This phenomenon can be ascribed to different causes, including restricted protein flexibility, low stabilization of the transition state of the enzyme–substrate intermediate, partial-enzyme denaturation by lyophilization, non-optimal acid–base conditions in the surrounding of the enzyme molecule, or poor catalyst dispersion (4). Several methods, such as the dispersion of the biocatalyst by immobilization on solid supports (5–9), the use of lyoprotectants (10, 11) or protein dissolution in the organic media by ion-pair forming surfactants (12), amphipatic lipids (13), or poly(ethylene glycol) (PEG) (14), were employed to increase enzymatic activity.

Although PEG was found to markedly improve the enzymatic activity of some hydrolytic enzymes in organic solvents, it has not been determined if the activation is due to lyoprotection or to biocatalyst dispersion–dissolution (15, 16). Here, we try to shed light on this issue by correlating the increment of activity and solubility of two lipases and subtilisin, in 1,4-dioxane, at different PEG–protein ratios.

Experimental

Materials

Lipase B from *Candida antarctica* (CALB) was purified, as reported by Secundo et al. (16), from a crude preparation (experimental product SP 525) kindly provided by Novo Nordisk. Lipase from *Pseudomonas cepacia* (lipase PC) was purified, as reported by Secundo et al. (15), from a commercial crude preparation of lipase PS (Amano). Subtilisin and PEG (MW 5000) were purchased from Sigma and 1,4-dioxane of spectrophotometric grade from Aldrich. All other reagents and compounds were of analytical grade.

Preparation of enzyme samples

Purified CALB (0.2 mg) and lipase PC (0.2 mg) were dissolved in potassium phosphate buffer (1 mL, 5 mM, pH 7), divided into 20-μg portions, and added to PEG (0.05–5 mg) dissolved in water (0.4 mL) (PEG–protein ratio (w/w) 2.5–250); final volume 0.5 mL. Subtilisin (3 mg) was

 DOI: 10.1139/V02-026 © 2002 NRC Canada

dissolved in potassium phosphate buffer (1 mL, 5 mM, pH 7), divided into 0.3-mg portions, and added to PEG (2.5–125 mg) dissolved in water (0.4 mL) (PEG–protein ratio (w/w) 8–417); final volume 0.5 mL. The samples were then frozen and lyophilized. Each sample was prepared in double to allow for the measurement of activity and to record the circular dichroism spectrum. Control samples were analogously prepared, but without PEG. The protein content was determined by Biorad Protein Assay.

Circular dichroism spectra

Far-UV circular dichroism (CD) spectra were recorded with a Jasco 500 A spectropolarimeter over the range of 200–250 nm for the sample dissolved in water and 210–250 nm for the samples dissolved in dioxane. (Below 210 nm, the high absorbance of dioxane causes a low signal-to-noise ratio that prevents the measurements.) All spectra were recorded at 25°C. The optical path was 0.5 cm in the case of lipases and 0.1 cm in the case of subtilisin. The PEG–enzyme samples were added to 1 mL of 1,4-dioxane (or water), vigorously shaken, and immediately used for CD analysis. All spectra were baseline corrected.

Measurements of catalytic activity

The transesterification between 1-octanol and vinyl acetate to give 1-octyl acetate and acetaldehyde was used as model reaction for the three enzymes considered. In all cases, 1 mL of 1,4-dioxane containing 1-octanol (0.19 M) and vinyl acetate (1.1 M) was added to the different enzyme samples. All the reagents, enzyme samples, and 1,4-dioxane were equilibrated against molecular sieves ($a_w < 0.1$) before being used. The reaction mixtures were shaken at 200 rpm and 25°C. At scheduled times, aliquots were withdrawn from the reaction mixtures and the conversion determined by GLC. (HP-1 Crosslinked Methyl Silicone Gum, 25 m, 0.32 mm ID, Hewlett-Packard; conditions: oven temperature from 35°C (initial time 10 min) to 160°C with a heating rate of 15°C min^{-1}, H_2 as carrier gas.) The retention times for vinyl acetate, acetic acid, 1-octanol, and 1-octyl acetate were 1.8, 2.2, 11.5, and 13.0 min, respectively. Using these reaction conditions, the catalytic activity for CALB, lipase PC, and subtilisin was, respectively, 2.20, 0.16, and 0.028 μmol min^{-1} for the samples without PEG, whereas it was 6.75, 0.68, and 0.098 μmol min^{-1} for the samples at the highest PEG–protein ratio tested (250 for lipases and 417 for subtilisin).

The possibility that PEG could affect the enzymatic activity by competing as a nucleophile with octanol seems very unlikely because, as shown in Fig. 2, the activity increased as a function of PEG concentration or, when the plateau value was reached, remained constant.

Results and discussion

Figure 1 shows that CALB, at a PEG–protein ratio higher than 125 (w/w), is fully solubilized in 1,4-dioxane, as shown by the almost complete overlap between the spectra recorded in the organic solvent and in water. In addition, the similarity between the spectra outside the range typical for a protein, in our case from 350 to 250 nm (data not shown), should rule out the presence of scattering phenomena usually caused by sizeable aggregates or very fine protein dispersions (17). Moreover, it is worth noting that the enzyme only showed a CD signal in dioxane when it was previously lyophilized from an aqueous solution containing PEG. When the enzyme was suspended in dioxane, it did not give a CD signal in the 210–350 nm range, even when PEG was subsequently added (up to 5 mg mL^{-1}) to the protein suspension. This result, which is in agreement with previous observations on other proteins (14), demonstrates that CALB is soluble in 1,4-dioxane and its secondary structure is the same as in water. On the other hand, the spectra obtained for CALB at PEG–protein ratios lower than 125 showed a proportionally lower signal, which can be attributed to a decrease in the solubility of the protein (14). Analogous behavior was observed for lipase PC and subtilisin (spectra not shown).

Fig. 1. Circular dichroism spectra, in water and 1,4-dioxane, of CALB colyophilized with PEG. PEG–protein ratio of 250 for the spectrum recorded in water (*g*) and 2.5 (*a*); 5 (*b*); 25 (*c*); 50 (*d*); 125 (*e*); and 250 (*f*) for those recorded in 1,4-dioxane.

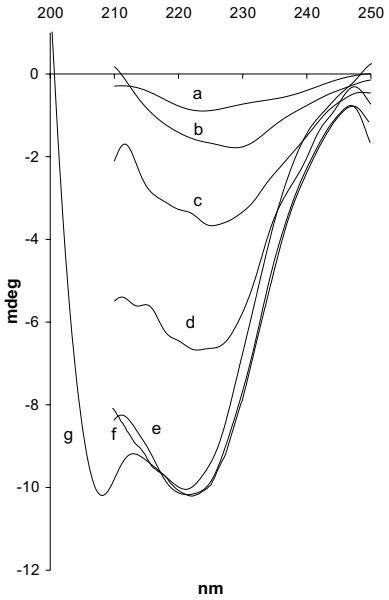

Figure 2 compares the increment of activity and solubility of the three enzymes as a function of the PEG–protein ratio. From zero to the highest ratio tested, not only did the activity increase 3.1-, 4.3-, and 3.5-fold for CALB (*a*); lipase PC (*b*); and subtilisin (*c*), respectively, but the enzymes were also fully solubilized. Nevertheless, it is evident that for all the enzymes the initial increment of activity was much steeper than that of solubility. Table 1 reports the increments of activity and solubility for CALB, lipase PC, and subtilisin at low PEG–protein ratios. It can be seen that the increment of activity was for all the enzymes much higher than the increment of solubility. For example, passing from 0 to a PEG–protein ratio of 2.5 for the lipases or 8 for protease, the increment of activity was 4.4-, 7.1-, and 4.1-fold higher than that of solubility for CALB, lipase PC, and subtilisin, respectively.

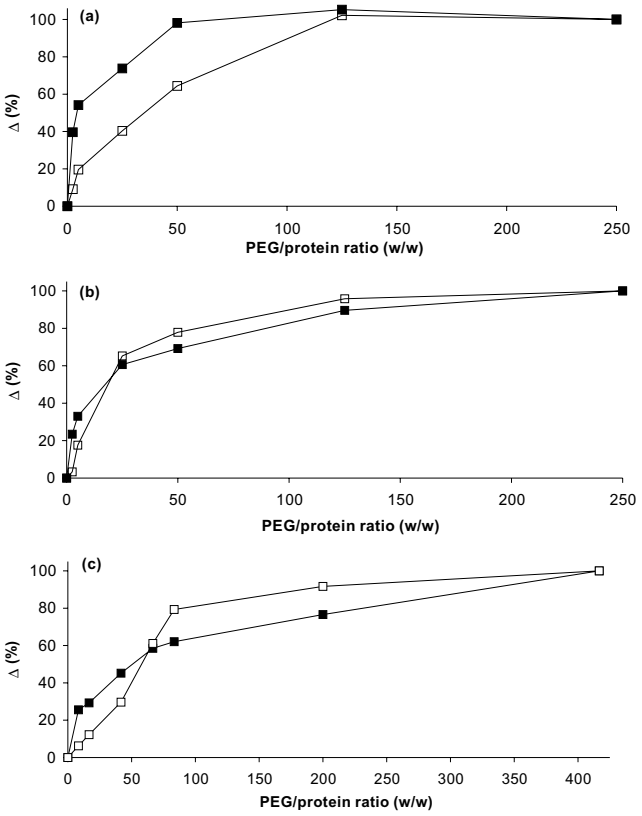
These data prove that the activating effect of PEG is not directly correlated to enzyme solubility. As a consequence, the activity increase should be due to a lyoprotective effect

© 2002 NRC Canada

Fig. 2. Increment of activity (■) and solubility (□) of CALB (*a*); lipase PC (*b*); and subtilisin (*c*) as a function of the PEG–protein ratio. The increment value (Δ) for activity and solubility is defined as $\Delta = (x - x_o)/(x_{max} - x_o)$, where x is the initial reaction rate or, for solubility, the CD signal at 220 nm obtained at a given PEG–protein ratio; x_o and x_{max} are the values obtained in the absence of PEG and at the highest PEG–protein ratio tested, respectively. For solubility, x_o was considered 0. (There was no CD signal for all the enzymes tested.) Each point was the average of three measurements.



of PEG on the secondary structure of the enzyme (18, 19), rather than to the relaxation of diffusional limitations obtained through the solubilization of the enzyme in the organic medium. It is worth pointing out that the data reported here are in agreement with our previous findings (16), which, through the method proposed by Wescott and Klibanov (20) and Bedell et al. (21) (a method that correlates the catalytic activity with the relative percentage of active and chemically inactivated enzyme present in a given amount of enzyme protein), proved that the activating effect of PEG on CALB is not due to the relaxation of diffusional limitations. Furthermore, we have previously found that different formulations of lipase from *Pseudomonas cepacia* (crude powder, Celite adsorbed, or PEG modified) have very similar K_M values (22). This result also suggests the absence of diffusion limitations. Concerning this point, however, it should be emphasized that a recent study by Rees and Halling (23) demonstrated that both of these approaches (K_M determination and use of mixtures of active and inactivated enzyme) were unable to explain the severe "solid-phase" mass-transfer limitations that occur in lyophilized enzymes in organic media. In conclusion, the present work indicates that the lyoprotectant effect of PEG plays a major role in improving biocatalyst performance in organic solvents. Furthermore, the comparison of the effects produced by different concentrations of a given additive on the activity and solubility of an enzyme in organic solvents appears to be a simple and general approach to distinguish between the lyoprotective and dispersive action of the additive itself.

Table 1. Increments of activity and solubility for CALB, lipase PC, and subtilisin at low PEG–protein values.

Enzyme	PEG–protein ratio	Increment of activity (%)[a]	Increment of solubility (%)[a]
CALB	2.5	39.6	9.1
CALB	5	54.2	19.6
Lipase PC	2.5	23.5	3.3
Lipase PC	5	33.0	17.6
Subtilisin	8	25.6	6.3
Subtilisin	17	29.3	12.3

Towards an unprotected self-activating glycosyl donor system: Bromobutyl glycosides

Benjamin G. Davis, Steven D. Wood, and Michael A.T. Maughan

Abstract: Bromobutyl mannopyranosides have been successfully used as both protected and unprotected glycosyl donors both with and without the use of an external activator.

Key words: glycosylation, unprotected glycosyl donors, oligosaccharides.

Résumé : On a utilisé avec succès des mannopyranosides de bromobutyle comme donneurs, tant protégés que non protégés, de glycosyles et avec ou sans l'aide d'activateur externe.

Mots clés : glycosylation, donneurs de glycosyles non protégés, oligosaccharides.

[Traduit par la Rédaction]

Oligosaccharides and glycoconjugates are essential tools for the investigation of the enormous variety of biological functions that require specific carbohydrate-containing structures (1). Furthermore, their potential as therapeutic agents is clear (2). As a result, the formation of the glycosidic linkage continues to be a dominant theme in carbohydrate chemistry (3). Yet despite the development of many elegant strategies, there is still no generally efficient and stereoselective method available. To this end, a number of glycosyl-donor systems have been developed, but few chemical systems allow the use of unprotected glycosyl donors; one exception has been Hanessian's 3-methoxypyridyl (MOP) glycoside system (4). It has been estimated that, on average, the need for protecting groups introduces an additional six steps to each overall glycoside bond formation. If the use of protecting groups could, therefore, be avoided or limited, while maintaining control of reactivity, then overall efficiencies may be improved. To this end, and as part of an ongoing programme to develop novel glycosylation systems and strategies (5), we have begun to investigate a new class of glycosyl donors: 4-bromobutyl glycosides. This communication describes our first results in this area.

Our goal was to create a glycosylation system that (*i*) uses sufficiently stable donors to allow preparation in unprotected form but that can still be activated; and (*ii*) may self-activate or activate under mild conditions. We reasoned that spontaneous 5-*exo* cyclization (Scheme 1) through nucleophilic attack of the C-1 oxygen atom in **1**, for example, would yield an anomeric furanosyl cation, which would closely resemble those postulated as intermediates in the activation of Fraser-Reid's powerful pentenyl glycoside class of glycosyl donors. (6) This would not only yield THF as a volatile, non-nucleophilic leaving group, but such a cyclization would also be favoured over any potentially competing cyclic ether formation with the free hydroxyls of the unprotected donor through, for example, 8-*exo* cyclization of OH-2 onto the primary bromide of the aglycon.

Clearly, the use of activation conditions that are compatible with the presence of free hydroxyl groups is essential to the use of unprotected glycosyl donors. We chose to investigate two potential activation conditions: self-activation and soft Lewis acid activation (e.g., Hal^+, Ag^+).

Our first target donor, mannoside **1**, was prepared as shown in Scheme 2. Penta-*O*-acetyl-D-mannose **6** was synthesized in quantitative yield using well-established methods from D-mannose and acetic anhydride with pyridine as a catalyst. Our strategy for creating **1** relied on the different hard and soft Lewis basicities of the anomeric *O*-1 and the aglycon primary bromide of bromobutyl glycosides, respectively (Scheme 1). Formation of 4-bromobutyl tetra-*O*-acetyl-α-D-mannopyranoside **2** was accomplished through a glycosidation using pentaacetate **6** and 4-bromobutanol, in which the hard Lewis acid $BF_3{\cdot}Et_2O$ catalysed the loss of the acetate group from the anomeric position of **6** without affecting the soft Lewis base aglycon primary bromide or indeed without activating **2** as a glycosyl donor through the mechanism envisaged in Scheme 1. In this regard, an additional aiding factor is that because of the disarmed (7) nature of **2,** this should be less reactive than the target unprotected donor **1**. 4-Bromobutanol was readily prepared through the

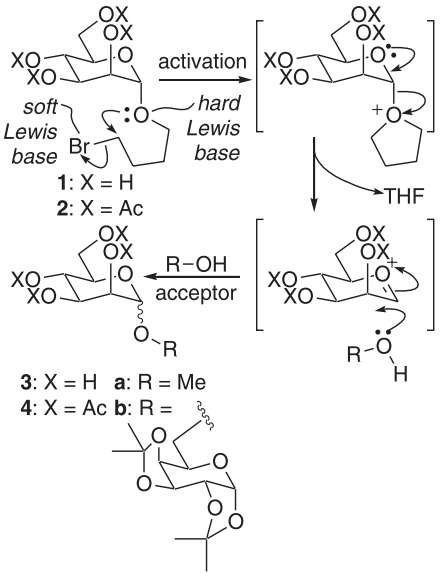
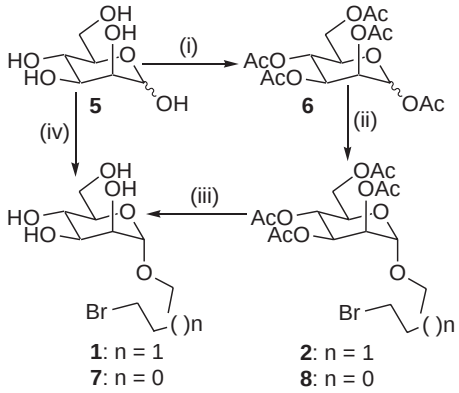
Scheme 1.



reaction of THF with 48% HBr (aq.) (8), which was preferred for large-scale work over the use of Me_2BBr (9). More than five equivalents of $BF_3{\cdot}Et_2O$ were required for effective conversion of **6** to the α-anomer **2**[3] (the sole product); the exclusive stereoselectivity for this *trans*-glycoside may be attributed to neighbouring group participation by the C-2 acetate group. While higher conversions were obtained through the use of a large excess of 4-bromobutanol, the 43% yield of **2** obtained through the use of 1.1 equivalents represents an efficient 83% yield when based on recovered starting material and was, therefore, the preferred procedure for scale-up. The use of higher equivalents of Lewis acid or increased reaction times led to no significant change in the yield of **2**.

The final step in the formation of fully deprotected donor 4-bromobutyl tetra-*O*-acetyl-α-D-mannopyranoside **1**[4] was carried out in a single efficient (87% yield) Zemplén deacetylation. Small amounts of methyl glycoside **1** (7% yield) were also recovered, encouragingly suggesting that through its action as a glycosyl donor, substitution of the anomeric 4-bromobutoxy group by MeOH had occurred at some point during the deprotection process. Since methyl glycosides are not products of the deprotection of mannosides (for example, the corresponding 3-bromopropyl mannoside (vide infra)), the formation of these methanolysis products under conditions not typically associated with lability of the glycosidic bond gave us our first indication of the successful action of 4-bromobutyl glycosides as glycosyl donors. As a consequence of this methanolysis, care was required during deacetylation of **2**. As might be anticipated, removal of the disarming effect of the acetyl groups meant that **1** would potentially prove more reactive as a glycosyl donor than **2** and that, similarly, each of the intervening partially deacetylated intermediates would prove even more reactive than the previous. After extensive screening, the use of a ~0.017 M methoxide solution freshly prepared from anhydrous MeOH and reaction times of 18 h proved optimal; shorter reactions times led to incomplete deprotection, whereas extended reaction times led to significant accumula-

Scheme 2. Reagents and conditions: (*i*) Ac_2O, py (3:2), 100%; (*ii*) $Br(CH_2)_{3+n}OH$, DCM, $BF_3{\cdot}Et_2O$, 43% for **2**, 39% for **8**; (*iii*) MeONa, MeOH, 87% for **1**, 98% for **7**; (*iv*) $Br(CH_2)_{3+n}OH$, $BF_3{\cdot}Et_2O$, 18% for **1**, 25% for **7**.



[3] **2**: $BF_3{\cdot}Et_2O$ (6.00 g, 42.3 mmol, 5.5 equiv.) was added dropwise to a solution of **6** (3.00g, 7.69 mmol) and 4-bromobutanol (1.30 g, 8.47 mmol, 1.1 equiv.) in dry DCM (20 mL) at 0°C under N_2. After 1.5 h, the reaction solution was warmed to room temperature and stirred for a further 16.5 h, when TLC (EtOAc–hexane, 50:50) showed conversion of starting material (R_f = 0.5) to a major product (R_f = 0.65). The reaction mixture was poured into ice water (10 mL) and extracted with DCM (3 × 20 mL). The organic extracts were combined, washed with water (15 mL), dried ($MgSO_4$), filtered, and the solvent removed. The residue was purified by flash chromatography (EtOAc–hexane, 40:60) to give recovered bromobutanol, starting material **6** and product **2** (1.61 g, 43% yield, 83% based on recovered starting material) as a white solid; mp 61–62°C. $[\alpha]_D^{22}$ = + 46.4 (*c*, 0.34 in $CHCl_3$). IR (cm^{-1}): 1747 (C=O). ^1H NMR (300 MHz, $CDCl_3$) δ: 1.78 (m, 2H, $OCH_2CH_2CH_2CH_2Br$), 1.88 (m, 2H, $OCH_2CH_2CH_2CH_2Br$), 2.00, 2.05, 2.11, 2.16 (4s, 4 × 3H, 4 × Ac), 3.46 (m, 2H, CH_2Br), 3.72 (m, 2H, $OCH_2CH_2CH_2CH_2Br$), 3.96 (ddd, *J* = 10, 6, 3 Hz, 1H, H-5), 4.14 (dd, *J* = 12, 3 Hz, 1H, H-6), 4.29 (dd, *J* = 12, 6 Hz, 1H, H-6′), 4.81 (d, *J* = 2 Hz, 1H, H-1), 5.23–5.33 (m, 3H, H-2, H-3, H-4). ^{13}C NMR (300 MHz, $CDCl_3$) δ: 20.7, 20.7, 20.8, 20.9 (4 × CH_3CO-), 27.9, 29.3 ($OCH_2CH_2CH_2CH_2Br$), 33.3 (CH2Br), 62.5, 66.1, 67.4, 68.6, 69.0, 69.6 ($OCH_2CH_2CH_2CH_2Br$, C-2, C-3, C-4, C-5, C-6), 97.6 (C-1), 169.8, 170.2, 170.3, 170.6 (4 × CH_3CO-). ES-MS *m*/*z* (MeOH): 505, 507 ($M+Na^+$). ES-HRMS calcd. for $C_{18}H_{31}BrNO_{10}$: 500.1131; found: 500.1131 ($[M + NH_4]^+$).

[4] **1**: A freshly prepared solution of NaOMe–MeOH (3 mL, 0.1 M) was added to a solution of **2** (1.00 g, 2.07 mmol) in dry methanol (15 mL) at room temperature under nitrogen. After 18 h, TLC (ethyl acetate–hexane, 50:50) showed the conversion of **2** (R_f = 0.65) to **1** (R_f = 0.05). The mixture was run through a Dowex 50W (H^+) plug (1 × 4 cm, eluant MeOH) and the solvent removed. The residue was purified by flash chromatography (15% MeOH–$CHCl_3$) to yield **1** (0.57 g, 1.82 mmol, 87%); mp 104–105°C. $[\alpha]_D^{22}$ = + 36.0 (*c*, 0.2 in MeOH). ^1H (250 MHz, CD_3OD) δ: 1.78 (m, 2H, $OCH_2CH_2CH_2CH_2Br$), 1.98 (m, 2H, $OCH_2CH_2CH_2CH_2Br$), 3.50 (m, 2H, CH_2Br), 3.70 (m, 2H, $OCH_2CH_2CH_2CH_2Br$), 3.60–3.90 (m, 5H, H-2, H-3, H-4, H-5, H-6), 3.96 (dd, *J* = 12, 3 Hz, 1H, H-6′), 4.78 (d, *J* = 2 Hz, 1H, H-1). ^{13}C (250 MHz, CD_3OD) δ: 30.0, 31.9 ($OCH_2CH_2CH_2CH_2Br$), 35.1 (CH_2Br), 63.8, 68.5, 69.5, 73.1, 73.5, 75.6 ($OCH_2CH_2CH_2CH_2Br$, C-2, C-3, C-4, C-5, C-6), 102.4 (C-1). ES-MS *m*/*z* (MeOH): 337, 339 ($[M + Na]^+$, 100%). ES-HRMS calcd. for $C_{10}H_{23}BrNO_6$: 332.0709; found: 332.0716 ($[M + NH_4]^+$). Anal. calcd. for $C_{10}H_{19}BrO_6$: C 38.11, H 6.08; found: C 37.95, H 6.04.

tion of methyl mannoside products. The anomeric mixture of glycosides formed (the formation of some methyl β-D-mannopyranoside suggests that there was a lack of neighbouring group participation and therefore the lack of a C-2 acetate) and the disarming effect (7) of the acyl groups in **2**, likely means that methanolysis occurred when the donor was fully deprotected as **1**. It should be noted that although **1** is an effectively active glycosyl donor, it is nonetheless stable even to flash column chromatography on silica: an unusual and highly convenient stability that may be attributed to silica as a mild, hard rather than soft, Lewis acidic medium. As an alternative direct method for the direct synthesis of **1** from D-mannose **5**, Fischer glycosidation was also investigated. Treatment of a suspension of **5** in neat 4-bromobutanol with $BF_3{\cdot}Et_2O$ gave, after extensive purification, a low yield (18%) of **1**; although this was only a one-step procedure, inferior overall yield and use of large quantities of 4-bromobutanol meant preparation via **2** was selected as a superior route.

The results of glycosylation reactions[5] with **1** and **2** are shown in Table 1. We were delighted to see that simply by stirring **1** with MeOH as a glycosyl acceptor and *without activator*, methyl mannoside **3a** (10) was formed in a low 20% yield after 10 h, but in a fair 53% yield after 60 h. The α:β stereoselectivity (9:1) observed is consistent with the stereoselectivities of other non-participatory mannosyl donors. (3) Although these results were encouraging, we reasoned that use of a soft Lewis acid might increase rate and (or) efficiency because of the differing nature of the Lewis basicities of **1** (Scheme 1). Thus, the use of IBr (11) led after 12 h to increased rate and yield when compared with glycosylations without an activator. Unfortunately, prolonged reaction times with IBr did not lead to enhanced yield and so AgOTf was tested as an alternative halophilic Lewis acid. Using AgOTf, we were extremely pleased to observe a yield of 66% of **3a**. These improved conditions were also successfully applied to the synthesis of disaccharide **3b** (60% yield) through the use of diacetone galactose (DAG) as an acceptor, thereby demonstrating potential for oligosaccharide synthesis and confirming the compatibility of the method with acid-sensitive protecting groups. The possibility exists that although none was isolated, self-condensation of **1** may account for the only fair yield of **3b**, and we are now investigating the use of *O*-6 protected donors.

Having demonstrated the ability of **1** to act as a glycosyl donor, peracetylated **2** was examined next. Consistent with our earlier hypothesis (vide supra) and with the disarmed (7) nature of **2**, glycosylation did not proceed either in the absence of an activator or in the presence of IBr. Through the use of AgOTf, however, fair yields of methyl mannoside **4a** (12) (43%) and disaccharide **4b** (51%) were obtained. The exclusive α-stereoselectivity that was observed for **4a**,**b** may be attributed to neighbouring group participation by the C-2 acetate group.

Finally, to test the hypothesis that cyclization to form a furanosyl oxonium leaving group is an essential precursor step in the mechanism of glycosylation, two analogous peracetylated (**8**) and deprotected (**7**) 3-bromopropyl mannopyranosides were prepared using analogous routes to those used for the preparation of **1** and **2** (Scheme 2). Consistent with the need for cyclization, neither **7** or **8** were able to act as glycosyl donors under the conditions that had proved successful for **1** or **2**.[6]

In summary, this communication describes the first examples of a new class of glycosyl donor: bromobutylglycosides (BBGs). Deprotected BBG **1** appears to possess a remarkably balanced reactivity that allows its ready preparation and

[5]General procedure for glycosylation reactions: To a solution of **1** (100 mg, 0.32 mmol, 1 equiv.) in DMF (5 mL) under nitrogen, was added acceptor MeOH (64 μL, 1.6 mmol, 5 equiv.). The solution was stirred at room temperature for 60 h, any precipitate removed by centrifugation and the solvent removed. The residue was purified by flash chromatography (15% MeOH– $CHCl_3$) to yield **3a** (33 mg, 53%, α:β = 9:1) as a white solid. Parallel reactions were repeated under similar conditions using, IBr (66 mg, 0.32 mmol, 1 equiv.) or silver triflate (82 mg, 0.32 mmol, 1 equiv.) to yield 22 mg (α:β, 8:1, 36%, after 12 h) or 41 mg (α:β, 9:1, 66%, after 24 h) of **3a**, respectively.

[6]As usefully highlighted by a referee, the inactivity of 3-bromopropyl glycosides does not exclude the possibility of direct Fischer glycosylation that could be catalyzed by the equivalent of HBr (in spontaneous and IBr-activated reactions) or TfOH (in AgOTf-activated reactions) that is liberated. To test this hypothesis, **1** was used to glycosylate MeOH activated with AgOTf in the presence of the hindered base 2,4,6-tri-*tert*-butylpyridine (TTBP) [D. Crich D, M. Smith, Q.J. Yao, J. Picione, Synthesis, 323 (2001).] and yielded 64% of **3a** after 24h; near identical to that obtained without base. Other aspects of the mechanism, including the detection of THF, are currently in progress.

© 2002 NRC Canada

purification and yet is sufficiently reactive to act as an *unprotected* glycosyl donor *even in the absence of activator*. In addition, although **1** is strongly activated by soft Lewis acid catalysis its relative resistance to hard Lewis acid catalysis allows, for example, its direct preparation through Fischer glycosidation. Although the yields for glycosylations using BBGs are thus far only fair or low,[7] the potential to avoid the use of protecting groups might offset overall glycosylation efficiencies. The breadth of the utility of **1** with other acceptors and the investigation of bromobutyl-glycosides of other parent carbohydrates is underway, the results of which will be presented in due course.

Acknowledgments

We would like to thank HEFCE (SDW), the Royal Society (BGD), and the University of Oxford for funding and the EPSRC for access to the Mass Spectrometry Service at Swansea and the Chemical Database Service at Daresbury. Last but not least we would like to thank Prof. J. Bryan Jones for his constant inspiration and encouragement.

Rationalization of enzyme enantioselectivity by active-site cubic-space models

Gianluca Ottolina and Giacomo Carrea

Abstract: Active-site models of enzymes are important tools that help researchers in understanding and predicting the stereochemical outcome of enzymatic reactions. In this article, various active-site models for dehydrogenases, hydrolases, oxygenases, and oxynitrilases have been reviewed.

Key words: Active-site model, cubic space, enzyme model, dehydrogenases, hydrolases, oxygenases, oxynitrilases.

Résumé : Les modèles de sites actifs d'enzymes sont des instruments précieux pour aider aux chercheurs à comprendre et à prédire le résultat stéréochimique de réactions enzymatiques présentant de l'intérêt. Dans cet article, on passe en revue une variété de modèles de sites actifs de déshydrogénases, d'hydrolases, d'oxygénases et d'oxynitrilatases.

Mots clés : modèle de site actif, espace cubique, modèle d'enzyme, déshydrogénases, hydrolases, oxygénases; oxynitrilatases.

[Traduit par la Rédaction]

Introduction

For an enzyme to be a useful catalyst, it is desirable to understand the factors controlling its selectivity; in particular how the selectivities of specific enzymes can be correlated with the structural features of the substrate they process. In absence of such data, one must rely upon arbitrary screening to find an enzyme suitable for a given reaction. Knowledge of the enzyme–substrate interactions that regulate and control enzyme selectivity will permit the development of active-site models capable of accurately predicting both whether an enzyme will accept a new structure as a substrate and what the stereochemical outcome of the reaction will be.

In 1964, Nobel Laureate Vladimir Prelog devised an active-site model for horse liver alcohol dehydrogenase (HLADH), based on diamond-lattice section approach (1). This model, which was very successful for interpreting the steric reaction course of six-membered ring ketones and alcohols, was derived from previous observations made for the reduction of carbonyl compounds by *Curvularia falcata* (Prelog's rule, Fig. 1). The HLADH model was updated by Jones and Beck (2) as depicted in Fig. 2, but was not further refined for several reasons, including (*i*) the model cannot rationalize the *cis–trans* ratios of the 4-alkylcyclohexanols obtained by the reduction of the corresponding 4-alkylcyclohexanones; (*ii*) the substituent in (3*R*)-3-alkylcyclohexanones must be in an axial position before reaction can occur; (*iii*) the forbidden positions are rather scattered, which is inconsistent with an extensive enzyme surface.

To overcome this weakness, Jones and Jakovac (3) proposed a model based on cubic space (Fig. 3). The model described the active site of HLADH and was proposed as a complementary way to reliably predict enzyme specificity after the X-ray structure of HLADH was solved. The information gained from the diamond-lattice section was introduced in the new model along with newly acquired data. This information was used to identify the active-site regions open to substrate occupation (allowed regions) and those where substrate binding was precluded (forbidden regions) (Fig. 4). The use of a cubic framework eliminated many of the chemical and conformational disadvantages of previous models based on carbon-bond lengths and angles, and the cubic section could be made as specific and flexible as needed by appropriate selection of the unit volume. Jones and co-workers (4) also proposed an active-site model, based again on the cubic-space approach, for pig liver esterase (PLE, Fig. 5).

Several active-site models based on the cubic-space approach have been developed; many are well defined while others are simple sketches of enzyme-active sites. These models are used by many researchers to predict the stereochemical outcome of enzymatic reactions. In the following report, we will briefly review these models and discuss their applications.

Cubic-space approach

The cubic-space approach is principally adopted in the absence of a three-dimensional structure of the enzyme, and is an empirical method based on substrate selectivity. To build a new model, it is necessary to collect experimental data from numereous substrates with high selectivity (chemo-, regio-, or enantio-) and well-defined or unique conformations. The substrates are then aligned along the reactive moi-

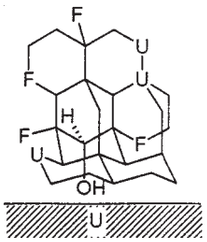

Fig. 3. A perspective (left-front viewpoint) of the HLADH cubic-space model.

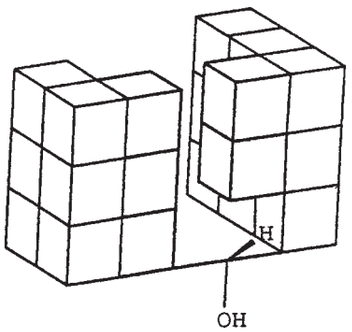

ety of interest (e.g., the ester group for hydrolysis, sulfur for sulfoxidation) and overlaid to identify the components that can occupy common volumes. The overlapping moieties, of course, whether polar or nonpolar, have to be coincident, and the selectivity predicted in the formation of the products must agree with the experimental product. The emerging three-dimensional picture is inserted inside a "cage" composed of several cubes (the cubic space) of a convenient edge (usually 1.54 Å). The cubes not occupied by the common volumes of the substrates are removed and the final cage thus obtained is identified as the active-site model.

To correctly use the model, the substrate must be placed inside the cage following a few simple rules such as alignment of the carbonyl or hydroxyl group along the C–OH bond. The rules concerning substrate positioning inside the active-site models reflect the chemical logic used to construct such models. Since these models are kept as simple as possible they cannot predict the kinetic and quantitative features of the reactions such as V_{max}, K_M, or yield.

Dehydrogenases

Alcohol dehydrogenases, which catalyze the oxidoreduction of a broad structural range of aldehydes, ketones, and alcohols, are among the most useful enzymes for organic synthetic purposes. The active-site model for HLADH has been proposed by Jones and Jakovac (3) and is depicted in Fig. 3. Hydride is delivered to, or removed from, the coenzyme at the front of the model (as shown in Fig. 3), with the C–OH bond, which projects downward to coordinate with the active-site Zn^{2+} atom in the region below, forbidden to the substrates. The rules governing the correct positioning of the substrates inside the active-site model are described in detail in the original paper (3).

Fig. 4. Front view of the HLADH model. Top covers the 2*R*-alkylcyclohexanones and the bottom the 2*S*. The cyclohexanone rings are shown in the conformations required for correct orientation of the carbonyl group at the hydride delivery site.

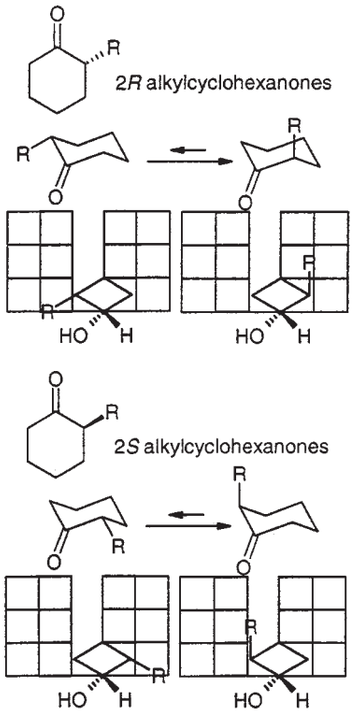

Figure 4 shows the picture for 2-alkylcyclohexanones, where all the possible absolute configurations and conformations for the substrates are taken into account and every structure is separately placed inside the model and evaluated. For the (2*R*)-series, reduction is strongly disfavored because the required binding of both conformations (Fig. 4, top left and top right) would place the R substituent in the forbidden region of the model. The same situation holds for the thermodynamically preferred conformer of the (2*S*)-series (Fig. 4, bottom left). The disfavored conformer (Fig. 4, bottom right) can, however, effectively bind to give a productive enzyme–substrate complex since the axial substituent can be accommodated at the boundary of the limited region. Reduction would therefore lead to (1*S*,2*S*)-2-alkylcyclohexanol. The experimental results were in full agreement with this prediction. For branched 2-*iso*-propyl and 2-*tert*-butylcyclohexanones, it was experimentally demonstrated that they are not substrates — this was also predicted by the HLADH model because the substituent at C-2 overlaps in the forbidden region in all possible conformations.

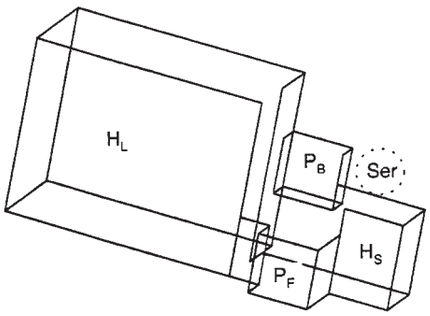
Fig. 5. A perspective (right-front viewpoint) of the PLE cubic-space model. The hydrophobic large (H_L), hydrophobic small (H_S), polar front (P_F), and polar back (P_B) pockets are depicted. The catalytic region (serine) is encircled.



This HLADH model has been successfully applied to many substrates, such as monocyclic and bicyclic ketones or alcohols, including the desymmetrization of meso compounds.

Hydrolases

Pig liver esterase (PLE) is a serine hydrolase, which catalyzes the hydrolysis of various ester structures with high selectivity. Numerous stereoselective modifications of prochiral substrates and the resolution of racemates have been reported. As already mentioned, Jones and co-workers (4–6) developed a cubic-space model for this enzyme, which after some refinements (taking into account the increased quantity of experimental data subsequently produced), was defined as shown in Fig. 5. This suggests that a model could in principle be based on a minimal set of substrates and then amplified to accommodate new substrates. (Obviously the amplified model cannot contradict previous predictions of substrate selectivity.) One point raised during the development of the PLE model was that PLE contains several isozymes. It has been demonstrated, however, that all the isozymes act in a more or less similar manner and that for preparative purposes PLE can be used as though it were a single species. Thus, the active-site model holds for all the isozymes that, from a selectivity point of view, behave as a single species. PLE is quite sensitive to reaction conditions; in fact, in many reactions enantioselectivity is influenced by temperature and by the presence of organic co-solvents such as acetone, dioxane, acetonitrile added to solubilize the substrates. These observations suggest that when designing an enzyme active-site model the reaction conditions must be carefully taken into account. Reliable predictions from the model can, therefore, only be expected for reactions carried out under the conditions adopted for its development. Figure 6 illustrates that the model can explain the high stereoselectivity of PLE in the hydrolysis of a biphenylyl malonate substrate to give the half-ester with the expected (*R*) absolute configuration. When the malonate is positioned within the active-site model as dictated by the guidelines, an ES-complex is formed, where the pro-*S* methyl ester is within the radius of action of the serine group, the second nonhydrolyzed methyl ester is located in the P_F pocket, the C-2 methyl extends into the empty space above the active site, and the biphenylyl group is directed into the H_L pocket.

Fig. 6. Fitting of dimethyl 2-(3-biphenylyl)-2-methyl-malonate into PLE model is shown from the right-front perspective.

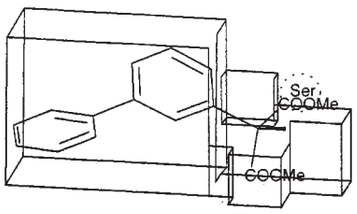


Fig. 7. A perspective (right-front viewpoint) of the lipase PS cubic-space model according to Lemke et al. (9). In the figure the serine of the catalytic triad is also localized.

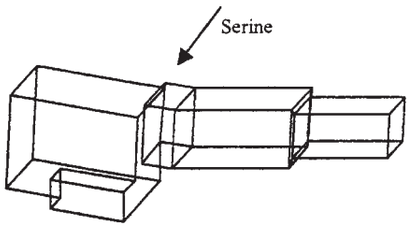

Several groups have applied this predictive model for numerous new substrates such as the hydrolysis to the half-ester of benzene-1,2-diacetic ester chromium carbonyl (7) or the resolution of racemic methylsulfinylacetates (8).

One of the most popular lipases for synthetic applications is lipase PS (Amano Pharmaceutical) from *Pseudomonas cepacia*. This lipase has been used for the regio- and stereoselective hydrolysis and alcoholysis of carboxylic esters and anhydrides and for the regio- and stereoselective transesterification of alcohols. Lipase PS shows a broad range of substrate acceptability and thus has stimulated the development of a cubic-space model for the enzyme. Two models have been independently devised by Lemke et al. (9) and Grabuleda et al. (10) and they are shown in Figs. 7 and 8, respectively. For the first model, a set of 61 3-(aryloxy) propan-2-ols acetylated with vinyl acetate in THF by lipase PS were used. For the second model, the data were collected from the literature and refer to various substrates acylated with vinyl acetate in different organic solvents. It is interesting to note that even if the models were based on two different sets of molecules they share some similarity. The model in Fig. 7 (9) shows that the substrate is oriented mainly by two hydrophobic pockets with very different shapes: one is a tube-like pocket with a very limited diameter, while the other has a cube-like shape; both are located close to the active serine. The other model (Fig. 8), also shows two hydrophobic pockets that accommodate the large and the small hydrophobic substituents and also a hydrophilic pocket that essentially accommodates the hydroxyl group (10). Interestingly, the small hydrophobic pocket is tube-shaped as in the Lemke et al. model (9), while the total volume of the second model is smaller, which probably reflects the different structures of the two sets of substrates. When developing their model, Grabuleda et al. (10) took into consideration only those compounds that displayed very high selectivity with lipase PS and were, therefore, rather insensitive to variations in the reaction conditions. Indeed the enantiomeric ratio (*E*)

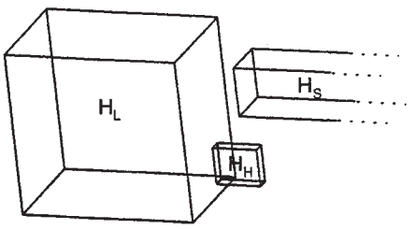
Fig. 8. A perspective (right-front viewpoint) of the lipase PS cubic-space model according to Grabuleda et al. (10). Important substrate-binding regions are identified as the following: $H_{L,}$ large hydrophobic pocket; H_S, small tunnel-shaped hydrophobic pocket; and H_H, hydrophilic pocket for hydroxyl group.



for this set of substrates ranged from 45 to over 300, where binding inside the active site was not heavily influenced by the nature of the medium. This choice, however, is also a limit of the model that cannot predict the influence of variations with the reaction medium on enzyme stereoselectivity.

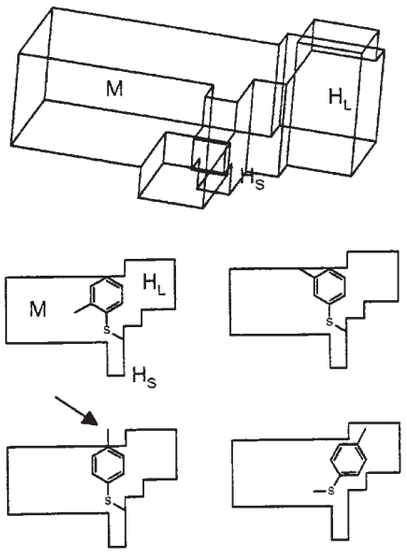
The cubic-space approach has also been used to simulate the active site of other lipases. These models, however, were mainly two-dimensional with the active site not fully described; still, some important predictive features were retained. These models, which are not described here, refer to lipase YS (11), lipase AK (12), lipase QL (13), and *Rhizopus delemar* lipase (14).

Oxygenases

The enantioselective sulfoxidation of sulfides to sulfoxides has been accomplished with different microrganisms and free enzymes. Among these, cyclohexanone monooxygenase (CHMO) from *Acinetobacter calcoaceticus* NCIMB 9871 has been the most investigated. This flavoenzyme catalyzes the sulfoxidation of numerous alkyl aryl sulfides, dialkyl sulfides, alkyl disulfides, and cyclic organic sulfites to optically active sulfoxides and sulfates (15, 16). The structure of the sulfides dramatically influence not only the enantioselectivity, but also the stereochemical outcome of the reaction, giving sulfoxides ranging from 99% ee with (*R*)-configuration to 93% ee with (*S*)-configuration (16). To explain the puzzling behavior of CHMO, an active-site model starting from a set of 31 substrates has been developed (17). Figure 9 depicts the active-site model, where it is possible to see the three-binding pockets that accommodate the substrates and an example of the applicability of this model. The series of *o*-, *m*-, and (*p*-methyl)-phenyl methyl sulfides display an interesting reversal in stereoselectivity yielding products that go from (*R*)-sulfoxide for *o*- and *m*-substrates to (*S*)-sulfoxide for the *p*-substrates. At the bottom of Fig. 9, the binding modes for these three substrates are depicted. It appears that the methyl group for the *p*-substituent in the (*R*)-conformation protrudes outside the M pocket in a forbidden position, which therefore precludes oxidation. The *p*-substituted phenyl ring can, however, be accommodated in the H_L pocket, leading to (*S*)-(*p*-methyl)-phenyl methyl sulfoxide.

CHMO also catalyzes another mechanistically different reaction within the confines of the same active site, i.e., the Baeyer-Villiger oxidation of ketones to esters or lactones. Thus, the same active-site model of CHMO should also explain the stereoselectivity of enzymatic Baeyer-Villiger oxidations. In fact, the model was shown to be applicable to this type of reaction and has provided useful insight to understanding the behavior of the enzyme (18, 19). In the Baeyer-Villiger oxidation reaction, the priority rules for the migrating group are strictly respected. In the enzymatic reaction, however, an "abnormal" oxygen insertion (with reversal of the priority rules) is observed along with the "normal" oxygen insertion. This behavior can be explained by the model, as illustrated for the oxidation of racemic bicyclo[3.2.0]hept-2-en-6-one (Fig. 10). With the (1*R*,5*S*)-enantiomer, oxygen insertion takes place exclusively on the more substituted C–C bond ("normal" mode), because the "abnormal" oxygen insertion is prevented by steric–enzymatic constraints. The opposite is true for the (1*S*,5*R*)-enantiomer, even though the selectivity is lower because of less stringent steric hindrances.

Fig. 9. Top: A perspective (right-front viewpoint) of the CHMO cubic-space model. Important binding regions for substrates are identified as the following: M, main hydrophobic pocket; H_L, large hydrophobic pocket; H_S, small hydrophobic pocket. Bottom: Top perspective view of the preferred binding modes of *o*-, *m*-, and (*p*-methyl)-phenyl methyl sulfide.



The model also holds with cyclic thiolactones, which are known to be suicide inhibitors of CHMO. The substrates (sulfides or ketones) examined so far are mainly oriented inside the active-site model by hydrophobic interactions and steric hindrances. The contribution of polar substrates also has to be taken into consideration by locating the electon-rich and electron-poor regions inside the active-site model (20).

The fungi *Helminthosporium* sp. NRRL 4671 and *Mortierella isabellina* ATCC 42613 convert a wide range of prochiral sulfides to the corresponding chiral sulfoxides, the former with a preference for the (*S*) configuration at sulfur and the latter for the opposite configuration. Active-site models for enzymes capable of this type of biotransformations have been developed by Holland and co-workers (21–23) and are shown in Figs. 11 and 12. These models, which can

predict and correlate substrate–product relationships for the reactions catalyzed by these whole-cell biocatalysts, have as a common feature a binding site for polar substrate moieties. The model for *Mortierella isabellina* can also be applied to other reactions catalyzed by this enzyme, such as benzylic hydroxylations and epoxidation of suitable substrates.

Two models have also been proposed for sulfide oxidations catalyzed by 2,5-diketocamphane 1,2-monooxygenase and 3,5-diketocamphane 1,6-monooxygenase from *Pseudomonas putida* NCIMB 10007. These models, which are based on 23 different phenyl-, benzyl-, methyl-, and ethyl-alkyl sulfides appear, however, exceedingly detailed, which makes their application rather laborious (24).

Oxynitrilase

A model for (*R*)-oxynitrilase has been developed from a small set of substrates. The active site, which essentially appears as a wide parallelepiped, lacks detail (25). The model is, therefore, only useful as an approximate guide to predict whether a substrate, on the basis of its encumbrance, can bind to oxynitrilase.

Conclusion

The empirical approach based on cubic space has demonstrated its validity as a general tool to quickly get answers for a specific enzyme–substrate combination. We have shown several examples using this methodology and also how to build and use the cubic-space enzyme model. The accessibility and the chemo-, regio-, and enantioselectivity are

Fig. 11. A perspective of the cubic-space model for sulfoxidation by *Helminthosporium*. The oxidation centre and the polar binding region (P) are indicated. The preferred binding mode for benzyl alkyl sulfides is also displayed.

predicted for the compounds of interest with a good confidence. Unfortunately, this approach cannot give information on the kinetic parameters that govern enzyme catalysis.

The cubic-space approach is also challenged by the increased availability of computer power, which makes the extensive use of molecular modelling and (or) chemometric techniques possible.

Molecular dynamic simulations, used in conjunction with appropriate thermodynamics-based models, allow qualitative predictions on the selectivity of many reaction types; however, the application of quantum mechanical – molecular mechanical methods is required for the development of quantitative models of actual reactivity patterns (26–30). Unfortunately, these methods require the 3D structure of the enzyme, are very computer-time demanding, and the results obtained might not be fully supported by the experimental data. On the other hand, chemometric techniques such as 3D-QSAR are becoming more popular and various methodologies are used. This last approach is, however, so far mostly applied in the pharmacological area; few reports deal with the biocatalytic area (31–33).

Structural effects on chemo- and enantioselectivity of *Candida antarctica* lipase B — Resolution of β-amino esters

Szilvia Gedey, Arto Liljeblad, László Lázár, Ferenc Fülöp, and Liisa T. Kanerva

Abstract: The *Candida antarctica* lipase B-catalyzed reactions of five β-amino esters with neat butyl butanoate and with 2,2,2-trifluoroethyl butanoate in diisopropyl ether were studied, as were the reactions of the same β-amino esters and their *N*-butanamides with neat butanol. The possibility for sequential resolution, where the amino and ester functions of the substrate both react with an achiral butanoate, became less likely with increasing size of the substrate from ethyl 3-aminobutanoate (**1a**) to pentanoate (**1b**) or larger. On the other hand, the alcoholyses of *N*-acylated β-amino esters successfully proceeded in butanol with $E > 100$. Gram-scale resolution of the *N*-butanoylated **1a** was performed to demonstrate the usefulness of the method.

Key words: lipase, interesterification, acylation, alcoholysis, resolution, β-amino esters.

Résumé : On a étudié les réactions, catalysées par la lipase B de *Candida antartica*, de cinq esters β-aminés avec du butanoate de butyle pur et avec du butanoate de 2,2,2-trifluoroéthyle dans l'éther diisopropylique ainsi que les réactions des mêmes esters β-aminés et des leurs *N*-butanamides avec du butanol pur. La possibilité d'une résolution séquentielle, dans laquelle les fonctions aminées et esters du substrat réagissent toutes les deux avec le butanoate achiral, diminue avec une augmentation de la taille du substrat en passant de 3-aminobutanoate (**1a**) à 3-aminopentanoate d'éthyle (**1b**) ou plus long. Par ailleurs, les alcoolyses des esters *N*-acétyl-β-amino effectuées dans le butanol se produisent avec succès, avec $E > 100$. Afin de démontrer l'utilité de la méthode, on a réalisé une résolution du *N*-butanoyl-3-aminobutanoate d'éthyle (**1a**) à l'échelle du gramme.

Mots clés : lipase, interestérification, acylation, alcoolyse, résolution, esters β-aminés.

[Traduit par la Rédaction]

Introduction

In recent years, there has been increased interest in β-amino acids, in consequence of their unique pharmacological properties, their ability to modify biologically active peptides, their importance in the preparation of peptidomimetics and natural products, and so on (1–5). A number of syntheses and transformations leading to both racemic and enantiomeric β-amino acids and esters were previously reviewed (6–11).

Received 24 October 2001. Published on the NRC Research Press Web site at http://canjchem.nrc.ca on 6 May 2002.

Dedicated to Professor J. Bryan Jones on the occasion of his 65th birthday.

The pioneering works of Jones and Klibanov on understanding enzymatic possibilities beyond biology have efficiently encouraged synthetic chemists in using enzymes to cause chiral induction in the preparation of a wide variety of enantiopure compounds (12, 13). Effective enzymatic methods to prepare β-amino acid enantiomers include the lipase-catalyzed enantioselective acylation of amino esters and β-lactam derivatives as well as penicillin or the penicillin G acylase-catalyzed enantioselective hydrolyses of *N*-acylated amino acids (14–26).

The properties and the wide application area of *Candida antarctica* lipase B (CAL-B) as a regio- and enantioselective catalyst in organic synthesis are widely described (14, 26–30). These procedures include highly enantioselective reactions of monofunctional alcohols and amines as well as highly regio- and enantioselective reactions of bifunctional diols and dicarboxylic acid esters. On the other hand, in the previous CAL-B-catalyzed reactions of ethyl 3-aminobutanoate (**1a**) with achiral esters, low chemoselectivity led to the simultaneous *N*-acylation and interesterification of the ethyl ester function and finally to the formation of a highly enantiopure product **4a** through the sequential steps A + B and C + D (Scheme 1) (21). The prevailing reaction route was A + B in the case of alkyl-activated 2,2,2-trifluoroethyl butanoate and C + D in the case of butyl butanoate as achiral acyl donors. To our knowledge, this work was the first time when 2,2,2-trifluoroethyl esters ((*R*)-**4a** ($R^2 = CH_2CF_3$) from

(*R*)-**2a** and (*R*)-**3a** (R^2 = CH_2CF_3) from *rac*-**1a**) were obtained as resolution products, although the quasiirreversible nature of such esters as acyl donors has been well attributed. As previously shown, 2,2,2-trifluoroethyl ester rather than 2,2,2-trifluoroethanol was needed for the formation of the products. The above observations awoke our interest to study the structural effects of β-amino ester substrates on the chemo- and enantioselectivity of CAL-B. In the present work, amino esters **1b**–**1e** and *N*-butanoylated dimethyl aspartate **2e** were subjected to CAL-B-catalyzed reactions with neat butyl butanoate (R^2 = Bu) and with 2,2,2-trifluoroethyl butanoate (R^2 = CH_2CF_3) in diisopropyl ether (Scheme 1).

Additionally, the CAL-B-catalyzed alcoholyses of **1a**–**1e** and those of the *N*-butanoylated **2a–2e** in neat butanol were studied as an one-step resolution possibility (Scheme 2). Gram-scale resolution of **2a** was performed to illustrate the usefulness of CAL-B-catalyzed alcoholysis.

Results and discussion

Reactions of 3-substituted 3-aminopropanoates with achiral esters

In the case of compounds **1a**–**1e**, the reaction with butyl and 2,2,2-trifluoroethyl butanoates can take place at the ester (interesterification) and amino (*N*-acylation) groups of the substrates. On this basis and on the basis of the previous results for **1a** (21), low chemoselectivity for the transformations of **1b**–**1e** by CAL-B was expected. However, the present results indicate magnificent structural effects on enzymatic chemoselectivity toward step C and reduction in the number of observed reaction steps from maximal four (steps A–D) to only one (step C) with increasing size of R (Table 1). Chiral GLC analysis and the comparison of the results to those of the previous works (21, 22) predict that the same enantiomer reacts faster in every step. Thus, the *R*-enantiomer is more reactive for the reactions starting from **1a** and **1b** and the *S*-enantiomer for those starting from **1c**–**1e** in such a way that the same steric demand at the stereocenter becomes fulfilled. Some uncertainty about enantiopreference exists in the case of very low concentrations of almost racemic products **2d**–**4d** (Table 1, row 4).

Scheme 2.

	R	R^1
a	Me	Et
b	Et	Et
c	^{i}Pr	Et
d	Ph	Et
e	CO_2Me	Me

For the CAL-B-catalyzed reactions of **1a**–**1e** (Scheme 1) with neat butyl butanoate (R^2 = Bu) and with 2,2,2-trifluoroethyl butanoate (R^2 = CH_2CF_3) in diisopropyl ether, the substitution of R with methyl (**1a**), ethyl (**1b**), and further with isopropyl (**1c**) causes the acylation step A to become progressively less favorable as compared to the interesterification step C. Thus, when 2,2,2-trifluoroethyl butanoate (R^2 = CH_2CF_3) is an acyl donor, enhanced chemoselectivity toward the formation of the corresponding products **3a**-**3c** (R^2 = CH_2CF_3) is best seen from the area ratios of the GLC chromatograms, leading to the product distribution (**2**:**3**:**4**) of 12:2:10 for **1a** (R = Me) and that of 2:10:1 for **1b** (R = *i*-Pr) at 52% total conversion. The predominance of interesterification is even more clearly seen for the reactions in butyl butanoate (R^2 = Bu) where the acylation products **2b**, **2c**, and **2e** and **4c** and **4e** were not detected at all during the course of the reaction (Table 1, rows 2, 3 and 5), except that traces of **2b** (R^1 = Et) appeared when the reaction approached 90% total conversion. Those traces are evidently due to the enzymatic interesterification between **4b** (R^2 = Bu) and ethyl butanoate (another interesterification product) rather than to the acylation of **1b** through step A. Moreover, the drop in ee of **4a** (R^2 = Bu, Δ solid line) and **4b** (R^2 = Bu, ▲ dotted line, Fig. 1) starts at 80–90% total conversion. Thus, e.g., the $ee_{(R)\text{-}\mathbf{4b}}$ of >99% at 50% and that of only 92% at 97% total conversions are observed. It is reasonable to propose that the reaction of the less reactive (*S*)-**3** to (*S*)-**4** affects the enantiopurities of (*R*)-**4** at longer reaction times.

The enzymatic interesterification of **3b** (R^2 = Bu) with ethyl butanoate back to **1b** explains the drop in $ee_{(S)\text{-}\mathbf{1b}}$ (■ dotted line, Fig. 1) starting at around 80% total conversion. In the case of **1a** (□ solid line), only a minor drop in ee is observed. The different behavior of the two compounds (**1a** and **1b**) is easily deduced from Fig. 1. Thus, the products **3a** (○ solid line) and **3b** (● dotted line) are first enriched with

respect to the more reactive *R*-enantiomer. There is a change to the less reactive *S*-enantiomer (and minima in the figure) with total conversion when the more reactive *R*-enantiomer reacts further to the product (*R*)-**4**. As a result, **3a** is already of high (*S*)-enantiopurity (ee > 95%) whereas **3b** is almost racemic (ee close to 20%) at 80% total conversion. Accordingly, the *R*-enantiomer of **3b** is available for enzymatic reaction with ethyl butanoate back to (*R*)-**1b** leading to a drop of $ee_{(S)\text{-}\mathbf{1b}}$.

The phenyl substituent in **1d** allows CAL-B-catalyzed acylation with butyl butanoate in parallel with interesterification, leading to the formation of **4d** (R^2 = Bu) through routes A + B and C + D (Table 1, row 4). The reaction is extremely slow, leading to the product distribution (**2d**:**3d**:**4d**) of 20:100:7 (the ratios of the relative amounts) after 55 h. Enantioselectivity is negligible, as can be concluded from the low ee values in general and for **4d** (R^2 = Bu, ee = 16) in particular.

The CAL-B-catalyzed reaction of **1e** in butyl butanoate (Table 1, row 5) proceeds with high chemoselectivity (66 h is needed before amide formation is detected), low regioselectivity now complicating the situation. Thus, both the α- and β-methyl ester functions are highly reactive, the regioselectivity somewhat favoring the reaction at the α-ester group. Moreover, the reactions continue from the mixed esters to the dibutyl ester, poor enantiopurities being observed at every stage of the sequence. The methods for the determination of regioselectivity were based on our previous works (26, 31).

For considering how substrate structure can affect the chemoselective outcome of CAL-B-catalyzed reactions, the binding modes for the enantiomers of secondary alcohols is useful (30). Accordingly, for acylation reactions (steps A and D) the medium size group R of β-amino esters **1** and **3** binds to the so-called stereospecificity pocket of the enzyme as is shown for the anionic tetrahedral intermediate leading to products **2** and **4**, respectively, in Fig. 2. Holding in this model, it is concluded that the fit of group R into the pocket becomes less likely the bigger it is in size. Finally, the multistep reaction in Scheme 1 turns to a single-step resolution through step C as is the case for the reaction of **1c** (R = *i*-Pr) in butyl butanoate (Table 1, row 3). Structural effects on CAL-B-catalyzed interesterification reactions (and alcoholysis reactions below) are more difficult to explain because, e.g., binding modes for recognizing chirality in the acyl site of the enzyme are not available. Moreover, the number of usable experimental data is limited. The work is continuing to get more insight into the chemoselectivity control that could favor acylation over interesterification.

To conclude, CAL-B poorly recognizes stereocenters at the acyl part of substrates **1**, leading to moderate enantioselectivities (*E* 10–15) for the formation of **3** (R^2 = CH_2CF_3 or R^2 = Bu) as was calculated in the cases where the formation of products **2** and (or) **4** was slow enough or not observed at all. Excellent enantioselectivities for the acylation step D (and A) can be expected on the basis of high ee values (>99% for **4a** and **4b**, Table 1) and on *E* > 100

previously observed for the CAL-B-catalyzed reaction of **3a** in neat butyl butanoate (21). It is worth mentioning that *E* values are not available for all transformations due to the sequential course of the reactions. Although with increasing R the same trend toward enhanced chemoselectivity for the formation of products **3** is evident for the reactions of substrates **1** with butyl and 2,2,2-trifluoroethyl butanoates, the stereochemical outcome in the terms of product enantiopurities is more appropriate in the former case. Thus, e.g., the transformation of racemic **1a** to two highly enantiopure fractions ((*S*)-**3a** (R^2 = Bu) + (*S*)-**1a** (R^1 = Et)) and ((*R*)-**4a** (R^2 = Bu)), is possible at ca. 80% total conversion (Fig. 1, solid lines). This was performed in a gram-scale in the previous work (21). The enantiomers (*S*)-**1b** (ee 96%) and (*R*)-**4b** (R^2 = Bu, ee > 99%) can also be obtained by the same procedure at ca. 70% total conversion (dotted lines) but at that point the product ratio (**1b**:**3b**:**4b**) of 3:10:2 (the ratios of the relative amounts) strongly disfavors the chemical yields.

Resolution of β-amino and *N*-butanoylated β-amino esters in butanol

CAL-B was previously shown to catalyze the alcoholysis of **2e** smoothly in a neat alcohol as a solvent (26). In the present work, the alcoholysis of **1a**–**1d** (R^2 = H) and **2a**–**2d** (R^2 = PrCO) in butanol was utilized to study substrate effects on enzymatic enantioselectivity (Scheme 2). The results are presented in Table 2. As above, the (*R*)-enantiomer is the faster-reacting enantiomer for **1a** and **1b**, while the (*S*) counterpart reacts faster in the other cases. Low enantioselectivities are obvious for the substrates **1** with free amino groups, **1b** being an exception (Table 2). Moreover, there is almost no reactivity in the case of compound **1d**. The reactions differ from the interesterification reactions of route C in Scheme 1 by solvent effects, but evidently in some mechanistic ways, too. In support of this and as already mentioned in introduction, alcoholysis between **1a** and the slightly nucleophilic 2,2,2-trifluoroethanol (0.1 M) in diisopropyl ether or in neat 2,2,2-trifluoroethanol does not proceed in the presence of CAL-B, although products **3a**–**3c** (R^2 = CH_2CF_3) were readily detected for the reactions with 2,2,2-trifluoroethyl butanoate (Table 1) (21).

The results in Table 2 clearly indicate that the CAL-B-catalyzed alcoholyses of *N*-butanoylated compounds **2** (R^2 = PrCO) all proceed in a highly enantioselective manner. This result shows that CAL-B is able to recognize stereocenters at the acyl part of an ester when a proper substrate structure is available. Unreasonably long reaction times needed for the resolution of **2c** and **2d** can be seen as limitations, however. To this end, the gram-scale resolution of **2a** by CAL-B catalysis was performed. As reported in the experimental section, the products (*S*)-**2a** and (*R*)-**4a** were both obtained with ee = 99% from one reaction at 50% conversion.

Experimental

Racemic ethyl (**1a**–**1d**) and butyl (**3a**–**3d**, R^2 = Bu) 3-aminoalkanoates were prepared from the corresponding acids using thionyl chloride and dry ethanol or butanol and were available from the previous work (22). Dimethyl aspartate **1e** was prepared from commercial dimethyl aspartate hydrochloride (26). The *N*-butanoylated counterparts **2a**–**2e** and **4a**–**4e** (R^2 = Bu) were prepared from **1a**–**1e** and **3a**–**3e** (R^2 = Bu) using butanoyl chloride in the presence of triethyl amine. GLC–MS was used to detect the products **3a**–**3c** and **4a**–**4c** (R^2 = CH_2CF_3). Acyl donors were prepared from the corresponding acid chlorides and alcohols. CAL-B (Chirazyme L2) was purchased from Boehringer–Mannheim. The solvents were of the best analytical grade from Lab Scan.

^{1}H NMR spectra were recorded using a Bruker AM 400 spectrometer. Multiplicities were recorded as s (singlet), d (doublet), dd (double doublet), t (triplet), q (quartet), m (multiplet), and om (overlapping multiplet). MS spectra

© 2002 NRC Canada

were obtained on a VG Analytical 7070E instrument equipped with a Vaxstation 3100 M 76 computer. Elemental analyses were performed with a PerkinElmer CHNS-2400 Ser II elemental analyzer. Optical rotations were measured with a JASCO DIP-360 polarimeter, and $[\alpha]_D$ values are given in units of 10^{-1} deg cm^2 g^{-1}.

Enzymatic resolutions

In a typical small-scale experiment, one of compounds **1a**–**1e** (0.1 M) was dissolved in butyl butanoate (2 mL) or in diisopropyl ether (2 mL) containing 2,2,2-trifluoroethyl butanoate (0.2 M). As another possibility, one of compounds **1a**–**1e**, **2a**–**2e** (0.1 M) was dissolved in butanol (2 mL), which served as a nucleophile and a solvent. For the reactions with achiral acyl donors, conversion was determined by using hexadecane (0.01 M) as an internal standard. In the case of butanolysis reactions conversion was obtained by equation $c = ee_s/(ee_s + ee_p)$ (32). The enzyme preparation (30 or 40 mg mL^{-1}) was added to start the reaction. The reaction mixture was shaken at room temperature. The progress of the reaction was followed by taking samples (0.1 mL) at intervals and analysing them by gas chromatography on a Chrompack CP-Chirasil-DEX CB column (25 m), except in the cases of **1d**, **1e**, or **2e** as substrates. A Chrompack CP-Chirasil-L-Val column (25 m) was then used. For good baseline separation, the unreacted amines in the sample were derivatized with acetic or butanoic anhydride in the presence of pyridine containing 1% 4-*N*,*N*-dimethylaminopyridine.

Gram-scale butanolysis of *N*-butanoylated ethyl 3-aminobutanoate 2a

Racemic **2a** (2.28 g, 11.3 mmol) was dissolved in butanol (113 mL) and CAL-B (5.65 g, 50 mg mL^{-1}) was added. The reaction was stirred at room temperature until 50% conversion was reached after 11.5 h. The enzyme was filtered off and the solvent was evaporated. The resolution products (the unreacted (*S*)-**2a** and the (*R*)-**4a** (R^2 = Bu) formed) were purified by column chromatography, using elution with petroleum ether:propan-2-ol (100:6), the elution sequence being product (*R*)-**4a** before the unreacted (*S*)-**2a**.

(*S*)-**2a**: 0.99 g, 4.92 mmol. $[\alpha]_D^{20}$ –17.9 (c = 1.0, MeOH), ee 99%. M = 201 according to MS. ^{1}H NMR (400 MHz, $CDCl_3$, Me_4Si) δ: 0.94 (3H, t, *J* = 7.4, $CH_2CH_2CH_3$), 1.23 (3H, d, *J* = 6.6, $CHCH_3$), 1.27 (3H, t, *J* = 7.2, OCH_2CH_3), 1.65 (2H, m, $CH_2CH_2CH_3$), 2.14 (2H, t, *J* = 7.4, $CH_2CH_2CH_3$), 2.52 (2H, dd, *J* = 5.4, 1.4, $CHCH_2CO$), 4.15 (2H, q, *J* = 7.2, OCH_2CH_3), 4.37 (1H, m, CH), 6.22 (1H, broad s, NH). $C_{10}H_{19}NO_3$ requires (%): C 59.68, H 9.52, N 6.96; found (%): C 59.44, H 9.72, N 6.64.

(*R*)-**4a** (R^2 = Bu): 1.18 g, 5.15 mmol. $[\alpha]_D^{20}$ +16.0 (c = 1.0, MeOH), ee 99%. M = 229 according to MS. ^{1}H NMR (400 MHz, $CDCl_3$, Me_4Si) δ: 0.94 (6H, t, *J* = 7.3, $COCH_2CH_2CH_3$, $CH_2CH_2CH_2CH_3$), 1.22 (3H, d, *J* = 6.8, $CHCH_3$), 1.38 (2H, m, $CH_2CH_2CH_2CH_3$), 1.51–1.71 (4H, om, $CH_2CH_2CH_2CH_3$, $COCH_2CH_2CH_3$), 2.14 (2H, t, *J* = 7.4, $COCH_2CH_2CH_3$), 2.52 (2H, d, *J* = 5.4, $CHCH_2CO$), 4.09 (2H, m, $OCH_2CH_2CH_2CH_3$), 4.37 (1H, m, CHNH), 6.26 (1H, broad s, NH). $C_{12}H_{23}NO_3$ requires (%): C 62.85, H 10.11, N 6.11; found (%): C 62.51, H 10.22, N 5.94.

Conclusions

In the presence of CAL-B, the reactions of β-amino esters **1a**–**1e** with neat butyl butanoate and with 2,2,2-trifluoroethyl butanoate in diisopropyl ether have been studied (Scheme 1, Table 1). CAL-B mediates interesterification between achiral and amino esters over the *N*-acylation of the amino group, increasing size of the R and the nature of an achiral acyl donor strongly affecting the behavior. The equilibrium (**1** + $PrCO_2Bu$) ⇌ (**3** + $PrCO_2Et$) of step C decreases the enantiopurities of **1** at high total conversions and therefore excludes the possibility for successful sequential resolution except in the case of **1a**. 2,2,2-Trifluoroethyl butanoate as an acyl donor is expected to be worse in this respect.

In an attempt to find a useful method for the resolution of the present amino esters by CAL-B, the butanolyses of **1a**–**1e** and that of the *N*-butanoylated derivatives **2a**–**2e** in neat butanol were studied. The latter system led to excellent enantioselectivities (*E* > 100) in all cases except when the aspartate **2e** was used as substrate (*E* = 55, Scheme 2, Table 2).

Chemo-enzymatic synthesis of the C_{15}–C_{23} unit of Leptomycin B

Michael Scheck and Herbert Waldmann

Abstract: The asymmetric synthesis of the C_{15}–C_{23} unit of Leptomycin B (LMB) is described. All four stereocenters of the C_{15}–C_{23} unit were prepared from one building block exhibiting only one stereocenter. This building block was synthesized via either an enzymatic transformation or starting from a chiral reagent.

Key words: Leptomycin, natural product synthesis, enzymatic transformation, Aldol reaction, *Pseudomonas fluorescence* lipase (PFL).

Résumé : On décrit la synthèse asymétrique de l'unité C_{15}–C_{23} de la leptomycine B. Les quatre stéréocentres de l'unité C_{15}–C_{23} ont été préparés à partir d'un seul bloc ne comportant qu'un seul stéréocentre. Ce bloc a été synthétisé par le biais d'une transformation enzymatique ou à partir d'un ensemble chiral.

Mots clés : leptomycine, synthèse d'un produit naturel, transformation enzymatique, réaction aldolique, lipase *Pseudomonas fluorescence* (PFL).

[Traduit par la Rédaction]

Introduction

Leptomycin B (LMB, **1**) is an unsaturated branched-chain polyketide isolated from *Streptomyces sp* (1, 2), which was found to induce arrest of the eukaryotic cell cycle at G1 and G2 phases (3). LMB is a specific inhibitor of proteins containing a nuclear-export signal and has been used as an important tool in the study of this phenomenon (4). It inhibits nucleo-cytoplasmic translocation of molecules such as the HIV-1 Rev protein and Rev-dependent export of mRNA, thereby inhibiting the propagation of HIV-1 in low nanomolar concentrations (5, 6). LMB also interacts with the nuclear-export signal of Hepatitis B Virus X and causes the virus to accumulate in the nucleus (7). Other proteins that are influenced by LMB are actin (8), c-Abl (9), cyclin B1 (10), MDM2/p53 (11), IκB (12), MPF (13), and PKA (14). The suggested inhibition mechanism involves the direct binding of LMB to CRM1 (chromosomal region maintenance), which blocks the binding of CRM1 to proteins containing the nuclear-export signal (6, 15), via the interaction with a cysteine residue in CRM1 (16).

Due to these outstanding properties, LMB is an interesting target for total synthesis. The absolute stereochemistry was proven through the only known total synthesis by Kobayashi et al. (17) Herein we report the synthesis of the C_{15}–C_{23} fragment employing a substrate-controlled diastereoselective aldol reaction to assemble two smaller subunits, which are both derived from monoprotected chiral diol **6**.

Results and discussion

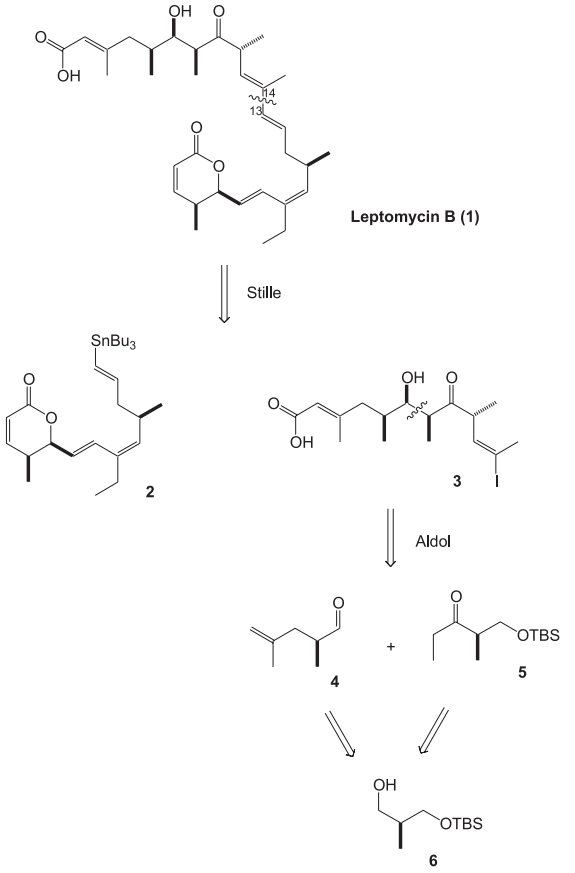
The retrosynthetic analysis of LMB (**1**) described in Scheme 1 dissects the molecule at the central diene moiety (C-13 and C-14) using the Stille transformation to provide two fragments of nearly equal size and structural complexity. The northern half (**3**) contains a polypropionate unit with four stereocenters, which can be derived from fragments **4** and **5** by a diastereoselective aldol reaction. In turn, both fragments can be synthesized from the same building block (**6**). Through this sequence all four stereocenters in **3** can be traced back to a single stereocenter in **6**.

Synthesis of the key building block **6** begins from methylmalonic acid diethyl ester (**7**), which was first reduced with borane and then acetylated to afford diacetate **8** (Scheme 2). Via an enzymatic resolution with *Pseudomonas fluorescens* lipase (PFL), the selective hydrolysis of diacetate **8** to monoacetate **9** could be achieved with an enantiomeric excess of 95% (18, 19). Protection of the free hydroxy function of **9** as a TBS-ether and cleavage of the acetate with potassium carbonate in methanol provided the central building block **6**. (*R*)-Methyl-3-hydroxy-2-methylpropanoate (**10**) also yielded **6** after TBS-protection and reduction with diisobutylaluminiumhydride (DIBAH).

Swern oxidation of alcohol **6**, followed by Grignard addition of ethylmagnesium bromide to the resulting aldehyde furnished alcohol **11**, which was oxidized with tetrapropylammonium perruthenate (TPAP) and *N*-methylmorpholine *N*-oxide (NMO) to ketone **5** (Scheme 3). The second building block (**4**) for the asymmetric aldol reaction was also synthesized from **6**. After transformation of the hydroxy

 DOI: 10.1139/V02-070 © 2002 NRC Canada

Scheme 1. Retrosynthetic analysis of Leptomycin B (LMB, **1**).



function of **6** into an iodide (**12**) a Cu(I)-catalyzed cross-coupling with 2-propenylmagnesium bromide led to silyl-protected alcohol **13** (19). Deprotection of the silyl ether **13** with tetrabutylammonium fluoride buffered with acetic acid and subsequent Swern oxidation provided aldehyde **4**.

Coupling of fragments **4** and **5** was achieved by a diastereoselective substrate-controlled Aldol-addition of a Ti(IV)-enolate (Scheme 4) (20). Although this represents a mismatched case between the influence of the C-20 and the C-16 stereocenters, Felkin–Anh control by C-20 is slightly favored affording an approximate 1.8:1 mixture of *syn* diastereomers, with the desired diastereomer predominating (21). The desired product could be readily separated by preparative HPLC. Finally, the keto function was protected as a 1,3 dioxolane and the hydroxy function as a methoxymethyl ether (**15**).

Compound **15**, which represents the C_{15}–C_{23} fragment of LMB, was synthesized in a highly convergent fashion using **6**. The terminal olefin provides a handle for extension to the desired carboxylic acid, while the TBS protected alcohol should allow conversion to the desired trisubstituted vinyl iodide.

Experimental

General methods

All reactions were carried out under argon unless water was used.

Solvents were dried by distillation prior to use. Tetrahydrofuran was distilled from sodium–benzophenone and

methylene chloride over CaH_2 immediately prior to use. ^1H and ^{13}C NMR spectra were recorded in $CDCl_3$ on Bruker AC-250, AM-400, or DRX-500 spectrometers (250, 400, and 500 MHz, respectively). The enantiomeric excess was determined with gas chromatography, which was carried out on a Hewlett Packard 5890 Series II gas chromatograph with a capillary column Lipodex E (with chiral stationary phase) from Macherey&Nagel, a mass selective detector Hewlett Packard MSD 5972 A, and using the racemate as the reference. All measurements were carried out with helium as carrier gas. Optical rotations were measured with a PerkinElmer 241 polarimeter at ambient temperature. TLC was conducted on Merck aluminum slides coated with silica gel 60 F254. Flash column chromatography was performed using Baker silica gel 60 (corn size 30–60 μm). HPLC was carried out with a L-6000A-HPLC from Merck/Hitachi with diode-array detector L-3000. A EC 250/4 Nucleosil (100–5) PPN from Macherey&Nagel was used as column. Mass

spectrometry and high resolution mass spectrometry were carried out with a Finnigan MAT 90.

2-Methyl-1,3-propanediol

To a solution of 2.17 g (12.5 mmol) of methylmalonic acid diethyl ester (**7**) in 20 mL of THF was added 12.5 mL (18.8 mmol) of a 1.5 M solution of borane in THF at –78°C. The mixture was allowed to warm to room temperature and stirred overnight. A 10% aqueous solution of citric acid was added until a clear solution was obtained. The solvent was removed under reduced pressure and the resulting white solid was dissolved in water. The solution was extracted with methylene chloride (4 × 50 mL) and the combined organic layers were dried over $MgSO_4$. Column chromatography (cyclohexane–ethyl acetate 1:1) afforded 0.98 g (10.9 mmol, 87%) of the title compound as a colorless oil. ^{1}H NMR (250 MHz, $CDCl_3$) δ: 0.88 (d, J = 7.8 Hz, 3H, CH_3), 1.63–1.70 (m, 1H, CH), 3.40–3.63 (m, 4H, CH_2), 3.71 (br s, 2H, OH). The ^{1}H NMR data is in concordance with literature (18).

2-Methyl-1,3-propanediyl diacetate (8)

To a solution of 1.0 g (11.0 mmol) of 2-methyl-1,3-propane diol in 20 mL of THF was added 16.6 g (54.5 mmol) of acetic acid anhydride and 6.6 mL (82 mmol) of pyridine and the mixture was stirred at room temperature for 2 days. The solvent was removed under reduced pressure and the resulting white solid was dissolved in 30 mL of water. The solution was extracted with diethyl ether (3 × 40 mL) and dried over $MgSO_4$. After solvent removal in vacuo, 1.83 g (10.5 mmol, 95%) of the title compound were obtained as a colorless oil ^{1}H NMR (250 MHz, $CDCl_3$) δ: 1.02 (d, J = 7.5 Hz, 3H, CH_3), 2.01 (s, 6H, CO-CH_3), 2.14–2.21 (m, 1H, CH), 4.01 (d, J = 4.9 Hz, 4H, CH_2). The ^{1}H NMR data is in concordance with literature (18).

(2*R*)-Acetic acid-3-hydroxy-2-methyl-propyl ester (9)

To a suspension of 1.83 g (10.35 mmol) of 2-methyl-1,3-propane diacetate (**8**) in 100 mL phosphate buffer (0.1 M, pH 7) was added 900 mg of *Pseudomonas fluorescens* lipase immobilized on Sol-Gel-AK and the mixture was stirred at 30°C for 2.5 h. Diethyl ether (100 mL) was added and the solution was filtered to recover the enzyme. The solution was extracted with diethyl ether (2 × 100 mL), the organic layers were combined and dried over $MgSO_4$. Column chromatography (cyclohexane–ethyl acetate 1:1) afforded 0.43 g (3.26 mmol, 31%) of the title compound as a colorless oil. $[\alpha]_D^{20}$ +7.1 (c = 0.9, $CHCl_3$). ^{1}H NMR (250 MHz, $CDCl_3$) δ: 0.98 (d, J = 8.6 Hz, 3H, CH_3), 2.01 (s, 3H, CO-CH_3), 2.04–2.11 (m, 1H, CH), 2.27 (s, 1H, OH), 3.43–3.54 (m, 2H, CH_2-OH), 4.01–4.12 (m, 2H, CH_2-O-CO). The ^{1}H NMR data is in concordance with literature (18).

(2*R*)-Acetic acid-3-([*tert*-butyldimethylsilyl]oxy)-2-methyl-propyl ester

To a solution of 430 mg (3.26 mmol) of (2*R*)-acetic acid-3-hydroxy-2-methyl-propyl ester (**9**) in 1.5 mL of dry *N*,*N*-dimethylformamide were added 0.60 g (9.8 mmol) of imidazole and 0.72 g (4.6 mmol) of *tert*-butyldimethylsilyl chloride, and the mixture was stirred at room temperature for 2 days. Water (2 mL) and diethyl ether (10 mL) were added and the aqueous phase was extracted with diethyl ether (4 × 20 mL). The combined organic layers were washed with 10 mL of a 5% aqueous sodium hydrogencarbonate solution and dried over $MgSO_4$. Column chromatography (cyclohexane–ethyl acetate 50:1) afforded 0.79 g (3.23 mmol, 100%) of the title compound as a colorless oil. $[\alpha]_D^{20}$ +5.0 (c = 0.8, CH_2Cl_2). ^{1}H NMR (250 MHz, $CDCl_3$) δ: 0.02 (s, 6H, Si-CH_3), 0.87 (s, 9H, Si-C$(CH_3)_3$), 0.97–1.03 (m, 3H, CH-CH_3), 1.90–1.98 (m, 1H, CH), 2.02 (s, 3H, CO-CH_3), 3.42 (d, J = 6.4 Hz, 2H, CH_2-O-Si), 3.87–4.02 (m, 2H, CH_2-O-CO). The ^{1}H NMR data is in concordance with literature (18).

(2*S*)-3-([*tert*-Butyldimethylsilyl]oxy)-2-methyl-1-propanol (6)

To a solution of 0.75 g (3.04 mmol) of (2*R*)-acetic acid-3-([*tert*-butyldimethylsilyl]oxy)-2-methyl-propyl ester in 5 mL of methanol was added 5 mL of a 10% aqueous potassium carbonate solution. The mixture was heated at reflux for 5 h and the then solvent was removed under reduced pressure. The resulting white solid was dissolved in 10 mL of water and extracted with methylene chloride (4 × 20 mL). The combined organic layers were dried over $MgSO_4$. Column chromatography (cyclohexane–ethyl acetate 4:1) afforded 0.43 g (2.09 mmol, 69%) of the title compound as a colorless oil. $[\alpha]_D^{20}$ +11.0 (c = 1.2, $CHCl_3$). ^{1}H NMR (250 MHz, $CDCl_3$) δ: 0.02 (s, 6H, Si-CH_3), 0.84 (d, J = 7.8 Hz, 3H, CH-CH_3), 0.87 (s, 9H, C$(CH_3)_3$), 1.89–2.04 (m, 1H, CH), 2.68 (br s, 1H, OH), 3.29–3.74 (m, 4H, CH_2-O-Si and CH_2-OH). The ^{1}H NMR data is in concordance with literature (22).

(2*R*)-3-([*tert*-Butyldimethylsilyl]oxy)-2-methyl propanoate

To a solution of 1.0 mL (9.02 mmol) of (*R*)-methyl-3-hydroxy-2-methyl propanoate (**10**) in 5 mL of dry *N*,*N*-dimethylformamide were added 1.87 g (27.3 mmol) of imidazole and 2.30 g (14.7 mmol) of *tert*-butyldimethylchlorsilane. The mixture was stirred for 3 h at room temperature, then 40 mL of water and 40 mL of diethyl ether were added and the aqueous phase was extracted with diethyl ether (4 × 40 mL). The combined organic extracts were washed with 40 mL of a 5% aqueous sodium hydrogencarbonate solution and dried over $MgSO_4$. Column chromatography (cyclohexane–ethyl acetate 5:1) afforded 2.09 g (9.00 mmol, quantitative) of the title compound as a colorless oil. $[\alpha]_D^{20}$ +18.1 (c = 4.0, $CHCl_3$). ^{1}H NMR (250 MHz, $CDCl_3$) δ: 0.02 (s, 6H, Si-CH_3), 0.87 (s, 9H, C$(CH_3)_3$), 1.11 (d, J = 6.8 Hz, 3H, CH-CH_3), 2.43–2.54 (m, 1H, CH), 3.22–3.46 (m, 2H, CH_2), 3.56 (s, 3H, O-CH_3). The ^{1}H NMR data is in concordance with literature (23).

(2*S*)-3-([*tert*-Butyldimethylsilyl]oxy)-2-methyl-1-propanol (6)

To a solution of 1.94 g (8.40 mmol) of methyl-(2*R*)-3-([*tert*-butyldimethylsilyl]oxy)-2-methyl propanoate in 25 mL of THF was added 18.5 mL of a 1.0 M solution of diisobutylaluminiumhydride in heptane at –78°C. The solution was stirred for 2 h at that temperature and additional 15 h at room temperature. The mixture was quenched with 40 mL of methanol and 15 mL of brine at –78°C. After stirring for 1 hour the mixture was dried over $MgSO_4$ and

© 2002 NRC Canada

filtered through Celite. After solvent removal 1.64 g (8.06 mmol, 96%) of the title compound was obtained as a colorless liquid. $[\alpha]_D^{20}$ +11.0 (*c* = 2.0, CH_2Cl_2). ^{1}H NMR (250 MHz, $CDCl_3$) δ: 0.02 (s, 6H, Si-CH_3), 0.84 (d, *J* = 7.3 Hz, 3H, CH-C*H*$_3$), 0.87 (s, 9H, $C(CH_3)_3$), 1.89–2.04 (m, 1H, CH), 2.68 (br s, 1H, OH), 3.29–3.74 (m, 4H, C*H*$_2$-O-Si and C*H*$_2$-OH). The ^{1}H NMR data is in concordance with literature (22).

(2*S*)-3-([*tert*-Butyldimethylsilyl]oxy)-2-methyl-1-propanal

To a solution of 0.67 mL (7.8 mmol) of oxalyl chloride in 60 mL of methylene chloride was added 0.74 mL (10.4 mmol) of dimethyl sulfoxide at –78°C. After stirring for 20 min, 1.05 g (5.17 mmol) of (2*S*)-3-([*tert*-butyldimethylsilyl]oxy)-2-methyl-1-propanol (**6**) was added and after 30 min 5.1 mL (36.2 mmol) of triethylamine. After stirring for additional 5 min at –78°C, the solution was allowed to warm to room temperature and stirred for 1 hour. After cooling to –78°C water (25 mL) was added, the mixture was allowed to warm to room temperature and the aqueous layer was extracted with methylene chloride (4 × 60 mL). The organic layers were combined and dried over $MgSO_4$. Column chromatography (cyclohexane–ethyl acetate 10:1) afforded 0.71 g (3.51 mmol, 68%) of the title compound as a colorless oil. $[\alpha]_D^{20}$ +25.5 (*c* = 2.2, $CHCl_3$). ^{1}H NMR (250 MHz, $CDCl_3$) δ: 0.02 (s, 6H, Si-CH_3), 0.87 (s, 9H, $C(CH_3)_3$), 1.06 (d, *J* = 5.3 Hz, 3H, CH-C*H*$_3$), 2.42–2.48 (m, 1H, CH), 3.41–3.51 (m, 2H, CH_2), 9.63 (s, 1H, COH). The ^{1}H NMR data is in concordance with literature (24).

(2*R*)-1-([*tert*-Butyldimethylsilyl]oxy)-2-methyl-3-pentanol (11)

To a mixture of 1.6 g (65 mmol) of magnesium fillings in 10 mL of diethyl ether was added approx. 5% of 7.1 g (65 mmol) of bromoethane in 20 mL of diethyl ether. After the solution had turned cloudy the rest of the bromoethane was slowly added and the mixture was heated at reflux for 1 h. A solution of 6.62 g (32.6 mmol) of (2*S*)-3-([*tert*-butyldimethylsilyl]oxy)-2-methyl-1-propanal in 15 mL of diethyl ether was slowly added and the mixture was heated at reflux for 2 h. The mixture was then poured on ice and acetic acid was added until the magnesium had completely dissolved. The layers were separated and the aqueous layer was extracted with methylene chloride (4 × 60 mL). The organic layers were combined and dried over $MgSO_4$. Column chromatography (cyclohexane–ethyl acetate 10:1) afforded 7.14 g (30.7 mmol, 94%) of the title compound as a colorless oil. $[\alpha]_D^{20}$ +18.3 (*c* = 2.1, $CHCl_3$). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.02 (s, 6H, Si-CH_3), 0.86 (s, 9H, $C(CH_3)_3$), 0.89–0.92 (m, 3H, CH-C*H*$_3$), 0.93–0.97 (m, 3H, CH_2-C*H*$_3$), 1.41–1.52 (m, 2H, C*H*$_2$-CH_3), 1.60–1.71 (m, 1H, CH), 2.85 (br s, 1H, OH), 3.45–3.50 (m, 2H, O-CH_2), 3.65–3.73 (m, 1H, C*H*-OH). ^{13}C NMR (100.6 MHz, $CDCl_3$) δ: – 0.03 (Si-CH_3), 9.90 (CH_2-*C*H$_3$), 10.59 (CH-*C*H$_3$), 13.82 (*C*-$(CH_3)_3$), 26.85 (C-(*C*H$_3$)$_3$), 27.90 (*C*H$_2$-CH_3), 39.26 (*C*H-CH_3), 67.13 (CH_2-O), 76.03 (CH-OH). MS (70 eV) *m*/*z* (%): 232 (3.1) $[M]^+$, 205 (2.1) $[M - C_2H_5]^+$, 190 (15.4), 189 (94.8), 147 (13.0), 131 (17.8), 117 (7.8) $[M - CH_3 - CH_3 - C(CH_3)_3 - Si]^+$, 89 (15.6), 83 (11.1), 75 (5.3) $[HO{=}Si(CH_3)_2]^+$, 73 (12.3) $[C_4H_9O]^+$, 71 (25.5), 59 (100) $[C_3H_7O]^+$, 57 (47.4) $[C(CH_3)_3]^+$, 55 (12.9), 43 (33.5)$[C_3H_7]^+$, 42 (49.6), 41 (36.1). FAB-HRMS: calcd. for $C_{12}H_{28}O_2Si$: 232.4351; found: 232.4379.

(2*R*)-1-([*tert*-Butyldimethylsilyl]oxy)-2-methyl-3-pentanone (5)

To a mixture of 6.91 g (29.8 mmol) of (2*R*)-1-([*tert*-butyldimethylsilyl]oxy)-2-methyl-3-pentanol (**11**), 6.11 g (44.7 mmol) of *N*-methylmorpholin *N*-oxide and 14.9 g of molecular sieves (4 Å) in 100 mL of methylene chloride was added 209 mg (0.59 mmol) of tetrapropylammonium perruthenate. The mixture was stirred for 1 day at room temperature, tetrapropylammonium perruthenate was filtered off, and the resulting brown solution was consecutively washed with 100 mL of a saturated solution of ammonium chloride, sodium chloride, and copper sulfate. The organic layer was then dried over $MgSO_4$. Column chromatography (cyclohexane–ethyl acetate 10:1) afforded 5.36 g (23.2 mmol, 78%) of the title compound as a colorless oil. $[\alpha]_D^{20}$ +4.3 (*c* = 0.2, CH_2Cl_2). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 0.01 (s, 6H, Si-CH_3), 0.85 (s, 9H, $C(CH_3)_3$), 0.99–1.03 (m, 6H, CH-C*H*$_3$ and CH_2-C*H*$_3$), 2.49 (q, *J* = 7.1 Hz, 2H, C*H*$_2$-CH_3), 2.74–2.79 (m, 1H, CH), 3.56–3.60 (m, 2H, O-CH_2). ^{13}C NMR (100.6 MHz, $CDCl_3$) δ: –5.60 (Si-CH_3), 7.43 (CH_2-*C*H$_3$), 13.06 (CH-*C*H$_3$), 18.15 (*C*-$(CH_3)_3$), 25.77 (C-(*C*H$_3$)$_3$), 35.95 (*C*H$_2$-CH_3), 48.26 (*C*H-CH_3), 65.71 (CH_2-O), 214.44 (C=O). MS (70 eV) *m*/*z* (%): 230 (8.0) $[M]^+$, 215 (3.1) $[M - CH_3]^+$, 189 (31.0), 174 (12.6), 173 (100) $[M - C(CH_3)_3]^+$, 147 (13.3), 143 (16.9) $[M - CH_3 - CH_3 - C(CH_3)_3]^+$, 131 (10.0), 115 (34.8) $[M - CH_3 - CH_3 - C(CH_3)_3 - Si]^+$, 99 (4.3) $[M - CH_3 - CH_3 - C(CH_3)_3 - Si - O]^+$, 75 (63.5) $[HO{=}Si(CH_3)_2]^+$, 73 (25.7) $[C_4H_9O^+]^+$, 69 (11.1), 57 (12.9) $[C(CH_3)_3]$. HRMS (FAB): calcd. for $C_{12}H_{26}O_2Si$: 230.4193; found: 230.4181.

(2*R*)-1-(*tert*-Butyldimethylsilyloxy)-3-iodo-2-methylpropane (12)

To a solution of 1.11 g (5.50 mmol) of (2*S*)-3-([*tert*-butyldimethylsilyl]oxy)-2-methyl-1-propanol (**6**) in 30 mL of toluene were added 2.2 g (8.3 mmol) of triphenylphosphine, 1.1 g (16.5 mmol) of imidazole, and 1.9 g (7.6 mmol) of iodine. The flask was protected against light and the mixture was stirred for 1 day at room temperature. The liquid was decanted and the bronze colored solid was extracted with ether (3 × 20 mL). The combined organic layers were washed with 50 mL of a concentrated solution of sodium hydrogen carbonate, sodium thiosulfate, and sodium chloride. The organic layer was dried over $MgSO_4$. Column chromatography (cyclohexane–ethyl acetate 10:1) afforded 1.71 g (5.47 mmol, 100%) of the title compound as a yellow oil. $[\alpha]_D^{20}$ +12.2 (*c* = 0.6, CH_2Cl_2). ^{1}H NMR (250 MHz, $CDCl_3$) δ: 0.02 (s, 6H, Si-CH_3), 0.87 (s, 9H, $C(CH_3)_3$), 0.96 (d, *J* = 7.3 Hz, 3H, CH-C*H*$_3$), 1.47–1.59 (m, 1H, CH), 3.14–3.23 (m, 2H, CH_2-I), 3.31–3.53 (m, 2H, CH_2-O).

(2*S*)-5-(*tert*-Butyldimethylsilyloxy)-2,4-dimethyl-1-pentene (13)

To a solution of 0.86 g (2.75 mmol) of (2*R*)-1-(*tert*-butyldimethylsilyloxy)-3-iodo-2-methylpropane (**12**) in 10 mL of THF were added 60 mg (0.30 mmol) of copper(I) iodide and 1.33 mL (10.9 mmol) of 1,3-dimethyl-3,4,5,6-

© 2002 NRC Canada

tetrahydro-2(1*H*)-pyrimidinone (DMPU). The mixture was cooled to –20°C and a freshly prepared solution of 2-propenylmagnesium bromide (6.85 mmol) in THF (7 mL) was added over 20 min. After stirring for 2 h at –20°C, the mixture was stirred for 1 h at 0°C and then quenched with 10 mL of saturated ammonium chloride solution. The layers were separated and the aqueous phase was extracted with ether (3 × 20 mL). The combined organic layers were washed with 20 mL of a concentrated solution of ethylene diamine tetraacetate and sodium chloride. The organic layer was dried over $MgSO_4$. Column chromatography (cyclohexane–ethyl acetate 8:1) afforded 581 mg (2.54 mmol, 93%) of the title compound as a colorless oil. $[\alpha]_D^{20}$ –3.4 (*c* = 0.9, CH_2Cl_2). ^{1}H NMR (250 MHz, $CDCl_3$) δ: 0.02 (s, 6H, Si-CH_3),), 0.83 (d, *J* = 6.5 Hz, 3H, CH-C*H*$_3$), 0.87 (s, 9H, C(CH_3)$_3$), 1.63 (s, 3H, CH_2=C-C*H*$_3$), 1.83–1.88 (m, 2H, C*H*$_2$-C=CH_2), 2.09–2.15 (m, 1H, CH), 3.35–3.41 (m, 2H, CH_2-O), 4.65 (d, *J* = 10.5 Hz, 2H, CH_2=C).

(2*S*)-2,4-Dimethyl-4-pentenol

To a solution of 6.57 g (28.8 mmol) of (2*S*)-5-(*tert*-butyldimethylsilyloxy)-2,4-dimethyl-1-pentene (**13**) in 10 mL of THF were added 85 mL (85 mmol) of a 1.0 M solution of tetrabutylammonium fluoride in THF, 11.0 g of molecular sieves (4 Å), 5 mL of acetic acid, and 5 g of glass splinters. The mixture was stirred for 2 days at room temperature. The solution was then filtered and 50 mL of water was added to the filtrate. The layers were separated and the aqueous phase was extracted with diethyl ether (3 × 50 mL). The combined organic layers were washed with 50 mL of a concentrated solution of sodium hydrogen carbonate and sodium chloride. The organic layer was dried over $MgSO_4$ and the solvent was removed under reduced pressure. The resulting oil was distilled under reduced pressure (*p* = 3 mbar, bp = 42°C) to afford 2.36 g (20.7 mmol, 72%) of the title compound as a colorless oil. $[\alpha]_D^{20}$ –3.9 (*c* = 0.7, $CHCl_3$). ^{1}H NMR (250 MHz, $CDCl_3$) δ: 0.90 (d, *J* = 7.3 Hz, 3H, CH-C*H*$_3$), 1.62 (s, 1H, OH), 1.76 (s, 3H, C-CH_3), 1.84–1.96 (m, 2H, CH-C*H*$_2$-C), 2.09–2.15 (m, 1H, CH), 3.42–3.53 (m, 2H, C*H*$_2$-OH), 4.65 (d, *J* = 11.6 Hz, 2H, CH_2=C). The ^{1}H NMR data is in concordance with literature (25).

(2*S*)-2,4-Dimethyl-4-pentenal (4)

To a solution of 0.67 mL (7.77 mmol) of oxalyl chloride in 60 mL of methylene chloride was added 0.74 mL (10.4 mmol) of dimethyl sulfoxide at –78°C and the resulting solution was stirred for 20 min. Next, 0.59 g (5.17 mmol) of (2*S*)-2,4-dimethyl-4-penten-1-ol was added and the solution was stirred for another 30 min. Then 5.06 mL (36.2 mmol) of triethylamine was added and the mixture was stirred for 5 min at –78°C. The reaction mixture was allowed to warm to room temperature and stirred for another hour. The solution was cooled to –78°C, water (25 mL) was added, and the mixture was allowed to warm to room temperature again. The aqueous layer was extracted with methylene chloride (4 × 60 mL). The organic layers were combined, washed consecutively with a saturated aqueous solutions of ammonium chloride and sodium chloride, and then dried over $MgSO_4$. Removal of the solvent under reduced pressure afforded 435 mg (3.88 mmol, 75%) of the title compound. $[\alpha]_D^{20}$ +3.3 (*c* = 0.1, $CHCl_3$). ^{1}H NMR (250 MHz, $CDCl_3$) δ: 1.06 (d, *J* = 8.3 Hz, 3H, CH-C*H*$_3$), 1.78 (s, 3H, C-C*H*$_3$), 2.06–2.33 (m, 2H, C-C*H*$_2$), 2.43–2.61 (m, 1H, CH), 4.81 (s, 1H, C=CH_2), 4.85 (s, 1H, C=CH_2), 9.63 (s, 1H, COH). The ^{1}H NMR data is in concordance with literature (25).

(2*R*,4*S*,5*R*,6*S*)-1-([*tert*-Butyldimethylsilyl]oxy)-5-hydroxy-2,4,6,8-tertamethyl-8-nonen-3-one (14)

To a solution of 1.39 g (6.00 mmol) of (2*R*)-1-([*tert*-butyldimethylsilyl]oxy)-2-methyl-3-pentanone (**5**) in 70 mL of methylene chloride was added at –78°C 18 mL (18 mmol) of a 1.0 M solution of $TiCl_4$ in methylene chloride. After 30 min, 2.21 mL (13.0 mmol) of *N*-ethyl-diisopropylamine was added dropwise and after 70 min a solution of 0.60 g (5.36 mmol) of (2*S*)-2,4-dimethyl-4-pentenal (**4**) in 5 mL methylene chloride was added. After strirring at –78°C for 1 h, the reaction mixture was allowed to warm slowly to –5°C. Saturated ammonium chloride solution (15 mL) and 20 mL buffer solution (pH 7) were added, the layers were separated, and the aqueous layer was extracted with diethyl ether (3 × 70 mL). The organic layers were combined, washed with 150 mL of a concentrated solution of sodium hydrogencarbonate and 150 mL of brine. After drying over $MgSO_4$, column chromatography (cyclohexane–ethyl acetate 10:1) afforded 780 mg (2.28 mmol, 42%) of crude product as a slightly red oil. The diastereomers were separated by HPLC, which lead to the desired diastereomer as a slight yellow oil. The diastereomers were found in a ratio of 1.8:1 and with a *syn–anti* ratio of 10:1. $[\alpha]_D^{20}$ +14.1 (*c* = 1.3, $CHCl_3$). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 0.03 (s, 6H, Si-CH_3), 0.88 (s, 9H, Si-C(CH_3)$_3$), 0.91–0.92 (m, 3H, C-CH_2-CH-C*H*$_3$), 1.11 (d, *J* = 6.1 Hz, 3H, O-CH-CH-C*H*$_3$), 1.16–1.18 (m, 3H, CH-CH-CO-CH-C*H*$_3$), 1.73 (s, 3H, C=C-CH_3), 2.02–2.04 (m, 3H, C=C-CH_3), 2.07 (dd, *J* = 7.4 and 14.2 Hz, 1H, C-CH_2-C*H*-CH_3), 2.66–2.68 (m, 1H, O-CH-C*H*-CH_3), 2.93–2.99 (m, 1H, CH-CO-C*H*-CH_3), 3.47–3.53 (m, 2H, O-CH_2), 3.68–3.69 (m, 1H, CH-O), 4.61 (s, 1H, C=CH_2), 4.69 (s, 1H, C=CH_2). ^{13}C NMR (125.6 MHz, $CDCl_3$) δ: –5.56 (Si-CH_3), 13.10 (CH-CH-CO-CH-*C*H_3), 14.21 (O-CH-CH-*C*H_3), 17.73 (C-CH_2-CH-*C*H_3), 19.37 (*C*(CH_3)$_3$), 22.15 (C=C-*C*H_3), 25.66 (C(*C*H_3)$_3$), 28.30 (C-CH_2-*C*H-CH_3), 41.53 (C-*C*H_2-CH-CH_3), 42.41 (CH-CO-*C*H-CH_3), 48.30 (O-CH-*C*H-CH_3), 65.16 (CH_2-O), 65.73 (CH-OH), 112.24 (*C*H_2=C), 142.95 (CH_2=*C*), 214.46 (C=O). Water content influences the selectivity of CALB-catalyzed kinetic resolution of phenoxymethyl-substituted secondary alcohols

Elisabeth Egholm Jacobsen and Thorleif Anthonsen

Abstract: Derivatives of 1-phenoxy-2-alkanols were kinetically resolved by esterification with irreversible and reversible acyl donors using lipase B from *Candida antarctica* (Novozyme 435) as a catalyst. To optimize the relative rate of reaction (the *E*-value), esterifications in eight different solvents with different water activities were performed. For 3-bromo-1-phenoxy-2-propanol (**1**), the *E*-values in all the solvents were higher when the water activity was increased, while the *E*-values for 1-phenoxy-2-pentanol (**2**) and 3-chloro-1-phenoxy-2-propanol (**3**) decreased by increasing water activity. The water content of the various reaction media with the same water activity was determined. Solvents such as 1,4-dioxane, acetonitrile, and tetrahydrofuran contained much more water than hexane, carbon tetrachloride, cyclohexane, toluene, and benzene. At high-water activity, the high-water content of the former group of solvents resulted in termination of the reaction at low conversion. The reason seemed to be that the acyl donor and possibly also the produced esters were hydrolyzed. This was not the case when the esterification was performed in water-immiscible solvents with the same water activity.

Key words: kinetic resolution, *E*-value, solvents, water activity, water content.

Résumé : Des dérivés de 1-phénoxyalcan-2-ols ont été résolus de façon cinétique par estérification avec des donneurs irréversibles et réversibles de groupes acyles, sous l'influence de la lipase B de *Candida antartica* (Novozyme 435) comme catalyseur. Afin d'optimiser la vitesse relative de réaction (la valeur *E*), on a effectué les estérifications dans huit solvants différents avec des activités aqueuses différentes. Pour le 3-bromo-1-phénoxypropan-2-ol (**1**), les valeurs *E* dans chacun des solvants augmentent avec une augmentation de l'activité aqueuse alors que les valeurs *E* pour le 1-phénoxypentan-2-ol (**2**) et 3-chloro-1-phénoxypropan-2-ol (**3**) diminuent avec une augmentation de l'activité aqueuse. On a déterminé la teneur en eau de divers milieux réactionnels de même activité aqueuse. Des solvants tels que le 1,4-dioxane, l'acétonitrile et le tétrahydrofurane contiennent plus d'eau que l'hexane, le tétrachlorure de carbone, le cyclohexane, le toluène et le benzène. À des activités aqueuses élevées, la teneur en eau du premier groupe de solvant provoque une terminaison de la réaction à des taux de conversion faibles. Il semble que ce résultat soit attribuable à une hydrolyse du donneur acyle et possiblement des esters produits. Ceci ne se produit pas lorsque l'estérification est réalisée dans des solvants immiscibles avec l'eau de teneur en eau similaire.

Mots clés : résolution cinétique, valeur *E*, solvants, activité aqueuse, teneur en eau.

[Traduit par la Rédaction]

Introduction

Resolution of racemic mixtures is a very popular method to produce enantiopure compounds. Resolution may be obtained either via diastereomeric complexes or by kinetic resolution. In a kinetic resolution, one enantiomer reacts faster than the other to form a product that is separable from the unreactive enantiomer. Kinetic resolutions may be catalyzed by enzymes. If the reaction is suboptimal it may be improved by changing the medium. When resolution is conducted as an enantioselective esterification in an organic medium, the water content of the reaction medium may be important. The influence of the water content of the reaction medium on the enantioselectivity (the *E*-value) of kinetic resolutions were studied in many different systems such as lipase-catalyzed esterifications. In some cases the value of *E* was unaffected by the water activity (1–3), whereas in other examples the *E*-value increased with increasing water activity (4). It has also been observed that the *E*-value decreased with increasing water activity (5, 6). Transesterification of sulcatol with porcine pancreatic lipase gave a tenfold increase in the *E*-value when the enzyme was dehydrated before use (7). The water-activity effect, however, has to be seen in connection with the solvent used in the reaction. It is

Scheme 1.

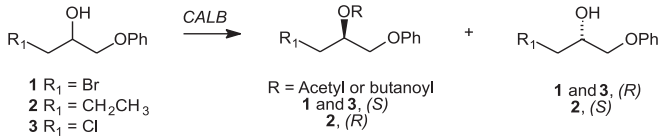

Fig. 1. Esterifications of 3-bromo-1-phenoxy-2-propanol (**1**) with vinyl butanoate in CCl_4 with a_w = 0.18 (-○-) and a_w = 0.65 (-□-) and in THF with a_w = 0.18 (-△-) and a_w = 0.39 (-◇-). Open symbols represent the ee values of the substrates; the corresponding filled symbols are the ee values of the products. Esterification of **1** did not take place in THF with a_w = 0.65.

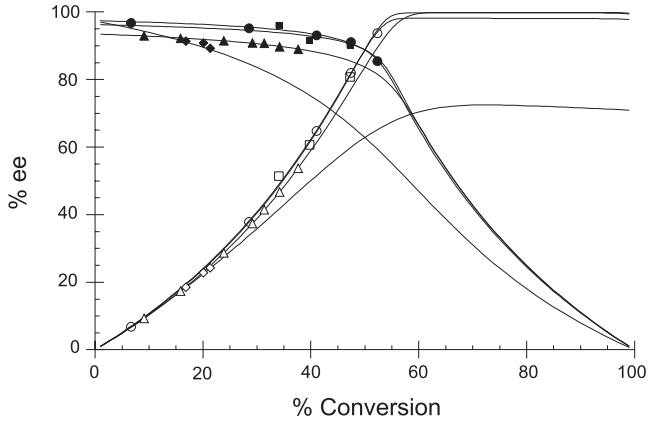

reported that better enantioselectivity is obtained in hydrophilic solvents than in hydrophobic ones, although hydrophobic solvents yield higher reaction rates than hydrophobic solvents (6). Although different substrates and enzymes were used under varying conditions in all these experiments, no general conclusions have been obtained. To determine the amount of water actually bound to the enzyme, the water activity of a system is more relevant than the total water content (8, 9) — addition of different salt hydrate pairs to the organic solvents is a simple method to vary the water activity in low-water media (10–12).

Results and discussion

The racemic secondary alcohols **1**–**3** (Scheme 1) were resolved by esterification catalyzed by immobilized lipase B from *Candida antarctica* (Novozyme 435). To increase the relative rate of reaction of the enantiomers (the *E*-value), medium engineering was performed.

The *E*-values of **1** increased with increasing a_w, Table 1. In the reactions of **1** in 1,4-dioxane, acetonitrile, and THF, a significant increase in the *E*-value was observed on going from a_w = 0.18 to 0.39; the reactions with a_w = 0.39, however, stopped at 30% conversion. When a_w = 0.65 the reactions did not exceed 1% conversion. When water-immiscible solvents were used, the *E*-values showed a moderate increase as a_w was increased from 0.18 to 0.65. The reactions were slow when a_w = 0.65, but did not stop until ca. 40–50% conversion was achieved (Fig. 1).

Water content can affect the enzyme-catalyzed kinetic resolution by esterification in organic solvents either by influencing the relative rate of formation of the two enantiomers

Table 1. *E*-values from kinetic resolution of **1** catalyzed by CALB with vinyl butanoate in different solvents with different water activity.

Solvent	Log *P*	a_w = 0.18	a_w = 0.39	a_w = 0.65
1,4-Dioxane	–1.1	25	47	Conv. <1%
Acetonitrile	–0.3	40	69	Conv. <1%
THF	0.5	30	73	Conv. <1%
Et_2O	0.9	23	24	Conv. <1%
Hexane	3.5	16	25	55
CCl_4	3.0	52	63	69
Toluene	2.5	35	42	52
Benzene	2.0	22	31	48

Table 2. Water content (μg water per g solvent) at different water activity in different solvents, measured at 30°C.

Solvent	Log *P*	a_w = 0.18	a_w = 0.39	a_w = 0.65
1,4-Dioxane	–1.1	360.1	433.0	5820.5
Acetonitrile	–0.3	1641.0	1862.0	12391.1
THF	0.5	882.7	904.2	13003.0
Et_2O	0.9	471.4	543.3	7980.2
Hexane	3.5	27.9	28.2	74.1
CCl_4	3.0	45.0	55.6	84.4
Toluene	2.5	138.4	142.3	510.4
Benzene	2.0	134.6	179.1	627.2

or by influencing the different equilibria of the system (18). The reason for the different reaction-rate patterns in the esterifications of **1** is that the water content at the same water activity is conciderably higher in 1,4-dioxane, acetonitrile, THF, and Et_2O compared with water-immiscible solvents, although the water activity is set by salt-hydrate pairs to be the same (Table 2). Compared with nonpolar solvents, polar solvents need higher water content to reach the same water activity (19). Solvents with high ability to solvate water have the lowest log *P* values. Other solvent parameters were not considered in this case.

The reaction system will consist of five different equilibria. If the esterification of a racemic mixture of alcohols is performed using an acyl donor, which is irreversible, e.g., vinyl butanoate (X = -CH=CH_2), there will be two irreversible esterification rxns. [1] and [2] and three reversible hydrolysis rxns. [3]–[5], Scheme 2. The reaction-progress graphs for the esterifications of rxn. [1] in CCl_4 with a_w = 0.65 and in THF with a_w = 0.39 reveal a large difference in the rate of the reactions, Fig. 2. From the figure it is also clear that the faster-reacting enantiomer (*S*) reacts much faster in CCl_4 than in THF. The relative rate of the two enantiomers in these media is, however, similar (*E* = 69 and 73, respectively).

The reactions are irreversible due to the nature of the acyl donor. Water in the medium can catalytically hydrolyze the formed esters, again with different rates. Thus the ester that was formed at a higher rate will also be hydrolyzed at a higher rate. Hence the ee of both the product (ester) and the remaining substrate (alcohol) will decrease. If the acyl donor is hydrolyzed (rxn. [5]), the esterifications (rxns. [1] and [2]) will slow down and will virtually stop. This was observed

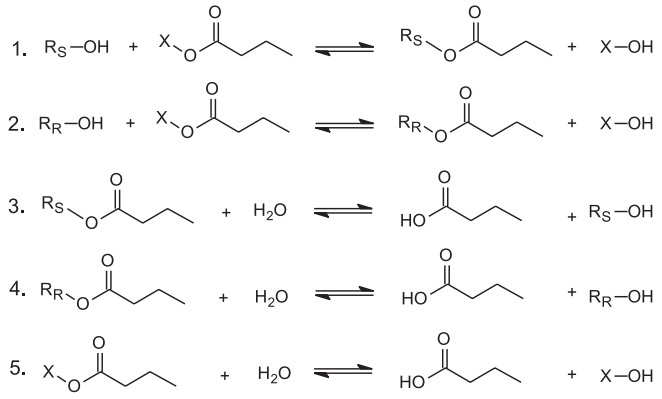
Scheme 2.



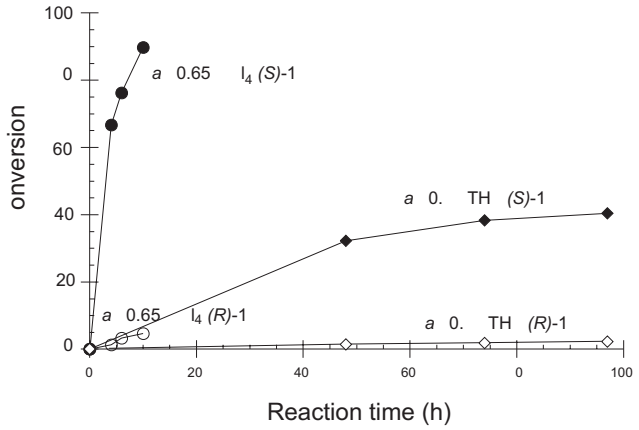
when **1** was esterified in 1,4-dioxane, acetonitrile, THF, and Et_2O with a_w = 0.65, Table 1. Even after an extra addition (10 equivalents) of acyl donor in acetonitrile, the degree of conversion did not exceed 6%. Moreover, formation of butanoic acid will take place (rxns. [3]–[5]).

It was shown that the *E*-value of the kinetic resolutions may depend on the acyl donor (20). In some cases, reversible or quasi-reversible acyl donors based on halogenated ethanols (X = CH_2CH_2Cl, CH_2CCl_3, CH_2CF_3 in Scheme 2) give higher *E*-values than the irreversible ones. When these acyl donors are used, however, all of the five reactions are reversible.

Pentanol **2**, when esterified with vinyl butanoate (vb) in hexane at a_w = 0.18, 0.39, and 0.65 showed the same tendency as **1** — an increased *E*-value with increasing water activity (Table 3). But when the acyl donors 2-chloroethyl butanoate (2-ceb), 2,2,2-trichloroethyl butanoate (2,2,2-tceb), and 2,2,2-trifluoroethyl butanoate (2,2,2-tfeb) were used, the *E*-value decreased with increasing water activity. From the esterification of **2** with different acyl donors it is clear that the acyl donor also can affect the rate of reaction. Esterification of **2** with vb is much faster than with 2-ceb, and when **2** was esterified with vb and 2-ceb in hexane, the reaction was faster when a_w = 0.18 compared with the same reaction in a_w = 0.39 (Fig. 3).

Esterifications of **3** with vinyl butanoate in toluene showed a moderate *E*-value; however, it decreased with increasing water activity. Reactions of **3** with 2-chloroethyl butanoate and vinyl acetate gave moderate *E*-values, but decreased with increasing a_w. Since **1**–**3** are different substrates, it was expected that the *E*-values would be different. In addition to different solvents, water activity and acyl donors are contributing factors to the difference in enantioselectivity. Previously we have reported that the size limitation for a secondary alcohol similar to **2** in the stereospecificity pocket of CALB is a propyl group connected to the stereocenter. When the alkyl chain is longer, CALB will not catalyze the reaction (21). The electronic effects of the small group will also play a role in orientation of the substrate, thus affecting both the reaction rate and the enantioselectivity.

Fig. 2. Reaction progress of the esterification of the two enantiomers of **1** with vinyl butanoate (vb) in CCl_4 with a_w = 0.65 show the faster-reacting enantiomer (-●-) and the slower-reacting enantiomer (-○-). The same esterification performed in THF with a_w = 0.39 shows the faster-reacting enantiomer (-◆-) and the slower-reacting enantiomer (-◇-).



Conclusions

The *E*-value increased with increasing water activity in esterifications of substrate **1** (R_1 = Br) with vinyl butanoate as acyl donor. Reactions in 1,4-dioxane, acetonitrile, THF, and Et_2O gave optimal *E*-values when a_w = 0.39, but the reactions stopped or reversed at a low degree of conversion. Esterifications in hexane, toluene, CCl_4, and benzene also proceeded as normal when the water activity was high (a_w = 0.65). The water content at the same water activity varies considerably depending on solvents. This causes the produced esters and the acyl donor to be hydrolyzed and thus terminates the reactions at a low degree of conversion in polar solvents. Esterifications of substrate **2** (R_1 = Et) and **3** (R_1 = Cl) with 2-ceb, 2,2,2-tceb, and 2,2,2-tfeb in toluene and hexane gave decreasing *E*-values with increasing water activity. Optimal conditions for resolution of substrates **1**–**3**

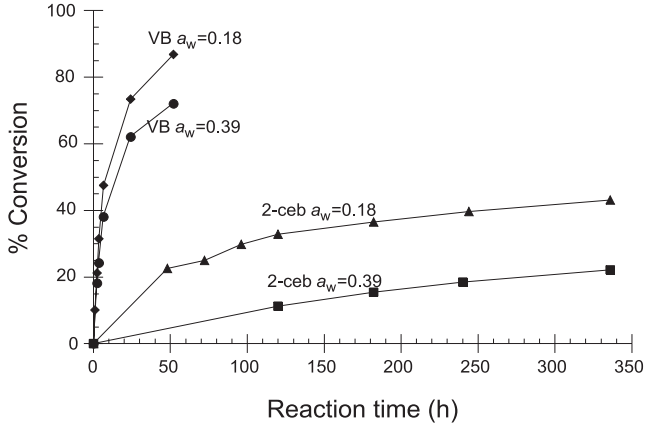
Fig. 3. Esterification of **2** with vinyl butanoate (vb) in hexane with a_w = 0.18 (-◆-) and a_w = 0.39 (-●-), and esterification of **2** with 2-chloroethyl butanoate (2-ceb) in hexane with a_w = 0.18 (-▲-) and a_w = 0.39 (-■-).



seem to be nonpolar solvents, irreversible acyl donor, and water activity between 0.39 and 0.65.

Experimental

General

Immobilized lipase B from *Candida antarctica* (CALB, Novozyme 435) from Novozymes, Denmark, has an activity of 19 PLU mg^{-1} for substrates **2** and **3** and 7 PLU mg^{-1} substrate **1**, and a water content of 2.16% w/w. All chemicals were purchased from Fluka except for vinyl butanoate, which was purchased from Aldrich. Petroleum ether has a boiling point range of 60–80°C. Column and flash chromatography were performed using silica gel 60 from Fluka, with pore sizes 0.0663–0.2000 mm and 0.035–0.070 mm, respectively.

Analyses

Optical rotations were determined using an Optical Activity Ltd. AA-10 automatic polarimeter; concentrations are given in grams per 100 mL. Chiral analyses were performed using a Varian 3400 gas chromatograph equipped with CP-Chirasil-Dex CB columns from Chrompack (25 m, 0.25 or 0.32 mm i.d., 0.25 μm film density). For chromatographic parameters, see individual compounds. NMR experiments were performed in $CDCl_3$ solutions, using Bruker DPX 300 and 400, operating at 300 and 400 MHz for ^1H and 75.4 and 100.6 MHz for ^{13}C, respectively. Chemical shifts are in ppm relative to TMS. Enantiomeric ratios (*E*) were calculated based on ping-pong bi-bi kinetics using the computer program E&K Calculator, version 2.03 (13). The *E*-values were determined from at least three experiments, with standard deviations less than 4. The water content in reaction mixtures was measured by the Karl Fischer method by a Metrohm 756 KF coulometer.

Determination of absolute configurations

The absolute configurations of the faster-reacting enantiomers of **1** and **2** were verified by comparison of optical rotation and retention times on GLC with authentic (*S*)-**1**, (*R*)-**2**, and (*R*)-**3** synthesized by a two-step procedure from (*R*)-phenyl glycidyl ether made from (*S*)-epichlorohydrin and phenol (14, 15). The synthesized alcohols had the following properties: (*S*)-**1** ee = 96%, $[\alpha]_D^{22}$ = + 5.26 (*c* 1.71, EtOH), (*R*)-**2**: ee > 99%, $[\alpha]_D^{20}$ = 6.86 (*c* 1.17, $CHCl_3$). The absolute configuration of **3** was assigned by comparing relative retention times on chiral GLC and supported by the known enantiopreference of CALB (16).

Enzymatic and nonenzymatic synthesis

Transesterifications

Substrate (**1**–**3**, 1.31 × 10^{-4} mol) and acyl donor (6.55 × 10^{-4} mol) were added to hexane (3 mL). Salt hydrates Na_2HPO_4 2/0 hydrate, $CaSO_4$ 2/0.5 hydrate, and Na_2HPO_4 7/2 hydrate (0.17 g of each) were added to give water activity values of 0.18, 0.39, and 0.65 at 30°C, respectively. The reactions were started by addition of lipase (20 mg) and performed in a shaker incubator at 30°C. Chiral GLC analyses gave ee_s and ee_p values from which the degree of conversion was determined according to $c = ee_s/(ee_s + ee_p)$. In control experiments (reaction conditions with no enzyme) no acylation was observed.

3-Bromo-1-phenoxy-2-propanol (1)

Phenyl glycidyl ether (1.19 g, 0.00793 mol) and AcOH (2.25 g, 0.0375 mol) were dissolved in dry THF (12.5 mL). Dry LiBr (1.74 g, 0.02 mol) was added and the mixture stirred at rt for 5 h. Water (12.5 mL) was added and the mixture extracted with Et_2O (5 × 10 mL). The extract was washed with water, dried over $MgSO_4$, filtered, and concentrated. The reaction product was purified by flash chromatography (pet. ether–acetone, 8:2), yield 1.56 g (85%), purity 99% (GLC). R_f = 0.38 (hexane–EtOH, 1:1). GLC (CP Chirasil DEX CB, 25 m, 0.32 mm i.d., 0.25 μm film density, 140–150°C, 0.5°C min^{-1}, 7.5 psi, 60 mL min^{-1}); acetate R_t(*R*): 16.96 min, R_t(*S*): 17.90 min, R_S= 3.40 (R_S is the resolution of the enantiomers (17)); butanoate: R_t(*R*): 29.61 min, R_t(*S*): 30.14 min, R_S = 2.37. ^1H NMR (300 MHz, $CDCl_3$) δ: 2.52 (br, 1H, OH), 3.62 (1H), 3.56 (1H), 4.15 (1 H), 4.02 (1H), 4.06 (1H), 6.90 (m, 3H), 7.25 (m, 2H, Ph). ^{13}C NMR (75.4 MHz, $CDCl_3$) δ: 33.1, 67.0, 67.8, 112.2 (2C), 119.2, 127.6 (2C), 156.0.

1-Phenoxy-2-pentanol (2)

Activated Mg (7.29 g, 0.30 mol) and EtBr (22.8 g, 0.21 mol) in dry Et_2O (100 mL) were stirred at 80°C under reflux. The reaction mixture was cooled to –78°C and Li_2CuCl_4 dissolved in THF (0.2 M, 6.5 mL) and dry Et_2O (200 mL) were added. Phenyl glycidyl ether (10.96 g, 0.073 mol) was added over a period of 1 h, the mixture was stirred at –78°C for 3 h, and left at rt overnight. Solvents were removed in vacuo and sat. NH_4Cl (250 mL) was added. After stirring at rt for 1/2 h, the mixture was extracted with Et_2O (150 mL), dried over $MgSO_4$, filtered, and concentrated. The reaction product was purified by flash chromatography (acetone–hexane, 3:7), yield 6.37 g (48.5%), purity 100% (GLC). R_f = 0.37 (acetone–hexane, 3:7). GLC (CP Chirasil DEX CB, 25 m, 0.25 mm i.d., 0.25 μm film density, 120–150°C, 1°C min^{-1}, 7.5 psi, 60 mL min^{-1}) acetate; R_t(*S*): 36.63 min, R_t(*R*): 37.29 min, R_S = 2.6; butanoate: R_t(*S*): 44.99 min, R_t(*R*): 45.59 min, R_S = 2.74. ^1H NMR (400 MHz,

$CDCl_3$) δ: 0.97 (t, 3H), 1.45 (m, 2H), 1.55 (m, 2H), 2.24 (br s, 1H, OH), 3.82 and 3.98 (dd, 1H each, -CH_2O-), 4.05 (m, 1H, -CHO-), 6.89 (m, 3H), 7.30 (m, 2H, Ph). ^{13}C NMR (100.6 MHz, $CDCl_3$) δ: 14.0, 18.7, 35.1, 69.9, 72.1, 114.5 (2C), 121.0, 129.5 (2C), 158.6.

3-Chloro-1-phenoxy-2-propanol (3)

A solution of Li_2CuCl_4 in dry THF (300 mL, 0.5 M) was added to a stirred solution of phenyl glycidyl ether (18.02 g, 0.12 mol) in dry THF (100 mL). The reaction mixture was stirred under N_2 for 18 h at rt and was stopped by addition of phosphate buffer (pH 7.0, 0.05 M, 150 mL). THF was evaporated to avoid emulsifying in the extraction with EtOAc (5 × 100 mL). The organic phase was washed with sat. NaCl solution, dried over $MgSO_4$, filtered, and concentrated by Kugelrohr distillation (0.1 mm Hg, 94°C). Yield 19.31 g (86.3%), purity 99% (GLC). R_f = 0.80 (acetone–hexane, 1:1). GLC (CP Chirasil DEX CB, 25 m, 0.32 mm i.d., 0.25 μm film density, 140–151°C, 0.5°C min^{-1}, 5 min hold time, 8.0 psi, 90 mL min^{-1}); acetate: R_t(*R*): 25.21 min, R_t(*S*): 26.63 min, R_S = 5.9; butanoate: R_t(*R*): 39.46 min, R_t(*S*): 40.15 min, R_S = 2.4. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 2.12 (s, 1H, OH), 3.74 (m, 1H), 3.79 (m, 1H), 4.08 (m, 1H), 4.11 (m, 1H), 4.23 (m, 1H), 6.90 (m, 3H), 7.33 (m, 2H, Ph). ^{13}C NMR (100.6 MHz, $CDCl_3$) δ: 46.4, 68.8, 70.3, 114.9 (2C), 121.9, 130.0 (2C), 158.6.

Acknowledgment

Biocatalytic oxidation of 4-vinylphenol by *Nocardia*

Kyung-Seon Lee and John P.N. Rosazza

Abstract: *Nocardia* species NRRL 5646 stereospecifically hydrates 4-vinylphenol (**15**) to *S*-1-(4′-hydroxyphenyl)ethanol (**17**), and further oxidizes **17** to 4′-hydroxyacetophenone (**18**). Labeled metabolites **17** and **18** obtained from incubations in D_2O and $H_2{}^{18}O$ support initial enzymatic tautomerization of **15** to a reactive quinone methide (**16**), which adds water in the first reaction. Commitment to catalysis is high in the hydration reaction, while the alcohol dehydrogenation reaction appears to be reversible. The stereochemical features of water addition, alcohol oxidations, and ketone reductions with growing culture biocatalysis were established by chiral HPLC. Alcohol oxidations or ketone reductions in 12 000 × *g* supernatants preferentially require $NADP^+$–$NADPH,H^+$ as co-factors. The alcohol dehydrogenase has broad substrate specificity, favoring the oxidation of primary alkanols and 4-hydroxybenzyl alcohols.

Key words : 4-vinylphenol, *Nocardia* sp., enantiospecific hydration, 1-(4′-hydroxyphenyl)ethanol, 4′-hydroxyacetophenone

Résumé : L'espèce *Nocardia* NRRL 5446 hydrate stéréospécifiquement le 4-vinylphénol (**15**) en *S*-1-(4′-hydroxyphénnyl)éthanol (**17**) qu'il oxyde aussi en 4′-hydroxyacétophénone (**18**). Les métabolites **17** et **18** marqués obtenus par incubation dans D_2O et $H_2{}^{18}O$ sont en accord avec un mécanisme impliquant une tautomérisation enzymatique initiale de **15** en une méthoquinone réactive (**16**) qui fixe de l'eau dans la première étape de la réaction. Dans la réaction d'hydratation, le degré de catalyse est élevé alors que la réaction de déshydrogénation de l'alcool semble réversible. Faisant appel à la CLHP chirale, on a déterminé les caractéristiques stéréochimiques de l'addition d'eau, des oxydations de l'alcool et des réductions de cétone par la catalyse de cultures en croissance. Les oxydations d'alcool ou réductions de cétones dans des liquides surnageant 12,000 x *g* requièrent le coupe $NADP^+$–$NADPH,H^+$ comme cofacteurs. La déshydrogénase de l'alcool possède une grande spécificité par rapport au substrat qui favorise l'oxydation d'alcools primaires et d'alcools 4-hydroxybenzyliques.

Mots clés : 4-vinylphénol, *Nocardia* sp., hydratation spécifique, 1-(4′-hydroxyphényl)éthanol, 4′-hydroxyacétophénone.

Introduction

Microbial and enzymatic transformations have been developed for nearly every class of natural and synthetic chemical products (1). Microorganisms and their enzymes are biocatalysts, which are now widely used as "reagents" in synthetic organic chemistry. Biocatalysts are valued for their intrinsic abilities to bind organic substrates and to catalyze highly specific and selective reactions under the mildest of reaction conditions. Biocatalytic transformations of abundant renewable natural chemicals afford attractive "green chemistry" alternatives to synthetic chemical approaches, which rely on petrochemically derived starting materials.

Green chemistry (2) presents a continuing need for the discovery of new biocatalysts capable of catalyzing useful chemical transformations by novel mechanisms. An ideal biocatalyst has few technical hurdles, such as the requirement for co-factors. They should be robust, stable, and recyclable, and ultimately be amenable to large-scale adaptation to bioreactor use, even under unusual reaction conditions (3).

p-Coumaric acid (4), ferulic acid (5), and caffeic acid are abundantly occurring phenolic acids commonly found in plants in their esterified or free-acid forms. The acids *p*-coumaric and ferulic compose nearly 4% of the dry weight of maize plant parts, rendering them available in the billions of pounds annually from this source alone (5). The large quantities of these natural compounds render them useful for the biocatalytic production of value-added aromatic natural chemicals. Systematic screening of microorganisms showed that the major and most common biocatalytic reaction with hydroxycinnamates is decarboxylation to the corresponding vinylphenols (hydroxystyrenes) (5, 6). Deuterium-labeling experiments showed that non-oxidative decarboxylations occurred by enzymatic tautomerization of *p*-hydroxycinnamates to doubly vinylogous β-keto acid intermediates that spontaneously decarboxylated (5, 6*a*). Phenolic cinnamate decarboxylation is capable of providing potentially huge quantities of oxygenated styrenes, which are difficult to produce by ordinary chemical means (5, 6*a*, *b*). Phenolic styrenes are valuable starting materials for oxygenated biodegradable polymers, fragrances, and flavors, and chiral intermediates for organic synthesis.

Biocatalytically unsubstituted styrene (**1**) is usually converted to styrene epoxides (**2**) of varying enantiomeric

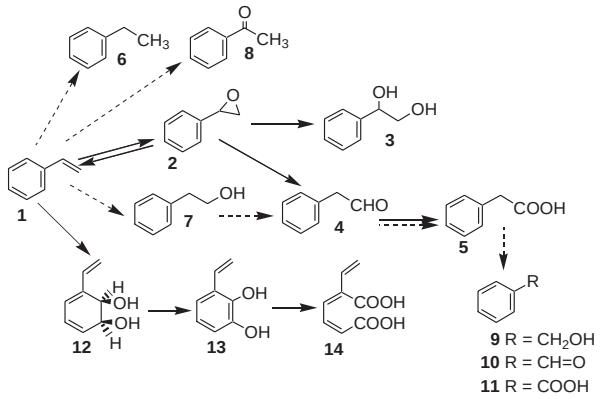
Scheme 1. A summary diagram of known styrene bioconversions. Solid arrows indicate aerobic conditions and dashed arrows indicate anaerobic conditions.



purities by enzymatic activation and insertion of molecular oxygen into the unsaturated styrene side-chain (7–9). Styrene epoxides (**2**) are also formed by hydrogen peroxide dependent-peroxidase mediated epoxidations (10). Styrene epoxides (**2**) are hydrolytically converted to diols (**3**) by epoxide hydrolases (8, 11), to phenylacetaldehyde (**4**) and phenylacetic acid (**5**) (9, 12), and to alkenes in a "reversal" of the epoxidation reaction (13). With anaerobic consortia, after water addition to the double bond, styrene (**1**) is oxidized through the phenylacetate route to yield various products, including ethylbenzene (**6**), phenylethanol (**7**), 1-phenylethanone (**8**), phenylacetaldehyde (**4**), phenylacetic acid (**5**), benzyl alcohol (**9**), benzaldehyde (**10**), and benzoic acid (**11**) (14). Styrene (**1**) is also metabolized via styrene *cis*-glycol (**12**) to 3-vinylcatechol (**13**) and 2-vinylmuconate (**14**), demonstrating double-bond and aromatic-ring oxygenation prior to ring fission (15) (Scheme 1).

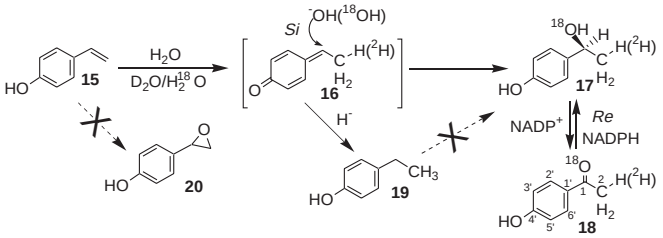
Much less is known about biocatalytic transformations of phenolic styrenes such as **15**. The introduction of oxygen into the styrene side-chain olefin by a hydration mechanism is a novel and relatively unexplored biocatalytic reaction. In this study, we examined the mechanism and disposition of **15** by growing cultures, induced resting cells and cell-free enzyme preparations of the *Nocardia* species, that afforded *S*-1-(4′-hydroxyphenyl)ethanol (**17**) by vinylphenol hydratase, and subsequently, 4′-hydroxyacetophenone (**18**) by an $NADP^+$-dependent alcohol dehydrogenase (Scheme 2).

Experimental

Chemicals

4-Vinylphenol (**15**) (10% solution in propylene glycol), 4′-hydroxyacetophenone (**18**), cinnamyl alcohol (3-phenyl-2-propen-1-ol), 2-hydroxybenzyl alcohol, 3-hydroxybenzyl alcohol, 4-hydroxybenzyl alcohol, oleyl alcohol, and vinyl acetate were obtained from Lancaster Synthesis Inc. (Windham, NH, U.S.A.). D_2O (99.9 atom% D), vanillyl alcohol (4-hydroxy-3-methoxybenzyl alcohol), cyclohexanol, tetralol (1,2,3,4-tetrahydro-1-naphthol), 4-methoxybenzyl alcohol, benzyl alcohol, 1-phenyl-1-propyl alcohol, 1-phenyl-2-propyl alcohol, and 3-phenyl-1-propyl alcohol were purchased from Aldrich (Milwaukee, WI, U.S.A.). Methanol, ethanol, 1-propanol, 1-butanol, 2-butanol, 2-phenylethyl alcohol, β-NAD^+ (99%), β-$NADP^+$ (sodium salt, 98%), and β-NADPH (tetrasodium salt, 95%) were obtained from Sigma (St. Louis, MO, U.S.A.). Coomassie Plus protein assay reagent and Albumin Standard (bovine serum album fraction V, 2 mg mL^{-1} in a 0.9% aqueous NaCl solution containing sodium azide) were obtained from Pierce (Rockford, IL, U.S.A.). $H_2{}^{18}O$ (96 atom% ^{18}O) and NMR solvents were purchased from Cambridge Isotope Laboratories, Inc. (Andover, MA, U.S.A.). HPLC solvents were obtained from Fisher Scientific (Fair Lawn, NJ, U.S.A.), and other reagents were analytical grade from Fisher Scientific unless otherwise indicated.

Scheme 2. Oxidation of 4-vinylphenol (**15**) to **17** and **18** by *Nocardia* sp.



Racemic 1-(4′-hydroxyphenyl)ethanol (**17**) was prepared as described by the $NaBH_4$ reduction of 4′-hydroxyacetophenone (**18**) in CH_3OH (16).

S-(–)-**17** was prepared by a modification of Reeve et al. (17), where the lipase mediated enantioselective esterification of *R*-(+)-**17** occurs, leaving unreacted *S*-(–)-**17** behind. Racemic **17** (4 mg) was dissolved in vinyl acetate (4 mL) as the acyl donor and as the solvent and lipase (4 mg, *Pseudomonas fluorescens* lipase, EC 3.1.1.3, 3097 units mg^{-1}, Fluka Chemical Co., Milwaukee, WI, U.S.A.) were added. After incubation for 12 h at 28°C, lipase was filtered off and the filtrate was evaporated. The residue was dissolved in CH_3OH (2 mL), filtered, and subjected to chiral HPLC analysis, where the enantiomeric excess of unreacted **17** was 98.8% ee of the *S*-(–)-isomer (Fig. 1B).

Analytical methods and instrumentation

TLCs were carried out on 0.25 mm layers of silica gel GF_{254} (Sigma) precoated on polyester plates (20 × 20 cm). The developing solvent was a mixture of CH_2Cl_2–CH_3OH–HOAc (95:5:0.5, v/v/v). Developed chromatograms were directly visualized under 254 and 366 nm UV light for fluorescence quenching or fluorescence. Plates were then spayed with diazotized sulfanilic acid reagent, which consisted of solution A (0.5% sulfanilic acid in 1 N HCl), solution B (0.5% $NaNO_2$ in water), and solution C (0.5% NaOH in 50% (v/v) C_2H_5OH–H_2O). Developed plates were first sprayed with a fresh mixture of equal volumes of solutions A and B, warmed with a heat gun, followed by spraying with solution C to develop the colors. Under these conditions, **15**, **17**, and **18** gave R_f values of 0.7 (scarlet), 0.3 (yellow), and 0.5 (orange), respectively.

HPLC was performed with a Shimadzu liquid chromatograph (Shimadzu Corporation, Kyoto, Japan) equipped with dual pumps (LC-6A) and a variable wavelength UV detector (SPD-6AV). Eluted peaks were detected at 280 nm and identified by comparison with standard compounds. Separations were carried out under isocratic

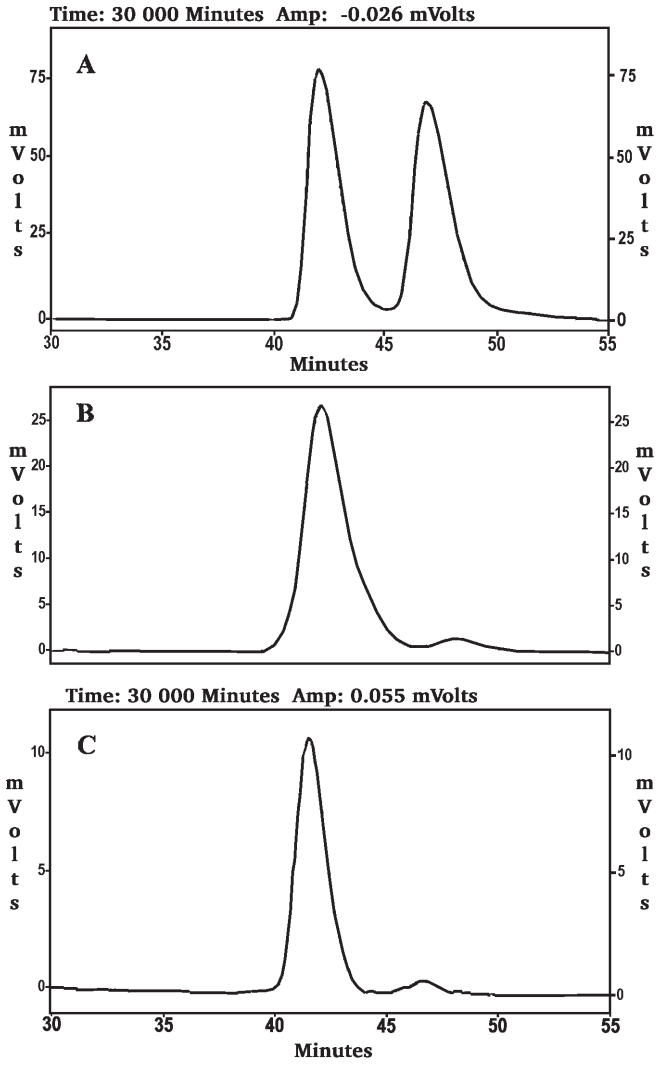
Fig. 1. Chiral HPLC resolution of *R*-(+)- and *S*-(–)-1-(4′-hydroxyphenyl)ethanol (**17**): (A) racemic **17**; (B) *S*-(–)-**17** resolved by *Pseudomonas fluorescens* lipase; (C) **17** isolated from reaction of *Nocardia* cultures with 4-vinylphenol (**15**).



conditions over a Hypersil C18 column (250 × 4.6 mm ID, 5 μm particle size, Alltech Associates, Inc., Deerfield, IL, U.S.A.) protected with a guard column (10 × 4.6 mm ID, 5 μm particle size, Alltech) eluted with CH_3OH–CH_3CN–H_2O (7:3:10, v/v/v) at a flow rate of 0.8 mL min^{-1} to give retention volumes (*Rv*) of 3.6 mL for **17**, 4.5 mL for **18**, and 10.1 mL for **15**. Standard curves were established over the range of 1–10 μg for **15**, 1–8 μg for **17**, and 0.2–0.8 μg for **18**.

Chiral HPLC was carried out with a Chiralcel OJ column (250 × 4.6 mm ID, 10 μm particle size, Chiral Technoloies Inc., Exton, PA, U.S.A.) linked to a Chiralcel OJ guard column (50 × 4.6 mm ID, 10 μm particle size) at a flow rate of 0.8 mL min^{-1} with *n*-hexane–2-propanol (9:1, v/v), which gave retention volumes (*Rv*, mL) of 16.6 for **15**, 16.8 for **18**, 33.6 for *S*-(–)-**17**, and 37.5 for *R*-(+)-**17**.

Flash column chromatography was conducted over silica gel, 40 μm for flash columns (J.T. Baker, Phillipsburg, NJ, U.S.A.).

Mass spectra were obtained by direct inlet probe mass spectrometry (DIPMS) performed on a Voyager mass spectrometer (ThermoQuest, Manchester, England). One dimensional ^1H and ^{13}C NMR spectra were obtained with a Bruker DMX-400 (operating at 400 MHz for ^1H and 100 MHz for ^{13}C) or an AMX-600 spectrometer (operating at 600 MHz for ^1H, Karlsruhe, Germany), equipped with an IBM Aspect 2000 processor and with VNMR version 4.1. Impurities in deuterated NMR solvents were used as internal standards. Chemical shift values (δ) are reported in parts per million (ppm) and coupling constants (*J* values) are given in Hz. Abbreviations for NMR are s, singlet; d, doublet; and q, quartet.

Fermentation and biocatalysis

Nocardia sp. NRRL 5646 was grown and maintained on slants of Sabouraud-dextrose agar or sporulation agar (ATCC No. 5 medium) (18). For analytical scale reactions, cultures were grown by a two-stage protocol (19) in 25 mL of sterile soybean meal-glucose medium held in stainless steel-capped 125-mL DeLong culture flasks. The medium contained 2% glucose, 0.5% yeast extract, 0.5% soybean meal, 0.5% NaCl, and 0.5% K_2HPO_4 in doubly distilled water, and was adjusted to pH 7.0 with 6 N HCl before being autoclaved at 121°C for 15 min. Cultures were incubated with shaking at 250 rpm at 28°C on an Innova 5000 Gyrotory tier Shaker (New Brunswick Scientific Co., Edison, NJ, U.S.A.). A 10% inoculum derived from a 72-hour-old first-stage culture was used to initiate the second-stage cultures, which were incubated as above for 24 h. For bioconversions, **15** and **17** were added directly, usually at concentrations of 1 mg mL^{-1}, and **18** was added at 0.4 mg mL^{-1} of media.

Induced *Nocardia* resting cells were prepared by adding 1 mg mL^{-1} **15** to 24-hour-old stage-two cultures. After an additional 24 h, incubations were filtered through a cheese cloth to remove soybean meal solids, and the cells were concentrated by centrifugation (Sorvall RC 26 Plus centrifuge with a SLA-600TC rotor, Kendro Laboratory Products, Newton, CT, U.S.A.) at 10 000 × *g* at 4°C for 20 min. Cell pellets were suspended and washed in cold phosphate buffer (pH 7.0, 0.1 M) and centrifuged again. Typical wet cell yields ranged from 20 to 24 g L^{-1}.

Cell-free extracts were prepared from induced cells. Typically, 15 g wet weight of cells were suspended in cold phosphate buffer (45 mL, pH 7.0, 0.1 M) containing dithiothreitol (1 mM) (Aldrich) and disrupted by a Sonifier Cell Disrupter 350 (Branson Sonic Power Co., Danbury, CT, U.S.A.) operating at 10 W with a 60% intermittent duty cycle for 5 min. Cell debris was removed by centrifugation at 12 000 × *g* for 30 min at 4°C to provide a supernatant as the cell-free extract. The cell-free extract was assayed for total-protein content by the Bradford protein microassay (20) with bovine serum albumin as the standard.

For preparative-scale conversions, stage-two incubations were carried out in 200 mL of medium held in 1-L DeLong flasks. After 24 h of incubation in the second stage, **15** was added as the substrate and incubated with shaking at 250 rpm at 28°C for 24 h. The reaction mixture was harvested, acidified to pH 2 with 6 N HCl, followed by centrifugation at 10 000 × *g* at 4°C for 20 min to remove

cells. The supernatant was extracted wiht EtOAc (3 × 200 mL), the combined EtOAc extracts were dried over anhydrous Na_2SO_4 and concentrated by rotary evaporation to give 431 mg of crude extract. The extract was dissolved in CH_3OH (5 mL), adsorbed onto 2 g of silica gel, and loaded onto a flash column (2 × 25 cm). The column was eluted stepwise with $CHCl_3$ and $CHCl_3$–CH_3OH (99:1 to 97:3) to give fraction A (39 mg) and fraction B (173 mg). These fractions were separately resolved by flash column chromatography over silica gel using mixtures of *n*-hexane–EtOAc (95:5) for fraction A, and *n*-hexane–EtOAc (8:2 to 7:3) for fraction B. The resulting pure products were subjected to chromatographic and spectral analyses.

Induced resting cell conversions of 4-vinylphenol

Induced resting-cell reactions were performed by suspending 0.6 g wet weight of *Nocardia* cells in phosphate buffer (25 mL, pH 7.0, 0.1 M) containing glucose (0.5%) and **15** (25 mg). Samples of 2.0 mL were diluted with CH_3OH (2.0 mL), filtered through 0.2-μm nylon membrane filters, and 10 μL of the filtrates were injected for HPLC analysis. The same procedure was used in induced cell conversions of **17** at 1 mg mL^{-1} and **18** at 0.4 mg mL^{-1}.

Reactions of 4-vinylphenol with *Nocardia* sp. in D_2O and 20% $H_2{}^{18}O$

Deuterium-incorporation experiments used induced resting cells of *Nocardia* sp. as described, except that flasks held phosphate buffer (25 mL, pH 7.0, 0.1 M) containing glucose (0.5%, prepared with 50 and 100% D_2O) and **15** (1 mg mL^{-1}). For each reaction, incubations were stopped after 24 h, acidified and pelleted as before, and supernatants were extracted with EtOAc (3 × 25 mL). The combined extracts were dried over anhydrous Na_2SO_4 and evaporated to dryness. The extracts were purified on glass preparative-TLC plates coated with 1-mm layers of silica gel GF_{254} (20 × 20 cm, Sigma). UV-quenching bands were scraped from plates, extracted with CH_3OH (3 × 20 mL), and the extracts were evaporated to dryness for ^{1}H NMR and MS analysis.

Labeled-oxygen incorporation experiments also used induced *Nocardia* resting cells that were suspended in a phosphate buffer (10 mL, pH 7.0, 0.1 M) containing glucose (0.5%, prepared with 20% $H_2{}^{18}O$) and contained in 50-mL DeLong flasks. After addition of **15** (30 mg), the incubation was carried out at 28°C with spinning at 250 rpm. The control consisted of an identical reaction mixture, except the buffer was prepared with unlabeled H_2O. The 24-hour-old culture solutions were extracted with EtOAc (10 mL), the extracts were concentrated and purified by preparative TLC, as previously mentioned, to give products that were subjected to spectral analysis.

Enantiospecificity of 4-vinylphenol hydration

The enantiospecificity of the hydration reaction was evaluated by adding **15** (25 mg) to 25 mL volumes of 24-hour-old stage-two cultures. Incubations were conducted in 125-mL DeLong flasks. Samples of 3 mL were taken after 24, 48, 72, and 144 h and each was extracted with EtOAc (3 mL). After evaporation, crude extracts were redissolved in CH_3OH to concentrations of 2 mg mL^{-1}, passed through syringe filters (Acrodisc 13 mm with 0.45 μm nylon membrane filter, Gelman Science, Ann Arbor, MI, U.S.A.), and the filtrate samples (20 μL) were injected for chiral HPLC analysis.

Substrate specificity of alcohol dehydrogenase in *Nocardia* cell-free extracts

Incubations in quartz cuvettes were conducted in phosphate buffer (1.0 mL, pH 7.0, 0.1 M) containing the substrates (3 mM), $NADP^+$ or NAD^+ (0.25 mM), and cell-free extract (500 μL, 1.70 mg protein). Substrates were dissolved in dimethylformamide (DMF), and 10 μL of the DMF solutions were added to incubation mixtures. Reactions were

monitored under initial-rate conditions by measuring changes in absorbance at 340 nm for 5 min at 20°C (Shimadzu 2101-PC equipped with UVPC Optional Kinetics Software v 2.5). The molar extinction coefficient used for NADPH at pH 7.0 was $\varepsilon_{340} = 6.22\ mM^{-1}\ cm^{-1}$.

Results and discussion

Conversion of 4-vinylphenol by *Nocardia* sp.

The reaction of *Nocardia* sp. with 4-vinylphenol (**15**) gave two major products identified as **17** and **18**. Characterization data for **17**: R_f = 0.3. ^1H NMR (CD_3OD) δ: 7.19 (d, ^2J = 8.4 Hz, 2H, Ar-2′, 6′H), 6.76 (d, ^2J = 8.4 Hz, 2H, Ar-3′, 5′H), 4.73 (q, ^2J = 6.5 Hz, 1H, C-1H), 1.35 (d, ^2J = 6.5 Hz, 3H, C-2H); identical to the results of Everhart and Craig (21). MS *m*/*z* (%): 138 ($[M]^+$, 15.4), 123 ($[M - CH_3]^+$, 63.5). Characterization data for **18**: R_f = 0.5. ^1H NMR (CD_3OD) δ: 7.87 (d, ^2J = 8.8 Hz, 2H, Ar-2′, 6′H), 6.82 (d, ^2J = 8.8 Hz, 2H, Ar-3′, 5′H), 2.51 (s, 3H, C-1H); spectrum was identical to that for authentic **18**. MS *m*/*z* (%): 136 ($[M]^+$, 35.2), 121 ($[M - CH_3]^+$, 100).

With induced resting cells, **15** was transformed to **17** (25%) and **18** (1%) within 48 h. Trace amounts of 4-ethylphenol (**19**) were detected as a peak at *Rv* 12.1 mL, but only after 144 h, indicating this to be a very minor biotransformation pathway. With racemic **17**, induced resting cells gave **18** in 10% yield, while **15** was undetectable. In the reverse direction, 4′-hydroxyacetophenone (**18**) gave **17** (33%) in 48 h, again producing trace amounts of 4-ethylphenol (**19**). Neither **17** nor **18** gave **15** as a product, indicating the irreversibility of the initial hydration reaction.

Resting cell incubations in 50% D_2O, 100% D_2O, and 20% $H_2{}^{18}O$ containing buffers were conducted to examine the source of oxygen and the mechanism by which *Nocardia* oxidized **15** to **17** and **18**. Reaction products isolated from these incubations were analyzed by mass spectrometry and ^1H NMR spectroscopy to determine the extent and positions of isotope incorporations. Tables 1*a* and 1*b* show the results of deuterium incorporation. For **17**, when compared with control reactions conducted in H_2O-containing buffer, ions at *m*/*z* 139 and 140 for $[M + 1]^+$ and $[M + 2]^+$ were enhanced by 9% and 1%, respectively, from 50% D_2O-containing buffer reaction, and 60% and 10%, respectively, from the 100% D_2O-containing buffer reaction. Fragment ions at *m*/*z* 123 and 124, where methyl groups were lost from the molecular ions, were essentially identical to those from unlabeled **17**, showing that all the deuterium in labeled **17** resided in the methyl groups. ^1H NMR of relative peak intensities for C-2H showed approximately 10 and 47% deuterium incorporations vs. signals for Ar-2′ and 6′-H, respectively, similar to the mass spectral findings. Similar analyses of **18** showed that all deuterium labeling resided in the C-2 methyl group. Deuterium incorporations of 59 and 11%, respectively, for $[M + 1]^+$ and $[M + 2]^+$ from 100% D_2O-containing reactions matched very well with the results for **17** from 100% D_2O. ^1H NMR results for **18** again gave 6.6% incorporation from the 50% D_2O reaction and 47% from the 100% D_2O buffer reaction. Results of deuterium incorporation from 50% D_2O buffers were inexplicably lower than expected.

Comparisons of $[M + 2]^+$ ions for **17** and **18** from reactions conducted in buffers prepared with 20% $H_2{}^{18}O$ (Tables 2*a* and 2*b*) revealed oxygen-incorporation levels of 18 and 14%, respectively. Relative intensities of $[M + 2 - CH_3]^+$ ions revealed 21 and 17% increases in similar ions vs. unlabeled **17**. Both results are consistent with complete incorporation of oxygen from water and not from molecular oxygen.

Labeling results permit a description of the reaction process as shown in Scheme 2. *Nocardia* contains a hydratase that binds and tautomerizes 4-vinylphenol (**15**) to a quinoid intermediate (**16**), which adds water to afford **17**. The tautomerization reaction is apparently partially reversible, because both **17** and its oxidation product **18** contain 1.4 deuterium atoms on the C-2 methyl group. Addition of oxygen from water and not air was clearly confirmed by the $H_2{}^{18}O$ labeling experiment, which gave nearly theoretical incorporations of ^{18}O into **17** and **18**. Slightly lower values than expected in deuterium and $H_2{}^{18}O$ incorporations can be explained by dilutions of isotopically labeled water by intracellular stores of water during the hydration reaction. Reactions conducted under an argon atmosphere with induced resting cells and in cell free extracts without cofactors gave similar products (data not shown), supporting

[a]Vanillyl alcohol was oxidized by cell free extracts containing $NADP^+$ at a rate of 101.2 μM sec^{-1} with a ΔmAbs sec^{-1} of 0.630.

the proposed hydration mechanism. The addition of water to a styrene double bond through a hydration mechanism and not by activation and insertion of molecular oxygen through an epoxide intermediate has not been observed before, except with a mixed anaerobic microbial consortium (14).

Hopper and co-workers (22) reported **17** and **18** as the products of *Pseudomonas* sp. derived, flavoprotein-catalyzed oxidations of 4-ethylphenol (**19**). 4-Ethylphenol methylenehydroxylase, *p*-cresol methylhydroxylase, and vanillyl alcohol oxidase (17, 22, 23) are all flavoproteins that oxidize 4-ethylphenol (**19**) to a proposed quinoid intermediate (**16**) similar to that proposed here for *Nocardia* sp. with **15**. The *R* vs. *S* stereochemistry of **17** produced in flavoprotein-mediated reactions varies with the enzyme used, and may be affected by the addition of electron acceptors (17). Heresztyn (24) and Eldin et al. (25) showed that 4-vinylphenol (**15**) could be microbiologically reduced to 4-ethylphenol (**19**). To rule out a combination of the 4-vinylphenol reduction and coupled flavoprotein oxidation of 4-ethylphenol (**19**) to **17**, *Nocardia* sp. was incubated with **19**. No metabolites were obtained, thus ruling out this oxidative pathway and the benzylic hydroxylation of **19** to **17**.

Enantiospecificity of 4-vinylphenol hydration

The stereospecificity of *Nocardia* 4-vinylphenol hydration was established by chiral HPLC comparison of **17** formed by *Nocardia* cultures to *S*-(–)-**17** prepared by *Pseudomonas fluorescens* lipase resolution of racemic **17** (17, 26). Chromatograms (Fig. 1) for racemic **17** (Fig. 1A), lipase resolved *S*-(–)-**17** (Fig. 1B), and **17** from incubation reactions (Fig. 1C.) clearly show that **17** produced by *Nocardia* is predominantly *S*-(–)-**17**. We then compared the enantiomeric purity of **17** formed by hydration of **15** vs. time (Table 3). From 24 to 144 h, yields of **17** ranged from 4% to about 25%, while the ee of *S*-(–)-**17** decreased from 90% at 24 h to 84% at 144 h. Over time, the reduction of **18** to **17**, a less favorable reaction over all, progressed from 0.5% at 24 h to about 6% at 144 h, while the ee of *S*-(–)-**17** ranged from 98 to 86% (Table 3). These results indicate that hydration occurs preferentially by *si*-face delivery of water to **16**, and that the reduction of **18** occurs preferentially by *re*-face hydride delivery. As both reactions progressed, the ee% decreased, suggesting the enhancement of *R*-(+)-**17** by reaction reversibility, or the involvement of more than one alcohol dehydrogenase with varying enantiospecificity or selectivity. In this regard, when racemic **17** was oxidized to **18**, small excesses of *R*-(+)-**17** (7.7% ee) accumulated as the reaction time and yield progressed (52% yield at 144 h) (Table 3).

Substrate specificity of alcohol dehydrogenase in cell-free *Nocardia* extracts

Both $NADP^+$ and NAD^+ were co-factors in the oxidation of **17** to **18** in *Nocardia* cell free extracts. The alcohol oxidation reaction, however, was nearly 17 times more favorable with $NADP^+$. The range of substrates used by the crude enzyme preparation was broad, as shown in Table 4. Among the primary alcohols, phenolic benzyl alcohols were favorable substrates with vanillyl alcohol giving the highest relative oxidation rates. Among the mono-phenolic benzyl alcohols, 4-hydroxybenzyl alcohol was most readily oxidized, indicating a preference for and a possible participation of the 4-phenolic moiety in the oxidation reaction. As a group of compounds, aliphatic alcohols including methanol, ethanol, 1-propanol, and 1-butanol were oxidized more readily than secondary alcohols. We compared the relative rates of oxidation vs. reduction of 4-hydroxybenzaldehyde–4-hydroxybenzyl alcohol and benzaldehyde–benzyl alcohol using crude cell free *Nocardia* extracts prepared from cells induced with 4-vinylphenol (**15**). In these preparations, the rate of alcohol oxidation was 13 times greater than aldehyde reduction, while the benzaldehyde reduction was greater by 14 times than the alcohol oxidation of benzyl

Dioxygenase-catalyzed *cis*-dihydroxylation of pyridine-ring systems

Derek R. Boyd, Narain D. Sharma, Ludmila V. Modyanova, Jonathan G. Carroll, John F. Malone, Christopher C.R. Allen, John T.G. Hamilton, David T. Gibson, Rebecca E. Parales, and Howard Dalton

Abstract: Toluene dioxygenase-catalyzed dihydroxylation, in the carbocyclic rings of quinoline, 2-chloroquinoline, 2-methoxyquinoline, and 3-bromoquinoline, was found to yield the corresponding enantiopure *cis*-5,6- and -7,8-dihydrodiol metabolites using whole cells of *Pseudomonas putida* UV4. *cis*-Dihydroxylation at the 3,4-bond of 2-chloroquinoline, 2-methoxyquinoline, and 2-quinolone was also found to yield the heterocyclic *cis*-dihydrodiol metabolite, (+)-*cis*-(3*S*,4*S*)-3,4-dihydroxy-3,4-dihydro-2-quinolone. Heterocyclic *cis*-dihydrodiol metabolites, resulting from dihydroxylation at the 5,6- and 3,4-bonds of 1-methyl 2-pyridone, were isolated from bacteria containing toluene, naphthalene, and biphenyl dioxygenases. The enantiomeric excess (ee) values (>98%) and the absolute configurations of the carbocyclic *cis*-dihydrodiol metabolites of quinoline substrates (benzylic *R*) and of the heterocyclic *cis*-diols from quinoline, 2-quinolone, and 2-pyridone substrates (allylic *S*) were found to be in accord with earlier models for dioxygenase-catalyzed *cis*-dihydroxylation of carbocyclic arenes. Evidence favouring the dioxygenase-catalyzed *cis*-dihydroxylation of pyridine-ring systems is presented.

Key words: dioxygenases; *cis*-dihydroxylation, pyridines, 2-pyridones, absolute configurations.

Résumé : On a trouvé que la dihydroxylation des carbocycles de la quinoléine, de la 2-chloroquinoléine, de la 2-méthoxyquinoléine et de la 3-bromoquinoléine, catalysée par la dioxygénase du toluène en utilisant des cellules complètes de *Pseudomonas putida* UV4, conduit aux métabolites correspondants énantiopurs, les *cis*-5,6- et 7,8-dihydrodiols. On a aussi observé que la *cis*-dihydroxylation de la liaison 3,4 de la 2-chloroquinoléine, de la 2-méthoxyquinoléine et de la quinoléin-2-one conduit au métabolite hétérocyclique *cis*-dihydrodiol (+)-*cis*-(3*S*,4*S*)-3,4-dihydroxy-3,4-dihydroquinoléin-2-one. Lorsqu'on a utilisé des bactéries contenant des dioxygénases du toluène, du naphtalène et du biphényle, on a isolé des métabolites hétérocycliques *cis*-dihydrodiols qui résultent d'une dihydroxylation aux niveaux des liaisons 5,6- et 3,4- de la 1-méthylpyridin-2-one. Les valeurs des excès énantiomériques (ee) (>98%) et les configurations absolues des métabolites des *cis*-dihydrodiols carbocycliques des substrats à base de quinoléine (groupe benzylique étant *R*) et des *cis*-diols hétérocycliques dérivés de substrats à base de quinoléine, de quinoléin-2-one et de pyridin-2-one (groupe allylique étant *S*) sont en accord avec les modèles antérieurs pour les réactions de *cis*-dihydroxylation des arènes carbocycliques catalysées par la dioxygénase. On présente des données favorisant la *cis*-dihydroxylation catalysée par la dioxygénase de systèmes à noyau pyridine.

Mots clés : dioxygénase, *cis*-dihydroxylation, pyridines, pyridin-2-ones, configurations absolues.

[Traduit par la Rédaction]

Introduction

The initial step in the bacterial metabolism of aromatic rings often proceeds via dioxygenase-catalyzed asymmetric dihydroxylation to yield *cis*-dihydrodiol metabolites (1–5). Polycyclic arenes and azaarenes (Scheme 1) are amongst the wide range of substrates (> 400) found to yield carbocyclic *cis*-dihydrodiol metabolites (2, 3).

To date, however, only a small number of *cis*-dihydrodiols has been obtained from enzymatic *cis*-dihydroxylation of

aromatic heterocyclic rings. These are generally derived from electron-rich five-membered aromatic heterocycles including thiophenes (e.g., **13**), benzothiophenes (e.g., **15**), and benzofurans (e.g., **17**) (Scheme 2).

Heterocyclic *cis*-diols $\mathbf{14}_{cis}$, $\mathbf{16}_{cis}$, and $\mathbf{18}_{cis}$ were found to spontaneously isomerize to the corresponding *trans*-isomers, $\mathbf{14}_{trans}$, $\mathbf{16}_{trans}$, and $\mathbf{18}_{trans}$ (6, 7). No direct evidence of dioxygenase-catalyzed *cis*-dihydroxylation of electron-poor heterocyclic arenes such as pyridine and quinoline has been reported (8–12). Alternative pathways for the bacterial metabolism of pyridine and quinoline rings, including azaarene hydration and monohydroxylation have, however, been discovered (8–12).

cis-Dihydroxylation of the carbocyclic ring and monohydroxylation of the azaarene ring in quinoline (**1**), isoquinoline, quinoxaline, and quinazoline substrates has been reported in *Pseudomonas putida* UV4 (12, 13). Unfortunately, the yields of *cis*-dihydrodiols obtained were generally low. A preliminary study from these laboratories on the biotransformation of quinoline substrates containing a substituent at C-2, such as azaarenes **2** and **3**, has shown that the yield of the corresponding carbocyclic *cis*-dihydrodiols **7**–**10** can be significantly increased (Scheme 1) (14). An unexpected heterocyclic *cis*-diol **12** was also isolated from quinoline substrates **2** and **3**. The possibility of *cis*-dihydroxylation occurring in the heterocyclic ring, either via the corresponding *cis*-dihydrodiols **20** and **21** or via benzo-fused 2-pyridone intermediate **24** as a precursor of metabolite **12**, was also briefly addressed (Scheme 3) (14).

Direct evidence of the stereoselective *cis*-dihydroxylation of a monocyclic 2-pyridone ring (**28**) to yield heterocyclic *cis*-diols **29** and **30** has recently been reported by Modyanova and Azerad (Scheme 4) (15, 16).

Results and discussion

A major objective of the present study was to conduct a more comprehensive search for evidence of dioxygenase-catalyzed *cis*-dihydroxylation of pyridine-ring systems — a topic that has received little attention in the literature (8–12). In this context, the reported bacterial *cis*-dihydroxylation of the benzo-fused pyridines **2**–**4** (14) and 2-pyridones **24** and **28** (15, 16) has now been re-examined. This extension of earlier work (12–16) involves a wider range of dioxygenases and substrates, with emphasis on the absolute configurations and enantiopurities of metabolites formed by *cis*-dihydroxylation of either the carbocyclic or the heterocyclic ring.

The biotransformation studies were carried out using mutant and recombinant strains of bacteria containing different types of ring-hydroxylating dioxygenase enzymes (Rieske-type nonheme iron oxygenases) (4), devoid of the corresponding *cis*-diol dehydrogenase enzymes, which are responsible for dehydrogenation of *cis*-dihydrodiols to the corresponding catechols. These mutant strains included *Pseudomonas putida* UV4 (a source of toluene dioxygenase, TDO) (17), *P. putida* 9816/11 (a source of naphthalene dioxygenase, NDO) (18), and *Sphingomonas yaniokuyae* B8/36 (a source of biphenyl dioxygenase, BPDO) (19). Recombinant strains used included *Escherichia coli* pKST11 (a source of TDO) (20) and *E. coli* JM 109 (DE3) pDTG141 (a source of NDO) (21) (Table 1).

Earlier studies of the biotransformation of parent quinoline substrate **1** with *P. putida* UV4 showed that diols could be formed by *cis*-dihydroxylation at the 5,6-bond (to yield the major *cis*-diol **5**) and the 7,8-bond (to yield minor *cis*-diol **6**) of the carbocyclic ring (12, 13) in relatively low yields (<10%). Other bioproducts of quinoline (**1**) included 3-hydroxy quinoline (**25**) and anthranilic acid, which could have resulted from *cis*-dihydroxylation at the 3,4-bond in the pyridine ring followed by decompositon of unstable 3,4-*cis*-diol **19** (Scheme 3, path A) (12, 13). When 2-chloroquinoline (**2**) was added as a substrate to the same strain, *cis*-dihydroxylation was found to occur preferentially within the carbocyclic ring at the 7,8-bond to give dihydrodiol **8** (20% yield) and also at the 5,6-bond to yield diol **7** (9% yield). A

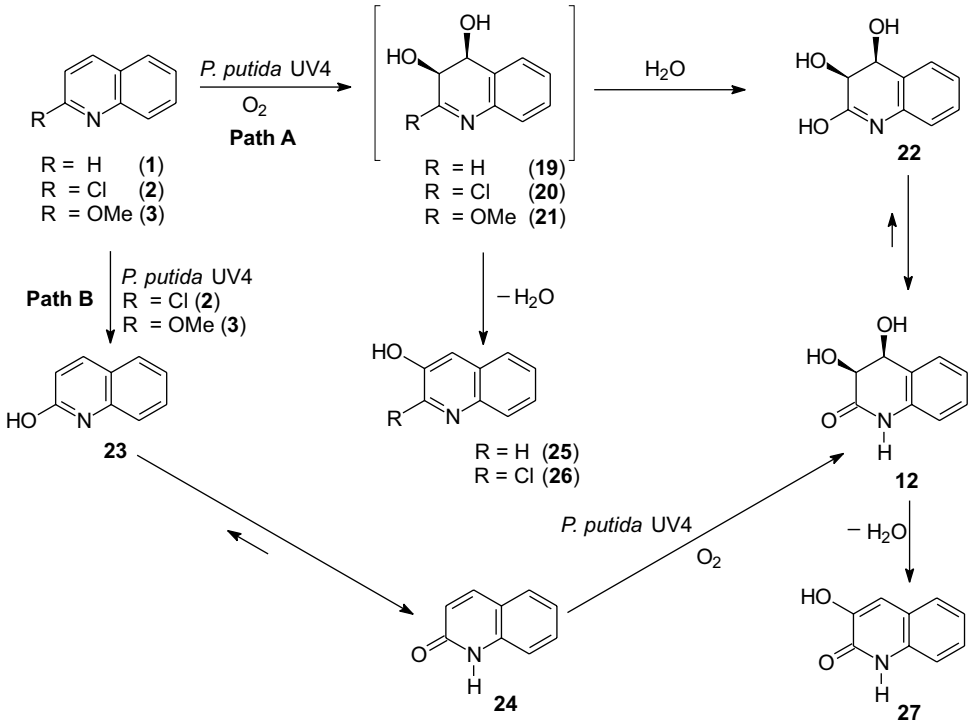
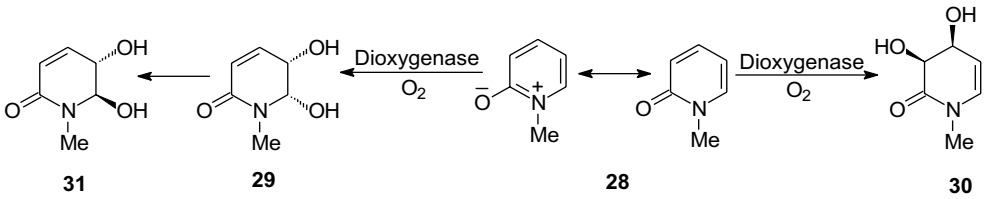


Scheme 4.



similar trend was found using the TDO-containing recombinant strain (*E. coli* pKST11), where diols **8** (11% yield) and **7** (4% yield) were isolated. The bacterial strains containing NDO showed a preference for *cis*-dihydroxylation at the 7,8-bond to give diol **8** (15% yield using *P. putida* 9816/11 and 5% yield using *E. coli* JM 109). 5,6-Dihydrodiol **7** was also produced using *P. putida* 9816/11 (6% yield). *S. yanoikuyae* B8/36 and *P. fluorescens* Q1 (a wild-type strain grown on quinoline as a carbon source) only yielded *cis*-7,8-dihydrodiol **8** (15% and 1% yields, respectively, Table 1). These results are similar to those reported earlier on the bacterial biotransformation of **1** using *P. putida* 86 (a wild-type strain grown on quinoline as a carbon source) (22). In the latter example, compound **8**, of unspecified ee and absolute configuration, was reported to be the sole *cis*-dihydrodiol metabolite (22).

cis-Diol bioproducts **7** and **8**, obtained from TDO-, NDO-, and BPDO-catalyzed asymmetric dihydroxylation of 2-chloroquinoline (**2**), were all found to be enantiopure (>98% ee) based on the ^{1}H NMR spectral analyses of the corresponding cyclic-boronate derivatives formed by using (–)-(*S*)- and (+)-(*R*)-2-(1-methoxyethyl)benzeneboronic acid (MEBBA). This method has previously been used to determine the absolute configurations of both mono- and polycyclic *cis*-dihydrodiol metabolites (23–25). From a comparison of the characteristic chemical-shift values of the MeO signals in the ^{1}H NMR spectra of the MEBBA esters (23–25) and the circular dichroism (CD) spectral data (compared with parent *cis*-dihydrodiols **5** and **6** of known configurations), metabolites **7** and **8** were assigned the 5*R*,6*S* and 7*S*,8*R* configurations, respectively.

The two major carbocyclic *cis*-dihydrodiols **7** (R_f = 0.3, 8% yield) and **8** (R_f = 0.45, 18% yield), isolated from the biotransformation of **2** using *P. putida* UV4, were accompanied by a more polar metabolite, **12** (R_f = 0.14, 2% yield). X-ray crystallographic analysis, using the anomalous dispersion method, confirmed that bioproduct **12** was an enantiopure sample of (3*S*,4*S*)-3,4-dihydroxy-3,4-dihydro-2-quinolone (**12**) (14). While neither the corresponding MEBBA-boronate derivatives nor the corresponding diMTPA esters could be synthesized, the enantiopurity of *cis*-diol **12** was confirmed as >98% ee (^{1}H NMR analysis) by the formation of a single diastereoisomer of the monocamphanate ester at C-4. It is noteworthy that, with the exception of *P. putida* UV4, no evidence of the more polar *cis*-dihydrodiol metabolite **12** was found with the other five dioxygenase-containing strains. When the biotransformation of **2** was repeated on a larger scale (50 g substrate **2** in 100-L fermenter using *P. putida* UV4) and a more rigorous extraction procedure involving total removal of water prior to extraction was

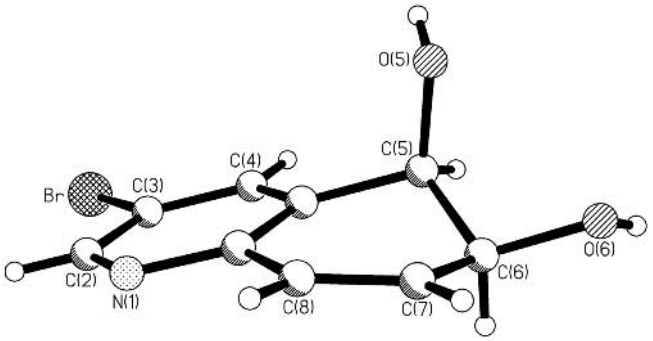
[a]All *cis*-dihydrodiols were enantiopure (>98% ee).

adopted, two additional metabolites were found. Carbocyclic *cis*-dihydrodiols **7** (ca. 5.4 g, 9%) and **8** (ca. 12.0 g, 20%) and the heterocyclic *cis*-diol **12** (ca. 3.1 g, 6%), were again the major bioproducts; the new metabolites were identified as 2-chloro-3-hydroxyquinoline (**26**) (ca. 0.5 g, 1%) and 3-hydroxy-2-quinolone (**27**) (ca. 1.5 g, 3%). It is probable that **27** was obtained by dehydration of the *cis*-diol **12** during the work-up procedure, since its dehydration was observed upon treatment with acid or at elevated temperatures. The presence of the minor phenolic metabolite (**26**) could be accounted for by the spontaneous dehydration of the transient *cis*-dihydrodiol **20**. When the total yields of 2-chloroquinoline metabolites **12**, **26**, and **27** are combined, the dioxygenase-catalyzed oxidation in the heterocyclic ring clearly emerges as a significant metabolic pathway (ca. 10% yield) compared with the total yield (ca. 29%) of carbocyclic ring *cis*-dihydroxylation products **7** and **8** (Scheme 3, path A).

2-Methoxyquinoline (**3**) also proved to be a substrate for *P. putida* UV4; it yielded, from dihydroxylation at the 5,6- and 7,8-positions, the anticipated carbocyclic *cis*-dihydrodiols **9** (R_f = 0.30, 2% yield) and **10** (R_f = 0.40, 7% yield), respectively (Scheme 1). Formation of the corresponding MEBBA derivatives, and CD comparison with *cis*-dihydrodiols **5** and **6**, indicated that metabolites **9** and **10** were enantiopure (>98% ee) and of the 5*R*,6*S* and 7*S*,8*R* configurations, respectively. The major metabolite (R_f = 0.14, 13% yield), formed from 2-methoxyquinoline (**3**) as the substrate and *P. putida* UV4 as a dioxygenase source, was *cis*-diol metabolite **12** of identical configuration (3*S*,4*S*) and enantiopurity (>98% ee) to that found earlier using **2** as substrate. Only 7,8-*cis*-dihydrodiol **10**, of identical ee value and absolute configuration, was obtained using NDO (*P. putida* 9816/11, *E. coli* JM 109) or BPDO (*S. yanoikuyae* B8/36) as the biocatalysts and **3** as the substrate (Table 1).

Fig. 1. X-ray structure of *cis*-diol **11**.



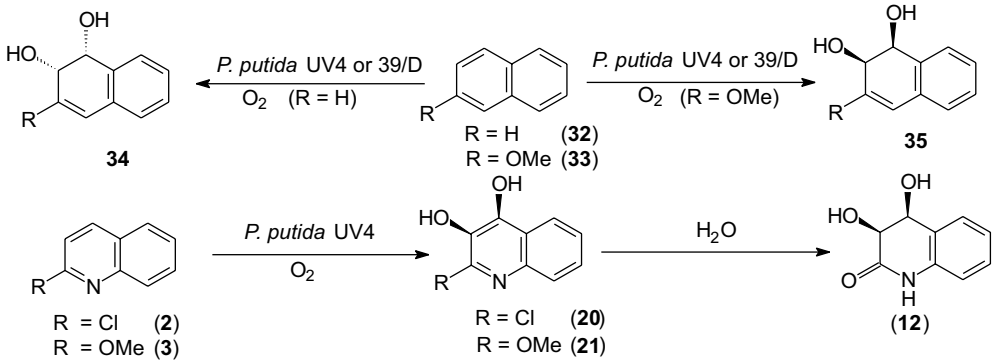
To decrease the possibility of dioxygenase-catalyzed *cis*-dihydroxylation of the heterocyclic ring, 3-bromoquinoline (**4**) was examined as a substrate with TDO (*P. putida* UV4). As anticipated, no hydroxylation occurred at the blocked 3,4-bond in the pyridine ring; the sole metabolite, *cis*-dihydrodiol **11** (23% yield) was enantiopure (>98% ee, (NMR analysis of the MEBBA-boronate derivatives), and resulted from attack at the 5,6-bond. The structure and absolute stereochemistry of *cis*-diol **11** was determined by X-ray crystallography using the anomalous dispersion method (Fig. 1). It again confirmed that 3-bromo-*cis*-5,6-dihydroxy-5,6-dihydroquinoline (**11**) was a single enantiomer and had a 5*R*,6*S* configuration, similar to the other 5,6-*cis*-dihydrodiol metabolites of substituted quinolines (e.g., **7** and **9**). The crystal structure of diol **11** showed no evidence of intramolecular H-bonding, but six intermolecular H-bonding interactions to four neighbouring molecules were observed.

Two feasible mechanisms could account for the formation of heterocyclic *cis*-dihydrodiol metabolite **12** during biotransformation of **2** and **3** in cultures of *P. putida* UV4. The first mechanism assumes that unstable *cis*-dihydrodiols **20** and **21** are the initial products of the direct dihydroxylation of the pyridine rings in the corresponding 2-substituted quinoline substrates, **2** and **3**, respectively (Scheme 3, path A). The postulated intermediates, imidoyl halide **20** and imidate **21**, are likely to spontaneously hydrolyze to yield trihydroxy product **22**, which exists preferentially as 2-quinolone tautomer **12**. Initial metabolites **20** (from **2**) and **19** (from **1**) (12, 13) could also dehydrate yielding the corresponding 3-hydroxyquinolines **26** and **25**, respectively. This evidence, based on the isolation of metabolites **12**, **25**, and **26**, is consistent with the mechanism shown in path A (Scheme 3).

The observation of the "NIH shift" has recently been shown to occur when aromatic hydroxylation proceeds via ei-

© 2002 NRC Canada

Scheme 5.



ther arene oxide isomerization (monooxygenase pathway) or *cis*-dihydrodiol dehydration (dioxygenase pathway) (26). Biotransformation of 3-deuterioquinoline (**1**) using *P. putida* UV4 yielded 3-hydroxyquinoline (**25**), with concomitant migration and retention of the deuterium atom (20% D) at an adjacent carbon atom, i.e., the NIH shift was observed (26). This provides further evidence in support of the formation of unstable *cis*-dihydrodiol **19** derived from the pyridine ring in substrate **1** (Scheme 3, path A).

A comparison of the enantiopurity and absolute configuration of *cis*-dihydrodiol metabolites **34** and **35**, obtained from naphthalene (**32**) and 2-methoxynaphthalene (**33**), respectively (27), with *cis*-dihydrodiol intermediates **20** and **21** from **2** and **3**, respectively, showed striking similarities (Schemes 1 and 5). The major *cis*-dihydrodiol metabolites from **33** were formed at the 5,6- and 7,8- bonds in the unsubstituted ring with TDO (using both *P. putida* 39/D and UV4) as biocatalyst (27); these *cis*-diols, derived from a carbocyclic ring, were of the normal benzylic *R* configuration as found in other bicyclic arenes, such as *cis*-diols **5**–**11** and **34**. Enantiopure *cis*-dihydrodiol **35**, a minor metabolite of **33** (27) was, however, found to have the opposite absolute configuration (benzylic *S*) to that normally found in carbocyclic rings (Schemes 1 and 5).

2-Substituted quinoline substrates **2** and **3** may be considered as isosteres of **33** and, when accepted as substrates by the TDO enzyme, would be expected to form *cis*-diols **20** and **21**, respectively, having the same absolute configuration (benzylic *S*) and enantiopurity as *cis*-diol **35** (>98% ee). As reported earlier, heterocyclic *cis*-diol metabolite **12** was a single enantiomer of identical absolute configuration (benzylic *S*). This observation provides additional indirect evidence favouring dioxygenase-catalyzed *cis*-dihydroxylation of the pyridine ring of substrates **2** and **3** to form the corresponding unstable metabolites **20** and **21**, respectively, as precursors of *cis*-diol **12** (Scheme 3, path A).

Direct evidence of the involvement of *cis*-dihydrodiol intermediates in the initial TDO-catalyzed biotransformation step of electron-rich five-membered aromatic rings was presented earlier (Scheme 2) (6, 7). Indirect evidence of dioxygenase-catalyzed dihydroxylation of the pyrrole ring in indole is also available. Thus, in the manufacture of indigo dye (28, 29), the spontaneous dehydration of the transient *cis*-dihydrodiol metabolite of indole to yield indoxyl (which further undergoes autoxidation) is assumed to occur. Until recently, it was not possible to find direct evidence of *cis*-dihydrodiol formation in the pyridine ring. The electron-poor pyridine-ring system has generally proved to be extremely resistant to dioxygenase-catalyzed *cis*-dihydroxylation where alternative metabolic routes are available. In the case of pyridine-substituted thioethers and arenes, dioxygenase-catalyzed oxidation has been observed only at the sulfur atom (sulfoxidation) (30) or at the carbocyclic ring (*cis*-dihydroxylation) (unpublished data).

In the light of recent direct evidence for *cis*-dihydroxylation of 1-methyl-2-pyridone (**28**) (15, 16), a second mechanism, to account for the formation of *cis*-dihydrodiol **12** from the 2-substituted quinolines **2** and **3**, was considered (Scheme 3, path B). Chemical or enzyme-catalyzed hydrolysis of the quinoline substrates could, in principle, occur in the aqueous-culture medium prior to the *cis*-dihydroxylation process yielding 2-hydroxyquinoline (**23**), which exists mainly as the 2-quinolone tautomeric form (**24**). The halogen and alkoxy substituents at C-2 in the pyridine ring of compounds **2** and **3** are susceptible to hydrolysis via an addition–elimination mechanism normally under acidic conditions. An aqueous–methanolic solution (D_2O–CD_3OD) of **2**, when heated (~45°C) for an extended period, did not undergo hydrolysis, suggesting that it was unlikely that more than a small proportion of substrates **2** and **3** would have hydrolyzed under the relatively mild aqueous conditions that existed during the biotransformation. GC–MS analysis, conducted during the course of the biotransformation of quinoline substrate **2**, showed minute traces of 2-quinolone (**24**) among the bioproducts, which could be due to chemical and (or) enzyme-catalyzed hydrolysis.

To test if **24** was a substrate, it was added to whole cells of *P. putida* UV 4. The corresponding *cis*-dihydrodiol (**12**) was found as the sole metabolite with an identical ee value (>98%) and absolute configuration (3*S*,4*S*) to that isolated from 2-substituted quinoline substrates **2** and **3**, but in a relatively low yield (10%). This observation confirms that metabolite **12** could be derived from **24**. Despite the latter result, the balance of evidence appears to favour path A and involvement of the transient *cis*-diol metabolites **20** and **21** as precursors of heterocyclic *cis*-diol **12**. A recent report of the TDO-catalyzed 3-hydroxylation of 4-picoline (4-methylpyridine) has assumed, without evidence, the initial formation of an unstable *cis*-dihydrodiol metabolite of the pyridine ring (31); the results presented in this study support this conclusion.

The NDO-catalyzed dihydroxylation of the pyridone ring in **28** has recently been found to yield two interesting and

relatively stable *cis*-diol metabolites, **29** and **30** (Scheme 4) (16).

In an extension of our earlier work on TDO-catalyzed formation of heterocyclic *cis*-diol **12** from substituted 2-pyridone **24** (14), a programme was undertaken to examine the range of dioxygenases capable of producing *cis*-diols **29** and **30** from pyridone **28**. It was hoped that this would result in higher yields (particularly of the very minor regioisomer **30**), and would allow absolute configurations to be assigned to *cis*-diols **29** and **30**. These *cis*-diol metabolites may be considered as synthetic precursors of polyhydroxylated piperidines, several of which have already been identified as potent inhibitors of glycosidases (32).

An evaluation of the relative merits of the NDO, BPDO, and TDO enzyme systems in the *cis*-dihydroxylation of 1-methyl-2-pyridone (**28**) was carried out by GC–MS analysis. Both of the *cis*-dihydrodiols, **29** and **30**, were found to be detectable and separable as the corresponding bis-trimethylsilyl ethers (*m*/*z* 287). Some evidence of the isomerization of *cis*-diol **29** to *trans*- isomer **31** was found during the analytical process. The yield of the initially formed major diol metabolite **29** from **28** was estimated from the combined yields of *cis*-and *trans*-diols **29** and **31**, respectively.

A range of mutant (*P. putida* 9816/11, *S. yaniokuyae* B8/36, *P. putida* UV 4) and recombinant strains (*E. coli* JM 109 (DE3) pDTG141) (which had previously been used with bicyclic substrates **2** and **3**) and a site-directed mutant (*E. coli* JM 109 (DE3) pDTG141 strain 352V), were applied to the monocyclic substrate **28**; the relative ratios of products are given in Table 2.

Naphthalene dioxygenase, present in *P. putida* 9816/11 and *E. coli* JM 109 (DE3) pDTG141, was found to give a similar ratio of *cis* isomers favouring 5,6-regioisomer **29** (93–96%) and a comparable isolated yield (41–52%). When a site-directed mutant strain was used, where phenylalanine 352 had been replaced by valine (352-V), the isolated yield decreased (10%) but the regioselectivity increased to exclusively yield metabolite **29**. Although the highest proportion of the minor *cis*-diol regioisomer **30** (10% relative yield) was obtained with the BPDO enzyme system, this was offset by a much lower isolated yield (2%). The observation that a monocyclic compound, having a significant degree of aromatic character, was a substrate for both the NDO and BPDO systems was surprising, since only a small number of monocyclic arene derivatives have proved to be substrates for these enzymes. In contrast, more than 200 monocyclic arenes have proved to be acceptable substrates with TDO (2, 3). Surprisingly, when **28** was added as a substrate to *P. putida* UV4, *cis*-diol **29** was detected in very low yield (<1%); the substitution pattern and polarity of substrate **28** may have been contributing factors to the low yield.

The structure and relative stereochemistry of 2-pyridone *cis*-dihydrodiols **29** and **30** were established earlier on the basis of rigorous NMR spectral analysis (16). Similar spectral data was obtained during the current study. In addition, the structure of major *cis*-diol **29** ($[\alpha]_D$ +40, MeOH) was confirmed by X-ray crystallography (Fig. 2); it showed that the C-5 and C-6 hydroxyl groups were in a *cis* relationship with pseudo-equatorial and pseudo-axial conformations, re-

Scheme 6.

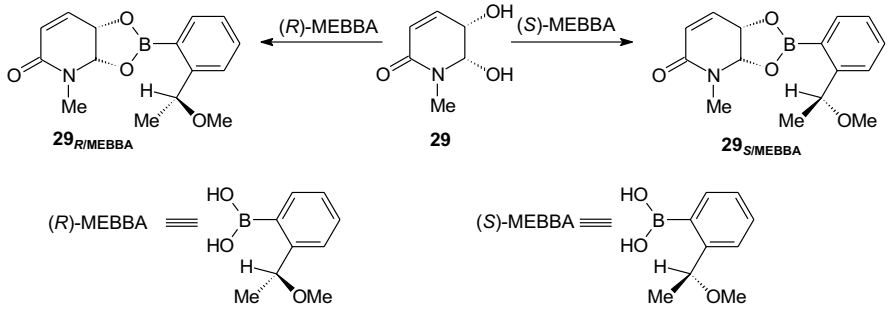

Fig. 4. CD spectra of the *cis*-diols (3*S*,4*S*)-**12**, **(**5*S*,6*S*)-**29** and **(3***S*,4*S*)-**30**.

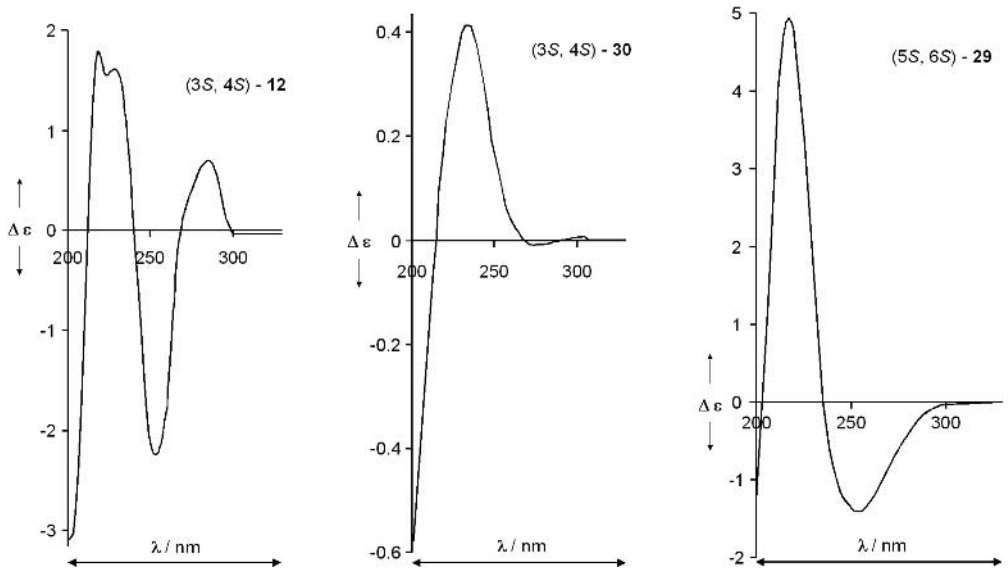


spectively. The adoption of a pseudo-axial conformation by the OH group at C-6 appears to be the result of steric interaction with the *N*-methyl group. The pseudo-axial conformation of the OH group proximate to a substituent and the formation of a single enantiomer are common features of *cis*-dihydrodiol metabolites of monosubstituted benzene substrates (14, 30). For comparison purposes, the X-ray crystal structure of heterocyclic *cis*-diol **12** is shown in Fig. 3 (14). The OH group at C-4 in **12** and at C-6 in **29** are both pseudo-axial due to steric constraints.

The crystal structure analysis also showed that the sample was enantiopure. There was no evidence of intramolecular H-bonding, but five intermolecular H-bonding interactions to four neighbouring molecules were observed.

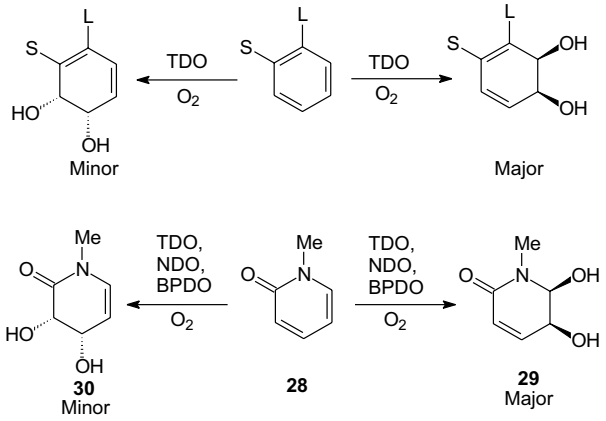
From the relative chemical shift positions of methoxyl signals of the cyclic boronate derivatives $\mathbf{29}_{R/\text{MEBBA}}$ (δ_{MeO} 3.24) and $\mathbf{29}_{S/\text{MEBBA}}$ (δ_{MeO} 3.22), a 5*S*,6*S* absolute configuration was tentatively assigned (23–25) to major *cis*-diol **29**; the boronates also confirmed its enantiopurity (>98% ee) (Scheme 6).

In the determination of absolute stereochemistry via analysis of the X-ray crystal structure (using the anomalous dispersion method), the refinement of the Flack (33) absolute-structure parameter (*x*) ideally yields a value of zero for the correct enantiomer and a value of unity for the incorrect enantiomer. In the analysis of *cis*-diol **29**, using the anomalous dispersion method, *x* was refined to a final value of 0.24 (35) for the 5*S*,6*S* enantiomer. This implies that, at a confidence level above 2σ (i.e., >95%), the inverse 5*R*,6*R* structure can be rejected, and hence the true configuration has to be 5*S*,6*S*. Although this indicates an emphatic preference, it fails to meet the commonly accepted level (3σ, 99.8%), which is regarded as equating to statistical certainty. (An independent refinement of the inverse structure (5*R*,6*R*) gave $x = 0.76$ (35), which also independently implies that this configuration can be rejected at better than the 2σ level, albeit not at the preferred 3σ level.)

The circular dichroism (CD) spectra of the bicyclic 3*S*,4*S*-*cis*-diol **12** and monocyclic diols **29** and **30** provided strong supporting evidence for the stereochemical assignments (Fig. 4). Based on a comparison of CD spectra of *cis*-diols **12**, **29**, and **30**, where a strong positive CD absorption was found at lower wavelengths (210–250 nm) and a weaker negative CD absorption at longer wavelengths (235–300 nm), a similar absolute configuration can be assigned to each of the *cis*-diol metabolites. Since the 3*S*,4*S* configuration of (+)-*cis*-diol **12** was rigorously established by X-ray crystallography, monocyclic *cis*-diols **29** and **30** should thus have the 5*S*,6*S* and 3*S*,4*S* configurations, respectively. Since the major *cis*-diol (**29**) was found to be a single enantiomer of 5*S*,6*S* configuration, *trans* isomer (+)-**31** ($[\alpha]_D$ +207, MeOH), obtainable upon gentle heating at ca. 50°C (16) (via

© 2002 NRC Canada

Scheme 7.



reversible ring opening to the corresponding aldehyde) must have a 5*S*,6*R* configuration.

Due to the very low relative yield (<10%) of the minor *cis*-diol (**30**) (Table 2), it was not possible to carry out its complete characterization. The presence of **30** was confirmed by ^{1}H NMR, MS, and GC–MS analysis. Unfortunately neither the corresponding diMTPA esters (from *R*- or *S*-α-methoxy-α-(trifluoromethyl)phenylacetic acid) nor the chiral boronate (MEBBA) derivatives (from *R*- or *S*-2-(1-methoxyethyl)phenylboronic acid) could be formed from *cis*-diols **12** and **30**. In both cases, this may have been due to intramolecular hydrogen bonding between the OH group on C-3 and the adjacent carbonyl group. As stated in the preceding paragraph, however, it was assumed from a comparison of the CD specta that minor *cis*-diol **30** was a single enantiomer of 3*S*,4*S* configuration.

The absolute configurations of *cis*-dihydrodiol metabolites **29** and **30** were found to be in accord with a stereochemical model based on the preferred *cis*-dihydrodiol enantiomers obtained from 1,2-disubstituted benzene substrates with TDO as biocatalyst (Scheme 7) (2). Earlier studies of the TDO-catalyzed *cis*-dihydroxylation of a range of mono-, 1,2-, 1,3-, and 1,4-di-substituted benzene substrates have shown that stereo and regioselectivity can be predicted by considering the substituent size (L = large, S = small) (2). If the *cis*-dihydroxylation of **28** (L = Me, S = O) is considered to occur in a similar manner to 1,2-disubstituted benzene substrates (including polycyclic systems) using several dioxygenase enzymes, then the observed relative yields, ee values, and absolute configurations are in accord with the stereochemical template used earlier (Scheme 7) (2). This premise also supports the view that **28** has a considerable degree of aromatic character and an appreciable resonance energy (34).

The heterocyclic *cis*-dihydrodiols from the quinoline and 2-pyridone substrates have potential as chiral ligands (**5**–**11**) and as precursors for the synthesis of azasugars, alkaloids (**29**, **30**), and enzyme inhibitors (**5**–**11**). Studies are currently in progress to evaluate their potential in these areas.

Conclusion

The biotransformation of quinoline ring systems to yield *cis*-dihydrodiol metabolites appears to be a relatively common metabolic pathway and eight examples (**5**–**12**) have been found. Carbocyclic *cis*-dihydrodiol metabolites **7**–**10**, obtained by TDO-catalyzed dihydroxylation, were single enantiomers of identical configuration (benzylic *R*) to *cis*-diols (e.g., **34**) derived from other polycyclic arenes (e.g., **32**) using TDO, NDO, and BPDO as biocatalyst. A novel enantiopure heterocyclic *cis*-dihydrodiol (**12**) was isolated as a metabolite from 2-chloroquinoline (**2**), 2-methoxyquinoline (**3**), and 2-quinolone (**24**). No direct evidence could be obtained for the formation of *cis*-diol metabolites **20** and **21** from *cis*-dihydroxylation of the pyridine ring of substrates **2** and **3**. Strong indirect evidence has, however, been found for the formation of *cis*-diols **19**–**21** as unstable metabolites of a pyridine ring. The absolute configurations of *cis*-diol metabolites **29** and **30**, derived from 1-methyl-2-pyridone (**28**), are consistent with the dioxygenase enzymes being able to accept substrate **28** as a pyridine derivative having a structure similar to 1,2-disubstituted benzene substrates.

Experimental

^{1}H NMR spectra of compounds were recorded on Bruker Avance DPX-300 and DRX-500 instruments. Mass spectra were recorded using a double-focusing triple-sector VG Autospec instrument. Accurate mass measurements were obtained by the peak-matching method using perfluorokerosene as the standard reference and were accurate to within ±0.006 amu. Flash chromatography and PLC were performed on Merck Kieselgel type 60 (250–400 mesh) and $PF_{254/366}$, respectively. Merck Kieselgel $60F_{254}$ analytical plates were used for TLC. Optical rotation ($[\alpha]_D$) measurements were carried out with a PerkinElmer 214 polarimeter at ambient temperature (ca. 20°C) and are given in units of 10^{-1} deg cm^2 g^{-1}. CD spectra were recorded using a JASCO J-720 instrument and spectroscopic-grade methanol as solvent.

GC–MS analysis of the crude EtOAc extract of *cis*-diol metabolites **29** and **30** was carried out after concentration under a stream of dry N_2 and treatment with *N*-methyl-*N*-(trimethylsilyl)trifluoroacetamide to yield the corresponding bis-trimethylsilyl ethers. The GC–MS instrument used consisted of a Hewlett Packard 6890 gas chromatograph directly attached to a Hewlett Packard 5973 Mass Selective Detector. The GC oven was equipped with a Hewlett Packard 7683 autosampler and fitted with a wall-coated open-tubular capillary column (12 m × 0.2 mm) with 100%

© 2002 NRC Canada

dimethyl polysiloxane (0.33 μm) as the bonded phase. The injector port was held at 250°C and the oven was programmed at 100°C for 1 min and then ramped to 300°C at 10°C min^{-1}. Helium was employed as carrier gas at a flow rate of 0.8 mL min^{-1} and the sample (1 μL) was injected at a split ratio of 25:1. Under these conditions the *cis*-diols **29** and **30** and the *trans*-diol **31** were eluted at 7.34, 6.96, and 6.00 min, respectively. The mass-selective detector was operated in the full-scan mode measuring ion currents between *m*/*z* 30 and 450 amu. The relative yields of diols were calculated by comparing the relative peak areas of diols (**29**/**31** and **30**).

Substrates **2**, **4**, **24**, and **28** were obtained from commercial sources. Substrate **3** (35) and (–)-(*S*)- and (+)-(*R*)-2-(1-methoxyethyl)benzene boronic acids were synthesized and used according to literature methods (23–25, 36).

Substrates were metabolized using growing cultures of *P. putida* UV4, a constituent mutant strain devoid of *cis*-diol dehydrogenase activity, according to the reported method (30). *P. putida* 9816/11, an inducible mutant, without the corresponding *cis*-diol dehydrogenase enzyme activity, was grown on minimal-salts medium containing 0.05% sodium succinate. The naphthalene dioxygenase (NDO) present was induced by addition of 0.5% sodium salicylate at the late exponential phase of growth. *S. yanoikuyae*, also an inducible mutant without the corresponding *cis*-diol dehydrogenase enzyme activity, was grown on minimal-salts medium with 0.5% sodium pyruvate and 0.05% of yeast extract; the late exponential phase of growth the biphenyl dioxygenase (BPDO) was again induced by the addition of *m*-xylene (0.05 mL L^{-1}) every 1/2 h for 7 h. When the cells were grown in a 100-L fermenter, continuous addition of the volatile inducer (*m*-xylene) was necessary since it was constantly depleted by the air supply. *E. coli* pKST11 biotransformations were carried on cells grown on minimal-salts medium supplemented with glucose (20 mM), thiamin (1 mM), and ampicillin (100 μg mL^{-1}) at 37°C. TDO activity was induced by the addition of 1 mM isopropyl-β-thiogalactopyranoside (IPTG). The NDO in *E. coli* JM109 was similarly induced by the addition of IPTG. *P. putida* Q1 was grown on minimal-salts medium supplemented with quinoline (0.3 mg mL^{-1}) as the carbon source.

Biotransformation of substrates: isolation and identification of metabolites

2-Chloroquinoline 2 with P. putida *UV4*

Biotransformation (10-L fermenter) of 2-chloroquinoline (**2**) (7.5 g) by *P. putida* UV4, repeated extraction of the aqueous biotransformed material with EtOAc, and removal of solvent from the extract under reduced pressure (Procedure 1), yielded a crude mixture of three *cis*-diols **12**, **7**, and **8**; these were separated by a combination of column chromatography ($CHCl_3$ → 10% MeOH–$CHCl_3$) and PLC (7% MeOH–$CHCl_3$). A larger-scale biotransformation (100-L fermenter) of 2-chloroquinoline **2** (50 g) was also carried out. The bioproducts were isolated by removal of water (reduced pressure) from the biotransformed material followed by hot extraction (45°C) of the residual material with 20% MeOH–EtOAc (Procedure 2). Column chromatography and PLC separations yielded five metabolites: **12**, **7**, **8**, **26**, and **27**. The yields obtained from the small and larger scale biotransformations, respectively, are shown together.

2-Chloroquinoline 2 with* E. coli *pKST11

Biotransformation of **2** (0.6 g) with *E. coli* pKST11, extraction (Procedure 1), and purification by PLC (7% MeOH–$CHCl_3$) yielded (+)-*cis*-(5*R*,6*S*)-2-chloro-5,6-dihydroquinoline-5,6-diol (**7**) (0.029 g, 4%) and (+)-*cis*-(7*S*,8*R*)-2-chloro-7,8-dihydroquinoline-7,8-diol (**8**) (0.080 g, 11%).

2-Chloroquinoline 2 with* P. putida *9816/11

Biotransformation of **2** (0.2 g) with *P. putida* 9816/11, extraction (Procedure 1), and separation by PLC (7% MeOH–$CHCl_3$), yielded (+)-*cis*-(5*R*,6*S*)-2-chloro-5,6-dihydroquinoline-5,6-diol (**7**) (0.014 g, 6%) and (+)-*cis*-(7*S*,8*R*)-2-chloro-7,8-dihydroquinoline-7,8-diol (**8**) (0.036 g, 15%).

2-Chloroquinoline 2 with* E. coli *JM109

Biotransformation of **2** (0.05 g) with *E. coli* JM109, extraction (Procedure 1), and PLC purification (7% MeOH–$CHCl_3$), yielded (+)-*cis*-(7*S*,8*R*)-2-chloro-7,8-dihydroquinoline-7,8-diol (**8**) (0.003 g, 5%).

2-Chloroquinoline 2 with* S. yanoikuyae *B8/36

Biotransformation of **2** (0.5 g) with *S. yanoikuyae* B8/36, extraction (Procedure 1), and PLC purification (7% MeOH–$CHCl_3$), gave (+)-*cis*-(7*S*,8*R*)-2-chloro-7,8-dihydroquinoline-7,8-diol (**8**) (0.091 g, 15%).

2-Chloroquinoline 2 with* P. fluorescens *Q1

Biotransformation of **2** (0.5 g) with *P. fluorescens* Q1, extraction (Procedure 1), and PLC purification (7% MeOH–$CHCl_3$) only yielded (+)-*cis*-(7*S*,8*R*)-2-chloro-7,8-dihydroquinoline-7,8-diol (**8**) (0.006 g, 1%).

2-Methoxyquinoline 3 with* P. putida *UV4

Biotransformation (10-L fermenter) of 2-methoxyquinoline (**3**) (7.0 g) with *P. putida* UV4 and extraction (Procedure 1) of bioproducts followed by separation of the crude mixture through a combination of column chromatography (0 → 10% MeOH–$CHCl_3$) and PLC (7% MeOH–$CHCl_3$) gave three compounds. The most abundent component (1.02 g, 13%) was found to be (+)-*cis*-(3*S*,*4S*)-3,4-dihydroxy-1,2,3,4-tetrahydro-2-quinolinone (**12**), which was indistinguishable from the sample obtained from substrate **3**. The other two components were identified as (+)-*cis*-(5*R*,6*S*)-2-methoxy-5,6-dihydroquinoline-5,6-diol (**9**) and (+)-*cis*-(7*R*,8*S*)-2-methoxy-7,8-dihydroquinoline-7,8-diol (**10**).

*(+)-*cis*-(5R,6S)-2-Methoxy-5,6-dihydroquinoline-5,6-diol (**9**)*

White crystalline solid (0.170 g, 2%); mp 182–184°C (MeOH–$CHCl_3$). R_f = 0.30 (7% MeOH–$CHCl_3$). $[\alpha]_D$ +80 (*c* 0.81, MeOH). *X-ray crystal data for cis-diol **12***

Previously deposited as CCDC 182/770.

1-Methyl-2-pyridone (28) with a range of dioxygenases

Biotransformation of 1-methyl-2-pyridone (**28**) was first carried out using *E. coli* JM109(DE3) pDTG141 an ampicillin-resistant recombinant-strain encoding NDO from *P. putida* 9816–4 and using IPTG as inducer under conditions previously reported (16). This biotransformation was then carried out using the other strains listed in Table 2 employing essentially the same conditions as for substrate **2**. Biotransformation of pyridone **28** with site-directed mutant-strain *E. coli* JM109(DE3) (pDTG141–352V) was carried out as reported (36).

Biotransformations of **28** (0.10 g, dissolved in 1 L of buffer) using strains listed in Table 2, were followed by removal of water by freeze-drying or evaporation under reduced pressure at ~30°C. Extraction of the residue with acetone, yielded a mixture of *cis*-diols **29** and **30**, which were separated by a combination of column chromatography and TLC (MeOH–MeCOMe–$CHCl_3$, 1:1:8). The yields of purified *cis*-diols **29** (major) and **30** (minor) were in the range of 15–20% and 0.7–1.5%, respectively.

(+)-cis-*(5*S*,6*S*)-1-Methyl-5,6-dihydroxy-5,6-dihydro-2-pyridone (**29**)*

Colourless crystals; mp 86–88°C (from CH_2Cl_2). $[\alpha]_D$ +40 (*c* 0.42, MeOH) (lit. (16) $[\alpha]_D$ +41, MeOH). Biomimetic decarboxylative condensation between malonate and acetate units attached to a glycoluril template

Hao Chen and Paul H.M. Harrison

Abstract: Compound **10** (3,4,7,8-tetramethyl-2,5-dithioglycoluril) was converted in two steps to **12a**, which contains a malonate and acetate unit attached to N1 and N6, respectively. These two groups are held in proximity in a manner analogous to the loaded ketosynthase domain of polyketide and fatty acid synthases. After cleavage of the methyl ester by pig liver esterase (PLE), a polar intermediate assigned to acid **15** was separated. This material undergoes conversion to acetoacetylglycoluril **18** upon attempted isolation. The overall conversion thus resembles the decarboxylative condensation catalyzed by ketosynthase. Furthermore, isotope labeling and product studies support a mechanism in which decarboxylation of **15** precedes an intramolecular Claisen-like condensation, as it is believed to occur for the ketosynthase enzymic case. The system thus provides a functional chemical model of the key carbon–carbon bond-forming step in fatty acid and polyketide biosynthesis.

Key words: biomimetic, decarboxylation, polyketide, esterase, Claisen condensation.

Résumé : Le 3,4,7,8-tétraméthyl-2,5-dithioglycouril (**10**) a été transformé en deux étapes en **12a** qui contient des unités malonate et acétate attachées respectivement en N1 et en N6. Ces deux groupes sont maintenus à proximité l'un de l'autre d'une façon analogue de celle que l'on retrouve dans le domaine chargé de la cétosynthase de synthases de polycétides et d'acides gras. Après clivage de l'ester méthylique par une estérase de foie de cochon, on a pu séparer un intermédiaire polaire attribué à l'acide **15**. Lorsqu'on essaye de l'isoler, ce produit se transforme en acétoacétylglycouril, **18**. La conversion globale est donc semblable à une condensation décarboxylante catalysée par la cétosynthase. De plus, un marquage isotopique et une étude des produits sont en accord avec un mécanisme dans lequel la décarboxylation du produit **15** se produit par une condensation intramoléculaire de type Claisen selon l'hypothèse généralement retenue pour le cas de la cétosynthase enzymatique. Le système fournit donc un modèle chimique fonctionnel de l'étape clé de la formation de la liaison carbone–carbone dans la synthèse des acides gras et des polycétides.

Mots clés : biomimétique, décarboxylation, polycétide, estérase, condensation de Claisen.

[Traduit par la Rédaction]

Introduction

The polyketides are a diverse group of natural products that includes many commercially important antibiotics such as erythromycin and monensin (1). The carbon skeletons of these secondary metabolites are derived from repetitive "head-to-tail" condensations of multiple acyl groups, commonly acetate and propionate. Studies on the giant multifunctional polyketide synthases (PKS), and the closely related fatty acid synthases (FAS) have revealed several classes of enzyme (2). The key carbon–carbon bond forming steps catalyzed by the ketosynthase (KS) component(s) of these enzymes, however, always involve the decarboxylative condensation of a malonate or 2-alkylmalonate unit onto an acyl moiety (Fig. 1). These two chemical groups are temporarily attached to KS via covalent thioester bonds that presumably hold and orient the two condensing entities in proximity. Based on early observations that include inversion of configuration at the malonate α-carbon and a lack of solvent isotope exchange, a concerted decarboxylative condensation was proposed (3). More recent data, however, including computational calculations for FAS (4) and experimental results for colletoketol and monocerin (5), support a mechanism in which decarboxylation of the malonate entity furnishes a transient enolate intermediate that is then efficiently trapped by the acyl electrophile. This process thus resembles that of other Claisen enzymes. For example, Knowles and co-workers (6) used the double-isotope fractionation test to establish a sequential deprotonation–condensation mechanism for malate synthase.

A chemical model of this intricate biochemical system could provide a test for the implications of these two distinct mechanisms, and might have use in natural product synthesis. There are, however, few examples of such a biomimic. Scott et al. (7) showed that base-promoted condensation of catechol acetate malonate provides acetoacetyl–catechol in

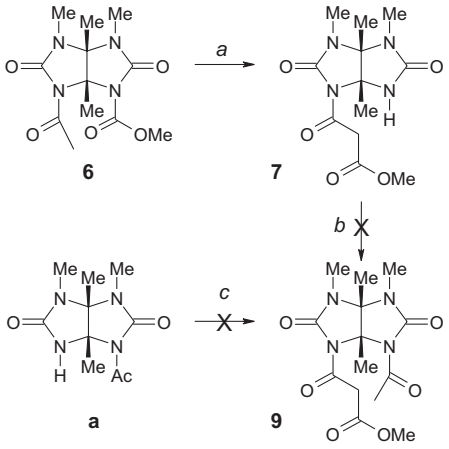
30% yield, but little mechanistic work or extension to effect repetitive cycles of acylation and condensation reactions was reported.

We have previously described the use of 3,4,7,8-tetramethylglycoluril (**1**) (8) as a template to promote intramolecular Claisen-like condensations between two acyl units. Thus, **1** could be converted via monoacyl derivatives **2** to symmetrically or asymmetrically substituted diacylglycolurils **3** (Scheme 1) (9–13). Treatment of **3** with base gives β-ketoacylglycolurils **4** in high yield. Labeling (10) and kinetic (13) studies support a mechanism in which the base abstracts a proton from one acyl group and the resulting enolate **5** is efficiently trapped by the second electrophilic acyl moiety. Subsequent rapid collapse of the ensuing tetrahedral intermediate, and proton transfers, followed by work-up generate **4**. Asymmetric diacylglycolurils afford moderate regioselectivity (ca. 83:17 for acetyl propionyl): the base removes a proton from the less-substituted acyl unit (9–12). The products **4** can be manipulated through a sequence of chemical steps to mimic the functional-group transformations that occur on FAS and PKS. Then, attachment of another acyl group leads to repetitive cycles of condensation and functional group manipulation at the ketone centre, affording fatty acids and polyketides through an iterative biomimetic synthetic sequence (10–12).

Although this system models many facets of the overall assembly of these natural products, the generation of the enolate through a base-promoted deprotonation contrasts with the biosynthetic events in which malonate is decarboxylated. We therefore investigated whether a glycoluril loaded with malonate and acyl groups would undergo decarboxylative condensation (*i*) to test such a system from a mechanistic standpoint; (*ii*) to examine whether enhanced regioselectivity could be obtained through such a method, and (*iii*) to apply the methodology to the synthesis of natural products. Herein we describe our first investigations of such a process and the key role of pig liver esterase in achieving this goal.

Scheme 2. Reagents and conditions: (*a*) KO-*t*-Bu, THF, 0°C, 20 min; (*b*) *n*-BuLi, then AcCl, THF; (*c*) *n*-BuLi, then $MeOC(O)CH_2COCl$ (**8**), THF.



Results

Although we had previously shown that condensation of 1-acetyl-6-carbomethoxyglycoluril (**6**) provides the monomethyl ester of malonylglycoluril **7** (Scheme 2) (10), attempts to acylate **7** with acid chlorides (e.g., AcCl) proved unsuccessful. Presumably, the NH site is less acidic than the malonate α-protons. The reaction of 1-acetylglycoluril with base followed by monomethylmalonyl chloride **8** also failed to furnish target compound **9**.

We therefore investigated the attachment of **8** to thio analog **10**, which had previously been shown to be more readily acylated than **1**. Treatment of **10** with *n*-BuLi followed by **8** furnished **11** in 40% yield (unoptimized; see Scheme 3). Acetylation of **11** at the N6 position with AcCl readily gave **12a** (66%). The reverse sequence, acetylation of **10** followed by acylation with **8**, failed to give **12a**, for reasons that remain unclear. Acylation of **11** with isobutyryl chloride or benzoyl chloride proceeded similarly, to furnish **13** and **14**, respectively.

We then turned our attention to the hydrolysis of the methyl ester functionality in **12a** to afford malonic acid **15**. Various chemical agents, including aqueous acidic or basic conditions, as well as TMSI (14), KO-*t*-Bu–DMSO (15), and KOTMS (16) failed to cleave the methyl ester, resulting in decomposition or partial conversion to products of acyl–nitrogen cleavage (**10** and **11**). We therefore examined the milder conditions and higher selectivity offered by enzymatic hydrolysis (17). Thus **11** and **12a** were separately treated with pig liver esterase (PLE) (18), an enzyme that has been extensively applied in synthesis as illustrated by the pioneering work of J.B. Jones (19).

Initial experiments with ester **11** and PLE demonstrated a relatively clean conversion to acid **16**, which was isolated and fully characterized, along with recovered starting material (Scheme 4). In contrast, when **12a** was subjected to the same

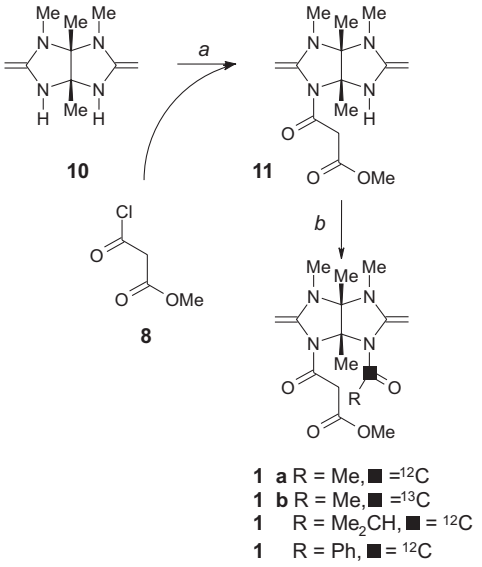
Scheme 3. Reagents and conditions: (*a*) *n*-BuLi, then $MeOC(O)CH_2COCl$ (**8**), THF, 40%; (*b*) RCOCl, proton sponge, CH_2Cl_2, rt, **12a**: 67%; **12b**: 32%; **13**: 49%; **14**: 74%.

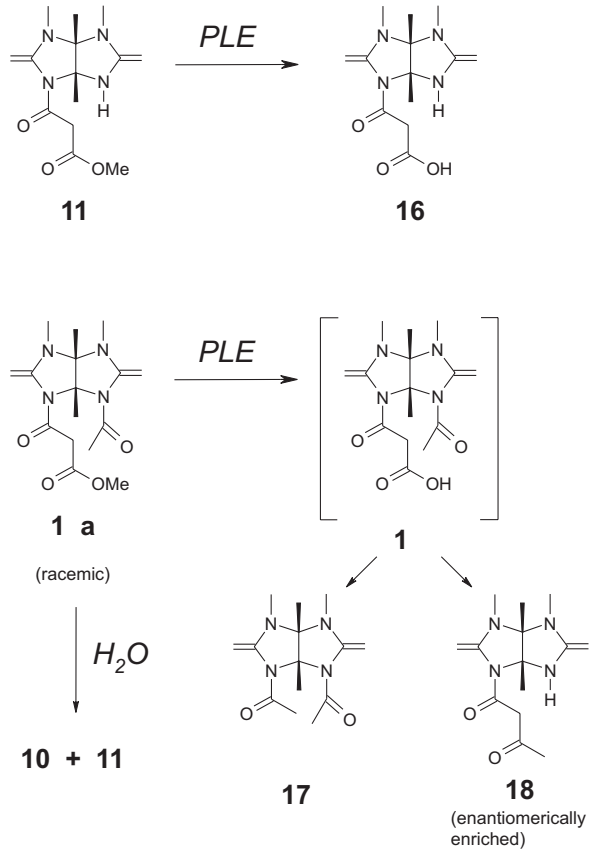


conditions, several products were observed, isolated by preparative TLC, and characterized. These products included (*i*) recovered **12a** (43%) that was identical to starting material by NMR, but which was no longer converted to products by repeated incubation with PLE, and which was optically active. (*ii*) Compounds **10** (15%) and (*iii*) **11** (21%), which were both observed in active-enzyme incubations as well as boiled controls and controls lacking the enzyme. (*iv*) Traces of diacetyldithioglycoluril **17**, identified by TLC comparison with authentic material (20); and (*v*) a polar component, tentatively assigned to acid **15**. Compounds **13** and **14** gave only unreacted starting material and **10** and **11** as products with PLE under similar conditions.

When elution of putative acid **15** from the TLC plate was attempted, condensation product **18**, which is much less polar than **15**, was obtained instead (5% unoptimized yield from **12a**), along with small amounts of **17**. Product **18** was spectroscopically identical to authentic material prepared by the previously reported base-catalyzed condensation of **17** (20), except that a strong positive band was observed in the CD spectrum, and a small but significant optical activity was seen. Efforts to purify **15** for full characterization have to date proved unsuccessful, despite using various media (Sephadex LH20, ion exchange resins, etc.).

To further probe the details of the observed overall transformation of **12a** to **18**, the result of the net putative ester hydrolysis, decarboxylation, and Claisen-like condensation, and to clarify the order of these events, we prepared the [1-^{13}C]acetyl derivative **12b** from **11** and [1-^{13}C]acetyl chloride. Treatment with PLE, separation of the presumed malonic acid, and condensation during isolation gave a sample of **18** (9% overall yield). Analysis by ^{13}C NMR spectroscopy revealed that most of the isotopic label was present at the ketonic carbonyl carbon site (δ 200.9), while some isotopic label was located at the amidic acyl carbonyl (δ 181.0) (Scheme 5). The ratio of enrichment at these two sites was ca. 86:14, as judged by the relative intensities of these two

Scheme 4. Products observed from separate incubations of (*a*) **11** and (*b*) **12a** with pig liver esterase.



peaks compared with their relative intensities in unlabeled **18**. All the product molecules were labeled within the limits of detection (<10% unlabeled), as shown by the presence of two-bond ^{13}C–^{1}H couplings at the α-carbon of the β-ketoacyl group in the ^{1}H NMR spectrum. By contrast, no molecules were detected that contained two labels, as judged by the lack of two-bond ^{13}C–^{13}C coupling between the two carbonyl carbon atoms.

Discussion

This investigation was initiated to determine whether a biomimetic decarboxylative condensation of a malonate unit with an acyl moiety could be promoted on a glycoluril template. Use of the readily acylated dithioglycoluril **10** and commercially available half-ester half-acid chloride of malonic acid **8** allowed the first direct attachment of a malonate group, protected as the half-methyl ester, to a glycoluril. With the subsequent straightforward attachment of an acetyl group at the N6 position, it only remained to remove the methyl ester protection in **12a** to provide substrate **15** for the study of the decarboxylation reaction.

Deprotection of the methyl ester proved challenging: several chemical reagents failed. We thus considered switching to a protecting group that could be more readily cleaved. However, such a process would require the preparation of an appropriate half-ester half-chloride of malonic acid, and we wished to establish the viability of the decarboxylative approach prior to undertaking this work. In the present study,

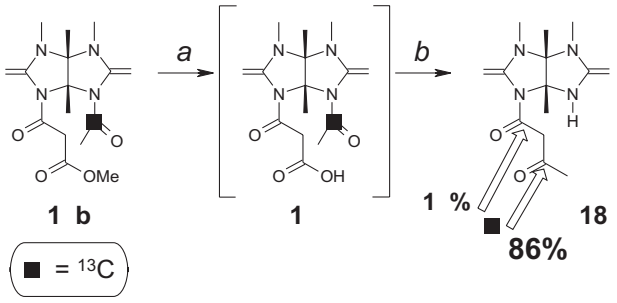
Scheme 5. Distribution of isotope in product **18** formed from: (*a*) incubation of **12b** with pig liver esterase; (*b*) separation on silica gel and elution with methanol.



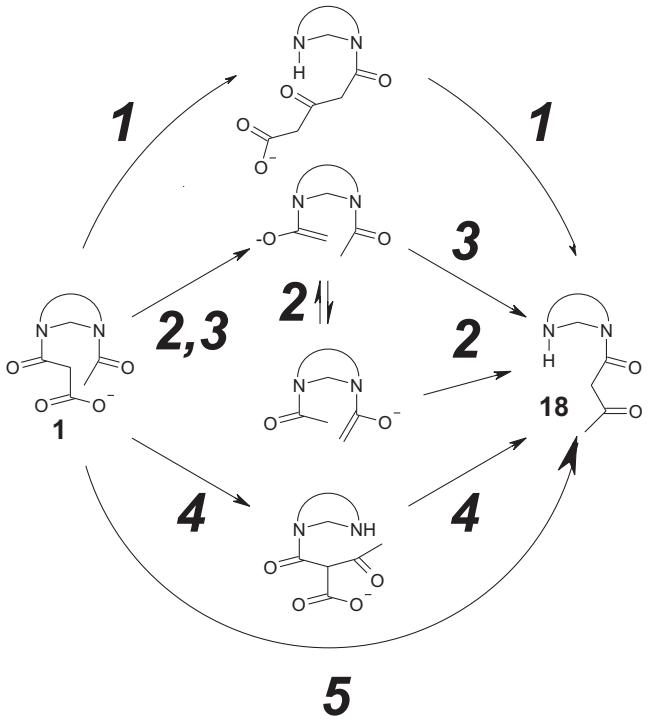
we show that, despite several side-reactions, **12a** can be converted to **18** by PLE, a result consistent with the desired sequence. Other protecting groups, which can be removed chemically under nonaqueous conditions, and which might be expected to avoid these side-reactions, are therefore currently being evaluated.

The major side-products, **10** and **11**, are probably produced by spontaneous hydrolysis of substrate **12a**, since they are also formed in control incubations lacking the active enzyme. This result is consistent with several observations of spontaneous hydrolysis under nonideal conditions, which we have made during our prior work with acylated glycolurils. This effect may be due to acyl group activation as the result of a twist around the amidic N–C bond, which we have observed to be substantial in X-ray crystallographic studies of related structures (21–23).

The remaining two products, putative acid **15** and traces of diacetyl derivative **17**, are only formed when active PLE is incubated with **12a**. Results that support this conclusion include (*i*) boiled controls do not give these products. (*ii*) Although the absolute configuration and enantiomeric excess remains to be determined, product **18** is formed as one predominant enantiomer, as shown by CD and optical activity. Starting material **12a** prior to incubation is racemic, and thus product **18** must have been formed using the enzyme at some point. (*iii*) Although **12a** isolated from the incubation failed to give a CD spectrum, this recovered sample of **12a** is essentially inert as a substrate for PLE, implying that one enantiomer has been processed with a substantive preference, leaving the other enantiomer unchanged. This conclusion is qualitatively supported by the observed optical activity of the sample. The established specificity of PLE thus suggests that ester hydrolysis is obligatory in the pathway to **18**. Two additional observations imply that this reaction precedes the condensation step, and that malonic acid **15** is the initial product. First, monoester **11**, which lacks the acetyl group for condensation, gives acid **16**, the product of the expected esterase activity. That **11** appears to be a better substrate than **12a**, coupled with the observation that **13** and **14** failed to act as substrates for PLE, suggests that the enzyme is sensitive to the size of the acyl group at N6. Second, the high polarity of **15** on TLC, greater than that of the other products and comparable to that of **16**, also supports the structure.

Although **15** was not characterized, there is an obligate reaction intermediate between **12a** and **18**, since the polar product assigned structure **15** was purified by TLC and

Scheme 6. Five possible mechanisms for conversion of **15** to **18**. The structure of the glycoluril has been abbreviated for clarity.



shown to furnish **18** only when eluted with methanol. It is unlikely that condensation of the malonate with the acetyl group precedes via ester hydrolysis and decarboxylation, since **12a** failed to undergo any apparent condensation reaction when treated with base, again pointing towards the proposed structure for **15**. That **18** is formed after preparative TLC supports its formation in a chemical process; thus PLE is not required to catalyze the condensation reaction.

There are several mechanisms by which **15** can be converted to **18** (Scheme 6). The results with isotopically labeled **12b** exclude a pathway in which the acetyl group is deprotonated and the resulting enolate attacks the malonate carbonyl (path 1, Scheme 6), at least as the dominant route. Pathway 4, involving condensation prior to decarboxylation, and concerted pathway 5, are consistent with the observed major location of the isotope at the ketonic position, but cannot account for the 14% of isotope that has scrambled to the amidic carbonyl during this reaction. These two routes would thus require a separate path (e.g., 1 or 2) to operate in competition.

While the present study cannot rigorously exclude these mechanistic possibilities, we prefer to invoke pathway 3, in which the desired malonate **15** is produced by PLE, and then undergoes a facile decarboxylation. The resulting enolate predominantly undergoes direct intramolecular nucleophilic attack to furnish the major isotopomer of **18** (path 3). A minor pathway, however, perhaps the intramolecular proton transfer (path 2), accounts for the partial scrambling of labeling between two sites, since this process interconverts nucleophilic enolate and electrophilic acyl acceptor sites. Nonetheless, the incomplete scrambling of the isotopic label in **12b** shows that this equilibration process cannot be complete. Finally, the formation of diacetyl glycoluril **17** may result from trapping of the enolate by water. That **17** is

© 2002 NRC Canada

a side-product, rather than an intermediate is shown by the incomplete scrambling of the isotopic label in **18** derived from **12b**. Further experiments to delineate the sequence of events in this system are currently underway.

Conclusion

Treatment with PLE converts compound **12a** to **18**, the result of overall ester hydrolysis, decarboxylation, and intramolecular condensation. The results are fully consistent with a mechanism in which the esterase selectively acts on one enantiomer of **12a**, to generate an intermediate, suggested to be malonic acid **15**. Upon isolation, intermediate **15** undergoes facile conversion to enantiomerically enriched **18**. Isotope labeling is consistent with the stepwise formation of an enolate intermediate that undergoes fast intramolecular nucleophilic attack onto the acetyl carbonyl carbon atom. Under the reaction conditions, partial isotope scrambling occurs as labeled **12b** is converted into **18**, in accord with a competing intramolecular proton transfer. Also, enolate protonation under the protic conditions results in trace amounts of the side-product diacetylglycoluril **17**. The results are therefore comparable with the proposed mechanism for decarboxylative condensation on the ketosynthase component of FAS and PKS, and provide an intriguing model of this fascinating biochemical system. Work to find a protective group for the malonate moiety that can be removed by a chemical reagent, allowing for isolation of the malonic acid intermediate and hence better control of the decarboxylative condensation process, is now underway.

Experimental

General

All reactions were performed in flame-dried glassware, under a positive pressure of nitrogen, unless otherwise noted. Air- and moisture-sensitive compounds were transferred by syringe. THF was freshly distilled under nitrogen protection from potassium–benzophenone. Flash column chromatography was performed with Kieselgel 60 (230–400 mesh ASTM) according to the method of Still et al. (24). Melting points are uncorrected. ^{1}H and ^{13}C NMR spectra were obtained on Bruker AC-200, AV-200, and AV-500 spectrometers. The reference for NMR chemical shifts was TMS. Data are given as chemical shift (δ), multiplicity (s = singlet, d = doublet, t = triplet, q = quartet, m = multiplet), coupling constant(s) (Hz), and integral. Fourier transform infrared (FT-IR) spectra were recorded on a Bio-Rad SPC 3200 spectrophotometer. Mass spectra were recorded on a VG analytical ZAB-E machine using electron impact (EI-MS), chemical ionization (CI-MS), and electrospray MS. High resolution mass spectra were also recorded on the same spectrometer.

1-(*O*-Methylmalonyl)-3,4,7,8-tetramethyl-2,5-dithioglycoluril 11

To a stirred suspension of finely powdered 3,4,7,8-tetramethyl-2,5-dithioglycoluril **(10)** (1 g, 4.35 mmol) in dry THF (200 mL) at room temperature was added *n*-BuLi (1.6 M in hexanes, 3 mL, 1.1 equiv, 4.78 mmol). The mixture was heated at reflux for 2 h. After cooling to room temperature, methyl malonyl chloride **8** (0.7 mL, 6.54 mmol) was added. The resulting solution was heated at reflux for 30 min, cooled, and filtered. The filtrate was concentrated to give crude product. Flash chromatography on silica gel in EtOAc–hexanes (30:70) gave pure **11** as a colorless powder (500 mg, 35%); mp 103–105°C. ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 7.29 (s, 1H), 4.67 (d, *J* = 17 Hz, 1H), 4.11 (d, *J* = 17 Hz, 1H), 3.70 (s, 3H), 3.30 (s, 3H), 3.15 (s, 3H), 1.75 (s, 3H), 1.62 (s, 3H). ^{13}C NMR ($CDCl_3$, 50 MHz) δ: 180.0, 177.5, 167.8, 167.5, 86.0, 83.5, 52.7, 45.9, 32.1, 30.2, 18.8, 16.1. EI-MS *m/z*: 330 [M^+], 142 (base), 109, 84, 56, 41. HRMS calcd. for $C_{12}H_{18}N_4O_3S_2$: 330.0820; found: 330.0819.

1-Acetyl-6-(*O*-methylmalonyl)-tetramethyl-2,5-dithioglycoluril 12a

A mixture of **11** (400 mg, 1.21 mmol) and proton sponge (389 mg, 1.82 mmol) dissolved in dichloromethane (40 mL) was stirred at room temperature for 30 min. Acetyl chloride (143 mg, 1.82 mmol) was added over 30 min at room temperature. The reaction mixture was quenched with 1 M HCl (2 mL) and the resulting organic layer washed with 3 portions of water. The organic extracts were dried over anhydrous Na_2SO_4, filtered, and concentrated in vacuo. The product **12a** (300 mg, 67%) was isolated as a white solid after flash column chromatography on silica gel in EtOAc–hexanes (30:70). ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 4.57 (d, *J* = 17 Hz, 1H), 4.15 (d, *J* = 17 Hz, 1H), 3.69 (s, 3H), 3.24 (s, 3H), 3.22 (s, 3H), 2.72 (s, 3H), 1.91 (s, 3H), 1.58 (s, 3H). ^{13}C NMR ($CDCl_3$, 50 MHz) δ: 178.1, 177.7, 173.1, 167.6, 167.5, 87.5, 85.4, 52.6, 46.3, 31.6, 31.3, 29.3, 18.7, 15.1. EI-MS *m/z*: 372 [M^+], 142, 56, 43 (base). HRMS calcd. for $C_{14}H_{20}N_4O_4S_2$: 372.0926; found: 372.0923.

1-([1′-^{13}C]Acetyl)-6-(*O*-Methylmalonyl)-tetramethyl-2,5-dithioglycoluril 12b

Compound **12b** was similarly prepared from **11** (500 mg, 1.52 mmol), proton sponge (486.5 mg, 2.27 mmol), and [1-^{13}C]acetyl chloride (178 mg, 2.27 mmol). Yield: 180 mg, 32%. ^{1}H NMR ($CDCl_3$, 200 MHz) as for **12a** except: δ: 2.73 (d, *J* = 7 Hz, 3H). ^{13}C NMR ($CDCl_3$, 50 MHz) as for **12a** except: δ: 173.0 enhanced. EI-MS *m/z*: 373 [M^+], 273, 142 (base), 109, 56, 44. HRMS calcd. for $C_{13}{}^{13}C_1H_{20}N_4O_4S_2$: 373.0959; found: 373.0966.

General procedure for pig liver esterase (PLE) incubations

To a solution of substrate in acetone and 0.1 M phosphate buffer (pH 8) was added PLE. The mixture was incubated for 5 h at 30°C, and then acidified to pH 4 with 1 M HCl and extracted with $CHCl_3$. The organic layer was washed with water, dried over Na_2SO_4, and concentrated in vacuo to afford crude product which was purified by preparative TLC (50:50 EtOAc–hexanes).

1-(3′-Oxobutanoyl)-3,4,7,8-tetramethyl-2,5-dithioglycoluril 18 from 12a

Compound **12a (**120 mg, 0.32 mmol) in 2 mL acetone and 20 mL buffer with 34 mg (680 units) PLE afforded crude product as a light brown solid. Preparative TLC of this solid gave recovered **12a** (51.6 mg, 43%, $[\alpha]_D^{20}$ – 4 ± 0.5 (*c* = 0.28,

© 2002 NRC Canada

$CHCl_3$)), **10** (9.5 mg, 15%), **11** (22.2 mg, 21%), and a polar product (**15**) that gave desired product **18** (5 mg, 5%) and **14** (traces as judged by TLC) after elution with methanol. Compound **18** was identical to material reported previously, except for optical activity: $[\alpha]_D^{20} - 4 \pm 1$ (c = 0.10, $CHCl_3$). mp: >260°C dec. ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 7.26 (s, 1H), 5.09 (d, J = 17 Hz, 1H), 3.90 (d, J = 17 Hz, 1H), 3.30 (s, 3H), 3.17 (s, 3H), 2.26 (s, 3H), 1.78 (s, 3H), 1.63 (s, 3H). ^{13}C NMR ($CDCl_3$, 125 MHz) δ: 200.8, 181.0, 177.6, 168.6, 85.9, 83.5, 54.0, 32.0, 30.2 (overlapped), 18.8, 16.0. CI-MS (NH_3) m/z: 315 $[M + H]^+$, 231.

Rearrangement of 12b

Compound **12b** (161 mg, 0.43 mmol) was treated with PLE (45 mg, 900 units) and the products were separated by preparative TLC to give recovered **12b** (64 mg, 40%), labeled **10** (11.9 mg, 14%), **11** (28 mg, 20%), and **18** as a pair of isotopomers (12 mg, 9%) as well as traces of labeled **14**. For **18**: ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 7.26 (s, 1H), 5.08 (dd, J = 6, 17 Hz, 1H), 3.90 (dd, J = 6, 17 Hz, 1H), 3.29 (s, 3H), 3.16 (s, 3H), 2.26 (d, J = 6 Hz, 3H), 1.78 (s, 3H), 1.62 (s, 3H). ^{13}C NMR ($CDCl_3$, 125 MHz) δ: 200.9 (enhanced), 181.0 (enhanced), 177.7, 168.7, 85.9, 83.6, 54.1 (d, J = 37 Hz), 32.0, 30.3 (d, J = 43 Hz), 30.3, 18.9, 16.1. CI-MS (NH_3) m/z: 316 $[M + H]^+$, 231, 171. HRMS calcd. for $C_{11}{}^{13}C_1H_{18}O_2S_2$: 315.0904; found: 315.0880.

1-Malonyl-tetramethyl-2,5-dithioglycoluril 16

Compound **11** (200 mg, 0.6 mmol) was treated with PLE (60 mg, 1200 units) in buffer (30 mL), and the product separated by flash column chromatography (washed with EtOAc–hexanes 50:50, then eluted with methanol) to give **16** (76 mg, 40%); $[\alpha]_D^{20}$ +2 ± 0.5 (c = 0.15, DMSO). FT-IR (cm^{-1}): 3275 (NH), approx. 3000 (v br, CO_2H), 2995, 2932 (CH), 1730 (C=O), 1689 (C=O). ^{1}H NMR (DMSO-d_6, 200 MHz) δ: 9.46 and 9.41 (br s, 2H), 4.41 (d, J = 16 Hz, 1H), 4.07 (d, J = 16 Hz, 1H), 3.24 (s, 3H), 3.03 (s, 3H), 1.66 (s, 3H), 1.61 (s, 3H). ^{13}C NMR ($CDCl_3$, 50 MHz) δ: 180.0, 176.8, 168.0, 166.8, 86.1, 83.5, 45.7, 31.7, 29.5, 18.2, 15.0. EI-MS m/z: 272 $[M - CO_2]^+$, 230, 184, 142 (base).

1-(*O*-Methylmalonyl)-6-isobutyryl-3,4,7,8-tetramethyl-2,5-dithioglycoluril 13

A mixture of **11** (20 mg, 64 μmol) and proton sponge (22.17 mg, 1.2 equiv.) was stirred in CH_2Cl_2 (3 mL) for 10 min. Isobutyryl chloride (73 μL, 1.2 equiv.) was added and stirring continued for 30 min. The reaction mixture was quenched with 1 M HCl (0.5 mL). The organic layer was washed with water (3 mL), dried over anhydrous Na_2SO_4, filtered, and concentrated in vacuo. The product **13** (12 mg, 49%) was isolated by flash column chromatography on silica gel in 30% EtOAc–hexanes. ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 4.97 (d, J = 17 Hz, 1H), 4.27 (m, 1H), 3.81 (d, J = 17 Hz, 1H), 3.70 (s, 3H), 3.32 (s, 3H), 3.18 (s, 3H), 1.97 (s, 3H), 1.60 (s, 3H), 1.19 (d, J = 7 Hz, 3H), 1.07 (d, J = 7 Hz, 3H).

1-Benzoyl-6-(*O*-methylmalonyl)-tetramethyl-2,5-dithioglycoluril 14

Compound **11** (150 mg, 0.46 mmol) was treated with proton sponge (148 mg, 1.5 equiv., 0.69 mmol) and benzoyl chloride (97 mg, 1.5 equiv., 0.69 mmol), similar to the procedure for **12a**, to afford **14** (148 mg, 74%). ^{1}H NMR ($CDCl_3$, 200 MHz) δ: 7.77 (d, J = 7 Hz, 2H), 7.46 (m, 3H), 4.63 (d, J = 17 Hz, 1H), 4.06 (d, J = 17 Hz, 1H), 3.64 (s, 3H), 3.36 (s, 3H), 3.24 (s, 3H), 2.07 (s, 3H), 1.73 (s, 3H). ^{13}C NMR ($CDCl_3$, 50 MHz) δ: 180.1, 177.1, 170.6, 167.7, 167.4, 134.6, 133.5, 130.7, 128.5, 87.2, 86.6, 52.6, 45.9, 31.9, 31.1, 18.8, 16.6. EI-MS m/z: 434 $[M^+]$, 334, 142, 105 (base), 77, 42. CI-MS (NH_3) m/z: 435 $[M + H]^+$, 335 (base).

Enantioselective enzymatic aminolysis of a racemic 2-isoxazolylacetate alkyl ester

Amy E. Sigmund, Kenneth C. McNulty, Dzuy Nguyen, Charlotte E. Silverman, Philip Ma, Jaan A. Pesti, and Robert DiCosimo

Abstract: *Pseudomonas cepacia* lipase or *Candida antartica* lipase B catalyzes the enantioselective aminolysis of a racemic 2-isoxazolylacetate alkyl ester, isobutyl 2-[3-(4-cyanophenyl)-4,5-dihydro-5-isoxazolyl]acetate, by 3-amino-*N*-(butoxycarbonyl)-L-alanine methyl ester, mono(4-methylbenzenesulfonate) to produce the corresponding amide, (*R*)-methyl-3-[[[3-(4-cyanophenyl)-4,5-dihydro-5-isoxazolyl]acetyl]amino]-*N*-(butoxycarbonyl)-L-alanine, which is an intermediate in the preparation of an isoxazoline-based platelet glycoprotein IIb/IIIa antagonist.

Key words: enantioselective aminolysis, *Pseudomonas cepacia* lipase, *Candida antartica* lipase B.

Résumé : La lipase de *Pseudomonas cepacia* ou la lipase B de *Candida antartica* catalyse l'aminolyse énantiosélective d'un ester 2-isoxazolylylacétate d'alkyle, le 2-[3-(4-cyanophényl)-4,5-dihydro-5-isoxazolyl]acétate d'isobutyle, par le mono(4-méthylbenzènesulfonate) de l'ester méthylique du 3-amino-*N*-(butoxycarbonyl)-L-alanine pour conduire à la formation de l'amide correspondant, la (*R*)-méthyl-3-[[[3-(4-cyanophényl)-4,5-dihydro-5-isoxazolyl]acétyl]amino]-*N*-(butoxycarbonyl)-L-alanine, un intermédiaire dans la préparation d'un antagoniste IIb/IIIa glycoprotéinique des plaquettes à base d'isoxazoline.

Mots clés : aminolyse énantiosélective, lipase de *Pseudomonas cepacia*, lipase B de *Candida antartica*.

[Traduit par la Rédaction]

Introduction

A variety of enzymes catalyze the enantioselective ammoniolysis or aminolysis of racemic esters. Several lipases have been used for the enantioselective ammoniolysis of free amino acid esters (1), and *Candida antartica* lipase B (CAL B) catalyzed the kinetic resolution of a racemic ester via ammoniolysis (2). D-Aminopeptidase (3), thiolsubtilisin (4), and papain (5) each catalyzed the aminolysis of α-amino acid esters to produce the corresponding chiral α-amino acid amides.

The lipase-catalyzed enantioselective aminolysis of racemic esters to produce chiral amides has been reviewed (6). Aminolysis of racemic 2-methyloctanoate by (*R*)-1-phenylethylamine in the presence of CAL B produced (*R*)-2-methyloctanoic-(*R*)-1-phenylethylamide in 30–40% diastereomeric excess (de) at ca. 100% conversion (7). Resolution of chiral amines by reaction with an isoalkyl ester in the presence of CAL B produced the corresponding chiral amides in high enantiomeric excess (8). A systematic study of the enzymatic aminolysis of racemic 2-methyl butyrate by benzylamine found that CAL B and the lipases from *Rhizopus niveus* and porcine pancreas were highly enantioselective (84–87% ee), while *Candida rugosa* and *Pseudomonas cepacia* lipases were neither highly active nor enantioselective (15% ee and 12% ee, respectively) (9). CAL B (Novo SP435) catalyzed the enantioselective aminolysis of racemic 3-hydroxyesters (10), or racemic 2-alkylesters or 2-haloesters (11), by aliphatic amines, where the degree of enantioselectivity was dependent on the substrate and nucleophile. For the enzymatic aminolysis of dimethyl 3-hydroxyglutarate by aliphatic and aromatic amines (12), CAL B yielded enantiopure monoamidation products in very high yield, while no amidation products were observed in the presence of lipases from *Candida cylindracea* and *P. cepacia* under identical reaction conditions.

An enantioselective enzymatic aminolysis of a racemic 2-isoxazolylacetate alkyl ester has now been employed to produce an intermediate in the preparation of roxifiban ((*R*)-methyl-3-[[[3-[4-(aminoiminomethyl)phenyl]-4,5-dihydro-5-isoxazolyl]acetyl]amino]-*N*-(butoxycarbonyl)-L-alanine monoacetate (Scheme 1)), a non-peptide platelet glycoprotein IIb/IIIa antagonist that has antithrombotic activity (13, 14). The aminolysis reaction produces the desired product with

high selectivity and de, despite the presence of a second alkyl ester functionality on both the reacting amine and the product amide.

Results and discussion

The 2-isoxazolylacetate alkyl ester intermediate (*R*)-methyl-3-[[[3-(4-cyanophenyl)-4,5-dihydro-5-isoxazolyl]acetyl]amino]-*N*-(butoxycarbonyl)-L-alanine ((*R*,*S*)-**1**) is currently synthesized in two steps (Scheme 2) (13*b*). Racemic isobutyl 2-[3-(4-cyanophenyl)-4,5-dihydro-5-isoxazolyl]acetate ((*R*/*S*)-**2**) is first converted into the chiral acid (*R*)-2-[3-(4-cyanophenyl)-4,5-dihydro-5-isoxazolyl]acetic acid ((*R*)-**3**) in an aqueous reaction mixture using *P. cepacia* (formerly *Pseudomonas sp.)* lipase (15), leaving the chiral isobutyl ester (*S*)-**2** unreacted. After isolation, (*R*)-**3** is reacted with thionyl chloride and diamine (*S*)-**4** (3-amino- *N*-(butoxycarbonyl)-L-alanine methyl ester, mono(4-methylbenzenesulfonate)), followed by the addition of diisopropylethylamine (DIEA) to produce (*R*,*S*)-**1**. In a separate step, recovered (*S*)-**2** is racemized for recycle by a catalytic amount of potassium *tert*-butoxide in toluene. This sequence of reactions provides (*R*)-**3** in 70% yield (after one recycle) from racemate (*R*/*S*)-**2**, and (*R*)-**3** is subsequently converted to (*R*,*S*)-**1** in 82% yield.

As an alternative to the two-step procedure described above, the lipase-catalyzed aminolysis of racemic (*R*/*S*)-**2** by diamine (*S*)-**4** to directly produce (*R*,*S*)-**1** was examined (Scheme 3). Several potential by-product-forming reactions which could have resulted in yield loss or a decrease in de of (*R*,*S*)-**1** included: (*i*) nonenzymatic aminolysis of (*R*/*S*)-**2** by (*S*)-**4**; (*ii*) enzymatic hydrolysis of (*R*/*S*)-**2** to (*R*)-**3** (if water is present in the organic solvent); (*iii*) enzymatic hydrolysis of the product (*R*,*S*)-**1** (if water is present in the organic solvent); (*iv*) enzyme-catalyzed aminolysis of (*S*)-**4** by an additional equivalent of (*S*)-**4**; or (*v*) enzymatic or nonenzymatic aminolysis of the product (*R*,*S*)-**1** to produce an aminated by-product. Regioselective aminolysis of non-chiral diesters catalyzed by PS30 lipase has been reported, where regioselectivity was attributed to a preference for aminolysis of a β-alkoxy ester relative to the remaining ester functionality (16).

The free amine of (*S*)-**4** was unstable, and readily dimerized and trimerized in both aqueous solution and in organic solvents in the absence of lipase. As a *p*-toluenesulfonate salt, (*S*)-**4** was stable in organic solvents, and it was first demonstrated that in the presence or absence of *P. cepacia* lipase (Amano PS30) or CAL B there was no significant change in concentration of (*S*)-**4** in diisopropyl ether (DIPE), methyl-*tert*-butyl ether (MTBE), heptane, dioxane, or toluene after 24 h at 25°C. In aqueous solution, a significant (>75%) decomposition of the *p*-toluenesulfonate salt of (*S*)-**4** occurred at 25°C in 0.40 M sodium phosphate buffer (pH 8.0) after 24 h, whereas the salt was stable for at least 18 h in aqueous 5 mM methanesulfonic acid (pH 2.5).

Prior to use in aminolysis reactions, a solution of 30–60 mg mL^{-1} of lipase in 0.10 M sodium phosphate buffer was adjusted to pH 8.0, and then lyophilized to obtain a "dry" enzyme catalyst. This catalyst was subsequently used in aminolysis reactions to produce (*R*,*S*)-**1**, where 52 mM (*R*/*S*)-**2** and from 37.5 to 100 mM (*S*)-**4** were reacted with the dried lipase in DIPE, MTBE, heptane, toluene, or acetonitrile, at temperatures of from 24– 40°C. Initially, the resulting product mixtures contained significant amounts of the ester hydrolysis product (*R*)-**3** as the sole reaction by-product, indicating that water was available in the reaction mixtures, possibly originating from the solvent, enzyme preparation, and (or) starting materials. None of the other potential reaction by-products described above occurred in significant amounts (<1%). Drying the solvents over activated molecular sieves prior to use improved selectivity to (*R*,*S*)-**1** over (*R*)-**3**, and the inclusion of 10–35 mg mL^{-1} of powdered, activated molecular sieves in the reaction mixture (17) further improved selectivity to (*R*,*S*)-**1**.

Table 1 lists the conversion of (*R*/*S*)-**2**, selectivity to (*R*,*S*)-**1** (vs. hydrolysis to produce (*R*)-**3**), and the corresponding de of (*R*,*S*)-**1** (where there was significant conversion) obtained using lyophilized PS30 lipase in dry DIPE, MTBE, heptane, toluene, or acetonitrile. There was no significant conversion of (*R*/*S*)-**2** in the absence of lipase under the reported reaction conditions. With lipase present, there was very little conversion of starting material in toluene or acetonitrile relative to the other solvents, and the reaction rate was considerably slower in heptane relative to MTBE or DIPE. The solubilities of (*R*/*S*)-**2**, (*R*,*S*)-**1**, and reaction by-products were low in all of these solvents, and reactions were run as heterogeneous mixtures (18). Following the progress of a reaction by sampling the heterogeneous mixture over time gave inconsistent results, so measurements of selectivity and de vs. conversion of (*R*/*S*)-**2** were performed by setting up a series of identical reactions, then working up individual reactions for analysis at predetermined times.

The de and selectivity for production of (*R*,*S*)-**1** at conversions of (*R*/*S*)-**2** between 20 and 55% in either DIPE or MTBE are depicted in Fig. 1. The selectivity to (*R*,*S*)-**1** in DIPE averaged ca. 95% at conversions of up to 45%, whereas in MTBE the selectivity was only ca. 90% at conversions of up to 52%. The de of (*R*,*S*)-**1** at a given conversion was similar in either solvent; for MTBE, the de decreased from 86 to 78% as conversion increased from 27 to 46%, and in DIPE, the de decreased from 86 to 74% as the conversion increased from 23 to 44%.

CAL B (19) also produced the desired diastereomer (*R*,*S*)-**1** in high de (Table 2), while *C. antartica* lipase A (CAL A) had the opposite enantioselectivity for (*R*/*S*)-**2** (producing (*S*,*S*)-**1** instead of (*R*,*S*)-**1**), demonstrating that not all enzymes capable of catalyzing the aminolysis of (*R*,*S*)-**1** by (*S*)-**4** produce the desired diastereomer. Although the de obtained using CAL B was moderately higher than that obtained with PS30 lipase in the same solvent (ca. 8% higher de at 35% conversion), the selectivity to the aminolysis product relative to hydrolysis product was significantly lower (81 vs. 89% at 35% conversion); all attempts to improve selectivity by removal of additional water from the

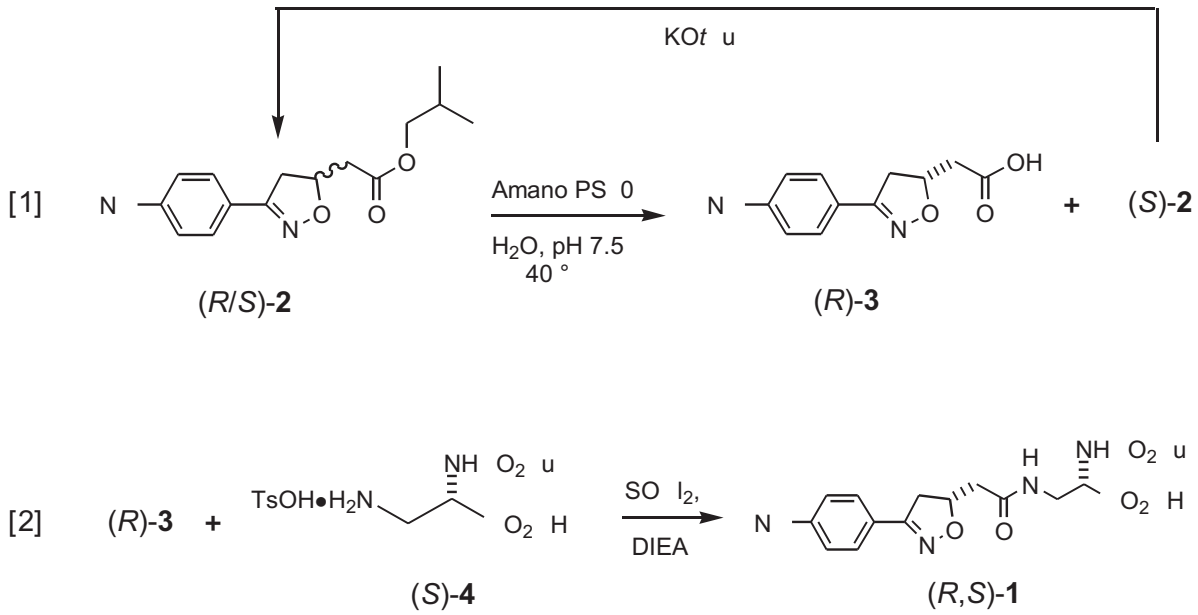
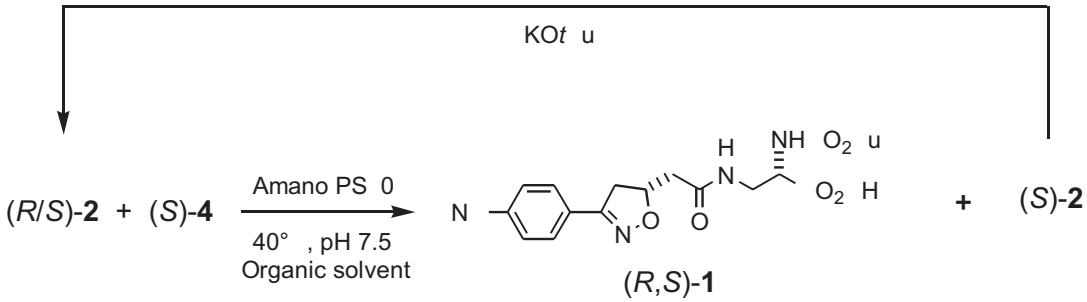
Scheme 2.



Scheme 3.



individual components of the reaction mixture, or from the reaction mixture itself, were unsuccessful. *Pseudomonas fluorescens* lipase (Fluka or Amano AK) gave no significant conversion of (*R*/*S*)-**2** to (*R*,*S*)-**1** under these same reaction conditions.

The PS30 or CAL B lipase-catalyzed aminolysis of racemic (*R*/*S*)-**2** by (*S*)-**4** to directly produce (*R*,*S*)-**1** has several advantages when compared to the two-step, resolution and aminolysis method. The reaction proceeds with significant enantioselectivity, reduces the number of process steps, eliminates several costly reagents, generates less waste, and permits facile product recovery. The heterogeneous product mixture can be diluted with additional solvent, which will dissolve (*R*,*S*)-**1** and unreacted (*R*)-**2** and (*S*)-**2**, and leave unreacted (*S*)-**4** (as the *p*-toluenesulfonate salt), molecular sieves, and the enzyme as filterable solids. The product (*R*,*S*)-**1** can then be isolated by column chromatography, selective precipitation, or fractional crystallization. Unreacted (*R*)-**2** and (*S*)-**2** can be recovered and racemized (13*b*) and this racemate recycled in a second enzymatic aminolysis reaction, thereby increasing the overall yield of (*R*,*S*)-**1** produced, and decreasing the amount of waste. (*R*,*S*)-**1** was produced in 78– 86% de, which corresponds to a yield of the desired diastereomer of 89–93%, respectively, (based on total (*R*,*S*)-**1** and (*S*,*S*)-**1** produced); the subsequent separation of these two diastereomers is readily performed by recrystallization, and produces the desired diastereomer in very high purity. Further improvement in de might be obtained by examining the dependence of enantioselectivity on the choice of alkyl ester substituent of (*R*/*S*)-**2**.

Experimental section

Starting materials ((*R*/*S*)-**2** and (*S*)-**4**) and products ((*R*,*S*)-**1**, (*S*,*S*)-**1**, (*S*)-**2**, (*R*)-**3**, and (*S*)-**3**) for the enzymatic aminolysis reactions were prepared and characterized according to published procedures (13*b*), or obtained from commercial sources. Enzymes were obtained from Amano, Sigma, Fluka, or Roche Molecular Biochemicals, and were used as received without further purification. Relative specific activities of commercial enzyme preparations were determined by measuring the rate of hydrolysis of *p*-nitrophenyl acetate (PNPA) (20).

HPLC analysis of reaction components

Analysis of mixtures of (*R*/*S*)-**2**, (*R*,*S*)-**1**, and (*S*,*S*)-**1**, and (*R*)-**3** and (*S*)-**3** (without separation of enantiomers or diastereomers) were performed by HPLC using UV detection at 260 nm on an Eclipse XDB-C8 column (4.6 ×

250 mm) at 40°C and a flow rate of 1.0 mL min^{-1}, using a gradient of two eluents: mobile phase A (0.1% trifluoroacetic acid – 0.1% triethylamine in distilled deionized water), mobile phase B (0.1% trifluoroacetic acid in THF (unstabilized)). The mobile phase gradient employed was: t = 0 min, 85% A, 15% B; t = 10 min, 85% A, 15% B; t = 32 min, 50% A, 50% B; t = 40 min, 50% A, 50% B; t = 42 min, 85% A, 15% B; t = 52 min, 85% A, 15% B.

Chiral HPLC analysis of (*R*)-**2** and (*S*)-**2**, and (*R*)-**3** and (*S*)-**3**, was performed using UV detection at 280 nm on a Daicel Chiralcel OJ column (4.6 × 250 mm) at 38°C and a flow rate of 0.90 mL min^{-1} of 0.25% trifluoroacetic acid in 81% hexane – 19% ethanol.

Chiral HPLC analysis of (*R*,*S*)-**1** and (*S*,*S*)-**1** was performed using UV detection at 280 nm on two Daicel Chiralcel OJ columns (4.6 × 250 mm) in series at 40°C and a flow rate of 0.75 mL min^{-1} of 80% heptane – 20% ethanol. The production of (*R*,*S*)-**1** and (*S*,*S*)-**1** as aminolysis reaction products was confirmed by preparing authentic samples of (*R*,*S*)-**1**, (*S*,*S*)-**1**, (*S*,*R*)-**1**, and (*R*,*R*)-**1**, separating all four diastereomers by chiral HPLC, and comparing product retention times with the authentic standards.

Lipase-catalyzed aminolysis of racemic isobutyl 2-[3-(4-cyanophenyl)-4,5-dihydro-5-isoxazolyl]acetate ((*R*/*S*)-2) by 3-amino-*N*-(butoxycarbonyl)-L-alanine methyl ester, mono(4-methylbenzenesulfonate) ((*S*)-4)

In a typical procedure, a series of 4 mL glass vials were charged with 30–60 mg of lipase and 1.0 mL of 100 mM NaH_2PO_4 (pH 8.0, adjusted with 50% aq NaOH), and the resulting solution was frozen and lyophilized. To each vial was then added 15 mg of (*S*)-**4** (38.3 mM), 15.0 mg of (*R*,*S*)-**2** (52.3 mM), 10–35 mg of powdered, activated 3 Å molecular sieves, 1.0 mL of diisopropyl ether (dried over activated 3 Å molecular sieves), and a magnetic stir bar. The vials were capped and the reaction mixtures stirred at 24–40°C for 18–48 h.

After the desired reaction time, the individual reactions were prepared for analysis by cooling the product mixtures to 24°C and then evaporating the solvent by flowing a

© 2002 NRC Canada

stream of dry nitrogen over the product mixture. The resulting solid was mixed with: (*i*) 18.0 mL of a 1:1 (v/v) mixture of tetrahydrofuran and 0.1% (v/v) acetic acid in distilled, deionized water (adjusted to pH 2.0 with 6.0 N HCl); (*ii*) 2.0 mL of 30 mM *p*-toluamide (HPLC external standard) in a 1:1 (v/v) mixture of tetrahydrofuran and 0.1% (v/v) acetic acid in distilled, deionized water (adjusted to pH 2.0 with 6.0 N HCl); and (*iii*) 0.108 mL of 6.0 N HCl. A 1 mL sample of the resulting mixture (mixture A) was centrifuged to remove undissolved solids, and the supernatant analyzed for (*R*/*S*)-**2**, (*R*,*S*)-**1**, and (*R*/*S*)-**3** by HPLC.

A second 2.0 mL sample of mixture A was evaporated to dryness under vacuum, then 1 mL of ethanol was added to the resulting solid and the suspension heated at 50°C for 1.0 min. The resulting suspension was filtered (0.45 μm) and analyzed by chiral HPLC for (*R*)-**2** and (*S*)-**2**, (*R*,*S*)-**1** and (*S*,*S*)-**1**, and (*R*)-**3** and (*S*)-**3**.

Baeyer-Villiger oxidations catalyzed by engineered microorganisms: Enantioselective synthesis of δ-valerolactones with functionalized chains

Shaozhao Wang, Gang Chen, Margaret M. Kayser, Hiroaki Iwaki, Peter C.K. Lau, and Yoshie Hasegawa

Abstract: Cyclohexanone monooxygenase (CHMO) from *Acinetobacter* sp NCIMB 9871 expressed in baker's yeast and in *E. coli* and cyclopentanone monooxygenase (CPMO) from *Comamonas* (previously *Pseudomonas*) sp. NCIMB 9872 expressed in *E. coli* are new bioreagents for Baeyer-Villiger oxidations. These engineered microorganisms, requiring neither biochemical expertise nor equipment beyond that found in chemical laboratories, were evaluated as reagents for Baeyer-Villiger oxidations of cyclopentanones substituted at the 2-position with polar and nonpolar chains suitable for further modifications. Two such functionalized substrates that can be transformed into highly enantiopure lactones were identified. The performance and the potential of these bioreagents are discussed.

Key words: enantioselective Baeyer-Villiger oxidations, biotransformations, cyclohexanone monooxygenase, cyclopentanone monooxygenase, engineered baker's yeast, recombinant *E. coli*, optically pure 2-substituted cyclopentanones, optically pure lactones.

Résumé : La monooxygénase de la cyclohexanone (« CHMO ») obtenue à partir d'*Acinetobacter* sp NCIMB 9871 extraite de la levure pâtissière et d'*E. coli* et la monooxygénase de la cyclopentanone (« CPMO ») de *Comamonas* (antérieurement *Pseudomonas*) sp. NCIMB 9872 extraite d'*E. coli* sont les nouveaux bioréactifs pour les oxydations de Baeyer-Villiger. Ces microorganismes, qui ne nécessitent ni expertise biochimique ni équipement supplémentaire par rapport à ce que l'on retrouve dans les laboratoires chimiques, ont été évalués comme réactifs pour des oxydations de Baeyer-Villiger de cyclopentanones substituées en position 2 par des chaînes polaires ainsi que non polaires susceptibles d'être modifiées ultérieurement. On a identifié deux de ces substrats fonctionnalisés qui peuvent être éventuellement transformés en lactones de grande pureté énantiomérique. On discute de la performance et du potentiel de ces bioréactifs.

Mots clés : oxydations de Baeyer-Villiger, biotransformations, monooxygénase de la cyclohexanone, monooxygénase de la cyclopentanone, levure pâtissière, *E. coli* recombinant, cyclopentanone substituée en position 2 optiquement pure, lactones optiquement pures.

[Traduit par la Rédaction]

Introduction

The transformation of cyclic ketones to lactones is most frequently performed using peroxyacids. The lactones are important intermediates in organic synthesis, and hence the reaction has been studied and extensively employed for over a hundred years since its discovery in 1899 by Baeyer and Villiger (1). Many developments and changes to the reaction occurred over the years (2), and the accepted two-step mechanism is familiar to chemists (2, 3). In general, this is a successful reaction and problems only arise when scaling-up is required because peracid oxidants are toxic and intrinsically unstable. For this reason, new oxidizing agents continue to be investigated and several have been introduced over the years (4). The growing interest in the preparation of optically pure compounds has stimulated interest in creating enantioselective Baeyer-Villiger oxidations, and a number of transition-metal-based oxidants have been described (5). The yields and enantiomeric excesses (ee) of the lactone products varied, but were typically in the order of 30–70% ee. "Biological" Baeyer-Villiger oxidants, recognized for their use for several decades, perform these oxidations on a broad variety of compounds, frequently with good yields and with superior enantioselectivity (6). Although many microorganisms produce enzymes that perform Baeyer-Villiger reactions, two bacterial species *Acinetobacter* sp. and *Pseudomona*, have received the most attention in recent years. These

organisms and (or) the Baeyer-Villiger enzymes (flavin monooxygenases) that they produce are biological reagents of real value in organic synthesis.

Pseudomonas sp. NCIMB 10007, which carries genes inducible by growth on (+)- or (–)-camphor to produce the camphore flavin monooxygenase enzymes, has been investigated in numerous reactions. The crude-enzyme extracts from this organism were separated on the basis of the co-factor requirement to give two fractions: NADH-dependent MO1 and NADPH-dependent MO2. These fractions were used as selective catalysts in reactions with various unnatural substrates (6*b*, *c*, 7, 8). Elective culture grown on cyclohexanol allowed Donoghue and Trudgill (9) to identify *Acinetobacter* sp. NCIMB 9871. Since then, CHMO has been the subject of several mechanistic and biochemical studies (10–12). Extraction of cyclohexanone monooxygenase from this strain (CHMO EC 1.14.13.22) was optimized by Trudgill (13), and both the microorganism and enzyme continued to be extensively investigated (see reviews listed in ref. 6). The high enantioselectivity and broad spectrum of substrate acceptability made the enzyme and the organism the most widely used bioreagents for Baeyer-Villiger oxidations. Since, however, *Acinetobacter* sp. NCIMB 9871 is a class 2 pathogen and the isolated CHMO enzyme is relatively unstable and requires the NADPH co-factor, these biotransformations were not embraced enthusiastically by nonspecialists. The recently constructed recombinant strains of baker's yeast [15C(pKR001)] and *E. coli* [BL21(DE3)(pMM4)] overexpressing CHMO, which can be used to perform enantioselective Baeyer-Villiger oxidations in ordinary shake flasks in any organic laboratory (14, 15), should place these versatile reagents at the disposal of all organic chemists.

Elective culture grown on cyclopentanol yielded *Pseudomonas* sp. NCIMB 9872, now identified as *Comamonas* (16). This organism was able to oxidize cyclopentanol, via cyclopentanone and δ-valerolactone, to glutarate and, presumably, to acetate by an inducible set of enzymes (17). Purified cyclopentanone monooxygenase (CPMO; EC 1.14.13.16) is NADPH-specific (17*b*, *c*). Compared with NCIMB 9871, it has been studied relatively little in Baeyer-Villiger oxidations of unnatural substrates, probably because it was assumed to have stereoselectivity similar to that of cyclohexanone monooxygenase from *Acinetobacter* (6*b*, *c*, 7, 18, 19). We have now cloned and overexpressed the gene for cyclopentanone monooxygenase in the laboratory *E. coli* strain DH5α, [*E. coli* (CPMO)] making it as accessible as *E. coli* (CHMO) for development as another reagent for biological Baeyer-Villiger oxidations (16).

In an earlier paper, we reported several successful Baeyer-Villiger oxidations of 2-alkyl cyclopentanones mediated by the recombinant yeast (CHMO) (20). Our objective in the current project was to evaluate the recombinant CHMO- and CPMO-expressing strains as reagents for Baeyer-Villiger oxidations of 2-substituted cyclopentanones with functional groups on the side chain. Several such substrates were prepared and subjected to biotransformations. The stereochemical results of this work are discussed in this paper.

Results

2-Cyclopentylcyclopentanone (**2c**) was purchased from Aldrich, and compounds **2d**–**f** were prepared in good yields by alkylation and decarboxylation of methyl cyclopentanone-2-carboxylate as shown in Scheme 1. 2-Allylcyclopentanone (**2a**) was prepared by direct alkylation of cyclopentanone. 2-Oxocyclopentyl-1-methanol (**2g**) and 2-alkoxymethylcyclopentanones **2h** and **2i** were synthesized in 3 and 4 steps, respectively, from methyl cyclopentanone-2-carboxylate. In these reactions, the ketone was protected as an ethylene ketal, and the ester group was reduced by $LiAlH_4$ to give hydroxyketal **4**. Subsequent hydrolysis of the ketal with a mild Lewis acid catalyst preserved the hydroxyl group and yielded hydroxyketone **2g**. Alkylation of **4** followed by hydrolysis with a dilute aqueous acid gave alkoxyketones **2h** and **2i** (Scheme 2). The synthesis of ester **2k** paralleled that for simple alkyl side chains. Coupling of ethyl cyclopentanone-2-carboxylate with bromoacetate, followed by acidic hydrolysis and decarboxylation, afforded the desired product **2k** (Scheme 1).

Whole-cell mediated oxidations were carried out in shake flasks as previously described (15*a*, 21). In most cases, one equivalent of β-cyclodextrin (relative to the ketone) was included in the reaction medium to diminish any of the toxic effects of the substrates. The reactions were monitored by chiral GC, and the concentrations of the ketone and the lactone were measured against an internal standard (methyl benzoate). Only the results that were consistent in terms of conversion, enantioselectivity, time, and isolated yields over the course of several fermentations are listed in Tables 1*a* and 1*b*. Controlled chemical-oxidation experiments were performed for all substrates, and it was possible to achieve baseline resolution for the majority of ketones and (or) lactones. The absolute configuration of ketones **2a** and **2b** were deduced by comparison with literature values as described in our earlier paper (20). The absolute configurations for **2c**–**f** were tentatively assigned by analogy with prior results (22)

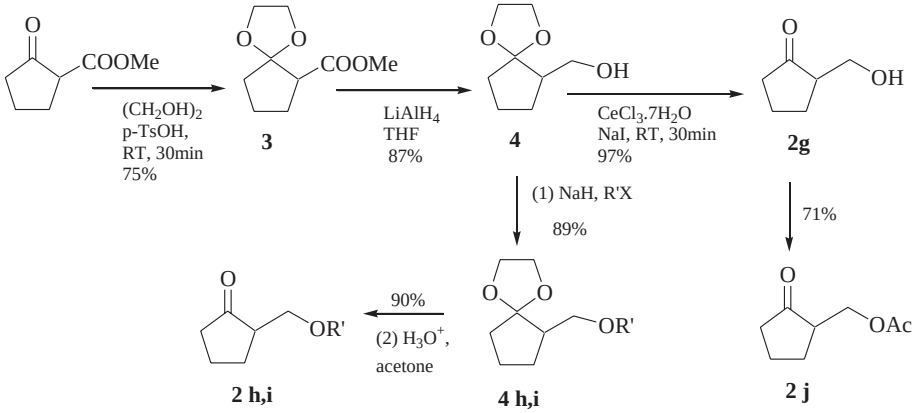
Scheme 2.



and with the demonstrated selectivity of the CHMO for (*S*)-cyclohexanones and cyclopentanones substituted with *n*-alkyl chains (6, 23). It should be noted that because of changes in numbering priority the *R*/*S* nomenclature is reversed for compounds **2a** and **2c**–**k**.

A majority of the reactions reported in Tables 1*a* and 1*b* were performed with the recombinant *E. coli* (CHMO); however, the same reactions that were re-investigated with the yeast (CHMO) gave virtually identical results, apart from small variations in the isolated yields. Compound **2d** appeared to be toxic to *E. coli* even in the presence of cyclodextrin and the successful transformation could only be achieved with the yeast (CHMO) strain. As can be seen in Table 1*a*, branching and increased bulk of the 2-substituents (**2c**–**e**) resulted in diminished selectivity of the CHMO oxidations. Parallel *E. coli* (CPMO) catalyzed reactions were generally faster and the lactones were isolated in excellent yields; however, the enantioselectivity of the transformation was consistently lower than that with CHMO. Extending the three-carbon chain by a bromine atom in compound **2f** restored CHMO's selectivity and the racemic ketone was kinetically resolved to give the lactone **5f** ($[\alpha]_D^{25}$ –63 (*c* 0.4, EtOAc), 95% ee) and the unreacted ketone **2f** ($[\alpha]_D^{25}$ –144 (*c* 1.65, CH_2Cl_2), 92% ee) in excellent isolated yields. The (*S*)-**2f** ketone was subsequently chemically oxidized to the corresponding lactone without loss of optical purity. Thus, readily prepared racemic 2-(3′-bromopropyl)-cyclopentanone (**2f**) introduces the possibility of further modification of the highly enantiopure δ-valerolactones.

The *E. coli* (CPMO) catalyzed oxidations, shown in Table 1*a*, were intentionally interrupted at low conversion levels to estimate the enantioselectivity values (*E*) (24), which turned out to be low, but consistently showed a slight preference for the *same* ketone enantiomer as the CHMO-catalyzed transformations. Uninterrupted *E. coli* (CPMO) mediated reactions rapidly produced racemic lactones in excellent yields. All starting materials were generally consumed, and neither by-products nor metabolites were evident in the GC traces of the crude-reaction mixtures. Only in the case of ketone **2f** did the CPMO-mediated transformation show significant enantioselectivity.

The 2-cyclopentanones substituted with polar oxygen-containing groups on the side chain were acceptable substrates for both CHMO and CPMO (Table 1*b*). Ketone **2g**, with an unprotected hydroxy group on the side chain, reacted very slowly with yeast (CHMO) to give (*R*)-**5g** (34% ee, $[\alpha]_D^{25}$ –11 (*c* 4.5, EtOAc)). The absolute configuration for this compound was confirmed by comparison with the previously reported rotation (25). The difficulty in transporting the more polar substrates across cell membranes could be partially responsible for the sluggishness of this transformation. When the hydroxy group in **2g** was masked in the form of its ether derivatives **2h** and **2i,** the oxidations were faster, which supports the transport-through-membranes hypothesis. Furthermore, the enantioselectivity of the latter transformations was improved, particularly in the case of ketone **2i** bearing a long allyloxy chain. In this case, the lactone product (*R*)-**5i** was obtained in 93% ee. When the allyl group in lactone **5i** was removed (Pd/C in *p*-toluenesulfonic acid–H_2O), the product **5g** was shown to have the same configuration (*R*) as the major lactone enantiomer obtained from the oxidation of ketone **2g** by yeast (CHMO) or *E. coli* (CPMO). Again, the two enzymes showed a preference for the *same* enantiomer, and again, the CHMO enzyme proved to be the more selective of the two. Ketone **2j** was transformed by *E. coli* (CPMO) to the known lactone (*R*)-**5j** (26). At 41% conversion and 53% ee the reaction was stopped, the lactone product was isolated, and the optical rotation was determined ($[\alpha]_D^{25}$ –15 (*c* 2.5, EtOAc)). In a parallel reaction catalyzed by *E. coli* (CHMO), the **2j** substrate was also consumed and at 49% conversion an unidentified optically active product was formed in 74% ee. Lactone **5j** from the CPMO oxidation was subsequently chemically hydrolyzed ($NaHCO_3$, MeOH, pH 11) to (*R*)-**5g** without a change in optical purity. Ketone **2k** was rapidly oxidized by *E. coli* (CPMO), but the *E*-value was only 8. At 52% conversion, the product mixture consisted of lactone **5k** (61% ee, $[\alpha]_D^{25}$ –10 (*c* 1.2, EtOAc)) and residual ketone **2k** (66% ee, $[\alpha]_D^{25}$ –12.5 (*c* 0.8, EtOAc)). The transformation with *E. coli* (CHMO) was very slow and apparently nonselective and, since large quantities of by-products and metabolites were formed in the early stages of the reaction, we did not pursue this transformation any further.

Discussion

Cyclopentanones substituted at the 2-position with alkyl chains of five carbons or longer are substrates to several Baeyer-Villiger monooxygenases. *Acinetobacter* species NCIB 9871 and TD 63 (23), *Pseudomonas* sp. NCIMB

10007, and enzyme fractions MO1 and MO2 from that organism were used in oxidations of these compounds. The highest enantioselectivities were reported in reactions catalyzed by the MO2 fraction (7). *Acinetobacter*-catalyzed reactions were found to be highly enantioselective in several of the compounds studied, but the yields were low because the lactonic products were further metabolized by a hydrolase present in the organism. The problem was minimized by adding tetraethyl pyrophosphate to the reaction medium to inhibit the hydrolytic enzyme, and the reactions were re-investigated using *Acinetobacter* TD 63, a related species, which does not produce lactone hydrolase (23). Using our nonpathogenic yeast (CHMO) strain, we were able to achieve excellent kinetic resolution of the 2-alkylcyclopentanones, provided that the chains were at least four-carbon atoms long (20). It was previously observed that cyclohexanone monooxygenase exhibits virtually complete enantioselectivity for the (*S*)-enantiomer of 2-alkyl cyclohexanones, with the exception of 2-methyl cyclohexanone (10, 23, 27). With cyclopentanones, however, the chains must be longer to obtain comparable enantioselectivities. Cyclopentanones and cyclohexanones with functionalized chains have not been evaluated as substrates for either *Acinetobacter* sp. or the isolated cyclohexanone monooxygenase enzyme, but they were used as substrates in oxidations with the MO2 fraction from the species NCIMB 10007 (7, 19) and NCIMB 9872 (7, 18, 19). These compounds were of particular interest to us, since the oxidations with our easy-to-use bioreagents could provide convenient routes to optically pure lactones, ready for further modification through classical chemical reactions.

Our earlier experiments (20) with the yeast (CHMO) have shown that, although 2-*n*-butylcyclopentanone was fully kinetically resolved over the course of the Baeyer-Villiger oxidation, the 2-allylcyclopentanone was not, giving at best the (*R*)-lactone with 51% ee. To investigate the effect of branching and of polar substituents on the selectivity of CHMO and CPMO, we evaluated several potential substrates

[a] Conversion from G.C.; [b] Isolated yield of chromatographically purified product; [c] Determined from chiral G.C.(Supelco β-Dex 225 column); [d] Calculated according to Ref.(24); [e] Not resolved on GC; [f] Ref. 23; [g] Ref. 7, 19. Note that because of change in numbering priority the R/S nomenclature for ketones and lactones **g-k** is reversed *vis a vis* that of compounds **2b** and **5b.**

listed in Table 1. The ability of CHMO to accommodate polar chains was intimated by the fact that both isolated enzyme (28) and our recombinant organisms successfully oxidized cyclohexanones with polar chains in the 3- and 4-positions (29). To the best of our knowledge, however, these compounds have not been tested as substrates for CPMO.

The point that needs to be stressed involves generalizations applied to the enantioselectivity trends of various oxygenases. Although these can be useful when one chooses an enzyme or an organism for a specific transformation, wide speculation, resulting in nonconfirmed assignments of absolute configuration, are unwarranted. We experienced this when comparing oxidations by CHMO and CPMO with those performed by MO2. In an earlier study, Adger et al. (18) showed that monooxygenase MO2 from camphor-grown NCIMB 10007 species converted racemic 2-(2′-acetoxyethyl)cyclohexanone (**6**) to the corresponding *R*-(–)-lactone **7a** (40% conversion, 83% ee), while purified CPMO from cyclopentanol-grown NCIMB 9872 transformed the same substrate to its *S*-(+) antipode **7b** (59% conversion, 42% ee), as shown in Table 1*b*. The rotations were reported and the absolute configurations were unambiguously confirmed after the two lactones were converted to the (*R*)- and (*S*)-lipoic acids. MO2 was also used to oxidize cyclopentanones **2j** and **2k** to lactones **5j** and **5k**, respectively, in better than 98% ee (7). The two lactones were reported as having the *R* configuration. Unfortunately, neither rotations nor references were specified. We were able to unambiguously identify lactone **5j** from the CPMO oxidation as the (*R*) enantiomer (vide supra), but the absolute configuration

© 2002 NRC Canada

of lactone **5k** has not yet been confirmed. Although it was shown (19) that enantioselectivity of CPMO (NCIMB 9872) can be opposite to that of MO2 (Table 1*b*, example 6), it appears that, at least for cyclopentanone **2j**, the enantioselectivities are the same and that both enzymes preferentially oxidize the (*R*) ketone.

In summary, the goals of this project were to determine (*i*) if cyclopentanones with more polar functionalized substituents in the 2-position are substrates for CHMO and CPMO; (*ii*) if highly optically enriched lactone (or lactones) suitable for further chain modifications could be identified; and (*iii*) if the performance of CPMO was adequately different from the CHMO to attempt its development as an alternative bioreagent for biological Baeyer-Villiger reactions. From the results reported here it is clear that while Baeyer-Villiger oxidations of 2-substituted cyclopentanones by CHMO- and CPMO-expressing strains are frequently nonselective, some compounds are oxidized with a very high enantiselectivity; in the present survey three of the candidates investigated (**2b**, **2f**, and **2i**) were found to meet the selectivity criteria. In general, of the two enzymes studied, CHMO was shown to be the more selective. On the other hand, oxidations with CPMO are appealing for another reason: these transformations are fast, clean, and there are no by-products or metabolites. Where enantioselectivity is not a primary concern, the *E. coli* (CPMO) strain (16) can serve as an excellent biological equivalent of organic peracids.

In conclusion, the results presented here indicate that "designer microbes" expressing various Baeyer-Villiger monooxygenases can contribute significantly to "developing synthetic methodology and "green" processes that meet criteria of a sustainable, environmentally conscious development (30)."

Experimental

Optical rotations were measured on a PerkinElmer 241 polarimeter operating at room temperature. IR spectra were recorded from thin films on a Mattson Satellite FT-IR spectrometer. ^{1}H and ^{13}C NMR spectra were recorded on Varian XL-200 or Bruker AMX-400 FT-NMR spectrometers. All spectra were recorded in $CDCl_3$ solutions unless otherwise specified. Chemical shifts are reported in ppm with TMS as internal standard. EI-MS spectra and HRMS were obtained on Kratos MS 50 mass spectrometer. Packed-column gas chromatography was performed on a Shimadzu GC-9A gas chromatograph employing a customer-packed column (1/8" × 1 m, 5% OV-101 on 100/120 Supelcoport, Supelco Inc.). Capillary gas chromatography was performed on a Hewlett Packard 5890 instrument employing a 0.54 μm × 1.00 mm × 15 m DB-1301 column (J&W) or Shimadzu GC-9A using a 0.32 μm × 0.25 mm × 30 m β-Dex 225 column (Supelco). All the GC instruments used flame-ionization detectors and helium as the carrier gas. The injector and detector temperatures were maintained at 225°C and 300°C, respectively. Thin-layer chromatography was performed on precoated silica gel 60 plates (Aldrich). Flash chromatography was performed on silica gel (200–425 mesh, Fisher Scientific or SiliCycle). Tetrahydrofuran was distilled from Na in the presence of benzophenone. Acetone was dried over $CaSO_4$ and distilled from $KMnO_4$. Methylene chloride was dried over anhydrous potassium carbonate, distilled, and stored over 3 Å molecular sieves. All solvents were purified by fractional distillation. Other reagents were obtained from commercial suppliers and used as received.

Protocols for biotransformations

Preparation of yeast cells (pKR001) and the general procedure for yeast-catalyzed Baeyer-Villiger oxidations were previously described (14, 21, 22). Maintenance and biotranformation protocols for the reactions with *E. coli* [BL21(DE3)(pMM4)] are outlined in refs. 15 and 29.

Protocol for *E. coli*-(CPMO) mediated oxidations

The *E. coli* strain DH5α[pCMP201] was streaked from a frozen stock on LB-ampicillin plates and incubated at 37°C until colonies were 1–2 mm in size. One colony was used to inoculate 10 mL of LB-ampicillin medium in a 50-mL Erlenmeyer flask and was shaken at 30°C and 250 rpm overnight. This culture was used at a 1:100 (v/v) ratio to inoculate an LB-ampicillin medium supplemented with 10% glucose in a baffled-Erlenmeyer flask. The culture was incubated at 30°C and 250 rpm until OD_{600} was approximately 1. IPTG (isopropyl thio-β-D-galactoside) stock solution (200 mg per mL in water) was added (0.1 μL per mL of medium) and the flask was shaken for another 30 min. The substrate was then added, and, if solubility was a problem, cyclodextrin was introduced at this stage. The culture was agitated at 30°C at 250 rpm and monitored by GC or TLC. The culture was saturated with NaCl and extracted with ethyl acetate. Combined extracts were washed once with brine and dried with anhydrous Na_2SO_4 or $MgSO_4$. The solvent was removed on a rotary evaporator and the residue was purified by flash chromatography.

Compounds 2d and 2e

Compounds **2d** and **2e** were prepared according to modified literature procedure (31). Anhydrous K_2CO_3 (5.5 g, 40 mmol) and acetone (20 mL) were placed in a three-neck round-bottom flask equipped with reflux condenser. After flushing the system with nitrogen, methyl cyclopentanone-2-carboxylate (20 mmol) and alkyl halide (20 mmol) were added, and the stirred reaction mixture, maintained under nitrogen, was gently heated at reflux for two days until all starting material was consumed or a significant amount of by-product was formed as shown by GC. The mixture was cooled to room temperature and poured into ice water. The aqueous phase was extracted with ethyl acetate (3 × 200 mL) and the combined extracts were washed with brine and dried over anhydrous Na_2SO_4. After removal of the solvent on a rotary evaporator the crude product **1d** (or **1e**) was purified by flash chromatography on silica gel using a mixture of hexane and ethyl acetate as eluent. The resulting 2-alkylketoester (**1d** or **1e**, 10 mmol) was dissolved in a mixture of glacial acetic acid (20 mL) and HCl (6 M, 10 mL) and gently heated at reflux under nitrogen until all starting material was consumed as shown by GC (usually 4–6 h). The reaction mixture was cooled to room temperature, poured into ice water, and extracted with ethyl acetate or petroleum ether (3 or 4 × 150 mL). The combined extracts were washed with water and then with saturated $NaHCO_3$. After drying over anhydrous Na_2SO_4, the solvent was

© 2002 NRC Canada

removed and the crude product **2** was purified by vacuum distillation.

2*-iso-*Butyl cyclopentanone (2d)

bp 120–140°C (18–25 Torr). IR ν_{max} (neat) (cm^{-1}): 2957.5 (s), 2869.1 (m), 1739.4 (s), 1467.1 (m), 1154.0 (m). ^{1}H NMR δ: 2.20 (m, 2H), 2.10 (m, 1H), 2.09–1.90 (m, 3H), 1.72 (m, 1H), 1.58 (m, 1H) 1.42 (m, 1H), 1.08, (m, 1H), 0.86 (d, *J* = 3.2 Hz, 3H), 0.82 (d, *J* = 3.0 Hz, 3H). ^{13}C NMR δ: 221.8, 47.4, 38.9, 37.9, 30.0, 26.1, 23.3, 21.4, 20.7.

2-Benzylcyclopentanone (2e)

Obtained after chromatography (hexane–ethyl acetate 10:1) in 85% yield as pale yellow oil: IR υ_{max} (neat) (cm^{-1}): 3000 (m), 2960 (s), 2870 (m), 1730 (vs), 1600 (w), 1490 (m), 1450 (s), 1400 (m), 1150 (s), 690 (s). ^{1}H NMR δ: 7.27 (m, 2H), 7.17 (m, 3H), 3.15 (dd, *J* = 7 and 3 Hz, 1H), 2.54 (dd, *J* = 7 and 6 Hz, 1H), 2.37 (m, 2H), 2.12 (m, 2H), 1.97 (m, 1H), 1.71 (m, 1H), 1.60 (m, 1H). ^{13}C NMR δ: 220.1, 140.0, 128.8, 128.4, 126.1, 51.0, 38.2, 35.6, 29.1, 20.5.

2-(3′-Bromopropyl)cyclopentanone (2f)

The racemic ketone (32) was purified by flash chromatography on silica gel using 10:1 petroleum ether–acetone as the eluant to give **2f** as colourless oil (2.6 g, 41% yield after two steps). IR ν_{max} (neat) (cm^{-1}): 2960 (m), 2875 (m), 1743 (s), 1374 (w), 1242 (m), 1157 (w). ^{1}H NMR δ: 4.00 (t, *J* = 3 Hz, 2H), 2.23 (m, 2H), 2.03 (m, 1H), 1.80–1.60 (m, 4H), 1.46 (m, 2H), 1.27 (m, 2H). ^{13}C NMR δ: 220.7, 64.1.3, 48.6, 38.0, 29.5, 26.6, 26.0, 20.6. MS *m*/*z* (%): 204/206 (1), 125 (100), 107 (38), 83 (26), 67 (37), 55 (85).

6-Cyclopentyltetrahydropyran-2-one (5c)

Ketone **2c** (100 mg, 0.66 mmol) was oxidized using *E. coli* (CHMO) and was purified by flash chromatography on silica gel (petroleum ether–ethyl acetate, 5:1) to afford **5e** (22 mg, 20%, 9% ee). IR ν_{max} (neat) (cm^{-1}): 2952 (s), 2869 (m), 1731 (s), 1243 (m), 1176 (m). ^{1}H NMR δ: 4.10, (m, 1H), 2.57 (m, 1Ha), 2.45 (m, 1Hb); 2.07 (m, 2H), 1.90 (m, 3H), 1.75–1.50 (m, 4H), 1.42 (m, 2H), 1.28 (m, 2H). ^{13}C NMR δ: 172.3, 84.5, 45.2, 29.7, 28.9, 28.8, 27.1, 25.6, 25.5, 18.7.

6-*iso*-Butyltetrahydropyran-2-one (5d)

Biotransformation of **2d** using *E. coli* (CHMO) followed by flash chromatography (petroleum ether–acetone, 7:1 then 5:1) gave **5d** (23%, 83% ee). IR ν_{max} (neat) (cm^{-1}): 2928 (s), 2855 (m), 1741 (s), 1463 (w), 1246 (m), 1047(m). ^{1}H NMR δ: 4.31 (m, 1H), 2.51 (m, 1H), 2.43 (m, 1H), 1.87 (m, 4H), 1.63 (m, 1H), 1.47 (m, 1H), 1.28 (m, 1H), 0.90 (d, *J* = 1 Hz, 3H), 0.88 (d, *J* = 1 Hz, 3H). ^{13}C NMR δ: 172.0, 78.7, 44.9, 29.4, 28.3, 23.9, 23.0, 22.0, 18.4.

6-Benzyltetrahydropyran-2-one (5e)

Biotransformation of **2e** (100 mg, 0.57 mmol) using *E. coli* (CHMO) followed by flash chromatography (petroleum ether–ethyl acetate, 4:1) gave **5e** pale yellow oil (28%, 61% ee). IR ν_{max} (neat) (cm^{-1}): 3060 (w), 3027 (w), 2951 (m), 2874 (m), 1733 (vs), 1496 (m), 1455 (m), 1238 (s), 1178 (m), 1040 (m), 749 (w), 700 (m). ^{1}H NMR δ: 7.33–7.14 (m, 5H), 4.51 (m, 1H), 3.09–2.88 (d ABquartet, *J* = 27 and 11 Hz, 2H), 2.57 (m, 1H), 2.44 (m, 1H), 1.89 (m, 2H), 1.52 (m, 2H). ^{13}C NMR δ: 171.6, 136.4, 129.5, 128.5, 126.8, 81.0, 42.1, 29.4, 27.0, 18.4.

(*R*)-6-(3′-Bromopropyl)tetrahydropyran-2-one (5f) (33)

Ketone **2f** (100 mg, 0.45 mmol) and γ-cyclodextrin (0.5 g) were added to YP-Gal (100 mL) in a 250-mL baffled-conical flask. The mixture was then shaken at 30°C at 250 rpm for 5–10 min to obtain a uniform dispersion. A 1-mL portion of yeast cells was added to the reaction flask and the culture was shaken at 30°C (250 rpm). The reaction monitored by GC and chiral-GC, and was stopped at 50% conversion. After saturating the mixture with NaCl, the organic layer was extracted with ethyl acetate (3 × 100 mL). The combined organic extracts were dried over anhydrous sodium sulfate and concentrated by rotary evaporation. Separation of chiral lactone and ketone by flash chromatography (hexane–acetone, 3:1) gave lactone **5f** as colorless oil (51 mg, 47% yield, 94% ee) and ketone (*S*)-**2f** also as colorless oil (53 mg, 47% yield, 92% ee). (*R*)-**5f**: $[\alpha]_D^{25}$ –63 (*c* 0.4, EtOAc, 95% ee (GC)). IR ν_{max} (neat): 2956, 1734 (s), 1242, 1944. ^{1}H NMR δ: 4.29 (m, 1H), 4.08 (m, 2H), 2.57 (m, 1H) 2.42 (m, 1H), 1.88–1.71 (dm, 6H), 1.51 (m, 2H). ^{13}C NMR δ: 171.3, 80.0, 64.1, 32.5, 28.0, 25.1, 24.5, 18.7. MS *m*/*z*: 223 ($[M + 1]^+$), 141, 112, 99, 55. HRMS calcd. for $C_8H_{13}BrO_2$: 220.0099 / 222.0078; found: 220.0099 / 222.0079. Unreacted ketone (42 mg, 42%) (*S*)-**2f**: $[\alpha]_D^{25}$ –144 (*c* 1.65, CH_2C1_2, 92% ee (GC)). An analytical sample of (*S*)-**2d** was oxidized with *m*-chloproperbenzoic acid (TFA, CH_2Cl_2) to give (*S*)-**5f** 92% ee (GC).

1,4-Dioxa-spiro[4.4]nonane-6-carboxylic acid methyl ester (3)

Methyl cyclopentanone-2-carboxylate (5.0 mL, 40 mmol) was added to a solution of *p*-toluene sulfonic acid (5.6 g, 40 mmol) in ethylene glycol (20 mL) and stirred at room temperature for 30 min. The mixture was poured into 50 mL 1 M KOH solution saturated with NaCl and extracted with ether (4 × 50 mL). The combined organic extracts were washed with brine and dried over anhydrous Na_2SO_4. The solvent was removed on a rotary evaporator to give **3** as a colourless oil, 4.73 g (75%). IR ν_{max} (neat) (cm^{-1}): 2950 (s), 2890 (m), 1700 (vs), 1480 (m), 1350 (m), 1210 (s), 1040 (m). ^{1}H NMR δ: 4.05–4.00 (m, 1H), 3.97–3.88 (m, 3H), 3.70 (s, 3H), 2.92 (t, *J* = 7.7 Hz, 1H), 2.12 (m, 1H), 1.98–1.79 (m, 4H), 1.67 (m, 1H). ^{13}C NMR δ: 172.8, 118.3, 65.1, 64.5, 52.2, 51.7, 51.6, 36.7, 26.9, 22.0.

1,4-Dioxa-spiro[4.4]non-6-yl-methanol (4)

1,4-Dioxa-spiro[4.4]nonane-6-carboxylic acid methyl ester (**3**, 3.8 g in 10 mL THF, 20 mmol) was added to a vigorously stirred suspension of $LiAlH_4$ (0.8 g, 21 mmol) in THF (60 mL) at 0°C. The mixture was stirred for 1.5 h and allowed to warm up to room temperature. The reaction was quenched by pouring it into an ice cold saturated tartaric acid solution and was then extracted with ethyl acetate (5 × 40 mL). The combined organic extracts were dried over anhydrous Na_2SO_4 and the solvent was removed on a rotary evaporator to give **4** as a colourless oil, 2.81 g (87%). IR ν_{max} (neat) (cm^{-1}): 3500 (m, br), 2950 (s), 2890 (s), 2390 (s), 2280 (m), 1460 (m), 1390 (m), 1330 (m), 1160 (s), 1100 (m), 1020 (s). ^{1}H NMR δ: 3.96–3.84 (m, 4H), 3.66–3.54 (m,

© 2002 NRC Canada

2H), 2.64 (br s, 1H), 2.34–2.05 (m, 1H), 1.84–1.76 (m, 1H), 1.74–1.46 (m, 5H). ^{13}C NMR δ: 119.0, 64.5, 64.0, 62.5, 47.0, 35.6, 25.6, 21.3.

2-Hydroxymethylcyclopentanone (2g) (34)

$CeCl_3 \cdot 7H_2O$ (1.86 g, 5 mmol) and KI (0.3 g, 1.8 mmol) were mixed with 18 g silica gel (200–425 mesh) in acetone (30 mL) and ground in a mortar. Compound **4** (0.96 g, 6 mmol) was added and the mixture was stirred at room temperature for 30 min. The silica was filtered off and the solid was washed with acetone. The solvent was removed on a rotary evaporator and the residue was purified by flash chromatography (hexane–ethyl acetate, 3:1) to give **2g** as a colourless oil, 0.67 g (97%). IR ν_{max} (neat) (cm^{-1}): 3427 (s, br), 2966 (s), 2877 (s), 1734 (vs), 1404 (m), 1154 (m), 1054 (m). ^{1}H NMR (acetone-d_6) δ: 3.73–3.64 (m, 3H, including an overlapping OH peak), 2.26–2.12 (m, 3H), 2.10–1.95 (m, 2H), 1.96–1.75 (m, 2H). ^{13}C NMR (acetone-d_6) δ: 219.5, 61.6, 51.7, 39.0, 27.1, 21.4.

6-Hydroxymethyltetrahydropyran-2-one ((*R*)-5g)

Ketone **2g** oxidized using yeast (CHMO) was purified by flash chromatography (petroleum ether–acetone, 2:1) to give colorless oil (16 mg, 14%, 34% ee). $[\alpha]_D^{25}$ –11 (*c* 4.5, EtOAc. Lit. (25) (*R*)-enantiomer: $[\alpha]_D^{25}$ –32 (*c* 1.3, $CHC1_3$)). IR ν_{max} (neat) (cm^{-1}): 3394 (m, br), 2947 (m), 2881 (w), 1723 (vs), 1249 (s), 1058 (s). ^{1}H NMR δ: 4.42–4.35 (m, 1H), 3.76 (dd, *J* = 12.1 and 3.2 Hz, 1H), 3.66 (dd, *J* = 12.3 and 5.5 Hz, 1H), 2.64–2.54 (m, 1H), 2.48–2.39 (m, 1H), 2.00–1.90 (m, 1H), 1.90–1.81 (m, 2H), 1.81–1.64 (m, 2H). ^{13}C NMR δ: 171.4, 81.0, 64.9, 29.6, 23.6, 18.3.

6-Methoxymethyl-1,4-dioxa-spiro[4.4]nonane (4h)

NaH (2 g, 50% dispersion in mineral oil, excess) was added to a 100-mL two-neck round-bottom flask and the system was flushed with nitrogen. NaH was washed 3 times with THF, and then was finally suspended in THF (10 mL). MeI (2 mL, excess) was added, followed by 1,4-dioxa-spiro[4.4]non-6-yl-methanol **4** (1.58 g in 40 mL THF, 10 mmol) with vigorous stirring. After reacting overnight, the mixture was poured onto ice cubes and extracted with ethyl acetate (3 × 35 mL). The combined extracts were washed once with 0.2 M KOH, once briefly with 0.5 M HCl, and once with brine. After drying over anhydrous K_2CO_3, the solvent was removed on a rotary evaporator to give the title product as a colourless oil, 1.11 g (89%). IR ν_{max} (film) (cm^{-1}): 2950 (vs), 2870 (vs), 1450 (s), 1380 (s), 1320 (s), 1200 (s), 1100 (vs), 750 (s). The crude product was used in the next step without further characterizations.

2-Methoxymethylcyclopentanone (2h)

6-Methoxymethyl-1,4-dioxa-spiro[4.4]nonane (**4h**, 0.8 g, 4.7 mmol) was dissolved in acetone (10 mL). In a separate flask $PdCl_2$ (30 mg) was dissolved in acetone (1 mL) and acetonitrile (0.5 mL). The two solutions were combined and TFA (1 mL) was added. The mixture was stirred at room temperature for 3 h, poured into brine, and extracted with ethyl acetate (3 × 35 mL). The combined extracts were dried over anhydrous Na_2SO_4 and the solvent was removed on a rotary evaporator. The residue was purified by flash chromatography (hexane–ethyl acetate, 10:1) to give **2h** as a colourless oil, 0.56 g (94%). IR ν_{max} (neat) (cm^{-1}): 2970 (s), 2920 (s), 2870 (s), 1730 (s), 1150 (m), 1120 (m). ^{1}H NMR δ: 3.53 (m, 2H), 3.30 (s, 3H), 2.34–1.96 (m, 5H), 1.80 (m, 2H). ^{13}C NMR δ: 219.5, 71.5, 59.0, 49.4, 38.6, 27.1, 20.8.

6-Methoxymethyltetrahydropyran-2-one (5h)

Ketone **2h** was oxidized using *E. coli* (CHMO) to give **5h**, which was purified by flash chromatography (petroleum ether–acetone, 5:1, then petroleum ether–acetone, 3:1) to give a colorless oil (16 mg, 14%, 44% ee). IR ν_{max} (neat) (cm^{-1}): 2940 (m), 2881 (m), 2815 (w), 1736 (vs), 1249 (s), 1071 (s). ^{1}H NMR δ: 4.46–3.90 (m, 1H), 3.55–3.47 (m, 1H), 3.36 (s, 3H), 3.28–3.18 (m, 1H), 2.62–2.53 (m, 1H), 2.43–2.34 (m, 1H), 1.98–1.87 (m, 2H), 1.74–1.62 (m, 2H). ^{13}C NMR δ: 172.6, 79.0, 74.4, 59.4, 29.6, 24.5, 18.3. The unreacted **2h** was also isolated: 7% ee; $[\alpha]_D^{25}$ –17 (*c* 1.3, CH_2Cl_2).

6-Allyloxymethyl-1,4-dioxa-spiro[4.4]nonane (4i)

Compound **4i** was synthesized according to the same protocol as **4h**, except allyl bromide was used instead of methyl iodide. The crude product was used in the following step without purification.

2-Allyloxymethylcyclopentanone (2i)

Crude **4i** dissolved in a mixture of acetone (20 mL) and HCl (5 mL, 2 M) was stirred at room temperature for 2 h. Acetone was removed by rotary evaporation and the residue was extracted with CH_2Cl_2. Combined extracts were dried over anhydrous Na_2SO_4 and the solvent was removed by rotary evaporation. The crude product was purified by flash chromatography (hexane–ethyl acetate, 6:1) to give **2j** as a colorless oil, 0.35 g (90% from **4i**). IR ν_{max} (neat): 3081 (w), 2967 (s), 2877 (s), 1737 (vs), 1647 (w), 1152 (s), 1088 (s), 926 (s). ^{1}H NMR δ: 5.84–5.73 (m, 1H), 5.20–5.04 (m, 2H), 3.87 (dt, *J* = 5.5 and 1.4 Hz, 2H), 3.57–3.48 (m, 2H), 2.31–2.10 (m, 3H), 2.12–2.00 (m, 1H), 2.00–1.91 (m, 1H), 1.88–1.76 (m, 1H), 1.76–1.65 (m, 1H). ^{13}C NMR δ: 219.3, 134.5, 116.6, 71.9, 68.9, 49.2, 38.5, 27.0, 20.7.

6-Allyloxymethyltetrahydropyran-2-one ((*R*)-5i)

Ketone **2i** oxidized using *E. coli* (CHMO) was purified by flash chromatography (petroleum ether–acetone 5:1 followed by petroleum ether–acetone, 3:1). $[\alpha]_D^{25}$ = –14.1 (*c* 2.2, $CDCl_3$). IR ν_{max} (neat) (cm^{-1}): 3078 (w), 2947 (m), 2876 (m), 1726 (vs), 1453 (m), 1347 (m), 1240 (s), 1062 (s), 932 (m). ^{1}H NMR δ: 5.91–5.80 (m, 1H), 5.25 (dq, *J* = 17.3 and 1.5 Hz, 1H), 5.16 (qd, *J* = 10.4 and 1.2 Hz, 1H), 4.46–4.39 (m, 1H), 4.01 (dd, *J* = 5.5 and 1.5 Hz, 2H), 3.56 (m, 2H), 2.60–2.52 (m, 1H), 2.48–2.39 (m, 1H), 1.98–1.88 (m, 2H), 1.87–1.76 (m, 1H), 1.75–1.63 (m, 1H). ^{13}C NMR δ: 171.2, 134.2, 117.3, 79.1, 72.5, 71.8, 29.6, 24.6, 18.2. MS *m*/*z* (%): 171 ($[M + 1]^+$, 0.2), 114 (48), 99 (58), 71 (100), 55 (28). The isolated chiral ketone **2i**, 19% yield, 81% ee: $[\alpha]_D^{25}$ – 56 (*c* 1.9, $CH_2Cl_{2)}$. Lactone (*R*)-**5i** was hydrogenated (5% Pd/C in methanol–water (2:1) containing 1% *p*-toluene sulfonic acid, 5 h) to give (*R*)-**5g** (60%, 93% ee) (25).

Metal substitution in thermolysin: Catalytic properties of tungstate thermolysin in sulfoxidation with H_2O_2

Martin Bakker, Fred van Rantwijk, and Roger A. Sheldon

Abstract: The catalytic Zn^{2+} ion was extracted from thermolysin, which had been covalently bound to Eupergit C. The apo-enzyme incorporated the oxometallate anions MoO_4^{2-}, SeO_4^{2-}, and WO_4^{2-} with partial restoration of the proteolytic activity. Tungstate thermolysin was moderately active in the sulfoxidation of thioanisole by hydrogen peroxide, whereas its activity towards phenylmercaptoacetophenone, which was designed to bind well in the active site of thermolysin, was much higher.

Key words: thermolysin, metal substitution, sulfoxidation.

Résumé : On a pu extraire l'ion catalytique Zn^{2+} de la thermolysine qui avait été liée de façon covalente à Eupergit C. L'apoenzyme incorpore alors les anions oxométallates MnO_4^{2-}, SeO_4^{2-} et WO_4^{2-} avec restauration partielle de l'activité protéolytique. La thermolysine au tungstate est modérément active dans la réaction de sulfoxydation du thioanisole par le peroxyde d'hydrogène alors que son activité est beaucoup plus élevée vis-à-vis de la phénylmercaptoacétophénone qui avait été choisie pour bien se lier dans le site actif de la thermolysine.

Mots clés : thermolysine, substitution d'un métal, sulfoxydation.

[Traduit par la Rédaction]

Introduction

Post-translational modification of the active site is a powerful tool for modifying the catalytic activity of enzymes (1). Yamamura and Kaiser (2) proved the validity of this notion by substituting the catalytic Zn^{2+} ion in the active site of carboxypeptidase A by Cu^{2+}, transforming the peptidase into an oxidase. More recently, the serine hydrolase subtilisin has been transformed into selenosubtilisin, which mimics glutathione peroxidase (3). We selected the neutral zinc-dependent protease thermolysin (4) from *Bacillus proteolyticus rokko* (E.C. 3.4.24.4) as an attractive candidate for metal substitution, because it is readily available and highly stable (5, 6). We were surprised to find that apothermolysin (7, 8), upon reconstitution with oxometallate anions, regained a part of its proteolytic activity. We present here our results on sulfoxidation in the presence of this tungstate thermolysin.

Results and discussion

Metal substitution in immobilized thermolysin

Thermolysin was fixed to Eupergit C (an acrylic copolymer containing an oxirane functionality) using a standard procedure recommended by the supplier. The catalytic Zn^{2+} ion was extracted from the Eupergit-fixed thermolysin by repeated treatment with an EDTA solution (7*a*) until the residual activity was lower than 1%. Treatment of the carrier-fixed apo-enzyme with Co^{2+} or Mn^{+2} ions resulted in a partial recovery of the proteolytic activity. We note, inter alia, that a twofold activation of thermolysin upon incorporation of a Co^{2+} ion has been reported (8), but our procedure was not optimized. Even the incorporation of the bulky oxometallate ions MoO_4^{2-}, SeO_4^{2-}, and WO_4^{2-}, which do not display proteolytic activity when freely dissolved, into apothermolysin partially restored the proteolytic activity of the latter (Table 1). We tentatively conclude that the oxometallate anions are correctly bound in the active site, in spite of their size.

Sulfoxidation mediated by tungstate(IV) thermolysin

Tungstate is known to catalyze various oxidations with H_2O_2 (9), and we surmized that incorporation of tungstate in the active site could transform thermolysin into an oxidation catalyst. We therefore investigated the use of Eupergit-bound tungstate thermolysin in sulfoxidation reactions with H_2O_2 (Fig. 1). The reactions were performed in *tert*-butyl alcohol at 40°C; the biocatalyst showed a high stability under these conditions. The aromatic sulfides **1**–**5** were selected as substrates for tungstate thermolysin because native thermolysin

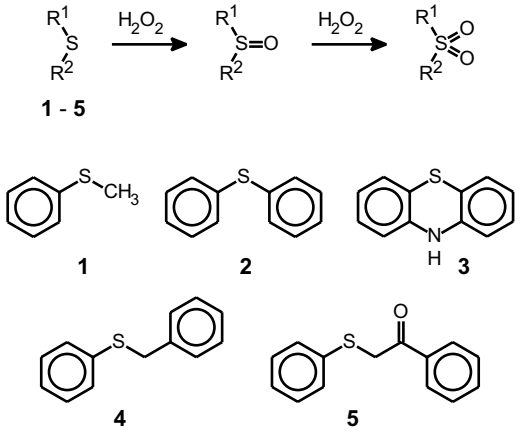
WO_4^{2-}	7	58

Fig. 1. Sulfides and sulfoxidation.



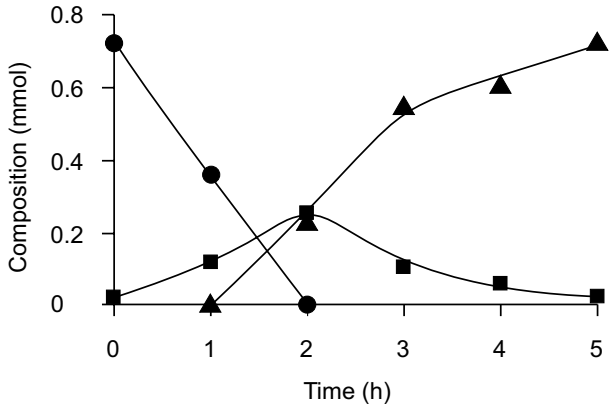
is known to favour reactants with bulky hydrophobic groups (10).

Thioanisole (**1**) was slowly converted into its racemic sulfoxide in the presence of tungstate(VI) thermolysin (Table 2). The further reaction to the sulfone, which is generally not observed in peroxidase-mediated sulfoxidation, was much slower and took 24 h to reach complete conversion. The reaction was much slower in the absence of any catalyst and did not progress beyond the sulfoxide stage; addition of sodium tungstate had no effect. We also performed a reaction in the presence of tungstate thermolysin and removed the catalyst by filtration after 2.5 h (9% conversion). The reaction slowly continued in the filtrate, at a rate comparable with that of the uncatalyzed reaction, to reach 55% conversion into the sulfoxide after 7 h.

The conversion of diphenyl sulfide (**2**) was insignificant, regardless of the presence of tungstate thermolysin. Phenothiazine (**3**), which has a planar and rigid structure, reacted much faster than **2** and was completely converted in 20 h. The uncatalyzed reaction was much slower, but in contrast with all of the other sulfides, sodium tungstate exerted a significant catalytic effect. Benzyl phenyl sulfide (**4**) was converted at a comparable rate.

The highest reaction rate was observed with phenylmercaptoacetophenone (**5**). Within 2 h a complete conversion into a mixture of the sulfoxide and the sulfone was observed. The reaction continued to complete conversion into the sulfone after 5 h (Fig. 2). The uncatalyzed reaction was much slower and no formation of the sulfone was observed. We tentatively attribute the high reactivity of **5** to its resemblance to the natural (peptide) subtrates of thermolysin.

Fig. 2. Time course of the tungstate thermolysin-mediated oxidation of **5**. ● (**5**); ■ (sulfoxide); ▲ (sulfone).



Hence, this result also supports the hypothesis that tungstate is incorporated into the active site.

Conclusion

The reconstitution of Eupergit C fixed apo-thermolysin with a range of metal and oxometal ions results in a partial recovery of the proteolytic activity. Incorporation of tungstate(IV) transforms thermolysin into a peroxidase, which is a moderately active catalyst for the oxidation of sulfides into their sulfoxides and sulfones. It accepts much bulkier substates than common peroxidases, but the sulfoxides are racemic. This surprising lack of enantioselectivity will be the subject of further investigation.

Experimental

Materials

Thermolysin from *Bacillus thermoproteolyticus rokko* (E.C. 3.4.24.4) was received from DSM Research (Geleen, The Netherlands) as a gift. Eupergit C (an acrylic copolymer containing an oxirane functionality) was kindly donated by Röhm GmbH (Darmstadt, Germany). 3-(2-Furylacryloyl)-glycyl-L-leucine amide (FAGLA) was purchased from Sigma. Thioanisole, diphenyl sulfide, diphenyl sulfoxide, diphenyl sulfone, phenyl benzyl sulfide, phenothiazine, disodium molybdate(IV), disodium selenate(VI), vanadium trioxide, disodium tungstate(VI), manganese(II) acetate, cobalt(II) chloride, zinc acetate, and copper(II) chloride were obtained from Aldrich. Ethylenediamine-(*N*,*N*,*N*′,*N*′)tetra-acetic acid (EDTA) was purchased from Acros.

Thermolysin was immobilized on Eupergit C by dissolving dialyzed and concentrated thermolysin (100 mg) in Hepes buffer (1.0 M, 50 mL) containing $CaCl_2$ (1 mM). Eupergit C (1 g) was added and the suspension was shaken for 72 h at 4°C. The solids were collected by filtration and washed (4 h) with Tris buffer (100 mM, 3 × 100 mL) containing 0.5% $CaCl_2$, to destroy any unreacted epoxide groups. 16.7 mg thermolysin was bound per g of carrier material.

Analysis and equipment

Proteolytic assay

The proteolytic activity of thermolysin was measured during the hydrolysis of FAGLA, according to the method developed by Feder (11). FAGLA (76.6 mg, 2.49 mmol) was dissolved in Tris buffer (50 mM, pH 7.5), containing $CaCl_2$ (10 mM, 100 mL). The FAGLA solution (3 mL) was mixed with a thermolysin sample (5–10 mg thermolysin on Eupergit C; 1–5 mg native enzyme) in a 3-mL quartz cuvette, stirred for 3 s, and placed in a UV spectrophotometer (Varian Cary 3). The absorbance at 345 nm was monitored while stirring. The data points were fitted to first-order kinetics and V_{max} was calculated using K_m = 30 μM (11). One unit (U) will hydrolyze 1 μmol FAGLA per min under V_{max} conditions.

Reaction monitoring

The sulfoxidation reactions of **1**, **2**, **4**, and **5** were monitored by reversed-phase HPLC, using a custom-packed 7 μ Symmetry C18 cartridge (Waters Radial-Pak, 8 × 100 mm) contained in a Waters RCM 8 × 10 compression unit at 1 mL min^{-1} eluent flow and UV detection (Waters 486) at 220 nm with Waters Millennium[32] software. Further analysis conditions are summarized in Table 3. The oxidation of **3** was more conveniently monitored by HPLC over a Chiralcel OD column.

Samples for analyzing the enantiomeric excess of the sulfoxides were diluted with hexane–isopropyl alcohol (75:25, v/v) and dried over Na_2SO_4. After centrifugation, the samples were analyzed by chiral HPLC, using a Chiralcel OD column (Diacel Chemical Industries, Ltd., 250 × 4.6 mm), hexane–isopropyl alcohol (75:25, v/v) at 0.6 mL min^{-1} as the eluent, and UV detection (Waters 486) at 220 nm with Waters Millennium[32] software. The same technique was used for monitoring the oxidations of **3**; eluent hexane–isopropyl alcohol (80:20, v/v).

Metal substitution in immobilized thermolysin

Thermolysin on Eupergit C (1 g) was shaken for 3 h in a solution of EDTA (2 mM, 100 mL), NaCl (1 M), and Tris buffer (50 mM, pH 7.5) at 4°C. The solids were collected by filtration and the treatment was repeated until the residual activity was less than 1%. Any excess of EDTA was removed from the immobilized apo-enzyme by washing 1 M NaCl (3 × 200 mL) containing Tris buffer (50 mM, pH 7.5).

The apo-enzyme was reconstituted by treatment with a 1 mM metal ion solution in Tris buffer (50 mM, pH 7.5) for 1 h at room temperature. The volume was measured and the Ca^{2+} concentration was increased to 10 mM. The resulting suspension was agitated overnight at 4°C and the proteolytic activity of the reconstituted catalyst was measured.

Table 3. HPLC conditions.

Reactant	Internal standard	Eluent composition (v/v)
1	1,2,3-Trimethoxybenzene	ACN–H_2O (35:65)
2	1,3-Dimethoxybenzene	ACN–H_2O (40:60)
4	1,2,3-Trimethoxybenzene	ACN–H_2O (45:55)
5	2-Oxindole	ACN–H_2O (40:60)

Synthesis of substrates and products

Phenylmercaptoacetophenone (**3**) was prepared by dissolving 2-bromoacetophenone (5 g, 25 mmol) in cold ethanol (50 mL). K_2CO_3 (6.9 g, 50 mmol) was added, and then thiophenol (2.75 g, 25 mmol) was slowly titrated over 2 h. The resulting mixture was stirred for 12 h and the solids were removed by filtration. The filtrate was washed with water and the aqueous layer was extracted with ethyl acetate. The combined organic layers were dried over Na_2SO_4 and concentrated in vacuo. Yellow crystals were obtained and recrystallized from an ethyl acetate–diethyl ether mixture. Yield 83%, purity (HPLC) 99%. mp: 227–229°C. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 4.25 (s, 2H), 7.25–8.22 (m, 10H). MS *m*/*z*: 228 ($C_{14}H_{12}OS$).

The sulfoxides and sulfones that were not commercially available were prepared from the sulfides by oxidation with H_2O_2 (12) and $KHSO_5$ (13), respectively, according to published procedures.

Oxidation procedure

Sulfide (0.8 mmol) and wet immobilized tungstate thermolysin (200 mg) were mixed in *tert*-butyl alcohol and stirred at 40°C in a sealed vessel until the reactant was dissolved. A 1 M aqueous H_2O_2 solution (1.6 mmol) was added to the reaction mixture over 2 h, using a Metrohm 665 Dosimat syringe-pump system, while stirring. Samples were withdrawn at regular intervals, treated with Na_2SO_3 (catalase in the case of phenylmercaptoacetophenone) to destroy the excess of H_2O_2, and analyzed by HPLC.

Acknowledgments

The authors express their thanks to DSM Research (Geleen, The Netherlands) for the kind gift of thermolysin. A generous donation of Eupergit C by Röhm GmbH (Darmstadt, Germany) is also gratefully acknowledged.

Second-generation MS-based high-throughput screening system for enantioselective catalysts and biocatalysts

Wolfgang Schrader, Andreas Eipper, D. Jonathan Pugh, and Manfred T. Reetz

Abstract: A high-throughput method is described, where the enantioselectivity of approximately 10 000 catalysts or biocatalysts can be determined per day. The method is based on electrospray mass spectrometric techniques using an eight-channel multiplexed (MUX) sprayer system connected to a time-of-flight mass spectrometer. The inlet of the ion source is controlled by a stepping rotor that is continuously moving from one sprayer to the next with a recording time of 100 ms for each channel and a delay time of 50 ms, thus allowing a spectrum to be obtained from each channel every 1.2 s. One cycle, where eight samples are being sprayed in parallel, requires around 70 s, which allows a 96-well microtiter plate to be screened in 14 min. Integration of two pseudo-enantiomers (*S*)-glycidyl phenyl ether and (*R*)-D_5-glycidyl phenyl ether is necessary to quantify the enantiomeric excess (ee-value), where one enantiomer is isotopically labeled to allow easy identification of the mass spectrometric signals. Errors of ~2% for the ee-values indicate that in addition to the significant improvement in sample throughput this is also a precise method for high-throughput screening. This second-generation assay is useful for combinatorial enantioselective transition-metal catalysis and in the directed evolution of enantioselective enzymes.

Key words: multiplexed ESI-MS, high-throughput screening, enantioselectivity, combinatorial catalysis, directed evolution.

Résumé : On décrit une méthode à grand débit à l'aide de laquelle on peut déterminer l'énantiosélectivité d'environ 10,000 catalyseurs ou biocatalyseurs par jour. La méthode est basée sur des techniques de spectrométrie de masse avec électronébulisation à l'aide d'un système de nébulisation multiplex à huit canaux relié à un spectromètre de masse à temps de vol. L'insertion dans la source ionique est contrôlée par un rotor variable qui se déplace continuellement d'un nébulisateur au suivant, avec un temps d'enregistrement de 100 ms pour chaque canal et un délai de 50 ms qui permet d'obtenir un spectre pour chaque canal toutes les 1,2 s. Un cycle, dans lequel on soumet huit échantillons à la nébulisation en parallèle, requiert 70 s; il est donc possible de traiter un bloc de 96 échantillons en 14 min. Quand un énantiomère est marqué d'un isotope, il est nécessaire d'introduire deux pseudo-énantiomères, l'oxyde de (*S*)-glycidyle et de phényle et l'oxyde de (*R*)-D_5-glycidyle et de phényle, pour identifier rapidement les signaux de spectrométrie de masse et pour quantifier les excès énantiomériques (valeur ee). Des erreurs d'environ 2% dans les valeurs ee indiquent que, en plus d'être une amélioration sensible au débit des échantillons, cette méthode s'avère aussi très précise pour une évaluation à grand débit. Cette méthode de deuxième génération est utile dans le domaine de la catalyse énantiosélective combinatoire par les métaux de transition et dans l'évolution orientée des enzymes énantiosélectifs.

Mots clés : spectrométrie de masse avec électronébulisation multiplex, évaluation à grand débit, énantiosélectivité, catalyse combinatoire, évolution orientée.

[Traduit par la Rédaction]

Introduction

The importance of enantiomerically pure or enriched organic compounds in pharmaceutical, agricultural, synthetic organic, and natural products chemistry is undisputed (1). Although classical separation of enantiomers is still used in industry (1*d*), in the future the most economically and ecologically attractive strategy is likely to be enantioselective catalysis. The two options are synthesized catalysts such as chiral transition-metal complexes (2) or biocatalysts (3). The former involves ligand tuning, a process requiring design, molecular modelling, and usually a great deal of trial and error. Recently, an alternative approach to the traditional development of chiral transition-metal catalysts has emerged,

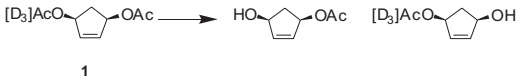
namely combinatorial methods in which large numbers of catalysts are produced in a parallel manner (4, 5). The challenges in this new field of endeavour are twofold because novel synthetic strategies as well as efficient high-throughput screening systems need to be developed. In the case of enzymes as asymmetric catalysts in organic chemistry, the method of directed evolution (6) has recently been applied for the first time (7). This entailed the creation of thousands of mutant enzymes, which were screened for enantioselectivity in a given synthetic transformation. Several cycles of mutagenesis screening resulted in highly enantioselective catalysts — knowledge of the structure or of the mechanism of the enzyme is not necessary.

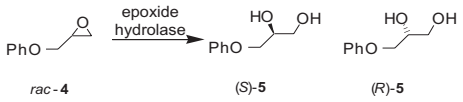
Both approaches to asymmetric catalysis rely on the availability of analytical systems capable of assaying the enantiomeric excess (ee) of large numbers of samples within a reasonable time span, and hence why various high-throughput and super high-throughput ee-assays have been recently developed (5). These assays have been based on color tests (7, 8), capillary-array electrophoresis (9), IR thermography (10), fluorescence (11), circular dichroism (12), or other systems (13–18). Mass spectrometry (MS) is a particularly powerful method for high-throughput analysis of products arising from general catalytic reactions (19), in the rapid LC–MS screening of chiral stationary phases (20), and in the FAB-MS study of crown ether complexes (21). Finn and co-workers (22) have recently developed an MS system for high-throughput determination of enantioselectivity based on the formation of diastereomers.

We have previously described an ee-assay based on the use of isotopically labeled substrates, detection being possible by MS using standard ionization methods such as electrospray ionization (ESI) or matrix-assisted laser-desorption ionization (MALDI) (23). Two fundamentally different stereochemical processes can be monitored by our method: (*i*) the kinetic resolution of racemates and (*ii*) the desymmetrization of prochiral compounds bearing enantiotopic groups (Scheme 1).

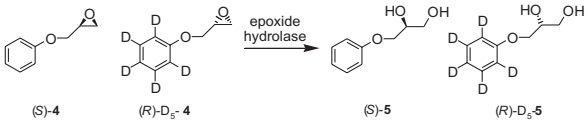
Scheme 2. Reaction of a pseudo-meso-compound (**1**) with formation of pseudo-enantiomers **2** and **3**.



Scheme 3. Kinetic resolution of glycidyl phenyl ether (**4**) by an epoxide hydrolase.



Scheme 4. Enzymatic hydrolysis of the pseudo-enantiomers (*S*)-glycidyl phenyl ether and (*R*)-D_5-glycidyl phenyl ether.



For kinetic resolution, pseudo-enantiomeric substrates must also be used, i.e., one of the enantiomers has to be isotopically labeled (23). After the reaction with the proposed enantioselective catalyst, the mixture can be analyzed using MS. Because of the isotopical labeling, the two pseudo-enantiomers are adequately separated with respect to their mass-to-charge ratios to allow for quantitative determination of their respective signals, while being chemically indifferent so as not to influence their catalytic conversion. In each case a simple kinetic experiment was necessary to exclude possible kinetic isotope effects in the actual reaction. The quantitative determination of both pseudo-enantiomers allows one to determine the enantioselectivity of a given catalytic or biocatalytic transformation.

We recently initiated a project concerning the directed evolution of an epoxide hydrolase obtained from *Aspergillus niger*, which had previously been used in the kinetic resolution of certain epoxides (24). Our goal was to perform several cycles of random mutagenesis to create an enantioselective enzyme mutant, which catalyzes the kinetic resolution of glycidyl phenyl ether (*rac*-**4**) (Scheme 3). The wild-type enzyme shows, however, only a slight degree of

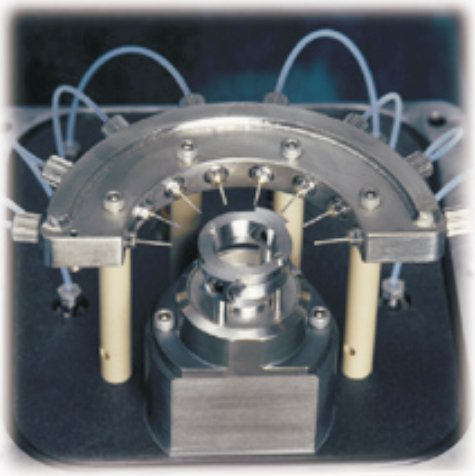
Fig. 1. MUX interface developed by Micromass, Manchester, U.K.



enantioselectivity, which is unfortunate because substrates of this kind are of great synthetic interest.

To evaluate thousands of mutant epoxide hydrolases, we envisioned the use of our ESI-MS-based assay (23). Accordingly, one of the enantiomeric epoxides needs to be labeled with deuterium and mixed with the nonlabeled enantiomer forming a pseudo-racemate (Scheme 4). We anticipated that the integration of the MS peaks of the nonlabeled (*S*)-diol ((*S*)-**5**) and the labeled (*R*)-diol ((*R*)-D_5-**5**) would provide a measure of enantioselectivity, and that it should also be possible to screen about 1000 reactions per day. In this paper we show that this is indeed the case. Moreover, we demonstrate that throughput can be increased by one order of magnitude by adapting and using a parallel eight-channel multiplexed ESI-MS system. Thus, the new ee-assay is capable of screening about 10 000 samples per day.

Experimental

Synthesis

The D_5-labeled glycidyl phenyl ether ((*R*)-D_5-**4**) was prepared analogously to the known procedure for the nonlabeled substrate (25). Model samples were prepared for analysis by mixing nonlabeled and D_5-labeled compounds to give a pseudo-racemate.

Multiplexed ESI-MS system

Electrospray mass spectrometry was carried out using an eight-channel parallel multiplexed (MUX) LC–MS system (Micromass, Manchester, U.K.). The analytical system combines a Waters 600 HPLC pump (Waters, Milford, MA, U.S.A.), one Gilson 215/889 eight-channel liquid autosampler equipped with a multi-injection module using 20 μL injection loops (Gilson, Middleton, WI, U.S.A.), eight reverse-phase columns (2.1 × 20 mm, Waters Symmetry, C8), and an eight-channel MUX ESI system (see Fig. 1) connected to a time-of-flight mass spectrometer (5*b*) (Micromass, Manchester, U.K.).

The MUX sprayer system, which consists of eight-electrospray nebulizers, was installed instead of the standard single-electrospray probe into the existing *Z*-spray ion source. This system sprays the fluids that arrive from the eight columns in a parallel manner. The inlet of the LCT is controlled by a stepping rotor, which opens to each sprayer in rapid succession. Each channel has a 100 ms recording time, with a 50-ms time delay before switching to the next channel. The data are written separately into eight different data files for each sample, thus acquiring a mass spectrum for each channel every 1.2 s. This "indexing" set-up means that only one channel is being analyzed at one time and that the data is written into the corresponding file, before the stepping rotor moves on to the next channel. Spectra were obtained in the scan mode between 100 to 800 mass units. Flow rates of 1 mL min^{-1} (MeOH–H_2O, 90:10) from the HPLC pump were adjusted to 100 μL min^{-1} for each channel through a Valco zero-dead-volume split system.

GC experiments

Control experiments to determine the ee-values were carried out using gas chromatography (GC). Accordingly, a RTX-5 column of 30 m length was used in combination with a flame-ionization detector. Product separation was achieved by using the following temperature program: start: 80°C, heating rate 8 K min^{-1} to 340°C, 10 min isotherm. This results in a retention time of 43.4 min for (*R*)-D_5-**5** and 44.8 min for (*S*)-**5**. The temperature of the injector was kept constant at 220°C.

For each sample the ee-value was determined three times. All data were averaged for each concentration (error < 0.1%).

Results and discussion

High-throughput screening ideally involves very fast, accurate, reliable, precise, and reproducible analysis. Depending on the information content that is required, limitations in any of these requirements can be accepted, provided that the overall gain in information is sufficiently satisfactory and that the main goal of high-sample throughput is achieved. Mass spectrometric methods using electrospray ionization are known to be not only fast enough, but also accomplish the other requirements for high-throughput screening systems (19).

For the determination of the enantiomeric excess, we previously developed an MS-based concept that used pseudo-enantiomers — one of the enantiomers was isotopically labeled (23). To test the feasibility of increasing throughput by using an eight-channel parallel multiplexed mass spectrometric (MUX HPLC – ESI-MS) system for high-throughput analysis of enantioselective reactions, a 96-deep-well microtiter plate was filled with 12 different samples containing the pseudo-enantiomers as shown in Scheme 4. These samples all have different ee-values as measured in control experiments using standard GC. All 12 samples were measured eight times in parallel with each of the channels spraying the same sample, thus allowing a direct comparison. The microtiter plate was scanned repeatedly overnight without operator intervention. Adequate statistical data were obtained.

For quantitative analysis, the areas below mass traces at *m/z* 191 and 196 for the nonlabeled and labeled enantiomers, respectively (both as Na^+ adducts) were integrated automatically (see Fig. 2) and then transferred into an Excel spread

sheet (26) for processing. A representative mass spectrum is shown in Fig. 3.

The enantiomeric purity of a given sample is generally defined by the enantiomeric excess (ee-value). Here the ee-values were derived by integrating the MS-peak areas of pseudo-enantiomeric diols (*S*)-**5** and (*R*)-D_5-**5**. The samples were prepared by mixing these two components to give a pseudo-racemate. In the actual application of the assay for the directed evolution of an enantioselective epoxide hydrolase, the reaction mixture contained not only (*S*)-**5** and (*R*)-D_5-**5**, but also the starting pseudo-enantiomeric epoxides (*S*)-**4** and (*R*)-D_5-**4**. We have ensured that the ratio of the starting epoxides was also reliably derived by the MS assay by integration of the relevant peaks at *m*/*z* = 173 and 178, respectively. According to the formula developed by Chen and Sih (27), the integration values of the products and the starting compounds allows for the determination of selectivity factors (*E*) in the kinetic resolution. Alternatively, the ee-value of the diol product in combination with an internal standard such as ametryne also allows for the determination of *E*, again using the formula of Chen and Sih (27). High accuracy in quantification is observed (see below). In the real application of the assay described here we used the latter method (28). Control experiments showed that no kinetic-isotopic effects were observed in the enzyme-catalyzed ring-opening reactions.

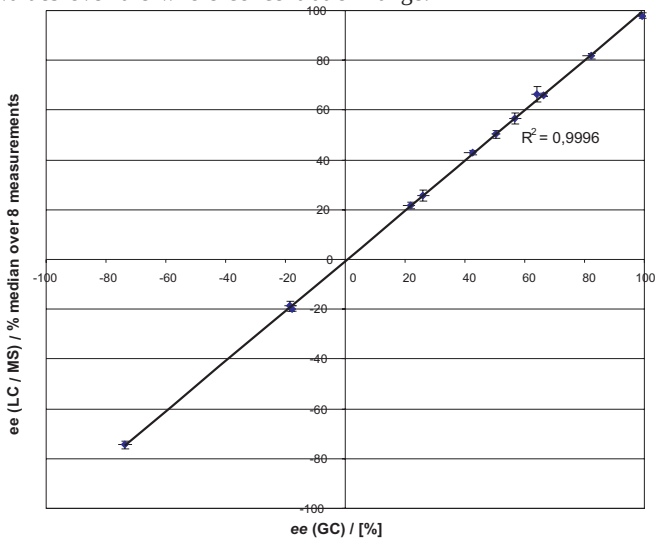
Fig. 4. Comparison of actual GC vs. average determined MS ee-values over the whole concentration range.



Rapid analysis was achieved using the MUX ESI-MS system. In the current setup the mass spectrometer can analyze eight parallel samples in about 70 s, thus allowing a 96-microtiter plate to be analyzed in 14 min. This corresponds to an overall analytical capability of ca. 10 000 ee- or *E*-determinations per day.

The use of a short HPLC column has the benefit of condensing the sample, which in turn reduces the effects of peak tailing, interference, and injection pressure fluctuations associated with simple direct-infusion analysis. In general, the more Gaussian-shaped the peak, the better the reliability of integration and therefore the greater the quantification of the method. Overall, the sample throughput is not compromised since analyte retention times of less than 30 s were observed and could be reduced further.

One of the major problems for high-throughput systems is that although they produce a high number of analytical data, the precision and accuracy is sometimes poor. In the present study, the MUX ESI-MS system provides very precise data, as can be seen in Fig. 4, where the MS-determined average ee-values are plotted against the GC values over the whole range. Moreover, accurate mass data using a time-of-flight analyzer have become available. This makes it possible to screen large libraries not only qualitatively, but also quantitatively. Table 1 shows typical results from measurements of samples in the wells of a microtiter plate. The average observed values correlate well with the corresponding GC values. The error of only 2% is quite acceptable for a high-throughput system.

The long-term stability of the sprayer system is also good. While evaluating the microtiter plate a series of 96 measurements were performed overnight on a given sample and compared with the standard values. In Fig. 5 three of such series are displayed. Difficulties can arise due to pressure fluctuations in the flow provided by the HPLC pump because the flow is divided into eight different channels supporting eight different electrosprays. Nonetheless, even though the sprayer of the ESI-MS system fluctuates, which results in larger differences in the total ion current, the ee-values remain unaffected. This is because the determination of the ee-values are based on the calculation of the ratio of the two main signals of the spectrum; the fluctuations are equal for both pseudo-enantiomers and thus do not affect the ratio.

The one limiting factor in this analysis is the dynamic range of the detector in the time-of-flight mass spectrometer (TOF-MS). The dynamic range of the multichannel plate detector (MCP) is linear over three orders of magnitude when the dead-time correction-software algorithm is applied. In absolute terms this corresponds to a maximum centroided-peak area of the monoisotopic MS peak of interest of 30 000 counts per second. Dead time arises because when an ion has been detected by the MCP there is a recovery time of approximately 4 ns before another ion arrival can be recorded. It should be noted that the presence of an intense MS peak in another region of the spectrum will have no local effect on the MS peak(s) of interest. This means that for direct quantitative analysis of the samples, the concentration range must be considered or an additional dilution step needs to be included. If necessary, a better dynamic range can be achieved by using another type of analyzer, such as a quadrupole MS instrument, which typically provides four to five orders of magnitude linear response. Quadrupole

instruments are currently limited to four-channel multiplexed ESI systems, which effectively reduces the analytical throughput by half (29). The eight-channel MUX ESI system is only compatible with time-of-flight instruments, where the necessary high spectrum acquisition rates are possible.

Conclusion

We have developed a high-throughput ee-assay based on the MS detection of isotopically labeled pseudo-enantiomers. Our results show that the multiplexed HPLC–ESI-MS system is capable of acquiring up to 10 000 ee- or *E*-determinations per day by having a cycle time of around 70 s for eight parallel experiments. The standard deviation for the observed ee-values is around 2%, thus allowing quantitative analysis of chemical catalyst or biocatalyst libraries with high precision and excellent reproducibility. This was demonstrated using a specific substrate of interest in the kinetic resolution of a chiral epoxide. Moreover, the assay can be expected to have general applications for analyzing kinetic resolutions and for analyzing the desymmetrization of prochiral compounds containing enantiotopic groups. Finally, it is likely that the system can be used to simultaneously assay the catalytic transformation of two or more substrates without carrying out any separation.

With an improved communication link between the MS operating software and the autosampler, the analysis of even larger libraries should be possible, since the actual flow of the sample through the column requires around 30 s, and a cycle time of 40–50 s seems possible even when a washing step of the autosampler is included.

Chloroperoxidase-catalyzed oxidation of methionine derivatives

Herbert L. Holland, Frances M. Brown, Damian Lozada, Benjamin Mayne, W. Rick Szerminski, and Aaron J. van Vliet

Abstract: Treatment of *N*-methoxycarbonyl *C*-carboxylate ester derivatives of L- and D-methionine and L-ethionine by chloroperoxidase–hydrogen peroxide resulted in oxidation at sulfur to produce the (R_S) sulfoxide in moderate to high diastereomeric excess. The (R_S) sulfoxide of methionine was also obtained in moderate to high diastereomeric excess from $(\pm)_{SO}$-*N*-methoxycarbonyl-L-methionine methyl ester sulfoxide by ester hydrolysis using α-chymotrypsin, *Aspergillus* sp. protease or subtilisin Carlsberg.

Key words: amino acid oxidation, biocatalysis, biotransformation, chloroperoxidase, enzyme catalysis, lipase, sulfoxidation.

Résumé : Le traitement de dérivés *N*-méthoxycarbonyle *C*-carboxylates des L- et D-méthionines et de la L-éthionine par de la chloroperoxydase et du peroxyde d'hydrogène conduit à l'oxydation au niveau du soufre et à la formation de sulfoxydes (R_S), avec des excès diastéréomériques qui vont de modérés à élevés. Le (R_S) sulfoxyde de la méthionine a aussi été obtenu avec un excès diastéréomérique élevé à partir de l'ester méthylique du de sulfoxyde $(\pm)_{SO}$-*N*-méthoxycarbonyl-L-méthionine, par hydrolyse de l'ester à l'aide d'α-chymotrypsine, de protéase d'*Aspergillus* sp. ou de subtilisine Carlsberg.

Mots clés : oxydation d'acide aminé, biocatalyse, biotransformation, chloroperoxydase, catalyse enzymatique, lipase, sulfoxydation.

[Traduit par la Rédaction]

Introduction

Sulfoxides of the sulfur-containing amino acids possess various biological properties. Oxidation of methionine residues in proteins is the target of continued interest, and can result in structural and functional changes in protein (1) and (or) cellular oxidative-stress properties (2). The reversible oxidation of methionine (**1**) can also be involved in other biological functions such as the modulation of potassium-channel activity (3) and the oxidation of high- density lipoproteins (4, 5). It is also implicated in ageing processes by the effect of methionine sulfoxidation on the activity of the human keratinocyte growth factor (6) and on the immunopeptide thymosin β-4 (7); the in vivo oxidation of methionine to the sulfoxide is an age-dependent process in humans (8). The carcinogenic properties of ethionine (**2**) have been linked to its in vivo oxidation to sulfoxide (9), while *S*-methylcysteine sulfoxide (**3**-sulfoxide) is responsible for the antibacterial action of cabbage (10) and possesses the ability to lower serum-cholesterol levels (11, 12).

Received 23 November 2001. Published on the NRC Research Press Web site at http://canjchem.nrc.ca on 17 April 2002.

This paper is dedicated to Professor J. Bryan Jones, whose introductory work, continued research, and present-day creations are all fundamental areas of biocatalysis.

1 **2** **3**

With the exception of L-methionine sulfoxide isolated from the blowfly *Phormia regina* (13), and *S*-methyl-L-cysteine sulfoxide from cabbage (14), both of which have the (S_S) configuration, no data are available on the configuration at sulfur in naturally occurring amino acid sulfoxides.

The stereoselective chemical oxidation at sulfur of a thia-amino acid has not been reported, and only recently have other chemical routes for the preparation of diastereomerically defined amino acid sulfoxides been systematically investigated (14). The value of biocatalytic oxidation for the stereoselective oxidation of sulfides to sulfoxides, however, is well established (15, 16), and was used for the oxidation of methionine by *Penicillium citreoviride*, but no stereochemical details were reported (17). Fungal biocatalysts oxidize various prochiral sulfides to chiral sulfoxides. The use of *Beauveria bassiana* ATCC 7159 and *B. caledonica* ATCC 64970 for the stereoselective oxidation of *N*-phthaloyl-methionines and -ethionines to the (S_S) methionine and ethionine sulfoxides has recently been reported (18, 19). The application of isolated enzymes for chiral sulfoxidation is less common, but chloroperoxidase (CPO) from *Caldariomyces fumago* has been systematically used for the oxidation of various sulfides (16, 20–22). Cyclohexanone monooxygenase (CMO) from *Acinetobacter* species has also been employed for moderate diastereomeric sulfoxidation of *S*-allylcysteine (alliin) (23).

With the latter exception, the present paper describes the first use of isolated enzymes, particularly the oxidizing species chloroperoxidase–hydrogen peroxide, for the stereoselective oxidation at sulfur in methionine and ethionine derivatives.

Results and discussion

Table 1 summarizes the optimum use of substrate-protecting groups for the chloroperoxidase-catalyzed oxidation of L-methionine derivatives, where maximum yield and diastereomeric excesses were obtained with the *N*-methoxycarbonyl (*N*-MOC) *C*-carboxylate methyl ester derivatives.

The configurations at sulfur of the sulfoxides listed in Table 1 were obtained by analysis of their ^{13}C NMR spectra. Although the ^{1}H NMR spectra of the two diastereomers (S_SS_C) and (R_SS_C) were essentially identical, the signals in ^{13}C NMR spectra from the α and β carbons to the sulfoxide sulfur were separable in methanol. Comparison with ^{13}C NMR spectra from diastereomerically pure L-methionine sulfoxide standards with similar protection groups (19), were then used to assign the configurations obtained by the CPO-catalyzed oxidations. The sulfoxides listed in Table 1 were predominantly (R_SS_C) configurations, and illustrate a consistent excess of the upfield-signal intensity in the stereochemically dependent pairs of signals at ca. δ 24 (C-3), 37 (S(O)-CH_3), and 50 (C-4). Confirmation that the diastereomeric pairs of all the sulfoxide products (possessing both (R_SS_C) and (S_SS_C) configurations) exhibited base-line peak separation in the ^{13}C NMR spectra was obtained from the ^{13}C NMR spectra of such products obtained using hydrogen peroxide as the oxidation reagent for the *N*-MOC ester derivatives.

The results obtained from CPO-catalyzed oxidation of D-methionine derivatives are listed in Table 2. The configuration at sulfur was again determined to be (R_S) by ^{13}C NMR spectral analysis of the α and β carbons to the sulfoxide sulfur (ca. δ 24 (C-3), 37 (S(O)-CH_3), and 50 (C-4)). The predominant (R_SR_C) configurations of the products illustrate a consistent excess of the downfield ^{13}C NMR signals in the stereochemically dependent pairs.

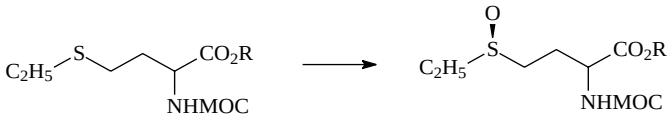
n-C_5H_{11}	MOC	10	0	—

Table 3. CPO-catalyzed oxidations of L-and D-ethionine derivatives.



C-2 configuration	R	Conversion (%)	de (%)	Sulfoxide stereochemistry
L (*S*)	CH_3	30	91	*R*
L (*S*)	C_2H_5	40	80	*R*
D (*R*)	CH_3	8	0	—

Table 3 illustrates that only the L-ethionine derivatives were effective substrates for CPO-catalyzed oxidation at sulfur. The configurations at sulfur were determined as described above, i.e., using ^{13}C NMR spectral analysis of α carbons to the sulfoxide sulfur (ca. δ 24 (C-3) and 51 (SCH_2CH_3)), and by comparison with the ^{13}C NMR spectra of stereochemically known samples (19). The predominant signal from the (R_SS_C) configurations of both diastereomerically enriched sulfoxides occurs as the upfield component of the stereochemically dependent pair of signals.

The formation of diastereomerically enriched sulfoxides by stereoselective hydrolysis of the methyl ester from diastereomeric *N*-MOC-L-methionine sulfoxides (1:1) is summarized in Table 4.

Of the hydrolytic enzymes that were successful in the stereoselective hydrolysis of this diastereomeric pair, subtilisin Carlsberg was the most efficient and gave both the acid and the unreacted ester products in moderate yield and high diastereomeric excess. Again, configuration at sulfur of both products was determined by ^{13}C NMR spectral analysis of the α and β carbons to the sulfoxide sulfur (ca. δ 24 (C-3), 37 (S(O)-CH_3), and 50 (C-4)), with (R_SS_C) configurations of diastereomerically enriched sulfoxides occurring as the upfield component of the stereochemically dependent signal pair and (S_SS_C) configurations with the predominant peak as the downfield component.

The CPO-catalyzed oxidations of a series of methionine-containing dipeptides are summarized in Table 5. Although the enzyme was capable of the oxidation of several of these substrates in acceptable yields, only one sulfoxide, from the

PHE-MET	<5	0	—

methyl ester of *N*-MOC, ALA-MET, was produced in a stereochemically acceptable form.

In the absence of a stereochemical standard for this product, the assignment of the configuration at sulfur was again based on ^{13}C NMR spectral analysis of the α and β carbons to the sulfoxide sulfur (ca. δ 24 (C-3), 37 (S(O)-CH_3), and 50 (C-4)), with the assumption that the (R_SS_C) configuration of *N*-MOC-ALA-MET methyl ester sulfoxide presumably resulted in signal intensities consistent with the standard L-methionine products. Nevertheless, the description of the methionine sulfoxide configuration of the dipeptide product as (R_SS_C) must be considered tentative.

The removal of both *N*-MOC- and methyl ester protecting groups from the diastereomerically enriched L-methionine, D-methionine, and L-ethionine sulfoxide enzyme-catalyzed products was performed in moderate yield by routine hydrolysis with barium hydroxide, generating the appropriate free amino-acid sulfoxides.

Experimental

Materials and methods

Melting points were determined on a Kofler hot stage and are uncorrected. The ^{1}H NMR spectra were recorded on a Bruker Advance series 300 spectrometer in $CDCl_3$ using residual $CHCl_3$ as the internal standard or CD_3OD using CH_3OH as the internal standard unless otherwise stated; chemical shifts are reported in ppm (δ) and the signals quoted as s (singlet), d (doublet), t (triplet), q (quartet), or m (multiplet). The ^{13}C NMR spectra were recorded at 75 MHz on the same spectrometer in $CDCl_3$, CD_3OD, or D_2O. Diastereomeric excess (de) was determined by ^{13}C NMR analysis of signals α and β to sulfur. Mass spectra were obtained using a Kratos 1S spectrometer. Optical rotations were recorded at ambient temperature in the stated solvent using a Rudolph Autopol 3 polarimeter. TLC was performed on Merck silica gel F_{254} plates, 0.2 mm, and column chromatography used Merck silica gel 9385, 230–400 mesh.

Chloroperoxidase from *Caldariomyces fumago* was obtained from the Sigma Chemical Co. (catalogue no. C-0278). α-Chymotrypsin, *Aspergillus* sp. protease, subtilisin Carlsberg, and *Aspergillus* lipase were obtained from Altus Biologics Inc.

Preparation of substrates

N-*Protection*

N-*t*-Boc-L- and D-methionines, *N*-acetyl-L-methionine, and *N*-formyl-L-methionine are commercial samples. *N*-chloroacetyl-L-methionine (24) and *N*-phthaloyl-L-methionine (19) were prepared from the amino acids as previously described.

N-MOC-L- and D-methionines, *N*-MOC-L- and -D- ethionines, and *N*-MOC-dipeptides were prepared by the following standard procedure. A stirred solution of L-methionine (2.08 g) in aqueous sodium hydroxide (40 mL, 2 M) at 0°C was treated with methyl chloroformate (10.4 mL) in 1 mL increments over 1 h. The pH was maintained above 10.5 by addition of 2 M sodium hydroxide as required. After the final aliquot of methyl chloroformate (0.4 mL) was added, the reaction mixture was allowed to reach room temperature and was then washed with an equal volume of ether. The aqueous layer was then cooled to 0°C, acidified to pH 2–3 with 10% HCl, and extracted with ethyl acetate (3 × 100 mL). The extract was dried ($MgSO_4$) and evaporated to yield *N*-MOC-L-methionine (2.34 g, 84%) as an oil. NMR data are listed below. Unless stated otherwise all products gave *m*/*z* MH^+ ions using FAB-NBA spectra.

Esterification

The esters of *N*-protected amino acids and dipeptides were all obtained by the following standard procedure using the appropriate alcohol. *N*-MOC-L-methionine (2.34 g) was dissolved in methanol (50 mL) and a catalytic amount of hydrochloric acid added to adjust the solution to pH 3.0. The solution was heated under reflux for 12 h, then evaporated. Water (50 mL) was added and the product extracted with ethyl acetate. The solution was washed with saturated $NaHCO_3$, dried, and evaporated to give *N*-MOC-L-methionine methyl ester as an oil (2.03 g, 81%). NMR data are listed below. Unless listed otherwise, all products gave *m*/*z* MH^+ ions using FAB-NBA spectra.

N-*Acetyl-L-methionine methyl ester*

^{1}H NMR (CD_3OD) δ: 1.9–2.2 (m, 2H), 1.94 (s, 3H), 2.08 (s, 3H, SCH_3), 2.42 (m, 2H), 3.60 (s, 3H, OCH_3), 4.58 (m, 1H), 6.72 (d, 1H, NH). ^{13}C NMR (CD_3OD) δ: 14.3, 21.4, 30.1, 31.0, 51.8, 51.9, 172.4, 173.0.

Preparation of standard protected sulfoxides

Standard diastereomeric sulfoxide mixtures of esters of *N*-protected amino acids and dipeptides were prepared using the following representative procedure: *N*-MOC-L-methionine methyl ester (2.03 g) was dissolved in methanol (40 mL) in an Erlenmeyer flask (100 mL). In a separate flask, hydrogen peroxide (1.13 g of 30% aqueous solution, 1.1 molar equivalents) was dissolved in methanol (15 mL). Both solutions were cooled to –20°C, then mixed and allowed to stand at –20°C overnight. The solvent was then removed by vacuum to give a quantitative yield of a 1:1 diastereomeric mixture of *N*-MOC-L-methionine methyl ester sulfoxides (oil).

Biotransformation procedures

Chloroperoxidase-catalyzed oxidations

The reactions were carried out using the following standard procedure: *N*-MOC-L-methionine methyl ester (33 mg, 0.15 mM) was dissolved in disodium citrate buffer (16.6 mL, 0.1 M, pH 5.0) in a 50 mL flask. The solution was stirred slowly at room temperature, and chloroperoxidase (2000 units) was added. A solution of hydrogen peroxide (56.6 μL of 30% aqueous solution) in disodium citrate buffer (1.6 mL, 0.1 M, pH 5.0) was then added via a syringe pump over 70 min, with addition occurring directly below the surface level of the reaction mixture. The reaction was stirred for a further 5 min, quenched by addition of aqueous saturated sodium sulfite (0.5 mL), and then continuously extracted with dichloromethane for 3 d. Evaporation of the extract gave a quantitative recovery of amino acid material, which was directly analyzed by ^{1}H and ^{13}C NMR. Configuration at sulfur of *N*-MOC-L-methionine ester sulfoxides was identified by ^{13}C NMR analysis.

Ester hydrolysis of N-MOC-L-methionine methyl ester sulfoxides

The diastereomeric mixture of chemically prepared *N*-MOC-L-methionine methyl ester sulfoxide (100 mg) was dissolved in phosphate buffer (0.1 M, pH 7.0, 20 mL), and then the stirred solution was treated with the appropriate Altus Chiroclec® enzyme (100 mg for each of α-chymotrypsin, *Aspergillus* sp. protease, subtilisin Carlsberg, or *Aspergillus* lipase in four separation experiments), each suspended in phosphate buffer (5 mL). The resulting reaction mixture was then stirred at room temperature for 5–60 min, monitored by TLC (silica gel, EtOAc–MeOH–AcOH, 79:20:1), and on ca. 50% completion the reaction was quenched by the addition of ethanol (5 mL) and then filtered. The filtrate was acidified to pH 3 by the addition of 10% HCl, then continuously extracted with dichloromethane for 3 d. Evaporation of the extract gave a quantitative recovery of amino acid material, which was directly analyzed by ^{1}H and ^{13}C NMR, and separated by chromatography using silica gel with 10% gradient elution (EtOAc–MeOH, 80:20 to MeOH). Spectral data are quoted above for *N*-MOC-L-methionine methyl ester sulfoxide and *N*-MOC-L-methionine sulfoxide products. Configuration at sulfur of *N*-MOC-L-methionine methyl ester sulfoxides was identified by ^{13}C NMR analysis.

Removal of *N*-MOC and ester-protecting groups

The following standard reaction procedure was used: *N*-MOC-L-methionine methyl ester sulfoxide (120 mg), prepared by CPO-catalyzed oxidation of *N*-MOC-L-methionine methyl ester, was dissolved in a mixture of distilled water (4 mL) and methanol (1 mL). Barium hydroxide (300 mg) was added, and the mixture stirred and heated at reflux for 4 h. Water (10 mL) was added and the mixture was cooled and adjusted to pH 5.75 with sulfuric acid (0.1 M), filtered (celite), and evaporated to yield a semi-solid (100 mg), which was then dissolved in distilled water (1 mL), filtered, and the filtrate diluted with acetone (7 mL). The resulting cloudy mixture was refrigerated overnight to produce crystals of L-methionine sulfoxide (62 mg, 76%), identified by ^{13}C NMR and other analytical comparisons with authentic samples (19) as (R_SS_C) material; mp230–235°C (lit. (25, 26) mp 239°C). $[\alpha]_D$ –75 (c = 0.5, H_2O) (lit. (25) $[\alpha]_D$ –77 (c = 0.5, H_2O)).

Formation of single diastereomers of β-hydroxy-sulfoxides by biotransformation of β-ketosulfides using *Helminthosporium* species NRRL 4671

Herbert L. Holland, Nancy Ihasz, and Brendan J. Lounsbery

Abstract: Single biotransformations of 1-(phenylthio)-2-propanone and 1-(*p*-methoxyphenylthio)-2-propanone by the fungus *Helminthosporium* species NRRL 4671 resulted in both sulfur oxidation to the sulfoxide and carbonyl reduction to the alcohol. The corresponding (S_S,S_C)-1-sulfinyl-2-propanols were obtained as single diastereomers following simple crystallization.

Key words: biocatalysis, biotransformation, carbonyl reduction, *Helminthosporium* sp. NRRL 4671, sulfoxidation.

Résumé : Des biotransformations uniques de la 1-(phénylthio)propan-2-one et de la 1-(4-méthoxyphénylthio)propan-2-one sous l'influence de champignons de l'espèce *Helminthosporium* NRRL 4761 provoquent à la fois une oxydation du soufre en sulfoxyde et une réduction du groupement carbonyle en alcool. Après une simple cristallisation, on a obtenu les ($S_S S_C$)-1-sulfinylpropano-2-ols sous la forme d'un seul diastéréomère.

Mots clés : biocatalyse, biotransformation, réduction d'un groupe carbonyle, *Helminthosporium* NRRL 4671, sulfoxydation.

[Traduit par la Rédaction]

Introduction

One of the key features of biocatalytic reactions is their ability to produce chiral products from non-chiral starting materials. This is particularly common for carbonyl groups, which can be reduced to secondary alcohols (1) or converted to cyanohydrins (2), and the oxidation of sulfides to generate sulfoxides (3). In contrast, however, the generation of two or more independent chiral centres from a non-chiral starting material in a single biotransformation is unusual. The formation of two chiral centres is primarily achieved by either the reduction of diketones to chiral diols (4), the use of an aromatic dioxygenase enzyme to produce an arene dihydrodiol (5), or the conversion of ketones into chiral diols by a combination of carbonyl reduction and hydroxylation reactions (6). The latter process, requiring the combined activity of two different enzymes, is carried out only by whole-cell biocatalysts.

Even more unusual is the formation of a product with two different chiral centres from a single non-chiral substrate. It has recently been reported that the dioxygenase activity of *Pseudomonas putida* results in the formation of dihydrodiol sulfoxides from aryl sulfides, products possessing three chiral centres (two of which are alcohols) that are formed by the activity of a single enzyme (7). The combined application of two or more different enzymes to generate two different chiral centres from a non-chiral substrate is also unusual, but has been reported in the whole-cell biocatalysis of conjugated unsaturated carbonyl substrates to give saturated alcohol products, which involves a combination of enoate reductase and alcohol dehydrogenase activities (8).

The present communication presents a new combined biocatalysis reaction, involving both the oxidation of sulfides and reduction of carbonyls in a single biotransformation process, resulting in the formation of chiral sulfoxide alcohols in high diastereomeric excess (de). Potential values of such 1,3-sulfoxide alcohols lie in their use as chiral synthons and reagents, the latter in the presence of metal catalysts with which they can execute hydrogen-bonding interactions.

Results and discussion

Biotransformation of 1-(phenylthio)-2-propanone (**1a**) and 1-(*p*-methoxyphenylthio)-2-propanone (**1b**) by *Helminthosporium* species NRRL 4671 resulted in the formation of the corresponding sulfoxide alcohols **2a** and **2b** as illustrated in Scheme 1 and summarized in Table 1. The configurations at the carbon and sulfur of **2a** and **2b** were determined independently by conversion to the sulfone alcohols (*S*)-**3a** and (*S*)-**3b** and the sulfoxide ketones **4a** and **4b** as shown in Scheme 2. Optical rotations of sulfones **3** were identical with those reported for stereochemically pure versions produced by biotransformation of the corresponding sulfone ketones (9). Enantiomeric purity was confirmed as ≥95% ee

by ^{1}H NMR analysis using Eu(thfc)$_3$ as a chiral-shift reagent.

Stereochemical analyses of sulfoxides (*S*)-**4** were carried out by ^{1}H NMR analyses using the Kagan chiral-shift reagent (*R*)-(–)-*N*-(3,5-dinitrobenzoyl)-α-methylbenzylamine (10, 11), confirming that the materials were 85-89% ee, which corresponds with the estimated original de values of products **2a** and **2b** that were determined by their ^{1}H NMR analyses (see *Experimental*). The (*S*)-configurations of **4** were determined by their optical rotations (negative) (3, 12, 13) and by the ^{1}H NMR shifts in the presence of Kagan reagent (10, 11).

Crystallization of products **2a** and **2b** gave samples with ≥95% de; it is apparent from the stereochemical analysis presented above that these arose from materials with a single configuration (*S*) at the carbon and a mixed configuration (ca. *S*:*R* = 93:7) at the sulfur. Both (*S*)-configurations are consistent with those produced by biotransformations of ketones (12) and sulfides (3) by *Helminthosporium*.

The biotransformation of β-ketosulfides to produce chiral β-hydroxysulfoxides represents a new version of single biocatalysis for the formation of molecules with two different chiral centres from non-chiral starting materials. This process is now under investigation using a variety of such substrates for microbial biocatalysts known for their ability to carry out both sulfide oxidation and carbonyl reduction reactions when applied to different independent substrates.

Experimental

Maintenance, growth, and biotransformations using *Helminthosporium* species NRRL 4671 were carried out as previously described (13). Isolated yields of products from 1 g of substrate were obtained as presented in Table 1. Preparations of **3a** and **3b** in yields of 85 and 97%, respectively, were performed by oxidations of **2a** and **2b** by the standard procedure using 1.5 equivalents of *m*-chlorobenzoic acid in CH_2Cl_2 at room temperature for 48 h. Preparations of **4a** and **4b** were performed by standard Jones oxidations at 0°C of **2a** and **2b** in yields of 71 and 60%, respectively.

Analytical data for biotransformation products **2** and their derivatives **3** and **4** are listed below.

(S_S,S_C)-1-(Phenylsulfinyl)-2-propanol (2a)

mp 55–57°C. $[\alpha]_D$ –260 (*c* 1.0, $CHCl_3$). ^{1}H NMR ($CDCl_3$) δ: 1.32 (d, 3H), 2.74 and 3.0 (m of ABX, 2H), 3.63 (br s, 1H, OH), 4.45 (m, 1H), 7.52 (m, 3H), 7.70 (d, 2H). ^{13}C NMR ($CDCl_3$) δ: 23.7, 64.1, 65.5, 124.2, 129.9, 131.9, 144.0. The (R_S,S_C) isomer produced two different sets of ^{1}H NMR peaks, located at δ 1.25 (d) (cf. 1.32 (d)) and 4.30 (m) (cf. 4.45 (m)), integration of which peaks together with the major ones at δ 1.32 and 4.45 was used to determine the initial de of 89%.

(S_S,S_C)-1-(*p*-Methoxyphenylsulfinyl)-2-propanol (2b)

mp 84–86°C. $[\alpha]_D$ –267 (*c* 1.0, $CHCl_3$). ^{1}H NMR ($CDCl_3$) δ: 1.32 (d, 3H), 2.73 and 3.0 (m of ABX, 2H), 3.73 (br s, 1H, OH), 3.82 (s, 3H), 4.45 (m, 1H), 7.02 and 7.58 (q of AB, 4H). ^{13}C NMR ($CDCl_3$) δ: 23.7, 56.0, 64.1, 65.4, 115.4, 126.5, 134.8, 162.7. The (R_S,S_C) isomer produced two different sets of ^{1}H NMR peaks located at δ 1.25 (d) (cf. 1.32 (d)) and 4.30 (m) (cf. 4.45 (m)), integration of which peaks together with the major ones at δ 1.32 and 4.45 was used to determine the initial de of 85%.

Structure-based rationalization of aldolase-catalyzed asymmetric synthesis

Junjie Liu, Grace DeSantis, and Chi-Huey Wong

Abstract: This paper describes a structure-based approach to elucidate the stereospecificity, including inversion of enantioselectivity, of the 2-deoxyribose-5-phosphate aldolase-catalyzed asymmetric aldol addition reaction using unnatural substrates designed for the total synthesis of epothilones. In addition, an aldolase variant with Ser-238 being altered for Asp was found to be 2.5 times more effective than the wild type in accepting the unphosphorylated substrate D-glyceraldehyde. A new H-bonding interaction between the Asp-238 carboxylate and the 3-hydroxyl of the substrate was identified and was used to rationalize the rate enhancements.

Key words: aldol reaction, 2-deoxyribose-5-phosphate aldolase, mutagenesis, inversion of enantioselectivity.

Résumé : Cette communication décrit une approche basée sur la structure d'élucider la stéréospécificité, y compris l'inversion d'énantiosélectivité, de la réaction d'addition aldolique asymétrique catalysée par l'aldolase de 2-désoxyribose-5-phosphate; cette étude fait appel à des substrats qui ne sont pas naturels et qui ont été développés pour la synthèse totale des épothilones. De plus, on a observé qu'une variante de l'aldolase, portant une Asp au lieu de la Ser-238, est 2,5 fois plus efficace que la forme naturelle pour accepter le substrat d-glycéraldéhyde non phosphorylé. On a identifié une nouvelle interaction par liaison hydrogène entre le carboxylate de l'Asp-238 et l'hydroxyle en position 3 du substrat; elle permet de rationaliser les augmentations de vitesses de réaction.

Mots clés : réaction aldolique, aldolase de 2-désoxyribose-5-phosphate, mutagénèse, inversion d'énantiosélectivité.

Introduction

Over the past 20 years, enzymes have been exploited as catalysts in large-scale organic synthesis. Recent advances in molecular genetics, protein engineering, and site-specific modification of enzymes have further expanded the scope of enzyme catalysis with regard to its synthetic application (1). Most of these new developments are based on the inspiring work of a few pioneers in the field, particularly that of Professor Bryan Jones (2). To date, many useful transformations based on enzymes have been developed on large scales for the chemical and pharmaceutical industries, and new developments based on biocatalysis continue to evolve (1, 3).

One subject of current interest to us is the use of enzyme-structure information to design new protein catalysts or new substrates for enzymatic reactions with altered stereoselectivity. The enzyme employed in this study is 2-deoxyribose-5-phosphate aldolase (DERA, EC 4.1.2.4), which catalyzes the aldol reaction between acetaldehyde and D-glyceraldehyde 3-phosphate to form D-2-deoxyribose-5-phosphate (4). The structure of this enzyme has been solved at the atomic level (~1 Å resolution) and the reaction mechanism has been studied in detail (Scheme 1) (5). The enzyme forms a Schiff base with acetaldehyde to generate an enamine intermediate, which then attacks the *Re*-face carbonyl of the incoming acceptor to form a new C–C bond with a new stereogenic center in the *R*-configuration. Both the Schiff base and the carbinol amine intermediates have been trapped and the structures have been determined (5). According to the structure, the C-3 phosphate of the acceptor substrate has H-bonding interactions with a hydrophilic site composed of Ser-238, Ser-239, and Gly-205, and the C-2 hydroxyl group has H-bonding interactions (5) through a water molecule with another hydrophilic site composed of Thr-170 and Lys-172. The C-2 hydrogen is positioned in a hydrophobic pocket (Fig. 1). The enzyme also accepts the corresponding unphosphorylated substrate and related structures with a much weaker affinity and activity (4).

Results and discussion

In an effort to find new substrates, we found that the enzyme catalyzes the aldol reaction with racemic 2-methyl-3-hydroxypropanal **1a** to give the pyranose **2a** (Scheme 2) (6). Characterization of the product by oxidative conversion to the lactone with Br_2 indicates that the enzyme exhibits a re-

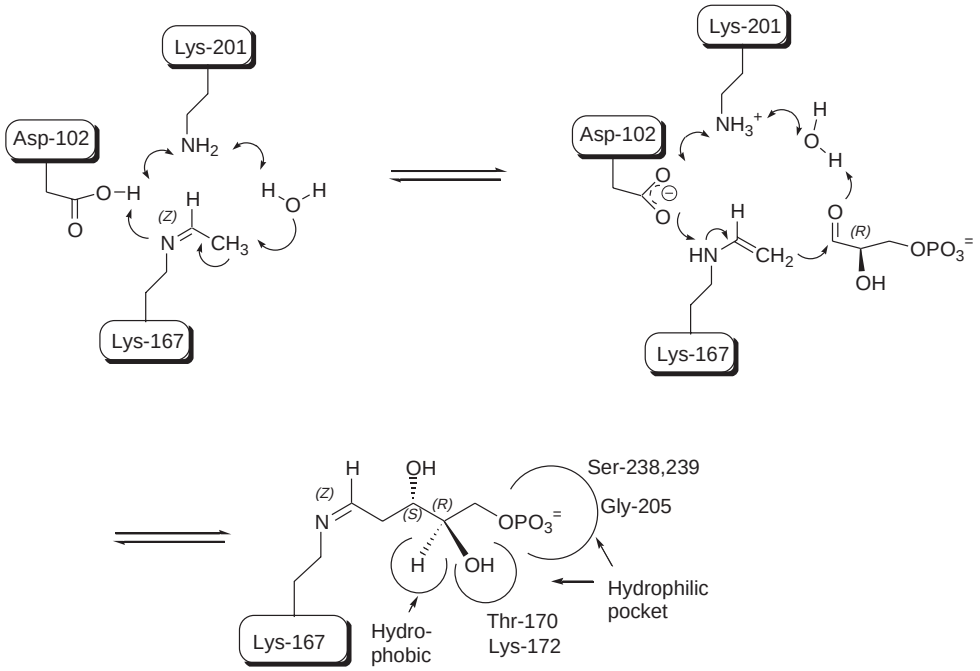
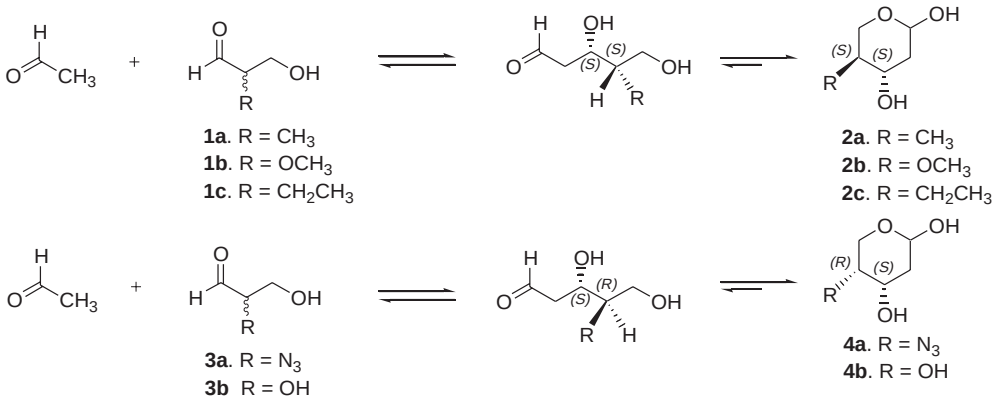
Scheme 1. Highlights of the mechanism of DERA catalyzed aldol addition reaction. Shown are those steps associated with C–H cleavage and C–C bond formation. Asp-102 and Lys-201 act as a proton relay system to assist the proton abstraction and carbonyl protonation mediated by the conserved water molecule. The enzyme side chains interacting with the phosphate group and the C-4 hydroxyl (corresponding to the C-2 OH of acceptor) have been identified and designated each as a hydrophilic pocket. The C-4 hydrogen is located in a small hydrophobic pocket without interaction with side chains.



Scheme 2. Enantioselective aldol reaction catalyzed by DERA. A reversal of enantioselectivity was observed with acceptor substrates with small hydrophobic substituents at C-2 as indicated in the conversions of **1a–c** to **2a–c**, respectively.



versal of enantioselectivity in the aldol reaction, accepting the L-aldehyde as an acceptor. Similarly, reverse enantioselectivity was observed with the 2-methoxy and 2-ethyl derivatives **1b** and **1c**, respectively. Alternatively, when the racemic 2-azido or 2-hydroxy derivative was used (**3a** and **3b**, respectively), enantioselectivity that followed that of the natural reaction was observed, i.e., the D-enantiomer was converted to the pyranose product (**4a** and **4b**). In all cases, no change in facial selectivity was observed (6). The equilibrium of the reaction is driven by the formation of the pyranose ring in favor of condensation (Fig. 2). With the enzyme structure now available, the results can be rationalized such that the 2-methyl, 2-methoxy, or 2-ethyl groups is bound to the hydrophobic pocket and the C-2 hydrogen is in the hydrophilic pocket. If the methyl, methoxy, or ethyl group was in the hydrophilic pocket, it would have a close contact with the water molecule and the carbonyl oxygen of Thr-170, resulting in a less favorable binding. Since the azide or the hydroxy group is considered to be hydrophilic, it fits into the hydrophilic pocket (Scheme 3).

In another effort to engineer the enzyme to accept unphosphorylated neutral substrates more effectively, Ser-238 was exchanged for Asp. It was anticipated that this change would still retain the hydrophilic nature of the C-3

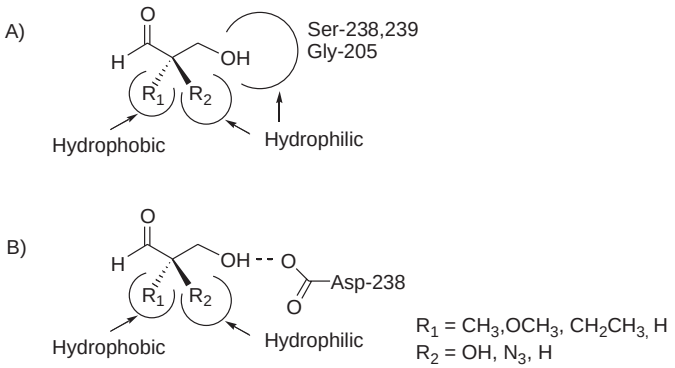
Scheme 3. (*a*) Acceptor model of wild-type DERA; (*b*) acceptor model of the Ser238Asp variant.



binding pocket, but substrates with a negative charge in the C-3 position would be disfavored. Indeed, the Ser238Asp-mutant enzyme is 2.5 times more active (based on the k_{cat}/K_m value of the retroaldol reaction) than the wild-type to D-glyceraldehyde as a substrate, as indicated in Table 1. Molecular modeling indicates that the C-3 hydroxy hydrogen forms a 2.9–3.2 Å hydrogen bond with the Asp-238 carboxylate, accounting for the increase in reactivity (Fig. 3).

In summary, this study has demonstrated that with a well-defined enzyme structure, one can effectively alter the substrate specificity of an enzyme by protein engineering or substrate design. Methyl pyranose **2a** has been used as a key synthon in the total synthesis of the anti-cancer agents epothilones (6, 7).[2] Work is in progress to further utilize the structural information to design new substrates for DERA-catalyzed aldol addition reactions.

Introduction

Benign prostatic hyperplasia (BPH) is a common condition afflicting men over the age of 40, with symptoms characterized by urinary obstruction resulting from enlargement of the prostate gland and increased noradrenergic tone in the hyperplastic prostate. Currently, transurethral prostatectomies are the second most common operation performed on males over the age of 65. To avoid surgery, pharmacological approaches are increasingly becoming the first option in treatment (1). Current treatment options include treatment with a 5-α reductase inhibitor, such as finasteride, for relief of symptoms through inhibition of the transformation of testosterone to dihydrotestosterone which results in reduction of prostatic mass (1*f*). The prostate is innervated with adrenergic nerves, which determine smooth muscle tone. The α_1 adrenoceptor has been identified as a target to alleviate the symptoms of BPH through decreasing the adrenergic tone of smooth muscle in the prostate (2). Three subtypes for the α_1 adrenoceptors have been identified (α_{1A}, α_{1B}, and α_{1D}). Selective antagonists for the α_{1A} receptor are expected to be more efficacious and to exhibit fewer side effects (3). The nonselective antagonists terazosin and doxazosin, and more recently tamsulosin, a subtype (α_{1A}/α_{1D})-selective antagonist, are currently in use.

Recently, Merck and Synaptic (4) reported candidate **1** as a new, potent, and selective α_{1A}-adrenoceptor antagonist. The dihydropyrimidinone moiety of **1** is a particularly interesting pharmacophore (3*a*, 5) in that this heterocycle has shown activity in a number of medicinal applications. Here we describe our work on the development of a highly efficient synthesis of the enantiomerically pure form of clinical candidate **1**. Retrosynthetically, the logical approach to **1** would involve the formation of a urea linkage (4,5) between the two penultimate building blocks **2** and **3** (Scheme 1). The preparations of non-racemic dihydropyrimidinone **2** and amine side chain **3**, as well as the formation of the urea linkage, and isolation of a crystalline form of the drug are also described.

Results and discussion

Typically, dihydropyrimidinones are constructed through variations of the Biginelli reaction (6). This reaction is a three-component coupling of an aromatic aldehyde, urea, and an acetoacetate to afford the heterocycle in generally moderate yields. The Biginelli reaction has been used in one form or another for over a century using Bronsted acids in protic media (7). In the last decade a number of improvements have been reported for this reaction using polyphosphate esters (8*a*, 8*i*), microwave-assisted synthesis (8*b*, 8*c*),

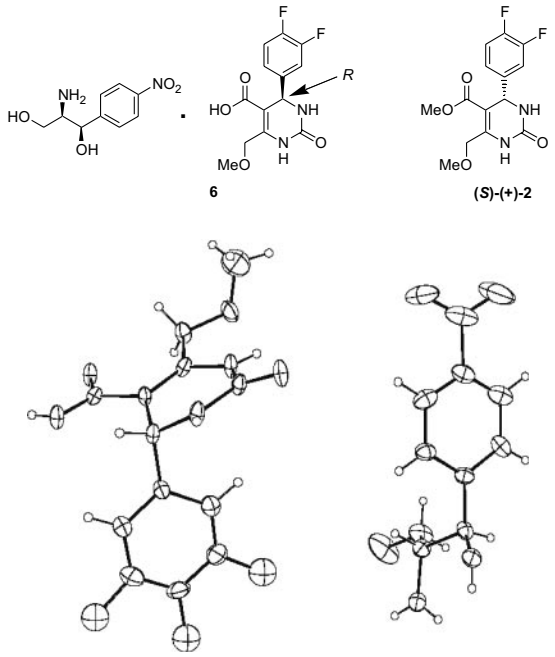
solid-phase synthesis (8*d*, 8*e*), solid-acid catalysis (8*f*), and fluorous synthesis (8*g*, 8*h*). A major improvement in the traditional Biginelli protocol was recently reported by us through the application of a Lewis acid catalysis which afforded much improved yields (9*a*). A combination of boron trifluoride etherate with a catalytic amount of acetic acid and a metal salt in THF has vastly improved the reaction. Metal salts such as $Cu(OAc)_2$, CuCl, $CuCl_2$, Cu_2O, $NiBr_2$, and $Pd(OAc)_2$ can be used equally well in this reaction. Alternative Lewis acids, such as $Ln(OTf)_3$ (9*b*), $FeCl_3$ (9*c*), or $InCl_3$ (9*d*) have also been reported for this three-component condensation. We determined that 1.7 equivalents of $BF_3{\cdot}Et_2O$ in combination with 10 mol% acetic acid and 10 mol% $Cu(OAc)_2$ gave the best overall results for this reaction. Heating a mixture of methyl 4-methoxyacetoacetate (**4**), 3,4-difluorobenzaldehyde (**5**), and urea with the acid mixture in THF afforded an 84% isolated yield of the desired dihydropyrimidinone (±)-**2** (Scheme 2).

The only preparation of an optically pure dihydropyrimidinone through an asymmetric variant of the Biginelli reaction was reported by Overman and co-workers (10). Our attempts at diastereoselective Biginelli reactions through cyclization of chiral ester derivatives of methoxyacetoacetate afforded only modest diastereoselectivity. A brief investigation of chiral ligands used in conjunction with the Lewis acid mixture of the boron–copper-mediated Biginelli reaction afforded no enantioselectivity. Most reports on the preparation of non-racemic dihydropyrimidinones have employed either classical resolution through diastereomeric salt crystallization (11) or chiral HPLC separation (12). For our needs, the former would require hydrolysis of the ester to the acid, resolution, and re-esterification, reducing the overall efficiency of the process, and the latter would not be amenable to large-scale preparation.

Fig. 1. Crystal structure of dihydropyrimidinone·D-*threo*-2-amino-1-(4-nitrophenyl)-1,3-propanediol salt (**6**).



A more effective approach for the resolution of **2** would be an enzymatic hydrolysis of the unwanted methyl ester to the acid, allowing easy separation of the enantiomers (Scheme 3) (13). A number of esterases, lipases, and proteases were screened for this reaction. Interestingly, none of the esterases or lipases tested were successful for this procedure (14). The protease enzyme Proteinase K (Sigma), however, gave excellent selectivity for conversion of the undesired methyl ester to the acid. Unfortunately, this enzyme is not widely available and is quite expensive to use in a bulk process. The search for a less expensive, commercially available protease led to the discovery of Subtilisin (Genencor Purafect 4000L) as a highly effective biocatalyst for the resolution of **2** to the desired (+)-methyl ester of the dihydropyrimidinone.

At the time of this work, only the rotation of the desired ester was known, since this material was previously resolved by chiral HPLC (4). Upon successful hydrolysis of the (–)-methyl ester to the free acid, we were able to evaluate the absolute configuration of the 6-aryl moiety. The acid was recovered from the aqueous phase of the resolution after workup, which was then crystallized from ethanol as a D-*threo*-2-amino-1-(4-nitrophenyl)-1,3-propanediol salt **6**. A crystal structure was obtained and the absolute stereochemistry of the 6-position of the acid was assigned as *R* relative to the stereocenters of the amine (Table 1).

By inference we could assign the desired enantiomer of **2** as the (*S*)-(+)-isomer (Fig. 1).

The optimization of the resolution procedure provided the desired (S)-(+)-methyl ester in 40–45% yield or 80–90% of the available enantiomer. The reaction was run with an enzyme loading of 40–50 wt% at ~6 g L^{-1} in a medium of 12% acetonitrile. Acetonitrile was needed to solubilize the ester. Without the co-solvent the reaction was very sluggish

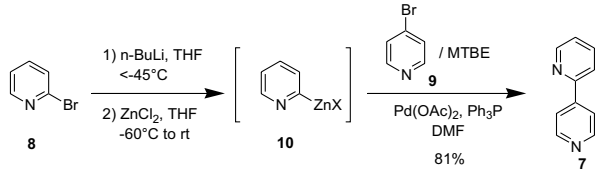
(>15 days reaction time); however, as the concentration of acetonitrile was increased to >20%, the enzyme was deactivated. Subtilisin was purchased as a solution containing propylene glycol as a stabilizer. By adjusting the concentration of the glycol to 12% an increased stability in reaction solution was obtained, but as the volume percent was increased to >15%, the additive slowed the rate significantly. The system was buffered at pH 8.5 using a Tris buffer and the reaction required 10–12 days at 37°C to complete. The reaction was stopped once the ee of the unhydrolyzed ester reached 98%. During the course of the reaction the pH of the mixture dropped due to the liberation of acid; therefore, aqueous sodium hydroxide was added to maintain the pH. Interestingly, during the course of the enzymatic resolution very little of the desired (+)-methyl ester was hydrolyzed by the enzyme. There was, however, a small amount of background chemical hydrolysis leading to a slight loss in yield. Upon reaching 98% ee, the reaction was worked up by adding toluene and extracting the methyl ester into the organic phase. The undesired free acid remained in the aqueous phase. The toluene was concentrated and the product was isolated in >40% yield by crystallization from toluene–heptane, with an increase in optical purity to >99% ee.

Synthesis of the second penultimate building block (**3**) required the preparation of the two-ring heterocycle. The original synthesis (4) of **3** was improved to afford a process capable of preparing multi-kilogram quantities of the side chain. Although 2,4′-dipyridyl (**7**) is commercially available, only gram quantities could be obtained. We therefore set out to prepare **7** through a selective coupling process (Scheme 4).

Traditionally, the synthesis of bipyridines has involved the construction of one pyridine ring upon an existing substituted pyridine (15). In recent years, cross coupling through organometallic species has increasingly become more practical (16), especially with the advent of the palladium-catalyzed cross-coupling reactions (17). The preparation of a dipyridyl is often encumbered by the selection of the coupling partners. Generally, the halides are available, which has been exploited by the use of Ullmann-like couplings to

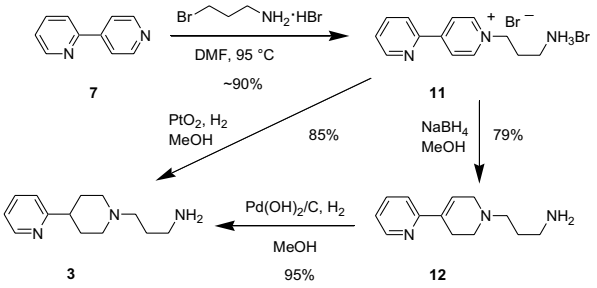
Scheme 4.



prepare the symmetrical bipyridines (18). In the case of unsymmetrical bipyridines, one of the halopyridines needs to be converted to a suitable coupling partner, such as a stannane (19), borane (20), or zinc halide (21). We sought to avoid the synthesis of an intermediate, as is necessary with the stannanes or boranes, and in the case of the former to avoid the use of tin reagents on a large scale. The Negishi coupling protocol (22) provided a straightforward approach using a zinc halide intermediate. Surprisingly, 2,4′-dipyridyl has not been previously prepared with this procedure. Both 2- and 4-bromo pyridines are available, but the better substrate for conversion to the zinc reagent is 2-bromopyridine (**8**). Previous reports show that 2-pyridyl zinc halide can be generated by halogen–metal exchange with either Rieke's zinc (21*d*) or with an alkyl lithium reagent followed by transmetalation with zinc chloride (21*e*, 22*b*). Accordingly, the metal–halogen exchange was carried out on **8** with *n*-BuLi at <–45°C. 2-Pyridyl–lithium was then transmetalated with zinc chloride in THF to afford intermediate **10**. 4-Bromopyridine (**9**) was purchased as its hydrochloride salt, which was partitioned between *tert*-butyl methyl ether (MTBE) and aqueous sodium carbonate to afford the free base in MTBE. The azeotropically dried MTBE solution was added directly to zinc reagent **10** followed by addition of palladium acetate and triphenylphosphine. The coupling reaction was carried out at 50°C. If the temperature exceeded 50°C, an exotherm occurred causing the reaction to reflux. Upon completion of the coupling, the reaction mixture was quenched with ammonium hydroxide and the solvent was concentrated and displaced with DMF. 2,4′-Dipyridyl **7** was obtained as a DMF solution in 81% yield. Alternatively,

© 2002 NRC Canada

Scheme 5.



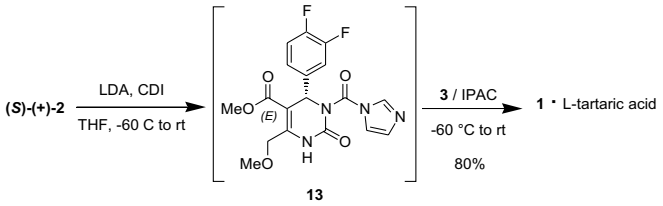
rather than preparing a DMF solution, **7** could be isolated as a solid; however, large losses were incurred during the isolation procedure.

The first step in the conversion of 2,4′-dipyridyl (**7**) to side chain **3** was the selective alkylation at the 4′-position. Heating a mixture of dipyridyl **7** and bromopropylamine hydrobromide in DMF at 95°C resulted in a high conversion to pyridinium salt **11**, with no competing alkylation at the 2-position. Alkylation reactions run at 1 M concentrations in DMF became quite thick, because the pyridinium salt started to crystallize. To alleviate stirring problems, the reaction was run at 0.5 M, but the reaction rate and yield suffered. By adding 10–15% water to the reaction mixture, however, the concentration and rate of reaction was maintained. At the end of the reaction, the water was removed by distillation and pyridinium salt **11** could be isolated in 95% yield after cooling and addition of MTBE.

At this stage, the piperidine ring (**3**) could be obtained by either a one- or two-step reduction process (Scheme 5). In the two-step process, pyridinium salt **11** was dissolved in methanol and 3.3 equivalents of $NaBH_4$ was added to produce tetrahydropiperidine **12** in 79% yield. The remaining olefin was then reduced at 40 psi hydrogen and 20% $Pd(OH)_2/C$ in methanol to afford **3** in 95% assay yield. Unfortunately, amine **3** was not crystalline. To facilitate isolation and handling of the product as a solid it was crystallized as the L-tartrate salt from ethanol in 93% recovery. Alternatively, pyridinium intermediate **11** could be reduced directly to **3** using PtO_2 as catalyst in methanol. In this case, the product could be isolated by crystallization as the dihydrobromide salt in 85% yield upon switching the solvent to a mixture of 2-propanol–hexanes (1:1).

The final coupling step used 1,1′-carbonyldiimidazole (CDI) as the urea linking agent (Scheme 6). The (*S*)-dihydropyrimidinone **2** was deprotonated with LDA in THF at <–55°C. CDI was then added and the mixture was warmed to complete the acylation to **13**. The mixture was then recooled to –60°C and the free base of **3** as an IPAc solution was added. The reaction proceeded regioselectively, with no acylation or coupling observed at the unprotected N-1 position. Following an aqueous work-up, the coupled product was isolated from 2-propanol by addition of L-tartaric acid. A sample of the salt was hydrolyzed and the free base was analyzed by chiral HPLC showing the product **1** to be >99% optically pure. The product L-tartrate salt was obtained as a 2-propanol solvate in 80% yield. Interestingly, this salt was reluctant to crystallize without the presence of 2-propanol. Fortunately, the 2-propanol solvate could be removed by aging the solid as a suspension in ethanol for a few hours. Upon filtration, unsolvated salt **1** was isolated in 80% yield.

Scheme 6.



In conclusion, a highly effective preparation of drug candidate **1** for the treatment of BPH has been designed and demonstrated. The key chiral dihydropyrimidinone was easily prepared in two steps using a Lewis acid-modified Biginelli reaction and a very efficient enzymatic hydrolysis to afford the resolved heterocycle in 67–75% overall theoretical yield. An improved process for preparing the side chain and coupling procedure have also been developed, which allows for the construction of the material in multi-kilogram quantities.

Experimental

(±)-4-(3,4-Difluorophenyl)-1,2,3,4-tetrahydro-6-(methoxymethyl)-2-oxo-5-pyrimidinecarboxylic acid methyl ester (2)

A mixture of 3,4-difluorobenzaldehyde (670 g, 4.7 mol), methyl 4-methoxyacetoacetate (702 g, 4.8 mol), urea (433 g, 7.2 mol), boron trifluoride diethyl etherate (1126 g, 7.9 mol), copper(II) acetate (94 g, 0.5 mol), and acetic acid (36 mL) in THF (7.5 L) was heated at reflux for ~8 h. The mixture was cooled to room temperature and ethyl acetate (8 L) and aqueous citric acid (10%, 7.5 kg) were added. The layers were separated and the aqueous layer was washed with ethyl acetate (4 L). The combined organic layers were washed with aqueous 10% Na_2CO_3 (2 × 5 kg) and 5% brine (5 kg). The organic layer was concentrated to 4.3 L, then toluene (5 L) was added, and the batch was concentrated to ~4 L. The batch was heated to 80°C to dissolve the solids and then cooled to room temperature, whereupon the product crystallized. Hexanes (450 mL) were added and the slurry was aged for 18 h. The solid was filtered and washed with toluene (2.5 L) and dried to afford 1.2 kg of racemic dihydropyrimidinone **2** in 84% yield; mp 92–94°C. IR (cm^{-1}): 3232, 3114, 293, 1695, 1652, 1515, 1435, 1093. ^1H NMR ($CDCl_3$) δ: 7.65 (s, 1H), 7.00 (m, 3H), 6.63 (s, 1H), 5.34 (s, 1H), 4.63 (m, 2H), 3.64 (s, 3H), 3.45 (s, 3H). ^{13}C NMR ($CDCl_3$) δ: 165.0, 152.2, 150.3 (dd, J = 249, 13 Hz), 149.8 (dd, J = 249, 13 Hz), 147.5, 140.2, 122.3, 117.4 (d, J = 18 Hz), 115.5 (d, J = 18 Hz), 98.3, 68.4, 59.0, 54.4, 51.3. Anal. calcd. for $C_{14}H_{14}F_2N_2O_4$: C 53.85, H 4.52, N 8.97; found: C 53.80, H 4.48, N 8.84.

(*S*)-4-(3,4-Difluorophenyl)-1,2,3,4-tetrahydro-6-(methoxymethyl)-2-oxo-5-pyrimidinecarboxylic acid methyl ester ((*S*)-2)

A suspension of the racemic dihydropyrimidinone (3.1 kg, 10.2 mol), Trizma hydrochloride (1.3 kg), Trizma base (5.5 kg) in water (992 L), and acetonitrile (110 kg) was heated to 37°C. Purafect 4000L (362 kg) was added and the

suspension was agitated for 10 d. The extent of the optical enrichment was followed by chiral SFC: Chiralcel OD-H (4.6 mm × 25 cm), isocratic elution at 30°C (290 bar), CO_2 with 6% methanol, 2 mL min^{-1}, 280 nm, retention times: (+)-DHP ester = 4.6 min, (–)-DHP ester = 5.3 min, (–)-DHP acid = 11 min; or chiral HPLC: Chiracel OD-H, isocratic elution at ambient temperature with 15% isopropanol in hexanes, 1 mL min^{-1}, 280 nm, retention times: (+)-DHP ester = 7.6 min, (–)-DHP ester = 9.1 min. The reaction was stopped once the DHP methyl ester (*S*)-(+)-**2** had been enriched to >96% ee. The batch was cooled to 20°C, and then toluene (182 kg) was added. The layers were separated and the aqueous layer was washed with toluene (133 kg). The combined organic layers were washed with water (132 L) containing NaCl (32 kg). The organic layer was concentrated to a volume of 4 L and filtered. Toluene was added to bring the volume to 11 L. Heptane (15.8 L) was added to the batch over 10 h with seeding (2 wt%) with pure (*S*)-**2** and aged for 18 h. The solids were filtered, washed with toluene–heptane (40:60, 5.7 L), and dried to afford 1.3 kg of (*S*)-**2** in 40% yield. The optical purity was assayed at >99% (*S*)-(+)-**2**; mp 92–94°C. $[\alpha]_D^{25}$ +89 (*c* 0.5, $CHCl_3$). IR (cm^{-1}): 3232, 3114, 293, 1695, 1652, 1515, 1435, 1093. Anal. calcd. for $C_{14}H_{14}F_2N_2O_4$: C 53.85, H 4.52, N 8.97; found: C 53.76, H 4.34, N8.81.

Dihydropyrimidinone·D-*threo*-2-amino-1-(4-nitrophenyl)-1,3-propanediol salt (6)

Crystals grew from an ethanol solution of **6** held at room temperature. A suitable crystal was selected and reflection data were collected on a point-detector diffractometer. The structure was solved by direct methods and determined to have two independent molecules of **6** present in the lattice along with ethanol molecules and disordered water molecules of solvation. Refinement proceeded normally with the final model using 648 parameters. All non-hydrogen atoms were refined with anisotropic thermal displacements except for the fluorine atoms (one of which is disordered) and those of the solvent molecules. The weighting scheme used was the standard SHELXL function with P^2 and *P* coefficients of 0.2562 and 0.0 respectively. Final agreement statistics are: $R = 0.105$, $wR = 0.371$, $S = 0.97$, $(\Delta/\sigma)_{max} = 0.01$. The maximum peak height in a final difference Fourier map is 0.80 e $Å^{-3}$ and it has no chemical significance.[3]

Preparation of 2,4′-Bipyridine (7)

Lithiation–transmetalation

n-BuLi in hexanes (2.5 M, 4.16 L, 10.4 mol) was added to THF (9.4 L) at <–45°C. 2-Bromopyridine (**8**) (881.4 mL, 9.24 mol) was added to the *n*-BuLi in THF at <–45 C and the mixture was aged for 1.5 h at –55°C. A suspension of zinc chloride (1352 g, 9.92 mol) in THF (9.9 L), previously heated at reflux over molecular sieves in a Soxhlet extractor for 2 h, was added to the batch and the mixture was warmed to room temperature and aged for 2 h.

Salt break of 4-bromopyridine hydrochloride

In a separate flask, 4-bromopyridine hydrochloride (**9**) (1300 g, 6.62 mol) was partitioned between methyl *tert*-butyl ether (MTBE) (6.5 L) and water (1 L). Aqueous Na_2CO_3 (2 M, 4.7 L, 9.4 mol) was added carefully over 10 min and the mixture was well-agitated for 10 min. The layers were separated and the organic phase was diluted with MTBE (6.5 L). The combined organics were azeotropically dried by concentrating to ~6.5 L at 48–54°C.

Coupling

The solution of **8** was added to the 2-pyridyl zinc mixture (**10**) over 10 min. Triphenylphosphine (177 g, 0.67 mol) was added followed by palladium(II) acetate (34.8 g, 0.15 mol). The mixture was then heated and maintained at 50°C. The reaction is exothermic above 50°C. The heating was discontinued, but the reaction temperature rose to 60°C over 10 min. The reaction mixture was cooled to room temperature and concentrated ammonium hydroxide (5 L) was slowly added and the mixture was stirred for 30 min. The layers were separated and the organic layer was washed with brine (4 L). DMF (5 L) was added and the mixture was concentrated to ~2 L. The concentrate contained 837 g of 2,4′-dipyridyl (**7**) (81% assay yield).

1-(3-Aminopropyl)-2,4′-bipyridinium bromide monohydrobromide (11)

To a solution of 2,4′-dipyridyl (**7**) in DMF (1.85 L, 444 mg mL^{-1}, 5.25 mol) was added 3-bromopropylamine-hydrobromide (1400 g, 6.39 mol) and DMF (3.5 L). The mixture was heated to 95°C and aged for 8 h. The reaction mixture was cooled to room temperature and MTBE (3.7 L) was added over 3 h, whereupon the pyridinium salt crystallized. The slurry was aged for 1 h and filtered. The solid was washed with MTBE–DMF (1:1, 4.2 L) and dried to afford 1866 g (95%) of the pyridinium salt **11**; mp 253–256°C. IR (cm^{-1}): 3030, 2933, 1638, 1558, 1506, 1216, 1185, 1149. ^1H NMR (DMSO-d_6) δ: 9.33 (d, J = 6.8 Hz, 2H), 8.82 (d, J = 6.8 Hz, 3H), 8.46 (d, J = 8.1 Hz, 1H), 8.10 (m, 4H), 7.63 (dd, J = 7.5, 4.8 Hz, 1H), 4.87 (t, J = 6.8 Hz, 2H), 2.93 (m, 2H), 2.33 (m, 2H). ^{13}C NMR (DMSO-d_6) δ: 152.8, 150.5, 149.6, 145.2, 138.2, 126.6, 124.4, 123.4, 57.0, 35.5, 34.1, 28.5. Anal. calcd. for $C_{13}H_{17}Br_2N_3$: C 41.63, H 4.57, N 11.20; found: C 41.40, H 4.46, N 11.10.

4-(2-Pyridinyl)-1-piperidinepropanamine (3)

Method A

Pyridinium salt **11** (1840 g, 4.9 mol) was dissolved in methanol (18 L). The slurry was cooled to 5°C and $NaBH_4$ (612 g, 16.2 mol) was added over 2 h. The mixture was concentrated in vacuo and MTBE (10 L) and 20% aqueous NaOH (20 L) were added. The layers were well-stirred and then separated. The aqueous layer was washed with MTBE (10 L). The combined organics were concentrated to afford **12** as a thick oil (836 g, 79% yield). The crude tetrahydropiperidine **12** was dissolved in methanol (8 L). To the methanol solution of crude **12** (812 g, 3.70 mol) was added 20%

[3] Crystallographic information has also been deposited with the Cambridge Crystallographic Data Centre (CCDC No. 177624). Copies of the data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: +44 1223 336033; or deposit@ccdc.cam.ac.uk).

$Pd(OH)_2$ (81 g) and the tetrahydropiperidine was hydrogenated at 40 psi hydrogen. The catalyst was removed by filtration through Celite 521 and the solids were rinsed with methanol (3 × 300 mL). The combined filtrates were concentrated to afford amine **3** as a yellow oil (755 g, 93%). Amine **3** (755 g, 3.4 mol) was dissolved in ethanol (8 L) and the solution was warmed to 65°C. A solution of L-tartaric acid (596 g, 3.97 mol) in ethanol (2.1 L) was added over ~1 h with seeding to crystallize the **3**-tartrate salt. The slurry was slowly cooled to ambient temperature over 18 h. The solids were filtered and washed with ethanol (2 × 1 L) and dried to afford the amine **3**-tartrate salt containing 11 wt% residual solvent (1401 g, 97% corrected yield); mp 101–103°C. IR (cm^{-1}): 3372, 2980, 1589, 1386, 1201, 1118. ^1H NMR ($CDCl_3$) δ: 8.48 (d, *J* = 0.3 Hz, 1H), 7.57 (dt, *J* = 7.7, 1.8 Hz,1H), 7.14 (d, *J* = 7.9 Hz, 1H), 7.07 (m, 1H), 3.03 (d, *J* = 11.5 Hz, 2H), 2.70 (m, 3H), 2.40 (m, 2H), 2.1–1.5 (m, 10H). ^{13}C NMR ($CDCl_3$) δ: 165.2, 149.1, 136.3, 121.2, 120.5, 56.8, 54.2, 44.7, 41.0, 32.1, 30.9.

Method B

Di-hydrobromide salt: Pyridinium bromide salt **11** (50 g, 0.13 mol) was dissolved in methanol (500 mL) and hydrogenated over PtO_2 (1.0 g) at 40 psi and 20°C. After 6 h, the slurry was filtered through Solka-floc® (powdered-cellulose filter aid) on a sintered glass funnel. The solids were rinsed with methanol (2 × 50 mL), and the solution was concentrated and turned over to 2-propanol by distillation at ambient pressure to a concentration of ca. 7.5 mL 2-propanol per g for a final volume of ca. 375 mL. The suspension was cooled to 20°C, and *n*-heptane (15 mL g^{-1}, 750 mL) was added over 1 h. The resulting slurry was filtered, rinsed with 2-propanol–heptane (1:2, 50 mL) and dried at 40°C in vacuo to afford of the dihydrobromide salt (45.5 g, 90% yield); mp 200–204°C. IR (cm^{-1}): 3411, 2934, 1589, 1472, 1435, 1200, 1146. ^1H NMR (DMSO-d_6) δ: 8.51 (m, 1H), 7.75 (dt, *J* = 7.5, 2.0 Hz, 1H), 7.30 (d, *J* = 7.5 Hz, 1H), 7.25 (m, 1H), 3.5–3.0 (br m, 10H), 2.92 (m, 3H), 2.08 (m, 6H). ^{13}C NMR (DMSO-d_6) δ: 162.7, 149.4, 137.3, 122.4, 121.9, 53.5, 52.2, 45.0, 36.7, 28.8, 22.0. Anal. calcd. for $C_{13}H_{23}Br_2N_3 \cdot H_2O$: C 39.12, H 6.31, N 10.53; found: C 39.22, H 6.11, N 10.47.

Salt break

The L-tartrate or dihydrobromide salt of **3** (3.0 mol) was added to 50% NaOH (2.29 kg) diluted with water (6 L). The free amine was extracted with isopropyl acetate (3 × 18 L) and the combined extracts were concentrated to afford 594.1 g of **3** as an oil (90% recovery), which was used without further purification in the following step.

(*S*)-6-(3,4-Difluorophenyl)-1,2,3,6-tetrahydro-4-(methoxymethyl)-2-oxo-1-[[[3-[4-(2-pyridinyl)-1-piperidinyl]propyl]amino]carbonyl]-5-pyrimidinecarboxylic acid methyl ester – tartrate salt

A solution of LDA (2 M in heptane–THF–ethylbenzene, 184 mL, 0.4 mol) was added to a –65°C solution of (*S*)-(+)-**2** (100 g, 0.4 mol) in THF (1 L). After 15 min, carbonyl diimidazole (62.3 g, 0.38 mol) was added in one portion. The resulting slurry was aged at –60°C for 15 min and then warmed to 20°C. After 1 h, the mixture was re-cooled to –60°C. A solution of amine **3** (100 g, 0.45 mol) in isopropyl acetate (IPAc) (300 mL) was added at <–45°C. The mixture was slowly warmed to 20°C. The reaction was quenched with water (1.5 L) and IPAc (1.5 L). The layers were separated and the organic layer was washed with water (2 × 1.5 L). The combined aqueous layers were washed with IPAc (0.5 L). The combined organic layers were extracted with 2 N HCl (1 × 1 L and 1 × 0.5 L). The combined acid extracts were neutralized with solid $NaHCO_3$ (450 g). IPAc (1 L) and water (1 L) were added and the layers were mixed and separated. The aqueous layer was extracted with IPAc (1 L). The combined organic layers were washed with water (2 × 1 L) and concentrated to an oil. The oil was dissolved in 2-propanol (1.27 L). The solution was warmed to 50°C. A solution of L-tartaric acid (38 g, 0.2 mol) in ethanol (175 mL) was added and the mixture was aged for 1 h, whereupon crystals formed. The slurry was cooled to 20°C, aged for 18 h, cooled to 0°C, and then aged for an additional 1 h. The solid was filtered, washed with 2-propanol (300 mL), and dried to afford 195 g of the **1** tartrate salt as a 2-propanol solvate (80% yield). The solvate was broken by stirring the solid in ethanol (975 mL) at 0°C for 2 h. The solid was filtered and dried to afford the L-tartrate salt of **1** (156 g, 80% yield); mp 145–148°C. $[\alpha]_{589}^{20}$ +127.5 (*c* 1.0, CH_3OH). Optical purity >99.9% by chiral HPLC assay. Enzymatic synthesis of octyl glucoside catalyzed by almond β-glucosidase in organic media

Amélie Ducret, Jean-François Carrière, Michael Trani, and Robert Lortie

Abstract: The synthesis of *n*-octyl-β-D-glucopyranoside can be performed by direct condensation of 1-octanol and glucose, catalyzed by immobilized almond β-glucosidase, using solid glucose suspended in 1-octanol as a reaction media. Both the rate of reaction and the conversion could be enhanced by using acetonitrile and *N*,*N*-dimethylformamide (DMF) as co-solvents, the latter giving the best results. The rate of reaction was dependent on the concentration of DMF and on the initial water activity (a_w), with higher water activity fostering faster reactions. The rate increased with DMF concentration, up to 20% DMF, but diminished rapidly at higher concentrations. Product concentration could be increased from 40 to 100 mM by going from 0 to 20% DMF; however, it was not sensitive to the initial water activity.

Key words: β-glucosidase, alkyl glycosides, reverse hydrolysis, water activity, organic solvent.

Résumé : La synthèse du *n*-octyl-β-D-glucopyranoside a été effectuée par condensation du octane-1-ol et du glucose, catalysée par la β-glucosidase d'amande immobilisée, en suspendant le glucose solide dans l'octane-1-ol. La vitesse de réaction de même que le taux de conversion ont été améliorés par addition de co-solvants tels que l'acétonitrile et le *N*,*N*-diméthylformamide (DMF), ce dernier permettant d'obtenir de meilleurs résultats. La vitesse de réaction dépendait de la concentration en DMF et de l'activité de l'eau initiale, des activités élevées favorisant des réactions plus rapides. La vitesse de réaction augmentait avec la concentration en DMF, jusqu'à 20% de DMF, mais diminuait rapidement à des concentrations supérieurs. On a pu augmenter la concentration en produit, de 40 à 100 mM en passant de 0 à 20% de DMF; cependant, elle n'était pas fonction de l'activité de l'eau.

Mots clés : β-glucosidase, glycosides d'alkyles, hydrolyse inversée, activité de l'eau, solvant organique.

Introduction

The use of enzymes in organic synthesis is now widely accepted and documented (1, 2). Simple enzymes like hydrolases have also found applications in synthesis (3). They are especially interesting because they do not require cofactors and many of them display good stability. Their use has expanded with the recognition that they can catalyze the reverse reaction, condensation, if the thermodynamic conditions are favourable, by, for instance, lowering the water activity (a_w) by working in organic solvents. This fact has been known for some time (4, 5), but became more prominent in the last 20 years or so (6, 7), and some rationalizations were made about the choice of solvent and the role of water (8, 9).

This approach can be used in the preparation of alkyl glycosides. These non-ionic surfactants obtained from renewable feedstock are stable under alkaline conditions (10) and completely biodegradable. They show antimicrobial properties and low toxicity (11), and they have numerous applications in areas such as cosmetics, pharmaceuticals, food, and detergents. As a good alternative to chemical syntheses, which require protection and deprotection of the hydroxyl groups, the use of glycosidases in the enzymatic synthesis of such compounds was emphasized since it permits the regio- and stereoselectivity to be obtained in one step under mild reaction conditions. Enzymatic synthesis of alkyl glycosides can be achieved by either a kinetically (transglycosylation) or a thermodynamically (condensation) controlled approach (12). In spite of numerous studies performed on the subject (13), only poor yields have been obtained, mostly because glycosidases lose activity at low water activity (14, 15).

In the present work, we report the effect of water and co-solvent on the activity of almond β-glucosidase in the synthesis of octyl-β-D-glucoside by direct condensation of glucose and 1-octanol. Almond β-glucosidase was selected because it is readily available, relatively inexpensive, and shows no inhibition by glucose when compared with various microbial glycosidases (16).

Materials and methods

Materials

Almond β-glucosidase (2.8 U mg^{-1}), *n*-octyl-β-D-glucopyranoside, *p*-nitrophenyl-β-D-glucopyranoside (*p*NPG), and 2-methyl-2-butanol were purchased from Sigma (St. Louis,

 DOI: 10.1139/V02-081 © 2002 NRC Canada

MO, U.S.A.). Glucose, Amberlite XAD-4 resin, sodium acetate, and $MgCl_2$ were purchased from BDH (Montreal, Quebec, Canada). The solvents used were always from the highest grade available and were used without further purification. Acetonitrile, 1-octanol, and the molecular sieves (3 Å) were purchased from Fisher Scientific (Nepean, Ontario, Canada). *N*,*N*-dimethylformamide (DMF), $BaCl_2$, and $Mg(NO_3)_2$ were purchased from Aldrich (Milwaukee, WI, U.S.A.). Methanol was purchased from J.T. Baker (Phillipsburgh, NJ, U.S.A.) and sulphuric acid from Anachemia (Montreal). NaCl was purchased from ACP Chemicals Inc. (Montreal). MilliQ+ water was used.

Immobilization of almond β-glucosidase on Amberlite XAD-4

Almond β-glucosidase (483 mg) was dissolved in sodium acetate buffer (2 mL, 50 mM, pH 5.0) and gently mixed with XAD-4 resin (2 g), which was previously washed and dried according to the procedure of Vulfson et al. (17). The mixture was then dried under vacuum for 20 h. The immobilized enzyme preparation contains 194.5 mg protein per g of dry weight. The immobilization yield was measured by suspending the preparation (3.5 mg) in a buffer (50 mL) containing *p*NPG (1.67 mM). Aliquots (0.75 mL) were taken, diluted with glycine buffer (1.0 mL, 0.4 M, pH 10.8), and the amount of *p*-nitrophenol released was measured at 430 nm.

HPLC analysis

HPLC analyzes were performed using a Waters Millennium[32] liquid chromatography system equipped with a Waters 600E solvent delivery system, a Waters 717 autosampler, and a Waters 410 refractive index detector, all purchased from Waters Scientific (Montreal).

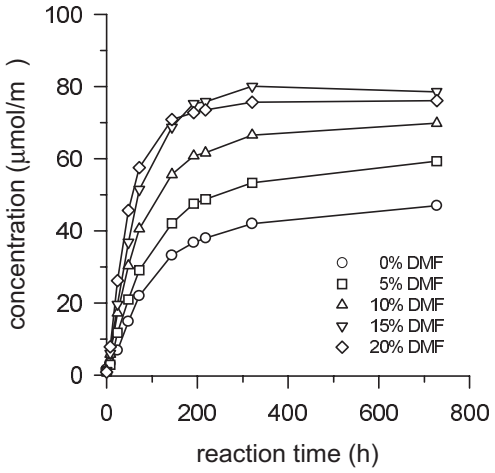
The analysis of octyl glucoside was performed using a reversed-phase column CSC-Inertsil, 150 Å/ODS2, 5 μm, 25 × 0.46 cm (CSC, Montreal). Periodically, 12 μL of reaction sample were dissolved in acetonitrile (320 μL) and 25 μL were injected. A mixture of acetonitrile–water (60:40, v:v) was used as the mobile phase. The flow rate was maintained constant at 1.0 mL min^{-1} and the column temperature at 25°C. The retention times of *n*-octyl-β-D-glucopyranoside and 1-octanol were 3.53 and 9.08 min, respectively.

Glucose analysis was accomplished on an ion-exclusion column ICSep ICE-ION-300, 8 μm, 30 × 0.78 cm preceded by the guard column ICSep ICE-GC-801 (Transition Technologies Inc., Toronto, Ontario, Canada). A sample of the mixture (100 μL) was dissolved in methanol (200 μL) and 10 μL were injected into the column. Sulphuric acid (0.0042 M) was used as the mobile phase. The flow rate was maintained constant at 0.5 mL min^{-1} and the column temperature at 60°C; 10 μL of each sample were injected. The retention times of glucose, methanol, acetonitrile, 2-methyl-2-butanol, DMF, and *n*-octyl-β-D-glucopyranoside were 13.1, 25.5, 28.2, 46.0, 62.2, and 80.5 min, respectively. The system was washed periodically with the mobile phase to elute 1-octanol (which has a retention time of several hours).

Enzymatic synthesis

Before starting the reactions, the immobilized enzyme (207 mg, corresponding to 40.3 mg of protein) and reaction media (300 mg glucose and 2 mL of a mixture of 1-octanol–DMF) were equilibrated separately in chambers containing saturated salt solutions to preset the water activity ($BaCl_2$, a_w = 0.90; NaCl, a_w = 0.75; $Mg(NO_3)_2$, a_w = 0.53; $MgCl_2$, a_w = 0.33). Equilibration of the different reaction media was followed by measuring their water content by coulometric Karl Fischer titration using a Metrohm 684 KF coulometer (Herisau, Switzerland). After addition of the enzyme in the reaction mixture, the vials were hermetically closed and the reactions were run at 50°C. In the reaction mixture, most of the glucose was present as a solid phase. It was verified that all the octyl glucoside formed during the reaction was soluble in the liquid phase. Aliquots of the liquid phase were taken periodically through a Mininert® valve (Supelco, Bellefonte, PA, U.S.A.) for HPLC analysis. The initial reaction rates were determined by linear regression over 4–7 points.

Fig. 1. Synthesis of octyl-β-D-glucoside with a_w = 0.90 (300 mg D-glucose, 2 mL 1-octanol–DMF, 207 mg immobilized enzyme).



Solubility measurement

The solid glucose as well as each solvent were previously equilibrated separately in chambers containing a saturated NaCl solution to preset the a_w to 0.75. Glucose (0.30–0.35 g) was then added to 2 mL of a mixture of 1-octanol–co-solvent. The hermetically closed vials containing the mixtures were kept under constant agitation at 50°C for several days and then transferred to an oven at the same temperature. The liquid phase was filtered (0.45 μm, Millipore, Bedford, MA, U.S.A.) and diluted with methanol for HPLC analysis. To prevent precipitation, all the equipment used was previously heated to 50°C. A second determination was performed by simply diluting the settled liquid phase in methanol before HPLC analysis. Both methods gave identical results.

Results and discussion

The immobilized preparation and the enzyme in solution both catalyzed the hydrolysis of *p*NPG at a rate of 2.1 and 1.9 μmol per min per mg protein, respectively. The immobilization yield is therefore around 100%. When the solid was filtrated from the reaction, the rate dropped to 20% of that observed without filtration. This indicates that in water only 20% of the enzyme desorbs from the resin, even with a very

Fig. 2. Effect of various co-solvents on the initial reaction rate (*a*) and on the maximum concentration of octyl glucoside (*b*) (300 mg D-glucose, 2 mL 1-octanol–co-solvent, 207 mg immobilized enzyme, a_w = 0.75).

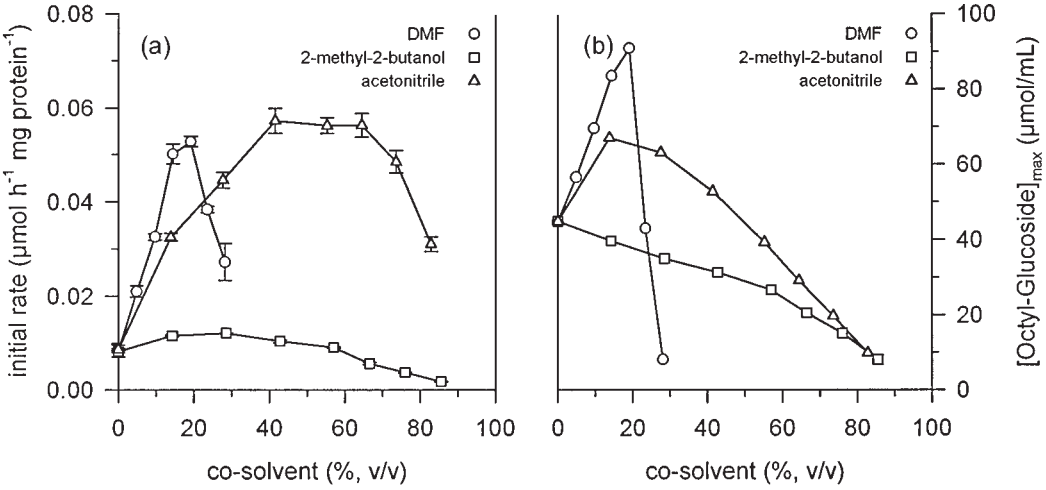

Fig. 3. Effect of co-solvent on the glucose solubility at a_w = 0.75.

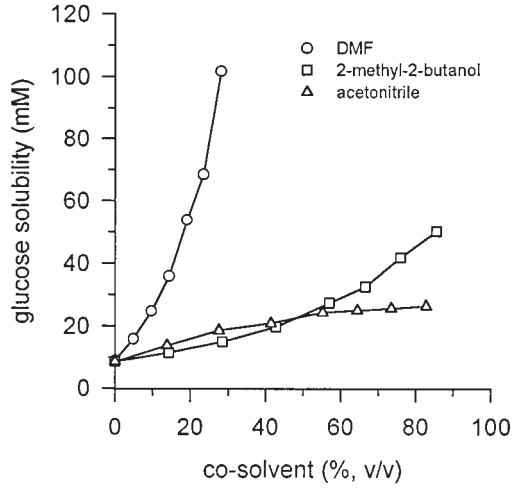


high liquid–solid ratio. In a much smaller volume of octanol, the enzyme should remain adsorbed (even in the presence of hydrophilic solvents).

A typical time course of the β-glucosidase-catalyzed condensation of glucose and octanol, at an initial a_w = 0.90 and various DMF concentrations, is presented in Fig. 1. As can be seen, the presence of the solvent affects both the initial rate and the equilibrium-product concentration. As shown in Fig. 2, other solvents at a_w = 0.75 have a different effect on the rate and equilibrium. The presence of 2-methyl-2-butanol impairs the synthesis by diminishing the maximum concentration of octyl glucoside reached as well as the initial rates at high concentrations (>50%). Conversely, addition of DMF or acetonitrile to the media increases the production of octyl glucoside — with a different maximum for each solvent. A sharp optimum concentration of DMF in the media (20%) led to the highest rate as well as the highest concentration of octyl glucoside at equilibrium (0.053 µmol per h per mg protein and 91 mM, respectively). Identical high values for the initial rates can be obtained with a broad concentration range of acetonitrile (40–65%); high concentrations of octyl glucoside, however, are only obtained with low percentages of acetonitrile (15–30%) and then rapidly diminish as the concentration of acetonitrile increases. When acetonitrile and DMF were used as co-solvents in water for the synthesis of 2-hydroxybenzyl-β-D-glucopyranoside catalyzed by almond β-glucosidase, the effect was not as favourable (18). In this case, acetonitrile had a positive effect on the product concentration between 80 and 95% (v/v), while DMF had no real positive effect.

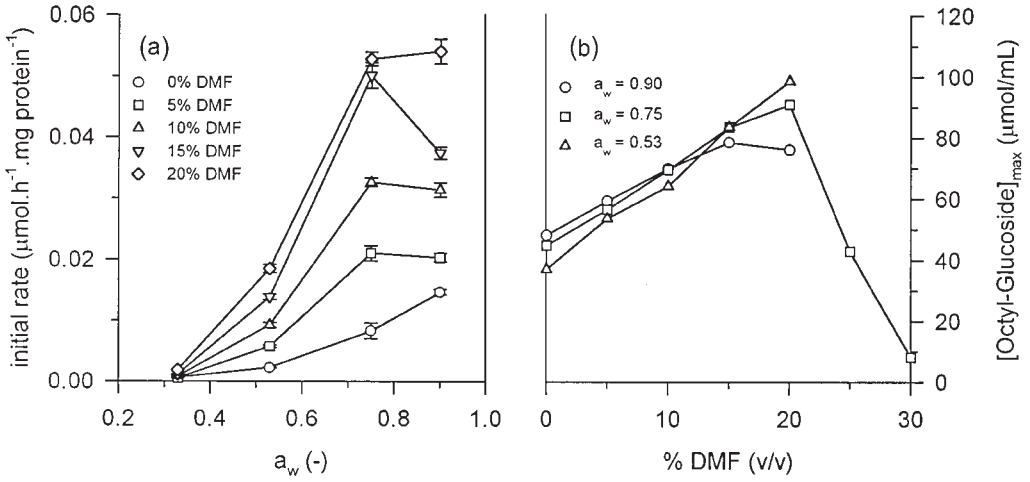
The addition of polar co-solvents increases the solubility of glucose in the reaction medium (Fig. 3), which could be responsible for the observed increase in the reaction rates upon the addition of small amounts of the co-solvent. The fact that the addition of 2-methyl-2-butanol and acetonitrile has a similar effect on the solubility of glucose, but a very different effect on the initial reaction rates indicates that an increase in glucose solubility is not a determining factor.

It is possible that the low reaction rate in octanol is partly caused by its low dielectric constant (8.1), which results in higher electrostatic interactions between the polar and the charged residues, thus decreasing the flexibility of the protein. Addition of co-solvents with higher dielectric constants such as DMF (38.2) or acetonitrile (36.6) (or increasing the water content) raises the dielectric constant, which leads to lower electrostatic interactions and higher protein flexibility and activity, whereas 2-methyl-2-butanol, with its low dielectric constant (5.8) has little impact on the activity. This is in agreement with previous observations for subtilisin suspended in tetrahydrofuran (19) and for α-chymotrypsin suspended in various solvents (20).

Since DMF fosters higher reaction rates and product concentrations at a_w = 0.75, a study of its effect at various water activities was performed. As can be seen in Fig. 4, the positive effect of DMF on the reaction rates observed at a_w = 0.75 is present at other water activities up to a concentration of 20%, after which the rates drop dramatically. The presence of DMF, up to 20%, fosters higher octyl glucoside equilibrium concentrations. For instance, at a_w = 0.53, nearly 100 mM (~30 g L^{-1}) of octyl glucoside is obtained at equilibrium, which is greater than the amount obtained without the addition of co-solvents (40–50 mM); the amount measured by Ljunger et al. (14) was the same. Furthermore, this

© 2002 NRC Canada

Fig. 4. Effect of water activity on the initial reaction rate (*a*) and effect of DMF on the equilibrium concentration of octyl-β-D-glucopyranoside (*b*) (same conditions as Fig. 1).



result has been obtained with a reaction rate superior to the highest rates observed without DMF. This high conversion is probably caused by the higher solubility of octyl glucoside in the presence of DMF (8). The solubility of glucose does not have to be taken into account, since the solution is always saturated, due to the presence of an excess of solid glucose, leading to small variations in the thermodynamic activity of glucose. It is difficult to explain the drop in conversion at concentrations higher than 20% DMF. We believe that equilibrium was reached, since addition of fresh catalyst does not change concentrations.

It should be noticed that the maximum concentration of octyl glucoside obtained increases only with the percentage of added DMF and, surprisingly, does not seem to be influenced by a_w (Fig. 4*b*). This is contrary to observations for 1-octanol without addition of co-solvent (14) and for 1-hexanol using various glycoside donors (21), where in both cases, the lowering of a_w induces higher octyl glucoside concentrations. The synthesis of 2-hydroxybenzyl-β-D-glucopyranoside in an aqueous-organic media was also favoured by low water activities (18). The presence of most of the glucose as a solid phase, on which water molecules can adsorb, may play a role, which should be investigated.

Optimized production of the Diels–Alderase antibody 1E9 as a chimeric Fab

Andrea Piatesi and Donald Hilvert

Abstract: Monoclonal antibody 1E9, which catalyzes the [4+2] cycloaddition between tetrachlorothiophene dioxide and *N*-ethylmaleimide, has been re-engineered for production as a chimeric human–murine Fab fragment in *Escherichia coli*. Stabilizing point mutations in the variable regions of the antibody were identified by replacing residues that rarely occur at individual positions in aligned immunoglobulin sequences with their consensus counterparts. By combining favorable substitutions, double ($Met^{H87}Thr–Gly^{L63}Ser$) and triple ($Met^{H87}Thr–Gly^{L63}Ser–Phe^{L95}Pro$) mutants were created, which can be produced in good yield (4 and 17 mg L^{-1} cell culture, respectively). The triple mutant exhibits a modest fourfold drop in the apparent k_{cat} value for the cycloaddition reaction, but the kinetic properties of the double mutant are indistinguishable from those of the parent murine IgG. The availability of recombinant versions of this catalytic antibody will facilitate efforts to determine the origins of its selectivity and catalytic efficiency through mutagenesis.

Key words: catalytic antibody, Fab fragment, bacterial production.

Résumé : L'anticorps catalytique monoclonal 1E9, qui catalyse la cycloaddition [4+2] entre le dioxide de tétrachlorothiophène et le *N*-éthylmaleimide, a été modifié afin de permettre la production d'un fragment chimérique (humain–murine) Fab dans l'*Escherichia coli*. L'identification des mutations ponctuelles stabilisantes dans les régions variables de l'anticorps, a été réalisée en remplaçant les résidus rarement présents dans les alignements des séquences d'immunoglobulines par les résidus de plus grande occurrence. En combinant les substitutions favorables, on a créé les mutants double ($Mer^{H87}Thr–Gly^{L63}Ser$) et triple ($Met^{H87}Thr–Gly^{L63}Ser–Phe–^{L95}Pro$) qui ont été produits avec de bons rendements (respectivement de 4 et 17 mg L^{-1} de culture cellulaire). Alors que le mutant triple présente, pour la réaction de cycloaddition, une diminution d'un facteur 4 de la valeur du k_{cat} apparent, les propriétés cinétiques du mutant double sont identiques à celles de la murine originelle. L'accessibilité à des versions recombinantes de cet anticorps permettra, par le biais de la mutagenèse, de déterminer les origines de l'activité catalytique de 1E9 ainsi que sa sélectivité.

Mots clés : anticorps catalytique, fragment Fab, production bactérienne.

[Traduit par la Rédaction]

Introduction

Over the last decade, tailored antibody molecules have been engineered to catalyze a wide range of chemical reactions, including transformations that are rare or unknown in nature (1–4). For example, antibodies raised in response to bicyclic compounds that mimic the highly ordered boat-like geometry of the Diels–Alder reaction promote [4+2] cycloadditions with significant rate accelerations (5–8). They also exert considerable control over the *exo–endo* selectivity and absolute stereochemistry of such reactions (6, 8, 9).

Antibody 1E9 is currently the most efficient Diels–Alderase known (7). It was raised against the *endo*-hexachloronorbornene compound (**1**) and catalyzes the cycloaddition of tetrachlorothiophene dioxide (**2**, TCTD) and *N*-ethylmaleimide (**3**, NEM) with multiple turnovers (Fig. 1). The initially formed adduct (**4**) spontaneously eliminates sulfur dioxide to give the dihydrophthalimide derivative **5**, and the latter spontaneously oxidizes in situ to yield *N*-ethyl tetrachlorophthalimide (**6**) as the final product. A k_{cat}/k_{uncat} value in excess of 1000 M has been determined for 1E9 (10), making this catalyst substantially more active than other Diels–Alderase antibodies for which effective molarities rarely exceed 10 M. It is also considerably more efficient than ribozymes selected for their ability to promote cycloadditions (11, 12) and several natural Diels–Alderase enzymes that have been recently characterized (13–15).

The crystal structure of 1E9 complexed with its hapten reveals almost perfect shape complementarity between protein and ligand (10). Molecular recognition is achieved through extensive van der Waals contacts, π-stacking interactions, and a strategically placed hydrogen bonding interaction to one of the succinimide carbonyl groups. Although originally

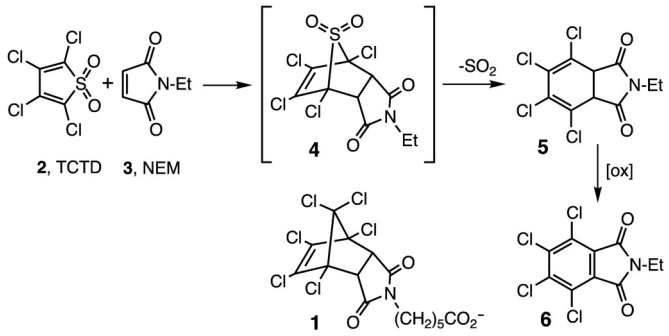
Fig. 1. Diels–Alder cycloaddition catalyzed by 1E9. The antibody was elicited in response to the tetrachloronorbornene derivative **1** (7). It catalyzes the reaction between tetrachlorothiophene dioxide (**2**, TCTD) and *N*-ethylmaleimide (**3**, NEM) to give the high-energy intermediate **4**, which subsequently breaks down to yield *N*-ethyltetrachlorophthalimide (**6**).



designed as an entropy trap, computational results suggest that enthalpic stabilization of the transition state through an unusually close fit to the apolar binding surface of the antibody active site and a strong hydrogen bond between the side chain of Asn^{H35} and the carbonyl of the dienophile component are responsible for catalysis (16).

In order to test these ideas and explore the relationship between binding energy and catalysis through systematic variation of antibody structure, recombinant versions of 1E9 are needed. This antibody has been successfully produced in a mammalian cell line as a recombinant chimeric murine–human IgG, but attempts to generate a more conveniently manipulated Fab fragment or a single-chain Fv in bacteria were unsuccessful (17, and unpublished results). Here we describe the design and characterization of variants of 1E9 that can be readily produced as Fab proteins in bacteria.

Experimental

Materials

Hapten **1** (7) and TCTD (18) were synthesized according to published protocols. NEM was purchased from *Aldrich*. The expression plasmid p4xH-M13 (19) was generously provided by Prof. P.G. Schultz. *E. coli* XL1-blue and TOPP2 strains were obtained from Stratagene (La Jolla, CA). Restriction enzymes and T4 ligase were purchased from New England Biolabs (Beverly, MA) and Fermentas (Vilnius, Lithuania), respectively. Polymerase chain reactions (PCRs) were carried out with thermostable HotStarTaq DNA polymerase from Qiagen (Basel, Switzerland). Oligonucleotides for mutagenesis and sequencing were prepared by Microsynth (Balgach, Switzerland). All nucleic acid manipulations were according to standard procedures (20). DNA sequencing was performed on an ABI PRISM 310 Genetic Analyzer from PE-Applied Biosystems (Foster City, CA).

Expression constructs

Poly(A)$^+$ mRNA was isolated from the hybridoma cells that produce antibody 1E9 and reverse transcribed to cDNA with avian myeloblastosis virus reverse transcriptase using oligo(dT) as a primer (17). The V_L and V_H genes were amplified by the polymerase chain reaction (PCR) using the following primers:

V_L-sense (5′-GCGTACGCTGAGCTCGTGATGACCCAGACTCCACTCTCC-3′, *Sac* I site underlined);
V_L-antisense (5′-TTTGATCTCAAGCTTGGTGCCACCACCGAACGTCGGAAA-3′, *Hin*d III site underlined);
V_H-Glu^{H6} sense (5′-CAGGTTCAGCTGCTCGAGTCTGGACCTGAACTGAAGAAG-3′, *Xho* I site underlined);
V_H-Gln^{H6} sense (5′-GTGTTAAGCTGGGGATCCTCTAGAGGTTGA-3′, *Bam*H I site underlined);
V_H-antisense (5′-TGAGGAGACGGTGACCGAGGTTCCTTGACCCCAGTAGTC-3′, *Bst*E II site underlined).

The amplified fragments were purified and inserted into vector p4xH (19) to give the expression plasmid p4xH-1E9.

The heavy chain was sequenced with primers HSEQF (5′-AGCAAAGCAGACTACGAGAAA-3′) and HSEQB (5′-GGGTGCCAGGGGGAAGAC-3′). The light chain was sequenced with the primer LSEQB (5′-CATCAGATG-GCGGGAAGATG-3′).

Site-directed mutagenesis

Mutations were introduced into p4xH-1E9 by a standard overlap-extension PCR technique (21). The flanking primers for the Phe^{L46}Leu, Gly^{L63}Ser, and Ile^{L72}Thr mutations were the V_L-sense and the V_L-antisense primers. For the Phe^{L95}Pro mutation, the flanking primers V_L-sense and 5′-CATCAGATGGCGGGAAGATG-3′ (antisense) were used. The flanking primers for the Leu^{H5}Val–Glu^{H6}Gln, Lys^{H12}Val, Met^{H28}Thr, Lys^{H46}Glu, Phe^{H59}Tyr, and Met^{H87}Thr mutations were 5′-GTGTTAAGCTGGGGATCCTCTAGAGGTTGA-3′ (sense) and 5′-TGAGGAGACGGTGACCGAGGTTCCTTG-ACCCCAGTAGTC-3′ (antisense).

The following mutation-containing primers were used together with the corresponding antisense sequences:

Phe^{L46}Leu (sense), 5′-GGCCAGTCTCCAAAG**CTG**CTGATCTACAAAGTT-3′;
Gly^{L63}Ser (sense), 5′-GTCCCAGACAGGTTC**AGC**GGCAGTGGATCA-3′;
Ile^{L72}Thr (sense), 5′-TCAGGGACAGATTTC**ACT**CTCAAGATCAGCAGA-3′;
Phe^{L95}Pro (sense), 5′-CAAAGTACACATTTT**CCG**CCGACGTTCGGT-3′;
Leu^{H5}Val/Glu^{H6}Gln (sense), 5′-CAGGTTCAGCTG**GTCCAG**TCTGGACCTGAA-3′;
Lys^{H12}Val (sense), 5′-CCTGAACTG**GTG**AAGCCTGGAGAGA-3′;
Met^{H28}Thr (sense), 5′-AAGGCCTCTGGATAT**ACT**TTCACAAATTATGGA-3′;
Lys^{H46}Glu (sense), 5′-AGGAAAGGCTTTA**GAA**TTGATGGGCTGGATA-3′;
Phe^{H59}Tyr (sense), 5′-ACTGGAGAGTCAACA**TAT**GCTGATGACTTCAAG-3′;
Met^{H87}Thr (sense), 5′-CTCAAAAATGAGGAC**ACT**GCTACATATTTCTGT-3′.

Mutagenized positions are denoted in bold. Mutant codons were chosen to exploit the most frequently used codon for a particular amino acid among highly expressed genes in *E. coli* (Wisconsin Sequence Analysis package, version 8, Genetics Computer Group, Inc.). The presence of the correct mutations was confirmed by DNA sequencing using the HSEQF, HSEQB, and LSEQB primers.

ELISA measurements

Antibody production was screened by enzyme-linked immunosorbent assay (ELISA) (22). The TOPP2 strain of *E. coli* was transformed with p4xH-1E9 and its derivatives, and the individual Fab variants were produced in 100 mL shake-flask cultures as previously described (19).

© 2002 NRC Canada

Periplasmic lysates were prepared, and after normalizing the total protein concentration, the samples were diluted 100-fold in PBS buffer containing 1% bovine serum albumin (BSA). Standard ELISA measurements were performed by immobilizing BSA–**1** conjugates on microtiter plates blocked with 3% BSA in PBS and titrating the crude lysates by serial dilution. Bound Fab was detected using goat anti-human IgG heavy and light-chain antibodies conjugated to horseradish peroxidase (Calbiochem, La Jolla, CA). The plates were developed with 2,2′-azino-bis(3-ethylbenzthiazoline-6-sulfonic acid) (ABTS), 0.02% H_2O_2 in 0.1 M citrate buffer (pH 4.0). Absorbance at 405 nm was recorded following color development.

Production and purification of chimeric 1E9 Fabs

Large-scale antibody production was achieved by culturing the transformed TOPP2 *E. coli* strains in shake-flasks (6 L) or by high-density fermentation (2 L) in a BIOFLO 3000 bioreactor (New Brunswick Scientific, Edison, NJ) as previously described (19). The chimeric Fab fragments were purified from crude periplasmic lysates by protein G affinity chromatography, followed by Mono S cation-exchange chromatography. Sample purity was assessed by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE). Protein concentration was determined spectroscopically at 280 nm, using molar absorption coefficients calculated as described by Pace et al. (23). An ε_{280} of 59 000 M^{-1} cm^{-1} was employed for all the Fab fragments except the triple mutant, which had a value of 57 500 M^{-1} cm^{-1}. Proteins were stored at 4°C in 20 mM Tris-HCl (pH 7.2) containing 0.5 mM EDTA and 100 mM NaCl.

Fluorescence titrations

Thermodynamic dissociation constants were determined as previously described (24). Titration curves were recorded by stepwise addition of a hapten stock solution (15 μM) to a diluted solution of the chimeric Fab fragment (26 nM) and subsequent measurement of the fluorescence. The excitation and emission wavelengths were 290 nm and 340 nm, respectively, and the corresponding bandpasses were 8 and 16 nm. The high voltage of the detector was set to 900 V. These measurements were carried out in 20 mM sodium acetate (pH 5.5) and 100 mM NaCl at 15°C.

The dissociation constant (K_d) for the Fab–hapten complex is given by $K_d = (E_T - EL)(L_T - EL)/(EL)$, where L_T represents the total hapten concentration, E_T is the total Fab concentration, and EL is the concentration of the Fab–hapten complex. This equation can be rearranged into $(L_T)(1/R - 1) = K_d + E_T(1 - R)$ for Scatchard analysis, where R denotes the ratio of the Fab–hapten complex concentration to the total Fab concentration (EL/E_T). Since $EL = (F_E - F)$ and $E_T = (F_E - F_{EL})$, where F_E represents the initial fluorescence of the Fab solution, F the observed fluorescence and F_{EL} the fluorescence of the protein at infinite hapten concentration, it is possible to plot $L_T(1/R - 1)$ vs. $(1 - R)$ and get K_d from the intercept and the total Fab concentration from the slope (24).

BIAcore measurements

The binding process between 1E9 Fab mutants and the hapten was monitored by the surface plasmon resonance (SPR) technique using a BIAcore 3000 instrument (Pharmacia, Uppsala, Sweden) (25, 26). All experiments were performed at 25°C. The surface of the dextran-chip was activated with 1-[3-dimethylamino)propyl]-3-ethylcarbodiimide hydrochloride and *N*-hydroxysuccinimide in 10 mM acetate (pH 4.0) and covalently linked to the BSA-hapten conjugate (SPR response: 400 RU). Fab samples were diluted in 10 mM HEPES buffer (pH 7.4) containing 150 mM NaCl, 3.4 mM EDTA, and 0.005% Tween 20 prior to SPR analysis. The Fab fragments were injected in the presence of the immobilized hapten at a flow rate of 5 μL min^{-1}. The association rate constant (k_{on}) was determined by measuring the rate of binding to the hapten at three different Fab concentrations (1, 0.6, and 0.4 μM). The dissociation phase (k_{off}) was monitored after the association process was complete. The dextran matrix was regenerated after each injection using 10 mM HCl. Rate constants were calculated from the SPR data using BIAevaluation 3.1 software (Pharmacia, Uppsala, Sweden). A single-site binding model (A + B = AB) was assumed for the analysis. The apparent dissociation constant ($K_d = k_{off}/k_{on}$) was calculated from the individual association and dissociation rate constants.

Kinetic assays

The reaction between TCTD and NEM was carried out at 25°C in 50 mM sodium acetate buffer (pH 5.5) containing 20 mM NaCl in the presence and absence of the antibody (1 μM). The substrates were diluted from stock solutions in acetonitrile; the final concentration of acetonitrile in the reaction mixture was 2% by volume. Initial velocities were determined by starch-I_2 bleaching at 606 nm (10, 17) at several concentrations of NEM while holding the concentration of TCTD constant at 150 μM. The data were corrected for the uncatalyzed reaction (7) and fitted to the Michaelis–Menten equation, $v_o/[Ab] = (k_{cat}[NEM])/(K_m + [NEM])$, where v_o is the initial rate, [Ab] and [NEM] are the active site and substrate concentrations, respectively, and k_{cat} and K_m are the catalytic rate and the Michaelis constants, respectively, at a fixed concentration of TCTD.

Thermal denaturation experiments

Thermal denaturation of the Fab variants was monitored by circular dichroism (CD) on an AVIV Circular Dichroism spectropolarimeter, Model 202 (AVIV Instruments, Lakewood, NJ) equipped with a single-position thermoelectric cuvette holder. CD spectra were recorded at 25°C in PBS (pH 7.4), with a protein concentration of 0.2 mg mL^{-1}. Spectra were obtained by averaging three wavelength scans from 260 to 200 nm in 1-nm steps, with a signal averaging time of 1 s and a bandwidth of 1 nm. Thermal denaturation curves were obtained using these samples in a 0.1-cm cuvette. The ellipticity at 216 nm was monitored as a function of temperature from 25 to 95°C in 1°C steps. For each point, the sample was first equilibrated for 2 min and then the signal was averaged for 3 s before moving to the next temperature.

Results

Production of 1E9 as a chimeric Fab fragment

Antibody production in microorganisms is often problematic. In some cases, fusion of the murine V_L and V_H variable

regions with the C_L and C_H1 regions of a human κ_1 and IgG1 antibody, respectively, can greatly increase the efficiency of expression in *E. coli* (19). Preliminary attempts to engineer 1E9 as a chimeric murine – human Fab fragment, however, only gave very low yields of protein (17, and unpublished results).

In retrospect, these disappointing results appear to be largely due to the introduction of an *Xho* I restriction site during cloning, which resulted in the replacement of Gln^{H6} with Glu. Although the sequence database shows that Gln and Glu occur with similar frequency at position H6 (27), comparison of known structures with these two residues at the H6 position reveals that the Gln and Glu side chains participate in distinct and highly conserved hydrogen-bonding networks with surrounding residues (28, 29). Not surprisingly, therefore, swapping these amino acids can have a significant deleterious effect on antibody production (28). Indeed, in the case of 1E9, reversion to the wild-type sequence greatly increases the yield of the chimeric Fab (≈ 20- to 30-fold determined by ELISA). Under fermentative conditions, this protein can be produced in sufficient amounts (0.7 mg L^{-1} cell culture) for kinetic and binding studies.

Nevertheless, detailed characterization of 1E9 would be facilitated by the availability of a more efficiently produced Fab. Steipe et al. (30) have compiled amino acid distributions in aligned immunoglobulin sequences and successfully used these distributions to predict stabilizing point mutations in the variable domains. They showed that replacement of nonconsensus residues with their consensus counterparts can greatly increase the stability and yields of recombinant antibodies (30–33). Moreover, the beneficial effects of these mutations are often additive. We have applied this approach to the optimization of the 1E9 Fab chimera.

Comparison of the 1E9 variable regions with the Kabat database of antibody sequences (27) identified several residues that appear rarely in antibodies (Fig. 2), making them good targets for mutagenesis. They include Phe^{L46}, Gly^{L63}, Ile^{L72}, and Phe^{L95} in the light chain and Lys^{H12}, Met^{H28}, Lys^{H46}, Phe^{H59}, and Met^{H87} in the heavy chain. With the exception of Phe^{L95}, which is in the L3 complementarity determining region (CDR), these residues are distant from the active site (Fig. 3) and were not expected to significantly influence binding or catalysis.

To optimize antibody production, the nonconsensus residues in 1E9 were individually replaced by their consensus counterparts (i.e., Phe^{L46}Leu, Gly^{L63}Ser, Ile^{L72}Thr, and Phe^{L95}Pro in the light chain and Lys^{H12}Val, Met^{H28}Thr, Lys^{H46}Glu, Phe^{H59}Tyr, and Met^{H87}Thr in the heavy chain) via standard mutagenesis protocols (20). In each case, the mutations were introduced into the human–murine chimeric Fab containing the wild-type Gln residue at position H6. The variants were produced on a small scale in *E. coli*, and the relative amount of active Fab in crude periplasmic lysates was determined by ELISA (data not shown) (22). Most of the targeted changes had little or no effect on protein production. The Met^{H87}Thr, Gly^{L63}Ser, and Phe^{L95}Pro mutations, however, gave approximately 2-, 4- and 16-fold higher titers, respectively, than the parent chimera.

Fig. 3. Crystal structure of the murine Fab fragment of 1E9 complexed with its transition state analogue (10). Noncanonical residues that were examined in this study are highlighted. Heavy chain: red; light chain: blue.

Fig. 4. SPR sensograms obtained with the chimeric Fab 1E9 double mutant. (A) 1 μM Fab; (B) 0.6 μM Fab; (C) 0.4 μM Fab. All measurements were carried out at 25°C at a flow rate of 5 μL min^{-1}. The BSA-hapten conjugate was covalently linked to the activated dextran surface of the chip. Regeneration of the chip surface was done with 10 mM HCl. The k_{on} and k_{off} values were calculated from the association and dissociation phases, respectively.

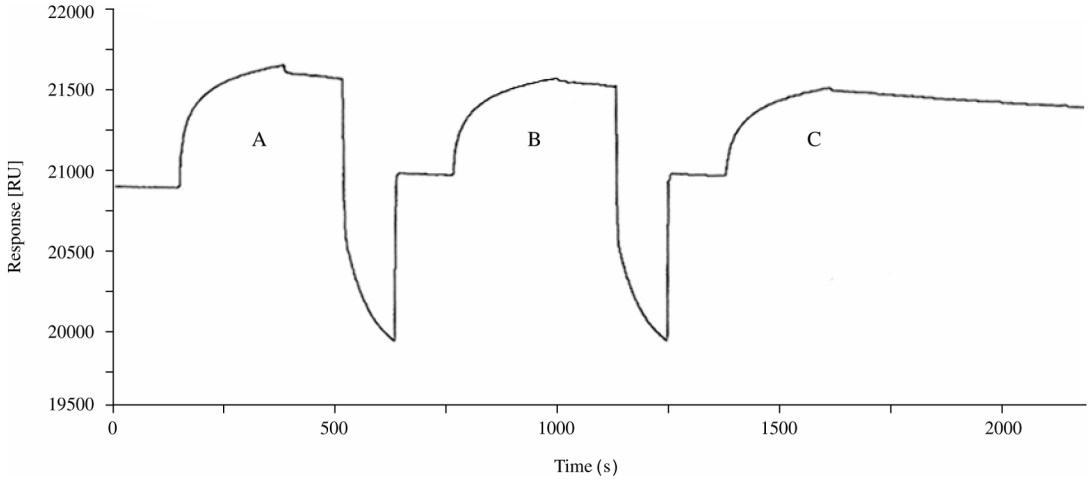

Table 1. Yields of chimeric 1E9 Fab variants.

Variant[a]	Shake-flask yield (mg L^{-1})	Fermentor yield (mg L^{-1})
1E9 IgG	n.d.	n.d.
Chimeric 1E9 Fab	n.d.	0.7
$G^{L63}S$	0.03	2
$M^{H87}T$–$G^{L63}S$	0.05	4
$M^{H87}T$–$G^{L63}S$–$F^{L95}P$	0.1	17

[a]All recominant proteins contained the wild-type Gln residue at H6.

The additivity of these substitutions was examined by construction of a double ($Met^{H87}Thr$–$Gly^{L63}Ser$) and a triple ($Met^{H87}Thr$–$Gly^{L63}Ser$–$Phe^{L95}Pro$) mutant. These variants were produced in parallel with the wild-type chimera and the $Gly^{L63}Ser$ single mutant in the TOPP2 strain of *E. coli* (19). All proteins were isolated and purified as previously described (19). Yields of Fab obtained from shake-flask and high-density fermentation experiments are compared in Table 1. In general, fermentation provides ca. 100-fold more antibody protein per liter of cell culture than the shake-flask cultures. The single-point mutation $Gly^{L63}Ser$ improves the yield by more than twofold compared with the parent Fab. A further twofold increase in production is obtained by adding the $Met^{H28}Thr$ mutation. The triple mutant is the most efficiently produced protein examined (17 mg L^{-1}), and can be obtained in ca. 25-fold higher yield than the wild-type 1E9 Fab.

Binding and catalytic properties

The chimeric 1E9 Fab fragments retain the recognition properties of the original IgG as revealed by ELISA. Dissociation constants were determined by fluorescence titrations of the recombinant proteins with hapten **1** (24). As summarized in Table 2, the chimeric Fab as well as the $Gly^{L63}Ser$ single and $Met^{H87}Thr$–$Gly^{L63}Ser$ double mutants appear to bind the ligand approximately one order of magnitude more tightly than the original IgG molecule. This gain in affinity, however, is lost in the $Met^{H87}Thr$–$Gly^{L63}Ser$–$Phe^{L95}Pro$ triple mutant. Although the side chain of the L95 residue is distant from the bound hapten (10), this residue is located in the CDR L3 loop, and the Phe→Pro substitution may slightly alter the shape of the active site.

Similar overall trends were observed in surface plasmon resonance (SPR) measurements with the recombinant proteins (Fig. 4, Table 2). The on rate for all the proteins examined is very similar (k_{on} ~ 6×10^4 M^{-1} s^{-1}). The off rate for the chimeric 1E9 Fab fragment and the single and double mutants is also similar (k_{off} ~ 3 to 4×10^{-4} s^{-1}) but roughly five times faster than the off rate determined for the full-length IgG and about seven times slower than k_{off} for the triple mutant. The SPR results thus confirm that the triple mutant binds the hapten significantly less tightly than the other Fab fragments. They also show that the Fab–hapten complex is relatively long-lived with a $\tau_{1/2}$ (= ln $2/k_{off}$) of 35 min in the case of the chimeric 1E9 Fab. Nevertheless, the dissociation constants calculated from these data ($K_d = k_{off}/k_{on}$) are about two orders of magnitude larger than the K_d values determined by fluorescence. This is due in part to the fact that the SPR experiments were carried out at higher temperature (25°C rather than 15°C), but similar discrepancies have been observed before and also likely reflect the different nature of interactions between the antibody and a solid support and between the antibody and a ligand free in solution (34). Avidity effects (34) probably account for the comparable affinity of the bivalent IgG and the recombinant Fab in the SPR experiment, a conclusion supported by the low k_{off} value determined for the IgG.

The 1E9 variants also all catalyze the Diels–Alder reaction between TCTD and NEM. The apparent k_{cat} and $(K_m)_{NEM}$ values obtained at 150 μM TCTD are summarized in Table 2 and are compared with the kinetic parameters of the murine IgG protein assayed under identical conditions. Within experimental error, the human–murine chimeric Fab and the $Gly^{L63}Ser$ single and $Met^{H87}Thr$–$Gly^{L63}Ser$ double mutants are indistinguishable from the IgG. In contrast, the

[c]SPR measurements at 25°C.

$Met^{H87}Thr$–$Gly^{L63}Ser$–$Phe^{L95}Pro$ triple mutant exhibits a fourfold decrease in k_{cat}, consistent with its diminished affinity for transition state analog **1**.

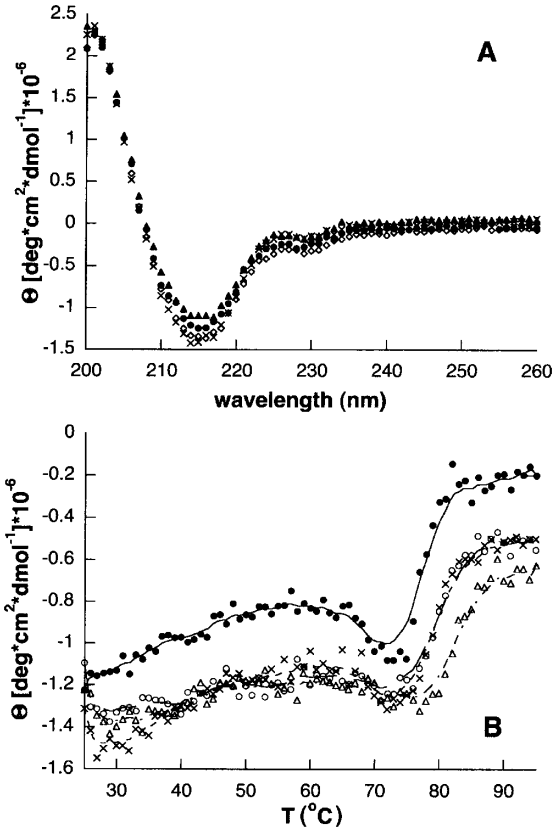
The murine immunoglobulin scaffold of 1E9 thus appears to be quite tolerant to substitutions of nonconsensus residues and to replacement of the mouse constant regions with human constant regions. The modest differences in binding and catalysis exhibited by the chimeric Fab fragments presumably reflect small adjustments in the variable domains, rather than dramatic changes in structure or mechanism.

Thermal denaturation experiments

Steipe et al. (30) have argued that consensus residues in antibodies are selected in part for the stability they confer to the immunoglobulin scaffold. The relative stability of the four chimeric Fab 1E9 variants generated in this work was therefore assessed by thermal denaturation. The CD spectrum of these proteins, like other proteins composed mainly of β-sheets, is characterized by a negative minimum at 216 nm and a positive maximum at 202 nm (Fig. 5*a*). Thermal unfolding can be readily assessed by monitoring increases in ellipticity at 216 nm as a function of increasing temperature. The resulting curves are complex, with an apparent gradual loss of some β-sheet structure below 65°C, followed by a major, irreversible transition between 70 and 80°C (Fig. 5*b*). Similar behavior has been previously observed for the denaturation of a nucleic acid-binding Fab (35). In that study, no evidence for unfolding below 70°C was found using differential scanning calorimetry, and the pretransition reduction in ellipticity was ascribed to temperature-induced changes in the β-sheet structure due to Fab solvent interactions or aggregation state.

From the thermal unfolding patterns shown in Fig. 5*b*, it appears that the wild-type Fab is significantly less stable than the other mutants. It has a T_m value of roughly 76°C, which is approximately 5°C lower than that of the $Gly^{L63}Ser$ single and $Met^{H87}Thr$–$Gly^{L63}Ser$ double mutants. The latter two proteins exhibit essentially superimposable unfolding profiles, with a much less pronounced pretransitional loss of ellipticity than for the chimeric 1E9 Fab, consistent with overall higher stability. The $Met^{H87}Thr$–$Gly^{L63}Ser$–$Phe^{L95}Pro$ triple mutant, which has an apparent T_m of 83°C, appears to be the most stable variant examined.

Fig. 5. (A) Circular dichroism (CD) spectra of the chimeric Fab variants. Spectra were measured in PBS buffer at pH 7.4 and 25°C. All the Fab concentrations were 0.2 mg mL^{-1}. Data are reported as molar ellipticity [θ]. (●) Wild-type chimeric 1E9 Fab; (O) $Gly^{L63}Ser$; (X) $Met^{H87}Thr$–$Gly^{L63}Ser$; (△) $Met^{H87}Thr$–$Gly^{L63}Ser$–$Phe^{L95}Pro$. (B) Thermal denaturation curves monitored by CD. All the spectra were obtained in PBS buffer at pH 7.4 and an Fab concentration of 0.2 mg mL^{-1}. CD data were recorded at 216 nm between 25 and 95°C in 1°C steps. Values are reported as molar ellipticity [θ]. (●) Wild-type chimeric 1E9 Fab; (O) $Gly^{L63}Ser$; (X) $Met^{H87}Thr$–$Gly^{L63}Ser$; (△) $Met^{H87}Thr$–$Gly^{L63}Ser$–$Phe^{L95}Pro$. T_m values were estimated from the midpoint of the irreversible transition that is observed between 75 and 85°C.



Discussion

In this study, we show that the catalytic antibody 1E9 can be produced conveniently in bacteria as a human–murine chimera and that the yields of functional protein are significantly improved when two or three noncanonical-framework residues in the heavy and light chain variable domains are

© 2002 NRC Canada

replaced with their consensus counterparts. The $Met^{H87}Thr–Gly^{L63}Ser$ double and $Met^{H87}Thr–Gly^{L63}Ser–Phe^{L95}Pro$ triple mutants are obtained in useful amounts by fermentation (4 and 17 mg L^{-1} cell culture, respectively) and exhibit binding and kinetic properties similar to those of the original murine IgG. Antibody 1E9 is closely related to other structurally characterized antibodies that bind hydrophobic ligands (10, 17), and the availability of this protein in recombinant form will greatly facilitate investigations of the evolution of shape complementarity and catalytic efficiency from a promiscuous primordial germ-line template. The triple mutant is the most efficiently produced protein examined, although a modest decrease in hapten affinity and catalytic efficiency compared with the double mutant suggests that the latter will be the best starting point for such studies.

Steipe et al. (30) originally developed the strategy employed here to predict stabilizing mutations in the V_κ domain of the anti-phosphorylcholine antibody McPC603, and subsequently exploited it in the construction of hyperstable V_L and V_H domains, which can be produced as soluble proteins in the cytoplasm of *E. coli* (31, 33). This approach has also been adopted to engineer stable heterodimeric Fv (32) and single-chain Fv fragments (36). Our results show that the canonical sequence approximation can aid the production of soluble, chimeric human–murine Fab fragments as well, and as seen in the earlier studies, yield appears to correlate with protein stability. Although a relatively small fraction of the canonical mutations we investigated (3 out of 9) have a beneficial effect on Fab yield — substantially lower than the 60% success rate reported for the prediction of stabilizing mutations in the McPC603 V_κ domain (30), the canonical sequence approximation provides a valuable approach for rationally optimizing the properties of immunoglobulin proteins in the absence of other information.

Given the large number of homolog and paralog sequences being generated in whole genome sequencing projects, this approach is likely to become a more valuable tool for enhancing the properties of proteins. The preparation of highly stable consensus versions of phytase (37), apomyoglobin (38), the DNA binding domain of the tumor suppressor p53 (39), and a functional GroEL minichaperone (40) illustrate its promise.

Methylamine adenine dinucleotide (MAD): a co-factor to turn alcohol dehydrogenases into aldolases

Denis Wahler and Jean-Louis Reymond

Abstract: Methylamine adenine dinucleotide (MAD) was prepared in seven steps and 15.3% overall yield from 1-acetoxy-2,3,5-tri-*O*-benzoyl-D-ribose by chemoenzymatic synthesis. The key step was the phosphate–phosphate coupling between adenosine monophosphate and 2,5-anhydro-1-deoxy-1-phenylacetamide-6-phosphate-D-allitol (**3**) mediated by carbonyl diimidazole (CDI), followed by the removal of the phenylacetamido group by penicillin G acylase. The MAD co-factor provided a primary amine functionality that was suitably positioned to promote the enamine aldolization of 2-oxopropionamide with aldehydes within the active site of alcohol dehydrogenases, which should lead to the transformation of these stereoselective enzymes into aldolases. Preliminary investigations did not reveal any activity with horse liver alcohol dehydrogenase or yeast alcohol dehydrogenase.

Key words: aldolases, alcohol dehydrogenases, co-factor enginering, nucleosides, acylases.

Résumé : On a réalisé une synthèse chimioenzymatique du dinucléotide de méthylamine et d'adénine (« MAD »), en sept étapes et avec un rendement global de 15,3%, en utilisant le 1-acétoxy-2,3,5-tri-*O*-benzoyl-D-ribose comme produit de départ. L'étape clé est le couplage phosphate–phosphate entre le monophosphate d'adénosine et le 2,5-anhydro-1-désoxy-1-phénylacétamide-6-phosphate-D-allitol (**3**) catalysée par le carbonyldiimidazole (CDI), suivie de l'élimination du groupe phénylacétamido par l'acylase de la pénicilline G. Le cofacteur MAD fournit une fonction amine primaire positionnée de façon appropriée pour favoriser une aldolisation de l'énamine du 2-oxopropanamide avec les aldéhydes dans le site actif des déshydrogénases de l'alcool, ce qui devrait conduire à une transformation de ces enzymes stéréosélectifs en aldolases. Des études préliminaires indiquent qu'il n'y a pas d'activité avec la déshydrogénase du foie de cheval ou la déshydrogénase d'alcool de la levure.

Mots clés : aldolases, déshydrogénases d'alcool, cofacteur d'ingénierie, nucléosides, acylases.

[Traduit par la Rédaction]

Introduction

Co-factor engineering is a purely chemical approach to enzyme modification, which offers the possibility to turn a given enzyme into a completely different biocatalyst by changing the nature of the reaction being catalyzed (1). Impressive examples of this approach include the transformation of phytases into peroxidases by combining them with vanadate (2), and the alkylation of the active-site cysteine residue in cysteine proteases such as papain with various co-factors to create novel enzyme activities (3). Herein we describe the synthesis and preliminary evaluation of methylamine adenine dinucleotide (MAD) as a co-factor to turn alcohol dehydrogenases into aldolases. This type of co-factor engineering should enable one to take advantage of the substrate versatility and high and predictable stereoselectivity of alcohol dehydrogenases, as has been explored in depth by Jones and co-workers (4), to achieve stereoselective aldol reactions. The work draws on the structural analogy between the transition states for hydride transfer and aldol addition to carbonyl compounds.

Results and discussion

The aldol reaction efficiently combines carbon–carbon bond formation with the creation of asymmetric centers. Aldol products are useful synthons appearing either as synthetic intermediates or in the final structures of many natural products. Natural aldolase enzymes provide biocatalytic aldolization routes to polyhydroxylated compounds, in essence carbohydrates and close derivatives (5). By contrast, less oxygenated aldols, such as polypropionates, remain the domain of pure synthetic chemistry (6). One notable exception is the aldolase catalytic antibodies developed by Wagner et al. (7), which allow for the preparation of optically and stereochemically pure non-carbohydrate aldols through

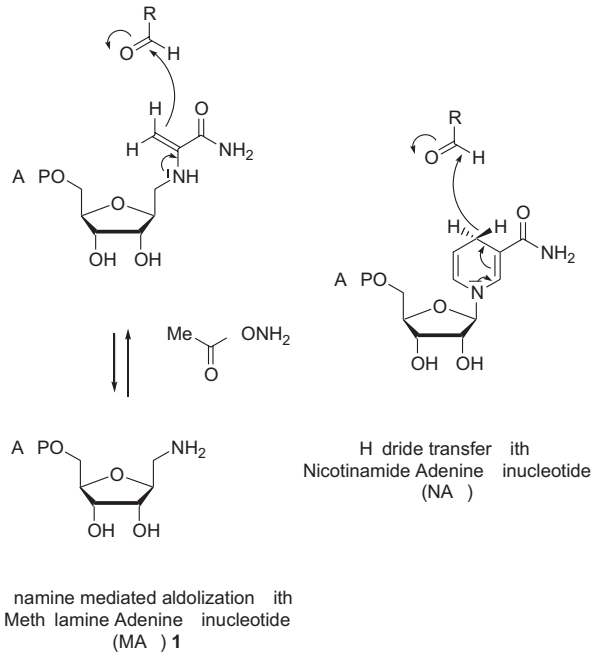
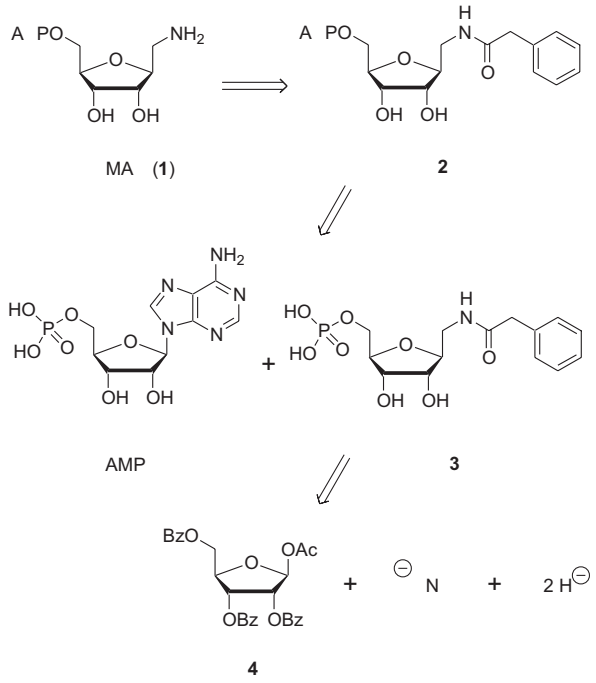
Scheme 1. Analogy between the targeted enamine-mediated aldolization with **1** and the hydride transfer process with NAD.



Scheme 2. Retrosynthetic analysis.



kinetic resolution of aldols by enantio- and stereoselective retro-aldolization (8). These catalytic antibodies demonstrate the versatility of the enamine mechanism for the aldol reaction. We have shown earlier that enamine-mediated aldolization by catalytic antibodies is possible using a co-factor approach by combining antibodies raised against a quaternary benzyl ammonium ion with the corresponding benzylamine (9).

Co-factor design

Drawing on the mechanistic analogy between the aldol reaction and the reduction of aldehydes, where in both cases a nucleophile is added to an electrophilic carbonyl group, we envisioned that co-factor engineering might convert alcohol dehydrogenases into aldolases. Thus MAD is expected to promote an enamine-mediated cross-aldolization between oxo-propionamide and an aldehyde within the binding pocket of an alcohol dehydrogenase (Scheme 1). The enzyme binding pocket should provide the correct relative positioning of the reactants and induce an electrophilic activation of the aldehyde carbonyl group, thus catalyzing the carbon–carbon bond formation using the primary amine functional group of the co-factor as a chemical catalyst. Aldol reactions readily occur under amine catalysis in aqueous environments (10). It should be noted that a catalytic effect on the rate-limiting carbon–carbon bond forming step should be sufficient to induce an observable catalysis of the overall process. Indeed, catalysis of the enamine formation step, which is not rate-limiting in enamine-mediated aldolization catalysis (11), is not required, but it might become necessary to optimized the catalyst.

Retrosynthetic analysis

Various nicotinamide adenine dinucleotide (NAD) analogs have been prepared by enzyme-catalyzed exchange of nicotinamide against modified nicotinamides (12). We approached the synthesis from a completely different and purely synthetic angle. MAD (**1**) could be obtained from deprotection of the protected MAD precursor (**2**), which would itself be the product of phosphate–phosphate coupling between adenosine monophosphate and a suitably protected synthetic monophosphate (**3**) (Scheme 2). Similar phosphate–phosphate coupling reactions have been described for the preparation of UDP-sugars (13). The phenacetyl group on the primary amine was planned for technical reasons as a hydrophobic and UV-active group to facilitate the isolation, purification, and identification of the coupling product **1**. Furthermore, the phenacetyl group could be removed enzymatically under mild aqueous conditions, which do not affect the labile diphosphate and glycosidic linkages present in the target molecule (14).

Synthesis

Intermediate **3** was first prepared from the commercially available 1-acetoxy-2,3,5-tri-*O*-benzoyl-D-ribose (**4**) (Scheme 3). Thus, reaction with trimethylsilyl cyanide and catalytic $SnCl_4$ gave cyanide **5** (15), which was selectively reduced using sodium tris(trifluoroacetoxy)borohydride in tetrahydrofuran to give primary amine **6** as described by Sauer and Schneller (16). Amine **6** was then directly acylated with phenacetyl chloride to give amide **7**. The benzoyl groups were removed under basic conditions to afford triol **8**. Direct phosphorylation of the primary alcohol in **8** with phophorus oxychloride in triethylphosphate solvent, a common method in nucleoside chemistry (17), gave intermediate **3** in 69% yield. Activation to the imidazolide and coupling with the tributylammonium salt of adenosine monophosphate yielded protected dinucleotide **2**. Finally, treatment with penicillin G acylase gave free-methylamine adenine dinucleotide **1**,

which was isolated as the trifluoroacetate salt by reversed-phase HPLC.

Interactions between MAD and alcohol dehydrogenases

Horse liver alcohol dehydrogenase and yeast alcohol dehydrogenase, both of which are commercially available and represent a broad spectrum of alcohol dehydrogenases, were selected as the target enzymes. We first tested whether MAD could inhibit the redox activity of the enzymes, and thus could bind to the active site. The alcohol dehydrogenase activity was measured using the fluorogenic oxidation of the chiral alcohols (*S*)-**9** and (*S*)-**11** (Scheme 4) (18). The oxidation products **10** and **12** undergo a rapid β-elimination in the presence of bovine serum albumin (BSA) to give strongly fluorescent umbelliferone **13**, which is readily detected at micromolar concentrations in microtiter plates.

Inhibition experiments of alcohol oxidation showed that our primary amine co-factor MAD (**1**) bound to the alcohol dehydrogenases, albeit weakly (Table 1). Only protected precursor **2** showed a good affinity for horse liver alcohol dehydrogenase. The inhibition of the ADH oxidation activity by **1** (1 mM) was unaffected by the presence of carbonyl compounds such as phenacetaldehyde, benzaldehyde, anisaldehyde, 1,2,3,6-tetrahydrobenzaldehyde, acetaldehyde, acetylacetone, crotonaldehyde, cinnamaldehyde, or 2-oxopropionamide (1 mM each). Since imine formation occurs spontaneously between amines and aldehydes with a pH-independent equilibrium constant of approximately 10 mM (19), the experiment showed that the binding pocket of the alcohol dehydrogenases did not strongly bind to the imines formed between these carbonyls and our primary amine co-factor.

Evaluation of MAD as an aldolization co-factor

Aldolization activity was investigated using a series of fluorogenic aldols such as **14** and close derivatives under the same conditions as those used for the ADH-activity assay (Table 2). Under these experimental conditions, these substrates undergo clean retro-aldolization in the presence of aldolase catalysts such as antibody 38C2 (20). Although these aldols do not posess the oxoamide carbonyl that would make them optimally suited to alcohol dehydrogenases according to our design, the approximation was judged close enough considering that alcohol dehydrogenases also easily accept various redox co-factors where the carboxamide group has been changed to other groups. There was no observable retro-aldolization catalysis with MAD and the dehydrogenases for these substrates, despite the fact that corresponding alcohol **11** is a good oxidation substrate for these enzymes. Direct aldolization was also tested for the cross-aldolization between 2-oxopropionamide and acetaldehyde, as well as for the direct dimerization of acetaldehyde

[a]λ_{ex} = 360 nm, λ_{em} = 460 nm
[b]Analytical column: Vydac 218TP-54 (C_{18}, pore size 300 Å), 0.45 × 22 cm, detection by UV at 214 or 230 nm, isocratic elution at 1.5 mL min^{-1}, A = 0.1 % TFA in H_2O, B = 50:50 CH_3CN–H_2O). t_R (2-oxopropionamide) = 3.9 min at 5% B, t_R (crotonaldehyde) = 5.2 min at 15% B.

Table 3. Analytical RP-HPLC conditions for MAD and intermediates.

Compound	% A	% B	t_R (min)
8	70	30	3.0
3	90	10	5.2
2	95	5	10.0
1	98	2	2

Note: Isocratic elution at 1.5 mL min^{-1}, detection by UV at 254 nm, A = 0.1% TFA in H_2O, B = 50:50 CH_3CN–H_2O, analytical column: Vydac 218TP-54 (C_{18}, pore size 300 Å), 0.45 × 22 cm.

to crotonaldehyde. In both cases there was no observable product formation.

Conclusion

MAD (**1**) has been prepared in seven steps by an efficient chemoenzymatic synthesis from protected D-ribose derivative **4**. Penicillin G acylase provided the key to remove the phenacetyl-protecting group of the primary amine function, which was used as a hydrophobic, UV-visible tag to facilitate the purification of intermediates. The structural and mechanistic analogy between the putative aldolization chemistry of MAD and the redox chemistry of the natural NAD co-factor suggests that our synthetic co-factor should be able to transform alcohol dehydrogenases into stereoselective aldolases. Our preliminary investigation using the alcohol dehydrogenases from horse liver and from yeast, however, do not seem to indicate any activity of this type. Although the enzyme preparations used might not contain a high concentration of active protein, we must conclude that aldolization catalysis as designed does not occur within the active site of these enzymes at a level that is detectable under our conditions. Further experiments with other alcohol dehydrogenases and other aldolization substrates may, however, afford different results. MAD also offers an attractive opportunity for enzyme evolution, which should be obtainable using fluorogenic substrates such as **14** as screening tools.

Experimental

All reagents and enzymes were purchased from Aldrich or Fluka. Chromatographies (flash) were performed with Merck Silicagel 60 (0.040–0.063 mm). CH_2Cl_2 was distilled from P_2O_5 prior to use. Preparative HPLC was done with HPLC-grade acetonitrile and MilliQ de-ionized water using a Waters prepak cartridge 500 g (RP-C18 20 μm, 300 Å pore size) installed on a Waters Prep LC 4000 system from Millipore, flow rate 100 mL min^{-1}, gradient +0.5% min^{-1} CH_3CN, detection by UV at 214 nm. TLC were performed with fluorescent F254 glass plates. MS and HRMS (high resolution mass spectra) were provided by Dr. Thomas Schneeberger (University of Bern). Fluorescence measurements were carried out using a Cytofluor II Plate-Reader from Perseptive Biosystems.

2,5-Anhydro-3,4,6-tri-*O*-benzoyl-1-deoxy-1-phenylacetamide-D-allitol (7)

As described in literature (15), a solution of $NaBH_3(O_2CCF_3)$ (1.0 g, 6.6 mmol) was prepared by adding under nitrogen pure trifluoroacetic acid (0.51 mL, 6.7 mmol) to an ice-bath-cooled, stirred suspension of $NaBH_4$ (0.26 g, 6.8 mmol) in dry THF (20 mL). A solution of cyanide **5** (2.2 g, 4.7 mmol) in dry THF (13 mL) was added at 0°C, and the mixture was stirred at 25°C for 18 h. The reaction was quenched with de-ionized water (5 mL) and concentrated to dryness. The residue was partitioned between EtOAc (20 mL) and sat. aq. $NaHCO_3$ (7 mL), and cooled in an ice bath. BnCOCl (2 mL, 14.7 mmol) was added, and the mixture was vigorously stirred at 0°C for 3 h. The layers were separated, the organic phase was washed once with water, dried over Na_2SO_4, and concentrated to dryness. The residue was purified by flash chromatography on silica gel (Hex–EtOAc, 50:50) to give **7** (1.8 g, 3 mmol, 65 % over the two steps) as a yellow syrup. IR (neat) (cm^{-1}): 3013, 1727, 1654, 1601, 1584, 1522, 1496, 1452, 1316, 1269, 1216, 1178, 1124, 1070, 1026. ^{1}H NMR ($CDCl_3$) δ: 8.09–7.22 (m, 20H), 6.03 (NH), 5.56 (dd, *J* = 4.4, 5.9 Hz, 1H), 5.32 (dd, *J* = 6.3 Hz, 1H), 4.45 (m, 4H), 3.60 (dd, *J* = 5.2, 5.5 Hz, 2H), 3.51 (s, 2H). ^{13}C NMR ($CDCl_3$) δ: 172.1, 169.9, 167.0, 166.1, 135.4, 134.1, 134.0, 130.4, 130.0, 129.6, 129.3, 129.1, 128.0, 80.8, 80.5, 73.3, 73.2, 64.8, 44.2, 41.2. MS *m/z*: 594 (M^+).

2,5-Anhydro-1-deoxy-1-phenylacetamide-D-allitol (8)

To a solution of K_2CO_3 (0.24 g, 1.68 mmol) in methanol (20 mL) and water (4 mL) was added a solution of compound **7** (1.0 g, 1.68 mmol) in methanol (20 mL). The mixture was stirred vigorously overnight at 25°C, and the solvent was removed in vacuo. The residue was dissolved in dichloromethane and water, and extracted several times with

© 2002 NRC Canada

water. The aqueous phase was then purified by preparative HPLC to afford **8** (0.35 g, 1.24 mmol, 74 %) as a light yellow syrup (Table 3). ^{1}H NMR (CD_3OD) δ: 7.28 (m, 5H), 3.85 (m, 4H), 3.69 (dd, *J* = 2.9, 11.8 Hz, 1H), 3.53 (dd, *J* = 2.9, 11.8 Hz, 1H), 3.51 (s, 2H), 3.40 (m, 2H). ^{13}C NMR (CD_3OD) δ: 173.9, 136.2, 129.7, 129.3, 127.6, 85.1, 82.9, 73.2, 72.0, 62.6, 43.7, 42.1.

2,5-Anhydro-1-deoxy-1-phenylacetamide-6-phosphate-D-allitol (3)

To a solution of **8** (0.430 g, 1.53 mmol) in $(EtO)_3PO$ (15 mL) was added under N_2 a solution of $POCl_3$ (0.8 mL, 8.7 mmol) and H_2O (0.080 mL) in $(EtO)_3PO$ (10 mL), in a bath cooled with acetone–ice. The mixture was stirred at 0°C for 3 h, and then $POCl_3$ (0.8 mL) and H_2O (0.070 mL) in $(EtO)_3PO$ (10 mL) were added at 0°C. The reaction mixture was then stored at 4°C for the night, and $NaHCO_3$ (4.8 g) in H_2O (40 mL) was added at 0°C. After one night at 4°C, the solution was extracted several times with CH_2Cl_2 to remove $(EtO)_3PO$. The aqueous phase was purified by preparative RP-HPLC to afford **3** (0.38 g, 1.05 mmol, 69 %) as a colorless syrup. ^{1}H NMR (CD_3OD) δ: 7.25 (m, 5H), 4.00 (m, 6H), 3.54 (s, 2H), 3.41 (d, *J* = 4.8 Hz, 2H). ^{13}C NMR (CD_3OD) δ: 174.4, 137.0, 130.2, 129.6, 127.9, 83.7, 83.3, 73.7, 72.8, 67.5, 43.8, 42.4.

6-Adenosine-diphosphate-2,5-anhydro-1-deoxy-1-phenylacetamide-D-allitol (2)

Tri-*n*-butylammonium-AMP (0.165 g, 0.3 mmol) was dissolved in dry DMF (0.5 mL) at 25°C under N_2. A solution of carbonyl diimidazole (CDI, 0.102 g, 0.63 mmol) in dry DMF (1 mL) was added, and the mixture was stirred at 25°C for 2 h. The excess CDI was destroyed by adding MeOH (0.026 mL), and the excess MeOH was removed under high vacuum. A solution of compound **8** (0.100 g, 0.28 mmol) in dry DMF (2.5 mL) was added, and the reaction was stirred at 25°C for 2 days. The solvent was removed in vacuo, and the residue taken in aq. 50 mM Tris buffer (10 mL, pH 7.45). The mixture was treated with ~150 U (0.067 mL) of calf intestinal alkaline phosphatase at 25°C overnight. After concentration in vacuo, the crude product was purified by preparative HPLC to give **2** (0.122 g, 0.18 mmol, 64 %) as a colorless solid; mp 132–133°C. ^{1}H NMR (D_2O–CD_3OD) δ: 8.64 (s, 1H), 8.34 (s, 1H), 7.23 (m, 5H), 6.09 (s, 1H), 4.03–3.81 (m, 9H), 3.55–3.39 (m, 6H). ^{13}C NMR (D_2O–CD_3OD) δ: 172.2, 151.0, 146.0, 136.1, 130.0, 129.9, 129.6, 127.9, 89.0, 85.3, 83.1, 82.5, 75.8, 73.1, 72.2, 71.3, 67.7, 66.2, 43.3, 41.8. ^{31}P NMR (D_2O) δ: –10.5, –14.8. MS *m/z*: 713 ($[M + Na]^+$), 691 ($[M + H]^+$). HRMS *m/z*: calcd. for $C_{24}H_{33}N_6O_{14}P_2$: 691.1530; found: 691.1547.

6-Adenosine-diphosphate-1-amino-2,5-anhydro-1-deoxy-D-allitol (1)

Compound **2** (0.060 g, 0.087 mmol) is dissolved in MeOH (1 mL), water (2.5 mL), and NaOH (0.1 M, 2.7 mL, pH 8) at 25°C. Penicillin G acylase immobilized on Eupergit C[14] (15 U, 0.140 g) was added and the suspension was stirred at 25°C for one day. After filtration, the solution was lyophilized, and the residue purified by preparative HPLC (A–B, 1.5 mL min^{-1}) to afford 0.050 g (0.087 mmol, quant.) of 6-adenosine-diphosphate-1-amino-2,5-anhydro-1-deoxy-D-allitol (**1**) as a colorless solid; mp 128°C. ^{1}H NMR (D_2O) δ: 8.60 (s, 1H), 8.35 (s, 1H), 6.07 (br d, 1H), 4.60–4.00 (m, 11H), 2.96 (m, 2H). ^{13}C NMR (D_2O–CD_3OD) δ: 151.5, 149.1, 146.3, 143.3, 119.5, 89.0, 85.3, 84.0, 79.3, 75.7, 73.2, 72.3, 71.4, 66.1, 41.8. ^{31}P NMR (D_2O) δ: –10.5. MS *m/z*: 632 ($[M – 2H + Na + K]^+$), 616 ($[M – 2H + 2Na]^+$), 610 ($[M – H + K]^+$), 594 ($[M – H + Na]^+$), 572 (M^+).

Hydroxynitrile lyase-catalyzed addition of HCN to 4-substituted cyclohexanones: stereoselective preparation of tetronic acids

Franz Effenberger, Jürgen Roos, Christoph Kobler, and Holger Bühler

Abstract: The addition of HCN to 4-alkylcyclohexanones **1** to give cyanohydrins **2** is strongly catalyzed by hydroxynitrile lyases (HNLs). With PaHNL, from bitter almond, *trans*-addition occurs almost exclusively, yielding *trans*-**2**. With MeHNL, from cassava, *cis*-addition is preferred to give *cis*-**2**. *cis*-Selectivity is nearly quantitative, especially for cyclohexanones with larger 4-substituents. Comparable results with respect to the stereoselectivity were observed in the HNL-catalyzed addition of HCN to 4-alkoxycyclohexanones **3a**–**g**. In contrast, the stereoselectivity in the HNL-catalyzed addition to 4-alkanoyloxycyclohexanones **3h**–**k** is very poor. The transformation of *cis*-4-propylcyclohexanone cyanohydrin (**2c**) into the corresponding *cis*-spirotetronic acid **7** occurs without any isomerization.

Key words: enzyme, hydroxynitrile lyase, cyclohexanones, cyanohydrins, *cis*/*trans*-stereoselectivity.

Résumé : L'addition du HCN sur les 4-alkylcyclohexanones (**1**) conduisant à la formation de cyanohydrines (**2**) est fortement catalysée par les lyases d'hydroxynitriles (« HNL »). Sous l'influence d'une PaHNL obtenue à partir de l'amande amère, l'addition se fait pratiquement exclusivement de façon *trans*, conduisant aux *trans*-2. Avec une MeHNL tirée de cassava, l'addition se fait préférentiellement de façon *cis* pour conduire aux *cis*-2. Dans les cas de cyclohexanones portant des substituants encombrants en position 4, la sélectivité *cis* est pratiquement quantitative. Des résultats de stéréosélectivités comparables sont aussi obtenus lors de l'addition de HCN, catalysée par une lyase d'hydroxynitrile, aux 4-alcoxycyclohexanones (**3a-g**). Par opposition, la stéréosélectivité de l'addition de HCN, catalysée par une lyase d'hydroxynitrile, sur les 4-alcanoyloxycyclohexanones (**3h-k**) est très faible. La transformation de la cyanohydrine de la *cis*-4-propylcyclohexanone (**2c**) en acide *cis*-spirotétronique correspondant (**7**) se réalise sans épimérisation.

Mots clés : enzyme, lyase d'hydroxynitrile, cyclohexanones, cyanohydrines, stéréosélectivité *cis/trans*.

[Traduit par la Rédaction]

Introduction

Tetronic acids **C** derived from 1-hydroxy-4-alkoxycyclohexane-1-carboxylic acids are of particular interest as herbicides and insecticides (1). The simplest approach to hydroxycarboxylic acids of this type would be the hydrolysis of cyanohydrins **B** accessible from the corresponding 4-substituted cyclohexanones **A** (Chart 1). The common chemical addition of HCN to 4-substituted cyclohexanones results in a *cis*/*trans*-isomeric mixture of cyanohydrins **B**, and the tetronic acids thus obtained would also be *cis*/*trans* isomers. Since the different stereoisomers of tetronic acids **C** reveal very distinct biological activities (1), the exclusive stereoselective preparation of one isomer, *cis* or *trans*, of 4-substituted cyclohexanone cyanohydrins **B** is an important target. Until now this could not be realized, and therefore the mixture of isomeric tetronic acids had to be separated by crystallization. This procedure is not only time-consuming but also the accumulation of the non-desired isomer is disadvantageous.

In this paper, we report on the enzyme-catalyzed addition of HCN to 4-substituted cyclohexanones, which stereoselectively yields the corresponding *cis*- or *trans*-cyanohydrins. Hydroxynitrile lyases (HNLs) have been applied as biocatalysts. By using PaHNL from bitter almond (*Prunus amygdalus*) *trans* isomers are preferentially formed, while with MeHNL from cassava (*Manihot esculenta*) *cis* isomers are the major products.

In a previous communication (2), a mainly mechanistic explanation of this unexpected *cis*/*trans*-selectivity is described and interpreted based on the X-ray crystal structure of the MeHNL (3), while the synthetic potential of the reaction is

not comprehensively examined. The MeHNL-catalyzed HCN addition to 4-substituted cyclohexanones (2) is mechanistically comparable with the hydrogenation of cyclohexanones to the corresponding alcohols using NADH-depending alcohol dehydrogenases (4).

Only very few samples of 4-substituted cyclohexanone cyanohydrins have been reported in the literature (5–9). In all cases, mixtures of *cis*/*trans* isomers are obtained. For the 4-methyl compound the *cis*:*trans* ratio is 1:2, while for the 4-*tert*-butyl-substituted derivative the *cis*:*trans* ratio is 1:3. Because these ratios are also found under base catalysis (8), it can be assumed that these ratios correspond to the thermodynamic equilibria.

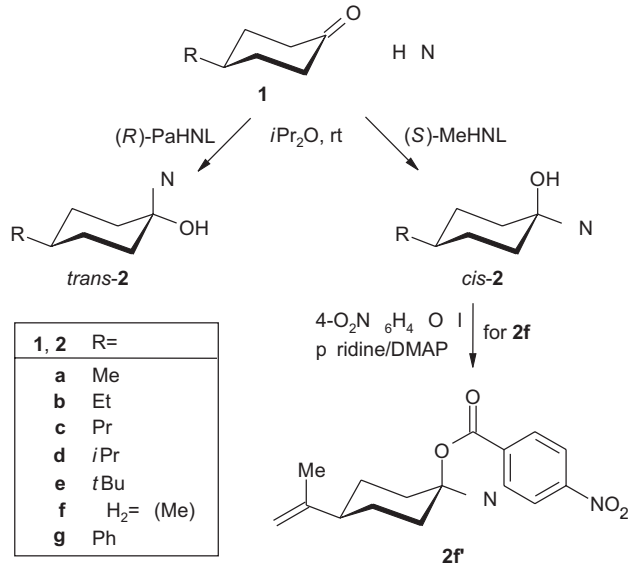
In recent times, HCN is often replaced by trimethylsilyl cyanide in the addition to carbonyl compounds, giving the corresponding *O*-trimethylsilyl cyanohydrins (10). With 4-substituted cyclohexanones only the cyanosilylation of *tert*-butyl- and benzyloxycyclohexanone was performed, yielding in both cases the *trans* isomer as major product. With various catalysts the percentage of the *trans* product in the reaction of 4-*tert*-butylcyclohexanone with trimethylsilyl cyanide could be increased up to 90% (11), compared with 80% *trans* isomer obtained with 4-benzyloxycyclohexanone using ZnI_2 as catalyst (12).

Results and discussion

Hydroxynitrile lyase-catalyzed HCN addition to 4-alkylcyclohexanones 1 (2)

To investigate the scope of the *cis*/*trans* selectivity of the enzyme-catalyzed HCN addition to 4-substituted cyclohexanones, the 4-alkyl-substituted compounds **1a**–**g** (13*a*–*c*) were investigated.

Scheme 1.



For the enzymatic reactions of the ketones **1**, the hydroxynitrile lyases (*R*)-PaHNL from almond and (*S*)-MeHNL from cassava were used. The results of the HNL-catalyzed addition of HCN to the 4-alkyl substituted cyclohexanones **1** (Scheme 1) are summarized in Table 1.

All investigated cyclohexanones **1** were found to be good substrates for both enzymes. The PaHNL-catalyzed conversion selectively afforded the *trans*-cyanohydrins (*trans*-**2**), while with catalyst MeHNL the corresponding *cis* isomers (*cis*-**2**) were formed almost exclusively for the larger 4-substituents. As can be seen from Table 1, the substituent R clearly influences the reactivity of the (*R*)-PaHNL-catalyzed reaction: with increasing steric demand of the R group the conversion rate is markedly diminished. The stereoselectivity, however, is fairly high in all cases with one exception; the *tert*-butyl derivative **1e** reacts very slowly, therefore the chemical addition becomes more dominant, causing diminished stereoselectivity (*cis*:*trans* = 10:90).

With the recombinant MeHNL from cassava, all substrates **1** were converted faster to the cyanohydrins compared with PaHNL (whose selectivity is almost independent of the steric demand of R) (Table 1). In contrast to PaHNL,

MeHNL is *cis*-selective and the stereoselectivity of the HCN addition strongly depends on the size of R, as can be clearly seen in the reactions of the homologues **1a**–**c** (R = Me, Et, Pr, respectively).

The structural assignment of the isomers by ^{13}C NMR spectroscopy followed from comparison with literature data (13*b*). The C-1 atom signal in the *cis* isomer is clearly shifted to a higher field compared with that of the *trans* isomer (see Table 4). Furthermore, the X-ray structure (14) of the nitrobenzoyl derivative **2f′** (Fig. 1, Table 2), obtained by nitrobenzoylation of the MeHNL-derived main isomer **2f** (Scheme 1), unequivocally confirms the assignment.

Hydroxynitrile lyase-catalyzed HCN addition to 4-alkyloxy- and 4-alkanoyloxycyclohexanones 3

In addition, to known cyclohexanones **3a**–**h** and **3l** (13*d*–*i*), the 4-alkanoyloxycyclohexanones **3i**–**k** had to be prepared. For this purpose, 4-hydroxycyclohexanone (**3a**) was acylated in the presence of pyridine and catalytic amounts of dimethylaminopyridine (DMAP) with either the respective acid chloride or anhydride to give the cyclohexanones **3i**–**k** in 45–65% yields (not optimized; see *Experimental*).

The HNL-catalyzed HCN addition to the 4-alkyloxy- and 4-alkanoyloxycyclohexanones **3** is depicted in Scheme 2, and the results are listed in Table 3.

Analogous to cyclohexanones **1**, compounds **3** were also converted using PaHNL as the catalyst with moderate to high stereoselectivity to *trans* isomers **4**. The *trans* selectivity of PaHNL with the substrates **3b**–**l** is comparable with the behavior of alkylcyclohexanones **1**. In the case of 4-hydroxycyclohexanone **3a**, both enzymes (PaHNL and MeHNL) show only a very low stereoselectivity. The MeHNL-catalyzed addition of HCN to compounds **3** again results in the preferred formation of the *cis* isomers (*cis*-**4**), with one exception. In the conversion of **3b** (R = MeO) the *trans* isomer dominates. For benzyloxycyclohexanone **3g** a long reaction time is required and a slight decrease of the *cis* stereoselectivity at low conversion was also observed.

The isomers were assigned by the chemical shift of the C-4 atom in ^{13}C NMR spectra and, due to deficiency of literature data, the structure was also determined by X-ray crystallographic analysis (14). The isomers *trans*-**4b** and *trans*-**4h**, obtained in the PaHNL-catalyzed HCN addition, were crystallized as nitrobenzoyl derivatives **4b′** and **4h′** (Scheme 2, Fig. 2, Table 2). As can be seen from Fig. 2, both compounds exist as *trans* isomers, confirming the assignment.

Preparation of spirotetronic acids

As mentioned in the introduction, isomerically pure cyclohexanone cyanohydrins are important as starting compounds in the stereoselective synthesis of tetronic acids known as potent insecticides or herbicides (1). In a recent publication (15), we described the preparation of optically active 5,5-disubstituted tetronic acids starting from chiral ketone cyanohydrins. This reaction sequence, involving a Pinner reaction of the cyanohydrin to give the corresponding hydroxy ester, acylation of the hydroxyl group, and subsequent hexamethyldisilazanide (LiN(SiMe$_3$)$_2$) mediated ring closure at –78°C following a known procedure (16), could be applied also for the preparation of spirotetronic acids. The synthetic route to *cis*-spirotetronic acid **7** from cyanohydrin *cis*-**2c** is shown in Scheme 3.

In the (*S*)-MeHNL-catalyzed HCN addition to 4-propylcyclohexanone **1c**, cyanohydrin **2c** was isolated in an isomeric ratio *cis*:*trans* = 96:4 (Table 1). Compound **2c** was directly converted to hydroxy ester **5** by treatment with HCl in ethanol at 90–100°C with 84% yield (15). Acetylation of hydroxy ester **5** with acetic anhydride–pyridine and DMAP in dichloromethane gave acetoxy carboxylate **6** in 83% yield. The cyclization of **6**, resulting in the spirotetronic acid **7** with 73% yield, was performed by using LiN(SiMe$_3$)$_2$ in THF at –78°C. Recrystallization of **7** from chloroform gave a single crystal suitable for X-ray crystallographic analysis

(17). The crystal structure unambiguously shows the *cis* conformation of the spirotetronic acid **7** (17).

Mechanistic interpretation of the *cis*/*trans* selectivity of MeHNL-catalyzed reactions

The stereoselectivity of the (*S*)-MeHNL-catalyzed reaction of 4-alkylcyclohexanones **1** can be explained as follows (2). From the X-ray crystal structure of (*S*)-MeHNL it is known that the active site is accessible via a narrow channel and consists of a small (S_1) and a larger (S_2) binding pocket (3*a*). In the active site the carbonyl group of the incoming substrate is fixed by hydrogen bonds from Thr11 and Ser80, as shown in the acetone-complexed MeHNL crystal structure (3*a*). The superposition of the catalytically inactive mutant MeHNL-Ser80Ala complexed with acetone cyanohydrin onto the MeHNL–acetone structure clearly reveals that the cyanohydrin is fixed in an analogous manner (3*b*). Cyclohexanones **1** are assumed to bind to the enzyme's active site in the channel either in an upright or a flat mode (2). In both cases, the cyanide ion attacks the substrate from the same direction, namely from below, giving either the *cis* isomer from the upright position or the *trans* isomer from the flat position. Taking into account the hydrogen bonding of the substrate and the chair-form of the cyclohexane ring with preferred equatorial 4-substituent R, in the case of cyclohexanones with a small R substituent, especially **1a** with R = Me, both positions in the channel are possible without unfavourable steric interactions between the substrate and the channel wall. Hence, the formation of both *cis* and *trans* isomers is possible. In this case, the percentage of the isomers varies and depends on enzyme activity and general reaction conditions. With increasing size of R, however, the upright binding mode is favored. As demonstrated by molecular modeling calculations of 4-*tert*-butylcyclohexanone cyanohydrin (**2e**), the flat position would lead to severe steric interactions between the substrate and the channel wall, whereas vertically arranged **2e** fits perfectly in the channel without unfavourable interactions (2). Hence, the formation of the *cis* isomer dominates.

Stereoselectivity of cyanohydrin formation from 4-alkoxy- and 4-alkanoyloxycyclohexanones 3

The improved *cis* stereoselectivity with increasing size of the R substituent is also observed for the MeHNL-catalyzed reactions of 4-alkyloxy-substituted homologues **3c**–**f**. Alkanoyloxy-substituted derivatives **3h**–**k**, however, gave only low *cis* selectivity in this addition reaction. A plausible interpretation of this result so far is not possible. Polar interactions and hydrogen bonding of the alkanoyloxy substituents with amino acids in the surrounding of the active site of the enzyme are assumed to be responsible for the different behavior in comparison with 4-alkylcyclohexanones **1**.

Since the reactions of the 4-isobutyloxy and the 4-benzyloxy derivatives (**3e** and **3g**) occur with relatively high *cis* selectivity, stereoisomerically pure *cis*-4-hydroxycyclohexanone cyanohydrin **4a** can be prepared either by hydrolysis or by hydrogenolytic cleavage of **3e** and **3g**, respectively.

As can be seen from Tables 1 and 3 and in contrast to MeHNL, the PaHNL-catalyzed addition of HCN to 4-substituted cyclohexanones **1** as well as **3** gives, in most cases, high *trans* selectivity independent of the kind of substituent. An explanation for PaHNL's high *trans* selectivity is not possible, since too little is known about its X-ray structure (18); a substrate–enzyme complex would be very helpful for the interpretation of our experimental results.

Experimental

General procedure for the preparation of cyclohexanones 3i–k

To a solution of **3a** (11.5 mmol) in CH_2Cl_2 (20 mL) or neat **3a** (13.1–15.4 mmol) was added pyridine (20–25 mL), DMAP (30–50 mg), and the respective acid chloride propionyl chloride and isobutyryl chloride (2 equiv) or butyric anhydride (2 equiv), and the reaction mixture was stirred for 3 h (**3i**, **3j**) or 5 h (**3k**) at room temperature. Then water (120 mL) was added, and the aqueous layer was extracted with diethyl ether (3 × 70 mL). The combined extracts were

© 2002 NRC Canada

washed with diluted HCl until neutral, dried (Na_2SO_4), and concentrated. The crude products were distilled.

4-Propionyloxycyclohexanone (3i)

Yield: 45%; bp 80–82°C (0.1 Torr). ^{1}H NMR (250 MHz, $CDCL_3$) δ: 1.18 (t, J = 7.6 Hz, 3H, C*H*$_3$CH$_2$), 2.00–2.17 (m, 4H, 4 CH), 2.30–2.43 (m, 4H, 4 CH), 2.49–2.62 (m, 2H, CH$_3$C*H*$_2$), 5.19 (quin, J = 4.8 Hz, 1H, 4-CH). ^{13}C NMR (63 MHz, $CDCL_3$) δ: 9.17 (CH_3), 27.84 (CH_3*C*H$_2$), 30.44, 37.27 (CH_2), 68.33 (C4), 173.81 (CO_2), 209.95 (CO).

4-Isobutyryloxycyclohexanone (3j)

Yield: 64%; bp 84–86°C (0.1 Torr). ^{1}H NMR (250 MHz, $CDCL_3$) δ: 1.20 (d, J = 7.0 Hz, 6H, 2 CH_3), 1.98–2.18 (m, 4H, 4 CH), 2.31–2.42 (m, 2H, 2 CH), 2.50–2.68 (m, 3H, (CH$_3$)$_2$C*H*, CH_2), 5.17 (tt, J = 5.6, 3.9 Hz, 1H, 4-CH). ^{13}C NMR (63 MHz, $CDCL_3$) δ: 19.01 (CH_3), 30.42 (CH_2), 34.21 (*C*H(CH$_3$)$_2$), 37.23 (CH_2), 68.10 (C4), 176.42 (CO_2), 209.94 (CO).

4-Butyryloxycyclohexanone (3k)

Yield: 65%; bp 91–93°C (0.1 Torr). ^{1}H NMR (250 MHz, $CDCL_3$) δ: 0.97 (t, J = 7.4 Hz, 3H, CH_3), 1.60–1.76 (m, 2H, CH$_2$C*H*$_2$CH$_3$), 1.96–2.17 (m, 4H, 4 CH), 2.31–2.42 (m, 4H, 4 CH), 2.49–2.61 (m, 2H, C*H*$_2$CH$_2$CH$_3$), 5.19 (quin, J = 4.8 Hz, 1H, 4-CH). ^{13}C NMR (63 MHz, $CDCL_3$) δ: 13.66 (CH_3), 18.56 (CH$_2$*C*H$_2$CH$_3$), 30.49 (CH_2), 36.46 (*C*H$_2$CH$_2$CH$_3$), 37.29 (CH_2), 173.02 (CO_2), 209.92 (CO).

General procedure for the (*R*)-PaHNL-catalyzed preparation of cyclohexanone cyanohydrins 2 and 4

A solution of (*R*)-PaHNL (19) (100 U per 100 mg support, total 200 U, 78 μL) was added to cellulose (Elcema-Cellulose P100PSC (Degussa); 1 g soaked in 10 mL of 0.02 M sodium citrate buffer, pH 3.3, for 2 h, and filtered off) followed by addition of diisopropyl ether (5 mL), substrate **1** or **3** (1 mmol), and HCN (20) (150 μL, 3.9 mmol). After stirring at room temperature for the times given in Tables 1 and 3, the support was filtered off, washed twice with diethyl ether, and the combined filtrates were concentrated under vacuum. For physical data see Tables 4 and 5.

General procedure for the (*S*)-MeHNL-catalyzed preparation of cyclohexanone cyanohydrins 2 and 4

A solution of (*S*)-MeHNL (21) (100 U per 100 mg support, total 180–200 U, 92–93 μL) was added to nitrocellulose [Blotting-Membrane (Schleicher & Schuell); 1 g, soaked in 50 mL of 0.02 M sodium citrate buffer, pH 3.3, for 0.5 h; the buffer was decanted and nitrocellulose centrifuged (5700 × *g* for 30 min) and dried under high vacuum for 5 h], followed after 15 min by addition of diisopropyl ether (5 mL), substrate **1** or **3** (1 mmol), and HCN (150 μL, 3.9 mmol). The reaction was performed as described above. For physical data see Tables 4 and 5.

Chemical reaction (blank experiment)

The chemical HCN addition was performed analogously with the enzymatic reaction, however, the enzyme solution was replaced by the same volume of 0.02 M sodium acetate buffer, pH 5.4. The reaction times correspond with those of the (*R*)-PaHNL-catalyzed reaction.

Determination of conversion and isomeric ratio

To a solution of crude **2** or **4** (10 μL) in CH_2Cl_2 (500 μL) was added acetic anhydride (50 μL) and DMAP (15 mg), and the reaction mixture was allowed to stand at room temperature for 15 min. The mixture was then filtered through a silica gel column (3 × 0.5 cm) with CH_2Cl_2 (4 mL). Conversion and isomeric ratio were directly determined from the filtrate by gas chromatography.

General procedure for the preparation of the nitrobenzoylated derivatives 2f′, 4b′, and 4h′

To a solution of **2f**, **4b**, or **4h** (0.35 mmol or 3.2–3.8 mmol, isomeric ratio given in Tables 1 and 3) in pyridine (5–30 mL) was added DMAP (ca. 0.1 equiv) and *p*-nitrobenzoyl chloride (1.5–2.0 equiv), and the reaction mixture was stirred for the given time. Then water (10 or 100 mL) was added, the layers were separated, and the aqueous layer was extracted with diethyl ether (3 × 50 mL). The combined extracts were washed with diluted HCl until neutral, dried (Na_2SO_4), and concentrated. The residue was chromatographed on silica gel with petroleum ether–ethyl acetate (3:1 to 10:1).

cis-*4-Isopropenyl-1-(4-nitrobenzoyloxy)cyclohexanecarbonitrile (2f′)*

Reaction time: 7 d at room temperature; mp 107°C (EtOH–CH_2Cl_2). ^{1}H NMR (500 MHz, $CDCL_3$) δ: 1.52–1.60 (m, 2H, 2 CH), 1.73 (s, 3H, CH_3), 1.84–1.87 (m, 2H, 2 CH), 2.02–2.08 (m, 3H, 3 CH), 2.75 (d, J = 13.2 Hz, 2H, 2 CH), 4.72 and 4.78 (each s, 1H, =CH_2), 8.21–8.35 (m, 4H, Ph). ^{13}C NMR (126 MHz, $CDCL_3$) δ: 20.98 (CH_3), 25.50, 34.26 (CH_2), 42.62 (C4), 71.51 (C1), 109.75 (=CH_2), 118.76 (CN), 123.86, 130.90, 134.44, 150.97 (Ph), 147.91 (C=), 162.38 (C=O).

trans-*4-Methoxy-1-(4-nitrobenzoyloxy)cyclohexanecarbonitrile (4b′)*

Reaction time: 3 h at 50°C; mp 146°C (MeOH). ^{1}H NMR (250 MHz, $CDCL_3$) δ: 1.81–2.57 (m, 8 H, 4 CH_2), 3.35–3.45 (m, 1H, 4-CH), 3.37 (s, 3H, CH_3O), 8.18–8.35 (m, 4H, Ph). ^{13}C NMR (63 MHz, $CDCL_3$) δ: 25.77, 30.81 (CH_2), 56.03 (CH_3O), 72.91 (C1), 74.19 (C4), 117.95 (CN), 123.78, 130.95, 134.40, 150.98 (Ph), 162.48 (C=O). Anal. calcd. for $C_{15}H_{16}N_2O_5$: C 59.21, H 5.30, N 9.21; found: C 59.29, H 5.37, N 8.97.

trans-4-Acetoxy-1-(4-nitrobenzoyloxy)cyclohexanecarbonitrile (4h′)

Reaction time: 7 d at room temperature; mp 173°C (EtOH). ^{1}H NMR (250 MHz, $CDCL_3$) δ: 1.84–2.10 (m, 4H, 4 CH), 2.10 (s, 3H, CH_3), 2.17–2.28 (m, 2H, 2 CH), 2.51–2.62 (m, 2H, 2 CH), 4.92 (tt, J = 7.4, 3.9 Hz, 1H, 4-CH), 8.18–8.36 (m, 4H, Ph). ^{13}C NMR (63 MHz, $CDCL_3$) δ: 21.22 (CH_3), 26.26, 31.45 (CH_2), 68.41 (C4), 72.55 (C1), 117.61 (CN), 123.82, 131.00, 134.15, 151.06 (Ph), 162.48 (PhC=O), 170.38 (CH_3C=O). Anal. calcd. for $C_{16}H_{16}N_2O_6$: C 57.83, H 4.85, N 8.43; found: C 57.66, H 4.89, N 8.34.

Ethyl *cis*-1-hydroxy-4-propylcyclohexanecarboxylate (5)

A solution of *cis*-**2c** (5.0 g, 29.9 mmol) in ethanolic HCl solution (60 mL) was stirred at 90–100°C for 16 h in a pressure vessel. To open the vessel, it was cooled with ice water.

© 2002 NRC Canada

The reaction mixture was diluted with diethyl ether (40 mL) and ice water was added until the white precipitate dissolved. The layers were separated and the aqueous layer was extracted three times with diethyl ether. The combined organic layers were washed with sat. $NaHCO_3$ solution, dried (Na_2SO_4), and concentrated. The residue was distilled under vacuum to give 5.4 g (84%) of **5**; bp 84°C (0.01 mm Hg). ^{1}H NMR (500 MHz, $CDCL_3$) δ: 0.88 (t, J = 7.3 Hz, 3H, CH_3CH_2), 1.19–1.38 (m, 10H), 1.60–1.81 (m, 6H), 2.92 (s, 1H, OH), 4.22 (q, J = 7.0 Hz, 2H, CH_3CH_2). ^{13}C NMR (126 MHz, $CDCL_3$) δ: 14.19, 14.34, 19.89, 27.54, 36.63, 39.34 (CH_3, CH_2), 61.66 (CH_3CH_2O), 73.99 (C-OH), 177.76 (C=O). Anal. calcd. for $C_{12}H_{22}O_3$: C 67.26, H 10.35; found: C 67.04, H 10.43.

Ethyl *cis*-1-acetyloxy-4-propylcyclohexanecarboxylate (6)

A solution of **5** (5.4 g, 25.2 mmol), pyridine (2 equiv), acetic anhydride (2 equiv), and a catalytic amount of DMAP in CH_2Cl_2 was heated under reflux for 1 h (GC control). The reaction mixture was concentrated, the residue was taken up in diethyl ether, and washed with 10% HCl solution, sat. $NaHCO_3$, and sat. NaCl solution, and then dried (Na_2SO_4) and concentrated. The residue was distilled under vacuum to give 5.4 g (83%) of **6**; bp 105°C (0.01 mm Hg). ^{1}H NMR (500 MHz, $CDCL_3$) δ: 0.88 (t, J = 7.2 Hz, 3H, CH_3CH_2), 1.12–1.35 (m, 10H), 1.63–1.76 (m, 4H), 2.09 (s, 3H, CH_3CO), 2.23 (dd, J = 14.9, 2.3 Hz, 2H, 2,6-CH_{eq}), 4.17 (q, J = 7.0 Hz, 2H, CH_3CH_2). ^{13}C NMR (126 MHz, $CDCL_3$) δ: 14.06, 14.31, 19.89, 21.14, 27.63, 31.85, 36.17, 39.16 (CH_3, CH_2), 61.08 (CH_3CH_2), 79.87 (C-O), 169.90, 172.89 (C=O). Anal. calcd. for $C_{14}H_{24}O_4$: C 65.60, H 9.44; found: C 65.58, H 9.43.

***cis*-4-Hydroxy-8-propyl-1-oxaspiro[4.5]dec-3-en-2-one (7)**

To a solution of $LiN(SiMe_3)_2$ [prepared from hexamethyldisilazane (3.3 mL, 16 mmol) and a 1.6 M solution of *n*-BuLi in hexane (10 mL, 16 mmol)] in THF (60 mL) at –78°C was added a solution of **6** (2.0 g, 7.8 mmol) in THF (20 mL) over 15 min. After stirring for 2 h (TLC control), water (20 mL) was added and the reaction mixture was allowed to warm to room temperature. The organic layer was extracted twice with sat. $NaHCO_3$ solution. The combined aqueous layers were adjusted to pH 1 with conc. HCl and extracted three times with ethyl acetate. The combined extracts were dried (Na_2SO_4) and concentrated. The residue was recrystallized from chloroform to give 1.2 g (73%) of **7** as colorless crystals; mp 218°C. ^{1}H NMR (250 MHz, DMSO-d_6) δ: 0.87 (t, J = 6.8 Hz, 3H, CH_3), 1.09–1.83 (m, 13H), 4.79 (s, 1H, =CH), 12.65 (br s, 1H, OH). ^{13}C NMR (126 MHz, DMSO-d_6) δ: 14.13, 19.28, 28.01, 32.35, 34.90 (CH_3, CH_2, CH), 82.57 (C-O), 86.33 (=CH), 172.04, 185.15 (C=O, C-OH). Anal. calcd. for $C_{12}H_{18}O_3$: C 68.55, H 8.63; found: C 68.46, H 8.70.

Tailoring the substrate specificity of secondary alcohol dehydrogenase

Robert S. Phillips

Abstract: Our research with the thermophilic secondary-alcohol dehydrogenase (SADH) from *Thermoanaerobacter ethanolicus* has provided novel information regarding the physical basis of enzyme substrate specificity and stereospecificity. We demonstrated that oxidation of secondary alcohols catalyzed by *T. ethanolicus* SADH exhibits temperature-dependent enantiospecificity. In other studies, we found that the structure of co-factor analogs also significantly affects the stereochemistry of the SADH reaction. More recently, we demonstrated that pH can also have a modest effect on SADH enantiospecificity. Organic solvents have also been shown by others to affect the stereochemistry of SADH reactions. We designed and prepared S39T and C295A mutant forms of SADH by site-directed mutagenesis, and we evaluated the effects of the mutations by analysis of the temperature dependence of the enantiomeric ratio (*E*) for simple chiral alcohols such as 2-butanol. This procedure allows for the determination of the differential Eyring parameters ($\Delta\Delta H^{\ddagger}$ and $\Delta\Delta S^{\ddagger}$) for the reaction. We demonstrated that this technique is a sensitive method for analysis of the effects of mutation on enzyme stereospecificity. S39T and C295A SADH exhibit significant changes in substrate specificity and stereospecificity consistent with the changes in the volume of the alkyl-binding pockets. Thus, it is possible to alter the substrate specificity and stereospecificity of alcohol dehydrogenase by changing either the reaction medium or the protein structure.

Key words: alcohol dehydrogenase, substrate specificity, stereospecificity, temperature dependence, site-directed mutagenesis.

Resumé : Dans le cadre de nos travaux sur la déshydrogénase d'alcools secondaires thermophile (« SADH ») provenant de *Thermoanaerobacter ethanolicus*, on a obtenu de nouvelles informations concernant la base physique pour la spécificité et la stéréospécificité de l'enzyme vis-à-vis des substrats. On a démontré que l'oxydation d'alcools secondaires catalysées par la déshydrogénase d'alcools secondaires provenant de *T. ethanolicus* présente une énantiospécificité qui dépend de la température. Dans d'autres études, on a trouvé que la structure des analogues du cofacteur affecte aussi de façon significative la stéréochimie de la réaction de la « SADH ». Plus récemment, on a démontré que le pH peut aussi avoir un modeste effet sur l'énantiospécificité des réactions de la « SADH ». On a mis au point et préparé les formes mutantes S39T et C295A de la « SADH » en faisant appel à de la mutagénèse orientée vers le site et, à l'aide d'alcools chiraux simples tel le butan-2-ol, on a évalué les effets des mutations par l'analyse du rapport énantiomérique sur la dépendance de la température, E. Cette procédure permet de déterminer les paramètres différentiels d'Eyring, $\Delta\Delta H^{\ddagger}$ et $\Delta\Delta S^{\ddagger}$ pour la réaction. On a démontré que cette technique s'avère une méthode sensible pour l'analyse des effets de mutation sur la stéréospécificité des enzymes. Les formes S39T et C295A de la « SADH » présentent des différences significatives de spécificité et de stéréospécificité qui sont en accord avec des changements dans le volume des poches qui lient les groupes alkyles. Il est donc possible de modifier la spécificité du substrat et la stéréospécificité de la déshydrogénase d'alcool en changeant le milieu réactionnel ou la structure de la protéine.

Mots clés : déshydrogénase d'alcool, spécificité du substrat, stéréospécificité, dépendance sur la température, mutagénèse orientée vers le site.

Introduction

Enzymes are remarkable not only for their catalytic efficiencies, but also for their high stereospecificities. This stereospecificity has been studied for more than a century, and in 1894 was central in the formulation of Emil Fisher's (1) seminal "lock and key" hypothesis for enzyme action. More recently, Ogston (2) developed his "three-point attachment" hypothesis to explain enzymatic stereospecificity. It is now recognized, however, that stereospecificity can be explained by only a single-point contact between two asymmetric molecules (3).

Alcohol dehydrogenases (ADHs) have served as a paradigm for the study of stereochemistry of enzymatic reactions.

The seminal work of Vennesland and co-workers (4) and Westheimer et al. (5) with yeast ADH demonstrated that the enzyme is stereospecific for the faces of the NADH dihydropyridine ring, as well as for the enantiotopic C–H bonds of ethanol. Prelog (6) studied the stereoselectivities of horse liver and microbial ADHs in cyclic ketone reduction, and found that most ADHs reduce ketones by hydride transfer to the pro-*R* face of the carbonyl, producing (*S*)-alcohols. This generalization, known as "Prelog's Rule," is still in widespread use. An empirical structural model of the horse liver ADH (HLADH) active site, known as the "diamond lattice section," was developed by Prelog (6) and further extended by Jones and co-workers (7). This model was used quite successfully by Jones (8) in predicting substrate activity and the stereochemistry of ADH. HLADH, however, has low activity toward most acyclic ketones, is not thermally stable or stable to immobilization, and is unstable in the presence of organic solvents. There has therefore been a need for more active and robust ADHs for synthetic applications. In this regard, ADHs isolated from thermophilic microorganisms have been especially interesting, since they are highly active with ketones, exhibit high thermal stability, and are stable upon immobilization and (or) in the presence of organic solvents. Thus, the thermophilic *Thermoanaerobacter brockii* ADH (TBADH) has been successfully used to synthesize several chiral compounds of interest (9–11).

Discussion

Effects of physical variables on stereochemistry of alcohol dehydrogenases — reaction medium engineering

We have been studying the effects of temperature and other physical variables on stereochemistry of enzymatic reactions. The stereospecificity of any enzymatic reaction can be defined by the enantiomeric ratio (*E*, eq. [1]) (12). (Note that the term "stereospecific" as used in organic chemistry refers to the difference between the reaction rates or products arising from pre-existing isomers (13). On the other hand, if a chiral center is formed during the reaction, and if the product favors one enantiomer, it is said to be "stereoselective" (13). By this definition, ADHs are stereospecific in the oxidation direction, but stereoselective in the reduction direction.) Under kinetic control, the ratio of observed products is equivalent to the ratio of the rate constants (k_{cat}/K_m) of formation (or reaction) of the enantiomers. The differential free energy of activation ($\Delta\Delta G^{\ddagger}$) is given by eq. [2]. The temperature dependence of $\Delta\Delta G^{\ddagger}$ can be given by the thermodynamic relationship in eq. [3]. Combining eqs. [2] and [3], one can write eq. [4].

$$[1] \qquad E = R/S = (k_{cat}/K_m)_R/(k_{cat}/K_m)_S$$

$$[2] \qquad \Delta\Delta G^{\ddagger} = -RT \ln E = \Delta G^{\ddagger}_R - \Delta G^{\ddagger}_S$$

$$[3] \qquad \Delta\Delta G^{\ddagger} = \Delta\Delta H^{\ddagger} - T\Delta\Delta S^{\ddagger}$$

$$[4] \qquad -RT \ln E = \Delta\Delta H^{\ddagger} - T\Delta\Delta S^{\ddagger}$$

$$[5] \qquad T_r = \Delta\Delta H^{\ddagger}/\Delta\Delta S^{\ddagger}$$

Thus, a plot of $-RT \ln E$ vs. T for the reaction of a pair of enantiomers is predicted to be linear, with a slope of $\Delta\Delta S^{\ddagger}$ and an intercept of $\Delta\Delta H^{\ddagger}$ (14, 15). If there is no enantiospecificity in a reaction, $E = 1$ and therefore $\Delta\Delta G^{\ddagger} = 0$. Equation [3] then can be rearranged to eq. [5], where T_r is the "racemic temperature," at which there will be no stereochemical discrimination in the reaction. If the differential activation enthalpy and activation entropy have the same sign (and thus favor different enantiomers), at temperatures below T_r, the stereochemical course of the reaction is dominated by the activation enthalpy difference, and the stereochemical purity of products is expected to decrease with increasing temperature. At temperatures above T_r, the reaction is controlled by the activation entropy difference, and the stereochemical purity of the reaction products increases with increasing temperature. The major product obtained at $T > T_r$ will, however, be the antipode to that obtained at $T < T_r$, and a temperature-dependent reversal of stereochemical configuration is predicted.

We demonstrated that 2-butanol oxidation catalyzed by *Thermoanaerobacter ethanolicus* SADH exhibits temperature-dependent enantiospecificity (14, 15). The T_r is 26°C for 2-butanol; at lower temperatures, the preferred substrate is (*S*)-2-butanol, but at higher temperatures (*R*)-2-butanol is preferred. For 2-pentanol, T_r is ~100°C, so the preferred substrate is the (*S*)-enantiomer throughout the normal range of the study. Thus, our work established the physical basis of the substrate size-dependent reversal of stereochemical configuration previously observed empirically at a single temperature by Keinan and co-workers (9). This temperature dependence of enantiospecificity is due to a dichotomy between the activation enthalpies and activation entropies for the enantiomers. (*S*)-Alcohols exhibit lower activation enthalpies, probably due to better van der Waals surface contacts with the active site. In contrast, (*R*)-alcohols have lower activation entropies, and they may become the favored substrates (or products in the reduction direction) at higher temperatures. This lower entropy may be either the result of less restricted freedom of movement of the substrate and enzyme side chains in the complex, and hence in the transition state(s) of the reaction, or the result of differences in active-site desolvation upon binding of the enantiomeric substrates. These results demonstrated that the stereoselectivity of enzymatic reactions is not solely due to enthalpic factors, and that the activation entropy may be equally important. This work was the first analysis of this kind performed for an enzymatic reaction. In recent years, a number of investigators have applied our method to other enzymes, especially lipases, and it was observed that entropy is often the main contributor to the differential activation free energy ($\Delta\Delta G^{\ddagger}$) (16–18).

In other studies, we found that the structure of the co-factor analogs also significantly affects the stereochemistry of the SADH reaction (19). For 2-butanone reduction at 37°C, the stereochemical purity of the (*R*)-2-butanol product increases from $E = 1.9$ with NADP as the co-factor to $E = 9$ using the co-factor analog, 3-acetylpyridineadeninedinucleotide phosphate (APADP). As expected, *E* values increase when (*R*)- and (*S*)-2-butanol oxidations are followed using APADP or thio-NADP as the co-factor, rather than NADP. Even NAD shows a significant increase in the (*R*)-preference compared with NADP, although the activity is relatively low. The effects of co-factor and temperature are additive; reactions catalyzed using co-factor analogues show a linear

dependence of –RT ln E vs. T, similar to that in the presence of NADP but shifted to more negative values (19).

We also evaluated the effects of chain length on k_{cat}/K_m for a series of (*R*)- and (*S*)-alcohols (15). For the (*S*)-alcohols, a linear free-energy relationship holds when ln (k_{cat}/K_m) is plotted against chain length of the large substituent. This result implies a constant mechanism for the (*S*)-alcohols. In contrast, the (*R*)-alcohols exhibit a convex plot, which implies that the rate-determining step changes with chain length. The slope of the (*S*)-alcohols plot gives $\Delta\Delta G_n^{\ddagger}$, which is the change in activation free energy per methylene group. This parameter was calculated between 20 to 60°C, and $\Delta\Delta H_n^{\ddagger}$ and $\Delta\Delta S_n^{\ddagger}$ were determined. $\Delta\Delta H_n^{\ddagger}$ was –3.3 kcal mol^{-1}, indicating that each methylene contributes binding energy toward the reaction, and that there are no unfavorable steric contacts. $\Delta\Delta S_n^{\ddagger}$ was –13 cal mol^{-1} deg^{-1}, and hence contributes negatively to catalysis. The decreasing rate for the (*S*)-alcohols with increasing chain length is due to this unfavorable entropy, which in turn is likely due to restricted freedom of rotation of the longer chains in the bound substrate. Thus, entropy emerges as a controlling factor for both stereospecificity and substrate specificity of SADH.

More recently, we demonstrated that pH can also have a modest effect on SADH enantiospecificity (20). For a simple enzyme mechanism using a general base catalytic group, where only the unprotonated enzyme can productively bind

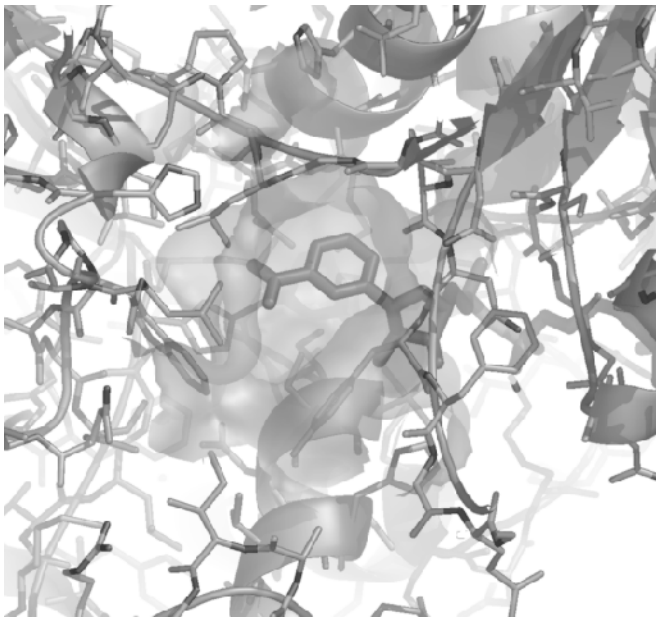
Fig. 2. Active site of *T. brockii* ADH showing the surface of the small alkyl-binding pocket, located behind and to the left of the nicotinamide ring (thick-stick structure in the center). This figure was prepared using PyMOL (DeLano Scientific) with the coordinates of 1YKF.pdb.



the substrate, k_{cat}/K_m is expected to vary with pH according to eq. [6], where K_1 is the acidity constant of the ionizable basic catalytic group on the protein.

$$[6] \qquad (k_{cat}/K_m)_{obs} = (k_{cat}/K_m)K_1/([H^+] + K_1)$$

If, however, the complete kinetic mechanism is operating so substrates can bind to either the protonated or unprotonated enzyme, and substrates are "sticky" (i.e., reaction to products is as fast as or faster than release of unreacted substrate), the apparent ionization constant (K_1) will shift by a factor of ($1 + C$), where C is the ratio of the rate constant of conversion of enzyme-bound substrate to product over the rate constant of the substrate released from the enzyme. The effect of this commitment is a shifting of the observed pK_a to lower pH by log ($1 + C$)[(pK_a)$_{obs}$ = pK_a – log ($1 + C$)]. In the presence of a catalytic commitment, the pH dependence is described by eq. [7]. For the reaction of enantiomeric substrates under kinetically controlled conditions, the enantiomeric ratio (E) is given by eq. [1]. Substitution of eq. [7] into eq. [1] gives eq. [8], which describes the effect of pH on E.

$$[7] \qquad (k_{cat}/K_m)_{obs} = (k_{cat}/K_m)K_1(1 + C)/([H^+] + K_1(1 + C))$$

$$[8] \qquad E = \left[\frac{(k_{cat}/K_m)_R K_1(1 + C_R)}{([H^+] + K_1(1 + C_R)}\right] \div \left[\frac{(k_{cat}/K_m)_S K_1(1 + C_S)}{([H^+] + K_1(1 + C_S)}\right]$$

$$[9] \qquad E = [(k_{cat}/K_m)_R(1 + C_R)]/[(k_{cat}/K_m)_S(1 + C_S)]$$

At $[H^+] << K_1$, eq. [8] reduces to eq. [1], which is the intrinsic ratio of the k_{cat}/K_m values. But at $[H^+] >> K_1$, eq. [8] will reduce to eq. [9], which contains the commitment ratio $[(1 + C_R)/(1 + C_S)]$ as well as the k_{cat}/K_m ratio. C_R and C_S are used to designate the commitments for substrate (R)- and (S)-enantiomers, respectively. Thus, if commitments for the enantiomeric substrates are significantly different, E can be pH dependent, varying between the values defined by eqs. [1] and [9]. Horse liver ADH does not show any effect of pH on enantiospecificity (E = 0.26) in the reaction of (R) and (S)-2-butanol, since identical pK_as of 8.0 are seen for both enantiomers (20). In contrast, the reaction of SADH with these alcohols shows a modest but significant influence of pH on enantiospecificity. At 65°C, the pK_a for the reaction of SADH with 1-propanol, which is a poor substrate and hence has a low commitment, is 6.82 ± 0.11. This pK_a value should be the true thermodynamic value. At 65°C, the reaction of (R)-2-butanol exhibits a pK_a of 6.60 ± 0.10, while that of (S)-2-butanol exhibits a pK_a of 6.85 ± 0.15. As a result, the E value for 2-butanol increases from 2.5 at pH 9 to 4.2 at pH 5.5.

The effects of solvents on the stereoselectivity of ADH reactions have been examined by two groups. Simpson and Cowan (21) examined the effects of polar water-miscible solvents, such as acetonitrile, methanol, and dimethylformamide, on the reduction of ketones by a secondary ADH from *Thermoanaerobacterium sp*. Addition of

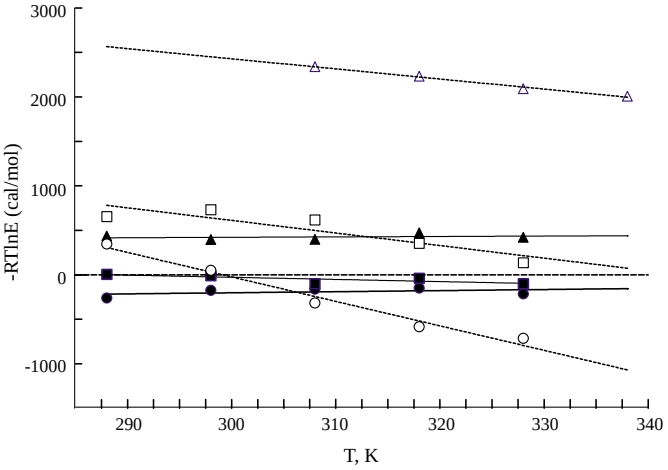
Fig. 3. Temperature dependence of stereospecificity for wild-type and C295A SADH (29). 2-Butanol (circles); 2-pentanol (squares); 2-hexanol (diamonds). Wild-type SADH (open symbols and dashed lines); C295A SADH (filled symbols and solids lines).



acetonitrile was found to increase the (*R*)-specificity for 2-butanol, from $E = 1.8$ without acetonitrile to $E = 4.7$ at 40% (v/v) acetonitrile. Jonsson et al. (22) studied the reduction of 2-pentanone by TBADH in hexane, hexane–water biphasic medium, and water. They found that the activity was much lower, and the stereoselectivity for reduction of 2-pentanone to 2-pentanol was considerably reduced in hexane at a low water activity ($a = 0.53$). The low enzyme activity at low water activity is associated with a large negative reaction entropy. The authors attributed these solvent effects to decreased flexibility of the enzyme in the non-aqueous medium.

Preparation of mutant SADHs with altered substrate specificity and stereospecificity — protein engineering

The ADH from mammalian liver and the SADHs from microorganisms are members of the "medium-chain" family of ADHs. Figure 1 shows the sequence alignment of human α, β, and γ forms of liver ADH, and the *T. ethanolicus*, *T. brockii*, and *Clostridium beijerinckii* ADHs. There is a relatively high-sequence identity between human and bacterial ADHs, with the residues of the catalytic zinc site especially conserved. The zinc is bound to Cys-47 in the consensus sequence and to His-69, both of which are conserved. The third zinc ligand, however, is consensus residue 179, which is Cys for the mammalian enzymes, but Asp for the bacterial enzymes. The structural zinc site seen in mammalian ADHs is not found in the microbial enzymes. The SADH S39T mutation was performed and the mutant protein was characterized (23). Ser-39 in SADH corresponds to Ser-49 in the sequence of horse liver ADH and Thr-49 in the sequence of α-human liver ADH (Fig. 1). This serine–threonine residue (49 in the consensus sequence in Fig. 1) is conserved in all members of this ADH family, and it is apparently required as part of a proton shuttle to allow protons to go in and out of the active site and facilitate substrate binding and catalysis (24). Mutation of this conserved serine–threonine to alanine results in the complete loss of activity in human liver ADH (25). We were interested in the effect of the S39T mutation on SADH stereospecificity, since there was a report that α-human liver ADH has greater (*R*)-specificity than horse liver ADH or β-human liver ADH (26). Interestingly, the specific activity of S39T SADH is about 50% higher than wild-type SADH with 2-propanol (23). This result is consistent with the report that the corresponding T40S mutation in *B. stearothermophilus* ADH reduced its activity by about 30% (24). Furthermore, the mutation of this threonine of β-human liver ADH to serine results in significantly greater reactivity with cyclohexanol and steroidal alcohols than the wild-type enzyme (26). Analysis of the temperature dependence of stereospecificity of S39T SADH for 2-butanol demonstrated a dramatic decrease in the T_r, from 26 to –110°C (23). Correspondingly, the (*R*)-selectivity for 2-butanone reduction has increased at 50°C from $E = 2.3$ to $E = 19$. This is consistent with the location in the crystal structure of Ser-39 in the large alkyl-group binding pocket, so the mutation to Thr increases the steric restraints in the large pocket, favoring the reaction of the (*R*)-alcohol. In the case of 2-pentanol, the effect of the S39T mutation is even more dramatic, reversing the preferred configuration from (*S*) to (*R*) throughout the temperature range studied (20–60°C). Interestingly, the value of k_{cat}/K_m of both enantiomers of 2-pentanol is greater with S39T SADH than with the wild-type enzyme, but the activity of (*R*)-2-pentanol is increased to a greater extent than (*S*)-2-pentanol.

Recently, we prepared the C295A mutant SADH, based on the results of modeling studies of the wild-type crystal structure with ethynyl ketoester substrates (28). Cys-295 was predicted to make up part of the putative small alkyl-group binding pocket, together with Ala-85 and Ile-86. As expected, these residues are not highly conserved, since they are not directly involved in catalysis. Cys-295 (residue 329 in the consensus sequence in Fig. 1) is replaced by the bulkier Tyr, Phe, or Leu in the human liver enzymes. The crystal structure of TBADH, showing the position of the small hydrophobic pocket as the surface just behind and to the left of the nicotinamide ring, is shown in Fig. 2. C295A SADH has specific activity with 2-propanol, which is about half that of wild-type SADH, but exhibits significant differences in both substrate specificity and stereospecificity, as shown in Table 1 (28). Wild-type SADH will reduce ethynyl ketones to (*R*)-alcohols if the alkyl group is propyl, isopropyl, or

© 2002 NRC Canada

smaller (Table 1) (27). Ethynyl ketones with butyl or larger alkyl groups provide (*S*)-alcohols upon reduction. Thus, the small alkyl pocket can only comfortably accommodate alkyl groups with three carbons or less. The stereoselectivity of C295A SADH is reversed for *n*-butyl and isobutyl ethynyl ketones, demonstrating that the C295A mutant enzyme has a larger hydrophobic pocket (Table 1). Even more striking, wild-type SADH does not reduce ketones with large α-branched substituents, such as 4-methyl-1-heptyn-3-one, at a rate that is synthetically useful. This racemic ketone, however, is an excellent substrate of C295A SADH, and is rapidly reduced to give a 2:1 mixture of enantiomerically pure (2*S*,3*S*) and (2*S*,3*R*) diastereomers of 4-methyl-1-heptyn-3-ol, in good chemical yield (Table 1) (28). Thus, the result shows that α-branching is not tolerated by wild-type SADH in the large alkyl substituent, likely due to unfavorable steric interactions with the nicotinamide ring of NADP, but in the C295A mutant SADH, the *sec*-pentyl substituent can fit into the small hydrophobic pocket. These results demonstrate that dramatic changes in substrate specificity of SADH can be achieved with only single-point mutations.

Remarkably, in sharp contrast to wild-type and S39T SADH, C295A SADH shows much lower temperature dependence of *E* values for 2-butanol, 2-pentanol, and 2-hexanol (Fig. 3) (29). The $\Delta\Delta H^{\ddagger}$ and $\Delta\Delta S^{\ddagger}$ values for 2-butanol with C295A SADH are dramatically reduced (Table 2). While the change in $\Delta\Delta H^{\ddagger}$ was expected as a result of the C295A mutation, the change in $\Delta\Delta S^{\ddagger}$ was unexpected. Close examination of the crystal structures of *T. brockii* ADH revealed a water molecule bound in the small alkyl binding pocket, 4 Å from the cysteinyl sulfur of Cys-295. This water molecule will evidently be expelled to the bulk solvent by the binding of a large substituent in the small pocket. Thus, the entropy term is likely due at least in part to the differential expulsion of this water by substrate (*R*)-enantiomers. Mutation of Cys-295 to alanine apparently prevents the binding of this water in the small alkyl binding pocket, eliminating the entropy. This result, together with the reversal of stereochemistry observed in the reduction of isobutyl ketones, provides strong evidence that Cys-295 is in the small hydrophobic pocket of SADH. The study of mutations of Cys-295 of SADH to other amino acids is currently in progress.

Conclusions

The stereospecificity of SADH from *T. ethanolicus* is influenced by temperature, co-factor structure, pH, and organic solvents. Furthermore, mutations of the amino acids in the proposed alkyl-group binding pockets can change both substrate specificity and stereospecificity, consistent with the changes in the volume of the alkyl-binding pockets. It is therefore possible to alter the substrate specificity and stereospecificity of alcohol dehydrogenases by changing either the reaction medium or the protein structure.

Kinetic resolution of oxime esters with lipases — synthesis of enantiomerically enriched building blocks with quaternary carbon centers and formal total synthesis of perhydro histrionicotoxin

Nicole Diedrichs, Ralf Krelaus, Ina Gedrath, and Bernhard Westermann

Abstract: Enantiomerically enriched oximes bearing stereogenic quaternary carbon centers can be obtained by lipase-catalyzed kinetic resolution of oxime esters. Substrate specificity, solvent effects, and the use of different lipases are discussed. Kinetic resolution of butyrylated oximes by lipase PS in the presence of *n*-butanol gave the best ee-values of both the saponified oxime and the residual oxime ester. Subsequent stereospecific Beckmann rearrangement of an enantiomerically enriched oxime provided lactams, which could be employed for the synthesis of optically active perhydro histrionicotoxin.

Key words: oxime, lipase, kinetic resolution, Beckmann rearrangement, perhydro histrionicotoxin.

Résumé : Le dédoublement cinétique d'esters d'oximes catalysé par une lipase permet d'obtenir des oximes énantiomériquement enrichies, portant des centres carbonés quaterneraires stéréogéniques. On discute de la stéréospécificité des substrats, des effets de solvant et de l'utilisation de diverses lipases. Le dédoublement cinétique d'oximes portant un groupe butyryle sous l'influence de la lipase PS, en présence de butanol, donne les meilleurs valeurs d'ee pour l'oxime saponifiée et pour l'ester d'oxime résiduel. Une transposition de Beckmann stéréospécifique subséquente d'une oxime énantiomériquement enrichi fournit des lactames qui peuvent être utilisés pour la synthèse de la perhydrohistrionicotoxine optiquement active.

Mots clés : oxime, lipase, dédoublement cinétique, transposition de Beckmann, perhydrohistrionicotoxine.

[Traduit par la Rédaction]

Introduction

Enzymes are used in organic chemistry for their numerous advantages as mild and easy-to-handle catalysts (1). Their exquisite chemo-, regio-, and stereoselectivity has been demonstrated numerous times. Most reported reactions are hydrolytic reactions, e.g., lipase-catalyzed esterifications, transesterifications, and saponifications of esters. In an overwhelming number of studies, employment of irreversible transacylating reagents has had a major impact in diversifying the use of hydrolytic enzymes (2). In this context, oxime esters have been used as irreversible acyl transfer agents, sometimes exhibiting superior activity compared with their anhydride or vinyl-derived congeners (3). Despite these advantages, the resolution of racemic oximes or oxime esters have been studied infrequently (4).

Oximes **1** are involved in many different reactions, the Beckmann rearrangement being one of the most prominent. Due to its stereospecificity, the synthesis of natural product precursors **3** (spirocyclic framework of histrionicotoxins) or products of pharmaceutical interest **4** (non-natural amino acids) via lactams **2** can be accomplished (Scheme 1). All oximes employed bear a common stereogenic quaternary-carbon center adjacent to the oxime functionality. Although other methods to provide enantiomerically pure building blocks possessing quaternary-carbon centers have been published, there is still a need for widely applicable procedures (5).

Herein we describe a general method to obtain enantiomerically enriched oximes **1** via kinetic resolution of racemic oxime esters with lipase PS. In addition, the application of these intermediates in the synthesis of the enantiomerically pure spirocyclic framework of histrionicotoxin is reported. The synthesis of non-natural amino acids has been described elsewhere (6).

Results and discussion

Synthesis of *E*-oximes

Racemic oximes (±)-**1** can be obtained from alkylated β-ketoesters (±)-**5** by treatment with hydroxyl ammonium chloride in pyridine–ethanol (Scheme 2) (6*a*). The reaction is carried out at 0°C to afford almost exclusively the *E*-oximes in quantitative yields (the ratio of *E*:*Z* stereoisomers is always >50:1 as determined by GLC analysis). The *E*-configuration of the oximes has been established by subsequent

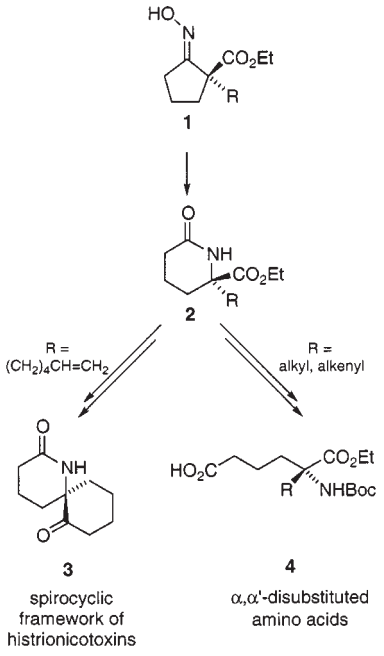
Scheme 1.

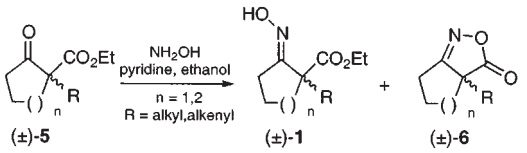


Beckmann rearrangements, which afforded lactams **2** as the sole products in high yields. The isoxazolidinone (±)-**6** is formed in quantitative yield, if the reaction is carried out under thermodynamic control (e.g., boiling chloroform).

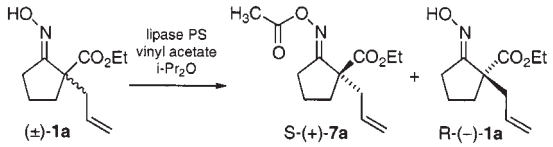
Lipase-catalyzed kinetic resolution of oximes (±)-1

Lipase-catalyzed kinetic resolutions can be carried out in two ways, either employing irreversible transacylating agents like vinyl acetate in the presence of racemic oximes or using racemic oxime esters in transesterification reactions. In our initial experiments, the kinetic resolution of oxime (±)-**1a** was carried out with lipase PS in the presence of vinyl acetate (Scheme 3). Kinetic resolution was achieved by stirring the oxime in diisopropyl ether with lipase PS. While high selectivities (ee-values > 90%) were obtained, the reactions took about one month. Optimization and screening of various lipases showed no significant effect. (The employed lipases were all of microbial origin: *Aspergillus niger*, *Candida antarctica*, *Candida cylindracea*, *Mucor miehei*, *Pseudomonas cepacia*, *Pseudomonas fluorescens* and *Mucor javanicus*.). We therefore abandoned this approach and envisioned carrying out kinetic resolution reactions starting from the corresponding racemic oxime esters (±)-**7a** and derivatives thereof.

Scheme 2.



Scheme 3.



All enzyme catalyzed reactions reported in this publication have been monitored by GLC (cyclodextrin-modified stationary phase for oximes) and HPLC (Daicel stationary phases for oxime esters). Using these materials, base-line separation of the racemic substrates was achieved in all cases. The respective assignment of the absolute (*S*)- and (*R*)-configurations of the quaternary stereogenic centers in (+)-**7a** and (–)-**1a** were based on chemical correlation to products obtained by PLE-catalyzed saponification of β-ketoesters (±)-**5** (7). The enantiomerically pure β-ketoesters obtained by this method have been employed in the total synthesis of the alkaloids (+)-nitramine and (–)-isonitramine. Thus, the stereogenic center in (+)-**7a** is (*S*)-configured, and in (–)-**1a** it is (*R*)-configured.

Lipase-catalyzed kinetic resolution of oxime esters

To identify the best stereodifferentiation by the enzyme, several carboxylic esters of the allylated oxime (±)-**1a** were reacted in diisopropyl ether as solvent containing *n*-butanol. The methoxy- and the chloro-substituted acetic acid derivatives (±)-**8a** and (±)-**9a**, respectively, were hydrolyzed very quickly, yet unselectively (Table 1). In addition, lipase PS did not accept the pivalic acid oxime ester (±)-**10a**. Further experiments showed that acetic acid oxime ester (±)-**7a** and butyrylated oxime ester (±)-**11a** were good substrates and the products were obtained with high enantiomeric excess (Table 1).

In polar solvents such as acetonitrile or acetone, only low ee-values were obtained. High ee-values were observed using

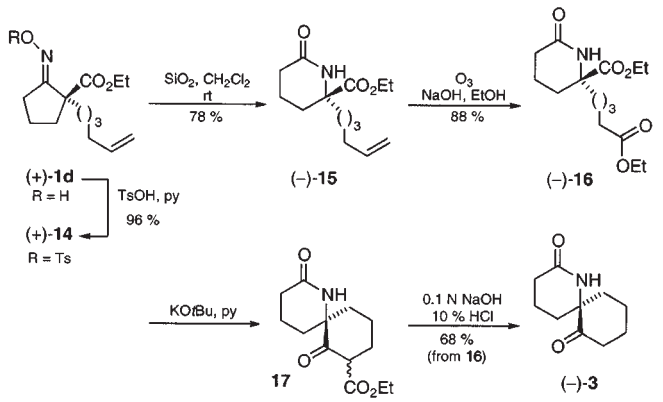
toluene and hexane, but prolonged reaction times (up to 20 d) were required for good conversion. We achieved the best results by using ethers as solvents; amongst the ones screened, diisopropyl ether proved to be most suitable for our purposes in terms of reaction times and selectivity.

Based on these initial results, we synthesized racemic butyrylated oxime esters (±)-**11a–f** (Scheme 4, Table 2). Kinetic resolution of these substrates was achieved over 3–5 days. Thus, stirring the oxime esters in diisopropyl ether with lipase PS in the presence of *n*-butanol gave rise to highly stereoselective saponifications of the substrates. No striking difference was observed on starting from cyclopentane (**11a–d**) or cyclohexane derivatives (**11e**, **f**). Similarly, the size of the alkyl side chain at the quaternary carbon center does not play a major role in stereodifferentiation. All products were isolated in high yields with good ee-values after column chromatography. The butyrylated oxime esters (–)-**11a–f** were saponified quantitatively in 10 min by stirring with potassium carbonate in methanol. The ester moiety at the quaternary center remains intact during the two-step procedure (kinetic resolution and hydrolysis).

Synthesis of the spirocyclic framework of histrionicotoxin (–)-3

Histrionicotoxin **12** and their hydrogenated congeners **13** (Fig. 1) are well-known neurotoxins used by natives of South America as arrow poisons. They have been isolated from skin extracts of the neotropical frog *Dendrobates histrionicus.* These spirocyclic alkaloids influence neurophysiological ion transport and their action on the acetylcholine receptor is of considerable biological interest (8). The total synthesis of racemic perhydro histrionicotoxin **13** was achieved by Kishi et al. (9*a*) and Corey et al. (9*b*); however, the total synthesis of enantiomerically pure histrionicotoxin was achieved only recently by an ingenious route reported by Stork and Zhao (10*a*).

Scheme 5.



Our route towards the enantiomerically pure spirocyclic framework is related to the methodology reported by Witkop and Kiessing (11) (Scheme 5). In this synthesis, the key step towards the spirocyclic framework is a Dieckmann reaction. To obtain suitable starting materials for this step, we chose to elaborate the enantiomerically pure oxime (+)-**1d**. The corresponding tosylate (+)-**14** was synthesized quantitatively by using tosyl chloride in pyridine. Rearrangement took place while stirring the tosylate in the presence of silica gel. Lactam (–)-**15** was isolated in 78% yield as the only regio- and stereoisomer. It is well known that the Beckmann rearrangement occurs with retention of the configuration at a migrating stereogenic center, and indeed, NMR experiments employing $Eu(hfc)_3$ proved that no racemization had taken place. (The racemic lactam (±)-**15** exhibits two triplets for the methyl group of the ethyl ester moiety at 1.32 and 1.64 ppm, whereas the homochiral lactam (–)-**15** shows only one triplet at 1.26 ppm (12).)

Ozonolysis of the double bond was carried out as described by Marshall et al. (13). Reaction with solid NaOH in

© 2002 NRC Canada

ethanol at –78°C provided the diester (–)-**16** in 88% yield. Subsequently, a Dieckmann reaction was carried out in the presence of potassium *tert*-butylate, affording the spirocycle **17** as a crystalline product. Without further characterization, saponification and decarboxylation was carried out leading to (–)-**3** in 68% yield (from **16**). Because racemic ketone (±)-**3** was used to synthesize perhydro histrionicotoxin, this synthesis represents a formal total asymmetric synthesis of this alkaloid (9). Currently we are exploring the synthesis of histrionicotoxin.

Conclusions

We have demonstrated that oxime esters are valuable substrates for kinetic resolution with lipases. Transesterification of the butyrylated oximes gave products containing a quaternary stereocenter adjacent to the oxime functionality; this method is therefore a valuable tool to provide building blocks with this structural feature. The configuration at the stereocenter could be unambigously determined by chemical correlation, which is based on the synthesis of known natural products.

The oximes were employed in Beckmann rearrangements leading to enantiomerically pure lactams. These lactams can be used for the synthesis of non-natural amino acids and for the preparation of spirocyclic alkaloids as demonstrated in the case of perhydro histrionicotoxin.

Experimental

All reagents were of commercial quality. Lipases were purchased from Fluka (Switzerland) and were provided by Amano (Japan). All solvents were distilled prior to use. Silica gel 60 F_{254} plates from Merck (Germany) were used for TLC. Column chromatography was performed using silica gel 60/230–400 mesh from Merck. NMR spectra were measured on a Bruker ARX 200 spectrometer (^{1}H 200 MHz and ^{13}C 50 MHz). IR spectra were measured on an FT-IR spectrometer NICOLET 510 P. Mass spectra were obtained with a FINNIGAN MAT 8430. The optical rotations were recorded on a PerkinElmer 241 polarimeter. For HPLC a Merck-Hitachi chromatograph equipped with an OB-H column from Daicel Chemical Industries (25 × 0.46 cm) was used. For GLC measurements an HP 8890 gas chromatograph with a Lipodex E cyclodextrin column (12.5 m, Macherey & Nagel, Germany) was used. Elemental analyses were carried out on a PerkinElmer analytical analyzer 241.

General procedure for the preparation of racemic oxime esters (±)-11a–f

To a solution of oxime (±)-**1** (5.0 mmol) in dry pyridine (25 mL), was added dropwise butyric acid chloride (5.0 mmol) over a period of 10 min at 0°C under an argon atmosphere. The reaction mixture was stirred for 1 h at this temperature and an additional 3 h at room temperature. After adding 5% hydrochloric acid (30 mL) the aqueous layer was extracted with diethyl ether (3 × 70 mL). The combined organic layers were washed with 10% hydrochloric acid (10 mL), saturated sodium bicarbonate solution (2 × 40 mL), and finally with saturated brine. The organic layer was dried over $MgSO_4$, filtered, and evaporated to dryness under reduced pressure. After column chromatography with dichloromethane–methanol (95:5) or distillation, the desired products were obtained in 81–94% yield.

General procedure for kinetic resolution of oxime esters (±)-11a–f

Lipase PS (500 mg) and *n*-butanol (5 mL) were added to a solution of (±)-**11** (2 mmol) in diisopropyl ether (15 mL). The reaction was monitored by HPLC. After the reaction, the enzyme was filtered through Celite™ and washed with diethyl ether. The crude residue was subjected to column chromatography using dichloromethane–methanol (98:2) as the eluent.

General procedure for saponification of oxime esters (–)-11a–f

To a saturated solution of K_2CO_3 in methanol (20 mL) was added oxime ester (±)-**11** (1 mmol) and the solution was stirred for 10 min. After evaporation to dryness, the residue was dissolved in water (45 mL). The aqueous layer was extracted with diethyl ether (3 × 50 mL). The combined organic layers were washed with 5% hydrochloric acid (10 mL) and saturated brine. After drying over $MgSO_4$, filtration and evaporation of the solvent gave the oximes (–)-**1** in quantitative yield.

Ethyl 1-allyl-2-[(butyryloxy)imino]cyclopentane carboxylate (11a)

^{1}H NMR ($CDCl_3$) δ: 0.94 (t, ^3J = 7.3 Hz, 3H, CH_3), 1.21 (t, ^3J = 7.1 Hz, 3H, CH_3), 1.66 (q, ^3J = 7.4 Hz, 2H, CH_2), 1.76–1.90 (m, 3H, CH_2), 2.15–2.83 (m, 7H, CH_2), 4.13 (q, ^3J = 7.1 Hz, 2H, OCH_2), 5.02–5.11 (m, 2H, $=CH_2$), 5.67–5.87 (m, 1H, =CH). ^{13}C NMR ($CDCl_3$) δ: 14.2, 14.5, 18.8, 22.0, 29.9, 35.2, 39.9, 57.3, 61.9, 72.8, 119.4, 133.9, 171.7, 172.9, 174.2. EI-HRMS calcd. for $C_{15}H_{23}NO_4$: 281.1627; found: 281.1625.

Ethyl 1-methyl-2-[(butyryloxy)imino]cyclopentane carboxylate (11b)

^{1}H NMR ($CDCl_3$) δ: 1.00 (t, ^3J = 7.3 Hz, 3H, CH_3), 1.26 (t, ^3J = 7.1 Hz, 3H, CH_3), 1.29 (s, 3H, CH_3) 1.63–2.02 (m, 5H, CH_2), 2.19–2.45 (m, 3H, CH_2), 2.58–2.76 (m, 2H, CH_2), 4.19 (q, ^3J = 7.1 Hz, 2H, OCH_2). ^{13}C NMR ($CDCl_3$) δ: 14.1, 14.5, 18.8, 21.9, 22.0, 29.7, 35.2, 39.4, 53.6, 61.8, 171.6, 174.0, 175.5. EI-HRMS calcd. for $C_{13}H_{21}NO_4$: 295.1471; found: 295.1488.

Ethyl 1-(but-3-enyl)-2-[(butyryloxy)imino]cyclopentane carboxylate (11c)

^{1}H NMR ($CDCl_3$) δ: 0.99 (t, ^3J = 7.4 Hz, 3H, CH_3), 1.26 (t, ^3J = 7.1 Hz, 3H, CH_3), 1.71 (q, ^3J = 7.4 Hz, 2H, CH_2), 1.78–2.81 (m, 12H, CH_2), 4.19 (q, ^3J = 7.1 Hz, 2H, OCH_2), 4.92–5.06 (m, 2H, $=CH_2$), 5.70–5.90 (m, 1H, =CH). ^{13}C NMR ($CDCl_3$) δ: 14.1, 14.4, 18.7, 22.0, 27.8, 29.8, 34.9, 36.2, 37.5, 57.7, 61.9, 115.2, 138.2, 172.0, 172.9, 174.5. EI-HRMS calcd. for $C_{16}H_{25}NO_4$: 295.1784; found: 295.1790.

Ethyl 1-(hex-5-enyl)-2-[(butyryloxy)imino]cyclopentane carboxylate (11d)

^{1}H NMR ($CDCl_3$) δ: 1.02 (t, ^3J = 7.4 Hz, 3H, CH_3), 1.24 (t, ^3J = 7.1 Hz, 3H, CH_3), 1.62 (q, ^3J = 7.4 Hz, 2H, CH_2), 1.68–2.73 (m, 16H, CH_2), 4.17 (q, ^3J = 7.1 Hz, 2H, OCH_2), 4.76–4.98 (m, 2H, $=CH_2$), 5.56–5.78 (m, 1H, =CH).

R-(–)-Ethyl 2-(hex-5-enyl)-6-oxo-piperidine-2-carboxylate ((–)-15)

Tosyloxime **14** (0.20 g, 0.49 mmol) was dissolved in CH_2Cl_2 (15 mL) and silica gel (10 g) was added. The reaction slurry was stirred for 16 h, after which TLC control showed no starting material. The silica gel was filtered off and washed several times with a methanol–CH_2Cl_2 mixture. Residual toluene sulfonic acid was removed by washing with water, if necessary. The combined organic extracts were dried over $MgSO_4$, filtered, and evaporated under reduced pressure to afford slightly yellow crystals (0.97 g, 78%); mp 46.6°C. $[\alpha]_D^{20}$ –8.83 (*c* 1.22, $CHCl_3$). ^{1}H NMR ($CDCl_3$) δ: 1.26 (t, ^3J = 7.1 Hz, 3H, CH_3), 1.32–2.46 (m, 14H, CH_2), 4.18 (q, ^3J = 7.1 Hz, 2H, OCH_2), 4.82 (m, 2H, CH_2=), 5.78 (m, 1H, CH=), 6.13 (s, 1H, NH). ^{13}C NMR ($CDCl_3$) δ: 14.0, 17.8, 22.5, 28.5, 30.4, 30.8, 3.1, 40.0, 61.6, 62.7, 114.7, 138.0, 171.5, 173.1. Anal. calcd. for $C_{14}H_{23}NO_3$ (253.17): C 66.36, H 9.16, N 5.53; found: C 66.12, H 9.13, N 5.72.

R-(–)-Ethyl 2-(5-ethoxy-5-oxopentyl)-6-oxo-piperidine-2-carboxylate ((–)-16)

Ozone was passed through a mixture of lactam **15** (0.12 g, 0.47 mmol) dissolved in CH_2Cl_2 (4 mL) and ethanolic NaOH (2.5 mL, 2.5 M) at –78°C. This process was stopped when the characteristic blue color appeared. The reaction mixture was warmed to room temperature and diluted with water and ether. The organic layer was separated and the aqueous phase was extracted with ether (3 × 50 mL). The combined organic extracts were dried over $MgSO_4$, filtered, and the organic solvent was evaporated under reduced pressure to afford a colorless oil (0.13 g, 88%), which was analytically pure. $[\alpha]_D^{20}$ –6.60 (*c* 2.0, $CHCl_3$). ^{1}H NMR ($CDCl_3$) δ: 1.22 (t, ^3J = 7.1 Hz, 3H, CH_3), 1.26 (t, ^3J = 7.1 Hz, 3H, CH_3), 1.50–2.30 (m. 14H, CH_2), 4.09 (q, ^3J = 7.1 Hz, 2H, OCH_2), 4.18 (q, ^3J = 7.1 Hz, 2H, OCH_2), 6.30 (s, 1H, NH). ^{13}C NMR ($CDCl_3$) δ: 13.9, 14.0, 17.7, 22.7, 24.6, 30.2, 30.7, 33.7, 39.4, 60.1, 61.6, 62.5, 171.8, 172.8, 173.0. Anal. calcd. for $C_{15}H_{25}NO_5$ (299.36): C 60.18, H 8.42, N 4.68; found: C 60.32, H 8.11, N 4.71.

(–)-1-Azaspiro[5.5]undecane-2,7-dione ((–)-3)

To potassium *tert*-butoxide (0.17 g, 1.6 mmol) dissolved in pyridine (3 mL) under an argon atmosphere was added dropwise diester **16** (0.20 g, 0.7 mmol) in pyridine (3 mL). The reaction mixture was stirred for 2 h at 20°C. Diluted HCl was added and then brine (10 mL) was added. After extraction with ethyl acetate (3 × 40 mL), the combined organic extracts were washed with 5% HCl, water, 5% $NaHCO_3$, and brine, and then dried over $MgSO_4$, filtered, and evaporated. The remaining oily residue (0.12 g, 75%) was stirred with 1% NaOH (3 mL) overnight at room temperature, after which the reaction mixture was cooled to 0°C and 10% HCl (5 mL) was added. β-ketoacid **17** crystallized and was filtered off, dried over P_2O_5 (67 mg, 75%), and used without further purification. The β-ketoacid was dissolved in xylene (2 mL) and after addition of a small amount of *p*-toluene sulfonic acid was heated at reflux for 2 h. The organic solvent was removed under reduced pressure to afford colorless crystals (0.48 g, 90%); mp 148°C; $[\alpha]_D^{20}$ –36.0 (*c* 2.0, $CHCl_3$). ^{1}H NMR ($CDCl_3$) δ: 1.58–2.68 (m, 14H, 7 × CH_2), 6.60 (s, 1H, NH). ^{13}C NMR ($CDCl_3$) δ: 23.0, 24.7, 26.2, 35.3, 35.6, 35.7, 36.5, 66.3, 174.4, 211.3. Anal. calcd. for $C_{10}H_{15}NO_2$ (181.23): C 66.27, H 8.34, N 7.73; found: C 66.12, H 8.76, N 7.72.

Acknowledgments

N. Diedrichs and I. Gedrath would like to thank the Fonds der Chemischen Industrie for a doctoral scholarship. R. Krelaus has been awarded the Graduiertenförderung, for which he is very grateful. The work has been supported by the Fonds der Chemischen Industrie and by gifts from Amano.

Novel esterase activity of dihydrolipoamide acetyltransferase AcoC of *Pseudomonas putida* identified by mutation of the *acoR* regulator

Paola Pedroni, Thomas Friedrich, Michael Breuer, Dani McBeth, and Bernhard Hauer

Abstract: A mutant strain of *Pseudomonas putida* (LU2201) expressing a novel ethylphenylacetate (EPA) esterase was isolated after mutagenesis of *P. putida* LU6456. The DNA fragment conferring the EPA^+ phenotype was cloned and characterized. It included the structural genes of the 2,3-butanediol catabolic pathway, including *acoC*, which catalyzes the acetyl transfer step (i.e., dihydrolipoamide acetyltransferase). The *acoC* gene product from LU2201 was expressed in *E. coli* and shown to be responsible for the novel EPA-esterase activity. Biochemical characterization revealed that the enzyme still retained the natural dihydrolipoamide acetyltransferase activity. Sequence comparison with the corresponding wild-type gene indicated a single-base pair change leading to a I238V replacement in the respective protein. Biochemical characterization of wild-type AcoC enzyme showed that it too was able to catalyze EPA hydrolysis despite the apparent absence of this activity in cells grown in the presence of EPA. Unlike the wild type, EPA serves as an inducer in the mutant strain. Inverse PCR was used to clone the putative regulator *acoR* from the *aco* operon in both wild type and mutant strains. Sequence analyses indicated an S14R exchange in the AcoR from the *P. putida* mutant. This mutation was located in the *N*-terminal region responsible for regulatory functions, presumably by interaction with signal molecules. This may account for the ability of EPA to induce expression of *acoC* only in the mutant strain.

Key words: *Pseudomonas putida*, ethylphenylacetate esterase, acetoin cleaving system, *acoC* gene, dihydrolipoamide acetyl-transferase, E2 component, *acoR* gene.

Résumé : À la suite d'une mutagénèse de *P. putida* LU6456, on a isolé une nouvelle souche mutante de *Pseudomonas putida* (LU2201) qui exprime une nouvelle estérase du phénylacétate d'éthyle (« EPA »). On a cloner et caractériser le fragment d'ADN qui confère le phénotype EPA. Il comporte des gènes structuraux de la voie catabolique du butane-2,3-diol, y compris l'*aco*C catalyse l'étape de transfert du groupe acétyle (soit l'acétyltransférase dihydrolipoamide). Le gène *aco*C produit à partir du LU2201 est exprimé en *E. coli* et il a été démontré qu'il est responsable de la nouvelle activité estérase EPA. La caractérisation biochimique montre que l'enzyme a conservé l'activité acétyltransférase dihydrolipoamide naturelle. Une comparaison de la séquence avec celle du gène correspondant de type sauvage montre qu'il ne s'est produit qu'un seul changement de paire de bases qui conduit à un remplacement 1238V dans la protéine respective. La caractérisation biochimique de l'enzyme *aco*C de type sauvage a permis de montrer qu'il est aussi capable de catalyser l'hydrolyse EPA malgré l'absence apparente de cette activité dans les cellules cultivées en présence d'EPA. À l'inverse du produit de type sauvage, l'EPA est un inducteur dans la souche mutante. On a utilisé une « PCR » inverse pour cloner le régulateur putatif *aco*R à partir de l'opéron *aco* des souches mutantes ou de type sauvage. Une analyse de la séquence indique qu'un échange S14R s'est produit dans l'*Aco*R provenant du *P. putida* mutant. Cette mutation est localisée dans la région *N*-terminale responsable des fonctions de régulation, probablement par interaction avec les molécules qui signalent. Ceci pourrait expliquer l'habilité de l'EPA à n'induire une expression d'*aco*C qu'à partir de la variété mutante.

Mots clés : *Pseudomonas putida*, estérase de phénylacétate d'éthyle, système clivant l'acétoïne, gène d'*aco*C, transférase d'acétyle dihydrolipoamide, composant E2, gène d'*aco*R.

Introduction

Hydrolases are biocatalysts that have various industrial applications. In particular, lipases and esterases are employed for the synthesis of enantiomerically pure compounds (1), where they have been used for the resolution of more than 1000 different compounds including alcohols, carboxylic acids, and lactones by hydrolysis or transesterification. To develop industrial biocatalytic processes, suitable microbes or enzymes must be found and developed. The classical enrichment technique is still successful, but it is a time-consuming and labour-intensive task, even though novel screening approaches have accelerated the screening process (2). To alter an enzyme, various approaches involving both rational and non-rational design have been successfully used (3). We are interested in using natural-evolutionary processes to obtain new catalytic activities under selective pressure (4).

Pseudomonas is biochemically very versatile and shows a remarkable metabolic diversity. Members of this genus produce a number of lipases and esterases (5–7). The strain *Pseudomonas putida* LU6456, however, cannot hydrolyze phenylacetic acid or lactic or methylpropionic acid esters. Instead of screening for these activities in different strains, we explored the potential of adaptating *Pseudomonas putida* LU6465, by growing it on the above substrates and thereby acquiring the potential to hydrolyze them.

To increase the isolation frequency of *Pseudomonas putida* derivatives capable of using these esters as their sole carbon source, we used a 25-kb fragment of *Pseudomonas* plasmid (CAM-OCT DNA) encoding a DNA-repair gene or genes (8).

In this paper, we describe the isolation and the molecular characterization of the gene locus providing *P. putida* mutant strain LU2201 with a novel ethylphenylacetate (EPA) esterase activity. The results show that this enzymatic function is an inherent property of the *acoC* gene product, the dihydrolipoamide acetyltransferase enzyme of the acetoin cleaving system. Comparative studies with the wild-type strain indicate that *P. putida* LU2201 carries a regulatory mutation in the *N*-terminal domain of the putative positive activator AcoR, which accounts for the EPA$^+$ phenotype.

Material and methods

Bacterial strains and growth conditions

Bacterial strains and plasmids used in this study are listed in Table 1. *P. putida* was cultivated at 30°C as previously described (8). EPA (0.1%, w/v), glucose (0.2%, w/v), acetoin (0.2% w/v), glycerol (0.4%, w/v) or succinate (0.2% w/v, pH 7) were used as different carbon sources to analyze the induction of EPA-esterase activity. *E. coli* was grown in an LB medium at 37°C.

Mutagenesis and isolation of the *P. putida* EPA$^+$ mutant strain

Before UV mutagenesis, *P. putida* wild-type strain LU6456 was transformed with pDM101, a plasmid which increases UV-mutagenesis frequency (8), and bacterial colonies containing the plasmid were selected on NB plates. Cells were collected, suspended in NaCl 0.9% (w/v), and spread onto M9 plates containing tryptophan and EPA to identify the EPA$^+$ phenotype (9). After one day incubation at 30°C, plates were subjected to UV radiation at 254 nm, with 1500 Erg intensity for 10 s. Plates were then incubated at 30°C for two days and then at room temperature for several days more.

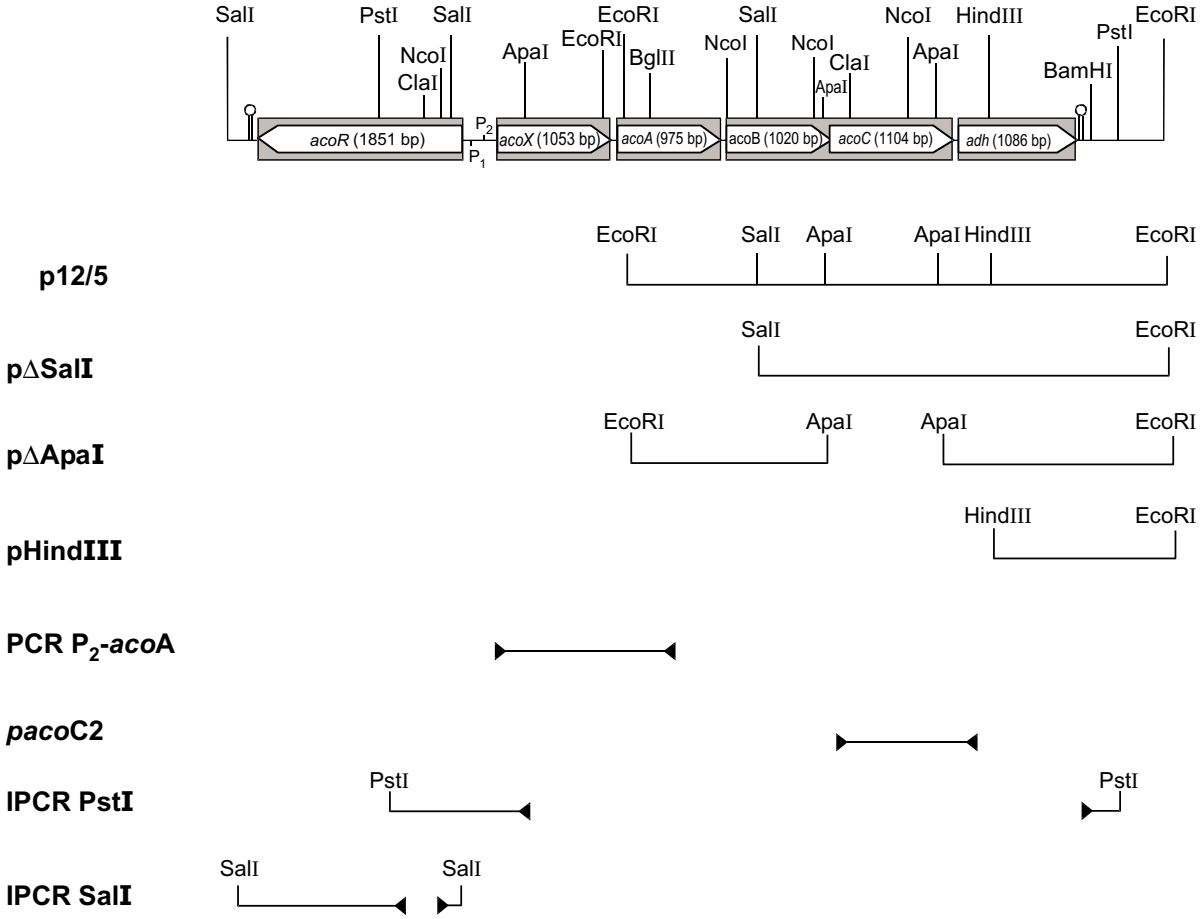
Fig. 1. Molecular organization of the 8.55 kb DNA fragment carrying the *P. putida* (LU2201 and LU6456) genes involved in the degradation of 2,3-butanediol and acetoin. Restriction map of the DNA region analyzed and physical organization of the genes is included. Indicated are the putative promoters (P_1: σ^{70}-type, P_2: σ^{54}-type) and the putative transcriptional terminators (stem-loops). Relevant DNA fragments used in this study. Triangles indicate the amplification directions of PCR and IPCR primers.



Recombinant DNA techniques, DNA sequencing, and PCR

Recombinant DNA techniques and PCR were performed according to standard protocols (9, 10). To clone the DNA fragment conferring the EPA^+ phenotype, total genomic DNA from *P. putida* LU2201 (0.5 μg) was digested with EcoRI and ligated to pUC19 vector. Approximately 3500 transformants were selected and screened for esterase activity.

IPCR amplifications

Inverse PCR (IPCR) reactions were carried using the Expand™ Long Template PCR System (Roche Biochemicals) according to Ochman et al. (11). The following amplification program was applied: initial denaturation at 95°C for 2 min, 30 cycles of denaturation at 95°C for 20 s, annealing at 65°C for 30 s, elongation at 68°C for 3 min, and a final elongation at 68°C for 8 min.

Expression of *acoC* gene in *E. coli* and purification of the recombinant enzyme

E. coli XL1-Blue transformed with *acoC* plasmids (Table 1) were grown in LB medium at 37°C. The expression of the *acoC* gene was induced by adding isopropyl-β-D-thiogalactoside (IPTG) to a final concentration of 1 mM. Cells were collected by centrifugation (10 min at 8000 × *g* at 4°C) and resuspended in 40 mL of homogenization buffer (20 mM NaH_2PO_4, 1% octylglucopyranoside, 0.05% NaN_3, pH 7). Cells were disrupted by sonication using a Branson Sonifier (1 × 8 min pulse 60% s^{-1} at 0°C) and the lysate was then centrifuged 10 min at 16 000 × *g* at 4°C to remove the cellular debris. The soluble extract was applied to a Chelating-Sepharose 6B column (1.5 × 12 cm, Pharmacia) loaded with Cu^{2+} and equilibrated with buffer A (20 mM NaH_2PO_4, 0.5% octylglucopyranoside, and 0.5 M NaCl, pH 7.7). The column was washed with 80 mL of buffer A and the adsorbed proteins were eluted with a linear gradient of 0 to 0.2 M imidazole-buffer A (pH 6.6). Elution was ended with 60 mL of buffer B. Fractions (5 mL) were collected at a flow rate of 1 mL min^{-1}. Esterase-containing fractions eluted at 0.16 M imidazole. Fractions with high EPA-esterase activity were pooled and concentrated. Purified samples were analyzed by SDS-PAGE and Western blotting and used in enzyme activity assays performed by HPLC.

Esterase activity assay

EPA-esterase production by cells containing suitable plasmids was directly tested on agar plates as described by

© 2002 NRC Canada

Sakimae et al. (12). HPLC analysis was used to determine the EPA-esterase activity in the soluble extracts, in purified samples of the recombinant enzyme, or in bacterial cell suspensions from different growth conditions. In the first two cases, the assay mixture contained 100 μL 1 M sodium phosphate (pH 7), 20 μL of EPA (1 g diluted in 10 mL of ethanol, 10% Triton X-100), and 100 μL of cell-free extract (in homogenization buffer, v.s.) or 0.2 to 6 μg of purified protein sample in a final volume of 1.0 mL. The reaction mixture was incubated at room temperature for 30 min and terminated by the addition of 0.1 mL of HCl (1 N). In the latter case, bacterial cells were collected from agar plates, suspended in 2 mL 100 mM KH_2PO_4 and diluted in H_2O to an OD_{600} value of 2.0. 100 μL of the diluted cultures were added to the same EPA-assay mixture described above. HPLC analysis was performed using a Lichrosorb RP15 column (4 × 250 mm; Merck, Darmstadt).

One unit (U) of EPA-esterase activity was defined as the amount of enzyme releasing 1 μmol of phenyl acetic acid per min.

Cleavage of ethyl-(*S*)-lactate (MEE) and methyl-(*R*,*S*)-ethylbutyrate (MBEE) was analyzed in the same way as EPA cleavage, using filter paper soaked with 0.1% of ethyl-(*S*)-lactate or methyl-(*R*,*S*)-ethylbutyrate, respectively.

Dihydrolipoamide acetyl transferase

Dihydrolipoamide acetyl transferase (DHLAT) activity was assayed by loading purified protein sample (8.5 μg) onto 10% polyacrylamide gels containing 0.2% SDS. The active protein band was visualized by precipitation of $Ca_3(PO_4)_2$ in the presence of acetylphosphate, coenzyme A, phosphotransacetylase from *Bacillus stearothermophilus*, and dihydrolipoamide during incubation of the gel as previously described (13).

Protein methods

Protein concentrations were determined using the method of Bradford (14), with bovine serum albumin as the standard. SDS-PAGE was carried out as described elsewhere (15).

Expression in pQE-8 plasmids yields recombinant protein with an *N*-terminal histidine tag. Immunoblot analyzes of purified preparations were performed using the QIA*express* Detection System (Qiagen GmbH, Hilden, Germany), which specifically identifies this tag. Using purified mouse monoclonal anti-$MRGS(H)_4$ antibodies according to manufacturer's instructions recombinant protein was detected.

Nucleotide sequence accession number

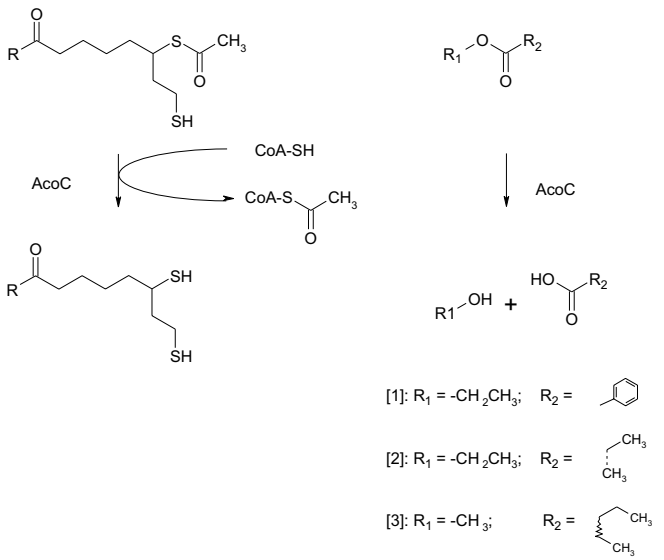
The nucleotide and amino acid sequence data reported in this paper have been submitted at the EMBL nucleotide sequence database under accession number Y11136.

Results

Cloning and characterization of the *P. putida* LU2201 DNA fragment conferring the EPA$^+$ phenotype

Using a method for enhanced UV-induced mutagenesis, we isolated a strain of *P. putida* LU6456 able to use EPA as the sole carbon source (EPA$^+$). This mutant strain designated LU2201 exhibited novel EPA-esterase activity not expressed in the wild type.

Fig. 2. (*a*) In vivo, AcoC (dihydrolipoamide *S*-acetyltransferase, EC 2.3.1.12) catalyzes the transfer of the acetyl group of *S*-acetyldihydrolipoamide to co-enzyme A. (*b*) Hydrolysis of ethyl-phenylacetate (1), ethyl-(*S*)-lactate (MEE) (2), and methyl-(*R*,*S*)-ethylbutyrate (MBEE) (3) by AcoC.



A genomic-DNA library was constructed from LU2201 in *E. coli* and screened for esterase activity by an EPA filter-paper assay and HPLC analysis. Nine (0.26%) EPA-positive transformants were obtained. The EPA-esterase activity measured in cell suspensions was approximately 0.9 U L^{-1}. All clones contained a pUC19 vector containing the same 5.1 kb EcoRI DNA insert. This plasmid was designated p12/5.

The nucleotide sequence of the 5.1-kb EcoRI DNA fragment was determined. DNA database searches revealed strong homologies to structural genes and proteins of the acetoin (3-hydroxy-2-butanone) cleaving systems from different bacteria. In particular, a nearly complete sequence identity to the *acoABC* genes and *adh* gene from *P. putida* strain PpG2 (16) was detected.

The 5.1-kb fragment lacks the putative σ^{54}-type promoter of the operon, the entire *acoX* gene, and the 5′ portion of *acoA*. (Fig. 1).

Identification of *acoC* as the gene responsible for EPA-esterase activity

To determine which gene was responsible for EPA-esterase expression, a deletion analysis of the p12/5 DNA insert was performed.

Three plasmids, pΔSalI, pΔApaI, and pΔHindIII were constructed (Fig. 1). EPA-esterase filter- paper assays showed that the only positive clone was pΔSalI, indicating that the EPA-esterase activity was associated with the *acoC* gene, which encodes dihydrolipoamide acetyltransferase (DHLAT). In vivo this enzyme transfers the acetyl-group of *S*-acetyldihydrolipoamide to coenzyme A (Fig. 2*a*).

The *acoC* gene was subcloned to the expression vector pQE-8 (Qiagen GmbH, Hilden, Germany) to express and

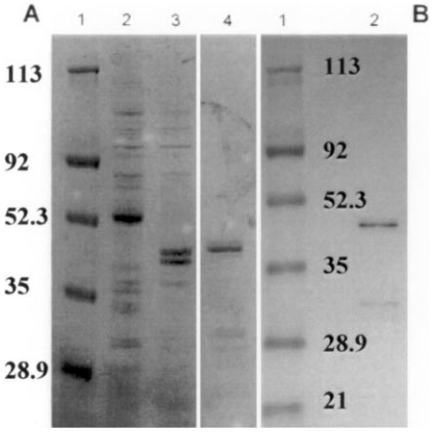
Fig. 3. Expression of *P. putida* LU2201 *acoC* gene in *E. coli* XL1-Blue. Coomassie Blue-stained 10% SDS-PAGE (**A**) and Western blot analysis (**B**) of soluble fractions and purified protein sample. Molecular mass standards (lane 1): 113, 92, 52.3, 35, 29.9, and 21 kDa. (*a*) Soluble proteins of the cell-free extract from *E. coli* XL1-Blue (lane 2, negative control), from *E. coli* carrying p*acoC* 2 plasmid (lane 3). Lane 4, purified AcoC enzyme from *E. coli* cells containing the p*acoC* 2 plasmid. (*b*) Purified AcoC enzyme from *E. coli* cells containing p*acoC* 2 (lane 2).



study the protein in *E. coli*. The resulting EPA^+ plasmids p*acoC* 2, (Table 1 and Fig. 1) leads to an EPA-esterase activity of 100.8 U L^{-1}, which is 112-fold higher than *E. coli* bearing the p12/5 plasmid.

Purification and biochemical properties of the recombinant AcoC enzyme

Purification of the recombinant enzyme expressed by p*acoC* 2 was accomplished in a one-step procedure as described above. SDS-PAGE and Western blot analyses of the purified protein sample are shown in Fig. 3.

Activity staining for DHLAT was carried out to verify that the purified AcoC enzyme still catalyzed its physiological reaction (Fig. 3). Protein degradation results in an additional signal with a smaller molecular weight visible in lane 2 of Figs. 3*b* and 4*b*. The positive result shows that the *acoC*-encoded polypeptide from the *P. putida* mutant is a bifunctional enzyme catalyzing both the cleavage of EPA esters and performing its natural reaction as DHLAT.

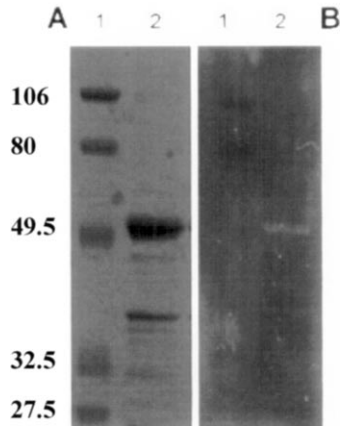
Sequence comparison to the *acoC* gene product from wild-type *P. putida* LU6456

A comparison of the mutant *acoC* gene to the wild type showed a single-base pair change. This mutation results in a conservative substitution of I238 for V in the mutated AcoC (Fig. 5). The amino acid sequences of the AcoC proteins from *P. putida* LU2201 and LU6456 strains were compared with various AcoC enzymes. The alignment shows that in the protein region where the I238V substitution occurred, AcoC sequences do not show a high degree of conservation.

EPA-esterase activity of *P. putida* wild-type AcoC enzyme

The *acoC* gene from the wild-type strain was cloned on plasmid p*aco*C3 and expressed in *E. coli*. The EPA-activity filter-paper assay also gave a positive response for extracts

Fig. 4. Dihydrolipoamide acetyl transferase (DHLAT) activity assay of the recombinant *P. putida* LU2201 *acoC* gene product. Coomassie Blue-stained 10% SDS-PAGE (*a*) and corresponding DHLAT activity staining gel (*b*) of purified protein sample. Lane 1, molecular mass standards: 106, 80, 49.5, 32.5, and 27.5 kDa; lane 2, purified AcoC enzyme from *E. coli* cells carrying p*acoC* 2 plasmid.



from strains carrying the wild-type gene. Expression experiments indicated that the product of the structural gene *acoC*, from both *P. putida* strains, is a bifunctional enzyme establishing that the I238V substitution alone cannot account for the EPA-esterase activity of LU2201.

Induction of EPA-esterase activity

We investigated the possibility that EPA-esterase activity could also be induced in the *P. putida* wild type using different substrates in addition to acetoin, the direct inducer of *aco* genes. Both strains were grown under different conditions and then bacterial-cell suspensions, collected from agar plates, were assayed for EPA-esterase activity by HPLC (Table 2). Several substrates were able to induce EPA-esterase activity in the *P. putida* wild type. In minimal medium, acetoin acted as the strongest inducer for both strains.

MEE and MBEE esterase activity of AcoC enzyme

MEE and MBEE esterase activities of AcoC enzyme were assayed in both *P. putida* and *E. coli* cells bearing different expression plasmids in which the genes were singularly and constitutively expressed. Both mutated and wild-type AcoC enzymes expressed in *E. coli* were able to hydrolyze MEE and MBEE esters in addition to EPA.

In both *P. putida* LU2201 and LU6456 there is no expression of the *acoC* gene when either MEE or MBEE esters are added as inducers, whereas EPA induces *acoC* expression in LU2201.

Identification and characterization of the regulatory gene *acoR*

To verify whether additional mutations might be present in the *P. putida* LU2201 genome, we characterized the remainder of the *aco* operon and the promoter region not included in the 5.1-kb DNA fragment originally cloned.

On the basis of the molecular organization of the *aco* gene cluster in *P. putida* strain PpG2, a 1.3-kb DNA fragment encompassing the putative σ^{54}-type promoter and the 5′ end of

Cultivation	*P. putida* LU6456 wild type EPA-esterase activity (U L^{-1})	*P. putida* LU2201 mutant EPA-esterase activity (U L^{-1})
MM + EPA	n.d.	141.1
MM + acetoin	18.93	303.1
MM + glucose	0.5	12.51
MM + glycerol	2.19	35.7
MM + succinate	0.28	4.3
LB	0.19	0.7
LB + EPA	0	2.1
LB + acetoin	2.42	27.1

Note: *P. putida* strains were grown on mineral medium (MM) + tryptophan (41 μg mL^{-1}) plates in the presence of EPA (0.1%, w/v), acetoin (0.2% w/v), glucose (0.2%, w/v), glycerol (0.4%, w/v) or succinate (0.2% w/v, pH 7) at 30°C. In MM + EPA, *P. putida* LU6456 is not able to grow.

the *aco* operon was isolated by PCR from both *Pseudomonas* strains (Fig. 1). Nucleotide sequence of PCR product P_2-acoA analysis showed the two DNA fragments isolated from *P. putida* wild type and the mutant strain were absolutely identical.

Regulatory genes (designated *acoR* or *acoK*) for the respective *aco* operons have been identified in *A. eutrophus*, *C. magnum*, and *K. pneumoniae* (17–19). In *P. putida* an *acoR*-like gene has not yet been identified. In both *P. putida* strains the DNA region upstream from the putative σ^{54}-type promoter of the *aco* operon was isolated by IPCR. Two IPCR-fragments of 1.2 and 1.6 kb were isolated (Fig. 1). These fragments comprise a total of 2.2 kb of DNA located upstream from the *aco* operon promoter. Nucleotide sequence comparison between the two *P. putida* genomic fragments identified a single-base pair change in the DNA from mutant strain LU2201. This mutation results in an S14R exchange in the corresponding polypeptide.

To study the function of the mutant gene *acoR*S14R in the wild type, we subcloned it in the HindIII site of the plasmid pLAFR1 (20). By conjugation, this construct was introduced into *P. putida*. Exconjugants containing pLAFR::*acoR*S14R had a EPA^+ phenotype. When grown on minimal medium containing EPA, theses strains had an EPA activity of 14.8 U L^{-1}.

Discussion

In the present paper, we isolated and characterized the gene locus conferring the capability to hydrolyze EPA-esters by a novel esterase from *P. putida*. The *P. putida* LU2201 genomic fragment responsible for the EPA^+ phenotype was cloned in *E. coli*. Sequencing analysis revealed that the cloned DNA encodes the structural genes involved in the cleavage of acetoin. Subcloning of the fragment showed that EPA-esterase activity was solely due to the *acoC* gene product DHLAT. Heterologous expression of the *acoC* gene from the *P. putida* mutant revealed that in addition to the cleavage of EPA esters the recombinant enzyme still catalyzes its physiological reaction. By comparative sequence analysis of *acoC* from wild type and LU2201, a single-base pair change causing a conservative I238V replacement in the *C*-terminal region of the mutant *acoC* was determined. Expression of the wild-type *acoC* gene in *E. coli* led to the detection of EPA-esterase activity in the wild-type enzyme as well.

Our findings show that the mutation detected in the AcoC protein from strain LU2201 does not account for the EPA^+ phenotype of this mutant. Rather, the *acoC*-encoded polypeptide from *P. putida* is a bifunctional enzyme and possesses the entire catalytic machinery required to perform both the hydrolysis of the EPA-ester bond and the acetyltransfer step to co-enzyme A. Other enzymes having bi- or even multifunctionalities are well known. For example, an enzyme from *Amycolatopsis* species, which was prematurely identified as an *N*-acylamino acid racemase turned out to be an *O*-succinylbenzoate synthase after a thorough investigation of its genetic environment (21).

In essence, our observations can be considered a snapshot in the course of enzyme evolution. Due to a mutation in the regulatory mechanism of an organism, a thus-far cryptic-catalytic function of an enzyme becomes apparent. In the course of evolution, this enzyme may evolve further away from its original ancestor. In this case, a situation may develop as we find it in the enolase superfamily, where a number of enzymes with different specificities evolved from the same molecular scaffold (12, 22, 23).

Expression experiments indicate that *P. putida* strain LU2201 is altered in its inducer specificity, since the mutant strain, unlike the wild type, is capable of recognizing EPA. This is likely due to a mutation in the regulatory apparatus of the *acoC* gene. This assumption is corroborated by the induction of EPA-esterase activity in *P. putida* wild type by

© 2002 NRC Canada

acetoin (Table 2). Isolation of the DNA region located upstream from the *aco* operon in both *Pseudomonas* strains enabled us to identify *acoR*, the product of which exhibited a striking homology to *A. eutrophus* and *C. magnum* AcoR polypeptides and to other transcriptional activators from different sources (17–19). In the AcoR of the mutant strain, we find an S14R substitution in the *N*-terminal part of the molecule. In similar regulatory proteins, this region was shown to be essential for the interaction with the respective signal molecules. We therefore suggest that mutation of *acoR*S14R alters the specificity of the respective protein in such a way that it can interact with EPA. The EPA–AcoRS14R complex acts as inducer for the *aco* operon, ultimately enabling AcoC to catalyze the hydrolysis of the non-natural substrate EPA. This hypothesis is supported as well by the results from the transformation experiments with pLAFR::*acoR*S14R.

Regulatory mutations may be important events for the in vivo development of new enzyme activities. A mutation in the regulatory apparatus of β-galactosidase is described to precede the evolution of this enzyme (24). In this case, however, the biocatalyst does not have bifunctional properties as in the case of AcoC.

The EPA-esterase activity of the bifunctional AcoC was not predictable from the structure of the protein. Rational approaches to identify the esterase from sequence data would likely have failed. This work describes a novel approach to identify biocatalysts. Regulatory mutants are generated, resulting in a deregulation of otherwise tightly repressed genes. This leads to the production of proteins, which normally would not have been detectable. By screening with the desired substrate, novel enzymes can de identified. This approach broadens the potential of screening for natural diversity; traditional techniques rely on the genes expressed under the respective growth conditions. Non-natural substrates, which are often targets of industrial biocatalysis, may not trigger the appropriate regulatory mechanism in vivo. Thus, potentially useful enzymes remain concealed. As shown for the EPA-esterase from *P. putida*, deregulation by mutation can give access to those hidden genes.

Enzymatic hydrolysis of β-lactam antibiotics at low pH in a two-phase "aqueous solution – water-immiscible organic solvent" system

Ghermes G. Chilov and Vytas K. Švedas

Abstract: The application of the two-phase "aqueous solution – water-immiscible organic solvent" system is suggested not for effective biocatalytic synthesis, but for hydrolytic purposes. Enzymatic hydrolysis of benzylpenicillin and *N*-phenylacetamidodesacetoxycephalosporanic acid to corresponding antibiotic nuclei 6-aminopenicillanic and 7-aminodesacetoxycephalosporanic acids in a two-phase water–butylacetate system at pH 3–4 is proposed as an alternative to the biocatalytic hydrolysis in an alkaline medium. An experimental study has been performed and a model has been developed, which describes the influence of pH, phase volume ratio, thermodynamic constants, and initial antibiotic concentration on the effectiveness of their hydrolysis in a two-phase "aqueous solution – water-immiscible organic solvent" system. The thermodynamic evaluation of penicillin G and 7-phenylacetamidodesacetoxycephalosporanic acid hydrolysis at low pH in a two-phase aqueous solution – water-immiscible organic solvent system has demonstrated high practical potential. The suggested approach allows for the exclusion of several technological steps during the transformation of natural β-lactam antibiotics to their semi-synthetic analogues: alkaline extraction of the biosynthetic antibiotic from butylacetate followed by its enzymatic hydrolysis at pH 7.5–8.0 and further acidification of the reaction mixture, which results in the precipitation of the antibiotic nucleus. Experimental observations also revealed a specific feature of this process: the kinetic supersaturation of the antibiotic nucleus slows down the attainment of the equilibrium, which should be taken into account when further developing this approach.

Key words: enzymatic hydrolysis, β-lactam antibiotic nuclei, two-phase systems, supersaturation, penicillin acylase.

Résumé : On propose l'utilisation du système à deux phases « solution aqueuse – solvant organique immiscible dans l'eau », non pas pour des synthèses biocatalytiques efficaces, mais pour des fins d'hydrolyse. On propose une hydrolyse enzymatique dans le système à deux phases eau–acétate de butyle à un pH allant de 3 à 4 comme alternative à l'hydrolyse biocatalytique en milieu alcalin de la benzylpénicilline et de l'acide *N*-phénylacétamidodésacétoxycéphalosporanique conduisant aux noyaux des antibiotiques correspondants, les acides 6-aminopénicillanique et 7-aminodésacétoxycéphalosporanique. On a effectué une étude expérimentale et on a développé un modèle qui permet de décrire l'influence du pH, du rapport des volumes dans la phase, des constantes thermodynamiques et de la concentration initiale d'antibiotique sur l'efficacité de leurs hydrolyses dans un système à deux phases « solution aqueuse – solvant organique à deux phases ». L'évaluation thermodynamique de l'hydrolyse de la pénicilline G et de l'acide 7-phénylacétamidodésacétoxycéphalosporanique à faible pH, dans un un système à deux phases « solution aqueuse – solvant organique à deux phases » a permis de démontrer le caractère très pratique de ce système. L'approche suggérée permet d'exclure plusieurs étapes technologiques de la transformation des antibiotiques β-lactames naturels en leurs analogues semi-synthétiques, telle l'extraction alcaline de l'antibiotique biosynthétique de l'acétate de butyle, suivie de son hydrolyse enzymatique à pH de 7,5 à 8,0 et de l'acidification subséquente du milieu réactionnel pour précipiter le noyau de l'antibiotique. Une réalisation expérimentale de cette approche a aussi permis de mettre en évidence une caractéristique spécifique du procédé: dans le développement de cette approche, on doit tenir compte du fait que la sursaturation cinétique du noyau antibiotique ralentit l'obtention de l'équilibre.

Mots clés : hydrolyse enzymatique, noyau antibiotique β-lactame, systèmes à deux phases, sursaturation, acylase de pénicilline.

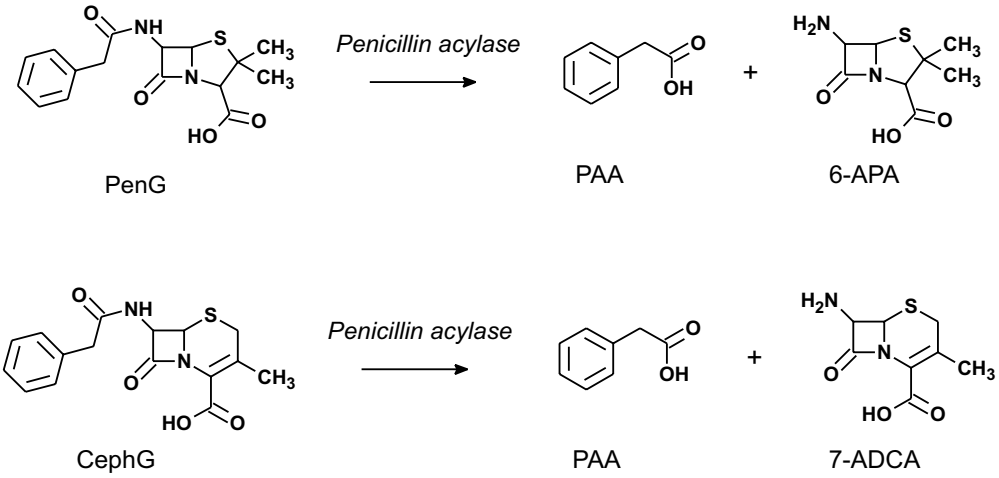
Fig. 1. Penicillin acylase catalyzed hydrolysis of benzylpenicillin (Pen G) and 7-phenylacetamidodesacetoxycephalosporanic acid (CephG) to antibiotic nuclei (6-APA and 7-ADCA, respectively) and phenylacetic acid (PAA).



Introduction

In a technological scheme of natural penicillin conversion to its semi-synthetic analogues, penicillin G (Pen G) is first extracted from the fermentation broth by organic solvent (butylacetate, amylacetate) at pH 2.0–2.5 (1). After back-extraction into aqueous solution, it is enzymatically hydrolyzed at pH 7–8 (Fig. 1). After acidification of the reaction mixture, the antibiotic nucleus is isolated by precipitation at its isoelectric point (pH 3.5) (2). Attractiveness of such process stems mainly from thermodynamic considerations, where antibiotic hydrolysis could reach nearly quantitative yields above pH 7 (3). Moreover, the optimum pH (7.5–8.0) of penicillin acylase catalytic activity coincides well with these conditions (4). The major shortcomings of the above-mentioned Pen G conversion to 6-aminopenicillanic acid (6-APA) include numerous pH shifts leading to formation of waste inorganic salts and degradation of a β-lactam ring in an alkaline medium. Additionally, kinetic factors such as strong product inhibition (competitive by phenylacetic acid and non-competitive by 6-APA) should be borne in mind (5). These drawbacks can, however, be avoided in the process presented in this work — the hydrolysis of biosynthetic β-lactam antibiotics Pen G and 7-phenylacetamidodesacetoxycephalosporanic acid (Ceph G) at pH 3–4 in a two-phase water–butylacetate system. Butylacetate containing the acidic form of the antibiotic can be directly added to an aqueous phase containing penicillin acylase, which is followed by partitioning of antibiotic between two phases, hydrolysis of the antibiotic in an aqueous phase, precipitation of an antibiotic nucleus (whose solubility in the considered pH range is the lowest possible), and partitioning of the second reaction product (phenylacetic acid) between the two phases. In addition to the reduction of technological steps, the suggested process can improve the quality and the yield of the reaction product since several factors leading to the degradation of β-lactam ring are excluded. It is worth noting that two-phase water-immiscible organic solvent systems have so far only been evaluated for performing synthetic reactions (6, 7), while the hydrolytic potential of these systems has been deprived of proper attention. For practical implementation of this process in hydrolysis (e.g., in the countercurrent biocatalytic reactor, as recently proposed by Straathof et al. (8)), it is necessary to conceive the thermodynamic and kinetic parameters of the system, which influence the effectiveness of this process. Here, a more detailed analysis of thermodynamic model of β-lactam antibiotic hydrolysis in a two-phase aqueous solution – water-immiscible organic solvent system is described and some kinetic features of the process are shown to be crucial. Critical evaluation of the experimental results and mathematic modeling demonstrate the potential of the proposed process.

Theoretical aspects

Thermodynamics of hydrolysis in a two-phase system at low pH

Thermodynamic regularities of antibiotic hydrolysis in a two-phase aqueous solution – water-immiscible organic solvent system should take into account the following physicochemical processes:

(*i*) Partition of acidic form of antibiotic (ABH) between two phases:

$$[1] \qquad ABH_{org} \Leftrightarrow ABH$$

with a partition constant of

$$[2] \qquad K_{P,ABH} = \frac{[ABH_{org}]}{[ABH]}$$

(*ii*) Dissociation of ABH in an aqueous phase (p*K* of the carboxylic group of β-lactam antibiotics is close to 2.5):

$$[3] \qquad ABH \Leftrightarrow AB^- + H^+$$

with a dissociation constant of

$$[4] \qquad K_{a,ABH} = \frac{[H^+][AB^-]}{[ABH]}$$

(*iii*) Enzymatic hydrolysis in an aqueous phase:

$$[5] \qquad AB^- + H_2O \Leftrightarrow AH + B^-$$

and the corresponding equilibrium constant:

© 2002 NRC Canada

$$[6] \quad K_{synth,AB} = \frac{[AB^-]}{[AH][B^-]}$$

where AH is a protonated form of phenylacetic acid and B^- is an anionic form of antibiotic nucleus.

(*iv*) Partition of a protonated form of phenylacetic acid between two phases:

$$[7] \quad AH \Leftrightarrow AH_{org}$$

with a partition constant of

$$[8] \quad K_{P,AH} = \frac{[AH_{org}]}{[AH]}$$

(*v*) Dissociation of phenylacetic acid in an aqueous phase:

$$[9] \quad AH \Leftrightarrow A^- + H^+$$

with a dissociation constant (p*K* 4.3) of

$$[10] \quad K_{a,AH} = \frac{[H^+][A^-]}{[AH]}$$

(*vi*) Protonation of an amino group of the antibiotic nucleus (p*K* about 4.7):

$$[11] \quad B^- + H^+ \Leftrightarrow BH^{\pm}$$

with a dissociation constant of

$$[12] \quad K_{a2,BH} = \frac{[B^-][H^+]}{[BH^{\pm}]}$$

(*vii*) Protonation of a carboxylic group of the nucleus (p*K* 2.5):

$$[13] \quad BH^{\pm} + H^+ \Leftrightarrow BH_2^{\pm}$$

with a dissociation constant of the Zwitter-ionic form of

$$[14] \quad K_{a1,BH} = \frac{[BH^{\pm}][H^+]}{[BH_2^+]}$$

(*viii*) Precipitation of the Zwitter-ionic form of antibiotic nucleus:

$$[15] \quad BH^{\pm} \Leftrightarrow BH^+_{ppt}$$

which should make its concentration in an aqueous phase equal to its solubility:

$$[16] \quad [BH^{\pm}] = [BH^{\pm}_{sol}]$$

Bearing in mind the relations mentioned above, we can trace the factors that determine the yield of antibiotic nucleus in the corresponding hydrolysis. Reserving η for the reaction yield, the total content of each component (i.e., concentrations of all ionic forms in the co-existing phases) can be represented as

$$[17] \quad [AB] = (1 - \eta)[AB]_0$$

$$[18] \quad [A] = \eta[AB]_0$$

$$[19] \quad [B] = \eta[AB]_0$$

Concentration of a certain ionic species in an aqueous medium can be expressed as

$$[20] \quad [AB^-] = [AB]F_{AB^-}$$

$$[21] \quad [AH] = [A]F_{AH}$$

where

$$[22] \quad F_{AB} = \frac{1}{1 + \frac{[H^+]}{K_{a,ABH}}(1 + \alpha K_{P,ABH})}$$

$$[23] \quad F_{AH} = \frac{1}{1 + \frac{[H^+]}{K_{a,AH}}(1 + \alpha K_{P,AH})}$$

which follow from the eqs. [2], [4], [8], and [10], respectively (where α is the phase-volume ratio). If concentration of the Zwitter-ionic form is confined by its solubility $[BH^{\pm}_{sol}]$,

$$[24] \quad [B] = [BH^{\pm}_{sol}]\frac{K_{a1,B}}{[H^+]}$$

then the thermodynamic equilibrium of hydrolysis can be expressed in the following way:

$$[25] \quad K_{synth,AB} = \frac{(1-\eta)[AB]_0 F_{AB}}{\eta[AB]_0 F_{AH}[BH^{\pm}_{sol}]\frac{K_{a1,B}}{[H^+]}}$$

The final expression for the reaction yield can be written as

$$[26] \quad \eta = \frac{1}{1 + K_{synth,AB}[BH^{\pm}_{sol}]\frac{K_{a1,B}}{[H^+]}\frac{F_{AH}}{F_{AB}}}$$

Factors that influence the yield of hydrolysis

As seen from the previous paragraph, the yield of the antibiotic nucleus is a complex parameter determined by the thermodynamic constant of hydrolysis, the dissociation and partition constants, and the solubility of the product. Using eq. [26], we can estimate their impact on the outcome of the process.

The effectiveness of the hydrolysis in a two-phase system under a given set of conditions does not depend on the initial antibiotic concentration. Such a conclusion might seem strange, especially if one takes into consideration that in the industrial processing of penicillin, hydrolysis at pH 7–8 (its starting concentration) does not exceed 0.25 M — because of the thermodynamic limitations. A further increase of the substrate concentration would lead to the decrease in the yield of 6-APA (9). But this conclusion is only valid for homogeneous solutions. If precipitation of the product(s) occurs, such a dependence on the initial substrate concentration would also disappear. From a practical point of view, the larger the substrate concentration converted, the higher the productivity of the process.

In evaluating the influence of different factors on the degree of antibiotic conversion, it is important to note that when some characteristics of the two-phase system (thermo-

© 2002 NRC Canada

dynamic constant of hydrolysis, dissociation and partition constants of certain reaction components) are fixed, parameters such as pH and phase volume ratio (α) represent extra degrees of freedom, which must be taken into account when looking for optimal processing conditions.

The pH dependence of a conversion is stipulated by the presence of ionogenic groups capable of dissociation in a pH range of 3–4. It follows from thermodynamic considerations that hydrolysis in an alkaline medium is nearly irreversible. Degradation of β-lactam rings at higher pH, however, limits its application for the biocatalytic process in this pH range, making the biocatalytic process optimal in a pH range of 7–8. In a two-phase system, the situation is quite different. Removal of both reaction products out of the reaction sphere (i.e., precipitation of 6-APA and partition of phenylacetic acid) promotes enzymatic hydrolysis, making the biocatalytic process optimal in acidic medium. In a two-phase system, a pH increase above pH 4.4 hampers extraction of phenylacetic acid into the organic phase, prevents 6-APA precipitation, and, in contrast to homogeneous reactions, does not improve hydrolysis. Analysis of eq. [26] shows that with a pH decrease, antibiotic conversion approaches a definite value:

$$[27]\quad \eta_{\mathrm{pH}\to 0} = \frac{1}{1 + K_{synth,\mathrm{AB}}\,[\mathrm{BH}^{\pm}_{\mathrm{sol}}]\dfrac{K_{a1,\mathrm{B}}}{K_{a,\mathrm{AB}}}\dfrac{1 + K_{P,\mathrm{ABH}}\,\alpha}{1 + K_{P,\mathrm{AH}}\,\alpha}}$$

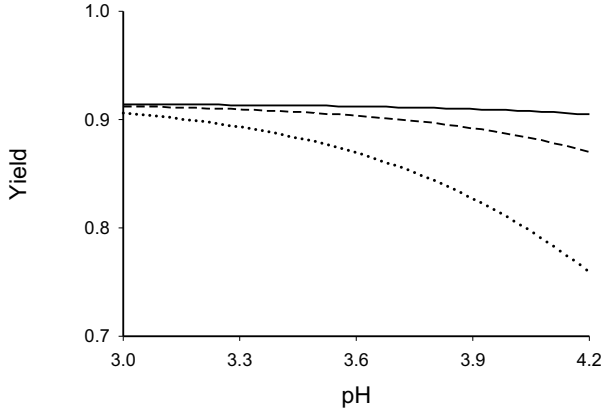
It is quite clear that the optimal yield is determined both by thermodynamic characteristics and phase volume ratio (α). The influence of the latter parameter, however, is quite limited. Generally, the values of the partition constants are several tens in its magnitude, and hence under reasonable values of α the value of $K_P\alpha$ sufficiently exceeds the unity. Taking this into consideration, eq. [27] may be reduced to

$$[28]\quad \eta_{\mathrm{pH}\to 0} = \frac{1}{1 + K_{synth,\mathrm{AB}}\,[\mathrm{BH}^{\pm}_{\mathrm{sol}}]\dfrac{K_{a1,\mathrm{B}}}{K_{a,\mathrm{AB}}}\dfrac{K_{P,\mathrm{ABH}}}{K_{P,\mathrm{AH}}}}$$

Finally, within the set of thermodynamic parameters and their combinations (which determine the yield), we can distinguish three basic parameters: (*i*) The product of the thermodynamic antibiotic synthesis constant and the solubility of the Zwitter-ionic form of the nucleus ($K_{synth,\mathrm{AB}}[\mathrm{BH}^{\pm}_{\mathrm{sol}}]$). It should be emphasized that the impact of these two parameters on the yield is reciprocal, i.e., any deterioration of the thermodynamics of the hydrolysis could, in principle, be compensated for by lowering the product solubility. (*ii*) The difference in the p*K* of the amino group of antibiotic nuclei and the carboxylic group of the substrate, where protonation of the former leads to the domination of the Zwitter-ionic form (low solubility), while deprotonation of the latter assists in the extraction of the substrate into aqueous phase. (*iii*) The ratio of the partition constants of antibiotic and the phenylacetic acid, where partition of the substrate into the aqueous phase and product withdrawal to the organic phase favors conversion.

Of particular interest is determining the degree of conversion under given conditions. This is especially intriguing, since biocatalytic hydrolysis at pH 7.5–8 was already shown to be quite acceptable. To illustrate this point, we first analyzed the dependence of the yield of 6-APA, calculated on the basis of the model presented above (Fig. 2), using thermodynamic parameters from the literature (Table 1).

Fig. 2. Dependence of 6-APA yield during Pen G hydrolysis in a two-phase system, calculated with the eq. [18] on the basis of constants given in Table 1. Dashed line $\alpha = 1$; solid line $\alpha = 5$; dotted line $\alpha = 0.2$.



According to thermodynamic predictions, the yield of 6-APA under pH 3–4 with a single hydrolytic step is close to 90%, which may be considered quite satisfactory. But one should determine whether such yields are achievable in practice and if the kinetics of the thermodynamically controlled hydrolysis of antibiotics under a given set of conditions is achievable. The aim of this paper is to report the results of Pen G and Ceph G hydrolysis in a two-phase aqueous solution – water-immiscible organic solvent system at acidic pH.

Materials and methods

Materials

6-APA, 7-ADCA, Pen G-K salt, Ceph G, and penicillin acylase from *E. coli* (ATCC 11105) were kind gifts from DSM (the Netherlands). The concentration of the enzyme-active sites was determined by titration with PMSF (15) and found to be 3.2×10^{-4} M. PAA was from Aldrich, butyl acetate from Fluka, acetonitrile (HPLC grade) from Kriochrom (Russia), sodium dodecylsulfate, the components of the buffer systems, and all other reagents were from Merck. In all experiments MilliQ (Millipore) water was used.

Enzymatic hydrolysis in a two-phase system

Each experiment was performed in a series of microtubes (Eppendorf) in a shaker at 20°C. The total reaction volume was 500 μL. A stock solution of Pen G (0.1 M) was prepared by dissolving the corresponding amount of Pen G–K salt in water. Equal volumes of BuAc and Pen G stock solutions (250 μL of each) were placed in a microtube and the pH was adjusted to a required value with phosphoric acid (less than 5 μL). At cephalosporin hydrolysis, a definite amount of Ceph G (acidic form) was placed in 250 μL of BuAc, the suspension was then treated in an ultrasonic bath (Branson 2510) for 10 min to dissolve the substrate, the required volume of water was added, the system was stirred in the centrifuge, and the pH was adjusted with a KOH solution.

[a]Values from ref. 10.
[b]Values from ref. 11.
[c]Values from ref. 12.
[d]Values from ref. 13.
[e]Values from ref. 14.

Reactions were started by adding 7.8 μL of stock PA solution.

Reactions in close-to-equilibrium systems

Reaction conditions (e.g., total reaction volume, temperature, phase volume ratio) were similar to those described above. Stock solutions were prepared by dissolving definite amounts of antibiotic and phenylacetic acid in water; after mixing with BuAc, a required amount of solid 6-APA (or 7-ADCA) was added, and the pH was adjusted with phosphoric acid.

Analysis

To analyze the total content of both the aqueous and organic phases, 10 mL of the stop-reagent (50% of HPLC eluent (v/v) and acetonitrile) was added to the reaction mixture (500 μL) at a definite moment. An aliquot of the obtained solution was diluted with the eluent [potassium phosphate buffer (0.68 g L^{-1}, pH 3.0), sodium dodecylsulfate (100 mg L^{-1}), and CH_3CN (24%, v/v)] and analyzed by HPLC using a Waters system with a Chrompack Nucleosil-C18 4.6 × 250 mm column, Waters Lambda-Max Model 481 detector at 210 nm, and a Waters 6000A pump with a flow of 1 mL min^{-1}. Once the 6-APA concentration in an aqueous phase was determined, the reaction mixture was centrifuged for 1 min at 13 200 rpm (Eppendorf 5415D), and then 10 μL of the aqueous phase were added to 1 mL of the stop-reagent. After dilution with the eluent, an aliquot was subjected to HPLC analysis.

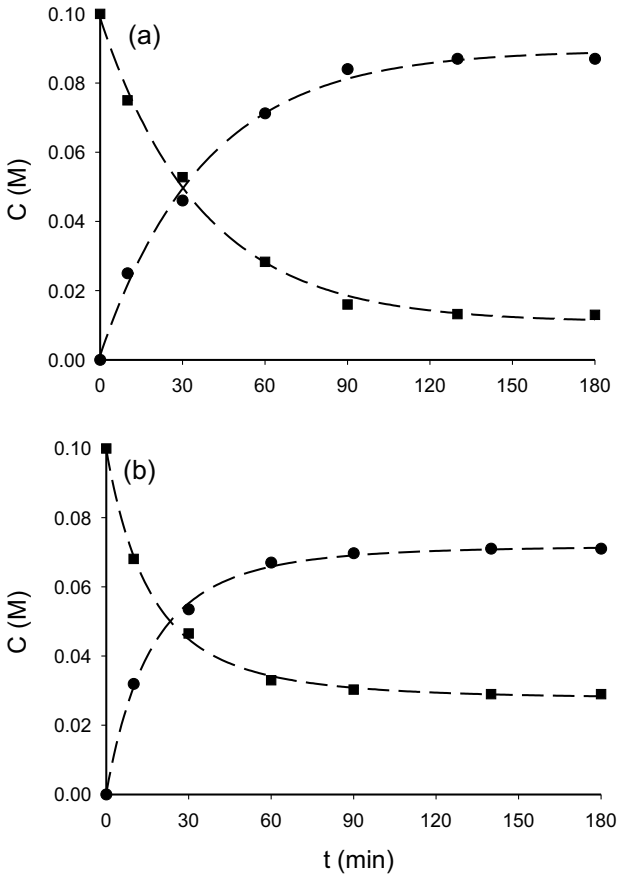
Results and discussion

Hydrolysis of antibiotics

Antibiotic hydrolysis in a two-phase aqueous solution – water-immiscible organic solvent system could be complicated by several factors, with the most negative ones being enzyme inactivation in the organic phase at low pH and β-lactam degradation.

The presence of a water-immiscible organic phase did not influence the activity or stability of native penicillin acylase: the loss of activity during the characteristic time of reaction (1–3 h) did not exceed 10%, which is quite acceptable for the thermodynamic evaluation of the system. Stabilized enzyme preparations should therefore be used in a preparative biocatalytic process to meet the economic and technological demands. In this study, we focused primarily on a thermodynamic evaluation of the new approach, and hence, did not apply standard techniques for PA stabilization (16, 17).

Fig. 3. Integral curves of Pen G (*a*) and Ceph G (*b*) hydrolysis in a two-phase system. (*a*) pH 3.8, 10 μM PA; (*b*) pH 3.5, 10 μM PA; (■), antibiotic (●), antibiotic nucleus.



Penicillin degradation was studied by Reschke and Schugerl (1), who observed lower stability of penicillin in an aqueous phase under pH 3–4 and no degradation in the organic phase. Based on their experimental data and accounting for the partition of antibiotic in a two-phase system (Table 1), we determined the chance of penicillin degradation at the stated experimental conditions to be less than 1%. In fact, we did not observe Pen G decomposition within an hour in a two-phase system at pH 3.5. Since Ceph G is known to be more stable in an acidic medium, there was no danger of decomposition.

Typical experimental integral curves of penicillin acylase-catalyzed β-lactam antibiotic hydrolysis in a two-phase system are given in Fig. 3. Effective enzymatic hydrolysis of both biosynthetic antibiotics Pen G and Ceph G took place at pH 3.8, followed by precipitation of corresponding antibiotic nuclei, which is in good agreement with the preliminary thermodynamic evaluation.

Withdrawal of both reaction products out of reaction sphere, i.e., precipitation of 6-APA (or 7-ADCA) and extraction of phenylacetic acid into the organic phase, is favorable from both a thermodynamic and a kinetic point of view. The pH dynamics during the course of hydrolysis must, however, being taken into consideration. Starting from the initial pH (3–4), there was no significant change in pH over the course

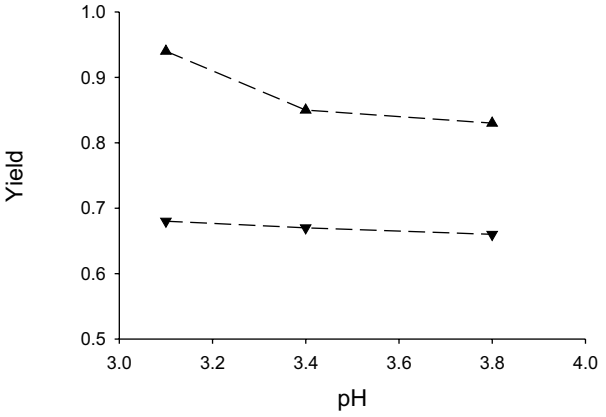
Fig. 4. Experimental dependence of conversion degrees in hydrolysis of 0.1 M antibiotic in a two-phase system. (▼), 6-APA; (▲), 7-ADCA.



of the reaction due to the balance of the dissociation and partition constants, which prevented formation of unwanted inorganic salts in a reaction mixture.

Experimental antibiotic nuclei yield dependence on pH

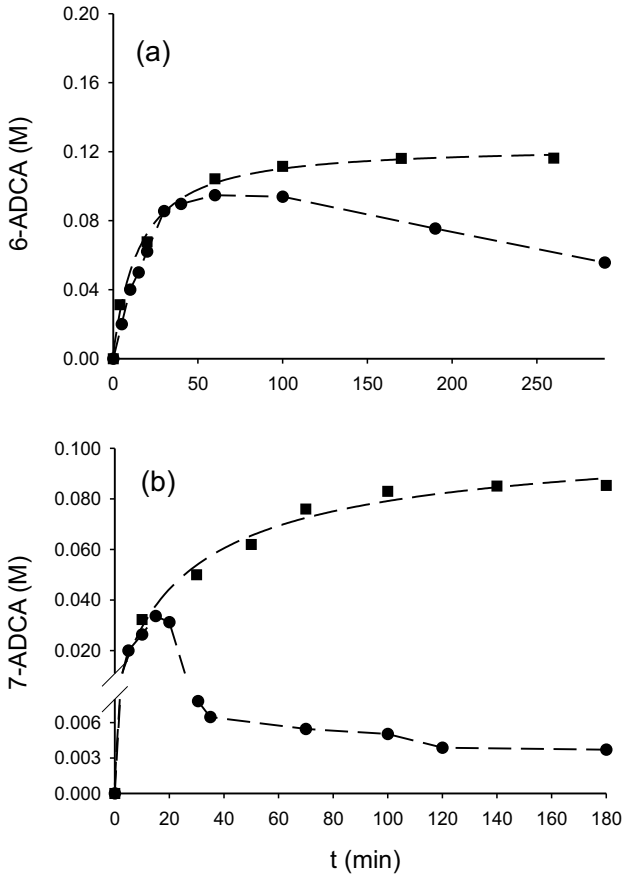
Hydrolysis of Pen G and Ceph G in a two-phase system (water–BuAc, 1:1) at pH 3–4 was carried out and the pH dependencies of the antibiotic conversion were obtained (Fig. 4).

In a chosen interval, the yield of hydrolysis (70% for 6-APA and 90% for 7-ADCA) was weakly dependent on pH. It should be noted that the yield of 6-APA evaluated on the basis of reported parameters (Fig. 2) exceeds the experimental yields by 20%. The discrepancy could arise from slightly different experimental conditions used in different laboratories when determining the numerous constants used for the evaluation (eq. [27] contains several parameters determined by different scientists). For example, there is a remarkable discrepancy for the Pen G synthesis constant: Švedas et al. (3) reported a value of 4300 M^{-1}, while Tewari and Goldberg (10) determined the value to be 680 M^{-1}. Bearing this in mind, we tested the thermodynamic model presented above, but initially sought to characterize the equilibrium state during the course of antibiotic hydrolysis in a two-phase system.

It is interesting to compare antibiotic hydrolysis under studied conditions in a biphasic system with that in a monophasic one at the same acidic pH and at traditionally used alkaline conditions (pH 8). Pen G and Ceph G hydrolysis in a monophasic aqueous system at low pH is thermodynamically unfavorable (see corresponding values of equilibrium constants) and is not practical due to very low product yield (less than 30%) as well as low conversion rates due mainly to very strong product inhibition at these conditions (data not shown). Thus, in comparison with the corresponding monophasic aqueous system, the biphasic system (where both reaction products are removed out of the reaction sphere due to extraction of phenylacetic acid into the organic phase and precipitation of 6-APA or 7-ADCA) favors the hydrolytic reaction with thermodynamic and kinetic feasibility.

Compared with the traditional hydrolysis of Pen G and Ceph G at pH 8, the suggested approach is subjected to less

Fig. 5. Supersaturation at antibiotic nucleus formation in the course of Pen G (*a*) and Ceph G (*b*) hydrolysis. (■), total antibiotic nucleus content; (●), concentration in aqueous phase; (……), saturation level.



product inhibition, and therefore is just 5 to 6 times slower. The total turnover rate is good enough for preparative conversion. Moreover, the conversion rate can be further increased by the appropriate choice of "acidic" PA, since enzymes of this family are remarkably different in their pH dependencies of catalytic activity (18). Furthermore, the overall antibiotic conversion in a suggested technological process can be increased up to the stoichiometric value by applying a continuous downstream processing scheme. Antibiotic extraction from a cultural broth can be coupled with further conversion in the biphasic system, which allows for downstreaming in the feed-countercurrent reactor, and thus, the possibility of reaching conversions that are close to unity (19). When comparing traditional hydrolysis with a putative one, the overall balance should take into account factors such as the decrease in the number of the technological steps, the formation of waste inorganic salt during numerous pH shifts in the traditional procedure, and the economic gains. It should also be done on the experimental process at the preparative scale.

Dependence of the antibiotic conversion on its initial concentration

The basic qualitative feature of the thermodynamic model of β-lactam antibiotic hydrolysis in a two-phase system with precipitation of the antibiotic nucleus is the independence of

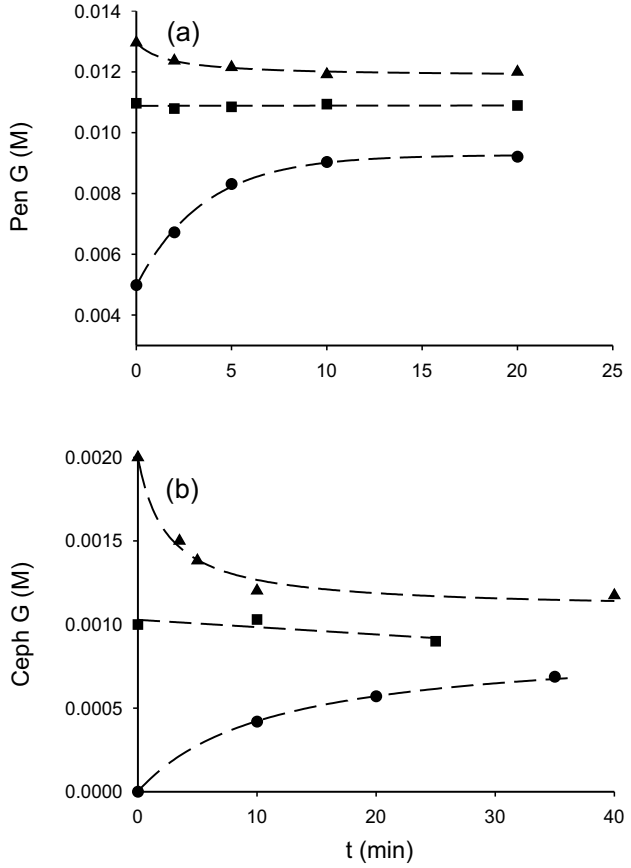

Fig. 7. Dependence of thermodynamically controlled antibiotic conversion degree in a two-phase system. (▼), 6-APA; (▲), 7-ADCA.

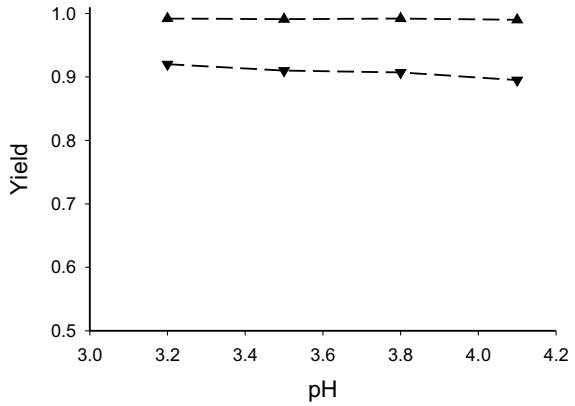

the conversion on the initial substrate concentration. Experimental study shows that this is a case for Ceph G hydrolysis, where the yield of 7-ADCA does not depend on the Ceph G concentration up to the 0.1 M (solubility limit of Ceph G under these conditions). An increase in the Pen G concentration from 0.1 to 0.2 M, however, decreases the yield of 6-APA from 67 to 57%. This fact pointed out one more discrepancy between the thermodynamic model and the experimental data. To solve this apparent contradiction, one might change the model, but there was no sufficient reason for such a change, and we wanted to be sure that the experimental data reflected a true equilibrium state. (Most of the doubts were related to the precipitation of 6-APA.)

Dynamic supersaturation of 6-APA in the course of reaction

Investigation of supersaturation effects was carried out by comparing the composition of aqueous phase with that of the whole system. Results are presented in Fig. 5.

Supersaturation takes place in both cases, and its scale is impressive: 12-fold for 6-APA and 35-fold for 7-ADCA. It therefore makes sense to consider these results in more detail. Normally, supersaturated solutions are usually unstable and supersaturation dissipates within several minutes, but this is not the case in this particular system. The process of antibiotic nuclei crystallization is complicated by various factors such as contact with the organic phase, presence of other reagents (Pen G and PAA), and the enzyme. In a separate experiment, we observed that addition of 6-APA or 7-ADCA crystals into the corresponding reaction mixture does not influence precipitation, which emphasizes the peculiarity of solid-phase formation under these experimental conditions. We noted that 6-APA supersaturation dissipates very slowly (tens of hours) and within the reasonable time interval, one cannot expect the concentration of antibiotic nuclei in aqueous phase to reach equilibrium. Despite a more sharp precipitation for 7-ADCA, equilibrium solubility is also not reached, and fourfold of oversaturation is left. Thus the stability of supersaturated solutions of antibiotic nuclei is most probably responsible for the discrepancy between the experimental and thermodynamic modeling presented above.

True equilibrium state of hydrolysis in a two-phase system

It is nevertheless important to know what yields could be expected if the problems with precipitation of the nuclei were solved. In other words, it is important to determine the true equilibrium state of hydrolysis in a two-phase system. For this purpose, we investigated the direction of the reaction in systems with designed composition of reagents (Pen G, 6-APA, PAA). By tracing the reaction direction it can be concluded where the equilibrium, the state of no macroscopic reagent conversion, is situated. At the same time there is no need to wait for the end of the reaction — it is enough just to check the initial direction and then again with each iteration step as the reaction approaches those concentrations that characterize the system at equilibrium. An analogous method is well known in mathematics as the method of division by half for root estimation, where the sign of a function is checked at each iteration step. If the sign changes, the size of the interval, which contains the root or the equilibrium (as in our case), is reduced. This method is even more attractive because only the initial interval of reaction is taken into account and thus supersaturation, reagent degradation, and other dynamic effects can be omitted.

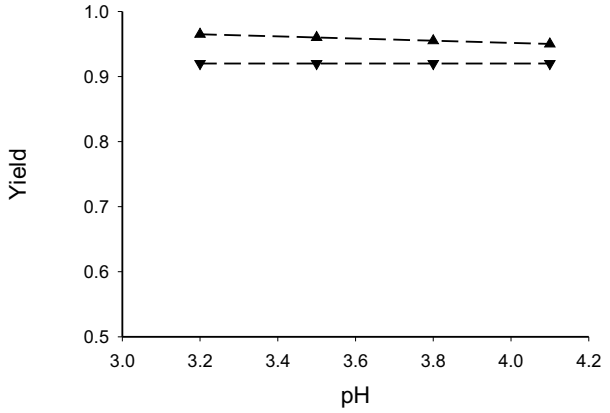
Fig. 8. Expected degrees of conversion in a two-phase system after formal elimination of supersaturation in accordance with eq. [21]. (▼), 6-APA; (▲), 7-ADCA.



Several typical dependencies are given in Fig. 6 to illustrate this proposed approach.

As can be seen, loading the system with 0.087 M 6-APA, 0.087 M PAA, and 0.013 M Pen G (which corresponds to 87% yield) leads to further hydrolysis of the antibiotic, affording equilibrium yields exceeding 87%. On the other hand, designing a yield of 95% causes a synthetic reaction, and thus the equilibrium value is less than 95%. Finally, in the system containing 0.089 M 6-APA, 0.089 M PAA, and 0.011 M Pen G (89% yield), no macroscopic changes in the concentrations were observed, which suggests a good approach to achieving equilibrium conditions.

A series of measurements under pH 3.2–4.1 was conducted and the thermodynamic equilibrium state of Pen G and Ceph G hydrolysis in a two-phase system (water–BuAc) was found. Results are presented in Fig. 7.

Correspondence of true equilibrium state and practical conversions

In the case of Pen G, thermodynamically estimated yields of hydrolysis (Fig. 2) are in good agreement with experimental values obtained under close-to-equilibrium conditions (Fig. 7). Moreover, the latter values also agreed with the yields in non-equilibrium (as far as nucleus precipitation is concerned) reactions. In fact, if the crystallization process is considered relatively slow in comparison with the chemical reaction, the yield will be determined by eq. [26], where the equilibrium solubility should be replaced by the current concentration (determined by supersaturation) in the aqueous phase. Then, other thermodynamic parameters being equal, the difference between thermodynamically and kinetically controlled yields will be stipulated only by the ratio of saturated and current concentrations according to eq. [26]. After several transformations, we obtain the following parametric relation between the conversion degrees and the ratio of concentrations of precipitating component:

$$[29]\quad \frac{[BH^{\pm}_{eq}]}{[BH^{\pm}_{kin}]} = \frac{\frac{1}{\eta_{eq}} - 1}{\frac{1}{\eta_{kin}} - 1}$$

where $[BH^{\pm}_{eq}]$ is the saturated (equilibrium) level and $[BH^{\pm}_{kin}]$ is the supersaturated (kinetically stipulated) concentration; η_{eq} and η_{kin} are the respective yields. Thus, on the basis of supersaturations observed, one can recalculate expected yields with the use of eq. [29]. Results of these calculations are presented in Fig. 8.

As can be seen, after formal elimination of supersaturation, the expected yields approximate the equilibrium values with good accuracy. This fact highlights that both the experimental results and the theoretical conceptions intrinsically agree.

Conclusion

A process of Pen G and Ceph G hydrolysis is studied in a two-phase system (water–BuAc) at pH 3–4. The thermodynamic model of the process is analyzed, incorporating the influence of pH, phase volume ratio, initial substrate concentration, and parameters of hydrolytic reaction (acid-base and interphase equilibria). For effective hydrolysis, we emphasize the crucial role of product withdrawal from the reaction sphere in a two-phase system: extraction of the emerging phenylacetic acid as well as precipitation of the antibiotic nucleus during the course of hydrolysis result in high yields. Experimental tests also revealed the formation of antibiotic-nucleus supersaturated solutions. For these solutions, being rather stable, the yield in hydrolytic reactions is smaller than predicted by the thermodynamic model. To study the true thermodynamic equilibrium state, a method is proposed where the initial reagent concentrations in an experimental system are set close to the equilibrium concentration values. Depending on whether hydrolysis or synthesis takes place, the interval of equilibrium concentrations is returned. Supersaturation effect is shown to decrease 6-APA yield from 90%, as it is set by thermodynamics, to 67%, and 7-ADCA yield from 99 to 90%, correspondingly.

Enzymatic oxidation of cyclopropylbenzene: structures of new metabolites and possible mechanistic implications

Vu P. Bui, Minh Nguyen, Jeff Hansen, John Baker, and Tomas Hudlicky

Abstract: Cyclopropylbenzene was subjected to whole-cell fermentation with either *Escherichia coli* JM109 (pDTG601) or *E. coli* JM109 (pDTG602), expressing toluene dioxygenase and toluene dioxygenase – dihydrodiol dehydrogenase enzymes, respectively. The corresponding metabolites, 3-cyclopropylcyclohexa-3,5-diene-1,2-diol (**3**) and 3-cyclopropylbenzene-1,2-diol (**5**) have been isolated in yields of 2.5 and 1 g L^{-1}, respectively. The absolute stereochemistry correlation for **3** is provided, along with a preliminary discussion of its potential in asymmetric synthesis. Possible mechanistic implications are indicated for the enzymatic oxygenation through the use of calculations. Experimental data are provided for all new compounds.

Key words: cyclopropylbenzene, bio-oxidation, *cis*-diene diol, catechol, JM109 (pDTG601), JM109 (pDTG602), dioxygenase.

Résumé : On a soumis le cyclopropylbenzène à une fermentation à l'aide de cellules entières d'*Escherichia coli* JM109 (pDTG601) ou d'*E*. coli JM109 (pDTG602) qui laissent écouler respectivement les enzymes dioxygénase du toluène et dioxygénase du toluène/déshydrogénase du dihydrodiol. On a isolé les métabolites correspondants, le 3-cyclopropylcyclohexa-3,5-diène-1,2-diol (**3**) et le 3-cyclopropylbenzène-1,2-diol (**5**) avec des rendements respectifs de 2,5 g/L et 1 g/L. On présente une corrélation absolue de la stéréochimie du produit **3** ainsi qu'une discussion préliminaire de son potentiel éventuel en synthèses asymétriques. En se basant sur des calculs théoriques, on indique les implications mécanistiques possibles pour l'oxygénation enzymatique. On rapporte les données expérimentales relatives à tous les nouveaux composés.

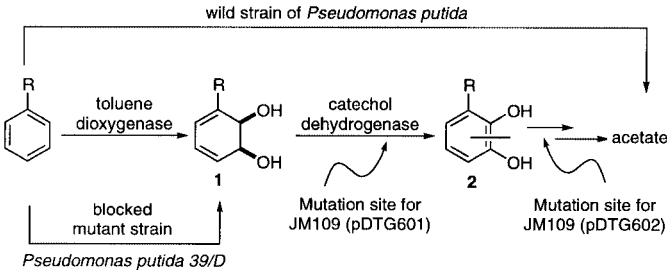
Mots clés : cyclopropylbenzène, biooxydation, *cis*-dièneediol, catéchol, JM109 (pDTG601), JM109 (pDTG602), dioxygénase.

[Traduit par la Rédaction]

Introduction

The historically significant disclosure of isolation of the first homochiral *cis*-cyclohexadiene diol by Gibson and coworkers (1) in 1968 was soon followed by detailed studies of the degradation pathways employed by soil organisms that grow on aromatic compounds. Gibson provided the first blocked mutants of *Pseudomonas putida*, whose use led to isolation of homochiral diols of type **1** (2). Eventually, the elucidation of the degradation pathway (Fig. 1) allowed the protein synthesis of the first two enzymes employed in the pathway, namely, toluene dioxygenase (TDO) and dihydrodiol dehydrogenase (DHDH), to be expressed in recombinant clones of *Escherichia coli* JM109 (3). Similar organisms have also been constructed to express the topologically similar enzymes, naphthalene (4) and biphenyl dioxygenase (5). The X-ray crystal structure has been solved for naphthalene dioxygenase (6).

Fig. 1. Natural degradation pathway of aromatics by eukaryotic organisms, and mutation points for specific enzyme expression.



Metabolites of type **1** have been extensively used in asymmetric synthesis (7) since 1987, when the first such application was disclosed by Ley et al. (8). Recently, we reported the synthetic applications of *E. coli* JM109 (pDTG602) to the practical preparation of substituted catechols (**2**), compounds which are difficult to prepare efficiently by traditional means (9). Although cyclopropyl catechol has been previously reported (10), the corresponding diene diol was unknown.

In this paper we report the results of the oxidation of cyclopropylbenzene with the organisms that express TDO

and TDO–DHDH. The isolation of the metabolites may provide clues to the mechanism by which oxygen is introduced into the aromatic nucleus. In addition, the vinylcyclopropanes generated by such means may serve as versatile intermediates for asymmetric syntheses.

Results and discussion

Whole-cell fermentation of either *E. coli* JM109 (pDTG601), expressing toluene dioxygenase (TDO) or *E. coli* JM109 (pDTG602) expressing both TDO and dihydrodiol dehydrogenase (DHDH), was performed in either a 10-L or 15-L fermentor, as previously described (9*b*, 11). When the cells were grown to optimum optical density (OD = 50–60 at 640 nm) (9*b*, 11), the substrate was introduced at a rate of 5 g h^{-1} and the biotransformation allowed to proceed for 5–6 h. After the separation of cells from the broth, diol **3** was isolated in a yield of 2.5 g L^{-1}. Diol **3** is essentially pure after extraction from the broth, but is somewhat unstable and soon thereafter begins to dehydrate to phenol **4** (Scheme 1).

Since this dehydration is greatly accelerated by the presence of acid, it is essential to use base-washed solvents when isolating **3**. The amount of **4** produced varies depending on the time and the amount of acid present. The dehydration process is self-catalytic, insofar as **4** is sufficiently acidic to catalyze further dehydration. Diol **3** can be stored for several weeks at –78°C.

Exposure of cyclopropylbenzene to *E. coli* JM109 (pDTG602) led to the formation of cyclopropyl catechol **5** in an isolated yield of 1 g L^{-1}. The identity of the metabolites was established by spectroscopic techniques. The absolute stereochemistry of diol **3** was confirmed by an independent synthesis of vinylcyclopropane **9** from diol **6** whose absolute stereochemistry is known (Scheme 2). Compound **9** was prepared by the selective reduction of diol **3** with potassium azadicarboxylate (PAD) in 73% yield. Diol **6** was also reduced with PAD (86%) and then protected to provide acetonide **7** (78%) (12). Grignard reagent **11**, derived from cyclopropyl bromide **10**, was coupled with **7** via a modified Corey–House synthesis (13) to give **8** in a low yield (16%). Deprotection of this material with THF–H_2O–TFA (4:1:1) afforded diol **9**, whose $[\alpha]_D$ (–126°) matched that of the material obtained via fermentation of cyclopropylbenzene.

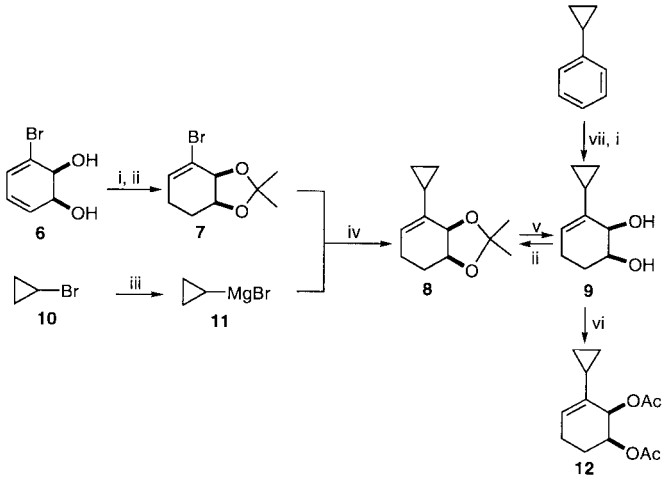

Fig. 2. Exploration of reactivity of oxygenated cyclopropylhexenyl systems.

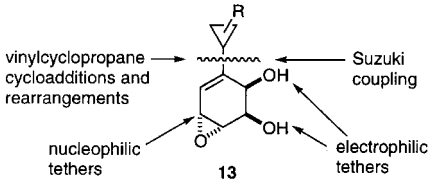

Diol **3** offers new opportunities for asymmetric synthesis through further transformations of the reactive vinylcyclopropane moiety. Two obvious applications are the tethered [5+2] annulation to 7-membered ring systems, discovered and developed by Wender et al. (14), simple thermolysis to cyclopentenes (15), or cascade radical cyclizations with concomitant unraveling of the cyclopropylcarbinyl system (Fig. 2). The electrochemical behavior of the vinylcyclopropane moiety will also be investigated (16).[2]

The development of such new technology also depends on our ability to efficiently couple cyclopropyl units to the vinyl bromide in **6** or **7** via a Suzuki-type process. The research on the synthesis of cyclopropyl boronates is ongoing and will be reported in due course.

Mechanistic implications

The mechanism of aromatic dioxygenation remains unknown, except for initial proposals by Gibson (17), who suggested dioxetane **14** as an intermediate. This proposal would account for the *cis*-configuration of diols **1** found in metabolites from biotransformation by prokaryotic organisms (Fig. 3) (18) and was supported by incorporation of ^{18}O from labeled dioxygen into both hydroxyl groups of the diol

[2] The vinylcyclopropane to cyclopentene rearrangement has been shown to be greatly accelerated by catalytic amounts of triarylaminium ions via a one-electron oxidation (16). We are investigating the initiation of the rearrangement by a one-electron electrochemical oxidation. Cyclic voltammetry of vinylcyclopropane **9** indicates an irreversible oxidation at $E_{1/2}$ = 1.2 V (0.15 M $LiClO_4$ in MeOH). Initial attempts at oxidative rearrangement consumed **9** and produced products that do not contain a cyclopropane ring and may contain a cyclopentene ring.

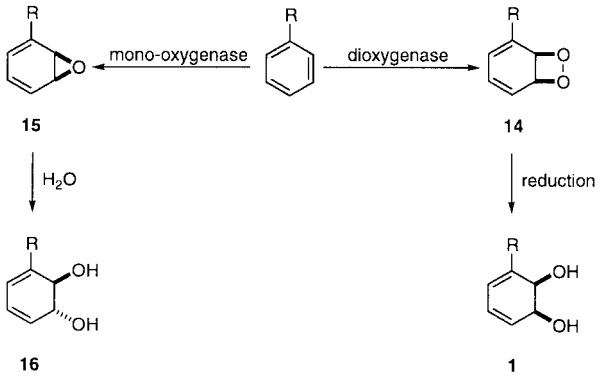
Fig. 3. Oxygenation of aromatics by prokaryotic and eukaryotic systems.



(19). On the other hand, eukaryotic oxidations are much better understood and known to proceed via arene oxides **15** (incorporation of only one oxygen from O_2), which are hydrolyzed to *trans* diols **16** (20).

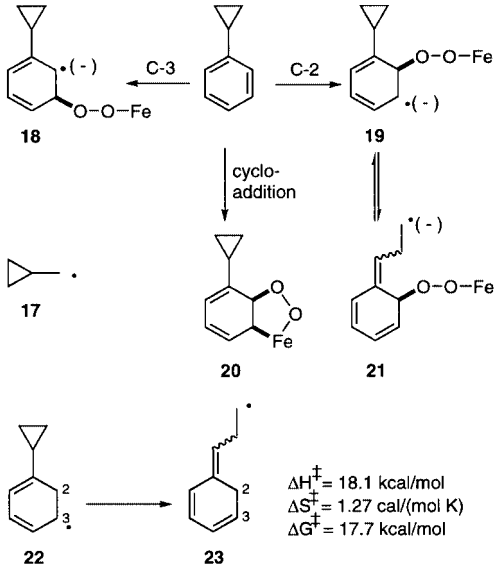
The suggestion of a dioxetane as an intermediate would require the participation of a singlet oxygen-type species. Alternatively, radical species such as iron-bound peroxy radicals or anionic species (peroxides) of either type **18** or **19** might lead to a stepwise formation of C–O bonds for the former cases or synchronous formation of cycloadducts of type **20** in the latter, as indicated in a very speculative way in Fig. 4 (21).

Since the full structure of naphthalene dioxygenase (NDO) has been determined (6), Gibson and co-workers (21*a*) provided further details on an alternative mechanism of dioxygenation by an iron-peroxide species either of a radical nature or as a partially reduced metal-bound peroxide. Intermediates analogous to **18** or **19** have been observed in the oxidation of indole by NDO in crystals grown in a rich medium containing indole.

Cyclopropylcarbinyl-type rearrangements have been observed during the investigation of the mechanism in the isopenicillin *N*-synthase reaction (22). Iron(IV)–sulfur-bound species have been proposed to account for the results, where trapping of the butenyl radical by the sulfur atom has been observed.

We therefore wished to compare the reactive tendency of a conjugated cyclopropylcarbinyl radical such as **19** to the well-known cyclopropylcarbinyl rearrangement (23). Since unrestricted Becke's hybrid three-parameter functional theory (UB3LYP) (24) provides a reliable level of theory for examining the cyclopropylcarbinyl radical system (25), the density functional theory methodology was used to examine the kinetics of the ring opening of the cyclopropylcarbinyl radical system (**22**) to the conjugated butenyl system (**23**) (Fig. 4). Calculations were performed using the Gaussian 98 program package (26). Structures were optimized and vibrational frequency calculations were performed using UB3LYP level of theory and the 6–31G(*d*) basis set (27). The transition structure was characterized by a single imaginary frequency, and thermochemical information was obtained using unscaled frequencies. Single-point energies were calculated using UB3LYP level of theory using the 6–311+G(2df,2p) basis set (28). At 35°C the ring opening of the cyclopropylcarbinyl radical **(17)** ($k_r = 1.4 \times 10^8$ s^{-1}) (29) is 10^8 times

Fig. 4. Mechanistic possibilities for *cis*-dihydroxylation.



faster than that of radical **22** ($k_r^{calcd} = 1.1$ s^{-1}). Radical stabilizing substituents at the carbinyl position are known to retard the rates of ring opening (30). Even if a radical is formed at C3, ring opening may not occur if the radical has a short lifetime.

Conclusions

The calculation described here for species such as **19** does not eliminate the possibility of intermediates of this type in the oxidation of cyclopropyl benzene even though products derived from the ring opening of the cyclopropane have not been observed in the reaction mixtures. While the nature of the *cis*-dihydroxylation remains a mechanistic enigma, recent evidence by Gibson points to a possible stepwise mechanism for this unique reaction. Whether the mechanism involves radical or anionic iron-bound species is at the moment unknown.

From a synthetic viewpoint, the cyclopropyl system further offers various synthetic manipulations and can be viewed as a chiral vinylcyclopropane synthon for incorporation into future synthetic schemes. Such endeavors will be reported in due course.

Experimental

3-Cyclopropylcyclohexa-3,5-diene-1,2-diol (3)

3-Cyclopropylcyclohexa-3,5-diene-1,2-diol was isolated from the crude mixture collected from the biotransformation of cyclopropyl benzene. This was accomplished by centrifugation of the cells and extraction of the broth with base-washed ethyl acetate. This process provides essentially pure diene diol, which can be further purified by flash column chromatography (hexanes–EtOAc, 4:1) to afford a white solid; mp 45–46°C (dec); $[\alpha]_D^{28}$ +11.39 (*c* 1.75, CD_3OD); R_f = 0.4 (hexanes–EtOAc, 1:1). IR (film) (cm^{-1}): 3274, 3008, 2911, 1453, 1090, 992, 804. ^1H NMR (300 MHz, acetone-d_6) δ: 5.75–5.85 (m, 1H), 5.54–5.66 (m, 2H), 4.17–4.26 (m, 1H), 3.63–3.81 (m, 2H), 3.40–3.51 (d, J = 7 Hz, 1H), 1.48–1.62 (m, 1H), 0.40–0.79 (m, 4H). ^{13}C NMR (75 MHz,

acetone-d_6) δ: 130.2, 127.4, 124.7, 118.7, 71.2, 69.0, 15.8, 7.6, 6.6.

2-Cyclopropylphenol (4)

2-Cyclopropylphenol was isolated from the crude mixture collected from the biotransformation of cyclopropyl benzene. The phenol was purified by distillation to afford a clear oil; R_f = 0.42 (hexane–EtOAc, 8:1). IR (film) (cm^{-1}): 3536, 1609, 1580, 1491, 752. ^{1}H NMR (300 MHz, DMSO-d_6) δ: 9.26 (s, 1H), 6.86–6.92 (m, 1H), 6.63–6.76 (m, 3H), 2.02–2.12 (m, 1H), 0.80–0.87 (m, 2H), 0.55–0.61 (m, 2H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 155.8, 129.4, 125.9, 124.5, 119.0, 114.6, 9.3, 7.7. EI-MS *m*/*z*: 136 (23), 134 (100), 133 (24), 115 (27), 107 (39), 106 (21), 105 (28), 91 (34), 89 (41), 78 (24), 77 (96), 61 (43). EI-HRMS calcd. for $C_9H_{10}O$ (M^+): 134.0732; found: 134.0732.

3-Cyclopropylbenzene-1,2-diol (5)

Metabolite **5** was prepared by biotransformation of the corresponding arene with *E. coli* JM109 (pDTG602); mp 41–42°C; R_f = 0.52 (hexane–EtOAc, 3:2). IR (film) (cm^{-1}): 3418, 1622, 1592, 1477, 775. ^{1}H NMR (300 MHz, DMSO-d_6) δ: 9.11 (s, 1H), 8.11 (s, 1H), 6.50–6.58 (m, 1H), 6.49 (t, J = 7.8 Hz, 1H), 6.16–6.21 (m, 1H), 2.01–2.12 (m, 1H), 0.79–0.86 (m, 2H), 0.50–0.57 (m, 2H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 143.4, 142.9, 128.8, 120.6, 119.7, 113.5, 9.4, 6.1. EI-MS *m*/*z* (%): 150 (100), 149 (6), 107 (26), 77 (44). EI-HRMS calcd. for $C_9H_{10}O_2$ (M^+): 150.0681; found: 150.0675. Anal. calcd. for $C_9H_{10}O_2$: C 71.98, H 6.71; found: C 72.07, H 6.69.

7-Cyclopropyl-2,2-dimethyl-3a,4,5,7a-tetrahydrobenzo[1,3]dioxole (8)

To a well-stirred solution of diol **9** (0.150 g, 1.0 mmol) in 2,2-dimethoxypropane (DMP) (20 mL), a catalytic amount of *p*-toluenesulfonic acid was added. The reaction mixture was stirred for 30 min and then quenched with 5% $NaHCO_3$ (2 mL). Solvent was removed under reduced pressure. The residue was diluted with brine (20 mL) and extracted with CH_2Cl_2 (3 × 30 mL). The organic layers were combined, dried ($MgSO_4$), and concentrated under reduced pressure. The crude residue was purified by flash silica gel chromatography (hexane–EtOAc, 8:1) to afford **8** (0.151 g, 80%); $[\alpha]_D^{20}$ +58.99 (*c* 1.0, CH_3OH); R_f = 0.57 (hexane–EtOAc, 8:1). IR (film) (cm^{-1}): 3082, 2985, 1456, 1367, 870. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 5.51 (t, J = 3.9 Hz, 1H), 4.37 (d, J = 4 Hz, 1H), 4.25–4.31 (m, 1H), 2.09–2.22 (m, 1H), 1.75–1.96 (m, 2H), 1.60–1.72 (m, 2H), 1.42 (d, J = 5 Hz, 6H), 0.32–0.71 (m, 4H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 137.3, 123.4, 108.5, 74.5, 73.8, 28.2, 26.8, 25.9, 20.9, 14.6, 5.9, 5.1. EI-MS *m*/*z* (%): 179 (57), 137 (33), 136 (66), 121 (29), 108 (25), 107 (28), 95 (21), 91 (100), 79 (45), 77 (23), 55 (26). EI-HRMS calcd. for $C_{12}H_{18}O_2$ (M^+): 194.1307; found: 194.1317.

3-Cyclopropylcyclohex-3-ene-1,2-diol (9)

Method A*: *From diol 3

To a well-stirred and ice-cooled solution of diol **3** (17 g, 0.11 mol) in methanol (50 mL), potassium azadicarboxylate (PAD) (76 g, 0.35 mol) was added. A solution of acetic acid (64 mL, 1 mol) in methanol (50 mL) was added dropwise to the reaction mixture at such a rate that 1–2 bubbles were produced per second. The mixture was allowed to warm to ambient temperature, with the color changing from yellow to milky white. The reaction mixture was stirred overnight and then quenched with saturated $NaHCO_3$ until effervescence ceased. Methanol was removed under reduced pressure. The residue was diluted with brine (20 mL) and extracted with ethyl acetate (4 × 40 mL). The combined organic phases were dried ($MgSO_4$) and concentrated to yield a reddish oil. The crude product was purified by flash silica gel chromatography (hexane–EtOAc, 3:2) to afford **9** (12.411 g, 73%); as a white solid; mp 96–98°C; $[\alpha]_D^{29}$ –126.0 (*c* 1.0, CH_3OH); R_f = 0.20 (hexane–EtOAc, 3:2). IR (film) (cm^{-1}): 3272, 3012, 1461, 989. ^{1}H NMR (300 MHz, DMSO-d_6) δ: 5.32 (s, 1H), 4.32–4.36 (m, 1H), 3.65 (t, J = 4 Hz, 1H), 3.35–3.42 (m, 2H), 1.92–1.99 (m, 2H), 1.52–1.63 (m, 1H), 1.38–1.46 (m, 2H), 0.33–0.56 (m, 4H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 138.6, 123.4, 70.0, 68.9, 25.3, 24.2, 14.9, 5.6. FAB-MS *m*/*z* (%): 137 (8), 93 (100). FAB-HRMS calcd. for $C_9H_{13}O$ ([MH – H_2O]$^+$): 137.0966; found: 137.0967. Anal. calcd. for $C_9H_{14}O_2$: C 70.1, H 9.15; found: C, 70.17, H 9.18.

Method B: From vinyl bromide 7

A 50-mL round-bottom flask equipped with a condenser and an addition funnel under argon atmosphere was charged with magnesium metal (0.76 g, 31.2 mmol) and a crystal of iodine. The addition funnel was charged with a solution of cyclopropyl bromide (0.76 g, 6.24 mmol) in anhydrous diethyl ether (10 mL) and this solution was added dropwise into the reaction flask. Once the reaction proceeded on its own, the addition was continued to maintain a constant reflux. After the addition was completed the reaction flask was heated to reflux for an additional 45 min. Grignard reagent **11** was then transferred into another reaction flask containing bromoacetonide **7** (1.29 g, 5.61 mmol) and tetrakis(triphenylphosphine) palladium (0.194 g, 0.17 mmol) in THF (25 mL). The reaction was heated at reflux for 5 h and then the reaction mixture was filtered through a thin layer of silica. The filtrate was concentrated under reduced pressure. Flash chromatography provided the coupled product **8** (0.174 g, 16%). Acetonide **8** was deprotected using a THF–H_2O–TFA (4:1:1, 10 mL) solvent mixture to afford diol **9** (0.104 g, 75%) whose physical data matched the compound obtained via the biotransformation of cyclopropylbenzene followed by PAD reduction.

Acetic acid 6-acetoxy-2-cyclopropylcyclohex-2-enyl ester (12)

To a well-stirred solution of diol **9** (0.105 g, 0.68 mmol) in CH_2Cl_2 (20mL), pyridine (0.16 g, 2.0 mmol) was added. Addition of acetic anhydride (0.21 g, 2.0 mmol) was followed by dimethylaminopyridine catalyst (0.2 mg, 0.20 mol%). The reaction mixture was allowed to stir for 20 h and quenched with saturated citric acid (2 mL). The reaction mixture was diluted with brine (20 mL) and extracted with CH_2Cl_2 (3 × 30 mL). The organic layers were combined, dried (Na_2SO_4), and concentrated under reduced pressure. The crude residue was purified by flash silica gel chromatography (hexane–EtOAc, 3:2) to afford **12** (0.156 g, 96%) as a white solid; mp 80.5–81.5°C; $[\alpha]_D^{29}$ –196.9 (*c* 1.0,

Biocatalyzed preparation of the optically enriched stereoisomers of 4-methyl-2-phenyl-tetrahydro-2*H*-pyran (Doremox®)

Elisabetta Brenna, Claudio Fuganti, Sabrina Ronzani, and Stefano Serra

Abstract: The four stereoisomers of the rose oxide analogue Doremox® were prepared in enantiomerically enriched form by enantiospecific bakers' yeast reduction of suitable derivatives and by lipase-mediated kinetic resolution of diol precursors.

Key words: yeast, lipase, odorant, reduction, kinetic resolution.

Résumé : Faisant appel à une réduction énantiospécifique de dérivés appropriés à l'aide de levure de boulanger ou à une résolution cinétique de diols précurseurs à l'aide de lipase, on a préparé une forme énantiomériquement enrichie des quatre stéréoisomères du Doremox®, un analogue de l'oxyde de rose.

Mots clés : levure, lipase, odorant, réduction, résolution cinétique.

[Traduit par la Rédaction]

Introduction

The use of cyclic ethers as fragrant ingredients for the preparation of perfuming compositions and perfumed articles originated with the two diastereoisomeric rose oxides (2*S*,4*R*)-*cis*-**1** and (2*R*,4*R*)-*trans*-**1**, after their discovery in rose oil (1) and geranium oil (2) and their availability through efficient synthetic procedures (3).

In the aim of improving the olfactory properties of **1**, several structural modifications were realized. For example, the isobutenyl unit was elongated to produce sesquiterpenoid homologues showing a rather complex odour profile (4), or one carbon atom of the tetrahydropyrane ring was substituted with an oxygen atom, to afford chiral 3-oxa analogues (5).

In 1993, 4-methyl-2-phenyl-tetrahydro-2*H*-pyran (Doremox®, **2**) was obtained by Firmenich (6) as a mixture of the two racemic *cis*- and *trans*-diastereoisomers, by hydrogenation of 5,6-dihydro-4-methyl-2-phenyl-2*H*-pyran in the presence of Pd on charcoal. This preparation represented a further evolution in the structure–activity study of the olfactory properties of rose oxide. The isobutenyl fragment of **1** was substituted with a phenyl group, to increase the substantivity of rose scent, i.e the persistence of the perfume material on blotters, skin, or in the intended application (7). Substantivity is mainly determined by vapor pressure, which depends in turn on molecular weight. The phenyl group increases the mass, without a substantial change of the shape of the molecule, and thus without affecting the main odour characteristics (8).

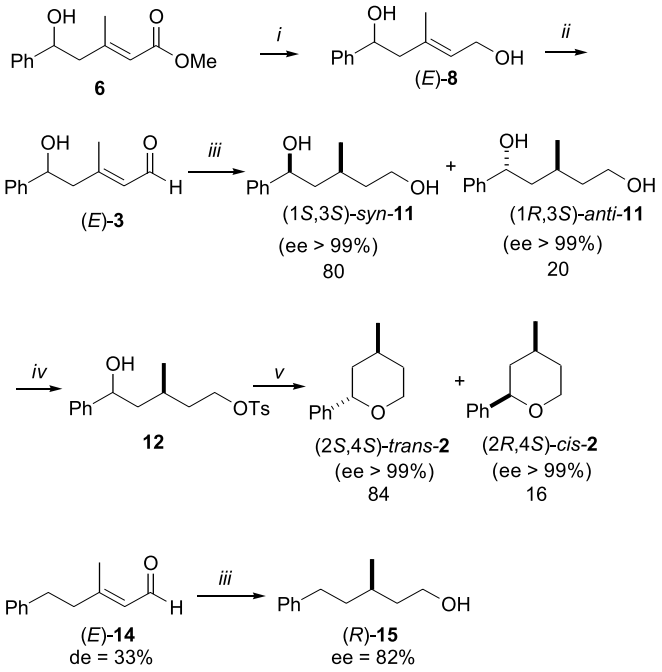
The two isomers (*cis*-**2** and *trans*-**2**) were separated by preparative gas chromatography, and their odour properties

 DOI: 10.1139/V02-042 © 2002 NRC Canada

Scheme 1. (*i*) Diisobutylaluminum hydride in toluene; (*ii*) MnO_2 in hot DMF; (*iii*) baker's yeast; (*iv*) $CHCl_3$, TosCl, pyridine; (*v*) MeONa, MeOH.



were described (6). The racemic *cis*-diastereoisomer was found to be very powerful and to have a green, rose oxide – diphenyl oxide type note. The racemic *trans*-isomer had a much weaker odour, with a green, vegetable, slightly dirty and minty character and a floral undertone. Both of them were described to be useful in the preparation of perfumes and concentrated perfuming bases, as well as of a variety of articles, such as soaps, bath or cosmetic formulations, air and body deodorants, detergents, fabric softeners, and household products.

Neither enantioselective synthesis of the four stereoisomers of Doremox®, nor olfactory evaluation of each distinct isomer have been performed so far. The wide diffusion of this fragrant component in many commercial preparations induced us to investigate the possibility of obtaining the enantiomerically enriched isomers of *cis*-**2** and *trans*-**2**, to select those showing the most powerful and interesting odour properties. Now we wish to report on the outcome of this investigation, which is part of a research project aimed at the preparation of the olfactory active stereoisomers of commercial fragrances (9), via biocatalyzed methods.

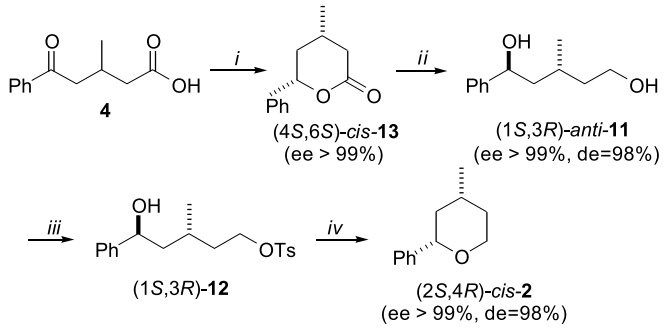
Results and discussion

Two different approaches to optically active Doremox® isomers were chosen on the basis of our past experience: (*i*) enantioselective synthesis based on bakers' yeast (BY) reduction; (*ii*) lipase-mediated kinetic resolution of suitable precursors.

Bakers' yeast approach

We had successfully developed synthetic methods for the preparation of enantiomerically enriched rose oxide (10) and Aerangis lactone (11), based on BY-enantiospecific and

Scheme 2. (*i*) Baker's yeast; (*ii*) $LiAlH_4$, THF; (*iii*) $CHCl_3$, TosCl, pyridine; (*iv*) MeONa, MeOH.



diastereoselective reduction of 1,5- and 1,4-difunctionalized synthons. Thus, as for the synthesis of **2**, we envisaged hydroxy aldehyde **3** and keto acid **4** as substrates for yeast fermentation.

Compound **3** was prepared according to this synthetic scheme. Reformatsky reaction of bromo derivative **5** (12) with benzaldehyde afforded a mixture of hydroxy ester **6** and lactone **7** (13) which were easily separated by column chromatography. DIBAL reduction of compound **6** in toluene solution gave unsaturated diol (*E*)-**8** (Scheme 1), which was straightforwardly oxidized to the desired aldehyde (*E*)-**3** (14) with MnO_2 in hot DMF; no oxidation of the benzylic hydroxylic group was observed in this reaction condition.

Keto acid **4** was prepared according to the following route. Friedel–Crafts acylation of benzene with the monochloride monomethyl ester of 3-methyl glutaric acid (**9**) (15) in the presence of aluminum(III) chloride gave mainly keto ester **10** (16), which was hydrolyzed with potassium hydroxide in methanol to afford keto acid **4** (17). Derivatives (*E*)-**3** and **4** were incubated with BY for 24 h, and, interestingly enough, the two reactions took different stereochemical courses.

Reduction of the double bond of derivative **3** (Scheme 1), in the presence of the benzylic stereocentre previously created without steric control, gave mainly (80%, GC–MS) diol (1*S*,3*S*)-*syn*-**11** (ee > 99%, chiral HPLC) and a minor quantity (20%, GC–MS) of diol (1*R*,3*S*)-*anti*-**11** (ee > 99%, chiral HPLC). The mixture of the two diastereoisomeric diols was converted into the corresponding monotosylate derivative **12** and, after treatment with sodium methylate in methanol, a sample of Doremox® with the following composition was obtained: (2*S*,4*S*)-*trans*-**2**, 86%, ee = 99% (chiral GC); (2*R*,4*S*)-*cis*-**2**, 14%, ee > 99%, $[\alpha]_D^{20}$ + 18.1 (*c* = 0.75, $CHCl_3$).

Reduction of the carbonyl function of racemic **4** (Scheme 2) gave lactone (4*S*,6*S*)-**13**, which was recovered in pure form after column chromatography, and reduced with $LiAlH_4$ to give diol (1*S*,3*R*)-*anti*-**11** (ee > 99%, de = 97%, chiral HPLC). This latter was then converted into (2*S*,4*R*)-*cis*-**2** (ee > 99%, de = 98%, $[\alpha]_D^{20}$ –54.1 (*c* = 1.05, $CHCl_3$)) according to the mentioned procedure, via the corresponding tosylate derivative (1*S*,3*R*)-*anti*-**12**.

In both cases the preferred isomer was produced enantiospecifically, but with different diastereoselection: *syn*-diastereoisomer prevailed when BY promoted the reduction of the double bond, while *anti*-diastereoisomer was obtained

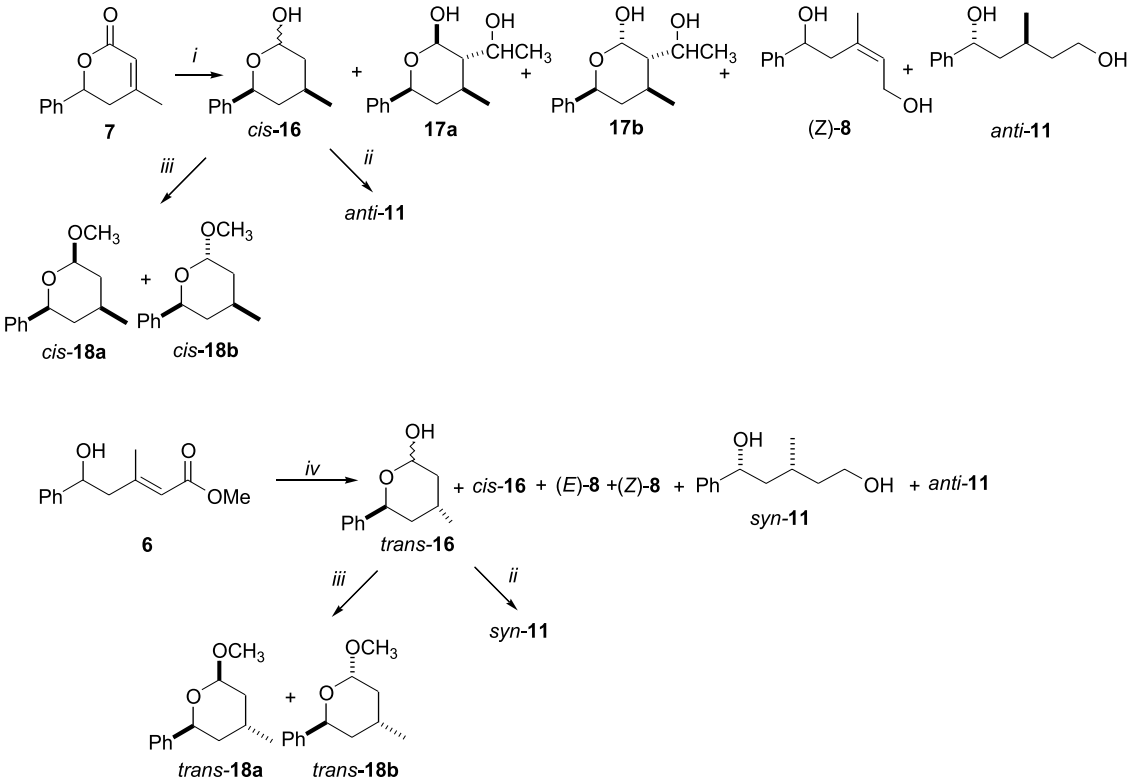
Scheme 3. (*i*) $LiAlH_4$, THF, then AcOEt; (*ii*) $NaBH_4$, MeOH–CH_2Cl_2; (*iii*) MeOH–HCl; (*iv*) $LiAlH_4$, THF, then MeOH.



when the reduction of the carbonyl was involved. As for diol *anti*-**11**, opposite enantioselection was observed: (1*R*,3*S*)-*anti*-**11** was the product of BY reduction of hydroxy aldehyde **3**, while its enantiomer (1*S*,3*R*)-*anti*-**11** was the result of yeast fermentation of keto acid **6**.[2]

Lipase-mediated kinetic resolution

A second approach to optically active Doremox® was investigated, to prepare all the four possible stereoisomers in enantiomerically enriched form. For this purpose the preparation of the two racemic diols *anti*-**11** and *syn*-**11** was optimized.

Lactone **7** was treated with lithium aluminum hydride in THF (Scheme 3). When the reaction mixture was quenched with ethyl acetate, a complex mixture of products was obtained. The following compounds could be isolated and identified: tetrahydropyranol *cis*-**16** (1:1 mixture of the two possible epimers at C-2, 40%), substituted tetrahydropyranols **17a** (11%) and **17b** (10%),[3] unsaturated diol (*Z*)-**8** (8%) (20), and diol *anti*-**11** (12%). The structural assignment to *cis*-**16** was based on ^{1}H NMR and mass spectrometry data, and on its chemical reactivity; it afforded diol *anti*-**11** upon $NaBH_4$ reduction, and it was transformed into the mixture of the epimeric methyl glycosides *cis*-**18a** and *cis*-**18b** by treatment with MeOH–HCl.

Low diastereoselection was obtained when hydroxy ester **6** was reduced (Scheme 3). GC–MS analysis of the reduction mixture allowed us to detect *cis*-**16** (25%) and *trans*-**16** (20%), *syn*-**11** (14%) and *anti*-**11** (10%), (*E*)-**8** (12%) and (*Z*)-**8** (6%) (20), and a complex system of compounds with retention times and mass spectra resembling those of **17a** and **17b** (12%). The reaction was then repeated using methanol to consume the excess of $LiAlH_4$ and the residue was chromatographed, to yield a nearly 1:1 mixture of *cis*-**16** and *trans*-**16** and a 2:1 mixture of *syn*-diol **11** and *anti*-diol **11**. The saturated diol fraction was enriched in the *syn*-diasteroisomer (de = 83%) by column chromatography. An analytical sample of *trans*-**16** was obtained by careful column chromatography and recrystallization from ether. This sample was reduced to *syn*-**11** with $NABH_4$ and converted into methyl glycosides *trans*-**18a** and *trans*-**18b** with MeOH–HCl.

Racemic diols *anti*-**11** (de > 99%) and *syn*-**11** (de = 83%) were acetylated with Ac_2O–Py, and the corresponding acetyl derivatives *anti*-**19** and *syn*-**19** were submitted separately to enzymic saponification, at pH 7.8 in the presence of lipase PS. As for diacetate *anti*-**19** (Scheme 4), the first enzymic saponification (monitored by chiral HPLC) afforded monoacetate (1*R*,3*S*)-*anti*-**20** showing 55% ee (chiral HPLC). This latter was acetylated and submitted again to lipase-mediated hydrolysis, to give (1*R*,3*S*)-*anti*-**20** with ee = 95% (chiral HPLC). Treatment with KOH in methanol gave (1*R*,3*S*)-*anti*-**11** (ee = 95%, chiral HPLC). Diacetate (1*S*,3*R*)-*anti*-**19** (ee = 41%), chiral HPLC of the corresponding diol), recovered

[2] When unsaturated aldehyde **14** (18*a*) (*E*:*Z*, 2:1) (Scheme 1) was submitted to yeast fermentation, saturated alcohol (+)-(*R*)-**15** (19) (ee 82%, chiral HPLC) was obtained. BY reduction of the conjugated double bond thus showed the same preferred enantioselectivity in structurally related compounds (CIP descriptors are different because the group priority changes from (*E*)-**3** to **14**).

[3] The formation of derivatives **17a** and **17b** was unexpected and unusual. ^{1}H NMR spectra showed that in both compounds the substituent $CH(OH)CH_3$ was located in the equatorial position (**17a** $J_{(H\text{-}3,H\text{-}4)}$ = 11.5 Hz, **17b** $J_{(H\text{-}2,H\text{-}3)}$ = 8.9 Hz).

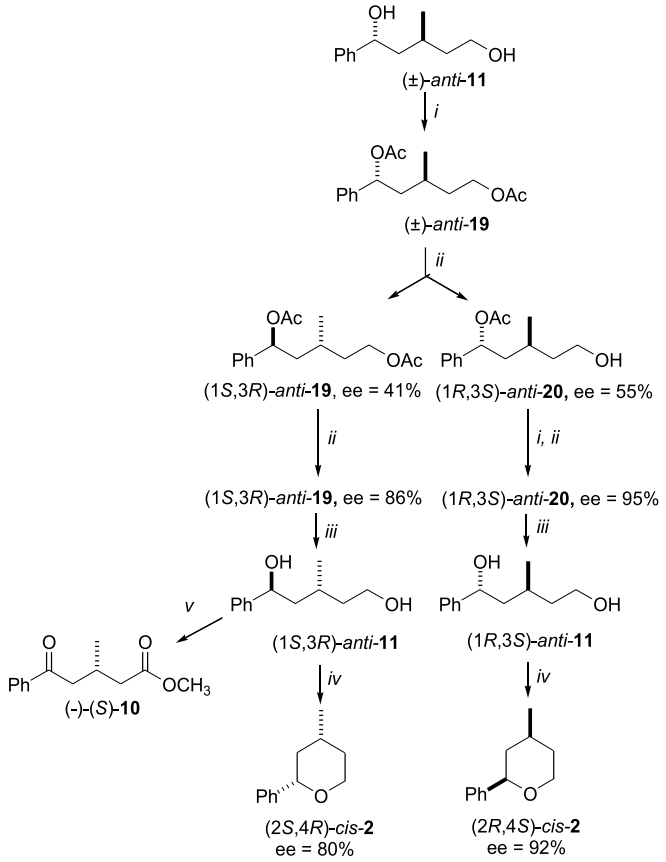
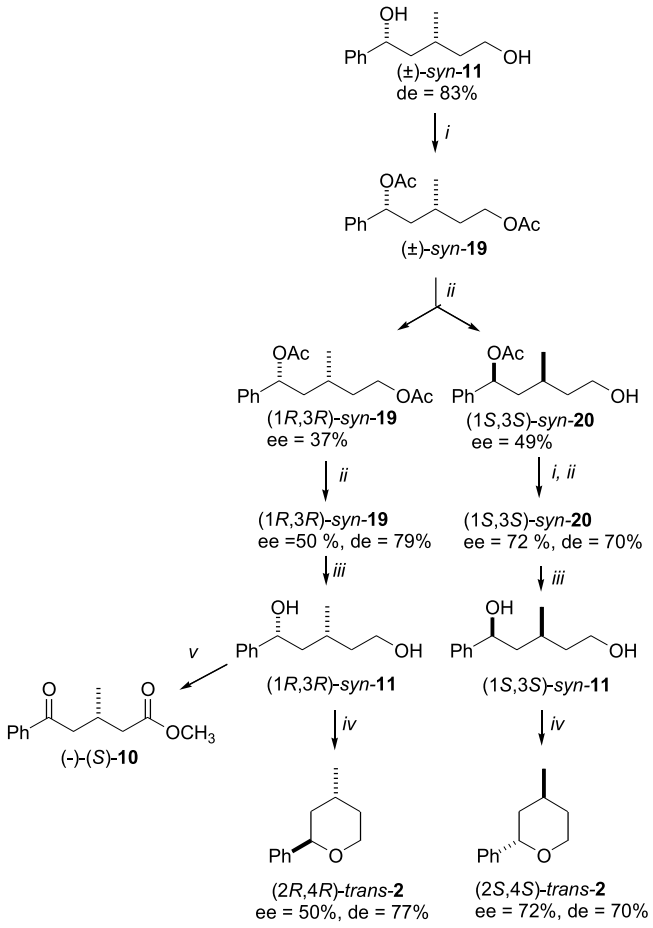
Scheme 4. (*i*) Acetic anhydride, pyridine; (*ii*) lipase PS, THF–water, pH 7.8, 0.025 M NaOH; column chromatography; (*iii*) KOH, MeOH; (*iv*) TosCl, pyridine, then MeONa in methanol; (*v*) Jones' reactive acetone.



Scheme 5. (*i*) Acetic anhydride, pyridine; (*ii*) lipase PS, THF–water, pH 7.8, 0.025 M NaOH; column chromatography; (*iii*) KOH, MeOH; (*iv*) TosCl, pyridine, then MeONa in methanol; (*v*) Jones' reactive acetone.



unreacted from the first saponification, was depleted of the (1*R*,3*S*) enantiomer as much as possible by prolonged enzymic reaction. Finally, it afforded diol (1*S*,3*R*)-*anti*-**11** with ee = 86% (chiral HPLC) by reaction with KOH in methanol.

The same procedure was applied to diacetate *syn*-**19** (Scheme 5). (1*S*,3*S*)-*syn*-**11** (ee = 72%, de = 70%) and (1*R*,3*R*)-*syn*-**11** (ee = 50%, de = 79%) were obtained from monoacetate *syn*-**20** and survived diacetate *syn*-**19**, respectively.

The four enantiomerically enriched diols were treated with tosyl chloride and pyridine, then with sodium methylate in methanol, to promote ring closure. The following samples of Doremox® were obtained: (*i*) (2*R*,4*S*)-*cis*-**2** (from (1*R*,3*S*)-*anti*-**11**): ee = 92%, de > 99% (chiral GC), $[\alpha]_D^{20}$ +52 (*c* = 0.27, $CHCl_3$); (*ii*) (2*S*,4*R*)-*cis*-**2** (from (1*S*,3*R*)-*anti*-**11**): ee = 80%, de > 99% (chiral GC), $[\alpha]_D^{20}$ – 42 (*c* = 1.2, $CHCl_3$); (*iii*) (2*S*,4*S*)-*trans*-**2** (from (1*S*,3*S*)-*syn* -**11**): ee = 72%, de = 70% (chiral GC), $[\alpha]_D^{20}$ + 14.6 (*c* = 0.3, $CHCl_3$); this sample contained 15% of (+)-*cis*-**2** with ee = 73%; (*iv*) (2*R*,4*R*)-*trans*-**2** (from (1*R*,3*R*)-*syn*-**11**): ee = 50%, de = 77% (chiral GC), $[\alpha]_D^{20}$ – 9.8 (*c* = 1.15, $CHCl_3$); this sample contained 11.5% of (–)-*cis*-**2** with ee = 65%.

Configurational assignment

The absolute configurations of the two stereocentres of diols *anti*-**11** and *syn*-**11** and of *cis*-**2** and *trans*-**2** were assigned by chemical correlation on the basis of these data: (*i*) ^{1}H NMR spectra of *cis*-**2** and *trans*-**2** had been described, so the relative configurations of Doremox® isomers and those of the diol precursors could be defined; (*ii*) samples of (–)-*anti*-**11** (ee > 99%) and of (+)-*syn*-**11** (ee = 50%, de = 79%) were oxidized to the corresponding keto acids upon treatment with Jones' reactive in acetone solution. These latter derivatives were purified by column chromatography of the correponding methyl esters (diazomethane). In both cases, (–)-(*S*)-**10** (lit. value (21*a*) $[\alpha]_D^{20}$ – 5.65 (*c* = 1.24, benzene) for the (*S*)-isomer, ee = 90%; lit. value (21*b*) $[\alpha]_D^{20}$ +9.25 (neat) for the (*R*)-isomer, ee > 96%) was obtained showing optical rotation values of –5.02 (*c* = 0.85, benzene; prepared from *anti*-**11**) and –3.21 (*c* = 0.73, benzene; prepared from *syn*-**11**). (*R*)-Configuration was assigned to C-3 in (–)-*anti*-**11** and (+)-*syn*-**11** (the CIP descriptor of the stereogenic carbon atom changes because the order of group priority is different). The absolute configurations of all the derivatives involved in the synthetic scheme was then deduced.

Thus, it was possible to verify that lipase PS promoted the saponification of both the diol isomers showing (*S*)-configuration at the carbon atom nearer to the reactive site.

Olfactory descriptions

Olfactory evaluation of Doremox® samples gave the following results: (*i*) (2*R*,4*S*)-*cis*-**2**, ee = 92%, de > 99%: rose oxide, diphenyl oxide, metallic, slightly plastic; (*ii*) (2*S*,4*R*)-*cis*-**2**, ee = 80%, de > 99%: rose oxide, powerful, nice; (*iii*) (2*S*,4*S*)-*trans*-**2**, ee = 72%, de = 70%: weak, rosy, plastic, citronellol, a rose oxide note is also present; (*iv*) (2*R*,4*R*)-*trans*-**2**, ee = 50%, de = 77%: rosy, rose oxide, metallic, off-note.

Experimental

Lipase PS *Pseudomonas cepacia* (Amano Pharmaceuticals Co., Japan) was employed in this work. GC–MS analyses were performed on a HP 6890 gas chromatograph equipped with a 5973 mass detector, using a HP-5MS column (30 m × 0.25 mm × 0.25 μm). The following temperature program was employed: 60°C (for 1 min)/6°/min to 150°C (for 1 min)/12°/min to 280°C (for 5 min). Chiral GC analyses of Doremox® stereoisomers were performed on a DeTBuSiBETA (086) 25 m × 0.25 mm column (Mega, Italy), installed on a DANI HT 86.10 gas chromatograph, with the following temperature program: 45°C (3′)/5°C/min to 75°C/0.5°C/min to 100°C/10°C/min to 180°C (5′): t_R (2*S*,4*R*)-**1a** = 45.4 min, t_R (2*R*,4*S*)-**1a** = 46.5 min, t_R (2*R*,4*R*)-**1b** = 49.2 min, t_R (2*S*,4*S*)-**1b** = 49.7 min. Chiral HPLC analyses were performed on a Chiralcel OD column (Daicel, Japan) installed on a Merck–Hitachi L-6200 apparatus: 0.6 mL min^{-1}, UV detector (254 nm), hexane:isopropanol (95:5). The following retention times were observed: (1*RS*,3*SR*)-*anti*-**19** (single peak) t_R = 11.4 min; (1*R*,3*S*)-*anti*-**20** t_R = 21.7 min; (1*S*,3*R*)-*anti*-**20** t_R = 28.9 min; (1*R*,3*S*)-*anti*-**11** t_R = 29.8 min; (1*S*,3*R*)-*anti*-**11** t_R = 30.6 min; (1*S*,3*S*)-*syn*-**19** t_R = 10.6 min; (1*R*,3*R*)-*syn*-**19** t_R = 11.1 min; (1*S*,3*S*)-*syn*-**20** t_R = 17.2 min; (1*R*,3*R*)-*syn*-**20** t_R = 23.9 min; (1*R*,3*R*)-*syn*-**11** t_R = 30.8 min; (1*S*,3*S*)-*syn*-**11** t_R = 41.9 min; (*R*)-**15** t_R = 14.9 min; (*S*)-**15** t_R = 17.2 min. ^{1}H NMR spectra were recorded at room temperature (r.t.) on a Bruker AC-250 spectrometer (250 MHz ^{1}H). The chemical shift scale was based on internal tetramethylsilane. Optical rotations were measured on a Dr. Kernchen Propol digital automatic polarimeter. Microanalyses were determined on a Carlo Erba 1106 analyzer. TLC analyses were performed on Merck Kieselgel 60 F_{254} plates. All the chromatographic separations were carried out on silica gel columns.

The mixture of (*E*)- and (*Z*)-methyl 4-bromo-3-methyl-2-butenoate (**5**) was prepared as described in ref. 12. The monochloride mono methyl ester of 3-methyl glutaric acid was prepared according to ref. 15. Aldehyde **14** was prepared according to ref. 18*a*, and the diasteroisomeric excess (33%) was determined on the basis of ^{1}H NMR spectra of (*E*)-**14** and (*Z*)-**14** in ref. 18*b*.

5-Hydroxy-3-methyl-5-phenyl-pent-2-enoic acid methyl ester (6) (13) and 4-methyl-6-phenyl-5,6-dihydropyran-2-one (7) (13)

A solution of bromo derivative **5** (38.4 g, 0.20 mol) and benzaldehyde (2.12 g, 0.20 mol) in 100 mL THF was added dropwise to a suspension of zinc (14.3 g, 0.22 mol) in 300 mL THF at 0°C. The reaction was refluxed for 2 h, poured into ice, and extracted with ethyl acetate. The organic layer was washed with a solution of ammonium chloride, dried (Na_2SO_4), and concentrated. Column chromatography (hexane–EtOAc, 9:1) provided hydroxy ester **6** (16.7 g, 38%) and lactone **7** (17.7 g, 47%).

6

GC–MS (t_R = 21.80 min) *m*/*z*: 186 (M^+ – 34) (50), 158 (100), 129 (40), 77 (25). ^{1}H NMR ($CDCl_3$, ppm): 7.32 (m, 5H, C_6H_5), 5.76 (q, *J* = 1.1 Hz, 1H, H-C_2), 4.89 (dd, *J* = 4.6, 8.1 Hz, 1H, H-C_5), 3.68 (s, 3H, $COOCH_3$), 2.53 (m, 2H, CH_2), 2.22 (d, *J* = 1.1 Hz, 3H, CH_3-C=C).

mp 60°C. GC–MS (t_R = 21.80 min) *m*/*z*: 188 (M^+) (10), 105 (8), 82 (100). ^{1}H NMR ($CDCl_3$, ppm): 7.35 (m, 5H, C_6H_5), 5.87 (m, 1H, H-C_3), 5.37 (dd, *J* = 3.9, 11.8 Hz, 1H, H-C_6), 2.62 (ddm, *J* = 11.8, 18.0 Hz, 1H, H-C_5), 2.42 (dd, *J* = 3.9, 18.0 Hz, 1H, H-C_5), 1.99 (m, 3H, CH_3-C=C).

(*E*)-3-Methyl-5-phenyl-2-pentene-1,5-diol ((*E*)-8)

A 1.5 M solution of diisobutyl aluminum hydride in toluene (69 mL, 0.103 mol) was added dropwise to a solution of hydroxy ester **6** (10.0 g, 0.045 mol) in 100 mL toluene at –10°C. The reaction was allowed to warm to 25°C, treated with water, filtered through a Celite cake, and extracted with ethyl acetate. The residue was chromatographed (hexane:EtOAc, 6:4) to give unsaturated diol (*E*)-**8** (6.82 g, 79%). GC–MS (t_R = 20.89 min) *m*/*z*: 174 (M^+ – 18) (0.04), 107 (71), 105 (83), 68 (100). ^{1}H NMR ($CDCl_3$, ppm): 7.25 (m, 5H, C_6H_5), 5.50 (tq, *J* = 6.7, 1.2 Hz, 1H, H-C_2), 4.76 (t, *J* = 6.7 Hz, 1H, H-C_5), 4.09 (m, 2H, CH_2OH), 2.35 (d, *J* = 6.7 Hz, 2H, CH_2), 1.71 (d, *J* = 1.2 Hz, 3H, CH_3-C=C). Anal. calcd. for $C_{12}H_{16}O_2$: C 74.97, H 8.39; found: C 74.75, H 8.53.

(*E*)-5-Hydroxy-3-methyl-5-phenyl-pent-2-enal ((*E*)-3) (14)

Manganese(IV) oxide (1.5 equiv) was added to a solution of unsaturated diol (*E*)-**8** (6.70 g, 0.035 mol) in 50 mL DMF. The suspension was heated at 80°C for 4 h, then filtered poured into water, and extracted with EtOAc. The organic phase was dried (Na_2SO_4), and concentrated in vacuo. The residue was chromatographed (hexane–EtOAc, 7:3) to afford (*E*)-**3** (6.05 g, 91%). GC–MS (t_R = 21.20 min) *m*/*z*: 190 (M^+) (0.01), 172 (6), 107 (92), 84 (100). ^{1}H NMR ($CDCl_3$, ppm): 9.99 (d, *J* = 7.9 Hz, 1H, CHO), 7.35 (m, 5H, C_6H_5), 5.95 (dt, *J* = 7.9, 1.1, 1H, H-C_2), 4.94 (dd, *J* = 4.9, 8.7 Hz, 1H, H-C_5), 2.68 (dd, *J* = 14.0, 8.7 Hz, 1H, H-C_4), 2.57 (dd, *J* = 14.0, 4.9 Hz, 1H, H-C_4), 2.22 (d, *J* = 1.1 Hz, 3H, CH_3-C=C).

Methyl 3-methyl-5-oxo-5-phenyl-pentanoate (10) (16)

Aluminum trichloride (15.9 g, 0.12 mol) was added to a solution of derivative **9** (17.8 g, 0.10 mol) in 300 mL benzene at 10°C. The reaction mixture was refluxed for 2 h, poured into ice and 10% HCl, and extracted with EtOAc. The organic phase was dried (Na_2SO_4), concentrated, and chromatographed (hexane–EtOAc, 95:5), to give keto ester **10** (14.1 g, 64%). GC–MS (t_R = 21.01 min) *m*/*z*: 220 (M^+) (1.4), 189 (7.1), 120 (75), 105 (100). ^{1}H NMR ($CDCl_3$, ppm): 7.97 (m, 2H, aromatic hydrogens), 7.40 (m, 3H, aromatic hydrogens), 3.67 (s, 3H, COOMe), 3.11 (dd, *J* = 16.0, 5.8 Hz, 1H), 2.84 (dd, *J* = 16.0, 7.3 Hz, 1H), 2.66 (m, 1H,

H-C_3), 2.44 (dd, J = 15.4, 6.1 Hz, 1H), 2.31 (dd, J = 15.4, 7.3 Hz, 1H), 1.05 (d, J = 6.6 Hz, CH_3).

3-Methyl-5-oxo-5-phenyl-pentanoic acid (4) (17)

Keto ester **10** (14.0 g, 0.064 mol) was hydrolysed with KOH (5.38 g, 0.096 mol) in 70 mL MeOH to afford, after the usual work-up, keto acid **4** (12.4 g, 93%). ^{1}H NMR ($CDCl_3$, ppm): 7.95 (m, 2H, aromatic hydrogens), 7.40 (m, 3H, aromatic hydrogens), 2.98 (m, 2H), 2.67 (m, 1H), 2.45 (m, 2H), 1.09 (d, J = 6.3 Hz, CH_3).

$LiAlH_4$ reduction of lactone 7

Procedure A

A solution of lactone **7** (18.8 g, 0.10 mol), in 30 mL THF was added dropwise to a suspension of $LiAlH_4$ (7.6 g, 0.20 mol), in 250 mL THF. The reaction mixture was stirred at r.t. for 12 h, then EtOAc was added to consume the excess $LiAlH_4$. The reaction mixture was poured into ice, extracted with Et_2O, dried (Na_2SO_4), and chromatographed (from hexane–EtOAc (95:5) to hexane–EtOAc (1:1)). The following products, in order of progressive elution, were isolated.

*(2*RS*,4*RS*,6*RS*)-4-Methyl-6-phenyl-tetrahydro-2*H*-pyran-2-ol and (2*RS*,4*SR*,6*SR*)-4-methyl-6-phenyl-tetrahydro-2*H*-pyran2-ol (*cis*-**16**, 1:1 mixture of the two epimers at C-2)*

7.68 g (40%), mp 67°C (diethyl ether). GC–MS (t_R = 19.34 min, single peak) m/z: 192 (M^+) (1.7), 174 (13), 159 (17), 104 (100). ^{1}H NMR ($CDCl_3$, ppm): 7.32 (m, 10H, $2C_6H_5$), 5.40 (m, 1H, H-C_2 of one epimer), 4.98 (dd, 1H, J = 11.8, 2.1 Hz, H-C_2 of one epimer), 4.74 (dd, 1H, J = 9.6, 2.1 Hz, H-C_6 of one epimer), 4.74 (dd, 1H, J = 11.3, 1.7 Hz, H-C_6 of one epimer), 2.16 (m, 1H), 1.78 (m, 5H), 1.39–0.97 (m, 4H), 0.94 (d, J = 6.6 Hz, 3H, CH_3 of one epimer), 0.90 (d, J = 6.6 Hz, 3H, CH_3 of one epimer). Anal. calcd. for $C_{12}H_{16}O_2$: C 74.97, H 8.39; found: C 75.13, H 8.48.

A sample of *cis*-**16** was treated with MeOH–HCl to give the mixture of the corresponding *O*-methyl glycosides *cis*-**18a** and *cis*-**18b** (3:1 mixture of the two epimers at C-2). GC–MS major epimer (t_R = 17.61 min) m/z: 206 (M^+) (2), 174 (41), 104 (94), 58 (100); minor epimer (t_R = 18.17 min): 174 (M^+ – 32) (3), 146 (27), 104 (100), 58 (50). ^{1}H NMR ($CDCl_3$, ppm): 7.32 (m, $2C_6H_5$), 4.90 (m, 1H of the major epimer), 4.74 (dd, J = 11.8, 1.9 Hz, 1H of the major epimer), 4.48 (dd, J = 9.8, 1.9 Hz, 1H of the minor epimer), 4.43 (dd, J = 11.3, 1.4 Hz, 1H of the minor epimer), 3.52 (s, OCH_3 of the minor epimer), 3.39 (s, OCH_3 of the major epimer), 2.16 (m, 1H), 1.83 (m), 1.45–1.10 (m), 1.00 (d, J = 6.3 Hz, CH_3 of the minor epimer), 0.93 (d, J = 6.8 Hz, CH_3 of the major epimer).

Procedure B

A solution of lactone **7** (18.8 g, 0.10 mol), in 30 mL THF was added dropwise into a suspension of $LiAlH_4$ (7.60 g, 0.20 mol), in 250 mL THF. The reaction mixture was stirred at r.t. for 12 h, then MeOH was added to consume the excess $LiAlH_4$. The reaction mixture was poured into ice, extracted with Et_2O, dried (Na_2SO_4), and chromatographed (from hexane–EtOAc (95:5) to hexane:EtOAc (1:1)). The following products, in order of progressive elution, were isolated: *cis*-**16** (8.64 g, 45%), (*Z*)-**8** (1.15 g, 6%), *anti*-**11** (3.49 g, 18%).

© 2002 NRC Canada

cis-**16** (8.50 g, 0.045 mol) was treated with $NaBH_4$ (2.56 g, 0.067 mol) in 50 mL CH_2Cl_2–MeOH (2:1) solution, to afford, after the usual work-up, *anti*-**11** (7.59 g, 87%).

$LiAlH_4$ reduction of hydroxy ester 6

Procedure A

The reduction of **6** (22.0 g, 0.10 mol), followed by treatment with EtOAc, gave the following mixture of products (GC–MS identification only): *cis*-**16** (25%, t_R = 19.35 min), *trans*-**16** (20%, t_R = 19.59 min), *syn*-**11** (14%, t_R = 20.80 min), *anti*-**11** (10%, t_R = 20.89 min), (*Z*)-**8** (6%, t_R = 21.03 min), (*E*)-**8** (12.5%, t_R = 21.19 min), unidentified products 12%, 23.72–24.12 min.

Procedure B

The reduction of **6** (22.0 g, 0.10 mol), followed by treatment with MeOH, gave a residue which was chromatographed, to give (after column chromatography) a 1:1 mixture of *cis*- and *trans*-**16** (2.96 g, 15%), a 9:1 mixture of (*E*)- and (*Z*)-**8** (1.82 g, 9%), and a 2:1 mixture of *syn*- and *anti*-**11** (12.4 g, 64%).

*(2*RS*,4*RS*,6*SR*)-4-Methyl-6-phenyl-tetrahydro-2*H*-pyran-2-ol and (2*RS*,4*SR*,6*RS*)-4-methyl-6-phenyl-tetrahydro-2*H*-pyran-2-ol (*trans*-**16***, mixture of two epimers)*

The 1:1 mixture of *cis*- and *trans*-**16** (2.96 g) was chromatographed (hexane–EtOAc, 9:1), to give, after crystallization from ether, *trans*-**16** (1.03 g), mp 72°C. GC–MS (t_R = 19.57 min (single peak)) *m*/*z*: 192 (M^+) (3.3), 174 (42), 159 (83), 104 (100). ^1H NMR ($CDCl_3$, ppm): 7.35 (m, $2C_6H_5$), 5.15 (m), 5.07 (dd, *J* = 9.1, 3 Hz, 1H), 4.74 (dd, *J* = 11.7, 2.3 Hz), 2.27 (m), 2.11–1.29 (m), 1.17 (d, *J* = 6.9 Hz, $2CH_3$). Anal. calcd. for $C_{12}H_{16}O_2$: C 74.97, H 8.39; found: C 75.26, H 8.11.

A sample of *trans*-**16** was treated with MeOH–HCl, to afford the mixture of the corresponding *O*-methyl glycosides *trans*-**18a** and *trans*-**18b** (2:1 mixture of the two epimers at C-2). GC–MS major epimer (t_R = 17.88 min) *m*/*z*: 174 (M^+ – 32) (23), 146 (25), 104 (100), 58 (85); minor epimer (t_R = 18.53 min) *m*/*z*: 174 (M^+ – 32) (4), 146 (21), 104 (100), 58 (50). ^1H NMR ($CDCl_3$, ppm): 7.35 (m, $2C_6H_5$), 4.96 (dd, *J* = 3.9, 9.3 Hz), 4.78 (t, *J* = 3.9 Hz), 4.71 (m), 3.50 (s, OCH_3 of the minor epimer), 3.39 (s, OCH_3 of the major epimer), 2.31 (m), 2.06–1.43 (m), 1.22 (d, *J* = 6.9 Hz, CH_3 of the major epimer), 1.21 (d, *J* = 6.7 Hz, CH_3 of the minor epimer).

Yeast reduction

A suspension of bakers' yeast (0.5 kg) and D-glucose (0.4 kg) in tap water (1.5 L) was stirred for 30 min at 32°C. A solution of the suitable substrate (0.03 mol) in ethanol (20 mL) was then added. After 48 h at r.t., Celite (200 g) was added, and the reaction mixture filtered, washing the Celite pad with ethyl acetate. The filtrate was adjusted to pH 4 with 2 N HCl, and extracted with ethyl acetate. The organic layer was dried (Na_2SO_4) and concentrated under reduced pressure. The residue was chromatographed on a silica gel column. The following derivatives were obtained upon BY reduction.

*(1*S*,3*S*)-3-Methyl-1-phenyl-pentane-1,5-diol ((1*S*,3*S*)-syn-**11**)*

2.99 g (44%) (from (*E*)-**3** (6.60 g, 0.035 mol)), ee > 99% (chiral HPLC), de = 60% (GC–MS). The sample contained 20% of (1*R*,3*S*)-*anti*-**11** (ee > 99%, chiral HPLC). ^1H NMR and GC–MS spectra were in agreement with those of (±)-*syn*-**11**.

General procedure of lipase-mediated kinetic resolution

A solution of the suitable diacetate (10.0 g, 0.036 mol) in 2 mL THF was added to a suspension of lipase PS (5 g) in 100 mL water at pH 7.8 at room temperature. The pH was kept constant by means of a pH-Stat. The reaction was monitored by chiral HPLC. When the mono alcohol mono acetate formed upon saponification reached ee ~ 50%, the reaction was stopped. The mixture was filtered, extracted with EtOAc, and chromatographed (hexane–EtOAc, 9:1). The mono alcohol mono acetate was acetylated with Ac_2O and pyridine, and submitted again to enzymic saponification to enhance ee.

Diacetate (1*S*,3*R*)-*anti*-**19** (2.20 g, 7.91 mmol) was hydrolysed with KOH (0.644 g, 0.012 mol) in 10 mL MeOH, to afford diol (1*S*,3*R*)-*anti*-**11** (1.39 g, 91%), ee = 86% (chiral HPLC), de > 99% (GC–MS). $[\alpha]_D^{20}$ –53.4 (c = 0.55, $CHCl_3$). ^{1}H NMR and GC–MS spectra were in agreement with those of (±)-*anti*-**11**.

(1*S,*3*S*)-3-Methyl-1-phenyl-pentane-1,5-diol ((1*S,*3*S*)*-syn-*11)

Mono alcohol mono acetate (1*S*,3*S*)-*syn*-**20** (1.30 g, 5.51 mmol) was hydrolysed with KOH (0.464 g, 8.26 mmol) in 10 mL MeOH, to afford diol (1*S*,3*S*)-*syn*-**11** (1.01 g, 95%), ee = 70% (chiral HPLC), de = 72% (GC–MS). $[\alpha]_D^{20}$ –15.5 (c = 1.05, $CHCl_3$). ^{1}H NMR and GC–MS spectra were in agreement with those of ((±)-*syn*-**11**.

(1*R,*3*R*)-3-Methyl-1-phenyl-pentane-1,5-diol ((1*R,*3*R*)*-syn-*11)

Diacetate (1*R*,3*R*)-*syn*-**19** (2.30 g, 8.27 mmol) was hydrolysed with KOH (0.694 g, 0.012 mol) in 10 mL MeOH, to afford diol (1*R*,3*R*)-*syn*-**11** (1.41 g, 88%), ee = 50% (chiral HPLC), de = 77% (GC–MS). $[\alpha]_D^{20}$ +11.05 (c = 1.05, $CHCl_3$). ^{1}H NMR and GC–MS spectra were in agreement with those of (±)-*syn*-**11**.

General procedure for the preparation of Doremox®

p-Toluene-sulfonyl chloride (1.47 g, 7.73 mmol) was added to a solution of the suitable diol (1.00 g, 5.15 mmol), in 10 mL CH_2Cl_2 and 2 mL pyridine at 0°C. The reaction mixture was stirred at room temperature for 3 h, then poured into water and extracted with CH_2Cl_2. The residue, obtained upon concentration, was dissolved in 10 mL MeOH, and treated with MeONa in MeOH (1 M, 8 mL). The reaction mixture was stirred at r.t. for 2 h, poured into water, and extracted with EtOAc. The organic phase was dried (Na_2SO_4), concentrated, and chromatographed (hexane–EtOAc, 95:5), to afford *cis* or *trans*-**2**.

*(2*R,*4*S*)-*cis-***2** *(from (1*R,*3*S*)-*anti-***11** *(1.1 g, 5.67 mmol))*

0.668 g (67%), ee = 92%, de > 99% (chiral GC). $[\alpha]_D^{20}$ +52 (c = 0.27, $CHCl_3$). GC–MS (t_R = 15.59 min) m/z: 176 (M^+) (100), 175 (90), 105 (73). ^{1}H NMR ($CDCl_3$, ppm): 7.31 (m, 5H, C_6H_5), 4.31 (dd, J = 1.9, 11.2 Hz, 1H, H-C_2), 4.15 (ddd, J = 1.5, 4.2, 11.2, 1H, C-H_6), 3.60 (m, 1H, H-C_6), 1.82 (m, 2H), 1.58 (m, 1H), 1.26 (m, 2H), 0.98 (d, J = 6.2 Hz, 3H, CH_3-C_4).

*(2S,4R)-cis-***2** *(from (1S,3R)-anti-***11** *(1.30 g, 6.70 mmol))*

0.778 g (66%), ee = 80%, de > 99% (chiral GC). $[\alpha]_D^{20}$ – 42 (c = 1.2, $CHCl_3$). ^{1}H NMR and GC–MS spectra were in agreement with those of (+)-*cis*-**2**.

*(2*S,*4*S*)-*trans-***2** *(from (1*S,*3*S*)-*syn-***11** *(0.981 g, 5.05 mmol))*

0.577 g (65%), ee = 72%, de = 70% (chiral GC). $[\alpha]_D^{20}$ +14.6 (c = 0.3, $CHCl_3$); this sample contained 13% of (+)-*cis*-**2** and 2% of (–)-*cis*-**2**. GC–MS (t_R = 16.05 min) m/z: 176 (M^+) (100), 175 (89), 105 (80). ^{1}H NMR ($CDCl_3$, ppm): 7.31 (m, 5H, C_6H_5), 4.67 (dd, J = 3.1, 9.6 Hz, 1H, H-C_2), 3.83 (m, 2H, CH_2-O), 2.10 (m, 1H), 1.92 (m, 2H), 1.61 (m, 1H), 1.34 (m, 1H), 1.17 (d, J = 7.1 Hz, 3H, CH_3-C_4).

*(2*R*,4*R*)*-trans-***2** *(from (1*R*,3*R*)*-syn-***11** *(1.30 g, 6.70 mmol))*

0.743 g (63%), ee = 50%, de = 77% (chiral GC). $[\alpha]_D^{20}$ –9.8 (*c* = 1.15, $CHCl_3$); this sample contained 9.5% of (–)-*cis*-**2** and 2% of (+)-*cis*-**2**. ^{1}H NMR and GC–MS spectra were in agreement with those of (+)-*trans*-**2**.

*(2*S*,4*R*)*-cis-***2** *(from (1*S*,3*R*)*-anti-***11** *(1.50 g, 7.73 mmol, obtained by reduction of (4*S*,6*S*)-***13**))*

0.925 g (68%), ee = 98%, de > 99% (chiral GC). $[\alpha]_D^{20}$ –54.1 (*c* = 1.05, $CHCl_3$). ^{1}H NMR and GC–MS spectra were in agreement with those of (+)-*cis*-**2**.

*(2*S*,4*S*)*-trans-***2** *(from (1*S*,3*S*)*-syn-***11** *(obtained by BY reduction of (*E*)-***3**))*

ee = 99%, de = 72% (chiral GC). $[\alpha]_D^{20}$ +18.1 (*c* = 0.75, $CHCl_3$); this sample contained 14% of (+)-*cis*-**2** with ee > 99%. ^{1}H NMR and GC–MS spectra were in agreement with those of (+)-*trans*-**2**.

Configurational assignment

Two samples of (–)-*anti*-**11** (ee = 86%, de > 99%) and (+)-*syn*-**11** (ee = 50%, de = 79%) were oxidized with Jones' reagent in acetone. The corresponding keto acids were treated with diazomethane in Et_2O, and the corresponding methyl ester derivatives were purified by column chromatography (hexane). The following samples of keto ester **10** were obtained: (*i*) (–)-**10** (from (–)-*anti*-**11**): chemical purity (GC–MS) = 98%. $[\alpha]_D^{20}$ –5.02 (*c* = 0.85, benzene) lit. value (21*a*) $[\alpha]_D^{20}$ –5.65 (*c* = 1.24, benzene) for (*S*)-isomer ee = 90%; lit. value (21*b*) $[\alpha]_D^{20}$ +9.25 (neat) for (*R*)-isomer ee > 96%; (*ii*) (–)-**10** (from (+)-*syn*-**11**): chemical purity (GC–MS) = 97%. $[\alpha]_D^{20}$ –3.21 (*c* = 0.73, benzene).

Conclusion

The preparation of the four stereoisomers of Doremox® in enantiomerically enriched form was accomplished. BY reduction of suitable precursors **3** and **4** resulted in enantiospecific and highly diastereoselective compounds. Diol precursors of (–)-*cis*-**2** (ee > 99%, de = 98%) or of (+)-*trans*-**2** (ee > 99%, de = 72%) were obtained when a carbonyl or a carbon–carbon double bond was reduced by yeast, under the influence of a preexisting stereocentre in position β. Thus, an interesting, unpredictable stereochemical feature of BY reduction was highlighted.

Lipase PS-mediated kinetic resolution of diol *anti*-**11** and *syn*-**11** was less efficient, but it allowed us to obtain both the enantiomers of the *cis* and *trans* series. The high reactivity of primary acetate groups towards saponification prevented the accomplishment of higher enantiomeric excesses. However, the enzymic reaction of diacetate derivatives enriched in the most reactive enantiomer allowed us to reach quite satisfactory enantiomeric excesses. Biocatalyzed reactions are once again the most effective in the optical activation of such scarcely functionalised substrates as diols *anti*-**11** and *syn*-**11**.

The whole work put into evidence the supremacy of yeast reduction with respect to lipase-mediated hydrolysis. Once the substrate has been accepted by yeast, the whole-cell reductive system always assures enantiospecific transformations, which greatly compensate for the troublesome work-up. Lipases are of much wider application, showing less demanding requisites on the substrate acceptance, but their stereochemical course is sometimes less satisfactory, and strongly dependent on structural factors.

The unusual behaviour of hydroxy ester **6** and lactone **7** under hydride reduction was fully described. Lactols were isolated, as well as products of a diastereoselective addition of some intermediates on EtOAc, followed by reduction.

Olfactory evaluation of optically enriched Doremox samples clearly showed that (2*S*,4*R*)-*cis*-**2** is the nicest and the most powerful isomer of the series. This stereoisomer, incidentally, has the same absolute configuration of the most appreciated of rose oxide isomers (22) (i.e., (2*S*,4*R*)-*cis*-**1**).

Selective biotransformation of substituted alicyclic nitriles by *Rhodococcus equi* A4

Ludmila Martínková, Norbert Klempier, Margit Preiml, Mária Ovesná, Marek Kuzma, Veronika Mylerová, and Vladimír Křen

Abstract: Nitrile hydratase from *Rhodococcus equi* A4 discriminated between geometric isomers of substituted alicyclic nitriles. The enzyme transformed *trans*-4-benzoyloxycyclohexanecarbonitrile (*trans*-**1a**), *cis*-3-benzoyloxycyclohexanecarbonitrile (*cis*-**2a**), *trans*-2-hydroxycyclohexanecarbonitrile (*trans*-**3a**), and *trans*-2-hydroxycyclopentanecarbonitrile (*trans*-**4a**) into the corresponding amides. On the contrary, *cis*-2-hydroxycyclohexanecarbonitrile (*cis*-**3a**) and *cis*-2-hydroxycyclopentanecarbonitrile (*cis*-**4a**) were not converted to a significant extent. *cis*-4-Benzoyloxycyclohexanecarbonitrile (*cis*-**1a**) was also a substrate of the enzyme but reacted slowly. Diequatorial arrangement of the substituents in *trans*-**1a**, *cis*-**2a**, and *trans*-**3a** appears to positively influence the activity of the nitrile hydratase.

Key words: nitrile hydratase, substituted cyclohexanecarbonitriles, substituted cyclopentanecarbonitriles.

Résumé : L'hydratase des nitriles obtenue à partir de *Rhodococcus equi* A4 donne lieu à de la discrimination entre des isomères géométriques de nitriles alicyliques substitués. L'enzyme a transformé les *trans*-4-benzoyloxycyclohexanecarbonitrile (*trans*-**1a**), *cis*-3-benzoyloxycyclohexanecarbonitrile (*cis*-**2a**), *trans*-2-hydroxycyclohexanecarbonitrile (*trans*-**3a**) et *trans*-2-hydroxycyclopentanecarbonitrile *(trans*-**4a**) en amides correspondants. Au contraire, le degré de conversion des *cis*-2-hydroxycyclohexanecarbonitrile (*cis*-**3a**) et *cis*-2-hydroxycyclopentanecarbonitrile (*cis*-**4a**) est faible. Comme substrat de cet enzyme, le *cis*-4-benzoyloxycyclohexanecarbonitrile (*cis*-**1a**) ne réagit que lentement. L'arrangement diéquatorial des substituants dans les isomères *trans*-**1a**, *cis*-**2a** et *trans*-**3a** semble influencer positivement l'activité de l'hydratase des nitriles.

Mots clés : hydratase des nitriles, cyclohexanecarbonitriles substitués, cyclopentanecarbonitriles substitués.

[Traduit par la Rédaction]

Introduction

The use of bacterial nitrile-converting enzymes for enantio-, regio-, and chemoselective hydration and hydrolysis of nitriles has been described in numerous works (1). This work reports the resolution of geometric isomers using a nitrile hydratase.

Different affinities of this enzyme for geometric isomers of *trans*-1,4-dicyanocyclohexane (DCC) were shown using *Corynebacterium* sp. C5 cells containing both nitrile hydratase and amidase. The relative specific activity of the biocatalyst for the *cis* isomer of DCC was only 6% of that for the *trans* isomer (2). The conversion of *trans*-DCC to *trans*-4-cyanocyclohexane-1-carboxylic acid was involved in the chemoenzymatic synthesis of the pharmaceutically important *trans*-4-aminomethylcyclohexanecarboxylic acid (tranexamic acid) (3).

The hydrolysis of alicyclic mono- and dinitriles and amides of *cis* configuration was reported to be catalyzed by *Rhodococcus rhodochrous* IFO 15564 with enantioselectivity in some cases (4), but the biotransformation of the corresponding *trans* isomers was not studied.

Whole-cell biocatalyst SP 409 (Novo Industri, not available commercially) hydrolyzed both *cis*- and *trans*-2-hydroxycyclohexanecarbonitrile and *cis*-2-hydroxycyclopentanecarbonitrile (5).

Here we report the discrimination of *trans* and *cis* isomers of the 3- and 4-benzoyloxy- and 2-hydroxy derivatives of cyclohexanecarbonitriles as well as 2-hydroxycyclopentanecarbonitriles by the nitrile hydratase from *Rhodococcus equi* A4.

Results and discussion

Hydrolysis of alicyclic nitriles, 2-hydroxycyclohexanecarbonitrile, 2-hydroxycyclopentanecarbonitrile (5), cyclopentanecarbonitrile (6), and 2-arylcyclopropanecarbonitriles (7), or the regioselective hydrolysis of DCC (2, 3, 8), *trans*-cyclohexane-1,4-diacetonitrile (9), and other saturated and unsaturated dinitriles (4) was the subject of few reports regarding enzymatic nitrile conversion. The present work demonstrated that the nitrile hydratase from *R. equi* A4, which showed a broad substrate specificity for aromatic,

Scheme 1.

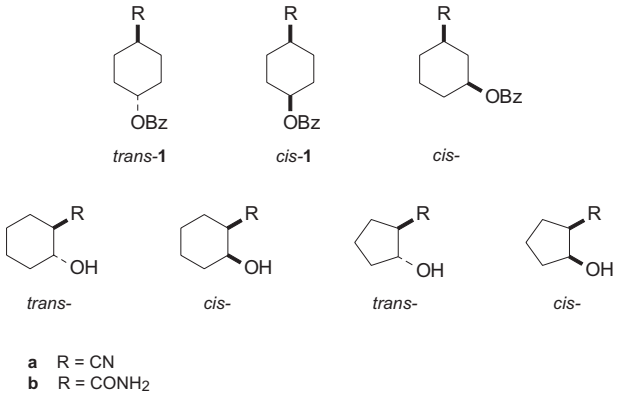

Table 1. Biotransformations of 2-hydroxycyclohexanecarbonitriles, 2-hydroxycyclopentanecarbonitriles, and 3-, 4-benzoyloxycyclohexanecarbonitriles by the nitrile hydratase of *Rhodococcus equi* A4.

Substrate[a]	Reaction time (h)	Product	Conversion (%)[b]	Isolated yield (%)
trans-**1a**	2	*trans*-**1b**	100	91
cis-**1a**	48	*cis*-**1b**	85	74
cis-**2a**	5	*cis*-**2b**	86	79
trans-**3a**	3.5	*trans*-**3b**	100	48
cis-**3a**	24	*cis*-**3b**	<5[c]	—
trans-**4a**	3	*trans*-**4b**	100	51
cis-**4a**	24	no reaction	—	—

[a]The structures (see Scheme 1) represent single enantiomers of *trans*-**1a**, *cis*-**1a**, *cis*-**2a**, *trans*-**3a**, *cis*-**3a**, *trans*-**4a**, and *cis*-**4a**, whereas the biotransformations were carried out with racemates.
[b]Determined by TLC (for compound **4a**) or HPLC (for other compounds).
[c]Traces of amide detected by NMR.

arylaliphatic, and aliphatic nitriles (10), is also useful for the hydration of alicylic nitriles. The use of the purified enzyme afforded 2-, 3-, and 4-substituted (hydroxy-, benzoyloxy-) alicyclic amides. On the contrary, whole-cell biocatalyst SP 409 exhibiting nitrile hydratase and amidase activities gave 2-hydroxycyclohexane- and 2-hydroxycyclopentanecarboxylic acids as the only products (5).

The syntheses of *cis*- and *trans*-2-hydroxycyclohexanecarboxamide (11), 2-hydroxycyclopentanecarboxamide (11), as well as *cis*- (12, 13) and *trans*-4-hydroxycyclohexanecarboxamide (13) have been published previously. Hydroxycyclohexanecarboxamides, both the *cis*- and *trans*-3-isomers, were reported as the respective *O*-acetyl derivatives only (12); however, no NMR data were given for these compounds.

All examined *trans* isomers of 2- and 4-substituted alicyclic nitriles (Scheme 1) were readily converted into the corresponding amides by the nitrile hydratase from *R. equi* A4 (Table 1). *trans*-4-Benzoyloxycyclohexanecarbonitrile (*trans*-**1a**) was transformed at a substantially higher rate than *cis*-**1a**. The reaction rate of *cis*-3-benzoyloxycyclohexanecarbonitrile (*cis*-**2a**) was somewhat lower than that of *trans*-**1a** (Table 1). The *trans* isomer of **2a** was not available.

An even more striking difference than between *trans*-**1a** and *cis*-**1a** was observed when comparing the activities of the nitrile hydratase towards *trans* and *cis* isomers of 2-hydroxycyclohexanecarbonitriles (*trans*-**3a** and *cis*-**3a**) or 2-hydroxycyclopentanecarbonitriles (*trans*-**4a** and *cis*-**4a**) (Table 1). In both pairs of nitriles, the compounds bearing *trans*-substituents were totally converted within 3 h to afford corresponding amides *trans*-**3b** and *trans*-**4b**, respectively. On the contrary, only traces of *cis*-**3b** were formed from *cis*-**3a**, and nitrile *cis*-**4a** was not transformed by the enzyme at all.

It is apparent that the enzyme prefers an equatorial position for both substituents, which can be adopted by the *trans*-1,2- and *trans*-1,4-isomers of the investigated substituted cyclohexanecarbonitriles. Nevertheless, this diequatorial arrangement of the substituents is also in accordance with *cis*-3-benzoyloxycyclohexanecarbonitrile (*cis*-**2a**), which is readily converted to the amide. The two large coupling constants J_{aa} = 9.2 and 9.7 Hz and J_{aa} = 8.7 and 8.8 Hz for H-1 and H-3, respectively, and the ^{1}H coupling pattern clearly reveal a diequatorial substituent position in *cis*-**2a**.

Impairment of the activity of the nitrile hydratase from *R. equi* A4 by steric effects, for example by nitriles with bulky groups such as 2-(3-benzoylphenyl)propionitrile, 2,6-dichlorobenzonitrile, and some 2-substituted benzonitriles, was previously observed (10). Its inefficient hydration of 2- and 4-substituted cyclohexane(pentane)carbonitriles with a *cis*-configuration suggested that this enzyme is more sensitive to steric hindrances than biocatalyst SP 409.

Experimental

NMR spectra of substrates were recorded on a Varian Gemini 200 spectrometer (200 and 50.3 MHz for ^{1}H and ^{13}C, respectively) in $CDCl_3$. NMR spectra of products of the biotransformation were recorded on a Unity Inova 400 MHz spectrometer (399.90 MHz for ^{1}H, 100.57 MHz for ^{13}C) in DMSO-d_6 at 30°C. The assignment was based on COSY, HMQC, and HMBC experiments performed using the manufacturer's software. Residual solvent signals (DMSO: δ_H 2.50 ppm, δ_C 39.60 ppm; $CDCl_3$: δ_H 7.27 ppm, δ_C 77.27 ppm) were used as internal standards.

Synthesis of substrates

Nitriles *trans*-**1a** (14), *cis*-**1a** (14), *cis*-**2a** (15), *trans*-**3a** (16), *cis*-**3a** (17), *trans*-**4a** (18), and *cis*-**4a** (17) were prepared according to literature reported procedures. ^{13}C and ^{1}H NMR data were previously reported for *trans*-**1a** (19), *cis*-**1a** (19), *trans*-**3a** (16, 20), *cis*-**3a** (20–22), *trans*-**4a** (18), and *cis*-**4a** (20–22) but no ^{1}H–^{1}H coupling constants were given.

General procedure of the biotransformation

The nitrile hydratase from *Rhodococcus equi* A4 (10) was diluted with KH_2PO_4–Na_2HPO_4 buffer (54 mM, pH 7.5) to a concentration of 22 μg of protein mL^{-1} (42 μg of protein mL^{-1} for *cis*-**2a**) and the substrates were added from stock solutions in methanol to make up final concentrations of 1.25 mM of *trans*-**1a**, *cis*-**1a**, and *cis*-**2a** and 5 mM of *trans*-**3a**, *cis*-**3a**, *trans*-**4a**, and *cis*-**4a**. Methanol did not exceed 5% (v/v) of the reaction mixture. The reactions were carried out in shaken vessels (850 rpm, Thermomixer Compact Eppendorf) at 30°C. At intervals, samples were withdrawn, the reaction was quenched with 1 M HCl (0.1 mL per 1 mL of sample) and the precipitated protein was removed by centrifugation. The supernatants were analyzed by HPLC as described below or by TLC on silica gel plates (Merck) developed with chloroform–ethyl acetate (10:1) (for substrates *trans*-**3a**, *cis*-**3a**, *trans*-**4a**, and *cis*-**4a**); the spots were visualized by charring with 5% sulphuric acid in ethanol.

Analytical HPLC

The concentrations of substrates and products were determined using an HPLC system consisting of a solvent-delivery system 600 (Waters), a photo-diode array detector 996 (Waters), and a refractive-index detector 2410 (Waters) and a Nova-Pak C_{18} column (5 μm, 3.9 × 150 mm, Waters). As mobile phases, 50% (v/v) acetonitrile (for compounds *trans*-**1a**, *trans*-**1b**, *cis*-**1a**, *cis*-**1b**, *cis*-**2a**, and *cis*-**2b**) or 10% (v/v) acetonitrile (for other compounds) in water plus 0.1 % (v/v) H_3PO_4 were employed at a flow rate of 1.0 mL min^{-1}. Compounds *trans*-**1a**, *trans*-**1b**, *cis*-**1a**, *cis*-**1b**, *cis*-**2a**, and *cis*-**2b** (retention times 5.6, 2.2, 5.0, 1.8, 5.5, and 2.1 min, respectively) were detected at 230 nm. Compounds *cis*-**3a**, *trans*-**4a**, and *cis*-**4a** (retention times 5.4, 3.5, and 2.9 min, respectively) were detected by the refractive-index detector.

Isolation and identification of products

Amides *trans*-**1b**, *cis*-**1b**, and *cis*-**2b** were extracted from supernatants of the reaction mixtures with ethyl acetate at pH 8.5–8.8 (NaOH). The reaction mixtures from the biotransformations of substrates *trans*-**3a** and *trans*-**4a** were lyophilized and extracted with methanol to give the respective amides *trans*-**3b** and *trans*-**4b**.

Exploratory synthetic investigations related to 12a-deoxypillaromycinone

Lan Wang, Sanath K. Meegalla, Cheng-Lin Fang, Nicholas Taylor, and Russell Rodrigo

Abstract: Furfural is converted to suitably substituted AB synthon **21** for 12a-deoxypillaromycinone in 10 steps by a sequence involving the following key steps: intramolecular Diels-Alder reaction of a furan, *5-endo-trig* cleavage of the oxabicyclo adducts **18**, and catalytic hydrogenation of the double bond of a tetrasubstituted enone to produce **19**. Enones **21a** and **21b** obtained by dehydrogenation of **19a** and **19b**, respectively, are then annulated with ethyl 2-methoxy-6-methylbenzoate in a four-step procedure to generate tetracyclic products **25** in 14 steps from furfural.

Key words: antibiotics, furan, intramolecular Diels-Alder, retro Diels-Alder.

Résumé : Le furfural peut être transformé par une séquence de synthèse en dix étapes en un synthon AB (**21**) portant des substituants appropriés pour la 12a-désoxypillaromycocinone; les étapes clés sont une réaction de Diels-Alder intramoléculaire sur le furane, un clivage *5-endo-trig* des adduits oxabicycliques (**18**) et une hydrogénation catalytique de la double liaison de l'énone tétrasubstituée conduisant au produit **19**. Les énones **21a** et **21b** été obtenues par déshydrogénation des produits **19a** et **19b** ont été soumises à une annellation en quatre étapes avec le 2-méthoxy-6-méthylbenzoate d'éthyle qui génère les produits tétracycliques **25** en 14 étapes à partir du furfural.

Mots clés : antibiotiques, furane, Diels-Alder intramoléculaire, rétro Diels-Alder.

[Traduit par la Rédaction]

Introduction

Pillaromycin A, isolated from a culture of *Streptomyces flavovirens* in 1970 (1), is an anti-neoplastic antibiotic that is structurally related to the anthracyclines and tetracyclines but with significantly reduced cardiotoxicity. The aglycone pillaromycinone was assigned the linear tetracyclic structure (**1**) characteristic of this group of antibiotics, by a combination of spectroscopic, degradative, and X-ray crystallographic studies (2). More recently, a re-investigation of the biosynthetic pathway to the aureolic acid group of antibiotics resulted in the isolation of premithramycinone **2** from a blocked mutant of *S. argillaceus*. This antibiotic aglycone, structurally similar to pillaromycinone, is the suggested precursor for the aureolic acid group, and is shown to arise by "tetracycline-type" folding of the initial decaketide (3).

All these tetracyclic antibiotic aglycones have been attractive synthetic targets, and although successful routes to the anthracyclinones and the tetracyclines have been developed, no synthesis of pillaromycinone has been reported. The AB *cis*-ring junction of the antibiotic coupled with the *cis* disposition of the A ring hydroxyl groups and the *peri* positioning of the phenolic hydroxyl groups in rings C and D constitute serious stereochemical and regiochemical problems that must be overcome in any synthetic endeavour. Two attempts have been made (4, 5), and both focused on solving the problem of the AB *cis*-ring fusion. In both instances, the C-12a hydroxyl group was omitted from the target and the desired stereochemistry was achieved by Diels-Alder cycloadditions.

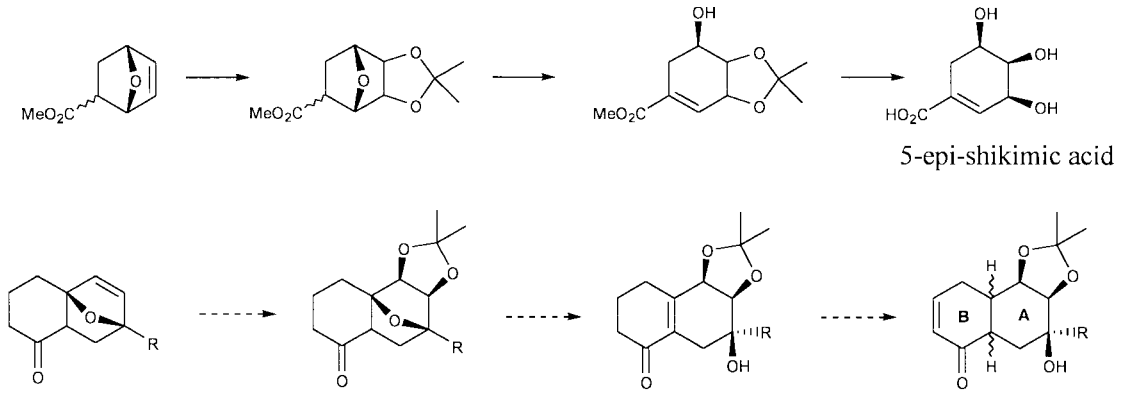
Scheme 1.



The latter synthesis (5) commenced with a homochiral diacetate derived from L-rhamnose in three steps. By incorporating a chiral centre from the starting material in the linker of an intramolecular Diels-Alder (IMDA) reaction stereochemical control was achieved in the cycloaddition to eventually obtain the desired *cis*-4a,12a ring fusion with the 4a*R* configuration of natural pillaromycinone. This was an elegant demonstration of fidelity in the transmission of stereochemical information in the IMDA reaction, but the "cost" of this strategy was paid for in separation of isomeric intermediates and in the 17 steps needed to obtain AB synthon **3** from L-rhamnose. The regio-controlled attachment of rings C and D to form the tetracyclic core of 12a-deoxypillaromycinone was effected by the Staunton–Weinreb procedure and the synthesis concluded with the 1,2-dihydro-2,3-cyclohexylidenyl-10,11-dimethyl derivative (**4**) of deoxypillaromycinone in 21 steps from L-rhamnose. The earlier synthetic work (4) also concentrated on the establishment of the *cis* AB-ring fusion, but this time by means of an intermolecular Diels-Alder reaction. Much experience with protection and deprotection sequences for the oxygen functional groups was gained, but this effort also ended short of the target at the tetracyclic intermediate (**5**) after 27 steps.

Our synthetic planning for this project relied on earlier work on the synthesis of the shikimic acids (6) and (±)-daunomycinone (7), and used a similar *5-endo-trig* cleavage of a 7-oxabicyclo[2.2.1]heptane adduct as the key step in the rapid production of a prospective AB synthon from furfural (Scheme 1).

Clearly, the major issues that had to be addressed by this investigation were (*i*) the relative stereochemistry of the AB-ring junction that ensues from saturation of the 4a–8a enone double bond; (*ii*) the exact nature of the acetyl group surrogate R, and its compatibility with the experimental conditions of the individual synthetic steps; and (*iii*) the attachment of rings CD at the 2,3-enone double bond of the AB segment. In this paper we report the outcome of our work and discuss its applicability to the future synthesis of (±)-12a-deoxypillaromycinone.

Results and discussion

Elaboration of a suitably substituted AB fragment

Furfural was treated with methyllithium, and resulting alcohol **6** was methylated with sodium hydride–iodomethane. 1′-Methoxyethyl furan **7** was deprotonated at the remaining α-position with *n*-butyl lithium, a 10% molar excess of 1,3-dibromopropane was then added rapidly at –78°C, and the solution was allowed to reach room temperature overnight. Chromatography of the resulting products provided 62% yield of desired bromopropylfuran **8**, a smaller amount of the dehydrobrominated allyl furan (5%), and 7% of the symmetrical dimer arising from substitution at both ends of the 1,3-dibromopropane. Inverse addition of the reagents did not significantly improve the yield of **8**. Iodide **9** was obtained in 95% yield from **8** by nucleophilic displacement with potassium iodide in purified (HPLC grade) acetone containing a small amount of sodium bicarbonate. These four routine transformations were conducted on ~20-g scales to furnish **9** in 30% overall yield (Scheme 2).

It was now necessary to set the stage for the IMDA reaction with the furan ring as the diene by appending a vinyl ketone residue (the dienophile) at the end of the three-carbon substituent. Various methods are available for accomplishing the transformation of **9** to desired enone **10**; these usually involve the addition of an organolithium or magnesium species to an acrolein (or substituted acrolein) followed by oxidation of the resulting alcohol (8). In our case, the alcohol obtained from **9** in this manner was much more sensitive to the oxidative conditions than alcohols from simple α-methyl furans, and hence the yields were poor and the enone was accompanied by products of decomposition and polymerization. We therefore sought an alternative that did not require oxidative conditions for the conversion of **9** to **10**. Although cyanide **11** could be prepared, it failed to react with vinyl lithium or vinyl magnesium bromide. Amide **12** prepared from acryloyl chloride and *N*,*O*-dimethyl hydroxylamine (9) seemed to be a promising option for this transformation. The conjugated double bond of **12** was "masked" by reacting it with furan (1.1 equiv zinc iodide, 50°C, 10 days) to produce *exo* adduct **13** exclusively. This compound was prepared on a large scale as a crystalline solid after column chromatography. Reaction of iodide **9** with 2.2 equiv of *tert*-butyllithium at –78°C followed by addition of the amide (1.5 equiv in ether) at –78°C provided ketone **14** after work-up in 75% yield. It was heated in dry benzene for 12 h to induce the retro Diels-Alder reaction and the solvent was removed under reduced pressure to leave crude enone **10**. Cyclization of **10** by treatment with a stoichiometric quantity of methyl aluminum dichloride in

i. MeLi, THF, 85% ii. NaH, MeI, 60% iii.BuLi, -78°C -> -20°C, $C_3H_6Br_2$, 61% iv. KI, Me_2CO, 91% v. Furan, ZnI_2, reflux, 10 days, 67% vi. **9**, *t*-BuLi, -78°C, 75% vii. PhH, reflux, 12h, PhH removed; CH_2Cl_2, $MeAlCl_2$, -78°C, 76%

dry methylene chloride at –78°C to produce a ~1:1 mixture of two IMDA *exo* adducts (8) (diastereomeric at C-9) in an overall yield of 68% (15.3% from furfural in six steps). This was an important but unavoidable consequence of the chirality at C-9 in our surrogate acetyl group; furthermore, the approximately equal amounts of diastereomers produced in the reaction indicated that the configuration at C-9 did not have any influence on the stereochemical outcome of the cycloaddition. The diastereomers were separated by chromatography on silica in 30% ethyl acetate–hexane to provide individual racemic ketones 2*S**,4a*S**,8a*R**,9*S** (**15a**, higher R_f), and 2*S**,4a*S**,8a*R**,9*R** (**15b**, lower R_f). The chirality at C-9 is immaterial as it must eventually be lost in the conversion of this group to the desired C-2 acetyl substituent, but it was convenient to separate the diastereomers at this stage and process them separately (as the 9*S** series from **15a** and the 9*R** series from **15b**) to accurately monitor the stereochemical integrity of each succeeding intermediate. The 500 MHz ^{1}H NMR spectra of the individual diastereomers, though complex in the δ 1.8–2.6 region, displayed the resonance of H-1α as a clear doublet of doublets at ca δ 1.5–1.65 with J = 12.4, 8.9 Hz (9*S** isomer) and 11.7, 8.2 Hz (9*R** isomer). These values of J_{gem} and J_{vic}, respectively, imply that the adjacent H-8a proton is in an α configuration; therefore, these signals are diagnostic for *exo* cycloaddition in the IMDA reaction. Similar observations have been recorded (8) for such adducts by other authors.

The alkene double bond of each isomer was hydroxylated with osmium tetroxide in pyridine to install the vicinal dihydroxy function (80%), which was then protected as the acetonide (70%) by treatment with 2,2-dimethoxypropane and *p*-toluene sulfonic acid in methylene chloride (Scheme 3). An X-ray crystallographic structure (Fig. 1) of acetonide **17a** (9*S** series) confirmed the earlier stereochemical assignments as well as the subsequent *exo* hydroxylation common in these oxabicyclo analogues of norbornene (6). Treatment of each of these acetonides with methoxide in methanol resulted in the expected (10) 5-*endo-trig* oxygen-bridge cleavage to produce the respective enones **18a** and **18b** in 72% yield. Many attempts were made to saturate the tetrasubstituted double bond of these enones. Catalytic hydrogenation (Pd, ethylacetate) of each isomer gave complex mixtures of stereoisomeric ketones as well as allylic alcohols of undefined stereochemistry. Use of dissolving metal reductions (sodium amalgam or Birch reduction) gave product mixtures lacking resonances attributable to the acetonide. Complexed tin hydrides and copper hydrides only returned the starting materials. A recent report (11) of the beneficial effects of DBU in the catalytic hydrogenation of the tetrasubstituted double bond of an enone was relevant to this problem. Thus, the hydrogenation of **18a** with hydrogen at atmospheric pressure, 20% palladium hydroxide on carbon, and 0.33 molar proportions of DBU in methanol containing 3% water produced single decalone **19a** in good yield. Furthermore, we were able to combine the reverse Michael oxygen-bridge cleavage with the hydrogenation by treating **17a** with 2 molar proportions of sodium methoxide under the above hydrogenation conditions for four days at room temperature. This resulted in the formation of **19a** in one pot and in 60% yield. Its ^{1}H NMR spectrum had a diagnostic signal for H-8a: an apparent triplet of doublets at δ 2.75 with two diaxial coupling constants ($J_{8,8a} \approx J_{4a,8a} \approx 11.8$ Hz) and one axial–equatorial coupling ($J_{8,8a} \approx 2.3$ Hz). This result suggested that hydrogenation of the tetrasubstituted enone double bond occurred from the α-face, which was followed by equilibration of the *cis*-fused decalone to the less crowded *trans*-isomer **19a** by base catalyzed epimerization at C-8a. In the expectation that the haptophilic influence (12) of the neighboring hydroxyl groups would promote hydrogenation from the β-face, we attempted the same reaction with bridged diol **16b**. The major constituent, estimated to be at least 80% of the crude product mixture, from this reaction displayed a similar triplet of doublets in its ^{1}H NMR spectrum at δ 2.75 with two diaxial couplings (J = 12.1 Hz) and one equatorial–axial coupling (J = 3.1 Hz) to the neighboring protons at C-8 and C-4a, respectively. The structure and relative stereochemistry of that material was confirmed as **20b** by an X-ray crystallographic determination (Fig. 2). 9*R** acetonide **17b** was treated with DBU, aqueous methanol, methoxide, $Pd(OH)_2$, and H_2 as before to produce a mixture of two inseparable isomers, the *trans*-decalone and presumably the α-*cis*-decalone, which were stirred without hydrogen for an additional three days to produce *trans*-decalone **19b** with a similar triplet of doublets (J = 11.9, 2.3 Hz) for

Scheme 3.

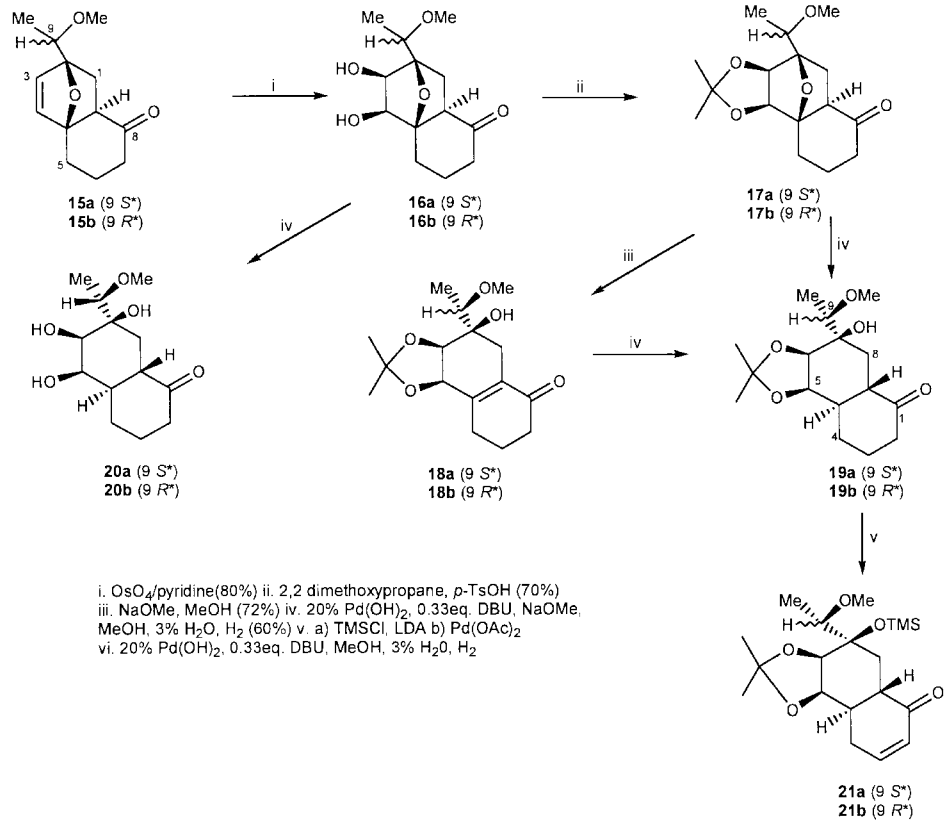

Fig. 1. The X-ray crystal structure of **17a**.

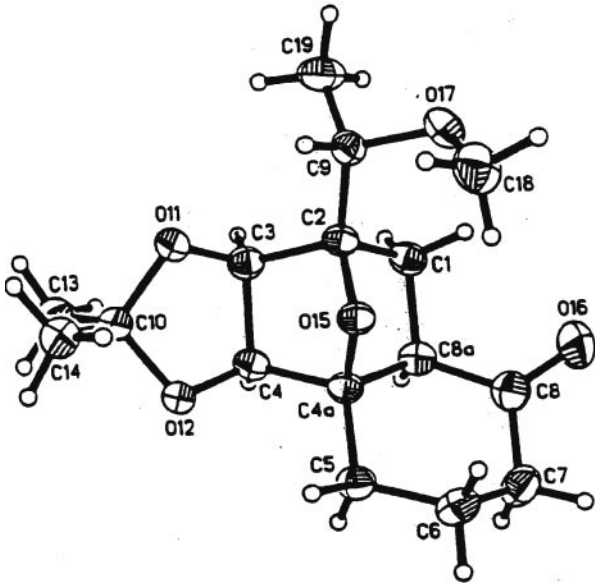

Fig. 2. The X-ray crystal structure of **20b**.

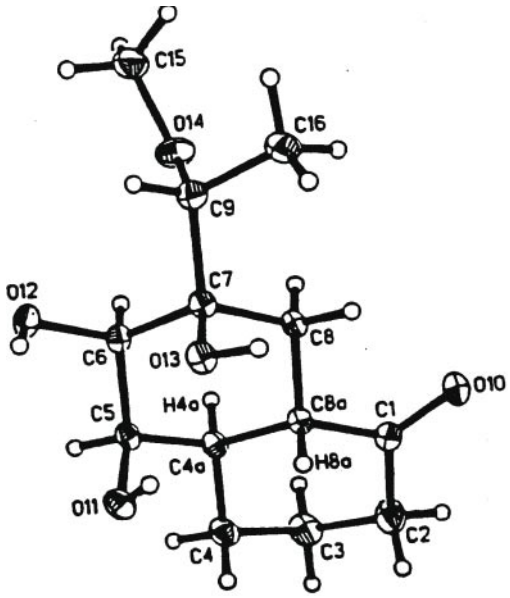

the β-oriented C-8a proton. The unfortunate but inescapable conclusion is that heterogeneous hydrogenation of these intermediates takes place predominantly from the α-face of the molecule and the expected haptophilic effect does not operate in these substrates.

In spite of this serious setback, we decided to continue with the final steps of the synthesis to test the viability of the plan for eventual synthesis of a tetracycle with the corrected AB *cis* ring fusion (vide infra). Dehydrogenation (13) of the kinetic enol silanes derived from **19a** and **19b** at C_2–C_3 was achieved with palladium acetate in 56% yield. Our synthesis of properly functionalized enones **21a** and **21b** was thus completed in ten steps from furfural in an overall yield of ~3%.

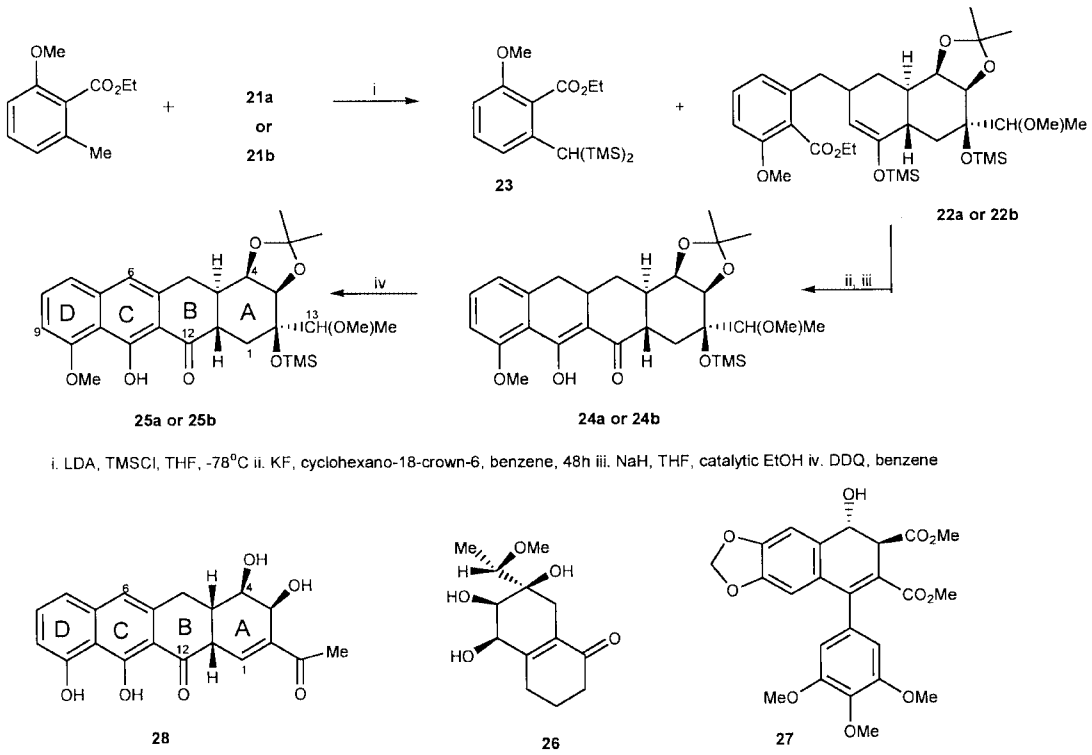
Scheme 4.



Attachment of the CD rings

After some experiments with 2-cyclohexenone (serving as a model for bicyclic enones **21**), we settled on a four-step conjugate addition–cyclization procedure to achieve the AB + CD connection with the proper regiochemical outcome. Deprotonation of ethyl 2-methoxy-6-methylbenzoate (14) with excess LDA at –78°C in THF–HMPA and reaction of the ensuing anion with each enone **21a** and **21b** separately at this temperature for 1 h was followed by quenching the reaction mixture with TMS chloride. Standard work-up and flash chromatography gave the crude silyl enol ethers **22** as yellow oils in 48% yield. The optimum ratio of reagents for this step was 4.5:1:0.5 (LDA–benzoate–enone) and the excess benzoate was recovered as its disilylated derivative **23**. The crude enol silanes were desilylated and subjected to a Dieckmann condensation with a catalytic amount of sodium ethoxide to produce the tetracycles **24**, which were dehydrogenated with DDQ in benzene to the desired naphthacenones **25** in 18% overall yield each for the four-step sequence (Scheme 4). These tetracycles are therefore obtainable in 14 steps from furfural. The 500 MHz ^{1}H NMR spectra provide conclusive support for the structure and stereochemistry of each compound. Thus **25b** displays an apparent triplet of doublets at δ 3.18 (J ~ 13–14, 3–4 Hz) for H-12a, representing two approximately equal diaxial and one small equatorial coupling (to H-1$_{eq}$). The other AB ring-junction proton, H-4a appears (superficially) as a triplet of triplets at δ 2.21 with two diaxial couplings (13–14 Hz each) and two axial–equatorial couplings (4–5 Hz each) to the neighbouring "equatorial" protons at C-4 and C-5. The 13-*S** isomer **25a** has a very similar spectrum, but the signals for H-12a overlap with the quartet for H-13 so that the approximate coupling constants cannot be measured. The signal for H-4a is, however, a similar triplet of triplets at δ 2.19 with coupling constants of 12.7 and 4.4 Hz.

This investigation has demonstrated that the plan outlined in Scheme 1 delivers a short synthesis (14 steps) of tetracycles **25** with all but one stereocentre (C-4a) correctly established for (±)-12a-deoxypillaromycinone. A method for rectifying the AB stereochemistry still remains to be developed, but now that the structure and stereochemistry of every intermediate has been conclusively established by this work our next goal will be the evaluation of hydroxyl-directed homogeneous hydrogenation methods using cationic Rh and Ir complexes (15). Substrates like **18** and **26** seem to be particularly appropriate for such explorations in view of the recently reported (16) hydrogenation of the tetrasubstituted double bond of α,β-unsaturated ester **27** containing an α-homoallylic hydroxyl group with a Rh(I) cationic complex to produce an 85% yield of hydrogenated products, in which α-hydrogen delivery predominated in a 20:1 ratio. We have already obtained **26** by extended treatment of **16a** with trifluoroacetic acid and confirmed its structure and stereochemistry by X-ray analysis. These investigations will commence shortly, and if successful, the CD annulation procedure developed here will be used to obtain an AB *cis*-fused tetracycle akin to **25**. Subsequent transformations, desilylation, dehydration, demethylation, oxidation at C-13, and acetonide hydrolysis are expected to lead to the first synthesis of (±) 12a-deoxypillaromycinone (**28**).

Experimental

General

Reactions that were expected to be sensitive to air or moisture were performed under an inert atmosphere of

© 2002 NRC Canada

argon. All glassware and syringes were dried in an oven, and then cooled in a dry box before use. All temperatures are in °C. Tetrahydrofuran (THF), diethyl ether, and benzene were distilled from sodium benzophenone ketyl. Dichloromethane, hexane, diisopropylamine, and HMPA were distilled from CaH_2. All reagents were purchased from Aldrich.

Thin layer chromatography was carried out on Merck 5554 precoated silica gel 60 F_{254} aluminum sheets. After development, the sheets were viewed under UV light or with an oxidizing stain solution consisting of ceric ammonium sulfate and hexammonium heptamolybdate in 1.8 M H_2SO_4. Flash chromatography was performed using Merck 9385 silica gel 60 (230–400 mesh). Fourier transform infrared spectra (FT-IR) were recorded on a Bomem MB-100 spectrometer as neat films between NaCl plates, or as KBr discs. ^1H and ^{13}C NMR spectra were obtained on Bruker AM-250, AM-300, and AMX-500 instruments. Samples were prepared in $CDCl_3$ unless otherwise stated. Chemical shifts for NMR were determined relative to the internal standard tetramethylsilane (δ 0.00) or $CHCl_3$ (δ 7.24) for ^1H spectra, and $CDCl_3$ (δ 77.0) for ^{13}C spectra. All ^1H NMR data listed have the following order: chemical shift (ppm), (multiplicity, coupling constants, number of protons, assignment). ^1H assignments were confirmed by decoupling. Mass spectra were run at the McMaster Regional Centre for Mass Spectrometry, McMaster University, Hamilton, Ontario. Elemental analysis were performed by MHW Laboratories, Phoenix, Arizona.

1-Furylethanol (6)

Methyllithium (300 mL, 1.4 M solution in ether, 4.2 mol) was added dropwise to a solution of 2-furfural (34 mL, 0.4 mol) in dry THF (400 mL) at –78°C under argon over 1.5 h. The solution was allowed to warm to –20°C while stirring for 3 h. Saturated NH_4Cl solution was added and the THF layer was separated and concentrated. The aqueous layer was extracted with EtOAc (3 × 100 mL) and the combined organic extracts were dried and concentrated in vacuo. Distillation under reduced pressure (water aspirator) gave a clear liquid (bp 70–74°C, 43 g, 85%). IR (neat) (cm^{-1}): 3350, 1150, 1009, 738. ^1H NMR (250 MHz) δ: 1.53 (d, J = 6.6 Hz, 3H, CHCH_3), 2.24 (br s, 1H, OH), 4.86 (q, J = 6.6 Hz, 1H, CHCH$_3$), 6.22, 6.31, and 7.36 (m each, 3H, furan-H).

2-(1′-Methoxy)ethylfuran (7)

Alcohol **6** (16.1 g, 0.14 mol) in THF (100 mL) was added dropwise to a suspension of NaH (9.0 g, 60% dispersion in mineral oil, 0.22 mol) in THF (50 mL) at 0°C under argon. The solution was stirred for 30 min and iodomethane (18 mL, 0.29 mol) was added dropwise over 15 min. The reaction was stirred overnight. Saturated NH_4Cl solution (100 mL) was added dropwise and the THF layer was separated and concentrated in vacuo. The residue was dissolved in ether (200 mL), dried, and concentrated to give a dark brown oil, which was distilled under reduced pressure (oil pump) to give a colourless liquid (bp 50–55°C, 10.5 g, 60%). ^1H NMR (250 MHz) δ: 1.50 (d, J = 6.6 Hz, 3H, CH_3), 3.27 (s, 3H, OCH_3), 4.36 (q, J = 6.6 Hz, 1H, CH), 6.33 (m, 2H, H-3 and H-4), 7.38 (m, 1H, H-5). HRMS calcd. for $C_7H_{10}O_2$: 126.0681; found: 126.0679. Anal. calcd. for $C_7H_{10}O_2$: C 66.66, H 7.93; found: C 66.61, H 7.91.

2-(3-Bromopropyl)-5-(1′-methoxy)ethylfuran (8)

n-BuLi (62.5 mL, 0.1 mol) was added dropwise to a solution of methyl ether **7** (12.6 g, 0.1 mol) in THF (100 mL) at –78°C under argon. The solution was allowed to warm to –20°C over 1 h, then stirred for 3 h. The reaction was cooled to –78°C and 1,3-dibromopropane (11.2 mL, 0.11 mol) was added and stirring continued overnight at ambient temperature. The solution was warmed to room temperature and saturated NH_4Cl was added, the organic layer was washed with brine, dried, and concentrated in vacuo. Chromatography using 3–5% EtOAc–hexane gave product **8** as a pale yellow oil (15.1 g, 61%), the dehydrobrominated product (5%), and the dimer (7%). IR (neat) (cm^{-1}): 1558, 1445, 1249, 1102, 1013, 790. ^1H NMR (250 MHz) δ: 1.48 (d, J = 6.6 Hz, 3H, CH_3), 2.18 (m, 2H, $CH_2CH_2CH_2Br$), 2.80 (t, J = 7.2 Hz, 2H, $CH_2CH_2CH_2Br$), 3.27 (s, 3H, OCH_3), 3.42 (t, J = 6.6 Hz, 2H, CH_2Br), 4.29 (q, J = 6.6 Hz, 1H, CH), 5.98 and 6.15 (d each, J = 3.1 Hz, 2H, H-3 and H-4). EI-MS m/z (%): 248, 246 (M^+, 1), 245 (7), 231 (31), 229 (31), 216 (27), 214 (27), 139 (34), 123 (78). HRMS calcd. for $C_{10}H_{15}{}^{79}BrO_2$: 246.0197; found: 246.0198.

2-(3-Iodopropyl)-5-(1′-methoxy)ethylfuran (9)

Bromide **8** (15.1 g, 0.061 mol), KI (25 g, 0.153 mol), and $NaHCO_3$ (0.5 g, 6 mmol) were dissolved in HPLC-grade acetone, and heated to reflux for 24 h under argon. The reaction was cooled, and the solvent was removed in vacuo. The residue was dissolved in diethyl ether and water was added. The aqueous layer was extracted with diethyl ether (3 × 200 mL), the combined organic layers were dried over Na_2SO_4, filtered, and concentrated in vacuo to give the crude iodide. Flash chromatography using 10% EtOAc–hexane provided pure iodide **9** as a pale yellow oil (16.3 g, 91%). IR (neat) (cm^{-1}): 1557, 1442, 1234, 1114, 1087, 789. ^1H NMR (250 MHz) δ: 1.50 (d, J = 6.6 Hz, 3H, CH_3), 2.18 (m, 2H, $CH_2CH_2CH_2I$), 2.76 (t, J = 7.2 Hz, 2H, $CH_2CH_2CH_2I$), 3.24 (t, J = 6.6 Hz, 2H, CH_2I), 3.30 (s, 3H, OCH_3), 4.32 (q, J = 6.6 Hz, 1H, CH), 5.98 and 6.15 (d each, J = 3.1 Hz, 2H, H-3 and H-4). HRMS calcd. for $C_{10}H_{14}O_2$: 166.0990 ($[M - HI]^+$); found: 166.0989 ($[M - HI]^+$).

2-(3-Cyanopropyl)-5-(1′-methoxy)ethylfuran (11)

Bromide **8** (2 g, 8.1 mmol) and tetrabutylammonium chloride (0.5 g, 1.8 mmol) were dissolved in CH_2Cl_2 and mixed with a saturated KCN solution (2.2 g, 33 mmol); the mixture was stirred at room temperature for 24 h and monitored by TLC while the color of the reaction turned to red-brown. Once the reaction was completed, the organic and aqueous layers were separated, the aqueous layer was extracted with ether (2 × 20 mL), the combined organic layers were dried over Na_2SO_4, and concentrated in vacuo to give a dark brown oil. Flash chromatography using 10% EtOAc–hexane provided pure nitrile **11** as a pale yellow oil (1.32 g, 84%). IR (neat) (cm^{-1}): 2246, 1114, 1087, 794. ^1H NMR (250 MHz) δ: 1.50 (d, J = 6.6 Hz, 3H, CH_3), 2.04 (m, 2H, $CH_2CH_2CH_2CN$), 2.39 (t, J = 7.2 Hz, 2H, $CH_2CH_2CH_2CN$), 2.80 (t, J = 6.6 Hz, 2H, $CH_2CH_2CH_2CN$), 3.30 (s, 3H, OCH_3), 4.32 (q, J = 6.6 Hz, 1H, CH), 5.98 and 6.15 (d each, J = 3.1 Hz, 2H, H-3 and H-4). HRMS calcd. for $C_{11}H_{15}NO_2$: 193.1103; found: 193.1112.

2β-(*N*-Methyl-*N*-methoxyamido)-7-oxabicyclo[2.2.1]hept-5-ene (13)

N,O-Dimethylhydroxylamine

N,*O*-Dimethylhydroxylamine hydrochloride (80 g) was added to a cooled (0°C) solution of KOH (80 g) in water (120 mL). *N*,*O*-dimethylhydroxylamine was distilled from the mixture to give a clear liquid (47 g); bp 41–43°C.

Reaction with acryloyl chloride (12)

N,*O*-Dimethylhydroxylamine (14.0 g, 0.24 mol) and pyridine (18.9 mL, 0.24 mol) in ether (100 mL) was added dropwise to a cooled (–78°C) solution of acryloyl chloride (19 mL, 0.24 mol) in ether (400 mL) under argon over a period of 1 h. The mixture was allowed to warm to 0°C while stirring for 3 h. The ether was decanted from the solid and the solid was washed with dry ether. The combined ether solutions were concentrated in vacuo to give a pale yellow liquid, which was distilled under reduced pressure (oil pump) to give a clear liquid (10.3 g); bp 45°C (0.05 mm Hg). IR (neat) (cm^{-1}): 1664, 1619. ^1H NMR (250 MHz) δ: 3.26 (s, 3H), 3.71 (s, 3H), 5.74 (dd, *J* = 10.35, 2.1 Hz, 1H), 6.41 (dd, *J* = 17.1, 2.1 Hz, 1H), 6.72 (dd, *J* = 17.1, 10.35 Hz, 1H). Anal. calcd. for $C_5H_9NO_2$: C 52.17, H 7.88, N 12.17; found: C 51.90, H 8.00, N 12.28 (17).

Diels-Alder addition to furan (13)

N,*O*-Dimethylacryloylamide **12** (10.33 g, 89 mmol) and zinc iodide (28.7 g, 90 mmol) were heated at reflux in distilled furan (90 mL) for 10 days. The reaction mixture was diluted with EtOAc (400 mL) and washed with H_2O (200 mL). The organic layer was separated, washed with brine, dried, and concentrated in vacuo (bath < 35°C) to give a yellow oil. Chromatography over silica using 80% EtOAc–hexane gave a colourless oil (**13**), which crystallized on refrigeration (mp 46–47°C; yield 67%). IR (neat) (cm^{-1}): 1660, 1440, 1381, 1317, 1032, 908, 704. ^1H NMR (250 MHz) δ: 1.57 (dd, *J* = 11.3, 8.4 Hz, 1H, H-6α), 2.12 (dt, *J* = 11.3, 4.5 Hz, 1H, H-6β), 2.67 (dd, *J* = 8.4, 4.1 Hz, 1H, H-5α), 3.22 and 3.68 (s each, 6H, NCH_3 and OCH_3), 5.07 (d, *J* = 4.5 Hz, 1H, H-1), 5.13 (s, 1H, H-4), 6.39 (ABq, *J* = 4.5 Hz, 2H, H-5 and H-6). HRMS calcd. for $C_9H_{13}NO_3$: 183.0896; found: 183.1074. Anal. calcd. for $C_{19}H_{13}NO_3$: C 59.03, H 7.15; found: C 59.13, H 7.13.

4-[5-(1-Methoxyethyl)furan-2-yl]-1-(7-oxabicyclo-[2.2.1]hept-5-en-2-yl)butan-1-one (14)

Iodide **9** (11.2 g, 38 mmol) was dissolved in anhydrous Et_2O (200 mL), and the solution was cooled to –78°C in a dry ice – acetone bath. *tert*-Butyllithium (52 mL, 1.7 M in pentane, 88.4 mmol) was added dropwise to the cooled solution, and the reaction was stirred for 1 h at –78°C. Amide **13** (10.5 g, 57 mmol) in Et_2O was purged with argon for 15 min and added to the reaction by cannulation at –78°C. The reaction was continued for a further 4 h, and was then quenched at low temperature with saturated NH_4Cl (100 mL). After warming to room temperature, the aqueous layer was extracted with Et_2O (3 × 50 mL) and CH_2Cl_2 (2 × 50 mL). The combined organic layers were dried over Na_2SO_4, filtered, and concentrated in vacuo. Flash chromatography of the crude ketone using 30% EtOAc–hexane provided pure product **14** as a yellow oil (8.2 g, 75%). IR (neat) (cm^{-1}): 1707, 1557, 1100, 793. ^1H NMR (250 MHz) δ: 1.48 (d, *J* = 6.6 Hz, 3H, CH_3), 1.95 (m, 3H, $CH_2CH_2CH_2CO$ and H-3β), 2.65 (m, 6H, $CH_2CH_2CH_2CO$, H-3α, and H-2α), 3.26 (s, 3H, OCH_3), 4.29 (q, *J* = 6.6 Hz, 1H, C*H*OMe), 5.08 (m, 2H, H-1 and H-4), 5.95 and 6.15 (d each, *J* = 3.0 Hz, 2H, furan-H), 6.38 (ABq, *J* = 5.7, 1.3 Hz, 2H, H-5 and H-6). HRMS calcd. for $C_{17}H_{22}O_4$: 290.1512; found: 290.1510.

2*H*-2-(1′-Methoxyethyl)-2,4a-epoxy-8aβ,4aα-1,8a,5,6,7,8-hexahydro-naphthalen-8-one (15a and 15b)

Ketone **14** (8.2 g, 37 mmol) was dissolved in dry benzene (50 mL) and heated to reflux for 12 h. Benzene was removed by distillation under reduced pressure (water aspirator, bath temperature 40°C). Enone **10** generated in situ was dissolved in dry CH_2Cl_2 (50 mL), and the solution was cooled to –78°C. Methylaluminum dichloride (41 mmol, 1.0 M in hexane) was added to the cooled enone solution, and the reaction was stirred for a further 1 h at –78°C. The reaction was quenched with 10% $NaHCO_3$, and warmed until no frozen material remained. The aqueous layer was extracted with CH_2Cl_2, and the combined organic layers were washed with H_2O, dried over Na_2SO_4, filtered, and concentrated in vacuo without external heat to provide a mixture of two stereoisomers. Flash chromatography using 30% EtOAc–hexane gave the C9-*S** isomer **15a** and C9-*R** isomer **15b** as pale yellow oils (total yield: 76%).[2]

C9-S* isomer 15a (R_f = 0.41)

IR (neat) (cm^{-1}): 1701, 1446, 1375, 1062, 715. ^1H NMR (500 MHz) δ: 1.23 (d, *J* = 6.4 Hz, 3H, Me), 1.61 (dd, *J* = 12.4, 8.9 Hz, 1H, H-1α), 1.8–2.31 (m, 2H), 2.22 (ddd, *J* = 14.8, 12.6, 5.0 Hz, 1H, H-5α), 2.37 (dd, *J* = 12.4, 3.2 Hz, 1H, H-1β), 2.39–2.44 (m, 2H), 2.45 (dd, *J* = 8.9, 3.1 Hz, 1H, H-8a), 2.52 (dtd, *J* = 14.0, 3.5, 1.6 Hz, 1H, H-7β), 3.42 (s, 3H, OMe), 3.66 (q, *J* = 6.4 Hz, 1H, H-9), 6.16 and 6.40 (d each, *J* = 5.8 Hz, 2H, H-3 and H-4). ^{13}C NMR (63 MHz) δ: 15.2, 21.8, 28.4, 31.4, 41.6, 53.0, 57.4, 76.8, 90.7, 91.8, 137.5, 138.5, 209.5. EI-MS *m*/*z* (%): 190 ($[M - CH_3OH]^+$, 41), 152 (20), 137 (80), 121 (100), 108 (69), 59 ($[Me - O{=}CHMe]^+$, 80). CI-MS *m*/*z* (%): 240 ($[M + NH_4]^+$, <2), 191 (100). HRMS calcd. for $C_{12}H_{15}O_3$: 207.1021; found: 207.1040 ($[M - Me]^+$). Anal. calcd. for $C_{13}H_{18}O_3$: C 70.27, H 8.11; found: C 70.12, H 8.02.

C9-R* isomer 15b (R_f = 0.31)

IR (neat) (cm^{-1}): 1710, 1449, 1322, 1102, 714. ^1H NMR (500 MHz) δ: 1.28 (d, *J* = 6.5 Hz, 3H, Me), 1.51 (dd, *J* = 11.7, 8.2 Hz, 1H, H-1α), 1.90–2.02 (m, 2H), 2.18–2.25 (m,

2*H*-2-(1′-Methoxyethyl)-3β,4β-dihydroxy-2,4a-epoxy-8aβ,4aα-octahydro-naphthalen-8-one (16a and 16b)

OsO_4 (4.0 g, 15.6 mmol) and bicyclic ketone **15a** or **15b** (3.46 g, 15.6 mmol) were dissloved in pyridine (40 mL) and stirred at room temperature under argon for 48 h. The resulting dark solution was stirred with a mixture of $NaHSO_3$ (8.4 g), pyridine (88 mL), and water (140 mL) for a further 4 h. The reaction was continuously extracted with EtOAc (600 mL) for 48 h. The organic layer was dried over Na_2SO_4, and EtOAc and pyridine were removed under reduced pressure. Flash chromatography using 70% EtOAc–hexane gave each diol as a white solid (3.2 g, 80%).

C9-S* isomer 16a

7-(1′-Methoxyethyl)-7β-trimethylsiloxy-5β,6β-di-*O*-isopropylidene-8aβ,4aα-hexahydro-naphthalen-1-one (21a and 21b)

A fresh LDA solution was prepared from *n*-BuLi (6.6 mL, 1.36 M in hexane, 9.0 mmol) and diisopropylamine (1.25 mL, 8.9 mmol) at 0°C in dry THF.

A solution of hydroxy ketone **19** (210 mg, 0.71 mmol) in dry THF was slowly added to the LDA solution at –78°C under argon. The mixture was stirred for 1 h at –78°C. TMSCl (1.8 mL, 14.2 mmol) was then added. The reaction was stirred for 30 min at –78°C and then allowed to warm to room temperature. The THF was evaporated under reduced pressure and the residue was diluted with dry hexane, white precipitates were filtered, and the hexane solution was concentrated in vacuo to give the crude silyl enol ether. The silyl enol ether was heated at reflux with $Pd(OAc)_2$ (177 mg, 0.78 mmol) in CH_3CN (20 mL) for 1 h under argon. The reaction mixture was filtered through a thin pad of Celite and the solvent was concentrated in vacuo to give a dark brown oil. Flash chromatography using 20% EtOAc–hexane of the crude mixture gave colourless crystals (116 mg, 56%) in each case.

C9-S isomer 21a*

^{1}H NMR (500 MHz) δ: 0.12 (s, 9H, $OSiMe_3$), 1.21 (d, J = 6.4 Hz, 3H, CH_3), 1.31 and 1.51 (s each, 6H, CH_3CCH_3), 1.52 (dd, J = 14.7, 11.8 Hz, 1H, H-8α), 2.09 (m, 1H, H-4a), 2.27 (dd, J = 14.8, 3.1 Hz, 1H, H-8β), 2.33 (dt, J = 19.1, 5.1 Hz, 1H, H-4α), 2.66 (td, J = 11.8, 2.9 Hz, 1H, H-8a), 2.7 (m, 1H, H-4β), 3.16 (q, J = 6.4 Hz, 1H, H-9), 3.28 (s, 3H, OMe), 4.07 (d, J = 5.7 Hz, 1H, H-6), 4.19 (t, J = 5.4 Hz, 1H, H-5), 5.78 (dd, J = 10, 2.2 Hz, 1H, H-2), 6.97 (ddd, J = 10, 6, 2.2, 1H, H-3). ^{13}C NMR (75 MHz) δ: 2.9 (3 × C), 13.8, 26.0, 26.2, 28.4, 32.0, 39.5, 40.6, 56.7, 74.5, 75.6, 76.6, 104.9, 108.6, 129.1, 149.3, 201.1. Me]$^+$, 8), 309 ([M – MeCHOMe]$^+$, 63), 279 ([M – $OSiMe_3$]$^+$, 41), 251 (72), 73 ([Me_3Si]$^+$, 51), 59 ([MeCH=OMe]$^+$, 100). HRMS calcd. for $C_{19}H_{33}O_5Si$: 369.2097 ([M + 1]); found: 369.2084.

11-Hydroxy-10-methoxy-2-trimethylsilyloxy-2-[1′-(1′-methoxyethyl)]-3β,4β-di-*O*-isopropylidene-1,2,3,4,4a,5,12,12a-octahydronaphthacene-12-one (25a and 25b) from 21a and 21b, separately

The LDA solution was prepared by adding *n*-BuLi (6.1 mL, 4.75 mmol) to freshly distilled diisopropylamine (0.66 mL, 4.75 mmol) in THF at 0°C under argon.

Ethyl 2-methoxy-6-methylbenzoate (0.208 mg, 1.08 mmol) in THF was added to the LDA solution under argon at –78°. The resulting dark red solution was stirred for 15 min and HMPA (0.169 mL, 0.978 mmol) was added. After 5 min, enone **21** (180 mg, 0.489 mmol) was slowly added and the solution was stirred for 1 h. TMSCl (0.5 mL, 3.91 mmol) was added and the mixture was allowed to warm to room temperature. The reaction mixture was slowly added to a solution of saturated $NaHCO_3$ (20 mL) and stirred for 15 min. The aqueous layer was extracted with EtOAc (3 × 25 mL). The combined organic layer was dried over Na_2SO_4, and concentrated in vacuo. Flash chromatography of the crude product using 20% EtOAc–hexane gave silyl enol ether **22** as a yellow oil (150 mg, 48%).

The silyl enol ether **22** (150 mg, 0.237 mmol) was dissolved in benzene (20 mL) and stirred with KF (30 mg, 0.52 mmol) and dicyclohexano-18-crown-6 (194 mg, 0.52 mmol) under argon for 48 h. The reaction was quenched by H_2O (15 mL), the aqueous layer was extracted with Et_2O (3 × 20 mL). The combined organic layer was dried over Na_2SO_4, and concentrated in vacuo. Flash chromatography of the crude product using 20% EtOAc–hexane gave a pale yellow oil (96 mg, 72%).

NaH (13.6 mg in 60% mineral oil, 0.34 mmol) was washed with dry hexane, which was then removed by Pasteur pipette. A solution of the above product (96 mg, 0.17 mmol) in THF was slowly added to a stirring suspension of NaH and a drop of ethanol in THF (10 mL). The reaction mixture was stirred at room temperature for 3 h, and then water (15 mL) was added. The resulting solution was neutralized with dry ice, and extracted with Et_2O (3 × 10 mL) and EtOAc (2 × 15 mL). The combined organic layer was dried over Na_2SO_4, and concentrated in vacuo. Flash chromatography of the crude product using 20% EtOAc–hexane gave yellow crystals of **24** (48 mg, 55%).

DDQ (21 mg, 0.093 mmol) was slowly added to a solution of **24** (48 mg, 0.093 mmol) in benzene (10 mL) under argon at room temperature. The reaction was stirred for 1 h, H_2O (10 mL) and ether (10 mL) were added to the solution, and the aqueous layer was separated and extracted with ether (3 × 10 mL). The combined organic layers were dried over Na_2SO_4 and concentrated in vacuo to give a dark oil. Flash chromatography of the crude product using 20% EtOAc–hexane gave naphthacenone **25** as a yellow solid (46 mg, 96%).

Regiospecific synthesis of lactose analog Gal-(β 1,4)-Xyl by transgalactosylation

Wolf-Dieter Fessner and Juan Manuel Juárez Ruiz

Abstract: A short enzymatic synthesis of disaccharide 4-*O*-β-D-galactopyranosyl-D-xylose (**1**) has been developed, which is of interest as a lactose analog for a non-invasive medicinal determination of lactose intolerance. The starting material, benzyl α-D-xyloside, was obtained by a Fischer-type glycosidation of D-xylose with benzyl alcohol, followed by anomeric differentiation of mixed glycosides using a glycosidase from *Aspergillus oryzae*. From several commercial β-galactosidases, which were screened for their transgalactosylation capacity, the enzyme from *Escherichia coli* was found to catalyze a virtually regio- and stereospecific galactosyl transfer from donor compounds *o*-nitrophenyl β-D-galactoside or lactose to the α-D-xyloside. Subsequent hydrogenolytic deprotection furnished desired disaccharide **1**.

Key words: oligosaccharide synthesis, β-galactosidase, lactose intolerance.

Résumé : On a mis au point une courte synthèse du disaccharide 4-*O*-β-D-galactopyranosyl-D-xylose qui présente de l'intérêt comme analogue de lactose pour procéder à une évaluation médicinale non invasive de l'intolérance au lactose. On a obtenu le produit de départ, l'α-D-xyloside de benzyle, par une glycosylation de type Fischer du D-xylose par l'alcool benzylique suivie d'une différentiation anomérique des glycosides mixtes à l'aide d'une glycosidase provenant d'*Aspergillus oryzae*. Diverses β-galactosidases commerciales ont été évaluées pour leur capacité à provoquer une transgalactosylation; on a trouvé que l'enzyme provenant d'*Escherichia coli* catalyse le transfert du galactosyle d'une façon virtuellement régio- et stéréospécique à partir de β-D-galactoside d'*o*-nitrophényle ou de lactose agissant comme composés donneurs vers l'α-D-xyloside. Une déprotection hydrogénolytique subséquente conduit au disaccharide **1** recherché.

Mots clés : oligosaccharide, synthèse, β-galactosidase, intolérance au lactose.

[Traduit par la Rédaction]

Introduction

Lactose is a milk disaccharide produced by nearly all mammalian species. For digestion, it must be hydrolyzed to D-galactose and D-glucose by lactase, an enzyme which is present on the brush border of small intestinal enterocytes. Evaluation of an enzyme deficiency (lactase insufficiency, lactose intolerance) (1, 2) is important in pediatrics and gastroenterology due to the high frequency of a genetic disposition. Because many of the standard diagnostic procedures are invasive, quite drastic, and unacceptable or dangerous for the testing of infants and young children, a non-invasive method for lactase determination has been proposed on the basis of 4-*O*-β-D-galactopyranosyl-D-xylose (**1**) (3), which can be administered as a substrate analog to lactose (4, 5). The xylose released from small quantities of this disaccharide by lactase activity is eliminated in the urine where it can be quantified colorimetrically. The β-Gal-(1,4)-Xyl disaccharide (**1**) is also well known as a fragment of the highly conserved linkage region between the core protein and the polysaccharide chain (glycosaminoglycan) in proteoglycans of connective tissue (6).

Chemical syntheses of **1** require a judicious installation of protective groups and suffer from long, tedious reaction sequences with little overall productivity (7–9). For a choice of alternative enzymatic strategies, the biosynthetic route involving specific UDP-Gal dependant galactosyltransferase enzymes (e.g., β4GalT7) (10) is burdened by technical difficulties, high costs, and the ambident reactivity of xylose (11, 12). On the other hand, glycosidases have been shown by numerous examples to allow the facile formation of glycosides by transglycosylation at low cost (13, 14). Disadvantages of this approach, however, include yield limitations due to competing hydrolysis reactions, and separation problems because of the formation of regioisomers and other by-products with similar physical properties, which is due to the low acceptor selectivity of glycosidases. For example, attempts to form Gal-(β 1,4)-linkages by transglycosylation to D-xylose (15, 16) or to different aryl- or alkyl-β-D-xylosides (17–20) as acceptors were generally met by concomitant

formation of the corresponding (β 1,3)-disaccharides in significant proportions.

Here we report a new enzymatic synthesis of **1** based on a successful regiospecific transgalactosylation to α-configurated benzyl D-xyloside.

Results and discussion

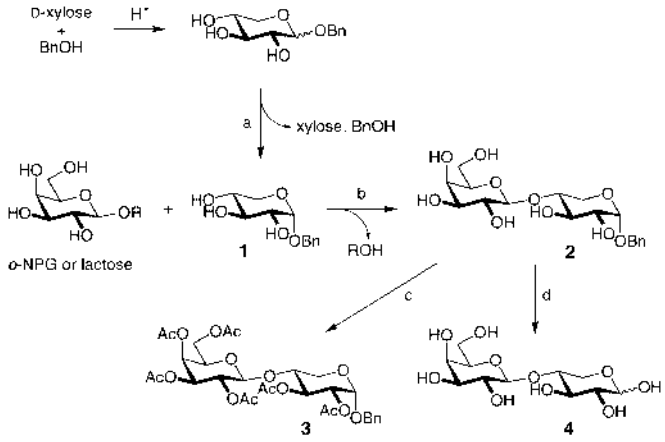
The synthetic strategy for constructing free-reducing disaccharide **1** (for possible use in clinical diagnosis) called for an anomeric protection group that ideally should confer several important properties to the synthetic intermediates: (*i*) it needs to be easily introduced in the starting material at low cost; (*ii*) it needs to be efficiently removed in the last step with avoidance of toxic reagents; (*iii*) it should facilitate monitoring of conversion and characterization at intermediate stages; (*iv*) it should simplify purification of the intermediates by a sufficiently high tendency to crystallize (particularly in view of a larger scale synthesis); and (*v*) it should exert pronounced stereoelectronic effects for substrate recognition during the transglycosylation process for an enhanced regioselectivity. Thus, from a choice of allyl, 4-pentenyl, and benzyl protection, the latter was given preference because it was expected to best meet these criteria.

Recently, we have developed a simple and efficient procedure for the anomeric differentiation of mixed α,β-glycosides using the hydrolytic function of glycosidases (21). Such anomeric mixtures are readily obtainable by acid-catalyzed Fischer-type glycosidation. Because many glycosidases with suitable substrate specificity and complementary anomeric preference are readily available from various sources (14), pure unprotected glycosides are efficiently accessible. Specifically, the α-configurated anomeric form of benzyl xylopyranoside **1** (Scheme 1) can be isolated in high yield at low cost using crude commercial enzyme preparations from *Aspergillus oryzae* (21).

Since prior attempts for D-xylopyranoside transgalactosylation were mainly performed on the β-configurated benzyl glycoside with unsatisfactory regioselectivity (17–20), α-anomer **1** was chosen for our study. Several commercial β-galactosidases (EC 3.2.1.23, e.g., from *A. oryzae*, *E. coli*, and CloneZyme® library enzymes of undisclosed origin) were screened for transgalactosylation activity in phosphate buffer at pH 7.0 using **1** as the acceptor component and *o*-nitrophenyl β-D-galactoside (*o*-NPG) as the donor component. Because individual regioisomers were not revealed upon TLC analyses using various solvents, crude product mixtures were analyzed by NMR spectroscopy for composition. Practically all enzymes tested were found to catalyze the desired reaction to a varying extent, producing disaccharide mixtures composed of **2** and considerable fractions of the undesired (β 1,3)-regioisomer. No formation of the (β 1,2)-disaccharide was observed, which is probably due to the steric inaccessibility to the biocatalysts. The enzyme from *E. coli* was unique, however, because it yielded the desired 1,4-regioisomer **2** as the only disaccharide product detectable by high-resolution NMR spectroscopy (de ≥ 95%).

Although the transgalactosylation proceeded with excellent regioselectivity, the presence of unreacted acceptor glycoside and free galactose from competing hydrolysis of the donor complicated product purification by silica gel column chromatography. Residual acceptor **1** could, however, be easily removed by selective extraction with ethyl acetate, while the more hydrophilic disaccharide derivative **2** remained in the aqueous phase. Further purification was performed by column filtration through a plug of reversed-phase silica gel. Free galactose was readily removed upon washing with water, while ethanol elution furnished pure benzyl-protected disaccharide **2** in 23% yield as a crystalline solid. Unambiguous structural proof was obtained by full characterization of corresponding peracetate **3**.

Scheme 1. Chemoenzymatic synthesis of disaccharide **4**. Reagents and conditions: (*a*) crude β-galactosidase from *A. oryzae*, H_2O, >60%; (*b*) β-galactosidase from *E. coli*, 23%; (*c*) Ac_2O, pyridine, 95%; (*d*) H_2–Pd/C, aq. EtOH, 80%.



It should be emphasized that the judicious choice of benzyl protection did indeed strongly facilitate product recovery and purification by easily scalable extractive manipulations and thus obviated the need for an exacting high-performance chromatographic separation. Although reaction conditions have not been further optimized, the yield is within the range commonly obtainable by preparative-scale transglycosylations (13, 14). An improvement may be expected from applications of glycosynthases that have been engineered to prevent product hydrolysis (22). Concerning the regioselectivity of the galactosyl transfer, it should be compared with the unfavorable 5:2 ratio of 3-/4-regioisomers obtained for the corresponding benzyl β-xyloside with the same enzyme. The unusually high regioselectivity in the case of α-xyloside may be due to a pronounced bend in the molecular shape of **1** induced by the steric bulk of the α-anomeric benzyl group. Rather than the linearly extended geometry of the β-xyloside, this seems to render the relative setting of the 3- and 4-hydroxyl groups sufficiently different from each other to facilitate discrimination by the galactosidase in favor of the desired compound.

The transgalactosylation was also tested using lactose as an alternative, inexpensive galactosyl donor. As expected, the reactions proceeded more slowly compared with those with the highly reactive *o*-NPG donor. Following the same work-up procedure, pure disaccharide **2** was obtained in 15% yield. The lower yield, as compared with the *o*-NPG donor, is in line with the relatively lower conversion rate because of the increasing likelihood of product hydrolysis at longer reaction times. Attempts were also made for an extended usage of the biocatalyst. Because a continuous operation

© 2002 NRC Canada

of the transglycosylation would be difficult to achieve given the propensity of the product to be hydrolyzed under the reaction conditions, batchwise recycling of the enzyme offered a better solution. Indeed, when the protein was recovered from the reaction mixture by ultrafiltration, it could be reused for at least four identical consecutive runs without noticeable detrimental effects on the reaction velocity or product yield.

Hydrogenolytic cleavage of the benzyl protection group in **2** was performed on 10% Pd/C catalyst. Complete conversion was only achieved by applying quite forcing conditions (60 bar H_2, 50°C), which may be related to the lower reactivity of an α-glycoside. The resultant product was purified by filtration through reversed-phase silica gel column using water as the eluent to furnish the free disaccharide **4** in 80% yield. The spectroscopic data of this compound was identical to values published for the disaccharide from chemical synthesis (7).

Conclusions

A short, versatile enzymatic synthesis has been developed for the lactose analog Gal-(β 1,4)-Xyl **4** by a highly regio- and stereoselective transgalactosylation of benzyl α-D-xyloside **1** as the acceptor. Unlike the situation for free xylose or the corresponding β-D-xyloside, the β-galactosidase from *E. coli* efficiently directs galactosyl transfer to 4-OH of the acceptor, which is likely supported by the steric influence of the bulky α-anomeric substituent that is presumed to restrict a competing access to 3-OH. The benzyl group is of further advantage for simple and effective isolation of the target disaccharide **2** from complex product mixtures by allowing group-specific extraction procedures. Thus, this synthesis is promising for the preparation of larger disaccharide quantities.

Experimental

General

NMR spectra were recorded on Bruker ARX-300 and Bruker AVANCE 500 spectrometers; chemical shifts are referenced to internal TMS ($CDCl_3$) or TSP (D_2O; 0.00 ppm). Mass spectra were recorded on a Bruker Esquire-LC system (ESI), and elemental analyses were performed on a Heraeus CHN-O-Rapid system. Optical rotations were measured with a PerkinElmer 241 apparatus in a 10-cm cuvette at λ = 589 nm. For ultrafiltration, an Amicon 8400 cell equipped with a YM 10 membrane was used. Column chromatography was performed on Merck 60 silica gel (0.063–0.200 mesh), and analytical thin-layer chromatography was performed on Merck silica gel plates 60 GF_{254} using anisaldehyde stain for detection. C_{18}-silica gel 100 (Fluka, 0.040–0.063 mm) was used for reversed-phase (RP) adsorption. β-Galactosidases from *A. oryzae* (Sigma, G-5160 or G-7138) and from *E. coli* (Roche Molecular Biochemicals, 150797 or Sigma, G-6008) were used as commercially supplied. The CloneZyme® glycosidase kit from Recombinant Biocatalysts Inc. (now Diversa) was used for transglycosylation screening.

Benzyl α-D-xylopyranoside (1)

The glycosidation mixture (21) from acidic equilibration of D-xylose with benzyl alcohol (0.1 M) was hydrolyzed in phosphate buffer (0.2 M, pH 4.5) at 37°C using the crude β-galactosidase preparation from *A. oryzae* with TLC monitoring. The unreacted benzyl α-D-xyloside (**1**) was isolated according to the published procedure (21) as a colorless crystalline solid in >60% absolute yield.

Benzyl β-D-galactopyranosyl-(1,4)-α-D-xylopyranoside (2)

o-NPG donor

Compound **1** (100 mg, 0.4 mmol) and *o*-nitrophenyl β-D-galactoside (250 mg, 0.8 mmol) were dissolved in phosphate buffer (8.0 mL, 50 mM; 1.0 mM $MgCl_2$, 5.0 mM mercaptoethanol, pH 7.0), and the mixture was incubated with β-galactosidase from *E. coli* (130 μL, 215 U) on a rotary shaker (50 rpm) at room temperature. Reaction was monitored for product formation by TLC (MeOH–toluene, 2:1, R_f (**2**) = 0.50). After 4 h, an additional equivalent of *o*-NPG was added to the solution, and agitation was continued for 1 h. The enzyme was removed by heating the solution at 80°C for 3 min, followed by centrifugation. Free nitrophenol and residual acceptor were removed by extraction with ethyl acetate (3 × 10 mL), and the aqueous phase was filtered through a plug of RP-silica gel (5.0 g). After washing with water (20 mL), the product was eluted with ethanol to furnish **2** as a colorless solid (37 mg, 23%).

Lactose donor

Compound **1** (23 mg, 0.1 mmol) and D-lactose (65 mg, 0.2 mmol) were dissolved in phosphate buffer (2.0 mL, 50 mM; 1.0 mmol L^{-1} $MgCl_2$, 5.0 mM mercaptoethanol, pH 7.0), and the mixture was incubated with β-galactosidase from *E. coli* (30 μL, 50 U) with shaking. After 3 h, a further equivalent of lactose was added to the solution, and agitation was continued for 2 h. The product was isolated as above to give pure **2** (4 mg, 15%).

Repetitive-batch operation

To a solution containing D-lactose (3.7 g, 10.8 mmol) in phosphate buffer (20 mL, 50 mM; 1.0 mmol L^{-1} $MgCl_2$, 5.0 mM mercaptoethanol, pH 7.0) was added a solution of **1** (1.00 g, 4.2 mmol) in acetonitrile (1.0 mL). The mixture was placed in an ultrafiltration cell and was incubated with β-galactosidase from *E. coli* (1.3 mL, 2150 U) at room temperature for 3.5 h with slow stirring. The product-containing solution was collected by pressure application, and the enzyme that was retained by the membrane was re-used for a subsequent, identical conversion.

The combined reaction volumes from consecutive batches were processed by extractive removal of **1** using ethyl acetate (3 × 30 mL), followed by solid-phase extraction of **2** on RP-silica gel essentially as described above. Isolated yield 334 mg (10%); $[\alpha]_D^{20}$ +63.7 (*c* 1.0, water); R_f = 0.42 (EtOAc–isopropanol–H_2O, 9:4:2). ^1H NMR (500 MHz, D_2O) δ: 7.49–7.41 (m, 5H, H_{ar}), 5.00 (d, 1H, 1′-H), 4.77 (d, 1H, 1-H_a), 4.62 (d, 1H, 1-H_b), 4.46 (d, 1H, 1″-H), 3.92 (d, 1H, 4″-H), 3.87–3.78 (m, 4H, 3′-H, 5′-H_a, 5″-H, 6″-H_a), 3.75 (dd, 1H, 5′-H_b), 3.70 (dd, 1H, 4′-H), 3.66–3.63 (m, 2H, 3″-, 6″-H_b), 3.60 (dd, 1H, 2′-H), 3.52 (dd, 1H, 2″-H) ($J_{1a,1b}$ =

Glucosyltransferases acting on starch or sucrose for the synthesis of oligosaccharides

Francisco J. Plou, M. Teresa Martín, Aránzazu Gomez de Segura, Miguel Alcalde, and Antonio Ballesteros

Abstract: In this work we review the extraordinary biotechnological potential of two glycosyltransferases, cyclodextrin glucanotransferase and dextransucrase, especially their utility in the synthesis of oligosaccharides. Both enzymes are non-Leloir transferases that require neither co-factors nor activated substrates, as they directly employ the free energy of cleavage of starch and sucrose, respectively. Cyclodextrin glucanotransferase is able to produce cyclodextrins from starch. In the presence of appropriate acceptors (e.g., carbohydrates), this enzyme furnishes oligosaccharides containing $\alpha(1\rightarrow4)$ bonds. Thus, we have found that glucose, maltose, and sucrose readily serve as acceptors to form the corresponding [Glc-$\alpha(1\rightarrow4)]_n$- oligosaccharides, with the degree of polymerization being controlled by the starch:acceptor ratio. The ability of other sugars and related compounds to act as acceptors is also reviewed. Dextransucrase is a glycansucrase that synthesizes dextran using sucrose as glucosyl donor. The formation of dextrans can be quantitatively replaced with the formation of novel oligosaccharides by adding alternative carbohydrate acceptors to the reaction medium. With the dextransucrase from *Leuconostoc mesenteroides* B-1299, we have investigated the synthesis of gluco-oligosaccharides containing $\alpha(1\rightarrow2)$ bonds using methyl 1-*O*-α-D-glucopyranoside as the acceptor. These products constitute a class of nondigestible nutraceutical oligosaccharides with prebiotic properties relating to the stabilization and enhancement of gastrointestinal tract flora, and are being increasingly used by the food industry.

Key words: glycansucrases, cyclodextrin glucanotransferase, cyclodextrin glucosyltransferase, dextransucrase, acceptor products, gluco-oligosaccharides, malto-oligosaccharides, coupling sugar, nutraceuticals, functional foods, prebiotics.

Résumé : Dans ce travail, on passe en revue le potentiel biotechnologique extraordinaire de deux glycosyltransférases, la glucanotransférase de la cyclodextrine et de la sucrase de dextrane, en particulier de leurs utilités dans la synthèse d'oligosaccharides. Les deux enzymes sont des transférases non Lenoir qui ne nécessitent pas de cofacteurs ou de substrats activés puisqu'ils utilisent directement l'énergie libre de clivage de l'amidon et du sucrose respectivement. La glucanotransférase de la cyclodextrine peut produire des cyclodextrines à partir de l'amidon. En présence d'accepteurs appropriés (par exemple des carbohydrates), cet enzyme conduit à la formation d'oligosaccharides contenant des liaisons $\alpha(1\rightarrow4)$. On a ainsi observé que le glucose, le maltose et le sucrose peuvent facilement servir d'accepteurs pour former les oligosaccharides [Glc-$\alpha(1\rightarrow4)]_n$- correspondants dans lesquels le degré de polymérisation est déterminé par le rapport amidon/accepteur. On a aussi passé en revue la possibilité d'autres sucres et de composés apparentés à agir comme accepteurs. La sucrase du dextrane est une sucrase de glycane qui synthétise du dextrane à partir du sucrose agissant comme donneur de glycosyle. La formation des dextranes peut être remplacée quantitativement par la formation de nouveaux oligosaccharides par l'addition de carbohydrates accepteurs dans le milieu réactionnel. Avec la sucrase de dextrane provenant du *Leuconostos mesentoroides* B-1299, nous avons étudié la synthèse de glucooligosaccharides contenant des liaisons $\alpha(1\rightarrow2)$ en faisant appel au 1-*O*-α-D-glucopyranoside de méthyle comme accepteur. Ces produits constituent une classe d'oligosaccharides nutraceutiques non digestibles possédant des propriétés prébiotiques découlant d'une stabilisation et d'une augmentation de la flore intestinale et qui sont de plus en plus utilisés dans l'industrie alimentaire.

Mots clés : sucrases de glycane, cyclodextrine, glucanotransférase, glucosyltransférase de la cyclodextrine, sucrase de dextrane, produits accepteurs, glucooligosaccharides, maltooligosaccharides, sucre qui se couple, nutraceutique, aliments fonctionnels, prébiotique.

Introduction

Oligosaccharides are generally considered to be carbohydrates consisting of 3–10 monosaccharide units. (However, from a dietary point of view, disaccharides such as leucrose or lactulose are also included in this group because of their similar properties.) There is increasing interest in developing efficient and scalable synthetic routes to oligosaccharides for addressing applications in the food (sweeteners, stabilizers, bulking agents, functional foods, etc.) and pharmaceutical industries (e.g., in prevention of infection, neutralization of toxins, immunotherapies for cancer) (1).

Considering this structural diversity of oligosaccharides (three different amino acids allow the synthesis of only six different peptides, while three different hexopyranose units will yield 720 trisaccharides), the stereo- and regioselectivity of biological catalysts may be considered a valuable and complementary aid to chemical synthesis (which needs complex protection and deprotection steps) for the preparation of structurally well-defined oligosaccharides.

Enzymatic oligosaccharide synthesis can be catalyzed by two different types of enzymes: glycosidases (EC 3.2) and glycosyltransferases (EC 2.4) (2). Glycosidases are widely available enzymes which in nature mediate the hydrolytic cleavage of glycosidic bonds and exhibit high stereoselectivities. To revert the in vivo hydrolytic function of glycosidases towards glycosidic bond synthesis, thermodynamic control (using low-water environments) and (or) kinetic control (using activated glycosyl donors) have been successfully employed. Despite the broad specificity of glycosidases and their numerous synthetic applications, the application of these catalysts is often limited by low yields and poor regioselectivity.

To the subclass of glycosyltransferases or transglycosylases belong all enzymes capable of transferring glycosyl groups. Some of these enzymes also have hydrolytic activity, which can be regarded as transfer of a glycosyl group from the donor to water. This subclass is further subdivided, according to the nature of the sugar residue being transferred, into hexosyltransferases (EC 2.4.1), pentosyltransferases (EC 2.4.2), and those transferring other glycosyl groups (EC 2.4.99). Within the sub-subclass 2.4.1, several related enzymes are worth mentioning. Under the term glycansucrases are considered glucansucrases and fructansucrases, bacterial enzymes acting on sucrose and utilizing it as the sole energy source for sugar synthesis (3). Glycansucrases share the same substrate specificity but catalyze the synthesis of a variety of oligo- and polysaccharides (Table 1). For example, they may transfer the glucosyl moiety of sucrose to dextran (i.e., dextransucrase, EC 2.4.1.5) or the fructosyl group to inulin (inulosucrase).

Other bacterial 2.4.1. enzymes (cyclodextrin glucanotransferases (CGTases), EC 2.4.1.19), cyclize part of an α-(1→4)-amylose chain by formation of an α-(1→4)-glucosidic bond yielding cyclodextrins (CDs).

In our laboratory we are currently studying two bacterial glucosyltransferases with considerable potential for oligosaccharide synthesis: cyclodextrin glucanotransferase and dextransucrase (a glycansucrase). These enzymes require neither sugar nucleotides (glycosyltransferases of the Leloir pathway, e.g., UDP-glucosyltransferase) nor sugar-1-phosphates (most glycosyltransferases of the non-Leloir pathway, e.g., phosphorylases) as donors (9). The synthesis of these activated substrates is rather difficult and expensive, as is the regeneration of sugar nucleotides. Rather, CGTase and dextransucrase use the free energy of cleavage of the readily available substrates starch and sucrose, respectively.

Cyclodextrin glycosyltransferase

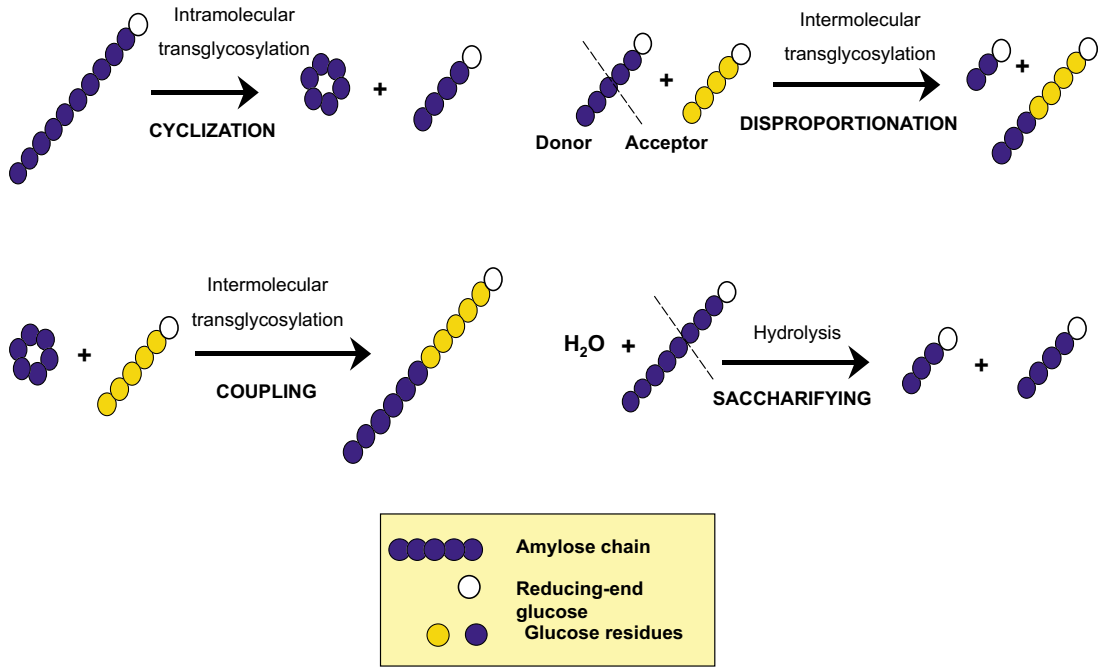
Cyclodextrin glucanotransferases (CGTases) catalyze the formation of cyclodextrins (CDs) from starch by way of an intramolecular transglycosylation reaction (cyclization). CDs are cyclic oligosaccharides composed of α(1→4)-linked glucose residues, that possess a hydrophilic exterior and a hydrophobic cavity, and have numerous applications in food, pharmaceutical, chemical, and cosmetic industries (10). CDs form inclusion complexes with a wide variety of organic molecules of suitable size (guest molecules). CGTases usually produce a mixture of α-, β-, and γ-CDs (structures containing six, seven, and eight D-glucose units, respectively) and are accordingly classified as α-, β-, or γ-CGTases (11).

Besides this cyclization process, CGTases catalyze three different reactions (Fig. 1): (*i*) coupling (the CD molecule is cut open and combined with a linear oligosaccharide to produce a longer linear oligosaccharide); (*ii*) disproportionation (transfer of part of a linear oligosaccharide chain to another linear oligosaccharide); (*iii*) and hydrolysis of starch (12).

Several highly thermostable CGTases have been isolated from thermophilic microorganisms, belonging to the species *Bacillus stearothermophilus* (13), *Thermococcus* sp. (14), *Thermoanaerobacterium thermosulfurigenes EM1* (15), and

© 2002 NRC Canada

Fig. 1. Reactions catalyzed by CGTase.



Thermoanaerobacter sp. (16). The two latter exhibit similar biochemical properties and are able to degrade starch into CDs under jet-cooking industrial conditions, thus avoiding the use of α-amylase pretreatment for the liquefaction of starch (17). In this way, the enzymatic synthesis of CDs starting from starch can be performed using one single enzyme (CGTase).

In our laboratory, we are studying the commercially available CGTase from *Thermoanaerobacter* sp., whose optimum temperature is 85°C at pH 5.5 (18). This enzyme is able to convert about 30% of a 25% (w/v) starch-slurry into a mixture of CDs, with a ratio α–β–γ of 3:5:2 (16).

The acceptor specificity of CGTase is rather broad. It is able to use various carbohydrates and related compounds such as natural glycosides, sugar alcohols, or vitamins as acceptors by way of intermolecular α-glucosylation reactions (coupling or disproportionation) (19). The transglycosylation capability of CGTase seems to be very dependent on the sources of CGTase (20).

The requirement for strong or moderately strong acceptor properties of a certain carbohydrate is a D-glucopyranose structure (chair form) with equatorial hydroxyl groups at C-2, C-3, and C-4 (21). Among monosaccharides, D-glucose, D-xylose, and L-sorbose are the most effective acceptors. As shown in Fig. 2, these compounds share the same configuration at the C-2, C-3, and C-4 of the pyranose moiety. CGTase transfers a glucosyl residue to the hydroxyl group at the C-4 of D-glucose and D-xylose, but to the 3-OH of L-sorbose. Monosaccharide derivatives such as methyl-α-D and methyl-β-D-glucosides are also efficient acceptors. On the contrary, D-galactose, D-ribose, D-mannose, D-arabinose, and D-fructose — which lack the above mentioned configuration of 2-OH, 3-OH and 4-OH — give rise to very low or even negligible yields of acceptor products.

The transglycosylation to disaccharides containing a nonreducing-end glucose residue occurs mainly or exclusively at the C-4 hydroxyl group of this glucose moiety (Fig. 2). Nakamura et al. (22) demonstrated that maltose and cellobiose have higher acceptor specificity than glucose for the transglycosylation reaction of CGTase. It is now well-documented that CGTase has a higher affinity to disaccharides compared with monosaccharides (20). This suggests that the acceptor-binding site can recognize at least two glucopyranose moieties. Disaccharides such as isomaltose, gentiobiose, turanose, maltulose, isomaltulose, cellobiose, and sucrose act as good CGTase acceptors, yielding the corresponding oligosaccharides. When these acceptors are present in the reaction mixture, they inhibit the formation of cyclodextrins because the glucosyl donor (starch) is deviated towards the acceptor reaction (19). The disaccharides α,α-trehalose and melibiose, despite having an available glucose moiety, are unexpectedly not acceptors.

A steric factor possibly plays a major role in diminishing the acceptor of malto-oligosaccharides larger than maltose (e.g., maltotriose). With increasing polymerization degree, the ability of the unsubstituted glucopyranosyl moiety to occupy a binding site of the enzyme must be lower.

Other carbohydrate derivatives such as glycosides, sugar alcohols, some vitamins, etc. have been also reported to act as acceptors (Table 2), in many cases with very notable yields. Transglycosylation often results in new properties (stability, solubility, etc.) of the glycosylated compound. Though mainly found in plants, there are numerous glycosides which occur in nature (e.g., aminoglycosidic antibiotics, glycosinolates, saponins, carotenoid glycosides, or terpenoid glycoside sweeteners). They are currently at the forefront of scientific investigation and already have a variety of uses including the treatment of congestive heart failure, lowering cholesterol, flavourings, antibiotics, and sweeteners. Stevioside, as isolated from the plant *Stevia rebaudiana*, has bitter taste and low solubility (26). CGTase-catalyzed glycosylation of stevioside decreases its bitterness and increases its solubility. The

glucosylation of another glycoside, rutin, increases its solubility in water 3×10^4 times (25).

Flavonoids can be used as protectors against UV radiation; however, their use is limited because of their low solubility (29). CGTase is able to transglycosylate starch to the flavonoid hesperidin (which presents vitamin-like activity).

In our laboratory, we have examined glucose, maltose, and sucrose as acceptors of CGTase. When using maltose or glucose as acceptors (30), and starch as donor, linear malto-oligosaccharides (MOS), composed of α-D-glucose residues linked by α(1→4) glycosidic bonds, are produced (Fig. 3). A homologous series of MOS was obtained, as shown in the HPLC chromatogram of Fig. 4. Malto-oligosaccharides constitute an important class of functional oligosaccharides in the food industry (10 000 metric tons/year), and appear to exert their nutraceutical effect by reducing the levels of undesirable anaerobic bacteria such as *Clostridium perfringens* in the intestinal tract (31).

The degree of polymerization of malto-oligosaccharides formed could be modulated by the ratio (w/w) starch–D-glucose provided. Figure 5 shows the effect of this ratio on product distribution, using 10% (w/v) soluble starch and varying D-glucose concentration. In the absence of D-glucose, the consumption of starch was directed preferentially to CDs (34% conversion after 48 h incubation, with a ratio α–β–γ, 2.2:3.6:1), whereas only 4.5% of initial starch was transformed into MOS. In the presence of a twofold weight excess of D-glucose with respect to soluble starch, the formation of CDs was negligible (30). The higher the percentage of D-glucose in the medium, the higher the selectivity to low-molecular-weight oligosaccharides (Fig. 5 illustrates this effect on selectivity to maltose).

Fig. 3. Scheme of the acceptor reaction using soluble starch as donor and D-glucose as acceptor, catalyzed by CGTase.

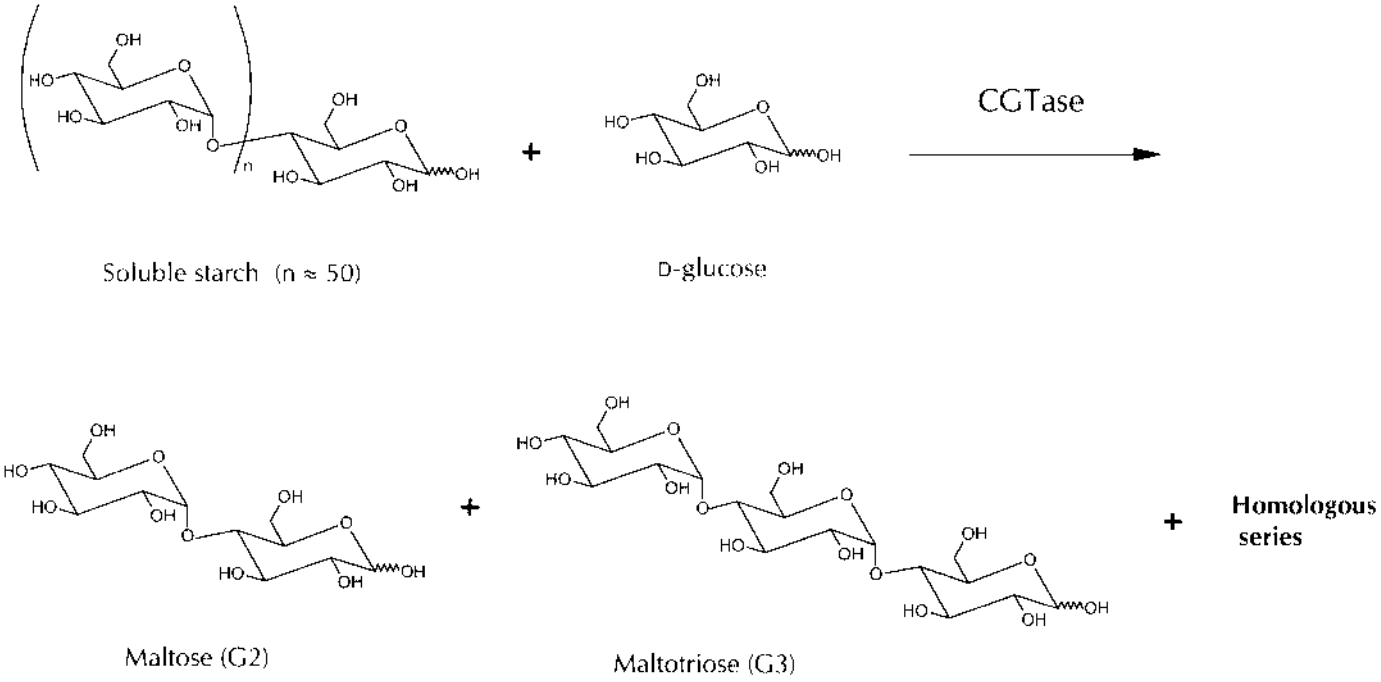

Fig. 4. HPLC chromatogram of the reaction mixture using soluble starch as donor and maltose as acceptor catalyzed by CGTase. Conditions: 10% soluble starch (w/v), ratio starch–maltose 1:2 (w/w), 10 mM sodium citrate buffer (pH 5.5) containing 0.15 mM $CaCl_2$, 60°C. HPLC conditions: two Aminex HPX-42A columns (300 × 7.8 mm, BioRad) put in series, water as mobile phase (0.7 mL min^{-1}), 85°C, refraction-index detector.

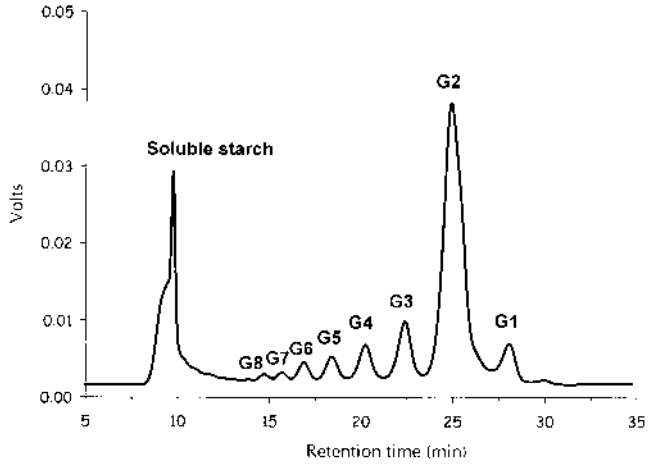

Fig. 5. Distribution of products of the acceptor reaction catalyzed by the CGTase from *Thermoanaerobacter* sp. using starch as the donor and D-glucose as the acceptor. The percentage of initial starch transformed into cyclodextrins (CDs) and malto-oligosaccharides (MOS) after 48 h incubation is represented as a function of the ratio starch–D-glucose (w/w). The percentage of maltose (G2) formed in the MOS series is also shown. Data from ref. 30.

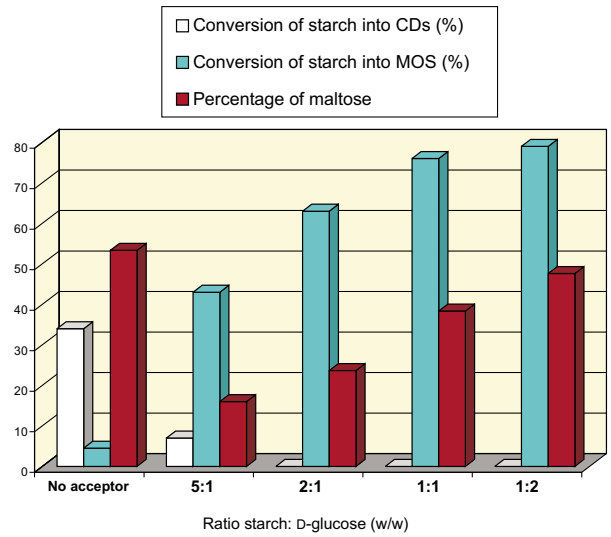

When using sucrose, glucosyl-sucrose (α-D-Glu-(1→4)-α-D-Glu-(1→2)-β-D-Fru) (Fig. 6) and higher polymerization products of the homologous series (called coupling sugar) are obtained (32). Coupling sugar is used as a non-cariogenic sweetener and viscosity control agent, with its higher chemical and thermal stability as compared to other sweeteners containing reducing sugars being notable (33).

The 3D structure of several CGTases has been reported (12, 15). This information can be very useful: (*i*) to predict if a certain molecule can become a CGTase acceptor; and (*ii*) to design mutants with modified selectivity.

For these acceptor reactions, the immobilization of the transferases constitutes an interesting strategy to achieve their stabilization and (or) the separation of the biocatalyst from the reaction mixture. Different approaches have been applied for the immobilization of CGTases, based on adsorption onto inorganic supports or covalent coupling to aminated resins (Table 3). However, the recovery of activity in the immobilized biocatalyst is generally low, especially

when compared with structurally related enzymes such as the glycosidases. This can be attributed to the complexity of CGTase structure (five domains) and mechanism (four possible reactions). We are currently investigating the covalent coupling of CGTase to epoxy-activated acrylic polymers with different morphologies.

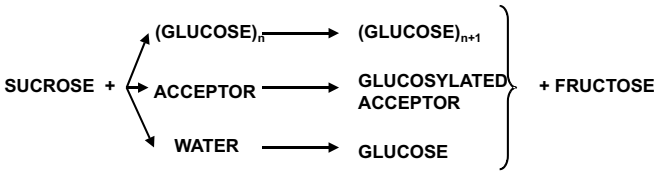
Dextransucrase

Dextransucrase (sucrose:1,6-α-D-glucan 6-α-D-glucosyltransferase, EC 2.4.1.5) polymerizes the glucosyl moiety of sucrose to form dextran, an α(1→6) linked glucan, also with α(1→2), α(1→3), or α(1→4) branch linkages depending on the producing enzyme. When, in addition to sucrose, other carbohydrates (such as maltose, isomaltose, etc.) are present, some of the glucosyl groups are transferred to the carbohydrates ("acceptor reaction") and are diverted from forming dextran to yield acceptor products (Fig. 7). The three reactions catalyzed by dextransucrase: (*i*) polymerization of the glucose moiety of sucrose; (*ii*) glucose transfer to acceptors; and (*iii*) sucrose hydrolysis, are competitive, indicating that they take place at the same active site (41).

In our laboratory, we have studied the dextransucrases from two different strains of *Leuconostoc mesenteroides* (NRRL B-512F and B-1299). The dextransucrase from *L. mesenteroides* NRRL B-512F synthesizes a dextran containing 95% α(1→6) and 5% α(1→3) osidic bonds, while the *L. mesenteroides* B-1299 dextran contains 65% α(1→6), 30% α(1→2) and 5% α(1→3)-branching linkages (42, 43).

Numerous sugars can act as acceptors of dextransucrase. The acceptors can be subdivided in: (*i*) the strong acceptors, such as maltose or isomaltose, that have an activator effect on the reaction rate (measured as fructose liberated) and

Fig. 7. Scheme of reactions catalyzed by dextransucrase.



strongly inhibit the synthesis of dextran; and (*ii*) the weak acceptors, like fructose or melibiose, that have an inhibitory effect on glucan formation but yield a low amount of acceptor products (44).

The acceptors can be also classified according to the acceptor products obtained, in: (*i*) those that give a homologous series of oligosaccharides, each differing one from the other by one glucose residue (e.g., maltose); and (*ii*) those acceptors that only form a single acceptor product containing one glucose residue more than the acceptor (41). The latter is the case of fructose, which is a major product in all the dextransucrase-catalyzed reactions (Fig. 7). There are two products formed, depending on the ring form of the fructose acceptor (pyranose or furanose): leucrose (5-*O*-α-D-glucopyranosyl-D-fructopyranose) and the minor product, isomaltulose (4-*O*-α-D-glucopyranosyl-D-fructofuranose). The leucrose synthesis process becomes particularly important at the final stages of the glucan synthesis reaction when the fructose concentration is high. A process for leucrose production by action of dextransucrase in the presence of sucrose and fructose has been developed on a pilot scale (45).

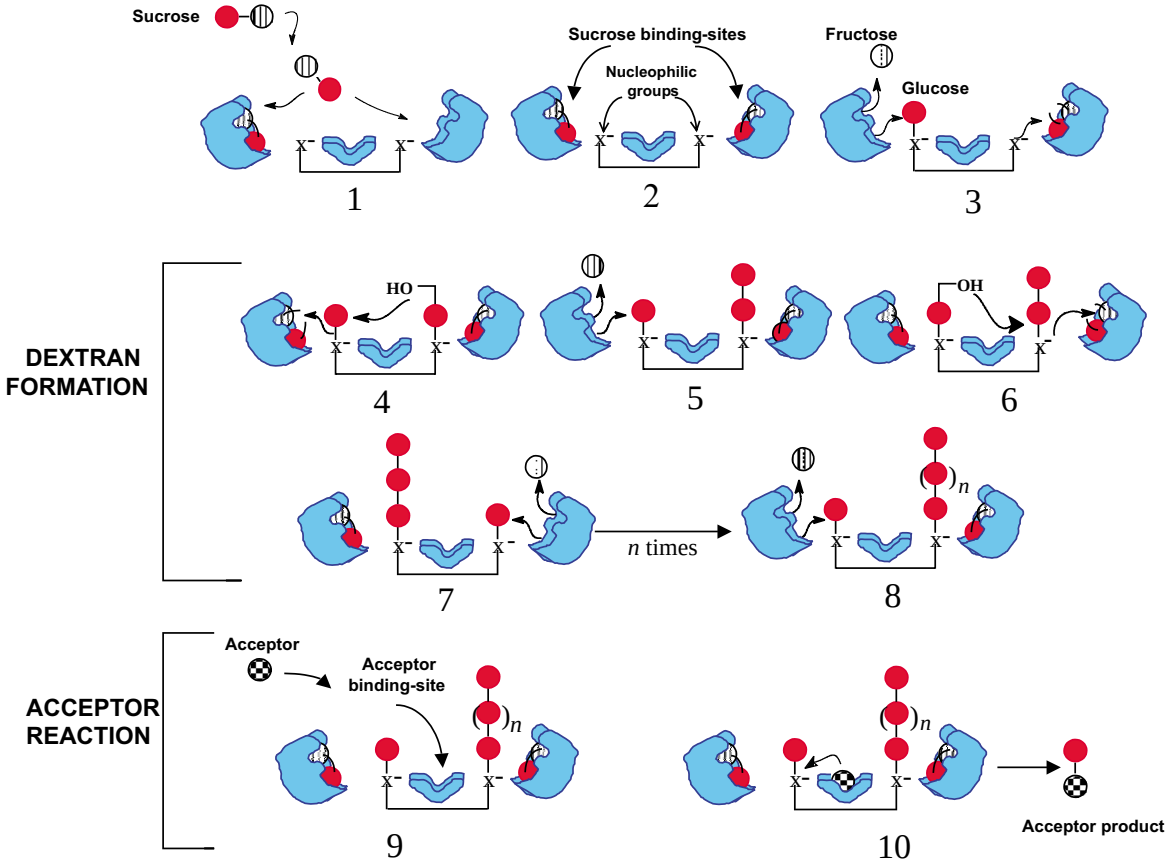
When using acceptors such as glucose, methyl 1-*O*-α-D-glucopyranoside, maltose or isomaltose, the glucose unit from sucrose is transferred to the C-6 hydroxyl of the monosaccharide or to the 6-OH of the nonreducing-end glucose of a disaccharide. This yields a series of isomaltodextrins of degree of polymerization of two to seven attached to the acceptor. Similar homologous series are obtained from 1,5-anhydro-D-glucitol, nigerose, and turanose (46).

Cellobiose gives an unusual series in which the first product is 2-α-D-glucopyranosyl cellobiose with glucose attached to the C-2 of the reducing end of cellobiose. With the cellobiose analog, lactose, only the first acceptor product is formed, but with similar regiospecificity (47).

An analysis of the data on acceptor reactions with dextransucrases suggests that a specificity of recognition exists. However, to extend this reaction to the synthesis of

© 2002 NRC Canada

Fig. 8. Mechanism of dextran synthesis and acceptor reaction of dextransucrase.



new glucoconjugates, it is necessary to progress in the understanding of the mechanism of the acceptor reaction (48). It is desirable to have a better knowledge of the protein determinants involved in: (*i*) the selectivity towards a given acceptor molecular structure; and (*ii*) in the regiospecificity of the enzyme.

The active site of *L. mesenteroides* B-512F dextransucrase is described as having two sucrose binding-sites and one acceptor binding-site (49). Figure 8 illustrates the proposed mechanism of dextran synthesis and acceptor reaction catalyzed by dextransucrase (50). The transfer of glucose units to yield dextrans supposes first the formation of two covalent glucosyl-enzyme complexes (41). Oligosaccharides can be synthesized by a nucleophilic attack of the hydroxyl group located at the nonreducing-end of the acceptor to the C-1 of one of the two glucosyl residues involved in the two covalent glucosyl-enzyme complexes. Various experiments tried to demonstrate that the acceptor binding-site is really unique and separated from the two active sites, but up to now there is no direct evidence that a separate acceptor binding-site exists (44). Kobayashi and Matsuda (50) suggested that one of the two sucrose binding sites may also be an acceptor binding-site.

Dextransucrases have not been reported as capable of transferring glucose to alcohols or polyols (51). This contrast with levansucrases, which are capable of transferring fructose to glycerol, although in low yield. However, nonconventional acceptors can be used with dextransucrase. Bucholz's group (52), using dextransucrase from *L. mesenteroides* B-512F, reported the glucosylation of D-sorbitol, α-D-glucosyl-1,6-D-sorbitol, α-D-glucosyl-1,6-D-arabonic acid, and D-glucal.

In our laboratory, we have investigated the acceptor reaction with maltose using B-512F dextransucrase (53). The first acceptor product which is formed, the trisaccharide panose, may also act as an acceptor, and a homologous series of products having isomaltodextrin residues attached through 6-*O* to the nonreducing glucosyl moiety of maltose were obtained. We observed that the lower the percentage of maltose, the higher the degree of polymerization of the acceptor products (but the concentration of the products decreases).

We have recently investigated the acceptor reaction using methyl 1-*O*-α-D-glucopyranoside as acceptor (54). To control the polymerization degree, the ratio sucrose–methyl 1-*O*-α-D-glucopyranoside was varied (from 5:1 to 1:5 w/w). The first acceptor product formed is 1-*O*-α-D-methyl-isomaltoside; this may also act as an acceptor, and a homologous series of products is formed (Fig. 9). In addition to isomalto-oligosaccharides, dextransucrase B-1299 afforded a series of glucooligosaccharides containing α(1→2) bonds. A great demand exists for glucooligosaccharides containing α(1→2) osidic bonds. These molecules — which belong to the group of prebiotics — are now produced on industrial scale (40 metric tons/year) for their dermocosmetic and nutritional (animal and human) applications (Fig. 10).

One of the most explored alternatives to stabilize dextransucrase is its entrapment in alginate beads (42, 55).

Although this method is normally more suitable for the immobilization of whole cells than for globular proteins, it is useful for dextransucrase, probably because the dextran layer that covers the protein surface prevents leakage of the enzyme through the matrix pores. We found that native and alginate-entrapped dextransucrases yielded similar gluco-oligosaccharides production in the acceptor reaction with maltose. However, the operational stability of the alginate-entrapped dextransucrase was found to be higher compared with the soluble enzyme, with the immobilized form retaining 100% of its initial activity after seven cycles of 24 h (53). Other methods have been tested by different groups to immobilize dextransucrase (e.g., in porous phenoxyacetyl cellulose, alkylamine porous silica, DEAE Sephadex, polyacrylamide, etc.) but either the immobilization yields were low or the enzyme was not stable (56).

Prebiotic Oligosaccharides

The main role of food is to provide nutrients for the metabolic requirements and well-being of humans. However, investigations in the last decade support the concept that, in addition to satisfying nutrition needs, diet may modulate various biochemical processes in the body and may play deleterious or beneficial roles in aging and disease. This hypothesis is becoming a kind of new frontier in nutrition sciences.

In this context, the concept of functional foods (other synonyms are nutraceuticals or pharmafoods) has appeared. In 1998, European experts approved that "a food can be regarded as functional if it is satisfactorily demonstrated to affect beneficially one or more target functions in the body, beyond adequate nutritional effects in a way which is relevant to either the state of well-being and health or the reduction of the risk of disease" (57). A functional food may be a macro- or a micronutrient, essential or not (58).

It was only in 1995 when the concept of prebiotic was introduced (59). Prebiotic is a nondigestible food ingredient (i.e., resistant to the action of human digestive enzymes) that affects beneficially the host by stimulating selectively the growth and (or) activity of one or a limited number of endogenous bacteria in the colon (mainly bifidobacteria and

© 2002 NRC Canada

lactic acid bacteria), and (or) inhibiting the proliferation of pathogenic microbes (60–62).

Several food-grade oligosaccharides that can be regarded as prebiotics are being currently commercialized (Fig. 10). Most of them are obtained by enzymatic methods. Because of their high solubility in water, they are easily incorporated into processed foods as functional ingredients. Apart from their prebiotic effect, there are reports of positive effects such as the enhancement of calcium absorption, stimulation of immune functions, reduction of cancer risk, modulation of lipid metabolism, etc. (60). In 1995, the world production of food-grade oligosaccharides was over 85 000 tons, most of them using biological catalysts (31).

In view of the functional effects of oligosaccharides, many companies and academic laboratories are examining novel compounds (second generation oligosaccharides) with new and (or) improved bioactivities, especially in terms of reduction of intestinal gas, tailoring the in vivo fermentation activity of desirable flora, and extended persistence throughout the colon (63).

We are particularly interested in glucooligosaccarides containing $\alpha(1\rightarrow2)$ bonds (GOS). They are not hydrolysed in the gastrointestinal tract and reach the colon promoting the growth of certain beneficial bacteria (*Bifidobacterium*, *Lactobacillus*) as opposed to pathogenic flora (64). It has also been suggested that some GOS can block colonization sites often occupied by pathogens (65). Furthermore, GOS are non-cariogenic, since salivary enzymes cannot hydrolyse the $\alpha(1\rightarrow2)$ bonds. By stabilizing intestinal floras and this protection against the proliferation of pathogenic microbes, it is envisaged that the use of such novel oligosaccharides may reduce the current excessive use of antibiotics in human and animal health.

Acknowledgments

We are very grateful to our European colleagues Dr. S. Pedersen (Novozymes A/S, Bagsvaerd), Dr. P. Monsan (INSA, Toulouse), and Dr. L. Dijkhuizen (University of Groningen), for very valuable help with this work, and to Dr. I.S. Gill (U.S.A.) for critical reading of the manuscript. This research was supported by the Comunidad de Madrid (Project 07G/0042/2000) and the Spanish CICYT (Project PPQ 2001–2294). We thank Instituto Danone, Gobierno Vasco, and Ministerio de Educacion, Cultura y Deporte for research fellowships.

This issue is dedicated to

Professor J. Bryan Jones

This special issue is dedicated to Professor Bryan Jones, on the occasion of his 65th birthday, to honour his outstanding contributions to organic chemistry, especially to recognize his pioneering use of enzymes in organic synthesis and pharmaceutical chemistry.

The paper by Mayer and co-workers entitled "Asymmetric total synthesis of (+)-exo-brevicomin based on enantioconvergent biocatalytic hydrolysis of an alkene-functionalized 2,3-disubstituted epoxide," that was dedicated to Bryan Jones, was published in the April issue and is reprinted here for completeness.

Associate Editors: R. Green and R. Kazlauskas

Le présent numéro est dédié au

Professeur J. Bryan Jones

Ce numéro spécial est dédié au professeur Bryan Jones, à l'occasion de son 65^{e} anniversaire de naissance, en reconnaissance de ses contributions exceptionnelles au domaine de la chimie organique et, en particulier, en reconnaissance de son utilisation novatrice des enzymes dans la synthèse organique et dans la chimie pharmaceutique.

L'article de Mayer *et al.* intitulé « Asymmetric total synthesis of (+)-exo-brevicomin based on enantioconvergent biocatalytic hydrolysis of an alkene-functionalized 2,3-disubstituted epoxide », dédié à Bryan Jones, a été publié dans le numéro du mois d'avril et il est reproduit ici pour compléter le recueil.

Directeurs scientifiques associés : R. Green et R. Kazlauskas

Professor J. Bryan Jones

Professor J. Bryan Jones

John Bryan Jones was born in the coastal town of Colwyn Bay in North Wales. He began his undergraduate education at the University of Wales, Cardiff, and remained there to obtain a Ph.D. in alkaloid chemistry under the supervision of Dr. A.R. Pinder in 1958. His first post-doctoral work was carried out as an ICI fellow, investigating polyacetylene synthesis with Professor Sir Ewart Jones at the University of Oxford, for which he was awarded a second doctoral degree, the D.Phil. Bryan Jones' next post-doctoral work was with Professor A.C. Cope at MIT, where he worked on amine oxides, after which he moved to Caltech and worked with Professor C. Niemann. In the latter project he was able to perform his first reaction using an enzyme (α-chymotrypsin), opening a research field that is still active 40 years later. Bryan Jones returned to Oxford as an ICI fellow, and in 1963 moved to the Chemistry Department at the University of Toronto, where he was appointed as a full Professor of Chemistry in 1974.

Professor Jones has been a pioneer in the application of enzymes as practical catalysts for organic synthesis. His basic work in this area was broadly focused on alcohol dehydrogenases and hydrolytic enzymes. The results obtained by his research group have demonstrated the unique benefits and broad applicability that the use of enzymes can bring to the production of chiral synthons, including key intermediates for antibiotics, insecticides, and pheromones. From an area that virtually did not exist when he began his work seriously in the early 1970s, the synthetic applications of enzymes has now become one of the most active research fields in chemistry. Furthermore, he has created an electronic database on the applications of enzymes and microorganisms in organic chemistry, which has now been converted into a state-of-the-art, fully structured and keyword-searchable database by Accelrys, a leading chemical software company in the U.K. This database, the only one in its field, is comprehensive for both journal and patent citations, and is now widespread in most of the important pharmaceutical and enzyme companies around the world, as well as in academic institutions.

More recently, he has addressed other frontiers of the field, involving the investigation of factors determining and controlling the catalytic activities and specificities of the enzymes of asymmetric synthetic value, using molecular modeling and graphics, molecular dynamics, and site-directed mutagenesis, in addition to organic chemistry methods. He applied the same strategy to design and synthesize compounds that can act as drugs by inhibiting medicinally important enzymes such as cysteine proteases and β-lactamases, and also to pro-drugs that can be activated in situ at targeted sites of disease. Part of this research was carried out within the Protein Engineering Network of the Federal Centres of Excellence program. A further area of related research was that of catalytic antibody activation of pro-drugs at a specifically targeted disease site.

Most recently, he has initiated a totally new area — that of creating unnatural and novel enzyme catalysts

Professeur J. Bryan Jones

Le professeur John Bryan Jones est né dans la ville côtière de Colwyn Bay, du nord du pays de Galles. Il a commencé ses études sous-graduées à l'Université de Wales, à Cardiff, où il a aussi obtenu son Ph.D. pour des travaux sur la chimie des alcaloïdes, sous la direction du Dr. A.R. Pinder, en 1958. Son premier travail post-doctoral a été réalisé à titre de boursier ICI, à étudier la synthèse des polyacétylènes avec le professeur Ewart Jones à l'Université d'Oxford; ces travaux lui ont valu un deuxième doctorat, le D.Phil. Bryan Jones a ensuite effectué un autre stage post-doctoral au cours duquel il a travaillé sur les oxydes d'amines, sous la direction du professeur A.C. Cope, au MIT, d'où il est passé à Caltech où il a travaillé avec le professeur C. Niemann. Au cours de ce dernier projet, il a réalisé sa première réaction à l'aide d'un enzyme (α-chymotrypsine), ce qui lui a ouvert le champ de recherches dans lequel il est encore actif après 40 ans. Bryan Jones est retourné à Oxford comme boursier ICI et, en 1963, il a déménagé au département de chimie de l'Université de Toronto où il a été nommé professeur titulaire de chimie en 1974.

Le professeur Jones a été un pionnier dans l'application des enzymes comme catalyseurs pratiques en chimie organique. Ses travaux fondamentaux dans ce domaine ont été orientés principalement sur les déshydrogénases de l'alcool et sur les enzymes permettant des hydrolyses. Les résultats obtenus par son groupe de recherches ont démontré les bénéfices uniques et le large spectre des domaines d'application qui peuvent être ouverts par l'utilisation des enzymes dans la production de synthons chiraux, y compris des intermédiaires clés pour les antibiotiques, les insecticides et les phéromones. Alors que ce domaine n'existait pratiquement pas lorsqu'il a débuté sérieusement ses travaux au début des années 1970, les applications synthétiques des enzymes sont maintenant devenues l'un des champs de recherches les plus actifs de la chimie. De plus, il a créé une banque de données électroniques sur l'application des enzymes et des microorganismes en chimie organique; la compagnie Accelrys, R.-U., un chef de fil dans le domaine des logiciels chimiques, l'a maintenant transformée en banque de pointe dans laquelle on peut faire des recherches par structures ainsi que par mots-clés. Cette banque de données est la seule dans son domaine, elle couvre entièrement les citations tirées des journaux et des brevets et elle est maintenant largement utilisée dans les compagnies pharmaceutiques et d'enzymes les plus importantes ainsi que dans les institutions académiques.

Plus récemment, il s'est intéressé à d'autres frontières du domaine, dont l'étude des facteurs qui déterminent et qui contrôlent les activités catalytiques et les spécificités des enzymes ayant une valeur en synthèse asymétrique; il a réalisé ces études à l'aide de modelage et de graphiques moléculaires, de dynamiques moléculaires, de mutagénèses orientées vers les sites ainsi qu'à l'aide de méthodes de la chimie organique. Il a appliqué la même stratégie à la conception et à la synthèse de composés qui peuvent agir comme médicaments par inhibition médicinale d'enzymes importants comme les protéases de la cystéine et les β-lactamases ainsi qu'aux prodrogues qui peuvent être activées *in situ* au niveau des sites ciblés de la maladie. Une partie de ces travaux a été réalisée dans le cadre du « Réseau de génie des protéines » créé dans le cadre du programme des centres d'excellence du gouvernement fédéral. Il s'est aussi intéressé à un autre domaine de recherches apparenté, celui de l'activation

© 2002 NRC Canada

via highly controlled chemical modification in combination with site-directed mutagenesis. This new strategy is at the cutting edge of the enzyme frontier and permits previously unattainable control and modulation of enzyme properties and selectivity, including stereoselectivity. It has also opened up a totally new strategy for pharmaceutical and drug development, involving targeting and then selectively destroying enzymes, proteins, and receptors that are involved in the mediation and promotion of diseases.

Professor Jones is recognized as one of the leading authorities on the synthetic uses of enzymes, a fact reflected by his numerous plenary lectures at international meetings. His work in this area has already attracted some 55 specialized papers in the journal "Bioorganic and Medicinal Chemistry" (Nos. **6** and **7**, 1994) in commemoration of his 60th birthday, in addition to the 35 papers in this special issue.

Professor Jones is a Fellow of the Royal Society of Canada and of the Chemical Institute of Canada, and a Killam Fellow of the Canada Council. Other honours include the Perlman award of the American Chemical Society (Microbial Chemistry Division), the Labatt Award and the Bader Award of the Canadian Society of Chemistry, the Chemical Institute of Canada Medal (1995), the Lemieux Award of the Canadian Society of Chemistry (1998), and the Steacie Award of the Canadian Society of Chemistry (2000). He was also awarded the Henry Marshall Tory Medal of the Royal Society of Canada in 2001, following the Chairman Medal of the Royal Society of Chemistry (London), and appointments as Dow Lecturer at the Ottawa-Carleton Institute, Suisse Romande Lecturer (Switzerland), and Austrian Chemical Society Lecturer. In 1994, Bryan Jones was named University Professor, the University of Toronto's highest academic rank, and celebrated his retirement from the University of Toronto in 1997.

He has published over 200 papers and book chapters, and co-authored and edited two Techniques of Chemistry volumes on "Applications of Biochemical Systems In Organic Chemistry" that have become the reference standards in the field.

We, together with all the contributors of this special issue, have the honour of congratulating Professor Jones for his research activities, and collectively celebrating his retirement from the University of Toronto after 34 years of magnificent service.

H.L. Holland
R. Kazlauskas

catalytique d'anticorps de prodrogues au niveau d'un site de maladie spécifiquement ciblé.

Tout récemment, il a initié une voie de recherches complètement nouvelle — celle de créer de nouveaux catalyseurs enzymatiques, non naturels, par le biais de modifications chimiques hautement contrôlées en combinaison avec de la mutagénèse orientée vers le site. Cette nouvelle stratégie est à la fine pointe de l'étude des enzymes et elle permet d'atteindre des niveaux de contrôles, de modulation des propriétés des enzymes et de sélectivité, y compris la stéréosélectivité, que l'on ne pouvait obtenir antérieurement. Il a aussi permis l'ouverture d'une toute nouvelle stratégie pour le développement de drogues et de médicaments, y compris la possibilité de cibler et ensuite de détruire sélectivement des enzymes, des protéines et des récepteurs impliqués dans la promotion des maladies.

Le professeur Jones est reconnu comme l'une des sommités dans l'utilisation synthétique des enzymes, un fait qui est reflété par ses nombreuses présentations plénières à des réunions internationales. Son travail dans ce domaine a déjà permis d'attirer environ 55 présentations dans le journal « Bioorganic and Medicinal Chemistry », Nos. **6** et **7** (1994), pour commémorer son soixantième anniversaire de naissance, en plus des 35 regroupés dans ce numéro spécial.

Le professeur Jones est un membre de la Société royale du Canada et de l'Institut de chimie du Canada et un Associé Killam du Conseil du Canada. Il a aussi reçu le prix Perlman de la Société américaine de chimie (Division de chimie microbiologique), les prix Labatt et Bader de la Société canadienne de chimie, la Médaille de l'Institut de chimie du Canada (1995), le prix Lemieux de la Société canadienne de chimie (1998) et le prix Steacie de la Société canadienne de chimie (2000). On lui a aussi octroyé la Médaille Henry Marshall Tory de la Société royale du Canada en 2001, la Médaille du président de la « Royal Society of Chemistry (London) » et il a aussi été Dow Lecturer à l'Institut Ottawa-Carleton, conférencier invité de la Suisse Romande et conférencier de la Société autrichienne de chimie. En 1994, Bryan Jones a été nommé « University Professor », le niveau académique le plus élevé de l'Université de Toronto et il a célébré sa retraite de cette université en 1997.

Il est l'auteur de plus de deux cents publications et de chapitres de livres et il est le coauteur et l'éditeur de deux volumes de Techniques de chimie sur les « Applications des systèmes biochimiques en chimie organique » qui sont devenus des volumes de référence standards dans ce domaine.

Avec tous ceux qui ont contribué à ce numéro spécial, nous avons l'honneur de féliciter le professeur Jones pour ses activités de recherches et pour célébrer ensemble sa retraite de l'Université de Toronto après trente-quatre ans de superbes services.

Asymmetric total synthesis of (+)-*exo*-brevicomin based on enantioconvergent biocatalytic hydrolysis of an alkene-functionalized 2,3-disubstituted epoxide

Sandra F. Mayer, Harald Mang, Andreas Steinreiber, Robert Saf, and Kurt Faber

Abstract: A short total asymmetric synthesis of (+)-*exo*- and (–)-*endo*-brevicomin ((+)-*exo*-**3** and (–)-*endo*-**3**), which are components of the attracting pheromone system of several bark-beetle species belonging to the genera *Dendroctonus* and *Dryocoetes*, was accomplished via a chemoenzymatic protocol. The key step consisted of biocatalytic hydrolysis by bacterial epoxide hydrolases of *cis*-configured 2,3-disubstituted oxiranes bearing olefinic side chains. This reaction proceeded in an enantioconvergent fashion, by affording a single enantiomeric *vic*-diol from the *rac*-epoxide in up to 92% ee and 83% isolated yield.

Key words: bacterial epoxide hydrolase, 2,3-disubstituted oxirane, enantioconvergent hydrolysis, (+)-*exo*-brevicomin, (–)-*endo*-brevicomin.

Résumé : Faisant appel à un protocole chimioenzymatique, on a réalisé une courte synthèse asymétrique totale des (+)-*exo*- et (–)-*endo*-brévicomines [(+)-*exo*-**3** et (–)-*endo*-**3**], des composants du système de phéromone d'attraction de plusieurs espèces de scolytes des genres *Dendroctonus* et *Dryocoetes*. L'étape clé implique une hydrolyse biocatalytique à l'aide d'hydrolases bactériennes d'époxyde d'oxiranes 2,3-disubstitués, de configuration *cis*- et portant des chaînes latérales oléfiniques. Cette réaction s'est produite de façon énantioconvergente en ne fournissant, à partir de l'époxyde racémique, qu'un seul énantiomère de diol vicinal, avec un rendement isolé de 83% et un e.e. de 92%.

Mots clés : hydrolase bactérienne d'époxyde, oxirane 2,3-disubstitué, hydrolyse énantioconvergente, (+)-*exo*-brévicomine, (–)-*endo*-brévicomine.

A partial-molar volume study of electrolytes in propylene carbonate-based lithium battery electrolyte solutions at 298.15 K

Jianji Wang, Yang Zhao, Kelei Zhuo, and Ruisen Lin

Abstract: Apparent molar volumes ($V_{2,\phi}$) and standard partial-molar volumes ($V^0_{2,\phi}$) of $LiClO_4$ and LiBr at 298.15 K have been determined from precise density measurements in solvent mixtures of propylene carbonate (PC) with dimethylformamide (DMF), tetrahydrofuran (THF), acetonitrile (AN), and methyl formate (MF). The scaled particle theory is used to calculate the contributions of the cavity formation and the electrolyte–solvent interactions to the standard partial-molar volumes. It is shown that $V^0_{2,\phi}$ is strongly dependent on the nature of the solvents, and the trends in $V^0_{2,\phi}$ with composition of the solvent mixtures are determined by the interaction volumes of electrolytes with solvents. The results are discussed in terms of ionic preferential solvation, packing effect of solvents in the solvation shell, and electrostriction of solvents by ion.

Key words: partial-molar volume, scaled particle theory, lithium salts, propylene carbonate, solvent mixtures, lithium battery electrolytes.

Résumé : En se basant sur des mesures précises de densité dans des mélanges de solvants de carbonate de propylène (PC) avec du diméthylformamide (DMF), du tétrahydrofurane (THF), de l'acétonitrile (AN) et de formiate de méthyle (MF), on a déterminé les volumes molaires apparents ($V_{2,\phi}$) et les volumes molaires partiels standards, ($V^0_{2,\phi}$) du $LiClO_4$ et du LiBr, à 298,15 K. On a utilisé la théorie de la particule pour calculer les contributions de la formation de la cavité et de l'interaction de l'électrolyte-solvant aux volumes molaires partiels standards. On a démontré que la valeur de $V^0_{2,\phi}$, dépend fortement de la nature des solvants et les tendances dans les valeurs de $V^0_{2,\phi}$ avec la composition des mélanges de solvant sont déterminées ceux qui sont présents dans les volumes d'interaction des électrolytes avec les solvants. On discute des résultats sur la base de la solvatation ionique préférencielle, de l'effet du tassement des solvants dans la couche de solvatation et de l'électrostriction des solvants par l'ion.

Mots clés : volume molaire partiel, théorie de la particule scalaire, sels de lithium, carbonate de propylène, mélanges de solvants, électrolytes de piles au lithium.

[Traduit par la Rédaction]

Introduction

Lithium batteries are often considered the future leaders in the battery industry, mainly because of their high energy and low environmental impact. As an important part of the battery, the quality of the electrolyte solution is one of the main factors for determining the performance, operating temperature range, and shelf life of batteries (1, 2). In widely produced commercial lithium batteries, liquid electrolytes are the most commonly used. These electrolyte solutions must be stable and highly conductive, and display low viscosity and perfect cycle efficiency. A great variety of solvents and electrolytes have been employed in an effort to improve battery characteristics. Among the solvents, propylene carbonate (PC) is widely used because of its high dielectric constant, wide liquid range, and good solubilizing power for lithium salts. Nevertheless, its viscosity is high and the Li-cycling efficiency using Li metal as anode is poor in the absence of additives. Addition of low-viscosity ethers like tetrahydrofuran (THF) and dimethoxyethane (DME), or linear carbonate like dimethyl carbonate (DMC) and diethyl carbonate (DEC), significantly increase the conductivity of the electrolyte solutions.

Molar volumes of electrolytes affect the properties of lithium-battery electrolyte solutions, such as conductivity and viscosity (2). They also influence the behavior of the electrodes during the cycling (3). Studies on volumetric properties are, therefore, important for developing an understanding of solute–solvent and solute–solute interactions in lithium batteries. A literature survey reveals that there have been numerous studies on conductivity and viscosity for lithium-battery electrolyte solutions. Very little investigation, however, has been carried out on the related volumetric properties. Zana et al. (4) have obtained the ionic volume of electrolytes in PC from the measurements of densities, ultrasonic vibration potentials, and transference numbers of electrolytes at 298.15 K. It was found that the electrostriction in

PC is close to that in water, ethylene glycol, ethanol, and dimethyl sulfoxide. Perron et al. (5) determined the apparent molar volumes of $LiClO_4$ and LiBr in aprotic solvents (DME, acetonitrile (AN), γ-butyrolactone, dioxolane, and to a lesser extent PC), together with other properties, such as solid–liquid phase equilibrium, heat capacities, conductivities, and viscosities. The solvation effect was discussed based on the low-concentration thermodynamic data. The volumes, heat capacities, and specific conductivities of $LiClO_4$ and LiBr, measured in mixtures of γ-butyrolactone (BUTY) with DME and of PC with BUTY, have been reported by Couture et al. (6). These results are compared with those of the electrolytes in the pure solvents. The properties of water in DME, BUTY, or the mixtures of the two solvents are modified significantly in the presence of LiBr but only slightly with $LiClO_4$. Brouillette et al. (7) characterized lithium bis(trifluoromethylsulfone)imide (LiTFSI) in solution, which is a promising electrolyte for high-energy lithium batteries. Its conductance, apparent volume, and heat capacity were measured over a wide range of concentration in glymes, tetraethylsulfamide, AN, BUTY, and PC at 298.15 K. Atkins et al. (8) reported the apparent molar volumes of several electrolytes in solvent mixtures of PC with AN, DME, or THF, but the volumes were measured at an electrolyte concentration of 0.05 mol dm^{-3}. No standard partial-molar volumes were reported for these systems. Recently, Naejus et al. (9) determined the standard partial-molar volumes of $LiClO_4$, $LiCF_3SO_3$, and $LiPF_6$ in PC, EC, or DMC, and of $LiClO_4$ in some mixtures of EC with DMC or PC. Partial-molar volumes of Li^+ and associated anions have been deduced.

All of these studies seem scarce considering that technologically advanced electrolytes have been used in the development of lithium batteries. In this paper, we studied the partial-molar volumes of $LiClO_4$ and LiBr in the mixtures of PC with *N*,*N*-dimethylformamide (DMF), THF, AN, and methyl formate (MF). LiBr was chosen to study the anion effect. The solvent mixtures selected are either currently used in the developmental secondary batteries, such as PC + THF (10), or show potential as battery solvents, such as PC + AN (11), PC + MF (12), and PC + DMF (13). The results have been discussed from ion–solvent interaction with the help of the scaled particle theory.

Experimental

Materials

$LiClO_4 \cdot 3H_2O$ (Beijing Baili Chem. Co., A.R.) was recrystallized twice from ethanol or acetonitrile, and dried at 453 K under vacuum for 4 days. $LiBr \cdot 2H_2O$ (Beijing Chem. Co., A.R.) was recrystallized from ethanol, and dried at 423 K under vacuum for 3 days.

Propylene carbonate (Luoyang Chemical Factory, A.R.) was dried over molecular sieves (4 Å) for several days, heated at reflux for 5 h in the presence of sodium, and then distilled at reduced pressure. The middle fraction of the distillate was collected. *N*,*N*-Dimethylformamide (Tianjin Chemical Factory, A.R.) was mixed with 10% (v/v) of benzene (Beijing Chemical Factory, A.R.). The azeotrope was distilled off under atmospheric pressure at about 353 K. The product was dried over a silica-gel drier and distilled at reduced pressure. Acetonitrile (Beijing Chem. Co., A.R.) was distilled after being stored over activated molecular sieves (3 Å) for several days. Tetrahydrofuran (Zhengzhou Chem. Co., A.R.) was stored over fine sodium wire for several days until no gas evolved upon introduction of fresh sodium. Methyl formate (Shanghai Chem. Co., C.R.) was distilled twice after being heated at reflux over P_2O_5.

Since all these solvents are highly hygroscopic, the purified solvents are stored over P_2O_5 in desiccators before use. The water content, determined by the Karl–Fischer method, was less than 100 ppm.

Measurements

All solutions were prepared by weight, and concentration of the salts is expressed by molality (mol kg^{-1}). Every precaution was taken to minimize contamination by water. The composition of binary solvents is always represented by mole fraction (x) of the co-solvent in the PC-based solvent mixtures.

Solution densities were determined to $\pm 1.5\times10^{-5}$ g cm^{-3} with an Anton Paar DMA 60/602 vibrating-tube digital densimeter. The temperature around the density-meter cell was controlled to 298.15 ± 0.005 K using a CT-1450 temperature controller and a CK-100 ultracryostat. The densimeter was calibrated with known densities of pure water and dry air every day. The other details have been described previously (14).

Results and discussion

Apparent molar volumes of the lithium salts in a given solvent mixture were calculated from the solution densities by

$$[1] \qquad V_{2,\phi} = M/\rho - 10^3(\rho - \rho_0)/(m\rho\rho_0)$$

where M and m are, respectively, the molar mass and molality of the lithium salts, and ρ and ρ_0 are the densities of the ternary solutions and the binary solvents, respectively. Apparent molar volumes of the lithium salts in PC-based solvent mixtures are given in Tables 1 and 2.

It was found that $V_{2,\phi}$ varied linearly with the square root of the molalities of lithium salts, and could be analyzed by least-square fitting to

$$[2] \qquad V_{2,\phi} = V^0_{2,\phi} + S_v m^{1/2}$$

where $V^0_{2,\phi}$ is the infinite dilution of the apparent molar volume that is equal to the standard partial-molar volume, and S_v is the experimental slope. The $V^0_{2,\phi}$ values obtained by least-square analysis for $LiClO_4$ and LiBr in PC-based solvent mixtures are listed in Table 3, along with their standard deviations.

The standard partial-molar volumes of $LiClO_4$ and LiBr have been reported in PC (4) (36.77, 15.32 cm^3 mol^{-1}, respectively) and in AN (5) (15.0, −4.8 cm^3 mol^{-1}, respectively). The present values (37.15, 15.26 cm^3 mol^{-1} in PC and 15.31, −4.90 cm^3 mol^{-1} in AN) are in reasonable agreement with those reported in literature. Atkins et al. (8) reported the apparent molar volume of 0.05 mol dm^{-3} $LiClO_4$ in THF (23.3 cm^3 mol^{-1}), which is in excellent agreement with the present value (23.43 cm^3 mol^{-1}). No literature data can be found for comparison in the mixed solvents.

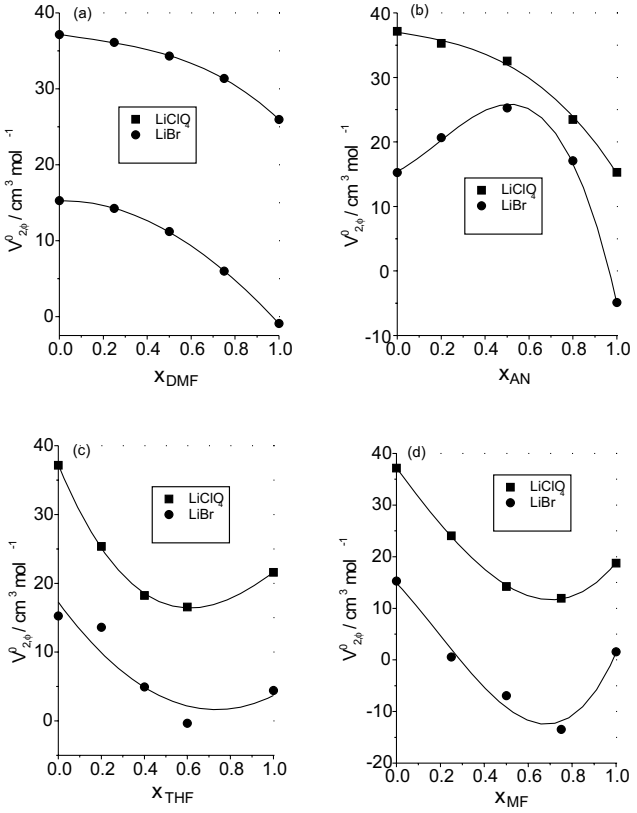
Fig. 1. Dependence of standard partial-molar volume of the lithium salts on the mole fraction of the co-solvent in PC based binary solvents: (*a*) PC + DMF; (*b*) PC + AN; (*c*) PC + THF; (*d*) PC + MF.



Dependence of $V^0_{2,\phi}$ on the composition of the mixed solvents

Figure 1 shows the variation of $V^0_{2,\phi}$ for $LiClO_4$ and LiBr with mole fraction of the co-solvent (DMF, AN, THF, MF) in the solvent mixtures. It can be seen that all values of $V^0_{2,\phi}$ for the electrolytes decrease with addition of the co-solvent, except for those of LiBr in the PC-rich region of PC + AN mixtures. The trends in $V^0_{2,\phi}$ with composition of the binary solvents are, however, different. They can generally be divided into two groups: one is characterized by the monotonous and slow decrease of $V^0_{2,\phi}$ over the entire solvent composition range, such as in PC + DMF and PC + AN mixtures; the other is reflected by an abrupt decrease in the PC-rich region and a minimum in the curve, such as in PC + THF and PC + MF mixtures. This suggests that the nature of the solvents and their interaction with electrolytes play an important role in the variation of $V^0_{2,\phi}$. The significant difference among the studied solvents is the dielectric property, as shown in Table 4. THF and MF have much lower dielectric constant values (ε) than PC, DMF, and AN. The electrostatic field of ions can penetrate much deeper into these low dielectric-constant solvents, leading to the increased electrostriction of the solvent and the decreased standard partial-molar volume of the electrolytes (5). We therefore conclude that dielectric property has an important influence on the variation of $V^0_{2,\phi}$ in the low dielectric solvents.

In addition, it is interesting to note that $\Delta V^0_{2,\phi}$ (difference between the two salts) varies with the mole fraction of the co-solvent, but the extent (not shown) is different in different solvent mixtures. Since both salts have the same cation, it appears that the anion effect is of some importance. Differences in molecular size and charge density between Br^- and ClO_4^- would result in different abilities of the solvent collapsing around them, which would affect the $\Delta V^0_{2,\phi}$ values in mixed solvents.

To get more information about electrolyte–solvent interaction, the scaled particle theory is applied later in the *Discussion*.

Application of scaled particle theory

The scaled particle theory (15, 16) was used to evaluate the measured particle volume as a sum of the geometric volume of solute molecule and the change in the solvent due to its interaction with the solute. That is,

$$[3] \qquad V^0_{2,\phi} = V_c + V_{in} + \beta RT$$

where V_c is the partial-molar volume of cavity formation, and V_{in} is the volume change associated with the solute–solvent interactions, namely the "interaction volume." This term is introduced to describe the difference in volume arising from the difference between the real potential of intermolecular interaction and the potential of the absolutely rigid core. β is the isothermal compressibility of the solvent. The term βRT describes the volume effect of the ideal part of the solute dissolution. It is equal to 1.1 $cm^3\ mol^{-1}$ in aqueous solution at 298.15 K and is often neglected.

Assuming the solute molecule can be approximated by hard sphere with radius r_3 and the thickness of the void space between solute and solvent is Δ, the cavity volume can be estimated from

$$[4] \qquad V_c = (4\pi N_0/3)(r_3 + \Delta)^3$$

where N_0 is Avogadro's number. The Δ value was determined by Glueckauf (17) as follows:

$$[5] \qquad \Delta = (3V_1/4\pi N_0)^{1/3} - r_1$$

where V_1 and r_1 are molar volume and radius of the solvent molecule, respectively. When binary solvents are used, Δ can be obtained from

$$[6] \qquad V_{1,2} = 4\pi N_0\, x(r_2 + \Delta)^3/3 + 4\pi N_0(1 - x)(r_1 + \Delta)^3/3$$

where $V_{1,2}$ is the molar volume of mixed solvents, which is equal in value to the molar mass of mixed solvent divided by its density, x is the mole fraction of co-solvent in the solvent mixtures, and r_1 and r_2 are radii of the solvent and co-solvent, respectively.

In this work, the values of V_c for Li^+, Br^-, and ClO_4^- were calculated by means of eqs. [4]–[6] on the basis of the small spherical ions in the study. Pauling's crystal radii (18) are used as ionic radii (r_3) in the calculations, and radii of the solvents were calculated from van der Waals volume using the method proposed by Bondi (19). The interaction volumes of the lithium salts with solvent mixtures were then calculated by eq. [3] and reported in Table 5, along with the partial-molar volumes of cavity formation. In the calculations, the term βRT is neglected.

It can be seen from Table 5 that in every mixed solvents, values of V_c vary slightly with the mole fraction of the co-solvent. In fact, V_c consists of two terms:

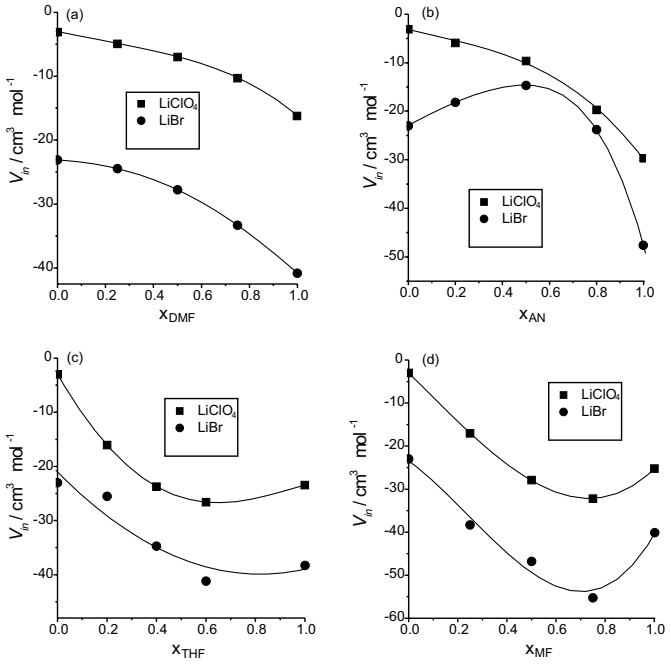
$$[7] \qquad V_c = V_g + V_v$$

where V_g is the geometric volume occupied by the solute molecule itself, and V_v is the "empty" volume, namely the volume of the void space surrounding the solute molecules (20), which is of great importance for highly structured solvents like water, but is negligible in the case of unstructured solvents like carbonate. As a first approximation for low molecular-weight substances, the value of V_g can be taken as the van der Waals volume (V_w), which is considered to be independent of the nature of solvent and the composition of solvent mixtures. It is therefore understandable that no significant changes were observed for V_c of the lithium salts in different solvents.

The interaction volumes, however, are found to be sensitive to the mole fraction of the co-solvent. Their negative values originated mainly from the electrostriction of solvent

© 2002 NRC Canada

Fig. 2. Dependence of interaction volume on the mole fraction of the co-solvent in PC based binary solvents: (*a*) PC + DMF; (*b*) PC + AN; (*c*) PC + THF; (*d*) PC + MF.



by electrolytes. The dependence of V_{in} for $LiClO_4$ and LiBr on the composition of the solvent mixtures is illustrated in Fig. 2. It is interesting to note that the trends in V_{in} with the mole fraction of the co-solvent are almost the same with those in $V^0_{2,\phi}$. We can, therefore, conclude that the trends in $V^0_{2,\phi}$ with composition of the solvent mixtures are determined by the interaction volumes of electrolytes with solvents.

Interactions of electrolytes with solvents

Volumetric properties are quite informative about solute–solvent interactions. Changes in the interaction volumes reflect the relative electrostriction (negative contribution) of the solvent in the presence of a given electrolyte. The contribution to the interaction of the electrolytes with solvents is essentially due to the following five factors: (*i*) steric effects of the solvent, which may force the solvent shell further from the ion and decrease the interaction of the cation with solvent (21); (*ii*) power of ion solvation, which can be expressed directly by the solvation number of ions. (Any decrease in the solvation number will allow tighter packing, i.e., greater electrostriction of the nearby but uncoordinated solvent molecules.); (*iii*) dielectric property of solvent. (According to the Drude–Nernst equation (22), the electrostatic field of an ion can penetrate much deeper into a low dielectric solvent, leading to the increased electrostriction of the solvent.); (*iv*) donor and acceptor ability of solvent, where the donor number (D_N) can be used to judge the interaction between cation and solvent (24), whereas the A_N number is considered to be a measure of solvating ability of anion (24); (*v*) the ability of solvent to collapse around an anion exerts a large influence on the interaction volume. The above related factors are combined to affect the electrostriction of the solvent by the ion.

Previous studies using IR, Raman, and ^{7}Li NMR (25–27) suggest that in the PC + DMF mixed solvents, the interaction between Li^+ and DMF is much stronger than that between Li^+ and PC, and the anion does not influence the solvation of Li^+. At the same time, a coordination number of 4 has been reported for Li^+ in PC (25), DMF, and AN (26). It can be seen in Table 4 that PC has the biggest molecular size in the studied solvents, indicating significant steric crowing of PC around the cation. When PC molecules are replaced by DMF in the solvation shell of the cation, the steric crowding of the solvent is reduced because of the smaller molecular size of DMF. This leads to the increased interaction of the cation with the solvent and the decreased interaction volumes. Since no great difference in molecular size and solvation properties toward Li^+ was observed between PC and DMF, it is not surprising that the variation in interaction volume is not significant from PC to PC + DMF mixtures.

Data on Gibbs energies of transfer (8) indicate that cations are solvated preferentially by PC in PC + AN mixed solvents. As shown in Fig. 2*b*, significant changes in V_{in} are observed when $x_{AN} > 0.5$, indicating significant displacement of PC by AN from the coordination sphere of the cation in this composition range. Although the preferential solvation of Li^+ in this binary solvent is different from that in PC + DMF, a similar solvation mechanism is operative in PC (25) and AN (26). Steric effect resulting from the large difference in molecular size between PC and AN (Table 4) is also a dominant factor for the decreased trend of V_{in} in PC + AN mixed solvents.

Both the D_N value and the Gibbs energies of transfer (8) indicate that cations are in general preferentially solvated by THF in PC + THF mixed solvents. Interaction volume values appear to broadly reflect the effect of preferential solvation as illustrated in Fig. 2*c*. At the initial addition of THF, V_{in} immediately decreases and a minimum value is observed at $x_{THF} \approx 0.6$. At this mixing ratio ($x_{THF} \approx 0.6$), a maximum conductivity of electrolytic solution was reported (28). It was found that this optimum mixing ratio does not depend on the concentration or kind of solutes; the solvation number of Li^+ is estimated to be unity in this mixing ratio (29). This suggests that it is the smaller radius of the solvated Li^+ that contributes to the increased conductivity. It is clear that the electrostriction increases and reaches a maximum with the decrease in the Li^+ solvation number from 4 (PC) to 1 ($x_{THF} \approx 0.6$). On the other hand, the dielectric property of the solvents also has an important effect on the electrostriction. THF has a much lower dielectric constant than DMF and AN, thus ions can penetrate much further into this solvent causing an increase in electrostriction and a decrease in V_{in}. These two contributing factors determine the trend of V_{in} in PC + THF to be much different from that in PC + DMF and PC + AN.

Similar dielectric effect is seen in PC + MF. In addition, MF has a stronger positive center on the formyl proton, which results in a stronger interaction with the anion (30, 31). This attractive interaction is also responsible for the increased electrostriction and the decreased interaction volumes. Except for MF, the other solvents are usually considered as weak anion solvators. Steric crowding of solvent around the anions will not occur to the same extent as

© 2002 NRC Canada

with the cations because of the much larger size of the anions and the weaker interactions with the solvents. Thus solvent molecules always collapse around the anion. It can be expected that the larger the anion, the less steric hindrance there would be to the packing of the solvent molecules. But this effect decreases because of the decreased charge field around the larger anion (ClO_4^-). Moreover, taking into account the difference of structure between the tetrahedral ClO_4^- and Br^-, a steric hindrance for the penetration of the solvent will occur for the first ion in the bulky solvent molecules and thus a higher value for V_{in} is expected. It can be seen from Table 5 that the values of V_{in} for $LiClO_4$ are higher than that of LiBr in every mixed solvent system. Thus, the ability of solvent to collapse around an anion is also a contributing factor to solvent electrostriction.

Conclusions

Addition of co-solvents like DMF, THF, AN, and MF to PC causes a significant decrease in the partial-molar volume of the electrolytes, the magnitude of which depends not only on the nature but also on the amount of the added co-solvent to the mixtures. Thus a noticeable solvent effect on the performance behavior of lithium batteries containing these solvents is expected.

The partial-molar volume of cavity formation is not sensitive to the nature of solvent and the composition of solvent mixtures, whereas the interaction volume is. The interaction volumes of the electrolytes with solvents determine the trends in the standard partial-molar volume of the electrolytes with the composition of solvent mixtures.

It is suggested that steric effects are a dominant factor for the interaction volume of electrolytes in PC + DMF and PC + AN. The large decrease in the solvation number of Li^+ and the dielectric effect are mainly responsible for the interaction volume in PC + THF and PC + MF, while the stronger anion–MF interaction has an additional contribution in PC + MF.

Effect of pH on the mechanism of OClO• oxidation of aromatic compounds

Doug Svenson, John F. Kadla, Hou-min Chang, and Hasan Jameel

Abstract: Contrary to previous reports, the reaction mechanism of chlorine dioxide (OClO•) with benzyl alcohols involves both radical cation and benzyl radical mechanisms dependent on pH. The primary reaction product between OClO• and 1-(3,4-dimethoxy-phenyl) ethanol at pH 8 is 3,4-dimethoxyacetophenone. At pH 4 no acetophenone was observed; the majority of the degradation products were chlorinated and aromatic ring-oxidized compounds. A primary kinetic isotope effect (k_H/k_D = 2.05) was observed in the reaction of OClO• with 1-(3,4-dimethoxy-phenyl)-(1-^{2}H) ethanol at pH 8, but was absent at pH 4 ($k_H/k_D \approx 1$). Similarly, the corresponding methyl ether (4-(1-methoxy)ethyl-1,2-dimethoxybenzene) was substantially less reactive at pH > 6. On the basis of these results, competing pH-dependent reaction mechanisms have been proposed, where at high pH OClO• reacts with benzyl alcohols via a OClO•–benzyl alcohol complex.

Key words: chlorine dioxide, mechanism, kinetic isotope effect, aromatic radical cation, benzyl radical.

Résumé : Contrairement à ce qui a été rapporté antérieurement, le mécanisme de réaction du dioxyde de chlore (OClO•) avec les alcools benzyliques varie avec le pH et il comporte des mécanismes avec cation radicalaire ainsi le radical benzyle. Le produit primaire de la réaction du OClO• et le 1-(3,4-diméthoxyphényl) éthanol à un pH de 8 est la 3,4-diméthoxyacétophénone. À un pH de 4, on n'observe aucune formation d'acétophénone; la majorité des produits de dégradation était formée de produits chlorés et de produits à noyau aromatique oxydé. On a observé un effet isotopique cinétique primaire (k_H/k_D = 2,05) dans la réaction du OClO• avec le 1-(3,4-diméthoxyphényl)-(1-^{2}H) éthanol, à un pH de 8, mais il est absent à un pH de 4 ($k_H/k_D \approx 1$). De la même manière, l'éther méthylique correspondant (4-(2-méthoxyéthyl)-1,2-diméthoxybenzène) est beaucoup moins réactif à des pH supérieurs à 6. Sur la base de ces résultats, on a proposé des mécanismes réactionnels en compétition qui dépendent du pH; à des pH élevés, les alcools benzyliques réagissent avec le OClO• par le biais d'un complexe OClO•–alcool benzylique.

Introduction

The reactivity of chlorine dioxide (OClO•) is an area of intense research due to the environmental and industrial importance of this oxidant. Chlorine dioxide is extensively used in the bleaching of wood pulps in the manufacturing of paper (1–4), in food processing (5–9), and water purification (10–16). The mechanism of chlorine dioxide oxidation of aromatic compounds has been well documented (17–25). It is reported to involve two consecutive one-electron transfer processes leading to the formation of various oxidation and substitution products. The rate-determining step (RDS) is the formation of the intermediate aromatic radical cation (26), with concomitant formation of chlorite ($OClO^-$). A second molecule of OClO• rapidly reacts with the radical cation forming the corresponding chlorous ester that, depending on the point of substitution, leads to various oxidation and substitution products (18).

In addition to the radical cation mechanism, benzyl radical formation during OClO• oxidation of aromatic compounds has been proposed. Brage et al. (18) reported a diphenylmethane product from the reaction of OClO• with 2-methoxy-4-methylphenol, and suggested that a benzyl radical intermediate was involved. Similarly, studies with allylic structures and conjugated aromatics (e.g. styrene) undergo hydrogen atom extraction or electrophilic additions of OClO• to form allyl and benzyl radical intermediates, respectively (27, 28). Molecular orbital calculations for veratryl alcohol show that benzyl hydrogen atoms should be labile toward free-radical induced reactions in the presence of OClO• (29). This is determined by the ΔH_f calculation of a benzyl radical vs. an aromatic radical cation. Calculations indicate that the formation of a benzyl radical requires approximately 11.7 kcal mol^{-1} less energy than that of an aromatic radical cation. Moreover, the stability of the radical cation intermediate will be pH-dependent and decrease with increasing pH (30–32). It is therefore expected that a benzyl radical intermediate may be involved in the reaction of aromatic compounds; the role of which is dependent on the compound structure and reaction conditions.

Table 1. Inorganic material balance after 60 min of reacting $OClO^{\bullet}$ with **1**. Reaction conditions: **1**–$OClO^{\bullet}$ (1:1 mol), temp = 25°C, $[\mathbf{1}]_o$ = 37.5 mM in HPLC-grade H_2O, constant pH.

	pH 4 (mol%)	pH 8 (mol%)
Cl^-	42 ± 5	17 ± 3
$OClO^-$	3 ± 1	48 ± 4
$OClO_2^-$	15 ± 3	16 ± 3
$OClO^{\bullet}$	—	18 ± 3
Cl_{org}	38 ± 4	—

Recently, Gunnarsson and Ljunggren (23) reported that in the reaction of $OClO^{\bullet}$ with 1-(3,4-dimethoxy-phenyl) ethanol the reaction rate and the products produced were dependent on the pH of the reaction system. Under acidic conditions (pH 2–4) various oxidation–substitution products were detected, whereas at mildly alkaline conditions (pH 8) the primary reaction product was 3,4-dimethoxy-acetophenone. Reaction mechanisms involving the initial formation of a radical cation intermediate were proposed. The oxidation and substitution at the benzyl carbon proceeded via a series of complex molecular rearrangements in which an initially formed aromatic radical cation is converted into an oxygen-centered radical (23). Based on the shift in oxidation product distribution over the pH range studied, we believe, however, that more than one oxidation mechanism may be taking place. In the present study, we investigate the reaction of benzyl alcohols with $OClO^{\bullet}$ and the effect of pH on the reaction mechanism.

Results and discussion

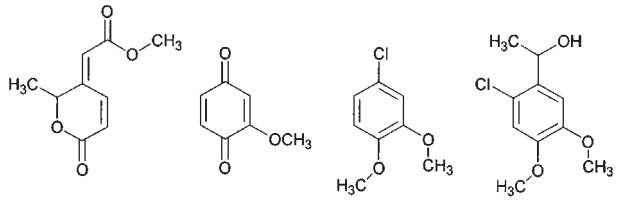
Effect of pH on the reaction of $OClO^{\bullet}$ with 1-(3,4-dimethoxyphenyl) ethanol

1-(3,4-Dimethoxyphenyl) ethanol (**1**) was reacted with equimolar amounts of $OClO^{\bullet}$ at 25°C and constant pH. The extent of the reaction increased with decreasing pH. At pH 8, ~25% of **1** was degraded after 60 min of reaction, compared with more than 80% at pH 4. The primary organic degradation product at pH 8 (>94%) was 3,4-dimethoxy-acetophenone (**4**), and the predominant inorganic product was chlorite ($OClO^-$). In fact, two equivalents of $OClO^-$ were generated for every equivalent of **1** reacted (Table 1). The large amount of $OClO^-$ produced and the decreased reactivity of **1** at pH 8 is consistent with the loss of oxidation power of the $OClO^{\bullet}$ system due to $OClO^-$ formation (33). The major remaining oxidation product at pH 8 (<6 mol%) was (2-methyl-6-oxo-6*H*-pyran-3-ylidene) acetic acid methyl ester (**5**). No chlorinated organic compounds were detected (34).

At pH 4, various oxidation–substitution products and chlorinated compounds were detected (Fig. 1), along with a large amount of chloride (Cl^-) ions (Table 1). At low pH, chloride ions arise from hypochlorous acid (HOCl) decomposition of chlorite (35). As illustrated in Scheme 1, aromatic ring oxidation–substitution via a radical cation intermediate generates one equivalent of chlorite and one equivalent of HOCl, which then rapidly reacts with $OClO^-$ to produce Cl^- according to eq. [1] (36–40).

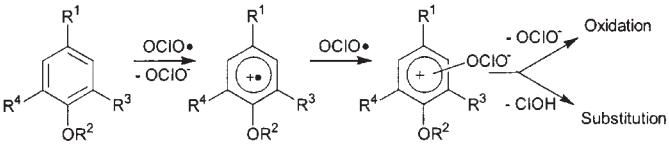
[1] $$2OClO^- + HOCl \rightarrow 2OClO^{\bullet} + Cl^-$$

Fig. 1. Oxidation products identified from $OClO^{\bullet}$ reactions with **1** at pH 4 are (2-methyl-6-oxo-6*H*-pyran-3-ylidene) acetic acid methyl ester (**5**), 2-methoxy-1,4-benzoquinone (**6**), 4-chloro-1,2-dimethoxy-benzene (**7**), and 1-(2-chloro-4,5-dimethoxy-phenyl) ethanol (**8**).



5 **6** **7** **8**

Scheme 1.



R^1, R^2 = alkyl
R^3, R^4 = alkyl, aryl, alkoxyl

HOCl is in equilibrium with elemental chlorine (Cl_2) through a hydrolysis reaction (eq. [2]):

[2] $$H^+ + Cl^- + HOCl \rightleftharpoons Cl_2 + H_2O$$

The rate of the hydrolysis is pH dependent, and increases with decreasing pH. The presence of Cl_2 explains the large amount of chlorinated organic products detected (**7**, **8**) at pH 4. In agreement with the findings of Gunnarsson and Ljunggren (23), aromatic oxidation (**5**, **6**) and chlorination (**7**, **8**) products dominate the reaction at lower pH. These products can be rationalized by a reaction mechanism involving a radical cation intermediate (Scheme 1). Likewise, the detection of **5** at pH 8 confirms the presence of a radical cation intermediate mechanism. The detection of **4**, with concurrent generation of 2 equivalents of $OClO^-$, which is consistent with two consecutive one-electron transfer reactions, suggests, however, the possibility of another mechanism, perhaps involving a benzyl radical. In the reactions of **1** with $OClO^{\bullet}$ at pH 8, Gunnarsson and Ljunggren (23) proposed a reaction mechanism in which an initially formed radical cation intermediate was converted into an oxygen-centered radical. This radical intermediate subsequently reacts with $OClO^{\bullet}$ to form a chlorate ester, followed by rearrangement to the acetophenone. No experimental evidence of an oxygen-centered radical was provided. The possibility of a benzyl radical intermediate was eliminated on the basis of reactions performed in the presence of $Br_2^{\bullet -}$ and oxygen. Based on the shift in oxidation-product distribution with increasing pH and the lack of substantial evidence that a benzyl radical is not involved, we believe that more than one oxidation mechanism is taking place. Scheme 2 depicts a competing pH-dependent reaction scheme for the production of the detected products from the reaction of $OClO^{\bullet}$ with **1**.

We propose that both a benzyl radical and an aromatic radical cation mechanism are taking place, with the extent of

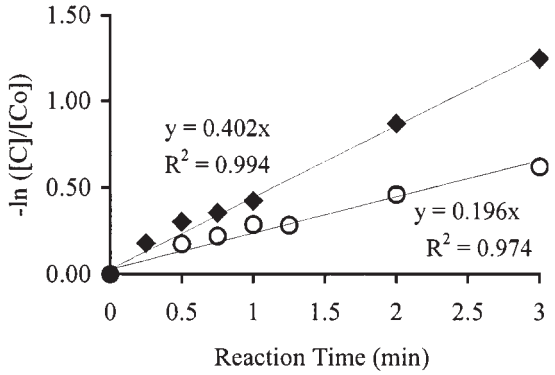
each mechanism determined by compound structure and reaction conditions (pH, solvent, etc.).

Fig. 2. Kinetic isotope effect for the reaction of OClO• and 1-(3,4-dimethoxy-phenyl) ethanol (◆) and 1-(3,4-dimethoxy-phenyl)-(1-^{2}H) ethanol (○). Pseudo-first-order reaction conditions: $[substrate]_o$ = 3 mM, $[OClO^•]_o$ = 100 mM, 25°C, pH 8, H_2O.



Investigation of a benzyl radical mechanism

A common method used to probe reaction mechanisms involves isotope labeling and the observance of an isotope effect (41). A primary isotope effect can be detected by kinetic measurements if the bond to the isotopically labeled atom is broken during the RDS. The presence (or absence) and the magnitude of such an effect can provide important information about the geometry of the transition state and its position along the reaction coordinate. The involvement of a benzyl radical intermediate in the OClO• oxidation of aromatic substrates was studied using deuterium-labeled 1-(3,4-dimethoxy-phenyl)-(1-^{2}H) ethanol (**2**). In this reaction system, the formation of an aromatic radical cation intermediate would not exhibit a primary isotope effect, whereas that involving a benzyl radical would (Scheme 3).

Under psuedo-first-order reaction conditions ($[substrate]_o$ = 3 mM, $[OClO^•]_o$ = 100 mM, 25°C), rate constants were determined for both **1** and **2** at pH 4 and pH 8. Figure 2 shows a plot of ln ([**1**]/[**1**]$_o$) and ln ([**2**]/[**2**]$_o$) vs time for the reactions run at pH 8. A primary kinetic isotope effect (k_H/k_D = 2.05) was observed in the reactions run at pH 8. No kinetic isotope effect was observed in the acidic media (pH 4, $k_H/k_D \approx 1$).

In a reaction system in which a three-bodied transition state (C···H···O) is linear, theory predicts $k_H/k_D \approx 1$ for reactions in which C–H cleavage occurs after the RDS and k_H/k_D = 6.9 for reactions in which C–H cleavage occurs before or during the RDS (42). Depending on the transition state, the value of k_H/k_D will vary. A maximum kinetic isotope effect (k_H/k_D = 6.9) will be observed when the transition state is symmetrical. Very exothermic or endothermic reactions (in which the transition state tends to occur early or late in the reaction coordinate, respectively) have smaller values of k_H/k_D (43). Accordingly, the results presented here indicate that in the reaction between OClO• and **1** at pH 8 the bond to the benzylic hydrogen is either only slightly or nearly completely broken at the transition state. That is, the transition state must occur quite close to the reactant or to the product.

To further investigate the reaction mechanism of OClO• at high pH, methyl ether 4-(1-methoxy)ethyl-1,2-dimethoxybenzene (**3**) was studied. At pH 8, the reaction between **3** and OClO• was extremely slow. The observed pseudo-first-order rate was more than an order of magnitude lower than that for the same reaction conditions with **1** (Table 2).

In a reaction mechanism involving an initial radical cation intermediate, methylation of the benzyl hydroxyl group should not affect the rate of the reaction, only the product distribution. The dramatic decrease in observed reaction rate, therefore, supports a benzyl radical mechanism. Moreover, these results indicate that the benzyl hydroxyl group is required to facilitate the oxidation.

Table 2. Pseudo-first-order rate constants for the reaction of $OClO^{\bullet}$ with various 1,2-dimethoxy-phenyl) ethanol derivatives.

Compound	pH	k (s^{-1})
1	8	0.402 ± 0.039
2	8	0.196 ± 0.015
3	8	0.029 ± 0.005

Chlorine dioxide has been reported to form complexes with various compounds. For example, $OClO^{\bullet}$ and $OClO^{-}$ form a well-characterized chlorine oxide association complex [$Cl_2O_4^-$] (44); H_2O–$OClO^{\bullet}$ complexes have also been well characterized (45, 46). It is therefore possible that $OClO^{\bullet}$ complexes react with the benzyl alcohol to form a chlorite ester as illustrated in Scheme 4. This association complex may lower the activation energy required for benzyl hydrogen atom removal, thus facilitating oxidation by a second $OClO^{\bullet}$ molecule.

This proposed reaction scheme would explain the small k_H/k_D (2.05), in which an asymmetrical transition state occurs. The RDS is the removal of the benzyl hydrogen atom.

Conclusions

Contrary to previous reports, the reaction mechanism of $OClO^{\bullet}$ with benzyl alcohols involves both radical cation and benzyl radical mechanisms. The rate and extent of each mechanism is dependent on the pH and the benzyl alcohol structure. The reaction rate decreases with increasing pH; at pH 8, the reaction of 1-(3,4-dimethoxyphenyl) ethanol is dramatically lower than at pH 4. Similarly, the reaction products are substantially different at pH 8 compared with those at pH 4. At pH 8 the primary product is 3,4-dimethoxyacetophenone, whereas at pH 4 no acetophenone was detected, and the majority of the degradation products were aromatic-ring oxidized and chlorinated compounds.

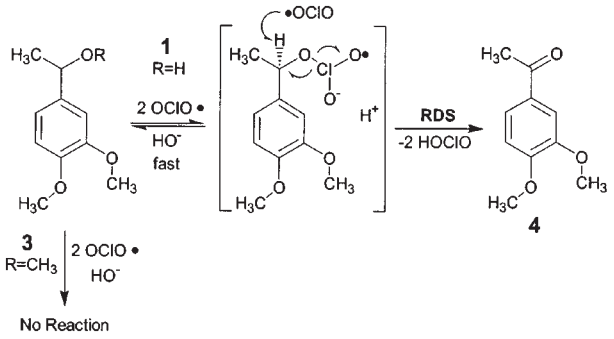
Methylation of the benzyl alcohol severely decreases the rate and extent of reaction with $OClO^{\bullet}$ at pH 8, indicating the involvement of the benzyl hydroxyl group in the reaction mechanism. Chlorine dioxide appears to react with benzyl alcohols via an association complex. These results, in combination with an observed kinetic isotope effect (k_H/k_D = 2.05), indicate a transition state in which complex formation likely lowers the energy required to remove the benzyl hydrogen atom thus facilitating oxidation. We therefore propose that two competing reaction mechanisms are taking place — at low pH a radical cation mechanism is involved in the rate-determining step, whereas at pH 8 a benzyl radical mechanism dominates.

Experimental

Materials

3,4-Dimethoxy acetophenone, sodium borohydride ($NaBH_4$), sodium borodeuteride ($NaBD_4$), *p*-dibromobenzene, biphenyl, and all solvents were purchase from Aldrich and used as received. Chlorine dioxide was produced by reacting 80% stabilized sodium chlorite (ACROS) with 1.5 equivalents of potassium persulfate (Fluka) in distilled water at room temperature. The resulting solution was stripped with UHP-nitrogen. Nitrogen gas containing

Scheme 4.



stripped chlorine dioxide was passed through a column of sodium chlorite (Aldrich), then scrubbed in cold HPLC water, and pH adjusted to 4 with 0.1% wt. aqueous sulfuric acid.

Compound synthesis

1-(3,4-Dimethoxyphenyl) ethanol (1)

1-(3,4-Dimethoxyphenyl) ethanol was prepared by reacting 3,4-dimethoxy acetophenone (**6**) with 2 equivalents of $NaBH_4$. The reaction was carried out in MeOH–H_2O (3:1) and heated at reflux for 3 h. The reaction mixture was neutralized with carbon dioxide, and extracted with 1,2-dichloroethane. A quantitative conversion of the acetophenone was obtained. ^{1}H NMR δ: 1.48 (d, 3H), 3.90 (d, 6H), 4.83 (q, 1H), 6.84 (q, 1H), 6.86 (q, 1H), 6.93 (d, 1H). MS *m*/*z* (%): 182 (M^+, 59), 167 (87), 153 (47), 139 (100), 124 (32), 108 (21), 93 (50), 77 (21), 65 (25), 51 (11), 43 (41).

1-(3,4-Dimethoxy-phenyl)-(1-^{2}H) ethanol (2)

1-(3,4-Dimethoxy-phenyl)-(1-^{2}H) ethanol was prepared similar to **1** using 1.5 equivalents of $NaBD_4$. ^{1}H NMR δ: 1.48 (d, 3H), 3.83 (d, 6H), 6.56 (q, 1H), 6.59 (q, 1H), 6.63 (d, 1H). MS *m*/*z* (%): 183 (M^+, 65), 168 (8), 167 (83), 151 (8), 139 (100), 124 (29), 108 (16), 95 (7), 79 (13), 77 (20), 43 (45).

4-(1-Methoxy)ethyl-1,2-dimethoxybenzene (3)

4-(1-Methoxy)ethyl-1,2-dimethoxybenzene (**3**) was quantitatively prepared by heating at reflux **1** in methanol with catalytic amounts of H_2SO_4 for 4 h. ^{1}H NMR: δ: 1.48 (d, 3H), 3.34 (s, 3H), 3.76 (s, 6H), 4.31 (s, 1H), 6.59 (d, 1H), 6.71 (d, 1H), 6.93 (m, 1H).

Reaction conditions

All reactions were run at 25 ± 1°C in a constant-temperature oil bath. The pH of the chlorine dioxide reactions was kept constant by using a pH-control feedback loop. Reactions were run in a 100-mL four-necked flask. An Omega™ pH controller (model PHCN-37) was connected to a Milton-Roy micro-chemical metering pump (model A771-155S). A sodium hydroxide solution (0.8 M) was delivered to the reaction vessel from a burette via Nalgene® PVC tubing. Volumetric addition of alkali did not exceed 1% of the total reaction volume. The reaction mixture was stirred with a Teflon-coated stir bar on a magnetic stir plate. Water and chlorine dioxide were pH adjusted using aqueous sodium

© 2002 NRC Canada

hydroxide (5 wt%) or sulfuric acid (5 wt%) to achieve a desired final pH and mixed for one minute prior to injection of an aqueous solution of the soluble model compound. Samples of the reaction were taken with a syringe through a rubber septum. In the kinetic experiments sampling was done every 15 s over the first few minutes, then at 2–5 min intervals over the next 30–60 min. The reaction was monitored until all of the model compound or chlorine dioxide was consumed.

Work-up procedures for the reaction mixtures

Organic compound concentrations were determined by gas chromatography. Samples (20 μL) of the reaction mixture were quenched either by adding ascorbic acid (0.5 mL, 0.4 M) or a saturated aqueous sodium thiosulfate solution (500 μL). The quenched samples were extracted with ethylacetate (0.5 mL) containing *p*-dibromobenzene or biphenyl (0.6 mg L^{-1}) as an internal standard. Thereafter, the samples were dried over anhydrous sodium sulfate and made up to 2 mL prior to GC analysis.

All compound analyses were carried out with a HP 5890 (splitless injection) instrument equipped with a flame ionization detector, using He as the carrier gas. Injector and detector temperatures were 240 and 280°C, respectively. Separations were achieved on a J&W DB-5 fused silica capillary column (30 m × 0.32 mm × 0.25 μm). Typical temperature programs were from 45 to 250°C at a rate of 10°C min^{-1} with an initial time delay of 1 min, and from 100 to 270°C at 10–20°C min^{-1}. In quantitative studies, *p*-dibromobenzene or biphenyl was used as an internal standard and the relative peak areas and corresponding response factors were used to calculate model-compound concentrations.

All GC–MS analyses were conducted as per GC analysis on a HP 5985B GC–MS, equipped with a DB-5 capillary column and using the same temperature program as per GC-analysis. In the EI mode, the electron energy used was 70 eV.

^{1}H NMR spectra were determined using a GE 300 MHz instrument. Samples were dissolved in $CDCl_3$. Chemical shifts are given in ppm downfield from TMS (tetramethylsilane).

Inorganic compound (chlorite, chlorate, and chloride) concentrations were measured using both a Waters Capillary Ion Analyzer (CIA) and iodometric titrations. A Waters AccuSep™ capillary (100 cm × 75 μm i.d.) and a chromate electrolyte were used for CIA analysis of anions. Chlorine dioxide concentrations were determined using a PerkinElmer UV/Vis spectrophotometer (model Lambda 3B) containing no organic compounds. The spectrometric wavelength was set at 380 nm (λ_{max} of ClO_2 = 357 nm) (17). In reactions containing organic compounds, chlorine dioxide was determined by iodometric titration.

The quantity of hypochlorous acid in a reaction medium was determined by trapping with aqueous solutions of dimethylsulfoxide (DMSO). Accordingly, samples (100 μL) of the reaction mixture were injected into cold aqueous solutions (0.5 mL) containing excess DMSO (0.25 M, pH adjusted to 8). Trapped samples were quenched after 15 s with a saturated sodium thiosulfate solution. The resulting dimethylsulfone content was determined by GC using cyclohexanol as an internal standard.

On the temperature dependence of the primary yield and the product $G\varepsilon_{max}$ of hydrated electrons in the low-LET radiolysis of liquid water

Jintana Meesungnoen, Jean-Paul Jay-Gerin, Abdelali Filali-Mouhim, and Samlee Mankhetkorn

Abstract: Monte-Carlo simulations are performed to calculate the temperature dependence of the primary hydrated electron yield ($G_{e^-_{aq}}$) for liquid water irradiated by low linear-energy-transfer radiation (LET ~ 0.3 keV μm^{-1}) in the range 25–325°C. Calculations are carried out by taking properly into account the effect of the time and temperature dependencies of the water dielectric constant on the electron–cation geminate recombination. Our computed $G_{e^-_{aq}}$ values slightly increase with increasing temperature, in good agreement with experiment. The product $G_{e^-_{aq}}\varepsilon_{max}(e^-_{aq})$, estimated by using existing experimental data of the maximum molar extinction coefficient $\varepsilon_{max}(e^-_{aq})$, remains nearly constant or slightly increases, depending on the temperature dependence chosen for ε_{max}. Our $G_{e^-_{aq}}\varepsilon_{max}(e^-_{aq})$ values compare generally well with most experimental data, as well as with the predictions of deterministic diffusion-kinetic model calculations. Moreover, our results indicate that the static dielectric constant of water (ε_s) does not play any significant role on the electron–cation recombination at early times. Such a finding is inconsistent with the interpretation, proposed by certain authors in the literature, that $G_{e^-_{aq}}$ should in fact decrease as temperature is increased because of an increased electron–cation geminate recombination due to a lowering of ε_s. Finally, the temperature dependence of the hydrated electron yields, calculated at various times between 10 ps and 1 μs, shows that at low LET, the time required to establish homogeneous chemistry in the bulk of the solution is ~10^{-6} s in the range ~25–100°C, and that this time diminishes to ~10^{-7} s at higher temperatures.

Key words: liquid water, radiolysis, temperature, hydrated electron (e^-_{aq}), radiolytic yields, electron–cation geminate recombination, dielectric constant, molar extinction coefficient of e^-_{aq}, homogenization time.

Résumé : À l'aide des méthodes de simulation Monte-Carlo, nous calculons la dépendance en température du rendement primaire en électrons hydratés ($G_{e^-_{aq}}$) produit lors de la radiolyse de l'eau liquide par un rayonnement de faible transfert d'énergie linéique (TEL ~ 0,3 keV μm^{-1}) dans la gamme 25–325°C. Les calculs sont effectués en prenant convenablement en compte l'effet des variations de la constante diélectrique de l'eau en fonction du temps et de la température sur la recombinaison géminée électron-cation. Les valeurs de $G_{e^-_{aq}}$ ainsi calculées augmentent légèrement avec la température, en bon accord avec l'expérience. Le produit $G_{e^-_{aq}}\varepsilon_{max}(e^-_{aq})$, estimé à partir de nos valeurs de $G_{e^-_{aq}}$ et des données expérimentales disponibles du coefficient d'extinction molaire maximal $\varepsilon_{max}(e^-_{aq})$, reste sensiblement constant ou augmente légèrement, dépendant du choix adopté pour la dépendance en température de ε_{max}. Nos valeurs de $G_{e^-_{aq}}\varepsilon_{max}(e^-_{aq})$ s'accordent bien en général avec la plupart des données expérimentales, ainsi qu'avec les prédictions de calculs modèles diffusionnels déterministes. De plus, nos calculs indiquent que la constante diélectrique statique (ε_s) de l'eau ne joue pas de rôle significatif sur la recombinaison électron-cation à temps court. Un tel résultat contredit l'interprétation, proposée par certains auteurs dans la littérature, que $G_{e^-_{aq}}$ devrait en fait décroître lorsque la température augmente à cause d'une recombinaison géminée électron-cation augmentée due à une diminution de ε_s. Enfin, la dépendance en température du rendement en électrons hydratés, calculée à différents temps entre 10 ps et 1 μs, suggère qu'à faible TEL, le temps au bout duquel le stade de chimie homogène s'établit au sein de la solution est de ~10^{-6} s dans la gamme ~25–100°C, et que ce temps diminue à ~10^{-7} s aux températures plus élevées.

Mots clés : eau liquide, radiolyse, température, électron hydraté (e^-_{aq}), rendements radiolytiques, recombinaison géminée électron-cation, constante diélectrique, coefficient d'extinction molaire de e^-_{aq}, durée de l'étape hétérogène.

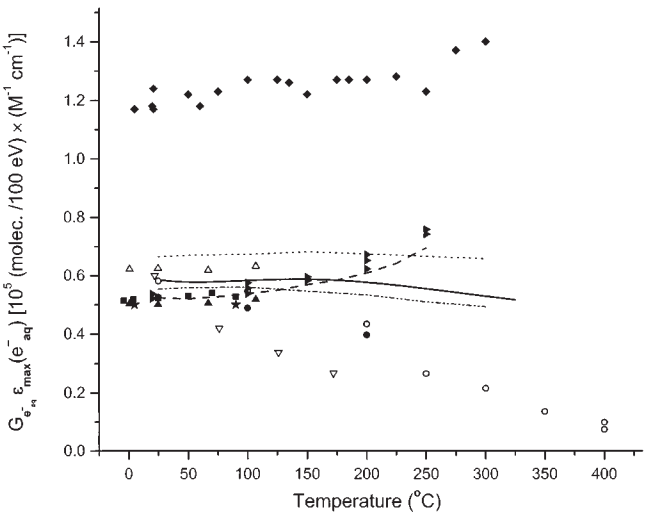
Introduction

Recently, Wu et al. (1) reported the temperature dependence of the product $G_{e^-_{aq}}\varepsilon_{max}(e^-_{aq})$, where $G_{e^-_{aq}}$ is the "primary" yield[2] and ε_{max} is the maximum molar extinction coefficient of the hydrated electron (e^-_{aq}), in light and heavy liquid water over the range 25–400°C, including the supercritical water regime. Using pulse-radiolysis experiments with 100-ns electron pulses, these authors observed that $G_{e^-_{aq}}\varepsilon_{max}(e^-_{aq})$ continuously decreases with increasing temperature above ~100°C, going from ~0.55×10^5 to ~0.1×10^5 (molec./100 eV) × (M^{-1} cm^{-1}) for D_2O between 100 and 400°C.[3] Wu et al. (1) argued that such a decrease of $G_{e^-_{aq}}\varepsilon_{max}(e^-_{aq})$ at high temperatures may result from an increased electron–cation geminate recombination due to the decrease of the static dielectric constant (ε_s) of water with increasing temperature (ε_s goes from ~79 at 25°C, density 1 g cm^{-3} to ~8 at 400°C, density 0.45 g cm^{-3}). These results are consistent with those measured by Dixon and Lopata (3), but in disagreement with most other experimental data (4–8), which show that $G_{e^-_{aq}}\varepsilon_{max}(e^-_{aq})$ is nearly constant or even slightly increases with increasing temperature (Fig. 1).

From their pulse-radiolysis experiments performed in alkaline solutions under hydrogen pressure, Christensen and Sehested (6) concluded that most of the increase of $G_{e^-_{aq}}\varepsilon_{max}(e^-_{aq})$ should be ascribed to an increase in ε_{max} rather than to an increase in $G_{e^-_{aq}}$. In contrast, Elliot et al. (9, 10) found for light and heavy liquid water that $\varepsilon_{max}(e^-_{aq})$ decreases linearly with increasing temperature up to 200°C, which is in agreement with the work of Shiraishi et al. (11), who estimated $\varepsilon_{max}(e^-_{aq})$ values for H_2O of 2.0×10^4 and 1.7×10^4 M^{-1} cm^{-1} at 25 and 200°C, respectively. In previous studies using γ-rays and dilute solutions of various scavengers, Burns and Marsh (12) found that $G_{e^-_{aq}}$ decreased from 2.7 molec./100 eV at ambient temperature to 0.4 ± 0.1 molec./100 eV at 400°C and density 0.45 g cm^{-3}. These authors argued that such a decrease of $G_{e^-_{aq}}$ with temperature was consistent with the low-static dielectric constant of water at high temperature, compared with its value at 25°C. This result, however, is markedly different from those of our previous Monte-Carlo simulations of water radiolysis (13) and also of the deterministic diffusion–kinetic model calculations of Swiatla-Wojcik and Buxton (14), which only show a slight increase of $G_{e^-_{aq}}$ with increasing temperature up to 300°C.

To gain further insights into the influence of temperature (in the range 25–325°C) on $G_{e^-_{aq}}$ and $G_{e^-_{aq}}\varepsilon_{max}(e^-_{aq})$, we extend in this work our previous Monte-Carlo calculations (13) of the temperature dependence of $G_{e^-_{aq}}$ to properly take into account the effect of the time and temperature dependencies of the water dielectric constant on the early time electron–cation recombination. Values of $G_{e^-_{aq}}\varepsilon_{max}(e^-_{aq})$ are calculated by using our computed $G_{e^-_{aq}}$ values and the temperature dependence of $\varepsilon_{max}(e^-_{aq})$ reported by Elliot et al. (9, 10) and that estimated from the data of Shiraishi et al. (7). Finally, we compare our values of $G_{e^-_{aq}}\varepsilon_{max}(e^-_{aq})$ with available experimental data, as well as with the predictions of previous deterministic diffusion–kinetic calculations.

Fig. 1. Effect of temperature on the product $G_{e^-_{aq}}\varepsilon_{max}$ [in (molec./100 eV) × (M^{-1} cm^{-1})] of hydrated electrons. The solid and dashed curves represent the values of $G_{e^-_{aq}}\varepsilon_{max}(e^-_{aq})$ obtained for light water, from our computed $G_{e^-_{aq}}$ values at 10^{-7} s, using the $\varepsilon_{max}(e^-_{aq})$ values of Elliot and Ouellette (eq. [I] of ref. 9, revised upward by 4.6% as described in ref. 10, and linearly extrapolated to 325°C) and those estimated from the data of Shiraishi et al. (7), respectively (see text). Experiments are from ref. 1: (●), H_2O and (○), D_2O; ref. 3: (▽), D_2O; ref. 4: (▲), H_2O and (△), D_2O; ref. 5: (■), H_2O; ref. 6: (◆), H_2O (alkaline solutions under hydrogen pressure); ref. 7: (▶), H_2O; ref. 8: (★), H_2O. For the sake of comparison, the products $G_{e^-_{aq}}\varepsilon_{max}(e^-_{aq})$ obtained from the deterministic diffusion-kinetic model calculations of $G_{e^-_{aq}}$ of Swiatla-Wojcik and Buxton for H_2O (– -- – -- –) (14) and D_2O (------) (45), using $\varepsilon_{max}(e^-_{aq})$ from Elliot and Ouellette (eq. [I] of ref. 9, revised as described in ref. 10, and linearly extrapolated to 300°C) and Elliot et al. (eq. [I] of ref. 10), respectively, are also included.



Monte-Carlo simulations

A detailed description of our Monte-Carlo modeling of the radiolysis of liquid water has been given previously (13, 15–18). In brief, the energy deposition by the incident radiation (high-energy protons) and by all the low-energy electrons (collectively named "secondary electrons") that it has generated occurs through the slowing down of those particles via various inelastic scattering processes, such as ionization, electronic and (or) vibrational excitation of single water molecules, and excitation of plasmon-type collective modes ("physical stage"). The species created during this stage rapidly reorganize and produce the "initial" radical (e^-_{aq}, $H^•$, $^•OH$, $HO^•_2/O^{•-}_2$) and molecular (H_2, H_2O_2) products of the radiolysis, distributed in a highly non-homogeneous

[2] The so-called "primary" (or "escaped") e^-_{aq} yield, denoted here $G_{e^-_{aq}}$, represents the number of hydrated electrons formed per 100 eV of absorbed energy that remain after spur expansion is complete. See, for example, ref. 2.

[3] The units for the radiation chemical yields used throughout in this paper are molecules per 100 eV (molec./100 eV). For conversion into SI units: 1 molec./100 eV ≈ 1.0364×10^{-7} mol J^{-1}. As for the maximum molar extinction coefficient $\varepsilon_{max}(e^-_{aq})$, the units used here are M^{-1} cm^{-1}.

track structure composed of small, spatially isolated regions of high ionization and excitation densities, commonly referred to as "spurs" ("physicochemical stage"). These two stages are handled by our simulation codes TRACPRO and TRACELE (16). The complex spatial distribution of reactants at ~10^{-13} s, which is provided as an output of the program TRACELE, is then used directly as the starting point for the so-called "stage of non-homogeneous chemistry." This third and final stage, during which the various species diffuse and react with one another until all spur reactions are complete, is covered by our TRACIRT simulation code (13, 15, 17, 18), using the "independent reaction times" (IRT) method (19) to model the non-homogeneous reaction kinetics.[4]

To reproduce the effects of ^{60}Co γ-rays or fast electrons, we use short (100-μm) segments of one hundred fifty 300-MeV proton tracks, over which the average linear-energy-transfer (LET) value obtained in the simulations is ~0.3 keV μm^{-1} at 25°C.[5] As for the calculation of $G_{e^-_{aq}}$ as a function of temperature, we use here an extended version of our computer code, which has recently been developed to include the effects of high temperature on water radiolysis (13). In this version, the thermalization distances (r_{th}) of subexcitation electrons[6] are assumed to decrease linearly with increasing temperature by a factor of 2 between 25 and 300°C (13). This choice was shown to offer the best agreement of $G_{e^-_{aq}}$ and G_{H_2} with experimental data at elevated temperatures in the case of low-LET radiation (13). Physically, such a decrease in r_{th} as the temperature increases[7] could be linked to an increase in the low-energy electron-scattering cross sections, which arise from the corresponding loss of structural order in liquid water owing to the increase in breaking of hydrogen bonds with temperature.

In the course of its thermalization, a subexcitation electron can encounter its geminate H_2O^+ partner and recombine to form H_2O^* (16).[8] To account for the effect of the Coulomb field of the geminate positive charge on the early time electron–cation recombination (22), we use in our simulations the following form for the time-dependent water dielectric constant ε(t) (23)

$$[1] \qquad \frac{1}{\varepsilon} = \frac{1}{\varepsilon_s} + \left(\frac{1}{\varepsilon_\infty} - \frac{1}{\varepsilon_s}\right) \exp\left(\frac{-t}{\tau_L}\right)$$

where ε_s and ε_∞ are the static (long-time) and high-frequency (short-time) dielectric constants, respectively, $\tau_L = (\varepsilon_\infty/\varepsilon_s)\tau_D$ is the longitudinal dielectric relaxation time, and τ_D is the Debye relaxation time. The temperature dependencies for ε_s and τ_D up to 325°C are described by polynomial and exponential fits to available experimental data (24–33), as shown in Figs. 2*a* and 2*c*, respectively. For ε_∞, whose data are rather scattered below 50°C and scarce at higher temperatures (24, 32), we assume the linear temperature dependence empirically described by Kaatze (24) between – 4.1 and 60°C, namely,

$$[2] \qquad \varepsilon_\infty = 5.77 - 2.74 \times 10^{-2}(T - 273.15)$$

where T is the absolute temperature in degrees Kelvin. In the model adopted here (34), this line (eq. [2]) is extrapolated to higher temperatures until it connects to $\varepsilon_\infty = 1$, and afterwards ε_∞ is assumed to remain constant at 1 up to 325°C (Fig. 2*b*).

Results and discussion

The results of the temperature dependence of our $G_{e^-_{aq}}$ values, computed at 10^{-7} s after the ionizing event,[9] are shown in Fig. 3. As can be seen, $G_{e^-_{aq}}$ increases with increasing temperature, going from ~2.8 molec./100 eV at 25°C to ~3.7 molec./100 eV at 325°C. Good overall agreement is observed with most available experimental data (7, 11, 35, 37–43), as well as with the predictions of the deterministic-spur diffusion-model calculations of Swiatla-Wojcik and Buxton (14). In fact, such an increase of $G_{e^-_{aq}}$ with temperature can readily be explained from the fact that many important spur reactions are not diffusion controlled and therefore have rate constants that increase less steeply with temperature than do the diffusion coefficients of the individual species; under those conditions, these reactions occur less as the temperature increases, which leads to more hydrated electrons being available to escape the spurs (13, 44). Our computed yields, however, are markedly different from the data of Burns and Marsh (12), who, as mentioned above, reported a dramatic decrease of $G_{e^-_{aq}}$ at 400°C.

The effect of temperature on the product $G_{e^-_{aq}}\varepsilon_{max}(e^-_{aq})$ can readily be obtained from our $G_{e^-_{aq}}$ values at 10^{-7} s and by using the values of $\varepsilon_{max}(e^-_{aq})$ reported by Elliot et al. (9, 10) and those estimated from the data of Shiraishi et al. (7). As far as the latter authors are concerned, they in fact measured

[4] The IRT simulation methodology has the advantage over deterministic-modeling calculations in that, instead of using the "typical, average spur" concept, it correctly incorporates reactants from the same ionization or excitation in their actual non-homogeneous spatial distribution. See, for example, refs. 14 and 20.

[5] Typically, about 5000 species are produced in those simulated track segments, thus ensuring only small statistical fluctuations in the determination of average yields.

[6] Subexcitation electrons are those that have kinetic energies lower than the first-electronic excitation threshold of the medium (~7.3 eV in liquid water) (21). They lose energy relatively slowly, the dominant mode of energy loss being the excitation of molecular vibrations.

[7] At 25°C, our calculated mean electron thermalization distance, averaged over the energy spectrum of the subexcitation electrons ("entry spectrum") (22), is ~88 Å, whereas at 325°C it is taken to be ~40 Å.

[8] Our simulations show that only electrons whose energy is below the subexcitation energy limit have an appreciable probability to recombine with their parent water cation prior to thermalization (22). In fact, the electrons that recombine tend to be the ones that, in the absence of cation, would thermalize relatively close to their starting position.

[9] Consistently with our previous Monte-Carlo simulations of the radiolysis of liquid water at elevated temperatures (13), the time scale of 10^{-7} s is chosen in accordance with the scavenging powers of solutes used by Elliot et al. (35) to measure their yields. Recall that the "scavenging power" is defined as the product of a solute (or scavenger) concentration and its rate constant for the scavenging reaction (k[S]), with units of s^{-1}. The reciprocal of the scavenging power gives a measure of the time scale over which the scavenging is occurring. See, for example, ref. 36.

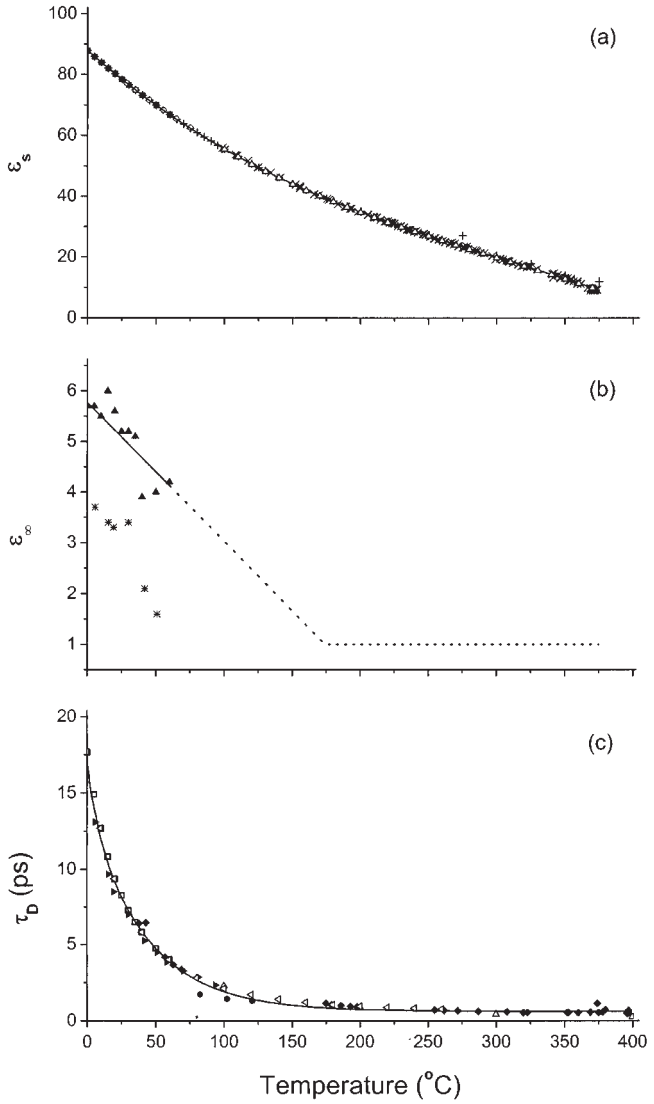
Fig. 2. Temperature dependencies of the static (ε_s) and high-frequency (ε_∞) dielectric constants, and the Debye relaxation time (τ_D) of liquid water. (*a*) The solid line is a polynomial fit to the available experimental data of ε_s. Experiments for ε_s are from ref. 24: (■); ref. 25: (+); ref. 26: (○); ref. 27: (×); ref. 28: (△). (*b*) The solid line represents ε_∞ from eq. [2] up to 60°C, as described by Kaatze (24). The dotted line denotes the curve extrapolated so that it connects to $\varepsilon_\infty = 1$ and remains constant at this value at higher temperatures (34). Experiments for ε_∞ are from ref. 24: (▲); ref. 32: (*). (*c*) The solid line is a third-order exponential decay fit to the available experimental data of τ_D. Experiments for τ_D are from ref. 24: (□); ref. 29: (●); ref. 30: (△); ref. 31: (◆); ref. 32: (▶); ref. 33: (◁).



$G(e^-_{aq})\,\varepsilon_{max}(e^-_{aq})$ at 5 ns as a function of temperature between 20 and 250°C (7).[10] Here, $\varepsilon_{max}(e^-_{aq})$ is estimated from these $G(e^-_{aq})\,\varepsilon_{max}(e^-_{aq})$ values by using our values of $G(e^-_{aq})$ computed at 5 ns and by assuming that $\varepsilon_{max}(e^-_{aq})$ does not change as a function of time. The corresponding plots of $\varepsilon_{max}(e^-_{aq})$ against temperature obtained from the data of these two groups are shown in Fig. 4. Using the $\varepsilon_{max}(e^-_{aq})$ values of

Fig. 3. Temperature dependence of the primary hydrated-electron yield ($G_{e^-_{aq}}$, in molec./100 eV) of the radiolysis of liquid water, over the range 25–325°C. The solid curve represents our Monte-Carlo calculations at 10^{-7} s (see text). Experiments are from ref. 7: (★); ref. 11: (■); ref. 12: (◇); ref. 35: (▽); ref. 37: (×); ref. 38: (*); ref. 39: (◀); ref. 40: (▲); ref. 41: (◁); ref. 42: (○); ref. 43: (●). For the sake of comparison, the deterministic spur diffusion model calculations of $G_{e^-_{aq}}$ (– – – -) from ref. 14 are also included.

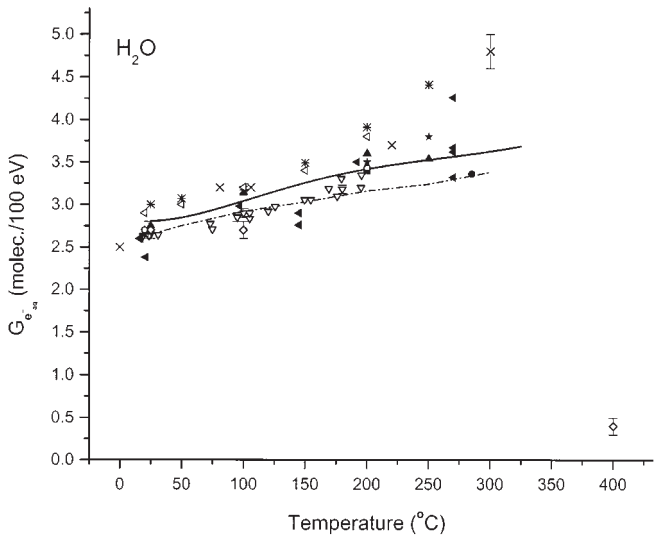


Fig. 4. Plots of the maximum molar extinction coefficient of the hydrated electron $\varepsilon_{max}(e^-_{aq})$ vs. temperature. The solid line represents $\varepsilon_{max}(e^-_{aq})$ obtained by Elliot and Ouellette (eq. [I] of ref. 9, revised upward by 4.6% as described in ref. 10, and linearly extrapolated to 325°C). The dashed line represents a polynomial fit to the data of $\varepsilon_{max}(e^-_{aq})$ (■) obtained by using the measured values of the product $G(e^-_{aq})\,\varepsilon_{max}(e^-_{aq})$ at 5 ns of Shiraishi et al. (7) and our computed values of $G(e^-_{aq})$ at 5 ns (see text).

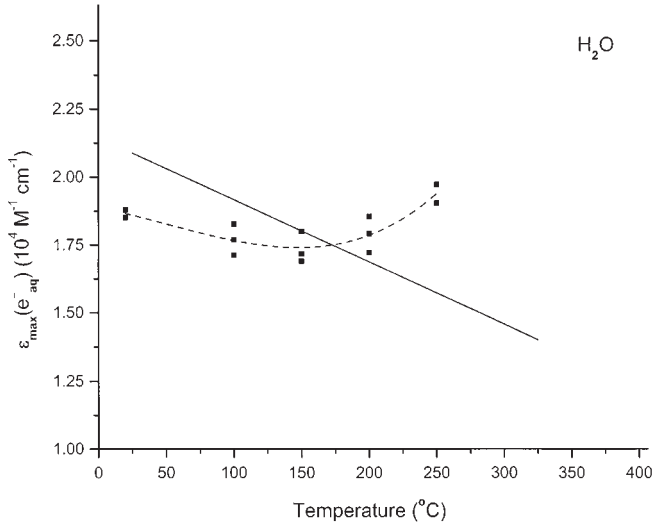

Elliot et al. (9, 10), which decrease linearly with increasing temperature, $G_{e^-_{aq}}\,\varepsilon_{max}(e^-_{aq})$ is found to be nearly constant below ~150°C and to slightly decrease at higher temperatures

[10]The symbol $G(e^-_{aq})$ is used in this paper for the yield of hydrated electrons measured or calculated at any specific time.

Fig. 5. Time dependence of the water dielectric constant $\varepsilon(t)$ computed from eq. [1] (23) using ε_s, ε_∞, and τ_D as described in Fig. 2, at 25, 100, and 300°C. At 25°C, for the sake of comparison of the various time scales involved, the electron thermalization time (obtained from our calculations), as well as the corresponding electron "trapping" and "hydration" times (46), are also indicated on the figure by arrows labelled e^-_{th} (thermalized electron), e^-_{tr} (trapped electron), and e^-_{aq} (hydrated electron), respectively. Note that geminate electron–cation recombination occurs before thermalization is complete (see ref. 22).

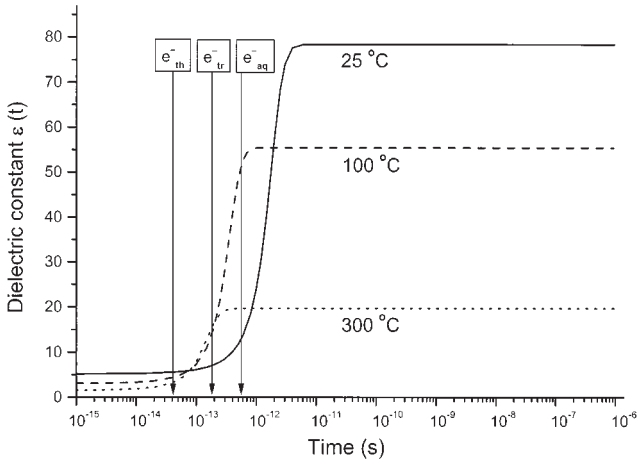

Fig. 6. Temperature dependencies of the hydrated electron yields $G(e^-_{aq})$ (in molec./100 eV) calculated from our Monte-Carlo simulations of the radiolysis of liquid water for various times from 10 ps to 1 μs, in the range 25–325°C.

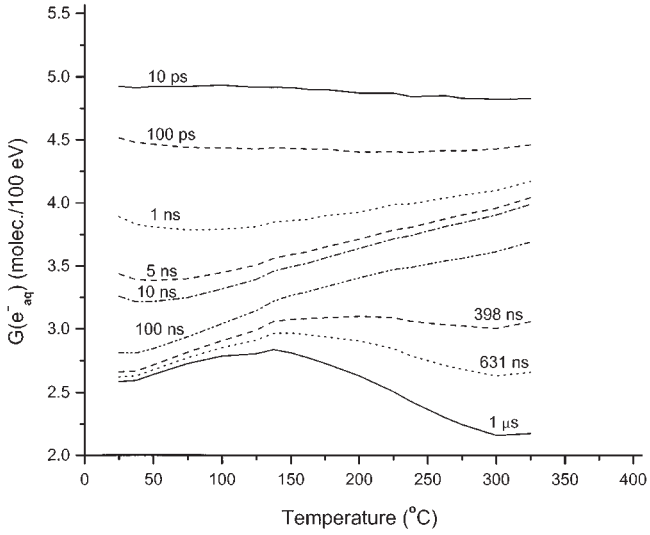

(see Fig. 1). In contrast, with the values of $\varepsilon_{max}(e^-_{aq})$ estimated from the data of Shiraishi et al. (7), there is an overall increase of $G_{e^-_{aq}}\varepsilon_{max}(e^-_{aq})$ with temperature over the whole range of temperatures considered. As can be seen from Fig. 1, our calculated temperature dependencies of $G_{e^-_{aq}}\varepsilon_{max}(e^-_{aq})$ are in good agreement with most available experimental data (4, 5, 7, 8). Moreover, our $G_{e^-_{aq}}\varepsilon_{max}(e^-_{aq})$ values agree well with those obtained from the deterministic diffusion-kinetic calculations of $G_{e^-_{aq}}$ of Swiatla-Wojcik and Buxton for H_2O (14) and D_2O (45), using the $\varepsilon_{max}(e^-_{aq})$ values in light and heavy liquid water reported by Elliot et al. (refs. 9 and 10 and ref. 10, respectively). Our results, however, notably differ from the experimental data of Wu et al. (1) and Dixon and Lopata (3), as well as from those of Christensen and Sehested (6) (see Fig. 1).

To better understand the influence of the water dielectric constant on the early time electron–cation recombination, and hence on $G_{e^-_{aq}}$, as a function of temperature, it is of interest to see the time dependence of ε at different temperatures. This is shown in Fig. 5, where ε, calculated from eq. [1] using ε_s, ε_∞, and τ_D as described above (Fig. 2), is plotted against time at 25, 100, and 300°C. As can be seen at 25°C, ε essentially reduces to ε_∞ at times lower than the longitudinal dielectric relaxation time of water ($\tau_L \approx 540$ fs). Since, at that temperature, the average electron thermalization time (22) is equal to ~41 fs (calculated from our simulations),[11] it follows that ε_s does not practically affect the recombination probability of an electron–cation pair.[12] The same conclusion should likely also apply at 100 and 300°C (where $\tau_L \approx$ 103 and 31.5 fs, respectively), even if the electron thermalization time is not well known at elevated temperatures.[13] These results show that the previous conclusion invoked by some authors (1, 12) that a decrease in $G_{e^-_{aq}}$ or $G_{e^-_{aq}}\varepsilon_{max}(e^-_{aq})$ at high temperatures would result from an increased electron–cation recombination due to the decrease of ε_s with increasing temperature, can hardly be justified. In parallel to these calculations, we have also computed $G_{e^-_{aq}}$ by using the square of the refractive index of liquid water for ε_∞, which is a smooth, slowly varying function of temperature, going from 1.77 at 25°C to 1.47 at 325°C (47). The values of $G_{e^-_{aq}}$ obtained (data not shown here) are similar to those calculated above by using the temperature dependence of ε_∞ given in Fig. 2*b*. As a result, the early time electron–cation recombination remains practically unaffected by the Coulombic attraction of the positive H_2O^+ ion. Similar conclusions were also obtained in our previous calculations of the thermalization distances and times of subexcitation electrons in solid water (22).

Figure 6 shows the temperature dependence of our $G(e^-_{aq})$ values over the range 25–325°C, calculated at different times from 10 ps to 1 μs. As can be seen in the time scale 10–100 ps, the yield of hydrated electrons remains nearly constant with temperature. In the range 1–10 ns, $G(e^-_{aq})$ initially decreases with increasing temperature, reaches a minimum around 40–100°C, and then increases at higher temperatures. Noteworthily, the temperature dependence of our computed $G(e^-_{aq})$ values at 5 ns agrees well with that of the product

[11]For the sake of comparison, it is interesting to recall here that, in liquid water at 25°C, the time scale for electron "trapping" is ~110–300 fs, while the electron "hydration" time is ~240–620 fs (46).
[12]Based on the fact that the recombination process of a subexcitation electron with its parent cation occurs before thermalization is complete (22).
[13]In fact, as we have mentioned above, the electron thermalization distance at 300°C is decreased by a factor of ~2 with respect to its value at 25°C. We can thus expect that the corresponding electron thermalization time, equal to ~41 fs at 25°C, will also be decreased by a similar amount.

$G(e^-_{aq})$ $\varepsilon_{max}(e^-_{aq})$ at 5 ns measured by Shiraishi et al. (7), which exhibits a minimum around 100°C. At 100 ns, $G(e^-_{aq})$ increases monotonically with temperature over all the temperature range considered (see also Fig. 3). At longer times, $G(e^-_{aq})$ first increases with temperature over the range ~25–140°C and then decreases at higher temperatures in the order 398 ns < 631 ns < 1 μs. At these latter times, the observed decrease in $G(e^-_{aq})$ above ~140°C is due to the reactions of e^-_{aq} with H_2O and with H^+ ions distributed homogeneously in the solution (13, 48, 49). At 1 μs, the influence of those two reactions already shows itself from ~100°C by a marked weakening in the slope of the curve of $G(e^-_{aq})$ vs. temperature. Consequently, for temperatures below ~100°C, we can consider that homogeneous chemistry takes over in the bulk of the solution at ~1 μs,[14] whereas at higher temperatures, this time diminishes to ~100 ns. This result agrees well with our previous Monte-Carlo simulation studies of water radiolysis at elevated temperatures (13, 48, 49).

Conclusions

In this paper, Monte-Carlo simulations of the low-LET radiolysis of liquid water are carried out to calculate the primary hydrated electron yields as a function of temperature, in the range 25–325°C. In the calculations, the effect of the time and temperature dependencies of the water dielectric constant on the electron–cation geminate recombination is properly taken into account. The product $G_{e^-_{aq}}\varepsilon_{max}(e^-_{aq})$ is estimated by using our computed $G_{e^-_{aq}}$ values with the maximum molar extinction coefficient $\varepsilon_{max}(e^-_{aq})$ obtained from existing experimental data. The results show that our values of $G_{e^-_{aq}}\varepsilon_{max}(e^-_{aq})$ are in good agreement with most experimental data, as well as with the predictions of deterministic diffusion-kinetic model calculations. Moreover, contrary to the interpretation proposed by certain authors in the literature, the static dielectric constant of water is found not to play any significant role on the electron–cation recombination at early times. However, more experimental work is required to better specify the temperature dependence of $G_{e^-_{aq}}$, especially above 300°C and in the supercritical regime of water (> 374°C, > 22.1 MPa or 218 atm) (1, 50). Finally, the temperature dependence of our $G(e^-_{aq})$ values, calculated at various times between 10 ps and 1 μs, shows that at low LET, the time required to establish homogeneous chemistry in the bulk of the solution is ~10^{-6} s in the range ~25–100°C, whereas this time diminishes to ~10^{-7} s at higher temperatures.

The determination of the stereochemistry of epoxides located at the 5,6-positions of decalinic systems: An empirical method based on ^{13}C NMR chemical shifts

Raquel M. Cravero, Guillermo R. Labadie, and Manuel González Sierra

Abstract: The ^{13}C NMR spectra of a series of 5,6-epoxides in decalinic systems were studied. The interpretation of the chemical shifts allowed us to formulate an empirical rule to predict the epoxide stereochemistry. A discussion of the scope and limitations of this method and its extension to larger carbon skeletons is also presented.

Key words: epoxide stereochemistry, ^{13}C NMR, NMR, decalinic systems, oxiranes.

Résumé : On a étudié les spectres RMN du ^{13}C d'une série de systèmes décaliniques portant un époxyde en 5,6. L'interprétation des déplacements chimique a permis de formuler une règle empirique permettant de prédire la stéréochimie de l'époxyde. On présente aussi une discussion relative à la portée et aux limitations de cette méthode et de son extension aux squelettes carbonés plus importants.

Mots clés : stéréochimie des époxydes, RMN du ^{13}C, RMN, systèmes décaliniques, oxiranes.

[Traduit par la Rédaction]

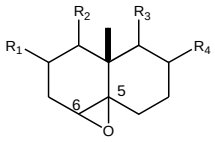
Introduction

^{1}H and ^{13}C NMR techniques are the most convenient methods for the elucidation of the oxiranic-ring stereochemistry in condensed polycyclic systems, and have been widely used in the structural analyses of epoxides isolated from natural sources (1–4).

Generally, the stereochemical assignment of the epoxides is achieved by observing the change in the chemical shift of the γ-carbons upon introduction of the oxiranic ring. Although several explanations regarding the mechanism of the γ-effects have been offered, no general agreement has been reached thus far about the factors that contribute to this effect. Nevertheless, semi-empirical rules have been developed to estimate the changes in the ^{13}C NMR chemical shifts, and they have been used successfully to predict the configuration of the epoxides within rigid-ring systems (5–8).

Recently, we have been investigating the epoxidation of highly substituted decalinic systems, and we wanted to examine further the stereochemical outcome of the process. Specifically, we were introducing an oxirane ring at the 5,6-position of the decalin, with one of the carbons of the oxirane being incorporated into the ring juncture (Fig. 1). A preliminary communication on this subject has been previously reported (9).

Fig. 1. General structure of the studied epoxides.



Experimental

The epoxides were prepared through a sequence involving a Birch-reductive alkylation with or without carbonyl-group reduction followed by treatment with *m*-CPBA in a heterogeneous phase as reported in the literature (10).

^{13}C NMR (50.3 MHz) spectra were recorded on a Bruker AC-200 E spectrometer in $CDCl_3$ solutions using standard conditions in 5-mm probe tubes at room temperature. The chemical shifts were recorded in δ (ppm). A complete report of the ^{1}H and ^{13}C NMR chemical shifts for the decalinic systems used in the present analysis were previously published (10, 11).

Results and discussion

In studies examining the synthetic preparation of Saudin, a series of angularly substituted synthetic decalins containing an oxirane moiety in the C_5–C_6 position were prepared (Scheme 1). It was deemed necessary to establish the stereochemistry of the epoxide in a straightforward and simple manner.

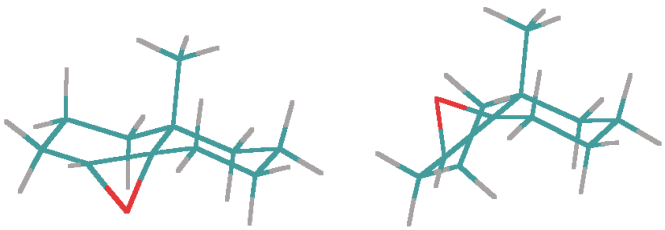
Fig. 2. Optimized computer generated structures of the α- and β-epoxides of the simpler decalinic model.



This problem resembled the one encountered by Carda et al. (1), who were dealing with a series of natural and synthetic epoxides of eudesmanolides, and we anticipated the same difficulties. It was therefore not unexpected to find that, regardless of the stereochemistry of the epoxides, the γ-effects on carbons C_8 and C_3 were mostly shielding effects, and were of no use as markers for the stereochemical assignment (Table 1).

We attribute these results mainly to the fact that, in this particular position, the α or β stereochemistry of the epoxides also determines the change in the *cis*/*trans*-ring fusion of the decalinic rings.

Optimized computer-generated structures[2] of the α- and β-epoxides of simpler decalinic models are shown in Fig. 2. It can be seen that the change in the stereochemistry of the ring junction induces changes in the conformation of the A ring in both series, and that such changes could explain the abnormal responses found for the chemical shifts of the γ-carbons.

Thus, taking in consideration the computed α- and β-epoxide structures and those of the parent olefins, we estimated the expected chemical shifts of the γ-carbons (C_8) for the epoxides using the parameters described in refs. 6 and 7 (Scheme 2). To calculate this, the following formulas were used: for the α-epoxides: $\delta_{C\text{-}8} = \delta_{C\text{-}8}$, olefin – (HC) + $(HC)_e$ + γ(OH); for the β-epoxides: $\delta_{C\text{-}8} = \delta_{C\text{-}8}$ olefin – (HC) + $(HC)_e$ + γ(OH).

A similarity is noticeable in the calculated increments for both series [$\delta_{C\text{-}8}$, olefin – (HC) + $(HC)_e$ + γ(OH)], giving an estimated shielding value of –3.83 ppm. The average experimental-shielding value found was –3.83 ppm for the α series and –3.34 ppm for the β series (Table 1).

In view of the impossibility of extracting any valuable information from the γ-effects, we focused on the observation of the behavior of the ^{13}C NMR chemical shifts of the oxirane carbons. Our attempts to relate the stereochemistry of oxiranes to the C_5 or C_6 chemical shifts in each series, through the use of the semi-empirical calculation rules available (6, 7), as well as the introduction of additional parameters into the semi-empirical calculation formula, also failed. We believed this failure could be attributed to the conformational changes produced by remote substituents on a rather flexible decalinic system, since such structural

[2] All the lowest energy conformations were found using the conformational search procedure with the MM+ molecular mechanics force field, as implemented in Hyperchem Pro 6.0. Each structure was then re-minimized with the AM1 semi-empirical method.

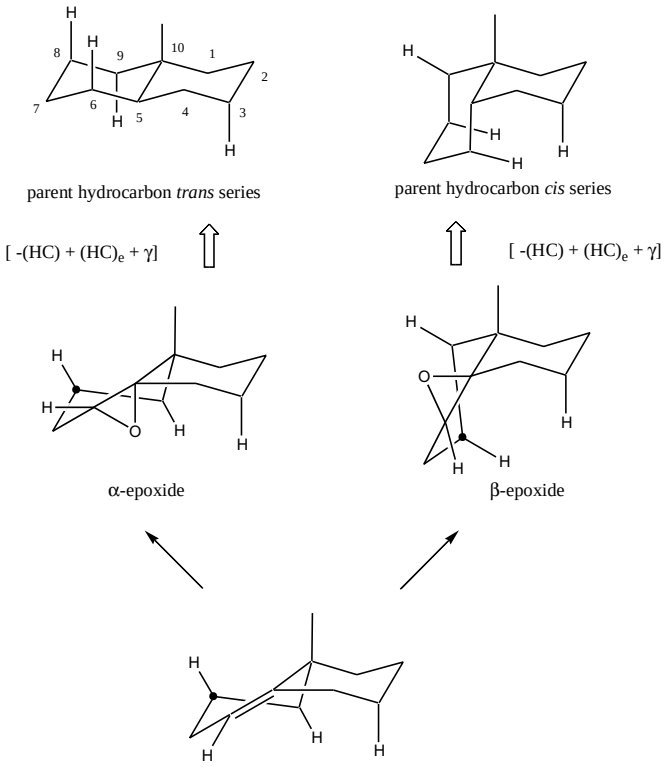
Scheme 2.



variations can be neither predicted nor adequately quantified. They might affect the validity of the semi-empirical parameters.

Because there is a great deal of overlap among the hydrogen signals, a conclusion about the shape of the rings in the various compounds could not be obtained from the spectral data. We therefore resorted to a computer-assisted conformational analysis to predict the conformational preferences of the ring system. This analysis showed different degrees of distortion in the dihedral angles and significant variations in the interatomic distances for the different substitution patterns of some decalinic derivatives.[3]

Table 2 shows the results of the dihedral-angle calculations for the A ring of some representative molecules, including the model α- and β-epoxides.

As expected, the C_7-C_6-C_5-C_{10} fragment shows an almost eclipsed relationship (dihedral angle of the α series: +2.53 ± 1.56°, and β series: –0.75 ± 1.48°) within a narrow degree of tolerance for both series. Fragments C_8-C_7-C_6-C_5 (dihedral angle of the α series: +11.48 ± 17.14°, and β series: +10.26 ± 10.15°) and C_6-C_5-C_{10}-C_9 C_5 (dihedral angle of the α series: –21.20 ± 7.92°, and β series: –0.44 ± 16.09°) show slightly larger dihedral angles, indicating that ring A resembles the half chair of cyclohexene, with the C_8 and C_9 carbons flipping above or below the equatorial plane of the cyclohexene ring according to the substitution pattern. Overall, there is no significant difference in the conformational behavior for both series.

We also considered using the ^{1}H NMR chemical shifts of some distinctive protons such as the oxirane -CH-O- and the angular C_{10}-methyl, but again, the observed values were not useful as stereochemical markers (2).

Comparing ^{13}C NMR chemical-shift differences between C_5 and C_6 in the *trans*- and *cis*-10-methyl decalins, however, showed a $[\Delta\delta_{5,6}]_{trans}$ = 16.80 for the *trans*-fused decalin and a $[\Delta\delta_{5,6}]_{cis}$ = 12.1 for the *cis*-fused decalin, rendering a relative $\Delta_{(trans\text{-}cis)}$ value of 4.7 ppm. Similar analyses of the ^{13}C NMR data for the synthetic epoxides (Table 3), showed that $[\Delta\delta_{5,6}]_{trans}$ = 6.71 ± 0.64 for the *trans* series and $[\Delta\delta_{5,6}]_{cis}$ = 1.96 ± 1.16 for the *cis* series, which produces a relative $\Delta_{(trans\text{-}cis)}$ value of 4.8 ppm.

It therefore seemed possible to predict the *trans* or *cis* stereochemistry of the ring fusion and, consequently, the α or β orientation relative to the C_{10}-substituent by using the ^{13}C NMR chemical-shift differences between the oxirane carbons.

By computing for each epoxide, the following rule was formulated:

$$\Delta\delta = \delta_{(\text{quaternary carbon})} - \delta_{(\text{tertiary carbon})}$$

The difference between the ^{13}C NMR chemical shifts of both oxirane carbon signals predicts that:

$$\Delta\delta_{\alpha\text{-epoxide}} > 5 \text{ ppm and } \Delta\delta_{\beta\text{-epoxide}} < 3.8 \text{ ppm}$$

Finally, to test the scope and reliability of this observation, this calculation was performed on some representative examples from the literature (12–14) (Scheme 3, Table 4). It was found that this empirical rule may be used with confidence within the limits stated above. Notably, there is a larger Δδ for most of the examples chosen from the literature, which is clearly related to the rigidity of the steroidal skeletons.

Conclusions

In this study, we looked for a marker that could be used to correlate the ^{13}C NMR chemical shift of various epoxides, located at the C_5-C_6 position of decalins with their stereochemistry. We found that the effect of the oxiranic ring on the γ carbons described previously in the literature does not apply, and attempted to rationalize the abnormal

© 2002 NRC Canada

behavior of the γ-carbons chemical shifts for the α and β series. We also discovered that the set of parameters used by semi-empirical methods known in the literature to predict chemical shifts cannot be used with confidence in this situation for such flexible systems. Finally, we found a correlation involving the chemical-shift difference between both α carbons of the oxirane that, within reasonable limits, can be used for the prediction of the stereochemistry of epoxides.

Sodium borohydride: A versatile reagent in the reductive *N*-monoalkylation of α-amino acids and α-amino methyl esters

Giancarlo Verardo, Paola Geatti, Elena Pol, and Angelo G. Giumanini

Abstract: α-Amino acids and α-amino methyl esters are easily converted to their *N*-monoalkyl derivatives by a reductive condensation reaction using several carbonyl compounds in the presence of sodium borohydride. This reducing agent has shown a wide versatility with minor but essential procedural variations. The reaction allows the α-monodeuterium labeling of the new *N*-substituent by use of sodium borodeuteride.

Key words: α-amino acid, α-amino methyl esters, sodium borohydride, reductive *N*-monoalkylation, carbonyl compounds.

Résumé : Les acides α-aminés et leurs esters peuvent facilement être transformés en leurs dérivés *N*-monoalkylés par le biais d'une réaction de condensation réductrice faisant appel à divers composés carbonylés, en présence de borohydrure de sodium. Il a été démontré que ce réactif présente une grande versatilité par rapport aux variations mineures, mais essentielles, dans les procédures. L'utilisation de borodeutérure de sodium permet d'obtenir les dérivés portant un atome de deutérium en position α de l'azote portant le nouveau substituant.

Mots clés : acide α-aminé, esters méthyliques d'acide α-aminé, borohydrure de sodium, *N*-monoalkylation réductrice, composés carbonylés.

Introduction

The use of peptides as drugs is often hampered by their poor bioavailability because of their enzymatic degradation by proteases (1), poor adsorption after oral ingestion, and rapid excretion through liver and kidneys. The introduction of modified amino acids or the use of peptidomimetics (2) can be a solution for these drawbacks. Amino acids may be modified by *N*-alkylation: peptoids (3), an important class of peptidomimetics, express *N*-alkylated glycine residues.

The synthesis of *N*-alkylated amino acids and amino esters has been extensively studied and a number of procedures are available. One interesting approach is the alkylation of sulfonamides (Mitsunobu reaction) both in solution using, e.g., 2,4-dinitrobenzenesulfonyl (4) or 2,2,5,7,8-pentamethylchroman-6-sulfonyl (5) as protecting groups, and in the solid phase with 2-nitrobenzenesulfonyl (6) as the protecting group. These methods require long reaction times, three or more reaction steps, and occasional racemization is observed. The alkylation of *N*-unprotected amino acids and esters was also reported (7), but is limited to *N*-benzylation. Alternatively, the desired amino function can be directly introduced by a S_N2 reaction with appropriate α-substituted carboxylic acid derivatives e.g., α-trifluoromethanesulfonyloxy carboxylate (8) or α-halo acids (9). The problems with these reactions are the availability of the suitable starting materials and, in the case of the α-halo acids, the fact that racemization and elimination are prominent side reactions. *N*-Alkylated amino acids were also prepared by acid hydrolysis of 2-amino nitriles, according to the Strecker synthesis using primary amines (10) or by the oxidation of allylamines obtained from the enantioselective reaction of an allylic substrate with benzylamine in the presence of a palladium catalyst bearing chiral ferrocenylphosphine ligands (11). Examples of catalytic hydrogenation of preformed imines obtained from the condensation reaction of amino acids and carbonyl compounds (9, 12) or benzylamine and α-keto acids (13) were also reported.

Reductive *N*-alkylation of amino acids and amino esters is a method widely used to synthesize the corresponding *N*-benzyl derivatives: $NaBH(OAc)_3$ (14), NaHTe (15), $NaBH_3CN$ (16), and $NaBH_4$ (12*c*, 17) were the reducing agents employed. Sodium triacetoxyborohydride has also been used to reduce imines derived from the reaction between α-keto esters and benzylamine (18). The last two reactants showed a larger range of applicability: in fact, they were used with carbonyl compounds (other than benzaldehyde), but sodium cyanoborohydride had to be used under inert atmosphere. Moreover, long reaction times (16–20 h) with amino acids (19) and large excess of the carbonyl compounds and the reducing agent with amides of amino acids (20) were needed. Sodium borohydride, on the other hand, has been used in water only on amino acids (12*e*) but, even when the reaction was carried out in the presence of large excess of reactants, yields were not satisfactory.

Results and discussion

On the basis of the knowledge we have acquired on the applications of sodium borohydride as reducing agent in the reductive *N*-alkylation of amines (21), we have now extended its use to α-amino acids (**1**) and α-amino methyl esters (**2**) in combination with several carbonyl compounds (**3**) (Scheme 1).

The carbonyl compound (**3**) was added at room temperature to a methanolic solution of **1** or a hydrochloride of **2** after its neutralization in situ with a slight excess of finely powdered NaOH. After 10 min, a time sufficient to form imine **4** or **5**, the reaction mixture was cooled to 0°C and solid $NaBH_4$ was added. GC–MS analysis of the reaction mixture before the addition of $NaBH_4$ indicated that higher temperatures and (or) longer contact times between **2** and **3** did not improve the formation of **5**; moreover, the conversion into the corresponding *N*-alkylated compounds **7** was lower. Since our goal was the use of $NaBH_4$ as the reducing agent in the reductive alkylation of both **1** and **2**, the physical form (pellets or granular) of the reductant and minor but essential procedural variations were found to be very important.

The reaction between the amino acids (**1**) and all the carbonyl substrates (**3**) was carried out in MeOH using $NaBH_4$ pellets (Method A). Unlike water (12*e*), this solvent, was able to solubilize all the species initially present and the species eventually forming in the process, and it also made the $NaBH_4$ reactive enough to reduce the imine **4**. The methanolic mixture obtained was acidified with 37% aqueous HCl up to the isoelectric point of the starting amino acid (**1**) and, after removal of the solvent and addition of acetone, a solid was obtained composed of a mixture of the *N*-alkyl amino acids (**6**) and NaCl as determined by ^1H and ^{13}C NMR and by qualitative analysis. To eliminate NaCl, the solid was washed with water, but unfortunately, all the *N*-alkyl derivatives of glutamic acid (**1f**) and, particularly, histidine (**1h**) were found to be widely soluble in water. this reason the yield of *N*-butyl- (**6fb**), *N*-benzyl- (**6fd**) glutamic acid, *N*-propyl- (**6ha**), *N*-butyl- (**6hb**), and *N*-benzyl histidine (**6hd**) were also determined by ^{1}H NMR using phenylacetic acid as internal standard (Table 1). This acid, as sodium salt in D_2O–NaOH, exhibited a singlet at $\delta = 3.54$, which was far away from all the other signals.

The use of acetone during the work-up of the reaction provided a solid that, freed from unreacted **3** and (or) the corresponding alcohol, happened to be less soluble in water during the elimination of NaCl.

N-Isopropyl phenylalanine (**6ce**) was obtained only in 63% isolated yield; however, a large excess (3 mol equiv) of acetone (**3e**) was used.

When propanal (**3a**) or butanal (**3b**) were used in combination with **2**, Method A was followed but granular $NaBH_4$ was added (Method B). These aldehydes reacted very quickly with **2**; therefore excess granular $NaBH_4$ was used to promote the reduction of **3a** or **3b**, which in turn caused the *N*,*N*-dialkylation of **2** as shown by the GC–MS analysis of the reaction mixture.

[a]Spectrum obtained after neutralization.

When sterically hindered 2,2,2-trimethylacetaldehyde (**3c**) or benzaldehyde (**3d**) were used in connection with **2**, the addition of acetic acid (1 mol equiv) and the less reactive pelletized $NaBH_4$ were found to be beneficial to the reaction (Method C). In fact, under these experimental conditions, carbonyl compounds (**3c**) and (**3d**) and imine **5** are more reactive towards **2** and $NaBH_4$, respectively, because they are partially protonated.

The reaction of **2** with acetone (**3e**), the least reactive carbonyl compound considered, required more acetic acid (2 mol equiv) than Method C. In addition, THF was added to reduce the reactivity of pelletized $NaBH_4$ towards **3e** (Method D).

With the sterically hindered and (or) less electrophilic 2,2,2-trimethylacetaldehyde (**3c**), benzaldehyde (**3d**), and acetone (**3e**), GC–MS analysis sometimes showed the presence of unreacted **2** or **5**. A further addition of **3** and $NaBH_4$ or $NaBH_4$ alone (see *Experimental*) was used to bring the reaction to completion. The results of the reactions involving **2** are listed in Table 2.

When $NaBD_4$ was used instead of $NaBH_4$, a deuterium atom was introduced in the α position of the entering *N*-substituent. This procedure was successfully employed in the synthesis of *N*-(1-deuterio)butyl phenylalanine (**6cb-*d***) and *N*-(α-deuterio)benzyl phenylalanine methyl ester hydrochloride (**7cd-*d***).

The mass spectra (EI positive ion at 70 eV) of some of *N*-alkyl derivatives of **6** and **7** showed the presence of the $[M + 1]^+$ peak (Tables 3 and 4) and the almost complete absence of the parent ion. This species might be produced by an ion–molecule reaction, as invoked to explain the behaviour of substituted malonic acids (22).

Data pertinent to the synthesized *N*-alkyl amino acids (**6**) and amino methyl esters hydrochlorides (**7**) are collected in Tables 3 and 4, respectively.

© 2002 NRC Canada

The GC–MS analyses of **7ad**, **7cb**, **7ec**, and **7fa** performed using a chiral column showed that the enantiomeric purity of the original α-amino acid methyl ester was retained.

Conclusions

In conclusion, the method described here is very simple, fast, and inexpensive, with respect to both the handling of chemicals and the equipment required. It is also applicable both to amino acids and amino methyl esters with various carbonyl compounds, and the preformation and isolation of the imine is not required. It appears essential, however, to find the most suitable conditions for successful experimentations.

Experimental

General

All the L-amino acids (**1a**–**j**), the L-amino acid methyl ester hydrochlorides (**2a**–**f**), the carbonyl compounds (**3a**–**e**), and $NaBD_4$ powder (96 atom% D, pelletized with an IR die) were purchased from Aldrich, Italy; $NaBH_4$ (Venpure®) caplets and granular was kindly donated by Morton International S.p.A. (now Rohm and Haas; Mozzate, Como, Italy). Thin layer chromatography was performed on silica gel (Kieselgel 60 F_{254} Merck, Darmstadt, Germany) and EtOAc–hexane (50:50) was used as the eluent. Solvents were used as received. GC–MS analyses were performed with a Fisons TRIO 2000 gas chromatograph–mass spectrometer, working in the positive-ion 70 eV electron-impact mode. Spectra were recorded in the range 35–450 u. Injector temperature was kept at 250°C and the column (Supelco SPB™-5, 30 m long, 0.25 mm i.d.) temperature was programmed from 60 to 300°C with a gradient of 10°C min^{-1}. Direct-inlet mass spectra (DI-MS) were obtained on the same instrument: temperatures between 150 and 250°C were found suitable to volatilize all the compounds into the ion source. The enantiomeric purity of **7ad**, **7cb**, **7ec**, and **7fa** was determined using chiral-GC analysis, upon comparison with the racemic mixtures obtained from the reaction of the corresponding D,L-amino acid methyl esters under the same conditions (using a Chrompack 7495 WCOT column, liquid phase Chirasil-val-L, 26 m long, 0.22 mm i.d.). IR spectra were obtained with a Nicolet FT-IR Magna 550 spectrophotometer using the KBr technique for solids and recorded in the range 4000–400 cm^{-1}. ^1H and ^{13}C NMR spectra were recorded at room temperature on a Bruker AC-F 200 spectrometer at 200 and 50 MHz, respectively, using D_2O–NaOH for the *N*-alkyl amino acids (**6**) and DMSO-d_6 for the *N*-alkyl amino acids methyl ester hydrochlorides (**7**) as solvents. NMR peak locations are reported as δ values from DSS (2,2-dimethyl-2-silapentane-5-sulfonate) and TMS, respectively. Some ^1H NMR multiplets are characterized by the term app (apparent): this refers only to their appearance and may be an oversimplification. Optical rotations were determined at 21°C using a POLAX-D polarimeter purchased from ATAGO (Japan). Elemental analyses were performed with a Carlo Erba Mod. 1106 elemental analyser and were in satisfactory agreement with calculated values. Melting points were determined with an automatic Mettler (Mod. FP61) melting point apparatus and are not corrected.

Method A

N-*Alkyl amino acids (6)*

The aldehyde (**3a**–**d**, 14.0 mmol) was added to a stirred solution of the amino acid (**1**, 10.0 mmol) in MeOH (25 mL) neutralized with finely powdered NaOH (0.42 g, 10.5 mmol). After 10 min at room temperature, the solution was cooled with an ice bath and $NaBH_4$ pellets (0.49 g, 13.0 mmol) were added. The reaction mixture was stirred for 120 min at 0°C, then acidified with 37% HCl up to the isoelectric point of starting amino acid **1**. The solvents were distilled off and the residue was triturated in acetone and filtered. The solid was washed with H_2O to remove NaCl and pure *N*-alkyl amino acid **6** was obtained.

With tyrosine (**1d**) and glutamic acid **(1f**), twice the amount of NaOH (0.84 g, 20.1 mmol) was used to neutralize all the acid centers.

When acetone **3e** was used as the carbonyl compound, the procedure was the same, but 30.0 mmol (2.20 mL) of **3e** was used.

Method B

N-*Propyl and* N-*butyl amino acid methyl ester hydrochlorides (7)*

Propanal or butanal (**3a** or **3b**, respectively, 14.0 mmol) was added to a stirred solution of the amino acid methyl ester hydrochloride (**2**, 10.0 mmol) in MeOH (50 mL) neutralized with finely powdered NaOH (0.42 g, 10.5 mmol). After 10 min at room temperature, the solution was cooled with an ice bath and granular $NaBH_4$ (0.30 g, 8.0 mmol) was added. The reaction mixture was stirred for 60 min at 0°C, then MeOH was distilled off, the residue re-dissolved in EtOAc, and NaCl filtered off. The organic phase was washed with brine and dried over Na_2SO_4. EtOAc was removed in vacuo and the residue, dissolved in Et_2O, was treated with ethereal HCl (2 M, 5 mL, 10 mmol); *N*-alkyl amino acid methyl ester hydrochloride **7** was filtered and washed with Et_2O. If the residue was insoluble in Et_2O, it was dissolved in EtOAc, treated with ethereal HCl and, after elimination of solvents under reduced pressure, **7** was crystallized from Et_2O.

Method C

N-*Benzyl and* N-*neopentyl amino acid methyl ester hydrochlorides (7)*

2,2,2-Trimethylacetaldehyde or benzaldehyde (**3c** or **3d**, respectively, 15.0 mmol) and acetic acid (0.57 mL, 10.0 mmol) were added to a stirred solution of the amino acid methyl ester hydrochloride (**2**, 10.0 mmol) in MeOH (50 mL) neutralized with finely powdered NaOH (0.42 g, 10.5 mmol). After 10 min at room temperature, the solution was cooled with an ice bath and $NaBH_4$ pellets (0.38 g, 10.0 mmol) were added. The reaction mixture was stirred for 60 min at 0°C and if the GC–MS analysis of the reaction mixture showed the presence of unreacted imine **5**, granular $NaBH_4$ (0.19 g, 5.0 mmol) was added. The reaction mixture was stirred for an additional 30 min, then MeOH was distilled off, the residue dissolved in EtOAc, and NaCl filtered

© 2002 NRC Canada

off. The organic phase was washed with saturated Na_2CO_3 solution and dried over Na_2SO_4. EtOAc was removed in vacuo and the residue, dissolved in Et_2O, was treated with ethereal HCl (2 M, 5 mL, 10.0 mmol); *N*-alkyl amino acid methyl ester hydrochloride **7** was filtered and washed with Et_2O. If the residue was insoluble in Et_2O, it was dissolved in EtOAc, treated with ethereal HCl and, after the elimination of solvents under reduced pressure, **7** was crystallized from Et_2O.

Method D

N-*Isopropyl amino acid methyl ester hydrochlorides (7)*

A solution of acetone (**3e**, 1.47 mL, 20.0 mmol) and acetic acid (1.14 mL, 20.0 mmol) in THF (6 mL) was added to a stirred solution of amino acid methyl ester hydrochloride **2** (10.0 mmol) in MeOH (18 mL) and THF (35 mL) neutralized with NaOH (0.42 g, 10.5 mmol). After 10 min at room temperature, the solution was cooled with an ice bath and $NaBH_4$ pellets (0.38 g, 10.0 mmol) were added. The reaction mixture was stirred for 60 min at 0°C and if the GC–MS analysis of the reaction mixture showed the presence of unreacted amino ester **2**, a solution of acetone (**3e**, 0.73 mL, 10. 0 mmol) and acetic acid (0.57 mL, 5.0 mmol) in THF (3 mL), and after 10 min $NaBH_4$ pellets (0.19 g, 5.0 mmol), were added. The reaction mixture was stirred for additional 30 min, then solvents were distilled off, the residue was dissolved in EtOAc, and NaCl filtered off. The organic phase was washed with saturated Na_2CO_3 solution and dried over Na_2SO_4. EtOAc was removed in vacuo and the residue, dissolved in Et_2O, was treated with ethereal HCl (2 M, 5 mL, 10.0 mmol); *N*-isopropyl amino acid methyl ester hydrochloride **7** was filtered and washed with Et_2O. If the residue was insoluble in Et_2O, it was dissolved in EtOAc, treated with ethereal HCl and, after the elimination of solvents under reduced pressure, **7** was crystallized from Et_2O.

Acknowledgments

Financial support was obtained from the Italian Ministry of University, Sciences and Technology (MURST 40% 2000 and 2001 to GV). PG is the recipient of a three-year scholarship from the Ministry of Agriculture. The authors are grateful to Dr. P. Martinuzzi for recording ^1H and ^{13}C NMR spectra and Mr P. Padovani for expert instrumental maintenance.

Vibrational spectroscopic studies of aqueous solutions of *tert*-butyl alcohol and *tert*-butylamine

Pius K. Kipkemboi and Allan J. Easteal

Abstract: Raman and FT-IR absorption spectra of aqueous *tert*-butyl alcohol (*t*-BuOH) and *tert*-butylamine (*t*-$BuNH_2$) in the region of the O–H and NH_2 stretching and bending modes have been measured as a function of organic co-solvent concentration in the whole co-solvent mole fraction region. The major observed changes of the aqueous binary solution spectra compared with the solvent spectra are a loss or gain of band intensity. In particular, the observed changes in intensities and linewidths of some bands were significantly more pronounced at low concentrations of organic co-solvents in water, where *t*-BuOH and *t*-$BuNH_2$ tend to integrate into the water structure. Clear evidence of structural enhancement of the network is obtained in dilute solutions as well as destruction of the network by hydrophobic interactions as the concentration is increased. Generally, the interpretation of the spectra is in agreement with the capacity of the hydrophobic co-solvent to break the structure of water in the more concentrated aqueous solutions and to enhance the structure in dilute solutions. Vibrational intensities and frequency shifts of some bands show definite trends with varying the concentration of the solutions. In the concentration-dependence study, unusual linewidth changes of certain bands were observed.

Key words: infrared, Raman spectra, aqueous, *tert*-butanol, *tert*-butylamine.

Résumé : On a mesuré les spectres d'absorption Raman et infrarouges en transformée de Fourier de solutions aqueuses de *tert*-butanol (*t*-BuOH) et de *tert*-butylamine (*t*-$BuNH_2$), dans la région des modes d'élongation et de déformation du O–H et du NH_2, en fonction de la concentration du cosolvant organique, sur toute la plage des fractions molaires du cosolvant. Les changements principaux observés dans les spectres en solutions aqueuses binaires par rapport à ceux des spectres du solvant sont des gains ou des pertes dans l'intensité de la bande. En particulier, les changements observés dans les intensités et les largeurs de quelques bandes sont beaucoup plus prononcés à de faibles concentrations des cosolvants organiques dans l'eau vers laquelle le *t*-BuOH et la *t*-$BuNH_2$ ont tendance de migrer dans la structure de l'eau. On a obtenu des données claires en faveur d'une augmentation de la structure du réseau en solutions diluées ainsi que de la destruction du réseau par les interactions hydrophobes avec une augmentation de la concentration. En général, l'interprétation des spectres est en accord avec la capacité du cosolvant hydrophobe à briser la structure de l'eau dans les solutions aqueuses plus concentrées et à les augmenter en solutions diluées. Les intensités vibrationnelles et les déplacements dans les fréquences de quelques bandes présentent des tendances bien définies avec les variations dans les concentrations dans les solutions. Dans l'étude sur la dépendance sur la concentration, on a observé des changements inhabituels dans la largeur de certaines bandes.

Mots clés : infrarouge, spectre Raman, aqueux, *tert*-butanol, *tert*-butylamine.

Introduction

Vibration spectra are, in general, sensitive to the local environment of a molecule, and information concerning the relative position of the molecule in quite a short time can be obtained from the spectra. Vibrational spectra of water or aqueous solutions have received considerable attention in relation to the liquid structure of water. Although numerous papers have been presented reporting spectra of inorganic electrolytes in aqueous solution, there are few studies on the vibrational spectra of organic molecules in water (1–10). It is of interest to interpret vibrational spectra of organic molecules in aqueous solution and to discuss the intermolecular interactions and liquid structures in the these systems.

In the present investigation, FT-IR and Raman spectra of aqueous *tert*-butanol and *tert*-butylamine in the O–H stretching and bending regions were measured at room temperature as a function of co-solvent concentration in the entire co-solvent mole fraction region. The purpose of this study was to investigate the structural changes brought about by a change in the concentration of co-solvent. It was anticipated that FT-IR and Raman spectroscopy of aqueous solutions of the aforementioned compounds would provide insights into the structural perturbations of bulk water, which are caused by hydrophobic co-solvents, and provide a structure-oriented conceptual framework for evaluating various hydrophobic effects. In the present study, the two co-solvents, *tert*-butyl alcohol (*t*-BuOH) and *tert*-butylamine (*t*-$BuNH_2$), were used

because they are relatively hydrophobic yet completely miscible with water in all proportions. H_2O + *t*-BuOH and H_2O + *t*-$BuNH_2$ mixtures provide a useful opportunity for investigating the interactions of a non-electrolyte with water. Both *t*-BuOH and *t*-$BuNH_2$ hydrophobic co-solvents may serve as model compounds for more complicated aqueous systems like surfactants, emulsions, and biopolymers.

Most of the essential functions of macromolecules in living materials are determined by the hydrogen-bonded structures. The vibrational modes of NH- and OH-stretch character, therefore, carry valuable function-related structural information. Since life is inseparably connected with the presence of water, water as a solvent should be used to study biological molecules (3). Overlap of the vibrational bands of water with those of solutes is inevitable, resulting in broad-band contours, which cannot usually be deconvoluted into their constituents (11, 12). In this study, we explored the fact that vibrational spectra of solvent water are very sensitive to the nature of solute. Network-perturbing hydrophobic organic co-solvents can provide useful information about aqueous solutions of non-electrolytes, but the interpretation is complicated by the different stretching frequencies for N–H···O bonds compared with O–H···O bonds.

Our previous work focussed on investigating the thermodynamic and mass transport behaviour of such systems (13–17). Studies of aqueous solutions of *t*-BuOH and *t*-$BuNH_2$ showed an "enhancement" of the water structure by the co-solvent (*t*-BuOH or *t*-$BuNH_2$) at very low concentrations. In contrast, at higher concentrations, both co-solvents disrupt the structure of the water, behaving as "structure breakers." In this work such previous data are extended and consolidated with Raman and FT-IR spectra. Although the vibrational spectra of the H_2O + *t*-BuOH system were previously reported (5), there are few data available for the H_2O + *t*-$BuNH_2$ system.

Experimental

Materials

tert-Butyl alcohol was supplied by Riedel-de Haën and *tert*-butylamine by Aldrich. The stated purity of both solvents exceeded 99.0 mol%. The solvents were dried using thermally activated molecular sieves (3 Å). Ultra-pure water from a milli-Q purification system was used.

Binary mixtures were prepared by weighing appropriate amounts of the components into fine glass vials using a balance with accuracy ±0.1 mg.

Apparatus and procedures

Raman spectra were recorded with a Jobin-Yvon V1000 spectrometer, a double monochromator instrument equipped with holographic gratings (1600 grooves per mm) for high resolution and good stray-light rejection. A Spectra-Physics Model 2016 argon ion laser was used as the excitation source and non-lasing plasma lines were removed with a Laser III premonochromator. The filtered laser light was diverted to the macro sampling chamber using a flip mirror. The Raman scattered radiation was detected with a gallium–arsenide photomultiplier tube (PMT), which was cooled by a Peltier-effect device to ca. 250 K to reduce the thermal noise. A spectralink module, connected to the PMT and interfaced to an IBM PC-compatible computer, provided photon counting, data acquisition, and monochromator drive. Liquid samples in glass vials were attached to a motor drive unit situated in the macrochamber of the spectrometer. The vial was then spun to enhance the Raman signal and to reduce the risk of sample decomposition. Typically 40–100 mW of focused-laser light was used. The Jobin-Yvon Prism software package was employed to operate the spectrometer. All data manipulations and spectral plottings were performed with Spectra Calc (Galactic Industries Corp.) software. The spectrometer was calibrated using the 514.5 nm line of the argon ion laser, and the spectra were reproducible to ±1 cm^{-1}. The spectra were obtained at a spectral resolution of 5 cm^{-1}, the data being collected at 2 cm^{-1} intervals. The scanning speed of the spectrometer was 1.0 cm^{-1} s^{-1} and the integration time was 0.5 s per data point. The acquisition time was 30 min. The spectral range covered was 4000–400 cm^{-1}. All the Raman spectra were recorded with the samples at room temperature.

Mid-IR spectra were recorded on a Digilab FTS-60 Fourier transform infrared spectrometer employing a Globar source, a KBr beam splitter, and an uncooled DTGS detector. The spectrometer was interfaced to a computer and a 68020 processor with Digilab software. The main body of the spectrometer was purged with dry nitrogen. Samples were examined as thin films using an attenuated internal

reflectance (ATR) accessory. Internal reflection spectroscopy was performed using multiple-reflection ATR parallelogram with a 45° angle of reflection. A clean dry Silicon ATR element was used to obtain a single-beam background spectrum. The ATR cell was then filled with a sample solution using syringe pressure and scanned to obtain absorbance spectra. The sample in the ATR cell was purged for at least 5 min with nitrogen gas before spectra were recorded. Between sample runs, the cell was flushed with water and acetone and then dried with ambient air. Thirty interferograms were collected, co-added, apodized with a triangular function, and Fourier transformed to give spectra of 4 cm^{-1} resolution. Spectral manipulations were performed with Spectra Calc. All spectra reported here were obtained using a Silicon ATR cell at room temperature. The spectral range covered was 4000–1050 cm^{-1}.

Results and discussion

Vibrational spectra of H_2O + *t*-BuOH mixtures

Figure 1 represents the Raman spectra of water, *t*-BuOH, and two *t*-BuOH solutions of different concentrations recorded in the frequency range of 400–4000 cm^{-1}. In Fig. 2, the Raman spectra of various H_2O + *t*-BuOH mixtures in the 2700–3800 cm^{-1} region are shown in more detail and compared with the spectrum of water. These spectra were recorded with the same incident-laser power and no further corrections, such as for refractive index, were made. Figure 2 allows us to follow the effect of *t*-BuOH concentration on the water organization. The broad feature dominating the spectrum is due to the O–H stretching mode of water. The strongest Raman band observed for liquid *t*-BuOH is polarized and found at ~752 cm^{-1}. This band is attributed to the in-phase C_3C–O stretching mode. A CH_3 stretching band for *t*-BuOH appears in the 2800–3000-cm^{-1} region and is clearly seen even in systems with high water content. In pure liquid *t*-BuOH only one broad O–H stretching vibration band appears in the high-frequency region centred around 3360 cm^{-1}, which has an antisymmetric contour. The band is very strong in the IR spectrum but very weak in the Raman spectrum. The small shoulder observed at ~3600 cm^{-1} in pure water seems to disappear as the concentration of *t*-BuOH increases. Nevertheless, it is difficult to determine if this apparent disappearance is due to the reduction in the intensity of this band or to the overlapping of the adjacent strong band. Needless to say, *t*-BuOH as well as *t*-$BuNH_2$ are not unique in this respect. For instance, hydrogen peroxide also suppresses the high-frequency shoulder in water (18). Electrolytes are also known to suppress the high-frequency shoulder in water (19).

In contrast, the position and shape of the O–H stretching vibrations of the two bands centred at ~3250 and 3400 cm^{-1} remain almost constant with an increase in the concentration

Fig. 4. IR spectra of H_2O + *t*-BuOH mixtures as a function of composition in the region 1100–1750 cm^{-1}; mol% of BuOH are noted on each curve. Spectra are plotted as recorded but shifted in a vertical direction.

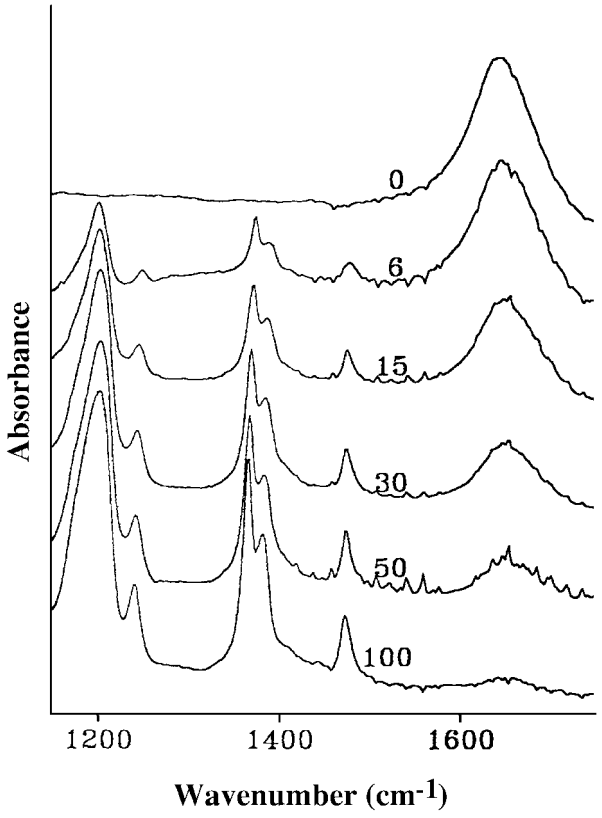

Fig. 5. Raman spectra of water, *t*-$BuNH_2$, and two *t*-$BuNH_2$ aqueous solutions in the frequency range of 400–4000 cm^{-1}; mol% of *t*-$BuNH_2$ are noted on each curve. Spectra are plotted as recorded but shifted in a vertical direction.

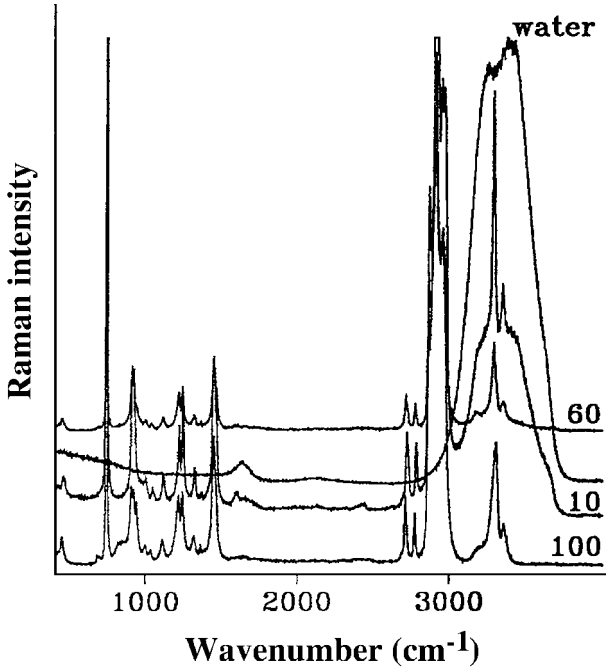

of *t*-BuOH. At low concentrations (≤15 mol% *t*-BuOH), however a sharp decrease in the intensity of the O–H stretching mode of water is observed. Thus, Figs. 1 and 2 show that the primary effect of the addition of *t*-BuOH is the reduction in the intensity of the two bands. The decrease in intensity of the two peaks at moderately high concentrations of *t*-BuOH (i.e., >15 mol%) is less noticeable indicating that the network structure of bulk water has been significantly disrupted at these concentrations.

The IR spectra of several H_2O + *t*-BuOH systems with increasing mole fractions of *t*-BuOH are presented in Fig. 3. The position of the low-frequency shoulder at ~3250 cm^{-1} remains relatively constant. It can be seen, however, that the prominence of the low-frequency shoulder continuously decreases with increasing *t*-BuOH content and eventually vanishes at high concentrations. It is difficult to follow the absorption profile of the high-frequency broad band centred at ~3400 cm^{-1} of water because it occurs in the same region as the strong broad absorption band of *t*-BuOH. It is noteworthy that the peak shows a frequency shift towards higher wavenumbers with increasing concentration of *t*-BuOH, at least up to 50 mol% co-solvent.

With the exception of the water bending mode at 1650 cm^{-1}, there were no significant changes in the Raman or IR spectra of the H_2O–*t*-BuOH system in the region below 2800 cm^{-1} with change in composition. But, as shown in Figs. 1 and 4, the intensity of the vibrational bending mode of water in both Raman and IR decreases considerably with increasing *t*-BuOH concentration until it vanishes at high concentrations, but its position seems to be invariant.

Vibrational spectra of H_2O + *t*-$BuNH_2$ mixtures

Figure 5 represents the Raman spectra of water, *t*-$BuNH_2$, and two solutions of *t*-$BuNH_2$ in water recorded in the frequency range of 400–4000 cm^{-1}. These spectra were recorded with the same incident-laser power and no further corrections, such as for refractive index, were made. The strongest Raman band observed for *t*-$BuNH_2$ is polarized and found at ~750 cm^{-1}. This band is attributed to the symmetric C_3C–N stretching mode. The CH_3 stretching bands of *t*-$BuNH_2$ appear in the 2800–3000 cm^{-1} region and are clearly seen even in systems with high water content. The vibrational spectrum of pure liquid *t*-$BuNH_2$ contains two peaks between 3200 and 3400 cm^{-1}. In this region of the Raman spectrum, the strongest band at 3310 cm^{-1} is polarized and it is assigned to the symmetric NH_2 stretching mode, while the weak depolarized band at 3360 cm^{-1} is assigned to the corresponding antisymmetric stretching mode. In the IR spectrum, the band at 3360 cm^{-1} is fairly strong, whereas the peak at 3310 cm^{-1} is very weak. Figure 6 shows in more detail the variations in the Raman-band profiles of the NH_2 stretching modes as a function of the concentration of *t*-$BuNH_2$ in water. The high-frequency band at ~3360 cm^{-1} attributed to the NH_2 antisymmetric stretch is generally weak and very broad, making it difficult to follow its variation in intensity with composition. Our interest is therefore directed toward the much stronger NH_2 symmetric peak at 3310 cm^{-1}.

The low-frequency band centred at ~3310 cm^{-1} exhibits a frequency shift to higher wavenumbers with increasing concentration of *t*-$BuNH_2$ and its intensity changes in a

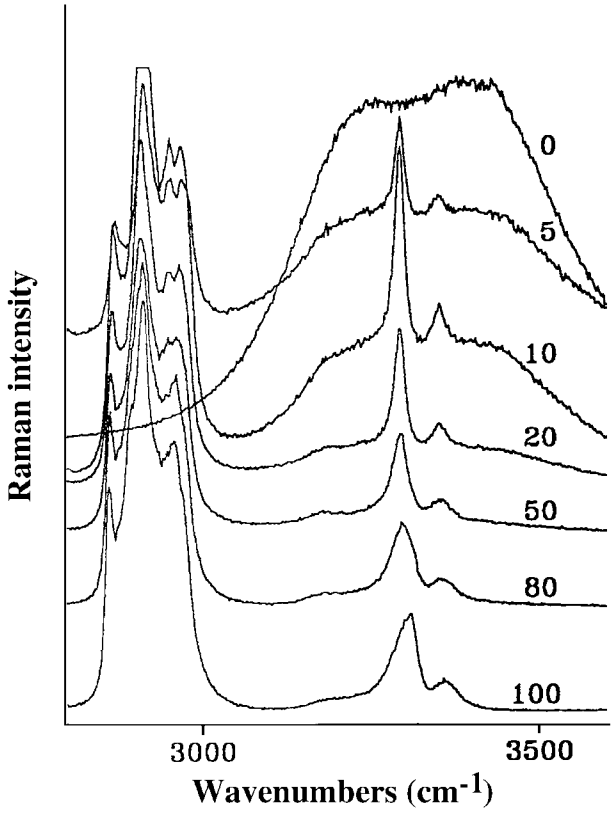
Fig. 6. Raman spectra for H_2O + *t*-$BuNH_2$ mixtures as a function of composition in the region 2700–3700 cm^{-1}; mol% of *t*-$BuNH_2$ are noted on each curve. Spectra are plotted as recorded but shifted in a vertical direction.



peculiar manner. As observed in Figs. 5 and 6, the intensity of the band seems to increase sharply as the concentration of *t*-$BuNH_2$ rises, passing through a maximum value in the water-rich region, and then shows a decreasing trend. To quantitatively follow the apparent change in peak intensity as a function of composition, the peaks were integrated. The CH_3 symmetric band at 2920 cm^{-1} was chosen as the reference band as it is very strong in Raman and its intensity does not seem to change significantly with the variation in the concentration of water, and furthermore, it is close to the band of interest. The band maxima of the NH_2 and CH_3 symmetric stretching vibrations were baseline corrected, and integration of the spectral profiles of their areas were determined using the Spectra Calc software. In Fig. 7, the variation of the integrated Raman intensity ratio ($I[3296cm^{-1}]_{NH_2}/I[2920cm^{-1}]_{CH_3}$) with composition is presented, where the peaks at 3296 and 2920 cm^{-1} are baseline corrected and the integrated intensity of the NH_2 and CH_3 components are measured. The concentration dependence of the integrated Raman intensity ratio is unique and characteristic. The ratio of integrated Raman intensity of the bands at 3296 and 2920 cm^{-1} as a function of *t*-$BuNH_2$ content is in qualitative agreement with previous results obtained with other techniques (13–16) — the intensity ratio shows a maximum around 10 mol% of *t*-$BuNH_2$. This demonstrates that *t*-$BuNH_2$ exhibits a strong hydrophobic hydration at low mole fractions, and that this hydration structure is broken down at higher mole fractions. We have followed the effect

95.0	3305	50.5
100	3310	52.3

of concentration on the full width at half-maximum (FWHM) of the NH_2 symmetric stretching band at ~3296 cm^{-1}. The variation in apparent frequency shifts and line widths at half-maximum with concentration are presented in Table 1. As seen in Table 1, the line width at half-maximum below 20 mol% *t*-$BuNH_2$ does not depend on the concentration in water-rich solutions, being nearly constant in the water-rich region, but the dependence is remarkable above this concentration, showing a continuous and virtually linear change of line width from 18.2 to 52.3 cm^{-1} on going from 20 to 100 mol% *t*-$BuNH_2$.

It can be assumed that in the water-rich region (presumably below 15 mol% *t*-$BuNH_2$), the structure of the solution corresponds to the structure of pure water and the amine

Fig. 8. IR spectra of H_2O + *t*-$BuNH_2$ mixtures as a function of composition in the region 2600–4000 cm^{-1}; mol% of *t*-$BuNH_2$ are noted on each curve. Spectra are plotted as recorded but shifted in a vertical direction.

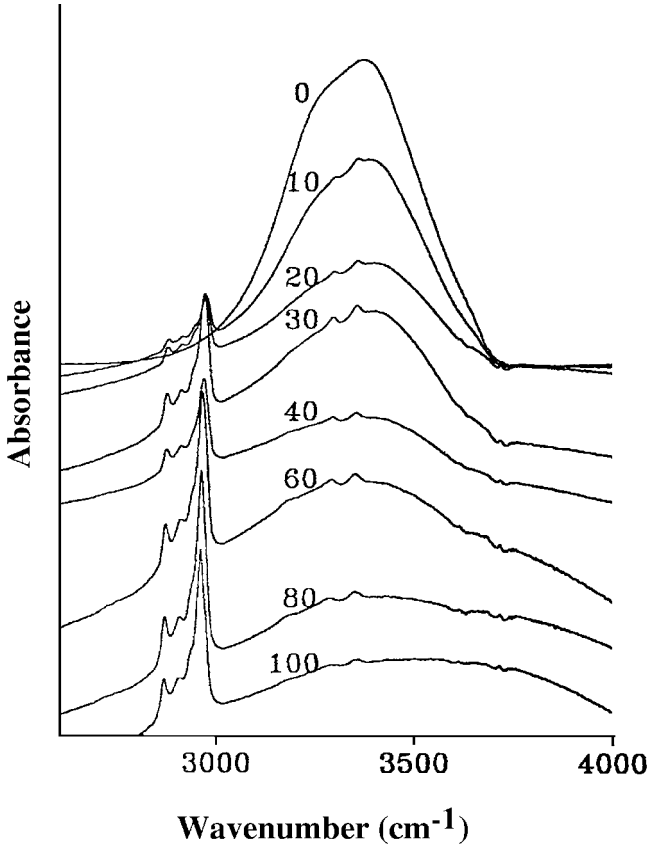

Fig. 9. IR spectra of H_2O + *t*-$BuNH_2$ mixtures as a function of composition in the region 1150–1750 cm^{-1}; mol% of *t*-$BuNH_2$ are noted on each curve. Spectra are plotted as recorded but shifted in a vertical direction.

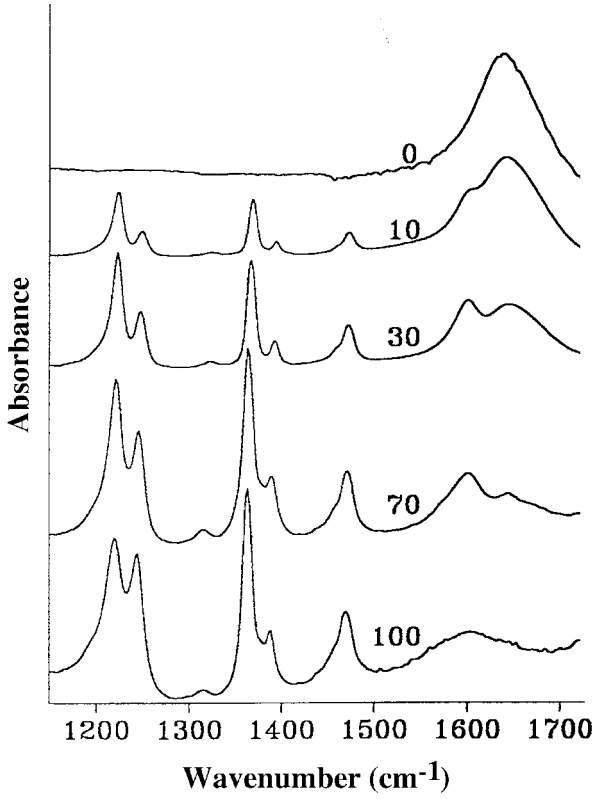

molecules are incorporated into the network structure of bulk water by cavity filling, thereby enhancing the water structure because of water–co-solvent hydrophobic interactions. But at higher concentrations of co-solvent the enhanced structure of water is gradually broken down by the organic co-solvent as the *t*-$BuNH_2$ molecules form hydrogen-bonds with water molecules. The formation of such hydrogen bonds between *t*-$BuNH_2$ and water gives rise to large line widths, similar to those in neat liquid *t*-$BuNH_2$. At relatively higher concentration of *t*-$BuNH_2$, the hydrogen bonds between *t*-$BuNH_2$ molecules are dominant — the more hydrogen-bonded the *t*-$BuNH_2$ molecules become the larger the observed line widths.

Good IR spectra of aqueous solutions of *t*-$BuNH_2$ were difficult to obtain due to the broad, intense water absorption bands, which obscure much of the mid-IR spectrum (the NH_2 stretching vibrations of *t*-$BuNH_2$, which are comparatively weak, occur in the same region). The O–H stretching region from 3100 to 3500 cm^{-1} is essentially opaque in the highly water-rich solvent (<10 mol% *t*-$BuNH_2$), and hence, the weak NH_2 stretching vibrations are completely masked.

As the concentration increases above 10 mol% *t*-$BuNH_2$, the broad O–H profile-band contour observed for water decreases gradually in intensity and the NH_2 stretching bands become more noticeable with no apparent shifts in their band positions. The band corresponding to the symmetric NH_2 stretching mode of *t*-$BuNH_2$, is a fairly intense band in Raman, but is much weaker in IR in comparison with the high-frequency band at ~3360 cm^{-1} attributed to the characteristic antisymmetric NH_2 stretching vibration. Changes in the relative intensities of these two bands were found to parallel the Raman intensity of the low-frequency component at ~3296 cm^{-1} (Figs. 6 and 7), since they seem to initially increase passing through maxima before apparently decreasing again with increasing concentration of *t*-$BuNH_2$. In Fig. 8, the variation in IR-band profiles of the OH and NH_2 stretching modes are shown as a function of concentration of *t*-$BuNH_2$ in water.

The bands at ~1645 and 1600 cm^{-1}, which are weak in the Raman but fairly strong in the IR, correspond to the bending vibrations of water and the NH_2 component of *t*-$BuNH_2$, respectively. The two bands are very sensitive to concentration. It is noteworthy that the peak absorbancies of the two bands vary in a nearly linear fashion with concentration, and can be used for analytical purposes. The trends of their absorbancies with concentration are shown in Fig. 9. It can be seen that the absorbance of the bending mode of water at ~1645 cm^{-1} decreases with the addition of *t*-$BuNH_2$ to water. The NH_2 bending mode initially appears as a shoulder at low concentrations of *t*-$BuNH_2$. As the mole fraction of *t*-$BuNH_2$ increases, this shoulder develops into a band centred at ~1600 cm^{-1}. Finally, the 1600 cm^{-1} band dominates the spectrum at high concentrations of *t*-$BuNH_2$, leaving the band at 1645 cm^{-1} as a shoulder.

Baker's yeast-catalyzed synthesis of optically pure 4-*tert*-butyl-3-hydroxy β-lactam *cis*-(3*R*,4*S*) and *trans*-(3*R*,4*R*) diastereomers

Margaret M. Kayser, Yan Yang, Marko D. Mihovilovic, Anton Feicht, and Fernande D. Rochon

Abstract: Baker's yeast (*Saccharomyces cerevisiae*) reductions were applied to the synthesis of the paclitaxel C-13 side-chain analogue. An easily synthesized α-keto-β-lactam (1-(4-methoxyphenyl)-4-*tert*-butylazetidin-2,3-dione, **4**) was reduced by yeast cells to give a mixture of enantiomerically pure *cis* and *trans* isomers. Both compounds were isolated and characterized, and their absolute configurations were confirmed by X-ray crystallographic analysis.

Key words: Taxol®, C-13 side-chain, paclitaxel analogues, optically pure α-hydroxy-β-lactams, baker's yeast-catalyzed reductions.

Résumé : On a fait appel à des réductions à l'aide de levure de bière (*Saccharomyces cerevisiae*) pour réaliser la synthèse un analogue du paclitaxel portant une chaîne latérale en C-13. Un α-céto-β-lactame facilement accessible par synthèse (1-(4-méthoxyphényl)-4-*tert*-butylazétidine-2,3-dione, **4**) a été réduit par des cellules de levure pour conduire à un mélange d'isomères *cis*- et *trans*-énantiomériquement purs. On a isolé et caractérisé les deux composés et on a confirmé leurs configurations absolues par une analyse cristallographique par diffraction des rayons-X.

Mots clés : Taxol® à chaîne latérale en C-13, analogue du paclitaxel, α-hydroxy-β-lactames optiquement purs, réductions catalysées par la levure de bière.

[Traduit par la Rédaction]

Introduction

Taxol® (paclitaxel), an important cancer chemotherapeutic agent, is produced through a semi-synthetic route involving the condensation of a natural precursor (10-deacetylbaccatin III) with a synthetic phenylisoserine side-chain (C-13 side-chain). The side-chain is essential for paclitaxel's biological activity (1), but a wide range of modifications is tolerated. For example, replacement of the phenyl group with aliphatic groups provides highly bioactive analogues (2–4). One of the most efficient coupling protocols for grafting the side-chain onto the taxane ring system uses the activated β-lactam derivative of phenylisoserine (5, 6). This methodology allows the introduction of various modified chains into the analogues. Promising results from the bioactivity studies with paclitaxel analogues (4, 6) prompted the search for new enantioselective routes to 3-hydroxy-β-lactams with various substituents in the 4-position (7). The most challenging aspect of these syntheses revolves around obtaining the correct (or desired) absolute configuration at the two stereogenic centres. Our strategy has been to use yeast-mediated reduction of racemic α-keto-β-lactam **1** as a way of introducing the required chirality into the side-chain precursors (8). The same methodology can be applied to the synthesis of various paclitaxel C-13 chain analogues.

We anticipated that the rigid skeleton of **1** might contribute to the enantioselectivity of the carbonyl reduction. Reduction of **1** (R = Ph) with commercial baker's yeast gave a mixture of *cis* and *trans* isomers. The natural paclitaxel side-chain (*cis*-(3*R*,4*S*)) was formed with 57% enantiomeric excess (ee), but its diastereomer (*trans*-(3*R*,4*R*)) was essentially optically pure (>98% ee) (Scheme 1). Kinetic data for the reductions with the fatty acid synthase (FAS)-deficient mutant suggested that two principal enzymes were involved in the reductions of this substrate: a fatty acid synthase that kinetically resolved the racemic mixture, leading to the formation of **2** (*trans*-(3*R*,4*R*)), and another, as yet unidentified reductase that produced *cis*-isomer **3** with low enantioselectivity (8).

We speculated that the low enantioselectivity in the latter case could be due to the nearly symmetrical structure of substrate **1**, where the 4-phenyl substituent resembles the *para*-methoxyphenyl (PMP) protective group on the nitrogen (8). The calculated structures of the two enantiomers can be overlaid on one another so that the aromatic groups are nearly coincident. The hydride transfers to one or the other are separated by only 0.5 Å. Thus, in principle, the enzyme's active site can accommodate both enantiomers (8). To test the validity of our reasoning, we wanted to investigate a less symmetrically substituted substrate such as 4-*tert*-butyl-3-oxo-β-lactam **4**. Additionally, this compound was of interest

in its own right, since the structure–activity studies on butitaxel analogues have shown them to possess excellent cytotoxicity and improved water solubility (9, 10).

Results and discussion

Racemic 4-*tert*-butyl-3-oxo-β-lactam **4** was assembled in three steps from readily available starting materials, as shown in Scheme 2 (11). Its baker's yeast-catalyzed transformation followed by TLC and GC showed an essentially complete reduction (>99%). A mixture of compounds identified as *trans* and *cis* isomers was isolated in 97% yield. The two products, cleanly resolved by GC, were separated by chromatography, purified by crystallization from EtOAc, and characterized. According to chiral HPLC, the *cis* diastereomer was formed in 95% ee, while the *trans* compound was optically pure (>98% ee).[2]

Sodium borohydride reduction of racemic **4** gave the *cis* alcohol as the only product. Conversely, alcohol *rac*-**6**, from the condensation–hydrolysis reactions (Scheme 2), was found to be a mixture of isomers (75% *cis* and 25% *trans*). NMR experiments performed on *rac*-**6** with a chiral solvating agent (*R*-(–)-2,2,2-trifluoro-1-(9-anthryl)ethanol (CSA)) demonstrated that the *cis* and *trans* isomers were resolvable. Under identical experimental conditions, the *cis* and *trans* products from the yeast-catalyzed reduction were not resolved, indicating that diastereomers *trans*-**5** and *cis*-**6** were optically pure. This was confirmed by chiral HPLC analyses of all products. To establish the absolute configurations, the crystal structures of **5** and **6** were studied by X-ray diffraction methods. The two compounds belong to the chiral $P2_12_12_1$ space group. Table 1 contains the crystal data and the experimental details of the structure refinement for **5** and **6**, while selected bond distances and angles are listed in Table 2. Labeled diagrams of the two compounds are illustrated in Figs. 1 and 2. The same labeling system was chosen for both crystals to facilitate comparison between the two structures.

[2] For all HPLC analyses the Chiracel OD-H column (Daicel Chemical Industries, Ltd.) was used and the solvent system was hexane–*iso*-propanol (9:1). The two diastereomers appeared as well-separated peaks on the capillary GC (capillary column 15 m × 0.53 mm, DB-1301, J & W Scientific).

C7-C4-C5	110.1(2)	109.3(2)

The crystallographic results clearly show the configuration at the two stereogenic centres. In **5** (Fig. 1), the *tert*-butyl and hydroxyl groups are on the opposite sides of the plane of the four-member ring (*trans*), while in **6** (Fig. 2), the two groups are on the same side of the plane, indicating a *cis* configuration. Since the measurements were made with Cu Kα radiation and the data was collected on the entire sphere (all the Friedel pairs were measured), the absolute configurations of the two compounds were unambiguously determined (12). The values of the Flack parameters are in agreement with the assigned configurations. In each structure, the four-member ring is planar with a mean deviation of 0.029(4) Å for **5** and 0.038(1) Å for **6** from the calculated best plane. The carbonyl oxygen atom O1 (deviation of –0.128(4) Å for **5** and –0.112(5) Å for **6**) and C11 (deviation of –0.030(4) Å (**5**) and 0.283(4) Å (**6**) are also close to the plane. The best plane was also calculated through the six atoms of the phenyl ring. The mean deviation is 0.005(1) Å for **5** and 0.002(2) Å for **6**. The atoms O3 (deviation of –0.011(3) Å for **5** and 0.031(3) Å for **6**) and N (deviation of –0.033(3) Å for **5** and 0.062(3) Å for **6**) are also in the phenyl plane. The dihedral angles between the phenyl and the four-member ring planes are very similar in the two structures: 47.2(1)° in **5** and 49.1(1)° in **6**.

Fig. 1. Labeled diagram of the *trans*-**5**.

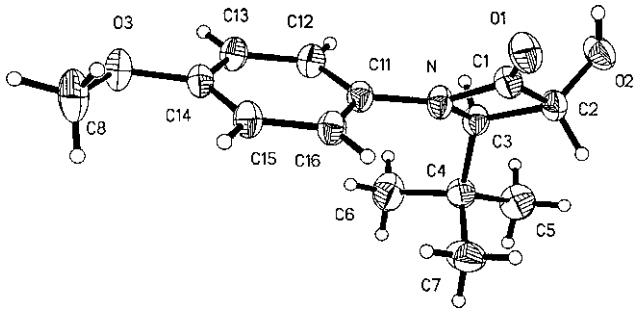

Fig. 2. Labeled diagram of the *cis*-**6**.

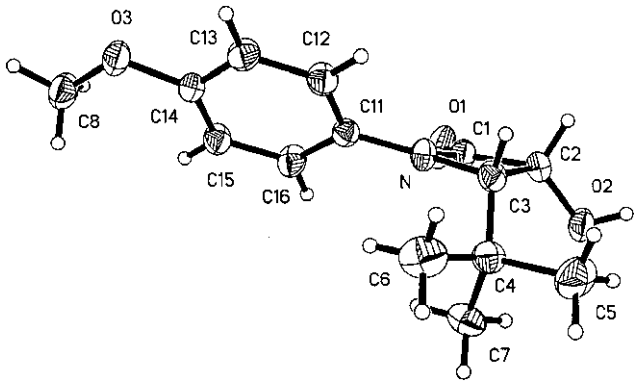

The torsion angles are listed in Table 3, confirming the configuration of the molecules. For example, we can compare the values of the torsion angles O2-C2-C3-C4 (116.6(2)° for *trans*-**5** and –5.8(3)° for *cis*-**6**), C1-N-C3-C4 (125.6(2)° for **5** and –115.4(2)° for **6**), C1-C2-C3-C4 (–123.5(2)° for **5** and 111.9(2)° for **6**), while N-C1-C2-O2 are very similar (124.4(2)° for **5** and 128.9(2)° for **6**).

The bond distances and angles are normal. In the four-member ring, the C—C bonds are as expected, while the N—C1 bond attached to the carbonyl group is shorter (av 1.353(3) Å) than the N—C3 bond (av 1.490(3) Å). The internal angles vary between 85.41(17) and 95.55(18)°. The angles at N (av 95.40(16)°) and at the carbonyl C atom (av 92.3(2)°) are larger than the others (av 85.89(15)°). The carbonyl bonds are 1.220(2) Å (**5**) and 1.216(3) Å (**6**).

The molecules are held together in the crystals by van der Waals forces and by intermolecular H-bonding between the hydroxyl group and the carbonyl O atom. The O··O distance in **5** is 2.760(2) Å, while the C2-O2··O1 and O2-H2··O1 angles are 101.4(1) and 145.6°, respectively. For **6**, the O··O distance is 2.728(2) Å (5), with the C2-O2··O1 and O-H··O angles 103.3(1) and 170.8°.[3]

[3] The crystallographic data for the structural analyses have been deposited with the Cambridge Crystallographic Data Centre (CCDC Nos. 171073 and 171074). Having confirmed the optical purity and absolute configurations, we attempted to scale up the synthesis of the two compounds. Using a small 500-mL fermenter capable of maintaining vigorous agitation and adequate aeration, we performed several transformations on the 1–2-g scale. In these reactions, all the substrate was consumed in 24–44 h and the isolated yields of the two diastereomers (*cis*–*trans* = 57:43) were consistently between 86–92%. The isolated products were almost completely metabolite-free. Most of the *cis*-(3*R*,4*S*) isomer crystallized from EtOAc as white needles. The remaining mixture, consisting of *cis*-(3*R*,4*S*) and *trans*-(3*R*,4*R*) (20:80), was separated by flash chromatography to give additional pure *cis*-(3*R*,4*S*) and *trans*-(3*R*,4*R*). The best total isolated yields of pure *cis*-(3*R*,4*S*) and *trans*-(3*R*,4*R*) were 96 and 89%, respectively.

In conclusion, the results described in this paper provide a simple protocol for the preparation of two optically pure diastereomers of *tert*-butyl substituted C-13 paclitaxel side-chain analogues. The absolute configuration of both compounds was established by X-ray crystallographic analysis. The *cis* isomer was previously prepared in an optically pure form via chemical synthesis involving several steps (11). Access to the *trans* isomer is difficult via chemical routes, and, to our knowledge, the biological activities of paclitaxel analogues with *trans* C-13 side-chains have not been extensively investigated. Our simple methodology makes both compounds easily available for further structure–activity studies. Although the natural stereochemistry (2′*R*,3′*S*) appears to be the most biologically active form of natural paclitaxel (13), it may not be the optimum stereochemistry for all analogues, and the availability of **5** (3*R*,4*R*) and other chains with that absolute configuration will allow us to study the impact of *erythro*-chains on the activity of paclitaxel analogues.

The results from small-scale fermentations suggest that this reaction can be adapted for a large-scale multigram fermentation, and that the two products can be easily isolated as optically pure compounds.

Finally, we would like to add a word of caution: It should not be assumed that the formation of alcohol **6** (*cis*-(3*R*,4*S*)), in an almost optically pure form, unambiguously supports our original speculation (8) that the parent ketone **4** with a bulky *tert*-butyl substituent is selectively reduced by a single yeast reductase, while the same enzyme is not selective compared with the more symmetrical phenyl-substituted compound **1.** Recent results showing that baker's yeast harbor a large number of reductases, which may compete for the same substrates, make such conclusions unwarranted without further studies leading to the identification of enzyme or enzymes involved in reduction of a particular substrate (14).

Experimental

Melting points were determined on a Fisher-Johns melting point apparatus and are uncorrected. Optical rotations were measured on a PerkinElmer 241 polarimeter operating at room temperature. IR spectra were recorded as thin films on NaCl plates on a Mattson Satellite FT-IR spectrometer. ^{1}H and ^{13}C NMR spectra were recorded in $CDCl_3$ solution at room temperature on a Bruker 200 FT-NMR spectrometer; chemical shifts are reported in ppm using Me_4Si as internal standard. *J* values are expressed in Hertz. Chiral-phase HPLC analyses were performed on a Chiracel OD-H column (4.6 × 150 mm) using hexane–isopropanol (90:10) as the mobile phase. A UV detector set at 254 nm was used to monitor the reactions. Commercial baker's yeast was obtained from a local grocery chain.

Micro baker's yeast reduction of 4-*tert*-butyl-3-oxo-β-lactam 4

Fresh baker's yeast (3 g) was added to a solution of sucrose (12 g) in sterilized water (150 mL) in a 500-mL Erlenmeyer flask. The mixture was shaken (200 rpm) for 30 min at 30°C to activate the yeast. Finely ground *tert*-butyl-β-lactam (150 mg) with β-cyclodextrin (1.2 g)[4] was added to initiate the reaction. After 32 h, the reaction mixture was saturated with NaCl and centrifuged at 3000 × *g* for 10 min to remove the yeast cells. The supernatant was extracted with EtOAc (120 mL, 2 × 80 mL). The cell pellet was also extracted with EtOAc (2 × 20 mL). The combined organic layer was washed with brine, dried over anhydrous $MgSO_4$, and concentrated in vacuum. Purification of the crude product by column chromatography on silica gel (hexane–EtOAc, 2:1) gave a mixture of diastereomers **6** and **5** (57:43, respectively, 146 mg, 97%). Separation by spinning

[4] It is possible to perform this transformation without β-cyclodextrin; however, the reaction is slower and thus more metabolites are present in the product mixture.

© 2002 NRC Canada

chromatotron using hexane–EtOAc (4:1 to 3:1) as the eluent gave **6** (66 mg), **5** (15 mg), and a mixture **6** and **5** (65 mg, 27:73). Recrystallization from EtOAc and hexane yielded optically pure product **6** as white needles and optically pure **5** as colourless cubic crystals.

Small-scale fermentation

Dry baker's yeast (10 g) was added to a solution of sucrose (40 g) in sterilized water (400 mL) contained in a 500-mL fermenter. The mixture was stirred vigorously at 30°C for 30 min to activate the yeast. The aeration was maintained at 230 mL min^{-1}. Finely ground 4-*tert*-butyl-3-oxo-β-lactam (1 g) with β-cyclodextrin (200 mg)[4] was added to the fermenting yeast and the reaction was monitored by GC. After 26 h, the conversion was 98% and the reaction was stopped since prolonging the transformation results in the formation of metabolites. The reaction mixture was saturated with NaCl and centrifuged at 3000 × *g* for 10 min to remove yeast cells. The cell pellet was washed with EtOAc. The supernatant was extracted continuously with EtOAc for 24 h and the combined extracts were washed with brine and dried over anhydrous $MgSO_4$. After removing the solvent under reduced pressure, the crude product was crystallized from EtOAc to yield (4*R*,3*S*)-4-*tert*-butyl-3-hydroxy-β-lactam (439 mg) as white crystals (>95% ee). The remaining mixture consisting of *cis*-(3*R*,4*S*) and *trans*-(3*R*,4*R*) (in a 20:80 ratio) was separated by flash chromatography using hexane–EtOAc (5:1 then 2:1) as the eluent to give an additional 59 mg of *cis*-(3*R*,4*S*) and 349 mg of *trans*-(3*R*,4*R*). The total isolated yields of pure *cis*-(3*R*,4*S*) and *trans*-(3*R*,4*R*) were 96% and 87%, respectively.

X-ray crystal structure analysis

The two compounds were crystallized from a diisopropylether–dichloromethane mixture. They were measured on an Enraf-Nonius CAD-4 diffractometer operating with the Cu Kα radiation. The intensity data were collected at room temperature (whole sphere) and were corrected for the effects of Lorentz and polarization. Crystal **6** was also corrected for absorption (integration). The SHELXTL system was used for all calculations and drawings. The coordinates of the first set of atoms were determined by direct methods and the positions of all the other atoms were found by the standard Fourier method. The structures were refined on F_o^2 using all reflections. The H atoms were fixed in idealized positions using a riding model with displacement parameters (U_{eq}) of 1.2U_{eq} (1.5 for methyl or hydroxyl groups) of the parent atom.

The Flack parameters (–0.1(3) for **5** and 0.1(3) for **6**) confirmed the absolute configuration of the two compounds.

Acknowledgments

Financial support (FDR and MMK) by the Natural Sciences and Engineering Research Council (NSERC) of Canada and Medical Research Fund of New Brunswick (MMK) are gratefully acknowledged. The NMR spectra were recorded at the Atlantic Regional Magnetic Resonance Centre at Dalhousie University, Halifax, Canada. The authors thank Dr. D.L. Hooper for the spectra with chiral solvating agents.

Fixed stereochemical control in the synthesis of new mono- and disubstituted 2-phenyl-6-aza-1,3-dioxa-2-borabenzocyclononenes

Hiram I. Beltrán, S. Jesús Alas, Rosa Santillan, and Norberto Farfán

Abstract: Five new boronates of the type 2-phenyl-6-aza-1,3-dioxa-2-borabenzocyclononenes (**6a**–**e**) were prepared from substituted 2-[(2-hydroxyethylamino)methyl]phenols (**4a**–**e**) and phenylboronic acid (**5**) in benzene–EtOH (4:1) mixtures. Tridentate ligands **4a**–**e** and boronates **6a**–**e** were characterized by ^{1}H, ^{13}C, ^{15}N, and 2D-NMR (HETCOR, NOESY, and COLOC) experiments, FT-IR, mass spectra, and elemental analysis, as well as ^{11}B NMR for the boron derivatives. Suitable monocrystals of 2-[(2-hydroxyethylamino)methyl]phenol hydrochloride (**4a**), *cis*-2-phenyl-6-aza-1,3-dioxa-2-borabenzocyclononene (**6a**), (2*S*,5*R*,6*S*)-2,5-diphenyl-6-aza-1,3-dioxa-2-borabenzocyclononene (**6b**), and (2*S*,4*R*,5*R*,6*S*)-2,4-diphenyl-5-methyl-6-aza-1,3-dioxa-2-borabenzocyclononene (**6e**) were obtained and their structures are discussed. The X-ray structures of **6a**, **6b**, and **6e**, as well as the NMR data established that the configurations at the nitrogen and boron atoms are both "*S*" and the transannular fusion is *cis*. A semi-empirical (SAM1) study was used to calculate the energy for all possible stereoisomers, showing that the stabilization increases as the THC (tetrahedral character of the boron atom) increases and also as the N→B bond distance decreases, in agreement with the experimental results and previous work related to amino acid boronates.

Key words: boron compounds, X-ray structures, NMR, boronates, synthesis.

Résumé : On a préparé cinq nouveaux boronates du type 2-phényl-6-aza-1,3-dioxa-2-borabenzocyclononènes (**6a**–**e**) en faisant réagit des 2-[(2-hydroxyéthylamino)méthyl]phénols substitués (**4a**–**e**) avec de l'acide phénylboronique (**5**) dans des mélanges 4:1 de benzène–éthanol. Les ligands tridentates (**4a**–**e**) et les boronates (**6a**–**e**) ont été caractérisés par les analyses élémentaires, par infrarouge à transformée de Fourier, par des expériences de RMN du ^{1}H, du ^{13}C, du ^{15}N et par RMN-2D (HETCOR, NOESY et COLOC) ainsi que par RMN du ^{11}B pour les dérivés du bore. On a obtenu des monocristaux appropriés du chlorhydrate du 2-[(2-hydroxyéthylamino)méthyl]phénol (**4a**), du *cis*-2-phényl-6-aza-1,3-dioxa-2-borabenzocyclononène (**6a**), du (2*S*,5*R*,6*S*)-2,5-diphényl-6-aza-1,3-dioxa-2-borabenzocyclononène (**6b**) et du (2*S*,4*R*,5*R*,6*S*)-2,4-diphényl-5-méthyl-6-aza-1,3-dioxo-2-borabenzo-cyclononène (**6e**) et on discute de leurs structures. Les structures des composés **6a**, **6b** et **6e** déterminées par diffraction des rayons-X ainsi que les données de la RMN ont permis d'établir que les configurations au niveau des atomes d'azote et du bore sont toutes les deux *S* et que la fusion transannulaire est *cis*. On a fait appel à des calculs semi-empiriques (SAM1) pour calculer l'énergie des tous les stéréoisomères possibles; ils montrent que la stabilisation augmente avec une augmentation du caractère tétraédrique de l'atome de bore ainsi qu'avec une diminution de la longueur de la distance N→B, en accord avec les données expérimentales obtenues ici et avec celles obtenues dans un travail antérieur sur des boronates apparentés d'acides aminés.

Mots clés : composés du bore, structures par diffraction des rayons X, RMN, boronates, synthèse.

[Traduit par la Rédaction]

Introduction

In previous studies we described the syntheses of a series of mono-, di-, tri-, and tetrameric boronates derived from tridentate ligands (1–8). These ligands possess one nitrogen and two oxygen donor atoms with several variations in the main skeleton, which allowed for the evaluation of the steric and electronic effects (Fig. 1). The studies showed that, in all cases, the boron atom is tetracoordinated and forms a coordinative bond with the nitrogen atom (6), which is responsible for the self-assembly of the macrocycles, whereby the oxygens build up five- or six-membered rings as well as intermolecular boron–oxygen bonds. Moreover, the reaction product is mainly dependent on the structure of the ligand and, to a lesser extent, on the steric and electronic factors. The use of a tridentate ligand such as 2,6-pyridinedimethanol lead to a tetrameric compound containing four 5-membered- and one 20-membered ring by self-assembly (1). The stabilization of all these compounds is due to tetracoordination of the boron atom.

It has been reported that the formation of dimeric and monomeric structures is highly dependent on reaction conditions as well as the structure of the salicylidenimino alcohol. It is therefore possible in certain cases to obtain either the

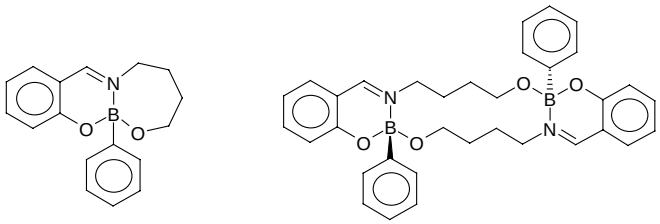

Fig. 3. Stereochemistry for the fused rings in amino acid boronates.

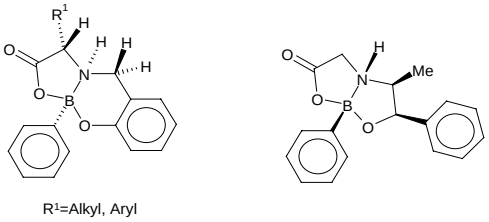

dimeric or monomeric derivatives in high yields by using kinetic or thermodynamic control (Fig. 2) (7). The use of long reaction times leads to monomeric structures (7, 8). In general, the N→B bond distances are between 1.6 and 1.7 Å, characteristic for dative nitrogen–boron bonds (1–13), and the boron atom shows a distorted tetrahedral geometry.

Regarding the stereochemistry of these compounds, a literature search showed preference for *cis*-fused transannular N→B bond (8–30). Moreover, the presence of a stereogenic center in the five-membered ring induces formation of the *cis–cis* isomer (8, 12) (Fig. 3).

Continuing in our investigations, we describe herein the preparation and complete characterization of five new 4,5-disubstituted-2-phenyl-6-aza-1,3-dioxa-2-borabenzocyclononenes (**6a**–**e**) prepared from 2-[(2-hydroxyethylamino)methyl]phenols (**4a**–**e**) and phenylboronic acid (**2**). Some of the phenols have found application as chelating agents for Cu(II) (31) and in catalytic enantioselective hydrogenation of ketones with ruthenium (32). Analogous compounds have been prepared by reduction of the corresponding Schiff base (33) and hydrogen-bonded structures for these derivatives have been reported (31, 34).

The aim of this work is to investigate the influence of nitrogen hybridization and the acidity of the amino alcohol to selectively form monomeric or dimeric boronates, since increased flexibility in the ligand should lead to release of strain at the fused bicyclic structure. In addition, it was desirable to establish the stereochemistry of these new boronates, which possess two fixed chiral atoms (nitrogen and boron) and to compare the theoretical and experimental results.

Tridentate ligands **4a**–**e** and monomeric boronates **6a**–**e** were characterized by ^{1}H, ^{13}C, ^{15}N, and 2D-NMR (HETCOR, NOESY, and COLOC) experiments, FT-IR, mass spectra, and additionally for boronates, the ^{11}B NMR spectra were recorded. Suitable monocrystals of 2-[(2-hydroxyethylamino)methyl]phenol hydrochloride (**4a**), *cis*-2-phenyl-6-aza-1,3-dioxa-2-borabenzocyclononene (**6a**), (2*S*,5*R*,6*S*)-2,5-diphenyl-6-aza-1,3-dioxa-2-borabenzocyclononene (**6b**) and (2*S*,4*R*,5*R*,6*S*)-2,4-diphenyl-5-methyl-6-aza-1,3-dioxa-2-borabenzocyclononene (**6e**) were obtained. The theoretical calculations (SAM1) support that compounds **6a**–**e** are energetically favored and indeed all the products obtained show *cis–cis* stereochemistry.

Results and discussion

Synthesis of 2-[(2-hydroxyethylamino)methyl]phenol hydrochlorides (4a–e)

The synthetic route to prepare 2-[(2-hydroxyethylamino)methyl]phenols **4a**–**e** involved the reaction of β-aminoalcohols **1a**–**e** with an equimolecular ratio of salicylaldehyde **2** under reflux of THF–MeOH (1:1) for 4 h to give corresponding Schiff bases **3a**–**e**, followed by reduction with sodium borohydride (Scheme 1). The products were obtained in moderate to high yields.

Synthesis of 4,5-disubstituted 2-phenyl-6-aza-1,3-dioxa-2-borabenzocyclononenes (6a–e)

The condensation of 2-[(2-hydroxyethylamino)methyl]phenol hydrochlorides **4a**–**e** with phenylboronic acid **5** in the presence of an excess of sodium bicarbonate was carried out at reflux in benzene–EtOH mixtures to yield the corresponding (2*S*,5*S*,6*R*)-2-phenyl-6-aza-1,3-dioxa-4,5-(*R*,*R*′)-2-borabenzocyclononenes **6a**–**e** in yields from 69 to 89%. These tricyclic derivatives show transannular N→B bonds with a tetrahedral geometry for the boron and nitrogen atoms (35) as well as five- and six-membered fused rings. In all cases, the configurations at positions 2, 5, and 6 are *S*, *R*, and *S*, respectively (Scheme 1).

Spectroscopic data

The ^{1}H NMR data of 2-[(2-hydroxyethylamino)methyl] phenol hydrochlorides **4a**–**e** is summarized in Table 1; ^{13}C and ^{15}N NMR are given in Table 2. For 4,5-disubstituted-2-phenyl-6-aza-1,3-dioxa-2-borabenzocyclononenes **6a**–**e**, the

^{1}H and ^{13}C NMR data are given in Tables 3 and 4, respectively. Table 5 summarizes the ^{15}N and ^{11}B NMR data.

NMR data of 2-[(2-hydroxyethylamino)methyl]phenol hydrochlorides (4a–e)

The ^{1}H NMR spectra show the phenolic OH between 10.42 and 9.68 ppm, followed by the nitrogen protons (H-3a and H-3b) in the range from 10.10 to 8.05 ppm — these protons are diastereotopic in **4b**–**e** and the proton antiperiplanar to the substituent is shifted to higher frequencies and labeled as H-3a. The salicylidene fragment shows an ABCD system, with H-10 observed as a double of doublets at higher frequency, followed by H-8 (ddd or t), H-7 (ddd), and H-9 (ddd or t). The protons in position 4 are diastereotopic for compounds **4b** and **4c**, showing an AB system with coupling constants of 13.2 Hz; for the remaining compounds these protons give rise to broad signals. Hydrogens in positions 1 and 2 are shifted according to substitution; for example, the signals for **4b** give an ABX system for protons H-1a, H-1b, and H-2 with a geminal coupling constant of 11.4 Hz and AX and BX couplings of 5.1 and 7.0 Hz, respectively.

The ^{13}C NMR spectra show the following trends: the resonance for C-6 always appears at higher frequencies (156.6 and 155.7 ppm) followed by C-10 (132.1–131.4 ppm), and C-8 (131.2–130.2 ppm); C-9 shows chemical shifts between 120.4 and 119.0 ppm, C-5 between 118.6 and 116.5 ppm, and C-7 is the most shielded at 116.6 to 115.4 ppm. The chemical shifts for C-1 and C-2 depend on substitution: a phenyl group at position 1 shifts the signal to higher frequencies ($\Delta\delta$ = 18.2 and 13.5 ppm, respectively) and a

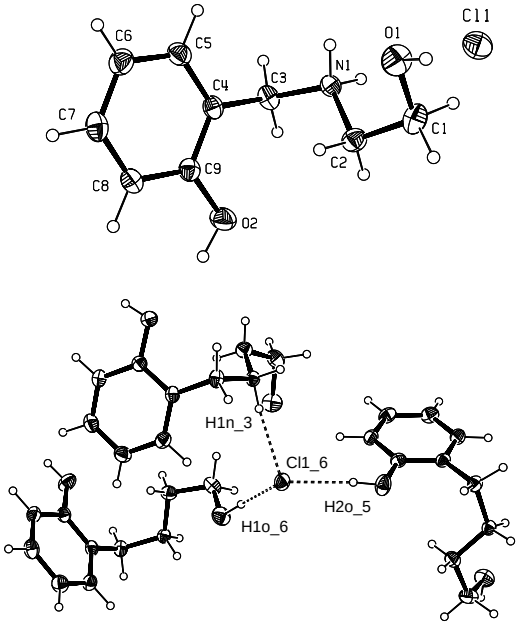
[d]**4e**: 139.5 (C-11), 127.2 (C-12), 128.8 (C-13), 128.7 (C-14), 12.1 (C-15).

Fig. 4. Molecular structure of **4a**.



similar behavior is observed for C-2. The shift induced by a methyl group is less than for phenyl substituents, thus C-4 appears between 46.0 and 43.3 ppm, showing no significant variations due to substitution.

Since all ^{15}N NMR spectra were determined on HCl derivatives, their chemical shifts are shifted to lower frequencies. Substituents at the β position show an additive effect with respect to compound **4a**. The ^{15}N chemical shift for **4a** is shifted to lower frequencies with respect to compounds **4b**–**e**, which show $\Delta\delta \approx 10$ ppm.

NMR data of 4,5-disubstituted 2-phenyl-6-aza-1,3-dioxa-2-borabenzocyclononenes (6a–e)

The ^{1}H NMR data for compounds **6a**–**e** show that H-12 is the most deshielded signal (7.72–7.48 ppm), followed by H-13 and H-14 (7.34 and 7.20 ppm, respectively). The chemical shift for the benzylidene fragment and the hydrogens at positions 1, 2, and 4 are very similar to those of the Schiff bases, while that of H-3 depends on the anisotropy of the vicinal group (7.29 (**6a**), 7.27 (**6b**), 6.87 ppm (**6c**)). The existence of two phenyl groups in **6d** shifts the signal to 4.07 ppm. In **6e**, methyl substitution at the opposite side of H-3 modifies the conformation at the five-membered ring in such a way that both phenyl groups affect its environment and there is an extra anisotropic contribution (4.32 ppm). For compound **6a**, the couplings for these signals were difficult to assign and selective decoupling experiments were carried out. Hydrogens at the 3 and 4 positions appear as an ABC system, with an additional coupling between H-4a and H-3.

The difference in chemical shifts with respect to the Schiff bases is approximately 1 ppm and the most shielded signal is C-6. The ipso (to boron) carbon (C-11) is observed in the range between 146.2 and 144.6 ppm, followed by the *ortho* (C-12), *meta* (C-13), and *para* carbons (C-14), which were assigned using HETCOR experiments.

The ^{15}N NMR chemical shifts of **6a**–**e** (–331.8 to –312.1) and those of tridentate ligands **4a**–**e** (Table 2), are in the characteristic range for tetracoordinated nitrogen atoms (36). In ^{11}B NMR, the signals are observed from 5.1 to 6.0 ppm, characteristic for tetracoordinated boron atoms (37).

IR and MS data of 4a–e and 6a–e

The IR spectra of compounds **4a**–**e** show strong N–H and O–H stretching bands, while the IR spectra of compounds **6a**–**e** show only the N–H band. The mass spectra of **4a**–**e** show the molecular ion peak, along with the loss of hydrochloric acid, and the hydroxytropylium and cycloheptatrienone ions. In most cases M^+, $[M - C_6H_5]^+$, and $[M - C_6H_6]^+$ are observed.

Molecular structures of 4a, 6a, 6b, and 6e

Crystallographic data for **4a**, **6a**, **6b**, and **6e** are listed in Table 6; selected bond lengths, bond angles, torsion angles, and plane deviations are summarized in Table 7. The molecular structures are shown in Figs. 4–7.

For **4a** all distances are in agreement with reported values (31, 34). The salicylidene and β-amino alcohol fragments have *gauche* conformations, with C(2)-N(1)-C(3)-C(4) and O(1)-C(1)-C(2)-N(1) torsion angles of 60.63(21)° and 58.17(22)°, respectively. There are two hydrogen-bonding interactions in the asymmetric unit, one intramolecular contact between H(1n) and O(1) with a magnitude of 2.359(23) Å (which is mostly responsible for the *gauche* conformation in this fragment), and a second intramolecular contact between Cl(1) and H(1o) with a value of 2.295(29) Å. There are also important interactions with the neighboring molecules. The first is for both hydrogens attached to nitrogen (H(1n)···Cl(1) = 2.376(25) Å, H(2n)···Cl(1) = 2.241(24) Å), and the second one between chlorines at opposite sides of the molecule and the phenolic hydrogen (H(2o)···Cl(1) = 2.202(33) Å).

With respect to the boronates, compounds **6a** and **6b** are shown in Fig. 5, while compound **6e** is shown in Fig. 6. Compound **6e** crystallized with a molecule of benzene and there are three different molecules in the unit cell. The concluding remarks of the obtained X-ray structures are as follows: (*i*) the N→B distances found are 1.647(2) Å for **6a**, 1.635(3) Å for **6b**, and 1.615(6), 1.643(3), 1.620(6) Å for **6e**, in agreement with the distances found in similar derivatives described in the literature (1–30). (*ii*) The B—$O_{aliphatic}$ distances are 1.465(2) Å for **6a**, 1.455(3) Å for **6b**, and 1.447(6), 1.454(6), 1.457(5) Å for **6**,which are also in agreement with values found for similar compounds (7, 8). (*iii*) The B—$O_{phenolic}$ distances are 1.462(2) Å for **6a**, 1.463(3) Å for **6b**, and 1.475(6), 1.459(6), 1.472(6) Å for **6e**, in agreement with the literature values for the same fragment (8). The structures possess similar dihedral angles for the H-N(1)→B(1)-C(10) fragment; the differences are due to the nature of the R^3 substituent in position 2 and, to a lesser extent, to the R^1 and R^2 substituents in position 1, resulting in dihedral angles of 18.16(126)° for **6a**, –38.72(172)° for **6b**, and –47.60(47)°, –48.79(44)°, –49.85(45)° for **6e**. Additionally, there are intermolecular hydrogen bonds between the NH proton and the aliphatic oxygen O(1) with magnitudes of 1.906(20) Å for **6a**, 2.256(24) Å for **6b**, and 2.313(3) and 2.327(3) Å for **6e**. In all cases, the six-membered ring containing the B-N-C(3)-C(4)-C(5)-O(3) fragment has a twisted boat conformation, the five-membered ring formed by the B-N-C(2)-C(1)-O(1) moiety (**6a** and **6b**) are in the half-chair conformation, with C(1) and C(2) out of the plane, and the three molecules in **6e** have envelope conformations with N(1) out of the plane.

Fig. 5. Molecular structures of **6a** and **6b**.

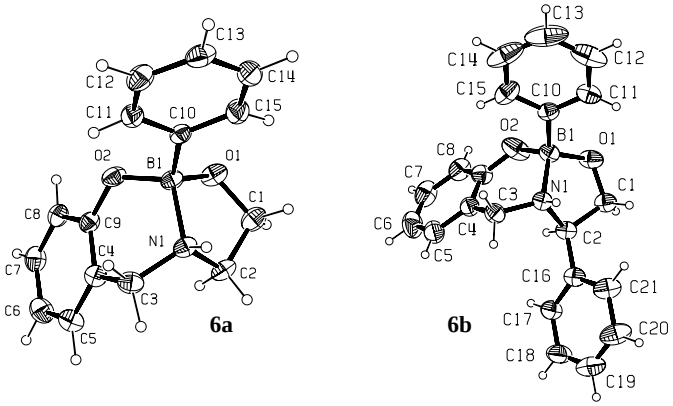

Fig. 6. Unit cell for compound **6e**.

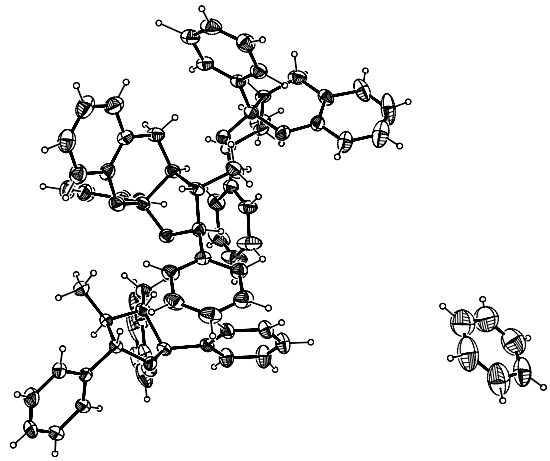

The tetrahedral character (THC) of the boron atom (38) is a useful parameter to evaluate the geometry of the boron atom for crystalline boronates (**6a**, **6b**, and **6e**). The THC was calculated from the boron-bond angles obtained by X-ray analysis as described by Höpfl (38), whereby a value of 100% corresponds to a perfect tetrahedral structure for boron. The values of THC (%) are 80.13 for **6a**, 76.86 for **6b**, and 74.44, 70.08, and 71.39 for **6e**. It is important to mention that the lower bond angle measured corresponds to the O(1)-B(1)-N(1) angle with THC values of 100.37(14)° for **6a**, 101.23(19)° for **6b**, and 101.1(4)°, 99.64(28)°, and 99.89(29)° for **6e**. This can be attributed to ring fusion.

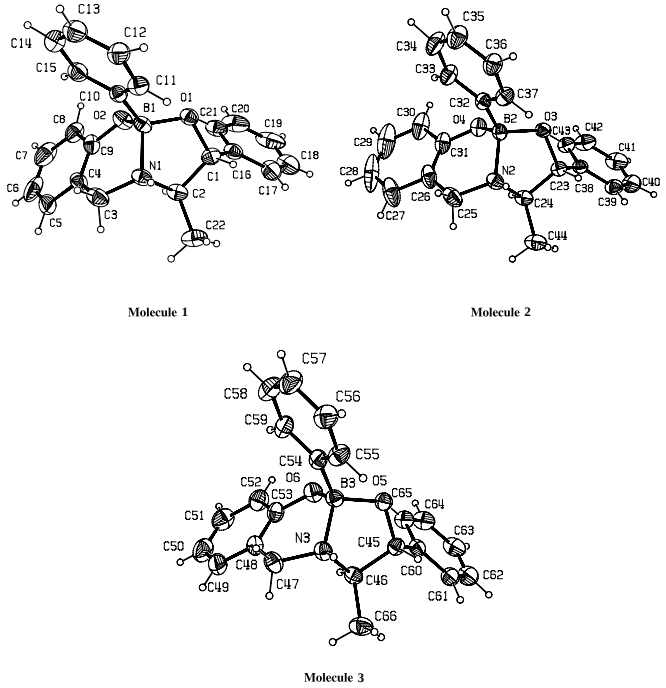
Semi-empirical calculations of boronates 6–9

To evaluate the influence of steric factors on this reaction, the geometry for all possible stereoisomers was determined by using a theoretical (AM1) approach (Fig. 8).

The computational study for semi-empirical calculations (AM1 method) was performed with Hyperchem (39). A full set of semi-empirical optimizations was carried out to determine the main preferences to obtain just the 2(*R*), N(*S*), B(*S*)

© 2002 NRC Canada

Fig. 7. Molecular structure of **6e**.



products (**6a**–**e**); all the stationary points were classified as minima by Hessian-matrix calculations with the same method (AM1). The coordinates used to obtain SAM1 results were obtained from X-ray analyses.

The data for compounds **6a**–**e**, **7a**–**e**, **8a**–**e**, and **9a**–**e** have been deposited as supplementary material.[2] All possible stereoisomers were minimized. In the case of compound **6a**, which was determined experimentally, there is only one counterpart (compound **8a**), while the remaining compounds have four possible stereoisomers. The data confirm that the compounds obtained experimentally are enthalpically favored, and there is an important steric effect controlling the formation of these fused compounds. The energy gap between stereoisomers **6** and **7** is between 5.2 and 3.1 kcal mol^{-1}, and they show two eclipsed interactions, while stereoisomers **8** and **9** show four *gauche* interactions. The deviation of the fused structure (*cis* or *trans*) depends directly on the substituent effect, as evidenced by the H-N-B-Ph torsion angles.

The calculated properties for each stereoisomeric series show that both the N→B bond length and the energy are inversely proportional to the THC values (supplementary material).[2]

Conclusions

In conclusion, boron compounds derived from the tridentate ligands **4a**–**e** yield fused five- and six-membered rings due to N→B bond formation (**6a**–**e**). In all cases, the ring fusion for the H-N→B-Ph fragment is *cis*, and the reaction is highly stereoselective yielding structures with "*S*" configuration at both the boron and the nitrogen atoms (**6b**–**e**). This was demonstrated by 2D-NMR NOESY experiments and confirmed by the X-ray analysis of compounds **6a**, **6b**, and **6e**. There is an increased tension at the five-membered ring; hence, the deviation of the boron atom from the idealized tetrahedral geometry is on average 77.5%. The theoretical calculations are in good agreement with the experimental data. These compounds show the same behavior as those containing tridentate ligands derived from amino acids. THC is a powerful tool to evaluate the stabilization of these types of molecules. The results show that the greater the stabilization of the compounds, the greater the THC value. In addition, there is a significant influence on the configuration of these newly formed stereogenic centers associated with the N→B bond lengths.

Fig. 8. Possible stereoisomers relative to the R^3 position.

	R^1	R^2	R^3
a	H	H	H
b	H	H	C_6H_5
c	C_6H_5	H	CH_3
d	C_6H_5	H	C_6H_5
e	H	CH_3	C_6H_5

Experimental

NMR experiments were performed on a Jeol Eclipse+400 spectrometer at room temperature. All ^1H and ^{13}C resonances are reported relative to TMS, ^{15}N resonances are relative to neat $MeNO_2$, ^{11}B spectra were obtained relative to $BF_3 \cdot OEt_2$, and all the samples were determined in DMSO-d_6 as solvent. The IR spectra were recorded as KBr pellets on a PerkinElmer 16F PC FT-IR spectrometer. Mass spectra were recorded on a Hewlett-Packard 59940-A spectrometer at 20 eV electron impact. Melting points were measured in open capillary tubes on a Gallenkamp MFB 595 apparatus and have not been corrected. Elemental analyses were determined on an Eager 300 equipment.

Preparation of 2-[(2-hydroxyethylamino)methyl]phenols (4a–e)

2-[(2-Hydroxyethylamino)methyl] phenol hydrochloride (4a)

Compound **4a** was prepared from 0.50 g (8.18 mmol) of ethanolamine (**1a**) and 1.00 g (8.18 mmol) of

salicylaldehyde (**2**) under reflux in a THF–MeOH mixture for 4 h to give **3a**, followed by reduction with 0.62 g (16.36 mmol) of sodium borohydride, and addition of 3.4 mL (40.90 mmol) of hydrochloric acid, to obtain a white solid. Suitable crystals were obtained from methanol. Yield 94% (1.57 g, 7.71 mmol); mp 152–154°C. IR ν_{max} (KBr, cm^{-1}): 3402, 3198, 3082, 2964, 2882, 2842, 2794, 2778, 1594, 1590, 1458, 1440, 1404, 1364, 1260, 1246, 1108, 1076, 922, 762. MS (20 eV) *m*/*z* (%): 167 (27), 136 (77), 107 (100), 77 (15). Anal. calcd. for $C_9H_{14}ClNO_2$: C 53.08, H 6.93, N 6.88; found: C 53.17, H 6.97, N 6.84.

*(***R***)-2-[(2-Hydroxy-1-phenylethylamino)methyl]phenol hydrochloride (4b)*

Compound **4b** was prepared from 0.50 g (3.64 mmol) of (*R*)-(–)-2-phenylglycinol (**1b**) and 0.45 g (3.64 mmol) of salicylaldehyde (**2**), to obtain a highly hygroscopic yellow powder. Yield 77% (0.79 g, 2.82 mmol); mp 83–85°C. IR ν_{max} (NaCl, cm^{-1}): 2928, 1596, 1458, 1420, 1264, 758, 734, 700, 496, 460, 454. MS (20 eV) *m*/*z* (%): 212 ([M^+], 41), 122 (2), 107 (29), 106 (100), 77 (4). Anal. calcd. for $C_{15}H_{18}ClNO_2$: C 64.40, H 6.49, N 5.01; found: C 64.25, H 6.53, N 5.16.

*(1***R***,2***S***)-2-[(2-Hydroxy-1-methyl-2-phenylethylamino)methyl]phenol (4c)*

Compound **4c** was prepared from 0.50 g (3.30 mmol) of (1*R*,2*S*)-(–)-norephedrine (**1c**) and 0.40 g (3.30 mmol) of salicylaldehyde (**2**), to give the product as a white solid. Yield 64% (0.62 g, 2.11 mmol); mp 164–166°C. IR ν_{max} (KBr, cm^{-1}): 3398, 3274, 3072, 2956, 2846, 1598, 1462, 1404, 1352, 1266, 1244, 748, 702. MS *m*/*z* (%): 293 ([M^+], 0.1), 257 (1.4), 150 (100), 122 (0.6), 107 (46.2), 106 (5.4), 77 (5.6). Anal. calcd. for $C_{16}H_{20}ClNO_2$: C 65.41, H 6.86, N 4.77; found: C 65.41, H 6.87, N 5.03.

*(1***S***,2***R***)-2-[(2-Hydroxy-1,2-diphenylethylamino)methyl]phenol (4d)*

Compound **4d** was prepared from 0.50 g (2.34 mmol) of (1*S*,2*R*)-(+)-2-amino-1,2-diphenylethanol (**1d**) and 0.29 g (2.34 mmol) of salicylaldehyde (**2**), to afford **4d** as a white powder. Yield 93% (0.78 g, 2.19 mmol); mp 188–190°C. IR ν_{max} (KBr, cm^{-1}): 3302, 3174, 3064, 3032, 2924, 2850, 1458, 758, 750, 700. MS *m*/*z* (%): 319 (0.4), 212 (87.2), 122 (0.9), 107 (32.9), 106 (100), 77 (5.9). Anal. calcd. for $C_{21}H_{22}ClNO_2$: C 70.88, H 6.23, N 3.94; found: C 70.85, H 6.25, N 3.95.

*(1***R***,2***R***)-2-[(2-Hydroxy-1-methyl-2-phenylethylamino)methyl]phenol (4e)*

Compound **4e** was prepared from 0.50 g (3.30 mmol) of (1*R*,2*R*)-(–)-norpseudoephedrine (**1e**) and 0.40 g (3.30 mmol) of salicylaldehyde (**2**), to give **4e** as a white hygroscopic solid. Yield 71% (0.69 g, 2.35 mmol); mp 50–52°C. IR ν_{max} (KBr, cm^{-1}): 3190, 2940, 1610, 1598, 1458, 1388, 1352, 1262, 1040, 1024, 758, 702. MS *m*/*z* (%): 257 (1.3), 150 (100), 122 (0.7), 107 (53.7), 106 (4.4), 77 (5.7). Anal. calcd. for $C_{16}H_{20}ClNO_2$: C 65.41, H 6.86, N 4.77; found: C 65.66, H 6.74, N 4.62.

Preparation of 4,5-disubstituted 2-phenyl-6-aza-1,3-dioxa-2-borabenzocyclononenes (6a–e)

cis-*2-Phenyl-6-aza-1,3-dioxa-2-borabenzocyclononene (6a)*

Compound **6a** was prepared by the reaction of 0.50 g (2.45 mmol) of **4a**, 0.30 g (2.45 mmol) phenylboronic acid (**5**), and 0.31 g (3.68 mmol) of sodium bicarbonate in a benzene–EtOH mixture for 12 h, to give a white solid; yield 69% (0.43 g, 1.70 mmol). Suitable monocrystals were obtained from a CH_2Cl_2–hexane mixture (4:1) ; mp 239–241°C. IR ν_{max} (KBr, cm^{-1}): 3068, 2962, 2944, 2928, 2900, 2870, 2740, 2664, 2620, 2552, 1608, 1488, 1462, 1452, 1432, 1378, 1368, 1292, 1266, 1248, 1216, 1202, 1180, 1112, 1082, 1038, 1016, 994, 982, 958, 938, 874, 822, 760, 738, 704. MS *m*/*z* (%): 253 ([M^+], 0.9), 222 (5.0), 176 (100), 175 (60.1), 174 (36.6), 147 (11.4), 146 (8.1), 107 (5.4), 91 (5.7), 77 (1.1). Anal. calcd. for $C_{15}H_{16}BNO_2$: C 71.18, H 6.37, N 5.53; found: C 71.45, H 6.41, N 5.76.

*(2***S***,5***R***,6***S***)-2,5-Diphenyl-6-aza-1,3-dioxa-2-borabenzocyclononene (6b)*

Compound **6b** was prepared from 0.30 g (1.07 mmol) of **4b**, 0.13 g (1.07 mmol) of phenylboronic acid (**5**), and 0.14 g (1.61 mmol) of sodium bicarbonate, to give **6b** as a brown solid; yield 74% (0.26 g, 0.80 mmol). Suitable monocrystals were obtained from a CH_2Cl_2–acetone–hexane mixture (2:1:4); mp 251–253°C. IR ν_{max} (KBr, cm^{-1}): 3066, 3004, 2954, 2928, 2870, 1608, 1490, 1460, 1448, 1432, 1300, 1286, 1238, 1214, 1186, 1114, 1080, 1062, 1042, 1034, 1004, 994, 970, 946, 872, 754, 740, 700. MS *m*/*z* (%): 329 ([M^+], 2), 298 (2), 252 (100), 251 (47), 250 (13), 174 (3), 146 (4), 107 (2), 91 (44), 77 (1). Anal. calcd. for $C_{21}H_{20}BNO_2$: C 76.62, H 6.12, N 4.25; found: C 76.33, H 6.05, N 4.12.

*(2***S***,4***S***,5***R***,6***S***)-2,4-Diphenyl-5-methyl-6-aza-1,3-dioxa-2-borabenzocyclononene (6c)*

Compound **6c** was prepared from 0.30 g (1.02 mmol) of **4c**, 0.12 g (1.02 mmol) of phenylboronic acid (**5**), and 0.13 g (1.53 mmol) of sodium bicarbonate, to give **6c** as a white solid; yield 89% (0.31 g, 1.27 mmol); mp 90–92°C. IR ν_{max} (KBr, cm^{-1}): 1488, 1462, 1432, 1300, 1284, 1266, 1220, 1112, 1102, 1080, 1042, 1026, 1010, 998, 956, 742, 700. MS *m*/*z* (%): 343 ([M^+], 3), 299 (1), 266 (100), 265 (40), 264 (8), 236 (9), 194 (42), 107 (2), 106 (1), 105 (10), 91 (4), 90 (8). Anal. calcd. for $C_{22}H_{22}BNO_2$: C 76.99, H 6.46, N 4.08; found: C 76.76, H 6.71, N 3.79.

*(2***S***,4***S***,5***R***,6***S***)-2,4,5-Triphenyl-6-aza-1,3-dioxa-2-borabenzocyclononene (6d)*

Compound **6d** was prepared from 0.30 g (0.84 mmol) of **4d**, 0.10 g (0.84 mmol) of phenylboronic acid (**5**), and 0.11 g (1.26 mmol) of sodium bicarbonate, to give **6d** as a white solid; yield 80% (0.27 g, 0.67 mmol); mp 204–206°C. IR ν_{max} (KBr, cm^{-1}): 1490, 1462, 1452, 1300, 1282, 1222, 1208, 1112, 1076, 1054, 1038, 1028, 1010, 960, 744, 724, 698. © 2002 NRC Canada

(2S,4R,5R,6S)-2,4-Diphenyl-5-methyl-6-aza-1,3-dioxa-2-borabenzocyclononene (6e)

Compound **6e** was prepared from 0.30 g (1.02 mmol) of **4e**, 0.12 g (1.02 mmol) of phenylboronic acid (**5**), and 0.13 g (1.53 mmol) of sodium bicarbonate, to give **6e** as a white solid; yield 87% (0.30 g, 0.88 mmol). Suitable monocrystals were obtained from a CH_2Cl_2–acetone–hexane mixture (2:1:4); mp 160–162°C. IR ν_{max} (KBr, cm^{-1}): 1490, 1286, 1212, 1040, 1026, 1006, 756, 744, 704. MS *m*/*z* (%): 343 ([M^+], 3), 266 (100), 265 (44), 264 (10), 236 (3), 194 (14), 107 (2), 106 (2), 105 (18), 91 (5), 90 (5). Anal. calcd. for $C_{22}H_{22}BNO_2$: C 76.99, H 6.46, N 4.08; found: C 76.81, H 6.80, N 3.82.

X-ray structures of boronates 4a, 6a, 6b, and 6e

X-ray diffraction analyses were determined on an Enraf Nonius-CAD4 diffractometer ($\lambda_{Mo\ K\alpha}$ = 0.71073 Å, graphite monochromator, T = 293 K, ω–2θ scan mode) and on an Enraf Nonius FR590 Kappa-CCD diffractometer ($\lambda_{Mo\ K\alpha}$ = 0.71073 Å, graphite monochromator, *T* = 293 K, CCD rotation images). The crystals were mounted in Lindeman tubes. For compounds **6a** and **6b**, an absorption correction was performed with SHELX-A(40); whereas for **4a** and **6e**, an absorption correction was not necessary due to the systematic scaling integration of the reflections. For all structures, corrections were made for the Lorentz and Polarization effects. The X-ray data was obtained through SHELXS-97 for the structure solution and through SHELXL-97 ver. 34 (40) for the refinement and data output; both programs are included in WIN-GX program set (41). The corresponding images were prepared with ORTEP 3 (42). All non-hydrogen atoms were found by Fourier map differences and were fully refined by anisotropic thermal parameters. Most of hydrogen atoms were determined by difference Fourier maps and refined with one overall isotopic thermal parameter, the other non-found hydrogens were added by geometrical situation and calculation.

X-ray diffraction, Raman spectroscopic, and solid-state NMR studies of the group 14 metal–(tetracarbonyl)cobalt complexes $Ph_3MCo(CO)_4$ (M = Si, Sn, Pb)

J.M. Geller, J.H. Wosnick, I.S. Butler, D.F.R. Gilson, F.G. Morin, and F. Bélanger-Gariépy

Abstract: Single-crystal X-ray diffraction studies illustrate that the three title compounds are isomorphous, belonging to the triclinic space group $P\bar{1}$, with slightly distorted trigonal bipyramidal geometry about cobalt. The solid-state ^{29}Si, ^{119}Sn, and ^{207}Pb cross-polarization magic angle spinning (CP MAS) NMR spectra are presented. The indirect spin–spin coupling constant (J), quadrupolar–dipolar shift (d), direct dipolar coupling constant (D'), anisotropy in spin–spin coupling (ΔJ), and the chemical shift tensor were extracted. A plot of the reduced coupling constant vs. *s*-electron densities at the nucleus indicates that the Fermi contact term may be dominant for the tin and lead complexes; however, the large ΔJ for all complexes indicate that there are also significant anisotropic terms. Trends in the Raman scattering spectra are also discussed.

Key words: ^{29}Si, ^{119}Sn, and ^{207}Pb CP MAS NMR, tetracarbonyl cobalt, spin–spin coupling, chemical shift tensor, quadrupole coupling, Fermi contact, cobalt–group 14.

Résumé : Des études par diffraction des rayons X par des cristaux uniques permettent d'illustrer que les trois composés mentionnés dans le titre sont isomorphes, appartenant au groupe d'espace triclinique $P\bar{1}$, avec une géométrie bipyramidale trigonale légèrement déformée autour du cobalt. On présente des études de RMN du ^{29}Si, ^{119}Sn et du ^{207}Pb à l'état solide avec polarisation croisée à l'angle magique de rotation. On en a déduit la constante de couplage spin-spin indirecte (J), le déplacement quadripolaire–dipolaire (d), la constante de couplage dipolaire directe (D'), l'anisotropie du couplage spin–spin (ΔJ) ainsi que le tenseur du déplacement chimique. Une courbe de la constante de couplage réduite en fonction des densités des électrons s au niveau du noyau indique que le terme de contact de Fermi peut être dominant pour les complexes de l'étain et du plomb; toutefois, les valeurs importantes de ΔJ pour tous les complexes indiquent que les termes anisotropiques ont aussi une grande importance. On discute aussi des tendances dans les spectres de diffusion Raman.

Mots clés : RMN, polarisation croisée, angle magique de rotation ^{29}Si, ^{119}Sn et ^{207}Pb, cobalt tétracarbonyle, couplage spin–spin, tenseur du déplacement chimique, couplage quadripolaire, contact de Fermi, cobalt groupe 14.

Introduction

The study of transition metal complexes by NMR is widespread since the technique can give information about the electronic environment and bonding, but studies of many transition metals have been limited because they have nuclear spins >1/2 and large quadrupole moments, which lead to increased linewidths and low sensitivity. From an NMR perspective, the ^{59}Co (spin = 7/2) nucleus is attractive due to its high magnetogyric ratio ($\gamma = 6.3175 \times 10^7$ rad T^{-1} s^{-1}) and its 100% natural abundance, both of which are helpful for high receptivity. The major drawback in the study of cobalt NMR comes from the large quadrupole moment (0.4×10^{-28} m^2), which often leads to rapid relaxation. Thus, in solution, direct observation of the ^{59}Co nucleus is limited to compounds with octahedral symmetry, i.e., with low quadrupolar coupling constants. The spin-lattice relaxation times, chemical shifts, and linewidths have been reported for a series of octahedral Co(III) complexes (1).

Cobalt complexes have also been studied in solution by observing a spin –1/2 nucleus bonded to the cobalt. Solution-phase NMR studies of ^{13}CO-enriched tetracarbonyl cobalt – group 14 complexes have illustrated that a downfield shift occurs for the axial carbonyl with respect to the radial CO on going down the group, and an axial–radial exchange process occurs that can be resolved at lower

temperatures (2). Compounds of the form $(C_6H_5)_3MCo(CO)_4$, where M is a group 14 element, have been extensively studied (3–6). The solution ^{207}Pb NMR spectra were studied for the series $R_3PbCo(CO)_4$ (R = methyl, ethyl, phenyl), and the ^{207}Pb chemical shifts display a difference of over 200 ppm on changing the R group from methyl to phenyl (7).

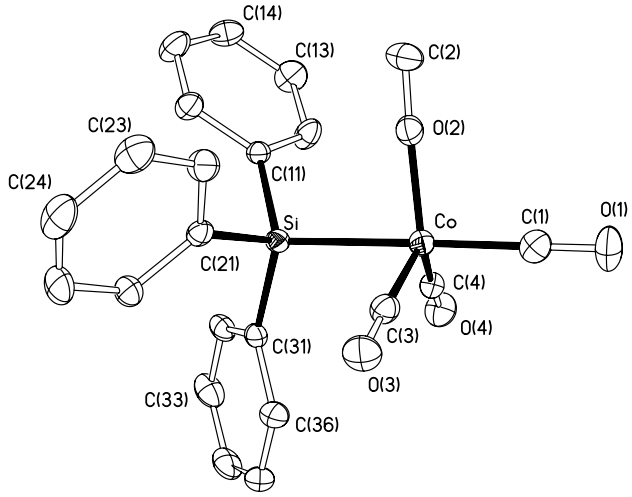
Solid-state NMR spectroscopy allows for a wider variety of compounds to be studied since the quadrupolar relaxation is slower in the solid phase. Similarly, complexes with axial symmetry are also amenable to examination. Direct excitation of the ^{59}Co central transition (+1/2 to –1/2) in solids has been reported; ^{59}Co NMR static spectra have been obtained for cobaltophthalocyanines (8), porphyrins (9, 10), and vitamin B_{12} (11). Most recently, the chemical shift tensors and orientations of the electric field gradients (EFG) were determined for a series of octahedral Co(III) complexes (12). In a number of porphyrin systems with axial symmetry, the ^{59}Co magic angle spinning (MAS) spectra were acquired directly because the quadrupolar–dipolar broadening was small (9). Both solid- and solution-state ^{59}Co NMR have been recently reviewed (13).

The ^{59}Co nuclear quadrupole coupling constants (χ) of the triphenyl silicon, tin, and lead tetracarbonyl cobalt complexes have been determined from single-crystal NMR studies. Differences in $d\pi$–$p\pi$ back-bonding to the group 14 metal (M) were postulated to influence the amount of paramagnetic shielding experienced by the ^{59}Co nucleus (14). These quadrupole coupling constants were in good agreement with the pure nuclear quadrupole resonance (NQR) frequencies reported by Brown et al. (15).

Various compounds can be examined if the ^{59}Co nucleus is studied indirectly through a spin 1/2 nucleus probe (*I*). The interest in *I*–Co spin pairs stems from the measurement of indirect spin–spin couplings ($J_{I,Co}$), which are not observed in analogous solution NMR experiments due to rapid relaxation and "self-decoupling" of the quadrupolar nucleus. The ^{31}P–^{59}Co and ^{15}N–^{59}Co spin pairs have been studied by this method (16–21). Residual dipolar coupling is also manifested in the MAS NMR spectrum of nucleus *I* by a skewing of the multiplet resulting from the *J* coupling between the *I* and *S* nuclei. More specifically, instead of observing $2S + 1$ evenly spaced peaks in the multiplet, the peaks are shifted so that the spacings are uneven. Analysis of spectra exhibiting quadrupolar-induced dipolar splitting can also yield information on the EFG tensor at the quadrupolar nucleus, the magnitude and sign of the quadrupolar coupling constant (χ), the direct dipolar coupling constant (*D*), anisotropy in spin–spin coupling (ΔJ), and the chemical shift tensor of nucleus *I*. A treatment based on first-order perturbation theory has been developed to interpret the MAS spectra of nucleus *I* (22–24).

In this paper, we present the ^{29}Si, ^{119}Sn, and ^{207}Pb solid-state CP MAS NMR spectra of the triphenyl-substituted group-14 cobalt(I) tetracarbonyls. These compounds were chosen because they contain a spin–spin (*I*–Co) pair with axial symmetry surrounding the cobalt nucleus. This work follows from our previous study on triaryl silicon–, tin–, and lead–managanese pentacarbonyls, where we illustrated that the Fermi contact term was the dominant mechanism in spin–spin coupling (25). We now make a comparison between this ^{59}Co series and the ^{55}Mn series to determine if the Fermi contact dominance in spin–spin coupling can also be established for the *I*–Co spin pairs.

Fig. 1. ORTEP diagram of $Ph_3SiCo(CO)_4$ showing 30% thermal probability ellipsoids.



Single-crystal X-ray diffraction methods were used to determine accurate molecular geometries for this series of compounds. The structure of the triphenylsilyl complex has been reported previously by McIndoe and Nicholson (26).

The approximate C_{3v} symmetry of the carbonyl groups around the cobalt nucleus led to an early interest in the vibrational spectra, with IR spectral studies of the carbonyl stretching frequencies (5), force constant calculations (6), and additional calculations by ^{12}C–^{16}O direct CO-factored methods (27). In this work, the Raman scattering spectra for the three complexes are reported.

Results and discussion

X-ray crystallography

Complexes **I**–**III** are isomorphous, crystallize in the space group $P\bar{1}$, and have one molecule per asymmetric unit. The ORTEP (36) diagrams are shown in Figs. 1–3, and details of the crystal data and structure refinements are given in Table 1. There are very few reports of Si–Co bond lengths studied by X-ray diffraction methods. In the trichlorosilyl and trifluorosilyl tetracarbonyl cobalt complexes, the Si—Co bond lengths are 2.254(3) and 2.226(5) Å, respectively (37, 38). These are significantly shorter than the Si—Co bond lengths for **I** (2.3799(14) Å) that we obtained, or the value of 2.3810(7) Å previously reported (26) for the same compound. The Co—Sn bond length in **II** (2.5950(8) Å) is within the range reported for the series $Cl_{4-x}Sn[Co(CO)_4]_x$ (x = 1–4), where the Sn—Co distances increase from 2.477(1) Å for $Cl_3SnCo(CO)_4$ (39) to 2.669(1) Å for $Sn[Co(CO)_4]_4$ (39). The Pb—Co distance in **III** is 2.667(2) Å; the only other Pb—Co bond lengths reported are 2.761(5) and 2.738(5) Å for the two independent Pb—Co distances in $Pb[Co(CO)_4]_4$ (40).

The geometry around the Co atom in all three complexes is a slightly distorted trigonal bipyramidal. For **I**–**III**, the M-Co-CO_{ax} angles are linear: 179.07(9), 178.9(2), and 179.1(5)°, respectively. There is some distortion of the equatorial carbonyls towards the Ph_3M ligand and away from the axial

carbonyl group, so that the average M-Co-CO_{eq} angles for the three complexes are 83.8(5), 82.8(5), and 83(1)°, respectively. Such a distortion from a trigonal bipyramidal structure towards a capped tetrahedron has been previously discussed (41). The average CO_{eq}-Co-CO_{eq} angles in the three complexes are 119(2), 118(2), and 118(2)°, respectively, further confirming the threefold symmetry surrounding the Co nucleus. In the three complexes, the ipso-carbon atoms of the triphenyl groups are rotated 37–43° (Table 2) from the ideal staggered position of 60° with respect to the triangle formed by the three equatorial carbonyl groups. This difference is attributed to the steric interaction between carbonyl carbons and the *ortho*-carbon atom of the phenyl rings. The closest intermolecular non-bonded C_{ortho}—$C_{carbonyl}$ distances are between 3.4 and 3.6 Å. The important bond lengths and angles for complexes **I**–**III** are listed in Table 2.

Raman spectroscopy

The IR spectra of **I**–**III** have been previously reported in the C–O stretching (5, 6, 27) and far-IR (42) regions, and the Raman spectra (Table 3) complement these IR data. Only the tin–cobalt IR stretching frequency has been previously assigned (42) and appears at 171 cm^{-1}. Based on this assignment, the $\nu_{M\text{-}Co}$ values for the silicon and lead complexes have been assigned as shown in Table 3. For the ν_{CO} vibrations, there is a decrease in wavenumber on going down group 14. The small decrease in the average of the ν_{CO} frequencies on going from silicon to lead suggests a decrease in multiple bond character for the M–Co bonds. The ν_{CO} *e*-mode is split due to crystal effects.

Table 3. Raman vibrational frequencies of solid compounds (cm^{-1}).

Mode/bond	**I** (Si)	**II** (Sn)	**III** (Pb)
	85 s	84 s	83 m
	112 m	109 s	107 s

	675 w	655 m	646 m
	706 w	699 w	695 w
ν_{CO} *e*	1994, 2008 m	1989, 2001 m	1988, 1997 m
ν_{CO} $a_1^{(1)}$	2037 s	2030 s	2023 s
ν_{CO} $a_1^{(2)}$	2093 m	2087 m	2080 m

Solid-state CP MAS NMR

A treatment based on first-order pertubation theory has been developed by Olivieri (23), which is valid in the limit $\chi/[4S(2S-1)\nu_s] << 1$, where ν_s is the Larmor frequency of the quadrupolar nucleus. Thus, for ^{59}Co ($S = 7/2$), provided that $\chi/84\nu_s << 1$, the splittings observed in the solid-state spectra under MAS can be treated by first-order perturbation theory. With the assumption that that the *J* tensor is co-linear with the internuclear dipole vector, the line splittings are given by eq. [1],

$$[1]\qquad \Delta\nu_m = -m_s J_{IS} + (3\chi D'/20\nu_s)(3\cos^2\beta^D - 1 + \eta\sin^2\beta^D\cos 2\alpha^D)[\{S(S+1) - 3m_s^2\}/\{S(2S-1)\}]$$

where $D' = (D - \Delta J/3)$ and the second-order quadupolar–dipolar splitting (*d*) is $3\chi D'/20\nu_s$. *D* is the direct dipolar coupling constant ($D = (\mu_o/4\pi)\gamma_s\gamma_I h^2/(4\pi(r_{IS})^3)$ and ΔJ is the anisotropy in the spin–spin coupling. α^D and β^D are, respectively, the azimuthal and polar angles relating the internuclear vector to the principle axis of the EFG and η is the asymmetry in the field gradient. Equation [1] assumes that the *J* tensor is co-linear with the internuclear dipole vector. From NQR studies (15), η was found to be 0.05 or less, indicating a near axially symmetric EFG about cobalt for all three complexes. The ^{59}Co ($S = 7/2$) resonance frequency at 7.05 T is 71.2 MHz, and the nuclear quadrupole coupling constants for these complexes range from 101 to 110 MHz at 298 K (14, 15). Thus, the first-order perturbation treatment is applicable for the three complexes studied here.

The local symmetry about the M–Co bonds (approximately C_{3v}) is sufficiently high and η is close enough to zero that it can be assumed that the angle β^D is 0° and the value of α^D is undefined, because it is multiplied by $\sin^2\beta^D$, which is 0. Hence, eq. [1] is reduced to the simple form

$$[2]\qquad \Delta\nu_m = -m_s J_{IS} + (3\chi D'/10\nu_s)[3/4 - 1/7m_s^2]$$
