Cyclic voltammograms of prodan at 293 K, and prodan bulk concentrations (c^*_{Pr}) in the order of 10^{-3} M are shown in Figs. 2*a* and 2*b*. An irreversible oxidation peak was observed on the anodic sweep at ~0.700 V. On the reverse sweep, a reduction peak appeared at ~0 V. An increase of the sweep rate from 0.025 to 100 V s^{-1} did not bring about any significant change in this picture. Typical voltammetric data for the anodic peak at different c^*_{Pr} in the 0.025–1.5 V s^{-1} range are tabulated in Table 1. Plots of the oxidation peak current ($I_{p,a}$) vs. $v^{1/2}$ were concave. $I_{p,a}/v^{1/2}c^*_{Pr}$ plots decrease with $v^{1/2}$ (Fig. 3), indicating that reaction(s) coupled to the initial electron transfer is (are) present (15). The anodic peak potential ($E_{p,a}$) was shifted in the anodic direction with an increase in the scan rate, while it was shifted in the cathodic direction as the c^*_{Pr} increases. Slopes of 0.021 ± 0.001 V/decade and −0.019 ± 0.001 V/decade were calculated from $E_{p,a}$ vs. log v and $E_{p,a}$ vs. log c^*_{Pr} plots, respectively. These findings are in good agreement with theoretical behaviour expected for electro-dimerization reactions through radical–radical coupling ("DIM1", see Scheme 1), where the coupling reaction is the rate determining step (RDS), i.e.:

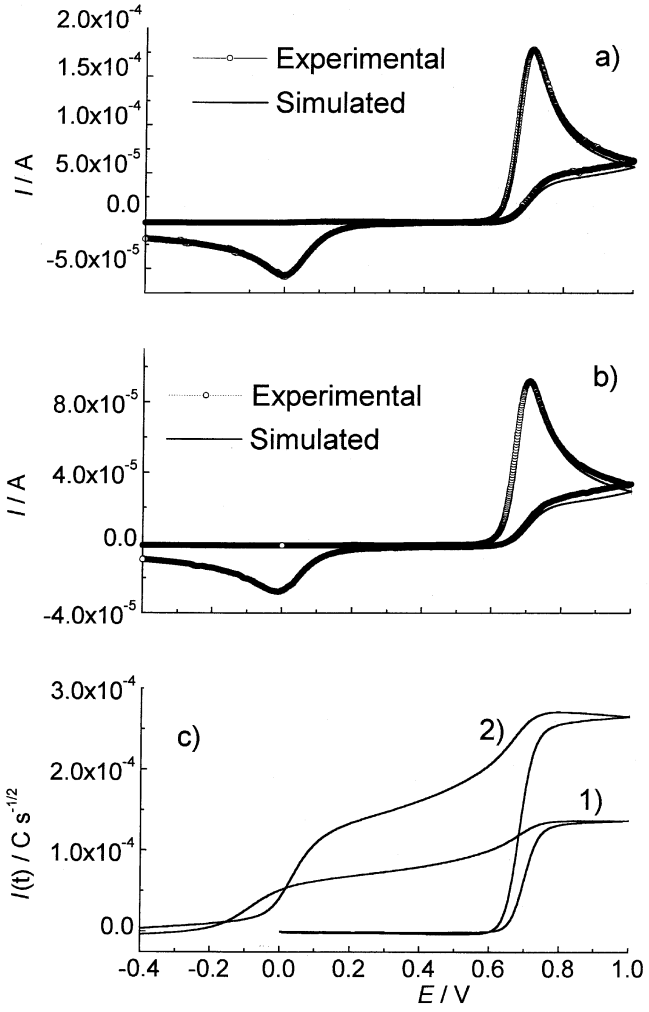
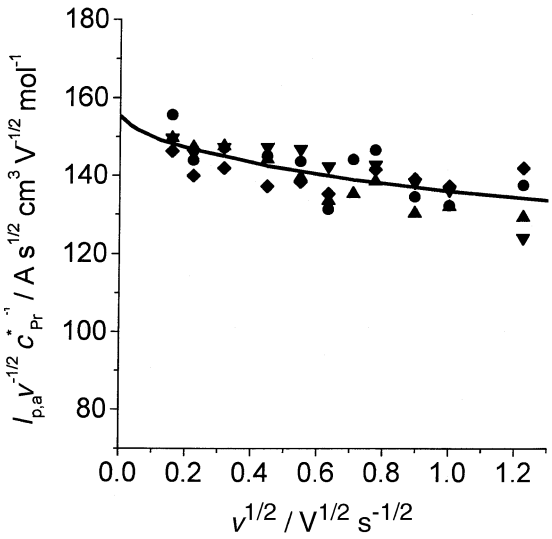
Fig. 2. (*a*) Experimental and (*b*) simulated cyclic voltammograms of prodan in 0.1 M $NaClO_4$ + ACN. Working electrode: Pt disk (A = 0.126 cm^2). Reference electrode: ECS. v = 0.050 V s^{-1}. c^*_{Pr} = (*a*) 5.4 × 10^{-3} M and (*b*) 2.8 × 10^{-3} M. (*c*) Convoluted cyclic voltammograms: (1) c^*_{Pr} = 2.8 × 10^{-3} M, v = 0.200 V s^{-1}; (2) c^*_{Pr} = 5.4 × 10^{-3} M, v = 0.050 V s^{-1} (T = 293 K).



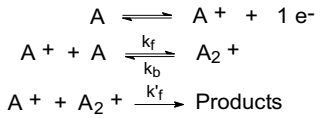
$\partial E_p/\partial \log v$ = 0.0197 V/decade and $\partial E_p/\partial \log c^*$ = −0.0197 V/decade at 25°C (16–18). Another dimerization mechanism ("DIM2", see Scheme 2) involving the radical cation – neutral substrate coupling was disregarded since the experimental data do not fit the parameters of diagnostic criteria for both limiting cases of the DIM2 mechanism, i.e., $\partial E_p/\partial \log v$ = 0.0296 V/decade and $\partial E_p/\partial \log c^*$ = –0.0296 V/decade or $\partial E_p/\partial \log v$ = 0.0197 V/decade and $\partial E_p/\partial \log c^*$ = −0.0394 V/decade at 25°C depending on the relative rate constants of chemical reactions involved in DIM2 mechanism (Scheme 2) (18). Because of the dependence of the peak potential on the scan rate one cannot distinguish between the two mechanisms. On the other hand, the variation of peak potential with log c^* is significantly different for the radical–radical coupling mechanism (DIM1, Scheme 1) and both limiting cases of the radical–substrate coupling mechanism (DIM2, Scheme 2) (18).

Fig. 3. Dependence of $I_{p,a}/v^{1/2}c^*_{Pr}$ on sweep rate at different concentrations. c^*_{Pr}: (●) 0.66 mM; (◆) 1.01 mM; (▼) 2.80 mM; (▲) 5.4 mM. The solid line is the simulated curve for Scheme 3 with the parameters shown in Table 2.



Scheme 1.

Scheme 2.



The reactivity of the radical ion has been largely studied (18–20), including the competitive radical–radical and radical–substrate coupling dimerization mechanisms by digital simulation (18). The applicability of the configuration mixing (CM) model to estimate energy barriers for these reactions has been also discussed (18).

Since reactants, transition states, and products for the two competitive mechanisms differ by only a single electron, steric factors should be the same for both pathways and it would be expected that the competition between the two mechanisms to be governed principally by electronic factors. On the basis of the CM model, it is possible to predict that radical–radical coupling dimerization (DIM1) will not have an electronic barrier, while that for radical–substrate coupling dimerization (DIM2) it will be significant. Moreover, the CM model predicts that DIM1 dimerization mechanism is ~7 kcal mol^{-1} thermodynamically more favourable than DIM2 dimerization mechanism (18).

Additionally, no complementary peak for the reduction peak is displayed on a third scan from cyclic voltammograms registered in the potential range from −0.4 to 1 V by using two consecutive cycles.

Convoluted cyclic voltammograms after subtraction of the background currents are shown in Fig. 2*c*. It can be observed that the convoluted current ($\bar{I}$(t)) value returns to zero after cyclic scan is complete. This behaviour indicates that the

product of the oxidation reaction is entirely converted back to the substrate (21). The advantages of the convolution technique in the treatment of experimental data from cyclic voltammograms are well known (15, 22). Similar to the pure diffusion control model, the mathematical expression for the limiting convolution current ($\bar{I}_L$) for electrodimerization reactions through radical–radical coupling under pure kinetic control is expressed as (22),

$$[1] \qquad \bar{I}_L = nFAD^{1/2}c^* \qquad \text{(1)}$$

where n is the number of electrons exchanged per molecule of the electrolyzed substrate, F is the Faraday constant, A is the electrode area, and D is the diffusion coefficient of the electroactive species. Limiting convolution currents can be used to determine the diffusion coefficient of prodan if $n = 1$ (from controlled-potential bulk electrolysis, see below). An average value of $\bar{D}$ ($(2.03 \pm 0.05) \times 10^{-5}$ cm^2 s^{-1}) was calculated for prodan at 293 K from the data extracted from convoluted voltammograms, similar to those shown in Fig. 2*c*. The plots of E vs. log $[(\bar{I}_L - \bar{I}(t))/I^{2/3}]$ were linear, with an average slope of 0.064 ± 0.002 V/decade, close to that theoretically predicted for a consecutive dimerization coupled to a reversible monoelectronic-transfer reaction, i.e., 0.0591 V/decade at 25°C (22).

To obtain more information about the overall reaction mechanism, additional experiments were performed by variation of temperature at lower concentrations and scan rates than those indicated previously. Marked changes were observed in voltammetric responses when concentration was decreased and temperature was increased (Fig. 4). At a low concentration and low scan rate ($c^*_{Pr} = 5 \times 10^{-5}$ M, v = 0.020 V s^{-1}), a new cathodic peak starts to appear in the potential range from 0.5 to 0.8 V as the temperature is increased (see Figs. 4*a*–*c*). This electrochemical signal can be assigned to the reduction of the radical monocation generated during the anodic scan. The cathodic peak observed in the potential range of 0.2 to −0.4 V at room temperature is poorly defined under these experimental conditions; however, a new complementary cathodic peak (0.5−0.8 V) was better defined at the lowest concentration and the highest temperature studied, i.e., 5.0×10^{-5} M and 318 K, respectively. This behaviour can be clearly inferred from cyclic voltammograms shown in Fig. 5, despite the fact that they are poorly defined at that low concentration of prodan.

A detailed evaluation of changes observed in cyclic voltammograms by variation of concentration, scan rate, and temperature led us to conclude that formation of the radical cations was followed by a reversible dimerization of the species producing a dimeric dication (Scheme 3). Dimeric dications can then be reduced during the cathodic scan (in one or two electrochemical steps) to give the neutral dimer, which can dissociate to regenerate the starting reactant. This process would give rise to a cathodic peak located at about 0 V. Further support to this mechanism is given below.

It is well known that the enthalpy of organic radical coupling reactions is negative (23). Although the contribution of reaction entropy for dimerization reactions can not be neglected, the reaction enthalpy would have a greater contribution than the reaction entropy on the Gibbs free energy. This can be inferred from experimental results obtained by Smie and Heinze (24) for the reversible dimerization of the radical cations formed through the anodic oxidation of diphenylpolyenes. Similar findings have also been recently reported for dimer dication formation through a reversible

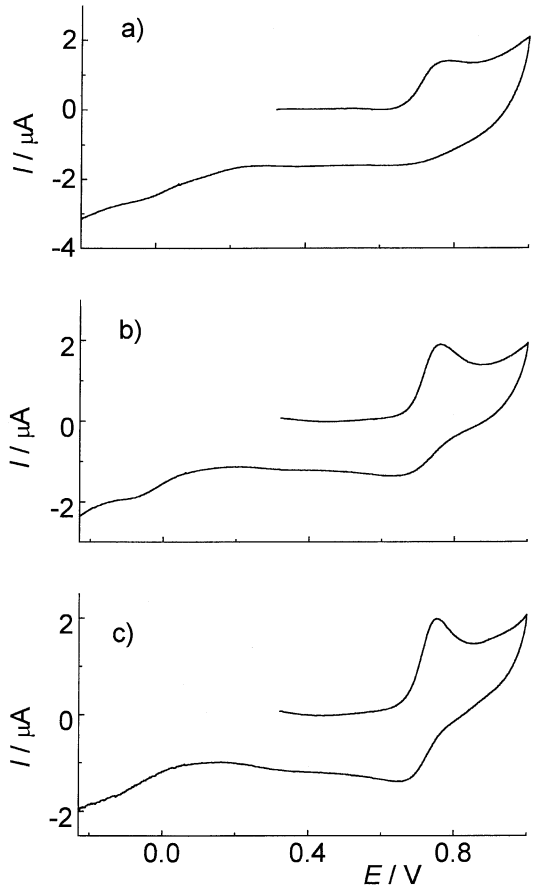
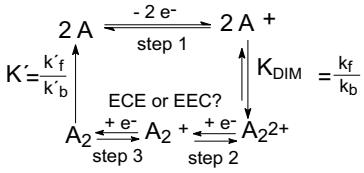
Fig. 4. Cyclic voltammograms of prodan in 0.1 M $NaClO_4$ + ACN obtained at different temperatures. c^*_{Pr} = 5.0 × 10^{-5} M, v = 0.020 V s^{-1}, T = (*a*) 293 K; (*b*) 304 K; and (*c*) 318 K.

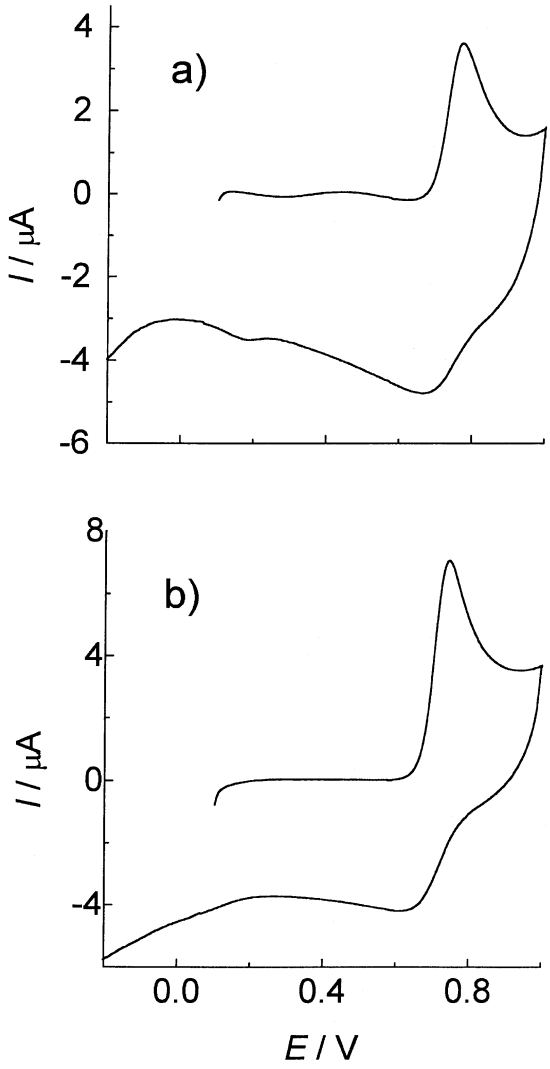


Scheme 3.



radical cation – radical cation dimerization with 3,3′,5,5′-tetramethyl-2,2′-bithiophene as the starting molecule (25). Thus, taking into account the voltammetric results obtained by changing temperature, which appear very similar to those found for systems mentioned above (24, 25), it is proposed that the dimerization equilibrium established between radical cations of prodan and the formed dimeric dication is shifted towards the radical monocation as the temperature is increased. Additionally, the dependence of voltammetric responses with concentration is another clear indication that the initial charge-transfer reaction is followed by a reversible second-order reaction, assumed to be a dimerization process. Thus, at higher temperatures and lower concentrations of the starting reactant, the follow-up chemical reaction attains a thermodynamic equilibrium. Although the electrogenerated radical cation undergoes fast dimerization in the time scale of the experiment, the dimeric product is dissociated into radical cations, which are reduced to the neutral species on the voltammetric reverse scan. At higher concentrations and lower temperatures, the overall electrochemical process is kinetically controlled and the dimerization reaction dominates (25). Under these conditions, cyclic voltammograms show only the cathodic peak in the potential range from 0.2 to −0.4 V, which can be ascribed to the reduction of the dimeric product.

Fig. 5. Cyclic voltammograms of prodan in 0.1 M $NaClO_4$ + ACN obtained at different prodan concentrations. T = 318 K, v = 0.100 V s^{-1}, c^*_{Pr} = (*a*) 5.0 × 10^{-5} M and (*b*) 1.0 × 10^{-4} M.



Simulation and fitting of cyclic voltammograms

The cyclic voltammograms (Scheme 3) at different sweep rates and concentrations of the reactant were generated by digital simulation to obtain parameters for diagnostic criteria. Thus, we found $\partial E_p/\partial \log v$ = (0.0223 ± 0.0003) V/decade and $\partial E_p/\partial \log c^*$ = –(0.0192 ± 0.0002) V/decade. Agreement between simulated and theoretical (see above) $\partial E_p/\partial \log c^*$ values is excellent, but the $\partial E_p/\partial \log v$ values differ by ~13%. This difference may be a consequence of additional steps that follow the dimer formation. Regardless, the difference is small enough to consider that the DIM1

mechanism still governs the dimer formation in Scheme 3. Experimental values (already shown above) agree very well with values calculated from the simulation for Scheme 3. Figure 3 also shows the variation in $I_{p,a}/v^{1/2}c^*$ with $v^{1/2}$ calculated from the simulation and the parameters of the best fitting (see below). As it can be observed, agreement with experimental values is also very good.

Experimental cyclic voltammograms were also fitted by digital simulation. The best fitting curves (solid lines in Figs. 2*a* and 2*b*) at different concentrations and scan rates were obtained when the Scheme 3 was used as the reaction mechanism model, i.e., considering a radical–radical coupling (DIM1). Simulations of cyclic voltammograms were also performed at other scan rates than those shown in Figs. 2*a* and 2*b*, i.e., 0.075, 0.100, and 0.2 V s^{-1} at the same concentrations indicated in the figures. The DIM2 mechanism gave a poorer fitting than the DIM1 mechanism, which is in good agreement with results of experimental data and diagnostic criteria (see above). It can be seen in Fig. 2 that the fits using the DIM1 mechanism were very good. The small differences found at the end of the anodic scan and the beginning of the reverse cathodic scan for the experimental and simulated curves might be explained by considering the difficulty in obtaining the faradaic currents properly corrected for by the background currents in that potential region.

The quantitative analysis results of the fitting of experimental cyclic voltammograms are gathered in Table 2. $E_f^\circ(1)$, $k_f^\circ(1)$, and $(1 - \alpha)_1$ are the formal potential, the formal heterogeneous rate constant, and the anodic transfer coefficient, respectively, for the main anodic charge-transfer reaction (Scheme 3, step 1). K_{DIM}, k_f, and k_b are the equilibrium constant and the forward and backward rate constants, respectively, for the dimerization reaction.

The low value for the dimer dissociation rate constant ($k_b = 0.04$ s^{-1}) explains that under normal experimental conditions the overall reaction is kinetically controlled even at low scan rates. In the voltammetric reverse scan the signal for the successive reduction of the dimeric product is, therefore, particularly strong.

The thermodynamic and kinetic parameters for reactions other than the dimerization reaction in Scheme 3 can also be obtained from the fitting procedure, although they are probably not meaningful, because it was assumed that the concentration of prodan dimer in solution is very low, if detectable at all. It has also not been possible to distinguish by digital simulation whether the reduction of the dimeric dication follows an EEC or an ECE reaction mechanism. The values of these thermodynamic and kinetic parameters were, however, used to generate theoretical cyclic voltammograms to establish diagnostic criteria, as was previously indicated.

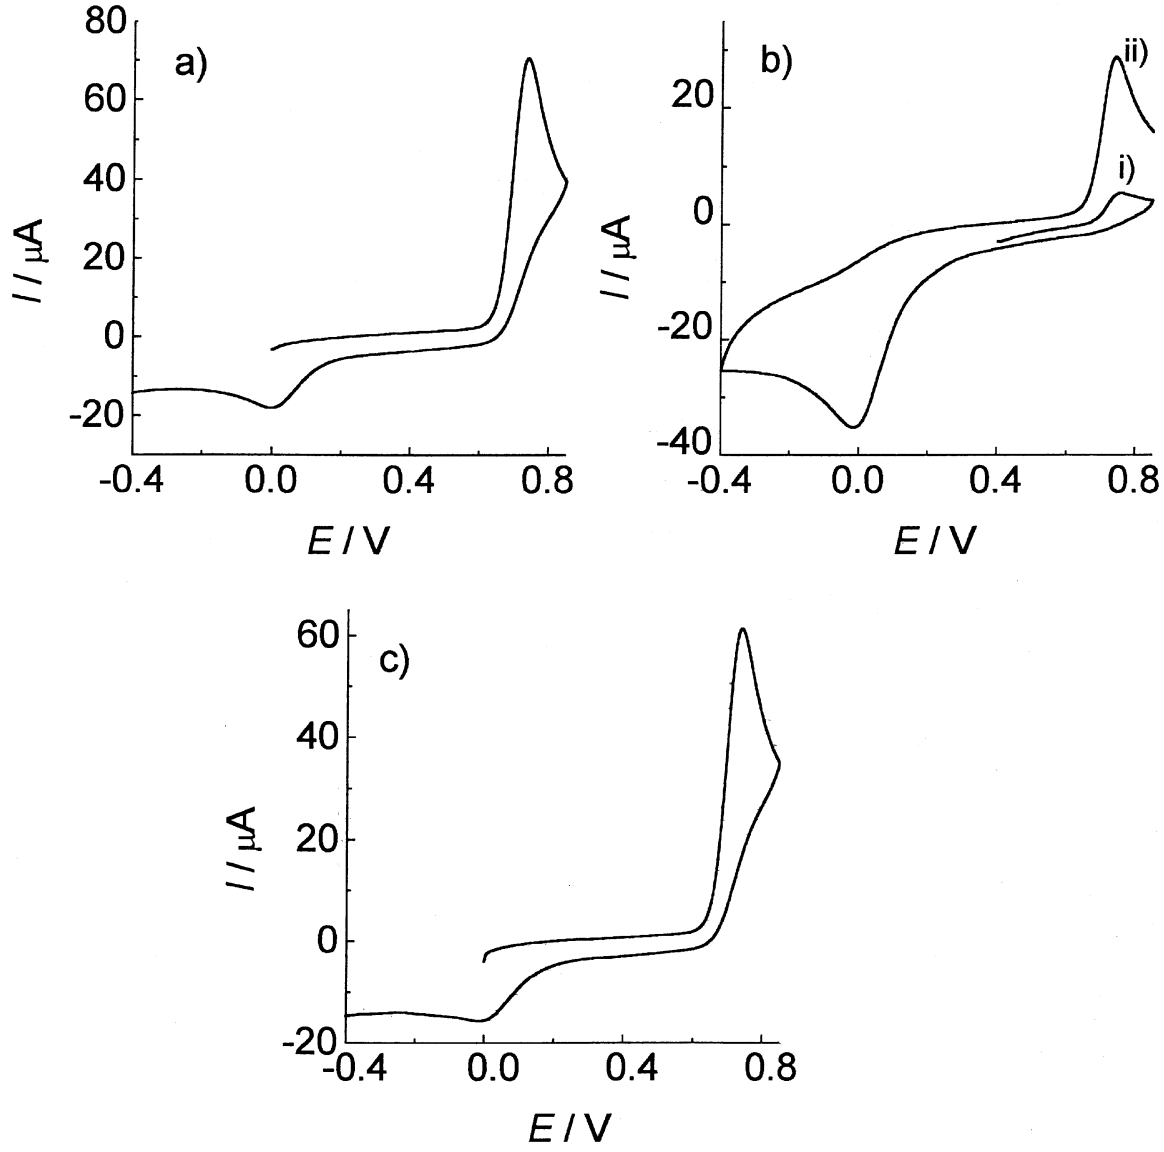
Through simulation techniques, Evans et al. (26) generated working curves for the mechanism shown in Scheme 1. There, $(E_p - E_f^\circ)$ for the anodic peak and cathodic–anodic peak current ratio were correlated to a kinetic parameter (Ψ_k) defined as $\Psi_k = Kc^*[a/(k_f c^* + k_b)]^{1/2}$, where a is the scan rate parameter (Fv/RT); the other parameters have been previously defined. For very large Ψ_k, Evans et al. (26) have shown that dimerization does not occur for any Kc^* value and the peak moves 28.5 mV in the positive direction of E_f°. As Ψ_k decreases, a transition to a pure kinetics region occurs, where essentially irreversible dimerization occurs. The peak potential moves 39.4 mV in the negative direction per decade decrease in Ψ_k until a transition occurs to the equilibrated dimerization, i.e., the pure diffusion region (27). In this region, $E_{p,a}$ again becomes independent of Ψ_k but is negative of E_f° to an extent dependent on Kc^*. This fact reflects the thermodynamic effect of the reversible dimerization following electron transfer (26). Thus, with the experimental $E_{p,a}$ at different concentrations of prodan and different sweep rates and kinetic parameters and $E_f^\circ = 0.740$ V (calculated from the best fitting, see Table 2), values for $(E_p - E_f^\circ)$ and Ψ_k were obtained. From interpolation in the $(E_p - E_f^\circ)$ vs. log Ψ_k plot (Fig. 1 in ref. 26), a $7 \times 10^6 - 2 \times 10^7$ M^{-1} range was established for K_{DIM}. The value of $K_{DIM} = 8.0 \times 10^6$ M^{-1} obtained from our best fitting of experimental data (Table 2) agrees well with values calculated from the Evans et al. plot. On the other hand, from the cathodic and anodic peak current ratio as function of log Ψ_k (Fig. 3 in ref. 26), the experimental log Ψ_k interval matches the range corresponding to a pure chemical-reaction kinetic-control region, with a reversible dimerization behaviour (defined as KP_r in ref. 26). These are complementary results, which allow us to infer that Scheme 3 proposed for the anodic oxidation of prodan is highly probable to be the correct one.

Controlled-potential bulk electrolysis

Bulk electrolysis were carried out at a potential ~0.1 V more positive than the anodic peak potential. The result found for the number of electrons exchanged per molecule of electrolyzed substrate from three replicated measurements, expressed as mean ± standard deviation, was $n = 1.00 \pm 0.25$. Cyclic voltammograms taken after 30 min of electrolysis by employing three consecutive hemicycles showed a pronounced diminution of the oxidation peak of prodan during the first anodic hemicycle (compare Figs. 6*a* and 6*b* (*i*)) as well as an increase in the reduction peak current during the second cathodic hemicycle. Also, an increase in the oxidation peak current during the third anodic consecutive hemicycle was observed (Fig. 6*b* (*ii*)), clearly showing that the original substrate is recovered after the cathodic scan. No new peaks were found on the second hemicycle (the cathodic hemicycle). Moreover, reverse controlled-potential bulk electrolysis performed at −0.2 V allowed the recovery of the cyclic voltammogram of prodan obtained from fresh solutions (compare Figs. 6*c* and 6*a*). On the other hand, the average cathodic charge (Q_c) obtained after performing the

© 2002 NRC Canada

Fig. 6. Cyclic voltammograms recorded: (*a*) before the electrolysis; (*b*) after 30 min of electrolysis by employing three consecutive hemicycles, where (*i*) and (*ii*) represent the first and the second anodic hemicycles, respectively; and (*c*) after performing the reverse electrolysis for 30 min (see text). $c^*_{Pr} = 1.76 \times 10^{-3}$ M, $v = 0.050$ V s^{-1}, $T = 293$ K.



reverse electrolysis for 30 min ($Q_c = 791 \pm 6$ μC) was very close to that measured during the anodic electrolysis, i.e., the anodic charge ($Q_a = 777 \pm 5$ μC). The original colourless of prodan + 0.1 M $NaClO_4$ + ACN solutions was retrieved after carrying out the reverse controlled-potential bulk electrolysis.

The dissociation of the reduced dimer (A_2 in Scheme 3) occurs extensively on reverse preparative-electrolysis time scale, from which the starting material can be regenerated. This would clearly explain the experimental results previously discussed for anodic and cathodic (reverse) controlled-potential bulk electrolysis.

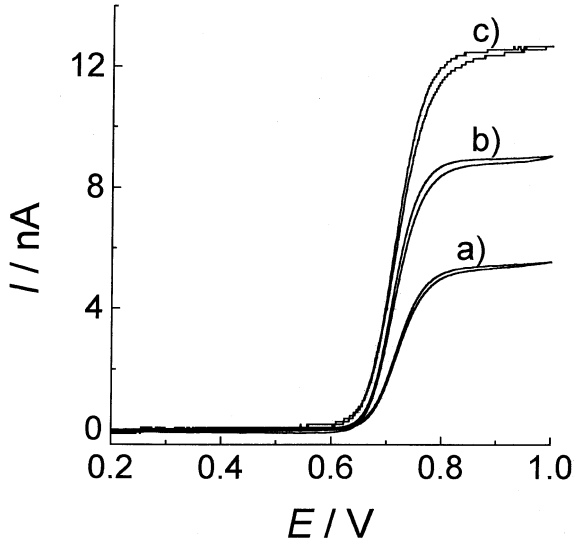
The UV–vis absorption spectra (28) obtained before and after the anodic electrolysis showed a few changes in the shape of the bands. The increase in absorbance (*a*) at λ = 346 nm is responsible for the apparition of a light yellow colour in the electrolyzed solutions — this colour disappears after the reverse electrolysis. These results indicate little or no increase in conjugation of the dimeric molecule (A_2 in Scheme 3) with respect to that of prodan.

Cyclic voltammetry at UME

Typical quasi-steady-state voltammograms obtained at Pt UME at low sweep rates are shown in Fig. 7. Under these conditions, quasi-steady-state responses are due to convergent diffusion predominating over planar diffusion (29–32). An expression for the diffusion-limited quasi-steady-state current (I_L) for a UME was derived by Saito (33),

© 2002 NRC Canada

Fig. 7. Quasi-steady-state cyclic voltammograms of prodan in 0.1 M $NaClO_4$ + ACN. Working electrodes: Pt disk UME: r = (*a*) 11 μm; (*b*) 18.3 μm; and (*c*) 26.5 μm. Reference electrode: ECS. $c^*_{Pr} = 5.6 \times 10^{-4}$ M, $v = 0.010$ V s^{-1}, $T = 293$ K.



$$[2] \qquad I_L = 4nFc^*Dr$$

where r is the UME radius; the other terms have been previously defined.

As stated elsewhere (30), the use of UME of convenient radius can mask coupled chemical reactions and, thus, the resulting current-potential curves do not differ from those obtained from a pure charge-transfer reaction. To assess this statement, and with the purpose of checking if eq. [2] corresponds also to the limiting current for the reaction mechanism shown in Scheme 3, digital simulations for UME were performed using POLAR 4.1 software. As far as we know, POLAR 4.1 is the only commercial program for the simulation of reaction mechanisms at UME. Linear sweeps at different dimerization rate constant in the 0.04–3.2 × 10^8 M^{-1} range for a given UME radius ($r = 11 \times 10^{-4}$ cm) and $c^* = 5.4 \times 10^{-3}$ M were, therefore, generated with POLAR 4.1. The other parameters for simulation were obtained from the fitting procedure carried out on Pt CSE cyclic voltammograms. It was found that $E_{1/2}$ is independent on k_f up to k_f = ~0.1, but for k_f values higher than ~3.2 M^{-1} s^{-1}, $E_{1/2}$ is linear with log k_f with a slope of –0.0131 V/decade. I_L is independent of k_f within 0.1% accuracy but varies linearly with UME radius and c^* for a given D. These results suggest that eq. [2] could also represent the limiting current for a mechanism of the type here proposed. Thus, the diffusion coefficient of prodan can be also calculated from eq. [2] when $n = 1$ (from controlled-potential bulk electrolysis) for a solution of prodan at $c^*_{Pr} = 5.6 \times 10^{-4}$ M and UME's of three different radii, i.e., 11.0 × 10^{-4}, 18.3 × 10^{-4}, and 25.6 × 10^{-4} cm. The corresponding limiting currents were: 5.31, 8.88, and 12.5 nA, respectively, (see Fig. 7). An average value for the diffusion coefficient of $\bar{D}$ = (2.22 ± 0.03) × 10^{-5} cm^2 s^{-1} was calculated.

For such cases where the electron number exchanged in the electrochemical reaction is unknown, we propose here an alternative method for the determination of the diffusion coefficient of the electroactive species that is independent of the exchanged electron number in the electrode process. It is based in the combination of convolution limiting currents on CSE and limiting currents on UME data through the ratio of $\bar{I}_L$ (eq. [1]) and I_L (eq. [2]),

$$[3] \qquad D = (AI_Lc^*_{con}/4rc^*_{UME}\bar{I}_L)^2$$

where c^*_{con} and c^*_{UME} are the reactant concentration for convolution and UME experiments, respectively.

An average value of $\bar{D}_{Pr}$ of (2.37 ± 0.06) × 10^{-5} cm^2 s^{-1} was calculated from a set of $\bar{I}_L$ and I_L for different prodan concentrations and different UME radii.

It seems reasonable to calculate a most probable value for the diffusion coefficient of prodan under the experimental conditions as an average of the values found from convoluted and UME voltammetry, i.e., $\overline{\bar{D}}_{Pr}$ = (2.2 ± 0.1) × 10^{-5} cm^2 s^{-1}.

Alternatively, another method based on the use of an internal standard was employed in quasi-steady-state CV UME measurements as another way to check the exchanged electron number in the electrode process. It is well known that ferrocene (Fc) undergoes an uncomplicated monoelectronic electrooxidation ($n_{Fc} = 1$) to its corresponding monocation. A diffusion coefficient value for Fc (D_{Fc}) in 0.1 M $NaClO_4$ + ACN reaction medium was previously determined in our laboratory, i.e., $D_{Fc} = 2.32 \times 10^{-5}$ cm^2 s^{-1} (11). Thus, taking into account the corresponding limiting currents (eq. [2]) for prodan- and Fc-redox couples at the same UME, one obtains

$$[4] \qquad \frac{n_{Pr}}{n_{Fc}}\frac{D_{Pr}}{D_{Fc}} = \frac{I_{L,Pr}}{c^*_{Pr}}\frac{c^*_{Fc}}{I_{L,Fc}}$$

where the symbols Pr and Fc represent to prodan and ferrocene compounds, respectively. An average value of 0.95 ± 0.01 was calculated for the right term of eq. [4]. From this result, and by using $D_{Pr}/D_{Fc} = 0.948$, it was determined that $n_{Pr} = 1.00$, which is in excellent agreement with the n value previously determined from controlled-potential bulk electrolysis measurements.

Analysis of the I vs. E characteristics obtained from digital simulation on UME using the reaction mechanism shown in Scheme 3 and employing parameters obtained from the best fitting of Pt CSE cyclic voltammograms renders values of $\partial E/\partial \log [(I_L - I)/I] = 0.055 \pm 0.008$ V/decade ($n = 1$) and $E_{3/4} - E_{1/4} = 0.060$ V at 293 K. Experimental E vs. log $[(I_L - I)/I]$ plots were linear, with slopes of 0.053 ± 0.002 V/decade, in reasonable agreement with the simulated value.

Moreover, a positive shift in the half-wave potential ($E_{1/2}$) of quasi-steady-state voltammograms was experimentally observed as the UME radius was decreased (see Fig. 7), with a slope of about 0.008 V/decade. Results for $E_{1/2}$ vs. UME radius from simulation experiments give an exponential decay-type plot. Nevertheless, in the narrow interval of the experimental radius variation, a near-linear variation of $E_{1/2}$ with r can be assumed from simulated data. From it, a slope of about −0.012 V/decade was calculated in the 11–26.5 μm radii interval. Thus, the experimental slope value is relatively close to that obtained by simulation. Shifts in $E_{1/2}$ on UME are reported to be a consequence of heterogeneous kinetics (34). Thus, for the narrow-radius interval worked in

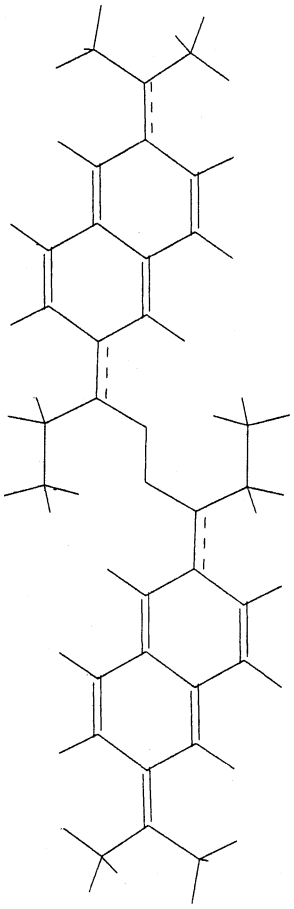
this paper, no definitive conclusion can be drawn about $E_{1/2}$ shifts.

Reactivity of prodan radical cations

Results for the electrooxidation of prodan found in this work for the 0.1 M $NaClO_4$ + ACN reaction medium suggest that the formation of radical cations in the first redox step is followed by a reversible dimerization to produce the corresponding dimeric dication (DIM1 mechanism, Scheme 3). These results also show that the coupling between the radical cations and neutral species can be ruled out (16, 18, 27). Besides, reversible dimerization reactions have been previously invoked in a number of electrochemical reaction schemes (26, 35–37).

The reactivity of prodan radical cations might be explained by considering that the radical cation generated in the initial step of the electrochemical oxidation would have a low stability, because the propionyl group present in the prodan structure is an electron withdrawing substituent. On the other hand, it has been generally found that electron donating substituents tend to stabilize radical cations (38, 39). Furthermore, in the absence of severe steric effects, the radical ion reactivity is dominated by the degree of coupling between charge and radical centres (19). Decoupling of these functions, charge, and radical centres is expected to enhance the reactivity of one or both of the centres. Substitution with heteroatom substituents at different positions of radical cations is expected to decouple the charge and radical centres. For example, dimerization rates of arene radical cations were observed to be greatly enhanced by methoxy and *N*,*N*-dimethylamino substituents, which separate the charge and radical centres (19). Thus, the dimerization of prodan radical cations would be favoured by the presence of *N*,*N*-dimethylamino group in its molecular structure (see Fig. 1). According to the different resonance structures of the prodan radical cation, the possible radical centres would be at carbons 1, 3, and 8 and the oxygen atom of carbonyl group. Taking into account steric factors, the radical centres at C8 and oxygen appear as the most reactive sites. From the analysis given above, prodan radical cations should have low stability and great capability for dimerization. This hypothesis is verified from experimental results, i.e., the coupling rate

Fig. 9. Structure of 6-propionyl-2-(*N*,*N*-dimethylamino)naphthalene dimer dication according to AM1 calculations when the σ bond was formed between oxygen atoms of the carbonyl groups. O—O Distance = 1.323 Å.



constant (k_f) of prodan radical cations is very high and the dissociation rate constant (k_b) is very low (see Table 2). This helps to explain why the complementary cathodic peak at about 0.5–0.8 V is poorly defined, even at high temperatures and low concentrations. The fact that the radical–radical coupling dimerization mechanism is favoured over the competitive radical–substrate dimerization mechanism can be explained by considering that the low stabilization of the radical cations does not allow sufficient time for diffusion of these species from the electrode surface to the solution, where collisions with parent molecules would be more likely. A covalent interaction between the two cationic species can be explained by taking into account the very low rate constant for the cleavage of the dimeric dication, despite the strong continued coulombic repulsion. This interpretation has been already given by Heinze and co-workers (25) for the reversible formation of bithiophene radical cations. Thus, taking into account the results published for oligoenes (24), thiantrenes, and bithiophenes (25), and those shown for prodan in this report, we propose that a σ bond is formed in the dimeric prodan structure. The dimer structure is still unknown. From AM1 calculations done by assuming a σ bond between the two radical cations in C8—C8 position as well as between the oxygen atoms of the carbonyl groups, the

dimerization coupling through O—O renders the most stable structure, according to the heat of formation of these species in the gas phase, i.e., $\Delta H^{2+}_{f,Pr}$ (C—C) = +615.2 kcal mol^{-1}; $\Delta H^{2+}_{f,Pr}$ (O—O) = +468.7 kcal mol^{-1}. The dimer structures obtained from AM1 calculation are shown in Figs. 8 and 9. To establish the most probable structure of the dication in solution, however, the solvation energies (not known) for these species must be considered as well as the isolation of the dimer should be performed. Further studies are in progress in this way.

Conclusions

The electrochemical oxidation of prodan in the 0.1 M $NaClO_4$ + ACN reaction medium is reported for the first time. Experimental results allow us to infer that the formation of radical cations in the initial electron transfer reaction is followed by a reversible dimerization of these species to produce the corresponding dimeric dication (DIM1 mechanism, Scheme 3). Additionally, both the digital simulation of cyclic voltammograms and the diagnostic criteria also show that the coupling between the radical cations and neutral species can be ruled out.

Crystal structure and spectral considerations of 5-methyl-2-nitraminopyridine *N*-oxide

A. Szemik-Hojniak, T. Głowiak, I. Deperasińska, and A. Puszko

Abstract: The crystal structure of 5-methyl-2-nitraminopyridine *N*-oxide (5M) has been determined and its electronic absorption spectra in the solution have been investigated. In the solid, two monomeric proton-transferred (PT) units of 5M are perpendicularly located in the crystal lattice. They are connected by two intermolecular hydrogen bonds of different strength (O-H···N 2.647(3) and 2.695(3) Å). In the gas phase the same relative arrangement of both 5M (PT) monomers has been found. As results from semiempirical PM3-CI calculations (12–14), the prototropic amino (H) ↔ imino (PT) equilibrium may occur in the solution. Assignment of experimental absorption bands to the calculated transition energies of both forms of 5M reveals that hydrogen bonded 5M (PT) dimers are dominant in cyclohexane while imino (PT) monomers seem to prevail in acetonitrile solution. The different character of electronic transitions and different relative arrangement of both monomers in amino (H) than in imino (PT) dimers are responsible for very low oscillator strengths and dipole moments of the former.

Key words: crystal structure, methylated nitraminopyridine *N*-oxides, semiempirical PM3-CI computations, intermolecular hydrogen bonding.

Résumé : La structure cristalline de *N*-oxyde de la 5-méthyl-2-nitraminopyridine (5M) a été déterminée et son spectre d'absorption électronique étudié. En phase solide, deux unités monomères avec un proton transféré 5M (PT) sont localisées perpendiculairement dans une cellule cristalline. Elles sont liées par deux liaisons hydrogènes O-H···N intermoléculaires et asymétriques, 2,647(3) et 2,695(3) Å. En phase gazeuse, le même arrangement des deux monomères a été observé. Les calculs semi-empirique PM3-CI (12–14) indiquent que l'équilibre prototropique amino (H) ↔ imino (PT) peut exister en solution. L'identification des bandes d'absorption expérimentale aux énergies de transition calculées des formes amino et imino de 5M montre que des dimères 5M (PT) liés par des liaisons hydrogènes sont majoritaires dans le cyclohexane alors que dans l'acétonitrile l'équilibre des deux formes se déplace en faveur du monomère imino (PT). Le caractère différent des transitions électroniques et les différents arrangements relatifs des monomères dans les amino (H) et imino (PT) dimères sont à l'origine des très faibles forces oscillatoires et de des moments dipolaires de la forme amino (H).

Mots clés : structure cristalline, *N*-oxydes de méthyl-nitraminopyridines, calculs semi-empiriques PM3-CI, liaison hydrogène intermoléculaire.

[Traduit par la Rédaction]

1. Introduction

Crystallographic structures and absorption spectra of several nitraminopyridine *N*-oxides (NAPNO) have been published recently (1–3). These compounds belong to a wide class of pyridine *N*-oxide derivatives known as antifungal drugs (4, 5) and those that crystallize as non-centrosymmetric crystals may display a nonlinear second-order response (6). Among the NAPNO series, till now, only one non-centrosymmetric compound has been found, i.e., the 3-nitraminopyridine *N*-oxide (1). Others (1, 2) had been shown to be centrosymmetric.

NAPNO dimers (1–3) are linked through N-H···O or O-H···N hydrogen bonds and therefore may be also treated as model compounds for planar and nearly planar, hydrogen bonded nucleobase dimers (7). Contrary to earlier recognized CT (charge transferred) derivatives of pyridine (8), pyridine *N*-oxides (9), and methyl-aminopyridine *N*-oxides (10), in the NAPNO series due to the proximity of the amino and the nitro group in one complexed nitramino (-NH-NO_2) function, a substantial distortion of electron density across the molecule takes place. This in turn affects not only the *push–pull* properties of the *N*-oxide group (1, 2, 8–11) but also decreases the electron accepting abilities of the nitro group itself (1, 2).

In previously published nitraminopyridine *N*-oxide compounds, the nitramino group was attached to the carbon atom in an ortho (2NAPNO), meta (3NAPNO), or para (4NAPNO) (1, 3) position with respect to the NO group. The second substituent in the 2NAPNO molecule (the methyl group)

was in position 3 (3M) (2) or in position 4 (4M) (2). In this work, being a continuation of our earlier study on methylated-2-nitramino pyridine *N*-oxides (2), the compound with the methyl group in position 5 of 2NAPNO, i.e., 5-methyl-2-nitraminopyridine *N*-oxide, henceforth called 5M, will be thoroughly discussed. In section 2, experimental details of X-ray analysis and PM3-CI computations are described while section 3A and B is devoted to the structure consideration. In particular we noticed that crystalline 5M proton-transferred (PT) dimers consist of two mutually perpendicular monomers with the amino hydrogen being at the NO group. Identical orthogonality of monomeric planes has also been found in the PM3-optimized 5M (PT) dimer (12–14). Contrary to that, a parallel arrangement of both monomers was stated in complementary calculated amino (H) dimers. In section 4, experimental absorption electronic bands of 5M in nonpolar and polar aprotic solvents are assigned to the calculated ones and the reasons for very small oscillator strength and dipole moment values observed in amino (H) dimers are analysed. This analysis is given within the framework of the results of the semi-empirical PM3-CI calculations. Conclusions are presented in section 5.

2. Experimental details and calculations

The title compound was obtained in accordance with the procedures described elsewhere (15). Crystals were grown from a methanol–water (1:1) solution. All X-ray measurements were performed on the KUMA KM-4 diffractometer with graphite-monochromated Cu K_α radiation at room temperature. The stability of the crystal was monitored by the measurement of three standards every 100 reflections. The data were corrected for Lorentz and polarization effects. No absorption correction was applied. Experimental details are given in Table 1.

Note: *U*(eq) is defined as one-third of the trace of the orthogonalized U_{ij} tensor.

The structure was solved by direct methods with SHELXS-97 (16) and refined by full-matrix least-square methods using SHELXL-97 (17) with anisotropic thermal parameters for non-H atoms. At intermediate stages of the refinement, the difference maps showed all H atoms. In the final cycles of the refinement parameters for H-1 and H-2 with isotropic thermal parameters were included. All other atoms were placed by geometry using a riding model and assigned thermal parameters equal to 1.2 times the U_{eq} of the attached C for aromatic H atoms and 1.5 times the U_{eq} of the attached C for methyl H atoms. Scattering factors were taken from *International tables for X-ray crystallography* (18). Final atomic parameters for 5M are presented in Table 2.

The UV absorption spectra in the solution were recorded on CARY-1 UV–vis spectrometer at 298 K. All solvents used were of spectral grade. The quantum-mechanical, semiempirical PM3 method (12–14) was used for calculations. Full geometry optimization was performed for a monomer and a dimer of 5M in its molecular (H) and (PT) form. The energies of the electronic excited states were determined by means of the configuration interaction (CI) with 257 singly excited configurations between 16 HOMO and 8 LUMO orbitals taken into account.

3. Structure considerations

A. Crystal structure

The final crystal structure with atom numbering of 5M, and the projection of the unit cell of 5M along the *y* axis are presented in Figs. 1(*a*) and 1(*b*), respectively. The bond length and valence angles for 5M are displayed in Table 3.

5M crystallizes in the centrosymmetric *C*2/*c* space group and, like earlier investigated non-methylated 2NAPNO (1) or methylated 4M (2), occurs in its (PT) form, i.e. with the amino proton being transferred to the NO group. Simultaneously, a bare nitrogen of the amino group becomes a hydrogen bond acceptor of the proton originating from the -NOH group of an adjacent 5M (PT) molecule. Hence, two different molecules A and B form a cyclic dimer with two different, intermolecular, asymmetric and linear hydrogen bonds; O(11)-H(1)···N(22) = 2.647(3) Å and O(21)-H(2)···N(12) = 2.695(3) Å. The corresponding two O-H-N angles are 180(4)° and 174(4)°, respectively. The two monomers of 5M dimer are perpendicularly located each with respect to another as illustrated in Fig. 1(*b*).

The methyl group substituted in the *meta* position in 5M or in the *para* position in 4M (2) relative to the NO group does not affect the electronic conjugation of the functional groups with the π system of the aromatic ring. Only a substantial steric hindrance due to the *ortho effect* was found in 3M (2) with the methyl group adjacent to nitramino group.

Table 4. Comparison of X-ray data of 5M with those of 4M (PT) (**2**) and 2NAPNO (PT) (**1**) structures.

Compound	5M	4M (PT)	2NAPNO (PT)
Displacement of the NO group (°)	(A) –174.0(2)	(A) 175.1(3)	(A) –176.2(2)
	(B) 176.2(2)	(B) 173.3(3)	(B) –174.7(2)
d (N—O)$_{NO}$ (Å)	(A) 1.376(3)	(A) 1.377(4)	(A) 1.383(3)
	(B) 1.374(3)	(B) 1.373(4)	(B) 1.375(2)
Displacement of $N_{(amino)}$ atom (°)	(A) 178.8(2)	(A) –175.6(3)	(A) 177.3(3)
	(B) –179.9(3)	(B) 178.7(4)	(B) 175.8 (2)
d (C_{ar}—N_{amino}) (Å)	(A) 1.360(3)	(A) 1.367(4)	(A) 1.368(3)
	(B) 1.354(3)	(B) 1.356(4)	(B) 1.364(3)
Displacement of the NO_2 group (°)	(A) –172.2(2)	(A) –178.9(3)	(A) –168.7(2)
	(B) 164.7(2)	(B) –170.8(3)	(B) –169.2(2)
d (N_{amino}—N_{nitro}) (Å)	(A) 1.334(3)	(A) 1.337(4)	(A) 1.349(3)
	(B) 1.332(3)	(B) 1.349(4)	(B) 1.347(3)
d (C_{ar}—N_{NO}) (Å)	(A) 1.355(3)	(A) 1.362(4)	(A) 1.367(3)
	(B) 1.358(4)	(B) 1.359(4)	(B) 1.361(3)

There, displacement of the whole NO_2 group is larger than in 5M and 4M (2). This is demonstrated in Table 4.

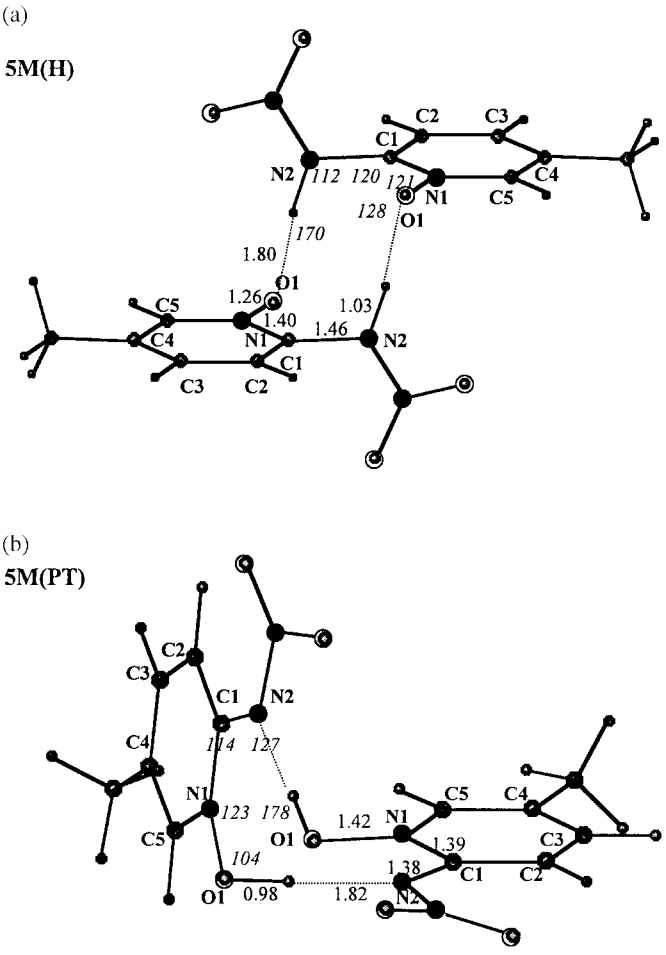
An average value of the appropriate dihedral angle in 5M, 4M (2), and 3M (2) is 168.45(2)°, –174.8(3)°, and –70.8(3)°, respectively. This angle in 5M is rather like that in non-methylated 2NAPNO (168.8(2)°) (1).

The appearance of the molecular (H) or (PT) form of the NAPNO series depends on the different arrangement of two monomers in the crystal lattice and on the degree of electronic conjugation of all functional groups with the π system of the pyridine ring. A perpendicular arrangement of both monomers in dimer predicts the (PT) form while a mutually parallel arrangement, the (H) form. It follows that an average displacement of the nitro group and of the amino nitrogen atom as well as an average C_{ar}—N_{amino} distance is usually slightly smaller in the (PT) form (2). On the other hand, displacement of the NO group from the ring plane and an average N—O bond length are slightly larger in (PT) than in (H) form.

As viewed in Fig. 1, both molecules of the 5M dimer are perpendicularly orientated, as for instance those in 4M (PT) dimer (2). Others with the parameters mentioned above also point at a (PT) form of 5M. For example, the average C_{ar}—N_{amino} distance in 5M (1.357(3) Å) is similar to that in 4M (PT) (1.361(4) Å), but significantly shorter than that in 3M (H) (1.401(2) Å). Also, the N—O distance in 5M (1.375(3) Å) is similiar to the N—O distance in 4M (PT) (1.375(4) Å) (2), while a substantially shorter value was found in 3M (H) (1.316(2) Å) (2).

In methylated derivatives of 4-nitropyridine *N*-oxide such as 3-methyl-4-nitropyridine *N*-oxide (9), 3,5-dimethyl-4-nitropyridine *N*-oxide (19), and 2,3-dimethyl-4-nitropyridine *N*-oxide (20), the average C_{ar}—C_{methyl} distance is about 1.50 Å. In methylated nitraminopyridine *N*-oxides, similar values of 1.502(4) Å in 5M and 1.495(6) Å in 4M (2) were found.

Fig. 2. (*a*) Atom numeration in 5M (H); and (*b*) in 5M (PT) (structures used in PM3 optimization).



B. Molecular geometries

PM3-optimized structures of the 5M monomer and dimer both in (PT) and in its complementary (H) form were used in theoretical absorption spectra calculations. More appropriate names of imino (PT) and amino (H) species are proposed for the gas and the liquid phase, in place of the (PT) and (H) forms, respectively, used for the solid state. Geometrical parameters of optimized molecules are consistent with experimental crystallographic data and some are given in Fig. 2.

Experimental, averaged N···H and H—O bond lengths are 1.69(4) and 0.98(4) Å, respectively, while the corresponding calculated values are 1.82 and 0.98 Å, respectively. Also the

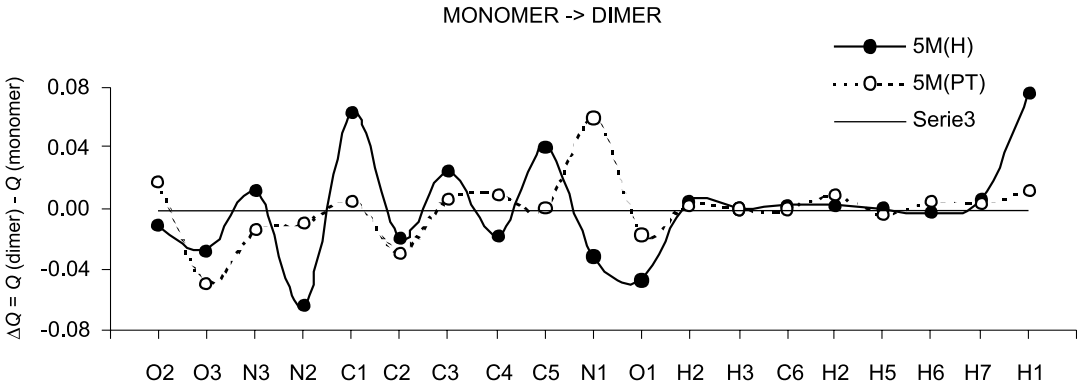
Fig. 3. The difference of charge distribution between the dimer and monomer of 5M vs. particular atoms of the 5M-amino (H) and 5M-imino (PT) form.



theoretical value (104.5°), ascribed to the NOH valence angle agrees with the experimentally obtained value of 103.5(2)°.

A relative arrangement of both optimized 5M (PT) monomers (Fig. 2(*b*)), shows the same orthogonality of planes as that found in the crystalline 5M (Fig.1(*b*)), 2NAPNO (PT) (1), and 4M (PT) dimers (2). In the same way, the planes of the calculated complementary 5M (H) monomers in the amino (H) dimer are observed to be parallel (Fig. 2(*a*)).

Results from total energy difference (3.58 kcal mol^{-1}) between amino (H) and imino (PT) species of 5M, show that the latter is more stable in the gas phase. Also the binding energy (E_B), calculated as the energy difference between the energy of dimer (E_D) and the sum of the energies of the two corresponding monomers (E_M), i.e., $E_B = E_D - 2E_M$, shows a better stability of the (PT) species (8.14 kcal mol^{-1}) than the amino (H) species (7.54 kcal mol^{-1}). Nonetheless, in the amino (H) ↔ imino (PT) prototropic equilibria in solution both species may occur. In a polar solvent, a larger dipole moment of the imino (PT) monomer (8.41 D), in comparison to the 5M (H) monomer (6.36 D), may shift the equilibrium in the direction of the imino (PT) species. On the other hand, almost dipole-less dimers (0.84 D for the 5M (PT) dimer and 0.01D for the 5M (H) dimer) point to the hydrogen-bonded dimeric structures that may be encountered in the non-polar solvents.

A distortion of the charge distributions found in NAPNO molecules (1, 2), as caused by the proximity of substituents with different mesomeric effects, brings about both structural and spectral consequences. The usual electron- and hydrogen-bond-accepting properties of the nitro group (20), are strongly weakened at the expense of the NO group (1, 2) and the intermolecular hydrogen bond is weakened at the expense of the NO group. Intermolecular hydrogen bonding occurs between the nitrogen (N(12) (or N(22))) and the protonated -N(21)-O(21)-H(2) (or N(11)-O(11)-H(1)) group of the neighboring 5M (PT) molecule instead of an intramolecular hydrogen bond with the nitro group. This is due to the slightly smaller negative charges on the oxygen atoms of the nitro group (O(12) (–0.671 e) and O(13) (–0.593 e)) than that on the amino nitrogen atom N(12) (–0.708 e) in the imino 5M (PT) monomer.

On dimerization, some changes in charge distribution are observed in both types of dimers, which are energetically stabilized in comparison to their monomeric units. These changes, as differences of charge distribution between dimer and monomer of the 5M (H) and 5M (PT) species vs. particular atoms are presented in Fig. 3.

Atoms N(13) (N(23)), N(12) (N(22)), and N(11) (N(21)) are those of the nitro, amino, and nitroxo groups, respectively, whereas oxygen atoms O(12, 13) (O(22, 23)) and O(11) (O(21)) belong to the NO_2 and to the NO group, respectively. Atoms C(11)-C(15) (C(21)-C(25)) are those of the pyridine ring and atom C(16) (C(26)) is from the methyl group. As seen in Fig. 3, changes of atomic charges due to complexation occur to the same extent both on the hydrogen bonding components as well as on the ring atoms. Electron density increases on the amino nitrogen atom N(12) (N(22)) being (–0.708 e) and (–0.718 e) in the 5M (PT) form of the monomer and dimer, respectively, and (–0.270 e) and (–0.334 e) in the 5M (H) form of the monomer and dimer, respectively.

The strongest effect of charge redistribution on dimerization can be noted with respect to the ring atoms C(11) (C(21)) and N(11) (N(21)) where atomic charges (with hydrogens summed into heavy atoms) for the monomer and dimer are 0.079 and 0.083, respectively, for the former and 0.436 and 0.496, respectively, for the latter. These changes are connected more with the cyclic shifts of the charge within the ring itself than with its migration from a particular functional group into the ring or vice versa. Spectral consequences of the variable charge distribution in 5M may be easily followed when HOMO and LUMO orbitals of both forms, as depicted in the molecular energy level diagram shown in Table 5.

Values included in Table 5 show the contributions of atomic orbitals of 5M (H) or 5M (PT) species of dimer into HOMO and LUMO orbitals. Charge distribution in HOMO and LUMO orbitals was calculated in the form of the sum of squares of three components, i.e. the N_2O_2 fragment (nitramino group), the pyridine ring (R), and the oxygen atom of the NO group (O). Summation has been extended over the factors of the *s*, p_x, p_y, and p_z orbitals of a given atom.

In both cases, as seen in Table 5, dimer orbitals form pairs of orbitals of a similar energy, being symmetric and antisymmetric combinations of monomer orbitals localized to the same extent on both units of dimer.

The HOMO orbitals of the 5M (H) dimer are mostly localized on the ring, with the exception of orbitals numbered 63 and 64, which are partially localized also on the O_{NO} atom. On the other hand, inspection of LUMO orbitals

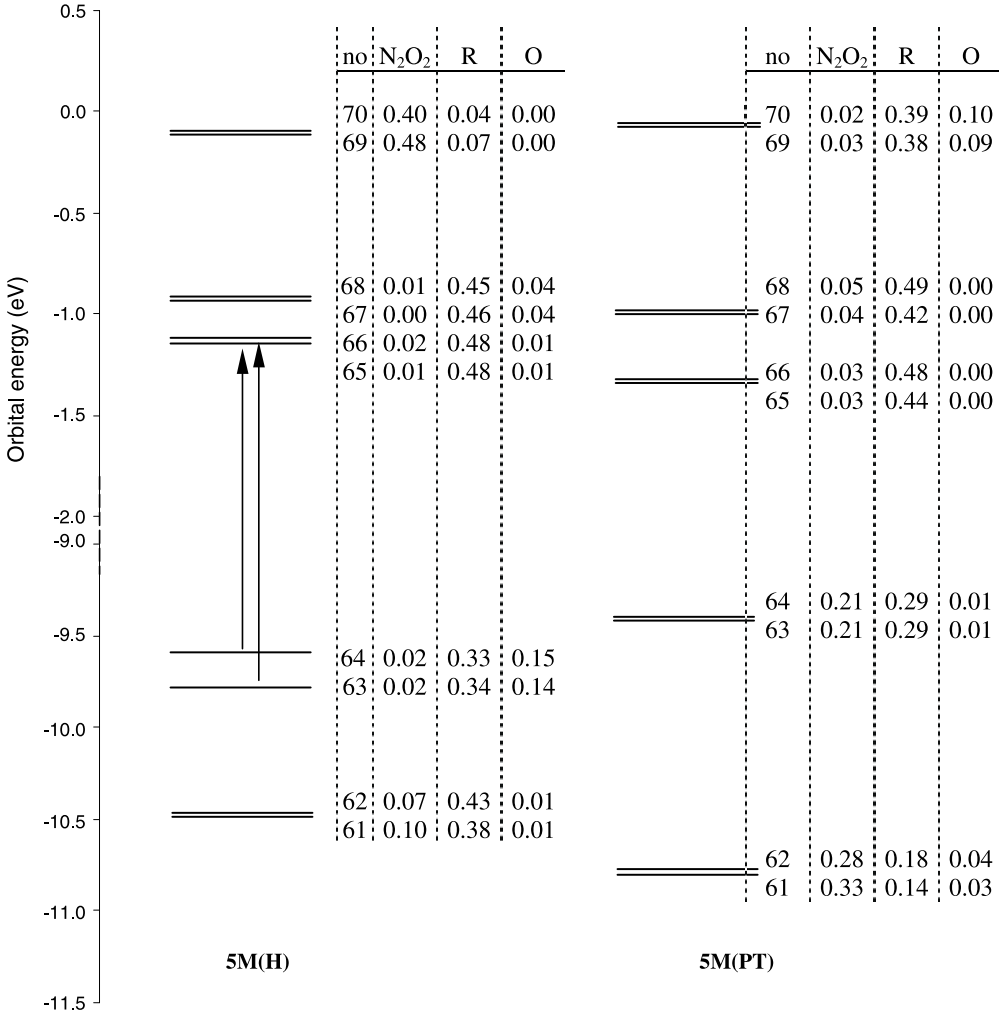
Table 5. The molecular orbitals energy diagram for 5M(H) and 5M(PT) and characteristics of localization of HOMO (61–64) and LUMO (65–70) orbitals.



Note: As an example: electronic configurations (64 → 65 and 63 → 66) have composed the $S_0 \rightarrow S_1$ transition in 5M (H) (see Table 6 and text for definition of N_2O_2, R, and O values).

shows that the first four orbitals of both 5M forms are practically localized on the ring while only orbitals numbered 69 and 70 of 5M (H) dimer are localized on the N_2O_2 fragment involving, in this case, the amino (-NH) nitrogen.

The HOMO orbitals of the 5M (PT) dimer have a mixed character being partly localized on the ring and partly on the N_2O_2 fragment involving the imino nitrogen atom (see orbitals numbered 61 and 62 in Table 5).

Such differences in the character of particular molecular orbitals of both forms of 5M can lead to changes in acid–base properties of the mentioned atoms and to a cooperative excited-state double-proton transfer (ESDPT) process in 5M dimers. ESDPT was also found in dimers of 7-azaindoles (7AI) (21, 22), 1-azacarbazoles (23), and in the 2-pyridone dimer (7) which are linked by two intermolecular N-H···N and N-H···O hydrogen bonds, respectively.

4. Experimental and calculated electronic spectra

The PM3-CI results of transition energy, oscillator strength, and dipole moment calculations for each transition of 5M (H) and 5M (PT) monomers and dimers are illustrated in Table 6.

Experimental absorption spectra of 5M in cyclohexane and in acetonitrile are demonstrated in Fig. 4 and Table 7.

In Fig. 4, the spectra are presented together with calculated and then Gaussian-diffused (half-width 1000 cm^{-1}) spectra in pure amino (H) and imino (PT) forms as well as in the 1:1 (H:PT) hypothetical mixture of both species (50% of amino and 50% of imino form (2)). One may diffuse the calculated spectra because each of the experimental bands is the envelope of several electronic transitions — each of them with their own Franck–Condon (FC) structure (24). In the solution, due to molecular properties, temperature, and interactions with solvent, each FC line is broadened and observed bands are diffused. It is difficult to differentiate the role of particular factors and for these reasons, in the first approximation, we simulate the spectrum as envelopes of Gaussian contours corresponding to the calculated electronic transitions. Their heights correspond to the calculated oscillator strengths. The value of 1000 cm^{-1} is taken as the width of each contour. Such a value leads to relatively good fits and it does not exceed the width of diffused bands of single

electronic transitions of hydrocarbons in more polar solvent (25). The simulated spectra may facilitate identification of the types of species present in the solution, so they may be treated as the reference spectra.

On the basis of calculated transition energies and oscillator strengths of the monomers and dimers (Table 6) of both forms, some differences between their spectra may be formulated as follows: (*i*) the first absorption band of the dimer (at about 29 000cm^{-1}) should be blue-shifted and of a higher intensity than that of the corresponding monomer; (*ii*) the spectra of (PT) and (H) forms differ both in the maxima positions and in intensity distributions. The first absorption band of the (PT) form (at about 28 000 cm^{-1}) is slightly red-shifted and has a higher intensity than that of the (H) form. In the higher wavenumber region of the (PT) spectrum, two distinct bands of a medium intensity are expected, compared to a single band of a higher intensity in the (H) form.

Absorption bands of the electronic spectra of 5M dimers, similarly to those of 3M and 4M (2), are built upon a large number of electronic transitions. Also, as previously demonstrated (1, 2), in the region of the first absorption band, i.e., between 25 000 and 35 000 cm^{-1}, the values of the oscillator strength of imino (PT) form are significantly higher than those of the amino (H) form. The transitions, building up the first absorption band, are more precisely described in Table 8.

Table 8 shows that differences between the spectra of the (H) and the (PT) forms have their source in the different character of electronic transitions. Thus, the first absorption band of the amino (H) species (between 29 000 and 33 000 cm^{-1}) is built upon the (R, O) → R transitions (R means the pyridine ring; and O is the oxygen atom of the NO group), i.e., the transition from the highest two HOMO orbitals (nos. 63, 64) to the first four lower lying LUMO orbitals (nos. 65–68). The parallel nature of both planes in the amino (H) dimer leads in some transitions to zero oscillator strengths as well as to a zero dipole moment, despite that each of the two components has a non-zero value.

In the case of (PT) form, the (N_2O_2, R) → R transitions (N_2O_2 is the nitramino fragment involving the amino nitrogen atom and the nitro group), i.e., from the above-mentioned HOMO orbitals (nos. 63, 64) into the six LUMO orbitals

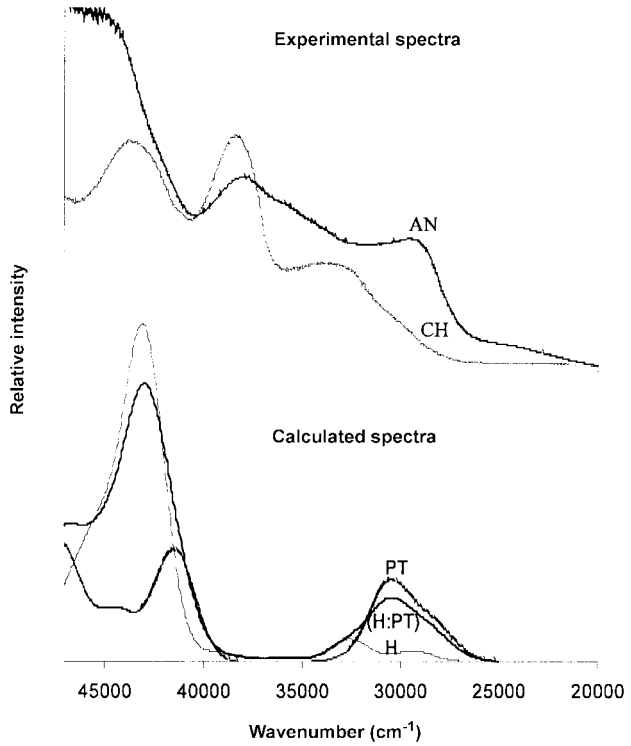
Fig. 4. Experimental electronic absorption spectra of 5M in cyclohexane (CH), and in acetonitrile (AN) solution. For comparison purposes, also the calculated (PM3-CI) electronic absorption spectra of pure amino (H) and imino (PT) form as well as that of 1:1 (H:PT) hypothetical mixture of 5M are demonstrated. They were simulated as the envelope of Gaussian contours corresponding to the calculated electronic transition. Their heights correspond to the calculated oscillator strengths. The value of 1000 cm^{-1} is taken as the width of each contour (see text for details).



(nos. 65–68, as well as to the highest two orbitals (nos. 69 and 70)) are dominant. A perpendicular arrangement of both monomeric units in the (PT) dimer, results in slightly larger values of oscillator strengths and dipole moment than in the (H) species.

Assignment of calculated transition energies (Table 6 and Fig. 4) to experimental absorption bands (Table 7), shows that: (*i*) in cyclohexane, the first two experimental bands at 29 753 cm^{-1} (shoulder 336 nm, I_A = 0.06) and at 33 545 cm^{-1} (298 nm, I_A = 0.15) may correspond to the first two calculated transitions of the 5M (PT) dimer which are at about 28 000 cm^{-1} (shoulder 28 573 cm^{-1}, f = 0.240) and at 30 590 cm^{-1} (maximum, f = 0.514), respectively. This allows a supposition that the hydrogen bonded and weakly polar imino 5M (PT) dimers may prevail in the non-polar solvent. This may be corroborated further by the presence of an experimental middle wavenumber region band at 38 372 cm^{-1} (260.6 nm, I_A = 0.33). The latter is seen in the theoretical absorption spectrum of a pure 5M (PT) form (Fig. 4) in the region between 35 000 and 42 000 cm^{-1} (41 436 cm^{-1}, f = 0.703). The last experimental band observed at 43 630 cm^{-1} (I_A = 0.32) might be ascribed to theoretical band of the 5M (PT) dimer at 44 404 cm^{-1} (f = 0.217); (*ii*) in acetonitrile, the region between 20 000 and 35 000 cm^{-1} of the experimental spectrum of 5M (Table 7), resembles rather more the calculated spectrum of a 1:1 (H:PT) hypothetical mixture (Fig. 4) than that of a pure (H) or (PT) form. In so strong a polar solvent, the intermolecular hydrogen-bonded network between 5M monomers may undergo a partial breaking and both types of polar monomers, theoretically, may appear in the solution. However, due to the significantly larger dipole moment of the imino (PT) monomer, the imino (PT) species may be the dominant one. In such a case, the experimental spectrum results from the overlapping bands of monomers and dimers and has a complicated character in comparison to the calculated one.

The first three experimental bands at 24 151 cm^{-1} (414 nm, I_A = 0.02), 29 603 cm^{-1} (337.8 nm, I_A = 0.13), and 38 051 cm^{-1} (262.8 nm, I_A = 0.19) may be assigned to the first three transition energies of the 5M (PT) monomer (Table 6). These are at 27 451 cm^{-1} (f = 0.198), at 30 039 cm^{-1} (f = 0.254), and at 41 564 cm^{-1} (f = 0.473), respectively. Experimental evidence pointing to the presence of amino 5M (H) monomers is reflected by the shoulder at 35 523 cm^{-1} (281.5 nm, I_A = 0.16) and the band at 45 021 cm^{-1} (222.1 nm, I_A = 0.35). Their theoretical transition energies, as calculated for the monomer of pure (H) form (Table 6),

© 2002 NRC Canada

are at 37 097 cm^{-1} (f = 0.016) and at 45 595 cm^{-1} (f = 0.316), respectively.

A small red shift of the experimental bands in acetonitrile solution, in comparison to calculated transition energies in the gas phase, results from dipole–dipole interactions that take place in the solution.

5. Conclusions

X-ray analysis and the results of PM3-CI calculations have been used to investigate the crystal structure and the spectral properties of 5M. The former shows that in the solid, the (PT) dimer is formed of two perpendicular monomeric units linked through two of different length, intermolecular O-H···N hydrogen bonds. The same orthogonality of both monomers was found in PM3-optimized imino 5M (PT) dimer.

From the results of PM3-CI computations it was concluded that the prototropic amino (H) – imino (PT) equilibria might be present in the solution.

Change in the acid–base properties of hydrogen bonding components caused by the charge redistribution on HOMO–LUMO transitions, seems to be a "driving force" for a possible excited-state-double-proton transfer (ESDPT) to occur in both types of 5M dimers.

Zero or nearly zero values of oscillator strength and dipole moment of the amino (H) dimer, in comparison to slightly larger although still small ones of the imino (PT) dimer, are due to the different character of electronic transitions and different relative arrangements of the two monomers in both dimers.

Assignment of experimental absorption bands to the calculated transition energies of both 5M species reveals that hydrogen-bonded dimers dominate in cyclohexane, whereas a shift in prototropic equilibrium in the direction of the monomeric imino (PT) form seems to prevail in acetonitrile solution.

Synthesis and solid-state molecular structures of bis- and mono-nitrosobenzene complexes of ruthenium porphyrins

Jonghyuk Lee, Brendan Twamley, and George B. Richter-Addo

Abstract: Bis-nitrosobenzene complexes of the form (por)Ru(PhNO)$_2$ (por = TPP, TTP; TPP = tetraphenylporphyrinato dianion, TTP = tetratolylporphyrinato dianion) have been prepared in good yields from the reaction of the (por)Ru(CO) precursor with excess PhNO in dichloromethane. The IR spectra of the complexes (as KBr pellets) displayed new bands at ~1348 cm^{-1}, due to υ_{NO}. The solid-state molecular structure of (TPP)Ru(PhNO)$_2$ was determined by single-crystal X-ray diffraction, and revealed that the PhNO ligands are bound to the Ru center via the *N*-binding mode. Reactions of the (por)Ru(PhNO)$_2$ complexes with excess 1-methylimidazole gave the mono-nitrosobenzene complexes (por)Ru(PhNO)(1-MeIm). The IR spectra revealed a lowering of υ_{NO} in these mononitrosobenzene derivatives by ~27 cm^{-1}, a feature consistent with the replacement of one π-acid PhNO ligand with the more basic 1-MeIm ligand. The solid-state molecular structure of (TPP)Ru(PhNO)(1-MeIm) reveals, in addition to the *N*-binding of the PhNO ligand, an essentially parallel arrangement of the C-N-O (of PhNO) and imidazole planes; this is in contrast with the (TPP)Ru(PhNO)$_2$ complex, in which the C-N-O planes (of PhNO) are essentially perpendicular.

Key words: nitroso, X-ray, ruthenium, porphyrin, imidazole.

Résumé : La réaction du précurseur (por)Ru(CO) avec un excès de PhNO, dans le dichlorométhane, permet de préparer les complexes du bis-nitrosobenzène, de la forme (por)Ru(PhNO)$_2$ (por = TPP, TTP; TPP = dianion tétraphénylporphyrinato, TTP = dianion tétratolylporphyrinato), avec de bons rendements. Les spectres IR des complexes (sous la forme de pastilles de KBr) présentent de nouvelles bandes aux environ de 1348 cm^{-1} dues à υ_{NO}. Faisant appel à la diffraction des rayons X sur un cristal unique, on a déterminé la structure moléculaire à l'état solide du (TPP)Ru(PhNO)$_2$; elle révèle que les ligands PhNO sont liés au centre Ru par le biais d'un mode de fixation par l'azote. Les réactions des complexes (por)Ru(PhNO)$_2$ avec un excès de 1-méthylimidazole conduisent à la formation de complexes mononitrosobenzène (por)Ru(PhNO)(1-MeIm). Le spectre IR de ces dérivés mononitrosobenzène met en évidence un abaissement d'environ 27 cm^{-1} de la υ_{NO}, une caractéristique en accord avec le remplacement d'un ligand PhNO π-acide par le ligand plus basique 1-MeIm. La structure moléculaire à l'état solide du (TPP)Ru(PhNO)(1-MeIm) met en évidence la fixation par l'azote du ligand PhNO ainsi qu'un arrangement essentiellement parallèle des plans C-N-O (du PhNO) et de l'imidazole; cette observation est en opposition à ce qui est observé avec le complexe (TPP)Ru(PhNO)$_2$ dans lequel les plans C-N-O (du PhNO) sont essentiellement perpendiculaires.

Mots clés : nitroso, diffraction des rayons X, ruthénium, porphyrine, imidazole.

[Traduit par la Rédaction]

Introduction

The binding of nitrosobenzene and related RNO compounds (R = alkyl, aryl) to the metal centers in heme biomolecules is a naturally occurring phenomenon, and evidence for RNO binding to the heme site has been established for hemoglobin, myoglobin, cytochrome P450, guanylyl cyclase, NO synthase, and other heme biomolecules; a comprehensive discussion of this subject area has been presented in a recent review (1). For example, various amine-containing drugs can be metabolized by cytochrome P450, resulting in RNO formation and binding to the heme, and the tight binding of the RNO group can inhibit the enzymatic activity.

Much of our understanding of RNO binding to the heme site in heme-containing biomolecules still comes from studies of RNO binding to synthetic metalloporphyrins. Mansuy et al. (2) reported, in 1983, that *i*-PrNO binds to ferrous porphyrins via the *N*-binding mode. Several years ago, we reported the first X-ray structural study of the binding of nitrosoarenes to ferrous and ferric porphyrins, and showed that the nature of binding (*N*-bound vs. *O*-bound) depended on the formal oxidation state of the metal (3). Since then, other structural reports have also been published on RNO binding to metalloporphyrins of Fe (4), Mn (5), Co (6), Ru (6), and Os (7).

We are particularly interested in RNO binding to Ru(II) porphyrins, since the latter species serve as good models for low-spin d^6 systems similar to low-spin ferrous heme. In this report, we present and describe the successful syntheses of bis-nitrosobenzene complexes of Ru(II) tetraarylporphyrins — namely (por)Ru(PhNO)$_2$ — and their ready conversion by reaction with 1-methylimidazole to the axially unsymmetrical (por)Ru(PhNO)(1-MeIm) derivatives. In particular, we examine the electronic and structural consequences of PhNO binding, and discuss the effect of the axial imidazole ligand on the orientation of the trans PhNO ligand.

Experimental section

All reactions were performed under an atmosphere of prepurified nitrogen, using standard Schlenk glassware, and (or) in an Innovative Technology Labmaster 100 dry box. Solutions for spectral studies were also prepared under a nitrogen atmosphere. Solvents were distilled from the appropriate drying agents under nitrogen, just prior to use (CH_2Cl_2 (CaH_2), hexane (CaH_2)).

Chemicals

(TPP)Ru(CO) and (TTP)Ru(CO) were prepared by published procedures (8). The samples were converted, in moist air, to (por)Ru(CO)$(H_2O)_x$ ($x \leq 1$) species (por = TPP, TTP) (9). PhNO (97%) and 1-methylimidazole (1-MeIm, 99+%) were purchased from Aldrich Chemical Co. and used as received. Chloroform-*d* (99.8%) was obtained from Cambridge Isotope Laboratories.

Instrumentation

Infrared spectra were recorded on a Bio-Rad FT-155 FT-IR spectrometer. Proton NMR spectra were obtained on a Varian 400 MHz spectrometer and the signals referenced to the residual signal of the employed solvent. All coupling constants are in Hz. FAB mass spectra were obtained on a VG-ZAB-E mass spectrometer. UV–vis spectra were recorded on a Hewlett-Packard model 8453 diode array instrument. Wavelengths are reported with ε values, or as % intensities for the samples whose yields were too small for accurate concentration measurements.

Preparation of (por)Ru(PhNO)$_2$ compounds (por = TPP, TTP)

(TPP)Ru(CO) (0.100 g, 0.135 mmol) and excess PhNO (0.040 g, 0.362 mmol) were dissolved in CH_2Cl_2 (20 mL). The reaction mixture was stirred at room temperature for 30 min, during which time it turned from red to brown. The solvent was removed in vacuo. The residue was redissolved in CH_2Cl_2 (10 mL), and the product solution was transferred to the top of a neutral alumina column (2 × 20 cm), and eluted with CH_2Cl_2 in air. The brown product was collected and dried in vacuo. The residue was dissolved in CH_2Cl_2 (10 mL). Slow evaporation of the solvent in air gave crystalline (TPP)Ru(PhNO)$_2$ (0.086 g, 0.093 mmol, 69% isolated yield). UV–vis (5.18×10^{-6} M in CH_2Cl_2) λ (nm) (ε (mM^{-1}, cm^{-1})): 307 (37), 411 (184), 525 (17). IR (KBr pellet) (cm^{-1}): υ_{NO} 1348 (s) (overlapping with the porphyrin band); also 3055 (vw), 3024 (vw), 1597 (m), 1587 (vw), 1529 (w), 1487 (w), 1454 (w), 1441 (w), 1306 (m), 1208 (w), 1177 (w), 1157 (vw), 1072 (m), 1010 (vs), 859 (m), 833 (w), 794 (m), 754 (s), 737 (vw), 714 (w), 702 (s), 665 (w), 528 (vw). ^{1}H NMR ($CDCl_3$) δ: 8.54 (s, 8H, pyrrole-H of TPP), 8.12 (m, 8H, *o*-H of TPP), 7.71 (m, 12H, *m*/*p*-H of TPP), 6.46 (br t, 2H, *p*-H of PhNO), 5.99 (br t, 4H, *m*-H of PhNO), 2.41 (br d, *J* = 6.8 Hz, 4H, *o*-H of PhNO). LR-FAB-MS *m*/*z* (%): 851 ([(TPP)Ru(NO)(PhNO)]$^+$, 26), 821 ([(TPP)Ru(PhNO)]$^+$, 19), 714 ([(TPP)Ru]$^+$, 100).

The (TTP)Ru(PhNO)$_2$ compound was prepared similarly from (TTP)Ru(CO) and excess PhNO. The brown product was obtained in 75% isolated yield. UV–vis (CH_2Cl_2) λ (nm): 310 (18), 413 (100), 525 (9). IR (KBr pellet) (cm^{-1}): υ_{NO} 1346 (s) (overlapping with the porphyrin band); also 3022 (vw), 2921 (vw), 1586 (vw), 1529 (w), 1454 (w), 1305 (m), 1212 (w), 1181 (m), 1108 (w), 1072 (m), 1010 (vs), 858 (m), 798 (s), 766 (m), 716 (m), 691 (m), 669 (w), 643 (vw), 524 (m). ^{1}H NMR ($CDCl_3$) δ: 8.54 (s, 8H, pyrrole-H of TTP), 7.99 (d, *J* = 8 Hz, 8H, *o*-H of TTP), 7.50 (d, *J* = 8 Hz, 8H, *m*-H of TTP), 6.43 (br, 2H, *p*-H of PhNO), 5.95 (br, 4H, *m*-H of PhNO), 2.67 (s, 12H, C*H*$_3$ of TTP), 2.38 (br, 4H, *o*-H of PhNO). LR-FAB-MS *m*/*z* (%): 907 ([(TTP)Ru(NO)(PhNO)]$^+$, 32), 877 ([(TTP)Ru(PhNO)]$^+$, 15), 770 ([(TTP)Ru]$^+$, 100).

Preparation of (por)Ru(PhNO)(1-MeIm) compounds (por = TPP, TTP)

To a CH_2Cl_2 (10 mL) solution of (TPP)Ru(PhNO)$_2$ (0.020 g, 0.021 mmol) was added 2 equiv of 1-MeIm. This mixture was stirred at room temperature for 30 min, during which time it turned from brown to red-purple. The solvent was removed in vacuo. An ^{1}H NMR spectrum of the residue in $CDCl_3$ showed the quantitative formation of (TPP)Ru(PhNO)(1-MeIm), together with the presence of some unreacted 1-MeIm. Spectroscopically pure (TPP)Ru(PhNO)(1-MeIm) was obtained in 80% yield by recrystallization of the residue from a CH_2Cl_2–hexane solution (1:3) at –20°C. UV–vis (3.19×10^{-6} M in CH_2Cl_2) λ (nm) (ε (mM^{-1}, cm^{-1})): 307 (42), 413 (257), 533 (24). IR (KBr pellet) (cm^{-1}): υ_{NO} 1322 (s); also 3127 (vw), 3052 (w), 3022 (w), 1596 (m), 1529 (m), 1482 (w), 1440 (m), 1348 (m), 1303 (m sh), 1237 (w), 1207 (w), 1177 (w), 1157 (w), 1109 (w), 1072 (m), 1008 (vs), 949 (vw), 924 (vw), 888 (vw), 833 (vw), 815 (vw), 793 (m), 752 (s), 701 (s), 665 (w), 615 (w), 527 (w). ^{1}H NMR ($CDCl_3$) δ: 8.37 (s, 8H, pyrrole-H of TPP), 8.05 (m, 8H, *o*-H of TPP), 7.64 (m, 12H, *m*/*p*-H of TPP), 6.39 (tt, *J* = 7.2, 1.2 Hz, 1H, *p*-H of PhNO), 5.96 (m, 2H, *m*-H of PhNO), 4.74 (dd (apparent t), *J* = 1.2, 1.2 Hz, 1H of 1-MeIm), 2.64 (m, 2H, *o*-H of PhNO), 2.18 (s, 3H, C*H*$_3$ of 1-MeIm), 1.58 (br dd (apparent br t), 1H of 1-MeIm), 1.22 (dd (apparent t), *J* = 1.2, 1.2 Hz, 1H of 1-MeIm). LR-FAB-MS *m*/*z* (%): 903 ([(TPP)Ru(PhNO)(1-MeIm)]$^+$, 18), 822 ([(TPP)Ru(PhNO) + H]$^+$, 19), 796 ([(TPP)Ru(1-MeIm)]$^+$, 51), 714 ([(TPP)Ru]$^+$, 100).

The (TTP)Ru(PhNO)(1-MeIm) compound was obtained similarly in 57% isolated yield after recrystallization from a CH_2Cl_2–hexane solution (1:5) at –20°C. UV–vis (CH_2Cl_2) λ (nm): 310 (8), 414 (100), 533 (4). IR (KBr pellet) (cm^{-1}): υ_{NO} 1321 (s); also 3127 (vw), 3020 (w), 2953 (vw), 2921 (w), 2869 (vw), 1530 (m), 1506 (w), 1449 (w), 1348 (m), 1287 (w), 1237 (w), 1212 (w), 1181 (m), 1108 (m), 1092 (w), 1071 (m), 1007 (vs), 947 (vw), 886 (w), 847 (vw), 798

X-ray crystallographic studies

Crystals were removed from the flasks and covered with a layer of hydrocarbon oil. Suitable crystals were selected, attached to a glass fiber and placed in the low-temperature nitrogen stream. Data were collected at low temperature using a Siemens (Bruker) SMART 1K instrument (Mo Kα radiation, λ = 0.71073 Å) equipped with a Siemens (Bruker) LT-2A low-temperature device. Data were measured using ω scans of 0.3° per frame for 30 s, and a full sphere of data was collected. The first 50 frames were recollected at the end of data collection to monitor for decay. Cell parameters were retrieved using SMART (10) software and refined using SAINTPlus (11) on all observed reflections. Data reduction and correction for *Lp* and decay was performed using the SAINTPlus software. Absorption corrections were applied using SADABS (12). The structures were solved by direct methods and refined by the least-squares method on F^2 using the SHELXTL v.5.10 program package (13). The structure was solved in the respective space groups by analyses of systematic absences. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were placed in their geometrically generated positions and refined using a riding model. No decomposition was observed during data collection. Details of the data collection and refinement are given in Table 1. Further details are provided in the Supporting information.[2] Displacement ellipsoids in Figs. 1 and 2 were drawn at the 50% probability level.

(TPP)Ru(PhNO)$_2$ (1)

Purple needles of the compound were grown by recrystallization from a CH_2Cl_2–hexane (1:10) mixture left for 1 week at –20°C. A total of 2132 frames were collected with a final resolution of 0.77 Å.

(TPP)Ru(PhNO)(1-MeIm)·(0.25CH$_2$Cl$_2$) (2)

Suitable crystals for X-ray crystallography were grown from a CH_2Cl_2–hexane solution (1:3) left for 2 weeks at

–20°C. A total of 1471 frames were collected with a final resolution of 0.84 Å.

Results and discussion

Synthesis of the bis-nitrosobenzene complexes

James and co-workers (14) previously reported the synthesis of (OEP)Ru(PhNO)$_2$ from the reaction of (OEP)Ru(CO) with excess PhNO in dichloromethane. Using similar methodology, we successfully synthesized and reported the related compound (OEP)Ru(ONC$_6$H$_4$NMe$_2$)$_2$ (6). We have now extended this synthetic methodology to the preparation of bis-nitrosobenzene complexes of *tetraaryl*porphyrin complexes of Ru.

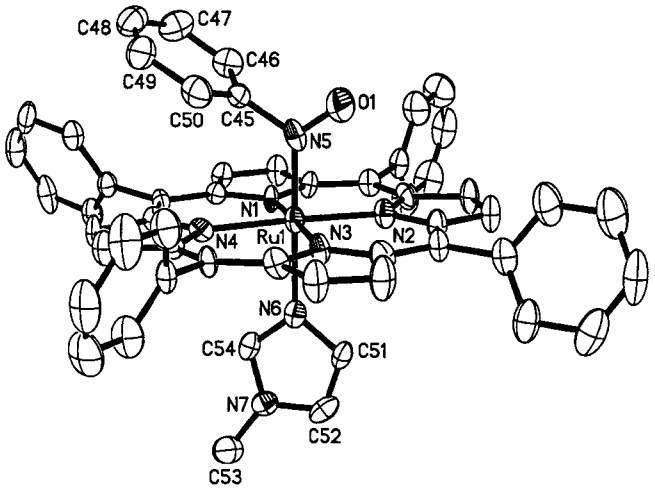
The reaction of excess PhNO with the (por)Ru(CO) compounds (por = TPP, TTP) generates, after work-up, the bis-nitrosobenzene complexes (por)Ru(PhNO)$_2$ in 69% (TPP) and 75% (TTP) isolated yields (eq. [1]).

[1] (por)Ru(CO) + excess PhNO $\rightarrow$ (por)Ru(PhNO)$_2$ + CO

These brown bis-nitrosobenzene complexes are moderately air-stable in solution and can be stored in air in the solid state for several months without noticeable decomposition. They are soluble in CH_2Cl_2 and toluene, but are insoluble in hexane. We were not able to detect the proposed intermediate (por)Ru(CO)(PhNO) compounds by IR spectroscopy, and this differs from the case of the previously reported (and similar) reaction of (OEP)Ru(CO) with *N*,*N*-dimethyl-*p*-nitrosoaniline to give (OEP)Ru(ONC$_6$H$_4$NMe$_2$)$_2$ via a detectable intermediate, (OEP)Ru(CO)(ONC$_6$H$_4$NMe$_2$) (6).

The IR spectra of the new (por)Ru(PhNO)$_2$ complexes (as KBr pellets) show new bands at ~1348 cm^{-1} assignable to υ_{NO}. The marked drop in υ_{NO} from free PhNO at 1506 cm^{-1} is consistent with the view that the π^* orbitals of the PhNO ligands withdraw electron density from the "(por)Ru" fragment in the (por)Ru(PhNO)$_2$ complexes (1). Further evidence of the PhNO ligands behaving as π-acids comes from the X-ray crystal structure of (TPP)Ru(PhNO)$_2$ (see later).

Fig. 2. Molecular structure of (TPP)Ru(PhNO)(1-MeIm). Hydrogen atoms have been omitted for clarity.



The ^{1}H NMR spectra of the (por)Ru(PhNO)$_2$ complexes in $CDCl_3$ show, as expected, peaks for both the porphyrin macrocycle and the PhNO ligands in these diamagnetic, and formally d^6, Ru(II) complexes. For example, the pyrrole-protons of the porphyrin macrocycle are at 8.54 ppm for both the (por)Ru(PhNO)$_2$ complexes (por = TPP, TTP). The *o*- and *m*-protons of the tetraaryl groups in (TTP)Ru(PhNO)$_2$ are resolved, and are at 7.99 and 7.50 ppm, respectively.

Synthesis of the mono-nitrosobenzene complexes

Many heme-containing biomolecules contain histidine as the axial proximal ligand. Thus, we were interested in synthesizing the axially unsymmetrical (por)Ru(PhNO)(1-MeIm) complexes to examine their spectroscopic properties and to determine the effect of the axial imidazole ligand on the binding of PhNO in these complexes.

The mono-nitrosobenzene complexes, (por)Ru(PhNO)(1-MeIm) (por = TPP, TTP), are readily prepared in 80% (for TPP) and 57% (for TTP) isolated yields, from the reaction of the precursor, (por)Ru(PhNO)$_2$, with an excess of 1-MeIm (eq. [2]).

[2] (por)Ru(PhNO)$_2$ + 1-MeIm $\rightarrow$ (por)Ru(PhNO)(1-MeIm) + PhNO

The ^{1}H NMR spectra of the crude product mixtures in $CDCl_3$ (after a 30 min reaction time in CH_2Cl_2 at room temperature, followed by solvent removal in vacuo, and redissolution of the product in $CDCl_3$) showed the presence of the desired mono-nitrosobenzene complexes and unreacted organic 1-MeIm as the only H-containing species. Despite the use of an excess of 1-MeIm in these reactions, the formation of the mono-nitrosobenzene complexes as the only Ru-containing products indicates that only one PhNO ligand in the (por)Ru(PhNO)$_2$ complexes is susceptible to substitution reaction under our reaction conditions. Interestingly, a similar observation has been made by James and co-workers (14) who reported that (OEP)Ru(PhNO)$_2$ reacts with 2 equiv of pyridine at room temperature to generate the mono-substituted product (OEP)Ru(PhNO)(py) within 10 min. We have also obtained ^{1}H NMR spectroscopic

© 2002 NRC Canada

evidence for the formation of (OEP)Os(PhNO)(1-MeIm) from the reaction of the previously reported $(OEP)Os(PhNO)_2$ with an excess of 1-MeIm.[3] These red-purple mono-nitrosobenzene complexes of Ru are moderately air-stable, showing no signs of decomposition in air after 1 month in the solid state and at least 8 h in solution. As with their bis-nitrosobenzene precursors, they are soluble in CH_2Cl_2 and toluene, but are insoluble in hexane.

The IR spectra of the (por)Ru(PhNO)(1-MeIm) complexes show bands at ~1321 cm^{-1} assignable to υ_{NO}. These bands are shifted by ~27 cm^{-1} to lower wavenumbers relative to the bis-nitrosobenzene precursors (υ_{NO} 1348 cm^{-1} (TPP) or 1346 cm^{-1} (TTP)). This shifting of υ_{NO} to lower wavenumbers is consistent with the replacement of one of the π-acid PhNO ligands (in the bis-nitrosobenzene precursor) with the more basic 1-MeIm ligand, which results in more Ru→N(O)Ph back-donation in the mono-nitrosobenzene complexes. The ^1H NMR spectra of the mono-nitrosobenzene complexes in $CDCl_3$ also reveal, in addition to porphyrin signals, peaks due to both the coordinated PhNO and 1-MeIm ligands. The chemical shifts of the $\delta_{pyrrole}$ protons of the mono-nitrosobenzene complexes (8.37–8.38 ppm) are slightly upfield shifted relative to those of the bis-nitrosobenzene complexes (8.54 ppm), indicative of a slight increase in electron-density of the porphyrin macrocycles in the mono-nitrosobenzene complexes relative to the bis-nitrosobenzene complexes. Importantly, the ^1H NMR spectrum of (TTP)Ru(PhNO)(1-MeIm) reveals that the *ortho*-protons of the *meso*-aryl substituent on the porphyrin rings are not equivalent, and the *meta*-protons are also nonequivalent; this is a common feature for *p*-substituted tetraphenylporphyrin complexes of the form (por)M(X)(Y) containing different ligands on each face of the porphyrin plane (15, 16). The ^1H NMR spectral peak patterns for the coordinated 1-MeIm ligands are assigned according to Leyden and Cox (17).

X-ray crystallographic characterization

The molecular structures of $(TPP)Ru(PhNO)_2$ and (TPP)Ru(PhNO)(1-MeIm) are shown in Figs. 1 and 2, respectively. Selected bond lengths, angles, and axial ligand orientations are shown in Fig. 3.

As can be seen in Figs. 1 and 2, the nitrosobenzene ligands are attached to the formally Ru(II) centers via an η^1-N bonding mode. The Ru—N(por) distances for $(TPP)Ru(PhNO)_2$ fall in the range of 2.047(2)–2.060(2) Å. Perpendicular atom displacements of the atoms in the porphyrin skeleton from the 24-atom mean porphyrin plane are shown in the middle of Fig. 3(*a*). The porphyrin macrocycle of $(TPP)Ru(PhNO)_2$ exhibits a *saddle* distortion, and the Ru atom resides in the plane of the porphyrin (a calculated displacement from the 24-atom mean porphyrin plane of only 0.03 Å).

The axial Ru—N (of PhNO) bond lengths in $(TPP)Ru(PhNO)_2$ are 1.953(2) and 2.049(2) Å, and the N—O bond lengths are 1.243(3) and 1.248(3) Å. The sum of angles around the nitroso nitrogens are ~360°, indicative of the planarity around the nitroso N-atoms. The axial N-Ru-N bond angle is 171.67(9)°, and this deviates only slightly from strict linearity. The axial ligand orientations in $(TPP)Ru(PhNO)_2$ are shown in Fig. 3(*a*). The PhNO ligands in $(TPP)Ru(PhNO)_2$ are oriented perpendicular to each other, and their C-NO groups essentially bisect the porphyrin nitrogens.

The molecular structure of (TPP)Ru(PhNO)(1-MeIm) was also obtained and shown in Figs. 2 and 3(*b*). As with $(TPP)Ru(PhNO)_2$, the nitrosobenzene ligand in (TPP)Ru(PhNO)(1-MeIm) is bound to the Ru(II) center via an η^1-N bonding mode. The Ru—N(por) distances are in the 2.039(4) Å to 2.062(5) Å range. Perpendicular atom displacements of the atoms in the porphyrin skeleton from the 24-atom mean porphyrin plane are shown in the middle of Fig. 3(*b*), and unlike $(TPP)Ru(PhNO)_2$, the porphyrin macrocycle of (TPP)Ru(PhNO)(1-MeIm) exhibits a *ruffled* distortion. The axial Ru—N(PhNO) and O—N(Ph) bond lengths are 1.884(6) Å and 1.267(7) Å, respectively. The axial ligand orientations in (TPP)Ru(PhNO)(1-MeIm) are also shown in Fig. 3(*b*). Interestingly, and unlike in the case of $(TPP)Ru(PhNO)_2$, the PhNO and 1-MeIm ligands in (TPP)Ru(PhNO)(1-MeIm) are oriented essentially parallel to each other, and their C-NO (for PhNO) and C-N-C (for 1-MeIm) groups essentially bisect the porphyrin nitrogens.

There are several notes of interest regarding the molecular structures of $(TPP)Ru(PhNO)_2$ and (TPP)Ru(PhNO)(1-MeIm). For example, the axial Ru—N(PhNO) bond length (1.953(2) to 2.049(2) Å) in $(TPP)Ru(PhNO)_2$ is longer than the related axial Ru—N(PhNO) distance of 1.884(6) Å seen in (TPP)Ru(PhNO)(1-MeIm), and this observation is suggestive of *decreased* Ru→N(O)Ph back-bonding in $(TPP)Ru(PhNO)_2$ relative to that in (TPP)Ru(PhNO)(1-MeIm). This view is consistent with the IR and ^1H NMR spectroscopic results discussed in the previous section. The O—N(Ph) bond lengths are not significantly different within these bis- and mono-nitrosobenzene complexes.

The most chemically interesting features of the structures of these (TPP)Ru(PhNO)-containing complexes are the axial ligand orientations. Indeed, the examination of the axial ligand orientations in heme model complexes is of importance due partly to the fact that the axial ligand orientations are affected by the electronic structure of the metal center. We have previously reported the single-crystal X-ray structure of the $(TPP)Fe(PhNO)_2$ complex containing two axial π-acidic PhNO ligands, and proposed that the presence of two axial π-acid ligands results in the perpendicular orientation of the axial ligands, and that this orientation maximizes the π-back-bonding from the HOMOs of the low-spin (TPP)Fe(II) fragment (namely the filled d_{xz} and d_{yz} orbitals) into the empty π* orbitals of the axial PhNO ligands (3). We have observed similar perpendicular axial ArNO ligand orientations in $(por)Os(ArNO)_2$ complexes (7). Indeed, and as expected, the PhNO ligands in $(TPP)Ru(PhNO)_2$ are oriented perpendicular to each other, indicating that the PhNO ligands act as π-acids in this complex.

[3] Data for (OEP)Os(PhNO)(1-MeIm). ^1H NMR ($CDCl_3$) δ: 9.18 (s, 4H, *meso*-H of OEP), 6.17 (br tt, 1H, *p*-H of PhNO), 5.74 (m, 2H, *m*-H of PhNO), 4.61 (dd (apparent t), *J* = 1.2, 1.2 Hz, 1H of 1-MeIm), 3.75 (m, 16H, CH_2CH_3 of OEP), 2.99 (m, 2H, *o*-H of PhNO), 2.08 (s, 3H, CH_3 of 1-MeIm), 1.75 (t, *J* = 8 Hz, 24H, CH_2CH_3 of OEP), 1.33 (br, 1H of 1-MeIm), 1.05 (dd (apparent t), *J* = 1.2, 1.2 Hz, 1H of 1-MeIm).

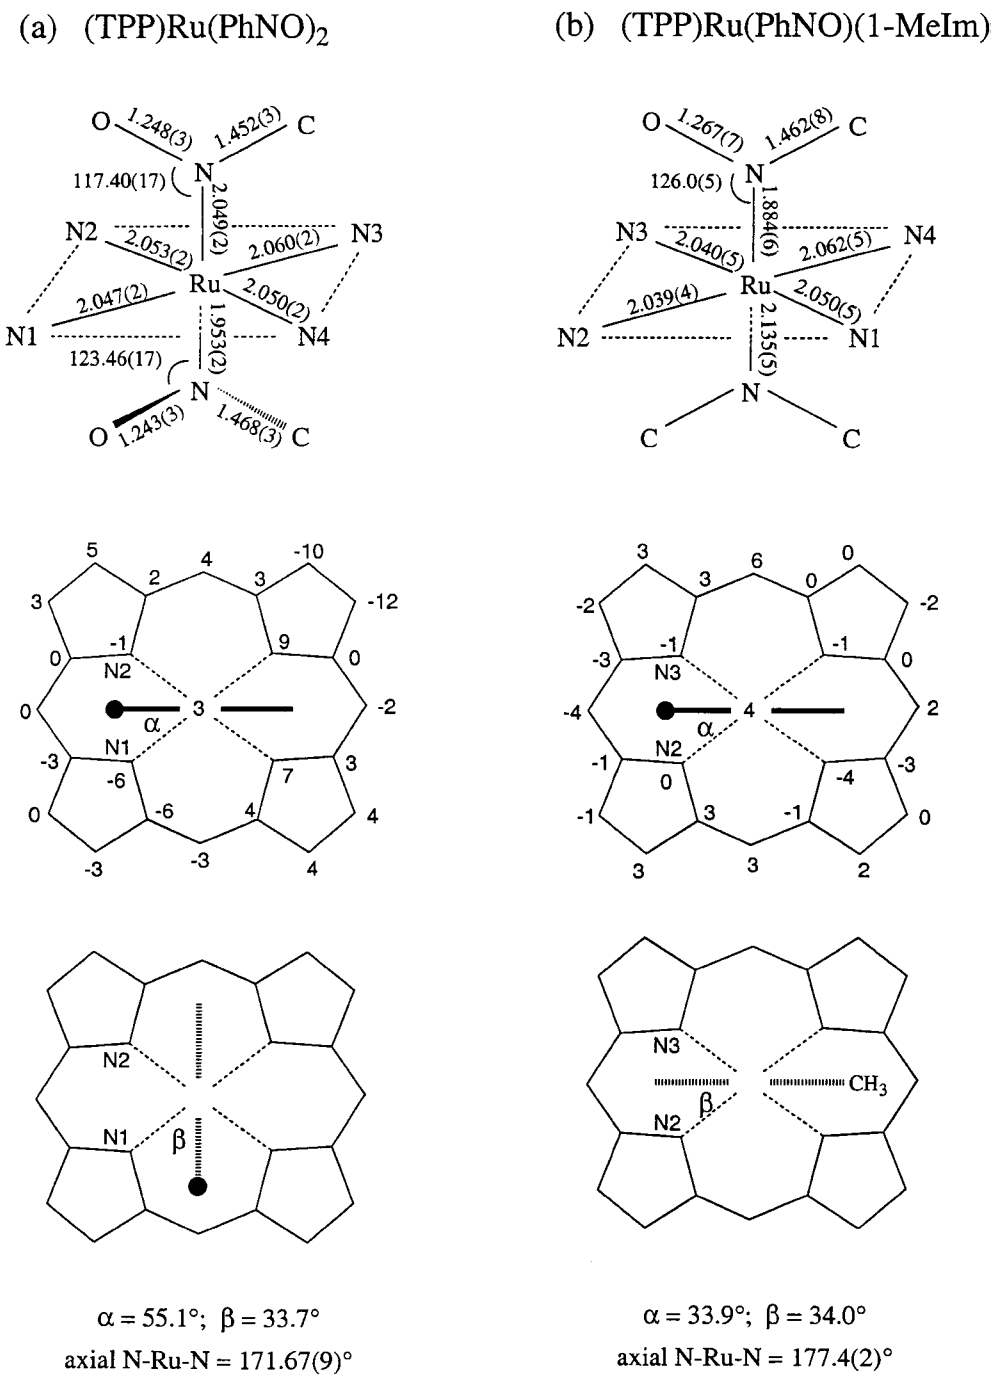
Fig. 3. Structural data for (*a*) (TPP)Ru(PhNO)$_2$ and (*b*) (TPP)Ru(PhNO)(1-MeIm). Selected bond lengths and angles are shown at the top. Perpendicular atom displacements from the 24-atom porphyrin plane (in 0.01 Å units) are shown at the middle. Also shown are the two axial ligand orientations at the middle and the bottom: α is the torsion angle involving O-N-Ru-N(por), and β is the torsion angle involving O-N-Ru-N(por) (for (TPP)Ru(PhNO)$_2$) or C-N-Ru-N(por) (for (TPP)Ru(PhNO)(1-MeIm)). The solid dot represents the nitroso oxygen atom, and the solid line represents the O-N-C unit of the PhNO ligand situated above the porphyrin plane. The dashed line represents the O-N-C unit of the second PhNO ligand situated below the porphyrin plane (for (TPP)Ru(PhNO)$_2$), or the C-N-C unit of the 1-MeIm ligand (for (TPP)Ru(PhNO)(1-MeIm)) situated below the porphyrin plane.



α = 55.1°; β = 33.7°
axial N-Ru-N = 171.67(9)°

α = 33.9°; β = 34.0°
axial N-Ru-N = 177.4(2)°

The axial ligand orientation observed for the solid-state structure of (TPP)Ru(PhNO)(1-MeIm) (Fig. 3(*b*)) provides an interesting comparison with that seen for (TPP)Ru(PhNO)$_2$ (Fig. 3(*a*)). Thus, the PhNO and 1-MeIm ligands in (TPP)Ru(PhNO)(1-MeIm) are nearly parallel to each other. This axial ligand orientation, observed for (TPP)Ru(PhNO)(1-MeIm), suggests that the 1-MeIm ligand could act as a π donor in this case. Indeed, the parallel orientation seen for (TPP)Ru(PhNO)(1-MeIm) might be expected to maximize the π-back-bonding from one of two filled d_π

© 2002 NRC Canada

orbitals of Ru(II) into the empty π^* orbital of the PhNO ligand.

Conclusion

We have successfully obtained isolable bis-nitrosobenzene and mono-nitrosobenzene complexes of ruthenium tetraarylporphyrins. The comparative spectroscopic and single-crystal X-ray crystallographic information obtained from this work reveals differences in the π-acidic and basic character of the PhNO and 1-MeIm ligands when situated *trans* to PhNO. This result is of great interest to model heme chemistry involving nitroso-based ligands, and poses additional questions that need to be addressed. For example, how important is axial ligand orientation for the dissociation of *trans* ligands? Such questions form the focus of future studies in this area.

Potentiometric study of equilibrium acidities of some carbon acids in acetonitrile

M. Stanczyk-Dunaj, W. Galezowski, and A. Jarczewski

Abstract: The pK_a values for 30 C-acids of the type $CH{\cdot}R^1{\cdot}R^2{\cdot}R^3$ — where the R^1, R^2, and R^3 substituents are H, alkyl, and aryl, and the most common electron withdrawing groups used in studies of proton-transfer reaction — are given herein. The pK_a values have been measured potentiometrically in acetonitrile, using a glass electrode. These values were determined in a buffer solution consisting of a C-acid and its tetrabutylammonium salt, at constant ionic strength (0.001 M), at 25°C. The measurements were done under nitrogen, to prevent oxidation of the anion. The influence of water within the sample of the tetrabutylammonium hydroxide base was negligible. The lowest pK_a value of 19.1 was found for bis(4-nitrophenyl)cyanomethane, while the largest pK_as that could be measured were limited by the basicity of the hydroxide ion, and did not exceed 28. A satisfactory agreement between spectrophotometric and potentiometric acidities was achieved.

Key words: C-acids, pK_a values, acetonitrile, potentiometry, proton transfer.

Résumé : On a mesuré les valeurs de pK_a de 30 C-acides du type $CH{\cdot}R^1{\cdot}R^2{\cdot}R^3$ dans lesquels les substituants R^1, R^2 et R^3 sont des H, alkyle, aryle et la plupart des groupes électroaffinitaires utilisés dans l'étude de la réaction de transfert de proton. Les valeurs de pK_a ont été mesurées potentiométriquement, dans l'acétonitrile, à l'aide d'une électrode de verre. Ces valeurs ont été déterminées dans une solution tampon formée d'un C-acide et de son sel de tétrabutylammonium, à force ionique constante de 0,001 M, à 25°C. Les mesures ont été faites sous atmosphère d'azote, pour éviter l'oxydation de l'anion. L'influence de l'eau contenue dans l'échantillon de la base, hydroxyde de tétrabutylammonium, est négligeable. La valeur la plus faible de pK_a est associée au bis(4-nitrophényl)cyanométhane alors que les valeurs les plus élevées étaient limitées par la basicité de l'ion hydroxyde et ne dépassaient pas 28. On a observé une corrélation satisfaisante entre les acidités spectrophotométriques et potentiométriques.

Mots clés : C-acides, valeurs de pK_a, acétonitrile, potentiométrie, transfert de proton.

[Traduit par la Rédaction]

Introduction

The pK_a values for C-acids of different structure and strength are crucial for studying proton-transfer reactions and the formation of hydrogen-bonded complexes in acetonitrile. They are essential for determining Brønsted parameters (1, 2) and the symmetry of the transition state (3–6), which are two of the major factors influencing deuterium kinetic isotope effects. Obviously, any discussion of the symmetry of the hydrogen bonds in the complexes formed with C-acids and strong organic bases in acetonitrile requires precise pK_a values (7, 8). Acetonitrile appears to be the most commonly used solvent in kinetic and equilibrium experiments of proton-transfer reactions.

A survey of spectrophotometric pK_a values for C-acids in acetonitrile has already been published (9). The aim of this paper is to measure the pK_a values for a set of 30 C-acids of the type $CH{\cdot}R^1{\cdot}R^2{\cdot}R^3$, where R^1, R^2, and R^3 are H, alkyl, aryl, and the most common electron withdrawing groups that activate C-acids, such as nitro, cyano, alkylsulfonyl, and carboxyalkyl (Table 1), all in acetonitrile, using the potentiometric method (10). The measurements were performed using buffer solutions of the appropriate C-acid and its tetrabutylammonium salt, at a constant ionic strength (0.001 M), at 25°C.

The spectrophotometric results reported in the previous paper (9) were measured in buffer solutions composed of a strong amine base of known potentiometric pK_a value, and its perchlorate or picrate salt. This way, the pK_a values for 11 of the C-acids most commonly used in kinetic and equilibrium experiments of proton-transfer reactions were found. This method is impractical, however, when (*i*) the absorption band of the salt of the C-acid is buried under the absorption of the amine base, which is in large excess compared with the C-acid; (*ii*) some amine bases tend to homoconjugate with their cations (11, 12), which causes undesirable complications; and (*iii*) spectrophotometric pK_a values for C-acids could show some scatter due to various errors in the pK_as of the amine bases. A comparison between the spectrophotometric and potentiometric pK_a values for C-acids is, therefore, of interest.

Since a water solution of tetrabutylammonium hydroxide was used to prepare the measuring buffer solutions, water

present in the system could have a significant effect on our results. Thus, some experiments concerning this effect were made.

Results and discussion

In the kinetic and equilibrium experiments, a number of strong C-acids of differring structure were tested (13) (Table 1). In previous kinetic and equilibrium experiments, uncomplicated C-acids, such as **3**, were used (14). At that time, the large primary deuterium kinetic isotope effect (KIE) values were attributed to three factors: steric hindrance of the reacting base (15, 16), symmetry of the transition state (9, 13, 17), and polarity of the solvent used (13, 18, 19). To find the factors influencing the values of KIE, the series of C-acids with increasing R substituent bulk, and hence increasing steric hindrance, were synthesized and used (2, 13, 16, 19, 20). Then, most kinetic experiments used strong C-acids with different steric hindrances in the vicinity of the reaction center.

The ionization process is multistep, leading from the carbon acid, via a carbanion or carbanion-like structure, to exocyclic nitronate, cyanate or other forms of anions stabilized by resonance provided for the appropriate electron withdrawing groups present in the molecule (21–24).

We have already found that the products of the proton-transfer reaction of a relatively strong carbon acid with a strong amine base in acetonitrile are mostly dissociated into free ions. Some ion association was observed for alkanenitronates, especially upon addition of cations that act as hydrogen bond donors (25). In this work, the use of tetrabutylammonium salts and moderate concentrations minimized ion association.

The pK_a values were calculated using eq. [1],

$$[1] \qquad pK_a = pH + \log [AH] - \log [A^-] - \log f$$

and activity coefficients were calculated from the Debye-Hückel equation (eq. [2]) (1).

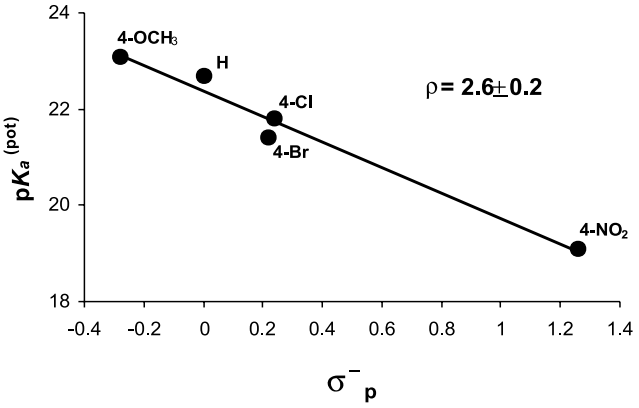
$$[2] \qquad -\log f = 1.51\ \mu^{1/2};\ \mu = 1 \times 10^{-3}\ M$$

The buffers were made by combining a solution of a C-acid (0.002 M) in acetonitrile and a very small volume of 40% tetrabutylammonium hydroxide solution at a 2:1 molar ratio. This way, the concentrations of [AH] (0.001 M) and [A^-] (0.001 M), and the ionic strength (0.001 M), were kept constant. The concentration of water (neglecting the content within the acetonitrile solvent) in the measuring buffers was 0.0224 M.

The strength of the OH^- base determines the limits of the pK_a values that can be measured by this method. Triphenylmethane, for instance, does not react with OH^- in acetonitrile, which could be anticipated taking into account the pK_a of 30.6 (26) for this C-acid in DMSO, and the typical ΔpK_a between acetonitrile and DMSO.

In acetonitrile, the pH of a 0.001 M solution of Bu_4NOH is approximately 30.2. Thus the hydroxide ion is by several pK units more basic in this solvent than is tetramethylguanidine (pK_a = 23.3) (27) or DBU (pK_a = 23.9) (10), while in water these bases are of comparable strength. The pK_a values for C-acids **1**–**30** are collected in Table 1.

Fig. 1. Hammet relationship for 4-X-phenyl(4-nitrophenyl)cyanomethanes in acetonitrile at 25°C. The σ values are the same as in ref. 10.



The strongest C-acid in this set appears to be bis(4-nitrophenyl)cyanomethane (**15**, pK_a = 19.1). Acetonitrile solutions of this C-acid in contact with traces of ground glass easily turn blue when a stopper is tightly fit to a measuring flask containing a solution of this acid. Acidities measured in this work are limited by the basicity of the hydroxide ion and do not exceed pK_a = 28. Ionization of considerably weaker C-acids could not be studied using bases much stronger than OH^- in acetonitrile anyway, because of the decomposition of the solvent (28). Acetonitrile is a C-acid itself, and its pK_a in MeCN can be estimated (p$K_a \approx 43$) from its pK_a in DMSO (p$K_a \approx 31.3$) (29) and $\Delta pK_a^{(MeCN-DMSO)}$. This estimate agrees with Schwesinger's assumption that the pK_a for MeCN is ca. 44 (28). More importantly, even carefully dried acetonitrile contains some water that will react with very strong bases, making the results of these experiments with dilute solutions dubious.

The pattern of the change in pK_a with varying substituents is trivial, except for the pK_a of 4-nitrophenyl[bis(ethylsulfonyl)]methane, which is greater than for the 4-cyanophenyl derivative. A Hammet relationship for the series of 4-X-phenyl(4-nitrophenyl)cyanomethanes gave $\rho = 2.6 \pm 0.2$ (Fig. 1), which shows the considerable sensitivity of the substituent on the phenyl ring to acidity levels. As expected, the replacement of the nitro- group by a cyano- group on the aliphatic carbon greatly reduced the acidity of 4-nitrophenylnitromethane (**3**) (pK_a = 20.4) by about 4.8 pK_a units, to 25.2 for 4-nitrobenzylcyanide (**10**). The influence of steric hindrance on the pK_a values — caused by the bulk of alkyl substituents in the vicinity of the reaction center — is clearly visible for the following group of carbon acids: 4-nitrophenylnitromethane (**3**) (pK_a = 20.4), 1-(4-nitrophenyl)-1-nitroethane (**4**) (pK_a = 23.2), 1-(4-nitrophenyl)-1-nitropropane (**5**) (pK_a = 23.6), 2-methyl-1-(4-nitrophenyl)-1-nitropropane (**6**) (pK_a = 25.7), and 2,2-dimethyl-1-(4-nitrophenyl)-1-nitropropane. (**7**) (pK_a = 26.2). In the series of 2,6-dialkyl-4-nitrophenylphenylcyanomethanes, the increase in pK_a with increasing steric hindrance is modest when the methyl groups are replaced with *i*-propyl groups, while all dialkyl derivatives are considerably weaker acids than the parent 4-nitrophenyl-phenylcyanomethane.

In the last column of Table 1, references to relevant kinetic studies of some C-acids are given. For comparison,

[a]In this work, standard deviations are typically less than 0.1.
[b]Spectrophotometric pK_a refs. are given in parentheses.

ten pK_as measured by the spectrophotometric method (9, 30) are given in the sixth column of Table 1. In each case satisfactory agreement was achieved. The largest differences, not exceeding 0.3 pK_a units, were found for **3**, **5**, and **6**, while for some C-acids the fit was perfect. The good correspondence of spectrophotometric and potentiometric pK_as is shown in Fig. 2.

There were two possibilities to distort the pK_a values: the consecutive oxidation reaction of an anion A^- (31, 32), and the influence of water brought to the system by the addition of tetrabutylammonium hydroxide base. This base is commercially available as a concentrated water solution (see *Experimental*). Then, too, the addition of the base to a C-acid solution in acetonitrile to make the buffer added some amount of water, in addition to water already present in even thoroughly-dried solvent, and that formed in the proton-transfer reaction. One could expect that the basicity of OH^- might be strongly dependent on the amount of water present in the medium. The response of the electrode to the concentration of water added to a tetrabutylammonium hydroxide

Fig. 2. The relation between spectrophotometric and potentiometric pK_as for various C-acids in acetonitrile at 25°C. The numbers denote C-acids according to Table 1.

solution (0.001 M) in acetonitrile or in the measuring buffers was weak for water concentrations in the range up to 0.2 M, however, as shown in Table 2. The concentration of water in the measuring solutions was 0.0224 M because of water content in the added base and water produced in the proton-transfer reaction. An important argument for the weak dependence of pK_a on water content in the ranges below 0.01 M lies in the virtually-equal results obtained by potentiometric and spectrophotometric methods (9). In the latter, the concentration of water was determined by the quality of the solvent and amine base. The content of 0.001% of water in acetonitrile makes approximately 0.00044 M solution.

Usually, alkanenitronates are reasonably stable in dilute solutions with a large excess of amine base, which is normally the case in spectrophotometric measurements. They become labile, however, in relatively concentrated solutions of buffers consisting of the alkanenitronate salts and nitroalkanes used in our potentiometric study. Then, as we already know, the anions derived from some cyano-group-activated C-acids, and those forming double-hydrogen-bonded complexes as products, are particularly sensitive to the trace amounts of oxygen present in the measuring system (17, 31, 32). All the measurements were therefore carried out under nitrogen. This made most of the anions of the C-acids stable for at least one hour. Benzyl cyanide, however, with an expected pK_a of 32 based on its pK_a in DMSO (pK_a^{DMSO} = 21.91) (33), decomposed in a 0.002 M hydroxide solution (even under anaerobic conditions) and is therefore not present in Table 1.

An approximately constant shift between the pK_a values measured in acetonitrile and in DMSO, $\Delta pK_a^{(MeCN-DMSO)}$, holds up for the results obtained in the present study (Table 3). Based on limited data, it seems that the pK_a shift for C-acids between DMSO and acetonitrile is 12 ± 1. Thus, this shift is larger for C-acids than for amine cations (with a range between 6–10) and phenols, or carboxylic acids (with a range between 10–12), and similar to that for indicators such as phenolphthalein or phenol red (27).

Experimental

The syntheses of C-acids have been completed as described elsewhere: 1-nitro-1-phenylethane (**1**) and bis(4-nitrophenyl)methane (**19**) (9, 43), 1-nitro-1-phenylpropane (**2**) (9, 43), 4-nitrophenylnitromethane (**3**) (14), 1-(4-nitrophenyl)-1-nitroethane (**4**) (20), 1-(4-nitrophenyl)-1-nitropropane (**5**) (20), 2-methyl-1-(4-nitrophenyl)-1-nitropropane (**6**) (20), benzylcyanide (Aldrich), malononitrile (**8**) (Fluka, purified by sublimation before use), diphenylcyanomethane (**9**) (Aldrich, sublimed before use), 4-nitrobenzylcyanide (**10**) (Fluka) (17), 4-nitrophenylphenylcyanomethane (**11**) (44, 45), bis(4-nitrophenyl)cyanomethane (**15**) (30, 44), 4-chlorophenyl(4-nitrophenyl)cyanomethane (**16**) (46), 4-bromophenyl(4-nitrophenyl)cyanomethane (**17**) (45), 4-methoxyphenyl(4-nitrophenyl)cyanomethane (**18**) (45), bis(4-nitrophenyl)methane (**19**) (47), tri(4-nitrophenyl)methane (**20**) (48), 2,4,6-trinitrotoluene (**21**) (49, 50, 51), 2,4,6-trinitrocumene (**22**) (46), phenyl[bis(ethylsulfonyl)]methane (**23**) (52), 4-chlorophenyl[bis(ethylsulfonyl)]methane (**24**) (52), 4-cyanophenyl[bis(ethylsulfonyl)]methane (**25**) (52), 4-nitrophenyl[bis(ethylsulfonyl)]methane (**26**) (53), di-*tert*-butyl-2-methylmalonate (**27**) (53), diethyl-(2,4-dinitrophenyl)malonate (**28**) (31), 2,4-pentanedione (**29**) (Adrich), 9-cyanofluorene (**30**) (9), (2,6-dimethyl-4-nitrophenyl)phenylcyanomethane (**12**). (2,6-Diethyl-4-nitrophenyl)phenylcyano-

methane (**13**) and (2,6-di-*i*-propyl-4-nitrophenyl)phenylcyanomethane (**14**) were obtained from a modified procedure by Leffek and Pruszynski (54); details will be described elsewhere (55). 2,2-Dimethyl-1-(4-nitrophenyl)-1-nitropropane (**7**) was prepared as described for **6** (20) (a major byproduct in this synthesis was p-(2,2-dimethyl-1-chloropropyl)nitrobenzene, which was very resistant to acidic or basic hydrolysis). Phenyl[bis(ethylsulfonyl)]methane **23**, 4-chlorophenyl[bis-(ethylsulfonyl)]methane (**24**), 4-cyanophenyl[bis(ethylsulfonyl)]methane (**25**), and 4-nitrophenyl[bis(ethylsulfonyl)]methane (**26**) were prepared according to Aiken et al. (64, 65).

Acetonitrile (Romil, spectro grade) was fractionally distilled over CaH_2 and carefully handled to prevent atmospheric contamination. Tetrabutylammonium hydroxide (40%), an aqueous concentrated solution, was purchased from Aldrich. A sample of this product was titrated with standardized HCl.

The IR, NMR, and MS spectra and melting points of these compounds are in agreement with those given in the references. The commercial products were purified before use to meet their specific physical properties.

The measurements of C-acid pK_as (**1**–**30**) were performed in an H-type cell equipped with a thermostated water jacket, to maintain a constant temperature (25 ± 0.1°C). The potentiometric cell and the procedure used have been described, in detail, by Leffek et al. (10).

The side arm of an external reference half-cell was dipped into a tetraethylammonium perchlorate solution (0.1 M). The reference electrode was a flowing junction, Ag/AgNO3 (0.01 M) in acetonitrile (half-cell). The middle compartment was closed on both sides with fine porosity sintered glass, and was filled with 0.1 M tetraethylammonium perchlorate in acetonitrile. The large compartment holding the glass electrode was filled with the buffer (acetonitrile) solution, and prepared with C-acid (0.002 M), and its tetrabutylammonium hydroxide (0.001 M) at constant ionic strength (0.001 M). Tetrabutylammonium hydroxide had been chosen because it eliminates homoconjugation, which is a distracting factor for many amine bases in acetonitrile (56). The middle and glass electrode compartments were equipped with taps, providing easy drainage after each set of measurements. When not in use, the glass electrode was kept in pure acetonitrile. The storage of the glass electrode in acetonitrile ensured the reliability and reproducibility of the measurements. The new electrode was conditioned in acetonitrile at least 2 days before use.

The calibration of the glass electrode (CORNING, Ag/AgCl category No. 476026) was accomplished with a series of buffer solutions, composed of tetraethylammonium picrate (0.002 M) and picric acid in the range of 0.0001 M to 0.007 M (7 buffers), according to the methods published by Leffek et al. (10) and Coetzee and Padmanabhan (57). The measurements were carried out using an Elmetron CX 721 multifunction computer meter.

The solutions and the measuring cell compartments were protected against oxygen, CO_2, and atmospheric moisture. Then the pK_a measurements were carried out in the following manner: into the measuring compartment, 10 mL of the appropriate C-acid (0.002 M) in acetonitrile was placed. This solution was purged with pure N_2 saturated with acetonitrile vapors, using a stainless steel injection needle to remove O_2 and repel eventual access of atmospheric CO_2 and moisture during equilibration. Then 6.5 μL of 40% tetrabutylammonium hydroxide (to make a 0.001 M solution of the salt) was added using a Hamilton microsyringe, with continuous bubbling of nitrogen. The needle was removed and the cell was tightly closed. Each pK_a value given in Table 1 is an average of three separate measurements. The pK_a values have been measured in 10 and 20 min intervals to assure equilibration of the system, and also to be sure that side effects are negligible. The readings were converted to pH, then the pK_a values were obtained from eq. [1]. The standard deviations were not larger than 0.1 pK_a unit.

A ^{19}F nuclear magnetic resonance study of the conjugate Brønsted–Lewis superacid HSO_3F–SbF_5. Part II.

Jobst Kühn-Velten, Matthias Bodenbinder, Raimund Bröchler, Gerhard Hägele, and Friedhelm Aubke

Abstract: Solutions of SbF_5 in HSO_3F with x_{SbF_5} = 0.012 to 0.405 are studied by 500 MHz ^{1}H NMR (299 K) and 471 MHz ^{19}F NMR (213–250 K), using NMR tubes fitted with fluoropolymer lining. The initial process during dissolution is the fast solvolysis of monomeric SbF_5 in HSO_3F according to $SbF_5 + nHSO_3F \rightarrow SbF_{5-n}(SO_3F)_n + n$HF ($n$ = 1, 2). All HF formed during solvolysis will no longer be removed by reaction with glass, but will remain in the superacid system. Besides participation in the fast formation of various fluoro-fluorosulfato anions $[SbF_{6-n}(SO_3F)_n]^-$ (n = 0, 1, 2) and acidium ions $[H_2X]^+_{(solv.)}$ (X= F, SO_3F), HF is involved in slow-exchange reactions of the type $[SbF_{6-n}(SO_3F)_n]^-_{(solv.)} + HF \rightarrow [SbF_{7-n}(SO_3F)_{n-1}]^-_{(solv.)} + HSO_3F$ (n = 1, 2) detected because of a delay of 3 months between sample preparation and measurements and confirmed by repeating theses measurements after a further 3 months. There are three notable differences to our earlier study, affecting concentrations of the fluoro-fluorosulfato antimonate anions observed: (*i*) in dilute solutions $[SbF_6]^-$ is formed in high concentrations (34.7–76.1%), with $[Sb_2F_{11}]^-$ now clearly detected at intermediate to high SbF_5 concentrations (up to 5.8%); (*ii*) bis-fluorosulfato anions (*cis*-, *trans*-$[SbF_4(SO_3F)_2]^-$) are found in much lower concentrations only, which decrease further with time, while tris-fluorosulfato anions ($[SbF_3(SO_3F)_3]^-$) are now no longer observed; (*iii*) these reduced concentrations of poly-fluorosulfato anions in dilute solutions are responsible for the formation of fewer μ-SO_3F-oligomers at lower concentrations, when more SbF_5 is added. As a consequence, the HSO_3F–SbF_5 magic acid system is now less complex than found previously and only seven anionic species are clearly observed.

Key words: superacids, antimony(V) fluoroanions, ^{1}H NMR, ^{19}F NMR, solvolysis.

Résumé : Faisant appel à la RMN du ^{1}H à 500 MHz (299 K) et à celle du ^{19}F à 471 MHz (213 à 250 K), on a étudié des solutions de SbF_5 dans du HSO_3F, avec x_{SbF_5} = 0,012 à 0,405 dans des tubes RMN recouverts d'un fluoropolymère. Le processus initial de la dissolution est une solvolyse rapide du SbF_5 monomère dans du HSO_3F suivant l'équation: $SbF_5 + nHSO_3F \rightarrow SbF_{5-n}(SO_3F)_n + n$HF ($n$ = 1, 2). Tout le HF qui se forme au cours de la solvolyse demeure dans le système superacide duquel il n'est pas éliminé. En plus de sa participation dans la formation rapide de divers anions fluoro-fluorosulfato $[SbF_{6-n}(SO_3F)_n]^-$ (n = 0, 1, 2) et d'ions acidium $[H_2X]^+_{(solv.)}$ (X = F, SO_3F), le HF est impliqué dans les réactions lentes d'échanges du type: $[SbF_{6-n}(SO_3F)_n]^-_{(solv.)} + HF \rightarrow [SbF_{7-n}(SO_3F)_{n-1}]^-_{(solv.)} + HSO_3F$ (n = 1, 2) que l'on a détectées en raison d'un délai de trois mois entre la préparation de l'échantillon et les mesures; celles-ci ont été confirmées en répétant ces mesures après un nouveau délai de trois mois. Il y a trois différences notables par rapport à notre étude antérieure, celles affectant les concentrations observées des anions fluoro-fluorosulfato antimoniates: (*i*) en solutions diluées, l'anion $[SbF_6]^-$ se forme à des concentrations élevées (34,7 à 76,1%) alors que l'anion $[Sb_2F_{11}]^-$ peut maintenant être détecté à des concentrations de SbF_5 allant d'intermédiaires à élevées (jusqu'à 5,8%); (*ii*) on n'observe que des concentrations beaucoup plus faibles des anions bis-fluorosulfato (*cis*-, *trans*-$[SbF_4(SO_3F)_2]^-$) et elles diminuent avec le temps alors que l'on n'observe plus la présence des anions ($[SbF_3(SO_3F)_3]^-$); (*iii*) lorsqu'on ajoute du SbF_5, ces concentrations réduites des anions poly-fluorosulfato en solutions diluées sont responsables pour la formation de moins d'oligomères μ-SO_3F à faibles concentrations. En conséquence, le système de l'acide magique HSO_3F–SbF_5 est maintenant moins complexe que ce que l'on croyait auparavant et on n'observe que sept espèces anioniques.

Mots clés : superacides, fluoroanions de l'antimoine(V), RMN du ^{1}H, RMN du ^{19}F, solvolyse.

Introduction

In the quest for strongly electrophilic or superelectrophilic (1) cations, conjugate Brønsted–Lewis superacids (2, 3) like HF–SbF_5 and HSO_3F–SbF_5 play an important role as reaction media and solvents. Examples of their applications range from the generation of the large family of carbocations (4) to more recent studies of the formation of superelectrophilic metal carbonyl cations (5), which are exclusively generated in superacids. Many of their salts and derivatives have recently been structurally characterized by single crystal X-ray diffraction and vibrational spectroscopy (5).

The conjugate superacid HF–SbF_5 (2, 3) appears to display higher Brønsted acidities at high SbF_5 concentrations (6, 7) and possesses a somewhat greater versatility in synthetic applications (5). This is on account of the smaller number and simpler composition of counteranions such as $[SbF_6]^-$, $[Sb_2F_{11}]^-$, $[Sb_3F_{16}]^-$, which are reportedly present (8) in solution.

On the other hand, magic acid HSO_3F–SbF_5 has found wider applications on account of practical considerations (2, 4). HSO_3F is at ambient temperatures compatible with glass (9) and can be purchased and purified easily (9). In contrast, anhyd HF (10) can only be handled safely in metal or fluoropolymer materials and is, on account of its high volatility, a considerable health hazard. It is also difficult to remove traces of H_2O from technical grade hydrogen fluoride, which requires the addition of reactive fluorides like BiF_5 or SbF_5. This is in contrast to the reported purification of HSO_3F (9) by distillation, which converts traces of H_2O into HF and H_2SO_4.

Both HF (11) and HSO_3F (2, 3) have, in spite of earlier claims (2), identical Hammett $-H_0$ values (12). This would suggest, that conjugate superacids with comparable concentrations of SbF_5 would be expected to show similar Brønsted acidities. But this is reportedly not the case (6, 7). In spite of its lower Brønsted acidity, magic acid has been the preferred medium for the generation of a large number of stable carbocations (1, 2, 4).

To understand more fully the composition and speciation in magic acid, we have recently reinvestigated the magic acid system at variable SbF_5 concentrations by modern NMR methods (13). As in all earlier studies (2, 14–16), all measurements are made in glass. Based on results which are described in detail (13), the following conclusions are reached: (*i*) the HSO_3F–SbF_5 system is more complex than previously (2, 14–16) assumed and 13 different anions are unambiguously identified; (*ii*) at low concentrations of SbF_5, monomeric anionic species of the type $[SbF_{6-n}(SO_3F)_n]^-$ (n = 1–3) dominate. At high concentrations of SbF_5, increasing amounts of oligomers are formed; (*iii*) μ-F bridges in oligomeric anions are found only in $[Sb_2F_{11}]^-$. In all other instances, the SO_3F group functions as a bridging group in oligomeric anions; (*iv*) there is strong evidence presented for the formation of $[H_3O]^+$ in magic acid. This evidence comes from ^1H NMR spectra of HSO_3F–SbF_5 at variable concentrations (13) and more convincingly from the isolation of $[H_3O][Sb_2F_{11}]$ from HSO_3F–SbF_5 and its subsequent structural characterization by single crystal X-ray diffraction (17); (*v*) the presence in the oxonium salt (17) of $[Sb_2F_{11}]^-$ as counteranion, which is barely detectable in the ^{19}F NMR spectrum of HSO_3F–SbF_5 solutions (13), points to slow exchange equilibria, which have so far not been described nor investigated; (*vi*) the formation of $[SbF_6]^-$ is not explainable by SO_3 elimination as proposed by Olah and co-workers (3, 4) or solely by ligand redistribution as suggested by Dean and Gillespie (15). A convincing rationale for its formation is still outstanding.

To account for the presence of $[H_3O]^+$, it was proposed (13), that initial fast solvolysis of monomeric SbF_5 in HSO_3F occurs, according to eq. [1]:

$$[1] \qquad n\mathrm{HSO_3F} + \mathrm{SbF_5} \rightarrow \mathrm{SbF_{5-n}(SO_3F)_n} + n\mathrm{HF}\ (n = 1, 2)$$

Some or most of the HF formed in this manner, will react with glass to form H_2O (in addition to SiF_4), which will then be protonated to $[H_3O]^+$ and hence acts as a base in the superacid. Consequently the in situ formation of the base H_2O will reduce the overall acidity of magic acid, relative to that of HF–SbF_5 (18). Consistent with these observations, there are two types of cations observed in the system: the acidium ion $[H_2SO_3F]^+$ and the oxonium ion $[H_3O]^+$. The concentrations of both are found to increase with increasing SbF_5 concentration as monitored by ^1H NMR (13).

The acidium ion is formed immediately in a fast reaction according to eq. [2] as an example:

$$[2] \qquad 2\mathrm{HSO_3F} + \mathrm{SbF_4(SO_3F)} \rightarrow [\mathrm{H_2SO_3F}]^+_{(\mathrm{solv.})} + [\mathrm{SbF_4(SO_3F)_2}]^-_{(\mathrm{solv.})}$$

This equation describes a Lewis acid promoted self-dissociation of HSO_3F (9).

We have now reinvestigated the magic acid system HSO_3F–SbF_5 with four important modifications to the previous study (13): (*i*) to avoid formation of $[H_3O]^+$ in substantial concentrations, measurements were conducted in NMR tubes with fluoropolymer lining; (*ii*) instead of a 200 MHz spectrometer (13) a 500 MHz spectrometer was employed, to achieve a higher separation of signals; (*iii*) we limited measurements to systems with x_{SbF_5} up to 0.4, to pay more attention to solutions with low and intermediate concentrations of SbF_5; and (*iv*) for each sample, ^{19}F NMR measurements in the Sb–F region were repeated after about 3 months, to detect any changes caused by suspected slow, previously (14–16) unreported equilibria.

In our earlier study (13), mainly broad, poorly resolved spectra for mol fractions x_{SbF_5} above 0.6 were observed. We, therefore, reduced the number of samples from nine to five. A number of oligomeric μ-SO_3F bridged fluoro-fluorosulfato anions, identified previously (13) for solutions with high SbF_5 concentrations only, appeared either in negligible concentrations or not at all. They were, therefore, not discussed in the present study.

Due to the collaborative nature of this study, the samples were prepared at UBC (Vancouver) and the spectra were recorded at the Heinrich-Heine-Universität (Düsseldorf). This caused a delay of 2–4 months between sample preparation and the first acquisition of NMR data. Hence the exact composition of the various samples immediately after mixing of SbF_5 and HSO_3F is unknown, but is assumed to be similar, than found previously (13), as will be discussed below. This procedure and repeated measurements after a further 3 months

[c] c_{rel} (relative concentrations (mol %)).

have allowed the detection of a slow SO_3F- vs. F exchange reaction which has been suspected (17), but has never been clearly demonstrated (14–16) before.

As in our earlier study (13), we have again avoided the use of diluents like SO_2ClF or SO_2F_2, which have been used by others (14–16) in studies of the HSO_3F–SbF_5 system, to reduce the viscosity of the system and to permit the recording of spectra at low temperatures (14–16). While there are practical considerations (1, 2, 4), which favor the use of diluents like SO_2ClF, SO_2F_2, and SO_2 in synthesis because they will facilitate the dissolution of hydrocarbon precursors for the generation of carbocations in superacids (4), in a study of this nature, diluents alter the nature of the solvent–solute interaction in HSO_3F–SbF_5 as will be discussed below.

The solutions with x_{SbF_5} up to 0.202 (samples 1–4) were measured at 213 ± 1 K. To investigate the temperature dependency of the product distribution, samples 1–5 were also measured at 233 ± 1 K up to 250 K in dependence of antimony pentafluoride concentration, as can be seen in Table 1.

To detect the nature and direction of slow reactions, involving equilibria of anions $[SbF_{6-n}(SO_3F)_n]^-_{(solv.)}$ (n = 1, 2) initially formed and anhyd HF generated in situ (see eq. [1]) or HSO_3F, a number of measurements were repeated after 3–6 months and in one case after 4 years.

In slow exchanges, several types of reactions involving octahedral anions may be anticipated: (*i*) a homotopic ligand exchange (*a*) -F vs. -F (-F = fluoro ligand) or (*b*) $-SO_3F$ vs. $-SO_3F$; or (*ii*) a heterotopic ligand exchange (*a*) -F vs. $-SO_3F$ or (*b*) $-SO_3F$ vs. -F, which in an acidic medium may be viewed as equilibrium reactions of the type:

$$[3] \qquad HSO_3F + [SbF_{6-n}(SO_3F)_n]^- \rightleftharpoons HF + [SbF_{5-n}(SO_3F)_{n+1}]^-$$

Processes of type (*i*) do not change the composition of the complex anions under investigation and will not be detected by NMR. They might be studied by isotopic labeling. In either case of processes of the type (*ii*), the nature of the anionic solute will change, which is detectable by NMR. These exchange reactions, involving octahedrally coordinated anions are expected to be slow.

Experimental

Preparation of NMR samples

The procedures for purification of fluorosulfuric acid (HSO_3F) (9) and antimony(V) fluoride (SbF_5) were identical to those reported previously (13). Also identical were the methods used to prepare the samples by mixing the components inside a dry box (13) (Vacuum Atmosphere Corporation Dry-Lab model DI 001-SG filled with dry N_2 and equipped with an HE493-Dry Train) by magnetic stirring in fluoroplastic containers. The compositions of the five samples were established by weighing inside the dry box, using a Mettler top loading balance. The NMR tubes of 5 mm o.d. were fitted with linings of FEP (copolymer of tetrafluoroethylene and hexafluoropropylene (DuPont de Nemours). Linings of 4.1 mm o.d. and 3.5 mm i.d. were made from the commercially available material (BEMU Inc., Krefeld) by Professor H.J. Frohn, University of Duisburg, who has pioneered this technique. The NMR tubes were fitted with Teflon stopcocks and sealed subsequently inside the dry box by epoxy resin. The concentrations of the five samples prepared, are listed in Table 1.

NMR spectroscopy

NMR spectra were recorded using a DRX Avance 500 NMR spectrometer (Bruker Analytische Meßtechnik GmbH, Karlsruhe), operating at 500 MHz and 471 MHz, respectively, for ^1H and ^{19}F NMR. Neither spinning nor internal lock compounds were used. The magnetic field was locked to D_2O and after replacing the lock sample, NMR spectra were recorded from mixtures of SbF_5 and HSO_3F. The DRX Avance 500 magnet was found to be very stable. The field drift was less than 0.01 ppm h^{-1}. Hence, NMR measurements without the use of a lock were judged to be sufficiently accurate. Specific acquisition and processing parameters for NMR spectra are listed in Table 2. All FIDs were zero filled, which led to an increase of data points in the real spectrum by a factor of two. Prior to Fourier transformation, line-broadening factors (LB) were applied to FIDs, as shown in Table 2 and in individual spectra. Phase and baseline corrections were done manually, to achieve optimal conditions for the recording of precision NMR spectra. All spectra were evaluated with a 1D-WinNMR 5.1 version 960901 (Bruker Franzen Analytik GmbH., Bremen), to extract accurate data for frequencies, intensities, and linewidths. Proton chemical shifts were referenced vs. external (ext.) TMS, while ext. CF_3COOH in D_2O was used (with δ_F = –76.04 ppm vs. $CFCl_3$) for the determination of fluorine chemical shifts. Fluorine NMR spectra showed dynamic NMR line shapes. Suitable temperatures were chosen and maintained to obtain good resolution as listed with individual spectra. Individual species found in magic acid mixtures via ^{19}F NMR were identified using standard F,F-COSY techniques and assignments described in the preceding paper.

Results

Discussion of typical NMR spectra — Results and observations

^{1}H NMR spectra

The results of the ^{1}H NMR spectra are listed in Table 3 and are compared to earlier results (13). A typical 500 MHz ^{1}H NMR spectrum for sample 2 x_{SbF_5} = 0.06 is shown in Fig. 1.

For samples 1–5 the dominant ^{1}H-signal is due to the acidium ions ($[H_2X]^+$, X = F, SO_3F). The second, weak resonance is, in agreement with earlier observations (13, 14), attributed to $[H_3O]^+$. Only minute amounts of $[H_3O]^+$ were observed, when using fluoropolymer linings, while considerable quantities were formed in glass NMR tubes (13). The difference in chemical shifts $\Delta_\delta = \delta_H$ (acidium ion) – δ_H ($[H_3O]^+$) increased with increasing values for x_{SbF_5} following a linear relation: $\Delta_\delta = 4.74x_{SbF_5} + 0.11$ with a correlation coefficient of 0.999.

^{19}F NMR Spectra

FSO_3 region:

^{19}F NMR (471 MHz) spectra of samples 1–5 were clearly divided into two separate regions, indicative for SO_3F and the Sb(V)F containing moieties. While most of the Sb(V)F species of type $[SbF_{6-n}(SO_3F)_n]^-$ and oligomers discussed in this paper are identified by their F-F coupling patterns, spectra in the fluorosulfato region are singlets. Long range couplings of type F-S-O-Sb-F were not resolved. These would allow structurally significant correlations. Demanding and costly experiments using ^{17}O or ^{33}S isotopes would be required, for a deeper, comprehensive analysis of magic acid anions in the F-SO_3 region.

In spite of these limitations, trends in chemical shifts and relative intensities of resonances may be used to correlate some of the observed SO_3F resonances and to assign these to species, identified unambiguously in the Sb-F- region as discussed below. For example, Fig. 2 shows that unequivocal evidence is obtained for $[SbF_5(SO_3F)]^-$ (B1), $[(SbF_5)_2$-μ-$SO_3F]^-$ (E), and the solvent HSO_3F. As in our previous study (13), the notation for species present in magic acids is adopted from ref. 16 and shown in Scheme 1 together with the NMR spin assignment. Assignments based solely on

Fig. 1. ^{1}H NMR (500 MHz) spectrum of sample 2: x_{SbF_5} = 0.064, t = 69 days, T = 299 K, LB = 0 Hz. Peak at δ_H = 9.8 ppm (acidium ion). Peak at δ_H = 9.38 ppm ($[H_3O]^+$). Insert: y-axis expanded; x-axis (δ_H [ppm] vs. ext. TMS).

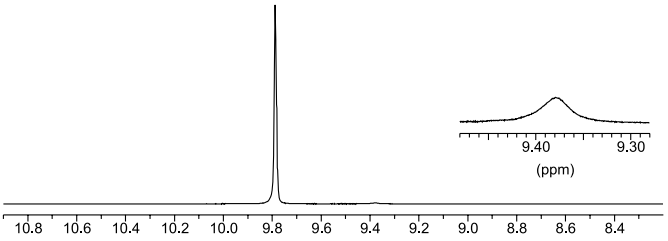

Fig. 2. ^{19}F NMR spectrum (471 MHz) in the HSO_3F region of sample 3: x_{SbF_5} = 0.100, t = 123 days, T = 213 K, LB = 1 Hz.: from left to right: peak 1: δ_F = 41.60 ppm, $[SbF_5(SO_3F)]^-$ (B1); peak 2: δ_F = 40.99 ppm, $[(SbF_5)_2$-μ-$SO_3F]^-$ (E); peak 3: δ_F = 40.33 ppm, HSO_3F (A). x-axis: δ_F [ppm] vs. $CFCl_3$ calc. (see text).

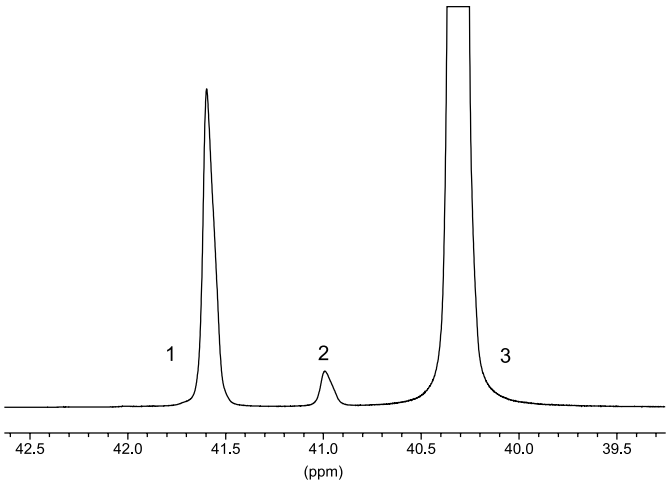

chemical shifts in the SO_3F-region are in general not possible, since as discussed above, spin–spin coupling data are not available in the F-SO_3 region. Numerical results for the -SO_3F region are listed in Table 4.

Since proton transfer is rapid on the NMR time scale, the dominant peak, assigned to HSO_3F, represents in principle the dynamically averaged chemical shift $<\delta_F>$ (19) originating from three specific contributions of δ_i following:

$$[4] \qquad <\delta_F> = \sum_{i=0}^{2} x_i \cdot \delta_i$$

where x_i stands for the mol fractions and δ_i for the specific chemical shifts of $H_i[SO_3F]^{i-1}$ (i = 0–2). Since the autoprotolytic constant K_{id} of HSO_3F is small, as discussed above, the apparent NMR signal will be dominated by the solvent formally described as $H_i[SO_3F]^{i-1}$ (i = 1). Hence ion specific chemical shifts δ_i (i = 0 or i = 2) are not extractable from this averaged signal.

F-Sb(V) region:

As discussed in our preceding paper (13), this region is most informative on account of the observation of F-F coupling, giving rise to multiplet structures. ^{19}F NMR (471 MHz) studies of the Sb(V)F regions lead to the spectra shown in Fig. 3, with the corresponding data listed in Tables 5(*a*), 5(*b*), and 6. Species identified well above the 1% level are shown in Table 7 and Scheme 1.

We wish to direct attention to the strong solvent effects, recognizable in Fig. 3, where from the bottom to top five spectra are shown with increasing SbF_5 concentration (samples 1–5). Species are identified by similarities of spectral structures (multiplet structures), not by the absolute values of their chemical shifts. It is useful to note, that $^2J_{FF}$ in -SbF_5 units is found to be around 100 Hz, while -SbF_4- units show significantly different values of around 120 Hz.

Obviously, where chemical shifts for individual species are influenced by solvent effects, they are less significant than coupling constants. Hence no attempt is made, to

correct δ_F data by the susceptibility of the samples. This striking solvent effect is thought to be due to a variation in concentrations of HSO_3F and HF, generated during solvolysis, with the HF concentration obviously decreasing

in the order of samples 1–5. Alternatively, the increased concentration of antimony containing species can contribute to an altered susceptibility of the samples. A more conclusive theory for topospecific chemical shifts δ_F in Sb(V)F species is not available at this time.

In our series, the chemical shifts δ_F of species E are nearly constant and not strongly dependent on x_{SbF_5}, while B1 shows a more complex behavior. A larger ratio for B1:E is found for measurements using fluoropolymer linings, compared to previous studies with conventional high precision glass NMR tubes (13). At $x_{SbF_5} > 0.2$ the ratio HSO_3F:B1 is larger for the series using fluoropolymer linings. As an example for the analytical procedures used, the ^{19}F NMR and the F,F-COSY spectra of sample 3 (x_{SbF_5} = 0.100) are shown in Figs. 4 and 5.

Discussion and general observations

As is apparent from Fig. 1 and Table 3, there are a number of fundamental differences to the spectra obtained by us previously on the HSO_3F–SbF_5 system without the use of fluoropolymer linings (13): (*i*) in the ^1H NMR spectra, the characteristic resonance at ~9.0 ppm is of very low intensity and barely detectable. The minute amount of $[H_3O]^+$ found in the present study appears to be due to trace impurities of HF (see Table 3) present in both the solvent (HSO_3F) and the solute (SbF_5), which are both handled in glass during their purification; (*ii*) *in the ^{19}F NMR spectra*, a resonance, previously found at ~–162 ppm and attributed to $SiF_{4(solv.)}$ or $[SiF_6]^{2-}$, is now absent; (*iii*) *in the S-F region* at ~45–40 ppm and *in the Sb-F region* of –90 to –140 ppm, fewer resonances are observed and the spectra are much simpler under those conditions (13); (*iv*) resonances, attributed to tris- and bis-substituted fluorosulfato-fluoro antimonate anions, are either absent or only seen at low concentrations of SbF_5. The polyfluorosulfato-antimonate anions are seen as monomeric building blocks for fluorosulfato bridged oligomers; (*v*) conversely, the $[SbF_6]^-$ anion found previously at concentrations of ~1%, is clearly detected and is now the dominant species in dilute solutions (sample 1), where it is present at 34.7%, which increased to 76.1% after 3 months. This increase by 41.4% is entirely at the expense of the fluorosulfato anions B1, F, and Z, whose combined concentrations decrease by a total of 41.5% over 3 months. Also the $[Sb_2F_{11}]^-$ anion is directly observed in samples 2–5. This has not been possible previously (13), even though the reported isolation and structural characterization of $[H_3O][Sb_2F_{11}]$ from magic acid (17) has provided evidence

for its presence in solution. The formation of $[Sb_2F_{11}]^-$ and possibly higher μ-F oligomers is attributed to the equilibria of the type:

$$[5] \qquad SbF_5 + [SbF_6]^- \underset{HF}{\overset{SbF_5}{\rightleftharpoons}} [Sb_2F_{11}]^-$$

Interestingly at x_{SbF_5} = 0.405, the concentration of $[Sb_2F_{11}]^-$ is higher than that of $[SbF_6]^-$ (see Tables 5 and 6); (*vi*) at high SbF5 concentrations (samples 4 and 5, x_{SbF_5} = 0.202 and 0.405, respectively), SbF_5 appears to be involved in formation of oligomeric species E, G, and I as well as other not identified oligomeric species (see Table 6). Consequently, solvolysis is now less likely (eq. [1]), HF formation

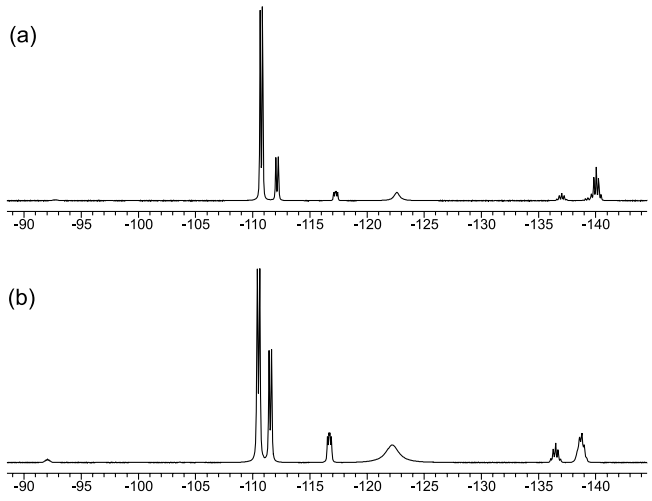
Fig. 4. (*a*) ^{19}F NMR spectrum (471 MHz) of the Sb-F region from sample 3: x_{SbF_5} = 0.100, t = 123 days, T = 213 K, LB = 4 Hz. x-Axis: δ_F (ppm) vs. $CFCl_3$ calcd. (see text); (*b*) ^{19}F NMR spectrum (471 MHz) of the Sb-F region from sample 3: x_{SbF_5} = 0.100, t = 233 days, T = 233 K, LB = 4 Hz. x-axis: δ_F (ppm) vs. $CFCl_3$ calcd. (see text).



is suppressed, and monomeric $[SbF_5(SO_3F)]^-$ (B1) is now the dominant anion, whose concentration is reduced only insignificantly by conversion to E, due to complexation; (*vii*) fluorosulfato bridged oligomeric anions have at comparable concentrations much lower abundances then reported previously (13); (*viii*) the total number of species which are clearly identified at significant levels and analyzed is reduced from 13 (13) to about seven.

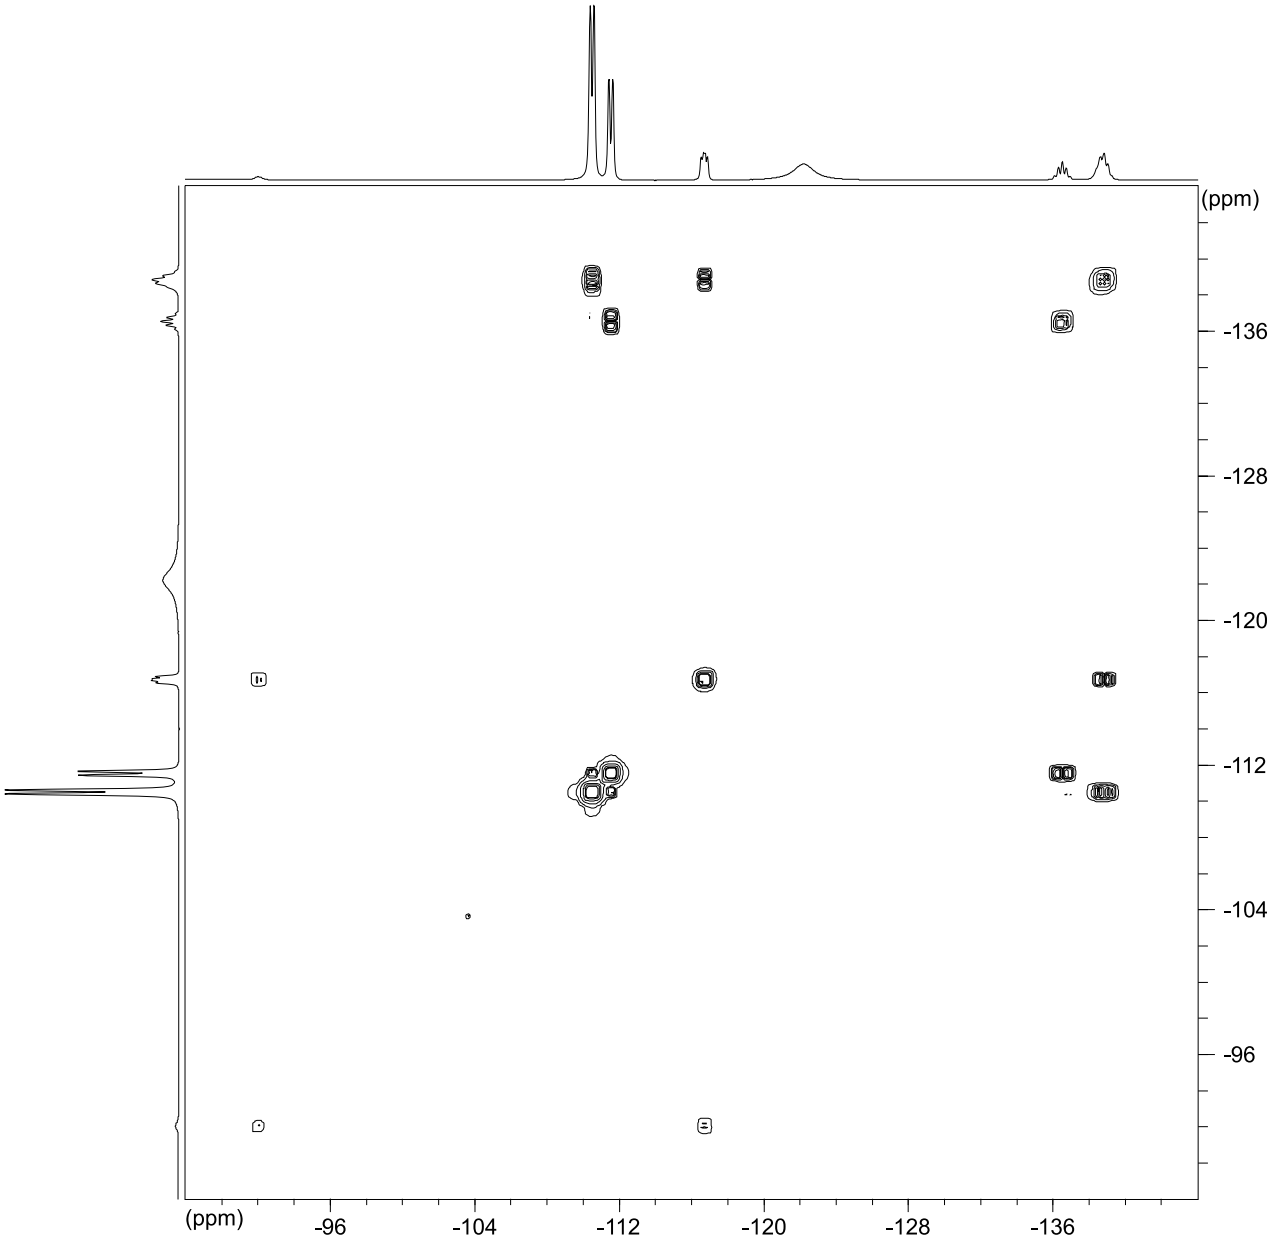
The latter is in part due to the smaller concentration range chosen for this study compared to the previous one (13), where many oligomeric species are only observed and analyzed at high SbF_5 concentrations. We have chosen in this study to forgo any detailed identification of these oligomers, with the exception of $[Sb_2F_{11}]^-$ and its fluorosulfato analogue $[(SbF_5)_2\text{-}\mu\text{-}SO_3F]^-$ and to concentrate on monomeric anions. A further reason for the low abundance of μ-SO_3F oligomers is the above noted absence of tris- and low concentrations of bis-fluorosulfato anions, as discussed above and illustrated by eq. [6]. Both are viewed as "building blocks" for μ-SO_3F bridged oligomers.

$$[6] \qquad [SbF_5(SO_3F)]^- + SbF_5 \rightleftharpoons [(SbF_5)_2\text{-}\mu\text{-}SO_3F]^-$$

An important feature is our failure now and previously (13) to detect any μ-F bridged oligomers, which also contain terminal -OSO_2F-groups, as had been found previously (2, 14–16). There are two reasons for these earlier claims: (*i*) some earlier studies (14–16) date back to the period of 1969–1978 and involve the early applications of NMR methods to superacids, with assignments occasionally very tentative and multiplets frequently unresolved; and (*ii*) earlier

© 2002 NRC Canada

Fig. 5. $^{19}F,^{19}F$ -COSY spectrum (471 MHz) of the Sb-F region from sample 3: x_{SbF_5} = 0.100. t = 233 days, T = 233 K. x-axis: δ_F (ppm) vs. $CFCl_3$ calcd. (see text).



studies have used diluents like SO_2ClF (16), SO_2F_2, or SO_2 (14) to avoid viscosity broadening and allow measurements at lower temperatures and at higher SbF_5 concentrations.

These diluents have, in our opinion, two effects on the protonic super acid: (*i*) they interrupt the hydrogen bonding in the superacids and exert a structure breaking effect; and (*ii*) the ionizing and solvolyzing ability of the superacid is significantly reduced. This is best illustrated by the observation of oligomeric μ-F bridged species in studies involving diluents. The use of diluents is in essence the addition of substantial amounts of an aprotic solvent to a protonic Brønsted acid. This results in formation of a mixed solvent system.

Hence, earlier studies (16) on solutions of HSO_3X (X = F, CF_3) and SbF_5 in SO_2ClF (16) are strictly not comparable to our studies of the binary system HSO_3F and SbF_5 reported here and previously (13). The same limitation must be applied to a very recent study of the HF–SbF_5 system in SO_2ClF (8(*b*)) and to measurements of the Brønsted acidities by NMR methods (6, 7).

The acidity rankings by Sommer et al. (6, 7) based on measurements in SO_2FCl are called into question.

In summary it is conceivable, that the *cis*-F bridged chain structures found in liquid SbF_5, are partly retained in the mixed solvent system HSO_3F–SO_2ClF, allowing reactions of oligomeric $(SbF_5)_n$ (n = 2, 3, 4) with the bases SO_3F^- (16) or F^- (19) to give F bridged oligomers with terminal $^-OSO_2F$ (16) groups. It is our observation, that in strongly solvolyzing and ionizing HSO_3F (9), oligomeric $(SbF_5)_n$ (n = 2, 3, 4) is broken up into monomeric species, even at high

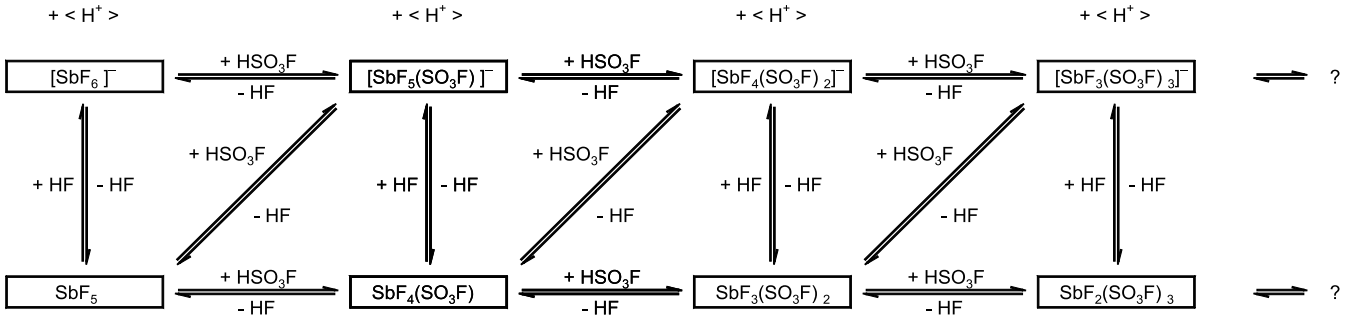
Scheme 2. Concerted reactions in magic acids made up from HSO_3F and SbF_5.



SbF_5 concentrations, and F bridged oligomers were not found in our study, with the exception of $[Sb_2F_{11}]^-$.

A summary of the proposed reactions

A very simple route to the main constituent of the magic acid system, the anion $[SbF_5(SO_3F)]^-$, is the direct reaction between monomeric SbF_5 and the self-ionization ion SO_3F^- according to:

$$[7] \quad SbF_{5\ (solv.)} + SO_3F^-_{(solv.)} \rightleftharpoons [(SbF_5(SO_3F)]^-_{(solv.)}$$

is probably incorrect for the simple reason that in HSO_3F the self-ionization constant of $K_{id} = 3.8 \times 10^{-8}$ (9) implies a very low concentration of SO_3F^- at 25°C.

A more likely formation reaction of the anion $[SbF_5(SO_3F)]^-$ is:

$$[8] \quad 2HSO_3F + SbF_{5\ (solv.)} \rightleftharpoons [(H_2SO_3F)]^+_{(solv.)} + [SbF_5(SO_3F)]^-_{(solv.)}$$

A probable first step in the formation of magic acids is the one-step fast solvolysis of SbF_5:

$$[9] \quad SbF_5 + HSO_3F \rightleftharpoons [SbF_4(SO_3F)] + HF$$

which is in our opinion the main source of HF as is discussed in this study. Due to the fluoropolymer lining inside the NMR tubes, HF formed via eq. [9] is no longer converted to $[H_3O]^+$ by a scavenger reaction with glass (from NMR tubes), as observed previously (13). Consequently HF can now get involved in anion formation in three ways.

Reaction with the Lewis acid SbF_5

$$[10] \quad 2HF + SbF_{5\ (solv.)} \rightleftharpoons [H_2F]^+_{(solv.)} + [SbF_6]^-_{(solv.)}$$

is expected to be fast. This will explain in part the high initial concentrations of $[SbF_6]^-$ at low x_{SbF_5} (0.012 and 0.064).

Reaction with a Lewis acid such as $SbF_4(SO_3F)$

$$[11] \quad 2HF + SbF_4(SO_3F)_{(solv.)} \rightleftharpoons [H_2F]^+_{(solv.)} + [SbF_5(SO_3F)]^-_{(solv.)}$$

is expected to be again a fast process. The analogous reactions in HSO_3F will result in an increase in the SO_3F contents of the anion. This was indeed observed in our earlier studies (13).

Slow -F vs. -SO_3F exchange

$$[12] \quad HF + [SbF_4(SO_3F)_2]^-_{(solv.)} \rightleftharpoons HSO_3F + [SbF_5(SO_3F)]^-_{(solv.)}$$

and

$$[13] \quad HF + [SbF_5(SO_3F)]^-_{(solv.)} \rightleftharpoons HSO_3F + [SbF_6]^-_{(solv.)}$$

Equation [13] explains the observed increase in $[SbF_6]^-$ with time in samples 1 and 2, noted in diluted solutions. It is clearly seen in Tables 5 and 6, that in samples 1–3, initially formed $[SbF_5(SO_3F)]^-$ is with time partly converted to $[SbF_6]^-$ and in samples 2 and 3 with increasing SbF_5 concentrations to $[(SbF_5)_2\text{-}\mu\text{-}SO_3F]^-$ (E). This is consistent with our experimental findings, where the species formed may be classified according to concentrations observed as shown in Table 7 and Scheme 1.

Conclusion

A system of concerted, slow reactions leads to equilibria in magic acids made up from HSO_3F and SbF_5 as shown in Scheme 2.

Solvolysis takes place in a horizontal direction, while vertical and diagonal directions indicate the addition of HSO_3F and HF, respectively, to Lewis acids of type $SbF_{5-i}(SO_3F)_i$. Complex anions of type $[SbF_{6-j}(SO_3F)_j]^-$ were formed, which were counterbalanced by $<H^+>$ symbolizing the acidium ions $H_2SO_3F^+$ and H_2F^+. Our present study unequivocally confirms the formation of species with $j = 0$–2 in relevant concentrations of >1 mol %. The main products (>5%) were $[SbF_6]^-$ and $[SbF_5(SO_3F)]^-$ while *cis*- and *trans*-$[SbF_4(SO_3F)_2]^-$ are formed in the 1–5% range.

None of the free Lewis acids $SbF_{5-i}(SO_3F)_i$ were detected in the ^{19}F NMR spectra. This indicates the high reactivity of such species to form the complex anions described above. Secondary addition products may be formed from the Lewis acids $SbF_{5-i}(SO_3F)_i$ and the complex anions $[SbF_{6-j}(SO_3F)_j]^-$ leading to oligomeric species as described formally by:

© 2002 NRC Canada

[14] $$a\mathrm{SbF}_{5-i}(\mathrm{SO_3F})_i + b[\mathrm{SbF}_{6-j}(\mathrm{SO_3F})_j]^- \rightleftharpoons [\mathrm{SbF}_{a(5-i)+b(6-j)}(\mathrm{SO_3F})_{ai+bj}]^-$$

Obviously, depending on a and b, several stereoisomers of such anions may exist, e.g., having μ-F- (in case of $[Sb_2F_{11}]^-$ only) and μ-O-S(O)(F)-O- bridges between or different location patterns for the -F and -SO_3F substituents attached to the octahedral skeletons of the antimony units (13). While a larger number of such anions were observed by NMR studies in glass NMR tubes (13) only a few and only simple species ($[Sb_2F_{11}]^-$, $[Sb_2F_{10}(SO_3F)]^-$, and $[Sb_2F_8(SO_3F)_3]^-$), all defined by $a = b = 1$, were visible above the 1% level when using fluoropolymer linings.

In the beginning phase of our studies we had considerable problems in understanding the spectrum of sample 1: high concentration of $[SbF_6]^-$, low concentration of $[SbF_5(SO_3F)]^-$, almost no $[SbF_4(SO_3F)_2]^-$, which indicates an excess of HF/F^- in this system. There appears to be more fluoride than would be formed according to Scheme 2 (magic acid equilibria). Consequently, traces of HF must originate from the materials used. Technical grade SbF_5 and HSO_3F have been carefully purified by established distillation methods (9(*b*)). However, even after purification the presence of trace amounts of HF in SbF_5 and (or) HSO_3F can not be ruled out. We do not expect that excess HF originates in considerable quantities as a result of an auto-dissociation of HSO_3F following (9):

[15] $$\mathrm{HSO_3F} \rightleftharpoons \mathrm{HF} + \mathrm{SO_3}$$

since the corresponding self-dissociation constant K_{sd}^{25} is as low as 3×10^{-7}. To support this assumption by experimental evidence we have studied a comparative series of magic acids derived from triflic acid CF_3SO_3H, where the formation of HF by an auto-dissociation analogue to eq. [15] is virtually impossible. Results of this investigations will be published as Part III in a separate consecutive paper of this series.

In summary, we view the distribution of monomeric anions found previously (13) at high dilutions to be representative of the nature and concentration of superacid anions formed in the absence of HF. All measurements in this concentration range made in the present study are affected by HF, causing a slow fluoro-fluorosulfato exchange because of the delay of 3 months between preparation and the initial measurements as discussed above. This is best shown in Table 7.

A necessary conclusion needs to be reached: the avoidance of H_2O formation by interaction of HF with glass and subsequent protonation to $[H_3O]^+$, demonstrated here, implies that magic acid (HSO_3F–SbF_5), when contained in fluoroplastic containers, must exhibit higher Brønsted acidities, than when used in glass. It will be difficult however to measure these acidities at high SbF_5 concentration, by reliable H_0 determinations (12). The use of indicator bases as practiced by Gillespie and Peel (20, 21) beyond the $-H_0$ value of 24 appears to be experimentally very challenging as discussed previously (22, 23). The use of H_2O as indicator proposed by Gold et al. (24, 25) appears to be unsound (22, 23). NMR methods by Sommer et al. (6, 7), cited here, involving solutions in diluents are problematic as well as discussed by us here and previously (13). It is hoped, that a new imaginative approach may be found, to allow H_0 measurement at these high acidities to confirm our conclusions.

Ligand scrambling reactions of cyano(thione)gold(I) complexes and determination of their equilibrium constants

Saeed Ahmad, Anvarhusein A. Isab, and Herman P. Perzanowski

Abstract: Ligand scrambling reactions in cyano(thione)gold(I) complexes ([>C=S-Au-CN]) to form $[Au(>C=S)_2]^+$ and $[Au(CN)_2]^-$ species have been investigated for a series of thiones in DMSO using ^{13}C and ^{15}N NMR spectroscopy. Rapid approach to equilibrium occurred and resulted in distinct signals for the [>C=S-Au-CN] and $[Au(CN)_2]^-$ complexes, both in ^{13}C and ^{15}N NMR. Equilibrium constants (K_{eq}) were determined for scrambling of all the complexes by integrating the CN resonances in the ^{13}C NMR recorded at 298 K. The influence of various factors (initial concentration, ionic strength, temperature, and solvent polarity) on the K_{eq} value was examined for a representative complex (ImtAuCN (Imt = Imidazolidine-2-thione)).

Key words: cyanogold(I) complexes, thiones, ligand scrambling, NMR, K_{eq}.

Résumé : Faisant appel à la spectroscopie RMN du ^{13}C et du ^{15}N et opérant dans le DMSO avec une série de thiones, on a étudié les réactions de brouillage de complexes cyan(thione)or(I) ([>C=S-Au-CN]) qui conduisent à la formation des espèces $[Au(>(C=S)_2]^+$ et $[Au(CN)_2]^-$. Il y a une approche rapide de l'équilibre et l'apparition de signaux distincts pour les complexes de [>C=S-Au-CN] et $[Au(CN)_2]^-$ tant en RMN du ^{13}C que celle du ^{15}N. On a déterminé les constantes d'équilibre ($K_{éq}$) pour le brouillage de chacun des complexes en intégrant les résonances du CN dans les spectres RMN du ^{13}C enregistrés à 298 K. Utilisant le complexe ImtAuCN (Imt= imidazoline-2-thione) comme exemple, on a examiné l'influence de divers facteurs (concentration initiale, force ionique, température et polarité du solvant) sur les valeurs de $K_{éq}$.

Mots clés : complexes cyanoor(I), thiones, brouillage de ligands, RMN, $K_{éq}$.

[Traduit par la Rédaction]

Introduction

It has been suggested that gold drugs (used for the treatment of rheumatoid arthritis (1, 2)) and their metabolites react in vivo with cyanide to form the intermediates $[RS\text{-}Au\text{-}CN]^-$ and [Et_3P-Au-CN], which undergo disproportionation generating $[Au(CN)_2]^-$ that is readily taken up by red blood cells (RBCs) (3–8). The cyanide is produced in the body by oxidation of SCN^- in polymorphonuclear leukocytes (3, 4). Although the concentration of cyanide in RBCs is very low (0.3 to 1 μM) (9), the very large formation constant of $[Au(CN)_2]^-$ ($\log \beta = 36$) (10) favors its formation. The level of $[Au(CN)_2]^-$ is higher for smokers than for nonsmokers because of inhalation of HCN from tobacco smoke (6, 11). Several studies describe the formation of $[Au(CN)_2]^-$ by disproportionation of L-Au-CN complexes in solution (12–18) according to the following equilibrium:

$$[1] \qquad 2\text{L-Au-CN} \rightleftarrows [AuL_2]^+ + [Au(CN)_2]^-$$

Cyano(ergothione)gold(I) is the only cyano(thione)gold(I) complex known to exhibit such a scrambling reaction in solution (18). However, cyano(*N*,*N*′-dimethylthiourea)gold(I) exists as an ionic complex ($[AuL_2]^+[Au(CN)_2]^-$) in the solid state (19). Cyano(thione)gold(I) complexes may be useful as models for the cyano intermediates of gold drugs ($[RS\text{-}Au\text{-}CN]^-$). Therefore, in the present study we carried out an investigation of scrambling reactions of various cyano(thione)gold(I) complexes. We were also able to measure the equilibrium constants (K_{eq}) for the scrambling of the complexes by integration of CN resonances in the ^{13}C NMR. Because of the possible biological implications of these reactions (3–6), the effects of several extrinsic factors on K_{eq} were systematically examined for one of the complexes (Imt-Au-CN). The external influences examined are the initial concentrations, ionic strength of the medium, temperature and the polarity of the solvent. The dependence of K_{eq} on initial concentration was studied in DMSO-d_6, while the effects of temperature and ionic strength were examined in methanol-d_4.

The structures of the thiones used in this study are described in Scheme 1.

Experimental

Chemicals

AuCN, using 99% ^{13}C- and ^{15}N-labeled KCN, was prepared according to the published procedure (13).

Table 1. Elemental analyses of the [>C=S-Au-CN] complexes.

	Found (calcd.) (%)			
Complex	C	H	N	S
DmTuAuCN	15.18 (14.68)	2.44 (2.46)	13.26 (12.85)	9.24 (9.80)
MeImtAuCN	17.37 (17.70)	2.31 (2.38)	11.38 (12.39)	10.54 (9.45)
DiapAuCN	19.58 (20.40)	2.73 (2.85)	11.19 (11.90)	8.42 (9.08)

N,*N*′-Dimethylthiourea, CD_3OD, and DMSO-d_6 were obtained from Fluka Chemical Co. All the thiones were synthesized according to the procedure described in the literature (by the addition of CS_2 to diamines in ether and then heating the resulting adduct at 100°C for 2 to 3 h, followed by its crystallization in methanol) (20, 21). In all ligands except DmTu and Diap, C-2 contains 5% labeled carbon-13.

Preparation of complexes

All [>C=S-Au-CN] complexes were prepared according to the published procedure, by refluxing an equimolar amount of the thione and AuCN in methanol and then crystallizing in methanol (22). The complexes of DmTu, Diaz, and Diap ligands could not be crystallized in methanol, instead sticky materials were obtained which were separated by addition of diethyl ether. The elemental analysis for five of the eight complexes is already reported (22) and for the remaining three complexes, it is given in Table 1.

^{1}H, ^{13}C, and ^{15}N NMR measurements

^{1}H NMR spectra were obtained on a Jeol JNM-LA 500 NMR spectrometer operating at a frequency of 500.00 MHz. ^{13}C NMR spectra were obtained at the frequency of 125.65 MHz with ^{1}H broadband decoupling at 298 K. The spectral conditions were: 32 000 data points, 0.967 s acquisition time, 1.00 or 30.00 s pulse delay, and 45° pulse angle. ^{13}C NMR chemical shifts relative to TMS were assigned according to the reference given in the literature (23).

The ^{15}N NMR spectrum was recorded at 50.55 MHz using $NH_4{}^{15}NO_3$ as the external reference, which lies at 375.11 ppm relative to pure CH_3NO_2 (380.2 ppm) (24). The spectral conditions for ^{15}N were: 32 000 data points, 0.721 s acquisition time, 2.50 s delay time, 60° pulse angle, and approx. 5000–10 000 scans.

T_1 values for the ^{13}C nuclei were measured only for the complex Imt-Au-CN using the inversion recovery method. The average values obtained were: 5.5 s for $[Au(CN)_2]^-$, 3.9 s for the CN carbon of Imt-Au-CN, and 5.0 s for the >C=S carbon of Imt-Au-CN. Based on these T_1 values, a delay time of 30.0 s was used to record the ^{13}C NMR spectra of all the complexes so that the spectra could be integrated quantitatively.

Results and discussion

The ligand scrambling reactions of the cyano(thione)gold(I) complexes in DMSO were investigated by ^{13}C and ^{15}N NMR spectroscopy. The ^{1}H NMR chemical shifts of N-H protons and ^{13}C NMR chemical shifts of all the ligands and their gold(I) complexes are given in Table 2.

In ^{1}H NMR, the N-H signal was broadened upon coordination and a down-field shift of almost 1.0 ppm was observed in the N-H proton of all the ligands. The appearance of the N-H signal in the ^{1}H NMR spectra of all ligands after complexation shows that the ligands were coordinating in the thione form in solution.

In ^{13}C NMR, no significant change in the chemical shifts of the ligands upon complexation was observed except in the C-2 resonance (Table 1). A shift of 8–10 ppm in C-2 resonance indicates that in all the complexes gold(I) is bonded to thione ligands through the sulfur atom only (22, 23). Typical ^{13}C and ^{15}N NMR spectra for a representative complex (Imt-Au-^{13}C^{15}N) are shown in Fig. 1.

The ^{13}C and ^{15}N NMR shifts of CN^- and coupling constants ($^1J_{C\text{-}N}$) of the [>C=S-Au-CN] complexes are given in Table 3.

In the CN region of the ^{13}C NMR spectrum, two intense resonances were observed for all the complexes (Fig. 1(*b*)). One CN resonance at 149.6 ppm is characteristic of $[Au(CN)_2]^-$ (13, 14), while the other resonance corresponds to the [>C=S-Au-CN] complexes. These two resonances demonstrate that [>C=S-Au-CN] type complexes undergo the same type of ligand scrambling reaction as given by eq. [1], i.e.,

$$[2] \qquad 2[>C{=}S\text{-}Au\text{-}CN] \rightleftarrows [Au(>C{=}S)_2]^+ + [Au(CN)_2]^-$$

The $[Au(CN)_2]^-$ resonance appeared as a triplet (or a broad singlet) with an average coupling constant of 5.9 Hz.

[a]Values in methanol.
[b]Not observed.

The triplet appearance of the $[Au(CN)_2]^-$ resonance occurred because the ^{13}C-^{15}N in $[Au(CN)_2]^-$ follows the AA′XX′ spin system as described in the previous studies (14, 15, 18). The ^{13}C-^{15}N resonance due to [>C=S-Au-$^{13}C^{15}N$] complexes is a doublet with the $^{1}J_{C\text{-}N}$ values given in Table 3. In the ^{13}C NMR of Imt-Au-CN in methanol, the $[Au(CN)_2]^-$ resonance was observed at 152.41 ppm. Separate resonances for thione ligands in [>C=S-Au-CN] and $[Au(>C=S)_2]^+$ species were typically not observed either due to their rapid exchange or because the chemical shifts of the two species are overlapped so that they could not be resolved. However, we were able to observe these for one of the complexes (Imt-Au-CN) at 240 K in methanol (Fig. 1(*c*)). The >C=S and C-4/5 resonances of Imt-Au-CN and $[Au(>C=S)_2]^+$ which were observed as average resonances at 298 K, were clearly separated into two peaks at 240 K (Fig. 1(*c*)). Thus, we were able to detect both species ($[Au(>C=S)_2]^+$ and $[Au(CN)_2]^-$) formed as a result of the scrambling of Imt-Au-CN. The analogous species in the scrambling of R_3P-Au-CN complexes ($[Au(R_3P)_2]^+$) was detected at room temperature by ^{31}P NMR (13, 14). For the DmTu-Au-CN complex, two resonances for methyl carbons of DmTu were detected

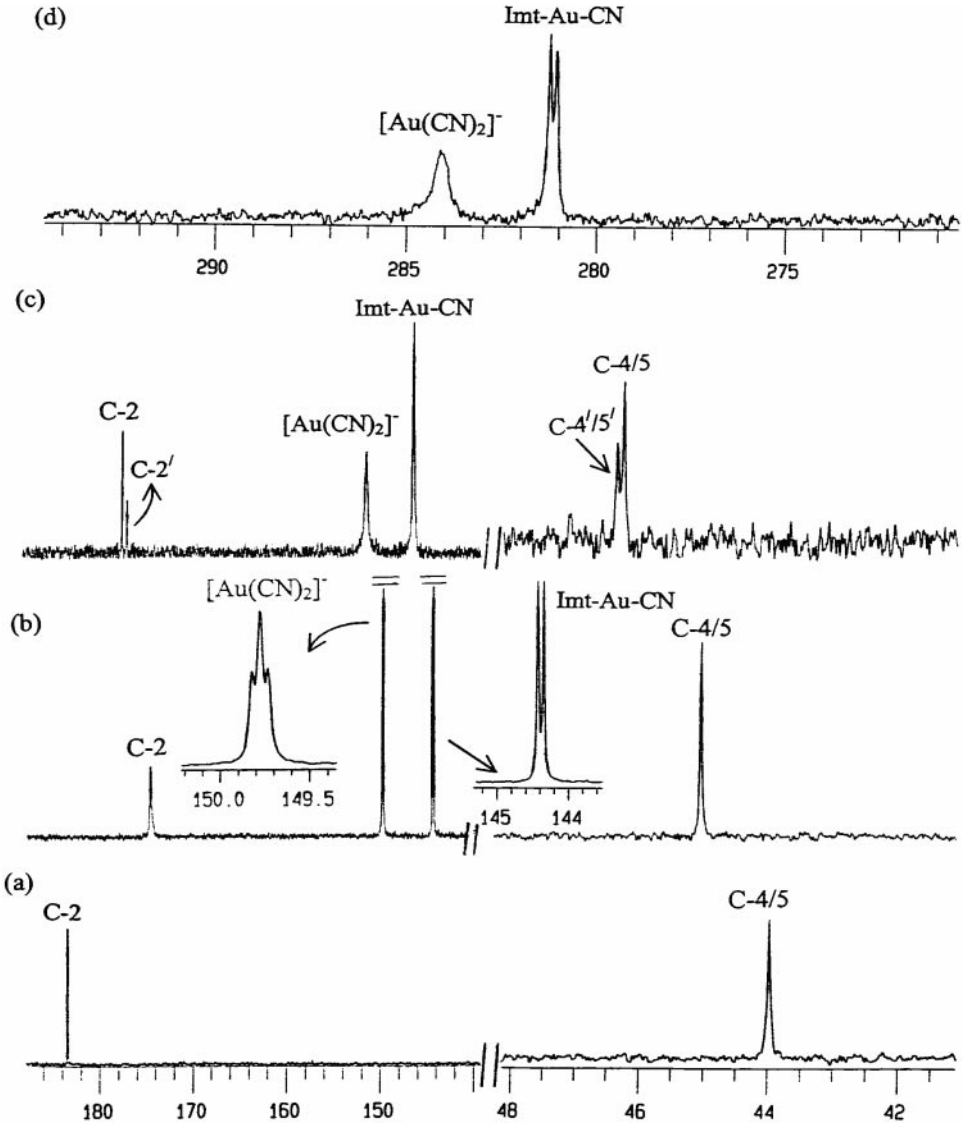
Fig. 1. (*a*) 125.65 MHz ^{13}C NMR spectrum of Imt in DMSO-d_6; (*b*) ^{13}C NMR spectrum of Imt-Au-$^{13}C^{15}N$ at 298 K in DMSO-d_6; (*c*) ^{13}C NMR spectrum of Imt-Au-$^{13}C^{15}N$ at 240 K in methanol (C-2 of the thione is enriched to 2% and C′ are the resonances corresponding to $[Au(Imt)_2]^+$); (*d*) 50.55 MHz ^{15}N NMR spectrum of Imt-Au-$^{13}C^{15}N$ in DMSO-d_6.



showing that the methyl groups are inequivalent. These two resonances for methyl carbons could not be due to the [DmTu-Au-CN] and $[Au(DmTu)_2]^+$ species, since we also observed two resonances for methyl carbons in the reaction of DmTu with $AgNO_3$. Two resonances were also observed for N-H (and CH_3) protons in ^1H NMR (Table 2). The crystal structure of DmTu-Au-CN demonstrates that both N-H hydrogen atoms of DmTu are involved in hydrogen bonding to the nitrogen of cyanide (19). Thus the two methyl groups and N-H protons would be inequivalent and behave differently in NMR.

Dimethyl sulfoxide is believed to interact weakly with AuCN, since in the ^{13}C NMR of a mixture of AuCN and DMSO, two CN resonances corresponding to $[Au(CN)_2]^-$ and DMSO–AuCN (135.03 ppm, $^1J_{C\text{-}N}$ = 10.1 Hz) species were observed. However, the CN resonance due to DMSO–AuCN was not observed in any of the thione complexes.

The results of the ^{15}N NMR studies are consistent with the ^{13}C NMR data. The ^{15}N NMR also showed two resonances for the CN^- nitrogen corresponding to equilibrium (2) (Fig. 1(*d*)). The resonance at 284.1 ppm was a triplet (or a broad singlet) of $[Au(CN)_2]^-$ with an average coupling constant of 5.9 Hz. The other resonance was a doublet due to ^{13}C-^{15}N coupling in the >C=S-Au-$^{13}C^{15}N$ complexes (Table 3). When a ^{15}N NMR of Imt-Au-CN was taken in methanol, a significant shift in these resonances was observed. The $[Au(CN)_2]^-$ resonance was observed at 264.7 ppm and the Imt-Au-CN resonance at 262.2 ppm.

Equilibrium constants (K_{eq}) were measured for the >C=S-Au-CN complexes at 298 K using a 0.025 M solution of each complex in DMSO-d_6. The K_{eq} values were calculated from the relative intensities of the ^{13}C-^{15}N resonances of [>C=S-Au$^{13}C^{15}N$] and $[Au(^{13}C^{15}N)_2]^-$ in the ^{13}C NMR, which gave the relative concentrations of all three species

Fig. 2. K_{eq} vs. [Imt-Au-$^{13}C^{15}N$]$_0$ at 298 K for concentrations ranging from 0.0125 to 0.10 M in DMSO-d_6.

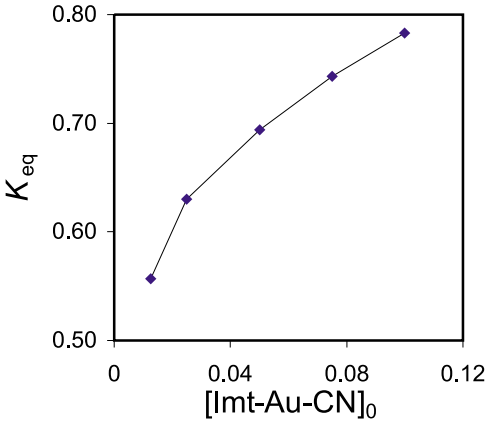

Fig. 3. K_{eq} vs. [NH_4NO_3] for 0.05 M Imt-Au-$^{13}C^{15}N$ at 298 K in methanol (NH_4NO_3 concentrations ranging from 0.2 to 1.0 M).

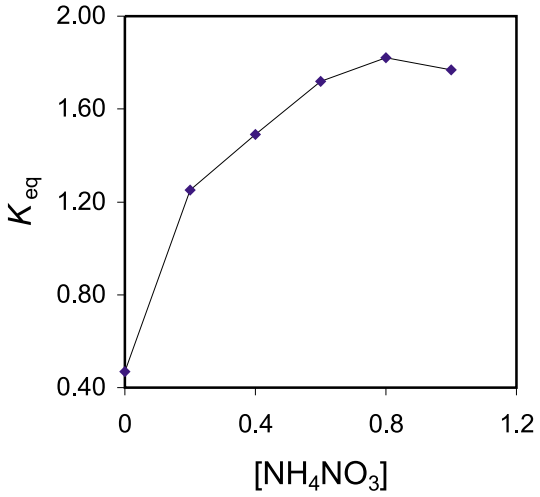


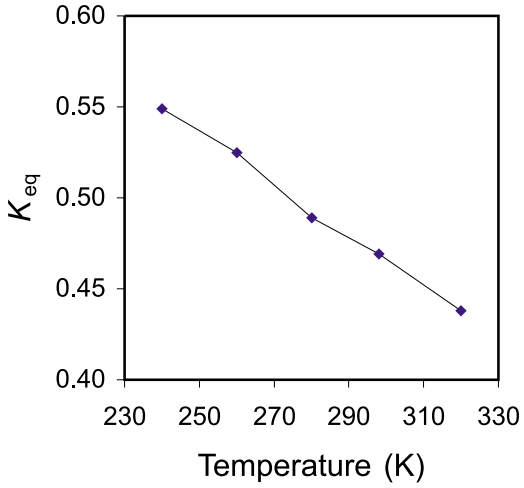
because of the stoichiometric relationship (I[Au($^{13}C^{15}N)_2]^-$ = I[Au (>C=S)$_2]^+$):

$$K_{eq} = \frac{(I[\mathrm{Au}(^{13}\mathrm{C}^{15}\mathrm{N})_2]^-)(I[\mathrm{Au}(>\mathrm{C}{=}\mathrm{S})_2]^+)}{(I[>\mathrm{C}{=}\mathrm{S}\text{-}\mathrm{Au}^{13}\mathrm{C}^{15}\mathrm{N}])^2}$$

Each K_{eq} is the result of five to six measurements. The average K_{eq} values thus found for the complexes are listed in Table 3 and for comparison, K_{eq} values of some known cyanogold(I) complexes are also given. The intensity of the CN resonances was found to be unchanged when spectra were taken after 1 week showing that the scrambling equilibrium was achieved rapidly for these complexes.

The effect of several factors on the magnitude of K_{eq} was examined for a representative complex (Imt-Au-CN). The first extrinsic factor examined was the initial concentration of the complex [Imt-Au-CN]$_o$. Initial concentrations ranging from 0.0125 to 0.10 M in DMSO-d_6 were used. A plot of K_{eq} vs. [Imt-Au-CN]$_o$ shows that K_{eq} value increases consistently with increasing [Imt-Au-CN]$_o$ (Fig. 2). An increase in [Imt-Au-CN]$_o$ generates more [Au(Imt)$_2]^+$ and [Au(CN)$_2]^-$ which in turn increases ionic strength resulting in the larger K_{eq} values (13).

Fig. 4. K_{eq} vs. temperature for 0.05 M Imt-Au-$^{13}C^{15}N$ in methanol for the temperature range 240–320 K.



The second external influence examined was the ionic strength of the solution. NH_4NO_3 (a salt having component ions with a low affinity for gold(I)) (13) was used to control the ionic strength of the solution. ^{13}C NMR spectra were acquired for 0.05 M [Imt-Au-CN] in CD_3OD with NH_4NO_3 at concentrations ranging from 0.20 to 1.0 M. Figure 3 shows a plot of K_{eq} vs. the concentration of NH_4NO_3. The K_{eq} value increases with NH_4NO_3 concentration up to 0.80 M. Since ionic complexes are generated by the scrambling process, an increase in ionic strength leads to an increase in the activity coefficients for [Au(Imt)$_2]^+$ and [Au(CN)$_2]^-$ with a subsequent increase in K_{eq}. A decrease in K_{eq} at [NH_4NO_3] greater than 1.0 M is perhaps due to ion pairing. This result is consistent with that reported for Et_3PAuCN (13). The increase in K_{eq} observed by increasing ionic strength is more than that observed by changing concentration.

To examine the effect of temperature on K_{eq}, the ^{13}C NMR spectra were obtained at the temperatures of 240, 260, 280, 298, and 320 K in CD_3OD. When K_{eq} values are plotted against temperature, an inverse correlation was observed (Fig. 4). The K_{eq} value decreased with increasing temperature indicating that the scrambling reaction is exothermic in the forward direction (eq. [2]) according to the van't Hoff equation ($\ln K = -\Delta H°/RT + C$). $\Delta H°$ for this reaction can be obtained if ln K is plotted vs. $1/T$ in the above equation. Such a plot is shown in Fig. 5 and the $\Delta H°$ value obtained from this plot is –1.81 kJ mol $^{-1}$.

Polarity of the solvent should also have a significant effect on K_{eq} because the increased solvation of the ionic species generated as a result of the scrambling process should ultimately result in larger K_{eq} values. The K_{eq} values obtained in different solvents using a 0.025 M solution of the complex are shown in Table 4. The K_{eq} values are consistent with the polarity of the solvent except methanol. Methanol being a protic solvent solvates the anion (25) ([Au(CN)$_2]^-$) (which is more stable) strongly and thus would result in a larger K_{eq}.

Besides external factors, it was observed in the scrambling reactions of cyanogold (I) complexes of phosphines, that K_{eq} is also affected by the intrinsic factors, which are electronic and steric (13). Among the intrinsic factors, the basicity of the phosphine was found to be the most important which

affects K_{eq}. An increase in K_{eq} was observed with an increase in basicity of the phosphine (13). However, the π accepting ability of the phosphines may be an additional factor in the stability of R_3PAuCN complexes, which would result in a lower K_{eq} value. As shown in Table 3, the K_{eq} values for the cyanogold(I) complexes of thiones are comparatively larger than for the complexes of phosphines. The larger K_{eq} values indicate that the thiones are more basic towards Au(I) but weaker π acceptors compared to the phosphines. The smaller Au—P bond length and greater Au—CN distance in R_3PAuCN complexes (26) compared to the Au—S and Au—CN distances in [>C=S-AuCN] complexes (19) also support this conclusion. For example, the Au—P bond length in Me_3PAuCN was found to be 2.275 Å (26), while in ImtAuCN, the Au—S distance was 2.294 Å (19). The corresponding Au—CN distances were 2.04 and 1.966 Å, respectively. The smaller Au—CN distance in [>C=S-AuCN] is due to greater donation of electron density by the thione.

In the scrambling reactions of cyano(phosphine)gold(I) complexes (13, 14), it was observed that with increasing basicity of phosphines, the δ (^{13}C) for CN also increased due to the increased π bond character in the Au—C bond, while the δ (^{15}N) was decreased. However, in the present study, $\delta^{13}C$ and $\delta^{15}N$ for CN and the coupling constants ($^1J_{C\text{-}N}$) in all the complexes are very close showing that the difference in their basicity is smaller. Table 3 shows the highest value of $\delta^{13}C$ for the CN resonance of Diaz–AuCN indicating that it is the most basic, while the PrImt–AuCN with the lowest $\delta^{13}C$ is the least basic among the thiones.

The present study concludes that cyano(thione)gold(I) complexes undergo a similar kind of scrambling process in solution as observed for cyano(phosphine)gold(I) complexes. However, the $[Au(>C=S)_2]^+$ species formed by the scrambling of >C=S-Au-CN complexes could only be detected at lower temperatures. The scrambling equilibrium is dependent on such factors as the initial concentration of the complex, ionic strength of the solution, temperature and polarity of the solvent, with polarity of the solvent showing a major influence on K_{eq}.

Alkoxide-functionalized cyclopentadienyl complexes of yttrium containing a two-carbon tether

Roland A.L. Gendron, David J. Berg, and Tosha Barclay

Abstract: The ligand $C_5H_4(CH_2CH_2CAr^F{}_2OH)$ (**3**) (Ar^F = 3,5-$C_6H_3(CF_3)_2$) was prepared in two steps, from the iodo ester $ICH_2CH_2CO_2Me$ by way of the cyclopentadienyl ester $C_5H_5CH_2CH_2CO_2Me$ (**2**), in 55% overall yield. Thermal reaction of **3** with $\{Y[N(SiMe_3)_2]_2(THF)_2(\mu\text{-}Cl)\}_2$ afforded the neutral chloride complex $\{\eta^5{:}\eta^1\text{-}C_5H_4[CH_2CH_2C(O)(3,5\text{-}C_6H_3(CF_3)_2)_2]\}YCl\{THF\}_n$ (**5a**: n = 2, **5b**: n = 1). Metathesis reactions of **5** with 1 equiv of $NaN(SiMe_3)_2$, LiO-2,6-*t*-$Bu_2C_6H_3$, and $LiCH(SiMe_3)_2$ afforded $\{\eta^5{:}\eta^1\text{-}C_5H_4[CH_2CH_2C(O)(3,5\text{-}C_6H_3(CF_3)_2)_2]\}Y\{N(SiMe_3)_2\}\{THF\}_n$ (**6**), $\{\eta^5{:}\eta^1\text{-}C_5H_4[CH_2CH_2C(O)(3,5\text{-}C_6H_3(CF_3)_2)_2]\}Y\{O\text{-}2,6\text{-}t\text{-}Bu_2C_6H_3\}\{THF\}_n$ (**7**), and $\{\eta^5{:}\eta^1\text{-}C_5H_4[CH_2CH_2C(O)(3,5\text{-}C_6H_3(CF_3)_2)_2]\}Y\{CH(SiMe_3)_2\}\{THF\}_n$ (**8**), respectively, (**a**: n = 2, **b**: n = 1). Exposure of the *bis*(THF) solvates to reduced pressure resulted in desolvation to the *mono*(THF) adducts for **5**–**8**. The solid state structure of **6b** was established by X-ray crystallography. In addition, formation of a spirocyclic ether ($C_4H_6CH_2CH_2C(O)(3,5\text{-}C_6H_3(CF_3)_2)_2$ **4**), obtained by the intramolecular cyclization of ligand **3**, was confirmed by X-ray crystallography.

Key words: yttrium, organometallic, cyclopentadienyl, X-ray, alkoxide, chelate, alkyl, hybrid ligand, NMR, cyclization.

Résumé : On a préparé le ligand $C_5H_4(CH_2CH_2CAr^F{}_2OH)$ (**3**) (Ar^F = 3,5-$C_6H_3(CF_3)_2$) en deux étapes à partir de l'ester iodé $ICH_2CH_2CO_2Me$, par le biais de l'ester cyclopentadiényle, $C_5H_5CH_2CH_2CO_2Me$ (**2**), avec un rendement global de 55%. La réaction thermique du composé **3** avec $\{Y[N(SiMe_3)_2]_2(THF)_2(\mu\text{-}Cl)\}_2$ conduit à la formation du complexe chloré neutre $\{\eta^5{:}\eta^1\text{-}C_5H_4[CH_2CH_2C(O)(3,5\text{-}C_6H_3(CF_3)_2)]\}YCl\{THF\}_n$ (**5a**: n = 2, **5b**: n = 1). Les réactions de métathèse des composés **5** avec un équivalent de $NaN(SiMe_3)_2$, LiO-2,6-*t*-$Bu_2C_6H_3$ et $LiCH(SiMe_3)_2$ conduisent respectivement au $\{\eta^5{:}\eta^1\text{-}C_5H_4[CH_2CH_2C(O)(3,5\text{-}C_6H_3(CF_3)_2)]\}Y\{N(SiMe_3)_2\}\{THF\}_n$ (**6**), $\{\eta^5{:}\eta^1\text{-}C_5H_4[CH_2CH_2C(O)(3,5\text{-}C_6H_3(CF_3)_2)]\}Y\{O\text{-}2,6\text{-}t\text{-}Bu_2C_6H_3\}\{THF\}_n$ (**7**) et $\{\eta^5{:}\eta^1\text{-}C_5H_4[CH_2CH_2C(O)(3,5\text{-}C_6H_3(CF_3)_2)]\}Y\{CH(SiMe_3)_2\}\{THF\}_n$ (**8**) (**a**: n = 2, **b**: n = 1). Si l'on soumet les produits *bis*(THF) solvatés **5**–**8** à une pression réduite, il en résulte une désolvatation conduisant aux adduits *mono*(THF). On a déterminé la structure du composé **6b** par diffraction des rayons X. De plus on a confirmé par diffraction des rayons X que la cyclisation intramoléculaire du ligand **3** conduit à la formation d'un éther spirocyclique, $C_4H_6CH_2CH_2(CO)(3,5\text{-}C_6H_5(CF_3)_2)_2$ (**4**).

Introduction

The development of *hybrid* ligands that contain both Cp and a pendant anionic group has been an important trend in organometallic chemistry of the lanthanides and group 4 elements during the past decade (1–3). The introduction of new Cp-alkoxide and Cp-amide mixed ligands has been especially successful because these ligands form metal complexes with coordination spheres that are more open than the corresponding *bis*(cyclopentadienyl) systems. Group 4 complexes containing these ligands have been extensively studied and have been widely applied to olefin polymerization chemistry (3). It is particularly surprising, then, that Cp-alkoxides have not been widely investigated as ligands in yttrium or lanthanide chemistry (2(*c*), 4, 5).[2] Ligands of this type developed for use in group 4 chemistry, however, are often poorly suited to group 3 and lanthanide chemistry because they do not possess sufficient steric bulk to satisfy the coordination sphere of the larger metals. In particular, many of the existing ligands bear no substituents on the alkoxide carbon.

In earlier work, we reported the preparation of a Cp-alkoxide ligand (**1**) with a single carbon bridge between the Cp unit and the alkoxide carbon (6). The preparation of simple

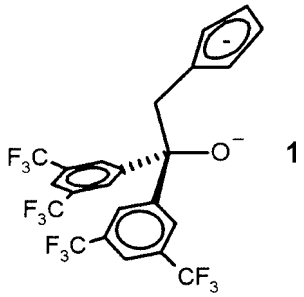
[2]Cyclopentadienyl ligands bearing *neutral* pendant donors are well known in yttrium and lanthanide chemistry. Literature prior to 1994 has been reviewed (5*a*). Several complexes of this type have been reported more recently (5(*b*)–5(*l*)).

 DOI: 10.1139/V02-174 © 2002 NRC Canada

yttrium complexes of the type (CpO)YX (CpO = **1**; X = Cl, Cp, $N(SiMe_3)_2$, 2,6-*t*-$Bu_2C_6H_3O$, $CH(SiMe_3)_2$) was generally complicated by the tenacious retention of additional anionic groups to form "*ate*" complexes of the type $(CpO)YX_2^-$, suggesting that ligand **1** lacks sufficient steric bulk to stabilize the neutral (CpO)YX species. Indeed, one of the most persistent problems encountered in previous work was rapid redistribution of the anionic *mono*(ligand) "ate" complexes to the *bis*(ligand) species $(CpO)_2Y^-$, clearly demonstrating the small effective size of **1**.



1

To *close down* the coordination sphere somewhat, **1** can be modified by adding bulk at the Cp or by extending the length of the tether by one carbon (7, 8). So far, our attempts to modify the ligand by using a substituted Cp (C_5Me_4, fluorenyl, indenyl) have not met with success, primarily because chelate coordination of the substituted Cp group does not occur (bridging interactions predominate, leading to insoluble materials). While work is still continuing in that direction, the second option may prove to be a better choice. This is a particularly attractive option because we have observed a tendency for ligand cleavage to occur between the alkoxide carbon and the lone CH_2 group in **1** (6). Presumably, addition of another CH_2 between the alkoxide and the Cp ring will help stabilize the ligand by removing any resonance effects involved in the ligand cleavage mechanism.

A two-atom backbone has been applied in organolanthanide chemistry for several neutral pendant donors (9) and one recently reported pendant alkoxide donor (10). The latter was found to stabilize larger iodide complexes, but no hydrocarbyl chemistry was reported. In the related yttrium hydride ($[Y(\eta^5:\eta^1\text{-}C_5Me_4SiMe_2NCMe_3)(\mu\text{-}H)(THF)]_2$) (4(*e*)), extension of the backbone by a single carbon, to give $[Y(\eta^5:\eta^1\text{-}C_5Me_4CH_2SiMe_2NCMe_3)(\mu\text{-}H)(THF)]_2$ (11), showed distinct changes in geometry and reactivity. The observed bite angles opened from 97.8(2)° and 97.4(2)° to 104.9(2)° and 104.3(2)°, respectively, and catalytic activity toward hydrosilation of styrene was higher in the yttrium complex with the longer "-CH_2SiMe_2-" link ($PhSiH_3$: 100% conversion, 1 h, vs. 80% conversion, 7 h) (11). This effect has been ascribed to an increased contribution of monomer in the monomer–dimer equilibrium for complexes containing the ligand with an extended backbone. VT-NMR studies on the monomer–dimer dissociation kinetics of $(Cp^*_2YH)_2$ indicated that the terminal hydride Cp^*_2YH is much more active toward olefin insertion than the dimeric form (12). This finding supports the theory of a dissociative mechanism as the rate-determining step in olefin insertion and, consequently, polymerization. Bulky ligands can only enhance dimer dissociation (i.e., backbone extension), so reactivity should increase with larger ligand size; however, excessive bulk leads to oversaturation of the metal and inhibits the approach of the inserting species. The solution is to use a synthesis that allows the adjustment of bulk in small increments, so as to approach, but not overshoot, the desired ligand size. The extension of the backbone by sequential addition of CH_2 units seems the most logical approach. In this contribution we report the synthesis of a new Cp-alkoxide ligand with an extended two-carbon backbone between the Cp and alkoxide carbons and the formation of several neutral yttrium complexes derived from it.

Experimental

General procedures

All manipulations were carried out under an argon atmosphere, with the rigorous exclusion of oxygen and water, using standard glovebox (Braun MB150-GII) or Schlenk techniques. Tetrahydrofuran (THF), hexane, and toluene were dried by distillation from sodium benzophenone ketyl under argon immediately prior to use. 3,5-*Bis*(trifluoromethyl)bromobenzene and methyl 3-chloropropionate were purchased commercially (Aldrich) and used as received. $Li[3,5\text{-}C_6H_3(CF_3)_2]$ was prepared from *n*-butyl lithium and $3,5\text{-}C_6H_3(CF_3)_2Br$ in hexane at –78°C. The precipitated fluorinated aryl lithium salt was washed with cold hexane and redissolved in diethyl ether before use. Care must be taken to keep $Li[3,5\text{-}C_6H_3(CF_3)_2]$ cold during all operations, since it is unstable above –20°C. The iodo ester ($ICH_2CH_2CO_2CH_3$) was prepared using conventional halogen exchange between methyl 3-chloropropionate and NaI in acetone (13). Yttrium tris(2,6-di-*t*-butylphenoxide) (14) and $\{Y[N(SiMe_3)_2]_2(THF)_2(\mu\text{-}Cl)\}_2$ (6) were prepared according to literature procedures.

^1H (360 MHz), ^{13}C (90.55 MHz), ^{19}F (338.86 MHz), and ^{29}Si (71.54 MHz) NMR were recorded on a Bruker AMX-360 MHz spectrometer. All deuterated solvents were dried over activated 4 Å molecular sieves, and spectra were recorded using 5 mm tubes fitted with a Teflon valve (Brunfeldt) at room temperature unless otherwise specified. ^1H and ^{13}C NMR spectra were referenced to residual solvent resonances. ^{19}F NMR spectra were referenced to external CCl_3F, and ^{29}Si NMR spectra were referenced to external TMS. Melting points were recorded using a Büchi melting point apparatus and are not corrected. Canadian Microanalytical (Delta, B.C) performed elemental analyses. Despite the use of co-oxidants such as V_2O_5 and PbO_2, the analytical data for most metal complexes were consistently 1 to 2% low in carbon. This may be due to metal carbide formation. Mass spectra were recorded on a Kratos Concept H spectrometer using chemical ionization (methane), electron impact (70 eV), or liquid secondary ion mass spectroscopy (LSIMS).

Methyl 3-cyclopentadienylpropionate (2)

To a dry 500 mL Schlenk flask was added $ICH_2CH_2C(O)OCH_3$ (1.61 g, 7.5 mmol), 10 mL diethyl ether, and a Teflon-coated stir-bar. The light yellow solution was stirred under argon and cooled to –78°C. In a separate 100 mL Schlenk flask, sodium cyclopentadienide (0.660 g, 7.5 mmol) was dissolved in 10 mL THF and added slowly via canula. The mixture was allowed to reach room temperature and stirred overnight under argon. The resulting white suspension was quenched with 1 M NH_4Cl (100 mL), and

© 2002 NRC Canada

the organic phase was extracted with 3 × 20 mL of diethyl ether and dried over anhyd $MgSO_4$. Removal of the solvent gave a mixture of the 1-alkylCp (**2a**) and 2-alkylCp (**2b**) isomers as yellow liquids in a 1.2:1 ratio. The 5-alkyl isomer was not observed. Yield: 0.751 g (66%). Major isomer **2a** (1-alkylCp): ^{1}H NMR (*d*-chloroform) δ: 6.40 (m, 1H, Cp-*H*3), 6.26 (dq, 1H, Cp-*H*4, *J* = 5.1, 1.5 Hz), 6.03 (m, 1H, Cp-*H*2), 3.67 (s, 3H, C(O)OCH_3)), 2.95 (dd, 2H, Cp-*H*5), 2.72 (t, 2H, CH_2C(O)OCH$_3$, $^3J_{HH}$ = 8.1 Hz), 2.57 (m, 2H, CH_2CH$_2$C(O)OCH$_3$, *J* = 8.1 Hz). ^{13}C NMR δ: 173.69 (*C*(O)OCH$_3$), 145.29 (Cp-*C*1), 134.12 (Cp-*C*3), 131.04 (Cp-*C*4), 126.90 (Cp-*C*2), 41.35 (C(O)O*C*H$_3$), 41.34 (Cp-*C*5), 33.98 (CpCH$_2$*C*H$_2$C(O)), 25.09 (Cp*C*H$_2$CH$_2$C(O)). Minor isomer **2b** (2-alkylCp): ^{1}H NMR (*d*-chloroform) δ: 6.41 (m, 1H, Cp-*H*3, overlaps **2a**), 6.39 (dq,1H, Cp-*H*4, *J* = 5.1, 1.5 Hz), 6.17 (m, 1H, Cp-*H*1), 3.67 (s, 3H, C(O)OCH_3)), 2.89 (dd, 2H, Cp-*H*5), 2.72 (t, 2H, CH_2C(O)OCH$_3$, overlaps **2a**, $^3J_{HH}$ = 8.1 Hz), 2.57 (m, 2H, CH_2CH$_2$C(O)OCH$_3$, overlaps **2a**, *J* = 8.1 Hz). ^{13}C NMR δ: 173.69 (*C*(O)OCH$_3$, overlaps **2a**), 147.47 (Cp-*C*2), 132.32 (Cp-*C*1), 132.13 (Cp-*C*4, overlaps **2a**), 129.67 (Cp-*C*3), 43.28 (C(O)O*C*H$_3$), 41.34 (Cp-*C*5), 33.98 (CpCH$_2$*C*H$_2$C(O), overlaps **2a**), 25.88 (Cp*C*H$_2$CH$_2$C(O)).

3-Cyclopentadienyl-1,1-di(3,5-bis(trifluoromethyl)phenyl)propanol (3)

A 5 mL ethereal solution of **2** (1.76 g, 11.6 mmol) was added dropwise to a cold solution of Li[3,5-$C_6H_3(CF_3)_2$] (37.1 mmol) in 30 mL of diethyl ether (–78°C) with vigorous stirring. The resulting deep red solution was stirred for an additional 30 min at –78°C before quenching with 100 mL of aqueous NH_4Cl (1 M). The organic phase was extracted with 3 × 20 mL diethyl ether and dried over anhyd $MgSO_4$. Filtration and removal of solvent under vacuum afforded **3** as a yellow oil that contained the 1-alkyl and 2-alkyl isomers in a 1.2:1 ratio. The product was further dried for 1 day over 4 Å molecular sieves and stored as a 0.46 M toluene solution to avoid intermolecular Diels-Alder dimerization. Yield: 5.02 g (79%). Major isomer **3a** (1-alkylCp): ^{1}H NMR (d_6-benzene) δ: 7.79 (s, 4H, *o*-arylC*H*), 7.59 (s, 2H, *p*-arylC*H*), 6.16 (m, 1H, Cp-*H*3), 6.17 (dq, 1H, Cp-*H*4, *J* = 5.2, 1.4 Hz), 5.69 (m, 1H, Cp-*H*2), 2.67 (m, 2H, Cp-*H*5), 2.00 (m, 2H, CpCH$_2$CH_2CO), 1.92 (m, 2H, CpCH_2CH$_2$CO), 1.45 (s, 1H, CO*H*). ^{13}C NMR δ: 147.77 (*ipso*-aryl*C*), 146.98 (Cp-*C*1), 135.04 (Cp-*C*3), 132.15 (q, aryl*C*CF$_3$, $^2J_{CF}$ = 34 Hz), 131.84 (Cp-*C*4), 131.56 (Cp-*C*2), 125.88 (*o*-aryl*C*), 125.82 (q, *C*F$_3$, $^1J_{CF}$ = 236 Hz), 125.87 (*p*-aryl*C*, overlaps *o*-aryl*C*), 65.65 (*C*OH), 43.19 (Cp-*C*5), 41.37 (CH$_2$*C*H$_2$CO), 24.57 (*C*H$_2$CH$_2$CO). ^{19}F NMR δ: –63.09 (C*F*$_3$). Minor isomer **3b** (2-alkylCp): ^{1}H NMR (d_6-benzene) δ: 7.79 (s, 4H, *o*-arylC*H*, overlaps **3a**), 7.59 (s, 2H, *p*-arylC*H*, overlaps **3a**), 6.25 (m, 1H, Cp-*H*3, overlaps **3a**), 6.34 (dq, 1H, Cp-*H*4, *J* = 5.3, 1.5 Hz), 5.91 (m, 1H, Cp-*H*1), 2.44 (q, 2H, Cp-*H*5), 2.00 (m, 2H, CpCH$_2$CH_2CO, overlaps **3a**), 1.92 (m, 2H, CpCH_2CH$_2$CO, overlaps **3a**), 1.37 (s, 1H, CO*H*). ^{13}C NMR δ: 148.83 (*ipso*-aryl*C*), 146.98 (Cp-*C*2, overlaps **3a**), 133.60 (Cp-*C*1), 132.14 (q, *C*CF$_3$, $^2J_{CF}$ = 34 Hz, overlaps **3a**), 131.80 (Cp-*C*4), 131.56 (Cp-*C*3, overlaps **3a**), 125.88 (*o*-aryl*C*), 125.82 (q, *C*F$_3$, $^1J_{CF}$ = 236 Hz, overlaps **3a**), 125.87 (*p*-aryl*C*, overlaps *o*-aryl*C*), 65.65 (*C*OH, overlaps **3a**), 41.08 (Cp-*C*5), 40.26 (CH$_2$*C*H$_2$CO), 24.57 (*C*H$_2$CH$_2$CO, overlaps **3a**). ^{19}F NMR δ: –63.09 (C*F*$_3$, **3a** and **3b**). LSI-MS *m/z* (%): 548 ([M]$^+$, 22), 530 ([M$^+$ – H$_2$O], 60), 240 ($C_6H_3(CF_3)_2CO$, 100), 213 ($C_6H_3(CF_3)_2C$, 50).

$C_4H_6CH_2CH_2C(O)(3,5\text{-}C_6H_3(CF_3)_2)_2$ (4)

A 10 mL toluene solution of **3** (1.02 g) became turbid after storage for 3 days at room temperature. Removal of toluene and recrystallization from hexane at room temperature produced long colorless prisms of the intramolecularly cyclized product **4**. Monitoring this reaction by ^{1}H NMR showed that cyclization was detectable after 2 days and essentially complete after 3 days for a dilute solution (0.03 M) in d_6-benzene at 22°C. Cyclization can be minimized by storage of dilute solutions of **3** in toluene at –30°C. Yield: 0.66 g (60%). ^{1}H NMR (d_6-benzene) δ: 7.94 (s, 2H, *o*-arylCH_a), 7.91 (s, 2H, *o*-arylCH_b), 7.57 (s, 2H, *p*-arylC$H_{a,b}$), 5.61 (m, 1H, C2-*H*, *J* = 5.5, 2.4 Hz), 5.38 (m, 1H, C3-*H*, *J* = 5.5, 2.4 Hz), 2.20 (m, 1H, C4-H_a, *J* = 5.5 Hz), 1.93 (t, 2H, C1-CH$_2$CH_2CO, $^3J_{HH}$ = 6.6 Hz), 1.92 (m, 1H, C4-H_b), 1.92 (m, 1H, C5-H_a), 1.47 (m, 1H, C5-H_b, *J* = 2.4 Hz), 1.33 (t, 2H, C1-CH_2CH$_2$CO, $^3J_{HH}$ = 6.6 Hz). ^{13}C NMR δ: 149.51 (*ipso*-arylC_a), 149.44 (*ipso*-arylC_b), 134.74 (*C*1), 134.17 (*C*2), 132.20 (q, *C*CF$_3$, $^2J_{CF}$ = 33 Hz), 125.83 (*o*-aryl*C*), 125.20 (q, *C*F$_3$, $^1J_{CF}$ = 273 Hz), 121.48 (*p*-aryl*C*), 97.03 (*C*OH), 86.127 (*C*3), 39.63 (CH$_2$*C*H$_2$CO), 37.57 (*C*4), 36.48 (*C*5), 30.89 (*C*H$_2$CH$_2$CO). ^{19}F NMR δ: –62.85 (C$F_{3a,b}$). EI-MS *m/z* (%): 548 ([M]$^+$, 100), 455 ([M$^+$ – F], 42), 241 (3,5-$C_6H_3(CF_3)_2CO$, 40).

$\{\eta^5\text{:}\eta^1\text{-}C_5H_4[CH_2CH_2C(O)(3,5\text{-}C_6H_3(CF_3)_2)_2]\}YCl\{THF\}_n$ (5a: *n* = 2, 5b: *n* = 1)

A 60 mL thick-walled Schlenk flask with a Teflon stopcock was charged with Y[N(SiMe$_3$)$_2$]$_3$ (0.352 g, 0.618 mmol), YCl_3 (0.060 g, 0.309 mmol), and 10 mL THF under an argon atmosphere. The flask was sealed and stirred at 80°C for 2 h. The colourless solution of {Y[N(SiMe$_3$)$_2$]$_2$(THF)$_2$(μ-Cl)}$_2$, formed in situ, was then cooled to –20°C and a 10 mL toluene solution of **3** (0.508 g, 0.927 mmol) was added slowly via syringe. The solution was once again sealed and heated at 80°C for 2 h, becoming more yellow in colour. Solvent was then removed in vacuo, and the off-white solid recrystallized from hot toluene in the glovebox, yielding the chloride (**5**) as small white nodules. Yield: 0.549 g (80%); mp 189 to 190°C. ^{1}H NMR (d_6-benzene – d_8-THF, 5:1) δ: 8.18 (s, 4H, *o*-aryl*H*), 7.67 (s, 2H, *p*-aryl*H*), 6.28 (br s, 2H, Cp*H*), 5.87 (br s, 2H, Cp*H*), 3.55 (m, 8H, α-THF *H*), 2.54 (br s, 2H, CH$_2$CH_2CO), 2.45 (br s, 2H, CH_2CH$_2$CO), 1.43 (m, 8H, β-THF *H*). ^{13}C NMR δ: 154.39 (*ipso*-aryl*C*), 131.30 (q, *C*CF$_3$, $^2J_{CF}$ = 32 Hz), 127.13 (*o*-aryl*C*), 126.30 (Cp-*C*1), 124.00 (q, *C*F$_3$, $^1J_{CF}$ = 283 Hz), 120.35 (*p*-aryl*C*), 111.01 (Cp*C*), 110.45 (Cp*C*), 79.49 (*C*OY), 67.48 (α-THF *C*), 42.55 (CH$_2$*C*H$_2$CO), 25.63 (*C*H$_2$CH$_2$CO), 24.57 (β-THF *C*). ^{19}F NMR δ: –62.58 (C*F*$_3$). Anal. calcd for (*mono*(THF) adduct **5b**) $C_{28}H_{22}ClF_{12}O_2Y$ (%): C 45.26, H 2.98; found: C 43.98, H 3.24.

$\{\eta^5\text{:}\eta^1\text{-}C_5H_4[CH_2CH_2C(O)(3,5\text{-}C_6H_3(CF_3)_2)_2]\}Y\{N(SiMe_3)_2\}\{THF\}_n$ (6a: *n* = 2, 6b: *n* = 1)

An Erlenmeyer flask was charged with **5** (0.122 g, 0.160 mmol) and 20 mL of toluene in the glovebox. To the rapidly stirred sticky suspension was added a 10 mL toluene

© 2002 NRC Canada

solution of $NaN(SiMe_3)_2$ (0.030 g, 0.16 mmol). The suspension was stirred at 70°C for 2 h, during which time the solids became white and free-flowing. Filtration through Celite on a glass frit and removal of solvent in vacuo gave the product as a crude yellow solid. Recrystallization of this solid from a toluene–hexane mixture gave pure **6** as a white powder. Yield: 0.090 g (65%); mp 135 to 136°C. **6a** (*bis*(THF) adduct): ^{1}H NMR (d_6-benzene) δ: 7.88 (s, 4H, *o*-aryl*H*), 7.63 (s, 2H, *p*-aryl*H*), 6.24 (t, 2H, Cp*H*, $^3J_{HH}$ = 2.5 Hz), 5.82 (t, 2H, Cp*H*, $^3J_{HH}$ = 2.5 Hz), 3.58 (m, 8H, α-THF *H*), 2.32 (br s, 4H, CH_2CH_2CO, CH_2CH_2CO), 1.27 (m, 8H, β-THF *H*), 0.09 (s, 18H, SiMe_3). ^{13}C NMR δ: 153.40 (*ipso*-aryl*C*), 131.17 (q, CCF_3, $^2J_{CF}$ = 33 Hz), 129.73 (Cp-*C*1), 126.28 (*o*-aryl*C*), 123.90 (q, CF_3, $^1J_{CF}$ = 273 Hz), 120.23 (*p*-aryl*C*), 110.91 (Cp*C*), 110.82 (Cp*C*), 78.89 (*C*OY), 70.46 (α-THF *C*), 43.04 (CH_2CH_2CO), 24.85 (β-THF *C*), 23.40 (CH_2CH_2CO), 4.50 (SiMe_3). ^{19}F NMR δ: –62.54 (CF_3). ^{29}Si NMR δ: –10.22 (*Si*Me_3).

Exposure of **6a** to vacuum for extended periods of time resulted in the loss of one THF molecule to give **6b**. The NMR data for **6b** were essentially identical to those for **6a**, with the exception that the THF resonances integrated to only 4H each rather than 8H. Anal. calcd for (**6b**) $C_{34}H_{40}F_{12}NO_2Si_2Y$ (%): C 47.06, H 4.65, N 1.61; found: C 46.12, H 4.55, N 1.55.

{η^5:η^1-C_5H_4[CH_2CH_2C(O)(3,5-$C_6H_3(CF_3)_2)_2$]}Y{O-2,6-*t*-$Bu_2C_6H_3$}{THF}$_n$ (7a: *n* = 2, 7b: *n* = 1)

Crude **7** was isolated as a white solid using a procedure analogous to **6** (0.300 g, 0.368 mmol), starting from **5** and Li(O-2,6-*t*-$Bu_2C_6H_3$) (0.088 g, 0.368 mmol). Repeated recrystallization from hexane at –30°C produced **7a** as small colourless crystals. Exposure to vacuum overnight produced the *mono*(THF) adduct (**7b**) with the same NMR data, suggesting fast exchange of the remaining THF. Yield: 0.271 g (75%); mp 110 to 111°C. ^{1}H NMR (d_6-benzene) δ: 7.80 (s, 4H, *o*-aryl*H*), 7.61 (s, 2H, *p*-aryl*H*), 7.32 (d, 2H, *m*-phenoxide *H*, $^3J_{HH}$ = 8.1 Hz), 6.83 (t, 1H, *p*-phenoxide *H*, $^3J_{HH}$ = 8.1 Hz), 6.22 (t, 2H, Cp*H*, $^3J_{HH}$ = 2.9 Hz), 5.82 (t, 2H, Cp*H*, $^3J_{HH}$ = 2.9 Hz), 3.34 (m, 8H, α-THF *H*), 2.52 (br t, 2H, CH_2CH_2CO), 2.37 (t, 2H, CH_2CH_2CO, $^3J_{HH}$ = 5.1 Hz), 1.47 (s, 18H, CMe_3), 1.08 (m, 8H, β-THF *H*). ^{13}C NMR δ: 162.22 (d, *ipso*-phenoxide *C*, $^2J_{YC}$ = 5.0 Hz), 154.24 (*ipso*-aryl*C*), 137.60 (*o*-phenoxide *C*), 131.64 (q, CCF_3, $^2J_{CF}$ = 32 Hz), 129.25 (Cp-*C*1), 126.62 (*m*-phenoxide *C*), 125.47 (*o*-aryl*C*), 123.71 (q, CF_3, $^1J_{CF}$ = 273 Hz), 121.82 (*p*-aryl*C*), 116.95 (*p*-phenoxide *C*), 111.42 (Cp*C*), 110.97 (Cp*C*), 79.18 (d, *C*OY, $^2J_{YC}$ = 3.8 Hz), 71.60 (α-THF *C*), 42.58 (CH_2CH_2CO), 34.89 (CMe_3), 31.22 (CMe_3), 24.80 (β-THF *C*), 23.96 (CH_2CH_2CO). ^{19}F NMR δ: –62.47 (CF_3). Anal. calcd for (*mono*(THF) adduct **7b**) $C_{42}H_{43}F_{12}O_3Y$ (%): C 55.27, H 4.75; found: C 54.03, H 4.90.

{η^5:η^1-C_5H_4[CH_2CH_2C(O)(3,5-$C_6H_3(CF_3)_2)_2$]}Y{CH-$(SiMe_3)_2$}{THF}$_n$ (8a: *n* = 2, 8b: *n* = 1)

Crude **8a** was isolated as a white solid using a procedure analogous to that used for **6**, starting from **5** (0.100 g, 0.122 mmol) and $LiCH(SiMe_3)_2$ (0.0203 g, 0.122 mmol). Repeated recrystallization from hexane at –30°C produced **8a** as a white microcrystalline solid. Exposure to vacuum overnight produced the *mono*(THF) adduct (**8b**). In solution, **8b** shows fluxional behavior, as evidenced by broadened resonances observed in the ^{1}H NMR spectrum. These broadened lines sharpen at higher temperatures (+80°C). Yield: 0.069 g (60%); mp 102 to 103°C. ^{1}H NMR (d_6-benzene) δ: 7.90 (br s, 4H, *o*-aryl*H*), 7.63 (br s, 2H, *p*-aryl*H*), 6.20 (br m, 2H, Cp*H*), 5.79 (br s, 2H, Cp*H*), 3.35 (m, 8H, α-THF *H*), 2.25 (br s, 2H, CH_2CH_2CO), 2.24 (br s, 2H, CH_2CH_2CO, overlaps preceding CH_2), 1.11 (m, 8H, β-THF *H*), 0.15 (s, 18H, SiMe_3), –1.11 (d, 1H, C*H*$(SiMe_3)_2$, $^2J_{YH}$ = 4.3 Hz). ^{13}C NMR δ: 152.81 (*ipso*-aryl*C*), 131.26 (q, CCF_3, $^2J_{CF}$ = 33 Hz), 126.20 (*o*-aryl*C*), 123.63 (q, CF_3, $^1J_{CF}$ = 273 Hz), 120.39 (*p*-aryl*C*), 111.39 (Cp*C*), 111.39 (overlapping Cp*C*), 78.92 (*C*OY, $^2J_{YC}$ = 3.7 Hz), 70.78 (α-THF *C*), 43.77 (CH_2CH_2CO), 24.50 (β-THF *C*), 23.27 (CH_2CH_2CO), 32.37 (d, *C*H$(SiMe_3)_2$, $^1J_{CY}$ = 39 Hz), 25.07 (β-THF *C*), 4.54 (SiMe_3). ^{19}F NMR δ: –62.53. ^{29}Si NMR δ: –7.56 (*Si*Me_3, $^2J_{YSi}$ = 1.6 Hz). Anal. calcd for (*mono*(THF) adduct **8b**) $C_{35}H_{41}F_{12}O_2Si_2Y$ (%): C 48.49, H 4.77; found: C 45.88, H 4.43.

X-ray crystallography

Crystals of **4** and **6b** were isolated from hexane and a toluene–hexane mixture, respectively. The crystals were placed in mineral oil under an atmosphere of argon and sealed in a glass capillary. Data were collected on a Siemens Smart 1000 (**4**) or a Nonius CAD 4F diffractometer (**6b**) equipped with graphite monochromated Mo Kα or Cu Kα radiation at 293 K, respectively. Structure solutions were carried out using teXsan98 (15) and refinement was done on *F*. Refinement of **4** was plagued by severe disorder problems and was only sufficient to establish the connectivity of the molecule.[3]

The data for **6b** were corrected for Lorentz and polarization effects, and a correction for secondary extinction was applied (coefficient = $2.91(4) \times 10^{-6}$). An empirical absorption correction was applied (absorption range: 0.92 – 1.00). Refinement proceeded normally although, as usual, rotational disorder of the CF_3 groups was observed. This was modeled successfully by allowing the six 0.5 occupancy fluorine atoms and the carbon of each CF_3 group to refine isotropically. The weak data set obtained for this crystal prevented anisotropic refinement of these atoms owing to the low data-to-parameter ratio. Hydrogen atoms were included in idealized positions and were not refined. The final Fourier difference maps showed maximum and minimum peaks of +0.66 and –0.52 e Å^{-3}, respectively, all in the vicinity of the disordered CF_3 groups. Thermal ellipsoid plots were drawn with ORTEP3 (16).

Results

Since the epoxide ring-opening route used to prepare **1** could not be used to prepare Cp-alkoxides with an extended

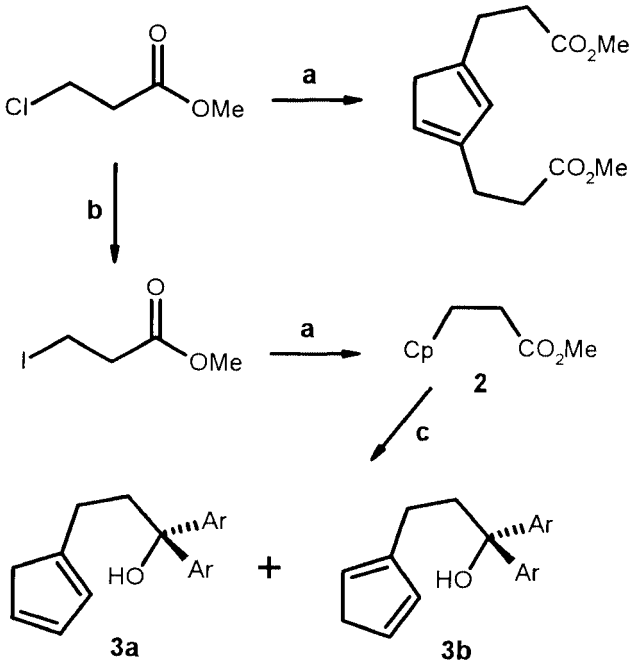
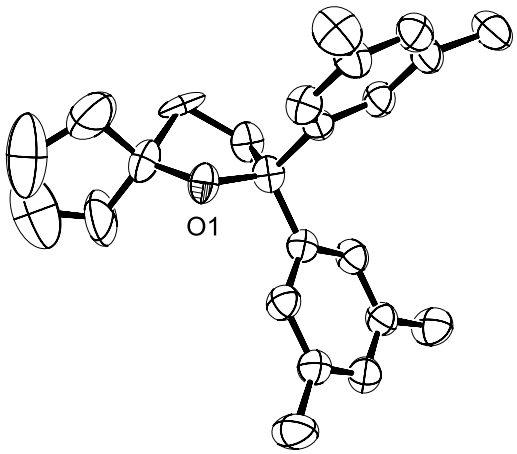
Scheme 1. (*a*) NaCp, THF–Et_2O, –78°C; (*b*) NaI, acetone, 24 h; (*c*) 3.2 equiv Li(3,5-$C_6H_3(CF_3)_2$), THF–Et_2O, –78°C.



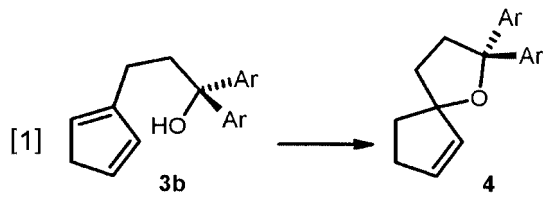
backbone, a new ligand synthesis was developed (Scheme 1). Although the three-step synthesis gives an overall yield of 55%, highly specific conditions are required in each step to achieve these results. The use of the iodo-ester and sodium cyclopentadienide appears to be critical in obtaining the desired cyclopentadienyl ester (**2**). We found that if the commercially available chloroester or the bromoester was not converted to the iodide, the diester $C_5H_4(CH_2CH_2C(O)OMe)_2$ was produced as the major product, rather than **2**. This was observed regardless of the addition rate or reaction temperatures. Similar disubstituted products have been observed by Peters (17) when RC(O)Cl was treated with NaCp. Selective substitution at the CH_2I group occurred with NaCp; use of LiCp resulted in a mixture of products. The crude ester was distilled under static vacuum (ca. 1 torr (1 torr = 133.322 Pa)) to give **2** as a yellow liquid containing a 1.2:1 mixture of the 1-alkyl and 2-alkyl isomers. The two fluorinated phenyl groups were incorporated at the ester carbon by the addition of 3,5-*bis*(trifluoromethyl)phenyl lithium to **2**. Three equiv of the lithium salt must be used because deprotonation of the cyclopentadienyl group occurs readily. Following hydrolysis of the reaction mixture, **3** was isolated as a pure yellow oil, again containing the 1-alkyl and 2-alkyl substituted isomers in 1.2:1 ratio.

The protonated ligand **3** must be stored at –30°C as a dilute toluene solution (<0.5 M) to avoid irreversible transformation products. As a neat oil, **3** undergoes the expected Diels-Alder cyclization in a period of about 1 week at room temperature. Even in dilute solution (0.5 M), however, the 2-alkyl substituted isomer (**3b**) undergoes alcohol addition across one double bond of the diene in Markovnikov fashion, to give the spirocyclic ether **4** (eq. [1]). The identity of **4** was initially determined by ^{13}C DEPT, which identified four inequivalent CH_2 carbons, and ^1H-^1H COSY experiments,

Fig. 1. ORTEP3 (16) plot for **4** (30% probability, fluorine atoms omitted for clarity).



which established connectivity of all protons observed in the ^1H NMR. The structure of **4** was unequivocally established by an X-ray diffraction study, although the quality of the X-ray data was only sufficient to establish connectivity (Fig. 1). This result was unexpected since tertiary alcohols are generally inactive to alkene addition. Some intramolecular additions of primary or secondary alcohols have been observed, but in the presence of palladium or rhenium compounds (18). The electron withdrawing properties of the *meta*-CF_3 groups of the phenyls presumably promote the cyclization of **3**, which occurs spontaneously at room temperature. The Diels-Alder reaction is competitive with the intramolecular cyclization only at higher concentrations (>0.5 M) of ligand.

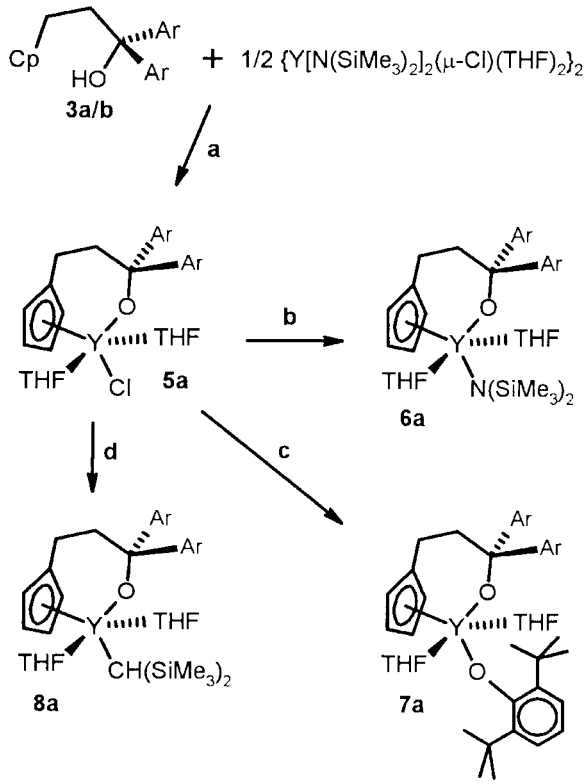


On a smaller scale, the cleanest and most straightforward way to access yttrium complexes containing the deprotonated form of ligand **3** is to prepare the chloride complex (CpO)YCl(THF)$_n$ (**5a**: n = 2; **5b**: n = 1, HCpOH = **3**) from **3** and $[Y\{N(SiMe_3)_2\}_2(THF)(\mu\text{-}Cl)]_2$, where the latter is prepared in situ from YCl_3 and $Y[N(SiMe_3)_2]_3$ in THF (Scheme 2). Reactions under 1 mmol in scale afford **5** in high yield (70–80%), but larger scale reactions generate oily by-products that must be separated by recrystallization from toluene–hexane mixtures. In general, all yttrium complexes containing the Cp-alkoxide derived from **3** exhibit lower melting points and much higher solubilities in hydrocarbons than their analogues derived from **1** (6). These observations suggest that intermolecular packing interactions or weak bridging interactions have been disrupted by the addition of another CH_2 unit in the ligand backbone.

Reaction of **5** with 1 equiv of $NaN(SiMe_3)_2$ initially forms a silyamide complex as the *bis*(THF) adduct (**6a**) (Scheme 2), which readily loses one coordinated THF to give the *mono*(THF) adduct (**6b**) under vacuum. NMR data

© 2002 NRC Canada

Scheme 2. (*a*) THF, 80°C, 2 h; (*b*) $NaN(SiMe_3)_2$, toluene, 70°C, 2 h; (*c*) $Li(O\text{-}2,6\text{-}C_6H_3(t\text{-}Bu)_2)$, toluene, 20°C, 2 h; (*d*) $LiCH(SiMe_3)_2$, toluene, 20°C, 2 h.



supports mirror plane symmetry for the *bis*(THF) complex (**6a**). Chemical shifts are essentially unchanged between the *bis* and *mono*(THF) adducts, suggesting that exchange of coordinated THF is rapid at room temperature. The two methylene carbons of the backbone show distinct resonances in the ^{13}C NMR, but their respective proton resonances are coincidental and show a broad singlet of integration 4 at δ = 2.32 ppm in the ^1H NMR.

X-ray quality crystals of **6b** were obtained through slow evaporation of a hexane solution of the *bis*(THF) adduct **6a**. The solid-state structure of **6b** is shown in Fig. 2, crystallographic data are summarized in Table 1, and selected bond distances and angles are presented in Table 2. The geometry at yttrium is best described as pseudo-tetrahedral with a single THF occupying the fourth coordination site. The formal coordination number at yttrium is 6, reduced from the 7-coordinate environment found in $\{\eta^5\text{:}\eta^1\text{-}C_5H_4[CH_2C(O)(3,5\text{-}C_6H_3(CF_3)_2)_2]\}Y\{O\text{-}2,6\text{-}t\text{-}Bu_2C_6H_3\}\{THF\}_2$ (6). The bite angle of the Cp^{cent}-Y-O (105.3(9)°) unit in **6b** is opened significantly compared with the phenoxide above Cp^{cent}-Y-O (93.77(13)°) or $\{\eta^5\text{:}\eta^1\text{-}C_5H_4[CH_2C(O)(3,5\text{-}C_6H_3(CF_3)_2)_2]\}_2Y^-\ Li^+\{THF\}_2$ Cp^{cent}-Y-O (95.69(13)°), as expected for the increased backbone chain length. This change is more dramatic than that seen in the analogous amido systems $[Y(\eta^5\text{:}\eta^1\text{-}C_5Me_4SiMe_2NCMe_3)(\mu\text{-}H)(THF)]_2$ (4(*e*)) and $[Y(\eta^5\text{:}\eta^1\text{-}C_5Me_4CH_2SiMe_2NCMe_3)(\mu\text{-}H)(THF)]_2$ (11), where the change in bite angle was only 7.0°. The average Y—Cp^{cent} distance is 2.339(14) Å, slightly shorter than that in $\{\eta^5\text{:}\eta^1\text{-}C_5H_4[CH_2C(O)(3,5\text{-}C_6H_3(CF_3)_2)_2]\}Y\{O\text{-}2,6\text{-}t\text{-}Bu_2C_6H_3\}\{THF\}_2$ (Y—Cp^{cent} = 2.400(5) Å) as a consequence of the reduced coordination number (CN) of **6b** (Y^{3+}: 1.04 Å, CN 6; 1.10 Å, CN 7). The yttrium nitrogen bond length Y(1)—N(1) of 2.207(8) Å of the *bis*(trimethylsilyl)amido group is comparable to that found in the homoleptic silylamide $Y[N(SiMe_3)_2]_3$ (Y—N 2.224(6) Å) (19).

$^bR_w = [\Sigma w(|F_o|\text{-}|F_c|^2)/\Sigma w(|F_o|)^2]^{1/2}$.

The phenoxide **7a** was formed cleanly from the reaction of **5** with 1 equiv of $LiO\text{-}2,6\text{-}t\text{-}Bu_2C_6H_3$ (Scheme 2) as the *bis*(THF) adduct, according to ^1H NMR spectroscopy. Coupling to ^{89}Y was observed in the ^{13}C NMR for both the *ipso*-phenoxide ($^2J_{YC}$ = 5.0 Hz) and the ligand YO*C* ($^2J_{YC}$ = 3.8 Hz) carbons. Elemental analysis supports facile loss of THF, as only the *mono*(THF) adduct (**7b**) was observed after exposure to vacuum.

Replacement of the phenoxide with more reactive hydrocarbyls was not successful by metathesis with $LiCH(SiMe_3)_2$ or $LiCH_2SiMe_3$, as the complex would not eliminate lithium phenoxide. Reaction of **5** with 1 equiv of

$LiCH(SiMe_3)_2$, however, readily forms the alkyl complex **8a** (Scheme 2) as a *bis*(THF) adduct, which again loses THF under vacuum to give a *mono*(THF) adduct (**8b**). Complex **8b** was produced in good yield, and both elemental analysis and NMR confirmed the degree of THF solvation. The Cp region of the ^{1}H NMR spectrum of **8b** is broadened somewhat at room temperature, but it sharpens to a pair of multiplets at 80°C, consistent with mirror plane symmetry. Amazingly, no noticeable decomposition of the alkyl complex was observed with repeated heating during the VT analysis. This is an interesting observation, since alkyl complexes of lanthanides are usually thermally unstable. Yttrium coupling was again observed for the alkoxy carbon of the ligand ($^2J_{YC}$ = 3.7 Hz) in the ^{13}C NMR of **8b**.

Discussion

Changing the length of the tether connecting the Cp and alkoxide functionality in the CpO ligand system has profound effects on the type of lanthanide complexes obtained. Extension of the chain by just one CH_2 unit (going from ligands based on **1** (6) to those based on **3**) completely avoids the problems associated with formation of anionic "ate" complexes. In fact, despite repeated attempts, we could not prepare the *bis*(ligand) "ate" complex $(CpO)_2Y^-$ Li^+ for the CpO ligand containing a two-carbon tether, whereas we had great difficulty *avoiding* this complex for the one-carbon tether ligand **1**. The neutral complexes (**5**–**8**) obtained here with the two-carbon tether show no tendency to undergo ligand redistribution reactions.

Despite the success in obtaining neutral, monomeric yttrium complexes, however, silylamide **6b** is not an active catalyst for ε-caprolactone polymerization, and the alkyl **8b** shows very modest oligomerization activity only. Complex **8b** shows no activity as an olefin polymerization catalyst. The reasons for this are not entirely clear, although the presence of coordinated THF may be expected to decrease activity. Related $(CpO)ZrCl_2$ complexes show very high ethylene polymerization activity for complexes containing the shorter tether (ligand **1**) (20),[4] so it seems unlikely that the perfluorophenyl substituted alkoxide is itself detrimental to insertion. Studies to examine the effects of longer chain tethers and replacement of the CF_3 substituents with CH_3 groups are continuing. We hope that these studies will clarify the reasons for the low insertion activity observed here. In addition, we are also investigating the use of complexes like **5** and **7** as Lewis acid catalysts.

Reactions of 1,3-dipolar aldazines and ketazines with the dipolarophile dimethyl acetylenedicarboxylate

Abdullah El-Alali and Ahmed S. Al-Kamali

Abstract: The prepared aldazines (aldehyde azines) and ketazines (ketone azines) were allowed to react with 2 mol of the acetylene derivative. The first products formed were pentalene azine derivatives, which in some cases underwent skeletal rearrangment into acyclic tetraene azines. The latter underwent, in the case of some aldazine products, further skeletal rearrangment into *N*-allyl pyrazoles. The occurence of these rearrangments is dependant on the nature of the aldehydes or ketones used.

Key words: dimethyl acetylenedicarboxylate (DMAD), aldazines, ketazines, *N*-allyl pyrazoles.

Résumé : On a fait réagir des aldazines (azines d'aldéhydes) et des cétazines (azines de cétones) avec deux molécules de dérivés acétyléniques. Les premiers produits formés sont des dérivés azines du pentalène qui, dans quelques cas, subissent des réarrangements du squelette conduisant à des azines tétraènes acycliques. Dans certains cas, ces dernières subissent d'autres réarrangements du squelette avec formation de *N*-allylpyrazoles. La formation de ces produits de réarrangements dépend de la nature des aldéhydes ou des cétones utilisées.

Mots clés : acétylènedicarboxylate de diméthyle « DMAD », aldazines, cétazines, *N*-allylpyrazoles.

[Traduit par la Rédaction]

Introduction

The 1,3-dipolar aldazines or ketazines are actually 1,3-heterodienes and have double 1,3-dipolar sites (Scheme 1).

These acyclic 1,3-heterodienes adopt the s-trans conformation due to steric interactions of the alkyl or aryl substituents. This conformation does not undergo the [4 + 2]-cycloadditions known as the Diels–Alder reactions (1, 2). The above mentioned heterodienes **1** (Scheme 1), reacted with 2 equiv of dipolarophiles, such as dimethyl acetylenedicarboxylate **2**, in [2 + 3]-cycloaddition (3–5) reactions and gave, in this case, the pentalene azines **3** (Scheme 2).

Only two aldazines out of 10 and three ketazines out of six stayed in the bicyclic azine **3** as the final products. The formation of the acyclic teraene azines **4**, as the final product of three ketazines, after their conversion with the acetylene derivative **2**, can only happen through skeletal rearrangment (5) of the bicyclic form **3** as depicted in Scheme 3. The *N*-allyl pyrazoles **7** as final products of the eight aldazines are formed through further skeletal rearrangment of the acyclic form **4**, leading to a zwitterion **5** and then to the intermediates **6**. The latter tautomerizes in the final stage to the *N*-allyl pyrazoles **7**, as shown in the slightly modified mechanism in the literature (5) (Scheme 3).

literature (3–5) and in this work do not give a clear explanation. Also the formation of *N*-allyl pyrazoles is highly interesting. Similar compounds in the literature possess biological activities such as antipyritic (6), antitumor (7), herbicidal (8), and antibiotic (9, 10). The bioassay of these compounds will be investigated later.

Results and discussion

Preparation of the aldazines and ketazines (Scheme 4 and Tables 1–4)

From Table 1, one can predict that only aromatic aldazines were prepared (11–13) and the 2-chlorobenzaldehyde **23** was not reported. All other reported aldazines were prepared in modified procedures. The characterization of the aldazine **23** is depicted in Table 2.

The aromatic ketazines **32–35** (Table 3), were also prepared by modified procedures. Only the ketazine **35** is reported (14). In the case of the ketazines, a few drops of glacial acetic acid were added to the reaction mixture which were not necessary for the preparation of aldazines, due to their high reactivity.

The characterization of the ketazines **32–34** is shown in Table 4.

The two available alicyclic ketones **36** and **38** were allowed to react with hydrazine monohydrate and gave the desired ketazines **37** and **39** (Scheme 5).

Preparation of the bicyclic azines (Scheme 6)

As depicted in Scheme 6, only the two aldazines (2-chlorobenzaldehyde azine **23** and 4-nitrobenzaldehyde azine **26**) stayed in the final product as the bicyclic forms **40** and

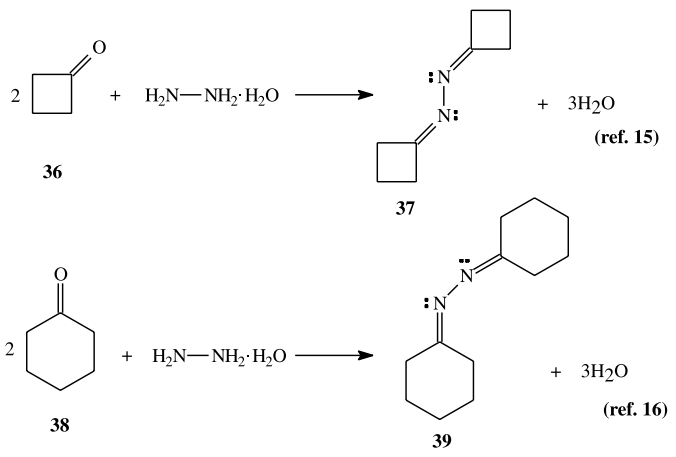
Scheme 5.



41, respectively. The 2-acetylthiophene azine **33** is the only aromatic ketone azine that formed the bicyclic diazine **42**. It could be, that from the above mentioned compounds, the electron-withdrawing chloro- and nitro- groups, and in the case of the thiophene moiety, the nature of the aromatic ring, why they stayed in the bicyclic form. The two acyclic ketone azines **37** and **39** were chosen because of this observation. These acyclic ketone azines gave the spiro bicyclic azines **43** and **44** (Table 5).

The physical and analytical data are shown in Table 6. Elemental analysis for the products **41, 42**, and **44** was not measured, instead, mass spectrometric data were measured in addition to the spectroscopic data (Table 7).

In the IR spectra, the imine stretching vibration is absent. Moreover, the spiro compounds **43** and **44** represent a good method for preparation of such spiro molecules.

Preparation of the acyclic tetraene azines (Scheme 7)

The acyclic tetraene azines **45–47** are symmetrical molecules as in the case of the bicyclic azines, but the stretching vibrations of the imine groups are present in the FT IR spectra at 1612.61, 1636.14, and 1674 cm^{-1} (17, 18). The chemical shift of the carbon of this imine group at 158 ppm is present, which is absent in the bicyclic spectra (Tables 8–10).

As shown in Table 8, the aryl groups carry in the compounds **45** and **47**, ethyl and amino groups in the para position, which are electron-donating groups. In compound **46**, the furan ring is an electron-rich molecule, and as a preliminary observation, these electron-donating groups could be the reason behind the ring-opening of the bicyclic forms, leading to the stable and highly conjugated acyclic forms. The elemental analysis for compounds **46** and **47** was not conducted, but mass spectrometric data are available (Tables 9 and 10).

Preparation of the *N*-allyl pyrazoles (Scheme 8)

The *N*-allyl pyrazoles **48–55** (Scheme 8) were formed by the reaction of the aldazines **18**, **19**, **20**, **21**, **22**, **24**, **25**, and **27** with 2 equiv of DMAD **2.** The reactions with phenylacetylene, diphenylacetylene, and methyl propiolate were unsuccessful. This could be due to the electron-poor LUMO of the DMAD **2**, which can react with the electron-rich HOMO of the 1,3-dipolar compounds. The nature of the aryl groups, yield, and time of reflux are given (Table 11).

No. of product	Ar	Yield %	Time of reflux
48		78	50 h
49		88	85 h
50		85	6 days
51		73	9 days
52		87	6 days
53		65	6 days
54		73	61 h
55		70	58 h

The physical and analytical data are given (Table 12), and the spectroscopic and spectrometric data are shown in Table 13. The formation of these products was identified mainly by NMR. The unsymmetrical shape was recognized by the number of carbon peaks in the ^{13}C NMR, where almost all carbon peaks were present. The four peaks of the ester carbonyls were apparent between 162–169 ppm and the peak of the allylic carbon atoms appeared between 58–64 ppm. In the ^{1}H NMR spectra, one observed four singlets between 3.8 to 4.0 ppm for the methyl groups of the esters. Moreover, the allylic protons in all compounds were observed as singlets between 5.9 to 7.2 ppm, whereas the vinylic protons appeared as singlets between 8.0 to 8.4 ppm. In the FT IR spectroscopy, the carbon double bonds and imine vibrations between 1600–1660 cm^{-1} were present as broad peaks and could not be singly specified. Vibrations of the carbonyl groups of the esters were present between 1724.89–1744.19 cm^{-1}.

Experimental

Materials and equipment

o-, *m*-, and *p*-Toluylaldehydes and *p*-methoxybenzaldehyde were purchased from Fluka Co. Cinnamaldehyde was purchased from the Gainland Chemical Co. Cyclobutanone was purchased from the Aldrich Co. Dimethyl acetylenedicarboxylate, 2-acetylfuran, 4-amino acetophenone, and 1-naphthalenecarboxaldehyde were purchased from the Merck Co. Hydrazine hydrate (51%) was purchased from Janssen-Chimica. The cyclohexanone was purchased from May and Baker Ltd. 2-Acetyl thiophene (19) and 4-ethyl acetophenone (20) were prepared following literature procedures. The solvents acetonitrile, methanol, ethanol, toluene, and *n*-hexane were dried and distilled over calcium hydride. Diethyl ether and THF were dried over sodium and benzophenone. All dried solvents were kept over activated molecular sieves. The liquid aldehydes and ketones were distilled prior to their use.

Analytical and preparative thin-layer chromatography (TLC) were performed on silica gel plates precoated with silica gel GF_{254} from theLaboratory Rasoyan Co.

Uncorrected melting points were obtained on an electrothermal melting point apparatus. Infrared spectra were recorded as KBr-disc or liquid films on a Matsson 5000 FT IR spectrophotometer. ^{1}H and ^{13}C NMR spectra were recorded with a Bruker AC-200 MHz in a solution of $CDCl_3$ and with TMS as an internal reference.

Electron impact (EI) mass spectra were recorded using a Finnigan MAT731 spectrophotometer at 70 eV. Elemental analyses were determined by M.H.W. Laboratories in Arizona, U.S.A.

The aldazines (18–27)

General procedure A (modified):

The aldehyde (2.1 mol) was added slowly to the cooled mixture of 1.0 mol hydrazine hydrate dissolved in ethanol or methanol. The mixture was heated over a steam bath for 1.0 h, then refluxed for several hours. The time of reflux depended on the nature of the aldehyde used. The reaction was followed by TLC. The solvent was removed in vacuo and the residue was recrystallized either from ethanol or methanol.

*2,2′-Dimethoxybenzaldazine (**18**):*

It was prepared following the modified procedure A. 2-Methoxybenzaldehyde (5.0 g, 0.041 mol) and 0.64 g (0.02 mol) of hydrazine were used. The reaction time was 3.0 h, mp 143 to 144°C, yellow needles, and 95% yield.

*4,4′-Dimethoxybenzaldazine (**19**):*

Procedure A was used; mp 167 to 168°C and with 91% yield.

*2,2′-Dimethylbenzaldazine (**20**):*

Procedure A was used. The reaction time was only 10 min at room temperature. The yellow solid was washed with ice water, and crystallized from ethanol; mp 68–70°C and with 85% yield.

*3,3′-Dimethylbenzaldazine (**21**):*

Procedure A was used; mp 106–108°C and with 82% yield.

*4,4′-Dimethylbenzaldazine (**22**):*

It was prepared following known procedure (12); mp 157–159°C and with 90% yield.

*2,2′-Dichlorobenzaldazine (**23**):*

Procedure A was used. Details are depicted in Table 2 in the text.

*1,1′-Naphthaldazine (**24**):*

Procedure A was used. The reaction time was 10 min at room temperature. The solid product was crystallized from ethanol with a few drops of hydrochloric acid; mp 155–157°C and with 86% yield.

*2,2′-Furfuralazine (**25**):*

Procedure A was used. The reaction time took 20 h under reflux. The residue was extracted with ether, dried over $MgSO_4$, and after removal of ether, a brown solid was obtained; mp 111 to 112°C and with 88% yield.

*4,4′-Dinitrobenzaldazine (**26**):*

Precedure A was used. The reaction time was 10 min at room temperature. The solid residue was crystallized in pyridine; m., 296 to 297°C and with 89% yield.

*Cinnamaldazine (**27**):*

Preparation and crystallization carried out as for compound **24**; mp 173 to 174°C and with 86% yield.

The acyclic ketazines (32–35)

General procedure B (modified procedure):

2.1 mol of ketone was added slowly to 1.0 mol of hydrazine hydrate with a few drops of glacial acetic acid dissolved in methanol or ethanol. The reaction mixture was then refluxed for 20–40 h depending on the nature of the ketone. The solid residue was extracted with ether and washed successfully with 10% $NaHCO_3$. The ether layer was dried over $MgSO_4$ and the solvent was removed in vacuo. The solid products were crystallized from ethanol.

*4.4′-Diethylacetophenone azine (**32**):*

Procedure B was used. Details in Table 4. Recrystallization was achieved from petroleum ether.

*2,2′-Diacetylfuran azine (**33**):*

Procedure B was used. Details in Table 4.

*2,2′-Diacetylthiophene azine (**34**):*

Precedure B was used. For details, see Table 4. Recrystallization as for compound **32**.

*4,4′-Diaminoacetophenone azine (**35**):*

Procedure B was used. Details in Table 4.

The alicyclic ketazines 37 and 39

*Cyclobutanone azine (**37**):*

It was prepared using a modified procedure to that reported in the literature (15).

A mixture of 1.17 g (17 mmol) of the cyclobutanone and 0.54 g (8 mmol) of the hydrazine hydrate in 40 mL of toluene and 10 mL of ethanol was refluxed for 4 h, then strirred at room temperature overnight. After removal of the solvents, the residue was extracted with 100 mL of ether and dried over $MgSO_4$. The ether layer was cooled in a dry ice bath. After a few hours, white crystals precipitated and were separated by suction filteration; mp 68 to 69°C and with 83% yield.

*Cyclohexanone azine (**39**):*

Procedure B was used without an acid catalyst. Another preparation was also elaborated following the reported procedure (16) as follows: a mixture of 16.5 g (0.17 mmol) of cyclohexanone, 4.0 g (0.08 mmol) of hydrazine hydrate, and 25 g (0.3 mole) of sodium acetate were dissolved in 100 mL of H_2O and 100 mL of ethanol. The reaction mixture was heated for 4 h over a water bath. Five times its weight of $ZnCl_2$ (82.5 g) was added to the reaction mixture and heated at 130°C. A complex compound precipitated ($C_{12}H_{20}N_2.HCl{\cdot}ZnCl_2$). The melting point was 271 to 272°C and it decomposed with ammonia gas and gave the oily product **39** in 75% yield.

The preparation of the products:

General procedure C (modified)

A mixture of 1.0 mol azine and 3.0 mol of DMAD was dissolved in dry acetonitrile and heated under reflux for a period of time (see Tables 5–13). After removal of the solvent in vacuo, the excess DMAD was removed under reduced pressure (0.5 mmHg (1 mmHg = 133.322 Pa), 50°C). The residual amber oil was redissolved in methanol, and scratched with a glass rod for a few hours. The formed solid was crystallized from methanol, and the liquid products were purified by TLC plates or column chromatography.

*The bicycle azines (**40**–**44**):*

*1,5-Bis(2′-chlorophenyl)-2,3,6,7-tetrakis(carbomethoxy)-1,5-dihydro-pyrazolo[1,2-a]pyrazole (**40**):*

Procedure C was used. Details in Tables 5–7.

*1,5-Bis(4′-nitrophenyl)-2,3,6,7-tetrakis(carbomethoxy)-1,5-dihydropyrazolo[1,2-a]pyrazole (**41**):*

Procedure C was used The oily product was separated on TLC plates (50% EtOAc in hexane). See details in Tables 5–7.

*1,5-Bis(2′-thiophenyl)-2,3,6,7-tetrakis(carbomethoxy)-1,5-dimethylpyrazolo[1,2-a]pyrazole (**42**):*

Procedure C was used. The oily product was separated on TLC plates (30% EtOAc in hexane). See Tables 5, 6, and 7.

*1,5-Bis(spirocyclobutane)-2,3,6,7-tetrakis(carbomethoxy) dihydropy-razolo[1,2-a]pyrazole (**43**):*

Procedure C was used. The oily product was separated on TLC plates (30% EtOAc in hexane). See details in Tables 5–7.

*1,5-Bis(spirocyclohexane)-2,3,6,7-tetrakis(carbomethoxy)dihydropy-razolo[1,2-a]pyrazole (**44**):*

Procedure C was used. Separation on TLC (30% MeOH in hexane). Details in Tables 5–7.

*The acyclic azines (**45**–**47**):*

All these compounds were prepared following procedure C, and their data are depicted in Tables 8–10.

*Methyl-2-oxo-3-carbomethoxy-4-methyl-4-(4′-ethylphenyl)-but-3-enoate azine (**45**):*

Separation on a TLC plate (30% EtOAc in hexane).

*Methyl-2-oxo-3-carbomethoxy-4-methyl-4-(2′-furfuryl)-but-3-enoate azine (**46**):*

Separation on a TLC plate (20% EtOAc in hexane).

© 2002 NRC Canada

*Methyl-2-oxo-3-carbomethoxy-4-methyl-4-(4'-aminophenyl)-but-3-enoate azine (**47**):*

Separation was achieved by recrystallization from methanol.

The N*-allylphyrazoles (**48**–**55**):*

All these products were prepared following procedure C. The data are depicted in Tables 11–13.

*Methyl-2-[3',4'-dicarbomethoxy-5-(2''-methoxylphenyl)-1'-pyrazolyl]-3-carbo-methoxy-4-(2''-methoxyphenyl)but-3-enoate (**48**):*

Separated by crystallization from methanol.

*Methyl-2-[3',4'-dicarbomethoxy-5'-(4''-methoxyphenyl)-1'-pyrazoly-l]-3-carbo-methoxy-4-(4''-methoxyphenyl)-but-3-enoate (**49**):*

Separated on a TLC plate (50% EtOAc in hexane).

*Methyl-2-[3',4'-dicarbomethoxy-5'-(2''-methylphenyl)-1'-pyrazolyl]-3-carbo-methoxy-4-(2''-methylphenyl)-but-3-enoate (**50**):*

Separation procedure used was the same as in compound **49**.

*Methyl-2-[3',4'-dicarbomethoxy-5'-(4''-methylphenyl)-1'-pyrazolyl]-3-carbo-methoxy-4-(3''-methylphenyl)-but-3-enoate (**51**):*

Separated by crystallization from methanol.

*Methyl-2-[3',4'-dicarbomethoxy-5'-(4''-methylphenyl)-1'-pyrazolyl]-3-carbo-methoxy-4-(4''-methylphenyl)-but-3-enoate (**52**):*

Separated by crystallization from methanol.

Methyl-2-[3',4'-dicarbomethoxy-5'-(1''naphthalyl)-1'-pyrazolyl]-3-carbo-methoxy-4-(1''-naphthalyl)-but-3-enoate (53):

Separated on TLC plates using (ether:dichloromethane, 0.5:9.5).

*Methyl-2-[3',4'-dicarbomethoxy-5'-(2''-furyl)-1'-pyrazolyl]-3-carbom-ethoxy-4-(2''-furyl)-but-3-enoate (**54**):*

Separation procedure used was the same as in compound **49**.

*Methyl-2-[3',4'-dicarbomethoxy-5'-styryl-1'-pyrazolyl]-3-carbometh-oxy-4-styryl-but-3-enoate (**55**):*

Separated on TLC plates (30% EtOAc in hexane).

Conclusion

The transformations in this work delivered three types of products namely, the bicyclic azines, the acyclic azines, and the *N*-allyl pyrazoles. Investigation of the rearrangements is now going on in our research laboratory to develop an explanation. Furthermore, the bicyclic azines (the pentalene derivatives) are compounds of interest to many researchers. The acyclic tetraene azines could undergo thermal or photochemical cyclization to become interesting compounds. As mentioned before, the *N*-allyl pyrazoles are promising compounds and could possess biological activities.

Structural and conformational studies of 5-(1*H*-pyrrol-2-ylmethylene)-substituted imidazolidine-2,4-diones and thiazolidine-2,4-diones

Alfonso de Dios, Maria Luz de la Puente, Alfonso Rivera-Sagredo, and Juan Felix Espinosa

Abstract: Some imidazolidine-2,4-dione (hydantoin) and thiazolidine-2,4-dione (TZD) derivatives with a 1*H*-pyrrol-2-ylmethylene substituent at the 5-position (**1**–**8**) have been synthesized via an aldol condensation reaction. A mixture of *Z*- and *E*- stereoisomers was obtained, as confirmed by HPLC and NMR studies. Assignment of the stereochemistry was achieved through chemical shift knowledge, NOE, and $^3J_{H,C}$ data. The conformation of the molecules depends on the configuration at the double bond. While the (NH,C *cis*) form is the most stable conformer for the *E*-isomer, the (NH,C *trans*) form is the preferred conformer for the *Z*-isomer. The temperature coefficients of the NH pyrrole protons reveal the existence of an intramolecular hydrogen bond for the *E*-isomers.

Key words: hydantoin, TZD, NMR spectroscopy, conformational analysis, temperature coefficient.

Résumé : Faisant appel à une réaction de condensation aldolique, on a réalisé la synthèse de dérivés de l'imidazolidine-2,4-dione (hydrantoïne) et de la thiazolidine-2,4-dione (TZD) portant un substituant 1*H*-pyrrol-2-ylméthylène en position 5 (**1**–**8**). La formation de mélanges de stéréoisomères *Z*- et *E*- a été confirmée par des études de CLHP et de RMN. L'attribution de la stéréochimie a été réalisée sur la base de connaissances chimiques et de données relatives aux valeurs $^3J_{H,C}$ et d'effet Overhauser nucléaire. La conformation des molécules dépend de la configuration de la double liaison. Alors que le forme NH,C *cis* correspond à la conformation la plus stable de l'isomère *E*, la forme NH,C *trans* correspond à la conformation la plus stable de l'isomère *Z*. Les coefficients de température des protons NH du pyrrole mettent en évidence l'existence d'une liaison hydrogène intramoléculaire pour les isomères *E*.

Mots clés : hydantoïne, TZD, spectroscopie RMN, analyse conformationnelle, coefficient de température.

[Traduit par la Rédaction]

Introduction

Imidazolidine-2,4-dione (hydantoin) (1) and thiazolidine-2,4-dione (TZD) (2) derivatives are good examples of compounds that exhibit a wide range of interesting biological properties. The hydantoin scaffold is a common feature present in orally active fibrinogen (1(*a*)) and angiotensin II (1(*b*)) receptor antagonists, anticonvulsant sodium channels (1(*c*)), and muscarinic receptor ligands (1(*d*)). The synthesis of combinatorial libraries of hydantoins for biological screening (1(*e*)) is a clear indication of their pharmaceutical relevance. On the other hand, some TZD derivatives that show high affinity for peroxisome proliferator-activated receptor γ (PPARγ) are very well known hypoglycemic drugs (2(*a*)).

As these two scaffolds are usually responsible for key interactions in the receptor binding sites, Structure-activity relationship studies (SAR) techniques have been employed to correlate biological activity with differences in steric and electrostatic parameters (1(*c*)). In this context, structural and conformational analysis of the aforementioned derivatives may be a very powerful tool to understanding possible binding modes, thus facilitating SAR studies.

As part of a medicinal chemistry project developed in our laboratories, we have synthesized several hydantoin and TZD derivatives (**1**–**8**, Fig. 1). *E*- and *Z*- isomers were isolated by preparative HPLC and their configuration assigned by NMR spectroscopy. The conformational preferences were investigated to gain insight into the influence of the geometry on the pharmacological properties of the compounds.

Results and discussion

Synthesis

Aldol condensations of commercially available or easily accessible starting materials with pyrrole-2-carboxaldehyde and using standard thermodynamic control conditions were carried out (3). An excess of aldehyde, a catalytic amount of amine base in THF, and long refluxing times were employed to afford mixtures of *E*–*Z* compounds (Scheme 1). Attempts to isolate the stereoisomers by silica gel chromatography were unsuccessful; thus purification was performed by HPLC.

An efficient system capable of baseline resolving the two *E*–*Z* isomers was developed. A series of parameters (composition of the mobile phase, column packing, and additives)

were tested to find suitable conditions for isolation of both isomers. Reverse phase chromatography using a gradient of water–acetonitrile and trifluoroacetic acid as additives and a variety of stationary phases, including C8–C18 and phenyl series, allowed the separation of the stereoisomers. For hydantoin derivatives, the major component of the *E*–*Z* mixture eluted earlier than the minor one. In contrast, for the TZD mixture the major component eluted in second place, which suggested a change of stereoselectivity relative to the hydantoin series.

As the reaction was carried out under thermodynamic control conditions, we envisioned that internal hydrogen bond formation between the C4 carbonyl group and the NH1′ of the pyrrole ring should favour the formation of the corresponding *E* isomer. In fact, the predominance of this configuration had been reported (100% of population based on NOE data) for related 3-(1*H*-pyrrol-2-ylmethylene)-indolin-2-ones (Fig. 2). The authors postulated an intramolecular hydrogen, located between the C-2 carbonyl oxygen atom of the indolin-2-one ring and the proton on the N1′ of pyrrole, to explain this selectivity. They did not, however, provide any experimental evidence to support its existence. In our experiments, analytical studies detected the presence of both stereoisomers and showed different isomer ratios for each case. Integration of the ^{1}H NMR spectra of the mixtures confirmed the change in stereoselectivity inferred from HPLC data. While the reaction progressed with high selectivity for the N-methyl (**1**, **2**) and the N-phenyl (**3**, **4**) hydantoins (93:7 and 86:14 *E*:*Z* mixture ratios, respectively), no significant selectivity was found for the NH hydantoins (**5**, **6**) (44:56, *E*:*Z*). Unexpectedly, the opposite selectivity was found for the TZDs (**7**, **8**), and the *Z*-isomer was the major product of the reaction (11:89, *E*:*Z*). The configurational assignment is described in detail in the following section.

Hydrogen bond formation alone, therefore, can not explain the observed stereoselectivity, and other factors have to be considered. Our data indicates that steric hindrance is more important than intramolecular hydrogen bonding in determining the stereoselectivity of the reaction. Steric interferences between the pyrrole ring and the N-substituent are present for the *Z*-isomers **2** and **4**, which favour the formation of the *E*-isomers **1** and **3** with high selectivity. However, the absence of steric hindrance for the *Z*-isomer **6** increases the proportion of this isomer. Moreover, the isomeric ratio obtained for TZD further supports the minor role of hydrogen bonding. For this latter compound, the *Z*-isomer **8** does not exhibit steric interferences and is the major product of the reaction.

Stereochemistry assignment

The first step was the assignment of all the proton and carbon resonances on the basis of ^{1}H, ^{13}C, correlation spectroscopy (COSY), heteronuclear single-quantum correlation (HSQC), and heteronuclear multiple-bond correlation (HMBC) experiments recorded in DMSO. The NH proton of the pyrrole ring was distinguished from the NH proton of the hydantoin moiety through its coupling to the pyrrole protons, as observed in a COSY experiment. The configuration at the double bond was determined through one-dimensional NOE spectroscopy (1D-NOESY) experiments. Inversion of the methyl protons in **1** produced a nuclear Overhauser effect (NOE) to the olefinic proton H6, whereas no NOEs to the pyrrole protons were detected, indicating that the methyl group and the olefinic proton are on the same side of the

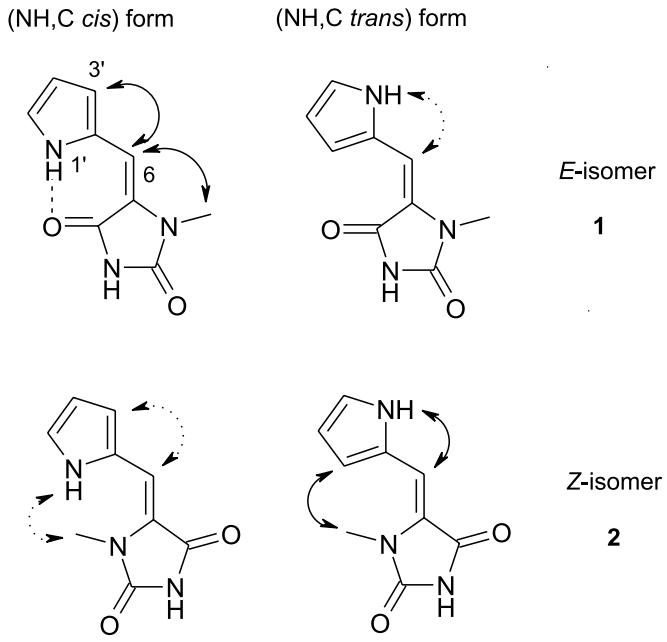
Fig. 3. Summary of the relevant NOEs observed for each conformer of hydantoins **1** and **2**. Solid and dotted arrows represent strong and weak NOEs respectively. The detected hydrogen bond is also shown.



molecule (Fig. 3). On the other hand, NOEs between the methyl protons and the pyrrole protons were observed for **2**. These results reveal that **1** is the *E*-isomer and **2** is the *Z*-isomer. Analogously, NOEs between H6 and the *ortho* protons of the N-phenyl ring, and between H6 and NH1, were observed for **3** and **5**, respectively, corresponding to the *E*-isomer. By contrast, NOEs between the pyrrole protons and the *ortho* protons of the N-phenyl ring, and between the pyrrole protons and the NH proton, were detected for **4** and **6**, respectively, which is consistent with the Z-isomers.

We have found a correlation between the *Z–E* configuration of the compounds and the chemical shifts of H6 and H1′ (Table 1). In this regard, the pyrrole H1′ appears at high frequency in the *E*-isomer relative to the *Z*-isomer, whereas the olefinic proton exhibits the opposite behaviour. This relationship may be attributed to the influence of the carbonyl group of the hydantoin ring. While the NH-pyrrole (H1′) is deshielded by the carbonyl in the *E*-isomer, the olefinic proton (H6) is deshielded in the *Z*-isomer, and the corresponding proton signals move to higher shifts.

Unfortunately, NOE analysis cannot be utilized for the elucidation of the stereochemistry of compounds **7** and **8**. Although Prabhakar et al. (2(*b*)) have proposed to use IR data for the configurational assignment of TZD analogues, we have been able to determine the stereochemistry by NMR data, using the relationship between configuration and chemical shift derived for compounds **1**–**6**. Thus, the comparison of H1′ and H6 chemical shifts of **7** and **8** (Table 1) suggest that the compounds correspond to the *E*- and the *Z*-isomer, respectively. This empirical assignment can be confirmed through three-bond ^{1}H-^{13}C coupling constants. It is well known that these couplings present a Karplus-type dependence on the dihedral bond that can be used for identification of configurational isomers (4). The magnitude of the

coupling from the olefinic proton (H6) to the carbonyl carbon (C4) across the double bond should indicate the relative disposition, which is higher for the *trans* arrangement (*E*-isomer). The validity of this prediction was verified for hydantoins **1**–**6**, whose stereochemistry was elucidated through NOE analysis as outlined above. $^{3}J_{C,H}$ spin-spin coupling constants were measured from gated ^{1}H-decoupling ^{13}C NMR spectra. C4 appeared as a doublet for the N-methyl and N-phenyl derivatives (**1**–**4**), and as a triplet for the N-H derivatives (**5** and **6**) because the carbon was also coupled to NH1. This extra coupling was removed by acquiring a ^{13}C spectrum with selective NH1 decoupling, resulting in a doublet from which the coupling of interest could be measured. The $^{3}J_{H6,C4}$ value for compounds **1**, **3**, and **5** (*E*-isomers) is 10.2 Hz in all the cases, whereas compounds **2**, **4**, and **6** (*Z*-isomers) present a lower value (5.9 Hz), consistent with NOE-based assignments. This relevant H,C coupling constant was also determined for **8**. The experimental value for this compound is 5.9 Hz, which indicates the *Z*-configuration at the double bond, in agreement with the stereochemistry deduced from chemical shift data.

Conformational analysis

The conformation of these derivatives depends on rotation around the C2′—C6 bond, which determines the relative orientation of the pyrrole and the hydantoin or TZD rings. The compounds can adopt the (NH,C *cis*) form or the (NH,C *trans*) form, as shown in Fig. 3 for **1** and **2**. The conformational analysis of 2-substituted pyrroles has attracted special attention in the literature. In particular, 2-formyl pyrrole has been extensively studied through several methods (5). The less polar (NH,O *cis*) form, stabilized by a hydrogen bond, was determined to be the most stable conformer through dipolar moment measurements (5(*a*)), IR data (5(*b*)), and NMR spectroscopy (5(*c*)). Particularly, coupling constant analysis showed that the (NH,O *cis*) conformer was 95% populated in solution (5(*c*)). This conformational preference was rationalized through molecular orbital calculations (6). Analogously, the conformation of 2-substituted imine derivatives has also been studied through dipolar moment measurements and five-bond H,H couplings (7). These studies demonstrated the preponderance of the (NH,N *cis*) conformer in solution, which was also proposed to be stabilized by a hydrogen bond. In contrast, divergent conclusions have been reported for 2-vinyl pyrroles, and the major conformation in solution remains unclear (8). In our

© 2002 NRC Canada

case, we predict the (NH,C *cis*) form to be the major conformer in solution for the *E*-isomers, allowing the pyrrole-NH and the carbonyl oxygen to form an intramolecular hydrogen bond; however, a preferred conformation cannot be anticipated for the *Z*-isomers.

The major conformation in solution was determined for the hydantoins **1**–**6** through 1D-NOESY experiments in DMSO. The H6/H3′ and the H6/H1′ NOEs are exclusive for the (NH,C *cis*) and the (NH,C *trans*) forms, respectively (Fig. 3). For **1**, **3**, and **5** (*E*-isomers), the H6/H3′ NOE is much stronger than the H6/H1′ NOE, indicating that the (NH,C *cis*) form is the preferred conformer in solution. The (H6/H3′):(H6/H1′) NOE intensity ratios, which account for the relative conformer populations, suggest that the N-methyl hydantoin displays the highest population of the (NH,C *cis*) conformer (Table 1). Interestingly, for hydantoins **2** and **4** (*Z*-isomers), the NOE intensities are interchanged and the H6/H1′ NOE is now much stronger than the H6/H3′ NOE. This finding reflects the existence of a conformational change around the C2′—C6 bond, and the (NH,C *trans*) form becomes the major conformer in solution for both compounds. This conclusion is reinforced by the observation of strong NOEs between H3′ and the methyl protons for **2**, and between H3′ and the phenyl protons for **4**. It is interesting to note that, for **4**, the predominance of this conformer can also be deduced from chemical shift data. Some of the pyrrole protons in this compound present anomalous, low δ_H values due to the shielding produced by the phenyl ring. While H3′ presents the lowest chemical shift (4.51 ppm), H1′ has a typical value (11.22 ppm), which reveals the proximity of H3′ to the phenyl ring, showing the predominance of the (NH,C *trans*) form. For the *Z*-isomer **6**, the H6/H1′ NOE is also stronger than the H6/H3′ NOE (Table 1), which indicates that the (NH,C *trans*) form is the major conformer in solution, although its population decreases relative to **2** and **4**.

As the pyrrole-NH and the carbonyl oxygen are located on the same side in the preferred conformer of the *E*-isomers, an internal hydrogen bonding may exist for this configuration, as proposed by Sun et al. (3) for the indolin-2-one series (Fig. 2). The exchangeable protons involved in hydrogen bonds tend to appear at higher shifts owing to the effect of the oxygen atom (9). Indeed, the chemical shifts of the pyrrole-NH in compounds **1**, **3**, and **5** are higher than the values in compounds **2**, **4**, and **6** (Table 1), which suggests the presence of an intramolecular hydrogen bond. This prediction has been demonstrated experimentally by studying the change of $\delta_{H1'}$ with temperature, expressed by the chemical shift temperature coefficient (9). As temperature changes affect the mobility of solvent molecules, the chemical shifts of exchangeable protons that are involved in intermolecular hydrogen bonds with the solvent have larger chemical shift temperature-dependence than the intramolecularly hydrogen bonded protons, which have little interaction with the solvent. The temperature coefficient of H1′ was determined for hydantoins **1**–**6**. The experimental values measured for **1**, **3**, and **5** (–1.0, –1.1, and –1.1 ppb K^{-1}, respectively) are much smaller than those obtained for **2**, **4**, and **6** (−4.4, −6.9, and −4.1 ppb K^{-1}, respectively). The comparison between sets of values confirms the presence of an intramolecular hydrogen bond for the *E*-isomers.

Similar investigations were performed for TZDs in DMSO. The temperature coefficients of H1′ for the *E*-isomer (**7**) and for the *Z*-isomer (**8**) are –1.2 and –4.4 ppb, respectively. These values indicate the presence of a hydrogen bond in **7**, which implies that the (NH,C *cis*) form is the preferred conformer for the *E*-isomer. Moreover, 1D-NOESY experiments were carried out for compound **8** (Fig. 2*b*). H6 inversion produces a strong NOE to H1′ and a weak NOE to H3′ (intensity ratio 10:1), demonstrating the predominance of the (NH,C *trans*) for the *Z*-isomer. The results point out that the conformational preferences for TZDs are similar to those found for hydantoins, and swapping the nitrogen atom for a sulfur atom at the 1-position does not change the conformational behaviour of the molecules.

The predominance of the (NH,C *cis*) form over the (NH,C *trans*) form for the *E*-isomers can be interpreted in terms of an intramolecular hydrogen bond that stabilizes this conformation. Nevertheless, there is no clear explanation for the preference of the (NH,C *trans*) form for the *Z*-isomers. As the pyrrole-NH is more accessible to the solvent in this latter conformer, we suggest that this orientation may facilitate the formation of intermolecular hydrogen bonds with solvent molecules.

Experimental section

Starting materials (1-methyl hydantoin (**9**), hydantoin (**10**), and thiazolidine-2,4-dione (**11**)) and reagents were commercially available (Aldrich Co.). 1-Phenyl hydantoin (**12**) was prepared according to the procedure reported by Casagrande et al. (10) as follows: N-phenyl glycine (3.02 g, 20 mmol) was suspended in 90 mL of water and 0.1 mL of glacial acetic acid. The mixture was stirred and heated at 60°C for 30 min. A solution of potassium cyanate (1.62 g, 20 mmol) in 10 mL of water was slowly added and the solution heated for 1.5 h. Then, 2.5 mL of concentrated HCl (35%) was added dropwise and the reaction was heated at 90°C for 16 h. After cooling the solution at room temperature, a precipitate was formed. The solid was filtered off, rinsed with water, dried under high vacuum, and triturated thoroughly to yield 1.75 g of pure product (49% yield). ES-MS: 175.0 ($[M^+ - H]$).

General procedure for the synthesis of imidazolidine-2,4-diones (1–6) and thiazolidine-2,4-diones (7–8)

To a suspension of the starting material (**9**–**12**, 1 equiv) in THF (10 mL), pyrrole 2-carboxaldehyde (2 equiv) was added in one portion. A catalytic amount of piperidine (0.1 equiv) was added, and the mixture stirred and heated at reflux for 5–16 h. Then, the reaction was cooled down to room temperature and the solvent evaporated in vacuo. The residue was diluted with EtOAc and sequentially washed with 5% aqueous HCl, water, and brine. After drying over Na_2SO_4 and evaporating the solvents in vacuo, the crude product was prepurified by silica gel chromatography to remove the excess of starting aldehyde and to afford pure *E*–*Z* mixtures. These mixtures were then subjected to preparative HPLC, as detailed in the text.

1-Methyl-5-(1H-pyrrol-2-ylmethylene)-imidazolidine-2,4-dione:* E-*isomer (1) and* Z-*isomer (2)

Obtained as a 93:7 *E–Z* mixture, with 65% overall yield after purification of the crude product using hexane–acetone (6:1). **1**: ^{1}H NMR (DMSO): 11.99 (s, 1H, NH1′), 11.45 (s, 1H, NH3), 7.08 (m, 1H, H5′), 6.58 (m, 1H, H3′), 6.47 (s, 1H, H6), 6.20 (m, 1H, H4′), 3.07 (s, 3H, Me). ^{13}C NMR (DMSO): 164.6 (C4), 152.7 (C2), 126.6 (C2′), 123.9 (C5), 122.0 (C5′), 116.0 (C3′), 110.0 (C4′), 107.9 (C6), 25.7 (Me). **2**: ^{1}H NMR (DMSO): 11.23 (s, 1H, NH1′), 11.20 (s, 1H, NH3), 6.96 (m, 1H, H5′), 6.52 (s, 1H, H6), 6.46 (m, 1H, H3′), 6.17 (m, 1H, H4′), 3.20 (s, 3H, Me). ^{13}C NMR (DMSO): 164.5 (C4), 155.3 (C2), 125.5 (C5), 123.8 (C2′), 121.3 (C5′), 112.4 (C3′), 110.0 (C4′), 102.3 (C6), 29.3 (Me). **1**, **2**: ESI+-MS: 192.1 ($[M + H]^+$).

1-Phenyl-5-(1H-pyrrol-2-ylmethylene)-imidazolidine-2,4-dione:* E-*isomer (3) and* Z-*isomer (4)

Obtained as an 86:14 *E–Z* mixture, with 60% overall yield after purification of the crude product using hexane–EtOAc (2:1). **3**: ^{1}H NMR (DMSO): 12.01 (s, 1H, NH1′), 11.73 (s, 1H, NH3), 7.57 (t, 2H, *m*-protons phenyl), 7.49 (t, 1H, *p*-proton phenyl), 7.42 (d, 2H, *o*-protons phenyl), 7.09 (m, 1H, H5′), 6.54 (m, 1H, H3′), 6.16 (m, 1H, H4′), 6.07 (s, 1H, H6). ^{13}C NMR (DMSO): 164.3 (C4), 152.1 (C2), 133.0, 129.6, 128.6, 128.5, 126.0 (C2′), 124.8 (C5), 122.6 (C5′), 116.6 (C3′), 110.2 (C4′), 108.2 (C6). **4**: ^{1}H NMR (DMSO): 11.46 (s, 1H, NH3), 11.22 (s, 1H, NH1′), 7.36–7.43 (m, 3H, *m*- and *p*-protons phenyl), 7.29 (d, 2H, *o*-protons phenyl) 6.83 (m, 1H, H5′), 6.72 (s, 1H, H6), 5.77 (m, 1H, H4′), 4.51 (m, 1H, H3′). ^{13}C NMR (DMSO): 164.7 (C4), 154.2 (C2), 124.1 (C2′), 134.6, 128.8, 128.5, 127.4, 123.3 (C5′), 116.6 (C5), 113.4 (C3′), 110.2 (C4′), 103.4 (C6). **3**, **4**: ESI+-MS: 254.1 ($[M + H]^+$).

5-(1H-Pyrrol-2-ylmethylene)-imidazolidine-2,4-dione:* E-*isomer (5) and* Z-*isomer (6)

Obtained as a 44:56 *E–Z* mixture, with 55% overall yield after purification of the crude product using hexane–EtOAc (1:3). **5**: ^{1}H NMR (DMSO): 11.93 (s, 1H, NH1′), 11.24 (s, 1H, NH3), 10.12 (s, 1H, NH1), 7.05 (m, 1H, H5′), 6.52 (m, 1H, H3′), 6.32 (s, 1H, H6), 6.17 (m, 1H, H4′). ^{13}C NMR (DMSO): 165.3 (C4), 153.2 (C2), 126.7 (C2′), 122.8 (C5), 121.6 (C5′), 115.2 (C3′), 109.7 (C4′), 107.6 (C6). **6**: ^{1}H NMR (DMSO): 11.18 (s, 1H, NH1′), 10.98 (s, 1H, NH3), 10.04 (s, 1H, NH1), 6.98 (m, 1H, H5′), 6.80 (m, 1H, H3′), 6.41 (s, 1H, H6), 6.19 (m, 1H, H4′). ^{13}C NMR (DMSO): 165.4 (C4), 155.0 (C2), 125.5 (C2′), 122.1 (C5), 121.6 (C5′), 112.3 (C3′), 110.5 (C4′), 100.9 (C6). **5**, **6**: ESI+-MS: 178.0 ($[M + H]^+$).

5-(1H-Pyrrol-2-ylmethylene)-thiazolidine-2,4-dione:* E-*isomer (7) and* Z-*isomer (8)

Obtained as an 11:89 *E–Z* mixture, with 75% overall yield after purification of the crude product using hexane–EtOAc (5:1–1:1). **7**: ^{1}H NMR (DMSO): 12.25 (s, 1H, NH3), 12.16 (s, 1H, NH1′), 7.27 (m, 1H, H5′), 7.25 (s, 1H, H6), 6.73 (m, 1H, H3′), 6.29 (m, 1H, H4′). **8**: ^{1}H NMR (DMSO): 12.25 (s, 1H, NH3), 11.67 (s, 1H, NH1′), 7.66 (s, 1H, H6), 7.20 (m, 1H, H5′), 6.47 (m, 1H, H3′), 6.35 (m, 1H, H4′). ^{13}C NMR (DMSO): 167.8 (C2), 167.2 (C4), 126.9 (C2′), 124.3 (C5′), 122.2 (C6), 115.1 (C5), 113.5 (C3′), 111.9 (C4′). **7**, **8**: ESI+-MS: 195.0 ($[M + H]^+$).

Analytical HPLC

The chromatographic system consisted of an HP 1100 liquid chromatograph (Hewlett-Packard, Germany) coupled in series with an HP photodiode array detector (PAD), an evaporation light scattering detector (Polymer Labs, U.K), and an HP single quadrupole mass-selective detector (MSD) with an installed electrospray ionization (ESI) source. Process control and data handling were carried out using HP ChemStation software. The chromatographic studies were performed using Spherisorb C8/C18 and Spherisorb P (Waters, U.S.A.) reverse phase columns (250 × 4.6 mm I.D., 5 μm particle size) protected by a pre-column filter filled with the corresponding stationary phases. The mobile phase consisted of water–TFA (0.05%, solvent A) and acetonitrile–TFA (0.05%, solvent B). Elution was carried out using a linear gradient, starting from 30% solvent B to 100% solvent B over 15 min. This gradient was followed by a 5 min isocratic elution with 100% B before going back to the initial solvent mixture in 5 min. An interval of 10 min was allowed between subsequent runs. When the phenyl package was the selected stationary phase, the gradient elution went from 5 to 65% B over 15 min, while the rest of the chromatographic parameters were kept as described above. All runs were performed at room temperature at a flow rate of 1 mL min^{-1}. The eluent was monitored by PDA detector and the absorbance spectra (210–400 nm) were recorded continuously during the course of each run.

Preparative HPLC

Reverse-phase purification was carried out using a Waters Delta Prep^{TM} 4000 liquid chromatograph (Waters, U.S.A.) controlled through the Millenium 32 software package. Purifications were conducted with a 250 × 2 cm Spherisorb C18 column, using the same eluents as in analytical HPLC but at a flow rate of 10 mL min^{-1}. All isomers so obtained were examined for purity by analytical HPLC.

NMR experiments

NMR spectra of **1**–**8** were acquired on a Bruker Avance 500 spectrometer in DMSO at 30°C with an inverse probe. Proton spectra were also recorded at 70°C. Proton and carbon chemical shifts were referenced to the residual solvent signals at 2.50 and 39.5 ppm, respectively. Different types of carbon experiments were performed: standard ^{13}C NMR spectra with proton broadband decoupling, the gated ^{1}H-decoupling version that yields proton-coupled spectra, and ^{13}C spectra with ^{1}H single frequency decoupling. One-dimensional spectra were acquired using 32K data points, which were zero-filled to 64K data points previous to Fourier transformation. Absolute value COSY, phase-sensitive HSQC, and HMBC spectra were acquired using gradient-selection techniques (gs-COSY, gs-HSQC, and gs-HMBC). Acquisition data matrices were defined by 1K × 256 points in t_2 and t_1, respectively. The 2D data matrices were multiplied by appropriate window functions and zero-filled to 1K × 512 matrices prior to Fourier transformation. 1D-NOESY experiments were carried out with the selective 1D double-pulse field gradient spin echo module (11) using a mixing time of 400 ms.

© 2002 NRC Canada

2D-NOESY experiments were also performed with the same mixing time and with 2K × 256 matrices. Data were processed using the XWINNMR Bruker program on a Silicon Graphics computer.

Conclusions

This report describes the synthesis, stereochemical assignment, and conformational studies of a number of 5-(1*H*-pyrrol-2-ylmethylene)-substituted imidazolidine-2,4-diones and thiazolidine-2,4-diones that may exhibit inhibitory activity against a wide range of receptors. We have demonstrated that, regardless of the type of ring (hydantoin or TZD) or the N-substitution for the hydantoin derivatives, the (NH,C *cis*) form is the most stable conformer for the *E*-isomer and the (NH,C *trans*) form is the most stable conformer for the *Z*-isomer. The conformation around the C2′—C6 bond is therefore controlled by the configuration at the double bond.

We have shown that the *E*-isomer has the pyrrole-NH involved in an internal hydrogen bond with the carbonyl oxygen of the hydantoin or TZD rings, whereas such interaction is absent in the *Z*-isomer, leaving both groups available to establish intermolecular hydrogen bonds with the protein receptor. On the other hand, the pyrrole-NH in the *E*-isomer may form simultaneous hydrogen bonds with two donor atoms: the carbonyl oxygen of the ligand and a second electronegative atom of the receptor. These three-centre hydrogen bonds are common in the crystal structures of protein complexes (12). Thus, the knowledge of the conformational preferences and the spatial relationship between the hydrogen bond donors (NH) and the acceptors (C=O) for these compounds constitutes useful information for developing structure–activity relationships.

Synthesis of heteronuclear bifunctional Lewis acids by transmetalation of 1,8-bis(trimethylstannyl)naphthalene with BCl_3

Marcus Schulte and François P. Gabbaï

Abstract: Reaction of 1,8-bis(trimethylstannyl)naphthalene (**1**) with an excess of BCl_3 at –78°, followed by warming to 0°C, results in the exclusive formation of the novel bifunctional Lewis acid 1-(chlorodimethylstannyl)-8-(dichloroboryl)naphthalene (**2**), a compound in which a boryl and a stannyl moiety coexist at the *peri*-positions of a naphthalene core. At elevated temperature compound **2** undergoes a chloride–methyl exchange, which affords 1-(dichloromethylstannyl)-8-(chloromethylboryl)naphthalene (**3**). Compounds **2** and **3** have been characterized by multi-nuclear NMR spectroscopy. The single crystal X-ray analysis for compound **3** reveals a sterically crowded structure with an essentially trigonal planar boron center, and a tin center pentacoordinated in a [4+1]-fashion. Upon exposure to traces of water, compound **3** is converted into the borinic acid derivative 1-(dichloromethylstannyl)-8-(hydroxymethylboryl)naphthalene (**4**), which has been characterized by multi-nuclear NMR spectroscopy and single crystal X-ray analysis.

Key words: multidentate Lewis acids, organoboranes, organostannanes.

Résume : La réaction du 1,8-bis(trimethylstannyl)naphthalene (**1**), et du BCl_3 a –78°C suivie d'une élévation de la température a 0°C mène à la formation de l'acide de Lewis bifonctionnel 1-(chlorodimethylstannyl)-8-(dichloroboryl)naphthalene (**2**). Ce nouveau composé, **2**, possède un groupement boryle ainsi qu'un groupement stannyle liés aux positions *peri* du noyau aromatique. Sous l'effet de la température, ce composé s'isomérise pour produire le 1-(dichloromethylstannyl)-8-(chloromethylboryl)naphthalene (**3**). Les composés **2** et **3** ont été caractérisés par RMN multinucléaire. La structure du composé **3**, qui a été déterminé par diffraction des rayons X sur monocristal, révèle l'existence d'un encombrement stérique important. Dans cette structure, l'atome de bore est trivalent et adopte une géométrie de coordination triangulaire et plane. L'atome d'étain est lié à quatre ligands et forme une interaction longue avec un atome de chlore provenant du bore. Le composé **3** s'hydrolyse pour former le 1-(dichloromethylstannyl)-8-(hydroxymethylboryl)naphthalene (**4**), un acide borinique qui a été caractérisés par RMN multinucléaire et par diffraction des rayons X sur monocristal.

Mot clés : acides de Lewis multidentates, organoboranes, organostannanes.

Introduction

Organostannanes have often been used as starting material for the vinylation, arylation, and alkylation of boron halides (1). In these reactions, carbon—boron bond formation is accompanied by elimination of a triorganotin halide species. Application of this synthetic strategy to the case of polydentate boranes has also been visited (2–5). For example, 1,2-(diboryl)benzenes are readily prepared by reactions of the corresponding distannanes with boron halide reagents (3–5). With the emergent use of boron polydentate Lewis acids in material science (6), molecular recognition (7–11), and catalysis (5, 12–15), the discovery of new synthetic routes to such species is fully warranted. As part of our ongoing efforts in this direction, we have studied the potential of 1,8-bis(trimethylstannyl)naphthalene (**1**) (16) to serve as a precursor to *peri*-borylated naphthalene derivatives. While this synthetic approach has been used for the preparation of gallium and indium *peri*-substituted naphthalene derivatives (17–19), we note that the *peri*-borylated derivatives (8, 20, 21) have been typically synthesized by the metathesis reaction of 1,8-dilithionaphthalene with boron halides or alkoxides.

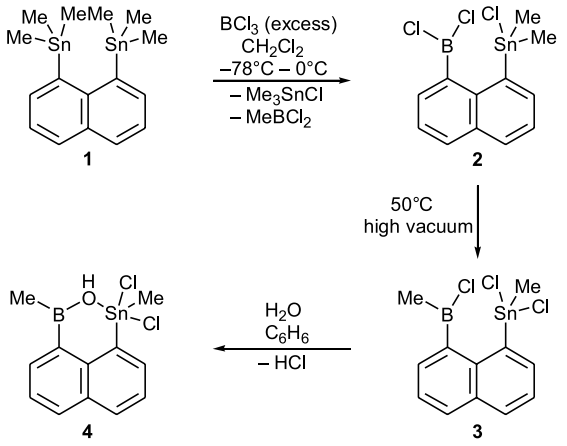
Results and discussion

The reaction of **1** with an excess of BCl_3 in CH_2Cl_2 at –78°C followed by warming to 0°C affords 1-(chlorodimethylstannyl)-8-(dichloroboryl)naphthalene (**2**) as a pale green oil (Scheme 1). Thus, despite the presence of an excess of BCl_3, only one of the stannyl groups of the starting material is replaced by a boryl moiety. This contrasts with the rapid formation of 1,2-bis(dichloroboryl)benzene in the reaction of 1,2-bis(trimethylstannyl)benzene with BCl_3 (3, 5). We note, however, that the reaction of 1,1′-bis(trimethylstannyl)ferrocene with BCl_3 results in the substitution of only one stannyl group, as observed in the case of **1** (22). The ^{11}B NMR spectrum of **2** displays a broad signal at

 DOI: 10.1139/V02-177 © 2002 NRC Canada

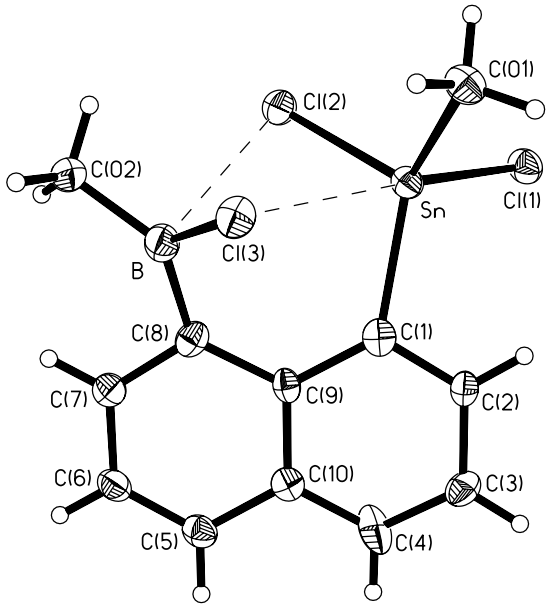
Scheme 1. Synthesis of the 1-stannyl-8-borylnaphthalenes **2**, **3**, and **4**.



δ 52.0 in the expected range for aryldichloroboranes. The ^{119}Sn NMR spectrum shows a signal at δ 140.0 indicating the formation of a chlorodimethylstannyl moiety at the aromatic core (23). Compound **2** is rather unstable and undergoes a rearrangement reaction when exposed to elevated temperatures. Upon heating to 50°C for 6 h in high vacuum, ligand exchange occurs leading to the formation of 1-(dichloromethylstannyl)-8-(chloromethylboryl)naphthalene (**3**) (Scheme 1). Recrystallization from toluene–pentane at –40°C affords **3** in the form of beige single crystals. The ^{11}B NMR spectrum of **3** displays a broad signal at δ 64.6. The ^{119}Sn NMR spectrum shows a signal at δ –8.3 indicating the formation of a dichloromethylstannyl moiety at the aromatic core (23). The identity of **3** is confirmed by the detection in the ^{1}H NMR spectrum of two equally intense singlets that correspond to the B-Me and Sn-Me groups, the latter displaying the expected tin satellites. Upon exposure to traces of water, compound **3** is converted into a borinic acid derivative 1-(dichloromethylstannyl)-8-(hydroxymethylboryl)naphthalene (**4**) (Scheme 1), which has been characterized by multi-nuclear NMR spectroscopy and single crystal X-ray analysis as well. While most NMR spectroscopic features are analogous to those of **3**, the resonance of the ^{119}Sn dichloromethylstannyl in **4** (δ –90.3) is shifted upfield, which likely reflects the coordination of an additional ligand at tin (24).

The structures of **3** and **4** have been confirmed by X-ray analysis (Figs. 1 and 2). Both compounds crystallize in the monoclinic space group $P2_1$ with two molecules in the unit cell. In addition to the naphthalene backbone, a methyl group, and two chloride anions that constitute the four primary ligands, the coordination sphere of the tin center of these derivatives also contains a bridging chloride (**3**) or hydroxide (**4**) ligand originating from the neighboring boryl moiety. The resulting intramolecular Sn···Cl(3) contact of 3.177(2) Å in **3** is long but remains within the sum of the van der Waals radii of these two elements. As a result, the coordination geometry of the tin atom in **3** is best described as monocapped tetrahedral ((4+1) coordination). In **4**, the bridging hydroxide forms a relatively short intramolecular

Fig. 1. ORTEP view of 1-(dichloromethylstannyl)-8-(chloromethylboryl)naphthalene (**3**) in the crystal, showing 50% probability ellipsoids and the atom numbering scheme. Selected bond lengths (Å) and angles (°): Sn—C(01) 2.117(6), Sn—C(1) 2.136(5), Sn—Cl(1) 2.370(2), Sn—Cl(2) 2.354(1), Sn···Cl(3) 3.177(2), B—C(02) 1.545(8), B—C(8) 1.546(9), B—Cl(3) 1.834(7), B···Cl(2) 3.069(7), C(01)-Sn-C(1) 131.2(2), C(01)-Sn-Cl(1) 102.6(2), C(01)-Sn-Cl(2) 110.3(2), C(01)-Sn···Cl(3) 76.5(2), C(1)-Sn-Cl(1) 101.1(2), C(1)-Sn-Cl(2) 106.8(1), C(1)-Sn···Cl(3) 77.2(2), Cl(1)-Sn-Cl(2) 99.82(6), Cl(1)-Sn···Cl(3) 176.24(4), Cl(2)-Sn···Cl(3) 83.91(5), C(02)-B-C(8) 128.4(5), C(02)-B-Cl(3) 115.7(5), C(02)-B···Cl(2) 88.5(4), C(8)-B-Cl(3) 114.7(4), C(8)-B···Cl(2) 96.4(4), Cl(3)-B···Cl(2) 96.5(3), Sn-Cl(2)···B 77.3(1), B-Cl(3)···Sn 81.7(2), Sn-C(1)-C(9) 127.7(4), B-C(8)-C(9) 129.5(5).



Sn···O contact of 2.370(3) Å, which confirms the participation of the hydroxide in the coordination sphere of the tin atom. Thus, and as confirmed by the difference between the three equatorial angles and the three axial angles involving Cl(1) ($\Delta\Sigma(\Theta)$) (25),[2] the coordination geometry of the tin atoms in **4** ($\Delta\Sigma(\Theta)$ = 71.9°) is closer to a trigonal bipyramid than in **3** ($\Delta\Sigma(\Theta)$ = 44.8°). The coordination geometry of the boron center is essentially trigonal planar (Σ_{angles} = 358.8° (**3**), 359.9° (**4**)). The slight deviation observed in the coordination geometry of the boron center in **3** can be correlated to the presence of a weak intramolecular B···Cl(2) contact of 3.069(7) Å. The structure of **3** and **4** presents a number of features characteristic of sterically hindered *peri*-substituted naphthalene derivatives (26). The Sn-C(1)-C(9) (127.7(4)° (**3**), 125.1(3)° (**4**)) and B-C(8)-C(9) (129.5(5)° (**3**), 127.2(3)° (**4**)) angles substantially deviate from the ideal value of 120°. The core of the naphthalene backbone is slightly twisted as reflected by the dihedral angles of 5.6° (**3**) and 4.2° (**4**) formed between the planes defined by C(1)-C(8)-C(9) and C(4)-C(5)-C(10). The stannyl and boryl moieties are displaced above and below the plane of the naphthalene

[2] $\Delta\Sigma(\Theta) = \Sigma\Theta_{eq} - \Sigma\Theta_{ax}$ has been used to quantify the distortion of a tetrahedral tin center ($\Delta\Sigma(\Theta) = 0°$) toward a trigonal bipyramidal geometry ($\Delta\Sigma(\Theta) = 90°$). The equatorial and axial angles are those involving the coordinated ligand that sits *trans* from the approaching ligand.

backbone by 0.376 and 0.553 Å, respectively in **3** and by 0.237 and 0.384 Å, respectively in **4**.

Experimental section

General methods

All experiments were carried out under a dry inert atmosphere of N_2 using standard Schlenk technique or a glove box (Unilab, M. Braun). The solvents were purified by distillation from appropriate drying agents under N_2. Boron trichloride was purchased from Aldrich and used without further purification. 1,8-Bis(trimethylstannyl)naphthalene was prepared according to a published procedure (16). The microanalyses were performed by Atlantic Microlab, Norcross, GA. The melting points were measured on samples in sealed capillaries and are uncorrected.

NMR spectroscopy

NMR spectra were recorded on a Varian Unity Inova 400 FT NMR spectrometer (399.67 MHz for ^{1}H, 128.23 MHz for ^{11}B, 100.50 MHz for ^{13}C, 149.04 MHz for ^{119}Sn) by using internal deuterium lock. Chemical shifts (δ) are given in ppm, and are referenced against external Me_4Si (^{1}H, ^{13}C), $BF_3{\cdot}Et_2O$ (^{11}B), and Me_4Sn (^{119}Sn).

Crystallography

Crystals of 1-(dichloromethylstannyl)-8-(chloromethylboryl)naphthalene (**3**) were grown from a toluene–pentane solution at −40°C, and of 1-(dichloromethylstannyl)-8-(hydroxymethyl)naphthalene (**4**) from a chloroform–pentane solution at room temperature, respectively. Owing to the reactive nature of the compounds, the crystals were handled under a blanket of dry mineral oil during mounting. The crystals selected for data collection were mounted on a glass fiber with apiezon grease, and rapidly transferred into the cold N_2 stream of the low-temperature accessory. Intensity data for the crystals were collected on a Siemens SMART CCD diffractometer at 110(2) K, using graphite monochromated Mo Kα radiation (λ = 0.71073 Å), and 0.3°-wide ω-scans with a crystal to detector distance of 5.0 cm. The structures were solved by direct method (27) and refined by full-matrix least-squares against F^2 (28). Crystallographic data are given in Table 1.[3]

1-(Chlorodimethylstannyl)-8-(dichloroboryl)naphthalene (2)

A solution of 1,8-bis(trimethylstannyl)naphthalene (**1**) (1.00 g, 2.20 mmol) in CH_2Cl_2 (10 mL) was cooled to –78°C and BCl_3 (2.50 g, 21.3 mmol) was added by Schlenk to Schlenk condensation. The reaction mixture was kept at –78°C for 60 min, warmed to 0°C, and all volatiles were removed in high vacuum to give **2** (829 mg, 2.12 mmol, 96%) as a pale green oil. Compound **2** was used in the next step without further purification. ^{1}H NMR (C_6D_6) δ: 0.36 (s, 6H, $^2J(^{117,119}\text{Sn-}^1\text{H})$ = 66, 69 Hz, CH_3), 7.04 (dd, 1H, $^3J(^1\text{H-}^1\text{H})$ = 7 + 8 Hz, H-3 or H-6), 7.22 (dd, 1H, $^3J(^1\text{H-}^1\text{H})$ = 8 Hz, $^4J(^1\text{H-}^1\text{H})$ = 1 Hz, H_{arom}), 7.27 (dd, 1H, $^3J(^1\text{H-}^1\text{H})$ = 8 Hz, $^4J(^1\text{H-}^1\text{H})$ = 1 Hz, H_{arom}), 7.44 (dd, 1H, $^3J(^1\text{H-}^1\text{H})$ = 7 + 8 Hz, H-3 or H-6), 8.03 (dd, 1H, $^3J(^1\text{H-}^1\text{H})$ = 7 Hz, $^4J(^1\text{H-}^1\text{H})$ = 1 Hz, H_{arom}), 8.65 (dd, 1H, $^3J(^1\text{H-}^1\text{H})$ = 7 Hz, $^4J(^1\text{H-}^1\text{H})$ = 1 Hz, H_{arom}). ^{13}C NMR (C_6D_6) δ: 5.1 ($^1J(^{117,119}\text{Sn-}^{13}\text{C})$ = 461, 483 Hz, CH_3), 124.9, 126.1, 126.3, 129.2, 133.9, 134.7, 134.8, 135.4, 137.8, 139.3 (all C_{arom}). ^{11}B NMR (C_6D_6) δ: 52.0. ^{119}Sn NMR (C_6D_6) δ: 140.0. No elemental analysis on account of the low stability of the compound.

1-(Dichloromethylstannyl)-8-(chloromethylboryl)naphthalene (3)

A sample of **2** (500 mg, 1.28 mmol) was heated to 50°C under a vacuum of 10^{-3} torr (1 torr = 133.322 Pa) for 8 h and the residue re-crystallized from a toluene–pentane mixture (1:1) to give **3** (419 mg, 1.07 mmol, 84%) as a beige solid; mp 110°C (decomposition (dec.)). ^{1}H NMR (C_6D_6) δ: 1.10 (s, 3H, $^2J(^{117,119}\text{Sn-}^1\text{H})$ = 73, 77 Hz, $SnCH_3$), 1.38 (s, 3H, BCH_3), 6.99 (dd, 1H, $^3J(^1\text{H-}^1\text{H})$ = 7 + 8 Hz, H-3 or H-6), 7.11 (dd, 1H, $^3J(^1\text{H-}^1\text{H})$ = 7 + 8 Hz, H-3 or H-6), 7.43

1-(Dichloromethylstannyl)-8-(hydroxymethylboryl)naphthalene (4)

To a solution of **3** (200 mg, 0.510 mmol) in benzene (10 mL) was added water (9.10 μL, 0.510 mmol) and the mixture stirred for 15 min. The solvent was evaporated in vacuo and the residue re-crystallized from $CHCl_3$–pentane (1:1) to give **4** (101 mg, 0.270 mmol, 53%) as a colorless solid; mp 139–140°C. ^1H NMR (C_6D_6) δ: 0.53 (s, 3H, BCH_3), 0.93 (s, 3H, $^2J(^{117,119}Sn\text{-}^1H)$ = 76, 80 Hz, $SnCH_3$), 5.55 (s, 1H, OH), 7.13 (dd, 1H, $^3J(^1H\text{-}^1H)$ = 7 + 8 Hz, H-3 or H-6), 7.21 (dd, 1H, $^3J(^1H\text{-}^1H)$ = 7 + 8 Hz, H-3 or H-6), 7.50 (dd, 1H, $^3J(^1H\text{-}^1H)$ = 8 Hz, $^4J(^1H\text{-}^1H)$ = 1 Hz, H_{arom}), 7.58 (dd, 1H, $^3J(^1H\text{-}^1H)$ = 8 Hz, $^4J(^1H\text{-}^1H)$ = 1 Hz, H_{arom}), 7.75 (dd, 1H, $^3J(^1H\text{-}^1H)$ = 7 Hz, $^4J(^1H\text{-}^1H)$ = 1 Hz, H_{arom}), 8.61 (dd, 1H, $^3J(^1H\text{-}^1H)$ = 7 Hz, $^4J(^1H\text{-}^1H)$ = 1 Hz, H_{arom}). ^{13}C NMR (C_6D_6) δ: 14.3 ($^1J(^{117,119}Sn\text{-}^{13}C)$ = 562, 588 Hz, $SnCH_3$), 22.7 (BCH_3), 125.00, 125.8, 127.6, 128.6, 132.7, 134.9, 138.9, 140.0 (all C_{arom}, only 8 signals detected). ^{11}B NMR (C_6D_6) δ: 51.0. ^{119}Sn NMR (C_6D_6) δ: –90.3. Elemental anal. calcd. (%) for $C_{12}H_{13}OCl_2SnB$ (373.62): C 38.57, H 3.51; found: C 38.44, H 3.48.

Conclusion

The reaction of **1** with boron trichloride results in the substitution of only one of the stannyl moieties of the starting material. Although an analogous partial transmetalation reaction is observed in the reaction of **1** with $GaCl_3$, these results come in marked contrast with those obtained in the reaction of 1,2-bis(trimethylstannyl)-benzene with boron trichloride (3). In the latter case, the reactions have been shown to result in a complete transmetalation of the stannyl moieties and formation of 1,2-diborylated benzene derivatives. Finally, compounds **1** and **2** constitute notable examples of heteronuclear bifunctional Lewis acids (2), whose acceptor properties should lie between those of the corresponding boron (3–15) and tin polydentate systems (23, 29).

The antimicrobial nalidixic acid as a probe for molecular recognition of α- and β-cyclodextrins

I.S. Shehatta, M.S. Ibrahim, and M.R. Sultan

Abstract: The inclusion of the antibacterial drug nalidixic acid (NAL) in α- and β-cyclodextrin (CD) cavities was studied using UV–vis absorption and voltammetric methods. It was corroborated that the UV absorption bands of NAL are intensified in the presence of α- and β-CDs. A pronounced decrease in the peak currents of NAL was also noticed upon the addition of α- and β-CDs. From the changes in the peak currents, it was concluded that NAL forms 1:1 inclusion complexes with the various hosts, which is also revealed in the phase solubility profile of the NAL–β-CD system, as a representative example. From voltammetric data, the logarithm of the binding constants were calculated to be 2.60 and 3.20 for α- and β-CDs, respectively. The magnitude of the formation constants, as well as the Gibbs free energies for NAL with α- and β-CDs, shows that NAL is bound more strongly to β-CD, with a more apolar cavity, than to α-CD. These observations suggest that hydrophobic interaction is the most important recognition element in the binding process. All orientations of entering NAL into the cavity have been considered herein, with the purpose of characterizing the inclusion complex of NAL with CD. Combining the experimental results and molecular modeling and energy calculations on the inclusion complexes yielded a more detailed picture of the solution structure of the complex formed between NAL and either α-CD or β-CD. It was inferred that the inclusion process can occur through the 2-methylpyridine side. An additional hydrogen bond was also found to be formed between the carboxyl group of NAL, which remains outside the β-CD cavity, and the secondary hydroxyl group of β-CD. This hydrogen bond should, therefore, be operating as an important second recognition element in the NAL–β-CD system.

Key words: cyclodextrins, host–guest association, inclusion complexes, nalidixic acid, solubility, voltammetry.

Résumé : Faisant appel à des méthodes voltampérométrique ainsi que de spectroscopie UV–vis, on a étudié l'inclusion de l'acide nalidixique (NAL), un antibactérien, dans des cavités de α- et β-cyclodextrines (CD). Il a été corroboré que l'intensité des bandes d'absorption UV du NAL est augmentée en présence des α- et β-CD. On a aussi noté une diminution sensible dans les courants de pic du NAL lors de l'addition des α- et β-CD. Sur la base des changements dans les courants de pic, on en conclut que le NAL forme des complexes d'inclusion 1:1 avec les divers hôtes; comme exemple représentatif, ceci se révèle à partir du profil de solubilité de phase du système NAL–β-CD. Utilisant les données voltampérométriques, on a aussi calculé que les valeurs du logarithme des constantes de fixation sont respectivement de 2,60 et 3,20 pour les α- et β-CD. L'amplitude des constantes de formation ainsi que des énergies libres de Gibbs pour NAL avec les α- et β-CD démontent que, par opposition à l'α-CD, le NAL est lié plus fortement à la β-CD qui comporte une cavité apolaire. Ces observations suggèrent que l'interaction hydrophobe constitue l'élément de reconnaissance le plus important du processus de fixation. Dans le but de caractériser le complexe d'inclusion du NAL avec la CD, on a considéré toutes les orientations du NAL au moment de son entrée dans la cavité. Une combinaison des résultats expérimentaux avec la modélisation moléculaire et les calculs d'énergie des complexes d'inclusion permettent d'obtenir une vue plus détaillée de la structure en solution du complexe qui se forme entre le NAL et l'α-CD ou la β-CD. On en déduit que le processus d'inclusion peut se produire par le côté de la 2-méthylpyridine. On a aussi trouvé qu'une liaison hydrogène se forme entre le groupe carboxyle du NAL, qui demeure à l'extérieur de la cavité de la β-CD, et groupe l'hydroxyle secondaire de la β-CD. On en conclut que la liaison hydrogène doit jouer un rôle de reconnaissance secondaire important dans le cas du système NAL–β-CD.

Mots clés : cyclodextrines, association hôte–invité, complexes d'inclusion, acide nalidixique, solubilité, voltampérométrie.

Introduction

Nalidixic acid is the first analogue of a class of the most important and impressive antimicrobial drugs called fluoroquinolones. This group of drugs inhibits the activity of bacterial DNA gyrase, an enzyme that controls the supercoiling of DNA by converting relaxed, covalently closed, circular DNA to a superhelical form by an energy-dependent strand breakage and resealing process (1). NAL has been extensively used as an antibacterial agent in the treatment of urinary tract infection and is effective against a variety of gram-negative pathogens (2, 3).

NAL is poorly soluble in water and its bioavailability is thus limited. Among the various approaches to improve the solubility and bioavailability of poorly soluble drugs are the use of cyclodextrin inclusion complexes, which have often proven to be successful (4, 5).

Cyclodextrins are cyclic oligosaccharides of α-D-glucose units, linked by α-1,4 bonds, and produced by enzymatic degradation of starch. They have doughnut shapes and a relatively hydrophobic cavity. These are among the most important and widely studied examples of host molecules that are able to form inclusion complexes with a variety of guests. Generally, the inclusion complex involves total or partial spatial entrapment of guest molecules in the cavity of the host molecule, without the formation of any covalent bonds. The stability of the complexes is primarily determined by how closely the guest and the lipophilic cone-like cavity are matched in size and shape. A perfect fit of the guest into the CD cavity enhances the host–guest interactions and leads to an increase in the value of the association constant.

Studies (6–9) regarding the interaction of NAL with cyclodextrins are surprisingly contradictory. α-CD has been reported to enhance the solubility of NAL (6); however, conflicting reports (7, 8) have concluded that an inclusion complex was not formed between NAL and β-CD. This lack of formation was attributed either to the NAL molecule being too large to be able to enter the β-CD cavity, or because of steric hindrance, although the average cavity diameter of β-CD is larger than α-CD. Two different association constant (*K*) values were also reported (7, 9) for the binding of NAL with γ-CD. Moreover, the data reported in literature were based upon UV, IR, X-ray, fluorescence, solubility, dissolution, and thermal methods (6–9). Electrochemical techniques have not been used to study the interaction of NAL with interesting hosts. In recent years, electrochemical investigations of substrate–cyclodextrin interactions (10–13) have provided a useful complement to the previously mentioned methods.

These considerations prompted us to study the interaction of NAL with α- and β-CDs using three independent techniques, namely solubility, spectroscopy, and voltammetry. In a continuation of our previous work (13–16), the aim of the present study was to improve the solubility of NAL in aqueous solution, and thereby to improve its bioavailabiliy. This goal was attained via the formation of an inclusion complex with β-CD. From that formation, the effects of β-CD concentration on the solubility of NAL in aqueous solution was determined. The association constants for the complexes formed between NAL and α-CD or β-CD were also calculated using voltammetric techniques. Moreover, the work was extended to an analysis of the influence of the CD cavity size on the complexation process with NAL, as well as to the driving forces for this process. Finally, molecular modeling and energy calculations were carried out to visualize the type of site interaction, and thus to elucidate the geometry of the inclusion complex.

Experimental

Materials

Nalidixic acid, α-CD, and β-CD were purchased from Sigma and were used as received. Stock solutions of α-CD and β-CD were prepared by dissolving the desired weights in water. Stock solutions of NAL were prepared by dissolving an appropriate amount of the drug in methanol. The supporting electrolytes (reagent grade, Merck, Darmstadt) were phosphate, Britton-Robinson (BR), and acetate buffers prepared in the usual way. The ionic strength was maintained constant (0.5 M) by adding $NaNO_3$. Double-distilled water was used to prepare the solutions. Methanol was the solvent of choice due to: (*i*) its ability to dissolve NAL appreciably; (*ii*) its structural similarity to water among other solvents; and (*iii*) its low affinity for binding with CD (17), which renders it a poor competitor with NAL for CD.

Apparatus

The solubility experiments were performed at constant temperature (25 ± 0.5°C) in a shaking water bath (Precision Scientific Group, Chicago, IL). The pH measurements were made using an ORION pH-meter, model M64 (ORION Research, Boston MA), accurate to ±0.05 pH unit. All spectrophotometric measurements were conducted using a Shimadzu UV-2101 PC UV–vis scanning spectrophotometer (Shimadzu, Kyoto, Japan), using matched quartz cuvettes of 1.0 cm path length. Differential pulse stripping voltammetry (DPSV) and cyclic voltammetry (CV) were carried out using a PAR Model 264A polarographic analyzer – stripping voltammeter, in conjunction with a PAR Model 303A HMDE and *x-y* recorder model RE0151. The area of the HMDE was 1.2×10^{-2} cm^2. The three-electrode system was completed by an Ag/AgCl (sat. KCl) reference electrode and a Pt-wire auxiliary electrode. A PAR Model 305 stirrer was also used for DPSV.

Methods

Solubility measurements

The solubilization of NAL in water and aqueous β-CD solution was carried out according to the method of Higuchi and Connors (18). An excess amount of NAL was added into the aqueous solutions containing increasing amount of β-CD solution (0 to 5×10^{-3} M). The mixture was shaken in a water bath (2 h, 310 K) and then agitated further at room temperature (70 h, 25 ± 0.5°C) until the equilibrium state was reached. The resulting suspension was filtered through filter paper (0.45 μm). The concentration of NAL in the filtrate was assayed spectrophotometrically at 257 nm; there was no interference from CD at this wavelength. The concentration of NAL was also determined potentiometrically. Each solubility was determined in triplicate.

© 2002 NRC Canada

Spectrophotometric measurements

Complex formation between NAL and α-CD or β-CD was also studied using the spectral shift of NAL upon the addition of various hosts. The concentration of NAL in these studies was 5×10^{-5} M, while the cyclodextrin concentrations were varied up to 12 mM.

Voltammetric measurements

For voltammetric measurements, the test solution was placed in a polarographic cell (volume ≈15 mL) and deoxygenated by bubbling nitrogen for 15 min. In the case of DPSV, the accumulation was performed on the HMDE, and the solution was stirred at the accumulation potential of $E_{acc} = -0.4$ V for 30 s. The voltammetric response was obtained using a pulse repetition time of 0.2 s, within an amplitude of 100 mV, and a scan rate of 20 mV s^{-1} (or 100 mV s^{-1} for CV, unless otherwise stated). While preconcentration was done in the stirred solutions, a quiescent period of 15 s was allowed before the potential scan was started. Typical CV peak potentials were reproducible to better than ±5 mV and DPSV peak potentials to ±2 mV. The concentration of NAL and the total volume of solution (10 mL) were kept constant, and the CD concentration varied, while carrying out the electrochemical procedures. All experiments were carried out at ambient temperature (25.0 ± 0.5°C).

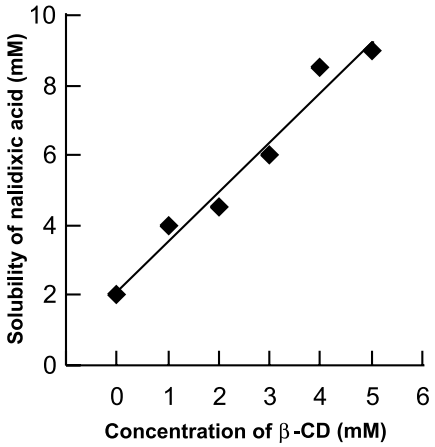
Molecular modeling and computational details

Molecular modeling and energy calculations were carried out on PCMODEL version 6.0 (Serena software). The starting geometry of α-CD or β-CD was generated by connecting two D-glycopyranose monomers (taken from the library) via an α-(1→4) glycosidic linkage, and then conjugated to determine the energy minimized conformation. This conjugation was continued by adding another D-glucopyranose moiety each time, until six or seven such molecules were arranged symmetrically to get a well-shaped structure having energy minimized conformations for α-CD and β-CD, respectively. Finally, the cavity dimensions (depth, diameter of the wider and narrower rims) were calculated and compared with the reported values. Similarly, the geometry of NAL was built from scratch using library molecular fragments to determine energy minimized conformation. The dimensions of the drug molecule were also calculated. All possible topologies for the entry of the guest (NAL) into the cavity of the host (α-CD or β-CD) were generated. The portion of NAL and the extent of its penetration in the CD cavity were also observed on the computer monitor on the entire *x*, *y*, and *z* axes. This molecular modeling can tell us what portion of the guest can penetrate and be retained inside the CD cavity if its length is more than the depth of the host cavity. Moreover, from what direction (wider or narrower rim of CD) the drug enters could also be visualized.

Results and discussion

To study the association of NAL with CDs, changes in the physicochemical properties of the drug (such as solubility, absorbance, and electrochemical behaviour) were followed, as a function of cyclodextrin concentration, by fixing the pH of the 5% v/v methanol–water solution.

Fig. 1. Phase solubility diagram of NAL in phosphate buffer (pH = 5), in the presence of different β-CD concentrations.



Solubility studies

Figure 1 shows the phase solubility diagram of NAL in aqueous solution in the presence of different concentrations of β-CD. The solubility of NAL increased in an approximately linear manner as a function of the β-CD concentration. This result would lead to the conclusion that a soluble complex having 1:1 stoichiometry was formed with β-CD, i.e. an A_L-type solubility diagram according to Higuchi and Connors (18). It was also assumed that a complex with a 1:1 stoichiometry was formed because the straight line had a slope less than unity (19). In aqueous solutions of the NAL–β-CD complex, the free drug molecules are in equilibrium with the drug molecules entrapped within the cavity. Thus, on increasing the concentration of β-CD, more NAL molecules will transfer from the aqueous solution to the hydrophobic cavity of β-CD. One can therefore expect that more NAL will dissolve in water in the presence of β-CD than will dissolve in the absence of it, and consequently, the solubility of NAL increases with increasing concentration of β-CD.

The apparent stability constant (log $K = 3$) of the formed complex was calculated from the solubility diagram according to eq. [1],

$$[1] \qquad K = \text{slope}/S_o\ (1 - \text{slope})$$

using the slope of the phase solubility diagram and the determined NAL solubility value in water for S_o. The obtained solubility value of NAL (S_o) in aqueous solution is in fair agreement with the literature values (20, 21).

The Gibbs free energies of transfer of NAL from aqueous solution to the cavity of β-CD (Table 1) have been calculated from the following equation,

$$[2] \qquad \Delta G^{\circ}_{trans} = -RT \ln (S/S_o)$$

where S and S_o are the solubilities of NAL in the presence and absence of β-CD. As can be seen from Table 1, the ΔG°_{trans} values are negative, and increase negatively with increasing β-CD concentration. This result indicates that the transfer process is spontaneous, and supports the view that β-CD is a more favourable environment than water for NAL. Moreover, the interaction between NAL and β-CD increases with increasing β-CD content.

Spectroscopic studies

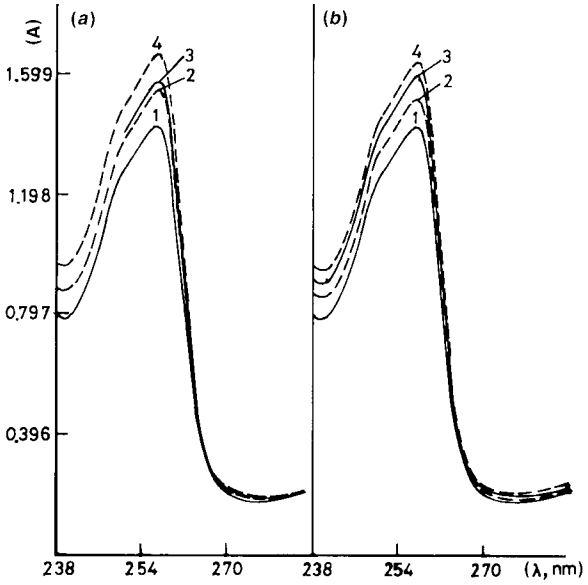
Complex formation between NAL and CDs was studied using the spectral shift method in 5% v/v methanol–water at pH = 5 (phosphate buffer). The absorption spectra of 5×10^{-5} M NAL in the phosphate buffer exhibited three distinct absorption bands at 218, 257, and 323 nm. Some important changes in the absorption spectra of NAL at 257 nm (Fig. 2) were observed upon the addition of α- and β-CD. As can be seen in Fig. 2, for both the NAL–α-CD and NAL–β-CD systems, the addition of the host molecule results in an increase in the absorbance intensity, but does not cause a shift in λ_{max}. Similar behaviour was observed for a hepatoprotectant drug thioctic acid – β-CD system (22), as well as for anthracene–, phenothiazine–, and thianthren–β-CD systems (12). As α-CD or β-CD shows no absorption above 220 nm, we can reasonably attribute these variations primarily to the formation of the inclusion complexes of the NAL–CD systems. These changes in the absorbance values are believed to result from changes in the solvent micro-environment upon inclusion of the solute. The changes observed in molar absorbance values may result from the loss of hydrogen-bonding that accompanies the transfer of the guest molecule from the solution to the cyclodextrin cavity. This hypothesis is reasonable based on the fact that there are no proton-donating groups inside the cavity of the cyclodextrin molecule.

However, the maximum change in absorbance ($\Delta A_{max} \approx 0.2$) was so small that the association constant K_{CD-NAL} could not be accurately determined by fitting the experimental data to the well-known UV-binding isotherm (23). This feature indicates that UV spectroscopy is not sensitive enough to be useful in the study of the CD–NAL system, or any other system, where the presence of CD does not result in a clear change in the spectroscopic properties of the drug. Similar conclusions have been obtained for the β-CD – thioctic acid system (22), as well as for other CD–substrate systems (24, 25).

Voltammetric studies

The nature of the electrochemical process of NAL in the absence and presence of various host molecules was investigated by cyclic voltammetry (CV). The cyclic voltammogram of free NAL (1.9×10^{-5} M) in the phosphate buffer is illustrated in Fig. 3 (curve 1), which shows two reduction processes, the first process (P_1) being reversible, followed by an irreversible process (P_2). The main process (P_2) was found to be the more concentration-sensitive peak, and was therefore assigned to the reduction of the carbonyl group (on C-4) to the 4-hydroxy product (26). The reduction peak P_1 has been reported previously for similar compounds (27), and was attributed to the reduction of Hg(II), which is bound

Fig. 2. UV–vis spectra of 5.0×10^{-5} M NAL in phosphate buffer (pH = 5, 5% methanol), in the absence (1), and presence of (*a*): (2) 1 mM, (3) 5 mM, and (4) 6 mM β-CD; and (*b*): (2) 2 mM, (3) 10 mM, and (4) 12 mM α-CD.



to the adsorbed Hg(II)–NAL film through the heterocyclic nitrogen atom N-8. We were interested in the most sensitive signal (P_2) for the following studies, and for the titrations with cyclodextrins. The cyclic voltammograms of NAL in the absence and the presence of α-CD, as a representative example, were recorded as a function of potential, in the phosphate buffer of varying pH (from pH 2 to pH 7), to elucidate the optimum pH for studying the interaction of NAL with different hosts (Fig. 3(*a*)–3(*c*)). In the presence of the host molecule, the peak potentials, as well as the peak currents of NAL are modified. As shown in Fig. 3, the peak currents (P_2) decreased to ca. 53%, 70%, and 43% (curve 2) of those recorded in the absence of α-CD (curve 1) for pH 2, 5, and 7, respectively. This behaviour suggests that the neutral NAL species (pK_a = 6.00) interact more strongly with cyclodextrins. On the other hand, the broadening of the CV peak (P_1) in the absence of α-CD (Fig. 3, curve 1), and its appearance as a needle-like peak in the presence of α-CD (Fig. 3, curve 2), is probably due to the morphology of the adsorbed film on the HMDE surface. As shown previously (28), the broad peak reflects a flat orientation of the adsorbed NAL species at the electrode surface; however, the needle-like peak points to a vertical orientation of the adsorbed NAL–α-CD complex. These results indicate that the complexation of the NAL molecules enhances the stacking interactions, and hence would be expected to facilitate the formation of a perpendicularly stacked layer of NAL–α-CD complexes on the electrode surface.

The effect of buffer constituents on the binding affinity of NAL to CDs was also studied at pH 5, in the presence of several supporting buffer electrolytes (e.g., acetate, phosphate, and BR buffers). The best results, with respect to shape and reproducibility, as well as to the enhancement of host–guest interactions, were obtained using the phosphate buffer solution; hence, the phosphate buffer (pH 5) was considered optimum, and was used throughout the present work.

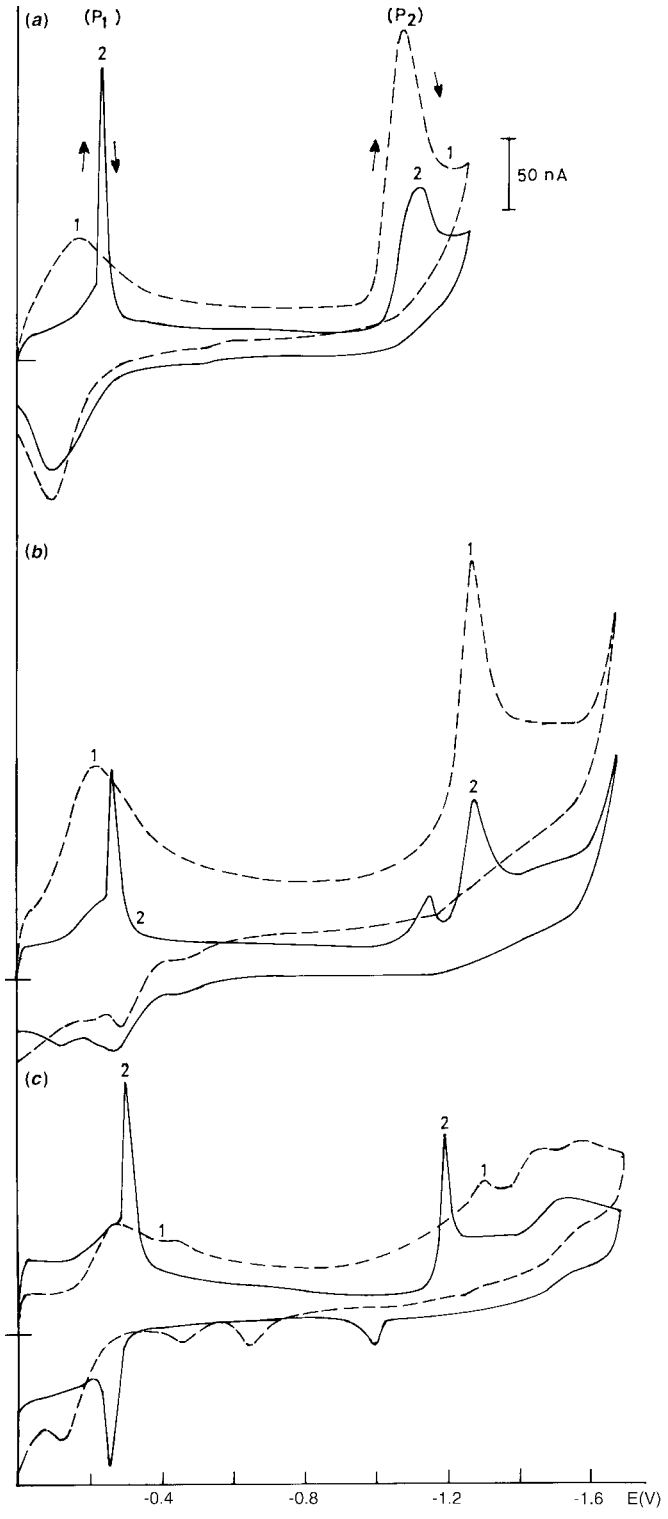
Fig. 3. Cyclic voltammograms for 1.9×10^{-5} M NAL solution in the absence (1), and in the presence of 5×10^{-3} M α-CD (2) at: (*a*) pH 2, (*b*) pH 5, and (*c*) pH 7 phosphate buffer (5% methanol), at HMDE, scan rate 100 mV s^{-1}.



The effect of scan rate (ν) on the NAL process (P_2) at the HMDE, in both the absence and the presence of host molecules, was examined. Experimental plots of i_p vs. $\nu^{1/2}$ for NAL, NAL–α-CD, and NAL–β-CD adducts showed linear dependence on the square root of the scan rate, indicating diffusional mass-transport of the electroactive species to the HMDE surface (29). By linear regression of the data, the following relations were obtained

[3] $$i_p \text{ (nA)} = 13.6 + 10.4\ \nu^{1/2} \quad (R = 0.987)$$

$$i_p \text{ (nA)} = -6.25 + 6.43\ \nu^{1/2} \quad (R = 0.999)$$

$$i_p \text{ (nA)} = -3.81 + 5.70\ \nu^{1/2} \quad (R = 0.998)$$

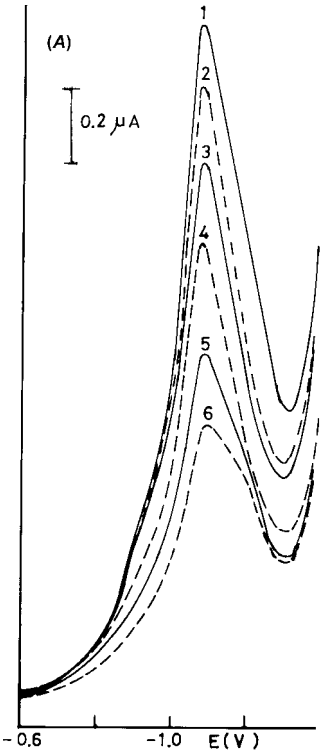
for NAL, NAL–β-CD, and NAL–α-CD, respectively. The slopes of the linear $i_p - \nu^{1/2}$ plots diminished markedly in the presence of β-CD and α-CD, to about 55% and 44% of their respective values in the absence of host molecule. In terms of these results, the decrease of the peak currents in the presence of various host molecules can be attributed to the decrease in the apparent diffusion coefficients of NAL–host adducts. From an analysis of these slopes, the diffusion coefficient (D_f) of free NAL was found to be 9.95×10^{-6} cm^2 s^{-1}, whereas $D_b = 1.98 \times 10^{-6}$ and 1.56×10^{-6} cm^2 s^{-1} were measured for the bound NAL in the presence of 1.7×10^{-3} M β-CD and 1.9×10^{-3} M α-CD, respectively. These values are in good agreement with those previously reported for the reduction of other species due to association with DNA (30) or with micellar assembles (31, 32). In principle, the formation of a substrate–micelle aggregate is expected to increase the effective radius of the substrate by a factor of about four, which explains the observed changes in diffusion coefficients (31). The peak current could also be reduced if the host molecule caused an increase in the viscosity of the solution resulting in a decrease in the diffusion coefficient, but no change in solution viscosity could be detected over the concentration range used for the host molecules. Therefore, the decrease of the peak current (detected upon the addition of the host) is obviously due to the lower diffusion coefficient of the bulky inclusion complexes, compared to that of free NAL.

Further evidence for the strong interaction of NAL with the asymmetric environment of the CD cavity was obtained from DPSV. The recorded DPS voltammograms of 5×10^{-6} M NAL in the phosphate buffer (pH 5) exhibited two cathodic peaks, at potentials −0.190 and −1.125 V, corresponding to peaks P_1 and P_2 obtained by CV. In the presence of different concentrations of β-CD or α-CD, the solution of NAL yielded electrochemical behaviour similar to solutions of the free guest, but the cathodic peak (P_2) potentials, as well as the peak currents, were considerably influenced (Fig. 4): the cathodic peak potentials were slightly shifted to the more negative potentials. This result reveals that NAL is more difficult to reduce in the presence of β-CD or α-CD — as a result of the NAL entering the hydrophobic cavity — with lower polarity relative to the bulk solution. Also, the peak current is diminished due to the decrease of the diffusion coefficients of the host–guest associates compared to that of the free guest, as discussed above.

The decrease in peak current (P_2) enables us to calculate the formation constant of the complexes formed between NAL and the studied host molecules. The *K* values could therefore be calculated from the following equation (as explained in our previous work (13)),

© 2002 NRC Canada

Fig. 4. Differential pulse stripping voltammograms for 5.0×10^{-6} M NAL in phosphate buffer (pH = 5, 5% methanol), at HMDE, in the absence (1), and presence of (2) 9.9×10^{-5} M, (3) 1.96×10^{-4} M, (4) 3.85×10^{-4} M, (5) 6.66×10^{-4} M, and (6) 8.25×10^{-4} M β-CD. Scan rate 20 mV s^{-1}, accumulation time 30 s, E_{acc} = –0.4 V, and pulse amplitude 100 mV.



$$[4] \qquad \frac{i_o}{i_o - i} = \frac{1}{1 - C} + \frac{1}{K(1 - C)[H]}$$

where i_o and i are the peak currents of free NAL and NAL in the presence of CDs, [H] is the concentration of CDs, and C is the proportionality constant. According to this equation, on plotting $(i_o/(i_o - i))$ vs. 1/[H], the ratio of the intercept to the slope gives the value of K. The plots in all NAL–guest systems are linear with good correlation coefficients ($R \geq 0.99$), indicating that 1:1 complexes are formed in all cases. The K values obtained by this approach, as well as the formation constant of NAL with γ-CD previously reported (7, 9), are shown in Table 2. There is fair agreement, within experimental error, between the K values of NAL–β-CD obtained from both voltammetric and solubility techniques.

Binding mode and mechanism of the inclusion complex

Valero et al. (33) have calculated the dielectric constant of the cyclodextrin cavities from the spectral dependence of the solvent polarity. They found that the cyclodextrin cavities of α-CD, β-CD, and γ-CD have lower polarity than bulk water, and that the β-CD interior is the most hydrophobic of the three cavities studied. This finding indicates that the microenvironment of a substrate in β-CD is more hydrophobic than the corresponding value for α-CD or γ-CD. This difference could lead to a tighter filling of β-CD (i.e. a greater penetration of the drug into the β-CD cavity), and consequently a greater hindrance of the entry of water molecules. This hypothesis is consistent with the trend of K values of NAL (Table 2). The binding constants listed in Table 2 indicate that the interaction of NAL–β-CD is particularly strong because of the snug fit of NAL into the β-CD cavity, but the binding of NAL to α-CD (with its smaller cavity) and to γ-CD (with its larger cavity) is poorer. This result highlights the importance of the size–fit relationship between the host and the guest in determining the strength of binding. The remarkable enhancement in the association constant with the decreasing dielectric constant of the CD cavity suggests, therefore, that the major contributing factor is the hydrophobic interaction.

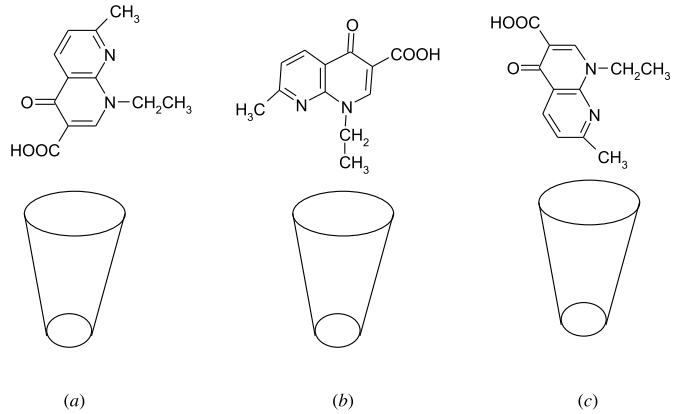
The change in standard Gibbs free energy (ΔG°) for the binding of NAL with the CDs was calculated from the well-known relationship:

$$[5] \qquad \Delta G^\circ = -RT \ln K$$

These values were found to be negative (Table 2), revealing that the binding process is favourable. Consequently, the transfer of NAL from an aqueous solution to the CD cavity is spontaneous. Moreover, the change in Gibbs free energy corresponding to the association process is close to, or even of the same order of magnitude as that calculated above, possibly indicating similar inclusion structures for NAL in both the α-CD and β-CD cavities.

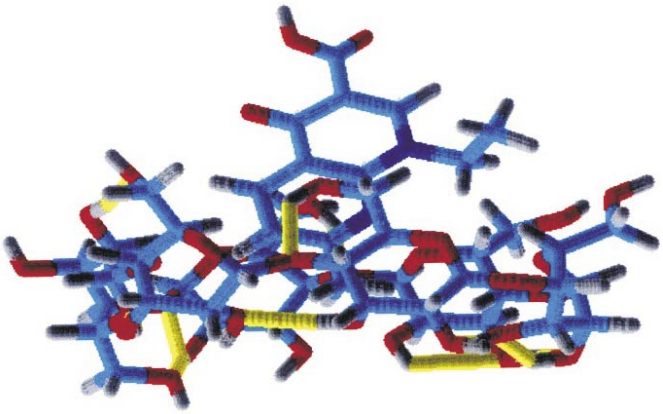
To elucidate the structure of the inclusion complex and the group responsible for the inclusion into CD, it is informative to consider the binding constants of smaller, nondrug molecules formed by groups contained in NAL. The K value (158.5) of the pyridine–α-CD complex was therefore taken from literature (34) for comparison.

NAL can enter the CD cavity in three different ways:



© 2002 NRC Canada

Fig. 5. Energy-minimized structure for the NAL–α-CD complex.



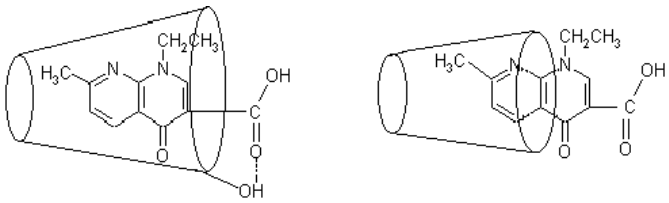
Orientation (*a*) may not be very likely because highly hydrophilic groups are included in the relatively hydrophobic cavity. Moreover, these groups (C=O and –COOH) are more stabilized by water molecules (through hydrogen bonding) than by CD.

If it is supposed that the complexation is due to the inclusion of the ethyl group at N-1 into the cavity of α-CD (orientation (*b*)), then the expected free energy change should be about 6 kJ mol^{-1}. This value is attributable to the change in free energy for each methylene group included in α-CD, ~3 kJ mol^{-1} at 298.15 K (14–16). However, we obtained 14.88 kJ mol^{-1} for the NAL–α-CD complex, which indicates that this topology for the entry of NAL into the α-CD cavity is also excluded. The smaller cavity of α-CD binds more tightly with a linear alkyl group than that of β-CD (14–16); however, the absorption spectra and the voltammetric studies, as well as the *K* values, show that the binding affinity of NAL to β-CD is better than to α-CD. Orientation (*b*) is therefore not the favourable one.

NAL is thus expected to take orientation (*c*) when complexing with CDs. The size of the 2-methylpyridine group seems to fit the cavity size of CD. It was reported (34) that the logarithm of the binding constant of pyridine with α-CD, at 298.15 K, is log K = 2.20, which is slightly smaller than that obtained for the NAL–α-CD complex. The inclusion of NAL into the cavity therefore proceeds in such a way that the methyl pyridine side penetrates the cavity. The inclusion process in NAL can thus occur through the 2-methylpyridine side, leaving the carboxyl group outside the hydrophilic cavity, protruding into water. This orientation leads to the formation of hydrogen bonds between the carboxyl group and the hydroxyl groups of β-CD, resulting in an enhancement of the stability of the NAL–β-CD complex. The release of originally incorporated water molecules from the CD cavity is another important factor that can also contribute to the stabilization of the NAL–CD complex. The high-enthalpy water molecules released can form hydrogen bonds with the bulk water molecules.

To test the reliability of these hypotheses, we carried out calculations on all possible complexes of NAL with α-CD or β-CD, taking into account the different modes of inclusion. The more favourable interaction energy was obtained for topology (*c*), where the energy was found to decrease by ≈ 176 and 226 kJ for α-CD and β-CD, respectively. This result reveals that NAL–β-CD is more stable than NAL–α-CD. The energy-minimized conformation of the NAL–α-CD structure, as a representative example, is shown in Fig. 5. This figure shows that the drug enters through the wider rim and penetrates through the axis of the CD cavity along its depth. It was observed that the maximum width of the NAL molecule (5.02 Å) was less than the diameter of β-CD (≈7 Å) (35), facilitating the penetration of the molecule into the β-CD cavity, but the length of the NAL molecule (7.88 Å) was more than the cavity depth (≈7 Å) (35). The protruding carboxylic group thus forms hydrogen bonds with the secondary OH group located on the larger rim of the β-cyclodextrin. The proposed structural formula of the NAL–β-CD inclusion complex is given in Fig. 6(*a*). On the other hand, as the width of NAL is larger than the diameter of α-CD (4.5 Å) (35), NAL should not be able to fully penetrate into α-CD. In other words, only part of the NAL molecule can be accommodated into the α-CD cavity, leaving the rest of the molecule protruding into water (Fig. 6(*b*)). This explains why the orientation of adsorbed NAL changes in the presence of α-CD, as discussed before in the section on cyclic voltammetry. In the case of γ-CD (diameter 8.5 Å), the NAL molecule is loosely packed into this large cavity, leading to weak interactions, and consequently, a small *K* value (Table 2).

Fig. 6. Proposed structural formula of nalidixic acid complexes with (*a*) β-CD and (*b*) α-CD.



Finally, the voltammetric study showed that the binding affinity of NAL is much higher at pH 5 than at the other pH values. This result indicates that the CD cavities have a preferential affinity for the neutral acid form than for the ionized ones. This preference can be explained as follows: NAL (pK_a = 6.00) at pH 5 is primarily in the neutral form, whereas at pH 2 and pH 7, NAL is in the cationic and anionic forms, respectively. At pH 2, NAL interacts with H^+ through N-8, forming the NAL cation, and this hinders full penetration into the cavity. At pH 7, NAL exists as the anionic carboxylate. The requirement for solvation of the charged carboxylate group by water may thus prohibit the 2-methyl group from fully penetrating the CD cavity, whereas deeper penetration may be possible with the neutral carboxylic acid group.

Studies of a benzoporphyrin derivative with Pluronics

N. Hioka, R.K. Chowdhary, N. Chansarkar, D. Delmarre, E. Sternberg, and D. Dolphin

Abstract: The synthetic route for the benzoporphyrin derivatives produces two regioisomers in equimolar quantities (ring A and B isomers). A derivative of the A-ring product, BPD-MA (benzoporphyrin-derivative monoacid ring A, verteporfin), has recently been approved in North America and Europe for the treatment of age-related macular degeneration. The B-ring isomers, contrary to the A-ring isomers, exhibit high aggregation in many formulations, which results in inadequate drug delivery for clinical uses. To avoid aggregation, a non-ionic surfactant polymer such as a Pluronic — poly(ethylene oxide)-poly(propylene oxide)-poly(ethylene oxide) — may be used as a formulation excipient. The triblock polymer investigated here is designated P123 (or poloxamer 403). When used to formulate a monoacid benzoporphyrin B-ring derivative (**2**), a critical micelle concentration of P123 in water occurred at approximately 0.015 to 0.03%. The apparent pK_a of compound **2** was dependent on its concentration in P123, and decreased as the molar ratio (P123:**2**) increased. High concentrations of P123 and neutral pH were found to be the best conditions to maintain the drug in its monomeric form. Kinetic studies suggest that the aggregate of **2** contains several molecules, and is formed by a catalyzed self-assembly process. Samples with 1 mg mL^{-1} of drug, at pH = 7.4, and 4.8% of Pluronic showed satisfactory capacity to load and keep monomers stable. This formulation has potential PDT applications.

Key words: Pluronic, poloxamers, block copolymers, photosensitizing drug, photodynamic therapy (PDT), formulation, micelles.

Résumé : La voie de synthèse des dérivés de la benzoporphyrine conduit à deux régioisomères en quantités équimolaires (isomères des cycles A et B). Un dérivé du produit du cycle A, BPD-MA, (le dérivé monoacide du cycle A de la benzoporphyrine, la vertéporfine) a récemment été approuvé en Amérique du Nord et en Europe pour le traitement de la dégénérescence maculaire associée à l'âge. Les isomères du cycle B, contrairement aux isomères du cycle A, présentent des niveaux d'agrégation élevés dans plusieurs formulations qui les rendent impropres à la dissémination du médicament pour les utilisations cliniques. On peut d'éviter l'agrégation en utilisant comme additif de formulation un agent de surface polymère, non ionique, tel qu'un Pluronique — poly(oxyde d'éthylène)-poly(oxyde de propylène)-poly(oxyde d'éthylène). Le polymère à trois blocs étudié ici est désigné P123 (ou poloxamère 403). Lorsqu'on l'utilise dans la formulation d'un dérivé monoacide du cycle B de la benzoporphyrine (**2**), on observe une concentration micellaire critique de P123 dans l'eau aux environs de 0,015 à 0,03%. Le pK_a apparent du composé **2** dépend de sa concentration dans P123 et il diminue avec une augmentation du rapport molaire (P123:**2**). On a trouvé que des concentrations élevées de P123 et un pH neutre correspondent aux conditions optimales pour maintenir le médicament dans sa forme monomère. Des études cinétiques suggèrent que l'agrégat de **2** contient plusieurs molécules et qu'il se forme par un processus d'autoassemblage autocatalysé. Des échantillons de 1 mg mL^{-1} de médicament, à un pH = 7,4 et une concentration de 4,8% de pluronique présentent une capacité satisfaisante à dissoudre et à maintenir les monomères stables. Cette formulation a du potentiel dans les applications de thérapie photodynamique (TPD).

Mots clés: Pluronique, poloxamères, copolymères à blocs, médicament photosensibilisant, thérapie photodynamique (TPD), formulation, micelles.

[Traduit par la Rédaction]

Introduction

Photodynamic therapy (PDT) is an approved treatment against cancer and age related macular degeneration, and has been shown to be efficient against psoriasis, arthritis and other diseases (1, 2). The first officially approved drug for PDT was Photofrin®, which exhibited some side effects such as prolonged skin photosensitivity, a long waiting time be-

tween intravenous injection and photo activation (2 days), and limited light penetration through tissue (1) of the 630 nm light used to activate it. The photoactive component of the liposomal formulated verteporfin (recently approved for the treatment of age-related macular degeneration) is a benzoporphyrin derivative monoacid ring A (BPD-MA, **1**). The synthetic route to this type of molecule provides, in equimolar quantities, two reduced porphyrin rings (A and B, which are ring regioisomers). Both sets of regioisomers show similar ability to accumulate selectively and be retained by abnormal or hyperproliferative cells, such as cancerous tissue (3–5). Both classes exhibit a tendency to form aggregates (6, 7), following the typical behavior of many porphyrin and chlorin compounds (8). The A-ring compounds exhibit less tendency to aggregate, however, and can be used in liposomal formulations (5, 9). In contrast, the B-ring derivatives exhibit high aggregation behavior, resulting in nonhomogeneous solutions and diminution of singlet oxygen formation (6), which is suggested as one of the most significant species involved in cell death (1, 10).

To avoid aggregation and to improve drug concentration in target tissues, the formulation of the drug is especially important. We have investigated the use of Pluronic (poloxamers), water-soluble triblock copolymers containing ethylene oxide units (PEO = the hydrophilic regions) at the extremities and propylene oxide units (PPO = the hydrophobic section) in the middle (often denoted PEO-PPO-PEO or $(EO)_m(PO)_n(EO)_m$). Because of their synthetic versatility, a number of copolymers are commercially available for distinct uses in different areas, which include drug solubilization and controlled release (11–13). Many of them are believed to form micelles with the terminal PEO sections hydrated at the surface and the PPO section in the hydrophobic core (12, 14).

The basis of this work was the investigation of drug formulations for PDT using Pluronic P123 and a benzoporphyrin B-ring derivative (**2**). P123 (or poloxamer number 403) has a molecular weight of 5750 with 30% of hydrophile PEO (m = 21 and n = 67).

Materials and methods

Reagents

Pluronic P123 (paste) was supplied by BASF, U.S.A. The photosensitizing drugs (BPD-MA **1** and **2**) were synthesized using standard procedures (15). 1,6-Diphenyl-1,3,5-hexatriene (DPH, Sigma) was used as received. The ionic strength was maintained by adding KCl (0.1 mol L^{-1}). Buffers (0.01 mol L^{-1}) were potassium phosphate (pH range 6.2–8.5) and potassium phthalate (pH range 3.9–6.1). All solvents were analytical grade.

2

Procedures

The aggregation process was monitored by UV–vis spectroscopy (Hewlett-Packard 8452 A and Cary-50). The spectra of **2** were obtained using cells with path length 0.01 cm (cylindrical-shaped) for concentrated solutions (approximately 1×10^{-3} mol L^{-1}) and 1.0 cm for dilute solutions (approximately 1×10^{-5} mol L^{-1}). The term molar ratio refers to the ratio [P123]:[**2**] using molar concentrations. For the stock preparation, P123 (paste, 2 g) was dissolved in 100 mL of water and mixed (Mixer Thermolyne, type 16700) for 2 to 3 h. All Pluronic concentrations are presented by percentage of weight of polymer per water volume (w/v). All stock solutions of **2** (prepared in dimethyl sulfoxide (DMSO)) and DPH (prepared in methanol) were protected from light and were refrigerated.

Critical micelle concentration (cmc)

The cmc determination (duplicate) was performed for Pluronic P123 by a solubilization method (13) using DPH as a probe, and by a method based on dye monomer–aggregate equilibration (16) using **2** as the probe. All Pluronic solutions were kept in a water bath for at least 4 h, to achieve thermal and mechanical equilibrium. A stock solution of DPH was prepared at 1.1×10^{-3} mol L^{-1}, and aliquots of 3.0 μL (microsyringe) were added to each 2.0 mL of Pluronic solution. For **2**, 4.0 μL from a stock solution (3×10^{-3} mol L^{-1} in DMSO) was added to each 2.0 mL of P123 solution, and mixed for 15 s (mixer). The solutions were kept in the dark (1 h for DPH and 30 min for **2**), before the visible or fluorescence (Aminco-Bowman Series 2) spectra were recorded.

Effect of pH

Solutions of **2** (1.14×10^{-5} mol L^{-1}) at different pH and in several fixed concentrations of P123 were investigated ([P123] from 0 to 0.16% w/v). The ionic strength was kept constant (0.1 mol L^{-1} KCl), and phosphate and phthalate potassium buffers (0.01 mol L^{-1}) were used. P123 solutions (2.25 mL) were previously prepared with KCl and KOH (to set the initial pH to approximately 7.3) and kept at least 4 h at 25°C. 14 μL of **2** (stock, $c = 2.05 \times 10^{-3}$ mol L^{-1} in DMSO) were added to the sample and mixed (using the mixer for 15 s). After 1 to 2 min, 0.25 mL (micropipette) of the buffer solutions, at the desired pH, were added, and the behaviour of monomer and aggregate equilibrium was monitored with respect to time. For 0, 0.04, and 0.06% P123, experiments were performed in duplicate. To investigate the effect of [**2**] on the pH dependence of aggregation, 0.06% of P123 was used with different concentrations of **2**.

Kinetic investigation of the aggregation process

The same procedures used to investigate the effect of pH on **2**–P123 solutions were used to study the aggregation behaviour with respect to time. Only the kinetics of acid-pH solutions were followed, because at neutral or alkaline pH the aggregation processes were too slow. The monomer and aggregate peaks were monitored simultaneously.

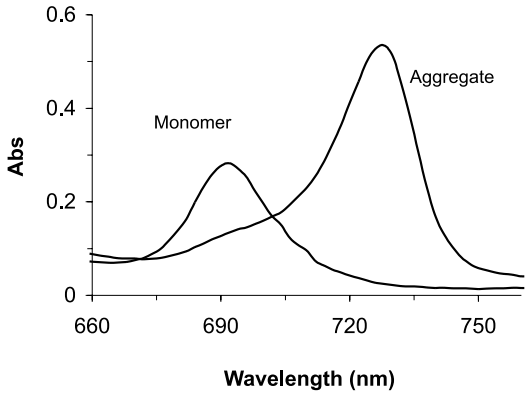
Fig. 1. Visible spectra of **2** in DMSO. Monomer and aggregate ([**2**] = 1.1 × 10^{-5} mol L^{-1} in DMSO–water).



Micellar size determination using laser light scattering

The micelle size was measured by laser light scattering (submicron particle sizer model 370, NICOMP, Santa Barbara, CA). Solutions with 1 mg of **2** and 10% of P123 (pH = 7.4) were analyzed. Solutions at low concentrations of **2** (3.5 × 10^{-6} mol L^{-1}) and Pluronic (0.06 and 0.2%), with pH = 7.4, were also examined.

Formulations

Solutions with different P123 concentrations were prepared by a thin film method. Compound **2** and P123 were codissolved in methylene dichloride; after solvent evaporation via rotary evaporation, the thin film produced was hydrated with an aqueous potassium phosphate solution. Samples were lyophilized and rehydrated using 1 mL of pure water, leading to final solutions composed of [buffer] = 0.01 mol L^{-1}, pH 7.4, [**2**] = 1.4 × 10^{-3} mol L^{-1} (1 mg mL^{-1}), and P123 concentrations as presented in Table 1. After the solution was well mixed, visible spectra were obtained with respect to time.

Aliquots of the solutions prepared as described in Table 1 were frozen immediately after rehydration, and were used to check the stability of the diluted samples. These solutions were defrosted and aliquots of 40 μL were added to 2.0 mL (1:50 dilution) of pure water and buffer solution (pH = 7.4, c = 0.01 mol L^{-1}). The stability of their monomeric species was followed with respect to time.

Results and discussion

For **2** in DMSO (or other organic solvents), the most intense Q-band appeared at 692 nm (ε = 32 000 M^{-1} cm^{-1}), corresponding to the monomeric species, while the aggregate peak showed a red-shifted band with a more intense peak at 715 to 738 nm (see Fig. 1). The wavelength of the aggregate peak was dependent on solution conditions. Samples exhibiting aggregation peaks usually precipitated with time.

For **2** in Pluronic solutions, the monomer peak had a molar absorptivity (ε) around 27 000 M^{-1} cm^{-1}, while the aggregate peak intensity was higher (approximately 50 000 M^{-1} cm^{-1}).

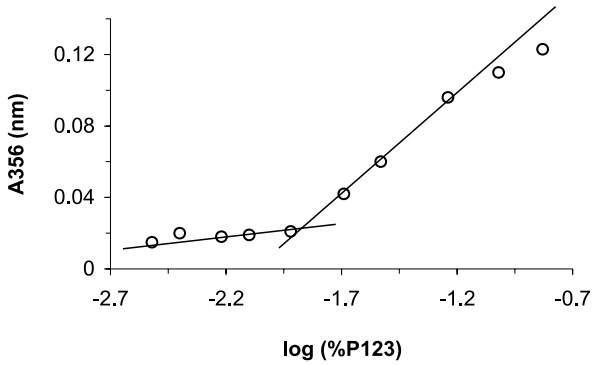
0	16.9	1.7	2
1	26.8	2.7	3
2	47.7	4.8	6
3	75.6	7.6	9
4	100.8	10.1	13
5	125.8	12.6	16
6	154.3	15.4	19
7	199.7	20.0	25

Fig. 2. Absorbance at 356 nm as a function of P123 concentration ([DPH] = 1.6 × 10^{-6} mol L^{-1}, pH = 7.25, [phosphate] = 0.01 mol L^{-1}, 30°C).



Critical micelle concentration of P123

DPH in methanol exhibits an absorption peak at 356 nm and an emission peak at 428 nm (excitation at 356 nm). DPH is insoluble in water (or low P123 concentration). As the P123 concentration increased, the absorbance and fluorescence intensity also increased. A plot of absorbance at 356 nm (or fluorescence intensity at 428 nm) vs. log (%P123) produced two straight lines whose intercept gave the cmc (see Fig. 2 as an example) (13).

Cmc determination using **2** (soluble in water at low concentration) as a probe is based upon a monomer ⇄ aggregation equilibrium (16). Compound **2** in aqueous solutions, at low P123 concentration, exhibited an aggregation band. At higher P123 concentration, this band decreased, while the monomer peak at 692 nm increased. This aggregation behavior of **2** enabled the determination of the P123 cmc. The absorption ratio of the aggregate and monomer peaks as a function of log (%P123) is shown in Fig. 3. The cmc value was obtained from the intercept.

Table 2 presents cmc values obtained from experiments with DPH and **2** under different conditions.

The cited cmc value for P123 at 25°C (13) is 0.03%, which agrees with our results using both probes (0.028% and 0.029% for DPH and **2**, respectively). At 30°C and pH 7.3, the value found with both compounds (0.020%) demonstrated again the agreement between these two methods. The values obtained with **2** at different buffer concentrations (0.01 and 0.1 mol L^{-1}) are in accordance with the literature, which predicts that the cmc decreases with salt

Fig. 3. Effect of P123 concentration on monomer–aggregate equilibrium (25°C) ([**2**] = 6×10^{-6} mol L^{-1}).

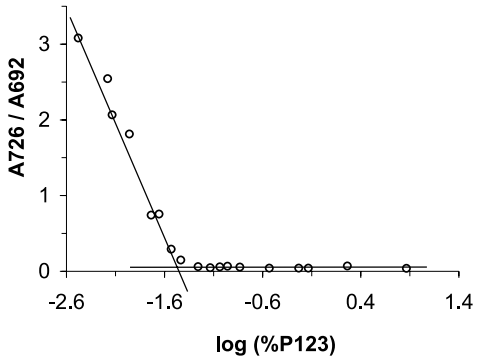

Fig. 4. Effect of pH on monomer–aggregate equilibrium ([**2**] = 1.14×10^{-5} mol L^{-1}, [P123] = 0.04%, [KCl] = 0.1 mol L^{-1}, [buffer] = 0.01 mol L^{-1}) (25°C). Experimental points were obtained at 90 min after buffer addition.

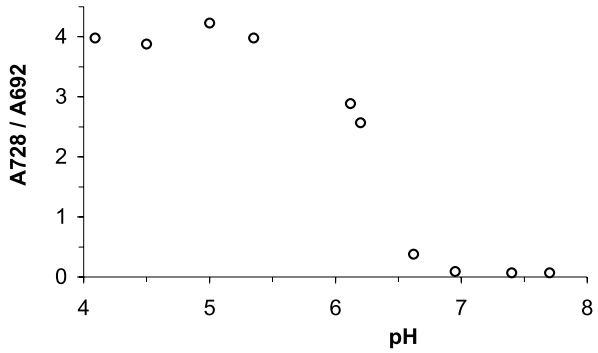

addition (13, 17). These experiments with **2** clearly demonstrated that the micelles of P123 stabilize it in the monomeric form.

Effect of pH on stability

Solutions of **2** in P123 at low pH showed a red-shifted peak corresponding to aggregates. All samples were, therefore, initially prepared at neutral pH (without buffer). At low pH, after buffer addition, a decrease of the 692 nm peak and a simultaneous increase in the aggregate band with respect to time was observed. At neutral or higher pH, aggregation was diminished (but not completely avoided), probably resulting from the negative–negative charge repulsion of the carboxylate group on **2**. The ratio between the aggregate and monomer peaks at an arbitrarily fixed time was taken as a parameter to estimate the magnitude of the effect. An example is presented in Fig. 4.

The extent of the aggregation process with pH (Fig. 4) permits an estimate of the pK_a value of **2** at that Pluronic concentration. This method cannot directly measure pK_a, however, since protonation is followed by aggregation. The pK_a value did not change with time of analysis. For the example presented in Fig. 4, the measured pK_a was 6.4. For solutions without Pluronic, **2** exhibits only one peak around 718 nm, which decreases with time at lower pH. To estimate these pK_as, absorbance as a function of pH was used. Measurements of these apparent pK_a values, obtained using this indirect technique at different P123 concentrations, are shown in Table 3.

Table 2. Average cmc values of P123 using DPH and **2**.

Probe	Temp (°C)	Phosphate (mol L^{-1})	pH	cmc
DPH	25	—	—	0.028
DPH	30	0.01	7.3	0.020
2	25	—	—	0.029
2	30	0.01	7.3	0.020
2	30	0.1	7.3	0.015

Table 3. Apparent pK_a for **2** and the maximum wavelength of the aggregate band at different P123 concentrations (25°C).

[P123] (%, w/v)	Molar ratio [P123]:[**2**]	pK_a (±0.1)	λ_{max} (nm)
0.0	0	6.8	718
0.02	3	6.6	728
0.04	6	6.4	728
0.05	8	—	734
0.06	9	5.8	734
0.07	11	—	735
0.08	12	5.8	734
0.12	18	5.6	736
0.16	24	5.7	736

Note: [KCl] = 0.1 mol L^{-1}; [buffer] = 0.01 mol L^{-1}; [**2**] = 1.14×10^{-5} mol L^{-1}.

In Pluronic solutions, the aggregate peak undergoes a red shift as the Pluronic concentration is increased, probably reflecting the different geometry and size of the micelles. The pK_a values (Table 3) obtained were higher than those expected for a simple carboxylic acid, and probably reflect the local environment.

Increasing the P123 concentration ([P123]:[**2**]) lead to a decrease in pK_a; this effect was caused by a Pluronic micelle forcing molecules of **2** inside the micelle core (away from the micelle surface). Consequently, the porphyrin is exposed to a less hydrophilic environment (18). An abrupt change in pK_a was observed between 0.04% and 0.06% (6.4 to 5.8). This suggested two different micelle populations. Perhaps, one was a unimolecular micelle (0.04%) and the other one was a multimolecular micelle (in 0.06% or higher) (11, 12). These values are more appropriately called the apparent pK_a, because P123 micelles can induce local pH changes (18). Table 4 provides data for the effect of the concentration of **2** on its apparent pK_a.

The apparent pK_a increased as the concentration of **2** increased. This effect resulted from the limited capacity of P123 micelles (at 0.06%) to support high quantities of **2** inside the micelle core (drug loading). As the [P123]:[**2**] molar ratio decreased, more drug molecules were exposed to the micelle surface or bulk solution where they could be protonated and suffer aggregation.

Kinetic investigation of the aggregation process

Acidic solutions of **2** and P123 were prepared by buffer (phthalate) addition. Visible absorption vs. time showed a quasi-isosbestic point at approximately 702 nm that was not

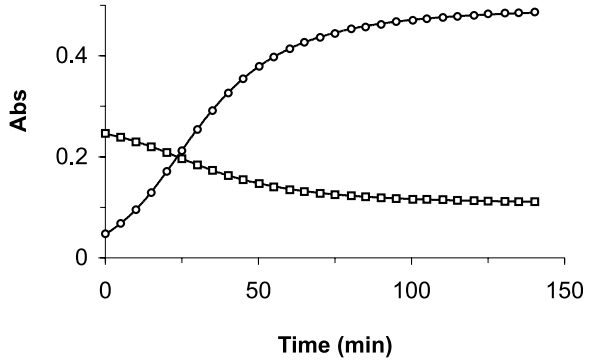
Table 4. Apparent pK_a values of **2** at different concentrations.

[**2**] (10^{-5} mol L^{-1})	Molar ratio [P123]:[**2**]	Apparent pK_a
0.33	32	5.5
1.14	9	5.8
2.02	5	6.2

Note: [P123] concentration fixed at 0.06% (25°C); [KCl] = 0.1 mol L^{-1}; [buffer] = 0.01 mol L^{-1}.

Fig. 5. Kinetic behaviour of **2**–P123 solutions in acidic media ([**2**] = 1.14×10^{-5} mol L^{-1}, [P123] = 0.04%, [P123]:[**2**] = 6, [phthalate] = 0.01 mol L^{-1}, pH = 4, [KCl] = 0.1 mol L^{-1}, T = 25°C). The line represents the theoretical fitting.



well-defined; the absence of a clear isosbestic point suggests a multiple-step reaction. Moreover, supposing dimeric aggregation, the kinetics data should obey a second-order rate equation (19), which is not shown in the present case. Figure 5 illustrates the monomer and aggregate absorption behavior with respect to time. As shown, there is a lag phase, which is preceded by what has been termed "a sigmoidal progress curve" indicating an autocatalytic-type reaction (20). The initial phase is a nucleation step, after which the nucleus promotes a catalytic process where more molecules are added, forming a polymeric aggregate. The initial nucleus could be a dimer of **2**, as is found in the aggregation process in homogeneous solutions (DMSO–water) (21). Figure 5 shows one example of the kinetics of the aggregation process for the drug in Pluronic solution at low pH. The kinetic data has been treated using an approach proposed by Micali et al. (20) and Pasternack et al. (22).

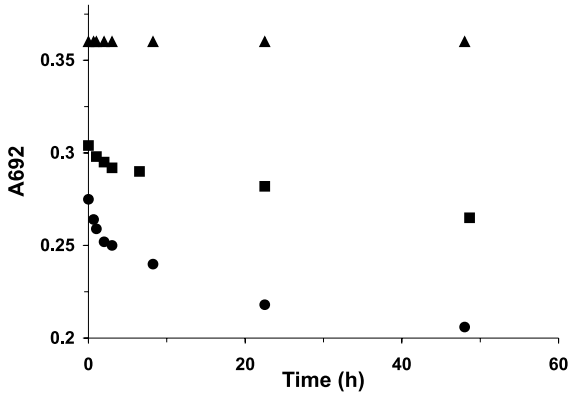
The basis of this kinetic treatment derives from chaos theory, which predicts that the rate constants are themselves time-dependent (20). The kinetic equation is shown in eq. [1]:

$$[1] \quad (abs - abs_i) \,/\, (abs_o - abs_i) = 1 \,/\, (1 + (m-1)\{k_o t + (n+1)^{-1} (k_c t)^{n+1}\})^{1/(m-1)}$$

where abs is the absorbance at time t, abs_o is the absorbance at $t = 0$, abs_i is the absorbance at infinite time, and m, n, k_o, and k_c are kinetic parameters.

The theoretical fit with experimental points (600 points) as a function of time was performed using the software Kaleidagraph (Synergy Software v 3.0.9), which resulted in an excellent correlation coefficient (>0.9999) for these absorption profiles at monomer and aggregate peaks.

Fig. 6. Absorption at monomer peak as a function of time ([**2**] = 1.4×10^{-3} mol L^{-1} (1 mg mL^{-1}), (25°C), pH = 7.4, [phosphate] = 0.01 mol L^{-1}). Light pathway cell length (0.01 cm). Sample 0 (●); sample 1 (■); samples 2–7 (▲).



Micelle size determination

Laser light scattering experiments showed that a solution of **2** and 10% P123 (pH approximately 7.4) resulted in one population of micelles whose size ranged from 15 to 20 nm. After 1 day, these micelles maintained the same size, and the visible spectra confirmed the presence of the drug in monomeric form. For solutions with low concentrations of P123 (0.06%) and **2** (3.5×10^{-6} mol L^{-1}) at pH 7.4, the experiments showed two micelle populations with sizes approximately 20 nm and 100 nm, although with a high χ-square error ($\chi_r^2 = 5$). After 1 day, both micelle populations increased their micelle size (almost double) and the drug started to exhibit the aggregation band. The presence of drug aggregation probably promotes micelle destabilization, inducing an increase in total particle size. Similar micelle (or colloid) size increase was exhibited in a 0.2% P123 solution. Because of the high χ error these results are not accurate, but suggest that a low [P123] results in micelles that cannot adequately sustain monomeric species of the drug.

Drug loading and stability

Samples formulated at pH 7.4 and compositions described in Table 1 were used to investigated the concentrations of P123 that can support 1 mg mL^{-1} of drug (in monomeric form) and their stability, with respect to time, for prolonged use. Figure 6 shows the initial capacity of Pluronic solution that is able to solubilize **2** in monomer form, as well as their stability over time after rehydration with 1 mL of water.

Samples containing P123 at concentrations of 1.7 and 2.7% (samples 0 and 1) exhibited low capacity to load **2** in its monomeric form (time zero). Their spectra did not exhibit an aggregation peak; however, undissolved material remained in the flask. Taking [**2**] = 1.4×10^{-3} mol L^{-1}, ε = 27 000 M^{-1} cm^{-1}, and considering the light path of the cell (0.01 cm), the expected absorbance at 692 nm should be approximately 0.378, which is close to the value of 0.36 obtained experimentally for sample 2 (4.8%) and those at higher [P123].

After 48 h, samples 2 (4.8%) to 7 (20.0%) did not exhibit an aggregate peak, and the absorption at 692 nm did not change (Fig. 7). Samples 0 (1.7%) and 1 (2.7%) exhibited a

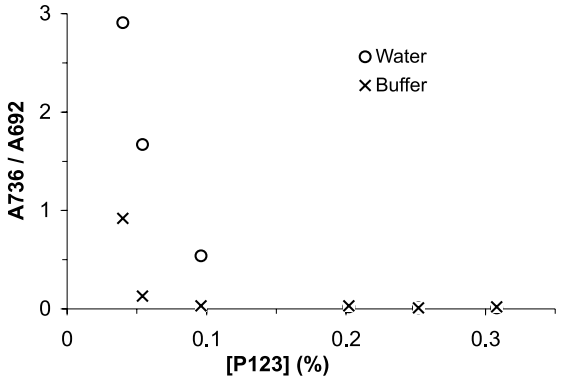
Fig. 7. Ratio of aggregate–monomer absorbances for [P123] solutions at 20 h after dilution (in pure water and in [phosphate] = 0.01 mol L^{-1}, pH = 7.4) ([**2**] = 2.8×10^{-5} mol L^{-1}, 25°C).



new band at 734–736 nm (not shown), which increased with time, while the monomer peak decreased. Thus, for drug loading and stability, samples formulated with P123 at concentrations below 4.8% are not useful for clinical use.

After 20 days (sample solutions were maintained at room temperature in the dark) the absorbance at 692 nm exhibited only a small decrease. The absorbance of sample 2 (4.8%) decreased 5.2%, and sample 4 (10.1%) decreased 4.3%. For samples 5 (12.6%) to 7 (20.0%), absorbance decreases were not observed. The pH of all solutions was 7.4, which means that despite the negative charge, **2** still tended to aggregate. It is important to note, however, that this tendency is much reduced when compared with low pH.

These results show that dilute buffered solutions (pH = 7.4) were more stable for all samples. This formulation process should, therefore, use buffer solutions at pH ≈ 7.4, rather than pure water. Previous buffer (from the cake) cannot adequately sustain the pH for formulations after dilution (1:50) in pure water. At 20 h, samples diluted in pure water exhibited aggregation at 0.20% (original 10.1%) of P123 (or higher), while for dilution made in the buffer, the solution at 0.10% (original 4.8%) of P123 was still stable.

Conclusion

Micelles of P123 in water can support **2** in its monomeric form. The monomer ⇄ aggregate equilibrium of the drug can provide a reasonable estimation of the pK_a for **2**, and permits cmc determinations for Pluronic. The apparent pK_a of **2** decreased as the molar ratio ([P123]:[**2**]) increased. Mixtures of **2** with low [P123] showed unstable micellar systems, leading to drug aggregation. Acidic solutions of the drug in Pluronic underwent aggregation via a self-catalytic process, where the rate constant, or "rate coefficient" (22), is time dependent, and can be analyzed by chaos theory. Prevention of the nucleation step can slow down the aggregation process. The best conditions for Pluronic micelles to sustain **2** as a monomeric species were high molar ratios and neutral pH. Samples with a Pluronic concentration of 4.8% (molar ratio = 6) or higher showed high drug loading and capacity to support the drug in monomeric form. After dilution (1:50) in buffer solution at pH 7.4, these samples still demonstrated high stability.

One-pot sequential Pauson–Khand reaction – transfer hydrogenation

André Hätzelt and Sabine Laschat

Abstract: The Pauson–Khand reaction of norbornene (**1**) and phenylacetylene (**2**) and subsequent $RuCl_2(PPh_3)_3$-catalyzed transfer hydrogenation of the resulting enone (**3**) can be carried out in a one-pot sequence if the base is added after an induction period. The desired ketones (**4a**, **4b**) were obtained in good yield as a mixture of diastereomers (diastereomeric ratio (dr.) 58:42). The relative rates of both the Pauson–Khand reaction and the transfer hydrogenation are decreased by a factor of 2 in the sequence, as compared with the isolated reactions.

Key words: Pauson–Khand reaction, transfer hydrogenation.

Résumé : La réaction de Pauson–Khand du norbornène (**1**) et du phénylacétylène (**2**) et la réaction d'hydrogénation par transfert, catalysé par $RuCl_2(PPh_3)_3$, de l'énone **3** qui en résulte peuvent être effectuées par le biais d'une séquence unitope si la base est ajoutée après une période d'induction. Les cétones recherchées (**4a**, **4b**) sont obtenues avec un bon rendement sous la forme de diastéréomères (58:42). Comparées aux vitesses de réaction isolées, les vitesses relatives de chacune des réactions de Pauson–Khand et d'hydrogénation par transfert sont plus lentes par un facteur de deux.

Mots clés : réaction de Pauson–Khand, hydrogénation par transfert.

[Traduit par la Rédaction]

Introduction

Among the various stoichiometric and catalytic organometallic reactions two types have received increased interest recently. One is the heterobimetallic catalysis, in which two different metal centres cooperatively promote a certain reaction (1). The other type deals with metal-catalyzed tandem or domino reactions, in which one particular metal complex controls a sequence of two or more reactions (2, 3). In contrast, only a few examples are known where different metal complexes were employed for each step within a one-pot sequence. Takahashi reported a one-pot sequential asymmetric hydrogenation utilizing Rh(I) and Rh(III) complexes (4). A one-pot sequence of a Heck reaction and ring-closing metathesis involving Pd complexes and Grubbs catalyst, was discovered by Grigg (5). We anticipated that a combination of C-C coupling and hydrogenation might be synthetically useful. However, such a combination requires that the two different metal complexes employed for each step do not interfere with each other. To address this issue, we chose a sequence consisting of a Pauson–Khand reaction (6) of norbornene (**1**) and phenylacetylene (**2**) to the cyclopentenone (**3**) followed by catalytic transfer hydrogenation (7) as a model system to give the diastereomeric ketones (**4a**, **4b**) (Scheme 1). Although both reactions are well known (6, 7), a combination of these has not yet been studied. Our preliminary results towards this goal are reported below.

Results and discussion

Transfer hydrogenations employing $RuCl_2(PPh_3)_3$ as the catalyst precursor require the presence of a secondary alcohol and a base as the cocatalyst (8). We were worried that the Pauson–Khand reaction might not tolerate these reaction conditions, and thus we first investigated the influence of solvent and various additives on the $Co_2(CO)_8$-mediated thermal cocyclization of **1** and **2** to give **3**. The reactions were monitored by capillary GC. The results in Table 1 indicate that both toluene and *i*-PrOH gave high conversions to the desired enone (**3**) (Table 1, entries 1, 2). However, in *i*-PrOH small amounts of the transfer hydrogenation products **4a** and **4b** were formed as well (9).[2] The Pauson–Khand reaction also proceeded cleanly in *i*-PrOH in the presence of KOH (Table 1, entry 3). When PPh_3 was added, high conversion to **3** was again observed irrespective of the solvent (Table 1, entries 4, 5). Running the cocyclization in the presence of $RuCl_2(PPh_3)_3$ afforded only the enone (**3**) albeit with lower conversion (Table 1, entries 6, 7). However, treatment of **1** and **2** with $Co_2(CO)_8$ in refluxing *i*-PrOH in the

[2]Recently Krafft reported the conversion of enynes to bicyclic cyclopentanones in *i*-PrOH in the presence of $Co_4(CO)_{12}$. Deuterium labeling studies showed that this sequential Pauson–Khand reaction – 1,4-reduction involves $HCo(CO)_4$ as a catalytic species, which delivers the hydride from *i*-PrOH to the cyclopentenone.

[c]KOH was added at the beginning.
[d]KOH was added after 30 min.
[e]KOH was added after 2 h.

presence of $RuCl_2(PPh_3)_3$ and KOH yielded exclusively enone **3** (entry 8). Surprisingly, the transfer hydrogenation was completely suppressed. In contrast, when isolated enone **3** was treated with 0.1 equiv of $RuCl_2(PPh_3)_3$ and 1.0 equiv of KOH in *i*-PrOH under reflux, the transfer hydrogenation was complete after 4 h, and the desired ketones (**4a**, **4b**) could be isolated after flash chromatography in 44% and 10% yield, respectively, together with 5% of the saturated alcohol **5** (Scheme 1).

According to results by Szabo and Bäckvall (8) in the transfer hydrogenations of ketones the active catalytic species ($RuH_2(PPh_3)_3$) is formed in situ during an induction period from $RuCl_2(PPh_3)_3$ via an alkoxide displacement – β-elimination sequence, giving $Ru(H)Cl(PPh_3)_3$, followed by a second alkoxide displacement – β-elimination sequence. Presumably, in our system the dihydride species or the chlorohydride complex interfere with the cobalt cluster. To avoid premature formation of $RuH_2(PPh_3)_3$ or $Ru(H)Cl(PPh_3)_3$, the base was added after a considerable induction period (30 min). As shown in entry 9 of Table 1, enone **3** and ketones **4a** and **4b** were obtained in a ratio of 46:28:26. In contrast to the above-mentioned case where the transfer hydrogenation was carried out in a separate step, no trace of the saturated alcohol (**5**) was observed in the sequential one-pot reaction. The amount of ketones **4a** and **4b** could be further increased when a prolonged induction period (2 h) was used (entry 10). Monitoring the consecutive reaction sequence by capillary GC (Fig. 1) revealed almost quantitative conversion to the enone (**3**) within 2 h, followed by clean transfer hydrogenation upon addition of the base, yielding **4a** and **4b** in a final diastereomeric ratio of 58:42. Again, no saturated alcohol (**5**) was found.

The inhibitory effect of $Co_2(CO)_8$ on the presumed Ru dihydride or Ru chlorohydride catalyst was further supported by the observation that the attempted transfer hydrogenation of enone **3** in the presence of $RuCl_2(PPh_3)_3$ (0.1 equiv),

© 2002 NRC Canada

KOH (1.0 equiv), and $Co_2(CO)_8$ (1.0 equiv) in *i*-PrOH did not gave any trace of the desired ketones (**4a**, **4b**). However, the enone (**3**) partially decomposed, and only 64% of **3** could be reisolated after 4 h.

According to qualitative kinetic experiments the reaction rates of both the Pauson–Khand reaction and transfer hydrogenation in the sequence are decreased by a factor of 2.3 and 1.7, respectively, as compared with the rates obtained for separately performed reactions.[3]

The results indicate that in our system the chlorohydride complex is probably the major active catalytic species. From seminal work by Sasson and co-workers (10) and Wilkinson and co-workers (11), it is known that $Ru(H)Cl(PPh_3)_3$ adds to C=C double bonds (in hydrogenations, isomerizations, and transfer hydrogenations) but is unreactive towards ketones (8, 12). In contrast, $RuH_2(PPh_3)_3$ readily converts ketones to the corresponding secondary alcohols (8). The dominating role of the chlorohydride would also explain the good results obtained when KOH was added after 2 h. In this case the conversion to the dihydride would be delayed and the chlorohydride would be present for a longer period of time. The decreased diastereoselectivity in the one-pot reaction may be due to conjugate hydride delivery to the enone (**3**) from the chlorohydride, giving the corresponding enolate, whose *Re* and *Si* faces are protonated by *i*-PrOH with equal probability. Alternatively, ketones **4a** and **4b** can undergo base-catalyzed enolization under the reaction conditions.

Experimental

General procedure for the thermal Pauson–Khand reaction

To a solution of $Co_2(CO)_8$ (680 mg, 2.00 mmol) in toluene or *i*-PrOH (20 mL) was added phenylacetylene (**2**) (200 mg, 2.00 mmol), and the resulting mixture was stirred for 1 h at room temperature. Norbornene (190 mg, 2.00 mmol) was then added, and the mixture was refluxed until TLC indicated complete conversion. The solvent was removed in vacuo and the residue was purified by flash chromatography on SiO_2 (hexanes – ethyl acetate 25:1) to give 350 mg (78%) of enone **3** as a colorless solid; mp 86°C. Spectroscopic and analytic data of **3** were in accordance with ref. 13.

General procedure for the transfer hydrogenation

To a solution of $RuCl_2(PPh_3)_3$ (40 mg, 0.042 mmol) in *i*-PrOH (30 mL) were added enone **3** (110 mg, 0.50 mmol) and KOH (28 mg, 0.50 mmol), and the mixture was refluxed for 4 h. After cooling to room temperature, the mixture was hydrolyzed with saturated (sat.) NH_4Cl solution (20 mL) and extracted with CH_2Cl_2 (3 × 20 mL). The combined organic layers were dried over $MgSO_4$ and purified by flash chromatography on SiO_2 (hexanes – ethyl acetate 50:1) to yield 50 mg (44%) of ketone **4a** as the first fraction, 10 mg (10%) of ketone **4b** as the second fraction, and 6 mg (5%) of alcohol **5** as the third fraction.

One-pot Pauson–Khand reaction – transfer hydrogenation

To a solution of $Co_2(CO)_8$ (0.86 g, 2.50 mmol) and $RuCl_2(PPh_3)_3$ (120 mg, 0.12 mmol) in *i*-PrOH (50 mL) were added phenylacetylene (**2**) (255 mg, 2.50 mmol) and then norbornene (**1**) (235 mg, 2.50 mmol), and the mixture was refluxed for 2 h. KOH (73 mg, 2.50 mmol) was then added, and heating was continued for 2 h. After cooling to room temperature, the mixture was hydrolyzed with sat. NH_4Cl solution (50 mL) and extracted with CH_2Cl_2 (3 × 50 mL). The combined organic layers were dried over $MgSO_4$, evaporated, and the crude product was purified by flash chromatography on SiO_2 (hexanes – ethyl acetate 50:1) to give 186 mg (33%) of **4a** and 136 mg (24%) of **4b**.

109 (22), 104 (56), 91 (48), 77 (16). HR-MS calcd. for $C_{16}H_{20}O$: 228.1514; found: 228.1513.

The relative configurations of **4a**, **4b**, and **5** were established by 2D NMR experiments (COSY, CH correlation, and NOESY).

Conclusion

In conclusion, it has been demonstrated that a two-step sequence of cobalt-mediated cocyclization followed by a ruthenium-catalyzed transfer hydrogenation can be performed in one pot in the presence of both metal centres that do not interfere with each other, as long as the second reaction is triggered by delayed addition of base. However, to overcome limitations such as decreased diastereomeric ratio of the transfer hydrogenation step and decreased reaction rates other catalyst systems must be explored.

An ab initio investigation of scandium chloro complexes

Cory C. Pye and Christopher R. Corbeil

Abstract: A series of geometry, frequency, and energy calculations of chloroaquascandium(III) complexes were carried out at up to the MP2/6-31+G* level. A thorough examination of all species up to and including hexacoordinate species, and with up to six chlorides, was carried out. The structures of the complexes are compared with experimental data where available. The solution chemistry of scandium(III) in the presence of chloride is discussed.

Key words: scandium, aqua complexes, chloro complexes, ab initio.

Résumé : Opérant au niveau MP2/6-31+G* de la théorie, on a calculé une série de géométries, de fréquences et d'énergies de complexes chloroaquascandium(III). On a procédé à un examen approfondi de toutes les espèces allant jusqu'aux espèces hexacoordinées et celles comportant jusqu'à six ions chlorures. On a comparé les structures calculées des complexes avec les données expérimentales disponibles. On discute de la chimie en solution du scandium(III) en présence de chlorure.

Mots clés : scandium, complexes aqua, complexes chloro, ab initio.

[Traduit par la Rédaction]

Introduction

Scandium chloride plays an important role in the purification of scandium metal. For scandium, electrochemical deposition from aqueous or organic electrolytes is impossible or ineffective, and one must resort to fused-salt electrolysis. Careful control of the conditions can afford high-purity scandium from electrolysis (1–4). To avoid oxide formation, the scandium chloride should be as free of water as possible. This can be achieved by adding ammonium chloride, which forms the stable ammonium hexachloroscandate(III) (5–7). Other purification techniques include chemical vapor deposition (8).

Scandium has recently been shown to occur as a hexahydrate in aqueous perchlorate solution through a combination of theoretical ab initio and Raman spectroscopic techniques, contradicting earlier reports of a heptahydrate (9). In perchlorate solution, a single isotropic Raman band at 442 cm^{-1} is assigned to the Sc-O symmetric stretching vibration. In 2.55 M scandium chloride solution, this band, which moves to 436 cm^{-1}, has a shoulder at 420 cm^{-1} and a new polarized band at 306 cm^{-1} appears, which was previously interpreted as evidence against a hexaaqua complex. The band at 306 cm^{-1} can be diluted out, whereas the band at ca. 440 cm^{-1} remains, which suggests that there exists an equilibrium between hexaaquascandium(III) and some chloro complex of unknown stoichiometry. It is our aim in this paper to more precisely define this chloro complex through an analysis of our ab initio calculations and comparison with the experimental literature.

Method

Calculations were performed using Gaussian 98 (10), utilizing the 6-31G*(11) and 6-31+G*(12) basis sets. The MP2 calculations utilize the frozen core approximation. The geometries were optimized using a stepping stone approach, in which the geometries at the levels HF/STO-3G, HF/3-21G, HF/6-31G*, HF/6-31+G*, MP2/6-31G*, and MP2/6-31+G* were sequentially optimized. Default optimization specifications were normally used. After each level, where possible, a frequency calculation was performed at the same level and the resulting Hessian used in the following optimization. *Z*-Matrix coordinates constrained to the appropriate symmetry were used as required to speed up the optimizations. Since frequency calculations are done at each level, any problems with the *Z*-matrix coordinates would manifest themselves by giving imaginary frequencies corresponding to modes orthogonal to the spanned *Z*-matrix space. The Hessian was evaluated at the first geometry (opt = CalcFC) for the first level in a series to aid geometry convergence. For structures which proved not to be local minima at the HF/6-31G* level, the subsequent calculations were not performed.

Results and literature comparison

In our previous work with scandium, we used the 6-31G* basis set for water, with a different scandium basis set (9). Since the time that these calculations were done, a 6-31G* basis set for scandium has been published (11). We therefore repeat our calculations on the aquascandium species up to the hexahydrate with this new basis set. Ammonium

hexachloroscandate(III) exists, and thus it seems reasonable to restrict our attention up to and including hexacoordination.

Aquascandium complexes ($Sc(H_2O)_n^{3+}$)

Figure 1 gives the structures of the aquascandium clusters. Compared with results from our previous paper, the Sc—O distances are shorter by between 0.005 and 0.02 Å, with the biggest differences occuring for the smaller clusters (see supplementary data)[2]. The agreement with the experimental solution value for the Sc—O distance remains excellent (9). In Fig. 2, the total electronic binding energies are given as a function of the total coordination number. For the aqua complexes, the total binding energies are, for the most part, within 20 kJ mol^{-1} of our previous results with a smaller scandium basis set. For the symmetric stretching vibrational frequency, the frequencies are systematically within 10 cm^{-1} lower of the previous result and are given in Fig. 3. We emphasize again in this work that, because of the effect of the second hydration sphere on the vibrational frequencies, the vibrational modes are underestimated by about 50 cm^{-1}, and thus we expect that for the chloro complexes, a similar pattern will be observed.

Chloroaquascandium complexes ($ScCl(H_2O)_n^{2+}$)

The structures of the monochloroaquascandium complexes are given in Fig. 4. Initially, for a given stoichiometry, a structure with the highest reasonable symmetry was tried first, followed by desymmetrized structures. Initial point groups for the bare through to the pentahydrated structure are $C_{\infty v}$, C_{2v}, C_{2v}, C_{3v}, C_{4v}, and C_{2v}, respectively. For the monohydrate, imaginary modes suggested a desymmetrization to the C_s point group, for which there are two structures. Only one of these structures (no. 2) is a local minima. Here, all atoms are in the symmetry plane. At the HF/6-31G* level, the C_{2v} structure is 24.6 kJ mol^{-1} higher in energy than the C_s no. 2 structure, whereas the other structure C_s no. 1 is 8.1 kJ mol^{-1} higher.

For the dihydrate, two different C_{2v} structures are possible, but neither is a local minimum. Of these two, the structure in which all atoms are in the same plane (no. 1) is lower

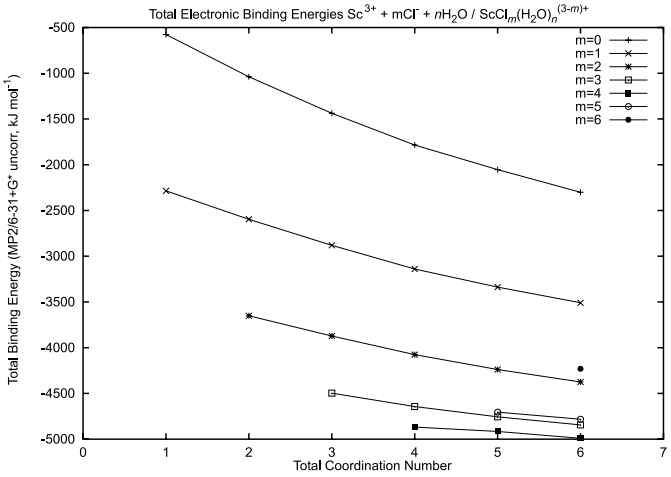

Fig. 3. Skeletal stretching frequencies of aquascandium complexes.

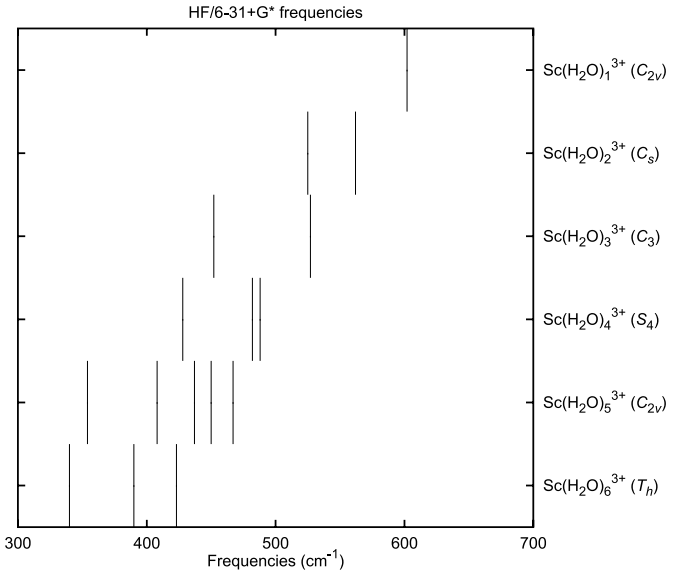


in energy, and so we retain this feature and desymmetrize to C_s, which is a local minimum and is only 0.14 kJ mol^{-1} lower in energy. This means that the potential energy surface is extremely flat in the out-of-plane deformation coordinate. The other C_{2v} structure (no. 2) is 15.6 kJ mol^{-1} higher in energy than the minimum, which is approximately twice as much as the difference between the two C_s structures in the monohydrate, and suggests that whatever factor is responsible for the difference is additive.

The trihydrate retained its symmetry. The C_{4v} tetrahydrate structure possessed an imaginary frequency of irreducible representation A_2. This suggested a desymmetrization to a C_4 point group, which was 9.3 kJ mol^{-1} lower, but also had an imaginary frequency. The final structure became C_{2v} and was an additional 2.9 kJ mol^{-1} more stable. The C_{2v} pentahydrate structure underwent a slight desymmetrization to C_2. Energetically there is very little difference, but the waters in the plane perpendicular to the Sc-Cl contact twist significantly out of that plane, which suggests a low twisting potential barrier.

The Sc—O and Sc—Cl distances of all monochloro complexes are given in the supplementary data.[2] The Sc—Cl distance increases with the addition of water, especially when the final water is added trans to the chlorine in the hexacoordinated species. All Sc—O distances lengthen considerably when a water is replaced by a chloride by between 0.01 to 0.07 Å, with typical values in the middle of this range. Although the Sc—O distance is moderately sensitive to the theoretical level (by 0.02 Å amongst HF/6-31G* to MP2/6-31+G*), the Sc—Cl distance is slightly more sensitive (0.04 Å) for the higher hydrates, with the correlated levels giving shorter distances. The longer distances upon chloride substitution should translate to smaller Sc-O vibrational frequencies, and the MP2 frequencies for the Sc-Cl vibration should be higher than those calculated at the Hartree–Fock level. These trends are verified, although the Sc-O decrease is much more pronounced.

In Fig. 5, the frequencies of the Sc-Cl and Sc-O stretching modes are plotted for the complexes. The Sc-Cl frequency is consistently the highest. For lithium chloride solutions, the effect of the environment as waters are added on the Li-Cl mode is to increase significantly the frequency, and thus we expect that the frequency will be even higher (13). This evidence, combined with the fact that dichloro complexes are energetically even more stable, makes it clear that the chloropentaaquascandium(III) complex is not responsible for the polarized mode at 306 cm^{-1}.

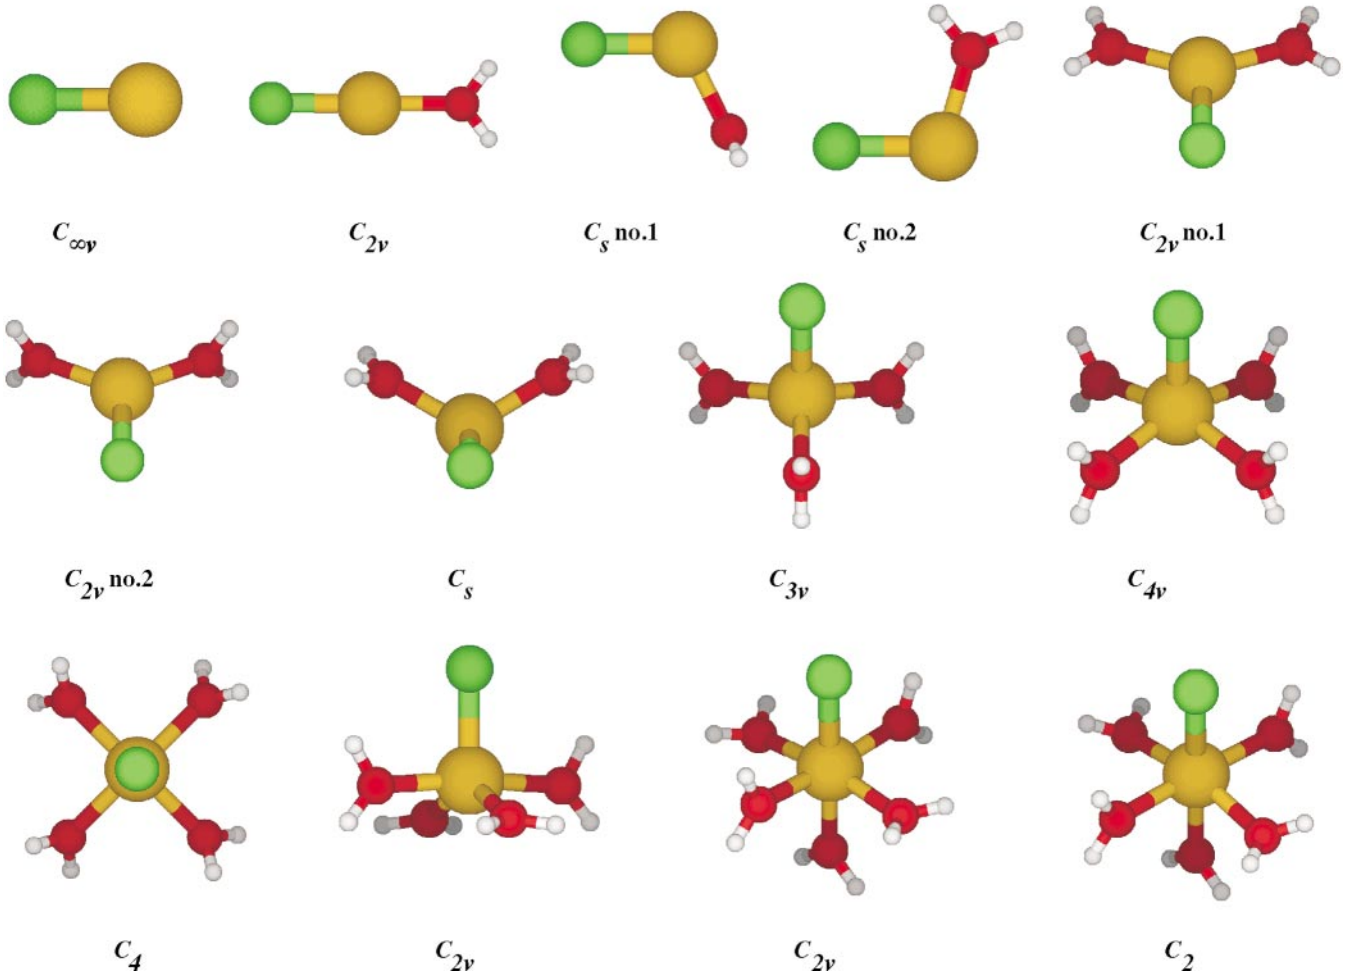
Dichloroaquascandium complexes ($ScCl_2(H_2O)_n^+$)

The structures of dichloroaquascandium complexes are given in Fig. 6. Initial point groups for the bare through to the dihydrated structure are $D_{\infty h}$, C_{2v}, and C_{2v}. For the trigonal bipyramidal pentacoordinate species, a D_{3h} trans and two C_s cis structures were tried, and for the octahedral hexacoordinate structures, a C_{2v} cis and D_{4h} trans structure were tried. The bare $ScCl_2^+$ distorted to form a C_{2v} structure, which was about 11 kJ mol^{-1} lower in energy at the HF/6-31G* level. Of the two C_{2v} structures tried for each of the monohydrate and dihydrate, structure no. 1 was preferred by 14 and 28 kJ mol^{-1}, respectively, at the same level. Of the two possible C_s structures for the cis trihydrate, neither was an energy minimum, and upon desymmetrization, underwent a pseudo-rotation to form the stable trans structure (D_{3h}). In the process, the structures gained 96 and 101 kJ mol^{-1}, respectively. Both the cis and the trans forms of the tetrahydrate are stable, although the cis structure desymmetrized to C_2 and is less stable than the trans by between 20–35 kJ mol^{-1}, depending on the level of theory.

The Sc—O and Sc—Cl distances of all dichloro complexes are given in the supplementary data.[2] The Sc—Cl distance is uniformly larger in the dichloro complex, regardless if we compare structures with the same number of waters (0.09 to 0.15 Å) or with the same coordination number (0.06 to

© 2002 NRC Canada

Fig. 4. Structures of aquamonochloroscandium complexes.



0.11 Å). The Sc—O distance is generally larger as well, but this effect is not as pronounced, and the difference tends to decrease as the number of waters increases. The longer distances upon chloride substitution should translate to smaller Sc-O and Sc-Cl vibrational frequencies.

We may compare the Sc—O and Sc—Cl distances found for $ScCl_2(H_2O)_4^+$ with the analog $ScCl_2(thf)_4^+$ from the experiment (14). The Sc—Cl distances are in the 2.405 to 2.408 Å range, whereas our calculations suggest a slightly shorter distance of 2.35 to 2.39 Å, depending on the level of theory. The theoretical distance of 2.21 Å is too long compared with the experimental Sc—O distance of 2.13 to 2.17 Å, although the effect of crystal packing forces and the different oxygen-bearing ligand must be considered as possible factors responsible for the deviation.

The experimental band at 306 cm^{-1} has been assigned to a Sc-Cl stretch in a chloro complex of scandium. The polarized nature of the band suggests that it would be a symmetric in-phase combination of both chlorides. Figure 7 gives the frequencies of the dichloro complexes. The only dichloro species fitting this description would be the *trans*-dichlorotetraaquascandium(III) species, which has a predicted Sc-Cl symmetric band at around 300 cm^{-1}. However, from known errors in metal–chloro stretching frequencies due to the neglect of the environmental effects, we know that

Fig. 5. Skeletal stretching frequencies of aquamonochloroscandium complexes.

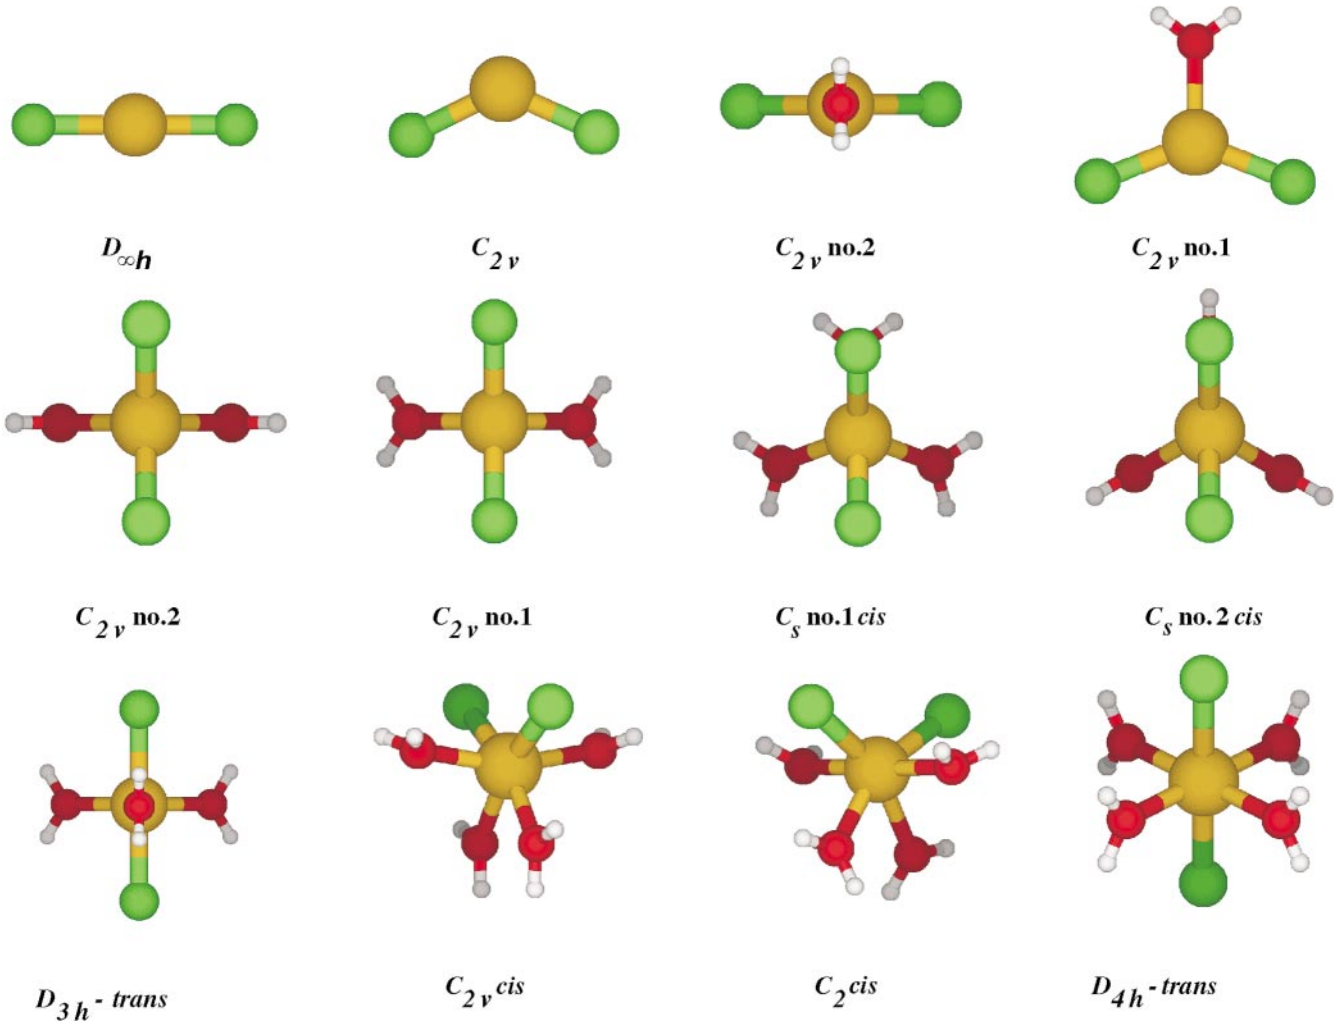
Fig. 6. Structures of aquadichloroscandium complexes.



this is most likely underestimated. In addition, the shoulder observed experimentally at 420 cm^{-1} might correspond to the Sc-O stretching mode at 353 cm^{-1} predicted theoretically, especially considering that the experimental mode at 442 cm^{-1} is predicted theoretically at 390 cm^{-1}. This species thus remains a possibility.

Trichloroaquascandium complexes ($ScCl_3(H_2O)_n$)

The structures of trichloroaquascandium complexes are given in Fig. 8. Trichloroscandium(III) itself has D_{3h} symmetry. When a single water adds to $ScCl_3$, two possible C_s structures can be formed, depending on the orientation of the water. The second structure is preferred at the HF/6-31G* level by 0.6 kJ mol^{-1}, and has no imaginary frequencies. Clearly the potential is very flat with respect to water librations. A second water will give a trigonal bipyramidal structure and therefore gives rise to trans or cis possibilities. For the waters in a trans arrangement, either a C_s or a C_{2v} structure can be formed. Similar to the one-water case, the C_{2v} structure is a local minimum, whereas the C_s structure has an imaginary frequency and is higher in energy by 5.3 kJ mol^{-1}. A stable C_s cis structure was also found 14–22 kJ mol^{-1} higher in energy, depending on theory. For the octahedral trihydrate, both facial (fac) and meridianal

Fig. 7. Skeletal stretching frequencies of aquadichloroscandium complexes.

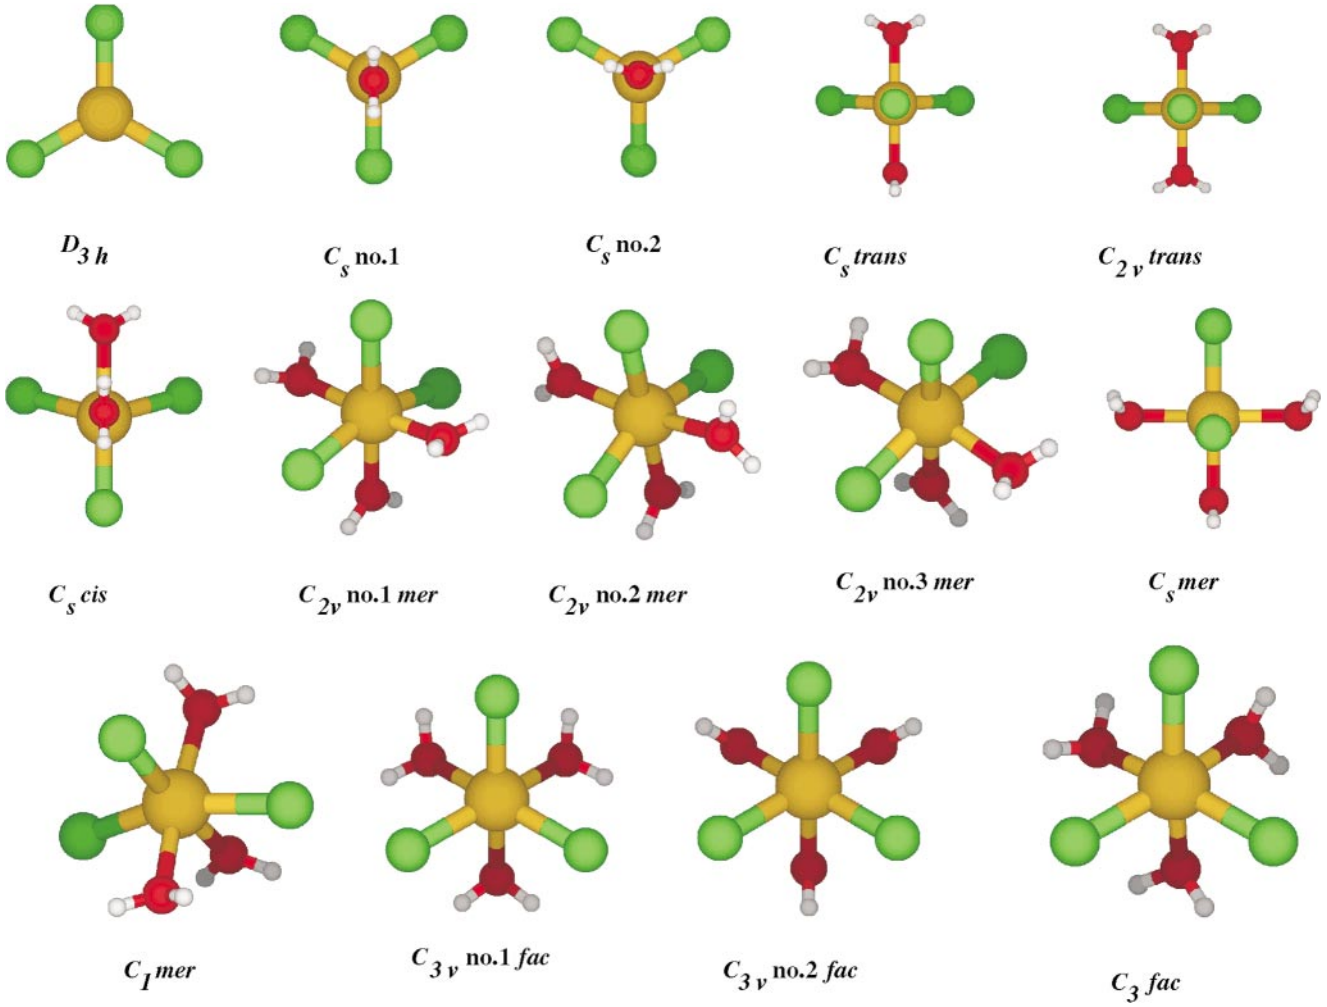
Fig. 8. Structures of aquatrichloroscandium complexes.

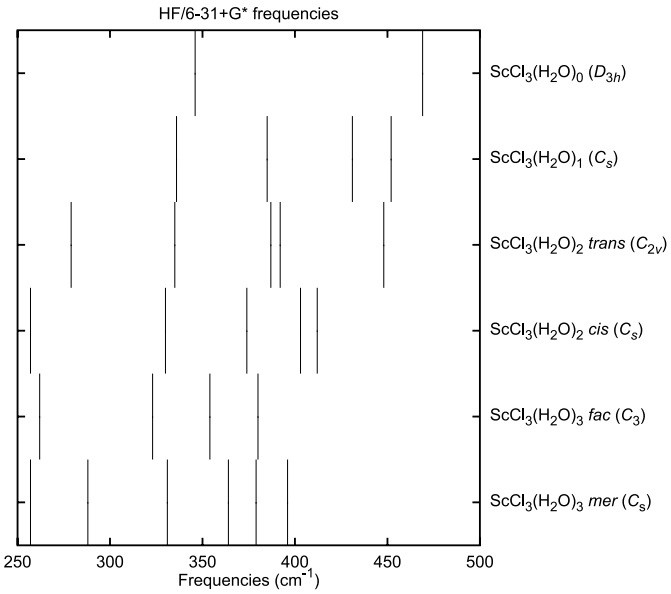


(mer) structures are possible. For the mer geometry, we tried three different C_{2v} structures. None of these structures were local minima, but the first one had the lowest energy overall, and were respectively 0.2, 25.5, and 29.8 kJ mol^{-1} higher than the best structure. The imaginary frequency suggested a desymmetrization to C_s. The structure obtained also has an imaginary frequency, so we removed symmetry, which gave a local minimum 0.2 kJ mol^{-1} lower. Of the fac structures, we started with two different C_{3v} structures, neither of which were minima, but both suggested a desymmetrization to C_3, which was a minima. The C_{3v} structures were 2.5 and 61.7 kJ mol^{-1} less stable than the C_3 structure. The fac structure was 9.0 kJ mol^{-1} less stable than the mer structure.

The Sc—O and Sc—Cl distances of all trichloro complexes are given in the supplementary data.[2] The Sc—Cl distance is uniformly larger in the trichloro complex, regardless if we compare structures with the same number of waters (0.06 to 0.09 Å) or with the same coordination number (0.02 to 0.05 Å). The Sc—O distance is generally larger as well, but this effect is not as pronounced.

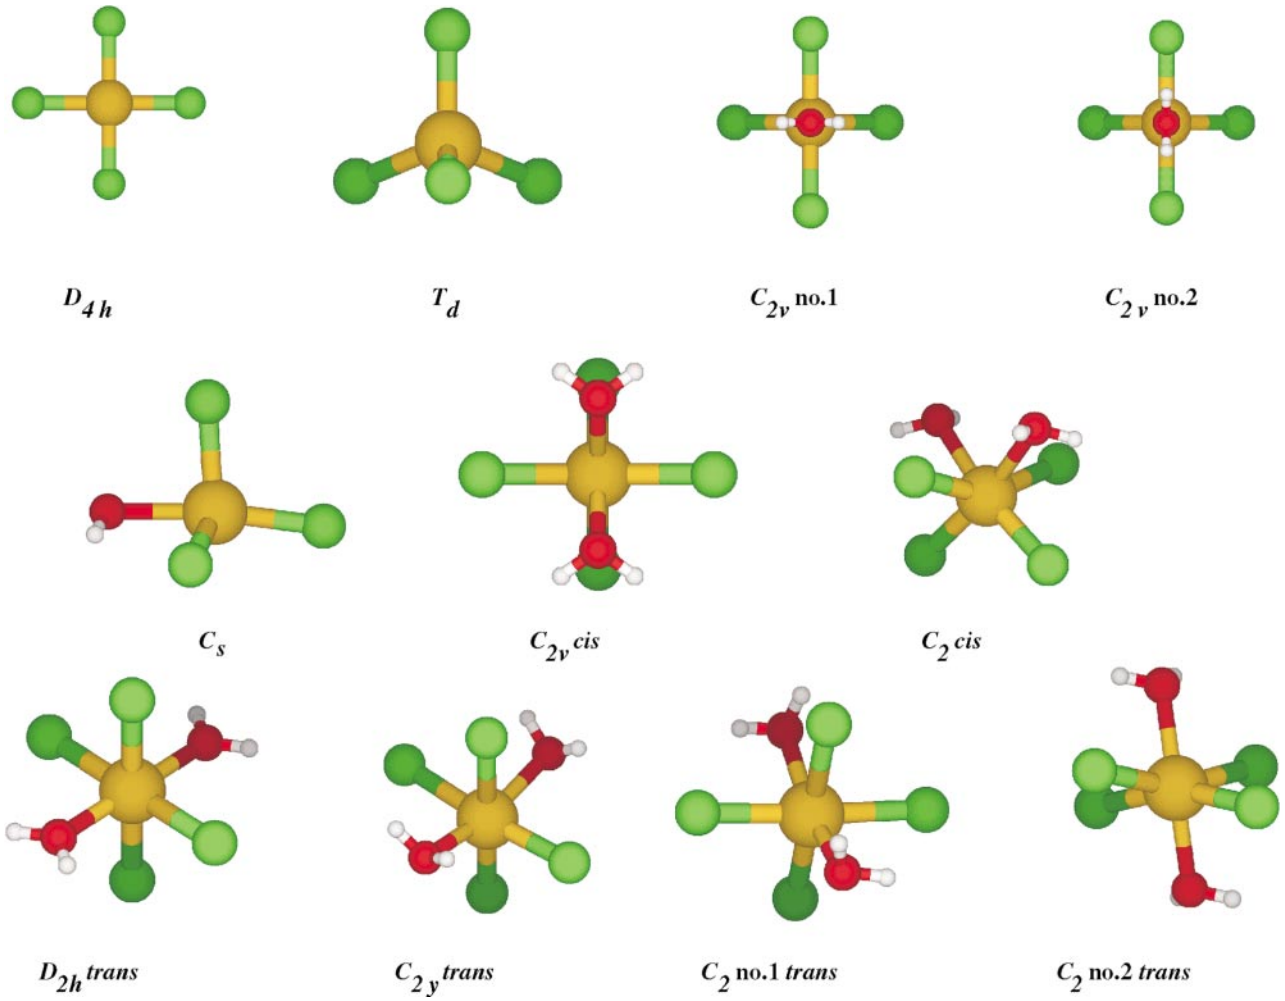
We may compare these structures to some observed experimentally. From gas-phase electron diffraction measurements of $ScCl_3$, the bond length was determined to be 2.291 Å, and supported by BP86/TZP calculations (2.285 Å) (15). Our result of 2.289 Å at the MP2/6-31+G* level compares very

Fig. 9. Skeletal stretching frequencies of aquatrichloroscandium complexes.



© 2002 NRC Canada

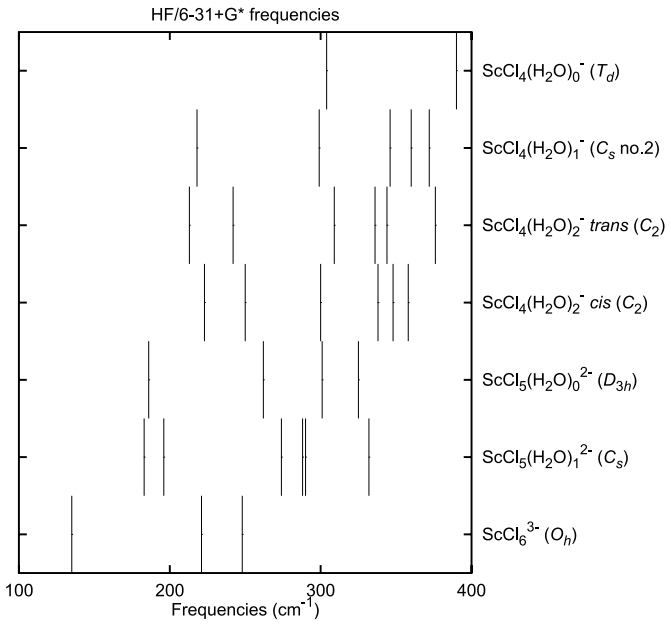
Fig. 10. Structures of aquatetrachloroscandium complexes.



favorably with both the ED and DFT results. The X-ray structure of $ScCl_3$(diglyme) and $ScCl_3$(DME)(MeCN) indicate that the fac structure is obtained (16). Sc—Cl distances of 2.3686 to 2.4104 Å and Sc—O distances of 2.165 to 2.257 Å may be compared with the analogous Sc—Cl distances of 2.37 to 2.41 Å and Sc—O distances of 2.29 to 2.30 Å depending on the level of theory. The Sc—Cl distance is described well, whereas the Sc—O distance is overestimated. Ligand effects and crystal packing must be invoked to account for the difference. The X-ray structure of $ScCl_3(thf)_2(H_2O)$ has also been determined to have the mer geometry (17). The Sc—Cl X-ray distances range from 2.399 to 2.478 Å and the Sc—O distances range from 2.170 to 2.197 Å. In $ScCl_3(H_2O)_3$, the Sc—Cl distance varies from 2.413 to 2.419 Å, and the mean Sc—O distance is 2.122 Å (18). We may compare this to the analogous ranges 2.37 to 2.46 Å and 2.23 to 2.26 Å. Again, as was the case for the fac structure and for the dichloro structures, the Sc—O distance is overestimated. This would tend to underestimate the vibrational frequency of the Sc—O stretching vibration.

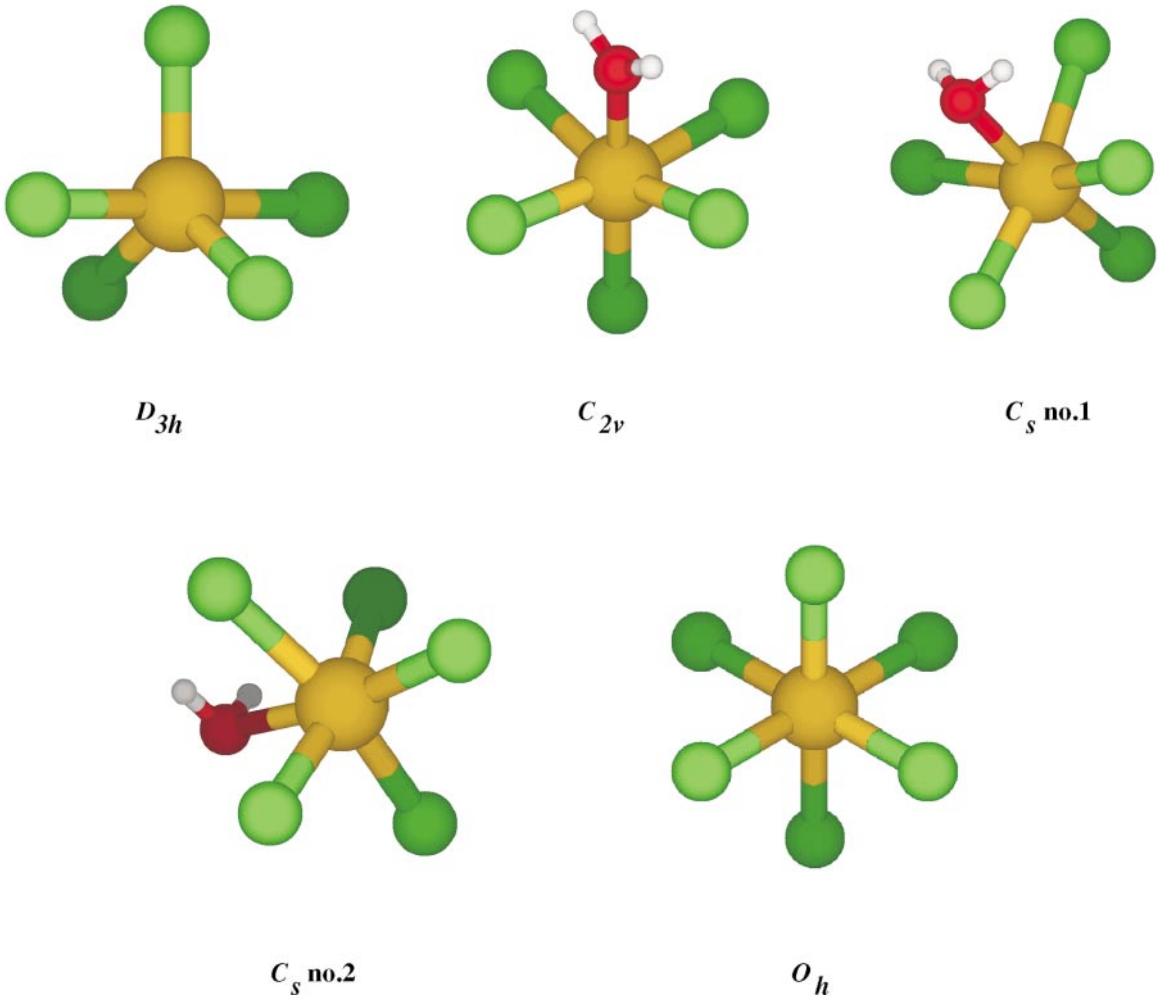
Figure 9 gives the frequencies of the trichloro complexes. Two trichloro species may be regarded as possible candidates based upon the frequency analysis. The *trans*-diaquatrichloroscandium(III) species has two polarized modes at 279 and 335 cm^{-1} which could correspond to modes

Fig. 11. Skeletal stretching frequencies of aquatetra, penta-, and hexachloroscandium complexes.



© 2002 NRC Canada

Fig. 12. Structures of aquapenta- and hexachloroscandium complexes.



at 306 and 420 cm^{-1}. In addition, the *mer*-triaquatrichloroscandium(III) has polarized modes at 257, 288, and 330 cm^{-1} which are also in the right range and given the shortcomings of the theory discussed in the diaqua section, could also be a candidate.

Tetrachloroaquascandium complexes ($ScCl_4(H_2O)_n^-$)

The structures of tetrachloroaquascandium complexes are given in Fig. 10. Tetrachloroscandium(III) can potentially have D_{4h} symmetry, but this structure has imaginary frequencies and becomes T_d after optimization. If a single water is added in an equatorial position of the trigonal bipyramid, two possible C_{2v} structures can be generated, neither of which is an energy minimum and which undergo a pseudo-rotation to become a C_s structure with the water in an axial position. The two C_{2v} structures, at the HF/6-31G* level, are 18 and 66 kJ mol^{-1} less stable, respectively. Adding a second water can give either a trans or a cis configuration. A D_{2h} structure was initially tried for the trans, but the presence of imaginary frequencies suggested desymmetrization to a C_{2v} structure. The resulting structure also had imaginary frequencies, so we desymmetrized to a C_2 structure. This structure also had imaginary frequencies so we removed all constraints which gave us a different C_2 structure (no. 2) which was a local minimum. These structures were less stable than C_2 no. 2 at the HF/6-31G* level by 36.4, 9.9, and 6.5 kJ mol^{-1}, respectively. For the cis structure, we tried a C_{2v} structure initially, which had an imaginary frequency, so we desymmetrized to a C_2 structure which was a local minimum and was more stable by 0.05 kJ mol^{-1}, indicating than the water twisting has a flat potential. The cis structure was more stable than the trans structure at all levels investigated.

If we compare the tri- and tetrachloro species with the same number of waters, some trends are apparent. In the monoaqua species, the Sc—O distance lengthens by over 0.16 Å, whereas it is not so obvious for the diaqua. In addition, the Sc—O distances in the diaqua are actually shorter than the monoaqua. The same lengthening trend is apparent if we compare species with the same coordination number. The Sc—Cl distances are always longer.

The frequencies of the species with at least four chlorides are given in Fig. 11. None of the chloroscandium complexes are consistent with two polarized modes in the correct frequency ranges.

Penta- and hexachloroaquascandium complexes ($ScCl_5(H_2O)_{0\,-1}^{2-}$ and $ScCl_6^{3-}$)

The structures of the penta- and hexachloroaquascandium complexes are given in Fig. 12. The penta- and hexa-

© 2002 NRC Canada

chloroscandium(III) species belong to the D_{3h} and O_h point groups, respectively. For the pentachloroaquascandium(III) complex, we initially tried a C_{2v} structure, which has an imaginary frequency, as does our first attempt at desymmetrizing to a C_s. Our second C_s structure is a minimum. At the HF/6-31G* level, these structures are 27 and 5 kJ mol^{-1} higher in energy than C_s no. 2.

The Sc—O distance in the pentachloroaquascandium is very similar to that of the tetrachloroaqua, and longer than in the tetrachlorodiaqua. The Sc—Cl distances, however, continue to increase as more chlorides and waters are added. The Sc—Cl distances of 2.58 to 2.63 Å are larger than the experimentally observed values in $ScCl_3$ (2.515 to 2.528 Å) and $Ba_2Cl[ScCl_6]$ (2.42 to 2.52 Å) (18).

Discussion

We have identified some preliminary candidates for the chloroaquascandium complex that gives rise to a polarized mode at 306 cm^{-1} by a comparison of the vibrational frequencies predicted and measured in the Raman solution spectrum. Although systematic errors in the calculation were approximately taken into account (20–27 cm^{-1} for Sc-Cl stretch in $ScCl_4^-$, 50 cm^{-1} for Sc-O stretch in $Sc(H_2O)_6^{3+}$) we have no way of knowing whether these errors are the same in the mixed chloroaquascandium complexes. In the absence of definitive assignments of known structures, we make the assumption that they are. It is clear that on thermodynamic grounds, a penta or hexachloro species is unlikely to exist. The monochloro complexes also are not candidates. Some viable possibilities thus are *trans*-dichlorotetraaquascandium(III), *trans*-trichlorodiaquascandium(III), and *mer*-trichlorotriaquascandium(III). Although many modes are predicted, many would be very similar to that of bulk water and would probably be indistinguishable from it. It should be noted that the depolarization ratios of all of these are small, and the higher frequency band is incorrectly predicted to have a higher intensity compared to the experimental ones at 306 and 420 cm^{-1}. In some cases there is a significant difference between the Raman intensities at the 6-31G* and 6-31+G* level. It is known that the Raman intensities are not that sensitive to the type of theory employed (HF, MP2, DFT), but that the basis set is important. Addition of a diffuse function to heavy atoms reduces the average errors by about 30% (19). The difference may be due to the model employed, in much the same way that the frequencies are altered by the inclusion of a second hydration sphere. The predicted frequencies with intensities at the HF/6-31+G* level are given in Fig. 13, with the polarized skeletal stretching bands indicated by an arrow. It is difficult to differentiate which of these structures is most likely solely from a comparison of the theoretical and experimental Raman spectra and we must incorporate some other data. Adding waters to form a second hydration sphere may clarify the possibilities, but this is not straightforward and is computationally very intensive, and thus we bring in some additional literature data.

In anion exchange studies, scandium in the presence of 12 M (and to some extent 7 M) HCl exchanges, suggesting that an anionic form exists, which is formulated as $ScCl_4^-$ (20). This would be consistent with our calculations on thermodynamic grounds. A later ion-exchange study showed the presence of cationic species at low chloride concentrations (21). An early vibrational spectroscopic study (22) on scandium chloride solutions agrees with the frequencies, but not the depolarization ratios, measured in our earlier paper (13). Some 45-Sc NMR measurements on scandium chloride solutions were interpreted on the basis of a series of hexacoordinate scandium complexes of varying chloride content (23). A Raman band at 332 cm^{-1} in 12 M HCl suggested the presence of tetrachloroscandium, consistent with our ab initio data. It was proposed that between 0–4 M of added HCl, either hexaaqua or hydroxo species are present, between 6–8 M, mono and dichloro complexes are present, and between 10–12 M, the tetrachloro complex dominates. Additional data suggested that at 4 N and 7 N HCl, the monochloro and dichloro complexes were dominant, respectively (24). Complex formation with chloride seems to start taking place at a concentration of greater than 0.3 M, but it is also claimed that the same thing happens for perchlorate at 0.1 M (25). Ultrasonic absorption measurements indicate that chloro complexes are formed as well in a hexacoordinate species (26). The molal activity coefficients of chloride, nitrate, bromide, and perchlorate solutions of scandium were measured and interpreted based on heptacoordination (27).

It appears as though the experimental data are difficult to reconcile with each other. The assumption of linear change in the chemical shift of ^{45}Sc NMR upon increasing chloride substitution (24) has not yet been proven. The existence of a monochloroaqua species at 3 M concentration is unlikely, as this species would produce an intense Sc-Cl band at high frequency, predicted to be at least 440 cm^{-1}. It is possible that the Sc-Cl band overlaps with the Sc-O band in hexaaquascandium(III) and is not resolved. More detailed Raman concentration studies are warranted, especially in the low Cl:Sc region. Our data, taken together with the experimental literature, suggest that the experimentally observed polarized bands at 306 and 420 cm^{-1} are due to *trans*-dichlorotetraaquascandium(III).

An anonymous reviewer suggested that we carry out some geometry optimizations and frequency calculations on polar species using the Onsager model at the HF/6-31G* and HF/6-31+G* levels. As a consistency check, we also performed Onsager dipole calculations on some non-polar species as well. Standard keywords (Volume, SCRF = (Dipole,Solvent = Water)) were used. For the charged complexes, the monopole contribution to the solvation energy dominates. As expected, molecules lacking a dipole moment gave a zero dipolar energy and no geometry change. The effect on $ScCl(H_2O)_5^{2+}$ was to lengthen the Sc—Cl by 0.07 (0.08) Å and to decrease the Sc—O distances by 0.01 to 0.02 Å. There was little effect on the Sc-O vibrational modes (<5 cm^{-1}) but the Sc-Cl stretching mode decreased by 43 (48) cm^{-1}, consistent with the large change in Sc—Cl distance. However, the effect on the distances of *cis*-$ScCl_2(H_2O)_4^+$, and the $ScCl_3(H_2O)_3$ isomers, was much less pronounced, with the Sc—Cl and Sc—O distances changing by at most 0.03 Å and the vibrational frequencies usually decreasing by within 10 cm^{-1}. It is clear that the Onsager model as applied here is insufficient to account for the variations between calculated and experimental X-ray distances

and frequencies. It is noteworthy that continuum model calculations with spherical cavities can sometimes give opposite changes in metal—oxygen bond lengths than molecularly shaped cavities or discrete models (28, 29). The solvation energy differences between isomers as predicted by the Onsager model (monopole + dipole) causes a reversal in the stability of the *cis-trans* dichlorotetraaqua (difference in solvation 90 kJ^{-1} mol) and *fac-mer* trichlorotriaqua (50 kJ mol^{-1}) complexes. Using the COSMO model of solvation at the gas-phase geometries does not cause a reversal in the stabilities. The trans isomer of $ScCl_2(H_2O)_4^+$ at the HF/6-31G* (HF/6-31+G*) level remains about 17 (23) kJ mol^{-1} more stable, although the cis isomer, as expected, is preferentially stabilized. Similarly, the meridianal isomer of $ScCl_3(H_2O)_3$ remains 6 (33) kJ mol^{-1} more stable than the facial isomer. It is clear that the calculation of solvation energies is very model-dependent, but a full account is beyond the scope of the paper. We prefer to use structural- and vibrational-based comparisons instead of energy criteria because lower levels of theory usually suffice for accurate descriptions of these.

Conclusions

Ab initio calculations on scandium aquachloro complexes are carried out. The agreement between the predicted and available X-ray structures is reasonable. The Sc—Cl distance is accurately predicted in the chloro complexes, whereas the Sc—O distance tends to be overestimated. Taking into account the systematic errors that this would likely cause on the Sc-O and Sc-Cl stretching frequencies, the experimental Raman spectrum of acidified 3.0 M scandium chloride solution is shown to be consistent with either a *trans*-dichlorotetraaqua, *trans*-trichlorodiaqua, or *mer*-trichlorotriaquascandium(III) complex. Assuming no band overlap, the monochloro, and the tetra- through hexachloro complexes can be ruled out at this concentration. The available experimental data, taken with our calculations, suggest that the dichloro species is most likely.

Aspects of the hydrolysis of formamide: revisitation of the water reaction and determination of the solvent deuterium kinetic isotope effect in base

H. Slebocka-Tilk, F. Sauriol, Martine Monette, and R.S. Brown

Abstract: A study of the hydrolysis of formamide is reported with the aims of isolating the water reaction for hydrolysis from the acid and base hydrolysis terms and determining the solvent deuterium kinetic isotope effect (dkie) on base-catalyzed hydrolysis. Respective activation parameters ($\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$) of (17.0 ± 0.4) kcal mol^{-1} and (–18.8 ± 1.3) cal mol^{-1} K^{-1} for the acid reaction and (17.9 ± 0.2) kcal mol^{-1} and (–11.1 ± 0.5) cal mol^{-1} K^{-1} for the base reaction were determined from Eyring plots of the second-order rate constants over the range of 27–120°C. Kinetic studies at the minima of the pH/rate profiles in the pH range from 5.6 to 6.2 in MES buffers at 56°C, and in the pH range of 4.25–6.87 in acetate and phosphate buffers at 120°C are reported. At 56°C the available data fit the expression k_{obs}^{56} = 0.00303[H_3O^+] + 0.032[HO^-] + (3.6 ± 0.1) × 10^{-9}, while at 120°C the data fit k_{obs}^{120} = (0.15 ± 0.02)[H_3O^+] + (3.20 ± 0.24)[HO^-] + (1.09 ± 0.29) × 10^{-6}. Preliminary experimental estimates of E_a (ln A) of 22.5 kcal mol^{-1} (15.03) for the water rate constant (k_w) are calculated from an Arrhenius plot of the 56 and 120°C data giving an estimated k_w of 1.1 × 10^{-10} s^{-1} ($t_{1/2}$ = 199 years) at 25°C. Solvent dkie values of k_{OH}/k_{OD} = 1.15 and 0.77 ± 0.06 were determined at [OL^-] = 0.075 and 1.47 M, respectively. The inverse value is determined under conditions where the the first step of the reaction dominates and is analyzed in terms of a rate-limiting attack of OL^-.

Key words: formamide, activation parameters, water reaction, acid and base hydrolysis, solvent kinetic isotope effect.

Résumé : On a effectué une étude de l'hydrolyse du formamide dans le but d'isoler la réaction d'hydrolyse par l'eau des termes d'hydrolyses acide et basique et de déterminer l'effet isotopique cinétique du deutérium du solvant (eicd) sur l'hydrolyse catalysée par la base. En se basant sur les courbes de Eyring des constantes de vitesse du deuxième ordre entre 27 et 120°C, on a déterminé les paramètres d'activation respectifs ($\Delta H^{\ddagger}$ et $\Delta S^{\ddagger}$) de (17,0 ± 0,4) kcal mol^{-1} et (–18,8 ± 1,3) cal mol^{-1} K^{-1} pour la réaction acide et de (17,9 ± 0,2) kcal mol^{-1} et (–11,1 ± 0,5) cal mol^{-1} K^{-1} pour la réaction basique. On rapporte aussi les études cinétiques aux minima des profils pH/vitesse, à des pH allant de 5,6 à 6,2, dans des tampons de MES, à 56°C et à des pH allant de 4,25 à 6,87, dans des tampons d'acétate et de phosphate, à 120°C. À 56°C, les données peuvent être accommodées par l'expression k_{obs}^{56} = 0,00303[H_3O^+] + 0,032[HO^-] + (3,6 ± 0,1) × 10^{-9} alors que, à 120°C, les données peuvent être accommodées par l'expression k_{obs}^{120} = (0,15 ± 0,02)[H_3O^+] + (3,20 ± 0,24)[HO^-] + (1,09 ± 0,29) × 10^{-6}. Sur la base d'évaluations expérimentales préliminaires de E_a (ln A) de 22,5 kcal mol^{-1} (15,03) pour la constante de vitesse de l'eau (k_w) faites à l'aide d'une courbe d'Arrhenius des données de 56 à 120°C, on a évalué que, à 25°C, k_w = 1,1 × 10^{-10} s^{-1} ($t_{1/2}$ = 199 ans). Des valeurs de l'eicd du solvant de k_{OH}/k_{OD} = 1,15 et 0,77 ± 0,06 ont été déterminées pour des valeurs respectives de [OL^-] = 0,075 et 1,47 M. La valeur inverse a été déterminée pour des conditions dans lesquelles la première étape de la réaction est dominante et on l'a analysée en fonction d'une attaque cinétiquement limitante de OL^-.

Mots clés : formamide, paramètres d'activation, réaction de l'eau, hydrolyses acide et basique, effet isotopique cinétique du solvant.

Introduction

Due to the obvious relevance to biological processes, considerable attention has been devoted to understanding the mechanism of hydrolysis of amides under both acidic and basic conditions (1, 2). Far less is understood about the mechanism by which water alone promotes the hydrolysis of amides. Water reactions or their kinetic equivalent, HO^-

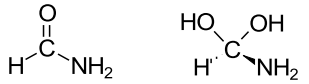
attack on the protonated amide, have been observed when the amide is activated in some way (3). Recently there has been interest in determining the water hydrolysis rate constants for peptides so that these values could be used as a background for comparison with enzyme-catalyzed rates (4). The latter water reactions are very much slower than those of activated amides so new, highly sensitive assay techniques using ^{14}C radioisotopic detection (4*a*) or post-hydrolytic conversion of products to fluorescent tracers (4*b*, 4*c*) were developed to follow reactions to a few percent completion at 25°C. Radzicka and Wolfenden (4*d*) determined activation parameters for water hydrolysis of some simple dipeptides by monitoring the hydrolyses in buffered media between pH 4.2 and 7.8 at several temperatures between 120 and 200°C, extrapolating the water rate constant to 25°C. In the latter studies, the $t_{1/2}$ for the water reactions at 25°C varied from 7 (4*a*) to 600 (4*d*) years.

Despite the above, information about the mechanism of the water reaction is sparse, particularly with respect to the partitioning of neutral tetrahedral addition intermediates. Earlier, we reported (5) ^{18}O=C exchange and solvent deuterium kinetic isotope (dkie) studies of the water reaction observed for trifluoromethyl-*p*-nitroacetanilide (**1**) (eq. [1]) an activated amide previously studied by Komiyama and Bender (3*d*).

[1] 
1 2

In that study we observed no ^{18}O=C exchange accompanying the hydrolysis in the water region, so we could not provide evidence that the reaction proceeded through a putative reversibly formed *gem*-diol intermediate (**2**). That intermediate, if formed, must break down to products faster than it reforms ^{18}O-exchanged starting material ($k_2 >> k_{-1}$) but how relevant those findings are to the water reaction of normal, and unactivated, amides remains to be established.



3 4

The water reaction of the simplest amide, formamide (**3**) has been investigated computationally to determine the overall reaction enthalpy for the neutral hydrolysis (6) and the free energy of activation for a hypothetical reaction involving one or more water molecules (7). The activation free energy for reaction with a single H_2O in the gas phase at 25°C is calculated to be ~55 kcal mol^{-1} (7*a*, 7*b*) but for the reaction in aqueous solvent involving three waters the value falls to ~48 kcal mol^{-1} (7*c*). The rate-limiting step for the three-water reaction is the formation of the tetrahedral addition product (**4**) with the great bulk of the free energy of activation (~33 kcal mol^{-1}) attributed to the entropy of restriction of freedom of the reaction partners in the transition state. More recently, Guthrie and Pitchko (8) introduced a valuable method termed the No Barrier Theory for calculating the activation free energies for hydration of carbonyl compounds, and computed a $\Delta G^{\ddagger}$ value of 31.9 kcal mol^{-1} for hydration of dimethyl formamide (DMF) via a three-water cyclic mechanism.

The high computed activation free energy for the water reaction of formamide and DMF can be compared to the activation parameters commonly found for the acid- and base-catalyzed hydrolysis of amides. Guthrie (9) reports that the free energies of activation for the acid hydrolysis of DMF and dimethyl acetamide at 25°C are 26.3 and 25.6 kcal mol^{-1}, respectively, while the corresponding base hydrolyses have values of 22.6 and 24.1 kcal mol^{-1}, respectively. Bolton and co-workers (10, 11) gave E_a ($\Delta S^{\ddagger}_{75}$) values of 18.8–21.5 kcal mol^{-1} (–17.4 to –22.0 cal K^{-1} mol^{-1}) for the acid hydrolysis of some primary amides and for *N*-methyl and *N*,*N*-dimethyl acetamide as well as $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ values of 11.7–17.4 kcal mol^{-1} (–29 to –39 cal K^{-1} mol^{-1}) for the base hydrolysis of a series of primary amides. Langlois and Broche (12) gave E_a ($\Delta S^{\ddagger}_{70}$) values of 18.4 kcal mol^{-1} (–24.7 cal K^{-1} mol^{-1}) for the acid hydrolysis of DMF, and 14.9 kcal mol^{-1} (–28.2 cal K^{-1} mol^{-1}) for its base hydrolysis. Although no experimental activation parameters for any of the reactions of **3** are available, it is striking that the computed barrier for its water reaction (7*c*), and that of DMF (8) is much larger than any experimental values for the acid- or base-catalyzed pathways of simple amides. An experimental search for the water reaction of some esters and simple amides like benzamide, butyramide, and acetamide was undertaken at high temperature in $NaHCO_3$–HOAc buffered media from pH 5–8 (13) but only the hydroxide process was claimed to be observed.

Our interest in amide water reactions was piqued by a report (14) stating that the pH/rate profile for hydrolysis of formamide between pH 1 and 9 at 80°C contains a slight plateau region at pH 6. The observed kinetics were fit to a general expression (k_{obs} = 0.0178[H^+] + 0.211[OH^-] + k_w) with the water reaction having a rate constant (k_w) of 8.4 × 10^{-8} s^{-1}, ($t_{1/2}$= 95 days). In the authors' words: "the k_w term is probably real, even though it is never large enough to contribute more than about 50% to the total reaction." Given the possibility that one might separate the water reaction from the H_3O^+ or HO^- reactions at some other temperature, we undertook a study of the hydrolysis of formamide at 56 and 120°C. Assessment of both the acid- and base-catalyzed hydrolyses at various temperatures was required to ascertain their importance in the neutral pH region where the water term is expected and so we obtained the activation parameters for both these processes. As part of the latter investigation we performed solvent deuterium kinetic isotope effect studies at 27°C in the base domain.

Experimental

Materials

MES buffer (morpholinoethanesulphonic acid) was reagent grade (Sigma). Acetic acid was distilled prior to use; NaH_2PO_4 and Na_2HPO_4 were used as supplied (Fisher). H_2O was made free from dissolved CO_2 and stored under Ar. D_2O (CDN Isotopes, 99.9 atom % D) was used as supplied as was formamide (99.5+%, A.C.S. reagent grade, Aldrich).

Kinetics

The rates of hydrolysis of formamide were determined by ^1H NMR analyses (Bruker DMX-Avance 500 spectrometer

equipped with a broadband inverse probe). The ^1H NMR spectra in water were accumulated using a standard presaturation water suppression technique. Solutions of base (0.015 and 0.075 M, (I = 0.1 M (KCl)) in either H_2O or D_2O were prepared under CO_2-free conditions and stored under Ar. Base concentrations were determined by titration with standardized 0.1 N HCl, phenolphthalein indicator. Hydrolysis in acid was carried out in 0.01 M and 0.1 M HCl, I = 0.1 M (KCl). For reasons of solubility of the formamide, ionic strength was not kept constant for the kinetic experiments in MES buffer (pH 5.6, 5.9, 6.2; $[buffer]_t$ = 0.01, 0.02, and 0.04 M for each pH). Each NMR tube contained 0.5 mL of the acid, base, or buffer solution and 5×10^{-4} – 1×10^{-3} M of formamide along with 10 μL of D_2O as a lock. For slower reactions, sealed NMR tubes were thermostated at the desired temperature and removed at various times to collect the NMR spectra. For faster reactions, the NMR data were acquired continuously from the tube placed in the probe held at the desired temperature, and every 32 scans were summed separately (the time being recorded as the midpoint of the number of scans utilized). This process was repeated up to at least two hydrolysis half-times. For very slow reactions under buffered conditions (pH 5.6, 5.9, and 6.2), sealed NMR tubes with solutions of formamide in 0.5 mL of MES buffer were placed in a thermostated bath held at 56°C and the NMR spectra were collected at various time intervals over a period of 6 months (Tables 1–4).

Table 3. Pseudo-first-order rate constants for formamide hydrolysis in buffered media at 56°C.[a,b]

pH (Uncorrected) at ambient temperature	pH (Corrected) measured at 56 °C	k (s^{-1}) (Extrapolated to [buffer] = 0)
5.6	5.5	$(1.48 \pm 0.02) \times 10^{-8}$
5.9	5.8	$(9.85 \pm 0.16) \times 10^{-9}$
6.2	6.1	$(9.50 \pm 0.39) \times 10^{-9}$

The specific kinetic experiments for the 120°C conditions are as follows: a 10 mL solution of amide in acetate or phosphate buffer of known concentration and pH, measured at 25°C, buffered at various values between pH 6.15 and 6.87 for phosphate, and 4.25–5.75 for acetate, was divided into 10 portions, each being sealed in an ampoule. The ampoules were thermostated at 120°C (silicon oil, Hi-temp bath 160A, Fisher Scientific) for a maximum time corresponding approximately to one half-time of hydrolysis. Samples were withdrawn from the bath at various times and plunged into an ice bath. These were opened and, after the addition of 10 μL of D_2O to 0.5 mL of the sample solution, analyzed by NMR. The rate constants quoted in Tables 3 and 4 were obtained from the intercepts of the plots of the observed rate constant vs. [buffer]. All the individual rate constants were determined in duplicate (original data in Tables 1S and 2S).[3]

Solvent deuterium kinetic isotope experiments were undertaken in D_2O at [NaOD] = 0.075 and 1.47 M, respectively, at 27°C. For the latter concentration, two independent runs were undertaken, while a single run was performed at the former concentration.

Pseudo-first-order rate constants (k_{obs}) for formamide hydrolysis under the various conditions were obtained by observing the rate of increase of the intensity of the signal at δ 8.46 attributable to the O=C-*H* proton of the formic acid

[3]Supplementary material may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council of Canada, Ottawa, ON K1A 0S2, Canada (http://www.nrc.ca/cisti/irm/unpub_e.shtml for information on ordering electronically).

formed (A) and the decrease of the intensity of the signal at δ 7.55 for that of formamide (B). The formamide signal at δ 7.55 appears as a doublet (J = 14.9 Hz) coupled to one of the NH protons while the two NH protons appear as two broad triplets coupled to ^{14}N. The one coupled to the formamide proton appears at δ 7.17 ($J_{N\text{-}H}$ ~ 60 Hz), while the other NH appear as a sharper triplet at δ 7.55 ($J_{N\text{-}H}$ ~ 62 Hz). Rate constants were evaluated from the slopes of the ln ($A/(A + B)$) vs. time plots with the errors in k_{obs} being determined as the standard deviation of the linear regression lines. Between 15 and 20 experimental points were used for each plot.

Activation parameters for the acid- and base-promoted hydrolyses were determined from plots of the log of the second-order rate constant ($k_{H_3O^+}$ or k_{HO^-}) vs. $1/T$ at four and five different temperatures including the reported data of Hine et. al (14) at 80°C with a total of seven and eight independent kinetic runs.

pH measurements of the reaction mixtures at ambient temperature and at 56°C were made with a Radiometer TTT2 unit and a Radiometer pHC4406 combined pH electrode. In the case of the reactions at 120°C, the pH was measured at ambient temperature before the reaction.

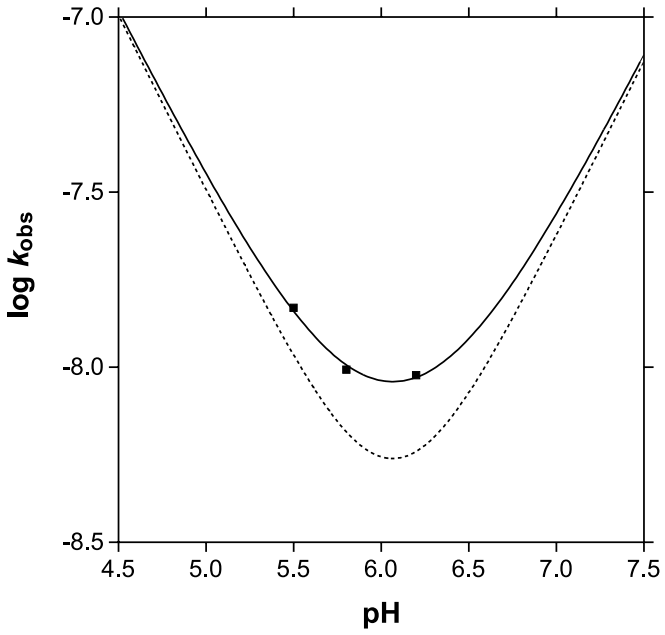
Results

Given in Tables 1 and 2 are the second-order rate constants for the HO^- and H_3O^+ catalyzed hydrolysis of formamide in water at various temperatures (including the 80°C data (14)). The 120°C acid and base values were derived under buffered conditions (Table 4, vide infra) at the lowest and highest pH values, where the respective reactions are first order in $[H_3O^+]$ and $[HO^-]$. Also included in Table 1 are the k_{OD^-} values at two $[OD^-]$ that give k_{OH}/k_{OD} values of 1.15 at $[OL^-]$ = 0.075 M, and 0.77 ± 0.06 at $[OL^-]$ = 1.47 M, T = 27°C.

Given in Table 3 are the rate constants determined under buffered conditions (MES, extrapolated to [buffer] = 0) at 56°C, while in Table 4 are the data at 120°C (acetate, phosphate extrapolated to [buffer] = 0). The original data in buffers used to construct these tables are given as Tables 1S and 2S, supplementary material.[3] The contribution of the acid plus base terms in the neutral pH region can be computed from the second-order rate constants provided in Tables 1 and 2. The hydroxide contribution at 5 < pH < 7 requires a correction of the $[HO^-]$ (13) attributable to the change in the K_w of water from $1 \times 10^{-13.997}$ at 25°C to $1 \times 10^{-13.11}$ at 56°C, and $1 \times 10^{-11.90}$ at 120°C (determined from the linear interpolation of the reported data (15) for K_w at 55 and 60°C, or the data at higher temperatures (16)).

Shown in Figs. 1 and 2 as dotted lines are the computed pH/rate profiles for hydrolysis only considering the H_3O^+ and HO^- terms at 56°C and 120°C, along with the experimental pseudo-first-order rate constants (■) in buffered conditions. The solid lines through the data in Figs. 1 and 2 come from NLLSQ fits of the 56 and 120°C data to the expression given in eq. [2], modeled for a process involving acid, base, and water terms. For the 56°C computation, values for the H_3O^+ and HO^- terms (Tables 1 and 2) were set as constants.

Fig. 1. Solid line: NLLSQ fit of the 56°C hydrolysis data in Table 3 to eq. [2] where $k_{H_3O^+}$ = 0.0032 M^{-1} s^{-1} and k_{OH} = 0.0303 M^{-1} s^{-1} are set constants and the autoprotolysis constant of water is pK_w = 13.11. Experimental data (■) for pseudo-first-order rate constants for hydrolysis from Table 3. Dotted line: computed pH/rate profile at 56°C for the hydrolysis of formamide assuming only the acid and base terms are operative.



$$[2] \qquad k_{obs}{}^{t} = k_{H_3O^+}[H_3O^+] + k_{OH}[OH^-] + k_w$$

The best fit lines are: $k_{obs}^{56} = 0.00303[H_3O^+] + 0.032[HO^-] + (3.6 \pm 0.1) \times 10^{-9}$, and $k_{obs}^{120} = (0.15 \pm 0.02)[H_3O^+] + (3.20 \pm 0.24)[HO^-] + (1.09 \pm 0.29) \times 10^{-6}$.

Discussion

Water reaction?

Activation parameters ($\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$) of (17.0 ± 0.4) kcal mol^{-1} and (–18.8 ± 1.3) cal mol^{-1} K^{-1} for the H_3O^+ catalyzed reaction and (17.9 ± 0.2) kcal mol^{-1} and (–11.1 ± 0.5) cal mol^{-1} K^{-1} for the HO^- reaction were determined from standard Eyring plots of the second-order rate constants given in Tables 1 and 2. These experimental values for formamide compare favorably with those reported for other amides (9–12). On the other hand, the activation parameters for the OH^- catalyzed hydrolysis gave a $\Delta G_{25}^{\ddagger}$ of 21.2 kcal mol^{-1} which is about 25% lower than the recently reported computational value of 27.3 kcal mol^{-1} (17).

We envision that the acid, base, and water pathways must have different activation parameters so that one might isolate the water process by changing the reaction temperature. However it is not easily predicted whether one should move to higher or lower temperatures than the 80°C used by Hine et al. (14) because the literature gives little guidance concerning the activation parameters of the three processes in any given case. Computations can sometimes be of assistance but for formamide the calculated free energy of activation for the water reaction of 48 kcal mol^{-1} at 25°C (7*c*) seems too high relative to the experimental activation

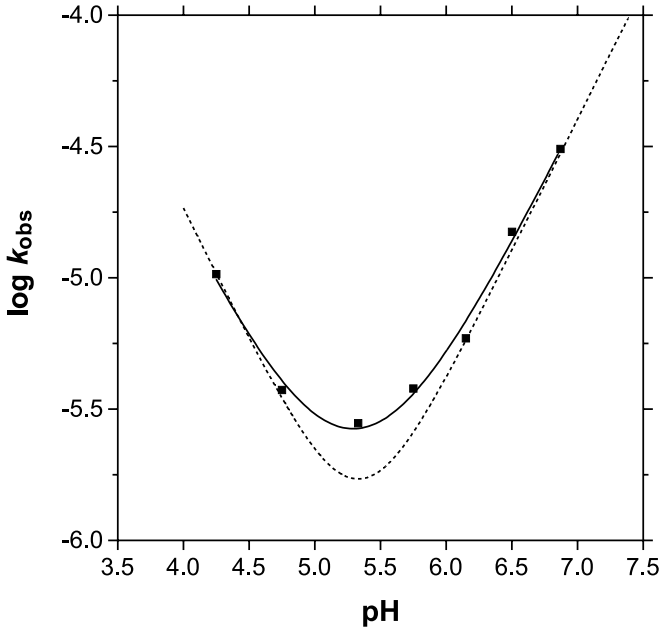
Fig. 2. Solid line: unconstrained NLLSQ fit of the 120°C hydrolysis data in Table 4 to eq. [2] with the autoprotolysis constant of water being set at pK_w = 11.90. Experimental data (■) for pseudo-first-order rate constants for hydrolysis under buffered conditions from Table 4. Dotted line: computed pH/rate profile for the hydrolysis of formamide at 120°C assuming only the acid and base terms are operative.



parameters we determined here for the acid and base processes for it to play any significant role at easily accessible temperatures. Guthrie and Pitchko's (8) recent computed value of $\Delta G^{\ddagger}_{25}$ = 31.9 kcal mol^{-1} for DMF hydrating via a three-water cyclic mechanism seems more reasonable as an upper limit for that amide, this value being some 5 to 6 kcal mol^{-1} larger than the acid and base values (9). Nevertheless, taken at face value the extant experimental rate data for formamide (14) suggest that the free energies for these processes must be similar if the water, acid, and base processes are competitive at 80°C. Esters, which are generally more reactive than their amide counterparts, might provide a starting point for comparison, but apparently the water reactions are exceedingly slow and little kinetic data are available. The water reaction for hydrolysis of methyl acetate has been estimated (18) to have a rate constant at 25°C of 3×10^{-10} s^{-1} corresponding to a half-time of 70 years, however, a plateau is not observed at intermediate pH in the hydrolysis of ethyl acetate (19). A more recent study involving six nonactivated esters at higher temperatures (13) concluded that only the hydroxide reaction is important down to pH values of about 5, except for *tert*-butyl acetate where a pH-independent reaction is said to occur. Kirby (20) has noted that activated esters such as alkyl and aryl haloacetates and substituted phenyl acetates do have water reactions with low activation enthalpies (7–14 kcal mol^{-1}) and large negative activation entropies (–40 to –50 cal K^{-1} mol^{-1}). This would be expected for highly ordered transition states in which charge buildup is avoided by several proton transfers accompanying the formation of a possible *gem*-diol intermediate. In our earlier study (5), we determined that the respective activation parameters of $\Delta H^{\ddagger}$ = 14.4 ± 0.6 and 11.7 ± 0.3 kcal mol^{-1} and $\Delta S^{\ddagger}$ = –36.1 ± 1.6 and –52.3 ± 1.3 cal K^{-1} mol^{-1} for the water-promoted hydrolysis of trifluoromethyl-*p*-nitroactetanilde and trifluoromethylacetanilide. Although the activation parameters were not determined for the acid and base processes, the above values are quite close to what was observed for the water reactions of activated esters.

How relevant these numbers might be to the hydrolysis of more normal, less-activated amides is unclear. As far as we know, the only other experimental activation parameters for water hydrolysis of amides were determined by Radzicka and Wolfenden (4*d*) who reported E_a values of 23–25 kcal mol^{-1} for the hydrolysis of three dipeptides, including glycyl-glycine, at pH 6.8 with temperatures between 120 and 200°C. The experimental $\Delta G^{\ddagger}_{25}$ = 31.71 kcal mol^{-1} for the hydrolysis of *N*-acetyl glycyl-glycine (4*d*) compares very well with the computed 31.9 kcal mol^{-1} value for DMF (8). These values can be compared with the reported (21) activation parameters for HCl- or NaOH-promoted hydrolysis for glycyl-glycine ($\Delta H^{\ddagger}$ ($\Delta S^{\ddagger}$), 20.3 kcal mol^{-1} (–24 cal K^{-1} mol^{-1}) and 16.9 kcal mol^{-1} (–26.8 cal K^{-1} mol^{-1}), respectively). Of course one must be mindful that acid, base, and neutral hydrolyses of dipeptides may involve different states of ionization of the substrates which may affect the various activation parameters in unpredictable ways.

Given the above, we set out to isolate the water reaction by obtaining the hydrolysis kinetics of formamide from initial rates at 56°C in the pH range of 5.6 to 6.2. The Table 3 data and Fig. 1 show a plateau at the pH minimum that we attribute to an observable water reaction having a computed k_{obs} value of (3.6 ± 0.1) × 10^{-9} s^{-1}, $t_{1/2}$ = 6.1 years! Concomitantly, we investigated the hydrolysis at 120°C in acetate and phosphate buffers. The enthalpies of ionization of these are small so that the dissociation constants do not vary much with temperature (15, 22). The kinetic data in Table 4, illustrated in Fig. 2, also plateau around the pH minimum. An unrestricted fit of these experimental buffer data to eq. [2] gives the values $k_{H_3O^+}$ = (0.15 ± 0.02) M^{-1} s^{-1}, k_{OH} = (3.20 ± 0.24) M^{-1} s^{-1}, and k_w = (1.09 ± 0.29) × 10^{-6} s^{-1}. For the latter term, $t_{1/2}$ = 7.3 days.

One can, through use of the best-fit rate constants above, determine that at the pH minima of 6.1 (56°C) and 5.3 (120°C), the water reaction contributes about 40% of the overall rate at either temperature. This, coupled with Hine's careful statements that the k_w term is never large enough to contribute more than about 50% to the total reaction at 80°C, is at first glance surprising. However, further analysis indicates this is a consequence of the similarity of the activation parameters for all three hydrolysis processes, and an interesting artifact of the drop in the autoprotolysis constant of water with increasing temperature which raises the [HO$^-$] and makes the base term more prominent at any given pH at high temperatures.

While it is now clear that there must be a water term in the hydrolysis of formamide, it is unfortunate that our best-fit water rate constants must have a 10–30% error which limits our ability to make conclusions and predictions. Nevertheless, since this is the only non-peptidic, nonactivated amide that has an experimentally demonstrated water reaction, we feel justified in putting forth a two-point experimental estimate of the Arrhenius parameters E_a (ln *A*) of 22.5 kcal

© 2002 NRC Canada

mol^{-1} (15.03) based on our 56 and 120°C data. Inclusion of Hine's 80°C k_w (14), which lies slightly above the two-point plot, does not change these values greatly. The estimated k_w at 25°C is thus 1.1×10^{-10} s^{-1} ($t_{1/2}$ = 199 years).[4]

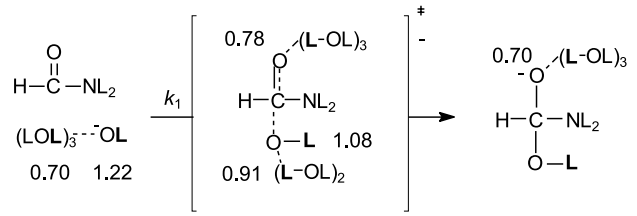
Solvent deuterium kinetic isotope effect in base

The HO^- promoted hydrolysis of formamide has recently been investigated by Marlier et al. (23) through the application of heavy atom kinetic isotope effects. They point out that the experimental data concerning the ^{18}O content of the formate product arising from alkaline hydrolysis in a solvent enriched with $^{18}OH_2$ could be accommodated by either of two scenarios. With water as the attacking nucleophile, the ^{18}O solvent kinetic isotope effect ($^{18}k_{obs}$) would be 1.022 while with hydroxide as the attacking nucleophile, $^{18}k_{obs}$ would be 0.982. Based on the experimental precedence that almost all the known cases of heavy atom isotope effects for attacking nucleophiles are normal, they proposed that a water molecule solvating the hydroxide was the actual nucleophile (through a general base pathway) and not hydroxide itself. A general base mechanism was also proposed in their earlier report of the heavy atom isotope effects for the alkaline hydrolysis of methyl formate (24), and supported by a more recent analysis of a proton inventory study of the base-promoted hydrolysis of ethyl acetate (25). Given our expectation that the general base process is expected to exhibit a substantial primary solvent deuterium kinetic isotope effect (skie) due to a proton in flight, we undertook studies on the alkaline hydrolysis of formamide in D_2O. All previous solvent dkie studies of the base-catalyzed hydrolysis of amides such as benzamides, toluamides, and anilides (1*d*, 2) yield values of about 1.0 or slightly inverse which are consistent with a direct nucleophilic mechanism.

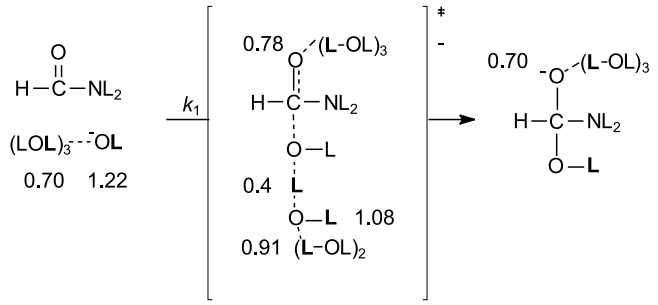
Analysis of the dkie requires consideration of the hydrolytic mechanism with respect to rate-limiting steps and partitioning of any anionic tetrahedral intermediates. Marlier et al. (23) and earlier, Kirsch (26), demonstrated that the rate law for alkaline hydrolysis of formamide contains both first- and second-order terms in hydroxide which is analyzed in terms of the mechanism presented in eq. [3] for which steady-state analysis gives the expression in eq. [4].

[3] 
$$[4] \qquad k_{hyd} = \frac{k_1[HO^-](k_3 + k_4[HO^-])}{k_2 + k_3 + k_4[HO^-]}$$

Scheme 1.



Scheme 2.



Graphical analysis (23, 26) of the partitioning of the tetrahedral intermediate (**TI**$^-$, eq. [3]) indicates that the k_3/k_2 ratio is 1.05, while the k_4/k_2 ratio is 2.15 M^{-1}. At low [HO^-] (<0.1 M), the second-order in [HO^-] pathway is relatively unimportant and **TI**$^-$ undergoes a substantial reversal, so k_{hyd} can be approximated as $k_1[HO^-]k_3/(k_2 + k_3)$. Analysis of the dkie at low [OH^-] is complicated since no step is entirely or substantially rate-limiting. On the other hand, at high [OH^-] the tetrahedral intermediate is driven forward via rapid capture by the second hydroxide so reversal becomes less important and attack becomes the rate-limiting step with k_{hyd} being approximated as $k_1[HO^-]$.[5] The skie data reported in Table 1 indicate that at [LO^-] = 0.075 M, where about 90% of the reaction proceeds by the first-order pathway (k_{OH}/k_{OD} = 1.15). At [LO^-] = 1.47 M, where about 75% of the reaction proceeds via the second-order pathway (k_{OH}/k_{OD} = 0.77 ± 0.06) which can thus be taken as the skie on k_1.

We analyze the latter data through the use of fractionation factors using the same general methodology we applied successfully to the base-promoted hydrolysis of some secondary and tertiary toluamides (27, 2*a*) and some esters (28). The solvent dkie can be predicted (29) as $k_{OD}/k_{OH} = \Pi\varphi^{TS}/\Pi\varphi^{GS}$, where $\Pi\varphi^{TS}$ and $\Pi\varphi^{GS}$ are the products of the various fractionation factors in the transition and ground states. Two possible cases that are considered are shown in Schemes 1 and 2 which involve, respectively, direct hydroxide attack and hydroxide acting as a general base for delivery of one of its solvating waters. In analyzing the dkie, we adopt Gold and Grist's (30) suggestion that HO^- has a fractionation factor of 1.22 while its three solvating waters each have fractionation factors of 0.7. During the direct attack of

[4] J.P. Guthrie (University of Western Ontario, private communication) informed us that the his No Barrier Theory calculations for the water reaction of dimethyl formamide (DMF, ($\Delta G^{\ddagger}_{25}$ 31.9 kcal mol^{-1})) lead to a computed water rate constant of 2.6×10^{-11} s^{-1}.

[5] This analysis is identical to that proposed by Marlier (ref. 23) and is substantially correct. However, at [HO^-] = 1.47 M the partitioning of the tetrahedral intermediate is ~4.1 in favour of product formation relative to reversal. Of that ratio, some 3.1 parts are attributed to the second-order pathway (k_4) and one part is attributed to the spontaneous pathway (k_3). Strictly speaking, while the dkie is substantially attributable to the attack step (k_1), there is a small additional component attributable to k_4 which should be inverse given OD^- in D_2O is a stronger base than is HO^- in H_2O.

© 2002 NRC Canada

hydroxide we assume in Scheme 1 that one of the solvating waters has been lost to liberate a lone pair required for attack on C=O, and that the developing O^- in **TI**$^-$ is associated with three solvating waters with fractionation factors similar to those of hydroxide. We assume that the transition state for attack (k_1) is late, being ~70% along the reaction coordinate to the tetrahedral species.

In the case of the general base mechanism given in Scheme 2, we assume that the fractionation factor for the proton in flight between the hydroxide and water is 0.4 (corresponding to a normal primary dkie of 2.5). All the assumed values are shown in bold type in Schemes 1 and 2: these give predicted solvent dkie's of ~1.0 for the direct attack of hydroxide and 2.2 for the general base mechanism.

The only substantial difference between the processes shown in Schemes 1 and 2 concerns the presence of the proton in flight which is solely responsible for the predicted normal dkie in the latter. Making the transition state in Scheme 1 later gives only a small increase in the predicted dkie because of the compensating effects of the loosening on waters solvating the attacking HO^-, and tightening of the waters solvating the developing O^- in **TI**$^-$. By converse, an earlier transition state for the direct attack of hydroxide, say 50% along the way to **TI**$^-$, gives a predicted dkie of 0.85, close to the experimentally observed value of 0.77 ± 0.06. That value seems to rule out the pathway given in Scheme 2, or any other pathway where there is much contribution from one or more protons in flight. In the limit of that mechanism, where the proton is nearly fully transferred from the attacking water to the general base HO^-, its associated fractionation factor would be close to unity leading to a drop in the predicted dkie toward the observed value. In the end this simply becomes a mechanism of direct hydroxide attack and cannot be distinguished from the process in Scheme 1.[6]

Conclusions

The main goals of the above study were to provide information about the water reaction of formamide, and provide the solvent dkie for the base reaction. Several important conclusions can be advanced.

We have determined the activation parameters for the H_3O^+ and HO^- promoted hydrolyses of formamide. The experimental $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ values are (17.0 ± 0.4) kcal mol^{-1} and (–18.8 ± 1.3) cal mol^{-1} K^{-1} for the H_3O^+ catalyzed reaction and (17.9 ± 0.2) kcal mol^{-1} and (–11.1 ± 0.5) cal mol^{-1} K^{-1} for the HO^- process. The values fit within the general range determined for acid- and base-catalyzed hydrolysis of other simple amides. However, the $\Delta H^{\ddagger}$ and $\Delta S^{\ddagger}$ values for the HO^- process give an experimental $\Delta G^{\ddagger}_{25}$ of 21.2 kcal mol^{-1} which is substantially lower than the recently computed value of 27.3 kcal mol^{-1} (17) which should prompt further efforts to refine the computational approaches.

We have determined k_w values of (1.09 ± 0.29) × 10^{-6} s^{-1} at 120°C and (3.6 ± 0.1) × 10^{-9} s^{-1} at 56°C, from which we estimated activation parameters of E_a = 22.5 kcal mol^{-1}, ln A = 15.03 from a two-point Arrhenius plot.

While it is apparent that a water reaction does exist at 56°C and at 120°C, in neither case does it contribute more than about 40% to the observed rate at the respective pH minima of 6.1 and 5.3. Hine et al. (14) also concluded that at 80°C, no more than 50% of the rate at the pH minimum can be attributed to the water reaction. Taken together, these studies indicate that it is improbable that conditions will be found where the water term for hydrolysis of formamide can be isolated (meaning contributing more than 95% at any given pH) from the corresponding acid and base reactions. This is an interesting consequence of two major factors: (1) the relative activation parameters of all three processes for this specific amide; and (2) the increase in the autoprotolysis constant of water as a function of temperature that increases the [HO^-] at any given pH, the net effect being to drive the pH minimum for the reaction to lower values at higher temperatures.

We have presented solvent deuterium kinetic isotope data for the base-catalyzed reaction at high [HO^-] where the kinetics are largely determined by the first step leading to the tetrahedral intermediate. The observed inverse value of k_{OH}/k_{OD} = 0.77 gives little evidence for a significant contribution of a proton in flight and strongly supports the mechanism involving the direct attack of hydroxide, similar to that believed operative for other amides, and at variance with a suggested water attack mediated by HO^-.

Crystal chemistry of tetraradial species. Part 10. Tilting at windmills: conformations of the tetraphenyl species $ZPh_4^{0,\pm1}$ (Z = B, C, N)[1]

Osvald Knop, Kathryn N. Rankin, T. Stanley Cameron, and Russell J. Boyd

Abstract: The equilibrium geometries of the isoelectronic $ZPh_4^{0,\pm1}$ (Z = B, C, N) molecules have been optimized, in S_4 and D_{2d} symmetries, at the HF/6-31G(d,p) and B3LYP/6-31G(d,p) levels, with the phenyl rings constrained to be planar. The ground-state conformations of all three species are shown to be of S_4 symmetry, but the difference of the energies of the S_4 and the D_{2d} conformations is estimated to amount to only ~1 kcal mol^{-1}, with a barrier to concerted rotational reorientation of the phenyl rings of ~5.0 kcal mol^{-1} for BPh_4^-, ~6.4 kcal mol^{-1} for CPh_4, and ~7.9 kcal mol^{-1} for NPh_4^+. A redetermination of the crystal structure of CPh_4 from –60°C X-ray data agrees with the results of previous determinations at ambient temperature; the CPh_4 molecule in the crystal is slightly compressed along the S_4 axis relative to the free molecule, otherwise the geometries of the two are essentially the same. Correlations between the optimized geometric parameters of the $ZPh_4^{0,\pm1}$ molecules have been examined and analyzed in detail, as have the substitution-induced changes in the geometry of the phenyl ring. The results confirm and strengthen the conclusions from the statistical studies by Domenicano et al. on the geometry of benzene rings monosubstituted by atoms of elements from the first row of the Periodic system.

Key words: tetraphenylborate, tetraphenylmethane, tetraphenylammonium, ab initio molecular geometries.

Résumé : Opérant au niveau HF/6-31G(d,p) et B3LYP/6-31G(d,p) de la théorie et en contraignant les noyaux phényles à être plans, on a optimisé les géométries à l'équilibre des molécules isoélectroniques $ZPh_4^{0,\pm1}$ (Z = B, C, N) dans les symétries S_4 et D_{2d}. On démontre que les conformations des trois espèces à l'état fondamental sont de symétrie S_4; toutefois, on a évalué que la différence d'énergie entre les conformations S_4 et D_{2d} n'est que d'environ 1 kcal mol^{-1} alors que la barrière à la réorientation rotationnelle des noyaux phényles d'environ 5,0 kcal mol^{-1} pour le BPh_4^-, d'environ 6,4 kcal mol^{-1} pour le CPh_4 et d'environ 7,9 kcal mol^{-1} pour le NPh_4^+. Une redétermination de la structure cristalline du CPh_4 à partir de données de rayons X obtenues à –60°C est en accord avec les déterminations antérieures à la température ambiante; par rapport à la molécule libre, la molécule de CPh_4 dans le cristal est légèrement comprimée le long de l'axe S_4, mais autrement les géométries des deux sont essentiellement les mêmes. On a examiné les corrélations entre les paramètres géométriques optimisés des molécules de $ZPh_4^{0,\pm1}$ et on les a analysées en détail comme on l'a fait pour les changements dans la géométrie du noyau phényle induits par une substitution. Les résultats confirment et renforcent les conclusions obtenues par les études statistiques de Domenicano et ses collaborateurs sur les géométries des noyaux benzéniques monosubstitués par des atomes d'éléments de la première rangée du tableau périodique.

Mots clés : tétraphénylborate, tétraphénylméthane, tétraphénylammonium, géométries moléculaires ab initio.

Introduction

The tetraradial homotetraaryl $ZAr_4^{0,\pm1}$ have always held stereochemical and crystallographic fascination because of their windmill-like geometries and often high symmetries, and they have engendered a substantial literature dealing with various aspects of their properties (2–11).

Of the many $ZAr_4^{0,\pm1}$ species reported, the three simplest, the tetraphenyls $ZPh_4^{0,\pm1}$ (Z = B, C, N) are examined de novo in this paper. Apart from the present common denominator, viz. a comparison of their geometry and symmetry in the free state, they are of interest each for different reasons. The BPh_4^- anion is widely used in preparative chemistry as a bulky counter-anion for stabilizing cationic species that otherwise might be unstable. Its geometry and symmetry in the over 1800 crystal structures of tetraphenylborates known

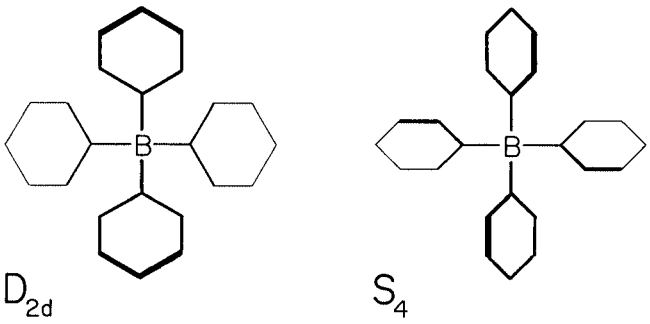
show a remarkable variation,[4] the reasons for which have been pondered (13–15) without, however, leading to definite conclusions.



The neutral tetraphenylmethane molecule is of interest because of the uncertainty regarding its ground-state conformation. The conformation found in the crystal is undoubtedly of S_4 symmetry (TEPHME (16); TEPHME02, TEPHME03, TEPHME11 (17); ref. 18 and below),[5] as are the conformations of all the other Group IV crystalline ZPh_4 (Z = Si, Ge, Sn, Pb) species,[6] as well as of free $SiPh_4$ (4), and very likely of its homologs (8); the crystal structure of CPh_4 at room temperature was the subject of a deliberate interlaboratory comparison (17). The conformation of *free* CPh_4, however, has been concluded from semiempirical calculations (4) to be of symmetry D_{2d}. The availability of these combined data thus seemed to afford an opportunity for examining the effect of packing forces in a molecular crystal on the structure of a tetraradial hydrocarbon molecule of high symmetry.

The tetraphenylammonium cation NPh_4^+ is an elusive species. Reference 19 is the only reference to its existence uncovered in an up-to-date search of Chemical Abstracts. It describes the formation of $[N(C_6H_5)_3(C_6T_5)]^+X^-$ (X = BF_4, I) from triphenylamine and the free $C_6T_5^+$ cation generated by β-decay from pertritiated benzene. Unfortunately, the extremely small quantities of the radiochemically identified products, and their spontaneous dissociation by fragmentation of a phenyl group, precluded any investigation of the bulk stability and structural properties of the cation.

The principal aim of this investigation is to provide, from ab initio calculations, a reasonably reliable structure for free BPh_4^- to serve as a reference in our statistical analysis of this anion in crystalline tetraphenylborates (to follow), to resolve the ambiguity concerning the ground-state conformation of free CPh_4 and compare its geometry to that found in the crystal, and to see whether the results of the calculations for NPh_4^+ may uncover reasons for the reticence of the chemical literature on the subject of this cationic species. The calculations are supplemented by a redetermination of the crystal structure of CPh_4 from data collected at a moderately low temperature (–60°C).

Symbols and notation are explained at the end of the paper. The orientations of the molecules have been standardized by rotation about the $S_4 \equiv z$ so as to position the C_6 centroid in the *yz* axial plane, as shown in the schematic projection in Fig. 1. *Proximal* refers to carbons C5 and C6, *distal* refers to carbons C2 and C3 (z(C2) < z(C6), z(C3) < z(C5), d(Z···C6) < d(Z···C2)). All coordinates and interatomic distances are in Å.

Procedures

The ab initio geometry optimizations of BPh_4^-, CPh_4, and NPh_4^+ in S_4 and D_{2d} symmetries were performed at the RHF/6-31G(d,p) level using GAUSSIAN98 (20), with the initial parameter estimates derived from the CPh_4 geometry in the crystal, and with the C_6H_5 ring constrained to be planar, but not coplanar with Z. In the later stages of the investigation, improved geometry optimizations were realized using density functional theory (DFT), again with the ring-planarity constraint.

The DFT calculations were carried out using the GAUSSIAN98 suite of programs (20). All geometry optimizations were performed using the B3LYP functional and 6-31G(d,p) basis set. The B3LYP functional is composed of Becke's (21, 22) three-parameter hybrid exchange functional B3, as implemented in GAUSSIAN98 (23), and the correlation functional of Lee et al. (24). Harmonic vibrational frequencies and zero-point vibrational energy (ZPVE) corrections were calculated at the same level of theory.

Details of the crystal-structure determination of CPh_4 are given in Table 1. Atom coordinates, thermal parameters, and interatomic distances and bond angles have been deposited.[7] Atom C(7) of the deposited material corresponds to C0 ≡ Z of Table 6. To match the standardized optimized atom coordinates (in Å) of CPh_4 in Tables A and B,[8] the crystallographic fractional coordinates have been appropriately transformed, as have those of ref. 17 (*R* in Table 6).

[4] The part of this paper pertaining to BPh_4^- constitutes in fact a preliminary to a forthcoming statistical investigation of the variability of the anion geometry.

Results and discussion

Ground-state conformations of free BPh_4^-, CPh_4, and NPh_4^+

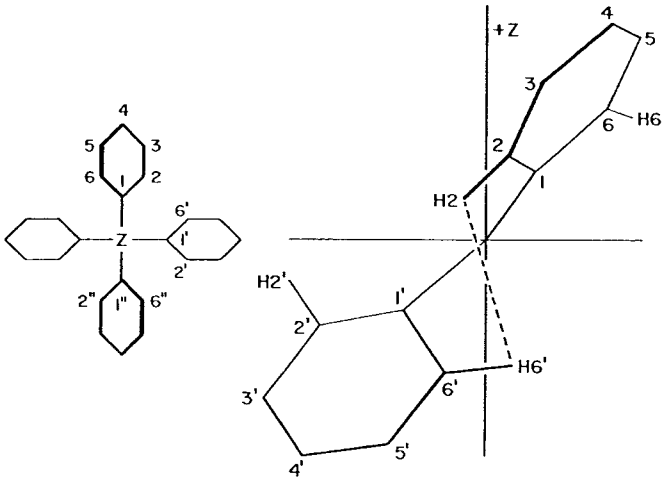
The results of the optimization of the equilibrium geometries of the three molecules in S_4 and D_{2d} symmetries are shown in Tables 2, 3, A, and B.[8] It was assumed: (*i*) that the minimum-energy conformation has one of these two symmetries; and (*ii*) that optimization at these levels is adequate to deliver geometries of these first-row species that will agree with the converging results of higher-level optimizations. The first assumption, unproven though almost certainly valid, was taken on trust, as it was not practical to examine the entire potential energy surface in general symmetry. The second assumption, however, can be tested against experiment, at least for CPh_4.

Optimizations in S_4 symmetry were started from a geometry with standard bond lengths and angles, a planar C_6H_5 ring, and valence angles C-Z-C = τ. They converged properly to an *E* minimum ($E(S_4^0)$ and $E(S_4^{00})$, respectively), corresponding to the geometries described in Tables 2, 3, A, and B.[8,9] Optimizations in D_{2d} symmetry, which were started with similar initial geometries, also converged to an *E* minimum ($E(D_{2d}^0)$ and $E(D_{2d}^{00})$, respectively), but their vibrational frequency analysis revealed that in every case there remained a single small imaginary frequency. This frequency ranged approximately (in the order Z = B, C, N) from –23 to –31 cm^{-1} for D_{2d}^0, and from –4 to –28 cm^{-1} for D_{2d}^{00}. Restarting the optimization from essentially the same initial geometry, but now under S_4 symmetry and with ϕ reduced from 90° by ~5°, returned the optimized geometry to that obtained in the D_{2d} optimization, with practically the same *E* but without removing the imaginary frequency. Examination of the computation results showed that it is the H and not the C atoms that undergo significant movement. The imaginary frequencies thus appear to arise from the inherent floppiness of the H atom in the D_{2d} conformation, in which the phenyl rings have C_s symmetry, and may reflect an incipient tendency of the molecule in this "averaging" conformation to assume a non-ambivalent conformation of S_4 symmetry, free from calculated imaginary frequencies (cf. S_4^ϕ below).

From the preceding it follows that the optimized energy of the D_{2d} conformation is a minimum. The differences $E_{min}(D_{2d}^0) - E_{min}(S_4^0)$ (Table 4) are quite small but, being all positive, they consistently favour the S_4 conformation as corresponding to the *global* (i.e., ground-state) minimum. The two minima are separated by a potential energy barrier to rotational reorientation of the phenyl rings about roughly the Z—C1 bond, with ϕ as the transition parameter; under S_4 symmetry the reorientations of the four phenyl rings along the $D_{2d} \rightarrow S_4$ transition path are concerted.

To obtain an estimate of the height of this barrier, an additional HF/6-31G(d,p) optimization (S_4^ϕ) was performed in S_4 symmetry for each Z, with ϕ fixed at ~68°, a value intermediate between those for the S_4 and D_{2d} minimum-energy conformations (cf. Tables 2 and A[8]). These optimizations converged properly, without imaginary frequencies. The $E(S_4^\phi)$ values were considerably above those for the S_4^0 and D_{2d}^0 minima, the difference $\Delta E(S_4^\phi) = E(S_4^\phi) - E(S_4^0)$ increasing from ~4.9 kcal mol^{-1} for BPh_4^- to ~6.0 kcal mol^{-1} for NPh_4^+ (Table 4). These $\Delta E(S_4^\phi)$ values thus provide lower-limit estimates of the three barrier heights.

Fig. 1. (*Left*) Numbering of the C atoms in a $ZPh_4^{0,\pm1}$ molecule. Standard orientation: Z at the origin, +*x* to the right of Z, +*y* up from Z in the page, +*z* up from the page. (*Right*) View of the shortest inter-ring H···H = *h* contact in the molecule. The horizontal line represents the intersection of the *xy* plane with the page; the +*z* axis is in the page, as indicated.



On the reasonable expectation that a comparison of the energies obtained for the isoelectronic BPh_4^-, CPh_4, and NPh_4^+ would reveal a trend, we carried out the analysis a step further. The curve representing the difference $\Delta E = E - E(S_4^0)$ as a function of ϕ is periodic, with $0° \le \phi \le 90°$ as the defining interval, but the portion of interest for the potential barrier to the $S_4 \leftrightarrow D_{2d}$ conversion extends only from ϕ ~ 45° to 90°. In this subinterval the function has, from the above, a minimum at ϕ ~ 50–58°, a minimum at ϕ = 90°, and a maximum between the two minima. Within these ϕ limits it should be possible to approximate $\Delta E(\phi)$ for each Z by a quartic polynomial $\sum_0^4 a_n \phi^n$ uniquely defined by the $\phi, \Delta E(\phi)$ pairs for S_4^0, S_4^ϕ, and D_{2d}^0 (Table 4), using the condition that, at the two minima, $(\Delta E)' = 0$. The height and the position of the barrier could then be estimated from the location of the maximum of the resulting polynomial. In addition, a cubic baseline could be constructed by a similar procedure.

The applicability of this approximation procedure was tested in two ways: (*i*) by using the approximation in an attempt to reproduce curve *a* of Fig. 3 of ref. 4 (strain energy E vs. torsional angle θ of the phenyl ring in CPh_4). This curve may be taken as representative of this type of energy vs. rotational displacement function; (*ii*) by equating $\Delta E(D_{2d}^0)$ for CPh_4 (Table 4) to zero, and again to twice its actual value, and repeating the above approximation procedure with the other $\phi, \Delta E(\phi)$ unchanged.

In (*i*) curve *a* is defined by 13 data points, with graphically interpolated positions of the two minima and of the maximum, the global minimum being at the smaller θ angle and the subsidiary minimum at θ = 90°. The coordinates of the data points were estimated from an electronic scan, and

[9] The optimized S_4 conformations of $ZPh_4^{0,\pm1}$ are typified by the CPh_4 molecule in the center of Fig. 3.

the curve was reconstituted by the above procedure from the positions of the minima (horizontal tangents) and a data point P chosen at or near the maximum and corresponding to the $\phi, \Delta E(\phi)$ point for S_4^{ϕ} in Fig. 2. The resulting θ_{max}, ΔE_{max} estimate was found to depend on the position of P; from the variation of the computed position of ΔE_{max}, it was estimated that the position of the interpolated maximum could be reproduced to within 5–10% of θ_{max} and ΔE_{max}. The *second* test produced changes of only ca ± 0.6° (i.e., ~1%) in the ϕ_{max}, and ca ± 0.2 kcal mol^{-1} (i.e., ~3%) in the ΔE_{max} estimates. A detailed examination of the results of the two tests showed that $\Delta E(\phi)$ is considerably robust with respect to the above approximation procedures. The procedure works best when the ΔE values at the two minima are similar, as is the case with $\Delta E(S_4^0)$ and $\Delta E(D_{2d}^0)$.

Estimates of the barrier heights above a horizontal ($\Delta E = 0$) and a cubic baseline (Fig. 2, inset) are listed in Table 4. They show a consistent increase from B to N, ranging from ~5.2 to ~8.1 kcal mol^{-1} for the horizontal and from ~4.7 to ~7.7 kcal mol^{-1} for the cubic baseline; the shifts of the position of ΔE_{max} are relatively small, from ~71° for B to ~74° for N. These low barrier values may explain the great variability of the BPh_4^- anion geometry with crystal environment.

As pointed out above, Mislow and co-workers (4) concluded, from their full-relaxation molecular mechanics calculations, that the ground-state conformation of free CPh_4 has the D_{2d} rather than S_4 symmetry, in contrast to all other observations on $ZPh_4^{0,\pm1}$ reported to date, with the exception of BPh_4^- in alkali and ammonium tetraphenylborates (10, 11). We do not know the reason for the disagreement with

our ab initio results, but it might be noted that the results of ref. 4 were obtained with one of the earliest molecular-mechanics force fields.

HF and DFT results compared

Comparing the results of the two optimizations for individual parameters (e.g., bond lengths, bond angles) is, overall, less informative than assessing the agreement between the two *globally*, i.e., in terms of the difference between corresponding parameter values taken together. A suitable measure here is $\mu = \sum|\Delta|/n$, where Δ is the difference between the corresponding coordinates of a C or an H atom, the sum taken over all the C or H atoms, respectively (Table 5). Alternatively, one can compare the lengths of the differential displacement vectors $D = [(\Delta x)^2 + (\Delta y)^2 + (\Delta z)^2]^{1/2}$ between the two sets of atom coordinates, and the mean, $\overline{D}$ of these vectors.

Generally, μ(H) and $\overline{D}$(H) values are about twice those for the corresponding μ(C) and $\overline{D}$(C), respectively (Table 5). The smallest differences between the two optimizations are for D_{2d}^{00} and D_{2d}^0, 0.005–0.01 Å for μ(C) and 0.01–0.02 Å for $\overline{D}$(C); the individual values for Z from B to N are indistinguishable within their statistics, and they would also be well within the 3σ limits of conventional crystallographic determinations. The μ(C) and $\overline{D}$(C) differences for S_4^{00} and S_4^0, numerically, are larger than those for D_{2d}^{00} and D_{2d}^0, but their substantial standard deviations again render their significance, with respect to the effect of Z, uncertain. One may conclude that, on the present evidence and for our purposes, the HF and DFT treatments lead to results that are in reasonable

overall agreement, without clear grounds for preferring one treatment to the other.

Tetraphenylmethane: ab initio vs. experiment

The three independent determinations of the crystal structure of CPh_4 from X-ray data obtained at 20°C and 26°C (17) agree closely among themselves.[10] The results of the present determination from –60°C X-ray data (set *T*, cf. Tables 1 and 6, Fig. 3, and material deposited[7]) are in excellent agreement with *R* (Table 5). Differences that might be attributed to the effect of temperature are, on the whole, well within 3σ of the *T* values: μ(C) for the coordinate differences between *T* and *R* is only 0.004(4) Å and $\overline{D}$(C) is only 0.009(6) Å, values eminently acceptable for careful conventional determinations from X-ray data. Within this accuracy, the experimental geometry of the CPh_4 molecule in the crystal can thus be regarded as established.

In the crystal, the CPh_4 molecule has a conformation of S_4 symmetry, so the comparison with the optimized ab initio molecular geometry has to be with S_4^{00} and S_4^0 and will involve essentially the carbon skeleton. Less reliance can be placed on the features involving the H atoms, in part because of the ring-planarity restriction in the ab initio calculations, and in part because of the residual uncertainties in the refined H atom location in experimental determinations. As seen in Table 6, the experimental ring geometry agrees well

[10]The parameters from the two 20°C data sets have been averaged here to give the *R* set, Table 6.

[a] $\Delta E = \sum_0^3 b_n\phi^n$, $(\Delta E)' = 0$ at $S_4{}^0$ and $D_{2d}{}^0$.

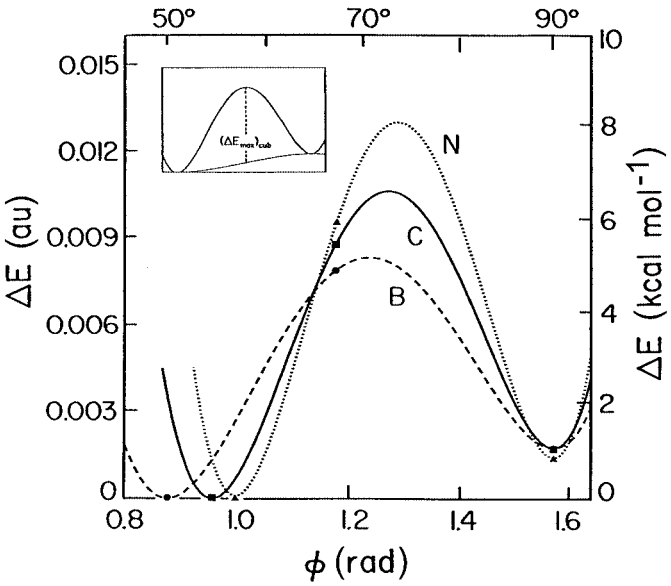
with $S_4{}^{00}$ and $S_4{}^0$, especially when account is taken of the differences between the $S_4{}^{00}$ and $S_4{}^0$ parameters themselves. Moreover, the exocyclic ζ_2 and ζ_6 angles, defining the extent of nonalignment of the C1-C4 ring axis with the Z—C1 bond, are the same in the free molecule and in the crystal. The valence angles α and β, however, which between $S_4{}^{00}$ and $S_4{}^0$ average to 105.2(2)° and 111.7(1)°, respectively, and thus do not depend greatly on the model, are 1.5(2)° smaller and 1.0(2)° larger, respectively, than those in the crystal; the tilt angle ϕ, 49.0° in both T and R, averages to 54.0(8)° in the free molecule, a significant difference of ~5°, given that it is computed from the general positions of all six C atoms in the ring.

Closer examination of the atom coordinates shows that the largest differences between corresponding coordinates occur in the z coordinate. In terms of $\bar{z}$(C) and $\bar{z}$(H) (Table 6), the differences between the optimized $\bar{z}$(C) and $\bar{z}$(H) means and those in the crystal are 0.055 Å and 0.071 Å, respectively, compared with −0.030 Å and −0.006 Å, respectively, for the $\bar{y}$(C) and $\bar{y}$(H) means, all referred to the standard orientation. Relative to the free CPh_4 molecule, the molecule in the crystal is thus somewhat compressed along the $z \equiv S_4$ axis but otherwise almost unchanged. There are several short intermolecular H···H contacts in the structure (Fig. 3, Table C), but it is not obvious which H···H interactions in particular can be regarded as jointly instrumental in this compression. The shortest two of these contacts, 2.44(2) and 2.57(3) Å (between nearest H2 and H5, and H3 and H4 atoms, respectively, of adjacent molecules) are comparable to the H2···H6′ = h contact between the *ortho*-hydrogens within a molecule, 2.54(2) Å (Fig. 1, Table 6).

Ground-state geometry of BPh_4^-, CPh_4, and NPh_4^+

The salient parameters of the gross geometry of these ground-state conformations are the bond length Z—C1 = d_0, the valence angles α and β, the tilt angle ϕ, the angles ζ_2 and ζ_6, and the distance h between the *ortho*-hydrogens H2 and H6′ of neighboring phenyl rings. To these *exocyclic* parameters may be added $\bar{\varepsilon}$, the mean charge on the *ortho*-hydrogens. The C—C bond lengths d_{ij} and the C-C-C angles ζ_i will be referred to as the *endocyclic* parameters.

Fig. 2. Variation of $\Delta E = E - E(S_4{}^0)$ with the tilt angle ϕ in $ZPh_4^{0,\pm1}$ (constructed from the approximation explained in text). Inset: the $(\phi,\Delta E)$ curve for BPh_4^- fitted with a cubic baseline.



Before discussing the specifics of the variation of these parameters with Z we may note the following: $\alpha < \tau < \beta$ and $\zeta_2 < \zeta_6$; the sum $2\alpha + 4\beta$ of the six valence angles has a minimum of 6τ at $\alpha = \beta = \tau$. The approximate numerical ranges of the exocyclic parameters are 45° < ϕ < 60°, 1.52 Å < d_0 < 1.70 Å, 2.45 Å < h < 2.65 Å. The changes in δ_i are compensatory ($\sum\delta_i = 720°$, $\sum\Delta\delta_i = 0$), and there is also approximate local compensation between neighboring angles, e.g., δ_1 and δ_2. The sum $\sum d_{ij}$ of the six C—C bond lengths decreases by about 0.5% from B to N, indicating (together with d_0) an overall contraction of the molecular dimensions.

The geometric parameters and $\bar{\varepsilon}$ are all affected by a change of Z, but to a considerably unequal degree. The sensitivity of a parameter x to a variation of Z (i.e., the relative magnitude of the effect of Z variation) can be assessed from the range/mean ratio of x. This ratio is approximately equal

$D_{2d}^{00} - D_{2d}^0$	0.011 (6)	0.015 (9)	0.020 (6)	0.028 (9)

[a] $\mu = \Sigma|\Delta|/n$, Δ = difference between corresponding atom coordinates in *B* and *A*.
$D = [(\Delta x)^2 + (\Delta y)^2 + (\Delta z)^2]^{1/2}$, differential displacement of atom; $\overline{D}$ = mean of *D*. All values in Å.

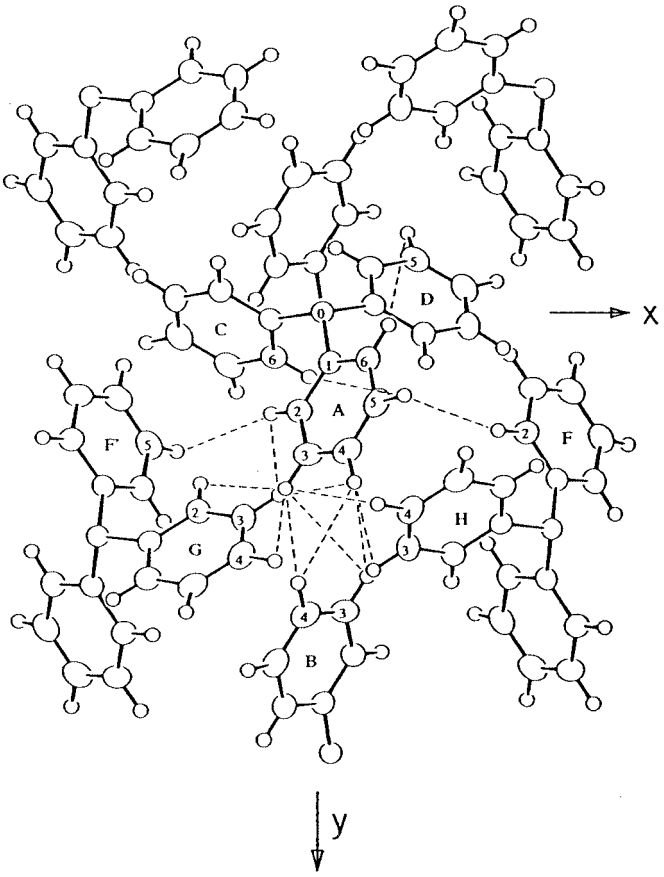
to $2\sigma(x)/\bar{x}$ (Table 7). With the exception of d_{45}, the sequential order of the ratio is the same for S_4^{00} and S_4^0; the difference of the two means falls within a single joint $\overline{\sigma}$ of the means and in most cases well below it, except for $\overline{\varepsilon}$ (<1.5$\overline{\sigma}$), d_{45} (~2$\overline{\sigma}$), d_{56} and d_{34} (~3$\overline{\sigma}$), and d_{23} (~7$\overline{\sigma}$). The agreement of the parameter values between S_4^{00} and S_4^0 is thus very good (cf. also Table 5).

The values of the range/mean ratio extend from 72% to 0.1% for S_4^{00}, and from 37% to 0.1% for S_4^0. On the whole, the parameters that respond most to the change of Z are the exocyclic parameters $\overline{\varepsilon}$, ϕ, d_0, and h, with ratios >5. Of the endocyclic parameters, the internal angle δ_1 at the α-carbon is affected highly significantly and, to a lesser degree, so are the angles δ_2 and δ_6 at the *ortho*-carbons. The effect of Z on the other δ_i and d_{ij} is much smaller and, for the bottom six entries in Table 7, is established not without uncertainty.

The pairwise mutual dependence, $y = a_0 + a_1x$, of the angles, distances, and $\overline{\varepsilon}$ is summarized for S_4^{00} and S_4^0, in terms of the *linear* coefficients of determination (r^2), in Table 8 and in the connectivity graphs of Figs. 4–6.[11] There being only three *Z* in the set, the statistical validity of the bivariate linear correlation is of necessity limited. Where a plot of a parameter *y* vs. a parameter *x* shows a monotonic but clearly not linear trend, the r^2(linear) value will not be high and the functional dependence cannot be established, statistically, because of the insufficient *n*.[12] This would be true a fortiori for multivariate linear or other correlations that undoubtedly exist (cf. ref. 29). Still, examination of Table 8 and Figs. 4–6 shows that there are many highly significant linear correlations, and analysis of a selection from these permits a number of interesting conclusions.

There is generally a satisfactory agreement between the $r^2(S_4^{00})$ and $r^2(S_4^0)$ values in an *x*,*y* pair. The obvious discrepancies in Table 8 — the signs of $r(S_4^{00})$ and $r(S_4^0)$ in

Fig. 3. Projection of a portion of the crystal structure of CPh_4 down the $z \equiv S_4$ axis (origin at C0). The intermolecular H···H contacts out to 3 Å from ring A (cf. Table C) are indicated by broken lines.



[11] Table 8 contains only those correlations for which $r^2 \geq 0.67$. A complete list of *r* and r^2 will be found in Tables D and E.
[12] Except for two-parameter model functions (power, exponential, logarithmic), but for these the regressions were found to yield r^2 and σ values not much different from those for the corresponding linear regression.

an *x*, *y* pair are not the same, or there is a gross difference in the magnitudes of the conjugate $r^2(S_4^{00})$ and $r^2(S_4^{0})$ — may have different origins: the trend in the *y*(*Z*) value is confused; the three values in a set are very small (numerical accuracy!); their range is too narrow; or a combination of these conditions may be present. The parameter triplets so affected are all endocyclic and have small range/mean ratios, typically <0.5 (Table 7). The statistical validity of the discrepant associations being questionable, they are ignored in the analysis below. Where strong, meaningful correlations exist, the $r^2(S_4^{00})$ and $r^2(S_4^{0})$ are both large and similar in value (Table 8), and the range/mean ratios of the correlated parameters are greater than ~0.5.

Regression equations for the strongest linear correlations ($r^2 \geq 0.95$) are listed in Table F. The signs of the correlation coefficients *r*(*x*,*y*), and the strength of the correlations as measured by $r^2(x,y)$, are presented synoptically in the connectivity graphs of Figs. 4–6.[13]

[13]To arrive at the sign of *r*(*x*,*y*) for a correlation between two parameters *x* and *y* that are not neighbours in the connectivity graph, a continuous path from *x* to *y* can be traced in the graph via intermediate legs. Obviously, for positive correlations this always leads to a positive *r*(*x*,*y*). In graphs for negative correlations, the sign changes at every step, so that *r*(*x*,*y*) will be positive for an even number of intermediate legs and negative for an odd number.

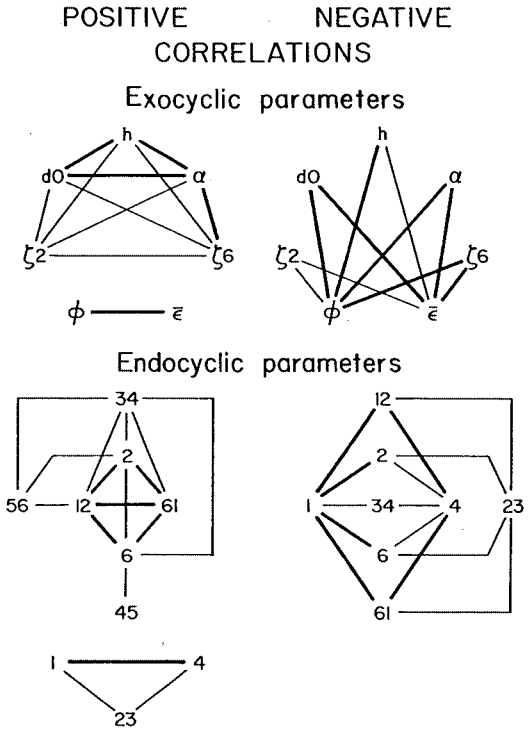
Fig. 4. Linear correlations between exocyclic, and between endocyclic parameters in $ZPh_4^{0,\pm1}$ (*i* stands for δ_i, *ij* stands for d_{ij}). Thick lines ($r^2 \geq 0.95$ for both $S_4{}^{00}$ and $S_4{}^0$), thin lines ($0.67 \leq r^2 < 0.95$ for either $S_4{}^{00}$ and $S_4{}^0$ or both). The tie lines imply correlations between nearest parameter neighbours only.



Exocyclic parameters (Fig. 4)

Since the underlying "chemical" variable Z is not specified numerically, to quantify the effect of its variation on the numerically expressed structural parameters one may select one of the latter as the primary parameter, through which Z correlates with the others. Such a parameter may be d_0, which governs the variation of the core geometry of the $ZPh_4^{0,\pm1}$, and which itself is electronically controlled by the Z—C(α) covalent bonding interaction, and is highly sensitive to the Z substitution (Table 7).

The Z—C1 bond length d_0 correlates strongly and positively with α and *h*. This is not unexpected. In the counterpart of the free $ZPh_4^{0,\pm1}$, the free $ZX_4^{0,\pm1}$ (X = H, halogen) molecules, the ligand is structureless, and the six X-Z-X angles are all equal to τ, regardless of the Z—X = d_0 bond length. In contrast, in the free $ZPh_4^{0,\pm1}$ the ligand is large and highly anisotropic, and its shape and steric interactions between neighboring ligands prevent the molecule from achieving T_d symmetry. Thus, under the S_4 symmetry of the ground-state conformation, the set of six C-Z-C angles is split into a subset of two angles ($\alpha < \tau$) and a set of four angles ($\beta > \tau$). While in $ZX_4^{0,\pm1}$ an increase in d_0 leaves the tetrahedral angle unchanged, in $ZPh_4^{0,\pm1}$ the factors causing α to be smaller than τ will weaken (the relative dimensions of the Ph group being essentially constant), and $\alpha \rightarrow \tau$ as $d_0 \rightarrow \infty$. The expected positive correlation of α with d_0 is observed, but the d_0,α variation is only approximately linear. The observed positive correlation of d_0 and *h* ($r^2 = 1.00$), the shortest distance between the *ortho*-hydrogens H2 and H6′ (Fig. 1), would be expected to arise for a similar reason.

Fig. 5. Linear correlations between mixed parameters in $ZPh_4^{0,\pm1}$ (see caption of Fig. 4).

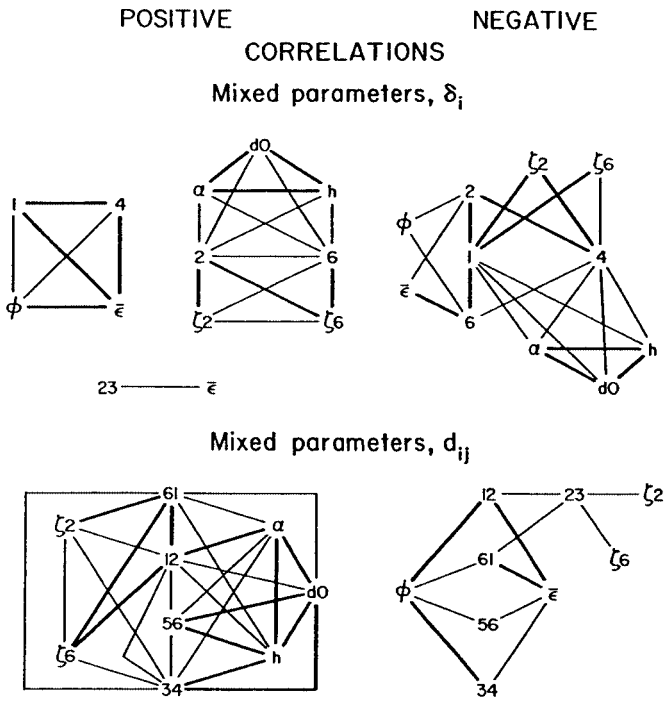


Fig. 6. Linear correlations between mixed parameters in $ZPh_4^{0,\pm1}$: effect of ring asymmetry (cf. caption of Fig. 4). Thick lines, $r^2 \geq 0.95$; thin lines, $0.9 \leq r^2 < 0.95$; broken lines, $0.67 \leq r^2 < 0.95$.

[a]Δ = mean(S_4^{00}) – mean(S_4^{0}); $\bar{\sigma}$ = joint σ of the means.
[b]Trend confused.

Fitting ϕ simultaneously to α and d_0 results in ϕ = 264.8 – 1.77α – 16.1d_0 (S_4^{00}, zero degrees of freedom), i.e., the negative contribution of α to ϕ is ca. seven times more important than the negative contribution from d_0.

Two of the exocyclic parameters, ϕ and $\bar{\varepsilon}$, are strongly positively correlated, but the correlations of both of them with the other five exocyclic parameters are negative, and most of them strong.

Endocyclic parameters (Fig. 4)

Collectively, the changes with Z, $\Delta\delta_i$, in the internal bond angles δ_i are subject to the condition $\sum\Delta\delta_i = 0$, which implies pair-wise correlations between all the δ_i. The strongest correlations are δ_1,δ_4 and δ_2,δ_6 (both positive), and δ_1,δ_2, δ_1,δ_6, δ_2,δ_4, and δ_6,δ_4 (all negative). The angle with the largest range (i.e., most responsive to Z, Table 7) is δ_1. The angle δ_4, with a range of only ~15% that for the δ_1 range, is covariant with δ_1 (δ_4 = 102.16 + 0.1435δ_1, r^2 = 0.998, for S_4^{00}, and δ_4 = 98.78 + 0.1722δ_1, r^2 = 0.999, for S_4^{0}); the two angles would be equal at ~119.3°, i.e., between C and N. The other strong positive correlation, δ_2,δ_6, arises from the contra-variant tendency of these two angles to compensate, unequally, for the change in the angle δ_1 they enclose (δ_6 = 9.966 + 0.921δ_1, r^2 = 0.999, for S_4^{00}; not indicated as strong in Fig. 4 because of the relatively low r^2 for S_4^{0}). The corresponding (δ_3,δ_5) also is positive and strong for S_4^{00} (δ_5 = 29.78 + 0.750δ_3, r^2 = 0.964), but again doubtful for S_4^{0}, and therefore not included in Fig. 4. The strong negative correlations δ_1,δ_2 and δ_1,δ_6 again are easily visualized because of compensation between neighboring angles.

Among the negative correlations between δ_i, evident for S_4^{00} but not for S_4^{0} (and therefore not included in Fig. 4), are δ_2,δ_3 (at the distal carbons C2 and C3) and the corresponding δ_6,δ_5 (at the proximal carbons C6 and C5). Both show clearly the difference between the proximal and the distal sides of the ring (δ_3 = 133.59 + 0.107δ_2, r^2 = 0.994, and δ_5 = 131.03 + 0.089δ_6, r^2 = 0.992).

The bond lengths d_{ij} show strong correlations among themselves (positive for d_{12},d_{61}) as well as with δ_i (positive for δ_2,d_{12}, δ_2,d_{61}, δ_6,d_{12}, δ_6,d_{61}; negative for δ_1,d_{12}, δ_1,d_{61}, δ_4,d_{12}, δ_4,d_{61}). It may be noted that, by virtue of their strong positive correlations, δ_1 and δ_4 correlate with other endocyclic parameters in the same fashion, though δ_4 somewhat less strongly. Thus δ_4 can replace δ_1 in the negative correlations δ_1,δ_2, δ_1,δ_6, δ_1,d_{12}, δ_1,d_{61}, and δ_1,d_{34}.

Mixed correlations (Fig. 5)

These are on the whole less predictable though more numerous. The strong negative correlations of δ_1 with ζ_2 and ζ_6 have their origin in the approximate coplanarity of the angles at C1 ($\delta_1 + \zeta_2 + \zeta_6$ ~ 360°). The angles δ_2 and ζ_2, and δ_6 and ζ_6 are covariant, as are d_{12} and ζ_2, and d_{61} and ζ_6, consistent with the quasi-isometric contraction of the molecular dimensions from B to N. The positive correlation between d_0 and δ_2, and between d_0 and δ_6, is the consequence of the successive negative correlations between d_0 and δ_1, and between δ_1 and δ_2 or δ_6.

To the correlations in Table 8 may be added those involving the exocyclic distances Z···C2, Z···C6, Z···H2, and Z···H6 (Table 9 and Fig. 6). With the exception of those involving $\bar{\varepsilon}$ they are all positive, again reflecting the contraction from B to N. As seen in the connectivity graph of Fig. 6, the distal parameters Z···C2 and Z···H2 (i.e., those on the H2···H6′ side of the ring) correlate much less strongly with ζ_2 than do the

proximal parameters Z···C6 and Z···H6 with ζ_6, the latter being unaffected by the interaction between the *ortho*-hydrogens, H2 and H6′.

As for the effects of the asymmetry of the Z···β-carbon distances (Z···C2 and Z···C6) on the skeletal geometry of the phenyl ring, these are small but not insignificant. The regression equations for the correlations δ_2,δ_6 ($\sigma = 0.1° \sim 3\%$ of range) and δ_3,δ_5 ($\sigma = 0.04° \sim 10\%$ of range) between the corresponding parameters in distal–proximal pairs in S_4^{00} (cf. preceding section) are evidence of the inequality arising from the lack of bilateral symmetry of the ring, i.e., the corresponding angles are consistently differentiated: $\delta_6/\delta_2 > 1$, $\delta_5/\delta_3 < 1$. The differences are even smaller for the d_{ij} bond lengths ($d_{61} = 0.262 + 0.818d_{12}$ for S_4^{00}, $r^2 = 0.962$, $\sigma = 0.0017$ Å $\sim 12\%$ of range, $d_{61}/d_{12} > 1$). These findings agree with the observations made on the statistical sample of ref. 26, where a similar conclusion was reached for the effects of the asymmetry in the Z···β-carbon distances in monosubstituted benzene derivatives (cf. below).

The mean atom change $\bar{\varepsilon}$ on the *ortho*-hydrogens H2 and H6 correlates highly with almost all the parameters (Tables 8 and 9). This, together with the large range/mean sensitivity ratio for Z substitution (Table 7), points to an important involvement of $\bar{\varepsilon}$ in the conformational behavior of the $ZPh_4^{0,\pm1}$ molecules.

Substituent-induced changes in the phenyl ring geometry

The geometry optimization of the three species affords an opportunity for examining, in some detail, the effect of Z on the endocyclic bond lengths and angles. A pioneering systematic investigation of this kind was undertaken by Domenicano and co-workers (25–29). It was based on an analysis of a large variety of experimental results for substituted benzene derivatives. While our results for the above three species offer a much narrower range of substitution, and can be compared with those of Domenicano and coworkers (25, 26, 29) only for benzene monosubstituted by elements of the first row, they have the advantage of being internally closely consistent, and free from adventitious structural and experimental influences.

The geometry of the (planar) Ph ring in the ground-state conformations of the three isoelectronic $ZPh_4^{0,\pm1}$ varies with Z in general in conformity with the findings of Domenicano et al. Thus the angle δ_1 at the α-carbon (and the covariant angle δ_4 at the δ-carbon) is smallest, and the angles δ_2 and δ_6 flanking δ_1 are the largest, for the σ-electron-*releasing* B atom, whereas the opposite is true for the σ-electron-*withdrawing* N atom.[14] Concurrently, the increase in δ_1 from B to N is associated with a small (ca. 1%) but clearly discernible shortening of the C1—C2 and C1—C6 bonds enclosing δ_1.[15] The magnitude of the electronic effect of Z on the C-C-C angles diminishes with the increasing distance from Z: the *range* of δ_1 (5.2–5.6°) is almost seven times that for δ_4 (0.8°). The compensation for the variation in δ_1 takes place almost entirely in the δ_2 and δ_6 angles at the β-carbons, and depends only slightly on Z:

	B	C	N
$\delta_1 + \delta_2 + \delta_6$ (for S_4^{00})	360.8°	360.1°	359.3°
$\delta_1 + \delta_2 + \delta_6$ (for S_4^0)	360.7°	360.1°	359.6°

(the δ_2 and δ_6, and the δ_3 and δ_5 angles, equivalent under D_{2d} symmetry, are differentiated under S_4).[16] The δ_5 and δ_6 angles at the γ-carbons also are smallest in BPh_4^-, and their ranges are much smaller than for the other endocyclic angles.

A more detailed comparison can be made with the results of Domenicano et al.'s (29) statistical investigation of the effect of monosubstitution on the endocyclic parameters in benzene derivatives, in which the substituent atom attached to the ring is from the first row. The data set in that study comprised 149 entries extracted from high-precision structures. The benzene rings were treated as if of C_{2v} symmetry, and bivariate correlations were calculated for all combinations of the appropriately averaged δ_i and d_{ij}. Interestingly, the only one of the 21 non-self-correlations that had an $r^2 > 0.95$ was δ_1, $(\delta_2 + \delta_6)/2$, with $r^2 = 0.98$ and a regression equation $(\delta_2 + \delta_6)/2 = 190.62 - 0.591\delta_1$).[17] This compares with our $r^2 = 1.00$ for δ_1,δ_2 in S_4^{00} (0.985 in S_4^0), and with $r^2 = 1.00$ for δ_1,δ_6 in S_4^{00} (0.957 in S_4^0). The corresponding regression equations (Table F)[8] are very similar to eq. [35] of ref. 29, and have $\sigma = 0.07° \sim 2\%$ and $0.17° \sim 5\%$ of range for S_4^{00} and S_4^0, respectively.

The only other of the combinations with $r^2 > 0.5$ in ref. 29 was δ_4,$(d_{12} + d_{61})/2$, with $r^2 = 0.64$; this corresponds to $r^2 = 0.97$ (S_4^{00}) and 0.98 (S_4^0) for δ_4,d_{12}, and to $r^2 = 1.00$ for

[14]For a carbon atom as a substituent, δ_1 is smaller than the 120° angle in the free benzene molecule. The value suggested in ref. 25 is 117.5–118.0°, in agreement with $\delta_1 = 117.5°$ in CPh_4 (Table 6).
[15]Reasons for these trends are advanced, in terms of hybridization effects or, alternatively, the VSEPR model, in ref. 26.
[16]The angles δ_1, ζ_2, and ζ_6 at C1 add up to 360° for both S_4^{00} and S_4^0, even though the phenyl ring and the C0—C1 bond are not coplanar.
[17]Recast from $(\delta_2 + \delta_6)/2 - 120 = -0.301(15) - 0.591(7)(\delta_1 - 120)$.

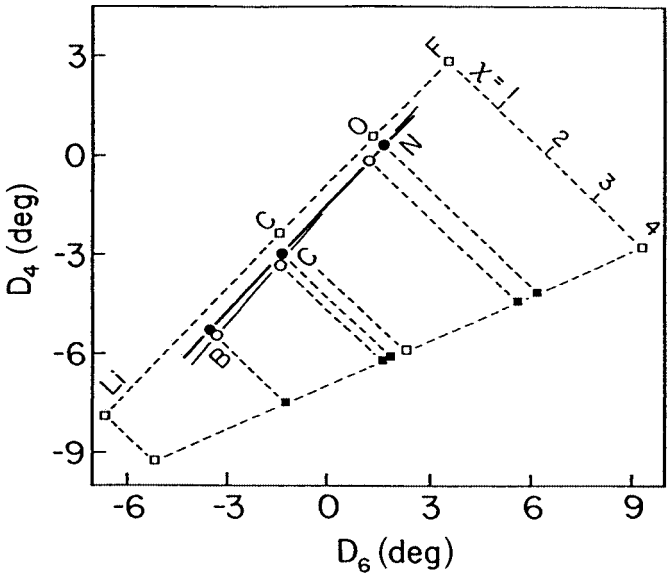
Fig. 7. Correlations of the symmetry distortion coordinates D_4 and D_6 (see text) for $ZPh_4^{0,\pm1}$ (S_4^{00} (solid circles, thick solid line); S_4^0 (open circles, thin solid line)). The electronegativities χ of the -$ZPh_3^{0,\pm1}$ groups (solid squares) refer to the χ(Pauling) correlation baseline defined by the points for Li, C, O, and F; open squares, see footnote 19 in text).



δ_4,d_{61} (both S_4^{00} and S_4^0). However, all the other correlations that for $ZPh_4^{0,\pm1}$ are highly significant have, in Table 3 of ref. 29, counterparts with r^2 values from ~0.3 to ~0.4, while for the remaining ones $r^2 \leq 0.1$. This seems to indicate that the statistical trends in ref. 29 parallel those for $ZPh_4^{0,\pm1}$ and, though obscured by the undiscriminating chemical variation in the underlying data set,[18] are in general agreement with our own observations.

The δ_1,$(d_{12} + d_{61})/2$ correlation in ref. 29 (expected to be high) was described as very poor ($r = -0.56$, $r^2 = 0.31$), the presumed reason stated being that the variance of $(d_{12} + d_{61})/2$ was due to thermal motion and inhomogeneity of the sample. The correlation improved significantly ($r = -0.83$, $r^2 = 0.69$) when instead of $(d_{12} + d_{61})/2$, the quantity a' (defined as the mean of the six C—C bond lengths subtracted from $(d_{12} + d_{61})/2$) was plotted against δ_1 (Fig. 5*a* of ref. 29). When we applied this averaging procedure to $ZPh_4^{0,\pm1}$, the resulting δ_1,a' correlation indeed was practically perfectly linear: $r^2 = 0.999$, $\sigma = 0.00014$ Å ~ 1.7% of the a' range for S_4^{00}, and $r^2 = 1.000$, $\sigma = 0.00006$ Å ~ 0.7% of the a' range for S_4^0. Since thermal motion and sample inhomogeneity are not factors in the ab initio set, the apparent improvement in this correlation over δ_1,d_{12} and δ_1,d_{61} (Table 8) is attributed to the averaging of the d_{12},d_{61}, d_{23},d_{56}, and d_{34},d_{45} values, and to the smoothing out of inaccuracies due to numerical rounding-off in the optimization.

Domenicano et al. (29) also investigated correlations between the symmetry distortion coordinates D_i, singling out those between D_3 and D_4, and between D_4 and D_6. They found that although D_3 and D_4 are of the same symmetry species, these two coordinates did not correlate, whereas D_4 and D_6, which are not of the same species, surprisingly correlated rather well. They also pointed out that "the angular variance of monosubstituted benzene rings can be completely represented by the latter two coordinates." Since the geometry of the phenyl rings in $ZPh_4^{0,\pm1}$, optimized under S_4, is not of C_{2v} symmetry (assumed in ref. 29), we examined the correlations with these coordinates appropriately modified:

$$D_3 = (2\sqrt{3})^{-1}(-d_{12} + 2d_{23} - d_{34} - d_{45} + 2d_{56} - d_{61})$$

$$D_4 = (2\sqrt{3})^{-1}(2\delta_1 - \delta_2 - \delta_3 + 2\delta_4 - \delta_5 - \delta_6)$$

$$D_6 = (2\sqrt{3})^{-1}(\delta_1 - \delta_2 + \delta_3 - \delta_4 + \delta_5 - \delta_6)$$

Unlike for the statistical sample, D_3 and D_4 for the three tetraphenyls *do* correlate: $D_3 = 0.00252 + 0.00181D_4$ for S_4^{00}, with $r^2 = 0.96$ as against $r^2 \sim 0.1$ for the statistical sample. The correlation between D_4 and D_6 was strongly confirmed: $D_4 = -1.512 + 1.079\ D_6$, $r^2 = 1.00$ for S_4^{00}; for S_4^0, $D_4 = -1.595 + 1.144D_6$, $r^2 = 0.999$. This compares with $D_4 = -0.99(7) + 1.20(4)D_6$, $r^2 = 0.81$ for the statistical sample, where most of the scatter seems to be due to chemical variation rather than to experimental error. In this correlation, low D_6,D_4 values correspond to substituents with low electronegativity, and high D_6,D_4 values to substituents with high electronegativity.

The good linearity of the D_6,D_4 plot in fact permits an estimate of the electronegativity of the $-ZPh_3^{0,\pm1}$ groups, viewed as substituents on the benzene ring, if one assumes that the electronegativity χ increases linearly, from Li to F, along the regression line. Using the D_6,D_4 points for $C_6H_5^-\cdots Li^+$, $C_6H_5CH_3$, C_6H_5OH, and C_6H_5F,[19] one obtains $D_4 = -0.899 + 1.005\ D_6$ ($r^2 = 1.00$), which is within 3σ of the corresponding line for the statistical sample, and quite close to the above regression line for the tetraphenyls. With Pauling's χ(Li) = 1.0 and χ(F) = 4.0, the values for χ(C) and χ(O) are 2.5 and 3.4, respectively; relative to this standard line, the χ for the tetraphenyls are then ~1.80, ~2.43, and ~3.55 for Z = B, C, and N, respectively (Fig. 7).

These three χ values for the tetraphenyls correlate well with δ_1 ($\delta_1 = 109.8 + 3.06\chi$, $r^2 = 0.997$, $\sigma = 0.22 \sim 4\%$ of range with δ_1 averaged over S_4^{00} and S_4^0). This compares with a corresponding correlation for a sample of benzene rings monosubstituted with elements of the *second* row (27) ($\delta_1 = 111.4 + 3.33\chi$), and confirms that in monosubstituted benzenes, in the absence of conjugation between the substituent and the ring, electronegativity of the substituent is by far the most important exocyclic factor affecting δ_1.

Transition-state geometry

The transition from the local-minimum D_{2d} conformation to the global-minimum S_4 conformation is a transition between two rotamers, characterized, essentially, by the tilt angle ϕ as the transition parameter. The tilt angle ϕ_b(Z) at the barrier (Table 4) and $\phi(S_4,Z)$ are related by $\phi(S_4^b, Z) = 50.1 + 0.417\phi(S_4^0,Z)$ ($r^2 = 0.999$) if the position of the barrier is estimated with $\Delta E = 0$ as the baseline, and by $\phi(S_4^b, Z) = 45.0 + 0.5\phi(S_4^0, Z)$ ($r^2 = 1.00$) with the cubic baseline of Fig. 2.

[18]Historical sampling is not necessarily a chemically representative sampling.
[19]Averaged from CALKOP, CALKUV, PHENLI, and SIMRUB for Li; TOLUEN for C; PHENOL03 for O; and C_6H_5F (30) for F.

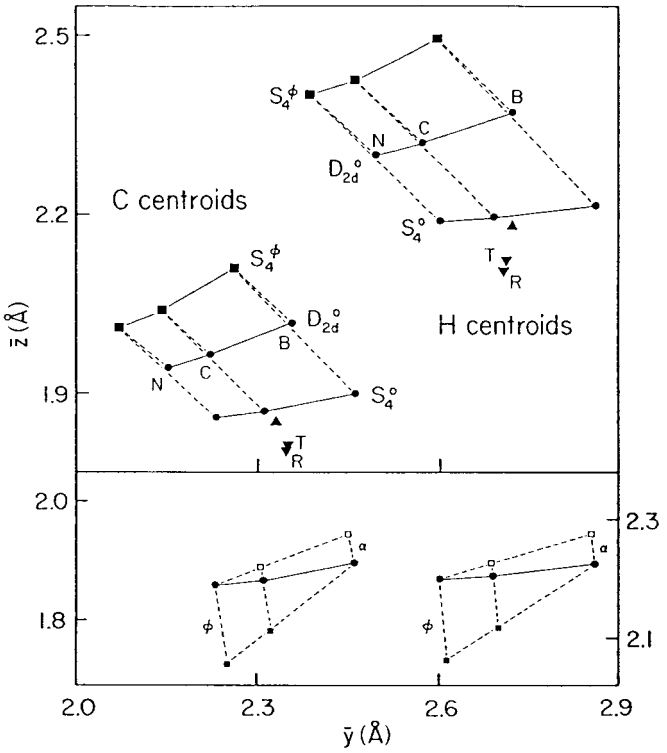
Fig. 8. (*Top*) Positions of the C_6 and H_5 centroids of $ZPh_4^{0,\pm1}$, approximately in the *yz* axial plane. Note the large shifts in these positions on passing, via S_4^{ϕ} under S_4 symmetry, from the S_4^{0} to the D_{2d}^{0} conformation. Circles, S_4^{0} and D_{2d}^{0}; squares, S_4^{ϕ}; triangles up, S_4^{00} for CPh_4; triangles down, see text for *R* and *T*. (*Bottom*) Variation of the valence angle $\alpha(Z) - \alpha(N)$ (open squares) and the tilt angle $\phi(Z) - \phi(B)$ (full squares) with the positions of the C_6 and H_5 centroids in the S_4^{0} conformations (circles). Note the different $\bar{z}$ scales for the two centroids; $\alpha(Z) - \alpha(N)$ and $\phi(Z) - \phi(B)$ are on arbitrary relative scales.



The valence angle $\alpha_b(Z)$ at the barrier is practically equal to the mean of $\alpha(S_4^{0},Z)$ and $\alpha(D_{2d}^{0},Z)$. For BPh_4^-, the value $\alpha_b(B) \sim 105°$ appears to coincide with the minimum in the bimodal distribution of experimental $\alpha(BPh_4^-)$ values in crystals (to be published). Apart from ϕ_b, however, the (interpolated) parameter values at the barrier are not dramatically different from those in the S_4 and D_{2d} conformations, and no particular geometric parameter can be singled out as privileged and distinctly associated with the conformation at the barrier. This is true even of the short H2···H6′ = *h* contact between the *ortho*-hydrogens, the repulsion between which has, traditionally, albeit vaguely, been regarded as responsible for the existence of the barrier. On the contrary, it appears that instead of any *single* factor, it is a combination of a number of geometric factors that produces the barrier to concerted reorientation of the rings under S_4 symmetry. This is illustrated by the shifts in the positions of the C_6 and H_5 centroids (Fig. 8). These shifts, for each Z, vary along the conformation pathway $D_{2d}^{0} \rightarrow S_4^{\phi} \rightarrow S_4^{0}$ in a manner that is analogous to going over the barrier in the $\phi,\Delta E$ plot of Fig. 2; the actual shifts at S_4^{b} would presumably be even larger than at S_4^{ϕ}. Since the positions of all six C atoms and all five H atoms are components of the centroids, the resulting means reflect the simultaneous involvement of all eleven independent atoms in the $ZPh_4^{0,\pm1}$ molecule (leaving aside the probably minor effects arising from the ring–planarity constraint in the model).

Figure 8 also shows the practically linear association of the centroid positions with α and φ.

Conclusions

The equilibrium molecular geometries of the isoelectronic BPh_4^-, CPh_4, and NPh_4^+ have been optimized, at the HF/6-31G(d,p) and B3LYP/6-31G(d,p) levels, in S_4 and D_{2d} symmetries, with the phenyl rings constrained to be planar. The ground-state conformations of all three $ZPh_4^{0,\pm1}$ species are found to be of S_4 symmetry, with the rings tilted (from Z = B to N) by an angle of $\phi \sim 48–57°$ relative to their positions ($\phi = 90°$) in the corresponding D_{2d} conformations. For CPh_4, this contradicts a conclusion from earlier, force-field calculations (4), according to which the ground-state conformation of the molecule has the D_{2d} symmetry, alone among its ZPh_4^0 congeners.

The energy of the D_{2d} conformation is only about 1 kcal mol^{-1} above that of the corresponding minimum-energy S_4 conformation. The height of the potential barrier to rotational reorientation of the ring under $S_4 \subset D_{2d}$ symmetry is estimated to range from ~5 kcal mol^{-1} for BPh_4^- to ~8 kcal mol^{-1} for NPh_4^+ (Table 4). The optimization results do not point to any clearly identifiable, distinguished geometric parameter that might be responsible for the existence of the barrier, except perhaps the short H···H distance *h* between the *ortho*-hydrogens of neighboring rings.

The crystal structure of CPh_4 has been redetermined from –60°C X-ray data, with the H atom positions reliably refined. It agrees well with the earlier determinations from room temperature data. The CPh_4 geometry in the crystal differs from the optimized geometry of CPh_4 only in that the molecule is slightly compressed along its S_4 axis.

All geometric parameters and the mean charge $\bar{\varepsilon}$ on the *ortho*-hydrogens are affected by change of Z, though to a widely unequal extent (Table 7). The $ZPh_4^{0,\pm1}$ molecule undergoes a quasi-isometric contraction of ~0.5% of the molecular dimensions from B to N. The C-Z-C valence angle ($\alpha < \tau$) decreases significantly from B to N, as does the Z—C bond length (d_0). The effects of the Z substitution are presented in terms of binary correlations between individual parameters, both numerically (Table 8) and in connectivity graphs (Figs. 4–6).

The ab initio calculations at the above levels show no obvious reason why the NPh_4^+ cation should be inherently unstable as an isolated molecule, at least in the absence of significant thermal energy.

The effect of Z on the geometry of the phenyl rings in $ZPh_4^{0,\pm1}$ has been examined in detail and compared with the results of statistical studies by Domenicano and co-workers (25–28). In this limited context, the internal consistency of the optimized parameters makes it possible to verify pertinent conclusions from these studies and significantly strengthen them. In particular, the small but not negligible effects of the lack of bilateral ring symmetry on the C—C bond lengths and endocyclic C-C-C bond angles have been assessed with some confidence.

List of symbols

Z	the central atom, at (0, 0, 0)
X′	the symmetry equivalent of the X = C, H atom at (y, $-x$, $-z$)
X″	the symmetry equivalent of the X = C, H atom at ($-x$, $-y$, z)
x, y, z	Cartesian atom coordinates in Å
$\bar{x}$(C) etc.	Cartesian coordinates (Å) of the C_6 centroid of the phenyl ring
$\bar{x}$(H) etc.	Cartesian coordinates (Å) of the H_5 centroid of the phenyl ring
τ	The tetrahedral angle, 109.47°
α	The valence angle C1-Z-C1″ (bisected by the S_4 axis)
β	The valence angle C1-Z-C1′; $\tan^2(\beta/2) = 1 + 2/\tan^2(\alpha/2)$
ζ_2, ζ_6	The angles Z-C1-C2 and Z-C1-C6, respectively (cf. Fig. 6).
δ_i	Endocyclic C-C-C angles, cf. Tables 2 and 3
ϕ	The tilt angle = the angle formed by the axial yz plane with the plane of the phenyl ring, with the molecule in standard orientation specified by Z and the centroid of the C_6 ring in the yz plane, and the S_4 axis in z. It is the acute angle in the S_4 conformations and 90° in the D_{2d} conformation.
E	Total electronic energy (au)
ZPE	Zero-point energy (au)
ε	Net atom charge (Mulliken) (e)
$\bar{\varepsilon}$	[ε(H2) + ε(H6)]/2
S_4^0	Global minimum-energy conformation in S_4/HF/6-31G(d,p)
S_4^{00}	Global minimum-energy conformation in S_4/B3LYP/6-31G(d,p)
S_4^{ϕ}	Geometry optimized in S_4/HF/6-31G(d,p) with ϕ fixed at the stated value
D_{2d}^0	Global minimum-energy conformation in D_{2d}/HF/6–31G(d,p)
D_{2d}^{00}	Global minimum-energy conformation in D_{2d}/B3LYP/6–31G(d,p)
R	Mean of the two independent structure determinations from 20°C data, EaPa (TEPHME02) and Tex (TEPHME03), of ref. 17; CPh_4 in S_4 conformation
T	Structure determination from –60°C data, this work; CPh_4 in S_4 conformation

Radiolysis of liquid water: An attempt to reconcile Monte-Carlo calculations with new experimental hydrated electron yield data at early times

Yusa Muroya, Jintana Meesungnoen, Jean-Paul Jay-Gerin, Abdelali Filali-Mouhim, Thomas Goulet, Yosuke Katsumura, and Samlee Mankhetkorn

Abstract: A re-examination of our Monte-Carlo modeling of the radiolysis of liquid water by low linear-energy-transfer (LET ~ 0.3 keV μm^{-1}) radiation is undertaken herein in an attempt to reconcile the results of our simulation code with recently revised experimental hydrated electron (e^-_{aq}) yield data at early times. The thermalization distance of subexcitation electrons, the recombination cross section of the electrons with their water parent cations prior to thermalization, and the branching ratios of the different competing mechanisms in the dissociative decay of vibrationally excited states of water molecules were taken as adjustable parameters in our simulations. Using a global-fit procedure, we have been unable to find a set of values for those parameters to *simultaneously* reproduce (*i*) the revised e^-_{aq} yield of 4.0 ± 0.2 molecules per 100 eV at "time zero" (that is, a reduction of ~20% over the hitherto accepted value of 4.8 molecules per 100 eV), (*ii*) the newly measured e^-_{aq} decay kinetic profile from 100 ps to 10 ns, and (*iii*) the time-dependent yields of the other radiolytic species $H^•$, $^•OH$, H_2, and H_2O_2 (up to ~1 μs). The lowest possible limiting "time-zero" yield of e^-_{aq} that we could in fact obtain, while ensuring an acceptable agreement between *all* computed and experimental yields, was ~4.4 to 4.5 molecules per 100 eV. Under these conditions, the mean values of the electron thermalization distance and of the geminate electron–cation recombination probability, averaged over the subexcitation electron "entry spectrum," are found to be equal to ~139 Å and ~18%, respectively. These values are to be compared with those obtained in our previous simulations of liquid water radiolysis, namely ~88 Å and ~5.5%, respectively. Our average electron thermalization distance is also to be compared with the typical size (~64–80 Å) of the initial hydrated electron distributions estimated in current deterministic models of "spur" chemistry. Finally, our average probability for geminate electron–cation recombination agrees well with an estimated value of ~15% recently reported in the literature. In conclusion, this work shows that an adaptation of our calculations to a lower hydrated electron yield at early times is possible, but also suggests that the topic is not closed. Further measurements of the e^-_{aq} yields at very short times are needed.

Key words: liquid water, radiolysis, electron–cation geminate recombination, electron thermalization distance, hydrated electron (e^-_{aq}), e^-_{aq} decay kinetics, time-dependent molecular and radical yields, Monte-Carlo simulations.

Résumé : Nous avons réexaminé le code Monte-Carlo que nous avons développé précédemment pour simuler la radiolyse de l'eau liquide par des rayonnements à faible transfert d'énergie linéique (TEL ~ 0,3 keV μm^{-1}) afin de voir s'il est possible de réconcilier les résultats de notre code avec les données expérimentales récemment révisées du rendement en électrons hydratés (e^-_{aq}) à temps courts. Les paramètres ajustables utilisés dans nos simulations sont la distance de thermalisation des électrons de subexcitation, la section efficace de recombinaison des électrons avec leurs cations parents de l'eau avant thermalisation et les rapports de branchement des différents mécanismes intervenant lors de la dissociation des états excités vibrationnels des molécules d'eau. En utilisant une procédure d'ajustement global, nous n'avons pas réussi à trouver un jeu de valeurs de ces paramètres permettant de reproduire *simultanément* : (1) le rendement révisé en e^-_{aq} de 4,0 ± 0,2 molécules par 100 eV à « temps zéro » (c'est-à-dire, une réduction de ~20 % par rapport à la valeur acceptée jusqu'ici de 4,8 molécules par 100 eV), (2) le profil cinétique de déclin des e^-_{aq} nouvellement

mesuré entre 100 ps et 10 ns et (3) les rendements en fonction du temps des autres espèces radiolytiques H•, •OH, H_2 et H_2O_2 (jusqu'à ~1 μs). En fait, le rendement le plus faible possible en e^-_{aq} que nous avons réussi à obtenir à « temps zéro », tout en veillant à garder un accord acceptable entre *tous* les rendements expérimentaux et calculés, s'élève à ~4,4–4,5 molécules par 100 eV. Dans ces conditions, les valeurs de la distance de thermalisation des électrons et de la probabilité de recombinaison géminée électron–cation, moyennées en tenant compte du spectre énergétique des électrons de subexcitation, ont été trouvées respectivement égales à ~139 Å et ~18 %. Ces valeurs sont à comparer avec celles obtenues dans nos simulations antérieures de la radiolyse de l'eau liquide, à savoir, ~88 Å et ~5,5 %, respectivement. Notre valeur moyenne de la distance de thermalisation des électrons est aussi à comparer avec la taille typique (~64–80 Å) des distributions initiales d'électrons hydratés déduites des modèles déterministes actuels de la chimie des « grappes ». Enfin, notre probabilité moyenne de recombinaison géminée électron–cation s'accorde bien avec une valeur estimée de ~15 % rapportée récemment dans la littérature. En conclusion, ce travail montre qu'une adaptation de nos calculs à un rendement plus faible en électrons hydratés à temps courts est possible, mais suggère aussi que le sujet n'est pas clos. D'autres mesures des rendements en e^-_{aq} à temps courts s'avèrent nécessaires.

Mots clés : eau liquide, radiolyse, recombinaison géminée électron–cation, distance de thermalisation de l'électron, électron hydraté (e^-_{aq}), cinétique de déclin des e^-_{aq}, rendements radicalaires et moléculaires dépendants du temps, simulations Monte-Carlo.

Introduction

Besides its intrinsic scientific interest, the radiation chemistry of liquid water is of considerable importance because of its relevance to a number of practical applications in fields such as radiation biology, nuclear-reactor chemistry, nuclear technology relevant to the storage of radioactive waste materials, free radical chemistry, environment, etc. As a matter of fact, the radiolysis of water and aqueous solutions has been the subject of numerous experimental and theoretical investigations for almost a century (for reviews of its long history, see refs. 1 and 2). The most recent developments include the study of water radiolysis by high linear energy transfer[3] radiation (3) and at high temperatures and pressures under supercritical conditions (>374°C, >22.1 MPa or 218 atm) (4). On the theoretical side, the entire water radiolysis process can now be efficiently modeled using Monte-Carlo codes[4] simulating the interaction of a variety of ionizing radiations with aqueous media at various temperatures, pH, and LET (7–11).

Briefly, the radiolysis of pure deaerated liquid water by low-LET radiation (such as ^{60}Co γ-rays or high-energy electrons) principally leads to the formation of the radicals and molecular products e^-_{aq}, H•, •OH, H_2, H_2O_2, and H_3O^+ (for reviews, see refs. 2, 12, and 13). Under usual irradiation conditions, these species are generated nonhomogeneously in small, spatially isolated regions of dense ionization and excitation (commonly referred to as "spurs") along the track of the radiation. The so-called "primary" radical and molecular yields (or "escape" yields) $G_{e^-_{aq}}$, $G_{H\cdot}$, $G_{\cdot OH}$, G_{H_2}, and $G_{H_2O_2}$ represent the numbers of species of each kind produced per 100 eV of absorbed energy[5] that remain throughout the bulk of the solution after spur expansion. At room temperature, the time required before homogeneous chemistry takes over in the solution is ~1 μs. For ^{60}Co γ radiation (photon energies of 1.17 and 1.33 MeV) or fast electrons of the same energies, at neutral pH and 25°C (average LET ~ 0.3 keV μm^{-1}) (14), the standard values of the primary yields are (2, 12, 13, 15, 16):

$$G_{e^-_{aq}} = 2.65 G_{H\cdot} = 0.60 G_{H_2} = 0.45$$

$$G_{\cdot OH} = 2.80 G_{H_2O_2} = 0.68 G_{-H_2O} = 4.15$$

where G_{-H_2O} denotes, at this stage, the corresponding yield of decomposition of water.

Within the lifetime of spurs, the yields of the radicals and molecular species produced by the irradiation vary with time. One of the main goals in the study of the radiation chemistry of water is the determination of these yields and their time dependences. The hydrated electron (e^-_{aq}) is probably the most studied of the transient chemical species formed in the radiolysis of water. The yield of e^-_{aq} was previously measured at early times by several authors in picosecond pulse radiolysis experiments. Hunt and co-workers (17) first obtained 4.0 ± 0.3 at 30 ps. Jonah and co-workers (18) subsequently measured the decay of e^-_{aq} between 100 ps and 3 ns and reported 4.6 ± 0.2 at 100 ps, a value later renormalized by Pimblott et al. (19) to ~4.8 after a reanalysis of existing transient absorption measurements, scavenger yield data, and stochastic diffusion-kinetic simulations. Sumiyoshi and co-workers (20) also determined 4.8 ± 0.3 at 30 ps. Our Monte-Carlo simulation code of water radiolysis (7–11), like most others, was adjusted for the greatest part on the basis of the time dependence of the e^-_{aq} yield measured by Jonah and co-workers (18). However, the numbers for the early-time e^-_{aq} yield in refs. 18 and 19 were recently revised downward by Bartels et al. (21), who reinvestigated the radiolysis spur decay kinetics of e^-_{aq} from 100 ps to 10 ns using a new time-correlated absorption spectroscopy technique. These latter authors fitted the shape of their relative e^-_{aq} decay kinetics with a functional form containing four exponentials and a constant (G_{inf}). The value of

[3] LET, or "stopping power", defined as the energy transferred per unit length of the track ($-dE/dx$).

[4] A number of investigators have developed Monte-Carlo computer simulations for modeling the initial formation of radiolytic species along charged-particle tracks and their subsequent chemical behavior in liquid water. See for example refs. 5 and 6.

[5] Throughout this paper, radiation chemical yields (*G*-values) are given in the units of molecules per 100 eV. For conversion into SI units (mol J^{-1}): 1 molecule per 100 eV ≈ 1.0364×10^{-7} mol J^{-1}.

© 2002 NRC Canada

G_{inf} = 2.5 was selected to match the most reliable scavenger yield data for water (2.7) for a scavenging power[6] of 10^7 s^{-1}. Based on this normalization procedure, Bartels et al. (21) then "extrapolated" their fitting function to short times and found a "time-zero" e^-_{aq} yield of 4.0 ± 0.2, a value consistent with the earlier measurements of Hunt and co-workers (17). The result that the *G*-value of 4.8 at 100 ps could be too high has received some support from LaVerne (22), who recently reported: "An initial e^-_{aq} yield of about 4.2 per 100 eV absorbed can still be reconciled with the inverse Laplace transform of the scavenger data presented previously (ref. 19)". Similar support was also obtained from the deterministic "average" spur diffusion model calculations of Swiatla-Wojcik and Buxton (23), which showed that the experimental yields in water radiolysis with radiation of LET from 0.2 to 60 keV μm^{-1} could be reasonably matched with an initial e^-_{aq} yield value of 4.2. This significant reduction (~20%) in the yield of e^-_{aq} at short times (over the hitherto accepted value of 4.8) (19, 20) thus prompted us to reexamine the values of certain physical and physicochemical parameters that enter our Monte-Carlo simulation code (7–11) to see if this latter could be reconciled with Bartels et al's (21) new experimental findings.

Monte-Carlo simulations

A detailed description of our Monte-Carlo modeling of the radiolysis of liquid water has been given previously (7–11). Briefly, during the "physical stage", the energy deposition by the incident radiation (high-energy protons or heavier ions) and by all the secondary electrons that it has generated occurs through the slowing down of those particles via a variety of inelastic scattering processes, including ionization, electronic and (or) vibrational excitation of single water molecules, and excitation of plasmon-type collective modes. The species created during this first stage undergo fast reorganization in the "physicochemical stage" and produce the "initial" radical and molecular products of the radiolysis, distributed in a highly nonhomogeneous track structure. Secondary electrons slow down to subexcitation energies[7] and, following thermalization,[8] get trapped and eventually become hydrated.[9] All the events of those two stages are handled by our step-by-step simulation codes, called TRACPRO and TRACELE. To reproduce the effects of ^{60}Co γ-radiolysis or of fast electrons, we use short (~100 μm) segments of one hundred fifty 300-MeV proton tracks, over which the LET is essentially constant and equal to ~0.3 keV μm^{-1} at 25°C. Such an analysis thus gives the track segment yields at a well-defined LET. The complex initial spatial distribution of reactants, which is provided as an output of the program TRACELE, is then used directly as the starting point for the "stage of nonhomogeneous chemistry". This third and final stage, during which the radiolytic species diffuse and react with one another in spurs, is covered by our TRACIRT simulation code, using the "independent reaction times" (IRT) method (6, 9, 10, 28) to model the nonhomogeneous reaction kinetics.

To reproduce the newly measured e^-_{aq} decay time profile between 100 ps and 10 ns and the reported reduction of ~20% in the yield of e^-_{aq} at "time zero" (21), a reexamination of certain adjustable parameters that intervene in the physical and physicochemical stages of our Monte-Carlo code is in order. These parameters comprise (*i*) the thermalization distance (r_{th}) of subexcitation electrons, (*ii*) the recombination cross section (σ_{rec}) of the electrons with their water parent cations prior to thermalization, and (*iii*) the branching ratios used for the different competing mechanisms in the decay of directly excited electronic states of water molecules or of vibrationally excited water molecules formed by electron–cation geminate recombination (8). The values of these parameters are obtained here by using a global-fit procedure, which consists in *simultaneously* fitting our calculated time-dependent yields of e^-_{aq} and of the other species ($H^\bullet$, $^\bullet OH$, H_2, and H_2O_2) to the available experimental data.

Values of r_{th} are computed by our Monte-Carlo code MTHREC (29, 30), which simulates on an event-by-event basis the transport of subexcitation electrons in water from their initial energies until they become thermalized.[10] The elastic and inelastic electron scattering cross sections employed are based on those of Michaud and Sanche (32), obtained from slow (~1–18 eV) electron-impact experiments on thin amorphous solid water films condensed at 14 K. The thermalization distances are obtained by averaging r_{th} over a large number (200 000) of histories of random-walking electrons. In the calculations, r_{th} is mainly determined by the electron mean free path (that is, the average distance between two consecutive scatterings) given by $\lambda_m(E) = \alpha/[n\sigma_t(E)]$. Here *n* is the number of molecules per unit volume,

[6] Recall that the "scavenging power" is defined as the product of a solute (scavenger) concentration and its rate constant for the scavenging reaction (k_s[S]), with units of s^{-1}. The reciprocal of the scavenging power gives a measure of the time scale over which the scavenging is occurring. See for example ref. 14.

[7] Subexcitation electrons are those that have kinetic energies lower than the first electronic excitation threshold of the medium (~7.3 eV in liquid water). They lose energy relatively slowly, the dominant mode of energy loss being the excitation of molecular vibrations. See for example refs. 24 and 25.

[8] The thermalization process of a subexcitation electron occurs in competition with the recombination of the electron with its water parent cation (to give a vibrationally excited water molecule, which may dissociate to form: (*i*) $H^\bullet + {}^\bullet OH$, (*ii*) $2\,H^\bullet + O(^3P)$, or (*iii*) $H_2 + O(^1D)$, where $O(^3P)$ and $O(^1D)$ denote the atomic oxygen in its ^3P ground state and in its singlet ^1D state, respectively) and with its dissociative attachment to a water molecule (to produce $H_2O^{-\bullet}$, which decomposes by giving a hydride anion and subsequently H_2 and OH^- by rapid reaction of H^- with an adjacent water molecule) (8). Note that this latter process is resonant; that is, it occurs over a limited electron energy range (for amorphous solid water the onset for H^- formation is at 5.5 eV with a maximum yield at ~7.4 eV) (26).

[9] Let us recall here that the electron "trapping" and "hydration" times are ~110–300 and 240–620 fs, respectively, in pure liquid water at 25°C. See for example ref. 27.

[10] Note that because of the occurrence of high density of electron traps in a polar medium such as liquid water, the subexcitation electrons have a strong tendency to get trapped prior to thermalization. It is entirely possible that they could actually never become thermalized. See for example ref. 31.

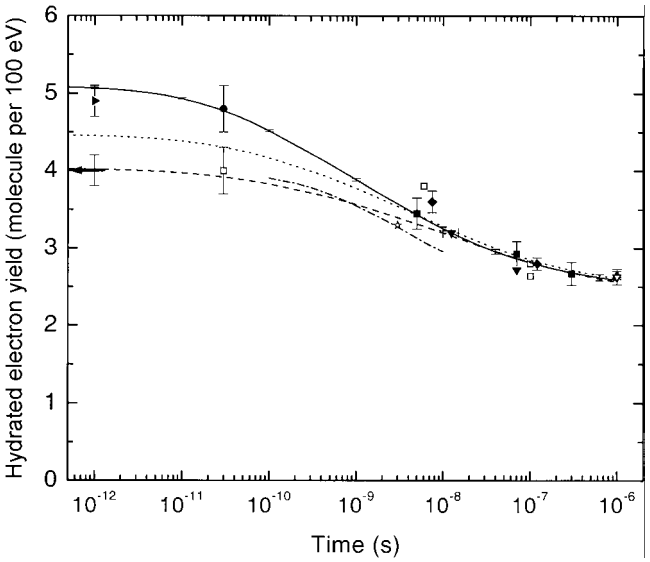
© 2002 NRC Canada

$\sigma_t(E)$ is the sum of the total cross sections at the energy E of the various interaction processes involved, and α is an adjustable coefficient introduced to account for possible differences between solid- and liquid-phase cross sections (8, 30). All our simulations (7–11, 30) of liquid water radiolysis have hitherto been carried out with $\alpha = 0.52$, which amounts to an increase of the solid-phase electron scattering cross sections of Michaud and Sanche (32) by a factor of about 2 (8, 30).[11] Given this value of α, the corresponding mean electron thermalization distance and time, averaged over the energy spectrum of the subexcitation electrons (the so-called "entry spectrum") (25, 29), are found to be equal to ~88 Å and ~41 fs, respectively, at 25°C (30, 34).[12]

The recombination of a subexcitation electron with its geminate water cation before thermalization is complete is also modeled within our MTHREC random-flight simulation code. In the absence of experimental values for liquid water, the cross section σ_{rec} for these electron–cation recombination processes is taken from gas-phase data (29, 35). In our simulations, we consider the cation[13] to be surrounded by a perfectly absorbing sphere whose scavenging radius is $(\sigma_{rec}/\pi)^{1/2}$, with an electron-energy-dependent cross section given by $\sigma_{rec} = 3\beta/E^{1.86}$. Here σ_{rec} is expressed in Å^2, E is in eV, and β is an adjustable factor introduced in the calculations to take into account possible differences in σ_{rec} between the gas phase and liquid water. In all our previous simulations (7–11, 30, 34), we have adopted $\beta = 1$. Under these conditions ~5.5% of the subexcitation electrons are found to initially recombine with their water parent cations (with an average recombination time of ~3.3 fs)[14] instead of becoming thermalized and subsequently hydrated or instead of undergoing a dissociative attachment to a water molecule (8, 29).

The various channels through which the excited water molecules decay and the branching ratios associated with each of them remain largely unknown in the liquid phase (8, 23, 37). Tables 5 and 6 of ref. 8 show how the partitioning of the different competing decay channels was dealt with in our previous simulations. These are based mainly on gas phase data and include both directly excited electronic ($\tilde{A}(^1B_1)$ and $\tilde{B}(^1A_1)$) states of water molecules and vibrationally excited water molecules ($H_2O^*_{vib}$) formed by the recombination of a subexcitation electron with its parent cation (8). It appears from our previous studies that the branching ratios for the various decay channels of directly excited water molecules have little effect in the yield calculations. To keep at a minimum the number of adjustable parameters employed in the computations, those branching ratios are taken to be the same as those previously published (Table 5 of ref. 8). Thus, only the branching ratios for the

Fig. 1. Time dependences of the e^-_{aq} yields (in molecules per 100 eV) calculated from our Monte-Carlo simulations of the low-LET (~0.3 keV μm^{-1}) radiolysis of liquid water at 25°C over the time interval ~0.5 ps – 1 μs using the following sets of adjustable parameter values: (*i*) $\alpha = 0.975$, $\beta = 115$ (dashed curve), and (*ii*) $\alpha = 0.73$, $\beta = 24$, and the revised values of the branching ratios for the dissociative decay channels of $H_2O^*_{vib}$ given in Table 1 (dotted curve) (see text). For the sake of comparison, the corresponding e^-_{aq} yields computed using our previously published set of adjustable parameter values are also included in the figure (solid curve). The arrow indicates the extrapolated e^-_{aq} yield of 4.0 ± 0.2 at "time zero," as reported in ref. 21. Experiment: ref. 6 (▶), ref. 16 (▲), ref. 17 (□), ref. 20 (●), eq. [9] of ref. 21 (– - – - – -), ref. 38 (■), ref. 39 (▼), ref. 40 (◆), ref. 41 (▽), and ref. 42 (☆).



[11]Such an increase was required to reproduce the observed time dependence of the e^-_{aq} yield in room-temperature, low-LET liquid water radiolysis between 30 ps and ~1 μs. This increase in the electron scattering cross sections of Michaud and Sanche (32) may arise from the difference in the degree of structural disorder of the liquid phase in comparison to the solid phase. In fact, low-energy electrons in the subexcitation range are known to be very sensitive to such structural effects owing to their non-negligible delocalized character. Their scattering cross sections are generally found to increase rapidly when the degree of order diminishes. See for example ref. 33.

[12]Let us recall that for each subexcitation electron energy there exists a specific distribution of electron thermalization distances. Our calculated distribution of r_{th} values at 25°C, averaged over the ensemble of subexcitation electrons, is characterized by a "most probable" value of r_{th} (equal to ~6.5 Å) and by an "average" thermalization distance (~88 Å). This relatively large average thermalization distance comes from the presence of a long tail in the distribution, which indicates that a number of electrons travel large distances (up to ~450 Å) from subexcitation to thermal energies.

[13]Note that in the simulations the water cations H_2O^+ are allowed to undergo a random walk during their very short lifetime (~10 fs) by means of a sequence of electron transfers from neighboring water molecules to the H_2O^+ hole (8, 36).

[14]This average recombination time of ~3.3 fs (calculated from our simulations) shows that the recombination process mainly occurs on the water cation and that it is justified to ignore the reaction $H_2O^+ + H_2O \rightarrow H_3O^+ + {}^{\bullet}OH$ (which would change the nature of the cation and therefore affect the values of σ_{rec}) (8, 29). In other words, the "dry" subexcitation electron recombines quickly (that is, in the first steps of its random walk) on H_2O^+. If it does not recombine quickly, it will never recombine, and will thus become thermalized (~41 fs; unless, of course, it makes a dissociative attachment on a water molecule), trapped (~110–300 fs), and hydrated (~240–620 fs) (27). In fact, to test the validity of these results we included both types of electron recombination (on H_2O^+ and on H_3O^+) in our calculations; indeed, the recombination on H_3O^+ was found to be negligible.

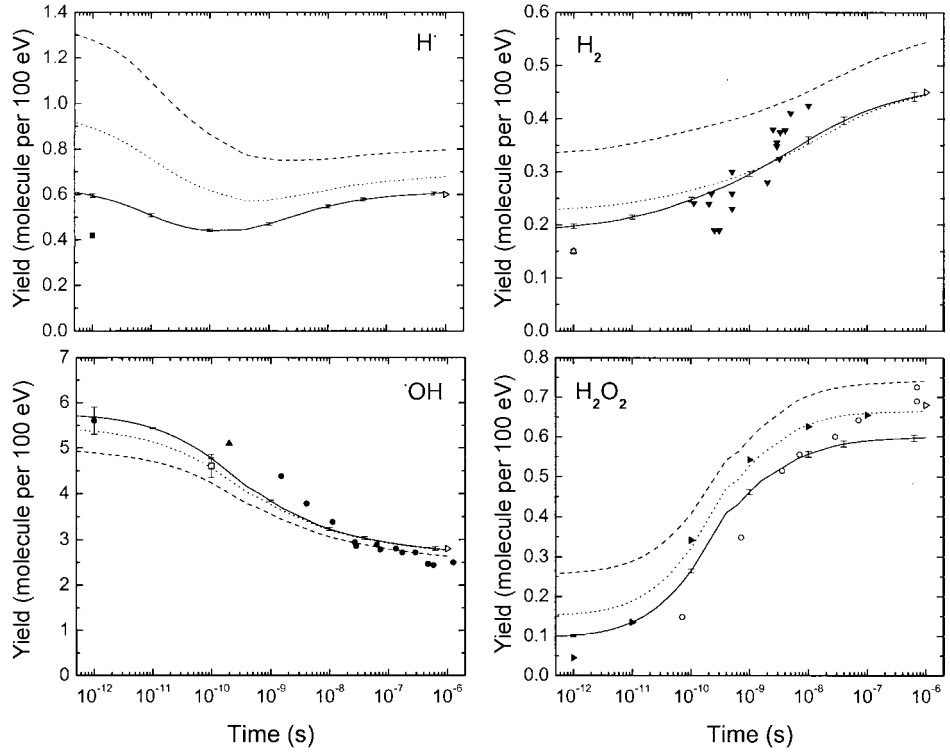
Fig. 2. Time dependences of the yields of $H^{\bullet}$, $^{\bullet}OH$, H_2, and H_2O_2 (in molecules per 100 eV) calculated from our Monte-Carlo simulations of the low-LET (~0.3 keV μm^{-1}) radiolysis of liquid water at 25°C over the time interval ~0.5 ps – 1 μs using the same sets of adjustable parameter values as in Fig. 1, namely: (*i*) α = 0.975, β = 115 (dashed curves), and (*ii*) α = 0.73, β = 24, and the revised values of the branching ratios for the dissociative decay channels of $H_2O^*_{vib}$ given in Table 1 (dotted curves) (see text). For the sake of comparison, the corresponding yields of the various species computed using our previously published set of adjustable parameter values are also included in the figure (solid curves). Experiment: refs. 2, 12, 15, and 16 (▷), ref. 6 (▶), ref. 21 (▲), ref. 22 (●), refs. 22 and 43 (○), ref. 44 (□), ref. 45 (▼), ref. 46 (△), and ref. 47 (■).



dissociative decay channels of $H_2O^*_{vib}$ (see Table 1) are treated here as fitting parameters.

Results and discussion

We have tried to readjust the above-mentioned parameters α and β to examine if our Monte-Carlo simulation results could be reconciled with Bartels et al's (21) new experimental findings; namely, the measured e^-_{aq} decay kinetics from 100 ps to 10 ns and the "extrapolated" e^-_{aq} yield of 4.0 ± 0.2 at "time zero." As a first step, the branching ratios for the dissociative deexcitations of $H_2O^*_{vib}$ were kept constant and equal to their previously employed values (Table 6 of ref. 8). We could, indeed, reproduce the ~20% decrease in the "time-zero" e^-_{aq} yield and also grossly the time dependence of the e^-_{aq} yield over the whole interval ~0.5 ps – 1 μs (Fig. 1), but at the expense of the yields of the other species ($H^{\bullet}$, $^{\bullet}OH$, H_2, and H_2O_2), which could not then be simultaneously and satisfactorily reproduced (Fig. 2). Moreover, closer examination of Fig. 1 clearly shows, in fact, that between 100 ps and 10 ns the shape of our computed time profile for the decay of e^-_{aq} is not in good accord with that measured by Bartels et al. (21). Such a fit was obtained with the values α = 0.975 and β = 115. Under these conditions, the mean electron thermalization distance calculated from our simulations is ~195 Å, a value that is relatively larger than the typical range (or "spur" radius) of ~64–80 Å used to describe the chemical evolution of the hydrated electrons in current deterministic models of "spur" chemistry.[15] In other respects, increasing the recombination cross section by a factor of 115 over the gas-phase value leads to an average ~25% recombination probability, which is also somewhat large in comparison with the probability for recombination of ~15% recently estimated by Bartels et al. (49) for the conduction-band secondary electrons in H_2O. Such an increase of the electron recombination cross section (from β = 1 to 115) was found to be necessary to decrease the initial e^-_{aq} yield from our previous value of ~5.1 to 4.0. The large increase in the thermalization distance then enabled us to reproduce the whole variation of the e^-_{aq} yield as a function of time down to the limiting yield ($G_{e^-_{aq}}$ = 2.65 at ~1 μs). As a second step, we tried to make various adjustments of the branching ratios associated with the dissociative deexcitations of $H_2O^*_{vib}$ to see if a better overall fit between computed yields and experiment could be achieved. The adjustments made had negligible effect on the calculated

[15]Our average thermalization distance should be compared with $< r > = 2\sqrt{2}\,\sigma/\sqrt{\pi}$, where σ is the characteristic radius of the three-dimensional Gaussian distribution describing the initial spatial distribution of e^-_{aq} in deterministic "average" spur models of liquid water radiolysis (29, 30). Most recent estimations of σ are 40–50 Å (6, 48).

Table 1. Branching ratios used in our simulations for the different competing mechanisms in the fate of vibrationally excited water molecules ($H_2O^*_{vib}$) formed by recombination of a subexcitation electron with its water parent cation (see footnote 9).

$H_2O^{+\bullet} + e^-$	→	$H_2O^*_{vib}$				
$H_2O^*_{vib}$	→	nondissociative deexcitation	35%	→	H_2O + release of thermal energy	
	→	dissociative deexcitation	65%	→	$H^\bullet + {}^\bullet OH$	79.8% (55%)
					$2H^\bullet + O(^3P)$	5.5% (24%)
					$H_2 + O(^1D)$	14.7% (21%)

Note: Previously employed values from ref. 8 are given in parenthesis.

time-dependent e^-_{aq} yield described above, while the time profiles of the calculated yields of $H^\bullet$, $^\bullet OH$, H_2, and H_2O_2 could be only slightly improved. Overall, the fits clearly remained largely unsatisfactory.

Having failed to satisfactorily reproduce Bartels et al's (21) new experimental data, we then applied our global-fit procedure in an attempt to find another set of values of the parameters α and β and also of the branching ratios for the dissociative decay channels of $H_2O^*_{vib}$ that would give: (*i*) the lowest possible e^-_{aq} yield at "time zero," (*ii*) a good reproduction of the time-dependent e^-_{aq} yield between ~0.5 ps and 1 μs, and in particular of the newly measured e^-_{aq} decay time profile between 100 ps and 10 ns, and (*iii*) a simultaneously acceptable overall agreement between our computed time-dependent yields for the other species, $H^\bullet$, $^\bullet OH$, H_2, and H_2O_2, and the existing experimental data. This could be achieved reasonably well with $\alpha = 0.73$ and $\beta = 24$. Here the corresponding limiting yield of e^-_{aq} at "time zero" is found to be ~4.4 to 4.5. As for the branching ratios for the dissociative deexcitations of $H_2O^*_{vib}$, their revised values are listed and compared with those previously employed (8) in Table 1. Under these conditions, the average electron thermalization distance and time calculated from our simulations are equal to ~139 Å and ~65 fs, respectively. Moreover, ~18% of the subexcitation electrons are found to initially recombine with their water parent cations (with an average recombination time of ~6.7 fs). This latter value is in good accord with the prompt electron–cation recombination (~15%) in water radiolysis reported recently by Bartels et al. (49). The various time-dependent yield results for e^-_{aq} and for the species $H^\bullet$, $^\bullet OH$, H_2, and H_2O_2 are shown in Figs. 1 and 2, respectively. As can be seen, there is a reasonable accord between our calculated yields and those measured experimentally (2, 6, 12, 15–17, 20–22, 38–47). Finally, to further test the validity of our results obtained with this new set of adjustable parameter values, we also performed various Monte-Carlo simulations under different experimental conditions (elevated temperatures, acidic pH, and high LET). The overall agreement between our computed yields and the available experimental data was satisfactory (data not shown).

Summary and conclusion

We have attempted to reconcile our Monte-Carlo calculations of the radiolysis of liquid water with the recently revised experimental e^-_{aq} yield data at early times of Bartels et al. (21). The electron thermalization distances, the geminate electron–cation recombination cross sections, and the branching ratios corresponding to the dissociative decay of vibrationally excited states of water molecules were taken as adjustable parameters in our simulations. Using a global-fit procedure, we have been unable to find a set of values for those parameters that could simultaneously reproduce the revised e^-_{aq} yield of 4.0 ± 0.2 at "time zero", the newly measured e^-_{aq} decay kinetic profile from 100 ps to 10 ns, and the time-dependent yields of the other radiolytic species ($H^\bullet$, $^\bullet OH$, H_2, and H_2O_2). The lowest possible limiting yield of e^-_{aq} at "time zero" that we could, in fact, obtain while ensuring an acceptable overall agreement between computed and experimental yields was ~4.4 to 4.5. Such a value turns out to be some compromise between the hitherto accepted value of 4.8 and that of 4.0 ± 0.2 "extrapolated" by Bartels et al. (21).

In conclusion, this work presents a possible adaptation of our calculations to a lower hydrated electron yield at early times, but it also suggests that the topic is not closed. To confirm Bartels et al.'s new experimental findings, as well as to clarify our understanding of the fast processes that occur in irradiated liquid water between the moment of energy deposition and ~1 μs later, further measurements of the e^-_{aq} yield values at very short times are needed.

Acknowledgments

We thank Professor Jay A. LaVerne (University of Notre Dame) for kindly sending us his data of refs. 22 and 43 on the $^\bullet OH$ and H_2O_2 yields as a function of time. The financial assistance of the Canadian Institutes of Health Research (Grant No. MT-14617) is gratefully acknowledged.

L'échelle pK_{HB} de basicité de liaison hydrogène des amines tertiaires aliphatiques

Jérôme Graton, François Besseau, Michel Berthelot, Ewa D. Raczyńska et Christian Laurence

Résumé : Le pouvoir accepteur de liaison hydrogène (liaison H) de 40 amines tertiaires a été mesuré à partir de leurs constantes de complexation 1:1 avec le 4-fluorophénol dans CCl_4 à 25°C (échelle pK_{HB}) par spectrométrie infrarouge à transformée Fourier (IRTF), ainsi qu'au moyen du déplacement de fréquence $\Delta\nu$(OH) de la bande ν(OH) méthanol complexé par liaison H avec ces amines. La comparaison des échelles de basicité de liaison H thermodynamique pK_{HB} et spectroscopique $\Delta\nu$(OH) et de basicité de Brønsted pK_a met en évidence la grande sensibilité de l'échelle pK_{HB} aux effets stériques, et l'absence de corrélation entre les échelles pK_{HB} et pK_a. L'échelle pK_{HB} des amines tertiaires s'étend de 2,71 pour la quinuclidine à –0,34 pour la *N*,*N*-diisopropyl-3-pentylamine. Les principaux effets expliquant ces variations (17 kJ·mol^{-1} sur une échelle d'enthalpie libre) sont les effets inductifs électroattracteurs et les effets stériques (e.g., ouverture des angles CNC et difficulté plus grande de la fixation du groupe OH sur les paires libres de l'atome d'azote). Les spectres infrarouges (IR) montrent que le 4-fluorophénol, outre sa fixation sur l'azote amino, se fixe également sur l'azote nitrile des amino-nitriles $Me_2NCH_2C{\equiv}N$ et $Me_2NCH_2CH_2C{\equiv}N$, sur l'oxygène de la *N*-méthylmorpholine, et sur les sites π des tripropargylamine $(HC{\equiv}CCH_2)_3N$ et tribenzylamine $(PhCH_2)_3N$. Dans ce dernier cas, les effets inductifs des trois substituants benzyle et surtout l'exceptionnel encombrement stérique de l'azote réduisent quasiment à néant sa basicité de liaison H, de telle sorte que la tribenzylamine, base de Brønsted azotée, se comporte essentiellement comme une base π de liaison H. À partir de cet exemple, on insiste sur les différences importantes entre les échelles pK_{HB} et pK_a des bases organiques.

Mots clés : basicité, liaison hydrogène, amines tertiaires, échelle pK_{HB}.

Abstract: The hydrogen bond acceptor strength of 40 tertiary amines has been measured by Fourier transform – infrared (FTIR) spectrometry from their 1:1 complexation constant towards 4-fluorophenol in CCl_4 at 25°C (the pK_{HB} scale). Also measured was the frequency shift, $\Delta\nu$(OH), of the ν(OH) band of methanol hydrogen-bonded to these amines. The comparison of the thermodynamic hydrogen bond basicity scale, pK_{HB}, with the spectroscopic one, $\Delta\nu$(OH), and with the Brønsted pK_a scale, points to the great sensitivity of pK_{HB} to steric effects. The pK_{HB} scale of tertiary amines extends from 2.71 for quinuclidine to –0.34 for *N*,*N*-diisopropyl-3-pentylamine. The main factors governing this important variation (17 kJ·mol^{-1} on the Gibbs energy scale) are the electron-withdrawing inductive effect and various kinds of steric effects (e.g., opening of the CNC angles and hindrance to OH fixation on the nitrogen lone pair). Infrared (IR) spectra show the attachment of 4-fluorophenol to the nitrile nitrogen of $Me_2NCH_2C{\equiv}N$ and $Me_2NCH_2CH_2C{\equiv}N$, to the oxygen of *N*-methylmorpholine, and to the π electrons of $(HC{\equiv}CCH_2)_3N$ and $(PhCH_2)_3N$, in addition to the attachment to the amino nitrogen. In $(PhCH_2)_3N$, the electron-withdrawing effect of the three benzyl substituents and, mainly, the very important congestion of the nitrogen lone pair reduce the nitrogen hydrogen-bond basicity almost to nothing, so that tribenzylamine, a nitrogen Brønsted base, turns to a π base in hydrogen bonding. From this example, the large differences between the pK_{HB} and pK_a scales of organic bases are emphasized.

Key words: basicity, hydrogen bonding, tertiary amines, pK_{HB} scale.

Introduction

Nous construisons actuellement (1) une échelle thermodynamique du pouvoir accepteur de liaison hydrogène (liaison H) des molécules organiques. Cette échelle repose sur la constante de formation de liaison H entre ces bases organiques et un donneur de liaison H de référence, dans des conditions standard de solvant, de température et de stœchiométrie. Reprenant l'idée originale de Gurka et Taft (2), nous mesurons cette échelle, notée pK_{HB} et appelée

échelle de basicité de liaison H, à partir de la formation de complexes 1:1 du 4-fluorophénol dans CCl_4 à 25°C dans le tétrachlorure de carbone (équations [1]-[3]). Le choix

[1] $$B + 4\text{-}FC_6H_4OH \leftrightarrows 4\text{-}FC_6H_4OH\cdots B$$

[2] $$\frac{K_c}{dm^3 \cdot mol^{-1}} = \frac{[4 - FC_6H_4OH \cdots B]}{[B][4 - FC_6H_4OH]}$$

[3] $$pK_{HB} = \log_{10} K_c$$

de ces conditions permet de mesurer la constante d'équilibre K_c avec précision dans une large gamme de basicité s'étendant d'environ $pK_{HB} = -1$ pour les bases très faibles à $pK_{HB} = +4$ pour les bases fortes. Il suffit de déterminer la concentration du 4-fluorophénol à l'équilibre, soit par résonance magnétique nucléaire (RMN) du ^{19}F (2), soit par spectrométrie UV sur la transition $\pi \rightarrow \pi^*$ à 281 nm (3), soit par spectrométrie infrarouge (IR) sur la bande ν(OH) à 3614 cm^{-1} (4).

Ces techniques montrent que le 4-fluorophénol n'est pas suffisamment acide et que CCl_4 n'est pas un solvant suffisamment polaire pour permettre le transfert du proton, même avec les amines les plus basiques (5, 6). Dans ce travail l'équilibre de transfert de proton [4] peut donc être négligé.

[4] $$4\text{-}FC_6H_4OH + NR_3 \leftrightarrows 4\text{-}FC_6H_4O^{-}\cdots{}^{+}HNR_3$$

L'intérêt de construire l'échelle pK_{HB} est double. D'une part, l'échelle pK_{HB} permet une comparaison quantitative des énergies de Gibbs ($\Delta G° = -5{,}7\ pK_{HB}$, $\Delta G°$ en $kJ \cdot mol^{-1}$) de formation de liaison H, interaction moléculaire omniprésente en chimie (7) et en biologie (8). D'autre part, alors que la basicité protonique de Brønsted est quantitativement bien définie par les échelles pK_a en phase aqueuse (9), et *GB* en phase gazeuse (10), la mesure de la basicité de Lewis reste à effectuer (11). Certains auteurs (11–13) s'accordent à reconnaître qu'une description quantitative et générale de la basicité de Lewis doit reposer sur au moins deux paramètres, l'un électrostatique, l'autre covalent. Dans la mesure où la liaison H est une interaction principalement électrostatique (14), l'échelle pK_{HB} pourrait mesurer la partie électrostatique des interactions entre les acides et les bases de Lewis.

Nous avons déjà mesuré pK_{HB} pour un grand nombre de bases carbonées, halogénées, oxygénées, soufrées et azotées (1). Dans cette dernière famille, nous avons étudié les nitriles (15), les amidines (16) les pyridines (17), les amines primaires (18) et les amines secondaires (19). Ce travail concerne la mesure par spectrométrie infrarouge à transformée Fourier (IRTF), de l'échelle pK_{HB} des amines tertiaires.

De manière à couvrir un vaste domaine de basicité et à déterminer les principaux effets structuraux modifiant la basicité de liaison H des amines tertiaires, nous avons sélectionné 40 composés incluant 12 alkylamines avec des groupes alkyles de longueur et de ramification différentes, 17 amines hétérocycliques, 9 amines substituées par différents groupes électroattracteurs ($CH{=}CH_2$, Ph, $C{\equiv}CH$, Cl, $C{\equiv}N$) et deux diamines. Nous obtenons ainsi une échelle qui s'étend sur trois unités de p*K*, soit environ 17 $kJ \cdot mol^{-1}$, de la quinuclidine ($pK_{HB} = 2{,}71$) à *i*-$Pr_2NCH(Et)_2$ ($pK_{HB} = -0{,}34$). Au-delà, nous trouvons la tribenzylamine, $(PhCH_2)_3N$, qui est une base azotée de liaison H si faible qu'elle se comporte comme une base π.

L'utilisation de la spectrométrie IRTF comporte trois principaux avantages. D'abord, la grande précision photométrique des spectromètres IRTF permet de mesurer les concentrations des espèces de l'équilibre [1] avec une meilleure précision que la résonance magnétique nucléaire (RMN) du ^{19}F initialement utilisée (2). Un autre avantage de l'infrarouge est de pouvoir mesurer la fréquence OH du complexe de liaison H, qui est d'autant plus basse que la liaison H est forte. Le déplacement $\Delta\nu(OH) = \nu(OH, \text{libre}) - \nu(OH\cdots N)$ est considéré (20) comme une échelle spectroscopique de basicité de liaison H des amines qu'il est intéressant de comparer à l'échelle thermodynamique pK_{HB}. Enfin la spectrométrie IR permet de déterminer si les autres sites potentiellement accepteurs de liaison H dans les amines substituées, e.g., l'oxygène de la *N*-méthylmorpholine ou l'azote sp de $Me_2NCH_2CH_2C{\equiv}N$, contribuent à la constante K_c mesurée. Dans ce cas, elle permet de séparer, dans la constante totale K_c mesurée, la partie due à l'azote amino de celle due aux autres sites accepteurs de liaison H (vide infra).

Partie expérimentale

Produits

Toutes les amines étudiées sont des composés commerciaux, à l'exception de la 4-phénylquinuclidine fournie par R.W. Taft (Université de Californie, Irvine). Les 3-chloroquinuclidine (**15**), 3-chlorométhyl-*N*-méthylpipéridine (**19**), 4-chloro-*N*-méthyl-pipéridine (**20**), *N*,*N*-diméthyl-3-chloropropylamine (**27**) et 1-(2-chloroéthyl)-pyrrolidine (**29**) ont été extraites de leurs chlorhydrates par neutralisation avec un excès de soude. Les liquides sont distillés puis séchés sur tamis moléculaire 4 Å (1 Å = 0,1 nm) et (ou) par chromatographie sur alumine basique. Les amines solides, ainsi que le 4-fluorophénol, sont purifiés par sublimation puis séchés sur P_2O_5. Le tétrachlorure de carbone est distillé puis stocké sur une colonne de tamis moléculaire 4 Å avant d'être soutiré. Le méthanol de qualité spectroscopique est séché sur tamis moléculaire 3 Å. Les produits purifiés sont manipulés en boîte sèche pour préparer les solutions et remplir la cellule IR.

Spectres IR

Ils sont enregistrés sur des spectromètres Bruker IFS 48 ou Vector 22 avec une résolution de 1 cm^{-1}. La cellule en quartz possède un trajet optique de 1 cm. Elle est thermorégulée à 25,0 ± 0,2°C à l'aide d'un système thermoélectrique à effet Peltier.

Constantes K_c

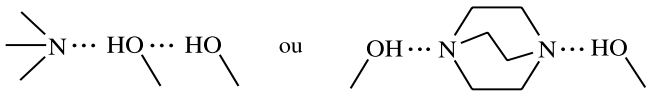
Elles sont définies par l'équation [5] dans laquelle C_c, C_a et C_b sont respectivement les concentrations en $mol \cdot dm^{-3}$ à l'équilibre du complexe, du 4-fluorophénol et

[5] $$K_c = \frac{C_c}{C_a C_b} = \frac{C^{\circ}_a - C_a}{C_a(C^{\circ}_b - C^{\circ}_a + C_a)}$$

de l'amine; C°_a et C°_b sont les concentrations initiales, déterminées par pesées, sauf pour l'amine gazeuse Me_3N qui a été dosée dans CCl_4 par neutralisation avec une solution aqueuse d'acide chlorhydrique. C°_a est de l'ordre de 4 $mmol \cdot dm^{-3}$ pour éviter l'autoassociation du 4-fluorophenol.

© 2002 CNRC Canada

C_b^o est ajustée de manière à ce que 20 à 80 % de phénol soit complexé. Le rapport des concentrations C_b^o/C_a^o varie ainsi entre 2 et 5 pour la quinuclidine la plus basique, et entre 100 et 220 pour l'amine la moins basique. La concentration C_a en phénol non complexé est déterminée à partir de l'absorbance de la bande ν(OH) à 3614 cm^{-1} par la loi de Beer–Lambert (coefficient d'absorption molaire égal à 237 $dm^3 \cdot mol^{-1} \cdot cm^{-1}$ dans CCl_4 à 25°C). On vérifie que l'espèce formée est le complexe de stœchiométrie 1:1 à partir de la constance de K_c calculée à cinq concentrations différentes d'amine. En tout état de cause, les solutions très diluées en 4-fluorophénol, ainsi que l'excès d'amine permettent de rendre minimale la présence de complexes 1:2 tels que :



L'erreur maximale sur pK_{HB} est estimée à ±0,03.

Déplacements de fréquence Δν(OH)

Le déplacement de la fréquence d'élongation ν(OH) par formation d'une liaison hydrogène OH···N ne peut pas être facilement mesuré avec le 4-fluorophénol, car la bande ν(OH) du complexe de liaison H est perturbée par (*i*) les bandes ν(CH) du 4-fluorophénol et de l'amine qui ne peuvent être parfaitement soustraites car elles sont légèrement déplacées par complexation et (*ii*) des bandes de combinaison de ν(OH···) avec les fréquences d'élongation et de déformation de la liaison H (21). Nous avons donc remplacé le 4-fluorophénol par un donneur de liaison H moins fort, le méthanol. La bande ν(OH···) des complexes de ce dernier avec les amines se situe en effet avant les bandes ν(CH), et sa forme quasi gausso-lorentzienne permet de bien pointer son maximum. On définit alors Δν(OH) par la différence [6]. La précision sur Δν(OH) est estimée à ±3 cm^{-1}.

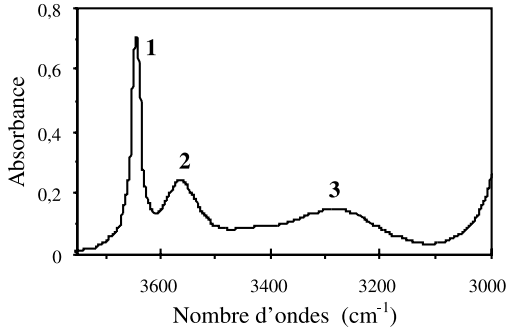
[6] $\Delta\nu(OH) = \nu(OH, \text{MeOH libre}) - \nu(OH\cdots, \text{MeOH complexé par liaison H})$

Calculs ab initio

Ils ont été effectués avec Gaussian 94 (22) sur un ordinateur personnel bi-processeur Pentium II 300 MHz. Les géométries des amines ont été optimisées au niveau HF/6–31G**. Pour les amines conformationnellement flexibles, nous n'avons pas exploré la totalité de l'espace conformationnel, mais nous sommes partis de plusieurs conformations initiales différentes et nous nous sommes appuyés sur des résultats conformationnels bien établis (23, 24). Les conformations trouvées les plus stables par calculs HF/6–31G** sont toujours en accord avec celles, expérimentales, des bases de données MOGADOC (25), pour la phase gazeuse ou structurale de Cambridge CSD (26), pour l'état solide.

Le potentiel électrostatique calculé autour de l'azote amino (pour la conformation la plus stable) est le potentiel électrostatique minimum sur la surface moléculaire définie, selon Bader et al. (27), par la surface d'isodensité électronique 0,001 e·$Bohr^{-3}$. Il est noté $V_{s,min}$ et donné généralement en $kcal \cdot mol^{-1}$ (1 cal = 4,184 J).

Fig. 1. Spectre IR dans la région (OH) d'une solution de méthanol (≈ 10^{-2} $mol \cdot dm^{-3}$) et de $Me_2NCH_2CH_2C{\equiv}N$ (en large excès) dans CCl_4 montrant (1) la bande ν(OH) du méthanol libre à 3644 cm^{-1}, (2) la bande ν(OH···N≡C) d'un premier complexe 1:1, déplacée de 80 cm^{-1}, et (3) la bande ν(OH···N) d'un second complexe 1:1, déplacée de 362 cm^{-1}.



Résultats

L'échelle pK_{HB} de basicité de liaison H des amines tertiaires est donnée dans le tableau 1 conjointement avec (*i*) les valeurs Δν(OH) du déplacement de la fréquence ν(OH) du méthanol par complexation avec ces amines, (*ii*) les valeurs pK_a de ces amines, dans l'eau généralement à 298 K, et (*iii*) le potentiel électrostatique autour de la paire libre de l'azote amino.

Pour cinq amines, nous observons sur le spectre IR, entre la bande fine ν(OH) du 4-fluorophénol libre à 3614 cm^{-1} (ou celle à 3644 cm^{-1} du méthanol) et la bande large ν(OH···N) correspondant au complexe sur l'azote amino, une bande supplémentaire (fig. 1). Puisque ces cinq amines possèdent un (des) site(s) potentiel(s) accepteur(s) de liaison H supplémentaire, nous attribuons cette bande supplémentaire à un deuxième complexe de liaison H se formant soit sur l'oxygène éther de la *N*-méthylmorpholine (**26**), soit sur l'azote sp des aminonitriles (**33**) et (**37**), soit sur le nuage π acétylénique de la tripropargylamine (**36**), soit enfin sur le nuage π aromatique de la tribenzylamine (**40**). En effet, ces bandes supplémentaires sont bien aux positions attendues pour les complexes de liaison H avec des éthers (28), des nitriles (15), des bases π acétyléniques (29), ou aromatiques (29).

Puisque nous sommes toujours en excès d'amine, la formation d'un complexe de stœchiométrie 2:1 (2 phénols – 1 amine) est peu probable, et nous avons essentiellement en solution deux complexes 1:1, un complexe OH···N sur l'azote amino et un complexe OH···X sur le site accepteur de liaison H supplémentaire. Dans ce cas, la constante de complexation mesurée à partir de l'absorbance de la bande ν(OH) du 4-fluorophénol libre correspond à la formation de ces deux complexes, et il est facile de montrer qu'elle est la somme de deux constantes, K_c(N) et K_c(X), ou 3 K_c(X) pour la tripropargylamine (**36**) et la tribenzylamine (**40**). La constante propre à l'azote amino peut donc être calculée à partir de l'équation [7] s'il

[7] $K_c(\text{totale}) = K_c(N) + xK_c(X)$ (x = 1 ou 3)

est possible d'évaluer K_c(X). Nous l'avons fait à partir des déplacements de fréquence IR Δν(OH···X), en utilisant les corrélations entre pK_{HB} et Δν(OH) établies dans des travaux

[b]Valeur statistiquement corrigée (en parenthèses).
[c]Valeur corrigée (en parenthèses) de la contribution d'un (ou de plusieurs) autre(s) site(s) accepteur(s) de liaison hydrogène (voir tableau 2).

précédents pour les familles des éthers (28), des nitriles (15) et des bases π acétyléniques (29) et aromatiques (29). Le détail des calculs est donné dans le tableau 2. Pour la tribenzylamine, nous avons vérifié expérimentalement que la constante de complexation sur l'azote amino n'est pas complètement égale à zéro. Avec une solution très concentrée en tribenzylamine (0,5 mol·dm^{-3}) et en diminuant la température pour déplacer les équilibres vers la formation des complexes, nous voyons en effet apparaître (fig. 2) une très faible contribution attribuée à une bande ν(OH···N).

Pour les polyamines, la constante mesurée correspond à plusieurs complexes 1:1 sur les multiples atomes d'azote (un excès d'amine permet de minimiser la formation de complexes de stœchiométries supérieures). En supposant que les *n* atomes d'azote de ces polyamines ont la même basicité, la constante mesurée est égale à *n* fois la constante propre à un atome d'azote. Cette correction statistique (30) de la valeur pK_{HB} par –log *n* (*n* = 2 pour **4**, **11, 13, 17**; *n* = 3 pour **23**, et *n* = 4 pour **31**) doit être effectuée pour relier pK_{HB} aux propriétés moléculaires caractérisant la basicité par atome d'azote ($\Delta\nu$(OH) ou potentiel électrostatique, ou constantes de substituants).

Discussion

Comparaison des échelles de basicité pK_{HB}, pK_a et $\Delta\nu$(OH)

Il est aujourd'hui bien établi que les échelles pK_{HB} et pK_a présentent d'importantes différences (1). Certains auteurs ont cependant proposé des relations par familles entre

Fig. 2. Spectres IR dans la région ν(OH) d'une solution de 4-fluorophénol ($4{,}8 \times 10^{-3}$ mol·dm^{-3}) et de tribenzylamine (0,53 mol·dm^{-3}) dans CCl_4 à –5, 25 et 45°C montrant (1) la bande ν(OH) du 4-fluorophénol libre à 3614 cm^{-1}, (2) la bande ν(OH···π) d'un premier complexe 1:1, déplacée de 58 cm^{-1}, et (3) le début d'une bande très large ν(OH···N) d'un deuxième complexe 1:1 (une perte d'énergie vers 3100 cm^{-1} due aux absorptions ν(CH) de la tribenzylamine cache le reste de la bande).

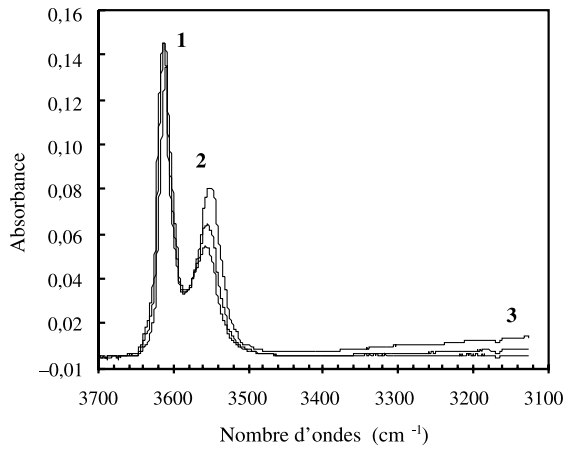

Fig. 3. Absence de corrélation entre les échelles pK_{HB} et pK_a des amines tertiaires. Les points des amines encombrées, e.g., **25**, **28** et **32**, ont des valeurs pK_{HB} trop faibles par rapport à la tendance générale.

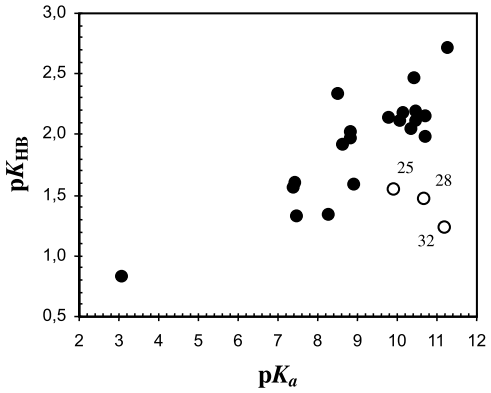

échelles de basicité de liaison H et l'échelle pK_a de protonation (31–34). Ces relations sont probablement fortuites ou n'ont qu'un domaine limité de validité, car pour la famille des amines primaires (18) il faut exclure les composés ayant une liaison hydrogène intramoléculaire, et pour celle des amines secondaires (19), pK_a n'explique que 74 % de la variance de pK_{HB}, ce que nous avons interprété (19) par une plus grande sensibilité de l'échelle pK_{HB} aux effets stériques que l'échelle pK_a. Les amines tertiaires donnent une corrélation encore plus mauvaise que les secondaires, puisque seulement 38 % de la variance de 23 valeurs pK_{HB} est expliquée par pK_a (fig. 3). La pentaméthylpipéridine (**32**), la tripropylamine (**28**) et la tributylamine (**25**) présentent à nouveau les déviations les plus importantes à la tendance générale (fig. 3). Elles montrent, puisque leur atome d'azote porte des substituants encombrants, que l'échelle pK_{HB} est plus sensible aux effets stériques que l'échelle pK_a.

La comparaison des échelles pK_{HB} et $\Delta\nu$(OH) met également en évidence la sensibilité de l'échelle pK_{HB} aux effets stériques. Dans des travaux précédents (17, 19, 28), nous avons montré que la diminution de basicité par effet stérique est plus importante pour pK_{HB} que pour $\Delta\nu$(OH). Ainsi les éthers ROR′ (28), les pyridines ortho-substituées 2-RC_5H_4N (17) et les amines secondaires RNHR′ (19), encombrées par des substituants R et R′ volumineux, ont-ils des valeurs pK_{HB} (très) faibles par rapport à leurs valeurs $\Delta\nu$(OH). Il en est de même pour les amines tertiaires. La figure 4 montre qu'il n'existe pas de relation générale entre

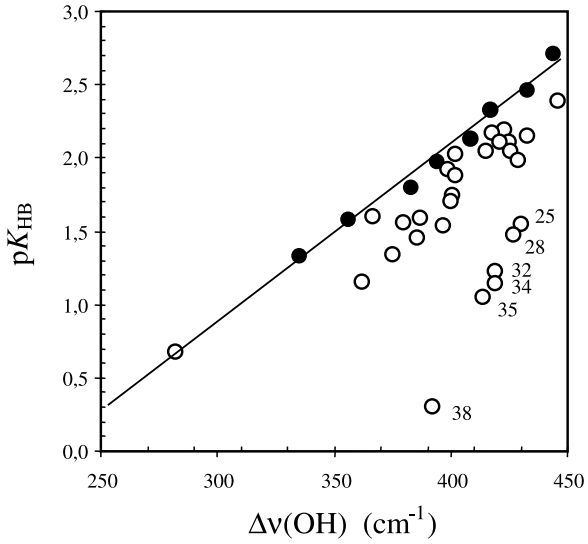
Fig. 4. Comparaison des échelles thermodynamique pK_{HB} et spectroscopique $\Delta\upsilon$(OH) de basicité de liaison H des amines tertiaires. Les amines (●) dont l'encombrement stérique est minimum dessinent une droite frontière au dessous de laquelle se placent les composés (○) dont l'encombrement stérique est plus ou moins important.



pK_{HB} et $\Delta\nu$(OH) (coefficient de corrélation r = 0,609 pour n = 36 points), principalement à cause des composés encombrés (e.g., **25**, **28**, **32**, **34**, **35** et **38**). Ainsi *c*-Hex_2NEt (**34**) a pratiquement la même valeur $\Delta\nu$(OH) (419 cm^{-1}) que $EtNMe_2$ (**6**) (418 cm^{-1}) mais une valeur pK_{HB} beaucoup plus faible (1,14 au lieu de 2,17). De même le passage de la 1-méthylpipéridine (**10**) à la 1,2,2,6,6-tétraméthylpipéridine (**32**) abaisse considérablement pK_{HB} (de 2,11 à 1,23) sans changer significativement $\Delta\nu$(OH) (421 cm^{-1} et 419 cm^{-1}). Il est cependant possible d'établir une corrélation limitée aux amines tertiaires les moins encombrées, en partant des amines bicycliques **1**, **2**, **4**, **15** et **31**, puisque la cyclisation tire vers l'arrière les trois chaînes alkyles, ce qui dégage au maximum la paire libre de l'azote. Ces composés, ainsi que deux amines monocycliques **18** et **23** et la triméthylamine (**8**) qui porte les trois groupes alkyles les moins volumineux dessinent une droite frontière (fig. 4, éq. [8]) au dessous de laquelle se placent les autres amines tertiaires. Celles-ci sont ainsi

[8] $pK_{HB} = 1{,}23\ [\Delta\nu(OH)/100] - 2{,}82$

$n = 8$; $r = 0{,}992$; écart type $s = 0{,}06$

désignées comme plus stériquement encombrées que les amines bicycliques. Ce sont effectivement les amines les plus encombrées **25**, **28**, **32**, **34**, **35** et **38** qui dévient le plus de la droite frontière (fig. 4).

Effets des substituants inductifs électroattracteurs

L'effet inductif et (ou) de champ (pour une discussion récente sur ces deux concepts d'effet électronique en série saturée, voir la référence 35) de substituants électroattracteurs diminue fortement la basicité de liaison H des amines tertiaires. Ainsi, l'effet inductif et (ou) de champ du chlore diminue pK_{HB} de 0,74 unité en passant de la quinuclidine (**1**), à la 3-chloroquinuclidine (**15**), et celui du groupe cyano diminue pK_{HB} de 1,46 unité de Me_3N (**8**) à $N{\equiv}CCH_2NMe_2$ (**37**). La constante de substituant σ_F (36) dont les valeurs (37) sont reportées dans le tableau 3 pourrait mesurer les variations de pK_{HB} dans les séries d'amines pour lesquelles les autres effets structuraux agissant sur la basicité de l'azote, essentiellement les effets stériques (38) et l'effet de polarisabilité (39) (il n'y a pas d'effet de résonance, car la paire libre de l'azote n'est conjuguée avec aucun système π dans les amines **1**–**40**), sont faibles et (ou) quasi constants. Cela semble être le cas dans la série des *N*,*N*-diméthylamines substituées $XNMe_2$ (éq. [9]), et mieux encore dans la série des amines hétérocycliques (éq. [10], fig. 5). Pour ces dernières, nous considérons la variation de pK_{HB}, ΔpK_{HB}, par

[9] $pK_{HB} = 2{,}02 - 4{,}57\ \sigma_F$

$n = 9$ (**8**, **11**, **13**, **16**, **21**, **22**, **27**, **33**, **37**);

$r = 0{,}956$; $s = 0{,}15$

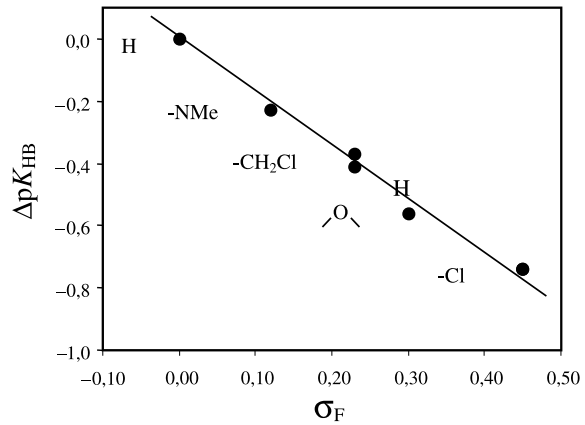
Fig. 5. Corrélation entre la constante de substituant inductive et (ou) de champ σ_F et la variation de pK_{HB} d'amines hétérocycliques par β-chloro, -oxo, et -aza substitution, et γ-chlorosubstitution.



[10] $\Delta pK_{HB} = -0{,}02 - 1{,}63\ \sigma_F$

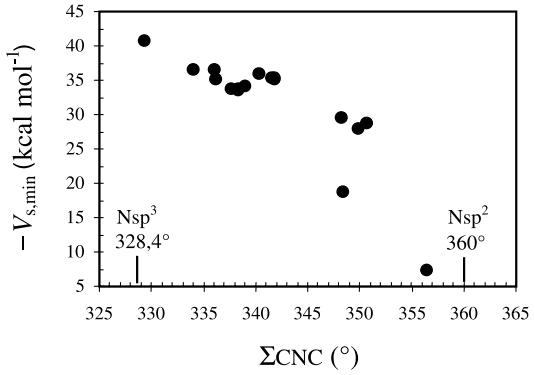
$n = 7$; $r = 0{,}995$; $s = 0{,}03$

(*i*) chloro-substitution en β de la fonction amine (**1**, **15** et **5**, **29**) (*ii*) chloro-substitution en γ, i.e., chlorométhyle-substitution en β (**10**, **19** et **10**, **20**), (*iii*) oxo-substitution en β (**10**, **26**) et (*iv*) aza-substitution en β (**10**, **17**). Dans la série $XNMe_2$, les constantes σ_F correspondent à une substitution directe de l'azote, tandis que pour les amines hétérocycliques, elles sont choisies pour une substitution en β; il est donc normal d'observer un plus faible coefficient de sensibilité aux effets mesurés par σ_F dans ce dernier cas. Le rapport des coefficients de régression des équations [9] et [10] correspond à un facteur d'atténuation de l'effet inductif de 1,67 par groupe méthylène qui est de l'ordre de grandeur de celui (1,95) trouvé pour les réactions de protonation en phase gazeuse (39).

Effets des substituants alkyles

Il est généralement établi que les groupes alkyles ont un effet inductif négligeable (36, 39, 40). Leur influence sur la basicité de liaison H des amines tertiaires est alors due principalement à leur effet de polarisabilité et à leurs effets stériques. Ces deux effets agissent en sens opposé sur pK_{HB}. L'effet de polarisabilité augmente la basicité de liaison H, probablement grâce à la contribution des forces de dispersion et de polarisation à l'énergie de liaison H (41). Cet effet est généralement mesuré par la constante de substituant σ_α de polarisabilité, définie par Hehre et al. (42) à partir de la variation, par substitution d'un modèle ad hoc (42, 43), du potentiel de polarisation calculé ab initio. La valeur absolue de σ_α augmente avec la longueur et la ramification du groupe alkyle (voir tableau 3).

Fig. 6. Corrélation entre $-V_{s,min}$, potentiel électrostatique autour de l'azote, et ΣCNC, somme des angles CNC, pour les alkylamines tertiaires.



À l'inverse, l'effet stérique affaiblit la basicité de liaison H. Nous l'avons établi pour les éthers (28), les pyridines ortho-substituées (17), les amidines (16) et les amines secondaires (19). Plusieurs mécanismes peuvent être envisagés dans le cas de la complexation des amines tertiaires par le 4-fluorophénol. Le premier consiste en l'ouverture des angles CNC de l'amine par répulsion stérique entre les trois substituants alkyles de l'azote. Cette ouverture provoque une diminution du caractère p de la paire libre de l'azote et donc de sa basicité intrinsèque. Le tableau 4 rassemble les valeurs ΣCNC de la somme des trois angles CNC autour de l'azote. Ces valeurs montrent que l'azote passe d'un état tétragonal (ΣCNC = 328,4° pour un azote sp^3) pour la quinuclidine (**1**) à un état quasi trigonal (ΣCNC = 360° pour un azote sp^2) pour les amines les plus encombrées. Cela entraîne un potentiel électrostatique moins négatif autour de l'azote : $|V_{s,min}|$ diminue de 40,72 kcal·mol^{-1} pour la quinuclidine (**1**) à 7,38 kcal·mol^{-1} pour *i*-Pr_2NCHEt_2 (**39**). La figure 6 montre la relation significative (r = 0,85 pour 17 alkylamines) entre $V_{s,min}$ et ΣCNC. Il s'ensuit un affaiblissement de la liaison H (une interaction moléculaire principalement électrostatique (41)) par diminution de

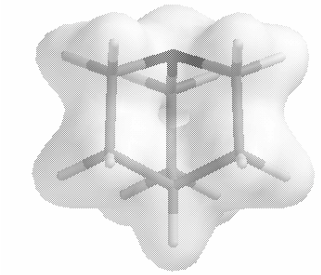
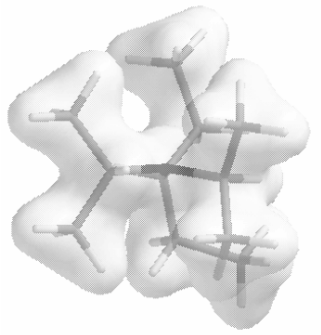
Fig. 7. Illustration de l'encombrement stérique de l'azote de *i*-Pr_2NCHEt_2 (**39**), comparativement à celui de la quinuclidine (**1**).



1

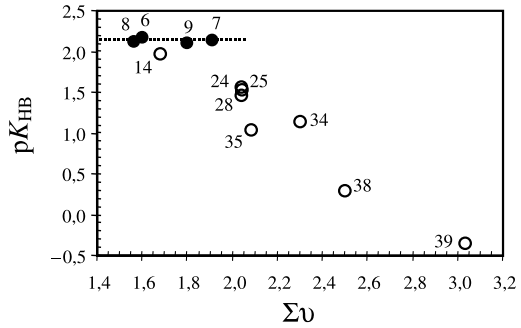


39

l'attraction électrostatique entre l'amine et le phénol. Le second mécanisme est dû à l'encombrement de la paire libre de l'azote. Celui-ci est évident pour *i*-Pr_2NCHEt_2 lorsque l'on compare son volume moléculaire à celui de la quinuclidine (fig. 7). Lorsqu'on approche une molécule de 4-fluorophénol dans l'axe de la paire libre de l'azote à une distance d(N···H) de 1,85 Å (valeur moyenne trouvée (44) dans la base structurale de Cambridge (26) pour 66 contacts de liaison H entre des phénols et des amines tertiaires), on constate un plus grand recouvrement des nuages électroniques du phénol et de l'amine pour les amines encombrées. Il s'ensuit une énergie de répulsion (le terme d'échange dans le calcul quantique de l'énergie (41)) plus importante qui diminue l'énergie de la liaison H. Le dernier mécanisme concerne l'augmentation de l'entropie de complexation. Nous avons trouvé (44) que celle-ci est de –55,8 $J \cdot K^{-1} \cdot mol^{-1}$ pour la complexation de la quinuclidine par le 4-fluorophénol, tandis que celle de l'amine encombrée *i*-Pr_2NEt s'élève à –74,0 $J \cdot K^{-1} \cdot mol^{-1}$ (valeur relative aux fractions molaires). Cette variation d'entropie de 18,2 $J \cdot K^{-1} \cdot mol^{-1}$ fait chuter pK_{HB} de 0,95 unité ($T\Delta S/5{,}709$) à 298 K.

De nombreux paramètres empiriques ont été proposés pour mesurer l'effet stérique des substituants, parmi lesquels les plus populaires sont les constantes de substituants E_s de Taft (45) et upsilon (υ) de Charton (46). Une équation multiparamétrique entre pK_{HB} et les constantes de

Fig. 8. Variation de pK_{HB} en fonction de la somme des constantes stériques υ des substituants alkyles de l'azote des amines tertiaires. Dans la série $AlkNMe_2$ (●), pK_{HB} reste quasiment constant entre 2,11 et 2,17 tandis qu'il chute jusqu'à –0,34 (**39**) quand les effets stériques augmentent.



polarisabilité σ_α et stérique E_s (ou υ) est cependant impossible à établir pour les trialkylamines pour deux raisons principales. La première est due à la corrélation significative entre les constantes σ_α et υ (ou E_s) (r = 0,945 pour les neuf substituants alkyles du tableau 3), car toutes deux augmentent avec la taille (i.e., le nombre d'électrons) du groupe alkyle. La deuxième raison provient de la non-additivité des effets stériques qui imposent des équations complexes (47) pour faire intervenir les trois constantes stériques des substituants alkyles. Néanmoins, une analyse grossière de l'influence des substituants alkyles sur la basicité de liaison H des amines tertiaires est possible à partir du graphe pK_{HB} versus Συ (fig. 8). On peut voir que lorsque la somme des constantes stériques des trois substituants (i.e., le volume, le nombre d'électrons et la polarisabilité) augmente, pK_{HB} reste constant pour les faibles effets stériques, tandis qu'il chute spectaculairement quand les effets stériques augmentent. En d'autres termes l'effet de polarisabilité réussit à compenser les effets stériques quand ceux-ci sont faibles (série $AlkNMe_2$ **6**–**9**) mais quand les trois chaînes alkyles continuent à s'allonger et à se ramifier, les effets stériques prédominent largement.

La tribenzylamine

Nous avons montré que la tribenzylamine est principalement une base π de liaison H, puisque la basicité de liaison H de son azote est extraordinairement faible ($pK_{HB} \approx -1{,}5$). Au contraire, c'est une base de Brønsted azotée dont le pK de l'ion tribenzylammonium est de 4,1 dans le DMSO et de 6,4 dans le méthanol (48) (nous n'avons pas trouvé la valeur pK_a dans l'eau). La comparaison de ces valeurs avec celles de l'ion triéthylammonium (respectivement 9,0 et 10,9) dans les mêmes solvants (48) met en évidence l'effet inductif électroattracteur des trois groupes benzyle.

Cet effet inductif doit également diminuer la basicité de liaison H. À partir de l'équation [9] et en supposant additives les valeurs σ_F, nous estimons un pK_{HB} de 1,33. Cette valeur est très éloignée de celle (–1,5) estimée à partir de la valeur expérimentale après déduction de la contribution des trois sites π (voir tableau 2). Pour diminuer encore de 2,83 unités (16,2 $kJ \cdot mol^{-1}$) le pK_{HB}, nous ne pouvons invoquer que d'exceptionnels effets stériques des trois groupes

© 2002 CNRC Canada

Fig. 9. Structure cristalline de la tribenzylamine illustrant l'encombrement stérique de l'azote par les trois groupes benzyle.

40

benzyle. La structure cristalline de la tribenzylamine (49) montre que l'atome d'azote est particulièrement encombré : comme l'illustre la figure 9, les trois noyaux aromatiques encerclent l'atome d'azote et empêchent quasiment l'accès de la paire libre à un donneur de liaison H.

Notons qu'il n'y a pas d'augmentation des angles CNC autour de l'azote, leur somme étant (49) de 329,9°. Le faible potentiel électrostatique (–19,4 kcal·mol^{-1}) semble dû principalement aux effets inductifs des trois benzyles. En effet, la comparaison des $V_{s,min}$ de Me_3N et $PhCH_2NMe_2$ montre qu'un groupe benzyle diminue $V_{s,min}$ de 7,53 kcal·mol^{-1}, valeur comparable au tiers (5,73 kcal·mol^{-1}) de la différence entre $(PhCH_2)_3N$ et Me_3N.

Conclusions

1. Nous avons mesuré la basicité de liaison H de 40 amines tertiaires vis-à-vis du 4-fluorophénol, dans CCl_4 et à 298 K (échelle pK_{HB}).
2. Cette échelle s'étend sur 24 kJ·mol^{-1} d'énergie de Gibbs de la quinuclidine à la tribenzylamine.
3. Les effets structuraux modifiant la basicité de liaison H sont, par ordre croissant d'importance, l'effet de polarisabilité, l'effet inductif et les effets stériques.
4. Ces derniers réduisent pratiquement à zéro le pouvoir accepteur de liaison H de la tribenzylamine, qui devient de ce fait une base π de liaison H. La tribenzylamine rejoint ainsi la 2,6-di*tert*butylpyridine (50) comme deuxième exemple de base azotée à système(s) π qui se protonne sur l'azote mais accepte la liaison H sur ses électrons π.
5. Ces différences entre sites de liaison H et sites de protonation, ainsi que l'absence de corrélation générale entre les échelles pK_{HB} et pK_a pour les amines secondaires (19) et tertiaires (ce travail) montrent que l'usage de l'échelle pK_a pour prévoir la basicité de liaison H est risqué. C'est l'échelle pK_{HB} qui est l'échelle de choix pour étudier le comportement accepteur de liaison H des molécules organiques.

ERRATUM

Ref.: Can. J. Chem. **80**(8): x (2002).

NRC Research Press inadvertently omitted the name of Victor Snieckus, one of the editors of the special issue dedicated to the memory of Professor Ray Lemieux.

We apologize to Dr. Snieckus, the Editors of the *Canadian Journal of Chemistry*, and our readership for this error. The page should have been published as follows:

This special issue is dedicated to the memory of

Professor Ray Lemieux

who was Canada's most distinguished organic chemist. His contributions to synthesis, structure, and bonding in saccharide chemistry are truly legendary.

Associate Editors: Bert O. Fraser-Reid and Victor Snieckus

Ce numéro spécial est dédié à la mémoire du

Professeur Ray Lemieux

le plus éminent organicien du Canada. Ses contributions dans le domaine de la chimie des glucides, plus particulièrement leur synthèse, leur structure et leurs mécanismes de liaison, ont été véritablement exceptionnelles.

Directeurs scientifiques associés : Bert O. Fraser-Reid et Victor Snieckus

The addition of organometallic reagents to tetramesityldigermene

Kyle L. Fujdala, David W.K. Gracey, Erica F. Wong, and Kim M. Baines

Abstract: The thermolysis and photolysis of hexamesitylcyclotrigermane in the presence of ethylmagnesium bromide has been investigated. Under photochemical conditions, ethyldimesitylgermane, 1,2-diethyl-1,1,2-trimesityldigermane and ethyl-1,1,2,2-tetramesityldigermane were isolated and, under thermal conditions, 1,2,2-triethyl-1,1-dimesityldigermane and 2,2-diethyl-1,1,1-trimesityldigermane were isolated. The photolysis of hexamesitylcyclotrigermane in the presence of methyllithium has also been investigated. In both cases, the organometallic reagent adds to tetramesityldigermene and dimesitylgermylene formed by photochemical or thermal cleavage of the cyclotrigermane. In the case of the addition of the Grignard reagent, the resulting germyl Grignard reagent undergoes a facile ligand exchange reaction.

Key words: digermene, germylene, Grignard reagents, alkyllithium reagents, germylmagnesium compounds, germyllithium compounds.

Résumé : On a étudié la thermolyse et la photolyse de l'hexamésitylcyclotrigermane en présence de bromure d'éthylmagnésium. Dans les conditions photochimiques, on a isolé de l'éthyldimésitylgermane, du 1,2-diéthyl-1,1,2-trimésityldigermane et du éthyl-1,1,2,2-tétramésityldigermane alors, que dans des conditions thermiques, on a isolé du 1,2,2-triéthyl-1,1-dimésityldigermane et du 2,2-diéthyl-1,1,1-trimésityldigermane. On a aussi examiné la photolyse de l'hexamésitylcyclotrigermane en présence de méthyllithium. Dans les deux cas, le réactif organométallique s'additionne au tétraméthyldigermène et au dimésitylgermylène qui se forment par clivage photochimique ou thermique du cyclotrigermane. Dans le cas de l'addition du réactif de Grignard, le réactif germylmagnésien qui en résulte subit une réaction facile d'échange de ligands.

Mots clés : digermène, germylène, réactifs de Grignard, réactifs alkyllithium, composés germylmagnésium, composés germyllithium.

[Traduit par la Rédaction]

Introduction

The reactivity of digermenes has been of interest since stable and relatively stable derivatives of these compounds were first synthesized twenty years ago (1). Despite two decades of research in this area, the addition of organometallic reagents remains a relatively unexplored area of digermene chemistry. We have reported that the addition of methylmagnesium halide to $Mes_2Ge{=}GeMes_2$ (Mes = mesityl = 2,4,6-trimethylphenyl) gives (dimesitylmethylgermyl)dimesitylgermylmagnesium bromide in good yield (eq. [1]) (2).

Furthermore, we discovered that thermolysis of the resulting germyl Grignard reagent in the presence of excess MeMgX leads to a facile ligand exchange reaction in which the mesityl groups on the germanium bonded to the magnesium were exchanged for methyl groups (eq. [2]).

[2] 
A mechanism involving the α-elimination of MesMgX followed by the addition of MeMgX to an intermediate germylene has been proposed to explain the observed ligand exchange (Scheme 1). Evidence in support of the proposed mechanism was provided by trapping the initially formed intermediate germylene with 2,3-dimethylbutadiene. We have also found that methylmagnesium halide adds regioselectively to germasilenes giving germyl Grignard reagents, which undergo an analogous methyl-for-mesityl exchange (2, 3). To investigate not only the generality of the Grignard addition to digermenes and the generality of the ligand exchange reaction, we now describe the addition of ethylmagnesium bromide to tetramesityldigermene generated either photochemically or thermally from hexamesitylcyclotrigermane. Furthermore, we also report on the addition of methyllithium to tetramesityldigermene and the thermal behaviour of the products obtained therefrom.

Results and discussion

The photolysis of hexamesitylcyclotrigermane (**1**) in toluene at –60°C in the presence of excess ethylmagnesium bromide, followed by hydrolysis using ammonium chloride, led to the isolation of three products: ethyldimesitylgermane (**2**), 1,2-diethyl-1,1,2-trimesityldigermane (**3**), and ethyl-1,1,2,2-tetramesityldigermane (**4**) in a 7.8:2.8:1 ratio (eq. [3]). All new compounds were characterized by ^{1}H, ^{13}C NMR, and IR spectroscopy and mass spectrometry, the details of which are given in the experimental section. In general, the greater shift dispersion of the ^{13}C NMR spectrum of a given compound was useful in determining the number of different mesityl or ethyl groups and the ^{1}H NMR spectrum gave the ratio of mesityl:ethyl:GeH groups. Finally, the high resolution mass spectrum was critical in determining the molecular formula of the compound.

The formation of compounds **2**–**4** can be understood on the basis of our previous mechanistic proposal. The photolysis of hexamesitylcyclotrigermane results in the formation of dimesitylgermylene and tetramesityldigermene (4). The formation of **2** is most easily accounted for by the quenching of ethyldimesitylgermylmagnesium bromide formed by the addition of ethylmagnesium bromide to dimesitylgermylene. Similarly, compound **4** is apparently derived from addition of the ethyl Grignard reagent to tetramesityldigermene to give the germyl Grignard reagent **5** followed by hydrolysis (Scheme 2). Compound **3** is believed to arise from **5** via an α-elimination of mesitylmagnesium bromide in the cold to give the germylgermylene **6**. Ethylmagnesium bromide could then add to **6**, giving **3** after hydrolysis (Scheme 2).

The reactivity observed in the addition of EtMgBr to $Mes_2Ge{=}GeMes_2$ parallels that for the addition of the methyl analog. However, unlike the methyl analog where a ligand exchange was observed only upon thermolysis of the germyl Grignard reagent at 105°C, the ethyl-for-mesityl exchange was observed at low temperature. Presumably, the more facile ligand exchange is the result of greater steric congestion in the germyl Grignard reagent, which is subsequently relieved upon elimination of mesitylmagnesium bromide. Ligand exchange in t-Bu_2MeSi-$GeMes_2MgX$ was also observed at lower temperatures compared to ligand exchange in Mes_2MeSi-$GeMes_2MgX$ (3).

Thermolysis of hexamesitylcyclotrigermane for extended periods of time gave two major products: 1,2,2-triethyl-1,1-dimesityldigermane (**8**) and 2,2-diethyl-1,1,1-trimesityldigermane (**9**) in a 1:1 to 2:1 ratio (eq. [4]). Compounds **8** and **9** were identified using standard spectroscopic techniques.

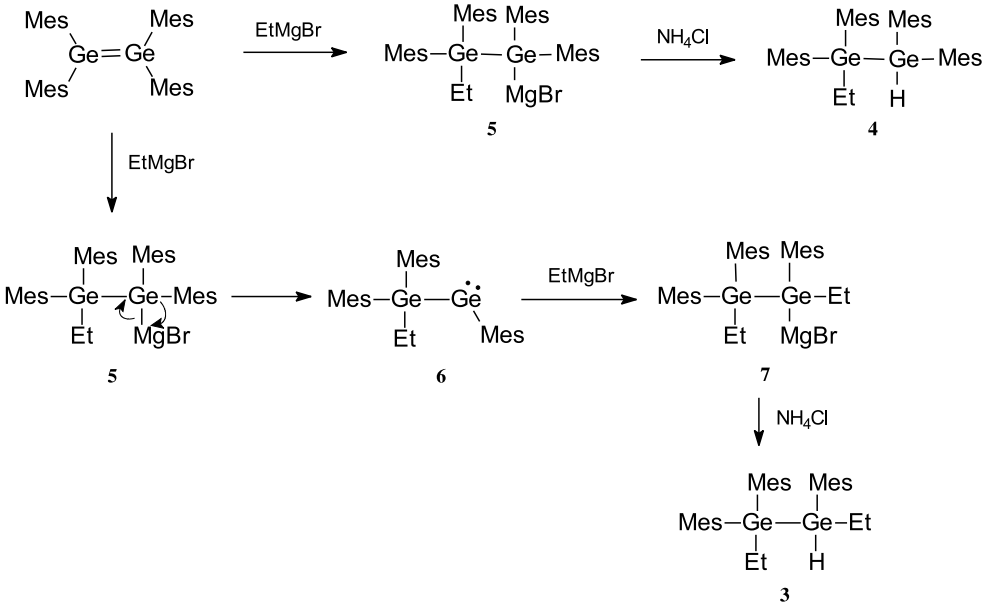
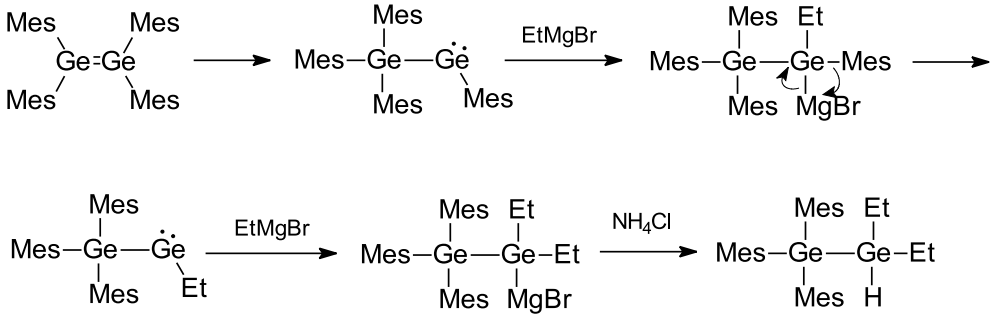
Scheme 2.



Scheme 3.



Formation of these two compounds can be easily explained based on our current mechanism. Compound **8** appears to be the result of an α-elimination of mesitylmagnesium bromide from germyl Grignard **7** to give ethyldimesitylgermylethylgermylene, followed by the addition of ethylmagnesium bromide to give **8** after hydrolysis. The formation of compound **9** is interesting since an analogous product was not observed in the addition of MeMgBr to the digermene. Tetramesityldigermene is known to undergo a facile mesityl migration to give trimesitylgermylmesitylgermylene (5). Addition of ethylmagnesium bromide to this germylene, followed by α-elimination of mesitylmagnesium bromide and the addition of a second equivalent of ethylmagnesium bromide, would result in the formation of germyl Grignard **10**, which upon quenching would give the observed product (Scheme 3). As in the analogous reaction with methylmagnesium halide, no apparent product derived from dimesitylgermylene was isolated. Presumably, ethylmagnesium bromide adds to Mes_2Ge: to give ethyldimesitylgermylmagnesium bromide; however, under the reaction conditions, complete ligand exchange occurs to give triethylgermane (after hydrolysis), which was not isolated. Thermolysis for shorter periods of time (2 h) gave a more complex reaction mixture. In addition to compounds **8** and **9**, compounds **2** and **3** were formed, providing evidence for the intermediate formation of ethyldimesitylgermylmagnesium bromide and the germyl Grignard **7**.

Again, there are both similarities and differences observed in comparison to the analogous thermolysis of hexamesitylcyclotrigermane with the methyl Grignard reagent. A facile ligand exchange was also observed in this system; however, the rate of addition of the bulkier ethyl group appears to compete with the 1,2-mesityl shift at 105°C.

Given the interesting reactivity of germyl Grignard reagents and the absence of any reported additions of alkyllithium reagents to Group 14 dimetallenes, we also investigated the addition of methyllithium to $Mes_2Ge{=}GeMes_2$ under similar conditions.

The photolysis of hexamesitylcyclotrigermane in the presence of methyllithium at –60°C followed by quenching the reaction mixture with a solution of ammonium chloride gave two products: methyl-1,1,2,2-tetramesityldigermane (2) (**11**)

[5] 
1 11 12

and dimesitylmethylgermane (6) (**12**) in modest isolated yields (eq. [5]). The compounds were identified by comparison of their spectroscopic data to that of authentic samples. Given that methyllithium does not react with the cyclotrigermane in the dark, it is reasonable to assume that methyllithium adds to both tetramesityldigermene and dimesitylgermylene (generated by photolysis of the cyclotrigermane) in the same manner as Grignard reagents. Thermolysis of hexamesitylcyclotrigermane in the presence of methyllithium gave only a complex reaction mixture, in contrast to the analogous reaction with methyl Grignard reagent.

In summary, the results described here for the addition of ethylmagnesium bromide to tetramesityldigermene and dimesitylgermylene parallel those previously observed for the addition of methylmagnesium bromide to digermenes and germasilenes. Hence, it has become increasingly apparent that the addition of Grignard reagents to both digermenes and germylenes and the ligand exchange of germyl Grignard reagents are all general reactions. Furthermore, alkyllithium reagents also appear to readily add to digermenes and germylenes, although thermolysis of the resulting mixture of germyllithium reagents does not lead to isolable species. We continue to explore the addition of a variety of organometallic reagents to digermenes and the chemistry of the resulting germyl metallic reagents.

Experimental

All experiments were carried out in flame-dried glassware under an inert argon atmosphere. Toluene, diethyl ether, and THF were freshly distilled from sodium/benzophenone. Ethylmagnesium bromide was prepared from commercially available ethyl bromide and magnesium (Lancaster Chemical Co.). The concentration of the Grignard reagent was determined by titration, prior to use. Chromatographic separations and purifications were carried out using a Chromatotron (Harrison Research) or on conventional silica gel preparative plates. Photolyses were carried out at 350 nm in a Rayonet photochemical reactor. The solution to be photolyzed was placed in a Schlenk tube and suspended in an immersion well filled with methanol at –60°C. The temperature of the methanol was maintained using a NESLAB ULT-80 low temperature bath circulator.

NMR spectra were recorded on a Varian Gemini 200, an XL-300, or a Varian Gemini 300 NMR spectrometer using benzene-d_6 as a solvent. IR spectra were recorded (cm^{-1}) as thin films on a PerkinElmer 2000 FT-IR spectrometer. A Finnegan MAT model 8200 mass spectrometer, with an ionizing voltage of 70 eV, was used to obtain electron impact mass spectra (recorded in mass-to-charge units (*m/z*) with ion identity and peak intensities relative to the base peak in parentheses).

Photolysis of hexamesitylcyclotrigermane in the presence of excess ethylmagnesium bromide

A solution of Ge_3Mes_6 (48 mg, 0.052 mmol) and freshly prepared ethylmagnesium bromide (1 mL, 1.5 mmol in Et_2O) in toluene (3 mL) was photolyzed (350 nm) for 22 h at –60°C. At the end of the photolysis, the solution was bright yellow-orange. The cold reaction mixture was quenched with aqueous ammonium chloride. The aqueous and organic phases were then separated. The aqueous phase was extracted with three portions of hexanes and the extracts were combined with the organic phase. The organic phase was dried over anhydrous magnesium sulfate and then filtered to remove the solid. Removal of the solvent in vacuo yielded a clear, colourless oil. ^{1}H NMR spectroscopic analysis of the reaction mixture showed three major products in a 7.8:1:2.8 ratio (**2**:**4**:**3**). The reaction mixture was separated by TLC using 8% CH_2Cl_2 in hexanes as the eluent to give ethyldimesitylgermane (**2**, 15.3 mg, 87%) and ethyl-1,1,2,2-tetramesityldigermane (**4**, 8.5 mg, 25%). Compound **3** was not isolated in pure form.

Thermolysis of hexamesitylcyclotrigermane in the presence of excess ethylmagnesium bromide

A solution of Ge_3Mes_6 (50.3 mg, 0.055 mmol) and freshly prepared ethylmagnesium bromide (1 mL, 1.65 mmol in Et_2O) in toluene (4 mL) was heated for 68 h at 105°C. After a few minutes of heating, the clear and colourless solution

© 2002 NRC Canada

became light yellow and some solid precipitated from solution. At the end of the thermolysis, the solution was cloudy grey in colour with a white solid precipitate. Following the thermolysis, the reaction mixture was quenched with aqueous ammonium chloride. The aqueous and organic phases were then separated. The aqueous phase was extracted with three portions of hexanes and the extracts were combined with the organic phase. The organic phase was dried over anhydrous magnesium sulfate and then filtered to remove the solid. Removal of the solvent in vacuo yielded a clear, colourless oil. ^{1}H NMR spectroscopic analysis of the reaction mixture showed two major products (**8** and **9**) in a 1:1 or 2:1 ratio. The product mixture was separated by TLC using 10% CH_2Cl_2 in hexanes as the eluent to give 2,2-diethyl-1,1,1-trimesityldigermane (**9**, 1.1 mg, 3.8%) and 1,2,2-triethyl-1,1-dimesityldigermane (**8**, 4.8 mg, 18.5%).[2]

Photolysis of hexamesitylcyclotrigermane in the presence of methyllithium

Methyllithium (1.0 mL of a 1.4 M solution in diethyl ether, 1.4 mmol) was added to a Schlenk tube containing a clear, pale yellow solution of Ge_3Mes_6 (53 mg, 0.057 mmol) dissolved in toluene (4 mL). The Schlenk tube was then sealed and placed in an immersion well, cooled to –60°C, and then irradiated for 13 h. After photolysis, the clear, deep yellow solution was warmed to room temperature and was quenched with aqueous ammonium chloride. The aqueous and organic phases were then separated. The aqueous phase was extracted with four portions of hexanes and the extracts were combined with the organic phase. The organic phase was washed three times with water and then dried over anhydrous magnesium sulfate. After filtration to remove the solid, removal of the solvent in vacuo yielded a pale yellow solid. The product mixture was separated by preparative TLC using hexanes–dichloromethane (99:1) as the eluent to give 1,1,2,2-tetramesitylmethyldigermane (2) (**12**, 16 mg, 44%) and dimesitylmethylgermane (6) (**11**, 7 mg, 38%), which were identified by comparison of their ^{1}H NMR spectra with authentic samples.

Attempted reaction of hexamesitylcyclotrigermane with methyllithium in the dark

Methyllithium (1.0 mL of a 1.4 M solution in diethyl ether, 1.4 mmol) was added to a Schlenk tube containing a clear, pale yellow solution of Ge_3Mes_6 (50 mg, 0.054 mmol) dissolved in toluene (4 mL). The Schlenk tube was covered in aluminum foil and left undisturbed for 14 h at room temperature (rt). No change in the colour of the solution was observed. Saturated aqueous ammonium chloride was then added to the solution. The aqueous and organic phases were then separated. The aqueous phase was extracted with four portions of hexanes and the extracts were combined with the organic phase. The organic phase was washed three times with water and then dried over anhydrous magnesium sulfate. After filtration to remove the solid, removal of the solvent in vacuo yielded a pale yellow solid. The solid was identified as hexamesitylcyclotrigermane (41.6 mg, 83%) by ^{1}H NMR spectroscopy.

Thermolysis of hexamesitylcyclotrigermane in the presence of methyllithium

Methyllithium (1.0 mL of a 1.4 M solution in diethyl ether, 1.4 mmol) was added to a Schlenk tube containing a clear, pale yellow solution of Ge_3Mes_6 (50 mg, 0.054 mmol) dissolved in toluene (4 mL). The Schlenk tube was then placed in an oil bath at 100°C for 14 h. The orange-brown solution was allowed to cool to rt. The colour of the solution changed to pale yellow upon quenching with saturated ammonium chloride; a gas was evolved. The aqueous and organic phases were then separated. The aqueous phase was extracted with four portions of hexanes and the extracts were combined with the organic phase. The organic phase was washed three times with water and then dried over anhydrous magnesium sulfate. After filtration to remove the solid, removal of the solvent in vacuo yielded a yellow oil. Analysis

[2] Due to the small quantities of samples, it was impossible to obtain enough material for elemental analysis.

© 2002 NRC Canada

of the oil by ^{1}H NMR spectroscopy revealed a complex mixture of products, which could not be separated or identified.

Organophosphazenes. 25. The synthesis and electrochemistry of the dicobalt hexacarbonyl complexes of phenylethynylcyclophosphazenes[1]

Maneesh Bahadur, Christopher W. Allen, William E. Geiger, and Adam Bridges

Abstract: The syntheses of the dicobalt hexacarbonyl complexes, $N_3P_3F_{6-n}(C{\equiv}CPhCo_2(CO)_6)_n$ (n = 1 (**3**), n = 2 (**4**)), is reported. The introduction of the organometallic fragment allows for simplification of the NMR spectra and separation of the isomers of the disubstituted (**4**) derivatives. Electrochemical studies show that **3** undergoes a reversible one-electron reduction. At 233 K, the geminal isomer of **4** undergoes two separate reversible one-electron reductions. The ESR spectra of the radical anions of **3** and **4** have been obtained and show the absence of delocalization of unpaired spin density from the organometallic cluster to the phosphazene.

Key words: cyclophosphazenes, cobalt–alkyne clusters, electrochemistry, ESR.

Résumé : On a réalisé la synthèse de complexes de dicobalt hexacarbonyle, $N_3P_3F_{6-n}(C{\equiv}CPhCo_2(CO)_6)_n$ (n = 1 (**3**), n = 2 (**4**)). L'introduction du fragment organométallique simplifie les spectres RMN et la séparation des isomères des dérivés disubstitués (**4**). Des études électrochimiques montrent que le composé **3** subit une réduction réversible à un électron. À 233 K, l'isomère géminé du composé **4** subit deux réactions séparées de réductions réversibles à un électron. Les spectres RPE des anions radicaux des composés **3** et **4** ont été mesurés et ils mettent en évidence l'absence de délocalisation de la densité de spin non pairée de l'agrégat organométallique vers le phosphazène.

Introduction

The reactions of main group organometallic reagents with halocyclophosphazenes has lead to the formation of a broad array of organophosphazene derivatives (1, 2). Within this class of compounds, the aryl derivatives have attracted the most attention (1, 3–5). The ethenyl derivatives have been widely exploited as monomers in olefin addition polymerization reactions leading to carbon chain polymers with cyclophosphazene substituents (6–8). By way of contrast, significantly less interest has been shown in the corresponding ethynyl derivatives, in which a direct phosphorus — ethynyl carbon bond exists. The first examples of this class of compounds, $N_3P_3F_{6-n}$ $(C{\equiv}CPh)_n$ (n = 1,2), and the dicobalt hexacarbonyl derivative of $N_3P_3F_5C{\equiv}CPh$ were reported by Chivers (9). Utilization of the reactions of lithioethynyl reagents with $N_3P_3F_6$ also provides trimethylsilylethynyl (10), alkylethynyl (11), and mixed aryl-phenylethynyl derivatives (12). Indirect routes involve catalyzed rearrangements of propargyl derivatives (13) and byproducts in the reaction of lithiopropene with $N_3P_3F_6$ (14). The electronic structure of these materials has been probed by UV–photoelectron spectroscopy (15). In this paper, we present the results of a study of the synthesis and redox processes of the dicobalt hexacarbonyl derivatives of phenylethynylfluorocyclotriphosphazenes. These investigations provide additional insights into the nature of the interactions between unsaturated organic substituents and the cyclophosphazene ring. A preliminary report of certain aspects of this work has appeared (16).

Experimental

Materials

Hexachlorocyclotriphosphazene ($N_3P_3Cl_6$) was converted to $N_3P_3F_6$ (17), which in turn was converted to $N_3P_3F_5(C{\equiv}CPh)$ (**1**), $N_3P_3F_4(C{\equiv}CPh)_2$ (**2**) (9, 10), and $P_3N_3F_5C_6H_4CMe{=}CH_2$ (5) by previously reported procedures. Butyllithium (2.5 M in hexane) and phenylacetylene were obtained from Aldrich Co. Dicobalt octacarbonyl (Johnson Matthey) was sublimed and used immediately. All manipulations were performed under nitrogen. All solvents were distilled from the appropriate drying agents prior to use, and further purification of the solvents for electrochemical and ESR experiments was achieved by three freeze–pump–thaw cycles followed by vacuum distillation.

Measurements

Infrared spectra were recorded on a PerkinElmer 1430 spectrophotometer. Mass spectrometry was carried out on a Finnigan 4610 spectrometer operating at 70 eV. NMR spectra were recorded on a Bruker WM250 spectrometer operating at: 250.1 MHz (^{1}H); 62.9 MHz (^{13}C); 235.35 MHz (^{19}F); 101.2 MHz (^{31}P) and using $CDCl_3$ for a lock compound. Tetramethylsilane (TMS) (^{1}H and ^{13}C) was used as an internal reference, while 85% H_3PO_4 (^{31}P) and $CFCl_3$ (^{19}F) were used as external references. Chemical shifts upfield from the reference are negative. Broad band ^{1}H decoupling was used for the ^{13}C, ^{19}F, and ^{31}P spectra. ESR measurements were performed on a modified Varian E-3 spectrometer with external diphenylpicrylhydrazide (DPPH) as a standard. Elemental analyses were performed by Robertson Laboratory, Inc. Electrochemical measurements were carried out using a Princeton Applied Research Model 173 potentiostat with a Hewlett-Packard 7004B *x-y* recorder as described in the literature (18). Solutions for cyclic voltammetry (CV) contained 0.5 mM of the metal complex and also contained 0.1 M Bu_4NPF_6 as the supporting electrolyte in THF. Potentials are reported vs. Ag/AgCl. Low-temperature CV solutions contained 0.1 M $Bu_4NCF_3SO_3$ as the supporting electrolyte. Low temperature was achieved by immersing the voltammetry cell in a dry ice – acetone slush bath. For rotating platinum electrode (RPE) measurements, a Sargent synchronous rotor (1800 rpm) was employed.

Syntheses of (dicobalt hexacarbonyl phenylethynyl) pentafluorocyclotriphosphazene ($N_3P_3F_5C{\equiv}CPhCo_2(CO)_6$) (3)

This preparation is a modification of a previously reported procedure (9). (β-Phenylethynyl)pentafluorocyclotriphosphazene ($N_3P_3F_5C{\equiv}CPh$, **1**) (0.74 g, 2.25 mmol), and dicobalt octacarbonyl (0.78 g, 2.25 mmol), were allowed to react in hexane (40 mL) in a nitrogen filled flask connected to a gas bubbler system. The reaction mixture was stirred at room temperature. The reaction was monitored by IR spectroscopy and found to be complete within 30 min. After the solvent was removed, the material was chromatographed on silica gel with hexane and methylene chloride (90:10 v/v) as the eluent. The product eluted as a red band. The red compound was isolated and crystallized from hexane as red microcrystalline material. MW: calcd. 616; found 617 (CI-MS). ^{13}C NMR δ: 99.5 ([*C*≡$CC_6H_5{\cdot}Co_2(CO)_6]_2$), 136.5 ([C≡*C*$C_6H_5Co_2(CO)_6]_2$), 130.0, 129.0, 128.8, (C_6H_5), 197.3 ($Co_2(CO)_6$). ^{19}F NMR δ: 57.4 (d, J_{PF} = 974 Hz, ≡PF[C≡$CC_6H_5Co_2(CO)_6$]), 72.9 (d, J_{PF} = 919 Hz, PF_2[cis]), 72.2 (d, J_{PF} = 946 Hz, ≡PF_2[trans]). ^{31}P NMR δ: 9.4 (t, J_{PF} = 929 Hz, ≡PF_2), 38.0 (d of t, J_{PF} = 975 Hz, $^2J_{PP}$ = 68.8 Hz, ≡PF[C≡$C_6H_5Co_2(CO)_6$]).

Synthesis of bis(dicobalt hexacarbonylphenylethynyl)-tetrafluorocyclotriphosphazene (2,2-$N_3P_3F_4(C{\equiv}CPhCo_2(CO)_6)_2$) (4)

Bis(phenylethynyl)tetrafluorocyclotriphosphazene ($N_3P_3F_4$[C≡CPh]$_2$) (0.7 g, 2.25 mmol), and dicobalt octacarbonyl (1.55 g, 4.5 mmol), were allowed to react in hexane (60 mL) in a nitrogen filled flask connected to a gas bubbler system. The reaction mixture was stirred at room temperature for 30 min and monitored by IR. After the solvent was removed, the material was chromatographed on silica gel with hexane and methylene chloride (90:10) as the eluent. Two red fractions were isolated, which were shown to be the geminal isomer and the cis–trans non-geminal mixture. The pure geminal isomer was obtained as dark red crystals from hexane solution at –20°C (0.89 g, 40% yield). The melting point of the geminal isomer was found to be greater than 225°C. Attempts to crystallize or sublime either of the non-geminal isomers were unsuccessful, nor could the isomers be separated. A yield of 0.14 g (15%) was obtained. Anal. calcd. for $C_{28}H_{10}F_4N_3P_3O_{12}Co_2$: C 34.12, H 1.01, MW 985; found: (geminal) C 34.21, H 0.92. Molecular ion M^+ was not observed in either EI- or CI-MS.

MS, cis-trans mixture (molecular ion ([M^+]) not observed), *m/e* (%): 901 ([M – 3CO]$^+$, 10), 845 ([M – 5CO]$^+$, 1.7), 817 ([M – 6CO]$^+$, 6.6), 789 ([M – 7CO]$^+$, 20.8), 761 ([M – 8CO]$^+$, 26), 733 ([M – 9CO]$^+$, 6), 705 ([M – 10CO]$^+$, 15), 677 ([M – 11CO]$^+$, 8), 649 ([M – 12CO]$^+$, 100).

Trans non-geminal

^{19}F NMR δ: 72.3 (complex d, J_{FP} = 888 Hz, ≡PF_2), 52.8 (complex d, J_{FP} = 937 Hz, ≡PF[C≡$CC_6H_5Co_2(CO)_6$]). ^{31}P NMR δ: 6.2 (t, J_{PF} = 997 Hz, ≡PF_2), 34.8 (d of d, J_{PF} = 944 Hz, $^2J_{PP}$ = 70 Hz, ≡PF[C≡$CC_6H_5Co_2(CO)_6$]).

Attempted reaction of the lithium salt of hexacarbonyl(phenylethyne)dicobalt

The reaction of $LiC{\equiv}CPhCo_2(CO)_6$, generated from lithium diisopropylamide and $HC{\equiv}CPhCo_2(CO)_6$, with an equimolar quantity of $N_3P_3F_5C_6H_4CMe{=}CH_2$ in hexane, resulted in a dark green solution, from which a green solid was isolated. The absence of detectable ^{31}P NMR resonances indicated that the phosphazene derivative was not formed.

Chemical reduction of 3 and 4

The reduction was carried out on a vacuum line with 0.75 mmol of **3**, or the geminal isomer of **4**, and 0.18 mg (0.75 mmol) of cobaltocene, in an ESR tube. The ESR tube

© 2002 NRC Canada

was connected to the vacuum line and evacuated. Approximately 0.5 mL of 2:1 tetrahydrofuran–dichloromethane (v/v) was introduced by vacuum transfer, and subsequently the ESR tube was sealed off. After thawing the sample, the reaction was carried out at –65°C (in a dry ice – acetone slush bath) for less than 5 min, and then the sample was frozen in liquid nitrogen. The ESR spectra were then immediately recorded at liquid nitrogen temperature.

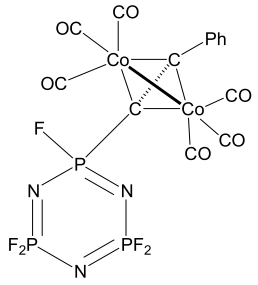
Results and discussion

The reaction of dicobalt octacarbonyl with **1** (9) and **2** lead cleanly to the respective dicobalt hexacarbonyl – alkyne cluster derivatives.

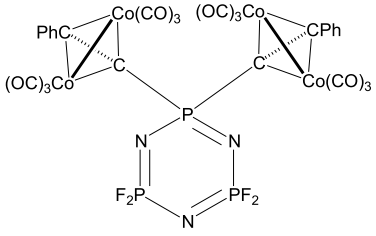
[1] $N_3P_3F_5C{\equiv}CPh + Co_2(CO)_8$ (**1**) $\rightarrow N_3P_3F_5(C{\equiv}CPhCo_2(CO)_6)$ (**3**)

[2] $N_3P_3F_4(C{\equiv}CPh)_2 + Co_2(CO)_8$ (**2**) $\rightarrow N_3P_3F_4(C{\equiv}CPhCo_2(CO)_6)_2$ (**4**)

An alternative route to the synthesis of dicobalt hexacarbonyl – alkyne complexes, via the reactions of $LiC{\equiv}CPhCo_2(CO)_6$ (19), was also attempted. All attempts to isolate cyclophosphazene derivatives failed. The major product was a green solid, which is believed to be an alkyne coupling product. A similar product was observed in the reactions of $LiC{\equiv}CSiMe_3Co_2(CO)_6$ with electrophiles, and was shown to be a dimer, $Co_2(CO)_6Me_3SiC{\equiv}C\text{-}C{\equiv}CSiMe_3Co_2(CO)_6$ (19).



3



4

Previous NMR studies have shown that **2** consists of a mixture of inseparable isomers, with the geminal (2,2-) species being in large excess over the non-geminal (2,4-) components (10). The addition of the dicobalt hexacarbonyl fragment allowed for the chromatographic separation of the geminal (**4g**) and non-geminal isomers (**4ng**). The cis and trans isomers of 2,4-[(α-methylethenyl)phenylethynyl]tetrafluorocyclotriphosphazene have also been separated as their dicobalt hexacarbonyl complexes (12). These studies show the applicability of metal complex formation to the often intractable problem of separation of cyclophosphazene regio- and stereoisomers. The addition of the dicobalt hexacarbonyl fragment to the alkyne also had a significant effect on the ^{31}P NMR spectra. A comparison of the NMR spectra of **1** (10) to **3** showed that the alkynylphosphorus center ^{31}P resonance undergoes a 32 ppm downfield shift while the $\equiv PF_2$ centers only change by about 2 ppm. This leads to a considerable simplification in the spectrum in **3**, since in **1** the two phosphorus shifts are only separated by 2 ppm. The intra-ring phosphorus–phosphorus coupling constant ($^2J_{PP}$) decreased by 32 Hz. Similar changes were observed in a comparison of the geminal isomer of **2** to **4g**, wherein the corresponding bis(alkynyl)phosphorus resonance underwent a 66 ppm downfield shift and $^2J_{PP}$ decreased by 41 ppm. The NMR spectra of the **4ng** isomers were also sufficiently simplified so that the principle parameters could be measured and reported. The factors controlling the chemical shifts in cyclophosphazenes are complex and not well understood (20). In the present case, a change of the exocyclic bond angle at the phosphorus center or an introduction of a significant paramagnetic term to the shift tensor from the transition metal component are both viable proposals. The $^2J_{PP}$ values in cyclophosphazenes are controlled by the electronegativities of the phosphorus substituents (20). The carbon atoms of the phosphazene substituent change, from approximate *sp* hydridization in **1** and **2**, to a lower *s* character in the organometallic derivatives, and hence the orbital electronegativity decreases, leading to the observed decrease in $^2J_{PP}$.

The IR spectra for complexes **3** (9) and **4g** showed five CO bands between 2000 and 2110 cm^{-1}. The IR spectrum for **3** (9) showed a PN stretching band at 1269 cm^{-1}, while the PN stretching band for **4g** appeared at 1242 cm^{-1}. The PN stretching frequency showed a steady decrease in going from $P_3N_3F_6$, to **3**, to **4g**, which reflects an increased electron donation to the phosphazene ring by the [C≡C-$C_6H_5Co_2(CO)_6$] substituent, in comparison to the fluorine atom (21). The change in the $\upsilon_{C\equiv C}$ absorbance from **2** (2139 cm^{-1}) to **4** (1562 cm^{-1}) indicates a significant reduction in bond order, and hence in orbital electronegativity. The mass spectrum of **3** showed the parent ion and the peaks associated with the sequential loss of the six carbonyl groups. By way of contrast, in both **4g** and **4ng**, the $[M - 3CO]^+$ fragment is the highest mass peak, followed by the $[M - 5CO]^+$ ion. The base peak was the $[M - 12CO]^+$ ion.

The electrochemistry of alkyne – dicobalt hexacarbonyl clusters ($Co_2(CO)_6(\mu\text{-}RC_2R)$ (R = CF_3, Bu, Ph)) has been examined in some detail (22–24). This background provides a frame of reference for understanding the electrochemical behavior of **3** and **4**. The cyclic voltammogram (CV) of **3** showed a reversible reduction at $E^\circ = -0.64$ V (298 K). The anodic to cathodic (i_a/i_c) current ratios were unity over a scan rate range of 40–400 mV s^{-1}. Comparison of CV peak separations (ΔE_p), and $i_p/\upsilon^{1/2}$ with those of ferrocene, under the same experimental conditions,[3] established the process as diffusion-controlled, leading to the formation of $\mathbf{3}^-$. A second irreversible reduction was observed at –1.67 V. If one scans beyond the second reduction, the reverse scan reveals an anodic peak at −0.98 V, presumably due to a decomposition product of $\mathbf{3}^{2-}$. Low temperature CV studies did not show any change in the behavior of **3**, except for shifts in the E° values (E° (**3**) = –0.55 V at 233 K) and smaller diffusion

[3] The variable scan rate data for **3** and **4**, Tables D1 and D2, can be found in the supplementary material. Supplementary data may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada (http://www.nrc.ca/cisti/irm/unpub_e.shtml for information on ordering electronically).

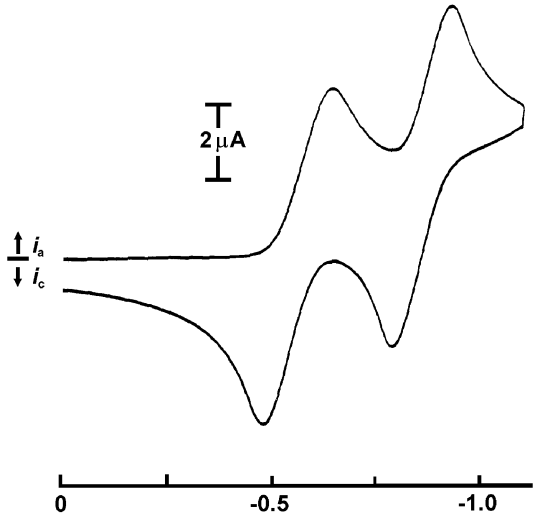

Fig. 2. Frozen solution ESR spectrum of the radical anion of **3**.

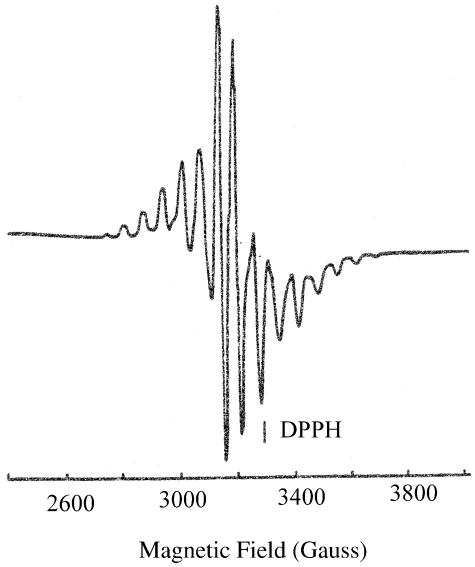

currents.[3] The room temperature CV for **4g** showed two closely spaced reduction waves in the potential range where only one was observed for **3**. The first process ($E°$ = −0.69 V) is reversible whereas the second (E = –1.08 V) is irreversible. The second process gives a follow-up product with an irreversible oxidation peak at 0.20 V, which was assigned to $Co(CO)_4^{-/0}$ (25). Other features in the potential range of 1.0 to –2.0 V are equivalent to those observed for **3**. There are, however, differences in the stabilities and formal potentials for formation of $\mathbf{3}^-$ and $\mathbf{4g}^-$**.** For **4g**, the i_a/i_c ratio increased from 0.66 at 40 mV s^{-1} to 0.96 at 400 mV s^{-1}. This indicates that the $\mathbf{4g}^{0/1-}$ redox process is only chemically reversible at the higher scan rates. Assuming that the decomposition of $\mathbf{4g}^-$ is a first-order process, a half-life of approximately 6 s can be calculated. The dianion, $\mathbf{4g}^{2-}$, has an even smaller half-life. The decomposition step of $\mathbf{4g}^{2-}$ can be avoided by a reduction in temperature. At 233 K, the CV of **4g** showed two reversible reduction steps, at −0.61 V and −0.94 V, for the $\mathbf{4g}^{0/-}$ and $\mathbf{4g}^{-/2-}$ steps, respectively (Fig. 1). Scans of the waves with a rotating platinum electrode established that they are both one-electron processes. Traditional diagnostic criteria (26) were used to demonstrate diffusion control through CV scans (Supplementary material, Tables D.1, D.2).[3] Within the limits of experimental error, the $i_p/\upsilon^{1/2}$ ratios for **3** or **4g** are the same (0.65 vs. 0.61) over the scan rate of 0.1 to 0.4 V s^{-1}. Thus, the following reactions (eq. [3]) govern the reductive behavior of the species under investigation. Previous investigations (22–24) have established that the lifetime of the radical anion derived from

[3] $\mathbf{3} + e^- \rightleftarrows \mathbf{3}^-$; $E°$ = –0.55 V

$\mathbf{4g} + e^- \rightleftarrows \mathbf{4g}^-$; $E°$ = –0.61 V

$\mathbf{4g}^- + e^- \rightleftarrows \mathbf{4g}^{2-}$; $E°$ = –0.94 V

dicobalt hexacarbonyl – alkyne clusters decreases as the electronegativity of the alkyne substituents decrease. For example, the room temperature lifetime of $[(CF_3)_2C_2Co_2(CO)_6]^-$ is greater than 1 h, whereas that of $[Ph_2C_2Co(CO)_6]^-$ is 17 ms (27). In **3** and **4g**, the effect of the strongly electron-withdrawing phosphazene (15) and the electron-donating phenyl group are counterbalanced to produce radicals of intermediate stability. The first reduction of **4g** takes place at a more negative potential compared with **3**, and the radical anion $\mathbf{3}^-$ is more stable than $\mathbf{4g}^-$. Both of these observations are a reflection of the decrease in the group electronegativity of the phosphazene substituent as a result of the replacement of a fluorine atom with the more electron donating alkyne – cobalt carbonyl cluster on going from **3** to **4g**.

The moderate stability of the radical anions allows for their characterization by ESR spectroscopy in frozen solutions. Chemical reduction was accomplished using cobaltocene (Cp_2Co) as the reductant. The ESR spectra of both $\mathbf{3}^-$ and $\mathbf{4g}^-$ showed 15 lines from hyperfine coupling to the two equivalent cobalt (I = 7/2) nuclei (Fig. 2). Hyperfine coupling to phosphorus was not observed. A first-order analysis yielded values of $\mathbf{g}_1$ = 2.04 and $\mathbf{a}_1$ = 67.8 G. These values are higher than those obtained from similar complexes that were interpreted in terms of anisotropic g and cobalt hyperfine tensors (27). The absence of phosphorus hyperfine coupling indicates that the unpaired electron is localized on the organometallic fragment and not delocalized to the phosphazene. The ultraviolet photoelectron spectra of alkynyl phosphazenes have also been interpreted as showing absence of π donation of the alkyne to the phosphazene (15). Thus, alkynylphosphazenes and their organometallic complexes are similar to alkenyl (15, 28) and arylphosphophosphazenes (5, 28, 29) in that the carbon–carbon π electron density is localized on the organic exocyclic substituent.

The coordination chemistry of *o,o′-i*-$Pr_2C_6H_3$-bis(imino)acenaphthene to group 13 trihalides

Hilary A. Jenkins, Carla L. Dumaresque, Dragoslav Vidovic, and Jason A. C. Clyburne

Abstract: The preparation of several complexes of the diimine ligand *o,o′-i*-$Pr_2C_6H_3$-bis(imino)acenaphthene (Ar-BIAN (**1**)) with group 13 trihalides (EX_3, E = B, Al, Ga; X = Cl, Br) is reported. Four compounds with the general formula [(Ar-BIAN)(EX_2)][EX_4] (**2**) have been prepared and isolated. Two complexes have been crystallographically characterized: [(Ar-BIAN)(BCl_2)][BCl_4] (orthorhombic, $P2_12_12_1$, a = 10.408(3) Å, b = 14.376(4) Å, c = 30.908(8) Å, Z = 4) and [(Ar-BIAN)($GaCl_2$)][$GaCl_4$] (monoclinic, $P2_1/m$, a = 9.0822(7) Å, b = 15.390(1) Å, c = 15.458(1) Å, β = 92.519(2)°, Z = 2). Attempts to prepare diazametaloles via reduction of the [(Ar-BIAN)(EX_2)][EX_4] compounds using sodium or potassium have thus far been unsuccessful.

Key words: boron, aluminium, gallium, complex, crystal structure, heterocycle.

Résumé : On a préparé plusieurs complexes du ligand diimide *o,o′-i*-$Pr_2C_6H_3$-bis(imino)acénaphtène (Ar-BIAN (**1**)) avec des halogénures d'éléments du groupe 13 (EX_3, E = B, Al, Ga; X = Cl, Br). On a spécifiquement préparé et isolé quatre composés de formule générale [(Ar-BIAN)(EX_2)][EX_4] (**2**). On a caractérisé deux de ces complexes par diffraction des rayons X, le [(Ar-BIAN)(BCl_2)][BCl_4] (orthorhombique, $P2_12_12_1$, a = 10,408(3), b = 14,376(4) et c = 30,908(8) Å, Z = 4) et le [(Ar-BIAN)($GaCl_2$)][$GaCl_4$] (monoclinique, $P2_1/m$, a = 9,0822(7), b = 15,390(1) et c = 15,458(1) Å, β = 92,519(2)°, Z = 4). On n'a pas réussi à préparer des diazamétaloles par le biais d'une réduction des composés [(Ar-BIAN)(EX_2)][EX_4] à l'aide du sodium ou du potassium.

Mots clés : bore, aluminium, gallium, complexes, structure cristalline, hétérocycle.

[Traduit par la Rédaction]

Introduction

Hydroborations are an important class of reaction in synthetic organic chemistry because the B—H bond readily adds across a wide variety of unsaturated fragments, including C=O and C=N bonds (1). Recently, reactions involving chloroboration (B-Cl addition) have been identified (2). To our knowledge, these reactions have not been extended to heavier group 13 elements, although enhanced reactivity would be anticipated for Al—Cl and Ga—Cl bonds as compared with the B—Cl bonds.

Our interest in group 13 element chemistry (3) led us to look at the synthesis of suitable heterocyclic systems as precursors to compounds that may engage in reactions analogous to hydroboration and haloboration. The ideal candidates for such reactions would be heterocyclic compounds, with donor substituents bound to the group 13 metal site; these donors would stabilize a tricoordinate metal centre via delocalization. The presence of a bulky substituent would facilitate synthesis and enhance the thermal stability of the complex. Currently there is great interest in unusual main group element heterocycles, including B (4, 5), Al (6), and Ga (7, 8) derivatives.

It became apparent to us that the bulky diimine ligand **1** (9) would be ideal for our studies since it is both a good donor and extremely bulky.

diimine ligand (**1**) is different from other diimine ligands as it has both better σ-donating and π-accepting properties than nonrigid diimines (9). Therefore, **1** could serve as an ideal starting material for the preparation of stable heterocyclic metal-containing ions (metal = boron, aluminium, and gallium) (**2**), which would serve as precursors to the requisite heterocycles (**3**). The nitrogen atoms are locked into a rigid *s-cis* conformation due to the presence of the naphthalene backbone, thus allowing for better metal coordination. Brookhart and co-workers (11) have recently reported Ni(II) and Pd(II) complexes of **1** that catalyze the polymerization of ethylene. These catalysts have activities similar to those of the early transition metal catalysts; however, they produce polymers with different structures and properties. Despite extensive use in transition metal chemistry ligand design, **1** has not been used in main group chemistry.

Herein we report our synthetic and structural studies on a series of bulky diazametalolium (**2**) complexes. A series of reactions involving **1** with EX_3 (E = B, Al, Ga; X = Cl, Br) has been examined, and the reaction products have been isolated and characterized. The products have the general formula $[(Ar\text{-}BIAN)(EX_2)][EX_4]$ (**3**). Attempts to prepare molecules such as **3** via reduction of **2** have thus far been unsuccessful.

Experimental methods

An MBraun UL-99–245 dry box and standard Schlenk techniques on a double manifold vacuum line were used in the manipulation of air- and moisture-sensitive compounds. Anhydrous solvents were used as received from Aldrich Chemical Company. NMR spectra were recorded on a Bruker AMX 400 MHz spectrometer in 5-mm quartz tubes. ^1H chemical shifts were reported in parts per million (ppm) downfield from tetramethylsilane (TMS) and were calibrated to the residual signal of the solvent. Infrared spectra were obtained using a Bomem MB spectrometer with the % transmittance reported in cm^{-1}. Melting points were measured using a Mel-Temp apparatus and are uncorrected. Ligand **1** was prepared using the published procedure (9). Note that ^{13}C NMR spectra were not obtained due to decomposition and low solubility of the ionic compounds.

Synthesis of [(Ar-BIAN)(BCl_2)][BCl_4]

Ar-BIAN (1.20 g, 2.5 mmol in 10 mL CH_2Cl_2) was added to a solution of 25 mL CH_2Cl_2 and 5 mL (5.0 mmol) of 1 M BCl_3 in hexanes, resulting in the formation of a dark red solution. The volume of solvent was reduced to ca. 25% of the original volume, and then the solution was cooled to –30°C. Small red crystals were obtained and the supernatant was removed via cannula under an atmosphere of argon. Yield: 1.05 g (1.47 mmol, 59%), decomposition temperature ≈ 140°C. IR (Nujol mull) (cm^{-1}): 1643, 1600, 1569, 1418, 1366, 1318, 1260, 854, 835, 802, 774, 691, 658, 634, 546. ^1H NMR (CD_2Cl_2) δ (ppm): 1.14 (broad, 12H), 1.42 (d, J_{HH} = 6 Hz, 12H), 3.01 (m, 4H), 6.9 (d, 7 Hz), 7.6 (m, 2H), 8.28 (d, J_{HH} = 8 Hz, 2H), 7.3–7.8 (6H aryl). Anal. calcd. for $C_{36}H_{40}B_2Cl_6N_2$: C 58.82, H 5.48, N 3.81; found: C 59.16, H 5.60, N 3.64.

Synthesis of [(Ar-BIAN)(BBr_2)][BBr_4]

Ar-BIAN (1.20 g, 2.5 mmol in 10 mL of CH_2Cl_2) was added to a solution of 25 mL of CH_2Cl_2 and 5 mL (5.0 mmol) of 1 M BBr_3 in CH_2Cl_2 to produce a dark red solution. The volume of solvent was reduced to ca. 25% of the original volume, and then the solution was cooled to –30°C. Solvent was removed under an argon atmosphere and dark red crystals were isolated in the dry box. Yield: 1.35 g (1.38 mmol, 55%), decomposition temperature ≈ 185°C. IR (Nujol mull) (cm^{-1}): 1635, 1597, 1570, 1319, 834, 733, 615, 588, 541. ^1H NMR (CD_2Cl_2, poor solubility) δ (ppm): 1.0 (d, J_{HH} = 6Hz, 12H), 1.45 (d, J_{HH} = 6 Hz, 12H), 3.3 (broad, 4H), aromatic region broad and not resolved. Anal. calcd. for $C_{36}H_{40}B_2Br_6N_2$: C 43.16, H 4.02, N 2.80; found: C 42.80, H 3.92, N 2.65.

Synthesis of [(Ar-BIAN)($AlCl_2$)][$AlCl_4$]

Aluminium trichloride (1.0 g, 7.50 mmol) was added to an oven-dried Schlenk flask containing 40 mL of CH_2Cl_2. Ar-BIAN (1.80 g, 3.75 mmol) in 5 mL of CH_2Cl_2 was added, and the solution turned dark red. Half of the solvent was removed under vacuum, and the reaction was cooled to –30°C in the freezer. A microcrystalline powder was obtained, and this material was washed with CH_2Cl_2. Yield: 0.95 g (1.27 mmol, 34%), decomposition temperature ≈ 185°C. IR (Nujol mull) (cm^{-1}): 1626, 1617, 1569, 1418, 1366, 1318, 1221, 854, 835, 802, 774, 490, 460. ^1H NMR (CD_2Cl_2) δ (ppm): 1.14 (d, J_{HH} = 6Hz, 12H), 1.30 (d, J_{HH} = 6 Hz, 12H), 3.0 (m, 4H), 7.2 (d, J_{HH} = 7 Hz, 4H), 7.3–7.8 (6 H aryl), 7.70 (m, 2H), 8.50 (d, J_{HH} = 8 Hz, 2H). Anal. calcd. for $C_{36}H_{40}Al_2Cl_6N_2$: C 56.34, H 5.25, N 3.65; found: C 56.20, H 5.11, N 3.59.

Synthesis of [(Ar-BIAN)($GaCl_2$)][$GaCl_4$]

Gallium trichloride (1.00 g, 5.68 mmol) in 15 mL of CH_2Cl_2 was added to an oven-dried Schlenk flask. Ar-BIAN (1.37 g, 2.84 mmol in 5 mL of CH_2Cl_2) was added to this colourless solution, which turned dark red. Another 5 mL of CH_2Cl_2 was added, and this solution was then cooled to –30°C. Flat red crystals were obtained and isolated after removal of the supernatant, via cannula, under an atmosphere of argon. Yield: 1.75 g (2.10 mmol, 74%), decomposition temperature ≈ 140°C. IR (Nujol mull) (cm^{-1}): 1621, 1596, 1572, 1488, 1420, 1366, 1300, 1270, 1055, 803, 777, 734, 584, 545. ^1H NMR (CD_2Cl_2) δ (ppm): 1.02 (broad, s, 12H), 1.45 (d, J_{HH} = 6 Hz, 12H), 3.1 (m, 4H), 6.90 (d, J_{HH} = 7 Hz, 2H), 7.3–7.8 (6 H aryl), 7.64 (m, 2H) 8.42 (d, J_{HH} = 8 Hz, 2H). Anal. calcd. for $C_{36}H_{40}Ga_2Cl_6N_2$: C 50.70, H 4.73, N 3.28; found C 50.54, H 4.63, N 3.15.

Attempts to reduce the compounds above in THF (1 to 2 mmol scale) with sodium or potassium were made, but unfortunately in our hands no pure compounds could be isolated from the reaction mixtures. The only compound identified (by NMR and melting point) was Ar-BIAN. Likewise, attempts were made to exchange the $[EX_4]$ anions with the weakly coordinating anion $[B(C_6F_5)_4]$ by treating **3** with $Li[B(C_6F_5)_4]$ in CH_2Cl_2 solution. In general, these attempts were unsuccessful, resulting in the formation of dark coloured solutions, from which the only pure compound isolated was Ar-BIAN.

Crystallographic studies

A single crystal of either [(Ar-BIAN)BCl_2][BCl_4]·1.25[CH_2Cl_2] or [(Ar-BIAN)$GaCl_2$][$GaCl_4$] was mounted on a glass fibre and centred on a Seimens 1K SMART/CCD diffractometer. Data were collected at –50°C using Mo (Kα) radiation. Lorentz and polarization corrections were applied, and data were also corrected for absorption using redundant data and the SADABS program. Direct methods and Fourier techniques were used to solve the crystal structures. Refinement was conducted using full-matrix least-squares calculations and SHELX-TL PC V 5.03. All non-hydrogen atoms were refined with anisotropic displacement parameters. The hydrogen atoms were included in calculated positions and were refined using a riding model. In the final stages of the refinement of [(Ar-BIAN)BCl_2][BCl_4]·1.25[CH_2Cl_2], R_1 = 0.1152, wR_2 = 0.2798, and the largest peak was 0.745 e $Å^{-3}$ and was associated with one of the methylene chloride solvent molecules. In the final stages of refinement of [(Ar-BIAN)$GaCl_2$][$GaCl_4$]· [CH_2Cl_2], R_1 = 0.0534, wR_2 = 0.1094, and the largest residual peak was 0.447 e $Å^{-3}$ and was associated with the residual methylene chloride solvent. Full crystallographic details can be found in Table 1.

Results and discussion

The Ar-BIAN ligand **1** was treated with a variety of group 13 compounds to prepare Lewis base coordination complexes. Lewis acids studied included BCl_3, BBr_3, $AlCl_3$, and $GaCl_3$. Of these reactions, solid materials were successfully isolated from BCl_3, BBr_3, $AlCl_3$, and $GaCl_3$. In general, treatment of **1** with 2 equiv of EX_3 in CH_2Cl_2 solution, followed by reduction of the solvent volume, resulted in the formation of a solid, bright red material. These compounds were characterized by ^1H NMR and IR spectroscopy. Poor solubility of these ionic compounds made NMR studies difficult, and it was discovered that the compounds decompose in CD_2Cl_2 solution (12). Fortunately, X-ray-quality crystals were obtained from the mother liquors of [(Ar-BIAN)BCl_2][BCl_4] and [(Ar-BIAN)$GaCl_2$][$GaCl_4$].

IR spectroscopic studies were performed on the [(Ar-BIAN)(EX_2)][EX_4] series of compounds. The stretching frequencies observed between 1660 and 1610 cm^{-1} have been tentatively assigned to the ν(C=N) stretches. The assignments for the [(Ar-BIAN)(EX_2)][EX_4] complexes are as follows (cm^{-1}): free ligand (1660 or 1640); E = B, X = Cl (1646); E = B, X = Br (1636); E = Al, X = Cl (1627);

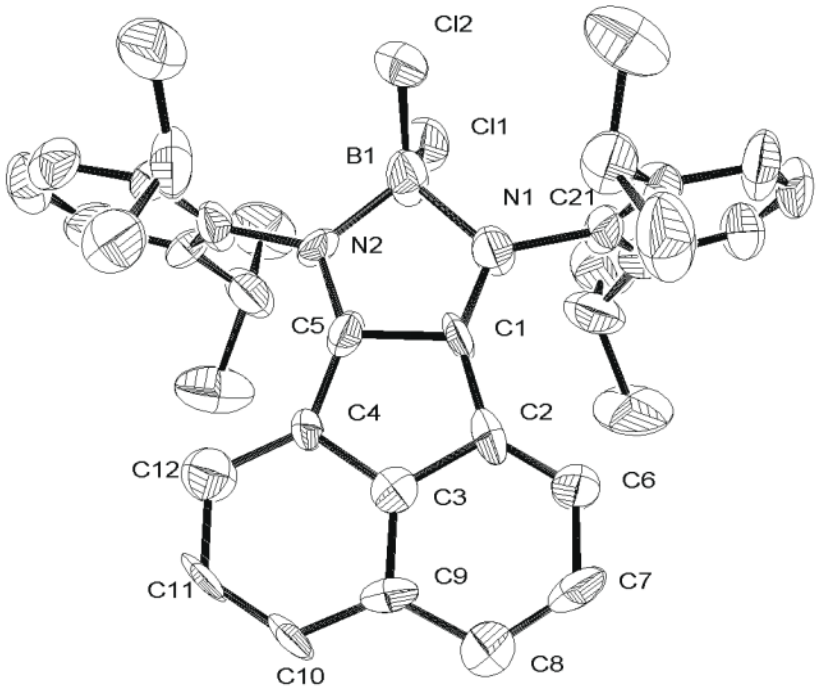
Fig. 1. ORTEP view of cation $[(Ar\text{-}BIAN)BCl_2]^+$ showing the labelling scheme. Thermal ellipsoids are shown at 50% probability level; hydrogen atoms have been removed for clarity.



E = Ga, X = Cl (1621). The C=N stretching frequency in the free ligand cannot be assigned unambiguously because of the presence of C—C stretching frequencies from the naphthalene backbone in this region (9). The absorptions for the C=N stretches in the complexes have been assigned because of the fact that these peaks were discernible as being quite strong and broad, consistent with a C=N stretch. More importantly, the position of this absorption shifts upon complex formation, and is dependent on the Lewis acid used in the complexation reaction.

The absorptions for the E—X bonds are also informative. The IR spectrum for $[(Ar\text{-}BIAN)EX_2][EX_4]$ reveals two different E—X stretches from the two types of E—X bonds present (i.e., one from the cation and one from the anion). These two stretching bands are present at 691(s-br) and 658(s-br) cm^{-1} (E = B, X = Cl), 588(s) and 541(s) cm^{-1} (E = B, X = Br), and 490(s) and 460(m) cm^{-1} (E = Al, X = Cl). The stretching bands have been assigned based on known E—X stretching regions and intensities (13). The stretches for Ga—Cl bonds were not observed in the IR spectrum of the $[(Ar\text{-}BIAN)GaCl_2][GaCl_4]$ complex, as Ga—Cl bonds absorb below 450 cm^{-1}.

Crystallographic studies on $[(Ar\text{-}BAIN)BCl_2][BCl_4]$ and $[(Ar\text{-}BAIN)GaCl_2][GaCl_4]$

$[(Ar\text{-}BIAN)BCl_2][BCl_4]\cdot 1.25[CH_2Cl_2]$ crystallizes in the uniquely determined orthorhombic space group $P2_12_12_1$, with four molecules in the unit cell. Crystals of this compound were not well-formed, and resulted in overall *R* values that are somewhat high. The X-ray analysis does show that $[(Ar\text{-}BIAN)BCl_2][BCl_4]$ exists in the solid state as discrete anions and cations, with no unusual interactions between the ions or the solvent.

The anion ($[BCl_4]^-$) is a distorted tetrahedron, with bond angles between 100(1)° and 118(1)°, and B—Cl bond lengths ranging from 1.74(3) to 1.95(3) Å. There are no unusual structural features associated with this anion. The closest interactions between ions are between Cl4 and C21 (3.77 Å), and B2 and the centre of the ring formed by C2–C9 (4.25 Å). The primary coordination sphere of the boron centre in the $[(Ar\text{-}BIAN)BCl_2]^+$ cation features two N→B dative bonds from the Ar-BIAN ligand (1.57(2) and 1.54(2) Å). Two B—Cl bonds complete the $[(Ar\text{-}BIAN)BCl_2]^+$ coordination sphere. The B—Cl bond lengths in the cationic fragment, 1.78(2) and 1.89(1) Å, are about the same as those of the anionic fragment. For comparison, the B—Cl bond length in BCl_3 is 1.74 Å.[3] An ORTEP view of the cation $[(Ar\text{-}BIAN)BCl_2]^+$ is shown in Fig. 1, and important bond lengths and angles are presented in Table 2.

$[(Ar\text{-}BIAN)GaCl_2][GaCl_4]$ crystallizes in the monoclinic space group $P2_1/m$, with two molecules in the unit cell. The X-ray analysis of this complex also revealed that it exists in the solid state as discrete anions and cations. The $[GaCl_4]^-$ anion is tetrahedral, with Ga—Cl bond angles between 106.54(9)° and 111.26(6)°, and bond lengths between 2.159(2) and 2.175(1) Å. There are no unusual structural features associated with this anion.

The primary coordination sphere of the cationic $[(Ar\text{-}BIAN)GaCl_2]^+$ fragment features two N→Ga dative bonds from the Ar-BIAN ligand (1.985(3) Å). This Ga—N bond

[3] Recently the reaction of a bulky 1,4-diazabutadiene with BCl_3 was reported, and the isolated compound was characterised as a 2,4,5-trichloro-1,3,2-diazaborolidine, which is a covalent alternative to the ionic diazaborolium salt. See reference 12. It is possible that a similar rearrangement occurs in the $[(Ar\text{-}BIAN)(EX_2)][EX_4]$ compounds reported here.

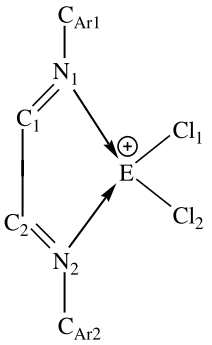
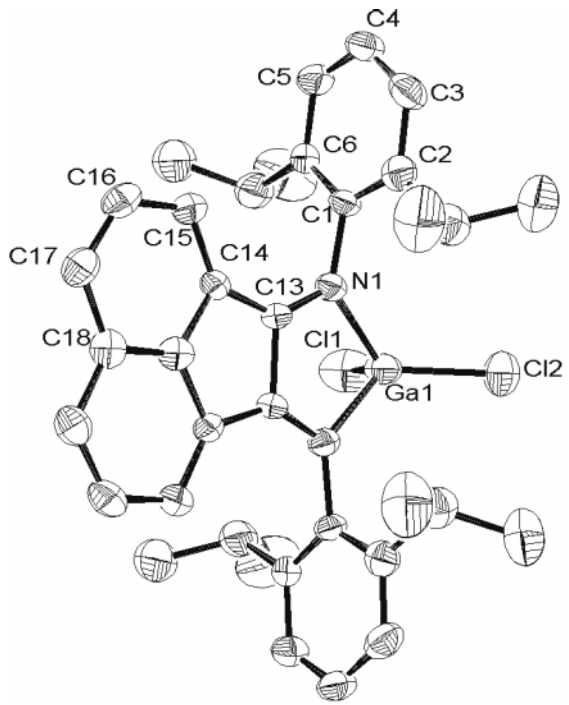
Table 2. Comparison of $[(Ar\text{-}BIAN)GaCl_2][GaCl_4]$, $[(Ar\text{-}BIAN)BCl_2][BCl_4]$, and $[(DAB)GaCl_2][GaCl_4]$.



General structure for comparison of bond lengths and angles in Ar-BIAN and DAB complexes

Parameter	$[(Ar\text{-}BIAN)BCl_2]^+$	$[(Ar\text{-}BIAN)GaCl_2]^+$	$[(DAB)GaCl_2]^+$
N—E	1.57(2), 1.54(2)	1.985(3)	1.979(5), 1.982(6)
E—Cl	1.78(2), 1.89(1)	2.106(2), 2.124(3)	2.105(2), 2.104(2)
N-E-N	99.6(9)	85.1(2)	84.4(2)
N-E-Cl	115(1), 115(1), 108(1), 110.7(9)	114.1(1), 111.9(1)	Not reported
Cl-E-Cl	108.5(7)	115.9(1)	118.2(1)

Fig. 2. ORTEP view of cation $[(Ar\text{-}BIAN)GaCl_2]^+$ showing the labelling scheme. Thermal ellipsoids are shown at 50% probability level; hydrogen atoms have been removed for clarity.



distance is somewhat unusual because in most acyclic trialkylamine adducts, the Ga—N bond distances are much longer, being somewhere between 2.1 and 2.2 Å (14). This is, however, not so surprising because N is sp^2 hybridized and therefore has a shorter covalent radius than an sp^3 hybridized nitrogen centre. The coordination sphere around the cationic gallium centre in $[(Ar\text{-}BIAN)GaCl_2]^+$ is completed by two Ga—Cl bonds of 2.106(2) and 2.124(3) Å. Important bond lengths and angles are reported in Table 2. An ORTEP view of $[(Ar\text{-}BIAN)GaCl_2]^+$ is presented in Fig. 2. As shown in Table 2, the metrical parameters observed for $[(Ar\text{-}BIAN)GaCl_2][GaCl_4]$ are similar to those reported for $[DABGaCl_2][GaCl_4]$ (DAB = *t*-BuN=C(H)-C(H) = N*t*Bu) (14).

There are no unusual long-range interactions between ions, and the closest interactions are the Cl5—C18 distance at 3.582 Å, and the Cl4 — centre of C13-C13A distance of 3.528 Å, and Ga2—C19 at 4.808 Å.

Attempts to prepare $[(Ar\text{-}BIAN)ECl_2][B(C_6F_6)_4]$ via ion-exchange reactions were unsuccessful. It was hoped that the strong electron donating ability of **1** would facilitate formation of $[(Ar\text{-}BIAN)ECl]^{++}$, via ion-exchange and halide abstraction from $[(Ar\text{-}BIAN)ECl_2]^+$, but this was not realised. We are currently working on the preparation of amido-substituted derivatives to facilitate the formation of $[(Ar\text{-}BIAN)ENR_2]^{++}$, recognising the isoelectronic relationship with, for example, the carbocation $[CR_3]^+$. Finally, attempts to reduce $[(Ar\text{-}BIAN)(EX_2)][EX_4]$ using Na or K to generate compounds such as **3** have thus far been unsuccessful.

Conclusions

Several new main group complexes were prepared based upon the *o*,*o*′-*i*-$Pr_2C_6H_3$-bis(imino)acenaphthene ligand. The Ar-BIAN ligand is easily prepared and is a robust ligand for supporting highly Lewis acidic main group element sites. Unfortunately, attempted reduction of $[(Ar\text{-}BIAN)(EX_2)][EX_4]$ to produce heterocycles such as **3** were unsuccessful.

Sequential dehydrochloride coupling of trichlorophosphine with 2,6-di-isopropylaniline: aminophosphine precursors to phosphetidines

Neil Burford, T. Stanley Cameron, Korey D. Conroy, Bobby Ellis, Charles L.B. Macdonald, Robyn Ovans, Andrew D. Phillips, Paul J. Ragogna, and Denise Walsh

Abstract: Various stoichiometric combinations of PCl_3 with $DippNH_2$ (Dipp = 2,6-di-isopropylphenyl) have been examined using ^{31}P NMR spectroscopy. The dehydrochloride coupling reaction is mediated by the moderate steric bulk of the Dipp substituent. Isolation procedures and characterization data are reported for the aminodichlorophosphine (**1**), the aminotetrachlorodiphosphine (**4**), and the dichlorophosphetidine (**7**). The observations offer new appreciation of dehydrochloride coupling products of halophosphines with primary amines.

Key words: phosphorus, nitrogen, phosphazanes, phosphetidines, iminophosphine.

Résumé : Faisant appel à la spectroscopie RMN du ^{31}P, on a étudié diverses combinaisons stoechiométriques de PCl_3 avec de la $DippNH_2$ ($DippNH_2$ = 2,6-di-isopropylphényle). La réaction de couplage avec déshydrochloruration est favorisée par l'empêchement stérique modéré du substituant Dipp. On rapporte les méthodes d'isolement et les données de caractérisation de l'aminodichlorophosphine (**1**), de l'aminotétrachlorodiphosphine (**4**), et de la dichlorophosphétidine (**7**). Les faits observés offrent une nouvelle appréciation sur la nature des produits de couplage avec déshydrochloruration d'halophosphines avec des amines primaires.

Mots clés : phosphore, azote, phosphazanes, phosphétidines, iminophosphine.

[Traduit par la Rédaction]

Introduction

The established structural diversity of nitrogen-phosphorus compounds is a manifestation of the strong and versatile N—P bond. A variety of N—P coupling reactions have been employed, but elimination of hydrogen chloride is prototypical and is responsible for the formation of mono-, bis-, and tris-aminophosphines from appropriate stoichiometric combinations of PCl_3 and a secondary amine (1). In comparison, reactions of PCl_3 with primary amines offer a more diverse array of structural options because of the possibility of P-N-P linkages, as illustrated in Fig. 1. In spite of ring strain, the four-membered, dimeric phosphetidine (phosphazane) frameworks **7** and **9** (2–7) are routinely isolated for conventional derivatives (R = Me, Et, Ph) (8). Less common are reports of the sequential (intermediate) metathesis products **1** (8), **2** (8), **3** (5), **4** (5), and **5** (9), and examples of the higher order chain **6** have not been reported (10–14).

Primary amines bearing 'bulky' substituents are predictably restricted from multi-dehydrochloride coupling reactions. In the case of R = 2,4,6-tri-tert-butylphenyl (Mes*), intramolecular hydrogen chloride elimination occurs to produce the iminophosphine Mes*N=PCl (15). We now show how both phosphetidine formation and intramolecular elimination are impeded by the presence of the 2,6-di-isopropylphenyl (Dipp) substituent, which provides intermediate steric influence on the thermodynamic and kinetic factors governing the coupling reaction. ^{31}P NMR spectroscopic studies of a series of stoichiometric combinations of PCl_3 and $DippNH_2$ reveal many of the sequential dehydrochloride coupling products, and assignments of ^{31}P chemical shifts have been confirmed for isolated samples of **1**, **4**, **7**, and **9** (3).

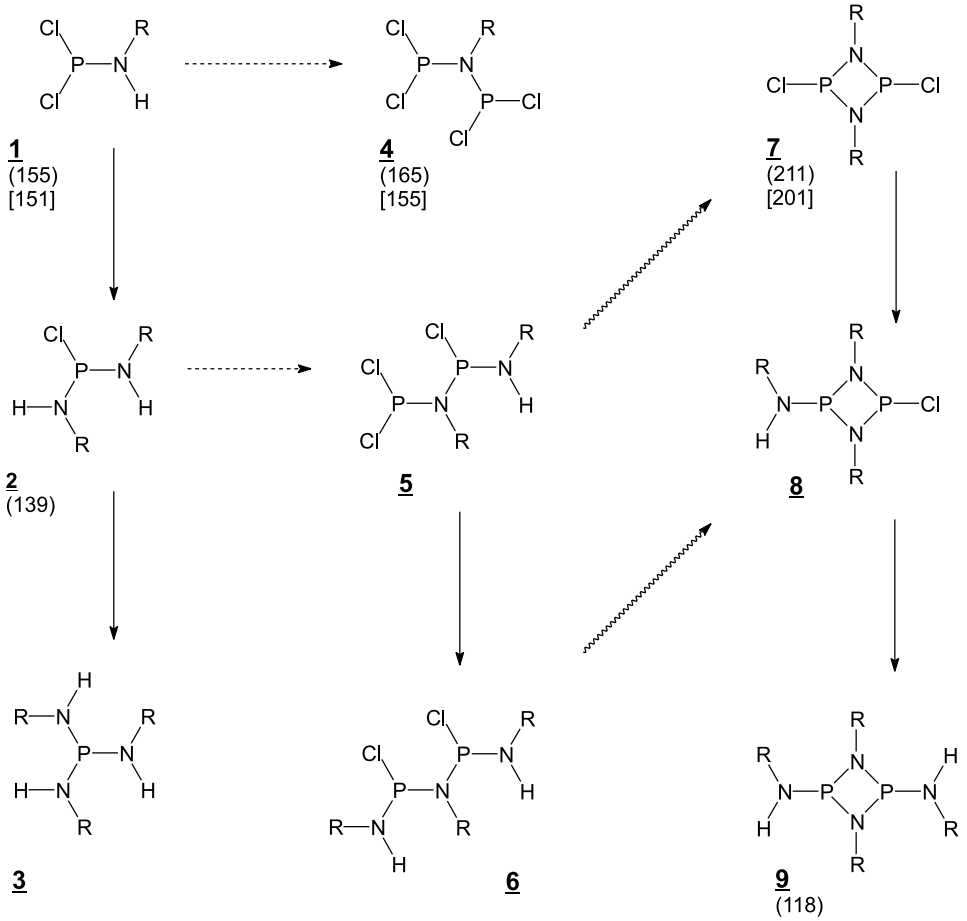
Experimental procedures (16)

General

Diethylether was obtained from ACP Chemicals Inc. and hexane from Anachemia. All other chemicals and reagents were obtained from Aldrich Chemical Company. All solvents were degassed and stored in evacuated bulbs. Solids were handled in a nitrogen-filled glove-box. Sample

 DOI: 10.1139/V02-161 © 2002 NRC Canada

Fig. 1 Potential products of sequential dehydrochloride metathesis from PCl_3 and RNH_2. Solid arrows represent addition of amine with loss of HCl, dashed arrows represent addition of phosphine with loss of HCl, and wavy arrows represent cyclisation with HCl elimination. ^{31}P NMR chemical shift assignments (ppm) are given in parentheses for *R* = Dipp, and in square brackets for *R* = Ph.



handling and reactions were performed under oxygen and moisture-free conditions. 2,6-Di-isopropylaniline ($DippNH_2$) was used as received. Dichloromethane was dried at reflux over CaH_2, P_4O_{10}, and CaH_2; hexane, toluene, and benzene were dried over potassium; and diethylether was dried over sodium/benzophenone. Deuterated solvents were dried over CaH_2. PCl_3 was distilled under vacuum.

IR spectra were recorded as Nujol mulls on CsI plates using a Nicolet 510 FT-IR spectrometer, and are presented as wavenumber (cm^{-1}) maxima, with ranked intensities for each absorption given in parentheses. The most intense peak is given a ranking of 1. Melting point samples were placed in 1.0 mm (O.D.) Pyrex capillaries, sealed under nitrogen, and measured using an Electrothermal® melting point apparatus. Solution and variable-temperature (VT) NMR spectra were recorded on a Bruker AC-250 NMR spectrometer. Solution NMR samples were flame-sealed in 5 mm Pyrex tubes. NMR spectra were referenced to the solvent and chemical shifts are reported in ppm relative to an external standard (TMS for ^1H and ^{13}C, 85% H_3PO_4 for ^{31}P).

^{31}P NMR spectra of reactions between PCl_3 and RNH_2 (*R* = Dipp or Ph)

Table 1 summarizes ^{31}P NMR spectra obtained for reaction mixtures, prepared at 0°C by the addition of $DippNH_2$ in toluene to PCl_3 in toluene at approximately 1 M concentration. The mixtures were stirred overnight with warming to room temperature and were filtered. Spectra of similar reaction mixtures involving $PhNH_2$ revealed many products. At equimolar stoichiometry, the prominent peaks were assigned to **1** (*R* = Ph, 151 ppm) and **7** (*R* = Ph, 201 ppm), with substantial unreacted PCl_3 (220 ppm). The aminodiphosphine **4** (*R* = Ph, 155 ppm) (12) was observed as a minor component. It was not possible to make other unequivocal assignments for reaction mixtures containing excess $PhNH_2$.

Isolation procedures and characterization data

DippN(H)PCl$_2$ (1)

$DippNH_2$ (4.0 mL, 21 mmol) in benzene (15 mL) was added via cannula to a stirred solution of PCl_3 (1.9 mL, 21 mmol) in benzene (15 mL) at 0°C. The resultant slurry was stirred overnight and the white precipitate was filtered through a fine glass filter. Benzene was slowly removed from the pale yellow solution to give colourless rod-shaped crystals. Yield 2.23 g (43%); mp 58–61°C. IR (Nujol mull) (cm^{-1}): 3314 (17), 2959 (2), 2923 (1), 2852 (3), 1583 (19), 1519 (13), 1462 (4), 1383 (11), 1364 (12), 1329 (14), 1252 (8), 1182 (6), 1100 (7), 1043 (9), 931 (10), 885 (15), 797 (5), 749 (18), 512 (16). ^1H NMR: 1.08 (d, $^3J_{HH}$ = 12 Hz),

	1:6			100	30	90	70	10	10	10	10		1	5	

Note: Chemical shifts are listed in order of peak intensity. Approximate peak intensities in each spectrum are given relative to the most intense peak (100%). Assignments are confirmed for **1**, **4**, **7**, and **9** (3) by characterization of isolated samples. Parentheses indicating assignments for **2**, **3**, **5**, **6**, and **8** are tentative and other minor signals are not assigned.

3.25 (sept, $^3J_{HH}$ = 12 Hz), 4.53 (s), 6.93–6.96 (m). ^{31}P NMR: 155. Anal. calcd. for $DippN(H)PCl_2$: C 51.81, H 6.52, N 5.03; found: C 51.36, H 6.79, N 5.08.

DippN(PCl$_2$)$_2$ (4)

PCl_3 (20 mL) and NEt_3 (40 mL) were distilled onto a frozen solution of $DippNH_2$ (5.0 g, 28 mmol) in hexane (30 mL). A yellow solution and a white precipitate formed on warming to room temperature. After stirring for 7 days, the solution was filtered and the solvent removed in vacuo. The resulting solid was sublimed onto a water cooled finger, under static vacuum with warming to 80°C, to give tan crystals of **4**. Yield 5.3 g (14 mmol, 50%); mp 69–71°C. IR (Nujol mull) (cm^{-1}): 1584 (20), 1433 (9), 1362 (8), 1322 (15), 1309 (18), 1158 (7), 1104 (12), 1095 (13), 1050 (17), 1040 (19), 903 (6), 883 (1), 799 (6), 718 (16), 515 (4), 490 (3), 481 (2), 451 (10), 437 (11), 417 (14). ^1H NMR: 1.19 (d, $^3J_{HH}$ = 7 Hz), 3.12 (sept, $^3J_{HH}$ = 7 Hz), 7.26 (m). ^{31}P NMR: 165 (reaction mixture), 165 and 211 (assigned to **7**). Anal. calcd.: C 38.03, H 4.52, N 3.70; found: C 38.08, H 4.52, N 3.75.

[DippNPCl]$_2$ (7)

$DippNH_2$ (10 mL, 53 mmol) in toluene (20 mL) was added via cannula to a three-chamber reaction vessel containing a stirring solution of PCl_3 (2.3 mL, 26 mmol) in toluene (15 mL) at 0°C. The solution was warmed to room temperature and a white precipitate formed. After stirring overnight, the mixture was degassed and filtered through a fine glass frit. Toluene was removed under vacuum and the resulting oil was dissolved in hexane (20 mL) to promote precipitation. The mixture was filtered and NEt_3 (3.7 mL, 26 mmol) was added, with the immediate production of a yellow solution and white precipitate. The mixture was filtered again and the solvent was slowly removed to give large white crystals, which were washed with fresh hexane. Yield 1.4 g (3.0 mmol, 23%); mp 208–215°C. IR (Nujol mull) (cm^{-1}): 1444 (4), 1363 (8), 1320 (11), 1276 (15), 1260 (14), 1249 (10), 1198 (5), 1180 (16), 1104 (9), 1056 (19), 1039 (17), 935 (13), 923 (7), 907 (2), 801 (1), 537 (12), 529 (18), 496 (5), 421 (3), 379 (20). ^1H NMR: 1.31 (d, $^3J_{HH}$ = 10 Hz), 3.04 (sept, $^3J_{HH}$ = 8 Hz), 7.2–7.4 (m). ^{31}P NMR: 211. Anal. calcd.: C 59.63, H 7.09, N 5.80; found: C 59.54, H 7.20, N 5.76.

X-ray crystallography

Crystals of **1**, **4**, and **7** were selected and mounted in Pyrex capillaries in the dry box. Data were corrected for Lorentz and polarization effects, and absorption. Structures were solved by direct methods and expanded using Fourier techniques. For compound **4**, only the chlorine atoms, the phosphorus atoms, and C(11) and C(12) were refined anisotropically. The standard reflections decreased by 25% during data collection, and a linear correction factor was applied. For compound **7**, only the chlorine atoms, phosphorus atoms, and C(9)-C(12) and C(19)-C(24) were refined anisotropically. Extinction corrections were not applied for compounds **4** and **7**. Hydrogen atoms were allowed to ride on the heavy atoms to which they are bonded, with C-H distances of 0.95 Å and fixed isotropic temperature factors. Calculations were performed using the teXsan crystallographic package (17). A summary of the crystallographic data is given in Table 2.[3]

Results and discussion

Reaction mixtures of PCl_3 and $DippNH_2$ with different stoichiometric combinations have been examined using ^{31}P NMR spectroscopy. Contrary to the reports describing isolation of phosphetidine (**7**) for many RNH_2 derivatives (R = alkyl and aryl) (4, 18), a number of products were observed for $DippNH_2$, with **7** as a minor component even at high excess of amine. Table 1 lists the ^{31}P chemical shifts observed for each stoichiometric combination, according to the relative peak intensity with respect to the most intense peak (100%). Chemical shift assignments for compounds **1**, **7**, and **9** (3) have been confirmed by characterization of isolated materials. In contrast to reactions involving amines

with small substituents (R = Me, Et, Bu) (18), the aminodiphosphine **4** (R = Dipp, 165 ppm) was not observed, even at a two-fold excess of PCl_3. Instead, compound **4** has been isolated from reactions in the presence of NEt_3 (see below).

Referring to Table 1, PCl_3 is observed as an excess component in the equimolar reaction with $DippNH_2$, and the prominent peak (155 ppm) is assigned to monoaminophosphine (**1**). The prominent peak (139 ppm) at a three-fold excess of $DippNH_2$ is assigned to the diaminophosphine (**2**), and is the prominent component at all reactions involving higher excesses of $DippNH_2$. Evidence for P-N-P linkages is only observed above a two-fold excess of $DippNH_2$, with two sets of doublets (148, 182 ppm; 161, 195 ppm; $^2J_{PP}$ = 45 Hz) exhibiting typical two-bond coupling constants. Although high-order tetraphosphorus assemblies are possible, these doublets are speculatively assigned to the nonsymmetric systems **5** and **8**, which are the likely precursors to **9** (3). Previous reports confirm that derivatives of **5** can been isolated (9). They are, however, prone to rapid cyclisation to give the phosphetidine framework (13), and on this basis the more prominent doublet signals are assigned to **8**.

^{31}P NMR spectra of reaction mixtures containing equimolar amounts of PCl_3 and $PhNH_2$ show **1** and **7** (R = Ph) as well as unreacted PCl_3, consistent with the established facile isolation of the phosphetidine **7** (8), but the spectra are more complicated in the presence of excess $PhNH_2$. In this context, the relative impedance of dehydrochloride PCl_3–$DippNH_2$ coupling is interpreted in terms of the steric imposition of the Dipp substituent restricting intermolecular interactions and influencing the nucleophilicity of the amine.

The absence of aminodiphosphine (**4**) in all reaction mixtures of PCl_3 with $DippNH_2$, and the prominence of the mono- (**1**) and diaminophosphine (**2**) (R = Dipp), indicates that the nucleophilicity of the nitrogen centre in **1** is insufficient to interact with a second PCl_3, so that attack at the phosphorus centre in **1** by $DippNH_2$ is relatively favoured. In this context, it is reasonable to assign the peak at 140 ppm to the trisaminophosphine (**3**) (R = Dipp), and to conclude that the formation of **5** is preferred over **4**, which facilitates the formation of **7** and renders **4** redundant in the reaction pathway.

High yield formation of compound **4** from PCl_3 and $DippNH_2$ in the presence of NEt_3 indicates that the nucleophilicity of the nitrogen center in **1** is enhanced by the presence of triethylamine, presumably due to partial or full deprotonation. ^{31}P NMR spectra of reaction mixtures containing NEt_3 show **4** and **7** as the only products, emphasizing the special stability of the phosphetidine (**7**).

Assignments of peaks in the ^{31}P NMR spectra to compounds **1**, **4**, **7**, and **9** (3) (R = Dipp) have been confirmed by isolation and structural characterization, as illustrated in Fig. 2. Some of the structural features of these compounds

[a]Two molecules in the asymmetric unit.

(Table 3) are worthy of comment. The aminodiphosphine (**4**) (*R* = Dipp) adopts a C_s conformation (*endo*,*exo*), contrasting the C_{2v} conformation (*exo*,*exo*) reported for the phenyl derivative of **4** (*R* = Ph) (12) and pentaphenylaminodiphosphine (5). Nevertheless, the structural trends indicate that larger substituents, such as Dipp, impose the (*endo*,*exo*) conformation (12). The typical planar environment at nitrogen bound to phosphorus is observed for all Dipp-N-P compounds described in this report, as demonstrated by the sum (approximately 360°) of the bond angles at nitrogen. The resulting $P(N)_2P$ plane in the phosphetidine (**7**) clearly demonstrates a *cis* conformation for the chlorine substituents,

© 2002 NRC Canada

consistent with the phenyl derivative (7), and the aryl substituents are perpendicular to the NP_2 plane.

Conclusions

Reactions of $DippNH_2$ with PCl_3 have been comprehensively evaluated by ^{31}P NMR spectroscopy. The observations confirm the intermediacy of aminophosphines in phosphetidine formation and offer insight to the mechanisms of P-N-P linkage assembly.

Sulfimidation of thio-ether crown systems: the X-ray crystal structure of the $\{[9\text{-ane}]S_2S(NH_2)\}^+$, $\{[9\text{-ane}]SS(NH_2)S(NH_2)\}^{2+}$, and $\{[9\text{-ane}]S(NH_2)S_2(\mu\text{-}N)\}^{2+}$ cations

Mark R. J. Elsegood, Liam M. Gilby, Kathryn E. Holmes, and Paul F. Kelly

Abstract: Treatment of the thio-ether crown [9-ane]S_3 (**1**) with 1 equiv of *O*-mesitylsulfonylhydroxylamine (MSH) yields the water-soluble protonated sulfimide $\{[9\text{-ane}]S_2S(NH_2)\}^+$ (**2**). Two equiv of MSH leads to the formation of $\{[9\text{-ane}]SS(NH_2)S(NH_2)\}^{2+}$ (**3**), while excess MSH generates the $\{[9\text{-ane}]S(NH_2)S_2(\mu\text{-N})\}^{2+}$ cation (**4**) (**2**–**4** form as salts of the $[Me_3C_6H_2SO_3]^-$ anion); the X-ray crystal structure of **2** and **3** confirms that one and two of the ring sulfurs, respectively, have been converted to terminal protonated sulfimides, while that of **4** reveals the presence of both terminal and bridging nitrogens.

Key words: sulfur-nitrides, macrocycles, sulfimides, amination.

Résumé : Le traitement du thioéther couronne [9-ane]S_3 (**1**) avec un équivalent de *O*-mésitylsulfonylhydroxylamine (MSH) fournit le sulfimide protoné soluble dans l'eau $\{[9\text{-ane}]S_2S(NH_2)\}^+$ (**2**). Deux équivalents de MSH conduisent à la formation du $\{[9\text{-ane}]SS(NH_2)S(NH_2)\}^{2+}$ (**3**) alors qu'un excès de MSH génère le cation $\{[9\text{-ane}]S(NH_2)S_2(\mu\text{-N})\}^{2+}$ (**4**) (les cations **2**–**4** ont été isolés sous la forme de sels avec l'anion $[Me_3C_6H_2SO_3]^-$). Les structures des composés **2**, **3** et **4** ont été déterminées par diffraction des rayons X; les deux premières confirment que respectivement un et deux des cycles contenant du soufre ont été transformés en sulfimides terminales protonées alors que la structure de la dernière révèle la présence d'atomes d'azote agissant comme ponts alors que d'autres sont en positions terminales.

Mots clés : soufre-nitrures, macrocycles, sulfimides, amination.

Introduction and discussion

We have recently reported on the reactivity of *S*,*S*′-diphenylsulfimide, (Ph_2SNH) towards a number of metal centres (1) and have subsequently extended such reactions to novel sulfimides prepared from disulfide starting materials (2). Although the reagent used to effect such reactions, *O*-mesitylsulfonylhydroxylamine (MSH), has long been known to react in this way with monosulfides (3), the concept of reacting with systems bearing two sulfide units does not appear to have been investigated before. This technique has the advantage of generating products with great potential to act as multidentate ligands, either because of the presence of a combination of N-donating sulfimide and S-donating sulfide units, or two sulfimides. Thus we have prepared 1,2-(PhS{NH})(PhS)C_6H_4 and 1,4-(PhS{NH})$_2C_6H_4$, which have the potential to act as a bidentate S,N donor, and as a bridging ligand, respectively.

In this study we have extended such reactions to a different class of starting material – the cyclic crown system [9-ane]S_3 (**1**). The latter is a classic example of a cyclic thioether, much studied for their ability to coordinate to metal centres through a number of the sulfur atoms (4). Many variations upon such systems have been prepared, in which the nature of the carbon backbone has been changed, or in which the sulfur(s) have been oxidized to SO units (5). The latter are isoelectronic with sulfimides (SNH (or SNR)), but do not share the potential versatility of the latter. Not only is the sulfimide nitrogen a very effective donor to metal centres, but it may also be derivatized by introduction of pertinent R groups, which could allow significant modification of the coordination properties. On the latter front we have already shown that effective coordination of sulfimide units is not simply limited to the "free" sulfimides by isolating complexes of $Ph_2SNCH_2CH_2CN$ (6).

Reaction of MSH with **1** in an equimolar ratio results in the formation of a salt of the protonated sulfimide (**2**) (Scheme 1). This precipitates from dichloromethane solutions as a white solid and may be recrystallized by diffusion of ether vapour into a methanolic solution. Compound **2** may be characterized by spectroscopy and X-ray crystallography. The diffraction study confirms the presence of the

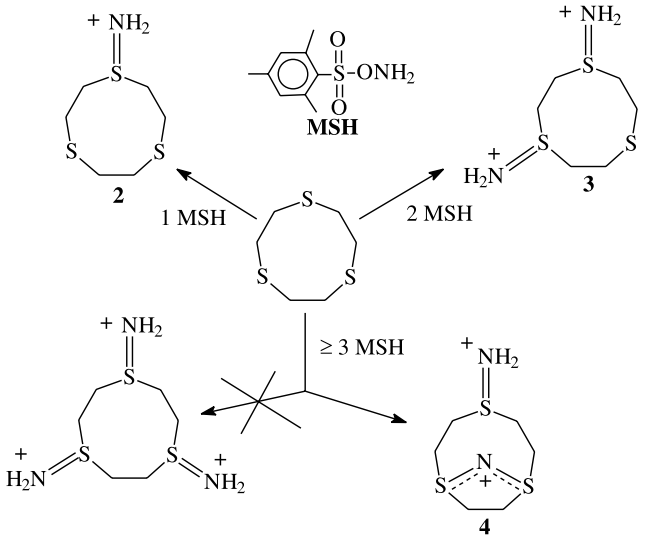
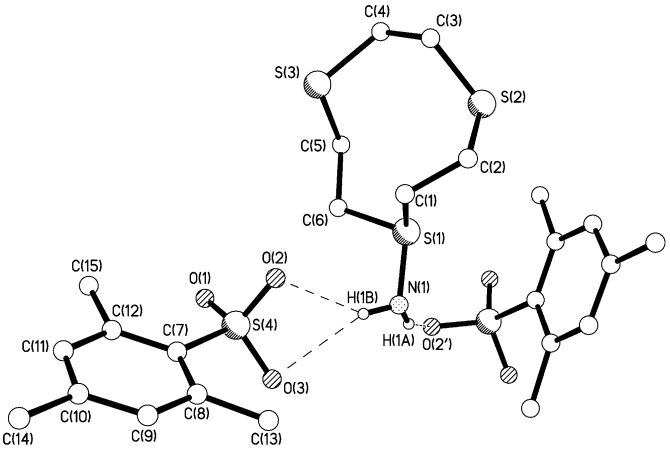
Scheme 1. The products of the reaction of **1** with varying equivalents of MSH.



$\{[9ane]S_2S(NH_2)\}^+$ cation in the salt $\{[9ane]S_2S(NH_2)\}[Me_3C_6H_2SO_3]$ (Fig. 1). As Fig. 1 shows, the cation **2** retains a cyclic structure, within which one of the sulfur atoms has the $[NH_2]^+$ group of the sulfimide unit attached (S—N bond distance = 1.6417(14) Å). The non-sulfimide sulfur atoms arrange themselves in an "up, down" manner relative to the sulfur atom that has reacted. The anion exhibits the expected structure, with significant H-bonding interactions between the N—H bonds of the cation and two of the oxygen atoms of the anion. Thus O(2) and O(3) have close, but asymmetric, contacts to H(1B) (2.25(2) Å to O(2) and 2.42(2) Å to O(3)), while O(2) from an adjacent anion interacts with the other N—H bond (H(1A)···O(2′) = 2.01(2) Å). Of the three oxygen atoms bound to the sulfur of the anion, therefore, O(1) has no close interactions, O(3) has one, and O(2), two. The net effect of this is to produce an overall array structure as shown. Only three lines are seen in the ^{13}C spectrum of the cation; this indicates that the solid state structure is not retained in solution (had it been, then all six carbons would appear unique). The ^1H spectrum, however, consists of six 8-line multiplets, indicating that while S(2) and S(3) may be undergoing fast inversion, the sulfimide sulfur is not (previous work has shown that optically active sulfimides racemize at around 80°C, for example) (7). Significantly, **[2]**$[Me_3C_6H_2SO_3]$ readily dissolves in water; if, after one hour, the water is removed in vacuo and the residue crystallized, IR spectroscopy and microanalysis suggest that there is no decomposition in aqueous solution, at least on a short timescale.

Spectroscopy and X-ray crystallography have shown that 2 equiv of MSH react with **1** to give $\{[9\text{-ane}]SS(NH_2)S(NH_2)\}^{2+}$ (**3**), in which two of the sulfur atoms of the crown have reacted to give terminal sulfimides (Scheme 1). The S—N distances of 1.6457(17) and 1.6450(15) Å are comparable with those in **2**. Again, the cyclic structure of the macrocycle is retained, yet the conformation of the ring is somewhat different, being less "twisted" than in **2**, and forming a "boat"-type structure (Fig. 2). ^1H NMR spectroscopy suggests that the solid-state

Fig. 1. The X-ray crystal structure of the cation in **[2]** $[Me_3C_6H_2SO_3]$ and its hydrogen bonding links to the oxygen atoms of adjacent anions (N.B. the overall stoichiometry has only one anion per cation). Selected bond distances (Å) and angles (°): N(1)—S(1) 1.6417(14), S(1)—C(1) 1.8090(14), C(1)—C(2) 1.5198(19), C(2)—S(2) 1.8114(15), S(2)—C(3) 1.8225(16), C(3)—C(4) 1.522(2), C(4)—S(3) 1.8157(16), S(3)—C(5) 1.8258(17), C(5)—C(6) 1.529(2), C(6)—S(1) 1.8120(16). N(1)-S(1)-C(1) 101.85(7), S(1)-C(1)-C(2) 108.58(10), C(1)-C(2)-S(2) 113.57(10), C(2)-S(2)-C(3) 103.09(7), S(2)-C(3)-C(4) 114.24(11), C(3)-C(4)-S(3) 116.43(11), C(4)-S(3)-C(5) 104.47(8), S(3)-C(5)-C(6) 114.72(11), C(5)-C(6)-S(1) 113.61(11), C(6)-S(1)-C(1) 104.61(7), C(6)-S(1)-N(1) 107.84(7).



structure is not retained in solution. The crystal structure determination reveals that the sulfimide nitrogen atoms are orientated such as to be divergent from the ring, with an angle of approximately 55° between them. The NH_2 units are involved in extensive H-bonding between the two $[Me_3C_6H_2SO_3]^-$ anions and two molecules of MeOH in the structure.

The analogous triply substituted species, however, is not isolated when 3 equiv (or an excess) of MSH are used. In this case **4** forms (Fig. 3), in which one terminal sulfimide and one nitrogen-bridging sulfimide unit are found. The latter N-sulfoniosulfimidium unit is well known but has always been reported in reactions between discrete units (such as the reaction of Ph_2SNBr with organo-sulfides) rather than the intramolecular rearrangement that presumably generates **4** (7). The mechanism for its formation is unclear, but the fact that the aforementioned *bis*-sulfimide forms from the reaction of 2 equiv of MSH indicates that there is no inherent instability for two adjacent sulfimide units. If we assume that $\{[9\text{-ane}]S(NH_2)S(NH_2)S(NH_2)\}^{3+}$ does initially form, it may simply be that the high charge–small size combination makes this unstable with respect to conversion to **4**, possibly by loss of $[NH_4]^+$. Indeed, prior to crystallization, crude **4** shows an IR stretch at 3182 cm^{-1}, which is indicative of the ammonium cation (we have noted the same band in $[NH_4][Me_3C_6H_2SO_3]$). Within the structure of **4**, the nitrogen bridge results in the formation of an NSCCS heterocycle, within which the atoms are effectively planar (max deviation from mean plane: ca 0.2 Å at the nitrogen). Although this motif is not uncommon, a search of the Cambridge Structural

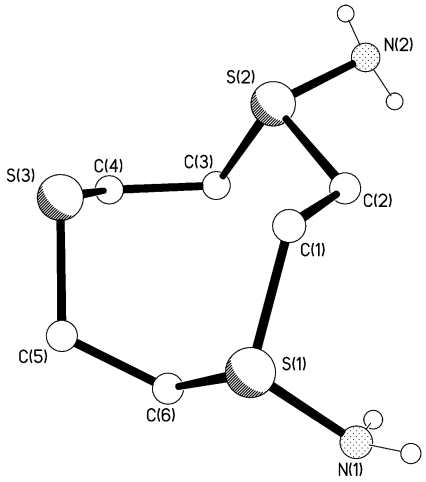
Fig. 2. The X-ray crystal structure of the cation in [**3**][$Me_3C_6H_2SO_3]_2$. Selected bond distances (Å) and angles (°): S(1)—N(1) 1.6357(17), S(2)—N(2) 1.6450(15), S(1)—C(1) 1.8166(17), C(1)—C(2) 1.526(2), S(2)—C(2) 1.8202(17), S(2)—C(3) 1.8283(17), C(3)—C(4) 1.525(2), S(3)—C(4) 1.8141(18), S(3)—C(5) 1.8089(18), C(5)—C(6) 1.520(2), S(1)—C(6) 1.8094(17). N(1)-S(1)-C(6) 98.24(9), N(1)-S(1)-C(1) 108.02(9), C(6)-S(1)-C(1) 106.79(8), N(2)-S(2)-C(2) 98.08(8), N(2)-S(2)-C(3) 106.79(8), C(2)-S(2)-C(3) 104.02(8), C(5)-S(3)-C(4)103.22(8), C(2)-C(1)-S(1) 118.21(12), C(6)-C(5)-S(3) 117.53(12), C(5)-C(6)-S(1) 114.25(12).



Database (8) revealed only one other example in which the ring is fused to another ring via S—C bonds (9). The latter species is a 1,4-dithia-7-azanorbornylium cation formed by the addition of the $[S_2N]^+$ cation to ethene. As a consequence of the formation of the NCSSC ring, the remainder of the atoms in the macrocycle are forced to adopt a "chair"-type conformation. The terminal sulfimide nitrogen atom is orientated perpendicular to the approximate "plane" made by the macrocycle.

The isolation of **2**, **3**, and **4** is significant for a number of reasons. In the case of **2** and **3** it represents an easy, one-pot, post-ring-closure derivatization of the crown that should allow further introduction of pertinent groups (including pendant arms potentially coordinating in their own right) via reaction at the nitrogen (7). This would, of course, greatly enhance the coordination chemistry of the crown systems, as would the fact that, unlike the parent crown, **2** is water soluble. Work to exploit both aspects of the chemistry of **2** is underway. In the case of **4**, the unique post-ring-closure formation of the transannular nitrogen bridge generates an unusual fused ring arrangement, and may well prove applicable to other systems. In this light, investigations into the reactivity of larger ring systems towards MSH are underway.

Experimental

MSH was prepared by the literature method (10) and [9-ane]S_3 was used as received from Aldrich. All reactions were performed under nitrogen using dichloromethane dried over calcium hydride and diethylether over sodium. Elemental analyses (PerkinElmer 2400 CHN Analyser) were performed by the Loughborough University service within the department of chemistry. NMR spectra were recorded in $CDCl_3$ on a Bruker AC250. IR spectra were recorded on a PerkinElmer PE2000 IR spectrometer as KBr discs (4000–400 cm^{-1}) and FAB-MS in 3-nitrobenzyl alcohol (positive-ion mode) on a JEOL JMS SX-102 mass spectrometer.

A solution of MSH (1.20 g, 5.6 mmol) in CH_2Cl_2 (10 ml) was added dropwise to a solution of [9-ane]S_3 (0.25 g, 1.4 mmol) in an equal volume of the same solvent. A precipitate appeared within a short time; after stirring overnight, the resulting precipitate was filtered, washed with CH_2Cl_2, and dried in vacuo yielding [**4**][$Me_3C_6H_2SO_3$]$_2$ as a white solid.

Slow diffusion of ether vapour into a methanol solution yielded crystals suitable for X-ray crystallography.

Yield 0.51g (60%); mp 132°C (dec). IR (cm^{-1}): 3442 (w), 3154 (m, br (ν N-H)), 2947 (s), 1604 (m), 1566 (m), 1444 (m), 1405 (m), 1226 (s), 1183 (s), 1161 (s), 1082 (s), 1011 (s), 892 (s), 851 (m (ν N-S)), 731 (m), 678 (s), 581 (s), 549 (m), 528 (m), 426 (m). ^{1}H NMR (CD_3OD) δ: 6.78 (4H, s, CH), 4.45 (2H, m, CH_2), 3.90–4.20 (10H, m, CH_2), 2.53 (12H, s, CH_3), 2.14 (6H, s, CH_3). ^{13}C NMR (CD_3OD) δ: 141.3, 140.8, 138.6, 132.2, 50.3, 44.0, 42.7, 23.7, 21.2. FAB-MS *m/e*: 210 ([M]$^+$). Anal. calc. for $C_{24}H_{36}N_2S_5O_6$ (%): C 47.4, H 5.9, N 4.6; found C 47.2, H 5.9, N 4.5.

X-ray crystallography for [2][$Me_3C_6H_2SO_3$], [3][$Me_3C_6H_2SO_3$]$_2$, and [4][$Me_3C_6H_2SO_3$]$_2$

Intensity data were collected using a Bruker AXS SMART 1000 CCD area detector diffractometer equipped with graphite monochromated Mo Kα radiation (λ = 0.71073) at 150 K. Narrow frames were collected (0.3° in ω) and an empirical absorption correction applied based on redundant and symmetry equivalent data. The structures were solved by direct methods and refined by full-matrix least squares on F^2. H atoms were refined with a riding model with H-atom U_{iso} values tied to those of the carrier atoms and set to 1.2 times U_{eq} (1.5 for methyl-H), except N*H*, where coordinates were freely refined. In compound [**3**][$Me_3C_6H_2SO_3$]$_2$, atoms S(1) and N(1) are disordered over 2 sets of positions, with occupancies of 94.0(2) and 6.0(2)%. This disorder was modelled with the aid of restraints on geometry and displacement parameters. Hydrogen atoms were not included on the minor disorder component. Compound

New hybrid inorganic-organic polymers containing cyclophosphazenes as pendant groups: Cyclophosphazene ligands containing hydrazone linkages and their conversion to polymers

Vadapalli Chandrasekhar, Venkatasubbaiah Krishnan, Arunachalampillai Athimoolam, and Gurusamy Thangavelu Senthil Andavan

Abstract: The reaction of the cyclotriphosphazene $N_3P_3Cl_5$[O-C_6H_4-*p*-C_6H_4-*p*-CH=CH_2] (**2**) with 10 equiv of *N*-methylhydrazine proceeds in a regio-specific manner to afford the multi-functional hydrazide N_3P_3[N(Me)NH_2]$_5$[O-C_6H_4-*p*-C_6H_4-*p*-CH=CH_2] (**3**). Condensation of **3** with *o*-hydroxy benzaldehyde or pyridine-2-carboxaldehyde affords the corresponding hydrazones N_3P_3[N(Me)N=CH-C_6H_4-*o*-OH]$_5$[O-C_6H_4-*p*-C_6H_4-*p*-CH=CH_2] (**4**) and N_3P_3[N(Me)N=CH-C_6H_4N]$_5$[O-C_6H_4-*p*-C_6H_4-*p*-CH=CH_2] (**5**), respectively. These hydrazones can be homopolymerized to afford polymers **6** and **7** containing multi-site coordinating cyclophosphazenes as pendant groups.

Key words: cyclophosphazene, hydrazone, pendant polymers, hybrid polymers, polymeric ligands.

Résumé : La réaction du cyclotriphosphazène $N_3P_3Cl_5$[O-C_6H_4-*p*-C_6H_4-*p*-CH=CH_2] (**2**) avec dix équivalents de *N*-méthylhydrazine se produit d'une façon régiospécifique et conduit à la formation de l'hydrazide multifonctionnel N_3P_3[N(Me)NH_2]$_5$[O-C_6H_4-*p*-C_6H_4-*p*-CH=CH_2] (**3**). Les condensations du composé **3** avec l'*o*-hydroxybenzaldéhyde ou la pyridine-2-carboxaldéhyde fournissent respectivement les hydrazones correspondantes N_3P_3[N(Me)N=CH-C_6H_4-*o*-OH]$_5$[O-C_6H_4-*p*-C_6H_4-*p*-CH=CH_2] (**4**) et N_3P_3[N(Me)N=CH-C_6H_4N]$_5$[O-C_6H_4-*p*-C_6H_4-*p*-CH=CH_2] (**5**). Ces hydrazones peuvent être soumises à des homopolymérisations qui conduisent aux polymères **6** et **7** portant cyclophosphazènes à plusieurs sites de coordination comme groupes pendants.

Mots clés : cyclophosphazène, hydrazone, polymères pendants, polymères hybrides, ligands polymériques.

[Traduit par la Rédaction]

Introduction

Among the inorganic polymers, polyphosphazenes ([N=PR_2]$_n$) occupy a prominent place (1). These constitute the largest family of inorganic polymers with over 800 representative examples. A remarkable feature of polyphosphazenes is that the property and function of each polymer can be readily fine tuned by varying the nature of the "R" group on the phosphorus atom. Thus, polymers with diametrically opposite properties such as water solubility or hydrophobicity, or with varied applications such as bio-inert materials or polymer electrolytes, are readily assembled by choosing an appropriate substituent on the phosphorus atom (1). Another versatility of polyphosphazenes is that unlike organic polymers, the structural diversity can be introduced by a macromolecular nucleophilic substitution reaction involving the reactive P—Cl bonds of polydichlorophosphazene ([N=PCl_2]$_n$) (2, 3). The latter itself is prepared from a ring opening polymerization of $N_3P_3Cl_6$, or by a condensation reaction involving either Cl_3P=$NSiMe_3$ (4) or Cl_3P=NP(O)Cl_2 (5, 6).

Another class of closely related polymers is those that contain a cyclophosphazene unit as a pendant group (7–15). In contrast to polyphosphazenes, which contain an inorganic backbone and (mostly) organic substituents, the pendant polymers contain an organic backbone and *intact* cyclophosphazene groups as the substituents. Although these polymers have received much less attention than polyphosphazenes, in principle these systems also possess a similar potential in terms of easy tunability of polymer property and function. The pendant polymers are obtained by polymerizing cyclophosphazenes containing vinyl groups (Scheme 1).

Pioneering studies by Allen and co-workers (7–11) have revealed that the presence of an appropriate spacer group "Z" and (or) the presence of electron releasing substituents on the olefinic moiety facilitate the homopolymerization of the monomer by minimizing the σ-electron withdrawing effect of the cyclophosphazene group (11). The utility of this approach for the preparation of useful polymers has been demonstrated by Inoue and co-workers (13–15). They have found that polymers containing etheroxy-substituted cyclophosphazenes readily form complexes with lithium

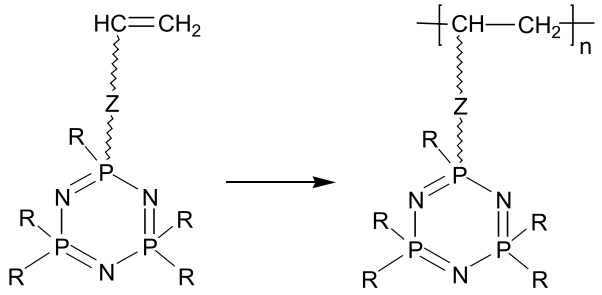
Scheme 1.



salts, which function as novel polymer electrolytes for lithium ion transport. We have been intrigued by the possibility of extending this approach to prepare new types of polymeric ligands that can bind to transition metal ions. Such ligands would also be of contemporary interest, in view of the importance of polymeric materials in organic synthesis, in the form of solid-phase inert supports or in the form of reagents and catalysts (16–21). Herein, we describe the synthesis and utility of a multi-functional cyclophosphazene monomer ($N_3P_3[N(Me)NH_2]_5[O\text{-}C_6H_4\text{-}p\text{-}C_6H_4\text{-}p\text{-}CH{=}CH_2]$) towards building new polymeric ligand systems.

Experimental section

General

Solvents and other general reagents used in this work were purified according to standard procedures. 4-Hydroxy-4′-vinylbiphenyl was prepared according to the reported procedure (13). 4-Hydroxy biphenyl (SD Fine Chemicals, India), *o*-hydroxybenzaldehyde (Fluka, Switzerland), and pyridine-2-carboxaldehyde (Fluka, Switzerland) were used as received. Hexachlorocyclotriphosphazene (Nippon Soda, Japan) was recrystallized from *n*-hexane before use. $N_3P_3Cl_5(O\text{-}C_6H_4\text{-}p\text{-}C_6H_4\text{-}p\text{-}CH{=}CH_2)$ was prepared according to the literature procedure (13, 22).

Instrumentation

^1H and ^{31}P NMR spectra were recorded on a JEOL-JNM LAMBDA 400 model spectrometer operating at 400.0 and 161.7 MHz, respectively. The chemical shifts are reported with respect to internal tetramethylsilane (^1H) and external 85% H_3PO_4 (^{31}P). FAB-MS were recorded on a JEOL SX 102/DA 6000 mass spectrometer using xenon (6 kV, 10 mA) as the FAB gas. TGA were recorded on a PerkinElmer Pyris 6 TGA model in a nitrogen atmosphere at a heating rate of 20°C min^{-1}. DSC were recorded on a PerkinElmer Pyris 6 DSC model in a nitrogen atmosphere at a heating rate of 10°C min^{-1}. Dilute solution viscosity studies were done on a Schott-Gerate viscometer using an Ubbelohde viscometer with a capillary pore size of 0.645 mm.

Preparation of $N_3P_3[N(Me)NH_2]_5[O\text{-}C_6H_4\text{-}p\text{-}C_6H_4\text{-}p\text{-}CH{=}CH_2]$ (3)

N-Methylhydrazine (2.03 g, 44.00 mmol) was dissolved in chloroform (40 mL) and to this was added a solution of **2** (2.03 g, 4.00 mmol) in chloroform. The reaction mixture was stirred at room temperature for 24 h. The *N*-methylhydrazine hydrochloride that formed was filtered and the solvent was evaporated in vacuo to afford **3**. It was purified, first by adding *n*-hexane to a solution of **3** in chloroform, and secondly by recrystallization from a mixture of chloroform and *n*-hexane (1:1). Yield: 1.82 g (81.9%); mp 62°C. ^1H NMR ($CDCl_3$) δ: 7.47–7.22 (m, 8H, aromatic), 6.75 (dd, 1H, J = 17.6 and 10.8 Hz, *H*RC=CH_2), 5.78 (d, 1H, J = 17.5 Hz, *trans*-HRC=C*H*H), 5.27 (d, 1H, J = 10.8 Hz, *cis*-HRC=CH*H*), 3.20 (broad, 10H, -NH_2), 3.06, 2.85, and 2.68 (d, 15H, J = 11.5, 11.0, and 10.8 Hz, -N(*Me*)). ^{31}P NMR ($CDCl_3$) δ: 29.4 (d, *P*(N(Me)NH_2)$_2$), 22.4 (t, $^2J_{P\text{-}N\text{-}P}$ = 40.4 Hz, *P*(OR)N(Me)NH_2). FAB-MS *m/z*: 555 ($[M]^+$). Anal. calcd. for $C_{19}H_{36}N_{13}OP_3$ (555.49): C 41.1, H 6.5, N 32.8; found: C 40.9, H 6.8, N 32.5.

Preparation of $N_3P_3[N(Me)N{=}CH\text{-}C_6H_4\text{-}o\text{-}OH]_5[O\text{-}C_6H_4\text{-}p\text{-}C_6H_4\text{-}p\text{-}CH{=}CH_2]$ (4)

To a solution of **3** (1.11 g, 2.00 mmol) in ethanol (50 mL) was added a solution of *o*-hydroxybenzaldehyde (1.46 g, 12.00 mmol) in ethanol (50 mL). The reaction mixture was heated under reflux for 17 h. It was then allowed to cool to room temperature and the solvent removed from it in vacuo to obtain **4**. Compound **4** was dissolved in acetonitrile (10 mL) and an excess of *n*-hexane was added to it, to allow re-precipitation. Yield: 1.39 g (64.5%); mp 117°C. ^1H NMR ($CDCl_3$) δ: 11.28, 11.09, and 11.03 (s, 5H, -O*H*), 7.64–7.51, 7.35–7.18, 7.13–6.99, and 6.82–6.75 (m, 28H, aromatic, N=CH), 6.72 (dd, 1H, J = 17.5 and 10.5 Hz, *H*RC=CH_2); 5.78 (d, 1H, J = 17.5 Hz, *trans*-HRC=C*H*H), 5.27 (d, 1H, J = 10.5 Hz, *cis*-HRC=CH*H*), 3.22, 3.14, and 2.99 (d, 15H, J = 8.8, 8.8, and 8.5 Hz, N(*Me*)). ^{31}P NMR ($CDCl_3$) δ: 16.4 (d, *P*(N(Me)N=CH-C_6H_4-*o*-OH)$_2$), 14.0 (t, $^2J_{P\text{-}N\text{-}P}$ = 58.2 Hz, *P*(OR)N(Me)N=CH-C_6H_4-*o*-OH). FAB-MS *m/z*: 1076 ($[M]^+$). Anal. calcd. for $C_{54}H_{56}N_{13}O_6P_3$ (1076.02): C 60.3, H 5.2, N 16.9; found: C 60.6, H 5.0, N 16.5.

Preparation of $N_3P_3[N(Me)N{=}CH\text{-}C_6H_4N]_5[O\text{-}C_6H_4\text{-}p\text{-}C_6H_4\text{-}p\text{-}CH{=}CH_2]$ (5)

To a solution of **3** (1.11 g, 2.00 mmol) in ethanol (50 mL) was added a solution of pyridine-2-carboxaldehyde (1.28 g, 12.00 mmol) in ethanol (50 mL). The reaction mixture was heated under reflux for 17 h. After allowing the reaction mixture to cool to room temperature, solvent was removed from it under vacuum to obtain **5**. Compound **5** was re-precipitated using acetonitrile as the polar solvent and *n*-hexane as the non-polar solvent. Yield: 1.34 g (66.9%); mp. 99°C. ^1H NMR ($CDCl_3$) δ: 8.53–7.09 (m, 33H, aromatic and N=C*H*), 6.74 (dd, 1H, J = 17.7 and 11.0 Hz, *H*RC=CH_2), 5.78 (d, 1H, J = 17.8 Hz, *trans*-HRC=C*H*H), and 5.27 (d, 1H, J = 11.0 Hz, *cis*-HRC=C*H*H), 3.38, 3.28, and 3.14 (d, 15H, J = 8.3, 8.3, and 8.3 Hz, N(*Me*)). ^{31}P NMR ($CDCl_3$) δ: 18.1 (d, *P*(N(Me)N=CH-C_6H_4N)$_2$), 13.7 (t, $^2J_{P\text{-}N\text{-}P}$ = 56.6 Hz, *P*(OR)N(Me)N=CH-C_6H_4N). FAB-MS *m/z*: 1001 ($[M]^+$). Anal. calcd. for $C_{49}H_{51}N_{18}OP_3$ (1000.97): C 58.8, H 5.1, N 25.2; found: C 58.5, H 5.7, N 25.5.

Preparation of (6)

Compound **4** (0.79 g, 7.4×10^{-1} mmol) was dissolved in 1,2-dichloroethane (10 mL) along with AIBN (2% by weight). The contents were purged with oxygen-free nitrogen for 30 min, and the reaction mixture was then

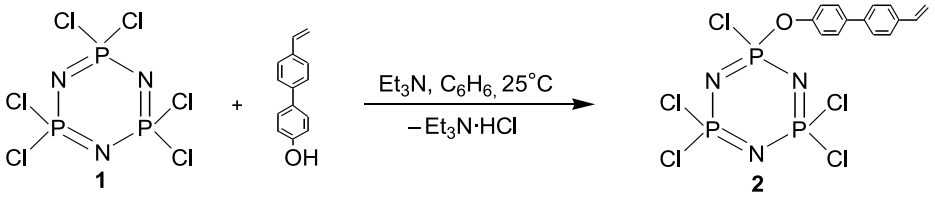
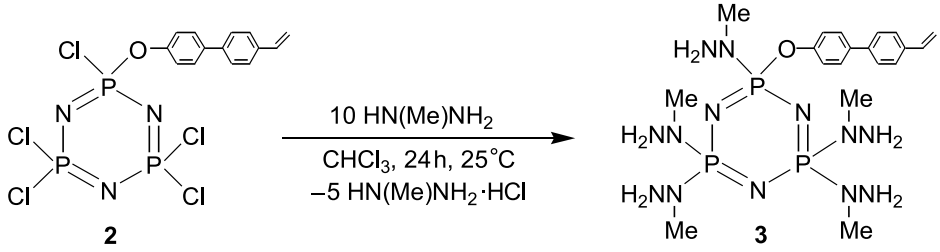
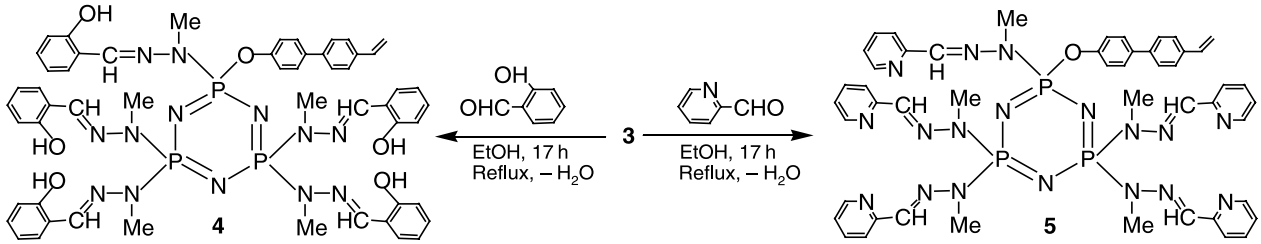
Scheme 2.



Scheme 3.



Scheme 4.



heated at 80°C for 24 h. It was then allowed to come to room temperature and poured into an excess of *n*-hexane to afford **6** as a powder. This was further purified by repeated re-precipitations (dichloromethane as the solvent and *n*-hexane as the non-solvent). Pure **6** was obtained as a white solid. It was dried in vacuum (10^{-3} torr (1 torr = 133.322 kPa)) at 40°C for 6 h. Yield: 0.48 g (60.7%). ^{1}H NMR ($CDCl_3$) δ: 11.27, 11.10, and 11.03 (s, 5H, O*H*), 7.10 (m(broad), 28H, aromatic and N=C*H*), 3.10 (m(broad), 15H, N(*Me*)), 1.25 (m, 3H, C*H*-CH_2). ^{31}P NMR ($CDCl_3$) δ: 16.4 (d, *P*(N(Me)N=CH-C_6H_4-*o*-OH)$_2$), 13.9 (t, $^2J_{P\text{-}N\text{-}P}$ = 58.3 Hz, *P*(OR)N(Me)N=CH-C_6H_4-*o*-OH). Intrinsic viscosity: 1.29 cm^3 g^{-1} (benzene), indicating a molecular weight of approximately 15 000 (22).

Preparation of (7)

The polymerization of **5** into **7** was carried out by using a similar procedure as those outlined above. The quantities used in this preparation are: **5** (0.74 g, 7.4 × 10^{-1} mmol). Yield: 0.40 g (54%). ^{1}H NMR ($CDCl_3$) δ: 8.48–7.10 (m(broad), 33H, aromatic and N=C*H*), 3.2 (m(broad), 15H, N(*Me*)), 1.26 (m, 3H, C*H*-CH_2). ^{31}P NMR ($CDCl_3$) δ: 18.06 (d, *P*(N(Me)N=CH-C_6H_4N)$_2$), 13.7 (t, $^2J_{P\text{-}N\text{-}P}$ = 54.9 Hz, P(OR)N(Me)N=CH-C_6H_4N). Intrinsic viscosity: 1.35 cm^3 g^{-1} (benzene), indicating a molecular weight of approximately 15 000 (22).

Results and discussion

Synthesis and spectroscopy of the cyclophosphazene derivatives 3 to 5

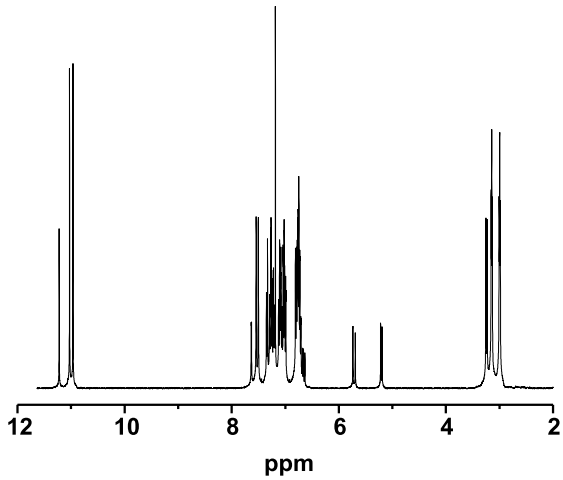
The cyclophosphazene $N_3P_3Cl_5$[O-C_6H_4-*p*-C_6H_4-*p*-CH=CH_2] (**2**) has been shown previously by Inoue and co-workers (13 to 15) and by us (22) to be an excellent monomer in terms of its ease of preparation, hydrolytic stability, and ready polymerizability. It is readily prepared by the reaction of $N_3P_3Cl_6$ (**1**) with 4-hydroxy-4′-vinyl biphenyl in the presence of triethylamine as the hydrogen chloride scavenger (Scheme 2).

The presence of five reactive P—Cl bonds allows **2** to be used as a precursor for further reactions with nucleophiles. Accordingly the reaction of **2** with 10 equiv of *N*-methylhydrazine results in the complete substitution of the chlorine atoms, affording N_3P_3[N(Me)NH_2]$_5$[O-C_6H_4-*p*-C_6H_4-*p*-CH=CH_2] (**3**). in an excellent yield (Scheme 3). This reaction is regio-specific; the *N*-methyl end of the difunctional reagent is found to exclusively attach to the phosphorus atom. Such behavior has also been noted earlier in the reactions of *N*-methylhydrazine with acyclic phosphorus(V) halides, such as P(O)Cl_3 or PhP(O)Cl_2 (23–26). The most important feature of the reaction of **2** with *N*-methylhydrazine is that the product (**3**) still contains five reactive groups in the form of peripheral -NH_2 units. Also, the polymerizable vinyl group remains intact in the conversion of **2** to **3**.

© 2002 NRC Canada

The condensation of **3** with 5 equiv of *o*-hydroxybenzaldehyde proceeds in boiling ethanol to afford the hydrazone **4**. Similarly condensation of **3** with pyridine-2-carboxaldehyde affords the hydrazone **5** (Scheme 4). Both of these cyclophosphazene derivatives contain a multi-site coordination environment in the form of the imino nitrogens, the cyclophosphazene ring nitrogen atoms, and the phenoxy oxygen (or the pyridyl nitrogen). The FAB-MS of **3**, **4**, and **5** show prominent parent ion peaks at 555, 1076, and 1001 respectively. The ^{1}H NMR spectrum of **3** shows the presence of the terminal -NH_2 groups as indicated by the appearance of a broad resonance at 3.2 ppm. This signal disappears upon the conversion of **3** into the hydrazones **4** and **5**. Interestingly, in the case of **4**, three hydroxy signals are seen as sharp singlets at 11.21, 11.01, and 10.95 ppm, respectively. The C*H*=N protons of **4** resonate at 7.55, 7.50, and 7.35 ppm. The vinyl protons appear as an AMX multiplet for all the three compounds **3**, **4**, and **5**. A representative ^{1}H NMR spectrum for compound **4** is given in Fig. 1. The presence (absence) of second order virtual coupling effects are helpful in the assignment of individual N-CH_3 chemical shifts. As can be seen from Fig. 2, in each of the compounds **3**, **4**, and **5**, three types of N-CH_3 resonances are expected. The most downfield N-CH_3 resonance is readily assigned to =P(OR)[N(CH_3)N=CHR′], because of the chemical shift, as well as the absence of virtual coupling effects. The other two

Fig. 1. ^{1}H NMR spectrum of compound **4**.



N-CH_3 resonances (Types B and C) show pronounced virtual coupling; these resonances are seen as virtual triplets with an intense central line. B and C themselves can be distinguished from each other. Thus the more shielded signal (C) is assigned as arising from the substituent flanked by the aryloxy group. Such effects have been well demonstrated in other situations among cyclophosphazenes (27).

Fig. 2. Virtual coupling effects in the N-Me region of the ^{1}H NMR of **4**.

Scheme 5.

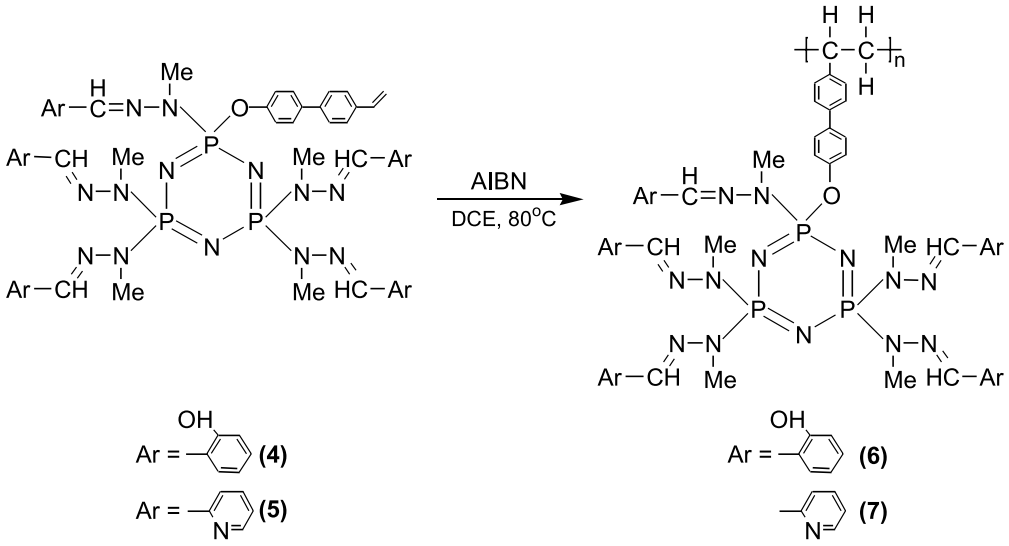

Table 1. ^{31}P NMR data for compounds **2**–**7**.

Compound	δ P(OR)(R) ν_A	δ P(R_2) ν_X	$^2J_{P\text{-}N\text{-}P}$ Hz
2	12.3	22.5	58.2
3	22.4	29.4	40.4
4	14.0	16.4	58.2
5	13.7	18.1	56.6
6	13.9	16.4	58.3
7	13.7	18.1	54.9

The ^{31}P NMR spectra of **3**, **4**, and **5** are of the AX_2 type. The chemical shift and coupling constant data for compounds **2**–**7** are summarized in Table 1. An interesting observation is that the conversion of the hydrazide **3** to the hydrazones **4** and **5** is accompanied by an upfield shift of the signals, along with a concomitant increase in the $^2J_{P\text{-}N\text{-}P}$ values.

Homopolymerization of 4 and 5

The compounds **4** and **5** can be readily homopolymerized in dichloroethane by using AIBN as the initiator to afford polymers **6** and **7** (Scheme 5). These polymers are obtained in their pure form by several re-precipitations, by dissolving in dichloroethane and using *n*-hexane as a non-polar solvent. The final dried products are air-stable powders soluble in a variety of organic solvents such as dichloromethane, tetrahydrofuran, etc. Dilute solution viscosity studies on **6** and **7** reveal that they have intrinsic viscosities of 1.29 and 1.35 $cm^3\ g^{-1}$, respectively, as measured in benzene. This suggests that these polymers have an MW of approximately 15 000 (22).

^{1}H NMR spectra of **6** and **7** show the complete disappearance of the AMX multiplet due to the vinyl protons and a broadening of other signals. The ^{31}P NMR spectra of **6** and **7** are of the AX_2 type, and the signal positions are unchanged vis-à-vis **4** and **5**. This strongly suggests that the cyclophosphazene moiety remains intact and does not suffer any degradation during the polymerization reaction.

Thermogravimetric analysis of the polymers **6** and **7** reveal that these are fairly robust polymers. Both of these polymers have similar degradation profiles. An initial decomposition leads to a char yield of approximately 68.5% at 400°C for **6** and 61.6% for **7**. Four further gradual decompositions occur. Even at 800°C, however, the char yields are fairly high (49.6% (**6**) and 45.9% (**7**)). Differential scanning calorimetric studies reveal that polymers **6** and **7** have high glass transition temperatures (T_g) viz., 139.4 and 119.6°C, respectively.

Conclusion

In conclusion, we have prepared new cyclophosphazene ligands containing hydrazone linkages and have successfully converted them into soluble and thermally stable polymeric systems, retaining the ligand framework as pendant groups. The metalation studies of these ligands are being pursued.

Formation and decomposition of the Sb(III)/Li cage [{Sb(P-*t*-Bu)$_3$}$_2$Li$_6$·6THF]

Alan Bashall, Felipe García, Gavin T. Lawson, Mary McPartlin, Alexander Rothenberger, Anthony D. Woods, and Dominic S. Wright

Abstract: The heterometallic Sb(III)/Li cage complex [{Sb(P-*t*-Bu)$_3$}$_2$Li$_6$·6THF] (**1**) is obtained by the low-temperature (<0°C) reaction of Sb(NMe$_2$)$_3$ with *t*-BuPHLi (1:3 equiv) in THF. Thermolysis of this reaction solution leads to the formation of the bicyclic distibane [(*t*-BuP)$_3$Sb]$_2$ (**2**). ^{31}P NMR spectroscopic studies reveal that this process involves initial formation of [(*t*-BuP)$_3$Sb]$^-$ and [*t*-Bu(H)PP-*t*-Bu]$^-$ anions. Complexes **1** and **2** have been characterized in the solid state by X-ray diffraction studies.

Key words: antimony, lithium, cage.

Résumé : La réaction dans le THF, à basse température (<0°C), du Sb(NMe$_2$)$_3$ avec du *t*-BuPHLi (1:3 équivalents) conduit à la formation du complexe hétérométallique en cage du Sb(III)/Li, le [{Sb(P-*t*-Bu)$_3$}$_2$Li$_6$·6THF] (**1**). La thermolyse de cette solution réactionnelle conduit à la formation du distibane bicyclique [(*t*-BuP)$_3$Sb]$_2$ (**2**). Des études par spectroscopie RMN du ^{31}P révèlent que ce processus implique une formation initiale d'anions [(*t*-BuP)$_3$Sb]$^-$ et [(*t*-Bu(H)PP-*t*-Bu]$^-$. Les complexes **1** et **2** ont été caractérisés à l'état solide par des études de diffraction des rayons X.

Mots clés : antimoine, lithium, cage.

[Traduit par la Rédaction]

Introduction

In the past decade there has been considerable interest in the coordination chemistry of *p* block imido anions (1, 2). Our principal focus in this area has been the applications of dimethylamido group 15 reagents (E(NMe$_2$)$_3$ (E = As-Bi)) in the synthesis of various group 15 imido anion frameworks (2). For example, the 1:3 stoichiometric reactions of E(NMe$_2$)$_3$ with primary amido lithium complexes (RNHLi) give general access to cage complexes of the type [{E(NR)$_3$}$_2$Li$_6$], containing [E(NR)$_3$]$^{3-}$ trianions (Scheme 1(*a*)) (3). The research groups of Stalke (1(*a*)) and Chivers (1(*b*)) have explored cage compounds containing the valence-isoelectronic group 16 dianions [E(NR)$_3$]$^{2-}$ (E = S, Se, Te) which can be obtained by the 1:2 reactions of RNHLi with [E(NR)$_2$] (Scheme 1(*b*)).

Group 15 and 16 imido anions of this type are normally chemically robust, and can be transferred *intact* to a range of main group and transition metals (2). In contrast, however, we have found that phosphinidine counterparts, such as [Sb(PR)$_3$]$^{3-}$, are considerably less thermodynamically stable (4). The phosphinidine cage [{Sb(PCy)$_3$}$_2$Li$_6$·6NHMe$_2$] (Cy = cyclohexyl) can only be obtained from the reaction of Sb(NMe$_2$)$_3$ with CyPHLi at temperatures below ca. 0°C (4(*a*)). At ca. 30–40°C this complex decomposes to form the Zintl compound [Sb$_7$Li$_3$·6Me$_2$NH], containing the Sb$_7^{3-}$ anion (4(*b*)). Comparatively little is known about the mechanism of "cage-to-alloy" reactions of this type (5). Likely key intermediates in this process are heterocyclic [(RP)$_n$Sb]$^-$ anions, from which elimination of cyclic phosphanes ((RP)$_n$) appears to be a fundamental step (6). The generally greater thermodynamic stability of the analogous [(RP)$_n$As]$^-$ anions has allowed the investigation of the reactivity and coordination chemistry of these species in their own right (7). However, their thermolability depends markedly on the organic group (R), and only when the organic substituent is aliphatic (e.g., R = *t*-Bu, Cy, 1-adamantyl) has it been possible to isolate [(RP)$_n$As]$^-$ anions at room temperature (*n* = 3 or 4) (6). In contrast, when an aromatic substituent is present rapid formation of the As$_7^{3-}$ ion occurs under these conditions (6(*b*)). The results of attempts to prepare [(RAs)$_n$As]$^-$ anions illustrate an even greater tendency for the formation of Zintl compounds. Significantly, only the bicylic diarsane [(*t*-BuAs)$_3$As]$_2$ could be isolated from the reaction of As(NMe$_2$)$_3$ with the aliphatic arsenide *t*-BuAsHLi at room temperature (6(*b*)), suggesting that oxidative coupling of the intermediate heterocyclic anions is a fundamental step in metal—metal bond formation.

We present here a study of the synthesis of the Sb(III) cage [{Sb(P-*t*-Bu)$_3$}$_2$Li$_6$·thf] (**1**) and its thermal decomposition.

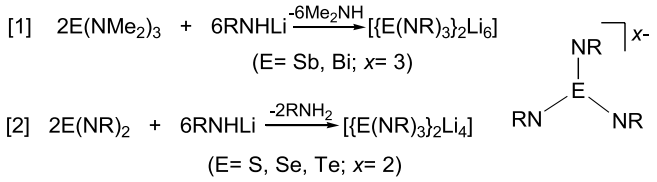
Scheme 1.



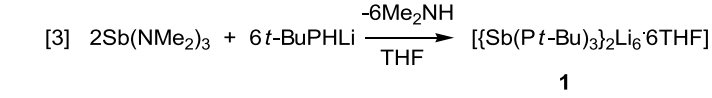
Surprisingly, the product in this case is not the anticipated Sb_7^{3-} anion but the new bicyclic distibane $[(t\text{-BuP})_3Sb]_2$ (**2**). The formation of **2** from **1**, both of which have been fully characterized in the solution and solid states, provides strong support for our hypothesis concerning the fate of $[(RP)_nSb]^-$ anions within a single, well-defined reaction system.

Results and discussion

Prior to the studies reported in this paper, the only group 15 phosphinidine cage to have been reported was $[\{Sb(PCy)_3\}_2Li_6{\cdot}6NHMe_2]$ (4(*a*)). The initial aims of the present study were to further explore the synthesis and structures of related cages containing $[Sb(PR)_3]^{3-}$ trianions and to examine the potential influence of the organic substituents (R) on their mode of decomposition. The low-temperature (<0°C) reaction of [*t*-BuPHLi] with $Sb(NMe_2)_3$ (3:1 equiv, respectively) in THF gives an orange-red solution from which the new phosphinidine cage $[\{Sb(P\text{-}t\text{-}Bu)_3\}_2Li_6{\cdot}6THF]$ (**1**) can be obtained as yellow crystals at –20°C, in 43% yield (Scheme 2). Although X-ray crystallography later showed that there are three uncoordinated THF molecules present in the lattice (in addition to the six-coordinated ligands of the cage), placing the complex under vacuum during isolation completely removes this lattice-bound solvent.

Like the previously reported complex $[\{Sb(PCy)_3\}_2Li_6{\cdot}6NHMe_2]$ (4(*a*)), crystalline **1** rapidly decomposes to a black solid even at room temperature under argon. For this reason it was necessary to use freshly prepared samples of the complex in all analytical and spectroscopic studies. These studies provided an initial indication of the empirical formula of the complex, and revealed that the Li^+ cations of the core of **1** are solvated by THF ligands rather than Me_2NH. Significantly, the room-temperature ^7Li NMR spectrum of the complex is that of a poorly resolved binomial septet ($^1J_{P\text{-}Li}$ ca. 12 Hz), which can be interpreted as arising from the coupling of the Li^+ cations to six equivalent ^{31}P centres of two $[Sb(P\text{-}t\text{-}Bu)_3]^{3-}$ trianions. This behaviour is identical to that of the previously reported complex $[\{Sb(PCy)_3\}_2Li_6{\cdot}6NHMe_2]$ ($^1J_{P\text{-}Li}$ ca. 14 Hz) (4(*a*)) and indicates that a similar fluxional "carousel" process is involved for **1** (in which the six Li^+ cations migrate around the equator of the cage). Unfortunately, the broadness of the resonance in the room-temperature ^{31}P NMR spectrum ($W_{1/2}$ ca. 60 Hz) made it impossible to discern any ^{31}P–^7Li coupling. The significant differences between the ^7Li and ^{31}P chemical shifts for **1** (δ 1.7 and δ –96.2 (in THF), respectively) compared to those observed for $[\{Sb(PCy)_3\}_2Li_6{\cdot}6NHMe_2]$ (δ 5.6 and δ –123.5 (in toluene), respectively) (4(*a*)) suggest that the electronic environments of both nuclei are highly sensitive to the nature of the Lewis base solvation of the Li^+ cations and the organic substituents present. In particular, the ^{31}P chemical shift indicates that the there is a lower development of negative charge on the P centres of **1** than is present in $[\{Sb(PCy)_3\}_2Li_6{\cdot}6NHMe_2]$.

Scheme 2.



Despite the careful handling of **1** during NMR spectroscopic studies, some thermal decomposition was nonetheless apparent in the room-temperature ^1H, ^{31}P, and ^7Li spectra. The decomposition process was followed by obtaining the ^{31}P NMR spectrum of the reaction solution (in THF) after prolonged storage at room temperature. After approximately 1 week, significant decomposition is apparent, with the deposition of a black solid (assumed to be Sb metal) and with the solution becoming redder in colour. The room temperature ^{31}P NMR spectrum of the reaction mixture shows that a significant amount of **1** remains (Fig. 1 (top) shows the fully coupled spectrum). The major product of this decomposition process is observed as an AX_2 system (t. δ 15.8, d. δ –125.7; $^1J_{PP}$ = 197.1 ± 1.1 Hz) (species **A** in Fig. 1). The chemical shifts and coupling constants of this species can be compared to those observed for the structurally characterized complexes $[(t\text{-BuP})_3AsLi{\cdot}TMEDA{\cdot}THF]$ (t., δ 7.9, d. δ –74.5; $^1J_{PP}$ = 176 Hz) and $[(t\text{-BuP})_3AsLi{\cdot}2DABCO{\cdot}THF]$ (DABCO = $N\{CH_2CH_2\}_3N$) (t., δ 5.0, d. δ –73.4; $^1J_{PP}$ = 178 Hz), containing the $[(t\text{-BuP})As]^-$ anion (6(*b*)). This species can be tentatively assigned to $[(t\text{-BuP})_3SbLi{\cdot}x THF]$, in which there is a significantly greater development of negative charge on the Sb-bonded P centres of the $[(t\text{-BuP})_3Sb]^-$ anion than occurs in the As counterparts (as is expected on the basis of the greater electronegativity of As). A minor product is also observed, which is characterized by an AMX system in the fully coupled ^{31}P NMR spectrum (dd. δ –16.2, d. δ –70.4; $^1J_{PH}$ = 205 ± 7 Hz, $^1J_{PP}$ = 291 ± 1 Hz) (species **B** in Fig. 1). On the basis of the similar appearance of the ^{31}P NMR spectrum to that of [*t*-Bu(H)PP(*t*-Bu)K·PMDETA] (PMDETA = $(Me_2NCH_2CH_2)_2NMe$) (dd. δ –8.9, d. δ –57.4; $^1J_{PH}$ = 201.4 Hz, $^1J_{PP}$ = 321.5 Hz) (8), this species is most likely to be [*t*-Bu(H)PP(*t*-Bu)Li·*x*THF]. The ^7Li spectrum of this solution (see Fig. 1, bottom) shows two major resonances, a binomial septet (δ 1.7) and a broad singlet (δ –0.4). The former corresponds to *intact* **1** and the latter (presumably) to $[(t\text{-BuP})_3SbLi{\cdot}x THF]$; a third ^7Li resonance corresponding to [*t*-Bu(H)PP(*t*-Bu)Li.·*x*THF] was not be observed, presumably owing to the minor amount of this species present.

The bicyclic distibane $[(t\text{-BuP})_3Sb]_2$ (**2**) was obtained initially by storage of the reaction solution from which **1** was obtained at room temperature for ca. 3 weeks. The complex can be obtained more reliably by bringing a solution of **1** (prepared in situ in the manner described above) to reflux briefly (ca. 10 min), followed by storage of the resulting solution for ca. 7 days at room temperature; **2** being obtained as large yellow crystals in 69% yield. The complex was characterized by mass spectroscopy (*m*/*z* $[MH]^+$ = 773), elemental analysis, and ^1H and ^{31}P NMR spectroscopy. There are only minor changes in the coupling constants and chemical

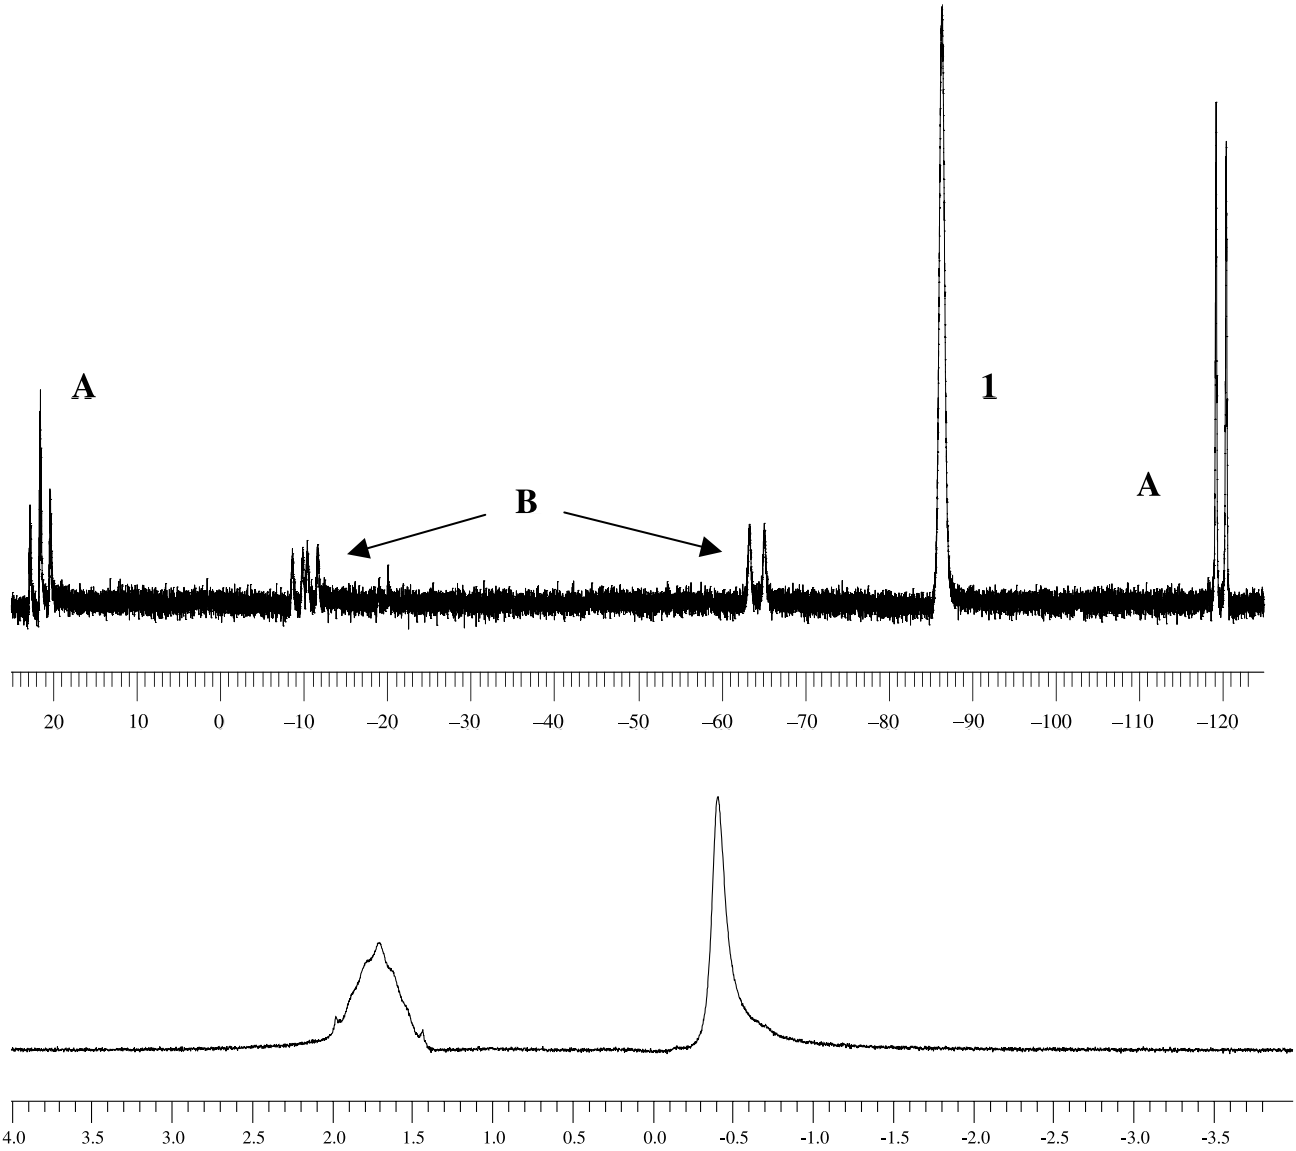
Fig. 1. In situ ^{31}P NMR spectrum of the reaction solution from which **1** is obtained (+25°C), after storage at room temperature for ca. 1 week (top); the ^{7}Li NMR spectrum of the same solution (bottom).



shifts observed in the ^{31}P NMR spectra of **2** in benzene (t., δ –11.9, d. δ –87.4; $^{1}J_{PP}$ = 173.2 Hz) and THF (t., δ –13.5, d. δ –89.2; $^{1}J_{PP}$ = 173.3 Hz). It should be noted that these parameters are significantly different to those assigned to the [(*t*-BuP)$_3$Sb]$^-$ anion, noted above. Pertinent to the ultimate formation of **2**, we have observed previously that the reaction of [(*t*-BuP)$_3$AsLi·2DABCO·THF] with [Au(PPh$_3$)Cl] or NH_4PF_6 gives the closely related diarsane [(*t*-BuP)$_3$As]$_2$ (9, 10). Thus, it appears that **2** arises from the coupling of [(*t*-BuP)Sb]$^-$ anions (observed in solution), either via one-electron oxidation or via protonation then loss of H_2 (Scheme 3).

The low-temperature X-ray structures of **1** and **2** were obtained. Details of the data collections and refinements for both are listed in Table 1. Tables 2 and 3 give selected bond lengths and angles for **1** and **2**, respectively.

The X-ray structure of **1** shows it to consist of heterobimetallic cage molecules containing a 14-membered $Sb_2P_6Li_6$ core (Fig. 2). In addition, there are three uncoordinated THF molecules in the lattice per molecule of **1**. The structure is similar to that of the previously characterized complex [{Sb(PCy)$_3$}$_2$Li$_6$·6NHMe$_2$] (4(*a*)). However, whereas the six Li^+ cations of the latter were solvated by Me_2NH ligands, in **1** all the Li^+ cations are coordinated by THF. The Sb—P bond lengths (mean 2.506 Å) and P-Sb-P bond angles (101.16(8)°) found in the [Sb(P-*t*-Bu)$_3$]$^{2-}$ anion units of **1** are similar to those observed for the [Sb(PCy)$_3$]$^{3-}$ trianions of [{Sb(PCy)$_3$}$_2$Li$_6$·6NHMe$_2$] (Sb—P range 2.516(5)–2.519(6) Å, P-Sb-P range 100.3(2)–103.4(2)°). The Sb—P bonds found in **1** are also similar to those observed in [SbP(2,4,6-Me$_3$C$_6$H$_2$)]$_2$ (2.561(2)–2.583(1) Å) (11) and [(CyP)$_4$SbNa·TMEDA·Me$_2$NH]$_2$ (2.489(3)–2.541(3) Å) (6(*a*)). Also similar to [{Sb(PCy)$_3$}$_2$Li$_6$·6NHMe$_2$] is the pattern of P—Li bond lengths, which are on average longer for the P—Li bonds connecting the two [Sb(P-*t*-Bu)$_3$]$^{3-}$ trianions in **1** (P(1)—Li(1) 2.640(18) Å) compared to those

found within the [Sb(P-*t*-Bu)$_3$Li$_3$] subunits of the complex (2.598(18)–2.605(18) Å) (cf. 2.62(3) Å for the bonds connecting the two [Sb(PCy)$_3$]$^{3-}$ trianions and 2.56(3)–2.62(3) Å within the [Sb(PCy)$_3$Li$_3$] units of [{Sb(PCy)$_3$}$_2$Li$_6$·6NHMe$_2$] (6(*a*)). These P—Li bonds are typical of those observed in the structures of Li phosphide complexes (12), e.g., with a mean of 2.61 Å in [CyPHLi·THF]$_\infty$ (13). One intriguing feature of [{Sb(PCy)$_3$}$_2$Li$_6$·6NHMe$_2$] was the solvation of all six of the Li$^+$ cations of the core by Me$_2$NH ligands, despite the fact that the complex was prepared in THF as the solvent (6(*a*)). The reasons for the absence of THF solvation in [{Sb(PCy)$_3$}$_2$Li$_6$·6NHMe$_2$] may well be steric in origin. It is noticeable in this regard that the average distance defining

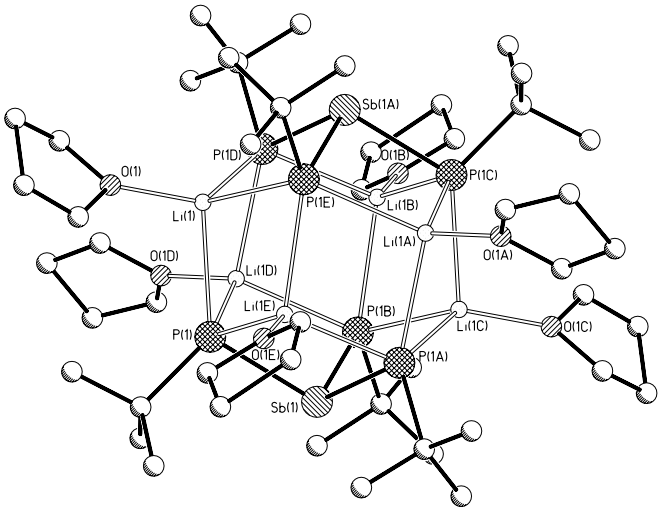
Fig. 2. Structure of cage molecules of $[\{Sb(Pt\text{-}Bu)_3\}_2Li_6{\cdot}6THF]$ (**1**). H-atoms have been omitted for clarity.



the space for complexation of the Li^+ cations in $[\{Sb(PCy)_3\}_2Li_6{\cdot}6NHMe_2]$ (7.64 Å) is significantly greater than that in **1** (7.26 Å).

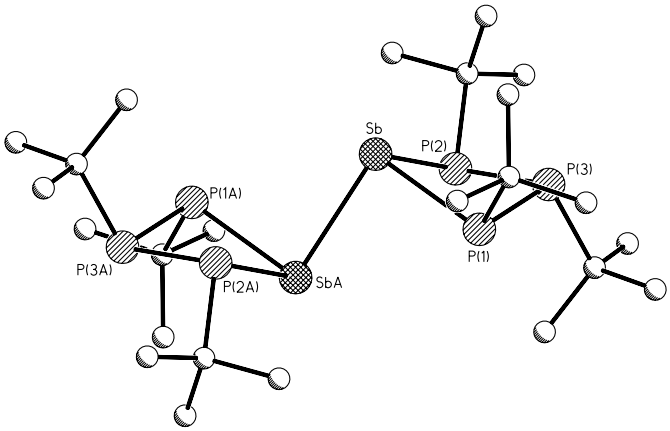
The X-ray structure of **2** shows that molecules of the complex have a centrosymmetric arrangement in the solid state, consisting of two $[(t\text{-}BuP)_3Sb]$ rings joined by an Sb—Sb bond (Fig. 3). The *t*-Bu groups of each ring unit adopt an all-*trans* arrangement with respect to each other, as is also the case in the As(III) analogue $[(t\text{-}BuP)_3As]_2$ (obtained by the coupling reaction of $t\text{-}BuPCl_2$ and $AsCl_3$ with Mg metal) (10). The latter is the most closely related compound to **2**. The Sb—Sb bond length in **2** (2.7922(7) Å) is similar to those found in other compounds containing Sb—Sb single bonds (14). The Sb—P bond lengths (mean 2.53 Å) are within the range of values found previously in the few Sb(III) phosphinidine compounds, e.g., $[SbP(2,4,6\text{-}Me_3C_6H_2)]_2$ (range 2.561(2)–2.583(1) Å) (11), $[\{Sb(PCy)_3\}_2Li_6{\cdot}6NHMe_2]$ (range 2.516(5)–2.519(6) Å) (6(*a*)) and in **1** (mean 2.506 Å). The P—P bonds within the $[(t\text{-}BuP)_3Sb]$ rings of **2** (2.214(2) Å) are as expected for single P—P bonds (ca. 2.21 Å[15]). The P-P-Sb (mean 87.6°), P-P-P (93.31(7)°), and P-Sb-P (78.92(5)°) bond angles within the $[(t\text{-}BuP)_3Sb]$ rings of **2** are well below the expected values for sp^3 hybridization at the P and Sb centres, as are the exocyclic P-Sb-Sb angles (mean 91.8°). The geometry at Sb can be rationalized in terms of this centre using essentially *p* orbitals to form the σ bonds, with the lone pairs on each metal centre having essentially *s*-character. Although intermolecular Sb···Sb interactions can often be observed in distibanes (Sb···Sb ca. 3.5–4.5 Å (14)), there are no such "closed-shell" interactions in the crystal lattice of **2**.

Experimental section

General experimental

The starting materials $Sb(NMe_2)_3$, $t\text{-}BuPH_2$, and compound **1** are air- and moisture-sensitive. They were handled on a vacuum line using standard inert-atmosphere techniques and under dry and oxygen-free argon. Although **2** was also handled in a similar way, it is considerably less air-sensitive and will survive brief air exposure without decomposition. $Sb(NMe_2)_3$ was prepared in the manner described in the literature (16). $t\text{-}BuPH_2$ was prepared by the reduction of $t\text{-}BuPCl_2$ with $LiAlH_4$ in Et_2O, in the manner described by us previously (6(*b*)). Toluene and THF were dried by distillation over sodium–benzophenone under N_2 prior to the reactions. The products were isolated and characterized with the aid of a N_2-filled glove box fitted with a Belle Technology O_2 and H_2O internal recirculation system. Elemental analyses were performed by first sealing the samples under argon in air-tight aluminium boats (1 to 2 mg) and C, H, and N content was analysed using an Exeter Analytical CE-440 elemental analyser. ^1H, ^{31}P and ^7Li NMR spectra were recorded on a Bruker AM 400 MHz spectrometer in dry deuterated THF and (or) benzene. ^1H NMR spectra were referenced to the internal solvent resonances. ^{31}P NMR spectra were referenced to an external standard of 80% H_3PO_4–D_2O and ^7Li spectra were referenced to a saturated solution of LiCl–D_2O. For the in situ studies of the decomposition reaction of **1**, a sealed D_6-acetone-filled capillary was used to obtain a lock.

Fig. 3. Structure of the distibane $[(t\text{-}BuP)_3Sb]_2$ (**2**). H-atoms have been omitted for clarity.



Synthesis of 1

A solution of $t\text{-}BuPH_2$ (1.1 mL, 9.0 mmol) in THF was reacted with *n*-BuLi (5.9 mL, 1.6 mol dm^{-3} in hexanes, 9.0 mmol) at 0°C. To the stirred solution of [*t*-BuPHLi] was added a solution of $Sb(NMe_2)_3$ (1.5 mL, 2.0 mol dm^{-3} in toluene, 3.0 mmol). The reaction mixture was allowed to warm gradually to 0°C, at which stage an orange-red solution was formed. Storage of the solution at –20°C (12 h) gave yellow crystals of **1**, suitable for X-ray diffraction studies. Elemental analysis and ^1H NMR spectroscopy shows that the three THF molecules in the lattice of **1**·3THF are removed by placing the crystalline complex under vacuum (1×10^{-1} atm (1 atm = 101.325 kPa), ca. 15 min). The following data refer to the dry, amorphous material obtained. Yield: 0.80 g (43%, based on Sb). ^1H NMR (D_6-benzene, +25°C, 400.16 MHz) δ: 3.6 (m., 12H, O–CH_2, THF), 1.7 (m., 12H, O-CH_2CH_2-, THF), 0.9 (m., 27H, *t*-BuP). ^{31}P NMR (D_8-THF, +25°C, 161.975 MHz) δ: –92.2 (s.). ^7Li NMR (D_8-THF, +25°C, 100.61 MHz) δ: 1.7 (s.) (minor resonance at –0.4 (s.)). Elemental anal. calcd. for **1**: C 46.9, H 8.3, P 13.9; found: C 46.3, H 8.2, P 14.9.

Synthesis of 2

The orange-red solution obtained from the reaction of $Sb(NMe_2)_3$ with [*t*-BuPHLi] (above) was allowed to warm to room temperature, at which stage a dark red solution was obtained (with some formation of Sb metal). The mixture was brought briefly to reflux (10 min) and the solution stored at room temperature (7(*d*)). Large, light-yellow crystals of **2** were formed (together with a black solid, presumed to be Sb metal). Crystals were suitable for X-ray diffraction studies. Yield: 0.80 g (69% based on Sb). Decomp. 220°C to black solid. MS (+ve ion *m/z* (%): 773 (60) ($[MH]^+$). ^{1}H NMR (D_6-benzene, +25°C, 400.16 MHz) δ: 1.38 (d., $^3J_{PH}$ = 11 Hz, 36H, *t-Bu*P-Sb), 1.35 (d., $^3J_{PH}$ = 7 Hz, 18H, P-P(*t-Bu*)P). ^{31}P NMR (D_6-benzene, +25°C, 161.975 MHz) δ: –11.9 (t., 2P, P-*P*(*t*-Bu)-P), –87.4 (d., 4P, *t*-Bu*P*-Sb) ($^1J_{PP}$ = 173.2 Hz) (s.) (t., –13.5, d. –89.2; $^1J_{PP}$ = 173.3 Hz in D_8-THF]. Elemental anal. calcd. for **2**: C 37.2, H 6.9, P 23.5.: found: C 37.3, H 7.1, P 24.1.

X-ray crystallographic studies of 1 and 2

Crystals of **1** and **2** were mounted directly from solution under argon using an inert oil (17) which protected them from atmospheric oxygen and moisture. X-ray intensity data for both complexes were collected using a Siemens *P*4 four-circle diffractometer. Details of the data collections and structural refinements are given in Table 1. Three carbon atoms of the unique, Li-bonded THF ligand in **1** are disordered equally over two sites, corresponding to two arrangements of the THF ligands being present in the crystal. Regions of ill-defined electron density in the voids of **1** were interpreted as severely disordered THF lattice molecules. Hydrogen atoms were placed in calculated positions in both structures (apart from those of the solute molecules in **1**). The structures were solved by direct methods and refined by full-matrix least-squares on F^2 (18).[2]

Conclusions and closing remarks

The study of the thermal decomposition of **1** into the bicyclic distibane **2** reported here provides further support for some of the overall conclusions which we had made previously, based on structural evidence from several different As(III) and Sb(III) systems (as outlined in the introduction to this paper) (5). However, this is the first *individual* reaction system in which we have been able to identify the key metal—metal bond forming process from a well-characterized cage precursor. The reasons why the decomposition of **1** stops at **2** (rather than proceeding to a Zintl compound, as was the case for $[\{Sb(PCy)_3\}_2Li_6{\cdot}6NHMe_2]$ (6(*a*)) are uncertain. However, the absence of Me_2NH solvation of the Li^+ cations of **1** provides some circumstantial evidence for the importance of Me_2NH in the decomposition process (5). In addition, the organic substituents may also have a subtle influence on the final product(s) of decomposition.

There still remain some fundamental features of the formation of Zintl ions that are unknown. In particular, the precise mechanism by which cages such as **1** are converted into heterocyclic anions of the type $[(RP)_nSb]^-$ is uncertain, as are the further steps involved in the formation of Sb_7^{3-} anions from bicyclic intermediates like **2**. Further studies (particularly of the reactivity of species like **2**) will focus on these issues.

Studies on electrochemical and coordination behaviour of phosphiniminocyclotrithiazenes

U. Swarnalatha, A. Sivaramakrishna, C.S. Venkatachalam, M.N. Sudheendra Rao, Tomonori Inoue, Tadaharu Ueda, and Masashi Hojo

Abstract: Electrochemical (polarographic, cyclic voltammetric, and coulometric) and coordination behaviour of several symmetrically and unsymmetrically substituted phosphiniminocyclotrithiazenes have been studied. Polarograms of $R_3PN\text{-}S_3N_3$ (R = C_6H_5, *p*-ClC_6H_4, *p*-$H_3CC_6H_4$, and (OC_4H_8N)), $Ph_2(OC_4H_8N)PN\text{-}S_3N_3$, and $Ph(OC_4H_8N)_2PN\text{-}S_3N_3$ give two cathodic waves. Cyclic voltammograms of $Ph_3PN\text{-}S_3N_3$ (**1**) and $(OC_4H_8N)_3PN\text{-}S_3N_3$ (**2**) reveal nearly the same oxidation peak potential but different reduction potentials. Controlled potential electrolysis of **1** and **2** at +0.6 V indicates exocyclic cleavage and ring degradation. Cathodic reduction behaviour of $Ph_3PN\text{-}S_3N_3$ suggests the possibility for the formation of 1,5-$(Ph_3PN)_2S_4N_4$ under electrochemical conditions. Reaction of nickel chloride hexahydrate with heterocycle **1** in 1:2 molar ratio in acetonitrile affords the complex, $[Ni(S_2N_2H)_2]$ (**A**) (90% yield) and $[Ph_3PNH_2]Cl$ salt as products. Analogous reactions with other ligands of this type (two symmetrical (sym.) and three unsymmetrical (unsym.)) except **2** also give **A,** while ligand **2** reacts with anhyd $NiCl_2$ in an equimolar ratio to afford a dark green, square-planar complex ($(OC_4H_8N)_3PN\text{-}S_3N{\cdot}NiCl_2$ (**B**)) whose ESCA results assist in providing its coordination details. The study reveals a high tendency of these heterocycles to different types of ring cleavage.

Key words: phosphiniminocyclotrithiazenes, polarography and cyclic voltammetry, substituent effect, nickel complexes, ESCA.

Résumé : On a étudié le comportement électrochimique (polarographique, voltampérométrie cyclique et coulométrique) et de coordination de plusieurs phosphiniminocyclotrithiazènes substitués de façon symétrique et asymétrique. Les polarogrammes des $R_3PN\text{-}S_3N_3$ (R = C_6H_5, *p*-ClC_6H_4, *p*-$H_3CC_6H_4$, OC_4H_8N) $Ph_2(OC_4H_8N)PN\text{-}S_3N_3$ et $Ph(OC_4H_8N)_2PN\text{-}S_3N_3$ présentent deux vagues cathodiques. Les voltampérogrammes cycliques du $Ph_3PN\text{-}S_3N_3$ (**1**) et $(OC_4H_8N)_3PN\text{-}S_3N_3$ (**2**) présentent des potentiels d'oxydation maxima qui sont pratiquement les mêmes, mais les potentiels de réduction sont différents. Une électrolyse du composé **1** à potentiel contrôlé, à 0,6 V, indique la présence de clivage exocyclique et de dégradation de cycle. Le comportement du $Ph_3PN\text{-}S_3N_3$ lors de la réduction cathodique suggère la possibilité de formation du 1,5-$(Ph_3PN)_2S_4N_4$ dans les conditions électrochimiques. La réaction du chlorure de nickel hexahydraté avec l'hétérocycle **1**, dans un rapport molaire de 2:1 dans l'acétonitrile, conduit à la formation du complexe $[Ni(S_2N_2H)_2]$ (**A**) (rendement de 90 %) et du $[Ph_3PNH_2]Cl$. Des réactions analogues (excepté celles avec le produit **2**) avec d'autres ligands de ce type (deux symétriques et trois non symétriques) conduisent aussi au produit à **A**. Le composé **2** réagit avec le $NiCl_2$ anhydre, dans un rapport moléculaire de 1:1, pour fournir un complexe plan carré, vert, $(OC_4H_8N)_3PN\text{-}S_3N{\cdot}NiCl_2$ (**B**) dont les résultats de spectroscopie d'électrons pour analyse chimique (« ESCA ») fournissent des détails relatifs à sa coordination. Cette étude révèle la grande tendance de ces hétérocycles à donner lieu à des types différents de clivage de cycle.

Mots clés : phosphiniminocyclotrithiazènes, polarographie, voltampérométrie cyclique, effet de substituant, complexes de nickel, ESCA.

Introduction

A variety of inorganic ring systems (1–2) have been the subject of both coordination and electrochemical studies in the last couple of decades. Electrochemical studies have helped in providing insight of chemical reactions and served also as a preparative method for both known and new compounds (3–9). Likewise, coordination studies have lead to

realizing many interesting results and novel complexes of transition metals (10–14).

Phosphiniminocyclotrithiazenes, $R_3PN\text{-}S_3N_3$ are a class of electron-rich inorganic heterocycles (15, 16) having a phosphinimino moiety as the exocyclic substituent and have served as stable derivatives of monosubstituted cyclotrithiazenes ($\text{-}S_3N_3$) (17–18). $Ph_3PN\text{-}S_3N_3$, the first example in this class (8 π system) to be reported in 1961 was subsequently obtained in an improved yield from a detailed reinvestigation study by Chivers and co-workers (19). Some of its reactivity aspects have also been demonstrated (20–22). Oakley and co-workers (20) have shown the usefulness of the redox potential data in rationalizing its electronic absorption and some reactivity features. In an extension of this work, we have prepared a variety of $R_3PN\text{-}S_3N_3$ heterocycles and studied their structural and reactivity aspects and have obtained many interesting results (23–26). In addition to the noticeable structural differences (27, 28), we have observed substituent-dependent pyrolytic behaviour of these heterocycles (29). We believe that the presence of a relatively bulky phosphinimino moiety as an exocyclic part of the S_3N_3 ring skeleton and the possibility of substituent variation on phosphorus render them as interesting examples for further studies. Sometime ago, we observed the tendency of these heterocyclic systems to nucleophilic attack by ammonia, amines (30), and phosphines (31, 32) and recently to oxidative cleavage by mild oxidants such as iodine (33).[4] The results suggested the preferential cleavage of the trithiazene ring skeleton over that of exocyclic substituent. These observations prompted us to undertake this study to probe the coordination and electrochemical behaviour of $R_3PN\text{-}S_3N_3$ ring systems for the first time. In this paper, we report polarographic, cyclic voltammetric, and bulk electrolysis studies as well as coordination behaviour with nickel chloride of many examples of symmetrically and unsymmetrically substituted phosphiniminocyclotrithiazenes.

Experimental

All handling and manipulation of air-sensitive compounds were done in a nitrogen or argon atmosphere. Solvents were purified using standard procedures (34). $NiCl_2{\cdot}6H_2O$, $NiSO_4{\cdot}7H_2O$, and NiI_2 (s.d. Fine Chemicals), and Ph_3P (Fluka) were used as received. Anhydrous $NiCl_2$ was prepared by the literature method (35). S_4N_4 (caution: explosion sensitive!) (36), $(OC_4H_8N)_3P$ (37), and different $R_3PN\text{-}S_3N_3$ derivatives employed in this study were synthesized by the reported methods (19, 23, 26, 37). Various spectral and analytical facilities used for characterization have been published elsewhere (26). Magnetic measurements were done in a vibrating sample magnetometer (EG & G PARC VSM-155) with 2 mg of the sample. Conductivity measurements were done using a conductometer (Toshniwal CL01/02A) with a glass electrode (cell constant: 1.2708 cm^{-1}) on 1 mM solution of the sample in CH_3CN. ESCA measurements were made using a VG ESCA LAB MK II X-ray photoelectron spectrometer.

Direct-current polarograms were measured on a dropping mercury electrode (DME) using a Yanagimoto polarograph (P-1000) and a Graphtec X-Y recorder (WX-4410-L0). Cyclic voltammograms were recorded at 25 ± 0.1°C with a microcomputer-controlled system at a scan rate of 100 mV s^{-1}. Glassy carbon electrode (Tokai Carbon GC-30S), freshly polished with a 0.1 μm diamond slurry was used as the working electrode and a platinum wire served as the counter electrode. $Ag/AgNO_3$ (0.01 mol dm^{-3} in MeCN) was the reference electrode. Coulometric experiments were performed on a GC fiber electrode using a potentiostat (Hokuto Denko HA-151). Dichloromethane (Wako GR grade) was used as the solvent. The electrolysis was followed by ^{31}P NMR spectroscopy using a JEOL JNM-LA400 instrument and (or) electronic spectroscopy using a double-beam spectrophotometer (Hitachi U-2000).

(*a*) Reaction of $Ph_3PN\text{-}S_3N_3$ (1) with $NiCl_2{\cdot}6H_2O$ in CH_3CN (2:1)

To a stirred slurry of $NiCl_2{\cdot}6H_2O$ (0.40 g, 1.67 mmol) in acetonitrile (25 mL), the red heterocyclic ligand **1** (1.39 g, 3.36 mmol) was added in batches over a 15 min interval at room temperature. The colour of the solution changed gradually to dark purple. After 20 h, it was filtered to isolate an off-white precipitate (0.26 g) and a dark purple filtrate. The CH_3CN extract of the precipitate (4 × 3 mL) when cooled gave a small amount of $[Ph_3PNH_2]Cl$ (40 mg), mp 228 to 229°C (lit. (38) value mp 230–232°C). Its IR and ^{31}P NMR chemical shift agreed well with an authentic sample (38). The acetonitrile insoluble residue (0.20 g) was metal free (chemical test for Ni was negative) and found to be water soluble.

The purple filtrate upon cooling for 36 h in the refrigerator gave $[Ph_3PNH_2]Cl$ (0.86 g). The residual mother liquor was concentrated and cooled in the deep freezer for a day to isolate purple crystals of $[Ni(S_2N_2H)_2]$ (**A**) (0.37 g, 90%), mp 155 to 156°C (lit. (39) value mp 156–158°C). Its nickel content, IR, and UV–Vis spectral data (552 nm (2.1×10^3); 399 nm (4.7×10^3); 305 nm (11.4×10^3)) agreed well with the literature data (39).

(*b*) Reaction of $Ph_3PN\text{-}S_3N_3$ (1) with $NiCl_2$ in CH_3CN (2:1)

Anhydrous nickel chloride (0.10 g, 0.77 mmol) was added in small amounts over a 15 min interval to a stirred slurry of ligand **1** (0.64 g, 1.55 mmol) in CH_3CN (25 mL) at room temperature. The observations were same as in reaction (*a*). After 16 h, it was worked up as in reaction (*a*) to isolate an off-white crystalline material ($[Ph_3PNH_2]Cl$ (0.23 g)) followed by the purple crystals of $[Ni(S_2N_2H)_2]$ (80 mg, 42%). An yellowish white insoluble residue (0.13 g) was also obtained from the precipitate part of the reaction.

(*c*) Reaction of anhyd $NiCl_2$ with Ph_3P and S_4N_4 in CH_3CN

To a stirred solution of Ph_3P (1.44 g, 5.50 mmol) in CH_3CN (25 mL) at room temperature, S_4N_4 (0.50 g, 2.72 mmol) was added as a solid in small amounts over a 20 min interval. When the reaction mixture had turned dark red in colour (ca. 2 h), anhyd $NiCl_2$ (0.18 g, 1.39 mmol) was added in aliquots over a 15 min interval and stirred for 20 h. The reaction mixture was filtered to obtain a dark purple

[a]All reactions were done in CH_3CN at room temperature for ca. 18 h by adding the ligand to a stirred slurry of the nickel salt.

[b]In all the reactions, an off-white insoluble residue was obtained in varying amounts. The ionic nature of this water soluble residue was revealed by its broad IR absorptions in the ν_{NH} and ν_{SO} regions at 3345 and 1095 cm^{-1}, respectively. It is possibly an ammonium salt of the S_xO_y anion.

[c]This reaction was done by the addition of five drops of water.

[d]Impure samples, ^{31}P NMR spectra showed strong singlets at 35.1 (E) and 35.6 ppm (G).

[e]Not isolated, ^{31}P NMR spectrum showed a strong singlet at 41.1, 40.6, and 42.0 ppm for the purple coloured reaction mixtures of **7**, **8**, and **9**, respectively.

filtrate and a pale yellow precipitate which when worked up as in reaction (*a*) gave $[Ph_3PNH_2]Cl$ (0.10 g) and a residue (0.11 g). The oily mass left after removal of the solvent from the purple filtrate was chromatographed over a silica gel column using benzene (caution: carcinogen!!) followed by benzene–dichloromethane (1:1) eluants to isolate Ph_3PS (0.40 g), $[Ph_3PNH_2]Cl$ (0.38 g), and $[Ni(S_2N_2H)_2]$ (0.20 g, 61%).

(*d*) Reaction of $(OC_4H_8N)_3PN\text{-}S_3N_3$ (2) with anhyd $NiCl_2$ in CH_3CN (1:1)

To a stirred slurry of anhyd $NiCl_2$ (0.15 g, 1.16 mmol) in acetonitrile (25 mL), was added the red ligand **2** (0.53 g, 1.20 mmol) as a solid in small amounts over a 15 min interval at room temperature. The colour of the solution gradually changed to purple along with the formation of a green precipitate. After 20 h, the green precipitate (0.32 g) was separated by a filtration and extracted with CH_3CN (8 × 3 mL). This extract, on cooling in the refrigerator for 10 h, gave a lustrous dark-green solid (0.22 g, 46%) which was identified as $(OC_4H_8N)_3PNS_3N{\cdot}NiCl_2$ (**B**), mp 184–186°C. IR (Nujol, cm^{-1}): 1443 (m), 1344 (m), 1293 (w), 1251 (m), 1152 (s), 1126 (s), 1104 (vs), 1018 (s), 1014 (m), 960 (vs), 880 (w), 835 (w), 700 (vs), 662 (w), and 595 (w). UV–vis (nm, L mol^{-1} cm^{-1}): 580 (9.1×10^3), 420 (4.1×10^3), 300 (1.9×10^3). ^1H NMR δ (ppm): 3.12 (m, 12H) and 3.60 (m, 12H). ^{31}P NMR δ (ppm): 33.7 (s,1P). XPE (B.E. in eV): 141.0 (P_{2p}), 170.5 (S_{2p}), 205.0 (Cl_{2p}), 292.5 (C_{1s}), 405.5 (N_{1s}), 536.5 (O_{1s}), 858.5 (Ni_{2p}). Elemental anal. calcd. for $C_{12}H_{24}N_5O_3PS_3NiCl_2$ (%): C 26.54, H 4.46, N 12.90, Cl 13.08, Ni 10.83; found: C 26.49, H 4.41, N 12.51, Cl 12.93, Ni 10.73 (leaving behind a white insoluble residue (60 mg)). A further quantity of **B** (0.12 g, 25%) was obtained when the concentrated purple filtrate was cooled in the freezer for a day.

(*e*) Reaction of $(OC_4H_8N)_3PN\text{-}S_3N_3$ (2) with $NiCl_2{\cdot}6H_2O$ in CH_3CN (1:1)

Nickel chloride hexahydrate (0.20 g, 0.84 mmol) stirred in CH_3CN (25 mL) at room temperature was added the ligand **2** (0.37 g, 0.84 mmol) in small amounts over a 15 min interval. The reaction mixture, which turned gradually to dark purple along with the formation of a green precipitate, was filtered after 18 h. The acetonitrile extract (3 × 10 mL) of the precipitate when cooled in the freezer for a day yielded a lustrous dark-green solid **B** (0.13 g, 38%). The purple filtrate was concentrated and cooled in the freezer to obtain a further quantity of **B** (50 mg, 14%).

(*f*) Reaction of anhyd $NiCl_2$ with $(OC_4H_8N)_3P$ and S_4N_4 in CH_3CN (1:1)

To a stirred solution of $(OC_4H_8N)_3P$ (1.05 g, 3.63 mmol) in CH_3CN (25 mL), S_4N_4 (0.33 g, 1.79 mmol) was added at room temperature over a 20 min interval. When the reaction mixture became dark red (ca. 2 h), anhyd $NiCl_2$ (0.23 g, 1.77 mmol) was added in aliquots over a 15 min interval and stirred for 15 h. The reaction mixture was then filtered to get

a green precipitate and dark purple filtrate. The CH_3CN extract (6 × 5 mL) of the precipitate when cooled in the freezer for a day gave the lustrous dark-green solid **B** (0.23 g, 31%). A further quantity of **B** (0.12 g, 17%) was recovered from the purple filtrate from which a slightly impure $(OC_4H_8N)_3PS$ (0.38 g) was also isolated in two subsequent crops.

All other reactions performed in this study are summarized in Table 1.

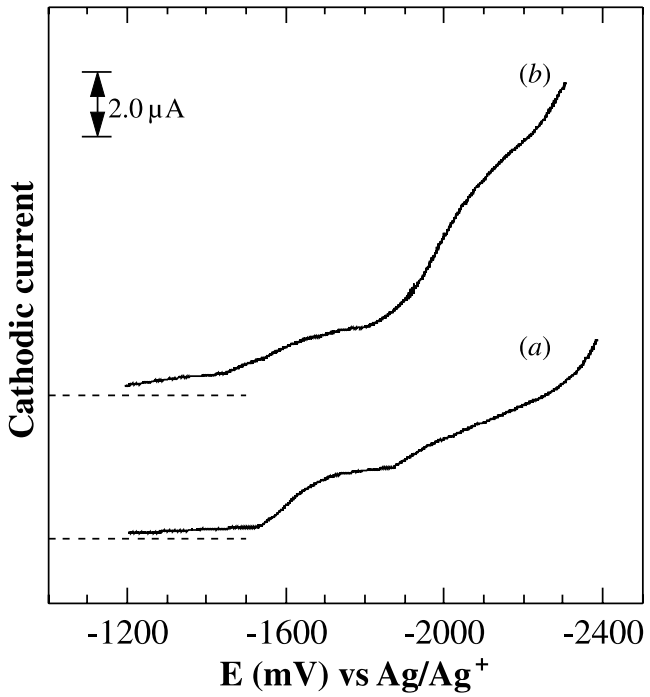
Results and discussion

The reported reactions of phosphiniminocyclotrithiazenes include: (*i*) adduct formation (20, 37); (*ii*) thermolysis (21, 23); (*iii*) substituent exchange (22); (*iv*) ring conversions (23); and (*v*) chemical and hydrolytic degradation (41). We have now studied the first electrochemical and coordination behaviour of several such heterocyclic systems carrying different substituents on phosphorus (Fig. 1) and the results are described here.

Electrochemical behaviour

A polarographic investigation was carried out on $R_3PN\text{-}S_3N_3$ (R = phenyl (**1**), morpholino (**2**), p-chlorophenyl (**3**), and *p*-tolyl (**4**)) (symmetrically substituted) and $Ph_2(OC_4H_8N)PN\text{-}S_3N_3$ (**7**) and $Ph(OC_4H_8N)_2PN\text{-}S_3N_3$ (**8**) (unsymmetrically substituted) to evaluate substituent effects on redox potentials, if any, in this class of heterocycles. All of them were found to give two cathodic waves (Fig. 2) with significantly differing $E_{1/2}$ values. A comparison (Table 2) reveals that among the symmetrical ones, $E_{1/2}$ for first and second waves vary over a 80 to 170 mV range, respectively.

Fig. 2. The polarograms of: (*a*) 0.5 mmol dm^{-3} $Ph_3PN\text{-}S_3N_3$, and (*b*) 0.5 mmol dm^{-3} 1,5-$(Ph_3PN)_2S_4N_4$ in dichloromethane containing 0.1 mol dm^{-3} *n*-Bu_4NClO_4.



The *p*-chlorophenyl derivative had the lowest value while the morpholino derivative had the greatest. Unsymmetrical ones showed very different $E_{1/2}$ values to each other. Also, no smooth trend in the $E_{1/2}$ values was observed in the series $(C_6H_5)_x(OC_4H_8N)_{3-x}PN\text{-}S_3N_3$ (x = 0, 1, 2, 3). Similar irregularities have been observed in ^{31}P NMR chemical shifts of several unsymmetrically substituted tri-coordinate phosphorus(III) and tetra-coordinate phosphorus(V) compounds containing amino substituents (42), which seem to suggest that the unsymmetrical environment around phosphorus has a more pronounced effect than the additive effects of the substituents attached (Table 2).

An interesting observation made in this study is that the polarographic reduction of **1** at –1.6 V produced a reduction wave at ca. –2.0 V that corresponded with the reduction wave of 1,5-$(Ph_3PN)_2S_4N_4$ (–1.99 V) thereby suggesting the possibility of the conversion of **1** to 1,5-$(Ph_3PN)_2S_4N_4$ under electrochemical reduction. Such a ring conversion occurring under the influence of a nucleophile has been previously observed (23, 30, 32). Conceivably, the dimerization of "$Ph_3PN\text{-}S_2N_2$" arising from the cleavage of $Ph_3PN\text{-}S_3N_3$ leads to the formation of this eight-membered heterocycle (eqs. [1] and [2]).

$$[1]\quad Ph_3PN\text{-}S_3N_3 + e^- \rightarrow Ph_3PN\text{-}S_3N_3^{-\bullet} \rightarrow Ph_3PN\text{-}S_2N_2 + NS^{\bullet}$$

$$[2]\quad 2Ph_3PN\text{-}S_2N_2 \rightarrow 1,5\text{-}(Ph_3PN)_2S_4N_4$$

The fragment $NS^{\bullet}$ possibly gets converted to S_4N_4. Chivers and Hojo (4) have observed a similar dimerization of "$Ph_2CNSNSO$" under electrochemical reduction. The polarograms of $R_3PNS_3N_3$ in acetonitrile containing

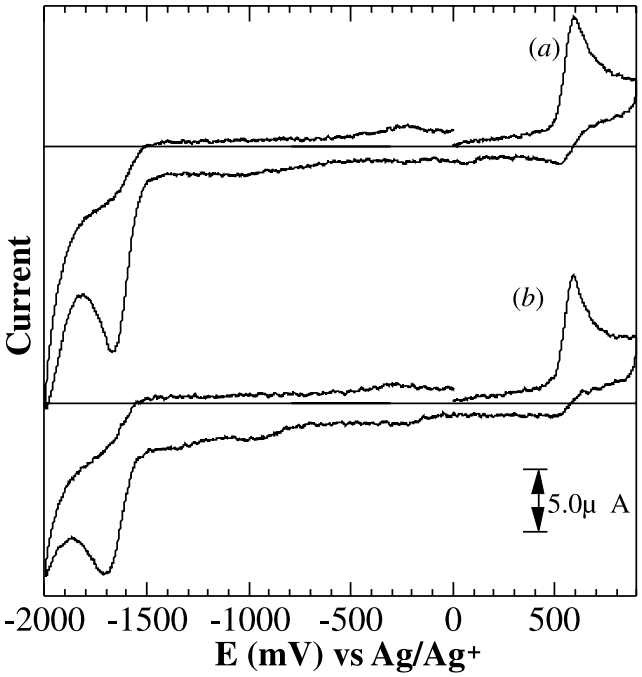
Fig. 3. The cyclic voltammograms of: (*a*) 0.5 mmol dm^{-3} $Ph_3PN\text{-}S_3N_3$, and (*b*) 0.5 mmol dm^{-3} $(OC_4H_8N)_3PN\text{-}S_3N_3$ in dichloromethane containing 0.1 mol dm^{-3} $n\text{-}Bu_4NClO_4$.



0.1 mol dm^{-3} Et_4NClO_4 were rather complicated; e.g., $Ph_3PNS_3N_3$ gave successively five cathodic waves at –1.25, –1.59, –1.98, –2.47, and –2.73 V vs. Ag/0.01 mol dm^{-3} $AgNO_3$–MeCN. The second and the third waves correspond to the two waves observed in dichloromethane.

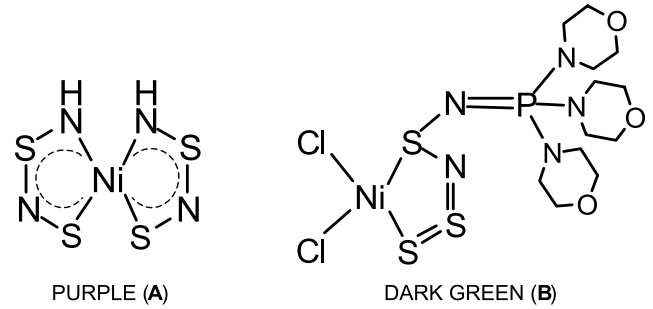
Figure 3 shows the cyclic voltammograms on the GC electrode of **1** and **2**. Both gave a sharp anodic peak nearly at the same potential (+0.6 V) but their cathodic peak potentials are found to be different. Other examples considered in the study also gave a similar anodic peak in the range +0.60 to +0.65 V. In an earlier study, Swarnalatha (33) observed the anodic peak potential values ($E_{a,p}$ vs. SCE) for **5**, $Ph[(C_6H_{11})_2N](C_5H_{10}N)PN\text{-}S_3N_3$, and $Ph[(C_6H_{11})_2N](Me_2N)\text{-}PN\text{-}S_3N_3$ in acetonitrile at 0.51, 0.56, and 0.61 V, respectively.

Controlled potential electrolysis of $Ph_3PNS_3N_3$ and $(OC_4H_8N)_3PNS_3N_3$ were carried out on a GC fiber electrode at +0.60 V. The initial red colour of the solution disappeared within a few minutes and the ^{31}P NMR spectra recorded for the solutions after electrolysis gave only one signal at 37.5 and 34.6 ppm, respectively, which may be due to the formation of the corresponding phosphinimines. The absence of characteristic UV–Vis absorptions of the heterocycle (15, 16) after electrolysis suggests the disruption of the S_3N_3 ring skeleton during electrolysis.

Coordination behaviour

A detailed study of the reactions of nickel chloride with $Ph_3PN\text{-}S_3N_3$ (**1**) was first carried out and only selected reactions were done in other cases which include **2**, **5**, and **6** (symmetrical variety) and **7**, **8**, and **9** (unsymmetrical variety). Ligand **1** reacts with nickel chloride at room temperature to afford the previously known nickel complex

Fig. 4. Complexes of nickel obtained in this study.



($[Ni(S_2N_2H)_2]$ (**A**)) (43) and the phosphiniminium salt ($[Ph_3PNH_2]Cl$ (**C**)) (38) as major products. Both the products were isolated in ca. 90% yield when the ligand (**1**) to hydrated $NiCl_2$ ratio was 2:1 which suggests that the reaction conceivably proceeds as in the eq. [3].

$$[3]\quad 2Ph_3PN\text{-}S_3N_3 + [Ni(H_2O)_6]Cl_2 \rightarrow [Ni(S_2N_2H)_2] + 2[Ph_3PNH_2]Cl + \cdots$$

The coordinated water molecules of nickel chloride are found to participate in the reaction but those performed with deliberate addition of water or with anhyd $NiCl_2$ afforded relatively low yields of **A** and **C** implying that: (*i*) H_2O only in small amounts is necessary for the reaction; and (*ii*) $NiCl_2$ and (or) CH_3CN employed in the study are presumably slightly wet. Depending on the conditions, varying yields of **A** and **C** were isolated from several of these reactions. This reaction, which occurs for different anions of nickel (Cl^-, I^-, SO_4^{2-}) was also favoured when the precursor reaction (that of S_4N_4 and Ph_3P) was performed in the presence of $NiCl_2$ (*Experimental*).

The purple complex **A** has attracted in the past, several studies. Scheme 1 shows the different reaction routes from which **A** has been isolated previously. It is noteworthy that methanol is used in all the methods which is presumably the source of protons. A notable feature of the present work is that **A** is isolated in near quantitative yield and by a simple work-up procedure without involving chromatography. Interestingly, ligands **5**–**9** also afforded the same complex (**A**) but its recovery from the reaction mixtures posed considerable difficulty. The corresponding phosphiniminium chloride by-product was either isolated in small amounts or identified by ^{31}P NMR spectroscopy.

Contrary to the ligands **1** and **5**–**9**, $(OC_4H_8N)_3PN\text{-}S_3N_3$ (**2**) reacts in an equimolar ratio with $NiCl_2$ (in both hydrated and anhydrous forms) under similar conditions to afford a dark green lustrous complex (**B**) in moderate to good yield (Fig. 4). The use of anhydrous salt and dry solvent were found to be more favourable for the formation of **B**, which could also be isolated from the analogous reaction of $(OC_4H_8N)_3P$ with S_4N_4 in presence of $NiCl_2$ in ca. 50% yield. Neither **A** nor the corresponding phosphiniminium chloride ($[(OC_4H_8N)_3PNH_2]Cl$) was isolated from any of the reactions tried. Though reasons for this unique behaviour are not clear, the differences in the stabilities of the (amino) phosphinimines and their possible derivatives may well be a contributing factor for this difference.

The complex **B** is air stable and less soluble in CH_3CN, CH_2Cl_2 and THF compared to **A**. Its solution though appears

purple, affords upon cooling shining dark green microcrystalline solid which is very different to **A**. On the basis of its elemental analysis, diamagnetic nature (μ_B = 0.13), negligible electrical conductivity (λ = 0.0021 ohm^{-1} cm^2), ^1H and ^{31}P NMR data and the fact that its IR spectrum resembles that of $(OC_4H_8N)_3PN\text{-}S_3N$ (31), we propose its structure as shown in Fig. 4. Complex **B** is a tetracoordinate, neutral, square-planar complex that has $(OC_4H_8N)_3PN\text{-}S_3N$ as the new ligand. Though many metal complexes of the bidentate ligand S_3N^- have been reported in the literature (45, 48–50), to the best of our knowledge this is the first time that a neutral S_3N ligand and its bidentate mode of ligation are observed. Unfortunately, all the efforts to obtain single crystals of **B** proved futile. However, its X-ray photoelectron spectral results (ESCA) were found to be in accordance with the structure proposed. The spectrum reveals the presence of all the constituent elements (*Experimental*) as well as the divalent and low-spin nature of nickel (51). The broad and unsymmetrical nature of the peak observed in the sulfur region (ca. 170 eV) was suggestive of the nonequivalent nature of sulfur atoms present in the ligand. This peak, upon repetitive deconvolution steps, gave features supportive of three kinds of sulfurs (Fig. 5) as in the structure proposed. In contrast, the nitrogen peak was found to be symmetrical and unresolved (FWHM = 2.52 V). A similar symmetrical and unresolved nitrogen peak was observed by Bossa et al. (52) for the nitrogens of $[Ni(S_2N_2H)_2]$.

Conclusion

New and interesting results as well as substituent-dependent behaviour were observed in the electrochemical and coordination studies of several phosphinimino cyclotrithiazenes (symmetrical and unsymmetrical ones). The synthetic advantage of the use of such heterocycles has been demonstrated. $Ph_3PN\text{-}S_3N_3$ serves as a source of the "$S_2N_2H^-$" ligand and affords $[Ni(S_2N_2H)_2]$ in near quantitative yield while $(OC_4H_8N)_3PN\text{-}S_3N_3$ offers a new and neutral S-N ligand. Its complex with nickel chloride was isolated and characterized. More coordination studies especially of the neutral ligand, $R_3PN\text{-}S_3N$ with different metal substrates merit consideration. Such studies are underway.

A theoretical study of the ^{77}Se NMR and vibrational spectroscopic properties of Se_nS_{8-n} ring molecules

J. Komulainen, R.S. Laitinen, and R.J. Suontamo

Abstract: The structures and spectroscopic properties of Se_nS_{8-n} ring molecules have been studied by the use of ab initio molecular orbital techniques and density functional techniques involving Stuttgart relativistic large core effective core potential approximation with double zeta basis sets for valence orbitals augmented by two polarization functions for both sulfur and selenium. Full geometry optimizations have been carried out for all 30 isomers at the Hartree–Fock level of theory. The optimized geometries and the calculated fundamental vibrations and Raman intensities of the Se_nS_{8-n} molecules agree closely with experimental information where available. The nuclear magnetic shielding tensor calculations have been carried out by the Gauge-independent atomic orbital method at the DFT level using Becke's three-parameter hybrid functional with Perdew/Wang 91 correlation. The isotropic shielding tensors correlate well with the observed chemical shift data. The calculated chemical shifts provide a definite assignment of the observed ^{77}Se NMR spectroscopic data and can be used in the prediction of the chemical shifts of unknown Se_nS_{8-n} ring molecules.

Key words: selenium sulfides, ab initio, DFT, effective core potentials, geometry optimization, energetics, fundamental vibrations, ^{77}Se chemical shifts.

Résumé : On a étudié les structures et les propriétés spectroscopiques de molécules cycliques de formule Se_nS_{8-n} en faisant appel à des techniques d'orbitales moléculaires ab initio et à des techniques de densité fonctionnelle impliquant l'approximation relativiste élevée de Stuttgart du potentiel effectif de coeur avec des ensembles doubles de bases zêta pour les orbitales de valence augmentées de deux fonctions de polarisation pour le soufre ainsi que le sélénium. On a réalisé des optimisations complètes de la géométrie pour chacun des trente isomères au niveau Hartree–Fock de la théorie. Les géométries optimisées ainsi que les vibrations fondamentales calculées et les intensités Raman des molécules de Se_nS_{8-n} sont en très bon accord avec les informations expérimentales disponibles. On a effectué des calculs de tenseur de blindage magnétique nucléaire en faisant appel à la méthode de l'orbitale moléculaire indépendante de Gauge, au niveau DFT, et à l'aide de trois paramètres fonctionnels hybrides avec corrélation de Perdew/Wang 91. Les tenseurs de blindage isotrope donnent une bonne corrélation avec les données de déplacements chimiques observés. Les déplacements chimiques observés fournissent une attribution définitive des données de spectroscopie RMN du ^{77}Se observées et peuvent être utilisés pour prédire les déplacements chimiques de molécules cycliques Se_nS_{8-n} inconnues.

Mots clés : sulfures de sélénium, ab initio, DFT, potentiels effectifs de coeur, optimisation de la géométrie, énergétiques, vibrations fondamentales, déplacements chimiques du ^{77}Se.

[Traduit par la Rédaction]

Introduction

It is well established that heteronuclear Se_nS_{8-n} ring molecules are formed in molten mixtures of sulfur and selenium or can be produced by a variety of synthetic routes (for a review see ref. 1). In most cases complicated molecular mixtures are formed, the characterization of which has turned out to be problematic. Because all crystal structures are disordered (2–11), X-ray crystallography has only demonstrated that the selenium sulfide phases contain crown-shaped ring molecules like S_8 (12–16) and Se_8 (17–20), but it has not been possible to identify individual molecular species or determine accurate bond parameters. Vibrational analysis has been used to assign the Raman spectra of 1,2,3-Se_3S_5 (8), 1,2,5,6-Se_4S_4 (9), and Se_7S (11) that are stoichiometrically pure or nearly so. While in more complicated mixtures it has not been possible to assign the Raman peaks to individual molecules, the force-field calculations have indicated the presence of Se—Se, Se—S, and S—S bonds in all sulfur-selenium mixtures even when the selenium content is low (21–24).

^{77}Se NMR spectroscopy is a powerful technique used to characterize selenium sulfide mixtures of complicated molecular composition (25–34). The assignment of the

^{77}Se NMR chemical shifts and the identification of individual Se_nS_{8-n} molecules have been based on the coupling information from the spectra of ^{77}Se-enriched samples (enrichment 92%) and the comparison of the enriched spectra with those from the natural-abundance samples where coupling information is only seen by the appearance of small satellites because of the low abundance of the ^{77}Se isotope. However, there remain several resonances in the ^{77}Se NMR spectra of the selenium sulfide phases, the assignment of which is only tentative (26).

While there are numerous MO calculations for S_8 at different levels of theory, the computational information for Se_8 is much sparser (see refs. 1, 35, and 36, and references therein). Theoretical studies of heterocyclic Se_nS_{8-n} mainly comprise the use of semi-empirical calculations in an attempt to assign the photoelectron spectrum of a binary selenium sulfide phase obtained from the equimolar melt (37), as well as the density functional calculations on geometries and the relative stabilities of the isomers of Se_2S_6 and Se_6S_2 (38). Recently we have explored the geometries and energetics of the whole series of thirty 8-membered selenium sulfide ring molecules by use of ab initio techniques involving split valence MIDI-4* basis sets for sulfur and selenium (39).

The goal of the present study is to gain theoretical support for the assignment of the ^{77}Se chemical shifts of the Se_nS_{8-n} ring molecules by MO techniques and to provide a definitive assignment for all the resonances observed by ^{77}Se NMR spectroscopy. Several theoretical calculations of ^{77}Se shielding constants and chemical shifts have been reported (see for instance refs. 40–42). It has been shown that accurate chemical shift calculations require large basis sets augmented by polarization functions with the effects of electron correlation taken into account. These kinds of calculations are very time consuming in the case of Se_nS_{8-n} molecules. Schreckenbach and Ziegler (43) have, however, demonstrated that the relative magnitudes of the ^{77}Se shielding tensors and chemical shifts can be calculated reliably using density functional theory and the frozen-core approximation. Se_nS_{8-n} ring molecules form a uniform homologous series (39), and the pseudopotential approach might well be suitable for extracting a definite interpretation of the ^{77}Se NMR spectrum of this complicated molecular system.

Calculations

The ab initio MO calculations of the 30 Se_nS_{8-n} ring molecules (see Table 1) have been carried out using the Stuttgart relativistic large core effective core potential approximation (RLC ECP) (44–46) by augmenting the double-zeta quality basis sets of the valence orbitals by two polarization functions (47). Full geometry optimizations and fundamental vibrations have been carried out at the RHF level of theory using gradient techniques. The fundamental vibrations and the zero point energies (ZPE) of the molecules were scaled by 0.8929 to eliminate systematic errors (48). The relative energies of the molecules were explored by calculating the total energies of the molecules at the DFT level of theory involving Becke's three-parameter hybrid functionals with the Perdew/Wang 91 correlation (B3PW91) (49–55) and using the HF-optimized geometries. The nuclear magnetic shielding tensor calculations were carried out using the Gauge-independent atomic orbital method (GIAO) (56–59) at the B3PW91 level of theory. All calculations were carried out with the GAUSSIAN 98 series of programs (60).

Results and discussion

Optimized geometries of Se_nS_{8-n}

The optimized bond lengths, bond angles, and dihedral angles of all 30 Se_nS_{8-n} molecules are presented in Table 2. The calculated S—S bond lengths range from 2.052 to 2.056 Å, the Se—S bond lengths show a range of 2.196–2.203 Å, and the Se—Se bonds vary between 2.332 and 2.338 Å. These values represent single bond lengths and are in excellent agreement with the experimental bond lengths in S_8 (12–16) and Se_8 (17–20). There is no experimental information of the bond lengths in heterocyclic Se_nS_{8-n} molecules. The calculated values, however, can be compared with the experimental Se—S bond lengths of 2.153(4)–2.181(3) Å observed in the $[(O_3S)SeS(SO_3)]^{2-}$ anion (61, 62).

The calculated bond angles of sulfur range from 107.33 to 108.03° and those of selenium from 104.91 to 105.85°. The torsional angles of all bonds in every molecule lie within a narrow range of 96.0 to 104.1°. Both the bond angles and

[a]The basis sets consist of the Stuttgart relativistic large core effective core potential approximation (RLC ECP) (44–46) with the double zeta quality basis sets for valence shell orbitals augmented by two polarization functions.
[b]The subscrift *n* denotes the number of selenium atoms in the molecule.
[c]Experimental bond parameters of S_8: $r_{S—S}$ = 2.023–2.060 Å, α_S = 105.8–109.0°, τ = 96.4–101.3° (12–16).
[d]Experimental bond parameters of Se_8: $r_{Se—Se}$ = 2.334–2.340 Å, α_S = 105.7–105.8°, τ = 101.0–101.4° (17–19).

the torsional angles also agree with the experimental values from S_8 (12–16) and Se_8 (17–20).

While our previous HF/MIDI-4* calculations slightly overestimate the chalcogen–chalcogen bond lengths (39), they are generally consistent with the present calculations for the Se_nS_{8-n} molecules.

Vibrational spectra of Se_nS_{8-n}

The calculated frequencies are all real, indicating that each molecule lies at a local energy minimum. The Raman spectra of S_8 (63), SeS_7 (23), 1,2,3-Se_3S_5 (8), 1,2,5,6-Se_4S_4 (9), Se_7S (11), and Se_8 (64) have been reported and can be compared with the calculated fundamental vibrations (see Table 3).

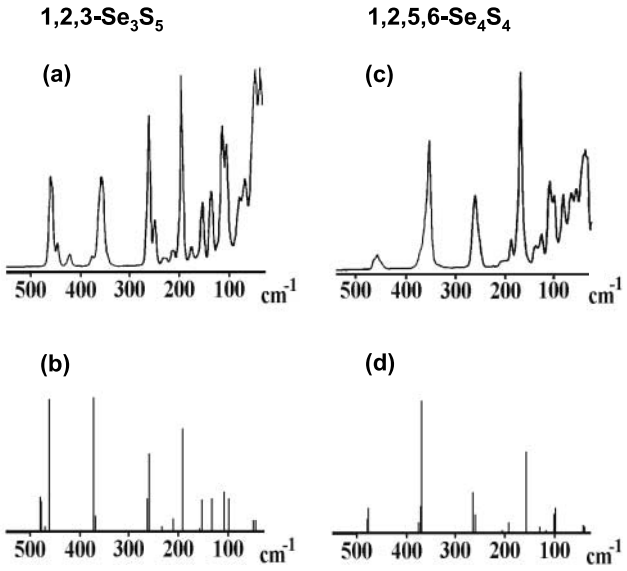
Fig. 1. (*a*) Observed Raman spectrum of 1,2,3-Se_3S_5.[8] (Adapted with permission by VCH-Wiley). (*b*) Calculated HF/RLC ECP frequencies and Raman intensities of 1,2,3-Se_3S_5. (*c*) Observed Raman spectrum of 1,2,5,6-Se_4S_4.[9] (Adapted with permission by American Chemical Society). (*d*) Calculated HF/RLC ECP frequencies and Raman intensities of 1,2,5,6-Se_4S_4.



It has been shown in Fig. 1 for 1,2,3-Se_3S_5 and 1,2,5,6-Se_4S_4 that there is a good agreement not only between the observed and HF/RLC ECP calculated frequencies but also between the observed and calculated Raman intensities. The spectral assignments obtained by the present calculations are also consistent with those based previously on the normal coordinate treatment (8, 22, 23). The calculated HF/RLC ECP fundamental vibrations can therefore form a basis for the assignment and identification of unknown eight-membered selenium sulfide ring molecules.

Energetics

The total energies of all Se_nS_{8-n} molecules are presented in Table 4. The total binding energies have been discussed at the B3PW91 level and are shown in Fig. 2. All molecules are stable with respect to free atoms. It can also be seen from Fig. 2 that the binding energy and therefore the stability of the species decrease with increasing selenium content. Qualitatively the predicted stabilities are consistent with those calculated previously at the MP2/MIDI-4* level of theory (39).

Compositions Se_2S_6, Se_3S_5, Se_4S_4, Se_5S_3, and Se_6S_2 lead to the possibility of isomerism. The relative stabilities of the different isomers can be calculated from B3PW91 total energies given in Table 4 and have been shown in Fig. 3. The zero-point energy and entropy contributions to relative energies are negligible. It can be seen that 1,2-Se_2S_6 (**A_2**), 1,2,3-Se_3S_5 (**A_3**), 1,2,3,4-Se_4S_4 (**A_4**), 1,2,3,4,5-Se_5S_3 (**A_5**), and 1,2,3,4,5,6-Se_6S_2 (**A_6**) are the most stable isomers within the given composition. They contain all selenium atoms and all sulfur atoms adjacent to each other, thereby maximizing the number of homonuclear bonds in the molecule and minimizing the number of heteronuclear Se—S bonds. This is in qualitative agreement with both the density functional

Fig. 3. Relative energies (in kJ mol^{-1}) of the different isomers of Se_2S_6, Se_3S_5, Se_4S_4, Se_5S_3, and Se_6S_2.

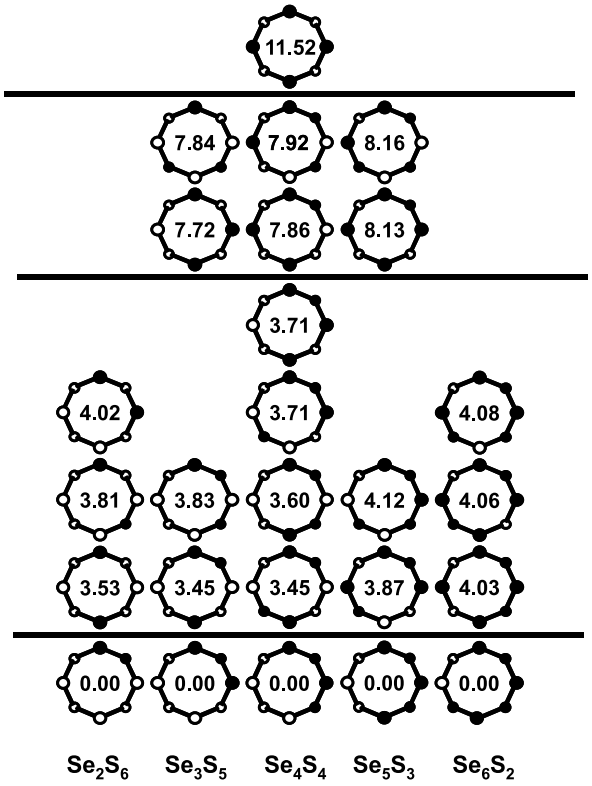

Fig. 4. The correlation of the calculated isotropic shielding tensors with the observed chemical shifts of Se_nS_{8-n} molecules for which the NMR spectroscopic information is unambiguous. The data points marked with ■ have been taken from ref. 26 and have been used in the least-squares fit. Those marked with ○ have been taken from refs. 9, 11, and 30, but they have not been used in the least-squares fit. The ^{77}Se chemical shifts are reported relative to neat Me_2Se ($\delta(Me_2Se) = \delta(SeO_2) + 1302.6$) (67).

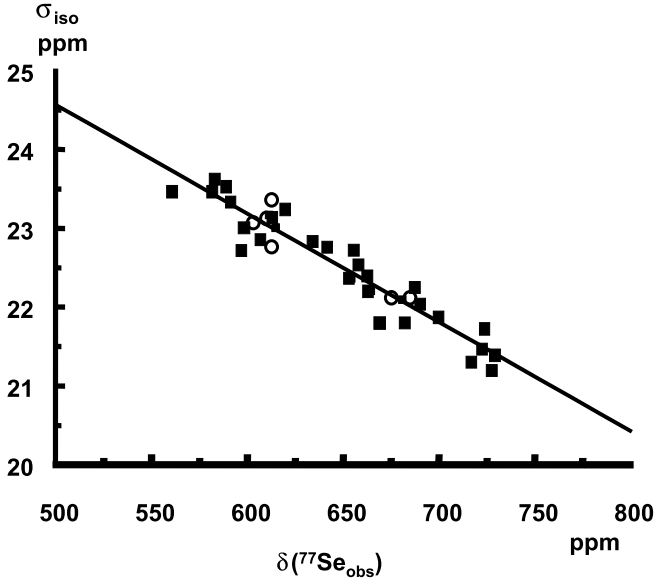

calculations on the energetics of Se_2S_6 and Se_6S_2 isomers (38) and our previous ab initio calculations on all Se_nS_{8-n} molecules (39). The highest relative stability of $\mathbf{A_2}$–$\mathbf{A_6}$ is also consistent with the Raman spectroscopic (21–24) and ^{77}Se NMR spectroscopic (26) observations that the most abundant species in the mixtures of eight-membered selenium sulfides have all selenium atoms and all sulfur atoms adjacent to each other.

The most stable isomers of Se_2S_6, Se_3S_5, Se_4S_4, Se_5S_3, and Se_6S_2 ($\mathbf{A_2}$–$\mathbf{A_6}$) each contain two heteronuclear Se—S bonds. It can be seen from Fig. 3 that the next most stable isomers (1,3-, 1,4-, and 1,5-isomers of Se_2S_6; 1,2,4- and 1,2,5-isomers of Se_3S_5; 1,2,3,5-, 1,2,3,6-, 1,2,4,5-, and 1,2,5,6-isomers of Se_4S_4; 1,2,3,4,6- and 1,2,3,5,6-isomers of Se_5S_3; 1,2,3,4,5,7-, 1,2,3,4,6,7-, and 1,2,3,5,6,7-isomers of Se_6S_2) each contain four Se—S bonds. They span a narrow energy range approximately 3.8(2) kJ mol^{-1} above the most stable isomer of the same chemical composition. An increment of ca. 4 kJ mol^{-1} is found in the energies of the isomers containing six Se—S bonds in the molecule (1,3,5- and 1,4,6-isomers of Se_3S_5; 1,2,4,6- and 1,2,4,7-isomers of Se_4S_4; 1,2,3,5,7- and 1,2,4,5,7-isomers of Se_5S_3). These isomers lie approximately 7.9(2) kJ mol^{-1} above the most stable isomers. The 1,3,5,7-Se_4S_4 isomer ($\mathbf{H_4}$), which contains eight Se—S bonds and lies 11.5 kJ mol^{-1} above the isomer $\mathbf{A_4}$, follows the same trend. These calculations indicate that the transformation of one Se—Se and one S—S bond into two Se—S bonds is an endothermic process with an energy difference of ca. 3.8 kJ mol^{-1}. It is in agreement with the earlier calculations (38, 39, 65) and is also consistent with the enthalpy of mixing of an equimolar sulfur–selenium melt of 1.3 kJ mol^{-1} (66) and with the reaction enthalpy of 5(3) kJ mol^{-1} (67), when 1 mol of $S_2(g)$ and $Se_2(g)$ is transformed into 2 mol of SeS(g). The maximum number of homonuclear bonds in the selenium sulfide rings can be rationalized by virtually identical electronegativities of sulfur and selenium, since the ionic contribution to heteronuclear bonding may be insufficient to compensate the orbital mismatch in size between sulfur and selenium.[2]

^{77}Se chemical shifts of Se_nS_{8-n}

The NMR shielding tensors of all selenium atoms in every Se_nS_{8-n} ring molecule have been calculated at the B3PW91 level using HF optimized geometries. While the present method does not provide for the absolute values of the shielding tensors, their relative values can be used to assign and predict the chemical shifts of Se_nS_{8-n} molecules that are a homologous series, the members of which have very similar molecular and electronic structures as well as chemical properties. The correlation between the calculated isotropic shielding tensors and the observed chemical shifts of the Se_nS_{8-n} molecules for which the chemical shift data are unambiguous (see ref. 26) is excellent, as shown in Fig. 4. The least-squares refinement of the calculated isotropic shielding tensors with the observed chemical shifts leads to the following relationship:

$$[1] \qquad \sigma_{iso} = -0.0138(8)\delta_{obs}(^{77}Se) + 31.5(5)$$

where σ_{iso} is the calculated B3PW91 isotropic shielding tensor and $\delta_{obs}(^{77}Se)$ is the observed chemical shift. The correlation

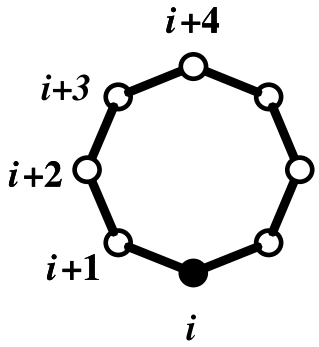
Fig. 5. The designation of the atomic positions relative to the active ^{77}Se nucleus.



coefficient of the least-squares fit is –0.952. The comparison of the calculated and observed chemical shifts is presented in Table 5.

While the coupling information observed in the ^{77}Se-enriched samples (enrichment 92%) could be used in the assignment of most resonances observed in the CS_2 solution of the quenched molten mixtures of sulfur and selenium to individual Se_nS_{8-n} molecules, several resonances appear as singlets even in the enriched samples, implying chemical and magnetic equivalence (26). The tentative assignment of these singlets was based on the resonances of the species that could be isolated, on the qualitative consideration of the trends in the chemical shifts, and on the relative intensities of the signals as a function of the selenium content in different samples (25, 26). In some cases alternative assignments were considered possible (26).

Table 6. Assignment of the singlets.

Molecule	Se atom position[a]	$\delta_{calc.}$ (ppm)[b]	δ_{trnd} (ppm)[c]	$\delta_{obs.}$ (ppm)[d,e]
SeS_7 (**A_1**)	1	696	699	699

1,3-Se_2S_6 (**B_2**)	1,3	717	713	717
1,4-Se_2S_6 (**C_2**)	1,4	729	719	729
1,5-Se_2S_6 (**D_2**)	1,5	669	693	687

[a]The numbering of the atoms starts from one selenium atom and proceeds around the ring molecule in such a fashion as to provide the lowest locants for all selenium atoms.
[b]The calculated chemical shifts have been obtained by the least-squares fit of the observed chemical shifts to the calculated isotropic shielding tensors. See Fig. 4 and eq. [1].
[c]The δ_{trnd} values have been calculated by using eq. [2] by considering the relative orientations of selenium and sulfur atoms in the molecules.
[d]The chemical shifts are reported relative to neat Me_2Se ($\delta(Me_2Se) = \delta(SeO_2) + 1302.6$) (67). [e]For observed chemical shifts see ref. 26.

A quantitative relationship between the chemical shifts ($\delta_{trnd}(^{77}Se)$) and the relative locations of the sulfur and selenium atoms in the eight-membered ring molecules has recently been derived (33):

$$[2] \qquad \delta_{trnd}(^{77}Se) = -66.6n_1 + 14.2n_2 + 19.7n_3 + 6.0n_4 + 699.0$$

where n_1 is the number of selenium atoms adjacent to the active selenium nucleus (i) and n_2, n_3, and n_4 are the number of selenium atoms in the i+2, i+3, and i+4 positions, respectively (see Fig. 5). The tentative assignment of most singlets

[a]The numbering of the atoms starts from one selenium atom and proceeds around the ring molecule in such a fashion as to provide the lowest locants for all selenium atoms.

[b]The calculated chemical shifts have been obtained by the least-squares fit of the observed chemical shifts to the calculated isotropic shielding tensors. See Fig. 4 and eq. [2].

(26) could be confirmed, but a revision in the assignment of the resonances to Se_2S_6 had to be made (33). Verna and Rauchfuss (32) also proposed a similar modification in the assignment of resonances to the Se_2S_6 isomers. It can be seen from Table 6 that our present B3PW91 calculations unambiguously verify the revised assignments.

The present calculations can also be used to predict chemical shift data for species the formation of which has not yet been observed. The predicted values are shown in Table 7.

Conclusions

Eight-membered selenium sulfide ring molecules Se_nS_{8-n} form a uniform homologous series with similar molecular and electronic structures. In this contribution we have demonstrated that Hartree–Fock calculations employing Stuttgart relativistic large core effective core potentials with double zeta quality basis sets for valence orbitals augmented by two polarization functions for both sulfur and selenium can efficiently be used in reliable geometry predictions of the molecules. The calculated fundamental vibrations and Raman intensities agree closely with experimental information where available and can be used in the identification of hitherto unknown molecular species, provided that they can be prepared stoichiometrically pure or nearly pure.

The energetics of the Se_nS_{8-n} molecules have been calculated at the B3PW91 level using HF-optimized structures. All molecules are stable with respect to free atoms, but the stability of the molecules decreases with increasing selenium content. It has also been shown that in the case of the existence of several isomers the most stable isomer contains all sulfur and all selenium atoms adjacent to each other, thereby maximizing the number of homonuclear bonds and minimizing the number of heteronuclear bonds. The stability of the isomers of a same molecular composition decreases with increasing number of Se—S bonds.

The GIAO calculations at the B3PW91 level using HF-optimized geometries provided isotropic shielding tensors that correlated well with the observed chemical shift data. The calculated values provided the unambiguous definite assignment of the observed ^{77}Se NMR spectroscopic data and can be used in the prediction of the chemical shifts of unknown Se_nS_{8-n} ring molecules.

Pentafluorophenyl and phenyl substituted azidoborates

Wolfgang Fraenk, Thomas M. Klapötke, Burkhard Krumm, Heinrich Nöth, Max Suter, Martin Vogt, and Marcus Warchhold

Abstract: The azidoborates $[(C_6F_5)_{4-n}B(N_3)_n]^-$ (n = 1–3) (**1**–**3**) were synthesized by reacting the corresponding borane with $[R]N_3$ (R = Me_4N, Ph_4P). To study the influence of the electron withdrawing C_6F_5-substituent on the boron atom, $[Me_4N][(C_6H_5)_3BN_3]$ (**4**) was also prepared. All compounds were fully characterized by IR, Raman, and multinuclear NMR spectroscopy in addition to characterization by single crystal diffraction analyses.

Key words: azidoborate, pentafluorophenyl, multinuclear NMR spectroscopy, X-ray crystallography.

Résumé : Les borates d'azide $[(C_6F_5)_{4-n}B(N_3)_n]^-$ (n = 1–3) (**1**–**3**) ont été synthétisé à l'aide de la réaction du borane correspondant avec les azides $[R]N_3$ (R = Me_4N, Ph_4P). Afin d'étudier l'influence de l'électron accepteur du substituant C_6F_5 sur l'atome du bore $[Me_4N][(C_6H_5)_3BN_3]$ (**4**) a été aussi préparé. Tous les produits ont été complètement caractérisé à l'aide de la spectroscopie multinucléaire RMN, IR, Raman, et de la diffraction des rayons X.

Mots clés : azidoborate, pentafluorophenyle, spectroscopie multinucleaire RMN, diffraction des rayons X.

Introduction

The preparation, chemistry, and thermal decomposition of boron azides R_2BN_3, diazides $RB(N_3)_2$, and their pyridine adducts R_2BN_3·py, $RB(N_3)_2$·py (R = organic substituent) is well established (1, 2). However, it is surprising that only a few examples of azido borates $R_{4-n}B(N_3)_n^-$ (n = 1–3, R = organic substituent) are known.

The first reported azidoborate was the $B(N_3)_4^-$ anion in the form of its lithium and sodium salts (3). It was obtained either by reacting $LiBH_4$ with an excess of HN_3 or by the reaction of $B(N_3)_3$ prepared in situ with NaN_3. Recently, we re-examined the highly energetic $B(N_3)_4^-$ anion and demonstrated that the tetraazidoborate anion can be synthesized in an alternative route by the reaction of $tmpB(N_3)_2$ (tmp = 2,2,6,6-tetramethylpiperidino) with 2 equiv of HN_3 (4). To our knowledge, $BCl_3N_3^-$ is the only well-investigated azido borate besides $B(N_3)_4^-$ (5). $[Me_4N][BCl_3N_3]$ was prepared by reacting $[Me_4N]N_3$ with BCl_3. To suppress competitive reactions (ligand exchange of $BCl_3N_3^-$ into $(BCl_2N_3)_3$ and BCl_4^-), it is absolutely necessary to avoid any excess of BCl_3. Apparently the $BF_3N_3^-$ anion shows a similar tendency to competing reactions, and therefore $BF_3N_3^-$ and $BF_2(N_3)_2^-$ were detected only by their ^{19}F NMR resonances (6).

We recently reported the irreversible dimerization of $(C_6F_5)_2BN_3$ (7), the reversible trimerization of $C_6F_5B(N_3)_2$ (8), as well as of *o*-difluorophenyl- and *o*-fluorophenyl substituted boron azides and diazides (9). Now we present the preparation and characterization of several pentafluorophenyl substituted azidoborates $[(C_6F_5)_{4-n}B(N_3)_n]^-$ (n = 1–3) (**1**–**3**). To investigate the electron withdrawing effect of C_6F_5 substituents on boron and the attached azide, we also prepared the $[(C_6H_5)_3BN_3]^-$ anion (**4**). The azidoborates were obtained in high yields by the reaction of $[R]N_3$ (R = Me_4N, Ph_4P) with the corresponding borane $(C_6F_5)_{3-n}B(N_3)_n$ (n = 0–2) or $(C_6H_5)_3B$, respectively. In addition to spectroscopic characterization (multinuclear NMR, IR, and Raman), the structures of all compounds have been confirmed by single crystal X-ray diffraction.

Results and discussion

As already mentioned, azidoborates are, in principle, accessible by two different methods. They can be prepared by the reaction of hydridoborates $[R_{4-n}BH_n]^-$ (n = 1–4; R = organic substituent) with HN_3 or by the reaction of boranes R_3B (R = organic substituent, halogen, azide, etc.) with ionic azides $[R]N_3$ (R = Na, K, Me_4N, etc.).

Because the first method requires a rather complicated synthesis of substituted hydridoborates, we decided to prepare the azidoborates **1**–**4** by the 1:1 reaction of $(C_6F_5)_{4-n}B(N_3)_n$ (n = 1–3) or Ph_3B with $[Me_4N]N_3$ (**1**, **4**) and $[Ph_4P]N_3$ (**2**, **3**) (eq. [1], [2]).

[1] $$(C_6F_5)_{4-n}B(N_3)_n + [R]N_3 \xrightarrow[CH_2Cl_2]{25°C} [R][(C_6F_5)_{4-n}B(N_3)_n]$$

(R = $[Me_4N]$, $[Ph_4P]$; n = 1–3 (**1**–**3**))

[2] $$(C_6H_5)_3B + [Me_4N]N_3 \xrightarrow[CH_2Cl_2]{25°C} [Me_4N][(C_6H_5)_3BN_3]$$

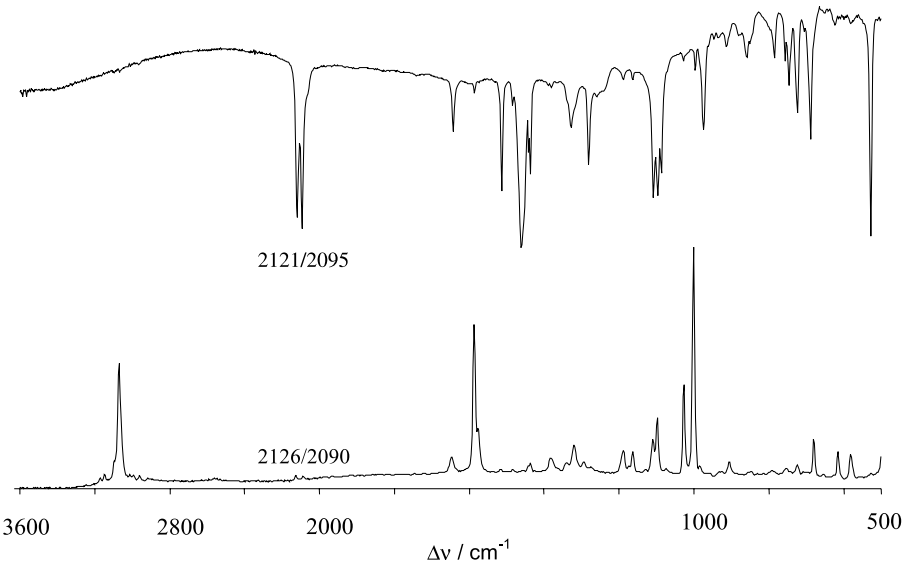
Fig 1. IR and Raman spectrum of $[Ph_4P][(C_6F_5)_2B(N_3)_2]$ (**2**).



The boron azides $(C_6F_5)_2BN_3$ and $C_6F_5B(N_3)_2$ were prepared by the reaction of the corresponding boron chloride with Me_3SiN_3 and were reacted with $[R]N_3$ (R = Me_4N, Ph_4P). The tetraphenylphosphonium cation was selected for **2** and **3** to guarantee solubility in common organic solvents.

All salts were obtained as colorless, non-explosive solids that decompose only slowly in air with the exception of the triazidoborate **3**. This observation is in agreement with the properties observed for $Ph_{3-n}B(N_3)_n$·py (n = 1–3) (1). In contrast to Ph_2BN_3·py and $PhB(N_3)_2$·py, the azide rich $B(N_3)_3$·py is highly sensitive towards moisture. Whereas **1**–**3** are readily soluble in CH_2Cl_2 and $CHCl_3$, **4** is soluble only in more polar solvents such as CH_3CN and DMSO.

Spectra

All azidoborates discussed here show the characteristic antisymmetric stretching vibration of the azide group ($\upsilon_{asym}N_3$) in the typical region for covalent boron azides, which is around 2120 cm^{-1} in the vibrational spectra. The IR spectra are dominated by a very strong absorption of $\upsilon_{asym}N_3$, whereas the Raman spectra show $\upsilon_{asym}N_3$ as a peak of very weak intensity. As in most other boron azides, $\upsilon_{sym}N_3$ cannot be definitely assigned. Figure 1 depicts the IR and Raman spectra of **2** as a representative example.

Azidoborates (**1**–**4**) can be well characterized by multinuclear NMR spectroscopy because all nuclei (^{11}B, ^{19}F, ^{14}N, ^{13}C, ^{1}H) are NMR active. The ^{11}B NMR resonances of **1**–**4** are shifted to a higher field, as expected, in comparison with the corresponding borane and are observed in the region of tetra-coordinated boron (δ = –9 to –1) (10). The largest high-field shifts are observed for **1** and **4** (Δ 67 and 69 ppm). The ^{11}B NMR nucleus of **4** (δ = –1.0) is deshielded compared with **1** (δ = –9.0). This can be explained by the increased shielding effect of the pentafluorophenyl groups. A high-field shift relative to the corresponding borane is also observed in the ^{19}F NMR spectra for the resonances of the *o*-fluorine atoms in **1**–**3**, which is generally found for adducts of pentafluorophenyl substituted boranes (8, 11–13). The ^{14}N NMR spectra show three well-resolved resonances for the nitrogen atoms of the covalently bound azide groups in the expected area (14). To determine one exact chemical shift, the ^{15}N NMR spectrum of **3** was additionally recorded over a longer period. The resonances were found at δ = –140.1 (N_β), –207.8 (N_γ), and –311.0 (N_α), which are in excellent agreement with the corresponding ^{14}N NMR data. The ^{13}C NMR spectra all show, in addition to the signals for the *o*-, *m*-, and *p*-carbon atoms of the C_6F_5 and C_6H_5 substituents, the B-C resonances as broad signals in the region of δ = 121–117. Characteristic data of the reported pentafluorophenyl substituted boron azides and triphenylazidoborate **4** are summarized in Table 1.

Crystal structures

In addition to characterization by multinuclear NMR and vibrational spectroscopy, the molecular structures of the azidoborates have been determined by single crystal X-ray crystallography. The crystallographic data for **1**–**4** are summarized in Table 3.

In all structures, the boron atom is surrounded by four substituents in a slightly distorted tetrahedral fashion, as is expected (Figs. 2–6).

The azidoborate anions and the $[Me_4N]$ and $[Ph_4P]$ cations are spatially separated and therefore no interactions exist. For **1**–**3** the B—N_α bond lengths range from 1.584(4) to 1.545(7) Å and are slightly longer than the corresponding distances found for the $B(N_3)_4^-$ anion (4). The azide unit is slightly bent (176.5(3)–174.6(4)°), as is typical for covalent azides, and the B-N-N angle is on an average 120°. The N_α—N_β bond lengths (1.220(5)–1.193(5) Å) are longer than the N_β—N_γ bond lengths (1.140(4)–1.132(4) Å), which show considerable N—N triple bond character. Selected bond lengths and angles of structurally characterized C_6F_5-substituted boron azides are summarized in Table 2.

The packing diagram of **3** (Fig. 5) allows for the rationalization of its high kinetic stability. Although **3** has three covalently bound azide groups, it is insensitive to electrostatic discharge, friction, and impact, in contrast to the explosive $[C_6F_5B(N_3)_2]_3$. This can be explained by the fact that the large and bulky $[Ph_4P]$ cations separate the $C_6F_5B(N_3)_3$ an-

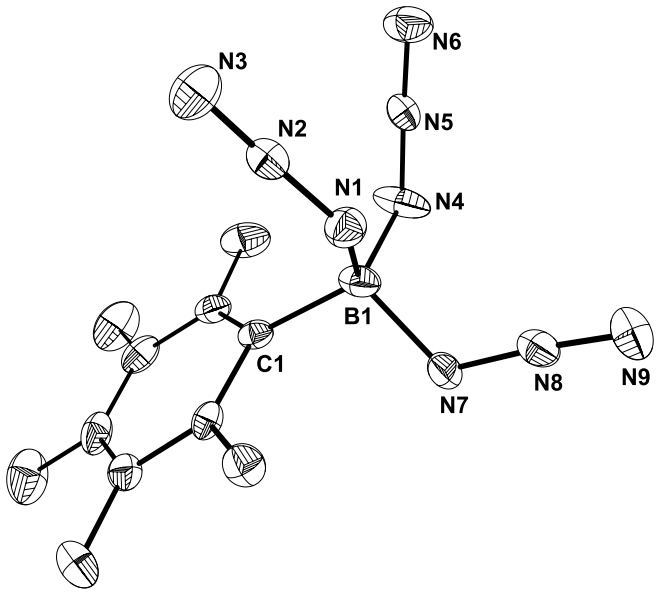

Fig 4. Molecular structure of the $[C_6F_5B(N_3)_3]$ anion of **3** with thermal ellipsoids drawn at the 25% probability level. The $[Ph_4P]$ cation is omitted for clarity. Selected bond lengths (Å) and angles (°): B(1)—N(1) 1.552(6), B(1)—N(4) 1.550(7), B(1)—N(7) 1.545(7), N(1)—N(2) 1.208(5), N(2)—N(3) 1.132(5), B(1)—C(1) 1.619(7); N(1)-N(2)-N(3) 174.6(4), B(1)-N(1)-N(2) 121.0(4), N(1)-B(1)-N(4) 109.9(4), N(1)-B(1)-N(7) 107.2(4), N(4)-B(1)-N(7) 106.6(4), N(1)-B(1)-C(1) 112.5(4), N(7)-B(1)-C(1) 107.0(4).

ions in the solid state and stop propagation of decomposition.

This observation has also been made for several binary azido-element anions such as $[Sn(N_3)_6]^{2-}$, $[Pb(N_3)_6]^{2-}$, $[As(N_3)_6]^-$, $[I(N_3)_2]^-$, and $[Au(N_3)_4]^-$ anions, which are kinetically stable as $[Ph_4P]$ and $[Ph_4As]$ salts despite possessing relatively high nitrogen contents (15–19).

Meanwhile, the results of a determination of the crystal structure of $[B(N_3)_4]^-$ as a tetraphenylphosphonium salt are also in agreement with the above species (20).

To investigate the difference between the C_6F_5- and the C_6H_5-substituents, the crystal structure of $[Me_4N][(C_6H_5)_3BN_3]$ (**4**) was determined (Fig. 6). The B(1)—N(1) distance is

Fig 5. View of the unit cell of **3** showing the separation of anion and cation.

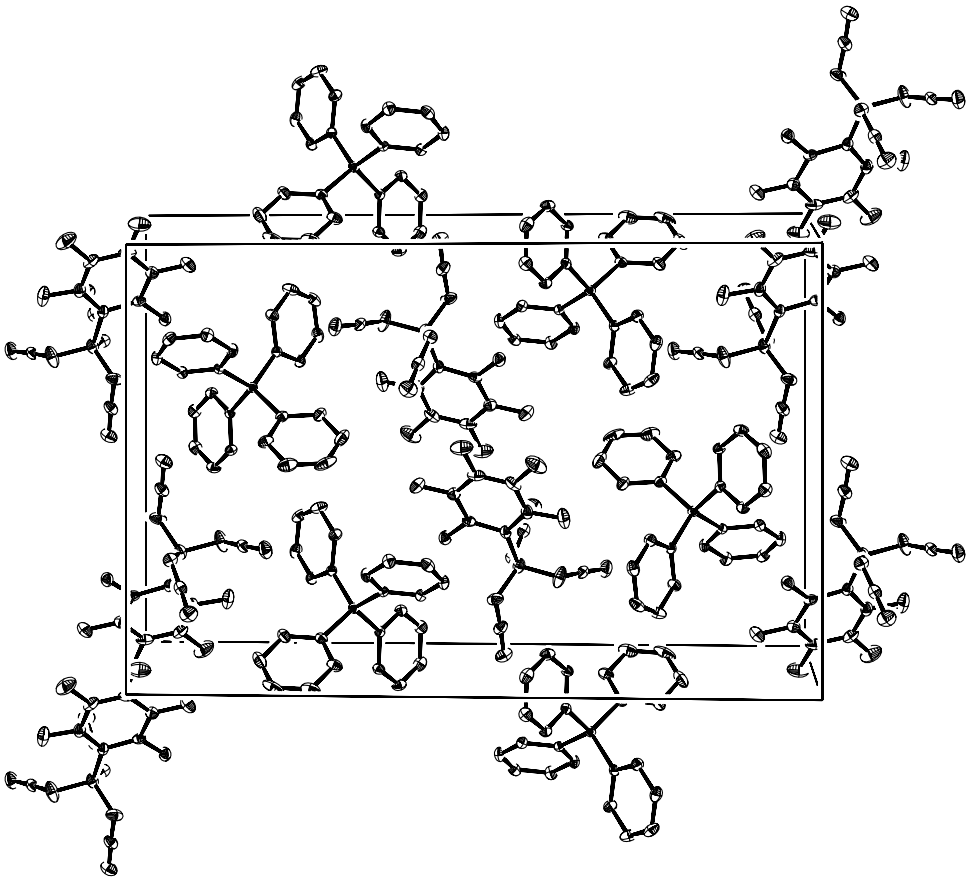

Fig 6. Molecular structure of the $[(C_6H_5)_3BN_3]$ anion of **4** with thermal ellipsoids drawn at the 25% probability level. The $[Me_4N]$ cation and hydrogen atoms are omitted for clarity. Selected bond lengths (Å) and angles (°): B(1)—N(1) 1.601(2), N(1)—N(2) 1.197(2), N(2)—N(3) 1.141(2), B(1)—C(1) 1.614(3), B(1)—C(7) 1.623(3); N(1)-N(2)-N(3) 176.3(2), B(1)-N(1)-N(2) 122.6(1), N(1)-B(1)-C(1) 104.9(1), N(1)-B(1)-C(7) 107.6(1), N(1)-B(1)-C(13) 109.0(1).

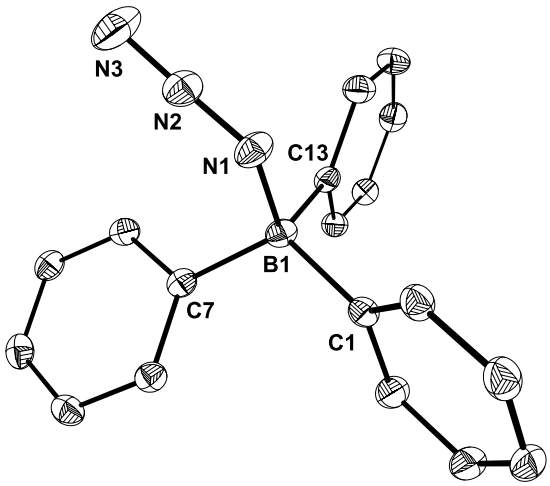

1.601(2) Å, slightly longer than the corresponding distance in **1** (1.584(4) Å). This can be explained by the fact that the electron withdrawing C_6F_5 substituents create a more Lewis acidic boron center than the C_6H_5 substituents, and therefore cause a shortening of the B—N_α bond length. In contrast, the N_α—N_β (1.197(2) and 1.206(4) Å) and N_β—N_γ (1.141(2) and 1.137(4) Å) bond lengths and the N-N-N (176.3(2) and 176.2(3)°) angles are almost identical.

Experimental

General

All manipulations of air- and moisture-sensitive materials were performed under an inert atmosphere of dry nitrogen using standard Schlenk techniques. Solvents were dried and degassed by standard methods prior to use. Raman spectra were recorded on a PerkinElmer 2000 NIR FT-Raman spectrometer fitted with a Nd-YAG laser (1064 nm) and infrared spectra on a PerkinElmer Spectrum One FT-IR spectrometer, as neat solids between KBr plates. The elemental analyses were performed with a C, H, N-Analysator Elementar Vario EL. NMR spectra were recorded on a JEOL Eclipse 400 instrument. Chemical shifts are recorded with respect to $(CH_3)_4Si$ (^1H, ^{13}C), $BF_3{\cdot}OEt_2$ (^{11}B), $CFCl_3$ (^{19}F), CH_3NO_2 (^{14}N), and H_3PO_4 (^{31}P). For the determination of the melting points, samples were heated in capillaries in a Büchi B540 instrument. C_6F_5H, C_6F_5Br, $[Me_4N]F$, $[Ph_4P]Br$, $AgNO_3$, Me_2SnCl_2, BCl_3 (1.0 M in hexane), Ph_3B, Me_3SiN_3, *n*-BuLi (2.5 M in hexane) were used as received (Aldrich, Fluka, FluoroChem). $[Me_4N]N_3$ (21), $[Ph_4P]N_3$ (22), $(C_6F_5)_2SnMe_2$

© 2002 NRC Canada

and $(C_6F_5)_2BCl$ (23), $C_6F_5BCl_2$ (11), and $(C_6F_5)_3B$ (12) were prepared as described in the literature.

X-ray crystallography

Data for **1**, **2**, and **4** were collected on a Siemens P4 instrument equipped with an area detector in the hemisphere mode, the data for **3** on a KappaCCD by using Mo Kα radiation. Data reduction was performed with the program SAINT. The structures were solved by direct methods (SHELXS-97 (24)) and data were refined by means of the full-matrix least squares on F^2 procedures using SHELXS-97 (Table 3).[2]

Preparations

Caution: Covalent azides are potentially explosive, AgN_3 is explosive; appropriate safety precautions are strongly advised.

$[Me_4N][(C_6F_5)_3BN_3]$ (1)

$[Me_4N]N_3$ (0.12 g (1.0 mmol)) was added to a stirred solution of 0.51 g (1.0 mmol) $(C_6F_5)_3B$ in 5 mL CH_2Cl_2 at ambient temperature. After stirring for 1 h the solvent was removed by vacuum evaporation. The remaining solid was purified by recrystallization from CH_2Cl_2 yielding **1** as colorless crystals. Yield: 0.50 g (80%); mp 179–180°C (decomp.).

$[Ph_4P][(C_6F_5)_2B(N_3)_2]$ (2)

To a stirred solution of 0.38 g (1.0 mmol) $(C_6F_5)_2BCl$ in 10 mL CH_2Cl_2, 0.15 mL Me_3SiN_3 (1.1 mmol) and 0.38 g (1.0 mmol) $[Ph_4P]N_3$ were added at –78°C. After stirring at ambient temperature for 1.5 h all volatiles were removed in vacuo leaving a colorless oil. The oil was purified by recrystallization from a mixture of CH_2Cl_2 and *n*-hexane (~1:20). Colorless crystals were isolated and dried in vacuo. Yield: 0.65 g (85%); mp 113–115°C.

Conclusion

The first organo-substituted azidoborates $[(C_6F_5)_{4-n}B(N_3)_n]^-$ (n = 1–3) (**1**–**3**) and $[(C_6H_5)_3BN_3]^-$ (**4**) were isolated in high yields in a one-pot synthesis and structurally characterized, by reacting the corresponding boranes with $[R]N_3$ (R = Me_4N, Ph_4P). In contrast to $BCl_3N_3^-$ and $BF_3N_3^-$, **1**–**4** showed no substituent exchange reaction. A comparison of the crystal structures of $[(C_6F_5)_3BN_3]^-$ (**1**) and $[(C_6H_5)_3BN_3]^-$ (**4**) showed that the electronegative C_6F_5-substituent causes a (slight) shortening of the B—N_α bond length. The spatial separation of the anion and the rather bulky tetraphenylphosphonium cation explains the stability of **3**.

Self-assembly using stannylplatinum(IV) halide complexes as ligands for organotin halides

Michael C. Janzen, Michael C. Jennings, and Richard J. Puddephatt

Abstract: The possibility of forming extended structures by self-association using transition metal halides as donors to organotin acceptors has been investigated. The stannylplatinum(IV) complex $[PtClMe_2(SnMe_2Cl)(bu_2bpy)]$ forms a 1:1 adduct $[PtClMe_2(SnMe_2Cl)(bu_2bpy)]\cdot Me_2SnCl_2$ with Me_2SnCl_2 in which the organoplatinum complex acts as a donor to the organotin halide. Similarly, $[PtClMe_2(SnMeCl_2)(bu_2bpy)]$ forms adducts $[PtClMe_2(SnMeCl_2)(bu_2bpy)]\cdot MeSnCl_3$ or $[PtClMe_2(SnMeCl_2)(bu_2bpy)]\cdot Me_2SnCl_2$, and $[\{PtClMe_2(bu_2bpy)\}_2(\mu\text{-}SnCl_2)]$ forms $[\{PtClMe_2(bu_2bpy)\}_2(\mu\text{-}SnCl_2)]\cdot Me_2SnCl_2$. Structure determinations on selected compounds show that the donor is the Pt-Cl group and the acceptor tin centre is 5-coordinate. In the similar bromo complex $[PtBrMe_2(SnMeBr_2)(bu_2bpy)]\cdot Me_2SnBr_2$ both the Pt-Br and PtSn-Br groups coordinate to the Me_2SnBr_2 acceptor with short (3.14 or 3.29 Å) and long (3.99 or 4.05 Å) contacts, respectively, so that the acceptor tin centre adopts distorted octahedral stereochemistry in the solid state and a folded polymeric structure is formed. Reaction of $[\{PtClMe_2(bu_2bpy)\}_2(\mu\text{-}SnCl_2)]$ with AgO_3SCF_3 yields the complex $[\{PtClMe_2(bu_2bpy)\}(\mu\text{-}SnCl_2)\{PtMe_2(bu_2bpy)O_3SCF_3\}]$, which is fluxional in solution.

Key words: platinum, tin, self-assembly, coordination chemistry, organometallics.

Résumé : On a étudié la possibilité de former des structures étendues par autoassociation en utilisant des halogénures de métaux de transition comme donneurs à des composés organostanniques agissant comme accepteurs. Le complexe stannylplatine(IV) $[PtClMe_2(SnMe_2Cl)(bu_2bpy)]$ et le Me_2SnCl_2 forment un adduit 1:1 $[PtClMe_2(SnMe_2Cl)(bu_2bpy)]\cdot Me_2SnCl_2$ dans le complexe organoplatine agit comme donneur pour l'halogénure d'organoétain. De la même manière, $[PtClMe_2(SnMeCl_2)(bu_2bpy)]$ forme les adduits $[PtClMe_2(SnMeCl_2)(bu_2bpy)]\cdot MeSnCl_3$ ou $[PtClMe_2(SnMeCl_2)(bu_2bpy)]\cdot Me_2SnCl_2$ alors que $[\{PtClMe_2(bu_2bpy)\}_2(\mu\text{-}SnCl_2)]$ forme $[\{PtClMe_2(bu_2bpy)\}_2(\mu\text{-}SnCl_2)]\cdot Me_2SnCl_2$. Des déterminations de structure effectuées sur des composés choisis montrent que le donneur est le groupe Pt-Cl et que le centre étain accepteur est pentacoordiné. Dans le complexe bromé semblable $[PtBrMe_2(SnMeBr_2)(bu_2bpy)]\cdot Me_2SnBr_2$ les deux groupes Pt-Br et PtSn-Br se coordonnent à l'accepteur Me_2SnBr_2 avec des contacts respectivement courts (3,14 ou 3,29 Å) et longs (3,99 ou 4,05 Å) qui font que le centre étain accepteur adopte une stéréochimie octaédrique déformée à l'état solide et qu'il y a formation d'une structure polymérique repliée. La réaction du $[\{PtClMe_2(bu_2bpy)\}_2(\mu\text{-}SnCl_2)]$ avec le AgO_3SCF_3 conduit à la formation du complexe $[\{PtClMe_2(bu_2bpy)\}_2(\mu\text{-}SnCl_2)\{PtMe_2(bu_2bpy)O_3SCF_3\}]$ qui, en solution, est en état de fluxion.

Mots clés : platine, étain, autoassemblage, chimie de coordination, organométalliques.

[Traduit par la Rédaction]

Introduction

The oxidative addition of the tin–halogen bond in organotin(IV) halides to transition-metal complexes is well established and provides an easy synthesis of stannylplatinum(IV) halides (1–7). For example, the oxidative addition of Me_3SnI to $[PtMe_2(bu_2bpy)]$ (**1**) (bu_2bpy = 4,4′-di-*tert*-butyl-2,2′-bipyridine) gives $[PtIMe_2(Me_3Sn)(bu_2bpy)]$ (1), which forms a complex $[PtIMe_2(SnMe_3)(bu_2bpy)]\cdot Me_3SnI$ by coordination of the Pt-I donor to the Me_3SnI acceptor, as shown in Scheme 1 (8). It was argued that the Pt-I group *trans* to Me_3Sn is polarized $Pt^{\delta+}\text{-}I^{\delta-}$, and as a result the iodide is a strong enough donor to form a complex with the weak acceptor Me_3SnI (9, 10). The platinum complex thus acts as a ligand for Me_3SnI through the Pt-I group.

Trimethyltin iodide is a tetrahedral monomer in the solid state, but many other organotin halides undergo self-association in the solid state (9–11). For example, Me_2SnCl_2 self-associates to form one-dimensional chains (Sn—Cl = 2.40(4) Å, Sn···Cl = 3.54(5) Å), and $MeSnCl_3$ also undergoes association by weak bridging through two of the three chlorine atoms (Sn—Cl = 2.283(2) Å, 2.318(1) Å; Sn···Cl = 3.714(2) Å) as illustrated in Chart 1 below (12, 13). The dimethyltin dihalides can also form adducts with one or two halide ions in which the tin centres adopt distorted trigonal bipyramidal or octahedral stereochemistry, respectively (Chart 1); they are stronger acceptors than the trimethyltin halides (14).

Based on the structures shown in Scheme 1 and Chart 1, it was considered possible that association between stannyl-

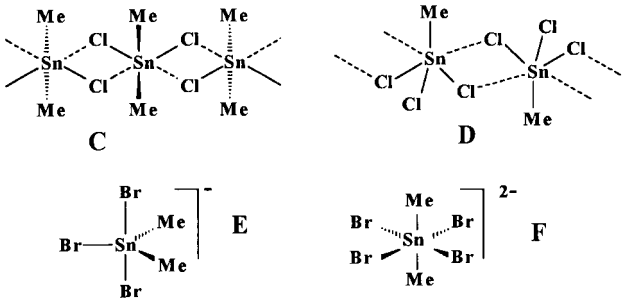
platinum(IV) complexes and excess Me_2SnX_2 (X= Cl, Br) or $MeSnCl_3$ could lead to new forms of supramolecular association through Pt-X···Sn and (or) PtSnX···Sn secondary bonding, and this paper reports the results of a systematic study of such systems.

Chart 1



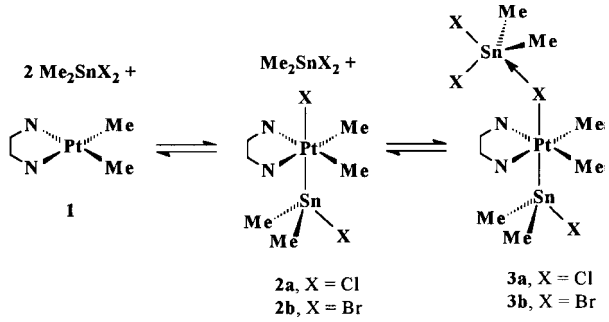
Results and discussion

Synthesis of the complexes

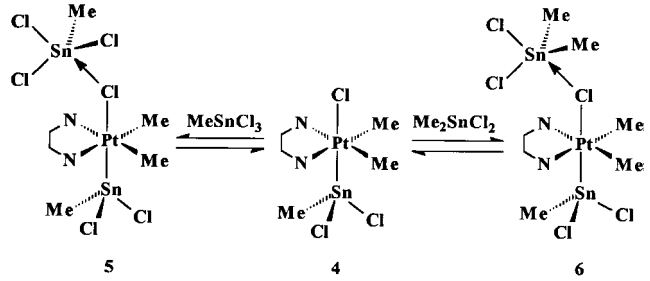
The reaction of complex **1** with Me_2SnX_2 gave the corresponding products of *trans* oxidative addition $[PtXMe_2(SnMe_2X)(bu_2bpy)]$ (**2a**: X = Cl, **2b**: X = Br), and crystallization in the presence of excess Me_2SnX_2 allowed isolation of the corresponding complexes $[PtXMe_2(SnMe_2X)(bu_2bpy)]\cdot Me_2SnX_2$ (**3a**: X = Cl, 3b:, X = Br) (Scheme 2). Similarly, reaction of **1** with $MeSnCl_3$ gave $[PtClMe_2(SnMeCl_2)(bu_2bpy)]$ (**4**), which could be crystallized with either $MeSnCl_3$ or Me_2SnCl_2 to give the complexes $[PtClMe_2(SnMeCl_2)(bu_2bpy)]\cdot MeSnCl_3$ (**5**) or $[PtClMe_2(SnMeCl_2)(bu_2bpy)]\cdot Me_2SnCl_2$ (**6**), respectively (Scheme 3). It was not possible to crystallize **2a** with $MeSnCl_3$, since a reaction occurred to give **4** with displacement of Me_2SnCl_2 from platinum.

In a similar way, crystallization of the μ-stannylene complex $[(\mu\text{-}SnCl_2)\{PtClMe_2(bu_2bpy)\}_2]$ (**7**) (2) with excess Me_2SnCl_2 yielded air-stable, colorless crystals of the complex $[(\mu\text{-}SnCl_2)\{PtClMe_2(bu_2bpy)\}_2]\cdot Me_2SnCl_2$ (**8**), as shown in Scheme 4. Although complex **7** contains two Pt-Cl groups that could act as ligands, it was not possible to crystallize a potential 1:2 complex $[(\mu\text{-}SnCl_2)\{PtClMe_2(bu_2bpy)\}_2]\cdot 2Me_2SnCl_2$.

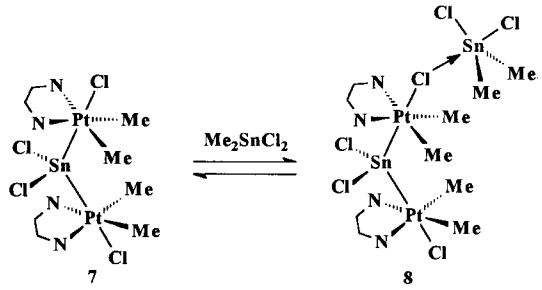
Scheme 2. NN = bu_2bpy.



Scheme 3. NN = bu_2bpy.



Scheme 4. NN = bu_2bpy.



In each case the adduct formation was reversible and the complexes existed in solution mainly in dissociated form at room temperature. For example, the ^1H NMR spectrum of **3a** at room temperature contained peaks assigned to the complex **2a** and free Me_2SnCl_2 (δ(MeSn) = 1.14, ^2J(SnMe) = 69 Hx) only, indicating effectively complete dissociation in solution. However, at lower temperatures there is an increase in the magnitude of the coupling constant ^2J(SnMe) for the Me_2SnCl_2 resonance (75 Hz at –2°C, 80 Hz at –67°C) indicating reversible coordination to the Me_2SnCl_2 that is more favorable at lower temperatures (8). At no temperature were separate signals for free and complexed Me_2SnCl_2 observed, indicating that exchange between free and complexed forms was rapid and making it difficult to determine the association constant. The adducts clearly must be characterized in the solid state by X-ray structure determinations, since the easy exchange, involving reversible addition of Me_2SnCl_2, makes solution characterization difficult.

One extreme formulation of the adducts is as complexes of 16-electron platinum(IV) complexes (15) with $[SnMe_xX_{5-x}]^-$ anions, and we have attempted to isolate further examples of

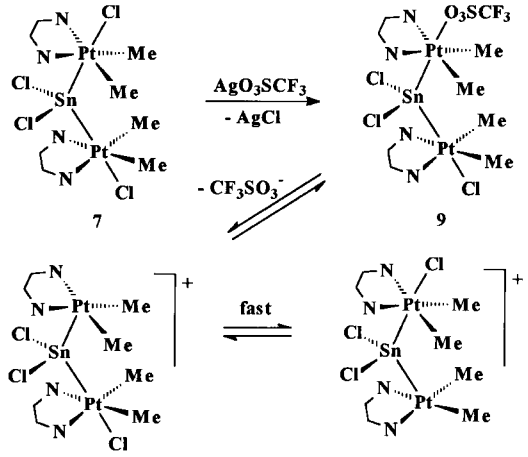
Scheme 5. NN = bu_2bpy.



the 16-electron complexes. In one case, a pure compound was isolated, but it could not be crystallized for structural characterization. Thus reaction of **7** with 1 equiv of silver triflate gave the corresponding triflate derivative [(μ-$SnCl_2$){$PtClMe_2(bu_2bpy)$}{$Pt(O_3SCF_3)Me_2(bu_2bpy)$}] (**9**) (Scheme 5). The ^{1}H NMR spectrum of **9** at room temperature contained only three aromatic bu_2bpy peaks, one *tert*-butyl peak, and one Pt-Me resonance. All peaks were broad, indicating fluxionality such that the two platinum centres become effectively equivalent through chloride for triflate exchange. At –80°C the ^{1}H NMR spectrum is very complex, indicating the presence of several complexes in equilibrium. In the solid state, the structure could be as shown in Scheme 5 but it could also be polymeric with intermolecular PtCl···Pt coordination and free triflate ions. The exchange in solution indicates very easy dissociation of triflate is possible, with subsequent chloride exchange giving effective twofold symmetry.

Structural chemistry

Complexes **5**, **6**, and **8** exist in the solid state as 1:1 complexes, as shown in Figs. 1–3, and relevant bond parameters are listed in Table 1. In each case, the chloride atom of the Pt-Cl group acts as a donor to the acceptor $MeSnCl_3$ in **5** or Me_2SnCl_2 in **6** or **8**, so that the organotin chloride has distorted trigonal bipyramidal stereochemistry. These structures therefore complement that found previously for a trimethyltin halide acceptor in [$PtIMe_2(Me_3Sn)(bu_2bpy)$]·Me_3SnI (Scheme 1) (8). The Pt—Sn bond lengths appear not to be greatly affected by adduct formation. For example, the Pt—Sn distances in complex **8** (2.5561(6) and 2.5479(6) Å) are similar to those in the parent complex **7** (2.5451(5) and 2.5386(6) Å),[2] and the distances in complexes **5** (2.5055(5) Å) and **6** (2.5011(6) Å) are similar to that in [$PtClMe_2(SnCl_2Ph)(bu_2bpy)$] (2.5186(6) Å) (2). They also fall in the range reported for other Pt—Sn bonded compounds (2.34–2.80 Å) (7).

Fig. 1. A view of the structure of complex **5**.

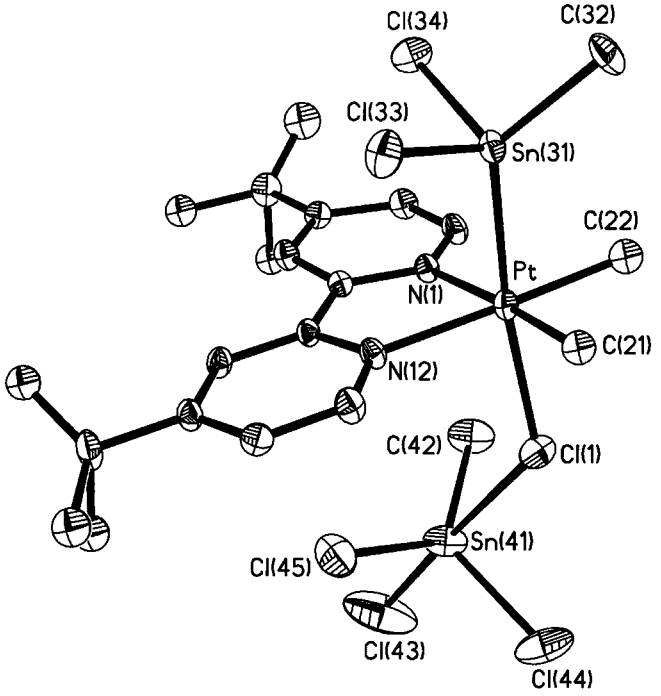


Fig. 2. A view of the structure of complex **6**.

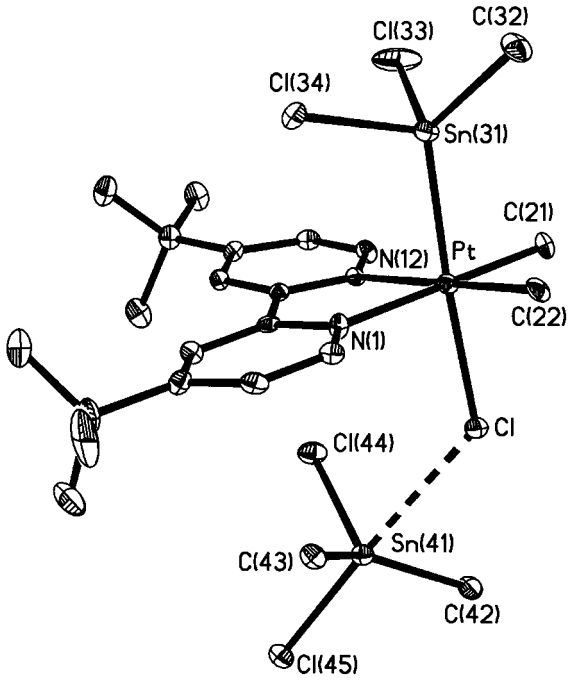

The main point of interest is the nature of the bridging chloride in the adducts. There are two extreme formulations possible, namely as 18-electron platinum complexes with weak Pt-X···Sn bonding or as weak complexes between a

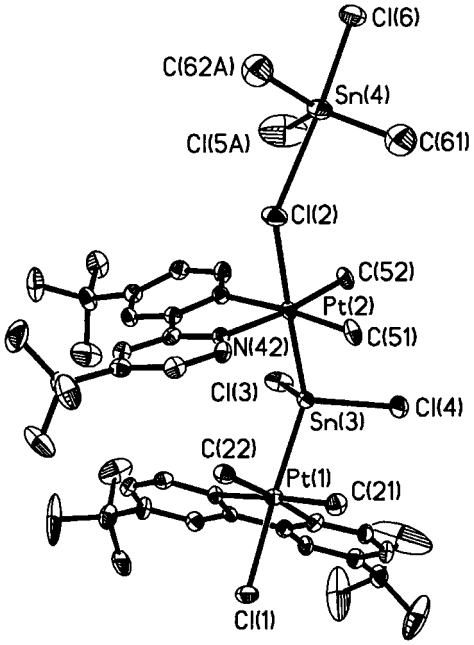
Fig. 3. A view of the structure of complex **8**.



16-electron platinum(IV) cation and the anionic tin halide complex $[Me_2SnCl_3]^-$ or $[MeSnCl_4]^-$. The first true 16-electron platinum(IV) complexes have been isolated recently (15). This issue is most readily addressed for complex **8**, since it contains Pt-Cl groups involved and not involved in coordination to tin, and axial Sn-Cl groups involved and not involved in coordination to platinum. The differences in bond lengths are *d*[Pt(2)Cl(2)] – *d*[Pt(1)Cl(1)] = 2.524(2) – 2.466(2) = 0.058 Å and *d*[Sn(4)Cl(2)] – *d*[Sn(4)Cl(6)] = 2.870(3) – 2.457(3) = 0.413 Å. It is clear that the formulation as 18-electron platinum complexes with weak Pt-X···Sn bonding is the correct one, based on this structural criterion, and it is also consistent with the solution properties discussed above. The Pt-Cl···Sn angles for the complexes fall in the narrow range 129–132° (Table 1).

The stereochemistry of the Cl···$SnMeCl_3$ unit of complex **5** is distorted trigonal bipyramidal with axial Cl.Sn-Cl and equatorial $SnMeCl_2$ groups. The equatorial substituents are displaced towards Cl(1) and away from Cl(43), as indicated by the angles Cl(1)Sn(41)C(42), Cl(1)Sn(41)Cl(44), Cl(1)Sn(41)Cl(45) = 83.3(3), 81.7(1), 84.8(1)° and Cl(43)Sn(41)C(42), Cl(43)Sn(41)Cl(44), Cl(43)Sn(41)Cl(45) = 97.1(3), 95.9(2), 97.0(2)°, respectively. The Sn—Cl bond distances follow the series bridging Sn—Cl (2.813(2) Å) >> axial Sn—Cl (2.365(3) Å) > equatorial Sn—Cl (2.319(3) Å, 2.311(3) Å). The Sn—Cl bond lengths in free $MeSnCl_3$ (2.283(2), 2.318(1) Å) are similar to the Sn—-Cl(equatorial) distances in **5**. The intermolecular Sn···ClSn bond distance in $MeSnCl_3$ (Chart 1, **D** (13)) is 3.714(2) Å and is significantly longer than the bridging Sn···Cl-Pt distance of 2.813(2) Å in complex **5**. There are no short intermolecular SnCl···Sn contacts involving the chloride ligands in the $PtSnMeCl_2$ and $MeSnCl_3$ groups in complex **5**. It is clear therefore that the Pt-Cl group is a stronger donor than the $SnMeCl_2$ group.

The Cl···$SnMe_2Cl_2$ units in complexes **6** and **8** have similar distorted trigonal bipyramidal stereochemistries at tin, with axial Cl···Sn-Cl and equatorial $SnMe_2Cl$ groups. The equatorial substituents are also displaced away from the terminal axial chloride and toward the more weakly bonding bridging chloride. For example, in **6** the angles Cl(45)Sn(41)C(42), Cl(45)Sn(41)C(43), and Cl(45)Sn(41)Cl(44) (99.4(2), 97.7(2), and 96.6(1)°, respectively) are all greater than 90°. The C-Sn-C angles for Me_2SnCl_2 in **6** (133.9(3)°) and **8** (126(1)°) are larger than the ideal angle of 120°, and the Cl···Sn-Cl bond angle (**6**, 177° (**6**), **8**, 175.90(9)° (**8**)) is close to linear in each complex. The order of the Sn—Cl bond lengths again follows the series: bridging chloride (3.04(1) Å (**6**), 2.870(3) Å (**8**)) >> axial chloride (2.457(3) Å (**6**), 2.428(2) Å (8)) > equatorial chloride (2.342(2) (**6**), 2.313(7) Å (**8**)). For comparison, the Sn—Cl distance in Me_2SnCl_2 is 2.40(4) Å and the intermolecular Sn···Cl distance is 3.54(5) Å (11). There are no short intermolecular SnCl···Sn contacts in complexes **6** and **8**, whereas such interactions in Me_2SnCl_2 give rise to the infinite chain structure **C** (Chart 1).

The structure of complex **3b** is of particular interest, and is shown in Fig. 4. Selected bond parameters are in Table 2. There are two independent molecules of $[PtBrMe_2(SnMe_2Br)(bu_2bpy)]$ and of Me_2SnBr_2 in the unit cell. The independent platinum complexes differ primarily

by rotation about the Pt—Sn bond, and the independent Me_2SnBr_2 molecules differ mostly by rotation about the bridging PtBr···Sn bond, as shown in Fig. 4*a*. There is a clear PtBr···Sn secondary bond to each molecule of Me_2SnBr_2 with distances Br(1)···Sn(60) and Br(2)···Sn(70) of 3.14 and 3.29 Å. There are also longer contacts between the bromide atoms of the $PtSnMe_2Br$ groups and the Me_2SnBr_2 groups. These distances Br(26)···Sn(70) and Br(56)···Sn(60) are 3.99 and 4.05 Å, which is marginally longer than the sum of the van der Waals radii of Br and Sn of 3.95 Å (16). The orientation of the SnBr···Sn groups is such that the bromide is directed towards the tin atom and essentially bisects the C-Sn-C angle of the Me_2SnBr_2 acceptor molecule. This orientation, observed in both independent units, suggests that there is an attraction involved but it must be a very weak one. To place these distances in perspective, the covalent bond distances are Sn(23)—Br(26) = 2.533(1) and Sn(53)—Br(56) = 2.557(1) Å for the $PtSnMe_2Br$ groups and for the Me_2SnBr_2 molecules, pseudo-axial Sn(60)—Br(63) = 2.558(1), Sn(70)—Br(74) = 2.587(1) Å and pseudo-equatorial Sn(60)—Br(64) = 2.492(1), Sn(70)—Br(73) = 2.499(1) Å. The differences between primary and secondary Sn—Br distances is then approximately 0.64 Å for the pseudo-axial bonds and 1.52 Å for the pseudo-equatorial bonds, again emphasizing that the PtBr···Sn secondary bonds are strong relative to the PtSnBr···Sn interactions. In the solid state structure of Et_2SnBr_2, the difference between primary and secondary Sn—Br distances is 1.27 Å, about midway between the values for the stronger and weaker secondary interactions in **3b**.

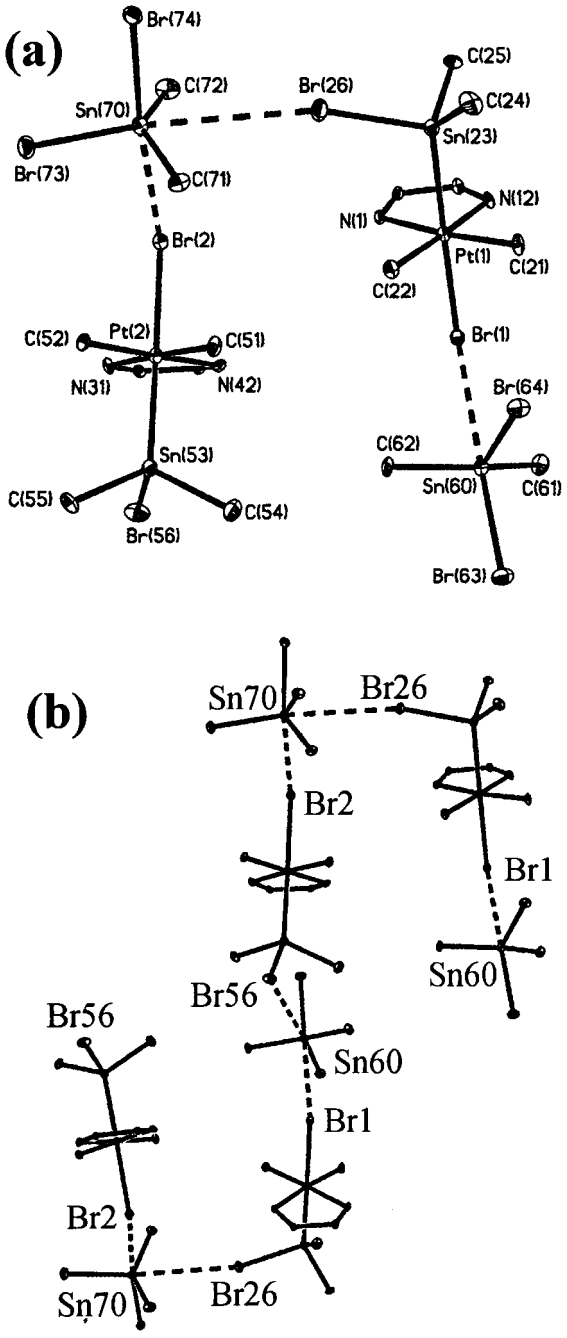
Another criterion for the strength of the secondary bonding is based on the stereochemistry at tin in the Me_2SnBr_2 acceptor molecules. In trigonal bipyramidal $[SnMe_2Br_3]^-$ the C-Sn-C angle is 133.2(8)°, whereas in octahedral $[SnMe_2Br_4]^{2-}$ the angle is 180° (14). In **3b**, the C-Sn-C angles are 131.9(3)° and 137.4(4)° for the two independent Me_2SnBr_2 acceptor molecules, very similar to the angle in the trigonal bipyramidal model compound. The analogous angle in the Me_2SnCl_2 complex (**6**) is 133.9(3)°, again very similar to the average C-Sn-C angle in **3b**. These data also indicate that the secondary SnBr···Sn bonding must be very weak, since the stereochemistry at the acceptor molecule is not significantly affected by it. If both types of secondary bonds are included, the solid state structure can be considered as a folded polymer, as illustrated in Fig. 4*b*.

Overall, it is clear that the secondary bonds formed by dimethyltin dihalide or methyltin trihalide acceptors can lead to supramolecular association and even to polymer formation in the solid state. At present, though, it is not easy to predict or control the degree of association. The secondary X···Sn bonds are weak coordinate bonds, and they appear to have similar energies to hydrogen bonds, aryl–aryl secondary bonds, or aurophilic attractions that have been used more extensively in supramolecular chemistry for assembling complex organometallic structures (11, 17). There is therefore a clear potential for further expansion of this field of research.

Experimental

NMR spectra were recorded by using Varian Mercury 400 or Inova 600 MHz spectrometers. Chemical shifts are reported in ppm with respect to TMS (^{1}H) reference. Unless otherwise specified, all quoted couplings to tin are for the ^{119}Sn isotope only. $[PtMe_2(bu_2bpy)]$ (18) and $[(PtClMe_2bu_2bpy)_2(\mu\text{-}SnCl_2)]$ (2) were prepared according to the literature procedures.

Fig. 4. Views of the structure of complex **3b**: (*a*) the two independent units $[PtBrMe_2(SnMe_2Br)(bu_2bpy)]\cdot Me_2SnBr_2$; (*b*) part of the folded polymeric structure formed by secondary Br···Sn bonding. Only the inner atoms of the bu_2bpy ligands are shown for clarity.



$[PtClMe_2(SnMe_2Cl)(bu_2bpy)]\cdot Me_2SnCl_2$ (3a)

An NMR tube was charged with **1** (40 mg, 0.081 mmol), Me_2SnCl_2 (178 mg, 0.810 mmol), and CH_2Cl_2 (0.5 mL). After 5 min, pentane was slowly layered on top of the solution

and the sample stored at –5°C. After several days colorless crystals suitable for X-ray crystallographic studies were formed. Yield 72%. ^{1}H NMR ($CDCl_3$) δ: 8.76 (d, 2H, $^3J_{H6H5}$ = 6 Hz, $^3J_{PtH6}$ = 16 Hz, H-6, 8.11 (d, 2H, $^4J_{H3H5}$ = 1.5 Hz, H-3), 7.60 (dd, 2H, $^3J_{H5H6}$ = 6 Hz, $^4J_{H5H3}$ = 1.5 Hz, H-5), 1.43 (s, 18H, *t*-bu), 1.32 (s, 6H, $^2J_{PtMe}$ = 55 Hz, Pt-Me), 1.18 (s, 6H, $^2J_{SnH}$ = 68.5 Hz, free Me_2SnCl_2), 0.38 (br s, 6H, $^2J_{SnH}$ = 50 Hz, Sn-Me). Anal. calcd. for $C_{24}H_{42}Cl_4N_2PtSn_2$ (%): C 30.90, H 4.54, N 3.00; found: C 30.77, H 4.46, N 2.94.

[PtBrMe$_2$(SnMe$_2$Br)(bu$_2$bpy)]·Me$_2$SnBr$_2$ (3b)

This was prepared similarly but using Me_2SnBr_2 in place of Me_2SnCl_2. Yield 74%. ^{1}H NMR ($CDCl_3$) δ: 8.78 (d, 2H, $^3J_{H6H5}$ = 4.5 Hz, $^3J_{PtH6}$ = 16 Hz, H-6), 8.11 (d, 2H, $^4J_{H3H5}$ = 1 Hz, H-3), 7.60 (dd, 2H, $^3J_{H5H6}$ = 4.5 Hz, $^4J_{H5H3}$ = 1 Hz, H-5), 1.43 (s, 18H, *t*-bu), 1.42 (s, 6H, $^2J_{PtMe}$ = 56 Hz, Pt-Me), 1.34 (s, 6H, $^2J_{SnH}$ = 65 Hz, free Me_2SnBr_2), 0.46 (br s, 6H, $^2J_{SnH}$ = 49 Hz, Sn-Me). Anal. calcd. for $C_{24}H_{42}Br_4N_2PtSn_2$ (%): C 25.95, H 3.81, N 2.62: found: C 26.05, H 3.89, N 2.63.

[PtClMe$_2$(SnMeCl$_2$)(bu$_2$bpy)]·MeSnCl$_3$ (5)

This was prepared similarly from **1** (40 mg, 0.081 mmol), $MeSnCl_3$ (195 mg, 0.810 mmol), and CH_2Cl_2 (0.5 mL). Yield 68%. ^{1}H NMR ($CDCl_3$) δ: 8.74 (d, 2H, $^3J_{H6H5}$ = 6 Hz, $^3J_{PtH6}$ = 15 Hz, H-6), 8.43 (d, 2H, $^4J_{H3H5}$ = 2 Hz, H-3), 7.72 (dd, 2H, $^3J_{H5H6}$ = 6 Hz, $^4J_{H5H3}$ = 2 Hz, H-5), 1.67 (s, 6H, $^2J_{SnH}$ = 99 Hz, free $MeSnCl_3$), 1.48 (s, 18H, *t*-bu), 1.45 (s, 6H, $^2J_{PtMe}$ = 56 Hz, Pt-Me), 1.03 (s, 3H, $^2J_{SnH}$ = 52 Hz, Sn-Me). Anal. calcd. for $C_{22}H_{36}Cl_6N_2PtSn_2$ (%): C 27.14, H 3.73, N 2.88; found: C 27.07, H 3.65, N 2.77.

[PtClMe$_2$(SnMeCl$_2$)(bu$_2$bpy)]·Me$_2$SnCl$_2$ (6)

This was prepared similarly from **1** (40 mg, 0.081 mmol), $MeSnCl_3$ (20 mg, 0.081 mmol), and CH_2Cl_2 (0.5 mL) followed by addition of Me_2SnCl_2 (89 mg, 0.405 mmol). Yield 77%. ^{1}H NMR ($CDCl_3$) δ: 8.74 (d, 2H, $^3J_{H6H5}$ = 6 Hz, $^3J_{PtH6}$ = 15 Hz, H-6), 8.43 (d, 2H, $^4J_{H3H5}$ = 2 Hz, H-3), 7.72 (dd, 2H, $^3J_{H5H6}$ = 6 Hz, $^4J_{H5H3}$ = 2 Hz, H-5), 1.48 (s, 18H, *t*-bu), 1.45 (s, 6H, $^2J_{PtMe}$ = 56 Hz, Pt-Me), 1.18 (s, 6H, $^2J_{SnH}$ = 68 Hz, free Me_2SnCl_2), 1.03 (s, 3H, $^2J_{SnH}$ = 52 Hz, Sn-Me). Anal. calcd. for $C_{23}H_{39}Cl_5N_2Pt$ (%): C 28.98, H 4.12, N 2.94; found: C 28.90, H 4.06, N 2.88.

[(PtClMe$_2$bu$_2$bpy)$_2$(μ-SnCl$_2$)]·Me$_2$SnCl$_2$ (8)

This was prepared similarly from complex **9** (45 mg, 0.035 mmol), Me_2SnCl_2 (38 mg, 0.175 mmol), and CH_2Cl_2 (0.5 mL). Yield 83%. ^{1}H NMR ($CDCl_3$) δ: 8.69 (d, 2H, $^3J_{H6H5}$ = 6 Hz, $^3J_{PtH}{}^6$ = 16 Hz, H-6), 8.07 (d, 2H, $^4J_{H3H5}$ = 1 Hz, H-3), 7.55 (dd, 2H, $^3J_{H5H6}$ = 6 Hz, $^4J_{H5H3}$ = 1 Hz, H-5), 1.40 (s, 36H, *t*-bu), 1.36 (br s, 12H, $^2J_{PtMe}$ = 59 Hz, Pt-Me), 1.18 (s, 6H, $^2J_{SnH}$ = 68 Hz, free Me_2SnCl_2). Anal. calcd. for $C_{43}H_{66}Cl_6N_4Pt_2Sn_2$.pentane (%): C 36.67, H 5.11, N 3.64; found: C 36.75, H 5.18, N 3.70.

(PtClMe$_2$bu$_2$bpy)(μ-SnCl$_2$)(PtMe$_2$bu$_2$bpy)(CF$_3$SO$_3$) (9)

To a solution of **9** (100 mg, 0.078 mmol) in CH_2Cl_2 (10 mL) was added AgO_3SCF_3 (20 mg, 0.078 mmol), and the mixture was stirred for 30 min in the dark. The solution was filtered through dry celite to remove AgCl. Pentane (40 mL) was added to the filtrate to precipitate the product, which was isolated by filtration, washed with pentane, and dried in vacuo. Yield 88%. ^{1}H NMR ($CDCl_3$) δ: 8.55 (br d,

X-ray structure determinations

Crystals were mounted on glass fibers. Data were collected by using a Nonius Kappa-CCD diffractometer with COLLECT (Nonius, 1998) software. Crystal cell refinement and data reduction were carried out using the Nonius DENZO package. The data were scaled using SCALEPACK (Nonius, 1998), and no other absorption corrections were applied. The SHEXTL 5.1 (G.M. Sheldrick, Madison, Wisc.) program was used to solve the structures by direct methods, followed by refinement by successive difference Fouriers. For complex **5** the *tert*-butyl groups were modeled as two half-occupancy isotropic groups. For **8** there was disorder at the $SnMe_2Cl_2$ acceptor, and atoms Cl(5) and C(62) were disordered across their two positions. This disorder was modeled as 50% of each atom type with the Sn—Cl (2.39 Å) and Sn—C (2.13 Å) distances being fixed. Crystal and refinement data are listed in Table 3.

Syntheses and structures of bis(imido)organophosphine dianions

Kevin S. Jack, John C. Jeffery, Angela P. Leedham, Jason M. Lynam, Michael Niedzwiecki, and Christopher A. Russell

Abstract: A bis(imido)phosphine dianion, $[R'P(NR)_2]^{2-}$ (R′ = *n*-Bu, R = N-N=CPh_2) is produced from the reaction of PCl_3 with benzophenone hydrazone (1:3 equiv) in THF–NEt_3, followed by metallation of the reaction mixture with 3 equiv *n*-BuLi. A more straightforward synthesis of a comparable dianion (with R′ = Ph, R = N-N=CPh_2) is the reaction of $PhPCl_2$ with benzophenone hydrazone (1:2 equiv) in THF–NEt_3, followed by metallation of the reaction mixture with 2 equiv *n*-BuLi.

Key words: phosphorus, lithium, imido, complexes, X-ray.

Résumé : Un dianion bis(imido)phosphines, $[R'P(NR_2)_2]^{2-}$ (R′ = *n*-Bu, R = N-N=CPh_2) est obtenu par une réaction du PCl_3 avec l'hydrazone de la benzophénone (1:3 équivalents), dans un mélange de THF–NEt_3, suivie d'une métallation du mélange réactionnel à l'aide de trois équivalents de *n*-BuLi. La synthèse d'un anion comparable (avec R′ = Ph, R = N-N=CPh_2) peut être réalisée plus facilement par réaction du $PhPCl_2$ avec l'hydrazone de la benzophénone (1:2 équivalents), dans le THF–NEt_3, suivie d'une métallation du mélange réactionnel à l'aide de deux équivalents de *n*-BuLi.

Mots clés : phosphore, lithium, imido, complexes, rayons X.

[Traduit par la Rédaction]

Introduction

Our recent studies have focussed upon the preparation of a family of ligands that are imido main group anions. Besides our own contributions to this rapidly developing area of main group chemistry, other distinguished scientists (such as Bailey, Chivers, Stalke, and Wright) have been instrumental in developing routes towards, and investigating the properties of, similar imido *p*-block anions; this area has recently been the subject of two review articles (1, 2). Many of the compounds that have been prepared are imido analogues of classical *p*-block oxoanions and several have the potential to act as ambidentate ligands. Four main synthetic strategies have been employed in the preparation of such anions.

Firstly, mixed metallation using alkyllithium and *p*-block dimethylamido reagents (notably $Sn(NMe_2)_2$, $As(NMe_2)_3$, $Sb(NMe_2)_3$, and $Bi(NMe_2)_3$) has been used extensively by Wright and co-workers (3) in the preparation of both imido and the related phosphinidene (RP^{2-}) anions of heavy group 14 and 15 elements.

Secondly, nucleophilic addition of lithium salts of primary amines to group 16 imines has been employed in the groups of Chivers and co-workers (2) and Stalke and co-workers (4) to generate imido analogues of group 16 oxoanions.

Thirdly, reaction of dilithium salts of primary amines with *p*-block element halides has been used by Chivers and co-workers (5) to prepare the imido analogue of the silicate tetraanion.

Fourthly, our own preferred method involves amination of a *p*-block element halide followed by metallation using an alkyllithium base to make an imido anion (1). As part of these investigations, we reported the preparation of the imido analogue of the phosphite dianion, $[HP(NR)_3]^{2-}$ (R = 2-methoxyphenyl) as a dilithium salt from the reaction of PCl_3 with 3 equiv of 2-methoxyaniline in THF–NEt_3, followed by metallation with *n*-BuLi (2 equiv) (6). We postulated that the product arose from a proton shift from an amide (N(H)R) group to the phosphorus center upon metallation of the proposed $E(N(H)R)_3$ intermediate. Our studies into related reactions using hydrazones in place of primary amines has inadvertently introduced to us a new direction that leads to this current report.

Results and discussion

Reaction of PCl_3 with benzophenone hydrazone (1:3 equiv) in THF–NEt_3, followed by metallation of the reaction mixture with 3 equiv *n*-BuLi produces $[Li_2$-*n*-$BuP(NR)_2]_2{\cdot}4THF$ (**1**), as shown in Scheme 1. Attempts to prepare and isolate the tris(amino)phosphine, $P(Ph_2C{=}N\text{-}N(H))_3$, and then investigate comparable metallation reactions have proved unsuccessful. Presumably, complex **1** results from one of two pathways: either amination in the first step is incomplete giving $ClP(N(H)R)_2$ (reaction of this with

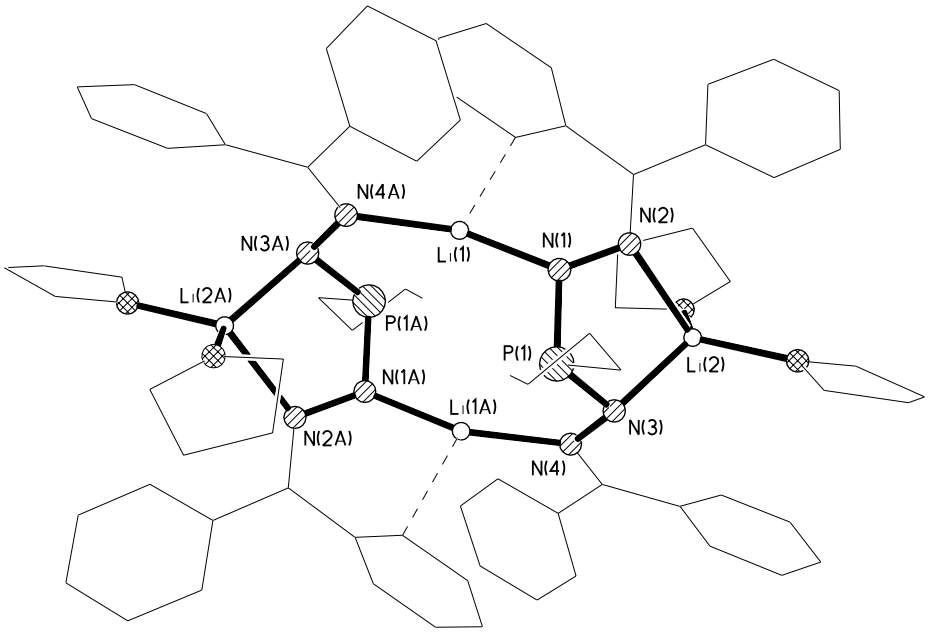
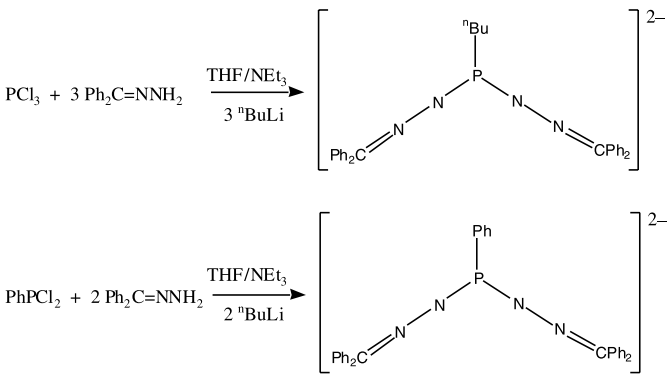
Fig. 1. The crystal structure of **1**. Hydrogen atoms have been omitted for clarity.



Scheme 1.



n-BuLi would be expected to deprotonate the amido protons and to eliminate LiCl to produce **1**), or alternatively, the *n*-BuLi may act as both a nucleophile and a base and may substitute an amide group of a fully aminated intermediate, $P(Ph_2C{=}N\text{-}N(H))_3$, which accompanied by metallation of the remaining amide protons would produce **1**.

We then devised a more logical and controlled synthetic route to comparable bis(imido)phosphine dianions (Scheme 1). This was achieved by the straightforward reaction of $PhPCl_2$ with benzophenone hydrazone (1:2 equiv) in THF–NEt_3, followed by metallation of the reaction mixture with 2 equiv *n*-BuLi, giving $[Li_2PhP(NR)_2]_2{\cdot}6THF$ (**2**) in good yield.

Complexes **1** and **2** are closely related to the bis(amido)organophosphine dianions recently reported by Nöth and co-workers (7). They prepared the complexes $[Li_2R'(P(NR)_2)]_n{\cdot}L_x$ ((**3**): R′ = *n*-Bu, R = *t*-Bu, L = OEt_2, *n* = 2, *x* = 2; (**4**): R′ = Ph, R = *t*-Bu, *n* = 2; (**5**): R′ = R = Ph, L = OEt_2, *n* = 2, *x* = 4; (**6**): R′ = Me, R = *i*-Pr, *n* = 4) as lithium salts by reaction of the bis(amino)organophosphine with *n*-butyllithium. Complexes **4**–**6** were synthesized by metallation of the parent bis(amino)organophosphine, whereas complex **3** was prepared by the substitution of the mesityl group of $mesP(N(H)t\text{-}Bu)_2$ by the butyl moiety.

Complexes **1** and **2** were initially characterised using ^1H, ^{31}P, and ^7Li NMR spectroscopy, IR spectroscopy, and elemental analyses. The lack of an N-H stretch in the IR spectra of **1** and **2** showed that all the N-bound protons of the hydrazone had been removed in each case. The ^{31}P NMR spectrum revealed singlet resonances at δ = 64.5 for **1** and 61.4 for **2**. More intriguingly, the ^7Li spectra for **2** showed one resonance if carried out in a polar solvent (δ = 2.1 in D_5-pyridine) but two resonances if carried out in a non-polar solvent (δ = 0.3 and –0.3 in D_8-toluene). This was taken to imply that either the compound is ion-separated in a polar solvent but ion-contacted in a non-polar solvent, or the degree of oligomerisation was variable in different solvents. To confirm these assignments and to explore further features of these molecules we undertook low-temperature single crystal X-ray diffraction studies. The crystal structures of **1** and **2** are illustrated in Figs. 1 and 2, and key bond lengths and angles are given in Tables 1 and 2, respectively.

Complexes **1** and **2** crystallize in essentially isostructural forms as centrosymmetric dimers, although complex **2** contains an additional molecule of lattice THF per monomer unit. Each dimeric molecule contains two bis(imido)organophosphine dianion units that are linked by two "bridging" lithium cations. An additional lithium cation is bound to each dianion unit in a "terminal" mode and plays no obvious role in holding the dimeric units together in the solid state. The phosphorus atoms of the bis(imido)organophosphine dianions are bound in distorted pyramidal geometries to a single organic moiety (*n*-Bu for **1**, Ph for **2**) and approximately equally to two benzophenone hydrazone units (P—N = 1.7038(18) and 1.7129(19) Å for **1**; 1.6883(13) and 1.7069(14) Å for **2**).

The "bridging" lithium cations exhibit the relatively rare two-coordinate bent geometry (N-Li-N = 153.0(2)° for **1;** N-Li-N = 152.70(17)° for **2**), coordinating asymmetrically to

the two bis(imido)organophosphine dianion units (Li—N = 1.935(4) and 2.079(3) Å in **1**; 1.937(3) and 2.053(4) Å in **2**). The asymmetry can be rationalized, as one of the nitrogen centers formally possesses a negative charge (and hence forms relatively short bonds with a strong ionic contribution) whereas the other nitrogen atom is formally saturated and hence forms a longer donor bond. There are long-range contacts in complex **1** between this lithium center and the *ortho*-carbon of one of the phenyl rings. In complex **2**, this lithium center has an η^2- contact with two of the carbon atoms of a phenyl ring. In both **1** and **2**, the formally two-coordinate lithium atom also forms long-range contacts with one of the phosphorus centers (Li···P = 2.625(4) Å in **1**; 2.598(3) Å in **2**). The "terminal" lithium atoms are bound to two nitrogen atoms (Li—N = 2.013(4) and 2.204(4) Å for **1**; 2.011(3) and 2.226(3) Å for **2**) from the same bis(imido)-organophosphine dianions and additionally bind two molecules of THF to complete a distorted tetrahedral coordination environment.

To probe the unusual lithium coordination geometries further we undertook a solid state ^{7}Li-MAS NMR study of **1** and **2**. This showed that both **1** and **2** give two lithium resonances (δ = –0.80 and 0.37 for **1**; δ = –0.84 and 0.71 for **2**) consistent with the two lithium environments observed in their solid-state structures. We have tentatively assigned the lower field resonance in each spectrum to be from the two-coordinate lithium center on the basis that proton dipolar decoupling of the ^{7}Li NMR spectrum of **2** results in a small narrowing of this peak. Moreover, the significantly larger quadrupolar coupling constant for the low-field resonance (from the manifold of side bands at low-spinning speeds) suggests that it is associated with the site of largest N-Li-N bond angles (8), i.e., the two-coordinate Li site. This may be

© 2002 NRC Canada

an indication of direct interaction with the protons on the phenyl rings that were alluded to in the solid-state structure. However, owing to the line width, overlap of the two resonances, and the small magnitude of the coupling, this purported interaction could not be assigned definitively.

Complexes **1** and **2** are structurally similar in the solid state to complexes **3** and **4**, which also form ion-contacted dimers with two bridging two-coordinate lithium centers and two "terminal" lithium centers. The chemically similar complexes **5** and **6** adopt a quite different structural arrangement to **1**–**4**. Complex **5** is a dimer where all the lithium centers bind the two bis(imido)organophosphine dianions together and are further solvated by diethylether molecules. Complex **6** forms a tetrameric unit where the lithium and nitrogen atoms form an intricate network. The precise factors that determine the structural make-up of the products are unclear at this moment.

The ligating ability of bis(imido)organophosphines has already been demonstrated by Nöth and co-workers (7). We are currently investigating the coordination chemistry of complexes **1** and **2** to a range of main group and transition metal centers.

Experimental

All reagents and products were handled on a vacuum line (in an efficient fume cupboard) under dry and oxygen-free argon or dinitrogen using standard inert atmosphere techniques (9). Toluene, THF, and hexane were dried over alumina, while a supported copper catalyst was used to remove trace oxygen from hydrocarbons prior to the reactions (10). The products were isolated and characterized with the aid of an argon-filled Saffron Beta glove box. ^{1}H, ^{31}P, and ^{7}Li NMR spectra were recorded on a Jeol Lambda 300 MHz Multinuclear FT spectrometer in dry deuterated pyridine or toluene (using the solvent resonances as the internal reference standard for ^{1}H spectra and an external standard of 85% H_3PO_4 and saturated aqueous LiBr as the references for ^{31}P and ^{7}Li, respectively). Solid-state ^{7}Li spectra were collected on a Bruker Avance 400 spectrometer operating at a resonant frequency of 155.52 MHz, using a standard Bruker 4 mm CPMAS probe and sample spinning of 5–15 kHz. All spectra were obtained using a single pulse and acquire sequence with ^{1}H decoupling (ca. 55 kHz) applied during the acquisition of the ^{7}Li FID. The ^{7}Li excitation pulse length was set at 1 μs (π/4 pulse) and 32 K imaginary points of data were collected with a total sweep width of 1 MHz, giving a total data acquisition time of 16 ms. Chemical shifts are reported with respect to the ^{7}Li resonance of a LiBr solution (0 ppm). Infrared spectra were recorded as Nujol mulls using NaCl plates and were run on a PerkinElmer Spectrum One FTIR spectrophotometer. Elemental analyses were performed by first sealing the samples under argon in air-tight aluminium boats (1–2 mg) and C, H, and N content was analysed using a PerkinElmer 240 Elemental Analyser.

Synthesis of 1

To a stirred solution of benzophenone hydrazone (1.47 g, 7.5 mmol) in 30 mL THF and NEt_3 (2 mL,), was added PCl_3 (0.22 mL, 2.5 mmol) dropwise. This solution was stirred for 1 h at room temperature before being filtered (porosity 3 sinter with Celite) and metallated with 3 equiv of *n*-BuLi (3.8 mL, 1.6 M solution in hexanes, 6 mmol). The resulting dark yellowy-orange solution was left for 72 h at 5°C and yielded pale yellow blocks of **1**.

Yield: 0.53 g (33%); mp 198–202°C. IR (cm^{-1}): no N-H bands. ^{1}H NMR (300 MHz, [D$_5$]-pyridine) δ: 7.8–6.9 (collection of overlapping m, 20H, $(C_6H_5)_2$C=N-N-), 3.6–3.7 (m, 12H, THF), 2.29 (m, 2H, -CH_2CH$_2$CH$_2$CH$_3$), 1.92 (m, 2H, -CH$_2$CH_2CH$_2$CH$_3$), 1.62 (m, 12H, THF), 1.49 (m, 2H, -CH$_2$CH$_2$CH_2CH$_3$), 0.82 (t, 3H, -CH$_2$CH$_2$CH$_2$CH_3). ^{31}P NMR (121.55 MHz, [D$_5$]-pyridine) δ: 64.5(s). ^{7}Li NMR (116.57 MHz, [D$_5$]-pyridine) δ: 2.1 (s). ^{7}Li NMR (116.57 MHz, [D$_8$]-toluene) δ: 1.0(s), –0.1(s). Synthesis of 2

Dichlorophenylphosphine (0.27 mL, 2 mmol) was reacted with 2 equiv of benzophenone hydrazone (0.79 g, 4 mmol) in THF (15 mL) and NEt_3 (3 mL). The resulting yellow solution was stirred for 3 h at room temperature before being filtered (porosity 3 sinter with Celite) and metallated with 2 equiv of *n*-BuLi (2.5 mL, 1.6 M solution in hexanes, 4 mmol). The solvent was removed in vacuo and the solid was redissolved in THF (3 mL), which was layered with hexane (6 mL). Golden yellow blocks of **2** were produced by storage of this mixture for 16 h at 20°C.

Yield: 1.18 g (81%); mp: no melting or decomposition up to 250°C. IR (cm^{-1}): no N-H bands. ^{1}H NMR (300 MHz, [D$_5$]-pyridine) δ: 7.6–6.7 (collection of overlapping m, 30H, $(C_6H_5)_2$C=N-N- and PC_6H_5), 3.5 (m, 24H, THF), 1.5 (m, 24H, THF). ^{31}P NMR (121.55 MHz, [D$_5$]-pyridine) δ: 61.4. ^{7}Li NMR (116.57 MHz, [D$_5$]-pyridine) δ: –0.6 (s). ^{7}Li NMR

X-ray crystallography

Data were collected on a Siemens SMART CCD area-detector diffractometer with Mo Kα radiation (λ = 0.71073 Å) (11) using a crystal mounted on a glass fibre in a rapidly cooled perfluoropolyether (12). Intensities were integrated from several series of exposures, each exposure covering 0.3° in ω. Details of the data collection, refinement and crystal data are listed in Table 3.[2] The structures were solved by direct methods and refined by least squares on F^2 values for all reflections (13). Absorption corrections were applied, based on multiple and symmetry equivalent measurements (14). All hydrogen atoms were constrained to ideal geometries and refined with fixed isotropic displacement parameters.

Boron halide chelate compounds and their activity towards the demethylation of trimethylphosphate

Timothy S. Keizer, Lauren J. De Pue, Sean Parkin, and David A. Atwood

Abstract: Salen(*t*-Bu)H_2 (*N*,*N*′-ethylenebis(3,5-di-*tert*-butyl(2-hydroxy)benzylidenimine) and its derivatives were used to prepare boron compounds having the formula L$(BCl_2)_2$ (L = salen(*t*-Bu) (**1**), salpen(*t*-Bu) (**2**), salben(*t*-Bu) (**3**), salpten(*t*-Bu) (**4**), salhen(*t*-Bu) (**5**)). These are formed from the reaction of the corresponding L$[B(OMe)_2]_2$ with BCl_3. In addition to being a new type of boron compound, they are also potential two-point Lewis acids. Indeed, they demonstrate Lewis acidic behavior in the dealkylation of trimethylphosphate. All of the compounds were characterized by mp, elemental analysis, ^{1}H and ^{11}B NMR, IR, MS, and in the case of **2** by X-ray crystallography.

Key words: boron, salen, dealkylation.

Résumé : On a utilisé le salen(*t*-Bu)H_2 (*N*,*N*′-éthylènebis(3,5-di-*tert*-butyl(2-hydroxy)benzylidènimide) et ses dérivés pour préparer des composés du bore de formules L$(BCl_2)_2$ (L = salen(*t*-Bu) (**1**), salpen(*t*-Bu) (**2**), salben(*t*-Bu) (**3**), salpten(*t*-Bu) (**4**) et salhen(*t*-Bu) (**5**) qui se forment par réaction du L$[B(OMe)_2]_2$ avec du BCl_3. En plus de correspondre à un nouveau type de composé du bore, ces produits sont potentiellement des acides de Lewis en deux points. Ils démontrent effectivement un comportement d'acide de Lewis dans la désalkylation du phosphate de triméthyle. Tous les composés ont été caractérisés par leurs points de fusion, une analyse élémentaire, par RMN du ^{1}H et du ^{11}B, par infrarouge et spectrométrie de masse et, dans le cas du produit **2**, par diffraction des rayons X.

Mots clés : bore, salen, désalkylation.

[Traduit par la Rédaction]

Introduction

Over the years, the dianionic Salen ligands (salen(*t*-Bu) = *N*,*N*′-ethylenebis(3,5-di-*tert*-butyl(2-oxo)benzylidenimine)) (Fig. 1) have been used in many applications (1, 2). The versatility of the ligand allows for the isolation of both monometallic and bimetallic derivatives usually involving the group 13 elements. For example, many compounds have been reported for aluminum (3–5), gallium (5, 6), and indium (7, 8). However, boron compounds of this type have been studied less extensively (9–11). Examples of Salen (L) boron compounds include alkoxide (L$[B(OR)_2]_2$, *R* = Me, Et) (9), siloxide (L$[B(OSiOPh_3)_2]_2$ (10), fluoride (L$[BF_2]_2$) (12), and acetate (L$[B(OAc)_2]_2$) (11) derivatives. Although these compounds are interesting from a fundamental standpoint, they are limited in usefulness because of their lack of reactivity or Lewis acid potential. In this paper we report the high-yield syntheses of new Salen-supported boron chloride derivatives, L$[BCl_2]_2$ (**1**–**5**). Preliminary work indicates that these chloride compounds will undergo salt elimination reactions, allowing for further derivatization of the boron atoms and thereby increasing their potential utility (13).

For instance, boron compounds could be useful as two-point Lewis acids. Many biological systems use a bis-metal complex to promote the binding and hydrolysis of phosphate esters (14). In recent years, synthetic derivatives containing *d*-block metals such as cobalt (15, 16), zinc (17–20), and copper (21, 22) have been used as catalysts for this reaction. A potentially important development in this area is the recent demonstration that boron bromide compounds such as salpen(*t*-Bu)$[BBr_2]_2$ can catalytically dealkylate a wide variety of phosphate esters (23). Herein, the boron chloride compounds L$[BCl_2]_2$ (**1**–**5**) will be synthesized, characterized, and examined as dealkylation agents for trimethylphosphate.

Results and discussion

Synthesis and characterization of 1–5

The boron chlorides (**1**–**5**) were prepared in nearly quantitative yield by combining the corresponding salen(*t*-Bu)$[B(OMe)_2]_2$ reagent with BCl_3 (Scheme 1). The resulting compounds have two four-coordinate boron atoms held in a bidentate manner by the Salen ligand. Each boron atom is bound by two chlorides, a nitrogen, and an oxygen from the Salen ligand. This reaction is unique and unusual in that all of the methoxide groups are replaced with chloride groups. It is known that boron trichloride mixed with trimethylborate (eq. [1]) undergoes a ligand redistribution to form $BCl(OMe)_2$ and BCl_2(Ome) (24). Thus, the reaction described in Scheme 1 is expected to produce compounds with various combinations of chlorides and methoxides on the boron

atoms. However, only the desired products $L[BCl_2]_2$ (**1**–**5**) were formed. The presence of the chelate apparently stabilizes the dihalide derivative relative to the other possibilities.

The ^{1}H NMR data for **1**–**5** contain two singlets for the *t*-Bu-Ph groups in the range δ: 1.22–1.45 ppm. There are multiple CH_2 peaks corresponding to the backbone protons from the ligand ranging from δ: 1.55–4.62 ppm depending on ligand type. There is one imine singlet for each compound in the range δ: 8.19–8.52 ppm. These values decrease with increasing backbone length. Thus, the most shielded shift (8.2 ppm) is associated with **4** and **5** and the less shielded shift at 8.5 ppm is associated with **1**. This might indicate a slight increase in nitrogen basicity for electron releasing "carbon rich" ligands and a moderate decrease in basicity for the "carbon poor" **1**, with a comparatively lower inductive effect. The ^{13}C NMR data also supports this trend. The chemical shift for the C=N group for **1**–**5** (166.7–163.4 ppm) decreases with the increase in the backbone length. The effect is more distinct between **1** (166.7 ppm) and **2** (164.9 ppm) than between **4** (163.7 ppm) and **5** (163.4 ppm). Thus, the inductive effect on the C=N is further evident when the backbone is increased from two carbons to three carbons rather than five carbons to six carbons. The ^{11}B NMR shows broad single peaks ranging from δ: 5.99–6.39 ppm with $w_{1/2}$ ranging from 28.2–56.7 Hz, which are in the region for tetrahedral boron (25). The IR data shows strong B-Cl stretches between 697–743 cm^{-1}. In the mass spectrum, the compounds show the parent ion with the isotope pattern appropriate for four chlorines and two borons. The most abundant peak for the compounds is the parent ion minus chlorine with the correct isotope pattern for three chlorines and two borons.

The structure of **2** (Fig. 2) was determined by X-ray crystallography. The geometry around the two boron atoms is slightly distorted from a tetrahedral geometry. Other Salen boron derivatives also show this distortion (9). The bite angles of the ligand on the boron atoms (N-B-O) are 110.1(4)° and 111.8(4)° (Table 1). These are slightly larger than other Salen-supported boron systems such as $salenN_3H[B(OMe)_2]_2$, which has an angle of 105.9(3)° (10). This deviation is in keeping with an increased *sp* hybridization in the N,O bonds and more obtuse angles with these atoms for **2** resulting from an increase in *p* character for the B—Cl bonds by comparison to B—OMe bonds (26). The (N-B-O) angles are significantly larger than the (N-Al-O) angle in salben(*t*-Bu)$[AlMeCl]_2$ (96.0(4)°) and the (N-Ga-O) angle in salphen(*t*-Bu)$[Ga(Et)_2]_2$ (92.5(2)°) (5). Thus, the angle decreases as the atoms increase in size, and displaces further "out" of the chelate. The B—Cl bond lengths are 1.849(5) Å, 1.855(5) Å, 1.841(5) Å, and 1.907(5) Å. These are comparable to a similar Schiff base compound, dichloro-[2-(1-imino-2,2,2-trichloroethyl)-4-methoxyphenoxido-O,N]boron, which

(*a*) (*b*) (*c*)

Table 1. Selected bond lengths (Å) and angles (°) for compound **2**.

Bond lengths	(Å)	Bond angles	(°)
B(1)—O(1)	1.422(5)	O(1)-B(1)-N(1)	110.1(4)
B(1)—N(1)	1.561(5)	O(1)-B(1)-Cl(1)	108.2(3)
B(1)—Cl(1)	1.849(5)	N(1)-B(1)-Cl(1)	109.7(3)
B(1)—Cl(2)	1.855(5)	O(1)-B(1)-Cl(2)	111.7(3)
C(1)—N(1)	1.295(4)	N(1)-B(1)-Cl(2)	106.5(3)
B(2)—O(2)	1.418(5)	Cl(1)-B(1)-Cl(2)	110.6(3)
B(2)—N(4)	1.548(5)	O(2)-B(2)-N(2)	111.8(4)
B(2)—Cl(3)	1.907(5)	O(2)-B(2)-Cl(4)	109.1(3)
B(2)—Cl(4)	1.841(5)	N(2)-B(2)-Cl(4)	111.0(3)
C(2)—N(2)	1.294(4)	O(2)-B(2)-Cl(3)	110.5(3)
		N(2)-B(2)-Cl(3)	104.9(3)
		Cl(4)-B(2)-Cl(3)	109.4(2)

has B—Cl bonds lengths of 1.855(7) Å and 1.841(7) Å (27). A noticeable trend in the length of the N→B dative bond occurs with the exchange of the substituents on the boron atom (28). The N→B lengths for **2** are 1.561(5) Å and 1.548(5) Å. These are shorter than the N→B bond length of salen[$B(OMe)_2$]$_2$ (1.615(2) Å) (9). An inverse relationship exists between the lengths of the C=N and N→B bonds. Where the N→B bond shortens the C=N bond lengthens. The C=N bond for 2 is 1.295(4) Å which is longer than that of the borate C=N bond (1.288(2) Å). The C=N and N→B bond lengths of **2** compare closely to those in the boron bromine derivative salben(*t*-Bu)[BBr_2]$_2$ (1.295(4) Å and 1.539(5) Å, respectively) (23).

Table 2. Percent dealkylation of trimethylphosphate.

L[BCl_2]$_2$	% Conversion[a] 30 min	% Conversion[a] 24 h
1	14	45
2	20	32
3	11	53
4	42	62
5	7	47

[a]Yields were calculated from the amount of MeCl produced to the amount of trimethylphosphate remaining in the ^{1}H NMR.

One unique aspect of these compounds (Fig. 3(*a*)) is that there are no corresponding transition metal derivatives. Rather, transition metals adopt fully chelated five-coordinate and more often six-coordinate complexes with the Salen ligands (Figs. 3(*b*) and 3(*c*)) (1). These ligands are very versatile in the fact that the "backbone" of the ligand may be altered. For instance, the length of the backbone may be increased to the point that binding to a single metal is ineffectual. Thus, the existence of **1**–**5** may indicate the possibility of isolating transition metals of the form L[MX_2]$_2$.

Demethylation of trimethylphosphate with compounds 1–5

It is known that boron trichloride will demethylate aryl ethers (29). Nevertheless, it has been found that BCl_3 alone is ineffective towards the demethylation of trimethylphosphate. Compounds (**1**–**5**), however, are capable of demethylating trimethylphosphate (Table 2). When compounds **1**–**5**

are added to a stoichiometric amount of trimethylphosphate, methyl chloride is produced. However, these species are less reactive than the boron bromide analogue, salpen(*t*-Bu)$[BBr_2]_2$ (23). For example, compound **2** demethylates 20% of the trimethylphosphate within 30 min whereas salpen(*t*-Bu)$[BBr_2]_2$ demethylates 89% of the trimethylphosphate within 30 min. This heightened activity may be explained by the fact that the B—Cl bond is less labile than the B—Br bond. In demonstration of this, it has been found that THF does not displace the chloride from **2** as readily as in the boron bromide compound, which forms an in situ cation (23). By analogy then, trimethylphosphate does not displace the chloride as well as bromide resulting in a decrease in dealkylation efficiency of the boron chloride compared with the boron bromide chelate. The bromide derivative can be made catalytic for the dealkylation of a wide range of phosphate esters, including trimethylphosphate, by the addition of BBr_3 (23). In this process it was not necessary to have two connected sites. This was confirmed by using a monometallic boron compound under the same conditions.

Experimental

General remarks

All glassware was rigorously cleaned and dried in an oven at 130°C for 24 h prior to use. They were assembled hot and cooled under nitrogen. All air-sensitive manipulations were conducted using standard bench top inert-atmosphere techniques in conjunction with an inert-atmosphere glove box. The ligand precursors (30) salen(*t*-Bu)H_2, salpen(*t*-Bu)H_2, salben(*t*-Bu)H_2, salpten(*t*-Bu)H_2, and salhen(*t*-Bu)H_2 were synthesized according to the literature procedure. Salen(*t*-Bu)$[B(OMe)_2]_2$, salpen(*t*-Bu)$[B(OMe)_2]_2$, salben(*t*-Bu)$[B(OMe)_2]_2$, salpten(*t*-Bu)$[B(OMe)_2]_2$, and salhen(*t*-Bu)$[B(OMe)_2]_2$ were prepared as reported previously (9). NMR data (^{1}H, ^{11}B) were obtained on JEOL-GSX-400 and 200 MHz instruments. Chemical shifts are reported relative to $SiMe_4$ for ^{1}H and ^{13}C and relative to $BF_3\cdot Et_2O$ in $CDCl_3$ for ^{11}B and are in ppm. Infrared data were recorded as KBr pellets on a Matheson Instruments 2020 Galaxy Series Spectrometer and are reported in cm^{-1}. EI (positive) (direct probe) spectra were acquired on a Kratos Concept IH at 70 eV. Elemental analyses were obtained on Vario EL III Elementar. X-ray data for **2** were obtained on a Nonius CCD unit employing Mo Kα radiation.[2] The structures were refined using the Siemens software package SHELXTL 4.0. All of the non-hydrogen atoms were refined anisotropically. The hydrogen atoms were put into calculated positions. Absorption corrections were not employed. Further details of the structure analyses are given in Table 3.

Salen(*t*-Bu)$[BCl_2]_2$ (1)

To a stirring solution of salen(*t*-Bu)$[B(OMe)_2]_2$ (2.5 g, 3.93 mmol) in toluene (75 mL) was added 1M BCl_3 in heptane (7.8 mL, 7.80 mmol). The reaction mixture was stirred for 24 h. The solution was concentrated to 5 mL, filtered, and dried. Yield: 2.41g (94%); mp 314–320°C (decomposition temperature (dec.)). IR (KBr pellet) (cm^{-1}): 2962 (s), 2905 (m), 2862 (w), 1627 (s), 1622 (m), 1573 (m), 1456 (m), 1427 (w), 1359 (w), 1310 (w), 1258 (m), 1210 (w), 1138 (w), 1026 (s), 995 (w), 917 (m), 869 (m), 769 (w), 470 (m), 706 (vs). ^{1}H NMR ($CDCl_3$) δ: 1.22 (s, 18H, C(C*H*$_3$)$_3$), 1.45 (s, 18H, C(C*H*$_3$)$_3$), 4.62 (br s, 4H, NC*H*$_2$), 7.10 (d, 2H, C$_6$*H*$_2$), 7.73 (d, 2H, C$_6$*H*$_2$), 8.52 (s, 2H, N=C*H*) ^{13}C NMR ($CDCl_3$) δ: 29.3 (C(*C*H$_3$)$_3$), 31.1 (C(*C*H$_3$)$_3$), 34.4 (N*C*H$_2$), 35.1 (N*C*H$_2$), 54.5 (*C*(CH$_3$)$_3$), 115.6 (Ph), 126.2 (Ph), 135.7 (Ph), 139.7 (Ph), 144.2 (Ph), 154.7 (Ph), 166.7 (N=*C*H). ^{11}B NMR ($CDCl_3$) δ: 6.21 ($w_{1/2}$ = 43.9 Hz). MS (%): 654 ([M]$^+$, 5), 617 ([M – Cl], 100), 582 ([M – 2Cl], 15), 547 ([M – 3Cl], 55). Anal. calcd. for $B_2C_{32}H_{46}N_2O_2Cl_4$: C 58.87, H 7.11, N 4.29; found: C 58.52, H 7.18, N 4.20.

Salpen(*t*-Bu)$[BCl_2]_2$ (2)

To a stirring solution of salpen(*t*-Bu)$[B(OMe)_2]_2$ (1.0 g, 1.54 mmol) in toluene (50 mL) was added 1M BCl_3 in heptane (3.1 mL, 3.10 mmol). The reaction mixture was stirred for 24 h. The solvent was removed and washed with 5 mL of hexanes. Filtration and vacuum drying afforded salpen(*t*-Bu)$[BCl_2]_2$. Yield: 0.85g (83%); mp 234°C. IR (KBr pellet) (cm^{-1}): 2963 (s), 2862 (w), 1631 (s), 1569 (m), 1557 (m), 1454 (m), 1429 (w), 1394 (w), 1364 (m), 1346

Salben(*t*-Bu)[BCl_2]$_2$ (3)

To a stirring solution of salben(*t*-Bu)[B(OMe)$_2$]$_2$ (0.5 g, 0.75 mmol) in toluene (50 mL) was added 1M BCl_3 in heptane (1.5 mL, 1.50 mmol). The reaction mixture was stirred for 24 h. The solution was concentrated to 5 mL, filtered, and dried. Yield: 0.41g (81%); mp 316–318°C (dec.). IR (KBr pellet) (cm^{-1}): 2949 (s), 2893 (w), 2862 (w), 1631 (s), 1574 (m), 1470 (w), 1405 (w), 1361 (w), 1254 (m), 1219 (m), 1204 (w), 1095 (w), 1018 (m), 1008 (m), 872 (s), 771 (m), 743 (m), 705 (m), 641 (w). ^{1}H NMR ($CDCl_3$) δ: 1.22 (s, 18H, C(CH_3)$_3$), 1.41 (s, 18H, C(CH_3)$_3$), 2.17 (m, 4H, CH_2), 4.03 (m, 4H, NCH_2), 7.20 (d, 2H, C$_6H_2$), 7.70 (d, 2H, C$_6H_2$), 8.21 (s, 2H, N=C*H*). ^{13}C NMR ($CDCl_3$) δ: 26.7 (*C*H$_2$), 29.6 (C(*C*H$_3$)$_3$), 31.1 (C(*C*H$_3$)$_3$), 34.2 (N*C*H$_2$), 35.0 (N*C*H$_2$), 52.5 (*C*(CH$_3$)$_3$), 125.3 (Ph), 125.9 (Ph), 128.2 (Ph), 129.0 (Ph), 137.8 (Ph), 154.5 (Ph), 164.2 (N=*C*H). ^{11}B NMR ($CDCl_3$) δ: 5.99 ($w_{1/2}$ = 49.5 Hz). MS (%): 681 ([M]$^+$, 2), 645 ([M – Cl], 100), 610 ([M – 2Cl], 20). Anal. calcd. for $B_2C_{34}H_{50}N_2O_2Cl_4$: C 59.98, H 7.41, N 4.12; found: C 61.35, H 7.36, N 4.01.

Salpten(*t*-Bu)[BCl_2]$_2$ (4)

To a stirring solution of salpten(*t*-Bu)[B(OMe)$_2$]$_2$ (0.68 g, 1.00 mmol) in toluene (50 mL) was added 1M BCl_3 in heptane (2.0 mL, 2.0 mmol). The reaction mixture was stirred for 24 h. The solution was concentrated to 5 mL, filtered, and dried. Yield: 0.64g (98%); mp 261–262°C (dec.). IR (KBr pellet) (cm^{-1}): 2961 (s), 2869 (w), 1630 (s), 1575 (m), 1474 (m), 1437 (m), 1395 (w), 1363 (m), 1251 (m), 1217 (w), 1190 (w), 1135 (w), 1078 (m), 1025 (m), 914 (m), 8749 (m), 771 (m), 731 (s), 644 (w). ^{1}H NMR ($CDCl_3$) δ: 1.28 (s, 18H, C(CH_3)$_3$), 1.45 (s, 18H, C(CH_3)$_3$), 1.59 (m, 2H, CH$_2$), 2.19 (m, 4H, CH_2), 3.98 (m, 4H, NCH_2), 7.19 (d, 2H, C$_6H_2$), 7.69 (d, 2H, C$_6H_2$), 8.19 (s, 2H, N=C*H*). ^{13}C NMR ($CDCl_3$) δ: 23.4 (*C*H$_2$), 29.2 (C(*C*H$_3$)$_3$), 29.5 (*C*H$_2$), 31.2 (C(*C*H$_3$)$_3$), 34.3 (N*C*H$_2$), 35.0 (N*C*H$_2$), 54.2 (*C*(CH$_3$)$_3$), 115.3 (Ph), 125.8 (Ph), 134.7 (Ph), 139.5 (Ph), 143.7 (Ph), 154.2 (Ph), 163.7 (N=*C*H). ^{11}B NMR ($CDCl_3$) δ: 5.90 ($w_{1/2}$ = 37.6 Hz). MS (%): 696 ([M]$^+$, 5), 659 ([M – Cl], 100), 624 ([M – 2Cl], 20). Anal. calcd. for $B_2C_{35}H_{52}N_2O_2Cl_4$: C 60.49, H 7.55, N 4.03; found: C 60.48, H 8.56, N 3.82.

Salhen(*t*-Bu)[BCl_2]$_2$ (5)

To a stirring solution of salhen(*t*-Bu)[B(OMe)$_2$]$_2$ (1.0 g, 1.46 mmol) in toluene (50 mL) was added 1M BCl_3 in heptane (2.9 mL, 2.92 mmol). The reaction mixture was stirred for 24 h. The solution was concentrated to 5 mL, filtered, and dried. Yield: 0.91g (91%); mp 302–304°C (dec.). IR (KBr pellet) (cm^{-1}): 2952 (s), 2904 (w), 2862 (w), 1632 (s), 1573 (m), 1458 (m), 1433 (w), 1359 (w), 1295 (w), 1254 (m), 1215 (w), 1079 (w), 1010 (m), 974 (w), 847 (m), 771 (m), 712 (s), 641 (w). ^{1}H NMR ($CDCl_3$) δ: 1.27 (s, 18H, C(CH_3)$_3$), 1.43 (s, 18H, C(CH_3)$_3$), 1.55 (m, 4H, CH_2), 2.02 (m, 4H, CH_2), 3.91 (m, 4H, NCH_2), 7.18 (d, 2H, C$_6H_2$), 7.68 (d, 2H, C$_6H_2$), 8.19 (s, 2H, N=C*H*). ^{13}C NMR ($CDCl_3$) δ: 25.7 (*C*H$_2$), 29.5 (C(*C*H$_3$)$_3$), 31.1 (C(*C*H$_3$)$_3$), 34.3 (N*C*H$_2$), 35.0 (N*C*H$_2$), 54.4 (*C*(CH$_3$)$_3$), 125.2 (Ph), 125.6 (Ph), 128.1 (Ph), 129.0 (Ph), 134.6 (Ph), 154.6 (Ph), 163.4 (N=*C*H). ^{11}B NMR ($CDCl_3$) δ: 6.39 ($w_{1/2}$ = 28.2 Hz). MS (%): 673 ([M – Cl], 100), 658 ([M – Cl – Me], 10), 638 ([M – 2Cl], 50). Anal. calcd. for $B_2C_{36}H_{54}N_2O_2Cl_4$: C 60.99, H 7.68, N 3.95; found: C 61.40, H 8.04, N 3.66.

Dealkylation of the trimethylphosphate

In an NMR tube, trimethylphosphate was added to an equimolar solution of the compound (**1**–**5**) in $CDCl_3$ and held at room temperature for 30 min and 24 h. The reaction was monitored by ^{1}H NMR (Table 2).

Addition of a Lewis base

In an NMR tube, 5 equiv of THF were added to a solution of **2** in $CDCl_3$. ^{11}B NMR ($CDCl_3$) δ: 6.04 ($w_{1/2}$ = 52.6 Hz).

Conclusion

A range of chelated boron compounds have been synthesized and fully characterized. They demonstrate that further derivatization of boron alkoxide compounds with Salen are possible and that some are active in the dealkylation of trimethylphosphate. It has been demonstrated that **1**–**5** are inefficient dealkylating compounds by comparison to the bromide analogues (23). Future work in this area entails increasing the activity of the boron chloride compounds and broadening their use as Lewis acid activators.

Synthesis, characterization, and structures of zircona- and boracyclosiloxanes with ferrocenyl substituents

Karena Thieme, Sara C. Bourke, Juan Zheng, Mark J. MacLachlan, Fojan Zamanian, Alan J. Lough, and Ian Manners

Abstract: The novel zirconatetraferrocenylcyclotrisiloxane $Cp_2Zr(OSiFc_2)_2O$ (**6**), dizirconatetraferrocenylcyclotetrasiloxane $[Cp_2Zr(OSiFc_2)O]_2$ (**7**), boratetraferrocenylcyclotrisiloxane $(C_6H_5)B(OSiFc_2)_2O$ (**8**), and diboratetraferrocenylcyclotetrasiloxane $[(C_6H_5)B(OSiFc_2)O]_2$ (**9**) with ferrocenyl (Fc = $Fe(\eta\text{-}C_5H_4)(\eta\text{-}C_5H_5)$) substituents at silicon have been prepared from the reactions of $Cp_2Zr(NMe_2)_2$ and $PhBCl_2$ with diferrocenylsilanediol $Fc_2Si(OH)_2$ (**3**) and tetraferrocenyldisiloxanediol $[Fc_2SiOH]_2O$ (**5**). The compounds were characterized by mass spectrometry, elemental analysis, UV–vis, IR, Raman, and multinuclear NMR spectroscopy, as well as single crystal X-ray diffraction. Thermogravimetric analysis and differential scanning calorimetry investigation of **6**–**9** showed that the cycles decompose before they can undergo any thermal ring-opening polymerization. In addition, no polymerization was detected in the presence of either $KOSiMe_3$ or HOTf. The bulky ferrocenyl substituents on the Si atoms are likely to be at least partially responsible for the inability of these heterocycles to undergo ring-opening polymerization.

Key words: heterocyclosiloxanes, ferrocenyl.

Résumé : Les réactions de $Cp_2Zr(NMe_2)_2$ et $PhBCl_2$ avec le diferrocénylsilandiol, $Fc_2Si(OH)_2$ (**3**) et le tétraferrocényldisiloxanediol, $[Fc_2SiOH]_2O$ (**5**), permettent de préparer les nouveaux composés zirconatétraferrocénylcyclotrisiloxane, $Cp_2Zr(OSiFc_2)_2O$ (**6**); dizirconatétraferrocénylcyclotétrasiloxane, $[Cp_2Zr(OSiFc_2)O]_2$ (**7**); boratétraferrocénylcyclotrisiloxane, $(C_6H_5)B(OSiFc_2)_2O$ (**8**) et diboratétraferrocénylcyclotétrasiloxane, $[(C_6H_5)B(OSiFc_2)O]_2$ (**9**) portant des substituants ferrocényles (Fc = $Fe(\eta\text{-}C_5H_4)(\eta\text{-}C_5H_5)$ au niveau du silicium. Les composés ont été caractérisés par spectrométrie de masse, analyse élémentaire, spectres UV–vis, IR, Raman et RMN multinoyaux ainsi que par diffraction des rayons X par des cristaux uniques. Une étude des composés **6**–**9** par analyse thermogravimétrique et par analyse calorimétrique différentielle permet de montrer que les cycles se décomposent avant de pouvoir subir la moindre polymérisation par ouverture de cycle. De plus, on n'a observé aucune polymérisation en présence de $KOSiMe_3$ ou de HOTf. Il est probable que l'empêchement stérique dû aux substituants ferrocényles attachés aux atomes de silicium est partiellement responsable pour le fait que ces hétérocycles soient incapables de subir une réaction de polymérisation par ouverture de cycle.

Mots clés : hétérocyclosiloxanes, ferrocényle.

[Traduit par la Rédaction]

Introduction

Inorganic rings continue to attract attention with respect to their novel structures and bonding (1), as potential catalysts (2), as ligands for transition metals (3), and as polymer precursors via ring-opening polymerization (ROP) processes (4). Cyclic siloxanes are well known as ROP monomers for the preparation of polysiloxanes (silicones) (5). In contrast, the polymerization behavior of cycloheterosiloxanes, analogous species in which atoms of heteroelements are incorporated into the ring structure, is much less explored (6). We have previously reported detailed studies of cyclic borasiloxanes (7, 8) and siloxane-bridged [3]-, [5]-, and [7]ferrocenophanes (9), which were found to undergo ring–ring redistribution reactions rather than ROP under the conditions studied. Recently an interesting reversible conversion

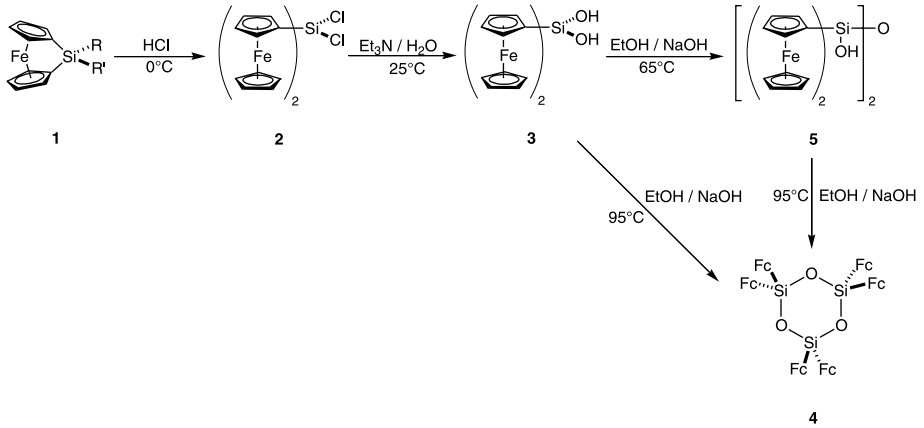
Scheme 1.



between a cyclotristannoxane (in solution) and a polystannoxane (in the solid state) has been demonstrated by Jurkschat and co-workers (10).

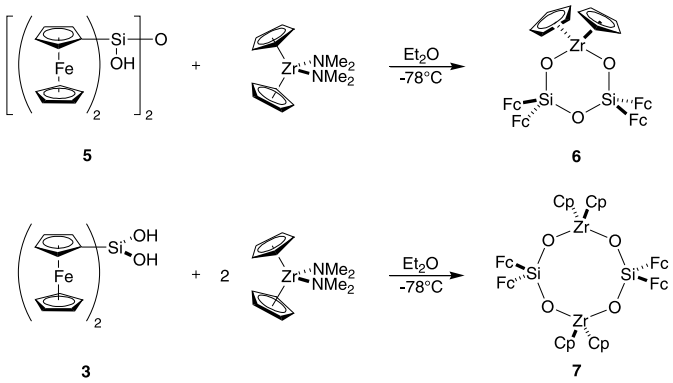
Our group has recently developed a facile route to dichlorodiferrocenylsilane (**2**) from the addition of 2 equiv. of HCl to the spirocyclic [1]ferrocenophane **1** (11, 12). Controlled hydrolysis of **2** affords diferrocenylsilanediol (**3**), which can then be condensed to give hexaferrocenylcyclotrisiloxane (**4**) (13). An intermediate in the condensation, tetraferrocenyldisiloxanediol (**5**), was isolated and found to possess an interesting hydrogen-bonded double-chain structure (14). We identified silanediol **3** and disiloxanediol **5** as convenient precursors to heterocyclosiloxanes with ferrocenyl substituents. In this paper we report on the synthesis, characterization, and ROP behavior of some ferrocenyl-substituted zircona- and borasiloxanes as part of our continuing studies on the ROP of inorganic heterocycles (15).

Results and discussion

Metallasiloxanes have attracted considerable interest because of their possible applications in many areas of chemistry and materials science. For example, these species have been studied as models for a variety of silica-based heterogeneous catalyst systems. A number of transition metals have been incorporated into heterosiloxanes, and the field has been recently reviewed (6).

As a consequence of the important role of Zr-based olefin polymerization catalysts, the incorporation of this metal into heterosiloxane rings is of significant interest. Moreover, zirconaheterocyclosiloxanes may be attractive as precursors to refractory $Zr_xSi_yO_z$ ceramics. However, to date, relatively few studies of such species have been reported. Roesky et al. (16) prepared an 8-membered $Zr_2O_4Si_2$ ring through reaction of a silanetriol with zirconocene dichloride. Under mass spectral conditions, this compound dimerized to form the cubic zirconasiloxane $[RSiO_3ZrCp]_4$. Hursthouse and coworkers (17), on the other hand, isolated a dianionic tris-chelate metallasiloxane $[NEt_2H_2]_2[(Ph_4Si_2O_3)_3Zr]$ from the reaction of diphenylsilanediol with tetrakis(diethylamino)zirconium. The structure of this compound revealed a central zirconium coordinated by six oxygen atoms in a distorted octahedral geometry. Finally, reaction of tetraphenyldisiloxanediol with

Scheme 2.



$Zr(CH_2SiMe_3)_4$ gave a siloxane with a 6-membered ZrO_3Si_2 ring that could be fired into a refractory coating (18).

Boracyclosiloxanes are also an interesting class of heterocycles to study. Wannagat and Eisele (19) reported the synthesis of the first example, the 6-membered ring $PhB(OSiMe_2)_2O$, via the [3 + 3] condensation reaction of 1,3-dichlorotetramethyldisiloxane with phenylboric acid in the presence of triethylamine. Further attempts to synthesize 6-membered rings often resulted in less strained 8- or higher-membered ring systems. Our previous studies of cyclic borasiloxanes with phenyl substituents on B and Si have shown that they do not ring-open to form linear polymer but instead undergo ring–ring interconversions (7). Similar systems have also been investigated resulting in 8-membered rings with different substituents, e.g., *tert*-butyl groups (20). The reaction of BI_3 with a trisilanol afforded an unusual dimeric boron-containing siloxane, with two trigonal-planar boron atoms bridging two silsesquioxane moieties (21).

Synthesis and characterization of zirconatetraferrocenylcyclosiloxanes 6 and 7

As ferrocene is sensitive to oxidation by acids, we selected bis(dialkylamino)zirconocene (rather than a zirconocene dihalide) to explore the use of **3** and **5** for the preparation of zirconasiloxanes. Dropwise addition of bis(dimethylamino)zirconocene to **5** in diethyl ether at –78°C afforded, after work-up, the zirconatetraferrocenylcyclosiloxane **6** in 95% yield (Scheme 2). Similarly, reaction of bis(dimethyl-

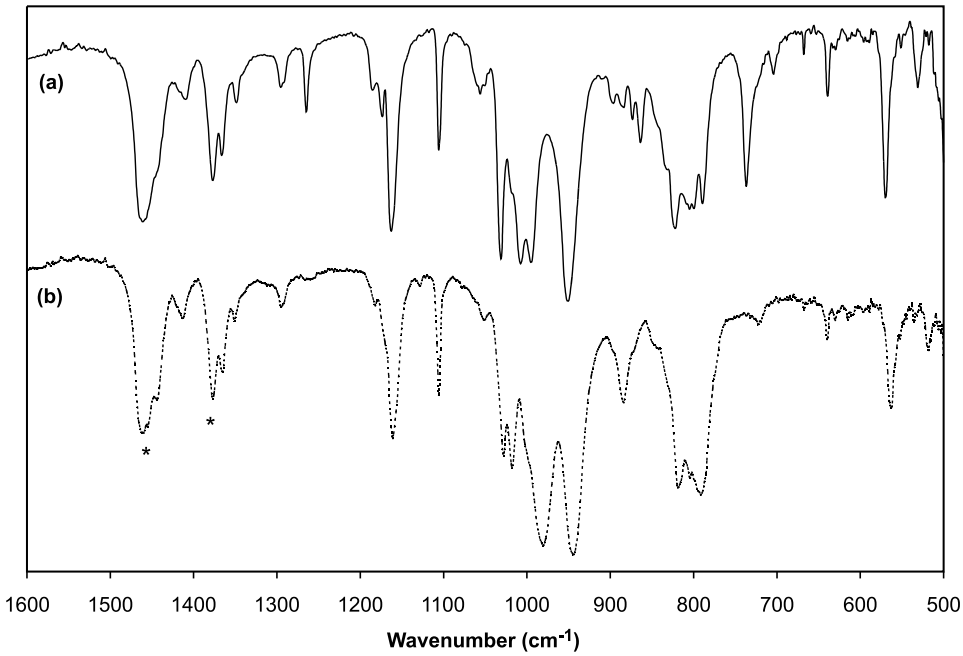
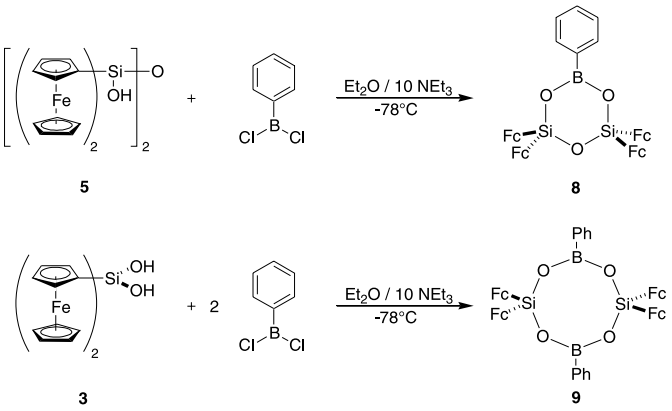


Scheme 3.



amino)zirconocene with **3** in diethyl ether at –78°C gave the dizirconatetraferrocenylcyclotetrasiloxane **7** in 95% yield. Both **6** and **7** were found to be orange, air-stable crystalline solids that decomposed only after a few days in solution in air.

Compounds **6** and **7** were both characterized by ^{1}H, ^{13}C, and ^{29}Si NMR, mass spectrometry, and IR, Raman, and UV–vis spectroscopy. The ^{1}H and ^{13}C NMR spectra of both compounds were consistent with the proposed structures. The ^{1}H NMR spectrum of **6** showed four signals attributed to Fe–Cp protons, whereas **7** showed only three such signals. This results from the higher symmetry of **7** with respect to **6**. Because of this effect, different coupling patterns are observed in the two compounds and smaller coupling constants are observed for the Cp ligands attached to Si in **6** (J = 0.9–1.2 Hz) than **7** (J = 1.5 Hz). Zirconasiloxanes **6** and **7** showed single ^{29}Si NMR resonances at –33.0 and –35.7 ppm (in C_6D_6), respectively. These are slightly upfield of the signals observed for **5** (–25.6 ppm in $CDCl_3$) and **3** (–25.1 ppm in DMSO-d_6). Both compounds **6** and **7** showed the molecular ions in their respective mass spectra and have UV–vis absorptions between 452 and 458 nm, typical of unstrained ferrocene derivatives bound to silicon (e.g., **5** has λ_{max} = 449 nm).

Synthesis and characterization of boratetraferrocenylcyclosiloxanes 8 and 9

Borasiloxanes containing a 6-membered ring were targeted, as such species would be expected to be significantly strained and likely to undergo ROP. Dropwise addition of phenylborondichloride, $PhBCl_2$, to a solution of siloxanediol **5** and triethylamine (as HCl acceptor) in ether at –78°C afforded the boracyclotrisiloxane **8** in 85% yield (Scheme 3). By an analogous procedure, the 8-membered heterocycle **9** was prepared in a low (ca. 25%) yield from silanediol **3**.

The new compounds were characterized by ^{1}H, ^{13}C, ^{29}Si, and ^{11}B NMR, mass spectrometry, IR, Raman, and UV–vis spectroscopy. The difference in the proton resonances of the boracyclosiloxanes was similar to that for the zirconacyclosiloxanes. That is, the increased symmetry from **8** to **9** simplified the Cp spectral region and changed the coupling constants of the protons on the Cp ligand attached to Si. In contrast to the zirconacyclosiloxanes, these rings showed rather different ^{29}Si NMR chemical shifts. While the chemical shift for **9** (–31.8 ppm in $CDCl_3$) was comparable to that observed for **7**, the value for **8** (–20.0 ppm in C_6D_6) was shifted downfield with respect to that of **6**. In comparison, the ^{29}Si NMR signal for the analog of **8** with phenyl substituents on each Si is observed at –16.5 ppm (in $CDCl_3$). The 6-membered ring **8** showed a broad signal in the ^{11}B NMR spectrum (30.5 ppm) in the region expected for a boron atom bonded to two oxygen atoms while the signal for **9** was slightly upfield (28.1 ppm) in the same region. Both **8** and **9** showed the molecular ion as the most intense peak in the mass spectrum and UV–vis absorptions characteristic of unstrained ferrocene moieties at λ_{max} = 450 nm.

Vibrational spectra of the zircona- and boratetraferrocenylcyclosiloxanes 6–9

Heterocyclosiloxanes **6–9** were investigated by IR and Raman spectroscopies. Both IR and Raman confirmed the presence of ferrocenyl moieties in the structures. Hexaferrocenylcyclotrisiloxane **4** was used as a model compound to assign the peaks attributed to ferrocenyl substituents. Table 1 lists the peaks observed in the IR (Nujol mull) and Raman spectra for the zirconacyclosiloxanes **6** and **7**. The IR spectra of **6** and **7**, which are very similar, are shown between 1600 and 500 cm^{-1} in Fig. 1. An Si-O stretching mode was observed in the IR spectrum at 1008 cm^{-1} in **6** and 1018 cm^{-1} in **7**. In addition, modes attributed to Zr-O-Si absorptions were observed in the IR spectra at 950 cm^{-1} in **6** and 980 and 944 cm^{-1} in **7**. For comparison, Hrncir (18) identified the Zr-O-Si mode at 962 cm^{-1} in a zirconatetraphenylcyclotrisiloxane. In general, Si-O modes occur between 900 and 1100 cm^{-1} and are highly dependent on the substituents on the silicon and the atoms attached to the silicon and oxygen. The symmetric Si-O stretch expected between 450 and 630 cm^{-1} could not be identified.

Peaks observed in the IR and Raman spectra of boracyclosiloxanes **8** and **9** are listed in Table 2. Vibrations attributed to Si-O stretching were observed near 980 cm^{-1} in the IR spectra of both compounds. Resonances observed near 1380 cm^{-1} in **8** and **9** were attributed to the B-O stretching mode. They could only be observed in the Raman spectra and in the IR of the 8-membered ring, which was measured in CCl_4 solution. A larger number of peaks observed in **8** and **9** that were not present in **4**, **6**, or **7** can be assigned to C-C or C-H stretching of the phenyl ring attached to the boron atom.

Single crystal X-ray diffraction studies of 6–9

To examine the conformations of the heterosiloxane rings with very bulky ferrocenyl substituents all four novel rings **6–9** were investigated by single-crystal X-ray diffraction. All four compounds were crystallized from dichloromethane or chloroform. For both systems the 6-membered ring was found to crystallize much more readily than the 8-membered ring. Crystals of the 8-membered rings (**7** and **9**) suitable for X-ray diffraction were obtained by slow evaporation of the solvent in an inert atmosphere glovebox. Data collection and refinement parameters for the cyclic heterosiloxane systems are summarized in Table 3. Selected bond lengths and angles of **6–9** are given in Tables 4–7, respectively.

Compound **6** crystallizes in the monoclinic space group $P2_1/n$ with $Z = 8$. The asymmetric unit contains two

independent molecules, A and B, which are shown in Fig. 2. The $ZrSi_2O_3$ rings observed in **6** appear in boat and twist–boat conformations; the sums of the interior bond angles, 717.15(27)° and 716.40(25)°, are close to the sum of 720° expected for a planar ring. The Fe atoms of the ferrocenyl groups attached to the same silicon centre are separated by 5.34–5.53 Å. Ferrocenyl substituents on adjacent silicon atoms have Fe centers separated by 6.64–7.13 Å for the *cis*-adjacent ferrocenyl groups and 6.74–9.58 Å for the *trans*-adjacent ferrocenyl group. These values, which are quite similar to the values observed in hexaferrocenylcyclotrisiloxane (**4**), should lead to significant metal–metal interactions and be observable by cyclic voltammetry. Steric crowding in the molecule is probably responsible for the slight ring tilts (0.6°–4.2°) observed in the ferrocenyl units. However, the values for the C—C bond length and the Fe–Cp and Fe–(η-C_5H_4)distances (1.640(3)–1.658(3) Å) are similar to those found in ferrocene.

Compound **7** crystallizes in the triclinic space group *P*-1 with $Z = 2$. Figure 3 shows two representations of the structure of **7**. The bond lengths observed in **7**, as given in Table 5, are similar to those observed in the 6-membered ring. Unlike the 6-membered ring **6**, which is essentially planar, the $Zr_2Si_2O_4$ ring in **7** adopts a twist–boat conformation in which the mean deviation from planarity is 0.29 Å. Fe atoms of ferrocene groups attached to the same silicon atom are separated by distances (5.48 and 5.56 Å) comparable to those in the 6-membered ring. However, the distance between the Fe atoms in the ferrocenyl groups on the opposite silicon atoms is much larger because of the larger ring size.

The *trans* ferrocenyl groups on opposing Si atoms are separated by 10.28 and 10.31 Å. Folding of the heterosiloxane ring leads to Fe–Fe distances for the *cis* ferrocenyl groups that are very different (7.77 and 10.63 Å). The cyclopentadienyl rings of the two closer ferrocenyl groups are tilted by 2.5° and 4.2°, whereas the other two ferrocenyl groups have ring tilts between 0.9° and 1.3°. With values between 1.647(3) and 1.653(3) Å, the Fe–Cp and Fe(η-C_5H_4) distances are in the range of ferrocene.

The 6-membered boraferrocenylcyclosiloxane **8** shows the highest crystallographic symmetry of the rings studied. As with the zirconaferrocenylsiloxane **6** it crystallizes in a monoclinic space group, $C2/c$, but **8** lies on a two-fold axis, and so only half of the molecule is in the asymmetric unit. Figure 4 shows two views of the borasiloxane **8**. The BSi_2O_3 ring is in a slight twist conformation with an interior angle sum of 716.91(54)° and a mean deviation from planarity of 0.066 Å. The Si–O distances in the ring system are similar to **6**, but the B—O bond lengths of **8** are much shorter than the Zr—O bond lengths of **6**. Moreover, the O-Si-O angles in **8** are smaller than in **6**. The ring tilts of the ferrocenyl groups are 1.3° and 3.3°. Ferrocenyl groups attached to the same Si are separated by 5.52 Å, whereas Fe–Fe distances for ferrocenes on adjacent Si atoms are 6.79, 7.46, and 9.09 Å.

Only the 8-membered borasiloxane ring **9** crystallized without solvent molecules in the lattice. This species crystallized in the triclinic space group P-1 with Z = 1, therefore the molecule has crystallographic inversion symmetry. The molecular structure of **9** is illustrated in Fig. 5. The B-O-Si angles are 137.37(13)° and 166.73(14)°, much larger than observed in **8** where the B-O-Si angles are 128.3(2)°. The $B_2Si_2O_4$ ring is in a chair-like conformation. The atoms in the ring are displaced by an average of 0.054 Å from planarity. Significantly, two of the ferrocenyl groups in this structure are almost parallel to the ring plane and are sitting right above it. This observation is in contrast to the other ferrocenylsiloxane rings **4** and **6**–**8** that we have investigated where the ferrocenes are arranged in a "pinwheel" above and below the ring. The distance between the Fe atoms of the two ferrocenyl substituents arranged over and beneath the ring is 8.21 Å, smaller than the distance between the Fe atoms of the remaining two opposite ferrocenyl groups (10.59 Å). The Fe–Fe distances between the *cis*-opposite ferrocenyl groups are equal (7.32 Å) as a consequence of the center of inversion. Compared with the corresponding 6-membered ring **8**, the Fe atoms of the ferrocenyl groups on the same silicon atom in **9** are separated by longer distances (6.01 Å). The ferrocenyl moieties show small ring tilts (1.2° and 1.3°).

Ring-opening polymerization behaviour of the heterosiloxanes 6–9

Many inorganic rings, including many cyclosiloxanes, undergo thermal ROP. To explore the possibility for thermal ROP of the zirconaferrocenylcyclosiloxanes **6** and **7**, the thermal behaviour of these species was examined. The thermogravimetric analyses (TGA) of both **6** and **7** showed onsets of decomposition at ~170°C. Past this temperature **6** shows a multistep decomposition that ends at ~600°C and gives a ceramic yield of about 30%. In the case of **7** there is a rapid one-step decomposition that ends at ~300°C and gives an ultimate ceramic yield of approximately 35%. Differential scanning calorimetry (DSC) of **6** and **7** up to 150°C showed no melt transitions or exothermic events that could be attributed to ROP processes. Subsequent ^{1}H NMR analyses of the DSC samples showed the presence of only **6** and **7**, respectively, and confirmed that thermal ROP was not taking place prior to decomposition.

The thermal behaviour of the boraferrocenylcyclosiloxanes **8** and **9** was also investigated by TGA and DSC.

Fig. 4. (*a*) Molecular structure of **8**. (*b*) Side-on view of **8**. The structures are shown with thermal ellipsoids at the 30% probability level.

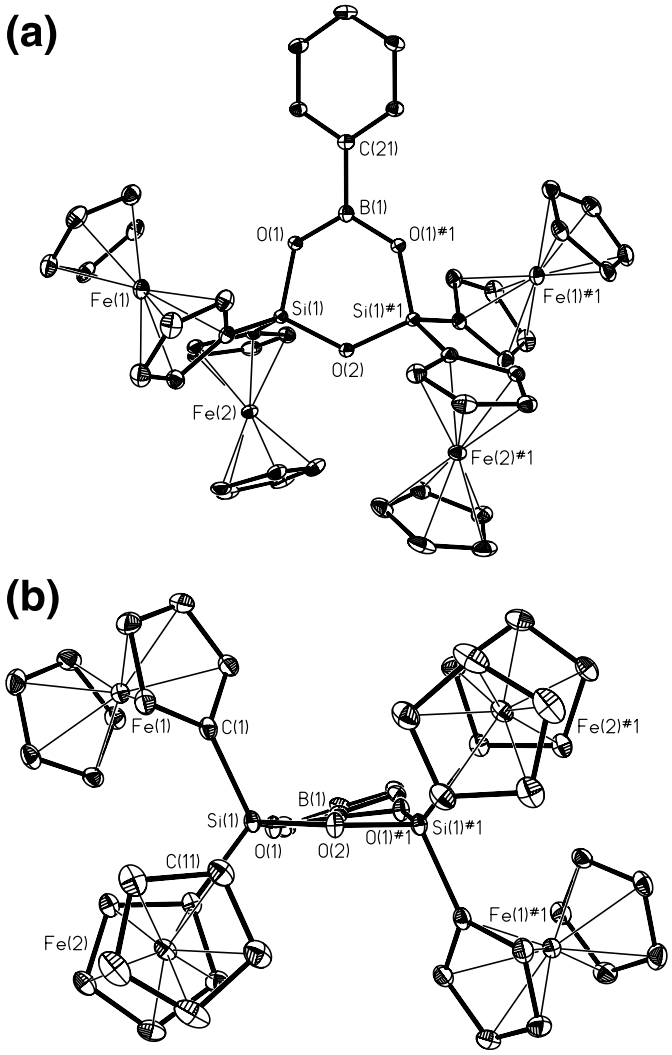

Fig. 5. (*a*) Molecular structure of **9**. (*b*) Side-on view of **9**. The structures are shown with thermal ellipsoids at the 30% probability level.

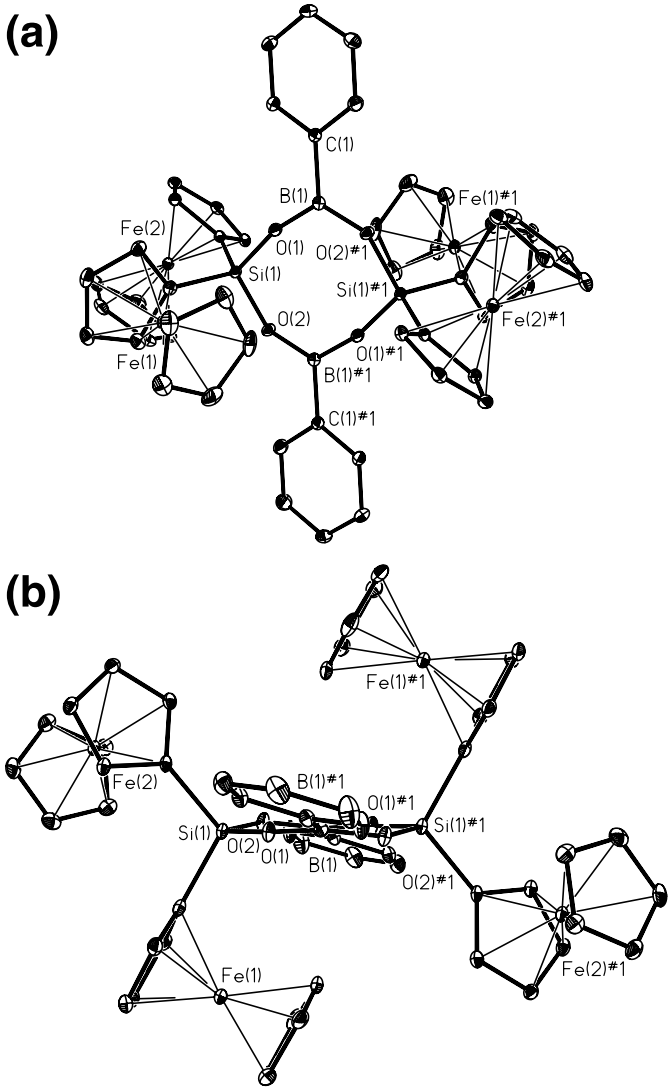

in the cases of the zirconium-containing rings, the ^{1}H NMR of the samples of **8** and **9** after DSC showed only the original rings and confirmed the lack of thermal ROP for these systems.

Attempts to induce anionic and cationic ROP of the rings were also made, but in no case was there evidence for the formation of ring-opened polymer or oligomers upon treatment with 10 mol% anionic ($KOSiMe_3$) or cationic (HOTf) initiator. In the case of the 8-membered boraferrocenylcyclosiloxane ring **9** there is ^{1}H NMR evidence for ring–ring redistributions in the presence of $KOSiMe_3$, as seen by the appearance of resonances due to both **8** and another unidentified product. Under these conditions ring rearrangement reactions are likely favoured over ROP, as previously observed for other boracyclosiloxane systems (7). It is well known that the presence of large substituents on monomers hinder ROP, and it is possible that the large ferrocenyl substituents on the silicon atoms of **6**–**9** significantly disfavour the formation of extended chain polyheterosiloxanes.

Experimental

General

$PhBCl_2$, $KOSiMe_3$, and HOTf were purchased from Aldrich and used as received. Triethylamine (Aldrich) was dried over sodium, distilled, and stored over molecular sieves prior to use. $Cp_2Zr(NMe_2)_2$ (22), $Fc_2Si(OH)_2$ (**3**) (13), and $[Fc_2SiOH]_2O$ (**5**) (13) were prepared according to literature methods.

All reactions and manipulations were carried out under an atmosphere of prepurified nitrogen using either an inert-atmosphere glovebox or Schlenk techniques, unless otherwise noted. Solvents were dried by standard methods, distilled, and stored under nitrogen. The 400 MHz ^{1}H NMR and 100 MHz ^{13}C NMR spectra were recorded on a Varian Unity 400 spectrometer. ^{1}H NMR spectra were referenced to residual protons in C_6D_6 at 7.15 ppm or $CDCl_3$ at 7.24 ppm, and ^{13}C NMR spectra were referenced to the C_6D_6 signal at 128.0 ppm or the $CDCl_3$ signal at 77.0 ppm. The 79.5 MHz

© 2002 NRC Canada

^{29}Si NMR spectra were recorded on a Varian Unity 400 spectrometer using a proton-decoupled pulse sequence and were referenced externally to $SiMe_4$ (TMS). The 160 MHz ^{11}B NMR spectra were recorded on a Varian Unity 500 spectrometer and were visualized by cutting off the broad glass peak from the FID. The spectra were referenced externally to $BF_3{\cdot}Et_2O$. UV–vis spectra were obtained in CH_2Cl_2 on a Perkin-Elmer Lambda 900 UV/VIS-near IR spectrometer using a 1-cm quartz cuvette. IR spectra were obtained as Nujol mulls or CCl_4 solutions with a Perkin-Elmer Protagon 500 FT-IR spectrometer. FT-Raman spectra were collected on a Bomem MB-157 FT spectrometer with a Spectra Physics diode pumped Nd:YLF laser (1064 nm, 350 kHz repetition rate). The instrument was configured in 180° backscattering mode using sealed glass capillary tubes to hold the neat samples. Electron impact (EI) and fast atom bombardment (FAB) mass spectra were obtained with a VG 70-250S mass spectrometer. Elemental analyses were performed by Quantitative Technologies Inc., Whitehouse, N.J. Thermogravimetric analysis was performed on a TA Instruments TGA Q500 instrument at 10°C min^{-1}, from 25°C to 900°C, under an atmosphere of prepurified nitrogen. Differential scanning calorimetry was performed on a TA Instruments DSC 2920 instrument calibrated at a heating rate of 10°C min^{-1} using a traceable indium reference standard with a melting point of 156.6°C and a heat of fusion of 28.71 J g^{-1}. Melting points were obtained with a Fisher-Johns melting point apparatus and are uncorrected.

Synthesis of $Cp_2Zr(OSiFc_2)_2O$ (6)

A solution of 0.200 g (0.236 mmol) of tetraferrocenyldisiloxanediol (**5**) dissolved in 150 mL diethyl ether was cooled to –78°C. A cooled solution of 72 mg (0.23 mmol) bis(dimethylamino)zirconocene in 20 mL ether was added dropwise to the stirred reaction mixture. The reaction solution was stirred for several hours while it warmed to room temperature and was then filtered through a frit. The solvent was removed from the yellow filtrate to give the crude product. Recrystallization from dichloromethane afforded 0.235 g (0.221 mmol, 95%) of **6** as an orange-yellow powder. ^{1}H NMR (400 MHz, C_6D_6) δ: 6.20 (s, 10H, Zr-Cp), 4.88 (qt, $^3J_{HH}$ = 0.88 Hz, 4H, C_5H_4), 4.80 (qt, $^3J_{HH}$ = 1.10 Hz, 4H, C_5H_4), 4.39 (qt, $^3J_{HH}$ = 1.18 Hz, 8H, C_5H_4), 4.23 (s, 20H, Fe-Cp) ppm. ^{13}C NMR (100 MHz, C_6D_6) δ: 114.03 (Zr-Cp), 74.74 (C_5H_4), 74.24 (C_5H_4), 71.49 (C_5H_4), 71.29 (C_5H_4), 69.44 (Fe-Cp), 69.21 (*ipso*-C_5H_4) ppm. ^{29}Si NMR (79.5 MHz, C_6D_6) δ: –33.0 ppm. UV–vis (CH_2Cl_2): λ (ε) 452 (408) nm (L mol^{-1} cm^{-1}). MS (EI, 70 eV): m/z (%) 1064 (M^+, 100), 627 (M^+-2FcH-Cp, 46), 186 (FcH^+, 68), 121 ($CpFe^+$, 39). mp: dec. >120°C. Anal. calcd.: C 53.24, H 4.20; found: C 52.38, H 4.11.

Synthesis of $[Cp_2Zr(OSiFc_2)O]_2$ (7)

A solution of 0.100 g (0.323 mmol) bis(dimethylamino)zirconocene in 30 mL diethyl ether was dropped into a stirred solution of 0.14 g (0.323 mmol) diferrocenylsilanediol (**3**) in ether at –78°C. A white precipitate formed while the mixture was warmed to room temperature over 6 h. The solvent was removed under vacuum, leaving a yellow residue. The product was dissolved in a minimum of dichloromethane, filtered, and recrystallized at –20°C. After the yellow powder was collected, it was dissolved in chloroform. Slow evaporation of the solvent gave yellow X-ray quality crystals of **7**. The overall yield was 95% (0.200 g, 0.153 mmol). ^{1}H NMR (400 MHz, C_6D_6) δ: 6.22 (s, 20H, Zr-Cp), 4.77 (t, $^3J_{HH}$ = 1.60 Hz, 8H, C_5H_4), 4.41 (t, $^3J_{HH}$ = 1.65 Hz, 8H, C_5H_4), 4.32 (s, 20H, Fe-Cp) ppm. ^{13}C NMR (100 MHz, C_6D_6) δ: 113.50 (Zr-Cp), 74.45 (C_5H_4), 72.82 (*ipso*-C_5H_4), 71.19 (C_5H_4), 69.32 (Fe-Cp) ppm. ^{29}Si NMR (79.5 MHz, C_6D_6) δ: –35.7 ppm. UV–vis (CH_2Cl_2): λ (ε) 458 (551) nm (L mol^{-1} cm^{-1}). MS (EI, 70 eV): m/z (%) 1302 (M^+, 15), 1051 (M^+-O_2ZrCp_2+H_2, 5), 865 (M^+-O_2ZrCp_2-FcH+H_2, 19), 799 (M^+-O_2ZrCp_2-FcH-Cp+H^+, 6), 733 (M^+-O_2ZrCp_2-FcH-2Cp, 4), 679 (M^+-O_2ZrCp_2-2FcH+H_2, 8), 186 (FcH^+, 100), 121 ($CpFe^+$, 40). mp: dec. >200°C. Anal. calcd.: C 55.30, H 4.33; found: C 54.62, H 4.21.

Synthesis of $(C_6H_5)B(OSiFc_2)_2O$ (8)

Tetraferrocenyldisiloxanediol (**5**) (0.106 g, 0.125 mmol) was dissolved in 150 mL of diethyl ether and cooled to –78°C. Ten equivalents (100 μL, 1.25 mmol) of triethylamine were then added to the solution. A solution of 20 mg (0.125 mmol) $PhBCl_2$ in 7 mL of diethyl ether was then added dropwise. The reaction mixture was stirred for an additional 2 h at –78°C and was then warmed to room temperature overnight. The mixture was filtered under nitrogen and the slightly yellow precipitate was washed with THF. Solvent removal under vacuum afforded a crude yellow solid that was dried under vacuum to remove excess triethylamine. The residue was then dissolved in dichloromethane and recrystallized at –55°C. Dark orange crystals that shattered under vacuum because of loss of solvent from the structure, were obtained. Compound **8** was isolated in an 85% (0.099 g, 0.106 mmol) yield. ^{1}H NMR (400 MHz, C_6D_6) δ: 8.36 (m, 2H, Ph), 7.30 (m, 3H, Ph), 4.68 (m, 4H, C_5H_4), 4.58 (m, 4H, C_5H_4), 4.30 (m, 4H, C_5H_4), 4.28 (m, 4H, C_5H_4), 4.22 (s, 20H, Cp) ppm. ^{11}B NMR (160 MHz, C_6D_6) δ: 30.5 ppm. ^{13}C NMR (100 MHz, C_6D_6) δ: 135.90 (Ph), 131.89 (B-Ph), 74.42 (C_5H_4), 74.20 (C_5H_4), 72.09 (C_5H_4), 71.95 (C_5H_4), 69.41 (Fe-Cp), 65.81 (*ipso*-C_5H_4) ppm. ^{29}Si NMR (79.5 MHz, C_6D_6) δ: –20.0 ppm. UV–vis (CH_2Cl_2): λ (ε) 450 (465) nm (L mol^{-1} cm^{-1}). MS (EI, 70 eV): m/z (%) 932 (M^+, 100), 746 (M^+-FcH, 9), 681 (M^+-FcH-Cp, 27), 577 (M^+-FcH-Cp-OBPh, 19), 466 (M^{++}, 11), 186 (FcH^+, 68), 121 ($CpFe^+$, 39). mp 249°C. Synthesis of $[(C_6H_5)B(OSiFc_2)O]_2$ (9)

A solution of 39.7 mg (0.249 mmol) $PhBCl_2$ in 10 mL diethylether was added dropwise to a stirred mixture of 0.108 g (0.249 mmol) diferrocenylsilanediol (**3**) and 0.348 mL (2.49 mmol) triethylamine in 150 mL ether at –78°C. A white precipitate, $[HNEt_3]Cl$, formed after 15 min, but to achieve complete conversion the mixture was stirred for another 8 h while it warmed to room temperature. Filtration through a glass frit, followed by washing with THF until the washings ran clear, gave a yellow solution that was evaporated to dryness to remove solvent and excess triethylamine. The yellow powder was then recrystallized from dichloromethane at –40°C to finally give ca. 30 mg (0.029 mmol, 23%) light orange crystals of **9**. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 8.18 (d, $^3J_{HH}$ = 7.8 Hz, 4H, Ph), 7.53 (m, 6H, Ph), 4.42

Thermogravimetric analysis of 6–9

For **6**: 5.6160 mg; multistage decomp. (% char yield): 170–195°C (83%); 195–250°C (52%); 250–295°C (46%); 295–600°C (30%); ceramic yield (900°C): 30%. For **7**: 5.3350 mg; one-stage decomp. (% char yield): 170–300°C (35%); ceramic yield (900°C): 35%. For **8**: 6.9610 mg; two-stage decomp. (% char yield): 275–400°C (80%), 400–540°C (78%); ceramic yield (900°C): 77%. For **9**: 5.7710 mg; two-stage decomp. (% char yield): 230–300°C (95%), 300–450°C (30%); ceramic yield (900°C): 18%.

Differential scanning calorimetry of 6–9

For **6**: 10.1 mg; 10–150°C. For **7**: 7.9 mg; 10–150°C. For **8**: 7.8 mg; 10–200°C. For **9**: 7.8 mg; 10–200°C. No thermal events consistent with melt transitions or ROP exotherms were observed for **6–9**.

Attempted anionic polymerizations of 6–9

The procedure for each sample is analogous and follows the sample procedure detailed. $Cp_2Zr(OSiFc_2)_2O$ (**6**) (11 mg, 9 μmol) was dissolved in 8 mL THF. The solution was initiated with 132 μL $KOSiMe_3$ (1 mg mL^{-1} in THF; 0.9 μmol). After the reaction mixture stirred for ca. 1d solvent was removed under vacuum to leave a yellow residue. The residue was redissolved in C_6D_6 and characterized using ^{1}H NMR. Only resonances for **6** and $KOSiMe_3$ were observed. For **7**: 22 mg, 16 mmol, 15 mL THF, 216 μL of 1 mg mL^{-1} $KOSiMe_3$ in THF. Only resonances for **7** and $KOSiMe_3$ were observed. For **8**: 20 mg, 22 mmol, 15 mL THF, 275 μL of 1 mg mL^{-1} $KOSiMe_3$ in THF. Only resonances for **8** and $KOSiMe_3$ were observed. For **9**: 15 mg, 15 mmol, 12 mL THF, 185 μL of 1 mg mL^{-1} $KOSiMe_3$ in THF. Resonances for **9**, the ring-contraction product **8**, and an unidentified nonpolymeric species were observed.

Attempted cationic polymerizations of 6–9

The procedure for each sample is analogous and follows the sample procedure detailed. $Cp_2Zr(OSiFc_2)_2O$ (**6**) (12 mg, 10 μmol) was dissolved in 8 mL CH_2Cl_2. The solution was initiated with 99 μL HOTf (1 μL mL^{-1} in CH_2Cl_2; 1.0 μmol). After the reaction mixture stirred for ca. 1 d, solvent was removed under vacuum to leave a yellow residue. The residue was redissolved in C_6D_6 and characterized using ^{1}H NMR. The presence of **6** and free ferrocene, due to Si–Fc cleavage (~5%), was detected. For **7**: 26 mg, 17 mmol, 15 mL CH_2Cl_2, 177 μL of 1 μL mL^{-1} HOTf in CH_2Cl_2. Only the presence of **7** was detected. For **8**: 21 mg, 22 mmol, 15 mL CH_2Cl_2, 199 μL of 1 μL mL^{-1} HOTf in CH_2Cl_2. The presence of **8** and free ferrocene, due to Si–Fc cleavage (~90%), were detected. For **9**: 17 mg, 16 mmol, 12 mL CH_2Cl_2, 145 μL of 1 μL mL^{-1} HOTf in CH_2Cl_2. **9** was no longer identifiable in the sample but a large ferrocene resonance is indicative of almost complete cleavage of this substituent from the ring. No resonances due to polymer or oligomer were observed for any of the trials.

Crystallographic structural determination

Selected crystal, data collection, and refinement parameters for **6–9** are given in Table 3. Selected intermolecular bond lengths and angles for **6–9** are given in Tables 4–7, respectively.[3] Single-crystal X-ray diffraction data were collected at low temperature under nitrogen with a Nonius Kappa-CCD diffractometer using graphite monochromated MoK_α radiation (λ = 0.710 73 Å). The data were integrated and scaled using the Denzo-SMN package (23). The SHELXTL/PC package was used to solve and refine the structures (24). Refinement was by full-matrix least-squares on F^2 using all data (negative intensities included). Refinement was optimized with hydrogen atoms in calculated positions. The weighting schemes were $w = 1/[\sigma^2(F_o^2) + (0.0328P)^2 + 4.0372P]$ for **6**, $w = 1/[\sigma^2(F_o^2) + (0.0321P)^2 + 1.8184P]$ for **7**, $w = 1/[\sigma^2(F_o^2) + (0.0443P)^2 + 5.6603P]$ for **8**, and $w = 1/[\sigma^2(F_o^2) + (0.0252P)^2 + 0.9821P]$ for **9**, where $P = (F_o^2 + 2F_c^2)/3$.

Summary

Our results show that diferrocenylsilanediol (**3**) and tetraferrocenyldisiloxanediol (**5**) are useful precursors to novel heterocyclosiloxanes with redox-active ferrocenyl substituents on the Si atoms. Zirconatetraferrocenylcyclosiloxanes **6** and **7** and boratetraferrocenylcyclosiloxanes **8** and **9** have been synthesized and characterized. The inorganic heterosiloxanes were also investigated by single crystal X-ray diffraction. Attempts to induce ROP of the cyclics have been unsuccessful to date. Future work will involve expansion of the range of inorganic elements incorporated into cyclosiloxane frameworks with an emphasis on the use of small substituents that would be expected to favour ROP processes.

The synthesis of [{*n*-$Bu_2Sn(S_2N_2)$}$_2$] and its use in the preparation of organometallic iridium sulfur nitrogen complexes

Stephen M. Aucott, Alexandra M.Z. Slawin, and J. Derek Woollins

Abstract: The addition of [*n*-Bu_2SnCl_2] to a solution of $[S_4N_3][Cl]$ in liquid ammonia gave after extraction of the dry reaction mixture the new tin disulfur dinitrido compound [{*n*-$Bu_2Sn(S_2N_2)$}$_2$] (**1**). Reaction of [{*n*-$Bu_2Sn(S_2N_2)$}$_2$] (**1**) with the pentamethylcyclopentadienyl (Cp*) iridium derivatives [{$IrCl(\mu\text{-}Cl)(\eta^5\text{-}C_5Me_5)$}$_2$] or [($\eta^5$-$C_5Me_5$)$IrCl_2(PPh_3)$] gave different products, which were dependent on the reactant ratios. A 1:1 reaction between **1** and [{$IrCl(\mu\text{-}Cl)(\eta^5\text{-}C_5Me_5)$}$_2$] gave only [($\eta^5$-$C_5Me_5$)$Ir(S_2N_2)$] (**2**) in moderate yield; the same product in higher yield was obtained from a 2:1 reaction between **1** and [(η^5-C_5Me_5)$IrCl_2(PPh_3)$]. Reaction of **1** and [(η^5-C_5Me_5)$_2IrCl_2(PPh_3)$] (1:1 molar ratio) in the presence of $NH_4[PF_6]$ gave the unusual bimetallic species [(η^5-C_5Me_5)$IrCl(PPh_3)(S_2N_2)Ir(\eta^5\text{-}C_5Me_5)][PF_6]$ (**3**). The X-ray crystal structures of **1**, **2**, and **3** are reported.

Key words: liquid ammonia, tin sulfur–nitrogen reagent, metathesis, sulfur–nitrogen metallacycle, iridium complexes.

Résumé : L'addition du [*n*-Bu_2SnCl_2] à une solution de $[S_4N_3][Cl]$, dans de l'ammoniac liquide, suivie d'une extraction conduit à la formation d'un mélange réactionnel sec du nouveau composé dinitrido disoufre étain [{*n*-$Bu_2Sn(S_2N_2)$}$_2$] (**1**). La réaction du composé [{*n*-$Bu_2Sn(S_2N_2)$}$_2$] (**1**) avec les dérivés pentaméthylcyclopentadiényl (Cp*) iridium [{$IrCl(\mu\text{-}Cl)(\eta^5\text{-}C_5Me_5)$}$_2$] ou [($\eta^5$-$C_5Me_5$)$IrCl_2(PPh_3)$] conduit à des produits différents suivant les rapports de réactifs. Une réaction 1:1 entre **1** et [{$IrCl(\mu\text{-}Cl)(\eta^5\text{-}C_5Me_5)$}$_2$] ne conduit qu'au produit [(η^5-C_5Me_5)$Ir(S_2N_2)$] (**2**) avec un rendement moyen; on obtient le même produit, avec un rendement un peu plus élevé par réaction 2:1 entre **1** et [(η^5-C_5Me_5)$IrCl_2(PPh_3)$]. La réaction du composé **1** avec [(η^5-C_5Me_5)$_2IrCl_2(PPh_3)$] (rapport molaire 1:1) en présence de $NH_4[PF_6]$ conduit à la formation de l'espèce bimétallique inhabituelle [(η^5-C_5Me_5)$IrCl(PPh_3)(S_2N_2)Ir(\eta^5\text{-}C_5Me_5)][PF_6]$ (**3**). On a déterminé les structures cristallines des composés **1**, **2** et **3** par diffraction des rayons X.

Mots clés : ammoniac liquide, réactif azote–soufre étain, métathèse, métallacycle soufre–étain, complexes de l'iridium.

[Traduit par la Rédaction]

Introduction

Silyl and tin reagents have proven useful sources of sulfur–nitrogen fragments in the synthesis of heterocycles (1, 2). In many examples the driving force of these reactions is the formation of M—X (M = Si or Sn; X = Br, Cl, or F) bonds. Thus, for example, bis(trimethylsilyl)sulfur diimide $(Me_3Si)_2N_2S$ reacts with $S_4N_4Cl_2$ and *o*-$C_6H_4(SCl)_2$, providing an $[N_2S]^{2-}$ fragment, to give S_5N_6 (3) and *o*-$C_6H_4(SN)_2S$ (4), respectively. Similarly [{$Me_2Sn(S_2N_2)$}$_2$] (5) supplies an $[S_2N_2]^{2-}$ fragment and gives the five-membered ring compounds $C(O)S_2N_2$ (6) and $S(O)S_2N_2$ (7) with carbonyl fluoride (COF_2) and thionyl fluoride (SOF_2), respectively. Metal sulfur nitrides (see references 8 and 9 for reviews) have been prepared analogously from Group 14 sulfur–nitrogen reagents and metal halides. Examples include formation of the eight-membered ring compound $(MeAsNSN)_2$ (10) by reaction of $(Me_3Si)_2N_2S$ with $MeAsCl_2$ and complexes of the type $[M(S_2N_2H)(PR_3)_2][X]$ (X = Me_2SnCl_3, PF_6, or BF_4) (11) by treating *cis*-$[MCl_2(PR_3)_2]$ (M = Pt or Pd) with [{$Me_2Sn(S_2N_2)$}$_2$] via the elimination of Me_3SiCl and Me_2SnCl_2, respectively. Group 9 metal complexes containing the $[S_2N_2]^{2-}$ ligand are uncommon (especially when compared with those of Group 10 and in particular those of platinum) examples being [(η^5-C_5H_5)$Co(S_2N_2)$] (12–14), [(η^5-C_5Me_5)$Co(S_2N_2)$] (13–14), and $[Ir(dppe)_2(S_2N_2)][BPh_4]$ (15) (dppe = *cis*-1,2-bis(diphenylphosphino)ethane) prepared by the action of S_4N_4 on [(η^5-C_5H_5)$Co(CO)_2$] or [(η^5-C_5H_5)Co(cod)], [(η^5-C_5Me_5)$Co(CO)_2$], and $[Ir(dppe)_2(CO)][BPh_4]$, respectively. We report here the synthesis of two new organometallic thiazene complexes of iridium [(η^5-C_5Me_5)$Ir(S_2N_2)$] (**2**) and [(η^5-C_5Me_5)$IrCl(PPh_3)$-$(S_2N_2)Ir(\eta^5\text{-}C_5Me_5)][PF_6]$ (**3**) prepared by metathesis using [{*n*-$Bu_2Sn(S_2N_2)$}$_2$] (**1**), a new example of a dialkyl–SnS_2N_2 dimer, of which only two other examples are known, the aforementioned methyl derivative [{$Me_2Sn(S_2N_2)$}$_2$] (5) and the *tert*-butyl analogue [{*t*-$Bu_2Sn(S_2N_2)$}$_2$] (16, 17).

Received 2 February 2002. Published on the NRC Research Press Web site at http://canjchem.nrc.ca on 12 November 2002.

Dedicated to Professor Tris Chivers in recognition of his unique contribution to main group chemistry.

Experimental

General

Unless otherwise stated, manipulations were performed under an oxygen-free nitrogen or argon atmosphere using pre-dried solvents and standard Schlenk techniques. The ammonia used was obtained from BOC Ltd and dried by passage through a column of NaOH. The reagents $[S_4N_3][Cl]$ (18) and $[\{IrCl(\mu\text{-}Cl)(\eta^5\text{-}C_5Me_5)\}_2]$ (19) were both prepared according to literature procedures, the latter from $IrCl_3{\cdot}3H_2O$ and pentamethylcyclopentadiene (both Strem). $[(\eta^5\text{-}C_5Me_5)IrCl_2(PPh_3)]$ was prepared by treating a CH_2Cl_2 solution of $[\{IrCl(\mu\text{-}Cl)(\eta^5\text{-}C_5Me_5)\}_2]$ with 2 equiv of PPh_3 (Aldrich) followed by precipitation of the product by the addition of diethyl ether. $[n\text{-}Bu_2SnCl_2]$, $NH_4[PF_6]$, and $Ag[PF_6]$ were purchased from Aldrich and used as received.

IR spectra were recorded as KBr pellets in the range 4000–220 cm^{-1} on a PerkinElmer system 2000 Fourier transform spectrometer. ^1H NMR spectra (250 MHz) were obtained using a Bruker AC250 FT spectrometer with δ referenced to external $SiMe_4$, ^{31}P NMR spectra (109.4 MHz or 101.3 MHz) either on a JEOL GSX270 or a Bruker AC250 FT spectrometer with δ referenced to external H_3PO_4, and ^{119}Sn NMR spectra (100.7 MHz) on a JEOL GSX270 spectrometer with δ referenced to external $SnMe_4$. Microanalyses were performed by the University of St Andrews Chemistry Department Service.

Preparations

$[\{n\text{-}Bu_2Sn(S_2N_2)\}_2]$ (1)

Ammonia (~200 cm^3) was condensed into a pre-cooled (–78°C, cardice–acetone) Schlenk flask. $[S_4N_3][Cl]$ (9.22 g, 44.82 mmol) was added to the ammonia in small portions over a 5 min period. The resulting dark red reaction mixture was stirred at –78°C for an additional 30 min. $[n\text{-}Bu_2SnCl_2]$ (27.24 g, 89.64 mmol) was then added to this mixture in small portions again over 5 min. Once the addition was complete the reaction vessel was topped with a bubbler and stirred at –78°C for 2.5 h then the cooling bath was removed and the reaction gradually warmed to room temperature. Once the ammonia had evaporated the reaction residue was dried in vacuo for ca. 1 h before being placed in a Sohxlet thimble. The residue was extracted with (40–60°C) petroleum ether (250 cm^3) until the extracts were nearly colourless (approximately 4–5 h). The resulting deep orange–red solution was placed in a freezer (–20°C) overnight and the deposited bright yellow crystals were collected by filtration under an atmosphere of nitrogen or argon and washed with cold (<0°C) hexanes (2 × 100 cm^3) and dried in vacuo. Yield: 20.98 g, 72%. IR (KBr pellet) (cm^{-1}): 2956 (m), 2918 (m), 2871 (m), 2853 (m), 1063 (s), 1033 (vs), 899 (vs), 769 (m), 697 (s), 668 (w), 622 (s), 443 (m), 385 (m). ^1H NMR (C_6D_6) δ: 1.55–0.78 (m, 36 H, *n*-Bu). ^{119}Sn (C_6D_6) δ: 37.8 (br s). EI–CI-MS *m/z* (%): 267 (*n*-$BuSnS_2N_2$, 20), 210 (SnS_2N_2, 13), 177 (*n*-BuSn, 17), 166 (SnSN, 11), 120 (Sn, 9), 64 sulfur–nitrogen(S_2, 100), 60 (NSN, 70), and 46 (SN, 35). Anal. calcd. for $C_{16}H_{36}N_4S_4Sn_2$ (%): C 29.45, H 5.56, N 8.59, S 19.62; found: C 29.21, H 5.29, N 8.50, S 19.73.

$[(\eta^5\text{-}C_5Me_5)Ir(S_2N_2)]$ (2)

Method A.

To an orange solution of $[\{IrCl(\mu\text{-}Cl)(\eta^5\text{-}C_5Me_5)\}_2]$ (197 mg, 0.247 mmol) in dichloromethane (20 cm^3) was added $[\{n\text{-}Bu_2Sn(S_2N_2)\}_2]$ (**1**) (161 mg, 0.248 mmol) in one portion. Over the course of 25 min the reaction mixture darkened to a deep red colour and stirring was continued for a total of 8 h. The reaction mixture was evaporated to dryness under reduced pressure and then taken up in toluene (25 cm^3). The slightly cloudy dark orange solution was then added to a column of silica (20 × 2 cm) and first eluted with toluene (200 cm^3), which was discarded, and then with acetone; the orange band that moved with the solvent front was collected and taken to dryness. The residue was dissolved in the min amount of warm (60–70°C) toluene and stored at 4°C overnight. The resulting well-formed dark orange–red crystals were collected by suction filtration and dried in vacuo. Yield: 107 mg, 53%.

Method B.

$[(\eta^5\text{-}C_5Me_5)IrCl_2(PPh_3)]$ (245 mg, 0.371 mmol) and $[\{n\text{-}Bu_2Sn(S_2N_2)\}_2]$ (**1**) (242 mg, 0.372 mmol) were stirred together in dichloromethane (20 cm^3) for 8 h. The product isolation procedure is exactly as described above (Method A). Yield: 131 mg, 84%. IR (KBr pellet) (cm^{-1}): 2984 (w), 2962 (w), 2921 (w), 2854 (w), 1490 (w), 1458 (s), 1427 (w), 1376 (s), 1158 (w), 1079 (w), 1027 (vs), 957 (s), 701 (vs), 697 (w), 636 (s), 612 (w), 590 (w), 502 (s), 453 (m), 397 (s), 383 (w). ^1H NMR (C_6D_6) δ: 1.65 (s, 15 H, C_5Me_5). FAB^+-MS *m/z*: 420 ($[M]^+$). Anal. calcd. for $C_{10}H_{15}IrN_2S_2$ (%): C 28.57, H 3.60, N 6.67, S 15.22; found: C 28.58, H 3.35, N 6.31, S 15.17.

$[(\eta^5\text{-}C_5Me_5)IrCl(PPh_3)(S_2N_2)Ir(\eta^5\text{-}C_5Me_5)][PF_6]$ (3)

Method A.

To a dichloromethane (20 cm^3) solution of $[(\eta^5\text{-}C_5Me_5)IrCl_2(PPh_3)]$ (237 mg, 0.359 mmol) were added as solids $[\{n\text{-}Bu_2Sn(S_2N_2)\}_2]$ (**1**) (117 mg, 0.180 mmol) and $NH_4[PF_6]$ (45 mg, 0.360 mmol); the resulting red–brown reaction mixture was stirred for 18 h at room temperature before filtration through Celite; the Celite was washed with a further 10 cm^3 of dichloromethane. The filtrate and the washings were evaporated to ca. 15 cm^3 and allowed to slowly decrease in volume over 2 weeks giving a small crop of orange–brown crystals, which were manually separated from the reaction residue, washed with diethyl ether, and dried in vacuo. Yield: 79 mg, 37%. Single crystals suitable for X-ray analysis were grown by diffusion of diethyl ether into a dilute dichloromethane solution of **3**.

Method B.

To a dichloromethane (20 cm^3) solution of $[(\eta^5\text{-}C_5Me_5)IrCl_2(PPh_3)]$ (105 mg, 0.159 mmol) was added as a solid $Ag[PF_6]$ (40 mg, 0.158 mmol), and the reaction mixture was stirred in the dark for 2 h. To this reaction mixture was added solid $[(\eta^5\text{-}C_5Me_5)Ir(S_2N_2)]$ (**2**) (67 mg, 0.160 mmol) in one portion and a further 10 cm^3 of dichloromethane. The mixture was stirred for an additional 2 h at room temperature in the dark and then filtered through Celite to remove the precipitated AgCl. The filtrate was then evaporated to ca. 5–6 cm^3 under reduced pressure. Precipitation was induced

The crystals used in the X-ray analysis of **3** were obtained via Method A. Further characterization was performed using material synthesized by Method B.

X-Ray crystallography

Table 1 lists details of data collections and refinements for **1**, **2**, and **3**. Data were collected at room temperature using Mo Kα radiation with a SMART system. Intensities were corrected for Lorentz polarization and for absorption. The structures were solved by the heavy atom method or by direct methods. The positions of the hydrogen atoms were idealized. High thermal motion in the *n*-butyl groups of compound **1** meant that the carbon atoms were refined isotropically subject to distance constraints. Refinements were by full-matrix least squares based on F^2 using SHELXTL (20).[2]

Results and discussion

The addition of [*n*-Bu_2SnCl_2] to a reaction mixture of [S_4N_3][Cl] in liquid ammonia gives, after extraction of the dry reaction residue with 40–60°C petroleum ether, the di-*n*-butyltin disulfur dinitrido compound [{*n*-$Bu_2Sn(S_2N_2)$}$_2$] (**1**) in 72% yield (eq. [1]). This reaction represents a more convenient route to this class of compound and uses a commercial source of tin and a stable readily prepared source of sulfur and nitrogen. By comparison the two previously reported examples of this type of compound employ tris(timethylstannyl)amine [$(Me_3Sn)_3N$] and S_4N_4 (eq. [2]) and the tin starting material **4** and elemental sulfur (eq. [3]) in their syntheses, which give [{$Me_2Sn(S_2N_2)$}$_2$] and [{*t*-$Bu_2Sn(S_2N_2)$}$_2$] + compound **5**, respectively. Compound **1** is a moderately air- and moisture-sensitive yellow crystalline

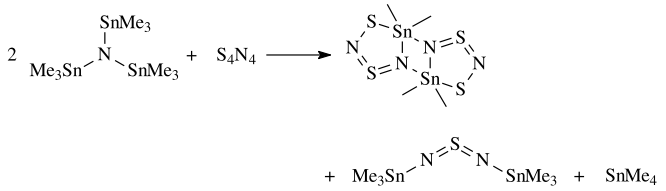
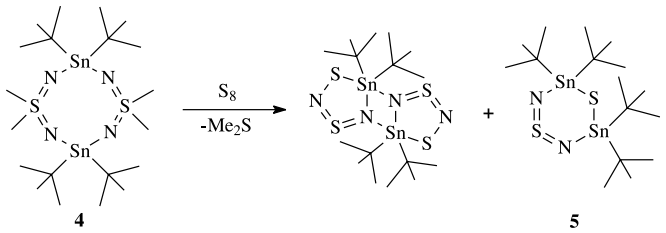
[2]



[3]



solid that is extremely soluble in most common organic solvents including pentane and hexane. The ^{1}H NMR (C_6D_6) is uninformative and is very similar to that of its precursor [*n*-Bu_2SnCl_2] with no evident ^{1}H-^{117}Sn or ^{1}H-^{119}Sn couplings. The ^{119}Sn NMR (C_6D_6) consists of a broad singlet at 37.8 ppm while the corresponding value of *n*-Bu_2SnCl_2 is 124.7 ppm. The IR spectrum shows absorptions that are comparable to those reported for [{$Me_2Sn(S_2N_2)$}$_2$] (5). The EI–CI mass spectrum of **1** failed to show the molecular ion of either the dimer or monomer, however it did show *m*/*z* 267, which corresponds to [*n*-$BuSnS_2N_2$]$^+$ along with other tin-containing fragments (see Experimental); in addition elemental analysis was within specified limits. The slow passage of nitrogen for 24 h over a diethyl ether solution of **1** led to small but well-formed crystals that were suitable for X-ray analysis. The crystal structure of **1** (Fig. 1) and selected bond lengths and angles together with those of [{*t*-$Bu_2Sn(S_2N_2)$}$_2$] for comparison are given (Table 2). The X-ray structural determination of [{*n*-$Bu_2Sn(S_2N_2)$}$_2$] (**1**) identified the SnS_2N_2 unit as a 1,3,2,4,5-dithiadiazastannole

Fig. 1. Crystal structure of [{*n*-$Bu_2Sn(S_2N_2)$}$_2$] (**1**) showing the 1.5 independent molecules.

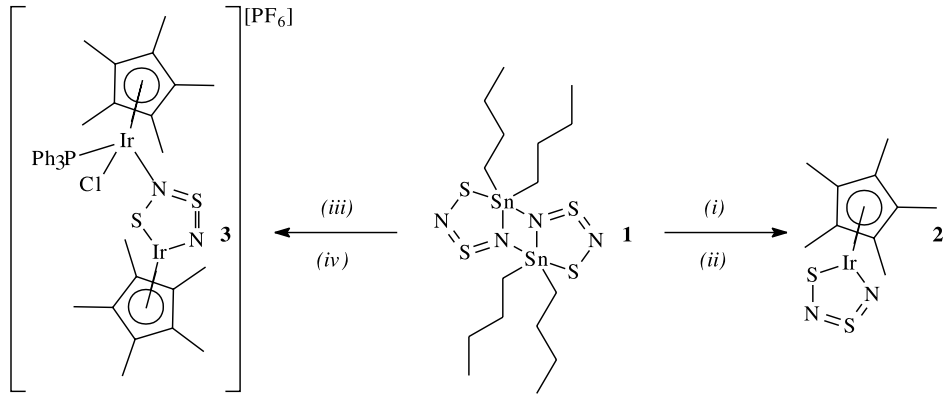
Scheme 1. (*i*) [{IrCl(μ-Cl)(η^5-C_5Me_5)}$_2$]; (*ii*) [(η^5-C_5Me_5)IrCl_2(PPh_3)]; (*iii*) [(η^5-C_5Me_5)IrCl_2(PPh_3)], $NH_4[PF_6]$; (*iv*) [(η^5-C_5Me_5)IrCl_2(PPh_3)], Ag[PF_6], [(η^5-C_5Me_5)Ir(S_2N_2)].



ring and highlighted the dimeric nature of the molecule. The unit cell of [{*n*-$Bu_2Sn(S_2N_2)$}$_2$] (**1**) contains 1.5 independent molecules consisting of three distinct *n*-$Bu_2Sn(S_2N_2)$ monomer units that have similar bond lengths and angles. The geometry about the tin atoms is distorted trigonal bipyramidal, the *n*-butyl groups and the tin-bound nitrogen atoms of the SnS_2N_2 rings in the equatorial positions with the tin-bound sulfur atoms of each SnS_2N_2 unit and the bridging nitrogen atoms occupying the axial sites. The three bond angles in the trigonal plane are all close to 120°, but the axial substituents occupy far from linear positions with average S-Sn-N = 152.3°. The ring Sn—N and Sn—S distances are close to those found in [{*t*-$Bu_2Sn(S_2N_2)$}$_2$] (17) and [{$Me_2Sn(S_2N_2)$}$_2$] (21) as is the pattern of average S—N bond lengths within the SnS_2N_2 ring, i.e., short (1.536 Å), medium (1.566 Å), and long (1.656 Å), a pattern also observed in other MS_2N_2 rings, for example [$(H_3N)Pb(S_2N_2)$] (22). The four-membered Sn_2N_2 rings are parallelograms, formed by the *n*-$Bu_2Sn(S_2N_2)$ dimer pairs and have average internal angles of N-Sn-N = 72.08° and Sn-N-Sn = 107.83°. The [$Sn(S_2N_2)$]$_2$ unit of the dimer consisting of two different *n*-$Bu_2Sn(S_2N_2)$ molecules is essentially planar with a mean deviation from the least squares plane of 0.06 Å and a maximum deviation of only 0.10 Å above the plane for Sn(1). The second pictured dimer made up of two repeat *n*-$Bu_2Sn(S_2N_2)$ units is closer to planarity with a mean deviation of 0.01 Å and a maximum deviation above the plane of 0.03 Å for N(5).

A previous attempt to obtain monocyclopentadienyl IrS_2N_2 complexes via oxidative addition to [(η^5-C_5H_5)Ir$(CO)_2$] with S_4N_4, a method that works well for the cobalt analogues [(η^5-C_5H_5)Co$(CO)_2$] and [(η^5-C_5Me_5)Co$(CO)_2$], gave only an insoluble black precipitate (14). An alternative synthetic method involving the treatment of [{IrCl(μ-Cl)(η^5-C_5Me_5)}$_2$] with [{*n*-$Bu_2Sn(S_2N_2)$}$_2$] (**1**) in dichloromethane proceeds via the elimination of [*n*-Bu_2SnCl_2] (^{119}Sn NMR evidence) and gives after chromatography on silica (eluting first with toluene and then with acetone) [(η^5-C_5Me_5)Ir(S_2N_2)] (**2**) in 53% yield (Scheme 1). Alternatively compound **2** can be prepared in higher yield (84%) by the reaction of 1 equiv of **1** and [(η^5-C_5Me_5)IrCl_2(PPh_3)], which proceeds via the elimination of PPh_3 (which undergoes further reaction with 0.5 equiv of **1** to give P(S)Ph_3 (^{31}P NMR evidence) and [*n*-Bu_2SnCl_2] (^{119}Sn NMR evidence); also shown by ^{119}Sn NMR were a number of other ^{119}Sn signals, presumably the by-products of the reaction between **1** and PPh_3, which we were unable to identify (Scheme 1). The air- and moisture-tolerant orange–red crystalline product is highly soluble in chlorinated solvents, benzene, and toluene and is slightly soluble in diethyl ether but is much less so in petroleum ether, hexane, and alcohols. The ^{1}H NMR (CD_2Cl_2) data shows the 15 Cp* (Cp* = pentamethylcyclopentadienyl) methyl group protons as a sharp singlet at δ 1.65 compared with 1.51 and a doublet at 1.32 $^4J_{^{31}P-^1H}$ = 2 Hz (both CD_2Cl_2) for [{IrCl(μ-Cl)(η^5-C_5Me_5)}$_2$] and [(η^5-C_5Me_5)IrCl_2(PPh_3)], respectively. The vibrational spectrum of complex **2** (KBr pellet) shows the expected bands due to the $[S_2N_2]^{2-}$ ligand at 1027 (vs) ν(NS), 701 (vs) ν(NS), 636 (s) ν(NS), 453 (m) ν(IrN), 397 (m) δ(NS), and 383 (w) cm^{-1} ν(IrS). Microanalytical data were in excellent agreement with the proposed formulation and the positive-ion FAB$^+$ mass spectra showed the molecular ion of **2** at *m*/*z* 420 ([M]$^+$). Large well-formed orange–red crystals, which were of X-ray quality were obtained by crystallization from hot (60–70°C) toluene. The X-ray structure of [(η^5-C_5Me_5)Ir(S_2N_2)] (**2**) is shown in Fig. 2 with bond distances and angles in Table 3 (along with those of [Ir(dppe)$_2$(S_2N_2)][BPh_4] (15) for comparison) and reveals that the IrS_2N_2 cycle is essentially planar, the largest deviation from the mean plane being only

0.007 Å with an S_2N_2 "bite angle" of 85.1(2)°. The bond lengths within the S_2N_2 unit of **1**, i.e., short (1.509(7) Å), medium (1.563(9) Å), and long (1.632(8) Å) seem to be in good agreement with those noted in previous studies (23–24) on monomeric PtS_2N_2 species, and in particular are consistent with the values reported for the only other crystallographically characterized monocyclopentadienyl MS_2N_2 complex [(η^5-C_5H_5)Co(S_2N_2)] (12), i.e., short (1.548(3) Å), medium (1.579(4) Å), and long (1.650(4) Å).

The reaction of [(η^5-C_5Me_5)IrCl_2(PPh_3)] with 0.5 equiv of **1** in the presence of $NH_4[PF_6]$ leads to the unusual bimetallic complex [(η^5-C_5Me_5)IrCl(PPh_3)(S_2N_2)Ir(η^5-C_5Me_5)][PF_6]·2H_2O (**3**) in low yield (37%) and poor purity (Scheme 1). A more rational approach, which gives this material in much higher yield (80%) and of more satisfactory purity involves the abstraction of a chloride ligand from [(η^5-C_5Me_5)IrCl_2(PPh_3)] with Ag[PF_6] followed by treatment of the resulting coordinatively unsaturated species with pre-formed [(η^5-C_5Me_5)Ir(S_2N_2)] (**2**). The resulting bright orange microcrystalline product is soluble in alcohols, THF, and chlorinated solvents, sparingly soluble in benzene and toluene, and insoluble in diethyl ether and hexane. The ^{1}H and ^{31}P NMR data (C_6D_6) of the dry crude reaction mixture suggests that this reaction proceeds cleanly to give only [(η^5-C_5Me_5)IrCl(PPh_3)(S_2N_2)Ir(η^5-C_5Me_5)][PF_6] (**3**), as only two Cp* environments are evident (Scheme 1). The first, bound to the iridium centre bearing the PPh_3 ligand, is a doublet at δ 1.31 $^4J_{^{31}P-^1H}$ = 2 Hz; the singlet at δ 2.08 we have assigned to the Cp* ligand of the (S_2N_2)Ir(η^5-C_5Me_5)] moiety. The ^{31}P NMR (CD_2Cl_2) data of **3** shows two phosphorus environments, a singlet at δ 9.7 ppm (cf. δ 2.4 (CD_2Cl_2) for [(η^5-C_5Me_5)IrCl_2(PPh_3)]) assigned to the PPh_3 ligand and the anticipated septet centred at –143.9 ppm due to the [PF_6]$^-$ counter-ion. The IR spectra of **3** (KBr pellet) displays characteristic absorption at 1024 (m) ν(NS), 701 (s) ν(NS), 636 (s) ν(NS), and 398 (w) cm^{-1} δ(NS) of the [S_2N_2]$^{2-}$ ligand (8, 23, 24, 25) and also a very strong band at 841 cm^{-1}, which is characteristic of the [PF_6]$^-$ anion. Microanalytical data were in good agreement with the proposed structure and the positive-ion FAB$^+$ mass spectra showed [M-(PF_6)]$^+$ at *m*/*z* 1045 along with several other identifiable fragments. Crystals suitable for X-ray crystallography were grown over 4 days by layering a dichloromethane solution of **3** with diethyl ether. Figure 3 shows a perspective view of the complex cation of **3** (water molecules and the [PF_6]$^-$ counter ion are not shown for the sake of clarity) and selected bond distances and angles are given in Table 3. The coordination geometry around Ir(1) closely resembles that in the mononuclear complex **2** (mean deviation from IrS_2N_2 plane = 0.008 Å) and it is evident that coordination to Ir(2) by the non-metal bound nitrogen N(2) causes only minimal changes in the bond lengths and bond angles of the IrS_2N_2 cycle. The geometry about Ir(2) is unremarkable; the P(1)-Ir(2)-Cl(1), P(1)-Ir(2)-N(2), and N(2)-Ir(2)-Cl(1) bond angles all being close to 90°. The iridium atom of the (η^5-C_5Me_5)IrCl(PPh_3) group Ir(2) lies 0.28 Å below the Ir(1)S_2N_2 plane and the Ir(2)-N(2) bond length 2.178(8) Å and the Ir(2)-N(2)-S(1) and Ir(2)-N(2)-S(2) bond angles

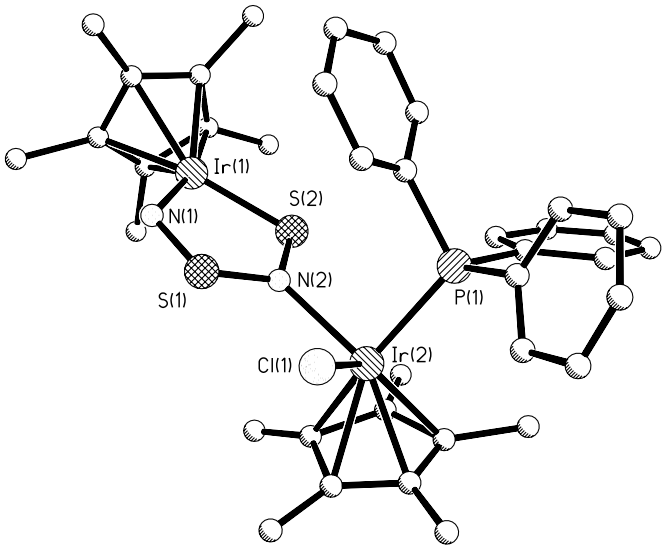
Fig. 3. Crystal structure of $[(\eta^5\text{-}C_5Me_5)IrCl(PPh_3)(S_2N_2)Ir(\eta^5\text{-}C_5Me_5)][PF_6]\cdot 2H_2O$ (**3**) (the water molecules and the $[PF_6]^-$ counter ion have been omitted for clarity).



117.1(5) and 125.1(5)° are in excellent agreement with those of the only other known example of a similar binuclear dithiadiaza complex — $[Ir(dppe)_2(S_2N_2)\{W(CO)_5\}][BPh_4]$ (15) [W—N(2) = 2.22(2) Å, W-N(2)-S(1) and W-N(2)-S(2) = 117.6(10) and 126.6(11)°, respectively.

Conclusion

The synthesis of $[\{n\text{-}Bu_2Sn(S_2N_2)\}_2]$ (**1**) from $[n\text{-}Bu_2SnCl_2]$ and $[S_4N_3][Cl]$ in liquid ammonia represents a convenient high-yield preparation of a potentially synthetically useful reagent. This usefulness is highlighted by its use in the preparation of $[(\eta^5\text{-}C_5Me_5)Ir(S_2N_2)]$ (**2**) only the third known monocyclopentadienyl MS_2N_2 complex and the first iridium example of this type of compound in good yield. This synthetic procedure involving the metathesis of metal halides with $[\{n\text{-}Bu_2Sn(S_2N_2)\}_2]$ (**1**) is currently being applied to the preparation of other monocyclopentadienyl MS_2N_2 complexes. We have also shown that novel binuclear species can be readily prepared from $[(\eta^5\text{-}C_5Me_5)Ir(S_2N_2)]$ (**2**) by simple halide abstraction reactions, which we are also studying in more detail.

Characterization of indirect ^{31}P-^{31}P spin-spin coupling and phosphorus chemical shift tensors in pentaphenylphosphinophosphonium tetrachlorogallate, $[Ph_3P\text{-}PPh_2][GaCl_4]$

Myrlene Gee, Roderick E. Wasylishen, Paul J. Ragogna, Neil Burford, and Robert McDonald

Abstract: Phosphorus chemical shift and ^{31}P,^{31}P spin-spin coupling tensors have been characterized for pentaphenylphosphinophosphonium tetrachlorogallate, $[Ph_3P\text{-}PPh_2][GaCl_4]$, using solid-state ^{31}P NMR spectroscopy. Spectra obtained with magic-angle spinning yield the isotropic value of the indirect spin-spin coupling, $|^1J(^{31}P,^{31}P)_{iso}|$, 323 ± 2 Hz, while 2D spin-echo and rotational resonance experiments provide the effective dipolar coupling constant, R_{eff}, 1.70 ± 0.02 kHz, and demonstrate that J_{iso} is negative. Within experimental error, the effective dipolar coupling constant and J_{iso} are unchanged at –120°C. The anisotropy in $^1\mathbf{J}(^{31}P,^{31}P)$, ΔJ, has been estimated by comparison of R_{eff} and the value of the dipolar coupling constant, R_{DD}, calculated from the P—P bond length as determined by X-ray diffraction. It is concluded that $|\Delta J|$ is small, with an upper limit of 300 Hz. Calculations of $^1\mathbf{J}(^{31}P,^{31}P)$ for model systems $H_3P\text{-}PH_2^+$ and $(CH_3)_3P\text{-}P(CH_3)_2^+$ using density functional theory as well as multiconfigurational self-consistent field theory ($H_3P\text{-}PH_2^+$) support this conclusion. The experimental spin-spin coupling parameters were used to analyze the ^{31}P NMR spectrum of a stationary powder sample and provide information about the phosphorus chemical shift tensors. The principal components of the phosphorus chemical shift tensor for the phosphorus nucleus bonded to three phenyl groups are δ_{11} = 36 ppm, δ_{22} = 23 ppm, and δ_{33} = –14 ppm with an experimental error of ±2 ppm for each component. The components are oriented such that δ_{33} is approximately perpendicular to the P—P bond while δ_{11} forms an angle of 31° with the P—P bond. For the phosphorus nucleus bonded to two phenyl groups, the principal components of the phosphorus chemical shift tensor are δ_{11} = 23 ppm, δ_{22} = –8 ppm, and δ_{33} = –68 ppm with experimental errors of ±2 ppm. In this case, δ_{33} is also approximately perpendicular to the P—P bond; however, δ_{22} is close to the P—P bond for this phosphorus nucleus, forming an angle of 13°. The dihedral angle between the δ_{33} components of the two phosphorus chemical shift tensors is 25°. Results from ab initio calculations are in good agreement with experiment and suggest orientations of the phosphorus chemical shift tensors in the molecular frame of reference.

Key words: Nuclear magnetic resonance spectroscopy, phosphorus chemical shift tensors, ^{31}P-^{31}P *J*-coupling tensors, density functional theory, multiconfigurational self-consistent field theory, phosphinophosphonium salts.

Résumé : Faisant appel à la spectroscopie RMN du ^{31}P, on a caractérisé les déplacements chimiques du phosphore et les tenseurs du couplage spin-spin ^{31}P,^{31}P du tétrachlorogallate de pentaphénylphosphinophosphonium, $[Ph_3P\text{-}PPh_2][GaCl_4]$. Les spectres déterminés en faisant appel à technique de rotation à l'angle magique permettent de tirer la valeur isotrope du couplage spin-spin indirect, $|^1J(^{31}P,^{31}P)_{iso}|$, 323 ± 2 Hz, alors que des expériences bidimensionnelles d'écho de spin et de résonance rotationnelle fournissent la constante de couplage dipolaire effective, R_{eff}, 1,70 ± 0,02 kHz et mettent en évidence que la valeur de J_{iso} est négative. Aux incertitudes près, la constante de couplage dipolaire effective et J_{iso} ne changent pas à –120°C. On a évalué l'anisotropie dans $^1\mathbf{J}(^{31}P,^{31}P)$, ΔJ, en comparant la valeur de R_{eff} et la valeur de la constante de couplage dipolaire, R_{DD}, calculée à partir de la longueur de la liaison P—P telle que déterminée par une étude de diffraction des rayons-X. On peut en conclure que la valeur $|\Delta J|$ est faible et que sa limite supérieure est de 300 Hz. Ces conclusions sont supportées par des calculs des valeurs $^1\mathbf{J}(^{31}P,^{31}P)$ pour les systèmes modèles $H_3P\text{-}PH_2^+$ et $(CH_3)_3P\text{-}P(CH_3)_2^+$ qui ont été effectués à l'aide de la théorie de la densité fonctionnelle et, dans le cas de $H_3P\text{-}PH_2^+$, à l'aide de la théorie de champ autocohérent multiconfigurationnel. utilisé les paramètres de couplage spin-spin observés expérimentalement pour analyser le spectre RMN du ^{31}P d'un échantillon de poudre stationnaire et d'en tirer des informations relatives aux tenseurs du déplacement chimique du phosphore. Les principaux composants du tenseur du déplacement chimique de noyaux phosphore liés à trois groupes phényles sont δ_{11} = 36 ppm, δ_{22} = 23 ppm et δ_{33} = –14 ppm avec une erreur expérimentale de ±2 ppm pour chacun des composants. Les composants sont orientés d'une façon telle que δ_{33} est approximativement perpendiculaire à la liaison P—P alors que δ_{11} forme un angle de 31° avec la liaison P—P. Pour les noyaux de phosphore liés à deux groupes phényles, les principaux composants du tenseur du déplacement chimique du phosphore sont δ_{11} = 23 ppm, δ_{22} = –8 ppm et δ_{33} = –68 ppm avec une erreur expérimentale de ±2 ppm pour chacun des composants. Dans ce cas, δ_{33} est approximativement perpendiculaire à la liaison P—P; toutefois, δ_{22} est près de la liaison P—P parce que ce noyau de phosphore forme un angle de 13°. L'angle dièdre entre les composants δ_{33} des tenseurs des déplacements chimiques de ces deux noyaux de phosphore est de 25°. Les résultats de calculs ab initio sont en bon accord avec les données expérimentales et ils donnent une idée sur les orientations des tenseurs des déplacements chimiques du phosphore dans le cadre de référence moléculaire.

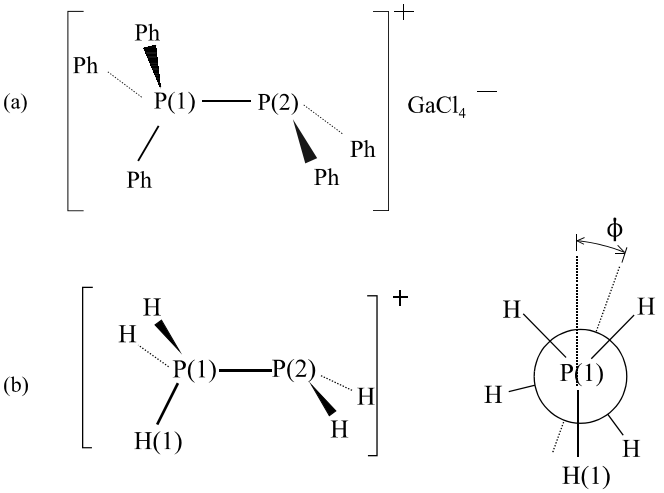
Mots clés : spectroscopie de résonance magnétique nucléaire, tenseurs du déplacement chimique du phosphore, tenseurs de couplages J ^{31}P-^{31}P, théorie de la densité fonctionnelle, théorie du champ autocohérent multiconfigurationnel, sels de phosphinophosphonium.

Introduction

The preparation and structural characterization of the first pentaphenylphosphinophosphonium salts was recently reported (1). In the solid state, the two different phosphorus nuclei are easily resolved using cross polarization (CP) magic-angle spinning (MAS) NMR spectroscopy. Initially, the observation of a large value for $|^1J(^{31}P,^{31}P)_{iso}|$, 323 Hz, was critical in identifying the presence of a P—P bond in this compound. As part of our continuing efforts to better understand phosphorus chemical shifts and indirect spin-spin couplings, the phosphorus chemical shift tensors as well as the one-bond P-P indirect spin-spin coupling tensor, $^1\mathbf{J}(^{31}P,^{31}P)$, have been characterized in the present work for pentaphenylphosphinophosphonium tetrachlorogallate, $[Ph_3P\text{-}PPh_2][GaCl_4]$, Fig. 1(*a*), using the dipolar-chemical shift method (2–11). X-ray diffraction data (1) for $[Ph_3P\text{-}PPh_2][GaCl_4]$ provide valuable structural information required for the determination of the anisotropy of $^1\mathbf{J}(^{31}P,^{31}P)$, ΔJ, from the observed spin-spin coupling data.

In addition to experimental characterization of NMR parameters, theoretical calculations offer a valuable tool for exploring trends in spin-spin coupling and chemical shift tensors (12–18). Theoretical methods have been applied to the calculation of *J*-coupling for a number of systems, for example the calculation of *J*-coupling across hydrogen bonds (19–22). In particular, density functional theory (DFT) (23–30) and multiconfigurational self-consistent field (MCSCF) (12, 31–36) theory provide estimates of $^1\mathbf{J}(^{31}P,^{31}P)$ for comparison with experimental results. The application of DFT methods to the calculation of *J*-coupling tensors has been successful in a number of cases (24–30, 37, 38). Here we apply DFT calculations on $H_3P\text{-}PH_2^+$ (Fig. 1(*b*)) and $(CH_3)_3P\text{-}P(CH_3)_2^+$ to serve as models for $Ph_3P\text{-}PPh_2^+$. While ab initio approaches such as MCSCF are more rigorous, they are limited to small molecules with relatively light nuclei. For this reason, MCSCF calculations have been performed on only the smaller of the two model systems, $H_3P\text{-}PH_2^+$. The experimental results for the phosphorus chemical shift tensors are complemented by ab initio calculations, which aid in fixing the chemical shift tensor orientation with respect to the molecular frame of reference (39–47).

Fig. 1. Schematic representation of (*a*) $[Ph_3P\text{-}PPh_2][GaCl_4]$, indicating the labelling convention for the two phosphorus nuclei and (*b*) $H_3P\text{-}PH_2^+$ with a Newman projection illustrating the definition of ϕ, which is the angle between the plane containing the P(1)—H(1) bond and the bisector of the H-P(2)-H angle.



Background theory

The conventions used to describe chemical shift and *J*-coupling tensors will be given in this section. The theory behind the dipolar – chemical shift method has been discussed extensively in the literature (2–7) and will not be presented in detail here.

For a solid powder sample containing an isolated spin-1/2 nucleus, the solid-state NMR spectrum yields the principal components of the chemical shift tensor, denoted by δ_{11}, δ_{22}, and δ_{33}, such that $\delta_{11} \geq \delta_{22} \geq \delta_{33}$; δ_{33} corresponds to the direction of greatest shielding. Three derived parameters may also be used to describe the principal components: the isotropic chemical shift, $\delta_{iso} = (\delta_{11} + \delta_{22} + \delta_{33})/3$, the span, Ω =

© 2002 NRC Canada

$\delta_{11} - \delta_{33}$, and the skew, $\kappa = 3\ (\delta_{22} - \delta_{iso})\ /\ \Omega$ (48). The latter two parameters describe, respectively, the breadth and shape of the observed powder pattern. The chemical shift, δ, and nuclear magnetic shielding, σ, are related as follows:

$$[1] \qquad \delta = \frac{\sigma_{ref} - \sigma}{1 - \sigma_{ref}} \approx \sigma_{ref} - \sigma$$

where σ_{ref} is the nuclear magnetic shielding constant for the reference compound. In the case of phosphorus, σ_{ref} is 328.35×10^{-6} for 85% H_3PO_4(aq) (49); hence it may be neglected in the denominator. The magnetic shielding is the more fundamental parameter as it describes the shielding in the compound of interest with respect to the bare nucleus.

The indirect spin-spin or *J*-coupling tensor, **J**, is described by three principal components, J_{11}, J_{22}, and J_{33}, such that $|J_{33} - J_{iso}| \geq |J_{11} - J_{iso}| \geq |J_{22} - J_{iso}|$. The isotropic *J*-coupling constant is $J_{iso} = (J_{11} + J_{22} + J_{33})/3$, while the anisotropy is $\Delta J = J_{33} - (J_{11} + J_{22})/2$, and the asymmetry, η, is $(J_{22} - J_{11})/(J_{33} - J_{iso})$ (50–52). According to Ramsey's theory (12, 13, 52–55), the observed **J** is a sum of contributions from three mechanisms. The spin-orbit (SO) mechanism involves the coupling between the nuclear spin and the orbital angular momentum of the electrons and is usually divided into diamagnetic (DSO) and paramagnetic (PSO) parts. The spin-dipolar (SD) mechanism involves the dipolar interaction between the nuclear and electron magnetic moments. Finally, the Fermi contact (FC) mechanism describes the interaction between a nucleus and electrons that have a finite probability of being at the nucleus of interest. Of all the mechanisms, only the FC is completely isotropic; hence it contributes to J_{iso} but not to ΔJ. There is also a cross term between the FC and SD mechanisms that contributes to ΔJ but not to J_{iso}. Observation of a sizable ΔJ indicates that this cross term and (or) mechanisms other than FC are significant (56–61). Although the FC is often assumed to make the largest contribution to J_{iso}, this is not always true (62 and refs. therein).

For samples containing isolated ^{31}P-^{31}P spin pairs, the standard MAS experiment yields δ_{iso} for each phosphorus site and $^1J(^{31}P,^{31}P)_{iso}$. If a stationary powder sample of such a spin pair is examined, the three principal components of each chemical shift tensor may be obtained as well as some information regarding the orientation of these tensors with respect to the effective dipolar coupling tensor. The unique axis of the direct dipolar coupling tensor is usually coincident with the internuclear vector, **r**; hence, some information regarding the chemical shift tensor orientation with respect to the molecular framework is available from the NMR spectra of powder samples. The orientation of the chemical shift tensor components with respect to **r** may be described by the Euler angles α, β, and γ (63, 64). This method of obtaining orientation information from the NMR spectra of powdered samples is termed the dipolar – chemical shift method (2–7). Unfortunately, since the dipolar tensor is axially symmetric, the orientation of the chemical shift tensors cannot be completely fixed in the molecular frame of reference (vide infra) (2–7) by experiment.

The actual dipolar coupling constant that is measured in any NMR experiment is an effective coupling constant, R_{eff}, with contributions from the direct dipolar coupling constant, R_{DD}, and ΔJ:

$$[2] \qquad R_{eff} = R_{DD} - \frac{\Delta J}{3}$$

R_{DD} is given by:

$$[3] \qquad R_{DD} = \frac{\mu_0}{4\pi}\left(\frac{\hbar}{2\pi}\right)\gamma_I\gamma_S\left\langle r_{IS}^{-3}\right\rangle$$

where $\langle r_{IS}^{-3}\rangle$ is the motional average of the inverse cube of the internuclear distance between the two spins, *I* and *S*. This relationship between R_{DD} and the distance between the two spins is important for structural investigations via solid-state NMR. For systems where R_{eff} is significantly different from R_{DD}, ΔJ may be determined unambiguously. When ΔJ is small, its contribution to R_{eff} may be masked by motional averaging. In such cases, precise characterization of ΔJ is very difficult. Conversely, quantitative determination of internuclear distances by measurement of R_{eff} requires that ΔJ and motional averaging be accounted for in some manner.

For systems containing effectively isolated homonuclear spin pairs, such as $Ph_3P\text{-}PPh_2^+$, analysis of the NMR spectra is facilitated by an independent measurement of R_{eff} using a 2D spin-echo experiment (45, 47, 65–68), which separates the chemical shift and spin-spin coupling interactions. The value of R_{eff} may be determined independently using rotational resonance (RR) experiments (43, 69–71) if the difference between the isotropic chemical shifts of the coupled nuclei is comparable to achievable MAS rates. Rotational resonance is achieved when the following condition is fulfilled:

$$[4] \qquad n\nu_{rot} = \nu_{iso}(I) - \nu_{iso}(S); \qquad n = 1,2,3,\ldots$$

where ν_{rot} is the MAS rate and ν_{iso} is the isotropic chemical shift in frequency units. The dipolar coupling interaction is "re-introduced" under these conditions; thus, R_{eff} may be obtained (43, 71).

Experimental and computational details

Sample preparation

A sample of $[Ph_3P\text{-}PPh_2][GaCl_4]$ was prepared as described in ref. 1. All samples were packed in an inert atmosphere as this compound is air sensitive.

NMR spectra

Phosphorus-31 NMR spectra were acquired for stationary or MAS samples of powdered crystalline $[Ph_3P\text{-}PPh_2][GaCl_4]$ at applied magnetic fields of 4.7 T (Chemagnetics CMX 200 spectrometer) and 9.4 T (Bruker AMX 400 spectrometer). The spectrometer frequencies for ^{31}P are 81.023 MHz and 161.978 MHz, respectively, for the applied fields mentioned above. The standard CP experiment with high-power proton decoupling was used in both cases. For experiments at 4.7 T, the sample was packed into a 4 mm zirconium oxide rotor. A proton $\pi/2$ pulse of 3.0 μs, contact time of 5.0 ms, and recycle delays of between 5 and 8 s were used. Spectra for MAS samples were also acquired on the 4.7 T system at several temperatures, ranging from ambient temperature to –120°C

© 2002 NRC Canada

using heated–cooled N_2 gas. Experiments at 9.4 T were performed on a sample packed into a 2.5 mm zirconium oxide rotor. Parameters similar to those for experiments at 4.7 T were used. All ^{31}P NMR spectra are referenced to the primary standard, 85% H_3PO_4(aq), by setting the isotropic peak in the ^{31}P CPMAS NMR spectrum of solid $NH_4H_2PO_4$ to +0.81 ppm (72). Gaussian line broadening of between 20 and 40 Hz for the spectra of MAS samples and between 100 and 200 Hz for spectra of stationary samples was applied. The 2D spin-echo experiment (65–67) was performed at 4.7 T using parameters identical to the 1D experiments. For each of 64 t_1 increments, 224 transients were acquired. The phase cycling of Rance and Byrd was used for this experiment (73).

Phosphorus-31 NMR spectra of stationary samples were simulated using WSOLIDS (74), a program developed in this laboratory that incorporates the POWDER routine of Alderman et al. (75). NMR spectra of MAS samples were calculated using NMRLAB (76), which uses the Monte Carlo method to sample crystal orientations for powder averaging. In our calculations, 10 000 crystallite orientations were used. The $F1$ projection of the 2D spectrum was calculated using SpinEcho (77), a program developed in this laboratory.

X-ray data collection at 20°C and –120°C

Although ambient temperature (23°C) X-ray diffraction data for $[Ph_3P\text{-}PPh_2][GaCl_4]$ have been previously reported (1); X-ray diffraction experiments have been repeated at 20°C and –120°C to remove instrument dependent variability. Results are summarized in Table 1. Agreement of the structures determined in ref. 1 and here is excellent.

Computational details

Density functional calculations were carried out using the Amsterdam density functional (ADF) package (78) in conjunction with the CPL module for calculating J-coupling (26, 27, 30, 79). The Vosko, Wilk, and Nusair (VWN) local density approximation (80) with the Becke88 (81) and Perdew86 (82) nonlocal gradient corrections were used for the exchange-correlation potential. Basis V, which is part of the standard ADF package, was used on all atoms. This triple-zeta basis set is composed of Slater-type orbitals and includes two polarization functions. Multiconfigurational self-consistent field calculations with complete active space self-consistent field (CASSCF) wavefunctions (31, 83–85) for **J** were performed using DALTON, an ab initio electronic structure program (86), installed on an IBM RS/6000 workstation. The cc-pVTZ basis set (87) was used on all atoms. For CASSCF wavefunctions, inactive and active molecular orbital combinations must be chosen. This selection was made based on MP2 natural molecular orbital occupation numbers and energies (88, 89). The inactive and active spaces are designated by *m*/*n*, indicating that there are *m* inactive orbitals and *n* active orbitals in the CASSCF space. The structure used for $H_3P\text{-}PH_2^+$ was optimized at the restricted Hartree-Fock (RHF) level using Gaussian 98 (90) with the 6–311++G(3df,3pd) basis set on all atoms. Calculations were also performed for different conformations, as described by the angle ϕ, which is the dihedral angle between the plane containing the P(1)—P(2) bond and also bisecting the H-P(2)-H bond angle and the plane containing the P(1)—P(2) and P(1)—H(1) bonds (see Fig. 1(*b*)). With the exception of ϕ, the structure is the same for each conformation. The structure used for $(CH_3)_3P\text{-}P(CH_3)_2^+$ is derived from the structure for $[Ph_3P\text{-}PPh_2][GaCl_4]$ obtained from X-ray diffraction data (1). The phenyl groups in $[Ph_3P\text{-}PPh_2][GaCl_4]$ are replaced by CH_3 groups with C—H bond lengths of 1.09 Å and all bond angles involving hydrogen set at 109.5°.

Calculations of phosphorus nuclear magnetic shielding tensors for $[Ph_3P\text{-}PPh_2][GaCl_4]$ were carried out at the RHF level using locally dense basis sets (91, 92); the 6–311++G(3df,3pd) basis set was used on the phosphorus and adjacent carbon atoms while the 6–31G basis set was used for the remaining atoms. The structure is taken from an X-ray diffraction study (1) with the exception of the C—H bond lengths, which were fixed at 1.08 Å. All calculations were performed with Gaussian 98 (90) using an IBM RS/6000 workstation. To facilitate comparison with experimental results, the calculated phosphorus nuclear magnetic shielding tensors were converted to chemical shift tensors using the relationship, $\delta_i = \sigma_{ref} - \sigma_i$. The absolute shielding scale for phosphorus is based on a shielding of 328.35 ± 0.63 ppm for the phosphorus nucleus of the reference, 85% H_3PO_4(aq) (49).

Results and discussion

Phosphorus-31 NMR spectra of $[Ph_3P\text{-}PPh_2][GaCl_4]$

The ^{31}P CPMAS NMR spectra for a crystalline powder sample of $[Ph_3P\text{-}PPh_2][GaCl_4]$ obtained at 4.7 T and 9.4 T are shown in Figs. 2 and 3, respectively. From the MAS spectra, the isotropic chemical shifts for each phosphorus nucleus and the magnitude of $^1J(^{31}P,^{31}P)_{iso}$ may be obtained (see Table 2, Fig. 2(*a*), and Fig. 3(*a*)). The assignment of the least shielded phosphorus site, δ_{iso} = 15.4 ppm, to P(1) is made on the basis of ab initio calculations of phosphorus nuclear magnetic shielding in $[Ph_3P\text{-}PPh_2][GaCl_4]$ (see Table 3). Known trends in phosphorus shielding — phosphines are in general more shielded than phosphonium centres (93–98) — support this assignment of phosphorus sites. The very small impurity peak at $\delta \approx 1$ ppm in Fig. 3 is attributed to a decomposition product. This is not observed in the spectra at 4.7 T (Fig. 2), probably owing to differences in the effectiveness of the rotors at excluding air from their contents.

To obtain information concerning the relative sign of J_{iso} and R_{eff} as well as the magnitude of R_{eff}, a 2D spin-echo experiment was carried out. The $F1$ projection is shown in Fig. 4 along with simulations using opposite signs (Fig. 4(*a*)) and the same signs (Fig. 4(*b*)) for $^1J(^{31}P,^{31}P)_{iso}$ and R_{eff}. From these simulations, $^1J(^{31}P,^{31}P)_{iso} = -323 \pm 2$ Hz and $R_{eff} = 1.70 \pm 0.05$ kHz. It should be noted that the $F1$ projection may be simulated using a positive J_{iso}; however, an unreasonably small value for R_{eff}, 1.10 kHz, must be used. Also, rotational resonance experiments at both 4.7 T and 9.4 T (see Figs. 2(*c*) and 3(*b–c*) confirm that R_{eff} = 1.70 kHz. In fact, the simulations shown in Figs. 2(*c*) and 3(*b–c*) lead to an error in R_{eff} of ±0.02 kHz. Hence, the combined analysis of the 2D spin-echo and RR spectra yields a value of 1.70 ± 0.02 kHz for R_{eff}.

Analysis of ^{31}P NMR spectra acquired at –70°C and –120°C at RR and off RR indicate that R_{eff} and J_{iso} are

independent of temperature within the error limits of our experiment. The larger error in R_{eff} obtained at lower temperatures, 1.70 ± 0.05 kHz, was necessary to account for the poorer quality of the spectra (not shown).

Using the data from the analysis of the ^{31}P NMR spectra of MAS samples and the spin-spin coupling data from the 2D spin-echo and RR spectra, the ^{31}P NMR spectra shown in Fig. 5, which are obtained at two applied magnetic fields for a stationary sample, may be analyzed. The simulations are shown in Fig. 5 and the principal components of the two phosphorus chemical shift tensors as well as spin-spin coupling parameters that give the best overall fit to all the experimental spectra are given in Table 2. Also, the MAS line shapes, especially for slower spinning (Figs. 2(*b*–*c*) and 3(*b*–*c*)), are sensitive to most of the parameters and are well reproduced using the data in Table 2. Further discussion of

the chemical shift tensors is presented together with theoretical calculations below.

Anisotropy in $^1J(^{31}P,^{31}P)$ for [Ph_3P-PPh_2][$GaCl_4$]

The P—P bond length in [Ph_3P-PPh_2][$GaCl_4$] is 2.220(6) Å (1), for which R_{DD} is calculated to be 1.80 ± 0.04 kHz from eq. [3]. Using this value and the measured R_{eff}, eq. [2] yields ΔJ = 300 Hz if one assumes that R_{DD} and R_{eff} have the same sign. If the signs are opposite, then ΔJ = 10.5 kHz; given that the magnitude of $^1J(^{31}P,^{31}P)_{iso}$ is 323 Hz, it is highly unlikely that ΔJ has this latter value. In fact, on the basis of theoretical calculations (vide infra) the latter value can be discarded. The value of 300 Hz for ΔJ is an upper limit, since part of the difference between R_{DD} and R_{eff} may arise from motional averaging. Bond lengths from X-ray diffraction and NMR data differ since different mean values are determined by the two experiments (99, 100), i.e., NMR measures $\langle r^{-3}\rangle^{-1/3}$, not $\langle r\rangle$. X-ray diffraction data tend to give values that are shorter than r_{eq} (100). Furthermore, any motion of the P—P bond axis will also reduce R_{eff} and lead to an apparent enhanced value of ΔJ. Variable temperature experiments were undertaken to investigate the significance of motion in the determination of R_{eff}. Our results indicate that R_{eff} is unchanged at lower temperatures, suggesting that either any motion is not sufficiently removed or that most of the difference between R_{eff} and R_{DD} is due to ΔJ. Data from X-ray diffraction experiments at low temperature may provide some insight. Perspective ORTEP views of [Ph_2P-PPh_3][$GaCl_4$] are shown in Fig. 6 for 20°C and –120°C. The method of Hirshfeld (101) as implemented in the *PLATON* program system (102) was used to calculate values for the P(1)—P(2) bond lengths that are corrected for librational effects, as manifested in the values of the anisotropic displacement parameters. For the ambient temperature dataset, a value of 2.2281 Å is obtained, compared with the value obtained without librational correction, 2.2242(9) Å. For the data collected at –120°C, the corrected bond length is 2.2238 Å, compared with the uncorrected value, 2.2222(7) Å. The difference between the R_{DD} values calculated using the corrected P—P bond lengths for the two temperatures is 10 Hz, which is within the experimental error in R_{eff} measured at both ambient temperature and at –120°C. In general, this motion is difficult to quantify, hence ΔJ is reported as an upper limit and additional NMR and X-ray experiments, particularly at lower temperature (e.g., liquid helium temperatures), may be necessary to evaluate what portion of the difference between R_{eff} and R_{DD} is due to averaging of R_{DD} by motion as opposed to ΔJ.

The anisotropy in **J** may be estimated from DFT or ab initio methods such as MCSCF. To minimize calculation time, particularly for the MCSCF calculations, a model system, H_3P-PH_2^+, is used for Ph_3P-PPh_2^+. In addition, a more realistic model system, $(CH_3)_3P$-$P(CH_3)_2^+$, is used for a DFT

Fig. 2. Experimental and calculated ^{31}P CP NMR spectra of MAS samples of [Ph_3P-PPh_2][$GaCl_4$], acquired at 4.7 T. The spinning rates are (*a*) 5.02 kHz (256 transients), (*b*) 2.17 kHz (128 transients), and (*c*) 2.70 kHz (256 transients). The centreband for each phosphorus nucleus is indicated. Note that spinning at 2.70 kHz corresponds to the $n \approx 1$ RR condition at 4.7 T.

calculation for the purpose of determining the limitations of the smaller model, $H_3P\text{-}PH_2^+$. The results from both computational approaches and for both model systems are given in Table 4. The conformational dependence of the P-P *J*-coupling, as described by ϕ (Fig. 1(*b*)), is considered for the smaller model system, $H_3P\text{-}PH_2^+$. It is evident from Table 4 that **J** is virtually independent of ϕ for $H_3P\text{-}PH_2^+$. This result is expected, since rotation of the PH_3 group about the P—P bond does not result in a significant change in the overall structure. This has also been observed in semi-empirical calculations of $^1J(^{15}N,^{13}C)_{iso}$ in CH_3NH_2 when the NH_2 group is rotated about the C—N bond (103). The average $^1J(^{31}P,^{31}P)_{iso}$ and ΔJ values over all conformations are approximately –341 and 361 Hz, respectively from DFT and –193 and 131 Hz, respectively from MCSCF. These averages are obtained by weighting the results according to the calculated Boltzmann distribution. For $(CH_3)_3P\text{-}P(CH_3)_2^+$, DFT predicts a significantly larger magnitude for J_{iso} relative to J_{iso} for $H_3P\text{-}PH_2^+$, due primarily to a larger FC contribution. The anisotropy in **J** is predicted to be 300 Hz, which is the same order of magnitude as the values of ΔJ for $H_3P\text{-}PH_2^+$.

Both the DFT and MCSCF calculations predict that J_{iso} and ΔJ are approximately equal in magnitude. This is in agreement with the experimental observations for $[Ph_3P\text{-}PPh_2][GaCl_4]$ and also with the literature (47, 104). There is a significant difference between the DFT and MCSCF results. Modification of the active–inactive space for the MCSCF calculations changes the calculated value of J_{iso} by about 9%, which does not account for the difference between the MCSCF and DFT data. Examination of the contributions from the various coupling mechanisms to J_{iso} (Table 4) reveals that the significant difference between the results for the two methods for J_{iso} lies in the FC contribution. Both methods predict that the FC mechanism dominates the value of J_{iso}. The DFT approach appears to be more successful in general when compared with the experimental results.

The DFT calculations presented in the literature have provided results for J_{iso} that are in good agreement with experiment for a number of systems. For example, Malkin et al. (28) calculated isotropic *J*-coupling constants involving ^1H, ^{13}C, $^{14/15}N$, ^{17}O, and ^{19}F in a number of small molecules as well as some larger organic molecules. Further work by Malkina et al. (29) identified some problems for systems containing formal lone pairs; however, the qualitative agreement is good. The use of Slater-type rather than Gaussian-type basis sets in conjunction with DFT has also been successful (30). This approach has been further developed to include relativistic corrections, giving very good results for coupling involving heavier nuclei (25–27, 105). Given the past performance of DFT for the calculation of *J*-coupling, the results presented here for $H_3P\text{-}PH_2^+$ and $(CH_3)_3P\text{-}P(CH_3)_2^+$ may be considered to be qualitatively reliable.

Comparison of experimental and calculated phosphorus chemical shift tensors

The experimental and calculated values of δ_{11}, δ_{22}, δ_{33}, δ_{iso}, Ω, and κ for the two phosphorus environments in $[Ph_3P\text{-}PPh_2][GaCl_4]$ are presented in Table 3. Calculations were performed on structure 1, which consists of $Ph_3P\text{-}PPh_2^+$ and the closest $GaCl_4^-$ ion, and structure 2, which consists of the isolated $Ph_3P\text{-}PPh_2^+$ ion. As is evident from comparison of the spans and skews for structure 1, the line shapes predicted by the ab initio calculations are in good agreement with the experimental results.

The difference in the isotropic phosphorus chemical shifts is reproduced reasonably well by ab initio calculations (Table 3). However, the calculated isotropic chemical shifts are significantly smaller than those from experiment; for P(1) in structure 1, the calculations predict a value for δ_{iso}, which is too shielded by 18 ppm and for P(2), δ_{iso} is predicted to be 13 ppm more shielded compared with experiment. This difference between experimental and calculated results may be attributed to deficiencies in the ab initio

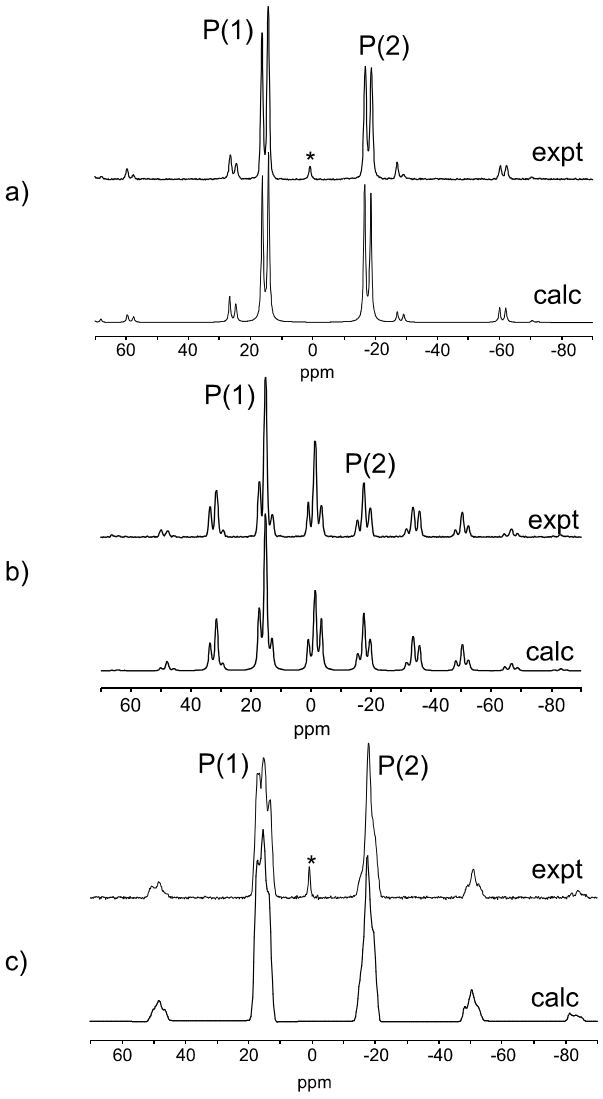
Fig. 3. Experimental and calculated ^{31}P CP NMR spectra of MAS samples of $[Ph_3P\text{-}PPh_2][GaCl_4]$, acquired at 9.4 T. The spinning rates are (*a*) 7.03 kHz, (*b*) 2.65 kHz, and (*c*) 5.36 kHz. In each case, 512 transients were acquired. The centreband for each phosphorus nucleus is indicated. A signal attributed to a decomposition product is indicated by an asterisk. Note that spinning at 5.36 kHz corresponds to the $n \approx 1$ RR condition at 9.4 T.



approach and (or) to intermolecular effects that are not properly accounted for in the calculations. For $[Ph_3P\text{-}PPh_2][GaCl_4]$, the difference between the phosphorus chemical shifts in solution (methylene chloride solvent) and the solid state is an indication of the significance of specific intermolecular effects such as ion pairing. The difference is greatest for P(2), which is more shielded by 7.2 ppm in the solid compared with solution. The presence of $GaCl_4^-$ ions may contribute to the difference between the experimental and calculated results. The closest contact between the $Ph_3P\text{-}PPh_2^+$ ion and the $GaCl_4^-$ ion occurs between P(2) and a chlorine atom, at a distance of 6.061 Å (1). Calculations for structure 1, which consists of $Ph_3P\text{-}PPh_2^+$ and the nearest $GaCl_4^-$, and structure 2, which consists of an isolated $Ph_3P\text{-}PPh_2^+$ ion, indicate that P(2) is most affected; each component is deshielded by about 4 ppm owing to the

Fig. 4. Experimental and calculated *F*1 projections of the 2D spin-echo ^{31}P NMR spectrum of $[Ph_3P\text{-}PPh_2][GaCl_4]$ acquired at 4.7 T. The peak marked by an asterisk is an experimental artifact. Simulations are shown with R_{eff} = 1.70 kHz and (*a*) $^1J(^{31}P,^{31}P)_{iso}$ = –323 Hz and (*b*) $^1J(^{31}P,^{31}P)_{iso}$ = +323 Hz.

presence of the anion. However, consideration of one anion is clearly not sufficient to reproduce the experimental trend. The line shapes, as described by Ω and κ, are not significantly different for structures 1 and 2.

As was noted in the background section, some chemical shift tensor orientation information is available from simulation of the experimental spectra obtained from powdered crystalline samples containing spin pairs. To describe the orientation of the chemical shift tensors, we employ the angles α, β, and γ (63, 64). The angle β is the angle between δ_{33} and **r**, while γ indicates if δ_{11} or δ_{22} is closest to **r**. The difference between the α angles for the two chemical shift tensors, $\Delta\alpha$, is the dihedral angle between the δ_{33} components. For P(1), it is concluded that δ_{33} forms an angle, β, of 99° ± 2° with respect to the P—P bond. This is equally well described by the supplement angle, 81°. For P(2), the corresponding angle is smaller, 78° ± 2°. The orientation of the δ_{33} components is illustrated in Fig. 7(*a*). The best simulations of the experimental spectra are obtained using a dihedral angle between the δ_{33} components, $\Delta\alpha$, of 25° ± 2°. The value of γ for P(1) is 2° ± 5° and 78° ± 2° for P(2), indicating that the orientations of δ_{11} and δ_{22} with respect to the P—P bond are quite different for the two phosphorus chemical shift tensors.

The orientations of the phosphorus chemical shift tensors in the molecular frame of reference may be predicted by ab initio calculations. The orientation of the P(1) and P(2) chemical shift tensors for structure 1 shown in Fig. 7(*b*) was obtained at the RHF level of theory. For P(1), δ_{33} forms an angle of 92° with respect to the P—P bond. This is in good agreement with the experimental result. The other two components are oriented as follows: δ_{11} forms an angle of 31° with respect to the P—P bond while δ_{22} is situated at an angle of 60° from the P—P bond; hence δ_{11} is closest to the P—P bond for P(1). The δ_{33} component for P(2) forms an angle of 80° with respect to the P—P bond, in excellent agreement with the experimentally observed value of this parameter. For this phosphorus environment, δ_{22} is closest to the P—P bond, forming an angle of 13°, while δ_{11} is situated at an angle of 81° from the P—P bond. This calculated result (δ_{11} is closest to the P—P bond for P(1) while δ_{22} is closest for P(2)) is in agreement with the experimental observation that the values of γ are very different for the two phosphorus chemical shift tensors. Finally, the experimental and calculated orientations may be compared by examining the relative orientation of the phosphorus chemical shift tensors, via $\Delta\alpha$. The calculated dihedral angle between the δ_{33} components, $\Delta\alpha$, is 23°, in excellent agreement with the

Fig. 6. Perspective ORTEP views of the $[Ph_2P–PPh_3]^+$ ion and the associated $[GaCl_4]^-$ ion at (*a*) –120°C and (*b*) 20°C. Non-hydrogen atoms are represented by Gaussian ellipsoids at the 50% probability level. Hydrogen atoms are not shown. The ions are shown in their relative crystallographic positions; no unusually close contacts (i.e., nearer than summed van der Waals radii) exist between these ions (or those generated by crystallographic symmetry). The atom P1 in this figure corresponds to P(2) in Fig. 1(*a*) and elsewhere in this manuscript; similarly, P2 in this figure corresponds to P(1) in Fig. 1(*a*) and elsewhere in this manuscript.

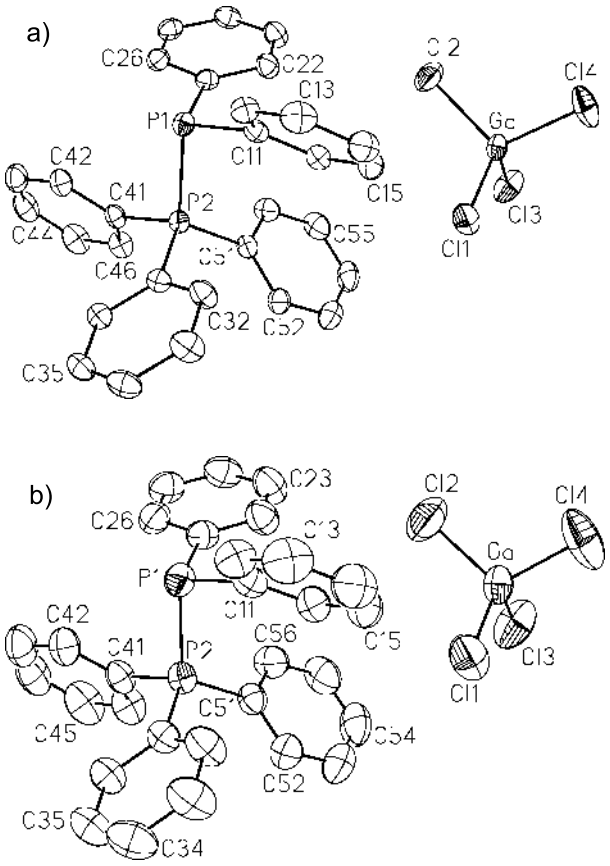

Fig. 7. Experimental (*a*) and calculated (*b*) orientation of the phosphorus chemical shift tensors for P(1) and P(2) in $[Ph_3P-PPh_2][GaCl_4]$. For P(1) in (*b*), the tensor is shown such that δ_{33} is in the plane of the page while δ_{22} is slightly in front of the plane and δ_{11} is behind the plane. For P(2) in (*b*), δ_{11} is perpendicular to the plane of the page and the other two components are in the plane. The $GaCl_4^-$ ion and hydrogen atoms have been omitted for clarity.

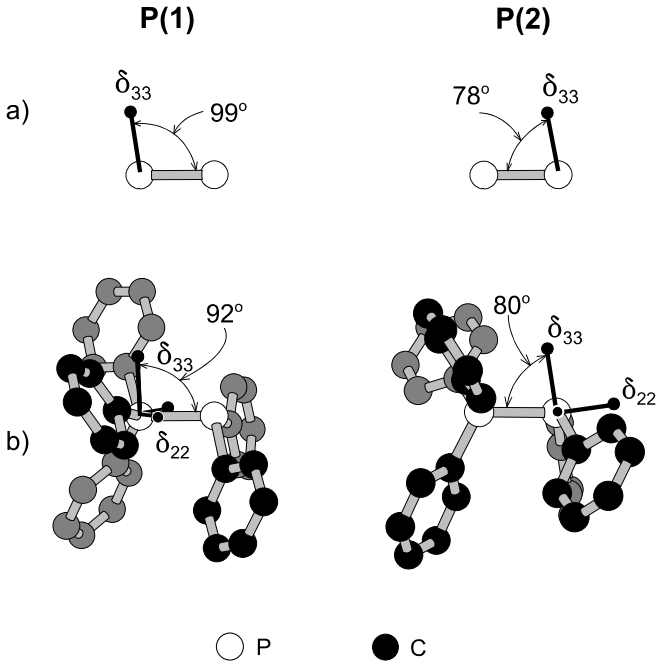

experimental value of 25°. The good agreement between the calculated orientation and the orientation information available from the experimental data suggests that the calculated phosphorus shift tensor orientations in the molecular axis system illustrated in Fig. 7(*b*) are reliable.

The phosphorus magnetic shielding tensors for P(1) and P(2) may be compared with phosphorus chemical shift tensors in related compounds. The observed span of the phosphorus chemical shift tensor for P(2) is larger than typical values for phosphines (106). The phosphorus NMR parameters obtained for a similar compound, $Mo(CO)_5(Ph_2P-PPh_2)$ (98), are comparable to the results presented here for $[Ph_3P-PPh_2][GaCl_4]$. It is also interesting to note that, although P(1) has a formal positive charge, the chemical shift is hardly affected compared with P(2), whereas for carbocations, the carbon site with the formal positive charge is highly deshielded (107). Also, the phosphorus environment for P(1) may be compared with a series of phosphine-X adducts (X = BH_3, CH_2, NH, and O). In these compounds, the phosphorus chemical shift tensor is oriented such that δ_{33} is along the P—X bond (108), which is quite different from P(1) in $[Ph_3P-PPh_2][GaCl_4]$. For example, in Ph_3P-BH_3, δ_{33} is oriented at an angle of 6.5° with respect to the P—B bond, while in $[Ph_3P-PPh_2][GaCl_4]$, δ_{33} is at 81° from the P—P bond. For P(2), the phosphorus chemical shift tensor orientation could be compared with the orientation in Ph_2P-PPh_2 (65); however, in that case, it was assumed that δ_{33} is along the direction of the formal lone pairs.

Conclusions

The indirect spin-spin coupling tensor, $^1\mathbf{J}(^{31}P,^{31}P)$, and the phosphorus chemical shift tensors for $[Ph_3P-PPh_2][GaCl_4]$ have been characterized by combining the dipolar-chemical shift NMR method with calculations from first principles and DFT. By using the P—P bond length from an X-ray diffraction study (1) and the effective dipolar coupling constant presented in this work, it is concluded that $|\Delta J|$ for $^1\mathbf{J}(^{31}P,^{31}P)$ has an upper limit of 300 Hz. This conclusion is supported by DFT and MCSCF calculations of $^1\mathbf{J}(^{31}P,^{31}P)$ for model compounds, $H_3P-PH_2^+$ and $(CH_3)_3P-P(CH_3)_2^+$. As well, the properties of $^1\mathbf{J}(^{31}P,^{31}P)$ for these model compounds have been investigated using these theoretical approaches.

The phosphorus chemical shift tensors obtained experimentally for $[Ph_3P-PPh_2][GaCl_4]$ are compared with the results from ab initio molecular orbital calculations. Good agreement is obtained between the experimental and calculated principal components of the chemical shift tensor. In

addition, the orientation of the two phosphorus chemical shift tensors in the molecular frame of reference is suggested by the theoretical calculations.

Acknowledgments

The Wasylishen group at the University of Alberta and the Burford group at Dalhousie University are acknowledged for their interest in this work. In particular, Dr. Edgar Ocando-Mavarez is acknowledged for his contribution to the early stages of this project as well as Dr. Guy Bernard for his assistance with the VT experiments. We are grateful to Dr. Jochen Autschbach and Prof. Tom Ziegler at the University of Calgary for providing the code to perform DFT calculations of **J**. R.E.W. acknowledges the financial support of the Natural Sciences and Engineering Research Council of Canada (NSERC) and the University of Alberta. R.E.W. is a Canada Research Chair in physical chemistry. M.G. thanks NSERC, the Izaak Walton Killam Memorial Trust, and the Walter C. Sumner Foundation for postgraduate scholarships at Dalhousie University. Spectra at 9.4 T were acquired at the Atlantic Region Magnetic Resonance Centre (Dalhousie University), which is also supported by NSERC.

Synthesis and characterization of a spirocyclic phosphaverdazyl radical – cyclophosphazene hybrid: Evidence for spin transfer from a verdazyl radical to a phosphazene ring

Tosha M. Barclay, Robin G. Hicks, Andrew S. Ichimura, and Greg W. Patenaude

Abstract: The synthesis and characterization of a new 6-phosphaverdazyl radical incorporated into a spirocyclic framework containing a cyclotriphosphazene ring is described. Reaction of 1,1,3,3-bis[*spiro*-2′,2″-dioxy-1′,1″-biphenyl]-5,5-bis(1-methylhydrazido)-1,3,5,2,4,6-cyclotriphosphazene (**7**) with trimethylorthobenzoate yielded 6-[2,2,4,4-bis(2,2′-dioxy-1,1′-biphenyl)-2,4,6,1,3,5-cyclotriphosphazen-6-yl]-1,2,5,6-tetrahydro-1,5-dimethyl-3-phenyl-1,2,4,5,6-tetrazaphosphorine (**8**), which was characterized spectroscopically and by X-ray diffraction. Oxidation of **8** yielded 6-[2,2,4,4-bis(2,2′-dioxy-1,1′-biphenyl)-2,4,6,1,3,5-cyclotriphosphazen-6-yl]-1,5-dimethyl-3-phenyl-6-phosphaverdazyl (**5**), which was characterized by EPR and ENDOR spectroscopy. Analysis of both spectra indicate that spin density from the phosphaverdazyl ring induces spin polarization into the phosphazene ring, as evidenced by hyperfine coupling to all three phosphorus nuclei.

Key words: heterocycle, phosphorus–nitrogen compounds, phosphazenes, stable radicals, verdazyls.

Résumé : On décrit la synthèse et la caractérisation d'un nouveau radical 6-phosphoverdazyle incorporé dans un squelette spirocyclique contenant un noyau cyclotriphosphazène. La réaction du 1,1,3,3-bis[spiro-2′,2″-dioxy-1′,1″-biphényl]-5,5-bis(1-méthylhydrazido)-1,3,5,2,4,6-cyclotriphosphazène (**7**) avec l'orthobenzoate de triméthyle conduit à la formation de la 6-[2,2,4,4-bis(2,2′-dioxy-1,1′-biphényl)-2,4,6,1,3,5-cyclotriphosphazén-6-yl]-1,2,5,6-tétrahydro-1,5-diméthyl-3-phényl-1,2,4,5,6-tétrazaphosphorine (**8**) que l'on a caractérisé de façon spectroscopique et par diffraction des rayons X. L'oxydation du composé **8** fournit le 6-[2,2,4,4-bis(2,2′-dioxy-1,1′-biphényl)-2,4,6,1,3,5-cyclotriphosphazén-6-yl]-1,5-diméthyl-3-phényl-6-phosphavervazyle (**5**) que l'on a caractérisé par RPE et par spectroscopie ENDOR. L'analyse des deux spectres, sur la base du couplage hyperfin avec les trois noyaux de phosphore, indique que la densité de spin provenant du noyau phosphaverdazyle induit une polarisation de spin dans le noyau phosphazène.

Mots clés : hétérocycle, composés phosphore–azote, phosphazènes, radicaux stables, verdazyles.

[Traduit par la Rédaction]

Introduction

Stable radicals have a long history (1, 2) and new examples of isolable molecules with unpaired electrons continue to fascinate chemists (3–5). There are also a number of useful applications of stable radicals, including their role in spin labeling (6), or their acting as building blocks for electronically conducting (7, 8) or magnetic (9, 10) materials, and catalysts for living radical polymer synthesis (11–13). For all these applications, a thorough understanding of the electronic structures of stable radicals is critical. Furthermore, purposeful designs and study of new stable radicals could lead to better components for the aforementioned applications.

We have been investigating the chemical and physical properties of verdazyl radicals (**1**) for quite some time (14–17). As part of our efforts to probe structure–property relationships in these systems we have prepared verdazyl analogues in which one of the skeletal carbon atoms has been replaced by a phosphorus atom — so-called "phosphaverdazyl" radicals (**2**; X or Y = P) (18). One derivative (compound **3**) exhibited unusually large EPR hyperfine coupling to the exocyclic nitrogen atom. Computational studies suggested that a novel spiroconjugative overlap

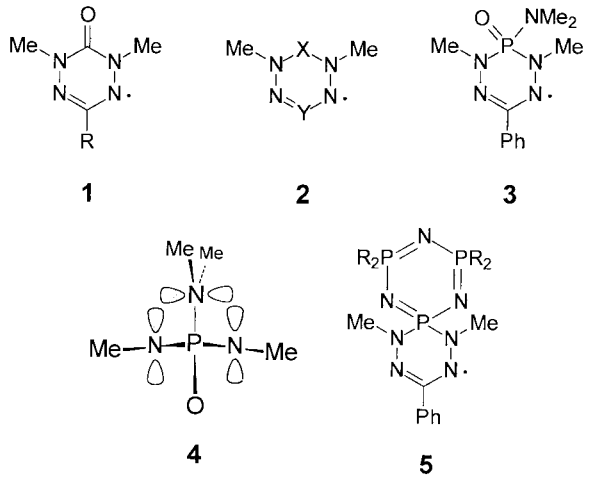
(depicted schematically in **4**) (19, 20) between the *p*-orbital of the exocyclic N and the verdazyl π system provided a through-space mode of spin propagation in phosphaverdazyl radicals (21). Connecting another ring to a phosphaverdazyl in a spirocyclic manner could lead to enhancement of spin leakage via spiroconjugation and provide a new mechanism for spin propagation (as an alternative to the more conventional π conjugation in delocalized radicals). These possibilities motivated the design and synthesis of compound **5** in which the phosphaverdazyl group is connected in a spirocyclic manner to a phosphazene ring. In this paper we describe the synthesis and characterization of an example of radical **5** and present spectroscopic evidence for spin transfer from the verdazyl to the phosphazene ring.



Results

The radical was prepared as shown in Scheme 1. Treatment of hexachlorocyclotriphosphazene with 2 equiv of 2,2′-biphenol according to literature procedures gave substituted dichlorophosphazene **6** (22). This intermediate was reacted with excess methylhydrazine to produce bis(hydrazide) **7**, which was subsequently condensed with trimethylorthobenzoate to give the spirocyclic phosphatetrazine **8**. Oxidation of **8** with benzoquinone gave the phosphaverdazyl radical **5** as a red-brown solid. Although **5** is very persistent, it gradually decomposes in solution or the solid state, predominantly back to the tetrazine **8**. Solutions of **5** can be quantitatively reduced back to **8** with ascorbic acid, confirming the identity of the radical (in conjunction with spectroscopic evidence, see below).

Single crystals of tetrazine **8** suitable for X-ray diffraction studies were grown from diethyl ether. Figure 1 displays the molecular structure of the tetrazine (which crystallizes with 1 equiv of ether in the lattice); a summary of pertinent bond lengths and angles is given in Table 1. The phosphazene ring is planar within experimental error and the P—N bond lengths within this ring range from 1.56 to 1.59 Å, values that can be regarded as typical for cyclotriphosphazene rings (23). The phosphatetrazine ring is puckered at the NPN portion and the two N-methyl groups are in quite different stereochemical environments. The methyl group on N7, which is adjacent to the C1—N6 double bond, is essentially coplanar with that bond. The other N-methyl group attached

to N4, however, is oriented nearly perpendicular to the N6-C1-N5 plane. This conformation is maintained in solution, as evidenced by the difference in chemical shifts (δ = 3.30 vs. 2.90 ppm) and in particular the difference in coupling constants to the P3 nucleus (J_{HP} = 8.82 vs. 11.04 Hz) in the ^{1}H NMR spectrum.

The EPR spectrum of **5** (g = 2.0043), Fig. 2, consists of (at least) 14 broad featureless lines that could not be further resolved despite considerable efforts to improve the spectral resolution. However, the isotropic hyperfine splitting evident in the EPR spectrum was resolved into unique pairs of

frequencies by the application of double resonance techniques. The Electron nuclear double resonance (ENDOR) spectrum of **5** is shown in Fig. 3. The hyperfine splitting is small enough so that the first order perturbation theory applies and two conditions must be considered to interpret the ENDOR spectrum. When the hyperfine splitting (a_N) is less than the larmor frequency (ν_N), a pair of resonances is observed that are centered at the larmor frequency and separated by the hyperfine splitting. When $a_N > \nu_N$, the two resonances are separated by twice the larmor frequency ($2\nu_N$) and centered at half the hyperfine splitting ($a_N/2$) (24). The application of these rules permits the unambiguous assignment of all observable and overlapping resonances in the spectrum. The final deconvolution of the ENDOR spectrum is also shown in Fig. 3 in which the seven pairs of resonances that correspond to ^{1}H, ^{31}P, and ^{14}N are clearly indicated. The hyperfine values obtained from this spectrum are $a(P_1)$ = 7.29 G, $a(2P_2)$ = 1.06 G, $a(2N_1)$ = 6.45 G, $a(2N_2)$ = 5.18 G, $a(6CH_3)$ = 4.24 G, $a(3H_{Ar})$ = 0.40 G, and $a(2H_{Ar})$ = 0.20 G. Based on our previous work on 6-phosphaverdazyls (18, 21), we assign the larger of the $a(^{31}P)$ values to the spirocyclic phosphorus atom and the smaller to the other two P atoms of the phosphazene ring. The ^{14}N hyperfine values of 6.45 and 5.18 G are assigned to the verdazyl di- and tri-coordinate nitrogens, respectively, and the largest of the proton hyperfine values corresponds to the six N-methyl protons; these three sets of couplings are fairly typical of verdazyl and phosphaverdazyl radicals. The small

Fig. 2. EPR spectra of **5** in toluene solution at 273 K (top, experimental solution; bottom, simulated solution). The sweep width of the experimental spectrum is 100 G. The arrow indicates the static field used for the acquisition of the ENDOR spectrum. The small asymmetric doublet in the center of the EPR spectrum is due to an unknown impurity.

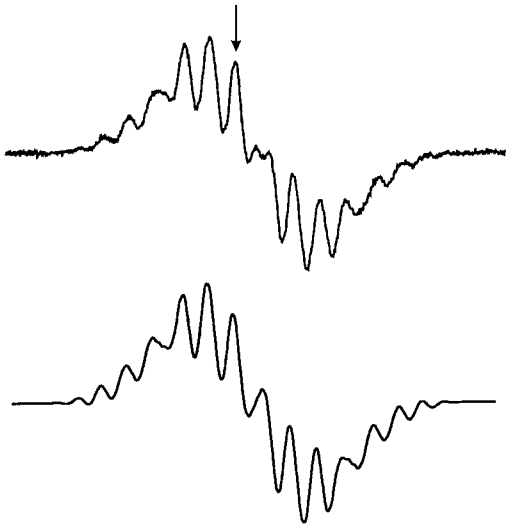

Fig. 3. ENDOR spectrum of **5** with peak assignments indicated.

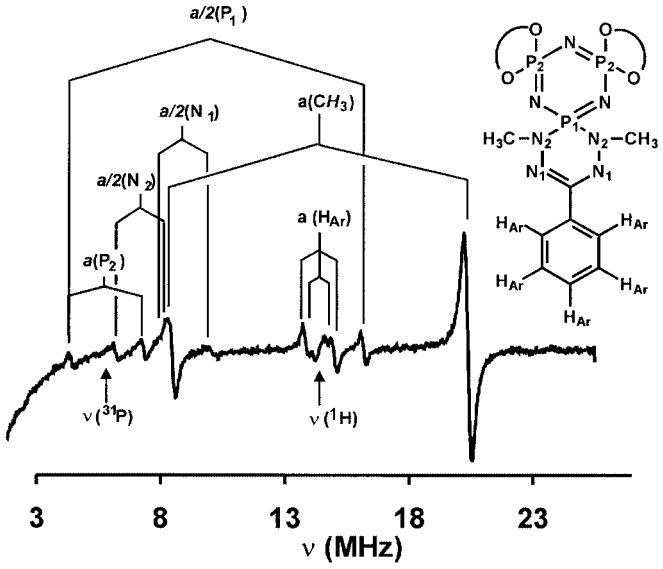


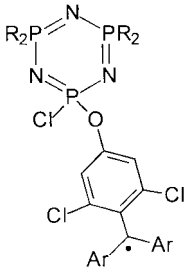
proton hyperfine couplings are assigned to the aromatic substituent of the verdazyl ring; these values are consistent with aromatic groups on related verdazyl radicals (25, 26). Hyperfine coupling to the nitrogen atoms of the phosphazene ring was not observed in the ENDOR spectrum. However, it proved possible to extract an approximate value for the pair of equivalent phosphazene nitrogen atoms through simulation of the EPR spectrum. The hyperfine splitting values to the other nuclei determined from the ENDOR spectrum constants, a value of 0.65 ± 0.15 G for the pair of phosphazene nitrogen atoms, and the appropriate number of equivalent nuclei were used in a first order perturbation treatment to simulate the EPR spectrum. The con-

© 2002 NRC Canada

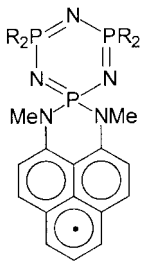
volution employed a Gaussian lineshape and linewidth of 0.90 G. The simulated spectrum, Fig. 2, closely matches the experimental one and demonstrates that the hyperfine splitting constants were assigned correctly. The uncertainty in the phosphazene ^{14}N hyperfine splittings comes from the relatively large linewidth needed to reproduce the intensity distribution of the solution spectrum. Such small hyperfine coupling to nitrogen, < 0.65 G, may be undetectable by ENDOR at X-band because of quadrupole broadening from the ^{14}N (I = 1) nucleus.

Discussion

Rings, chains, and polymers built from catenated phosphazene units $(R_2P{=}N)_n$ are among the best known nonmetal inorganic systems (27, 28). Their fundamental chemistry, structure, and bonding has attracted a great deal of attention, and the general robustness of the PN backbone has led to a variety of technological applications based on phosphazene high polymers (29). However, despite their formally conjugated electronic structures, they exhibit poor delocalization compared with conjugated organic systems. As such, phosphazenes are generally colorless and are poor electrical conductors in their native ("undoped") state, and charge carriers in them can be introduced (by oxidation or reduction) only with great difficulty (30, 31). The concept of introducing spin into a PN backbone has also received little attention. Two other cyclophosphazenes with radicals as substituents, compounds **9** (32) and **10** (33), have been reported. In both these systems, EPR evidence suggested that the radicals induced spin polarization in the phosphazene ring. Hyperfine coupling to the phosphorus nucleus ($a(^{31}P)$ = 5.25 G for **9**, 1.275 G for **10**) closest to the radical centers was inferred based on spectral simulations for each, although it should be noted that the assignments for **10** were tentative owing to the complexity of the EPR spectrum. In the present work on radical **5**, the spectroscopic evidence shows that there is substantial spin polarization through the spirocyclic phosphorus ($a(^{31}P)$ = 7.29 G) that extends to the remote ^{31}P ($a(^{31}P)$ = 1.06 G) and ^{14}N atoms of the phosphazene ring.

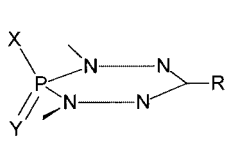


9

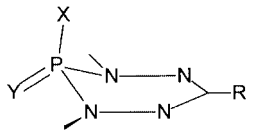


10

It is instructive to compare the results for **5** to related phosphaverdazyls. Our EPR and computational studies on **3** and other derivatives establish a correlation between the hyperfine coupling to the phosphorus atom and the overall ring geometry (21). Briefly, when the P atom has strong π-donor substituents (as is the case for **3**) a planar phosphaverdazyl ring **11** is favoured, and the phosphorus hyperfine coupling in this radical is very small (<< 1 G). Other phosphaverdazyl radicals lacking in π-donor groups tend to favour a half-chair geometry (**12**) and have substantial $a(^{31}P)$'s (e.g., when X = Ph and Y = O, $a(^{31}P)$ = 5.2 G (18)). The relatively large hyperfine value for the analogous phosphorus atom in **5** suggests that the phosphaverdazyl ring of this radical is also bent.

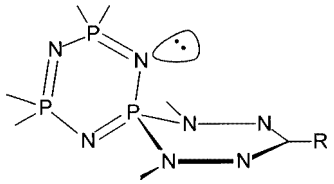


11



12

Spiroconjugation as a means of spin propagation in radicals is rare but has been noted previously on other radical systems (8, 34–36). The design of phosphaverdazyl radical **5** was meant to enhance the spiroconjugative interactions seen in **3** (depicted schematically in **4**). The spectroscopic data suggest that the amount of spin density on the phosphazene nitrogen atoms of **5** is, at best, much smaller than was found on the exocyclic nitrogen atom in **3**. This may be evidence that, for the phosphaverdazyl systems, the relative orientation of the interacting orbitals is a necessary but not sufficient condition for spiroconjugation. The natures of the nitrogen atoms of **3** and **5** potentially engaged in spiroconjugation with the verdazyl SOMO are in fact quite different: In the former, the tricoordinate nitrogen atom possesses a doubly occupied *p*-orbital (i.e., a lone pair) that can adopt the appropriate orientation for spiroconjugative overlap with the verdazyl SOMO. In the latter, the phosphazene nitrogen atoms are dicoordinate and the lone pair is constrained to point directly towards the verdazyl ring (**13**). This lone pair orbital is therefore orthogonal to the verdazyl π-SOMO. There is, of course, a nitrogen atom *p*-orbital forming part of the phosphazene π framework that is oriented ideally for spiroconjugation, but our spectroscopic data seem to suggest that the effect is not realized. However, the observation of some spin density on the remote phosphorus atoms suggests that some other mechanism — likely through-bond — is responsible for spin leakage within the phosphazene ring.



13

Experimental

General

All reactions and manipulations were carried out under an argon atmosphere using standard Schlenk or glove box techniques. Solvents were dried and distilled under argon prior to use (CH_2Cl_2, CaH_2, THF, Na/benzophenone). All reagents were purchased from Aldrich and used as received. Mass spectra were recorded on a Kratos Concept IH MS system. IR Spectra were recorded as Nujol mulls or KBr presses on

© 2002 NRC Canada

a PerkinElmer Spectrum One Spectrometer. NMR spectra were recorded on a Bruker AMX360 spectrometer. Elemental analyses were carried out by Canadian Microanalytical Services Ltd. (Vancouver, B.C.).

Synthesis of 1,1,3,3-bis[*spiro*-2′,2″-dioxy-1′,1″-biphenyl]-5,5-bis(1-methylhydrazido)-1,3,5,2,4,6-cyclotriphosphazene (7)

A solution of **6** (22) (1.045 g, 1.81 mmol) in 35 mL CH_2Cl_2 was added dropwise to a solution of $MeNHNH_2$ (0.44 mL, 8.3 mmol) in 30 mL CH_2Cl_2 at 0°C. A white precipitate formed during the addition. The reaction mixture was stirred for 12 h. The solution was filtered in vacuo and the filtrate concentrated to a white solid. The crude solid was chromatographed on silica gel (3:1, $CHCl_3$–CH_3CN) to give **7**. Yield: 1.045 g (97%); mp 245–246°C. IR (KBr) (cm^{-1}): 3327 (w), 3259 (w), 3185 (w), 2786 (w), 1609 (m), 1568 (w), 1500 (s), 1476 (s), 1438 (s), 1264 (s), 1230 (s), 1197 (s), 1173 (s), 1093 (s), 1037 (m), 1016 (m), 982 (m), 959 (s), 945 (s), 919 (s), 866 (s), 812 (m), 783 (s), 754 (s), 735 (s), 719 (s), 685 (m), 624 (s), 609 (s), 588 (w), 569 (w), 533 (s), 523 (m), 497 (m), 477 (m). ^{1}H NMR (CD_2Cl_2) δ: 7.6–7.3 (m, 16H), 3.61 (br s, 4H), 2.94 ppm (d, 6H, J = 11.0 Hz). ^{13}C NMR (CD_2Cl_2) δ: 148.7 (t, J = 3.4 Hz), 130.1, 130.0, 129.3, 126.3, 122.1, 40.2 ppm (d, J = 7.91 Hz). ^{31}P NMR ($CDCl_3$) δ: 31.3–30.5 (m), 29.0–28.5 ppm (m). CI-MS (methane) *m/z* (%): 594 ([M + 1], 100), 622 ([M + 29], 21). Anal. calcd. for $C_{26}H_{26}N_7O_4P_3$: C 52.62, H 4.42, N 16.52, P 15.66; found: C 52.71, H 4.44, N 16.48, P 16.57.

Synthesis of 6-[2,2,4,4-bis(2,2′-dioxy-1,1′-biphenyl)-2,4,6,1,3,5-cyclotriphosphazen-6-yl]-1,2,5,6-tetrahydro-1,5-dimethyl-3-phenyl-1,2,4,5,6-tetrazaphosphorine (8)

A solution of **7** (410 mg, 0.691 mmol), trimethylorthobenzoate (0.24 mL, 1.40 mmol), and ~10 drops acetic acid in 110 mL MeOH was gently refluxed for 5 days during which a white precipitate formed. The solution was cooled in an ice bath and the solution was gravity filtered to yield crude **8**. The product was purified by chromatography on silica gel (benzene) to give the product as a clear oil, which on crystallization from ether gave light pink rectangular rod-like crystals. Yield: 273 mg (58%); mp 251–253°C. IR (KBr) (cm^{-1}): 3333 (w), 1501 (w), 1476 (w), 1438 (w), 1264 (m), 1228 (s), 1192 (sh), 1168 (s), 1117 (w), 1093 (s), 1044 (w), 1014 (w), 962 (m), 946 (w), 926 (w), 908 (m), 874 (m), 818 (w), 785 (w), 754 (w), 741 (w), 719 (w), 711 (w), 693 (w), 624 (w), 610 (m), 584 (w), 534 (w), 521 (w), 476 (w). ^{1}H NMR ($CDCl_3$) δ: 7.7–7.3 (m, 21H), 6.17 (d, 1H, J = 5.88 Hz), 3.30 (d, 3H, J = 8.82 Hz), 2.90 ppm (d, 3H, J = 11.04 Hz). ^{13}C NMR ($CDCl_3$) δ: 148.3 (t, J = 4.52 Hz), 141.0 (d, J = 15.8 Hz), 132.5, 129.7, 129.6, 129.5, 128.9 (d, J = 7.91 Hz), 128.4, 126.5, 125.9, 121.8 (d, J = 12.4 Hz), 38.9 (d, J = 4.52 Hz), 36.6 ppm (d, J = 7.91 Hz). ^{31}P NMR ($CDCl_3$) δ: 28.5 (d, J = 67.88 Hz), 10.72 ppm (t, J = 68.33 Hz). EI-MS *m/z* (%): 680 ([M + 1]). Anal. calcd. for $C_{33}H_{28}N_7O_4P_3$: C 58.33, H 4.15, N 14.43, P 13.67; found: C 58.13, H 4.07, N 14.27, P 13.83.

$D_{calcd.}$ (g cm^{-3})	1.35
Absorption coefficient (μ) (mm^{-1})	0.21
R_1, wR_2[a,b]	0.064, 0.131

[a] $R_1 = (\Sigma||F_o| - |F_c||)/\Sigma|F_o|$ for reflections with $F > 2\sigma(F)$.
[b] $wR_2 = [\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]]^{0.5}$ for all reflections.

Synthesis of 6-[2,2,4,4-bis(2,2′-dioxy-1,1′-biphenyl)-2,4,6,1,3,5-cyclotriphosphazen-6-yl]-1,5-dimethyl-3-phenyl-6-phosphaverdazyl (5)

Benzoquinone (~8 mg) was added to a solution of **8** (99 mg, 0.146 mmol) in 5 mL THF. The solution turned an intense cherry red. The solution was concentrated in vacuo to give a red oil. The crude product was chromatographed on alumina (CH_2Cl_2) to give **8** as a red oil. UV–vis (THF): λ_{max} = 540 nm. ($t(1/2)$ = 2.1 days at 1.5 × 10^{-3} mol L^{-1}). The solid radical also decomposed over a period of several days, predominantly to the tetraazaphosphorine **8**. Freshly prepared solutions of **5** could be quantitatively (as monitored by ^{1}H NMR) reduced back to **8** using ascorbic acid as a reducing agent.

X-ray measurements on 8

Relevant crystallographic information is presented in Table 2. Colorless blocks were mounted on a glass fibre with silicone grease. Data were collected on a Smart 1000 diffractometer (Mo Kα, graphite monochromated radiation (λ = 0.71073 Å). Data were collected for $4 < 2\theta < 50°$. A total of 13 920 reflections were measured, of which 6474 were independent and 2261 were used in the refinement of 470 parameters ($I > 2.0\sigma(I)$). An empirical absorption correction (SADABS) was applied. The structure was solved by direct methods (SHELXS-97: G.M. Sheldrick. SHELXS user manual. Madison, WI. (1997)), and the hydrogen atoms were placed at idealized positions and refined according to the riding model. The structure was refined according to the full-matrix least squares method on F^2 (SHELXL-97: G.M. Sheldrick. SHELXS user manual. Madison, WI. (1997)). Complete crystallographic data for **9** has been deposited in Supporting Information.[2]

EPR and ENDOR spectroscopy

A solution of **5** suitable for ENDOR measurements was prepared by dissolving 0.0735 mmol of **8** in 10 mL toluene under a nitrogen atmosphere. Then, 0.037 mmol of *p*-benzoquinone was added and the solution was stirred for 1.5 h at room temperature. An additional 40 mL of toluene was added to the flask so that the final concentration of the radical was ~1.5 mM. An aliquot of the solution was placed in a suprasil quartz EPR tube, degassed three times, and sealed off under vacuum. Spectra of solution EPR and ENDOR were recorded at 273 K on a Bruker ESP300E spectrometer equipped with a DICE ENDOR accessory. The temperature was controlled with an Oxford Instruments 900E liquid helium cryostat. The EPR spectrum was obtained using a modulation amplitude of 0.2 G, power setting of 0.1 mW, and a modulation frequency of 100 kHz. For the ENDOR spectrum, the power was set at 32 mW, the modulation amplitude was 141 kHz, modulation frequency was 12.5 kHz, and the static field is indicated by the arrow in Fig. 3.

Conclusion

In conclusion, the spirocyclic fusion of a phosphaverdazyl radical to a phosphazene has been shown to be an effective means of introducing spin into the PN backbone. This raises some intriguing questions pertaining to the possibility of phosphazene rings or linear chains being effective mediators of spin-spin *communication* in di- or polyradicals. Virtually all exchange-coupled diradicals involve systems in which linear π conjugation provides the predominant pathway for spin exchange; alternative effective pathways are essentially unknown. Efforts to prepare phosphazene-bridged verdazyl di- and tri-radicals are now underway and results will be reported in due course.

Structural studies of dithiatetrazocines: X-ray crystal structures of the symmetric dithiatetrazocines *p*-$XC_6H_4CN_4S_2CC_6H_4X$ [X = NO_2, Br] and the first unsymmetric dithiatetrazocine, *p*-$BrC_6H_4CN_4S_2CC_6H_4NO_2$

Andrew D. Bond, Delia A. Haynes, and Jeremy M. Rawson

Abstract: Oxidation of equimolar amounts of [*p*-BrC_6H_4CNSSN]Cl and [*p*-$O_2NC_6H_4CNSSN$]Cl with elemental O_2 in the presence of Ph_3Sb in MeCN yields a mixture of the symmetric dithiatetrazocines, $O_2NC_6H_4CN_4S_2CC_6H_4NO_2$ (**1**) and $BrC_6H_4CN_4S_2CC_6H_4Br$ (**2**) as well as the unsymmetrically substituted derivative $BrC_6H_4CN_4S_2CC_6H_4NO_2$ (**3**). The structures of compounds **1**–**3** are determined by X-ray diffraction: **1** crystallizes in the monoclinic space group $P2_1/c$ (a = 8.6397(4), b = 5.8359(4), c = 14.9767(11) Å, β = 92.088(4)°) with half a molecule in the asymmetric unit; **2** crystallizes in the triclinic space group $P\bar{1}$ (a = 6.5330(5), b = 8.2084(6), c = 14.7264(9) Å, α = 84.483(4)°, β = 77.112(4)°, γ = 87.879(3)°); **3** was found to crystallize in two forms: recrystallization from CH_2Cl_2 at room temperature yielded a solvent-free, triclinic phase, space group $P\bar{1}$ (a = 6.5060(9), b = 7.0739(9), c = 9.1164(8) Å, α = 81.860(3)°, β = 83.406(5)°, γ = 66.589(5)°), whereas cooling a solution to –5°C yielded a solvated form, **3**·CH_2Cl_2, which crystallizes in the monoclinic space group $P2_1/m$ (a = 6.179(1), b = 10.960(2), c = 13.884(3) Å, β = 92.69(3)°). The NO_2···Br intermolecular interactions observed in the unsolvated structure of **3** are disrupted in the solvate structure; the CH_2Cl_2 molecule in the latter is aligned such that its molecular dipole interacts with both nitro and bromo groups, retaining a molecular chain motif. The structures are discussed in relation to their semi-empirically calculated molecular electrostatic potentials and calculations of intermolecular interactions using van der Waals forces combined with an electrostatic point charge model.

Key words: dithiatetrazocine, crystal structure, crystal engineering, molecular electrostatic potential.

Résumé : L'oxydation de quantités équimolaires de [*p*-BrC_6H_4CNSSN]Cl et de [*p*-$O_2NC_6H_4CNSSN$]Cl avec de l'oxygène élémentaire, en présence de Ph_3Sb, dans du MeCN, conduit à un mélange de dithiatétrazocines symétriques, $O_2NC_6H_4CN_4S_2CC_6H_4NO_2$ (**1**) et $BrC_6H_4CN_4S_2CC_6H_4Br$ (**2**), aux côtés du dérivé substitué de façon non symétrique, $BrC_6H_4CN_4S_2CC_6H_4NO_2$ (**3**). On a déterminé les structures des composés **1**–**3** par diffraction des rayons X: le composé **1** cristallise dans le groupe d'espace monoclinique $P2_1/c$ (a = 8,6397(4), b = 5,8359(4) et c = 14,9767(11) Å, β = 92,088(4)°), avec une demi-molécule dans la maille asymétrique; **2** cristallise dans le groupe d'espace triclinique $P\bar{1}$ (a = 6,5330(5), b = 8,2084(6) et c = 14,7264(9) Å, α = 84,483(4)°, β = 77,112(4)° et γ = 87,879(3)°); on a trouvé que **3** cristallise sous deux formes, la recristallisation dans le CH_2Cl_2, à température ambiante, conduit à des cristaux ne contenant pas de solvant, de phase triclinique et de groupe d'espace $P\bar{1}$ (a = 6,5060(9), b = 7,0739(9) et c = 9,1164(8) Å, α = 81,860(3)°, β = 83,406(5)° et γ = 66,589(5)°) alors que le refroidissement de la solution à –5°C livre une forme solvatée, **3**·CH_2Cl_2 qui cristallise dans le groupe d'espace monoclinique $P2_1/m$ (a = 6,179(1), b = 10,960(2) et c = 13,884(3) Å, β = 92,69(3)°). Les interactions intermoléculaires NO_2···Br observées dans la structure non solvatée de **3** sont interrompues dans la structure solvatée; la molécule de CH_2Cl_2 de cette dernière est alignée d'une façon telle que son dipôle moléculaire interagit à la fois avec le groupe nitro et le bromo tout en maintenant un motif de chaîne moléculaire. On discute des structures en fonction de leurs potentiels électrostatiques moléculaires calculés de façon semi-empirique et de calculs d'interactions intermoléculaires à l'aide de forces de van der Waals combinées à un modèle de charge ponctuelle électrostatique.

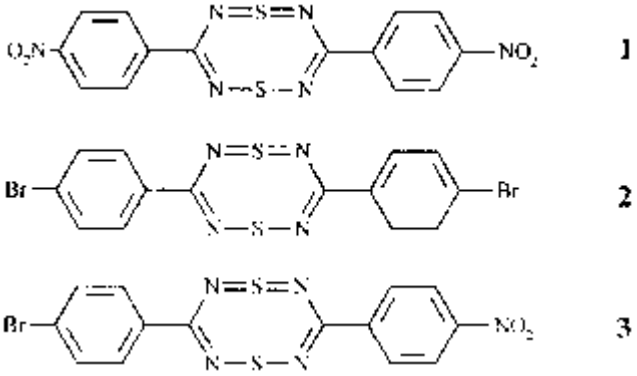
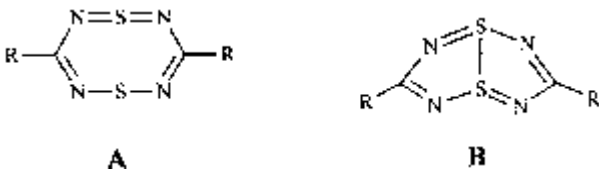
Introduction

We have been interested in the application of crystal engineering (1) in the design of sulfur–nitrogen radicals with unusual magnetic properties (2), including long range order (3) and structural bistability (4). A particular interest has been dithiadiazolyl radicals bearing perfluorinated substituents, and we have recently extended our studies to the design of simple fluorinated organics (5), as non-linear optical (NLO) materials, which will produce a second harmonic generation (SHG) response (6). A key component of the latter group of materials is the presence of a conjugated organic system with polarizable π-electrons. In addition, the material has to be macroscopically polar in order to show non-linear optical activity, and it is often the control of the crystal structure in all three dimensions to generate a macroscopically polar structure that proves problematic (7). In the current paper we report our initial studies on the synthesis of unsymmetrically substituted dithiatetrazocines (DTTA), bearing donor and acceptor groups, and report the first crystal structure of an unsymmetrically substituted dithiatetrazocine (**3**). We have found that it can be crystallized from CH_2Cl_2 in both solvated and desolvated forms dependent upon recrystallization conditions. The structures of **3** are compared with the symmetric derivatives, **1** and **2**.



Dithiatetrazocines were first prepared in 1981 by Woodward and coworkers (8) and exhibit an unusual structural dichotomy. A series of crystallographic studies have revealed two different geometries possible for the dithiatetrazocine ring, either a planar 10π aromatic structure (8, 9) with a nonbonding transannular S···S contact (**A**) or a folded structure (8, 10) with a long S—S bond (**B**).



A series of theoretical studies have been undertaken (11). Gleiter et al. suggested (12) that the planar, cyclic system is favoured by aromatic substituents, whereas heterocyclic rings bearing π-donor substituents induce a folding of the heterocyclic ring. The π-donor groups give rise to a lowering of the HOMO-LUMO gap in the planar geometry and the molecule then becomes susceptible to a pseudo Jahn-Teller distortion, generating a folded geometry.

Table 1. Optimized geometric parameters for **1**, determined using semi-empirical methods.

Parameter	**1**	AM1	PM3	PM5	MNDO
C—N (Å)	1.327–1.333	1.333	1.339	1.330	1.338
N—S (Å)	1.559–1.563	1.473	1.434	1.525	1.580
N-C-N (°)	128.8	123.0	129.4	126.5	128.2
C-N-S (°)	141.6–143.1	147.8	145.3	145.0	144.6

Initial studies indicated that the dithiatetrazocine ring is thermally very stable (8). Electrochemical studies (9) indicate that the planar dithiatetrazocines are quite resistant to oxidation and, for example, attempted oxidation (at S) using MCPBA or N_2O_4 proved unsuccessful (8, 13). This is, perhaps, surprising, given the isolation of both the S^{IV} and S^{VI} derivatives i.e., SR and S(O)R by other synthetic methods (14). By contrast, the folded dithiatetrazocines are significantly easier to oxidize (9) and chlorination of $(Me_2N)_2C_2N_4S_2$ with elemental Cl_2 leads to the unusual salt, $[(Me_2N)_2C_2N_4S_2Cl][Cl_3]$ (15). Reactivity studies on the heterocyclic ring N have focused on its basicity. It has been found to be a very poor base, showing no basic properties towards the strong acid $HClO_4$ (8). The ring also showed little reactivity towards nucleophiles, although hydrolysis by OH^- could be achieved to liberate the amidine (8). Subsequent work by Chivers et al. (16) has shown that the N atom can act as a very weak donor towards Pt, although it is liberated from the metal by other donor ligands such as THF. Electrochemical studies indicate a 1 e^- reduction to an 11π radical. Chemical studies indicate no reaction at the heterocyclic ring N with hydrazine, although reduction to the amidine could be achieved using Pd/C (13). Given the thermal stability of this ring system and its comparatively air-stable nature compared to many thiazyl rings, unsymmetrically substituted DTTAs seemed potentially novel and stable precursors for NLO-active materials.

Experimental section

The salts $[p\text{-}BrC_6H_4CNSSN]Cl$ and $[p\text{-}O_2NC_6H_4CNSSN]Cl$ were prepared according to the literature method (17). Ph_3Sb (Aldrich) was sublimed prior to use. All solvents were dried and freshly distilled under argon prior to use. Oxygen (BOC) was dried by passing through a P_4O_{10} column.

^1H NMR data were collected on a Bruker DPX 400 MHz NMR spectrometer. Mass spectra and accurate mass spectra were recorded on a Kratos Concept instrument in EI mode.

Semi-empirical molecular orbital calculations were made using MOPAC implemented through Quantum Cache 5.0 (Fujitsu Co.) running on a 1.8 GHz Pentium computer. Geometry optimization using PM3 proved to give marginally improved structural compatibility with the observed structures than MNDO, INDO, AM1, or PM5. In all cases geometry optimization led to planar DTTA rings, which exhibited substantial twist angles to the aryl substituents. Selected geometry-optimized structural parameters are given in Table 1. The PM3 method was utilized to determine subsequent molecular electrostatic potential maps and point charges for further calculations, since these produced the smallest twist

angle between aryl and DTTA rings during geometry optimization. Molecular electrostatic isopotential maps for **1–3** were determined using PM3 constrained to the crystal-structure geometry. Intermolecular interactions utilized in-house software (J.M. Rawson, 2001), including an atom-atom point charge model (using theoretically calculated point charges) and an atom-atom dispersion term for the van der Waals interactions. Full details are published elsewhere (18).

Preparation of 1–3

A solution of Ph_3Sb (0.68 g) in CH_3CN (10 ml) was added in small aliquots to a yellow suspension of equimolar quantities of [*p*-$BrC_6H_4CN_2S_2$]Cl (0.250 g, 0.846 mmol) and [*p*-$NO_2C_6H_4CN_2S_2$]Cl (0.220 g, 0.841 mmol) in CH_3CN (15 ml) under an oxygen atmosphere. The resulting purple solution was stirred at 60–75°C for 6 h under an atmosphere of oxygen. The resulting yellow product was adsorbed onto silica and separated by column chromatography (silica column, CH_2Cl_2 eluant). Pure samples of the dithiatetrazocines **1**, **2**, and **3** were isolated sequentially and identified by their ^{1}H NMR and mass spectroscopic data. The volume of each fraction was reduced and crystals of **1–3** suitable for X-ray diffraction formed by slow evaporation at room temperature. A further set of crystals of **3**·CH_2Cl_2 were also recovered from a solution stored at –5°C. Typical yields: **1** (24 mg, 14%), **2** (8 mg, 4%), **3** (10 mg, 3%), based on amount of [*p*-$O_2NC_6H_4CNSSN$]Cl and [*p*-BrC_6H_4CNSSN]Cl available.

Crystal structure determination

Single crystal X-ray diffraction analyses were performed using a Nonius Kappa CCD diffractometer equipped with an Oxford Cryosystems cryostream device. Crystals were mounted on the end of glass fibres using perfluoropolyether oil and data were collected at 180(2) K. Data were processed using the HKL package (19), and unit cell parameters were refined against all data.

Details of the crystal data and refinement are given in Table 2. Selected intramolecular bond lengths and angles are compiled in Table 3.[2]

Results

Preparation and crystal growth

Unsymmetrically substituted DTTAs were first reported by Rees and co-workers in 1989 (13), by condensation of a mixture of benzamidine and dimethylguanidine with SCl_2. They recovered a mixture of symmetrically substituted products (14.5%) and unsymmetrically substituted products (3%) in a non-statistical ratio. Subsequent studies by Boeré et al. (9) showed that unsymmetric dithiatetrazocines can be prepared by reaction of a dithiadiazolylium chloride salt with the silylated amidine in the minimum volume of refluxing MeCN. This scrambling reaction led to a statistical distribution of products (i.e., 50% unsymmetric product).

In our current studies, we utilized an alternative preparative route to DTTA rings, also developed by Boeré et al. (9). The two dithiadiazolylium salts, [*p*-BrC_6H_4CNSSN]Cl and [*p*-$O_2NC_6H_4CNSSN$]Cl, were prepared according to the literature method (17). Oxidation of equimolar quantities of these two salts with dry O_2 according to the literature method yielded a mixture of the symmetric dithiatetrazocines, **1** and **2**, as well as the unsymmetric derivative, **3**. Given the persistently low yields of this reaction, the relative recovered yields (ca. 14:4:3 for **1**:**2**:**3**) are perhaps not too significant, but likely indicate that a non-statistical mixture is present. We have not attempted alternative routes to these unsymmetrically substituted analogues, but it should be noted that purification by column chromatography proved facile. The three compounds were readily characterized by their ^{1}H NMR spectra and mass spectra. Both **2** and **3** provided signature isotope distribution patterns for their molecular ions caused by the two bromine isotopes (^{79}Br and ^{81}Br have equal natural abundances). The ^{1}H NMR chemical shifts and coupling constants for the aromatic ^{1}H nuclei in **3** can be tentatively assigned by direct comparison with the symmetrically substituted derivatives, **1** and **2**, and are in agreement with previous data (9).

The three dithiatetrazocines, **1**, **2**, and **3**, were separated by column chromatography and recrystallized from dichloromethane, yielding single crystals suitable for X-ray diffraction studies. Two sets of crystals of **3** were grown, one set from CH_2Cl_2 solution stored at room temperature, the other from a CH_2Cl_2 solution cooled to –5°C.

Crystal and molecular structure of 1

Compound **1** crystallizes in the monoclinic spacegroup $P2_1/c$, with half a molecule of **1** in the asymmetric unit. The intramolecular bond lengths and angles in the heterocyclic ring are similar to those previously reported and also to the other DTTA structures reported herein (Table 3). The whole molecule is close to planarity; the DTTA ring exhibits a mean deviation of 0.001 Å from planarity and the aromatic substituents are twisted by just 0.6° with respect to the DTTA ring plane.

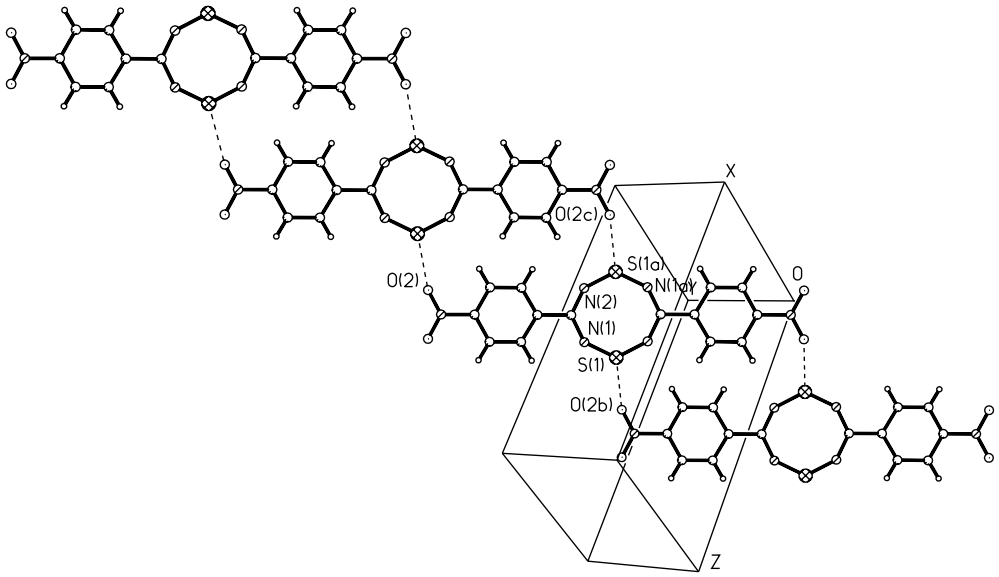
There are no intermolecular contacts substantially less than the sum of the van der Waals radii. The closest of the intermolecular contacts is an S···O contact (3.292(2)Å) between the DTTA ring and the nitro-substituent on the aromatic ring of an adjacent molecule. These contacts are slightly beyond the sum of the van der Waals radii (20) close to the ring plane (3.14 Å), but shorter than the sum of the van der Waals radii perpendicular to the plane (3.57 Å). Two pairs of these contacts link molecules together into a one-dimensional chain (Fig. 1). There are also N···O contacts between nitro groups; these comprise N(3)···O(1b) at 3.221(2) Å and N(3)···O(2b) at 3.582(3) Å and are also greater than the sum of the van der Waals radii (20) (3.14 Å). These interactions generate a herring-bone motif (Fig. 2).

Crystal and molecular structure of 2

Heterocycle **2** crystallizes in the triclinic space group $P\bar{1}$, with the asymmetric unit consisting of two half molecules of **2**. The intramolecular bond lengths are comparable with those of **1** (above, and see Table 3) and there is no significant

© 2002 NRC Canada

Fig. 1. Packing of **1** illustrating the intermolecular S···O contacts close to the molecular plane.



difference in molecular geometry between the two crystallographically unique molecules. In both cases the DTTA ring is essentially flat (mean deviation within 0.006 Å). In one of the unique molecules in the asymmetric unit, the phenylene and heterocyclic rings are essentially co-parallel (angle between mean planes is 1.5°), although the second crystallographically unique molecule is slightly more twisted with the corresponding twist angle being 8.8°.

There are no particularly close intermolecular contacts. One of the two crystallographically independent molecules forms pairs of S···Br contacts at 3.885(1) Å, close to the molecular plane linking crystallographically related molecules into chains (Fig. 3*a*). These contacts are beyond the sum of the van der Waals radii (3.14–3.87 Å). The second of the two crystallographically independent molecules also forms chains linked via pairs of S···N contacts (S(21)···N(22b) at 3.596(4) Å) also around, or beyond, the sum of the van der Waals radii (3.2–3.63 Å) (Fig. 3*b*). These two sets of chains are linked via Br···Br contacts at 3.526(1) Å, which are also close to the sum of the van der Waals contacts, i.e., 3.08 – 3.68 Å. This leads to a set of interlocking sheets of molecules.

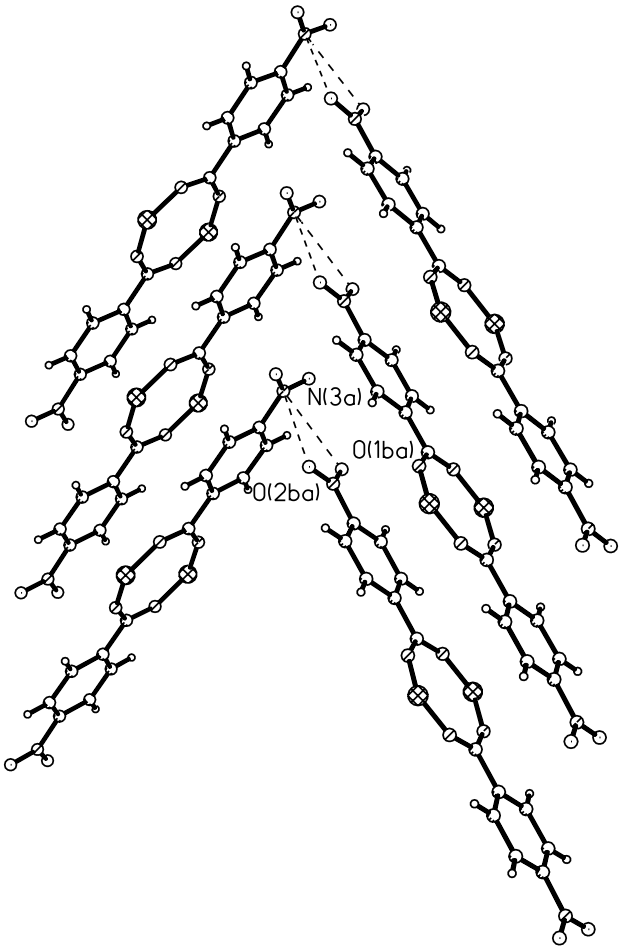
Crystal and molecular structure of 3

Attempts to crystallize the unsymmetric DTTA derivative **3** from CH_2Cl_2 yielded two sets of needle-like crystals; a solvate **3**·CH_2Cl_2 and an unsolvated form **3**.

Structure of 3

Dithiatetrazocine **3** crystallizes in the triclinic space group $P\bar{1}$, with half a molecule in the asymmetric unit and a consequent 50:50 disorder of the Br and NO_2 groups. The heterocyclic geometry is similar to those observed for **1** and **2**, although there is a slight increase in the intramolecular S···S contact. The heterocyclic ring, like **1** and **2**, is essentially planar (mean deviation 0.007 Å). The twist angle (15.1°) between aryl and DTTA rings is more marked than any of the other structures reported here. Nevertheless, the three rings in **3** remain close to co-planarity.

Fig. 2. Packing of **1** emphasizing the herring-bone motif and intermolecular nitro···nitro interactions.



The disorder in the substituent positions complicates discussion of some aspects of the crystal structure. However, the disorder does not affect the S···N contacts (S(11)···N(12c)

at 3.663(7) Å, cf. sum of the van der Waals radii at 3.20–3.63 Å) between DTTA rings, which link molecules along the crystallographic *a*-axis (Fig. 4). These contacts are similar in nature to those observed in **2** (Fig. 3). In addition a second in-plane contact is observed between the nitro–bromo substituent and the DTTA sulfur atom (Fig. 4). These are similar to the corresponding in-plane NO_2···S and Br···S interactions observed in **1** and **2**, respectively. The disorder in the nitro–bromo substituents inhibits a detailed discussion of the geometry of this contact. Nevertheless, the supramolecular NO_2···Br interaction appears present in the structure of **3**, and links molecules together along the crystallographic *c*-axis.

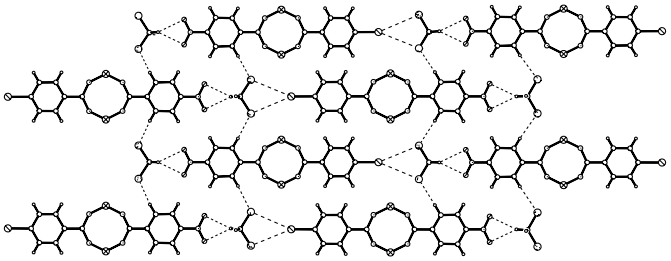
Fig. 5. View of the structure of **3**·CH_2Cl_2 (illustrating only the major components of the positional disorder of nitro and bromo substituents and CH_2Cl_2 solvate molecule).



Structure of 3·CH_2Cl_2

The structures of **1**, **2**, and the unsolvated form of **3** (above), as well as many other DTTA derivatives contain half-molecules in the asymmetric unit related through an inversion centre. In the case of **3**·CH_2Cl_2, the asymmetric unit comprises half a molecule of **3** and half a molecule of CH_2Cl_2, which are located on a mirror plane passing through the two Br–NO_2 functional groups. In the case of **3**·CH_2Cl_2 the Br–NO_2 functional groups exhibit positional disorder in an approximately 3:1 ratio. The terminal group disorder does not affect the DTTA ring geometry, which is comparable with other aryl derivatives described above (Table 3). The DTTA ring is planar within (0.01 Å) and approximately coplanar with the aryl ring (twist angle 0.4°).

A comparison of the structures of **3** and **3**·CH_2Cl_2 immediately reveals a disruption of the chain-like motif present in unsolvated **3**. The CH_2Cl_2 molecule is sited on the mirror plane and is also orientationally disordered over two sites in an approximately 1:1 ratio. The CH_2Cl_2 is located between molecules of **3** along the chain-forming direction. The disorder in both CH_2Cl_2 and Br–NO_2 groups complicates discussion of the intermolecular interactions between these two groups, although it is tempting to envisage the molecular dipole of the CH_2Cl_2 molecule aligning with the molecular dipole of **3**. Lateral interactions between molecular chains comprise S···Br (and S···O_2N) interactions (Fig. 5). The S···Br contact, present in the major component of the disorder, is 4.243(3) Å, somewhat longer than the corresponding S···Br contacts in **2**.

Discussion

The molecular structures of the aryl-substituted DTTA molecules, described herein, are similar to those reported for other derivatives described in earlier reports (8–10). Their planar 10π aromatic structures are consistent with previous studies, which indicate that folded structures are stabilized only when there is the possibility of π-donation into the thiazyl ring.

Our recent structural studies in dithiadiazolyl radical chemistry has successfully utilized molecular electrostatic potential (MEP) maps, coupled with a point charge model, to analyse the observation of polymorphism in the rigid dithiadiazolyl radicals, ClCNSSN and HCNSSN (18). To attempt to rationalize the structures of **1**–**3**, we have employed similar techniques. The focus of these current studies has been to examine whether structure-directing groups can be utilized to manipulate the solid state structures of DTTAs. In the current paper we examine the structures of these DTTAs, using the same methodology.

Molecular electrostatic potential maps

Calculations of the molecular electrostatic potential maps were carried out using semi-empirical methods. We found that of the methods employed (MNDO, AM1, PM3, and PM5), several gave similar geometries for the DTTA ring (Table 1) close to that observed experimentally for **2**. Whilst the twist angle between DTTA and aryl substituent is susceptible to crystal-packing effects, all semi-empirical methods gave substantial deviations from coplanarity. We chose the PM3 method, since this provided the smallest deviations from planarity and therefore best agreement with the observed structure. The molecular electrostatic potential maps (MEPs) determined using other methodologies did not differ substantially, although some variations in partial point charges were found.

The molecular electrostatic potential is the energy of a unit of positive charge ("a proton") as it interacts with a molecule, i.e., its interaction with the unperturbed molecular charge distribution, caused by the electrons and positive nuclei. The isopotential map represents a contour linking points with the same interaction energy. The value of the plot may be positive if the MEP at that point is repulsive, or negative if the sum of the electrostatic interactions is attractive (21). The isopotential maps for **1**–**3** are shown in Fig. 6 with dark grey regions representing a negative, attractive potential towards a positive charge, and light grey regions corresponding to positive, repulsive interactions. We feel that the electrostatic approach to analyse the bonding in thiazyl rings is particularly appropriate because of the strong polarity of the thiazyl bonds. Since electrostatic interactions exhibit an r^{-1} dependency, whereas van der Waals forces are a function of r^{-6}, then contacts beyond the sum of the van der Waals contacts may exhibit a substantial ionic contribution to the lattice energy. Current semi-empirical calculations on the DTTA heterocycle indicate substantial bond polarity within the heterocyclic ring as well as substantial partial charges on the nitro functional group. Conversely the Br atom is electrostatically near neutral. Given the sparsity of contacts less than the sum of the van der Waals radii in **1**–**3**, the electrostatic contribution is likely to be significant.

An examination of the in-plane packing motifs of **1**, **2**, and **3** (i.e., close to the molecular plane) reveals a recurring theme of intermolecular contacts to S. In **1**, the S···O contacts are 3.292(2) Å (Fig. 1) and geometrically similar interactions also occur in **3** and **3**·CH_2Cl_2 (Figs 4 and 5). Intermolecular S···Br contacts are observed in **2** and **3**. In **2**, the S···Br contact is 3.885(1) Å. In **3** and **3**·CH_2Cl_2 the corresponding values are somewhat longer (around 3.997(3) Å and 4.243(3) Å respectively). In addition, intermolecular S···N contacts close to the ring plane are observed in **2** and **3**. The intermolecular S···N contact between symmetry-related DTTA rings in the second crystallographically unique molecule of **2** is 3.596(4) Å. These are also observed in the structure of unsolvated **3**, at 3.663(7) Å.

A comparison of the observed structures with their molecular electrostatic potential maps clearly reveals the matching of electropositive (light grey) and electronegative (dark grey)

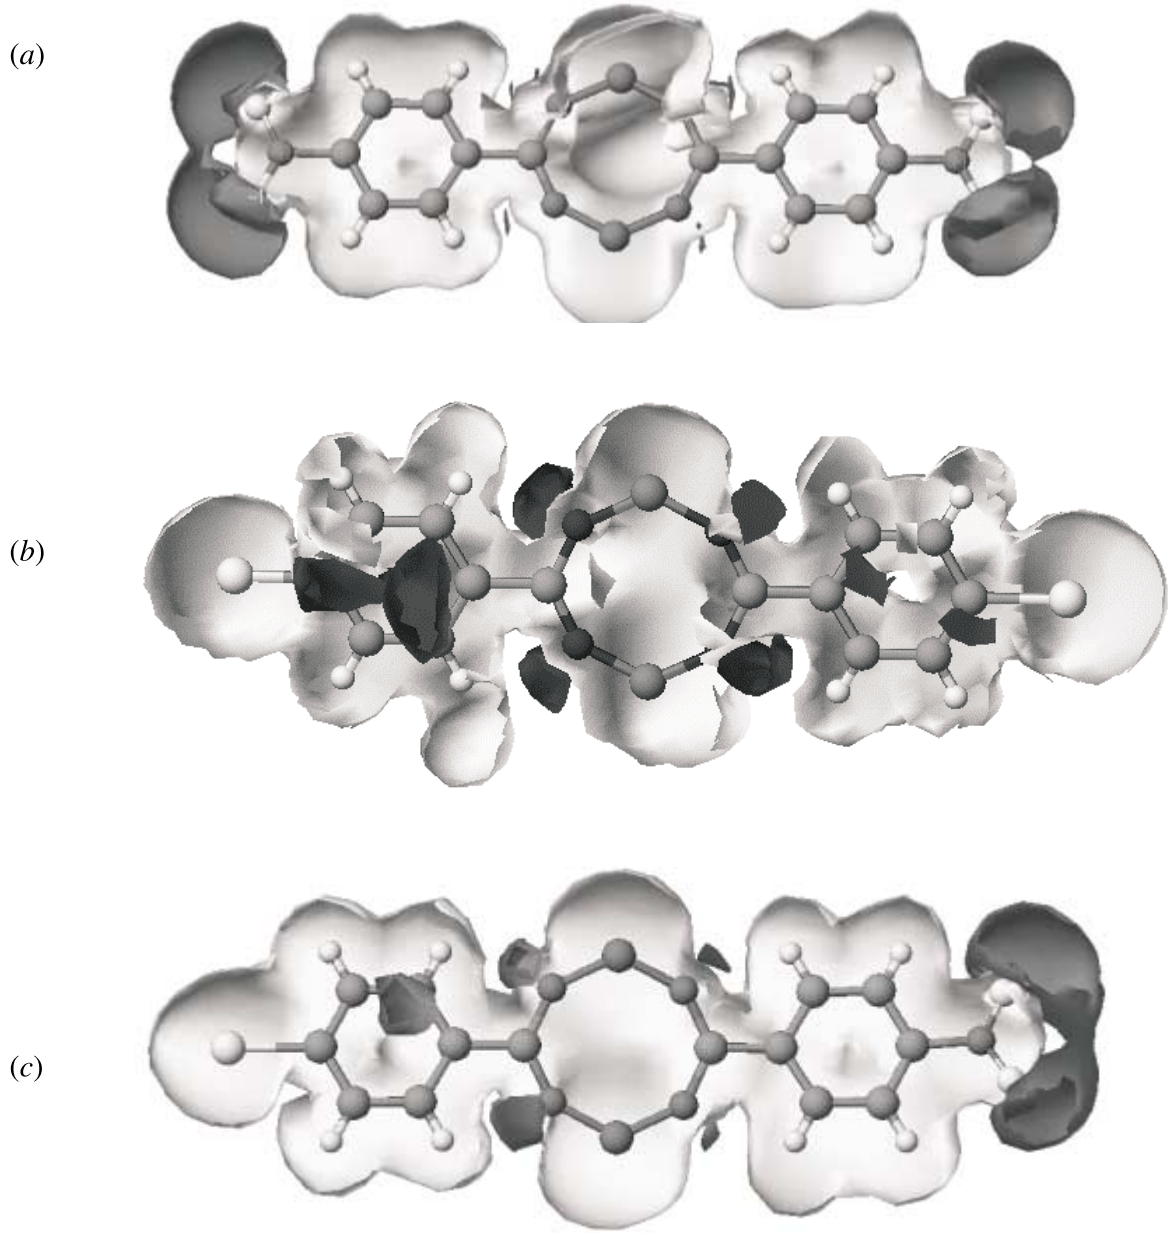
Fig. 6. Molecular electrostatic potential maps for (*a*) **1**, (*b*) **2**, and (*c*) **3** calculated using semi-empirical methods (MOPAC/PM3 employed through Quantum Cache (v. 5.0, Fujitsu Co.)). MEP determined at 0.04 au.



regions of the molecule in **1** and **3**, i.e., favouring S···O and S···N contacts. In contrast, the S···Br contact would appear to have little electrostatic contribution, and is likely to be predominantly induced-dipole – induced-dipole (van der Waals) forces, associated with the softer Br and S atoms. The greater partial charge on the DTTA ring N in **2** (cf. **1**) also promotes intermolecular S···N contacts between the DTTA rings. The observation of two sets of crystallographically distinct supramolecular chains of molecules, one linked via four S···Br contacts per molecule, and the other linked through four S···N contacts per molecule in **2**, is indicative of both sets of interactions having similar stabilities. Only in the case of **3** is a head-to-tail alignment of molecules anticipated (via NO_2···Br contacts), and indeed observed. In **1** and **2**, electrostatic N···O and van der Waals Br···Br contacts orient molecules approximately orthogonal to each other.

To examine the nature and relative stabilities of these interactions further, we utilized a point charge model to refine the packing geometry for a pair of interacting DTTA molecules. To simplify the problem, the molecular geometries were forced to be planar, and energy minimization was carried out with both molecules lying in the same plane, with their molecular long-axes parallel. It may be argued that the additional packing forces present in the solid state structure, coupled with the planarity restriction are likely to lead to some deviations between observed and calculated geometries. Nevertheless, our previous studies and the current investigations have generally found gratifying agreement

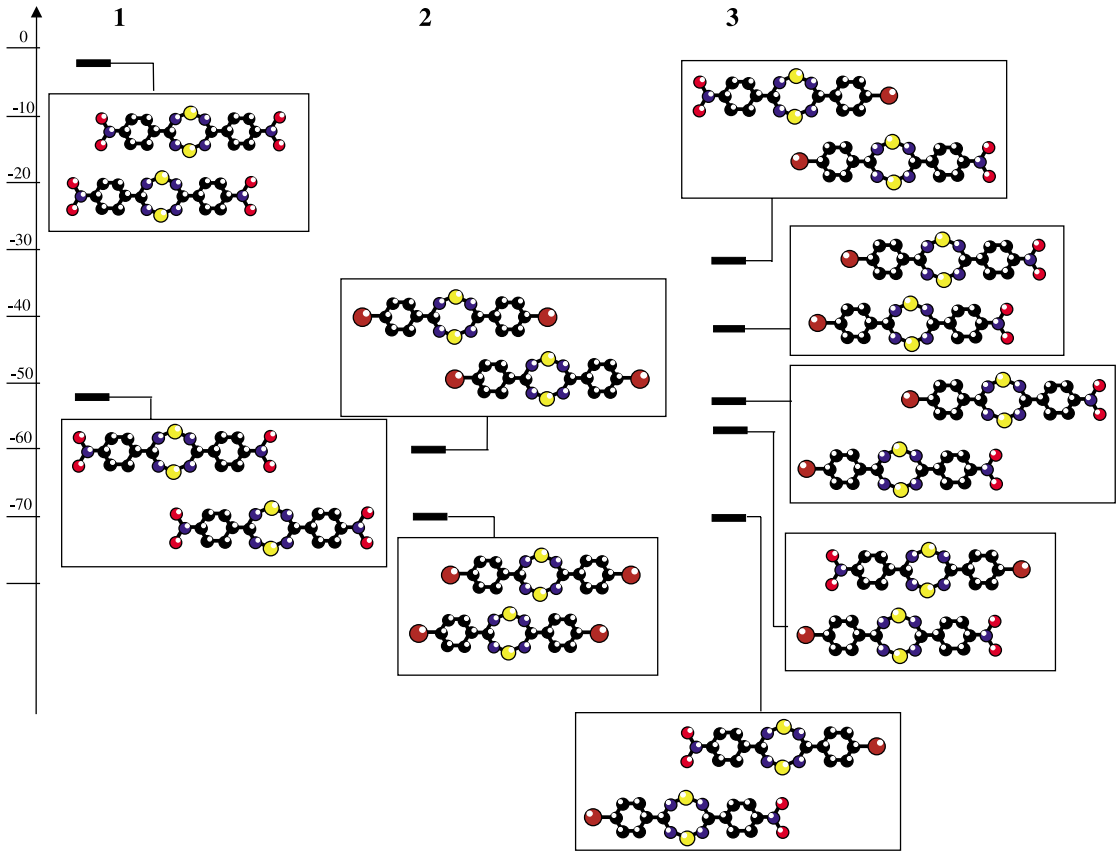
Fig. 7. Energy minima (kJ mol^{-1}) for parallel arrangements of **1**, **2**, and **3**, calculated using van der Waals interactions with a point charge model (Point charges were utilized from semi-empirical MNDO/PM3 calculations).



between observed and calculated molecular predisposition. Figure 7 shows the energy minima for the parallel arrangements of **1**–**3**.

In the case of **1**, the intermolecular S···N contacts between DTTA rings is clearly disfavoured in comparison to the S···O interactions. Whilst the optimized geometry gives some discrepancy with that observed (cf. calculated and experimental S···O contacts at 3.014 and 3.292(2) Å), the gross geometry of this energy minimum is clearly consistent with the crystal data.

In the case of **2**, the geometries associated with the intermolecular S···N and S···Br contacts were calculated to be much closer in energy and are consistent with the observation of both packing motifs in the structure of **2**. The calculated point charge on Br is essentially zero, and so the S···Br contact is predominantly van der Waals in nature, whereas the S···N interaction is electrostatically favoured. The detailed geometries of these interactions also show some discrepancy with the observed data (cf. calculated and observed S···N contacts of 3.184 and 3.596(4) Å and S···Br contacts of 3.990 and 3.885(1) Å). Despite these deviations, these geometries are in broad agreement with the observed structure and, we feel, remarkable given the simplicity of the model employed.

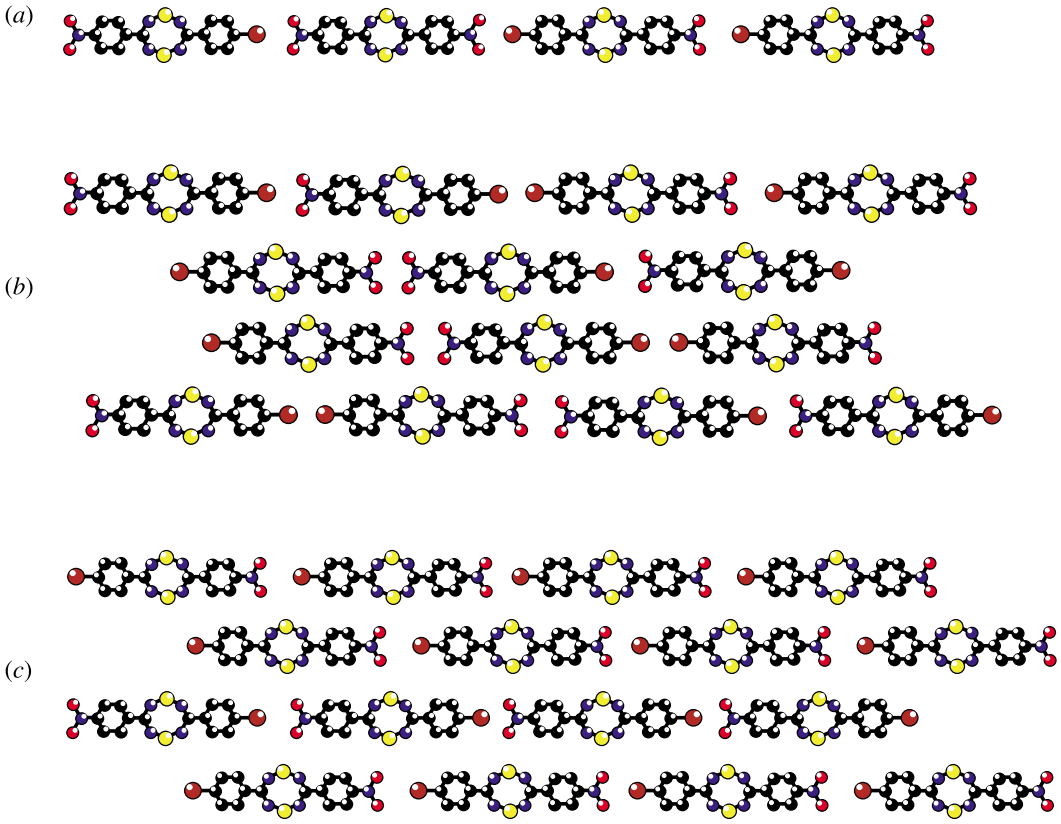
Calculations on **3** reveal similar energies for the two co-parallel modes of attachment via heterocyclic S···N contacts. Both of the parallel and anti-parallel modes with molecules linked via S···O contacts are calculated to be more stable with the anti-parallel arrangement preferred.

Origin of the disorder in 3

The observed structural disorder in **3** could arise from several possibilities. These have been discussed at length in the discussion of the biphenyl derivative, *p*-$IC_6H_4C_6H_4NO_2$ (22), which also exhibits similar structural disorder. Inclusion of small amounts of the symmetric derivatives **1** or **2** could result in inversion of the direction of chain polarity, giving rise to structural disorder. However, we discount this since the different components were separated by column chromatography and no evidence for contamination was observed by ^1H NMR or mass spectrometry. Alternatively the structure could be subject to random disorder within the chain. The calculated attachment energy for the NO_2···Br contact is ca. –7 kJ mol^{-1}, whereas both the NO_2···O_2N interaction and Br···Br interactions are calculated to be unfavourable by ca. +1 and +7 kJ mol^{-1}, respectively. Whilst this does not preclude random positional disorder, the nitro···bromo contact is the only one calculated to be favourable. It is notable that the energetically disfavoured in-plane NO_2···O_2N interactions and Br···Br interactions are not observed in either **1** or **2** and other packing motifs are adopted to avoid this unfavourable interaction. A third possibility is that the chains are macroscopically polar, but there is disorder in the arrangement of parallel chains. Calculations of the energy minima for

© 2002 NRC Canada

Fig. 8. Possible origins of the disorder in **3** arising from (*a*) doping with impurity (**1**), (*b*) random positional disorder, and (*c*) orientational disorder of parallel chains.



co-parallel and anti-parallel alignment of molecules on neighbouring chains (determined above) indicate that the small energy difference between these minima may give rise to the observed disorder. In light of the arguments presented here, we favour this latter possibility. These three possibilities are represented in Fig. 8.

Further studies are underway to investigate whether the disorder generates macroscopically polar regions of co-parallel alignment, which would give rise to an SHG response, or whether microscopic (random positional) disorder is present.

Summary and conclusion

Three new dithiatetrazocines have been characterized by X-ray crystallography, including the first structural study on a DTTA to possess unsymmetric substituents. Calculations indicate that the solid-state structures of these compounds are dictated by a combination of electrostatic and van der Waals interactions. In the structures of **1**–**3**, both electrostatic $S^{\delta+}\cdots N^{\delta-}$ and $S^{\delta+}\cdots O^{\delta-}$ contacts are identified as contributing to the packing, whereas van der Waals S···Br contacts compete with $S^{\delta+}\cdots N^{\delta-}$ interactions in **2**. The substantial orientational disorder in **3** may arise from either random disorder in the lattice at a molecular level, or through structural disorder at the macroscopic level. The structural analysis of these derivatives indicates that a model, combining electrostatic and van der Waals forces, may prove useful in predicting the structures of DTTA rings. We are currently pursuing the development of this model in the design of macroscopically polar materials.

Structural interrelationships between the bis(pentamethylcyclopentadienyl)arsenic(III) and antimony(III) cations and their precursor chlorides

Robert J. Wiacek, Jamie N. Jones, Charles L.B. Macdonald, and Alan H. Cowley

Abstract: The chloropnictines $(\eta\text{-}C_5Me_5)_2AsCl$ (**1**), $(\eta\text{-}C_5Me_5)_2SbCl$ (**2**), and $(\eta\text{-}C_5Me_5)_2BiCl$ (**3**) have been prepared by treatment of the appropriate element trichloride with LiC_5Me_5. X-ray crystallographic assays establish that in the case of **1**, both C_5Me_5 rings are attached to As in an $\eta^1(\sigma)$ fashion. In **2** and **3**, the C_5Me_5 rings are π delocalized and feature tri- and pentahapto ring binding, respectively, to the group 15 element. Conversion of **1** and **2** to the salts $[As(\eta\text{-}C_5Me_5)_2][AlCl_4]$ (**4**) and $[Sb(\eta\text{-}C_5Me_5)_2][AlCl_4]$ (**5**) was effected by reaction with the stoichiometric quantity of Al_2Cl_6. The X-ray crystal structure of **4** is surprisingly complex and features four independent ion pairs in the asymmetric unit with a variety of hapticities for the π-bonded C_5Me_5 rings. The structure of the stibocenium cation of **5** involves bis(η^4) attachment of the π-bonded C_5Me_5 rings.

Key words: main group metallocenes, arsocenium cations, stibocenium cations, group 15 pentamethylcyclopentadienyl chlorides.

Résumé : On a préparé les chloropnictines $(\eta\text{-}C_5Me_5)_2AsCl$ (**1**), $(\eta\text{-}C_5Me_5)_2SbCl$ (**2**) et $(\eta\text{-}C_5Me_5)_2BiCl$ (**3**) par traitement d'un trichlorure de l'élément approprié avec du LiC_5Me_5. Des essais à l'aide de la diffraction des rayons X ont permis d'établir que, dans le cas du composé **1**, les deux noyaux C_5Me_5 sont attachés au As d'une façon $\eta^1(\sigma)$. Dans les composés **2** et **3**, les noyaux C_5Me_5 comportent une délocalisation π et des liaisons de cycles tri- et pentahapto respectivement à l'élément du groupe 15. La conversion des composés **1** et **2** en sels $[As(\eta\text{-}C_5Me_5)_2][AlCl_4]$ (**4**) et $[Sb(\eta\text{-}C_5Me_5)_2][AlCl_4]$ (**5**) a été réalisée par réaction avec une quantité stoechiométrique de Al_2Cl_6. De façon surprenant, la structure obtenue par diffraction des rayons X par le composé **4** est complexe et implique quatre paires d'ions indépendantes dans une maille asymétrique d'hapticités variables pour les noyaux C_5Me_5 à liaisons π. La structure du cation stibocénium du composé **5** comporte une fixation bis(η^4) des noyaux C_5Me_5 à liaisons π.

Mots clés : métallocènes du groupe principal; cations arsocénium; cations stibocénium; chlorures de pentaméthylcyclopentadiényles du groupe 15.

[Traduit par la Rédaction]

Introduction

Our interest in group 15 metallocenium cations was prompted originally by collaborative structural work on the isoelectronic neutral metallocenes $Sn(\eta^5\text{-}C_5H_5)_2$ and $Pb(\eta^5\text{-}C_5Me_5)_2$ (1). In 1981, we presented spectroscopic evidence (2) for the formation of $[As(\eta^5\text{-}C_5H_5)(\eta^5\text{-}C_5Me_5)][AlCl_4]$, and the bis-pentahapto nature of this arsocenium cation was supported by semiempirical MO calculations (2, 3) on the prototypical phosphocenium cation $[P(C_5H_5)_2]^+$. Two years later, Jutzi et al. (4) isolated and structurally characterized the $[BF_4]^-$ salt of $[As(C_5Me_5)_2]^+$ and showed that the C_5Me_5 ligands are attached in an η^2 and η^3 fashion. Interestingly, nonempirical MO calculations on $[P(C_5H_5)_2]^+$ revealed that of four relatively stable structures, the one of lowest energy features η^1 and η^2 attachment of the two C_5H_5 rings (5). Thus far, no example of a structurally characterized phosphocenium ion has been reported. However, X-ray crystal structures have become available for the heavier congeneric stibocenium and bismocenium salts $[Sb(C_5Me_5)_2][AlI_4]$ (6), $[Sb(C_5H_2(t\text{-}Bu)_3)_2][AlCl_4]$ (6), and $[Bi(C_5H_2(t\text{-}Bu)_3)_2][AlCl_4]$ (7).

In view of the closeness in energy of several structures for the model phosphocenium cation noted above, it was anticipated that the geometries and ring hapticities of pnictocenium cations could be sensitive to the nature of the counteranion. Accordingly, we decided to attempt the synthesis and X-ray crystallographic characterization of the series $[M(\eta\text{-}C_5Me_5)_2][AlCl_4]$ (M = As, Sb, Bi). A further objective of the study was to assess the structural changes that take place as each metallocenium cation is generated by

chloride anion abstraction from the respective chloropnictine.

Experimental

General procedures

All solvents (diethyl ether, THF, pentane) were distilled over sodium benzophenone ketyl or CaH_2 (dichloromethane) and degassed prior to usage. Solid reactants were handled in a VAC Vacuum Atmospheres or M-Braun argon-filled drybox. All reactions were performed under a dry, oxygen-free argon atmosphere or under vacuum using standard Schlenk or drybox techniques. All glassware was oven-dried before usage.

The group 15 trichlorides and pentamethylcyclopentadiene were purchased from a commercial source and used without further purification. CD_2Cl_2 was obtained in sealed vials from a commercial source and used without further purification and $Li(C_5Me_5)$ was prepared via the reaction of C_5Me_5H with *n*-BuLi in THF solution.

Physical measurements

High-resolution mass spectra were measured on a VG Analytical ZAB-VE sector instrument. Solution-phase NMR spectra were recorded at 295 K on a GE QE-300 instrument (^{1}H, 300 MHz; ^{13}C, 75 MHz; ^{27}Al, 78.21 MHz) or a Varian Inovo-500 spectrometer (^{1}H, 500 MHz; ^{13}C, 125 MHz; ^{27}Al, 130 MHz). All NMR samples were flame-sealed or run immediately following removal from the drybox. ^{1}H and ^{13}C NMR spectra are reported relative to tetramethylsilane (0.00 ppm) and are referenced to solvent. ^{27}Al chemical shifts are reported relative to $[Al(D_2O)_6]^{3+}$ (0.00 ppm). All ^{13}C spectra were obtained under conditions of broadband proton decoupling. Melting points were obtained in sealed capillaries under argon (1 atm (101.325 kPa)) on a Fisher-Johns apparatus and are uncorrected.

X-ray crystallography

Suitable single crystals were covered with a perfluorinated polyether oil and the X-ray data were collected on a Nonius Kappa CCD diffractometer at 153 K. All structures were solved by direct methods and refined by full-matrix least squares on F^2 using the Siemens SHELX PLUS 5.0 (PC) software package (8). All nonhydrogen atoms were corrected for anisotropic thermal motion, and hydrogen atoms, which were included at calculated positions (C—H 0.96 Å), were refined using a riding model and a general isotropic thermal parameter. A correction was applied for Lorentz polarization for each structure. The total number of reflections, collection ranges, and final *R* values are listed in Table 1.[3]

Preparation of $(\eta\text{-}C_5Me_5)_2AsCl$ (1)

$Li(C_5Me_5)$ (0.814 g, 5.726 mmol) was added neat to a solution of $AsCl_3$ (0.532 g, 2.935 mmol) in THF (50 mL) at 0°C. The reaction mixture, which became yellow–orange immediately, was stirred overnight with gradual warming to

room temperature. After removing the solvent in vacuo, the product was extracted with pentane (100 mL), filtered through Celite®, and the filtrate concentrated to a volume of 20 mL. The resulting yellow solution was cooled to –20°C to afford a crop of yellow crystals, 0.913 g, 83.3% yield; mp 62–65°C. HR-MS (Cl^+, CH_4): calcd. for $C_{20}H_{29}AsCl$ $(M\text{-}H)^+$, 379.1173; found, 379.1167. ^1H NMR (CD_2Cl_2) δ: 1.69 (s, 30 H, C_5Me_5). ^{13}C NMR (CD_2Cl_2) δ: 124.48 (s, C_5Me_5), 13.02 (s, $C_5\mathit{Me}_5$).

Preparation of $(\eta\text{-}C_5Me_5)_2SbCl$ (2)

$Li(C_5Me_5)$ (1.071 g, 7.533 mmol) was added neat to a solution of $SbCl_3$ (0.862 g, 3.779 mmol) in THF (50 mL) at 0°C. The reaction mixture, which became red–orange immediately, was stirred overnight, with gradual warming to room temperature. After removing the solvent in vacuo, the product was extracted with pentane (100 mL), filtered through Celite®, and the filtrate concentrated to a volume of 20 mL. The resulting dark red solution was cooled to –20°C to afford a crop of purple crystals, 1.413 g, 87.4% yield; mp 100–103°C. HR-MS (Cl^+, CH_4): calcd. for $C_{20}H_{29}SbCl$ $(M\text{-}H)^+$, 425.0996; found, 425.1030. ^1H NMR (CD_2Cl_2) δ: 2.04 (s, 30 H, C_5Me_5). ^{13}C NMR (CD_2Cl_2) δ: 124.04 (s, C_5Me_5), 11.15 (s, $C_5\mathit{Me}_5$).

Preparation of $(\eta\text{-}C_5Me_5)_2BiCl$ (3)

$Li(C_5Me_5)$ (0.570 g, 4.009 mmol) was added neat to a solution of $BiCl_3$ (0.6430 g, 2.039 mmol) in Et_2O (50 mL) at –76°C. The reaction mixture, which became purple immediately, was stirred for 4 h. After the addition of pentane (50 mL), the mixture was filtered through Celite® and the filtrate concentrated to a volume of 20 mL. The resulting purple solution was cooled to –20°C to afford a crop of purple crystals, 0.205 g, 19.5% yield; mp 55–60°C. HR-MS (Cl^+, CH_4): calcd. for $C_{20}H_{29}BiCl$ $(M\text{-}H)^+$, 514.1840; found, 514.1819. ^1H NMR (CD_2Cl_2) δ: 2.58 (s, 30 H, C_5Me_5). ^{13}C NMR (CD_2Cl_2) δ: 123.35 (s, C_5Me_5), 10.03 (s, $C_5\mathit{Me}_5$).

Table 2. Selected bond distances and angles for $(\eta\text{-}C_5Me_5)_2AsCl$ (**1**).

Bond distance (Å)			
As(1)—Cl(1)	2.2395(13)	C(13)—C(14)	1.354(4)
As(1)—C(10)	2.038(3)	C(14)—C(10)	1.508(4)

C(10)-As(1)-C(20)	112.16(12)		

Preparation of $[As(\eta\text{-}C_5Me_5)_2][AlCl_4]$ (4)

A suspension of Al_2Cl_6 (0.104 g, 0.390 mmol) in CH_2Cl_2 (20 mL) was added to a stirred solution of $(\eta\text{-}C_5Me_5)_2AsCl$ (0.257 g, 0.675 mmol) in CH_2Cl_2 (20 mL) at room temperature. After stirring overnight, the resulting brown solution was filtered through Celite® and layered with an equal volume of pentane to afford red–brown crystals, 0.207 g, 51.7% yield; 156–160°C. HR-MS (Cl^+, CH_4): calcd. for $C_{20}H_{30}As$, 345.1563; found, 345.1565. ^1H NMR (CD_2Cl_2) δ: 2.13 (s, 30 H, C_5Me_5). ^{13}C NMR (CD_2Cl_2) δ: 130.80 (s, C_5Me_5), 10.62 (s, $C_5\mathit{Me}_5$). ^{27}Al NMR (CD_2Cl_2) δ: 116.3 (s, $[AlCl_4]^-$).

Preparation of $[Sb(\eta\text{-}C_5Me_5)_2][AlCl_4]$ (5)

A suspension of Al_2Cl_6 (0.264 g, 0.990 mmol) in CH_2Cl_2 (20 mL) was added to a stirred solution of $(\eta\text{-}C_5Me_5)_2SbCl$ (0.812 g, 2.777 mmol) in CH_2Cl_2 (20 mL) at room temperature. After stirring overnight, the resulting red solution was filtered through Celite® and layered with an equal volume of pentane to afford orange–red crystals, 0.704 g, 45.2% yield; 182–184°C. HR-MS (Cl^+, CH_4): calcd. for $C_{20}H_{30}Sb$, 391.1386; found, 391.1402. ^1H NMR (CD_2Cl_2) δ: 2.20 (s, 30 H, C_5Me_5). ^{13}C NMR (CD_2Cl_2) δ: 127.86 (s, C_5Me_5), 10.53 (s, $C_5\mathit{Me}_5$). ^{27}Al NMR (CD_2Cl_2) δ: 99.7 (s, $[AlCl_4]^-$).

Results and discussion

Of the chloropnictines $(\eta\text{-}C_5Me_5)_2ECl$ (E = P, As, Sb, Bi), only the phosphorus compound has been reported previously (9). We have prepared the heavier analogues by the salt elimination reactions of the element trichlorides with two equivalents of LiC_5Me_5:

$$[1] \qquad ECl_3 + 2LiC_5Me_5 \xrightarrow[-2LiCl]{} (\eta\text{-}C_5Me_5)_2ECl$$

(E = As (**1**), Sb (**2**), Bi (**3**))

The yields of **1** and **2** were excellent (~85%); however, that of **3** was considerably less (~20%) due to light sensitivity and facile thermal decomposition at ambient temperature. Satisfactory HRMS data were obtained for **1**–**3**; however, the ^1H and $^{13}C\{^1H\}$ NMR data were not particularly informative, showing complete equivalence of the methyl groups and ring carbon atoms. Given the strong probability of fluxional C_5Me_5 behavior in solution (10), X-ray crystal structure determinations for **1**–**3** became desirable. Each compound crystallizes in the triclinic space group *P*-1, and there are no unusually short intermolecular contacts.

Molecules of chloroarsine **1** possess a ring-canted structure of C_1 symmetry (Fig. 1). Moreover, the noneclipsed arrangement of the C_5Me_5 rings is strikingly different from the essentially eclipsed ring-parallel conformation of the analogous chlorophosphine $(\eta\text{-}C_5Me_5)_2PCl$ (**9**). However, like the latter compound, the C_5Me_5 rings of **1** are attached to the pyramidal group 15 center in an η^1 fashion and the double bonding within these rings is localized (Table 2). The fact that the sum of bond angles at arsenic for **1** (306.3(1)°) is less than that for the phosphorus analogue (314.8(1)°) (**9**) is consistent with periodic trends.

The chlorostibine **2** adopts a "bent-sandwich" structure (Fig. 2) and the C—C bond distances within the essentially planar rings, which range from 1.394(7) to 1.429(7) Å, are indicative of delocalized bonding (Table 3). The fact that for each ring, three Sb—C distances are ~0.2 Å longer (average 2.599(5) Å) than the other two (average 2.814(5) Å) implies that both of the C_5Me_5 rings are attached to antimony in an η^3 fashion. The ring centroid – Sb – ring centroid angle is 140.7(9)° and the interring angle is 28.5°.

Akin to **2**, chlorobismuthine **3** adopts a bent-sandwich arrangement of virtually planar, π-delocalized C_5Me_5 groups with an average intraring C—C bond distance of 1.43(2) Å (Fig. 3). The trend toward multihapto bonding is even more marked in the case of **3**, presumably due to the increased metallic character and more spatially extensive valence orbitals of this heavy group 15 element. Although the Bi—C distances range from 2.625(12) to 2.880(13) Å in both rings (Table 4), the C_5Me_5 rings are best regarded as η^5 bonded. The interring and ring centroid – Bi – ring centroid angles are 29.2 and 141.9(2)°, respectively.

The arsenocenium (**4**) and stibocenium (**5**) tetrachloroaluminates were prepared in moderate yields (~50%) by chloride anion abstraction from the precursor chlorides **1** and **2**, respectively:

[2] $(\eta\text{-}C_5Me_5)_2ECl + 1/2Al_2Cl_6 \rightarrow [E(\eta\text{-}C_5Me_5)_2][AlCl_4]$ (E = As (**4**), Sb (**5**))

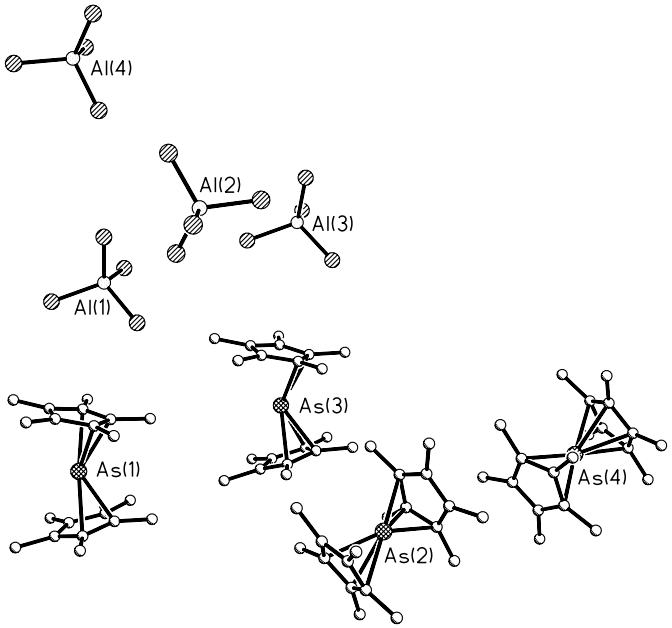
Fig. 4. Molecular structure of $[As(\eta\text{-}C_5Me_5)_2][AlCl_4]$ (**4**) showing the four independent cations and anions.



In the case of the corresponding reaction of $(\eta\text{-}C_5Me_5)_2BiCl$ (**3**) with Al_2Cl_6, the resulting bismuthocenium tetrachloraluminate was too unstable to isolate. The fact that a hexakis (*tert*-butyl)bismocenium tetrachloroaluminate salt has been isolated (7) (and structurally authenticated) is consistent with the relative sizes and kinetic stabilization capabilities of the C_5Me_5 and 1,2,4-*t*-$Bu_3C_6H_2$ ligands. For both **4** and **5**, the presence of the tetrachloroaluminate anion in solution was evidenced by a characteristically sharp ^{27}Al resonance in the approximate range δ: 100–120 (11). However, as with the precursor chlorides, ^1H and $^{13}C\{^1H\}$ NMR data were not particularly informative because of the possibility of rapid structural interconversions. More definitive information regarding the solid-state structures of **4** and **5** was forthcoming from X-ray crystallography. The solid state of **4** is unexpectedly complex in that the asymmetric unit contains four different cations that are distinguished primarily on the basis of ring hapticity. As shown in Fig. 4, cations 1

Table 6. Selected bond distances and angles for [Sb(η-$C_5Me_5)_2$][$AlCl_4$] (**5**).

Bond distance (Å)			
Sb—C(2)	2.613(2)	C(4)—C(5)	1.428(4)
Sb—C(3)	2.484(2)	C(5)—C(1)	1.416(4)
Sb—C(4)	2.510(3)	Al—Cl(1)	2.1265(11)
Sb—C(5)	2.653(2)	Al—Cl(2)	2.1430(18)
C(1)—C(2)	1.421(4)	Al—Cl(3)	2.1405(17)
C(2)—C(3)	1.436(4)		
C(3)—C(4)	1.431(4)		
Bond angle (°)			
C(3)-Sb-C(3′)	1.506(12)	Cl-Al-Cl(2)	1.944(2)
C(4)-Sb-C(4′)	106.95(13)	Cl(1)-Al-Cl(3)	109.49(5)
C(5)-Sb-C(5′)	129.96(11)	Cl(2)-Al-Cl(3)	107.73(6)

and 2 both feature η^3/η^3 attachment of the C_5Me_5 rings, while for cations 3 and 4, the hapticities are η^2/η^3 and η^3/η^4, respectively. For each molecule, the C_5Me_5 ligands are planar within experimental error and arranged in a staggered fashion (Fig. 5). A summary of pertinent metrical parameters for the four cations appears in Table 5. These results contrast interestingly with those reported for [As(η-$C_5Me_5)_2$][BF_4], the cation of which exhibits η^2 and η^3 binding of the C_5Me_5 moieties to arsenic (4). Clearly, the change of counteranion has a marked influence on the crystal structure of the resulting salt. Moreover, the present findings are consistent with MO calculations (5) on the model cation $[P(C_5H_5)_2]^+$, which revealed that four selected structures with different phosphorus-ring bonding modes lie within an energy range (25 kcal·mol^{-1}) that is commensurate with the sensitivity of such systems to crystal packing forces.

The stibocenium cation of **5** adopts a bent-sandwich structure of C_{2v} symmetry (Fig. 6). The eclipsed C_5Me_5 rings are planar within experimental error and the interring angle is 32.8° (Table 6). Since the Sb···C(1) distance (2.728(3) Å) is larger than the other four, which range from 2.484(2) to 2.653(2) Å and average 2.565(3) Å, the hapticity is considered to be bis-η^4 and the ring centroid – Sb – ring centroid angle is 161.1(2)°. Not unexpectedly, the structure of **5** is similar to that of [Sb(η-$C_5Me_5)_2$][AlI_4] (6). Here, however, the hapticity appears to be bis-η^3 and there is an interaction between antimony and one of the iodide ligands of the counteranion. Finally, the bulky nature of the 1,2,4-*t*-$Bu_3C_5H_2$ substituent is evidenced by the fact that these rings are essentially parallel in [Sb(1,2,4-*t*-$Bu_3C_5H_2)_2$][$AlCl_4$] (6).

Synthesis and characterization of the binuclear diamido titanium chalcogenides $[(Ar)NCH_2CH_2CH_2N(Ar)]_2Ti(\mu\text{-}E)_2$ (E = Se, Te)

Tianle Zhang, Warren E. Piers, and Masood Parvez

Abstract: Reaction of McConville's chelating amido titanium complex $[(Ar)NCH_2CH_2CH_2N(Ar)]Ti(CH_3)_2$ (Ar = 2,6-*i*-$Pr_2C_6H_3$) with either elemental Se or the tellurium atom source Te=PBu_3 resulted in the formation of *bis*-μ-chalcogenido dimers $[(Ar)NCH_2CH_2CH_2N(Ar)]_2Ti(\mu\text{-}E)_2$ (E = Se, **2**; Te, **3**) with concommitant loss of EMe_2. The dimers **2** and **3** were characterized spectroscopically and via X-ray crystallography. The two compounds are isostructural in the solid state. The tellurido dimer **3** may also be synthesized by reduction of the diamido dichloride $[(Ar)NCH_2CH_2CH_2N(Ar)]_2TiCl_2$ with Na–Hg amalgam followed by treatment with Te=PBu_3. This dimer is unreactive toward further Te=PBu_3 or stannanes such as $HSnBu_3$. Unlike decamethyltitanocene derivatives, the diamido complex is not an effective catalyst precursor for the heterohydrodecoupling of Te=PBu_3 and $HSnBu_3$.

Key words: diamido titanium complexes, selenides, tellurides.

Résumé : La réaction de McConville qui permet de chélater le complexe amido titane $[(Ar)NCH_2CH_2CH_2N(Ar)]Ti(CH_3)_2$ (Ar = 2,6-*i*-$Pr_2C_6H_3$) avec du sélénium élémentaire ou avec la source de tellure Te=PBu_3 conduit à la formation de dimères *bis*-μ-chalcogénido $[(Ar)NCH_2CH_2CH_2N(Ar)]Ti(\mu\text{-}E)_2$ (E = Se, **2**; Te, **3**), avec la perte concomitante de EMe_2. Les dimères **2** et **3** ont été caractérisés par spectroscopie et par diffraction des rayons X. À l'état solide, les deux composés sont isostructuraux. Le dimère tellurido (**3**) peut aussi être synthétisé par réduction du dichlorure de diamido, $[(Ar)NCH_2CH_2CH_2N(Ar)]TiCl_2$, avec de l'amalgame de sodium (Na–Hg), suivie par un traitement avec du Te=PBu_3. Ce dimère n'est pas réactif vis-à-vis le Te=PBu_3 ou les stannanes tels que $HSnBu_3$. Contrairement à ce qui est observé avec les dérivés du décaméthyltitanocène, le complexe diamido n'est pas un précurseur efficace du catalyseur pour l'hétérohydrodécouplage de Te=PBu_3 et $HSnBu_3$.

Mots clés : complexes amido titane, séléniures, telluriures.

[Traduit par la Rédaction]

Introduction

Decamethyltitanocene complexes have been found to mediate the heterodehydrocoupling of "Te" and $HSnBu_3$ to yield the distannyl telluride $[Bu_3Sn]_2(\mu\text{-}Te)$ (1). The reaction is highly selective for this product, but turnover numbers are relatively low. Mechanistic studies have shown that catalyst precursors in various oxidation states can provide entry into the catalytic cycle. Furthermore, these studies suggest that σ-bond metathesis reactions between Ti-X (X = alkyl or tellurium) and Sn-H moieties, insertion of "Te" into Ti—X bonds, and loss of $Te(SnR_3)_2$ from stannyltellurolates $Ti(TeSnR_3)_n$ are all potential primary reactions in the overall catalytic reaction.

The initial studies were carried out using titanocene(III) derivatives incorporating the bulky and electron donating C_5Me_5 (Cp*) ligand (2). In terms of catalyst modification, only a small range of changes in the nature of the Cp donor were possible, since a significant amount of steric bulk had to be maintained in order for the reaction to turnover (3). Thus, to find a catalyst that would offer improved performance for this reaction, we turned to non-Cp organotitanium complexes as potential catalyst candidates. One such family are the chelating diamido Ti(IV) complexes introduced by McConville and Scollard as living olefin polymerization catalysts (4), whose chemistry in other arenas has been explored only to a limited extent. While catalyst precursors incorporating this ligand do not catalyze the heterodehydrocoupling reaction, new Ti(IV) selenido and tellurido complexes are observed.

Results and discussion

McConville's dichloride complex $[(Ar)NCH_2CH_2CH_2N(Ar)]TiCl_2$ (Ar = 2,6-*i*-$Pr_2C_6H_3$) was prepared and converted to the corresponding dimethyl derivative **1** according to the literature procedure (4). Reaction of an excess of elemental selenium led to the slow uptake of the selenium while the reaction mixture changed in colour from yellow to red. On the other hand, reaction with 2 equiv of Te=PBu_3 (which serves as a soluble source of Te atoms (5)) gave a similar colour change

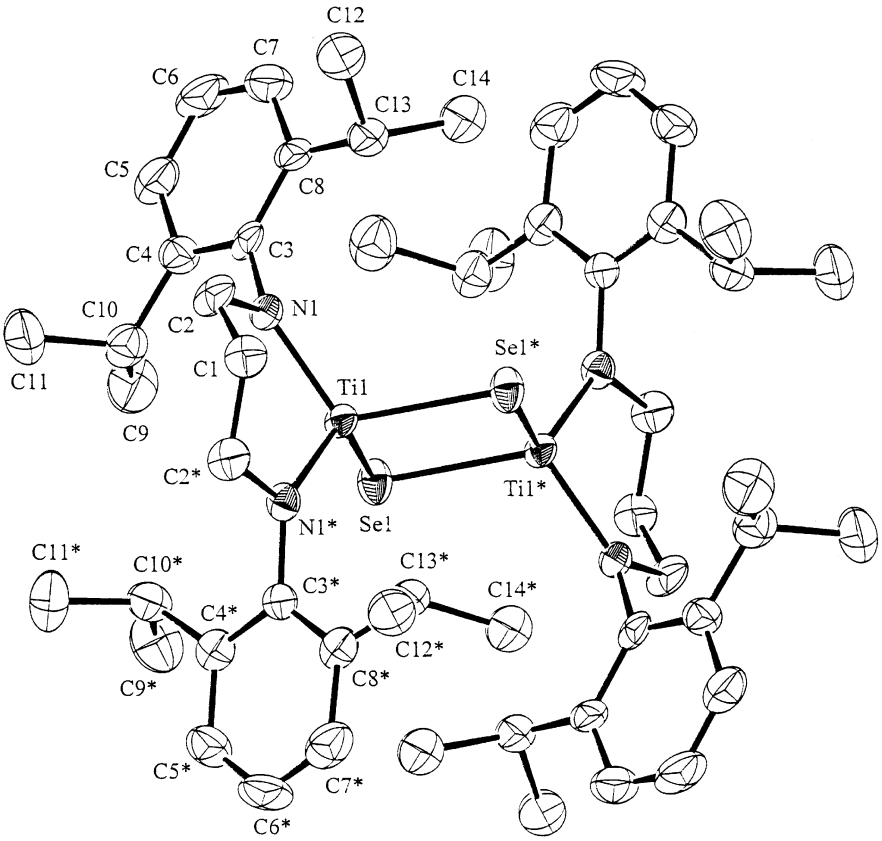
Selected bond angles (°): Ti(1)-Se(1)-Ti(1*) 84.45(7), Se(1)-Ti(1)-Se(1*) 95.55(7), N(1)-Ti(1)-N(1*) 103.0(3), N(1)-Ti(1)-Se(1) 117.25(17), N(1)-Ti(1)-Se(1*) 112.05(17), Ti(1)-N(1)-C(2) 117.8(4), Ti(1)-N(1)-C(3) 131.4(4), C(2)-N(1)-C(3) 110.7(5).



instantaneously (Scheme 1). From these dark red solutions, red precipitates were observed to form over time. Analysis of these solids revealed them to be the dimeric μ-chalcogenides $[(Ar)NCH_2CH_2CH_2N(Ar)]_2Ti(\mu\text{-}E)_2$ (E = Se, **2**; Te, **3**).

Proton NMR spectroscopy showed only amide ligand resonances, and resonances for the bridging chalcogenides could not be found in the ^{77}Se or ^{125}Te NMR spectra. Elemental analysis, however, supported the assignment, as did the results of X-ray diffaction analysis of single crystals of **2** and **3**. Figures 1 and 2 show the molecular structure of selenide **2** and telluride **3**, respectively, along with selected metrical parameters; further details on these structures can be found in the Supplementary Information.[2] The dimers are isostructural, containing two tetrahedral titanium centers edge-joined by the chalcogen atoms. The chelating amido ligands adopt a boat-like conformation, and although the dimers possess an inversion center, the two Ti—E bonds are as a result slightly different in length, making the Ti_2E_2 core slightly distorted from regularity. The equatorial Ti—E bonds (Ti—E(1)) are both shorter than the axial bonds

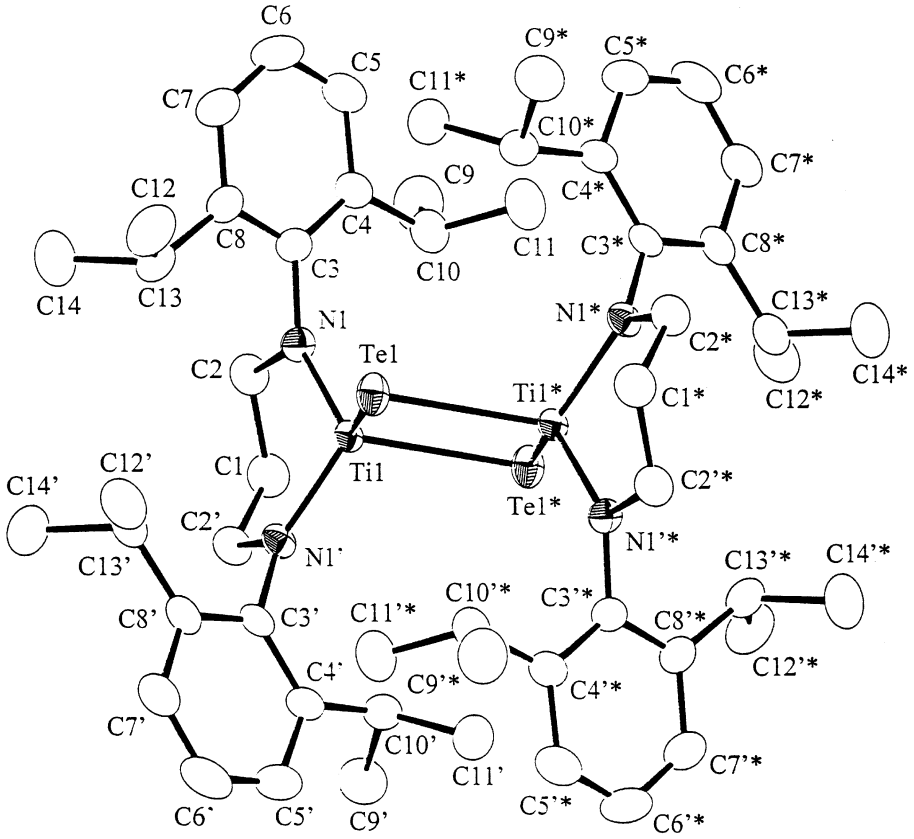
Fig. 2. ORTEP diagram of **3**. Selected bond distances (Å): Te(1)—Ti(1) 2.6169(14), Te(1)—Ti(1*) 2.6892(12), Ti(1)—N(1) 1.880(3), N(1)-C(2) 1.480(4), N(1)—C(3) 1.441(5), C(2)—C(1) 1.511(5). Selected bond angles (°): Ti(1)-Te(1)-Ti(1*) 81.82(3), Te(1)-Ti(1)-Te(1*) 98.18(3), N(1)-Ti(1)-N(1*) 102.84(19), N(1)-Ti(1)-Te(1) 117.55(10), N(1)-Ti(1)-Te(1*) 110.37(10), Ti(1)-N(1)-C(2) 118.0(3), Ti(1)-N(1)-C(3) 130.5(2), C(2)-N(1)-C(3) 111.5(3).



(Ti—E(1*)). The Ti—Se bonds of **2** are about 0.210 Å shorter than the Ti—Te bonds of **3** as expected on the basis of the differing atomic radii of the two chalcogens (6). Aside from other slight differences in the bond angles associated with the Ti_2E_2 cores, the molecules are very similar in structure.[2]

Insertion of chalcogen atoms into the M—C bonds of d° alkyl derivatives is facile (7) and thus a plausible route to these dimers likely begins with insertion of chalcogen into the Ti—C bonds to form methyl chalcogenolates. Previous work from our laboratories (7*a*, 7*b*, 8) and others (9) show that such derivatives are prone to loss of ER_2 to form chalcogenides; in this instance, loss of EMe_2 occurs. Both $SeMe_2$ and $TeMe_2$ were detected by ^1H and ^{77}Se or ^{125}Te NMR spectroscopy by comparison with authentic samples. We have also shown previously that loss of TeR_2 from some scandium *bis*-tellurolates is a bimolecular process (7*a*, *b*), so two distinct pathways to dimers **2** and **3** may be envisioned (Scheme 2). For E = Se, where the insertion reactions are much slower owing to the heterogeneity of the reaction, path "a" may be operative, while for E = Te, insertion is rapid and likely path "b" dominates. However, in situ NMR experiments have not been performed to pursue these issues. In any event, unimolecular loss of EMe_2 from putative *bis*-chalcogenolates $[(Ar)NCH_2CH_2CH_2N(Ar)]Ti(EMe)_2$ to form a terminal chalcogenide that dimerizes is unlikely, given our previous studies and the inherent instability of the Ti=E bonds of the heavier chalcogens (8).

Compound **3** was tested for activity as a catalyst precursor for the heterodehydrocoupling reaction between "Te" and $HSnBu_3$ and was found to be completely inactive. The production of $[Bu_3Sn]_2(\mu\text{-Te})$ occurs slowly in the absence of catalyst; addition of 10% of **3** did not result in noticeable rate acceleration, nor were any spectral changes in **3** observed. Indeed, separate experiments showed that **3** was unreactive toward both $HSnBu_3$ and $Te{=}PBu_3$ at room temperature. This contrasts sharply with the chemistry observed for the decamethyltitanocenes and suggests that the doubly telluride bridged **3** is not susceptable to dissociation and is also kinetically quite stable. A similar lack of reactivity toward further $Te{=}PBu_3$ and other small molecules was observed for the related β-diketiminato supported ditelluride dimer of scandium, $[(Ar)NC(Me)CHC(Me)N(Ar)]_2Sc(\mu\text{-Te})_2$ (Ar = 2,6-*i*-$Pr_2C_6H_3$) (7*b*).

In the titanocene chemistry, lower valent derivatives were also found to be catalyst precursors for the heterodehydrocoupling reaction (1). For example, the Ti(III)–Ti(III) dimer $[Cp^*_2Ti]_2(\mu\text{-Te})$ can be prepared from $Cp^*_2Ti(II)$ precursors and 0.5 equiv of $Te{=}PBu_3$ (10) and is catalytically competent. We thus attempted to prepare a similar diamido Ti(III)–Ti(III) dimer by reducing the diamido dichloride complex with Na–Hg amalgam to a suitable

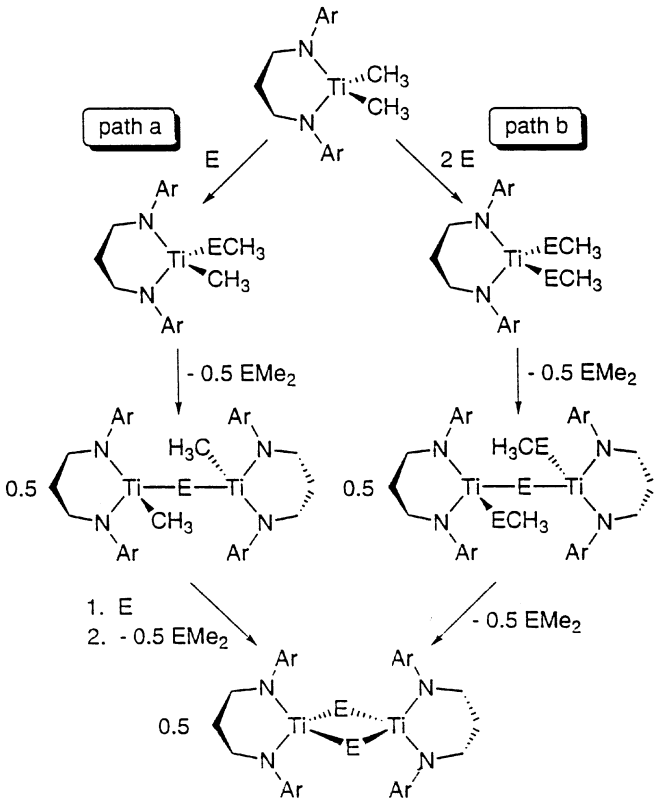
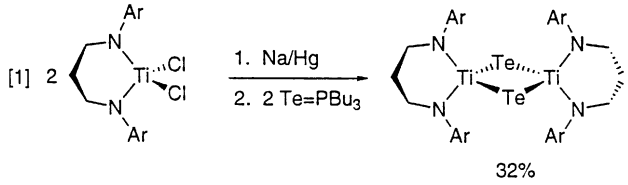
Scheme 2.



[(Ar)$NCH_2CH_2CH_2N$(Ar)]Ti(II) precursor. Although we could not isolate any of these compounds, in situ reduction of [(Ar)$NCH_2CH_2CH_2N$(Ar)]$TiCl_2$ in the presence of excess PMe_3 led to green-brown solutions that exhibited behavior consistent with reduced titanium amido complexes (11). Treatment of these solutions with varying amounts of $Te{=}PBu_3$ gave reaction mixtures from which we could isolate only Ti(IV)–Ti(IV) dimer **3** in as much as 32% yield (eq. [1]).



Experimental section

^1H, ^{77}Se, and ^{125}Te NMR experiments were performed on Bruker AC-200 or WH-400 MHz spectrometers and were recorded in C_6D_6, unless otherwise noted. Data are reported in ppm relative to solvent signals for ^1H spectra; for ^{77}Se and ^{125}Te spectra, the data are referenced relative to external EMe_2 (0.0 ppm). Chemicals were purchased from Aldrich-Sigma and used as received or purified according to standard procedures. Solvents were purified using the Grubbs–Dow purification system (12).

Synthesis of $[(Ar)NCH_2CH_2CH_2N(Ar)]_2Ti(\mu\text{-}Se)_2$, 2

Dimethyl complex **1** (0.100 g, 0.212 mmol) and elemental Se powder (0.040 g, 0.506 mmol) were loaded into a 25 mL round-bottomed flask and toluene (10 mL) was added. The mixture was stirred at room temperature for 2–3 days. The solvent was removed in vacuo and the resulting dark red solid taken up in dichloromethane (6 mL) and filtered to remove the excess selenium. The volume of the filtrate was reduced to ≈1 mL and hexanes were layered onto the solution. The resulting red precipitate was collected by filtration, washed with hexanes, and dried. Yield 0.038 g, 34%. ^{1}H NMR (CD_2Cl_2): 7.20 (m, 6H, Ar*H*), 3.65 (br m, 4H, NCH_2), 3.20 (sp, 4H, $CHMe_2$), 2.10 (m, 2H, NCH_2CH_2), 1.10 (d, 24H, $CHMe_2$). Anal. calcd. for $C_{27}H_{40}N_2SeTi$: C 62.42, H 7.72, N 5.39; found: C 62.25, H 7.88, N 4.89.

Synthesis of $[(Ar)NCH_2CH_2CH_2N(Ar)]_2Ti(\mu\text{-}Te)_2$, 3

Dimethyl complex **1** (0.100 g, 0.212 mmol) was dissolved in benzene (5 mL). A solution of $Te{=}PBu_3$ (0.140 g, 0.430 mmol) in benzene (3 mL) was added dropwise to the solution of **1** with stirring. The resulting solution was stirred for 24 h until a precipitate was observed, and concentrated to about 1–2 mL. Hexanes were added to precipitate the product. The product was collected by filtration and dried in vacuo. Yield: 0.068 g, 57%. ^{1}H NMR (CD_2Cl_2): 7.30 (m, 6H, Ar*H*), 3.61 (br m, 4H, NCH_2), 3.30 (sp, 4H, $CHMe_2$), 1.83 (m, 2H, NCH_2CH_2), 1.10 (d, 24H, $CHMe_2$). Anal. calcd. for $C_{27}H_{40}N_2TeTi$: C 57.06, H 7.10, N 4.93; found: C 57.10, H 7.32, N 4.53.

Alternative method

Dichloride $[(Ar)NCH_2CH_2CH_2N(Ar)]TiCl_2$ (0.800 g, 1.564 mmol) was added to a suspension of Na–Hg (0.430 g, 18.7 mmol Na, 40 g Hg) in benzene (30 mL) in the presence of excess PMe_3 (0.51 mL, 5.368 mmol). This mixture was stirred for 2 days and filtered. The resulting green-brown filtrate was transferred to a flask containing $Te{=}PBu_3$ (0.610 g, 1.85 mmol) and stirred for 4 h at which time a precipitate was observed. The solvent was reduced in volume and hexanes were added and the resulting suspension was filtered. Yield: 0.285 g, 32%.

X-ray crystallography

Suitable crystals were coated with Paratone-8277 oil (Exxon) and mounted on a glass fiber. All measurements were made on a Rigaku AFC6S diffractometer with Mo Kα radiation monochromatized with a Zr-filter. The data were collected at a temperature of 170(2) using the ω–2θ scan technique to a maximum 2θ value of 50.0; crystal data have been provided in Table 1. For **2**, of the 3067 reflections that were collected, 2973 were unique (R_{int} = 0.050), while for **3**, of the 3005 reflections that were collected, 2898 were unique (R_{int} = 0.021). The intensities of three representative reflections were measured after every 200 reflections. Over the course of data collection, the standards did not decrease. An empirical absorption correction (13) based on azimuthal scans of several reflections was applied, which resulted in transmission factors ranging from 0.551 to 0.602 for **2** and 0.559 to 0.659 for **3**. The data were corrected for Lorentz and polarization effects. The structures were solved by direct methods (14) and expanded using Fourier techniques (15). The non-hydrogen atoms of the complex were refined anisotropically. The structures of both **2** and **3** contain two partially occupied molecules of hexane solvates that were disordered. The carbon atoms of the solvates were refined with isotropic displacement parameters. Hydrogen atoms were included at geometrically idealized positions and were not refined; H's of the solvates were ignored. The final cycle of full-matrix least-squares refinement using F^2 was completed with the aid of SHELXL97 (16). The maximum and minimum peaks on the final difference Fourier map were in close proximity of the solvent molecules. All calculations for data reduction were performed using the teXsan (17) crystallographic software package of Molecular Structure Corporation.

Conclusion

In summary, diamido supported titanium complexes are not effective catalysts for the heterodehydrocoupling of Te and $HSnBu_3$, mainly owing to the dominance of the unreactive *bis*-μ-telluride complex **3** and the unavailability of lower valent complexes. The most effective means of preparing chalcogenides **2** and **3** is via the well-known elimination of ER_2 from chalcogenolato derivatives, which again is facile in these diamido titanium species.

Supramolecular self-assembly through tellurium···halogen secondary bonds: A hexagonal grid of Te_2Cl_2 and Te_6Cl_6 rings in the solid state structure of 1,1,3-trichloro-2,4,5,6-tetrahydro-1*H*-1λ^4-benzo[b]tellurophene

Julio Zukerman-Schpector, Ionel Haiduc, Robinson L. Camillo, João V. Comasseto, Rodrigo Luiz Oliveira R. Cunha, and Alvim Jorge

Abstract: 1,1,3-Trichloro-2,4,5,6-tetrahydro-1*H*-1λ^4-benzo[b]tellurophene (a = 8.807(1), b = 14.495(2), c = 9.263(1) Å, β = 110.18(1)°; $P2_1/a$, Z= 4, $R[F^2 > 2\sigma(F^2)]$ = 0.0383), prepared by reacting 1-ethynyl-1-cyclohexanol with tellurium tetrachloride, displays a hexagonal grid structure made of four-membered Te_2Cl_2 and 12-membered Te_6Cl_6 rings formed by self-assembly of Cl-Te-Cl rods through Te···Cl secondary bonds into a supramolecular 2D network. The comparison with structurally related compounds reveals that 2D layers can also be formed by similar self-assembly of eight-membered Te_4I_4 rings alone or in a combination of four-membered Te_2I_2 with eight-membered Te_4I_4 rings.

Key words: diorganotellurium(IV), supramolecular 2D assembly, self-assembly, secondary bonding.

Résumé : Le 1,1,3-trichloro-2,4,5,6-tétrahydro-1*H*-1λ^4-benzo[b]tellurophène (a = 8,807(1), b = 14,495(2) et c = 9,263(1) Å, β = 110,18(1)°; $P2_1/a$; Z = 4; $R[F^2>2\sigma(F^2)]$ = 0,0383), préparé par réaction du 1-éthynylcyclohexan-1-ol avec du tétrachlorure de tellure se présente sous la forme d'une structure en grille hexagonale formée de cycles à quatre chaînons de Te_2Cl_2 et à douze chaînons de Te_6Cl_6 qui résultent d'autoassemblages de tiges Cl-Te-Cl dans des liaisons secondaires Te···Cl formant un réseau supramoléculaire bidimensionnel. Une comparaison de cette structure avec celles de composés apparentés révèle que les couches bidimensionnelles peuvent aussi se former par un autoassemblage semblable de cycles à huit chaînons de Te_4I_4 seuls ou en combinaison de cycles à quatre chaînons de Te_2I_2 avec des cycles à huit chaînons de Te_4I_4.

Mots clés : diorganotellure(IV), assemblage supramoléculaire bidimensionnel, autoassemblage, liaison secondaire.

[Traduit par la Rédaction]

Introduction

The molecules of diorganotellurium(IV) dihalides, R_2TeX_2, display a ψ-trigonal bipyramidal geometry with the halogen atoms in axial positions and equatorial Te—C bonds. It is generally assumed, mainly on the basis of the well-known VSEPR theory (1), that a lone pair occupies a third equatorial site. However, these compounds are seldom monomolecular in the solid state, and they tend to form additional Te···X secondary bonds, leading to supramolecular self-assembly and self-organization (2). The secondary bond concept has been introduced by N.W. Alcock (3) to describe interactions between molecules that result in interatomic distances longer than covalent bonds and shorter than the sum of van der Waals radii. Secondary bonds (sometimes called "soft-soft interactions") (4) are typical for heavier p-block elements and they play an important role as bonding motifs in supramolecular organometallic chemistry (5).

Diorganotellurium(IV) dihalides display a broad variety of supramolecular structures in the solid state. Isolated, non-interconnected molecules are rare and occur only when the organic groups are very bulky (e.g., in $(1\text{-naphthyl})_2TeCl_2$)

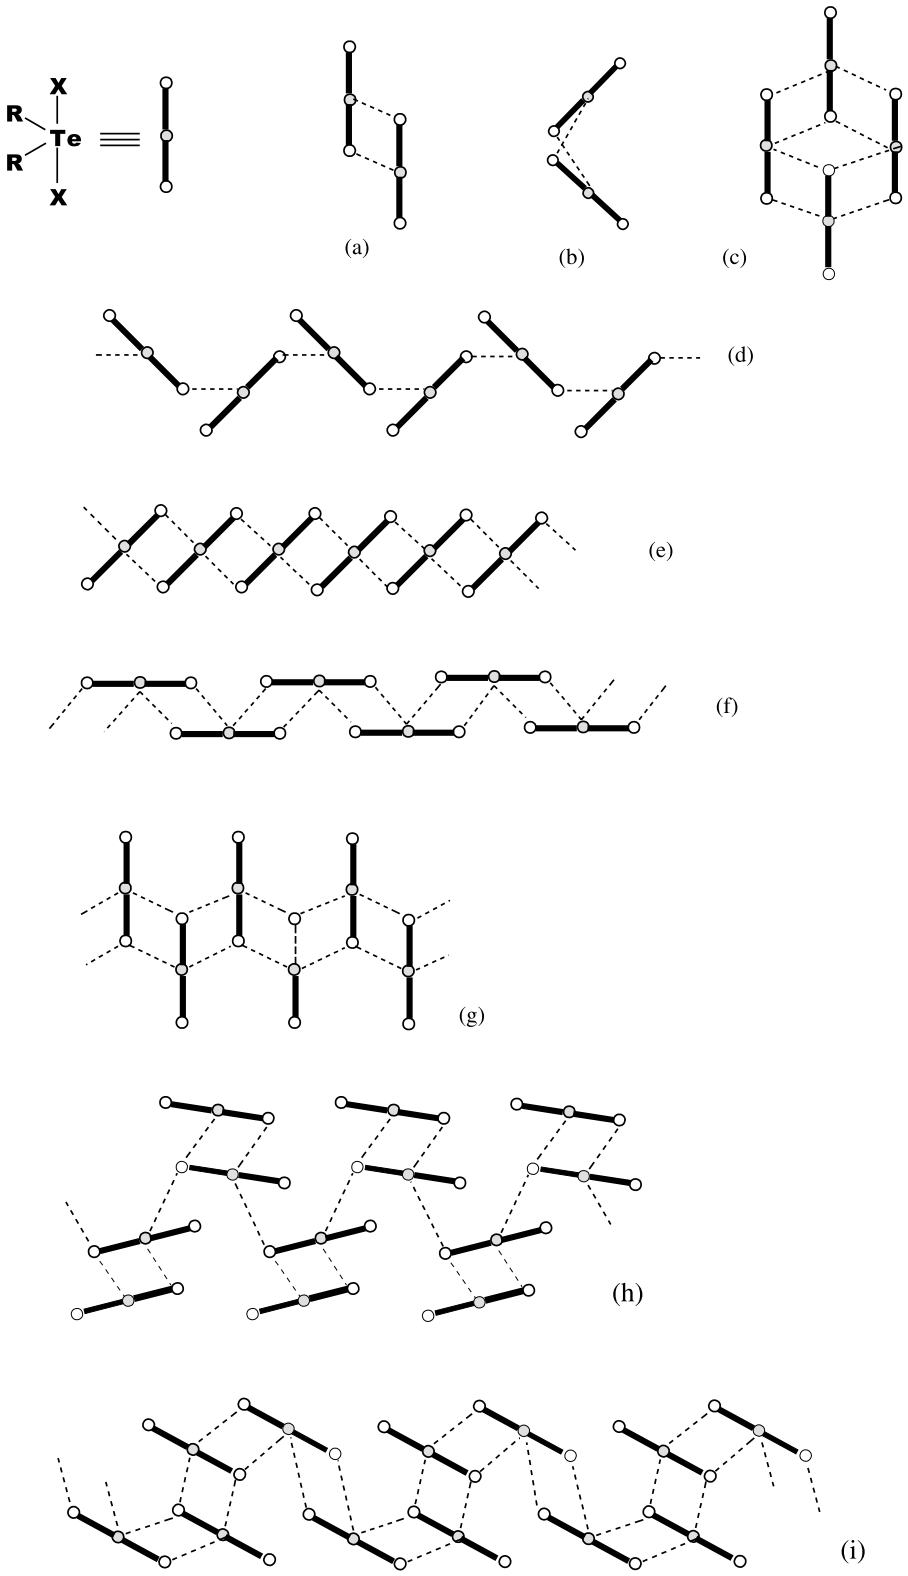
Scheme 1.



(6). The most common are dimeric and tetrameric supermolecules (7) (i.e., well-defined discrete oligomolecular species that result from the intermolecular association of a few components) and monodimensional chain-like arrays (8) (i.e., polymolecular entities that result from the spontaneous association of a large, undefined number of components) (9). These are illustrated in Scheme 1 where only the self-assembly of X-Te-X (X = halogen) rods is shown, with the

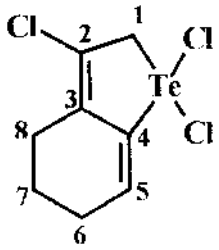
Scheme 3.



organic groups omitted for clarity. A tendency of X-Te-X rods to form dimers, which can further self-organize into various types of chains, is obvious in structures (f)–(i).

The supramolecular self-organization of diorganotellurium dihalides is accompanied by an increase in the coordination number of tellurium and severe alteration of the coordination geometry (10). Thus, the generally assumed ψ-trigonal bipyramidal geometry frequently becomes octahedral and the actual coordination number of tellurium is increased to six, by considering the secondary bonds.

The self-assembly modes shown in Scheme 1 illustrate an amazing structural diversity of diorganotellurium(IV) halides, which are sometimes ignored in crystal structure determinations, and are limited only to the description of the molecular structure. It can be anticipated that the work of the laddering principle (11) may reveal new types of such supramolecular self-organization.

Bidimensional layers and tridimensional networks are rare (vide infra). Intricate 3D networks occur in α-Me_2TeI_2 (12), Ph_2TeBr_2 (13), and Ph_2TeI_2(14).

We report here a novel mode of self-assembly for diorganotellurium(IV) dihalides, namely a 2D layered system based upon Te···Cl secondary interactions in rhomboidal Te_2Cl_2 and hexagonal Te_6Cl_6 cyclic units, which is observed in the crystal structure of 1,1,3-trichloro-2,4,5,6-tetrahydro-1*H*-1λ^4-benzo[b]tellurophene.

Experimental

Preparation of 1,1,3-trichloro-2,4,5,6-tetrahydro-1*H*-1λ^4-benzo[b]tellurophene (1)

The title compound was prepared by a cyclization reaction between 1-ethynyl-1-cyclohexanol and $TeCl_4$, in benzene, at room temperature, in ca. 12% yield (Scheme 2).

To a suspension of tellurium tetrachloride (2.69 g, 10 mmol) in dry and degassed benzene (50 mL) 1-ethynyl-1-cyclohexanol (1.36 g, 11 mmol) was added, and the mixture was stirred at room temperature for 12 h. Then the mixture was concentrated, and the solid residue was recrystallized from dichloromethane. Yield: 1.23 g (12%), yellow crystals, mp 223.6–224.7°C (uncorrected).

^{1}H and ^{13}C NMR spectra were recorded on a Bruker DRX-500 spectrometer and referenced to $(CD_3)_2SO$ (2.5 ppm for hydrogen spectra and 39.52 ppm for carbon-13 spectra). The ^{125}Te NMR spectrum was also recorded on a Bruker DRX-500 spectrometer and referenced to a diphenylditelluride solution (1 M in $CDCl_3$) as an external standard (419.536 ppm). The infrared spectrum was recorded on a PerkinElmer 1600 spectrophotometer. An uncorrected melting point was obtained on a Büchi Melting Point B-545. The elemental analysis was performed at the Microanalytical Laboratory of the Chemistry Institute, University of São Paulo. The solvents used were previously dried and distilled according to the usual methods (15), and they were degassed before use. Tellurium tetrachloride was prepared from elemental tellurium (230 mesh) and chlorine gas (16), and 1-ethynyl-1-cyclohexanol was purchased from Aldrich and used without further purification.

The individual resonances are assigned according to Scheme 3:

IR (KBr pellet) (cm^{-1}) 3040, 2922, 2866, 1615, 1595, 1493, 1423, 1380, 1171, 1085, 915, 837, 815, 662, 552. ^{1}H NMR (500.13 MHz, DMSO) δ: 6.03–6.01 (m, 1H, CH), 3.08 (s, 2H, CH_2TeCl_2), 1.64–1.62 (m, 2H, CH_2), 1.54–1.51 (m, 2H, CH_2), 0.83–0.78 (m, 2H, $CH_2CH_2CH_2$). ^{13}C NMR (125.77 MHz, DMSO) δ: 140.4 ($^1J_{^{13}C\text{-}^{125}Te}$ = 227.3 Hz, C_4), 137.2 ($^2J_{^{13}C\text{-}^{125}Te}$ = 42.9 Hz, C_5), 136.7 (C_2), 128.7 (C_3), 54.1 ($^1J_{^{13}C\text{-}^{125}Te}$ = 184.5 Hz, C_1), 27.2 (C_6), 25.9 (C_8), 19.8 (C_7). ^{125}Te NMR (157.79 MHz, DMSO) δ: 900.22. Anal. calcd. for $C_8H_9Cl_3Te$: C 28.33, H 2.68; found: C 28.24, H 2.66.

The well-resolved signals in the ^{13}C and ^{125}Te spectra shows that the compound is monomeric in solution.

Crystal structure determination

Data were collected on a CAD-4 Mach 3 Enraf Nonius diffractometer, in the $\omega/2\theta$ scan mode with ω scan width = 0.80 + 0.35 tan θ, using graphite monochromated Mo Kα radiation. Data were corrected for Lorentz, polarization, and absorption effects. The structure was solved by the standard heavy-atom Patterson method, followed by normal difference Fourier techniques. H-atoms were located on stereochemical grounds and refined with fixed geometry, each riding on a carrier atom with an isotropic displacement parameter amounting to 1.2 times the value of the equivalent isotropic displacement parameter of the atom to which they were attached. A summary of crystallographic parameters is presented in Table 1 (17).[3]

Results and discussion

X-ray diffraction quality crystals were obtained by recrystallization from hexane–dichloromethane by slow evaporation and were structurally investigated. The crystallographic data are listed in Table 1. The molecular structure of **1** is shown in Fig. 1 with the atom numbering scheme. The molecular parameters (bond lengths and bond angles) are summarized in Table 2. The molecule shows little deviation from planarity, which occurs in the partially unsaturated six-membered ring. The two Te—Cl bonds are basically colinear (Cl(1)-Te-Cl(2) 174.5(8)°) and the Cl-Te-Cl rod is perpendicular to the plane of the heterocycle (Cl(1)-Te-C(1) 87.5(2)°, Cl(1)-Te-C(8) 87.6(3)°, Cl(2)-Te-C(1) 90.0(2)°, and Cl(2)-Te-C(8) 87.2(3)°). The C(1)-Te-C(8) angle in the five-membered ring (83.2(3)°) shows the severe distortion from the regular trigonal bipyramidal geometry imposed by the inclusion of the tellurium atom in a five-membered ring. In fact, with the two additional secondary Te···Cl bonds, and with the bond angles observed, the coordination polyhedron of tellurium is more appropriately described as an octahedron with minor distortions only. The Te—Cl bond lengths (Te—Cl(1) = 2.519(3) and Te—Cl(2) = 2.510(3) Å) are in a range normally found for covalent tellurium—chlorine bonds, and are slightly elongated because of their

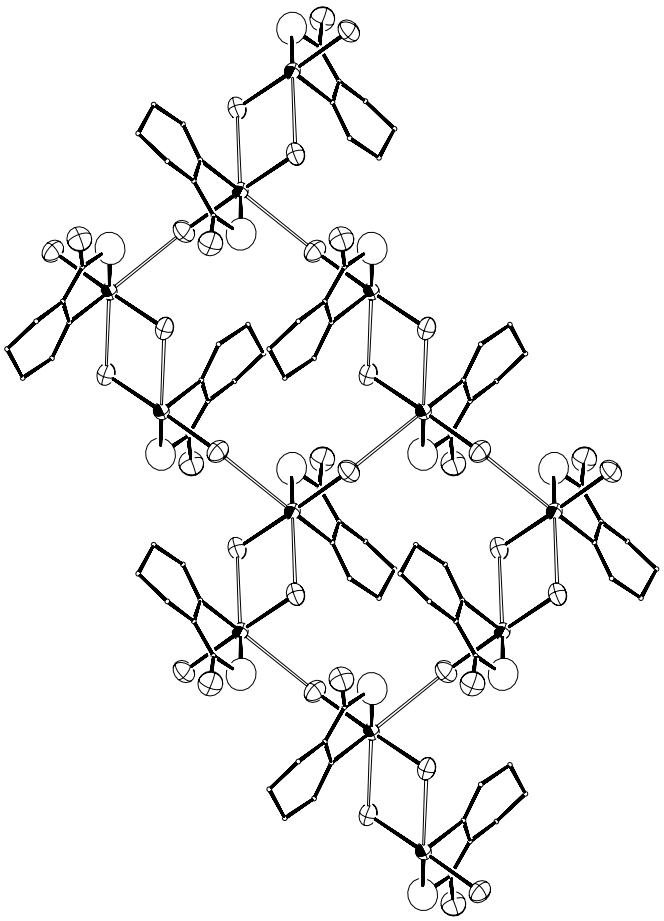
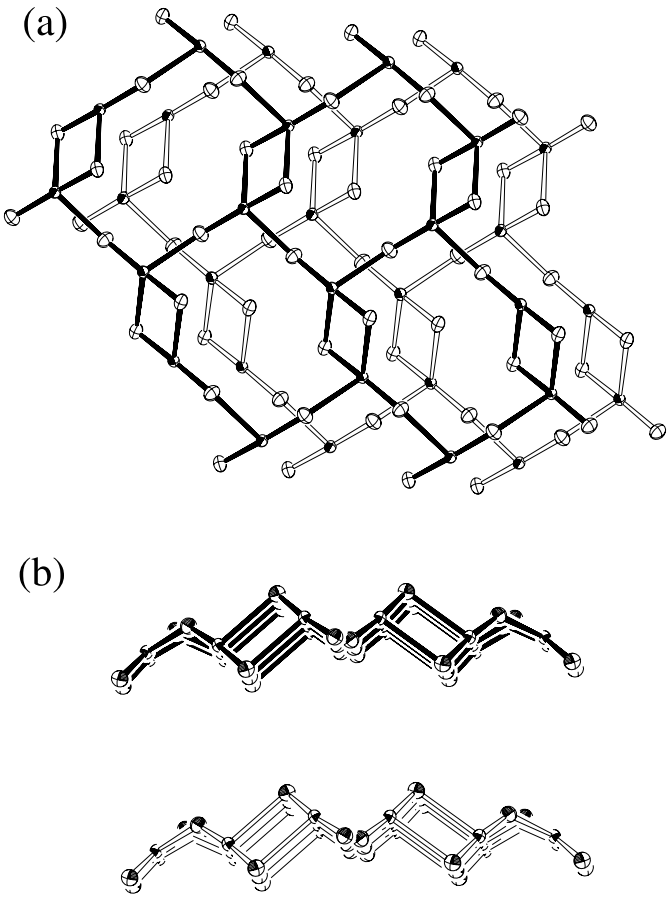
Fig. 2. The structure of the 2D supramolecular layer.



involvement in secondary bonds (see Table 3 (18) for some comparisons).

The molecules of **1** are associated into dimeric units through tellurium—chlorine secondary bonds. The dimeric units are formed with the participation of Cl(1) atoms, and the lengths of the Te···Cl(1a) secondary bonds are both 3.474(3) Å. In this pair, the Te_2Cl_2 rhomboid ring is basically planar and the organic parts of the molecules are located on opposite sides of the Te_2Cl_2 plane (*trans*-configuration). The second chlorine, Cl(2) connects the dimers through Te(1)-Cl(2)···Te(1a) bridges into a 2D corrugated sheet [Te···Cl(2) = 3.340(3) Å] with the organic rings alternating on the two sides of the layers, which are oriented parallel to the xy plane in the crystal. The layers are then stacked on top of each other along the z axis. It will be noted that the inter-dimeric Te···Cl(2) secondary bonds are shorter, and therefore stronger, than the Te···Cl(1) intradimeric bonds.

Fig. 3. The tellurium-chlorine skeleton of the layers. (*a*) View of the two stacked layers illustrating their relative sliding; (*b*) Side view illustrating the corrugated nature of the 2D layer.



A fragment of the 2D layer is shown in Fig. 2. Full lines represent normal covalent bonds and open lines indicate Te···Cl secondary interactions. The Te_2Cl_2 rings are associated with 12-membered Te_6Cl_6 rings and are incorporated into the hexagons, the latter thus defining the structure type. For more clarity, Fig. 3*a* is presented, in which the organic part of the molecules was omitted, leaving only the tellurium-chlorine backbone. In this figure two stacked layers are shown: one with all bonds as full lines, the other, located below, with open lines (again all bonds). The figure illustrates a sliding of the layers relative to each other, along the direction of the x-axis only. The corrugated structure of the layer is obvious in Fig. 3*b*, representing a side view along the x-axis. The apparently empty space is occupied by the organic part of the molecules, which determine a separation between two parallel layers A and B, measured by the

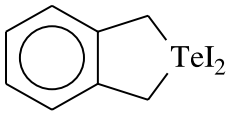
Te(A)···Te(B) distance of 9.26 Å. The intermolecular forces within the layers, due to Te···Cl secondary interactions, are stronger than the interlayer van der Waals forces and play a structure determining role. This can be correlated with the lamellar aspect of the crystals of compound (**1**).

The 2D layer structure found in this work prompted us to analyze the crystal packings and self-assembly modes of some other diorganotellurium(IV) dihalides that were reported as layered or 3D structures in the solid state. Thus, we found that an interesting comparison can be made with the structures of two polymorphs of a structurally related compound, α- and β-diiodobenzotelluracyclopentane (**2**) (Scheme 4). The results are illustrated in Scheme 5. Structure (a) is that of compound **1**, reported here.

A redrawing of the structure of α-diiodobenzotelluracyclopentane (19) from deposited data (CSD code DIPTEB10) reveals the presence of 2D layers made of four-membered Te_2I_2 rings combined with eight-membered Te_4I_4 rings in a corrugated layer (structure (b) in Scheme 5). It should be noted that in this image only the Te and I atoms effectively participating in the formation of the supramolecular array through Te···I(1) secondary bonds are shown; the I(2) atoms were omitted to simplify the picture. They are outside the plane of the paper.

Scheme 4.



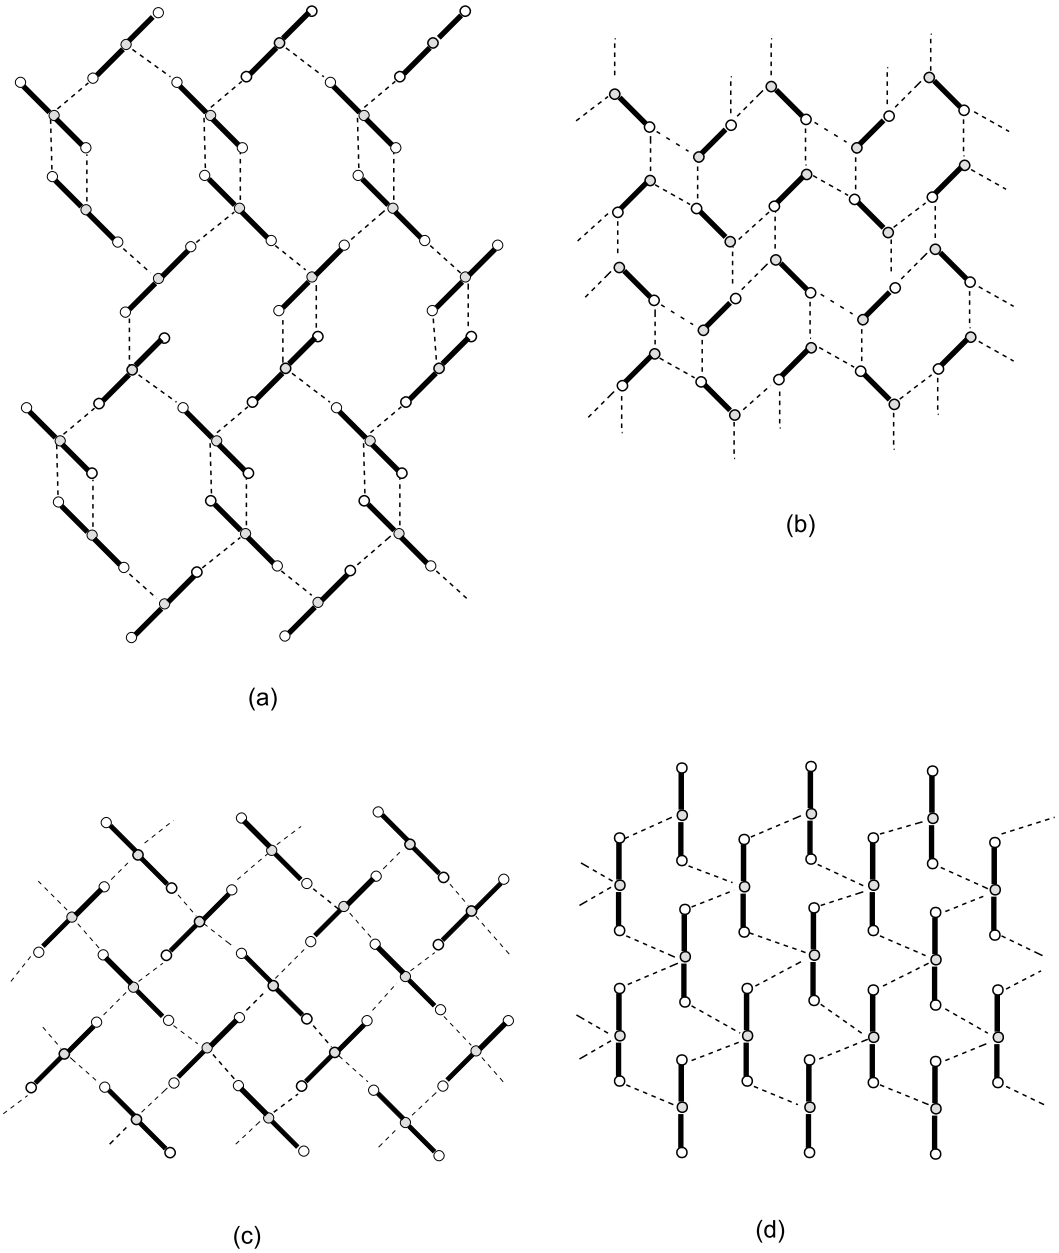
2

The β-polymorph of diiodobenzotelluracyclopentane (20) (CSD code DIPTEB02) is a supramolecular isomer and contains layers made of eight-membered Te_4I_4 rings only (structure (c) in Scheme 5). Since this is a view from the top it is somewhat misleading, as it suggests planarity. The corrugated nature of the layer is better illustrated by another view, shown in structure (d) (Scheme 5), which shows a reciprocal position and the interconnection of the I-Te-I rods related to that in the tetrameric supermolecules cited above.

The hexagonal grid structure, based upon the Te···Cl secondary interactions reported here, is reminiscent of the,

© 2002 NRC Canada

Scheme 5.



albeit different, hexagonal grid structure ("graphite-like") of $[O(SnMe_3)_3]Cl$, which is based upon Sn···Cl secondary bonds (21). Supramolecular hexagonal grids formed through hydrogen bonds can also be mentioned, e.g., in the structures of some cobalt-cupferrone-ethanol complexes (22) or the $Ni(HBim)_3$ anion (HBim = biimidazole) (23). This suggests that various types of intermolecular forces can lead to similar supramolecular architectures, and the subject deserves further attention.

Conclusions and outlook

We found in the title compound a hexagonal grid structure made of four-membered Te_2Cl_2 and twelve-membered Te_6Cl_6 rings formed through the self-assembly of Cl-Te-Cl rods through Te···Cl secondary bonds into a supramolecular 2D network. The comparison with a structurally related compound reveals that 2D layers can also be formed by similar self-assembly of four-membered Te_2I_2 with eight-membered Te_4I_4 rings (in α-diiodobenzotelluracyclopentane) or only of eight-membered Te_4I_4 rings (in β-diiodobenzotelluracyclopentane).

It is obvious from the data discussed here and illustrated in Schemes 1 and 5 that the mode of self-assembly of diorganotellurium(IV) halides is very sensitive to the size and shape of the organic part of the molecules (alkyl groups, aryl groups, heterocyclic moieties) and the nature of the halogen atoms. Therefore, it is worth exploring a range as broad as possible of such compounds by synthesizing new derivatives with different steric requirements of the R_2Te

fragments and with all four halogens, followed by their structural characterization and crystal packing analysis with the aid of modern X-ray diffraction techniques.

The synthesis and reactivity of a mixed nitrosyl–phosphinidene cluster of ruthenium: Formation of nitride and nitrene clusters

Ludmila Scoles, Brian T. Sterenberg, Konstantin A. Udachin, and Arthur J. Carty

Abstract: Reaction of the aminophosphinidene complex $[Ru_5(CO)_{15}(\mu_4\text{-PN-}i\text{-}Pr_2)]$ (**1**) with $[PPN][NO_2]$ (PPN = $Ph_3P{=}N{=}PPh_3$) led to the mixed nitrosyl–phosphinidene cluster complex $[PPN][Ru_5(CO)_{13}(\mu_2\text{-NO})(\mu_4\text{-PN-}i\text{-}Pr_2)]$ (**2**). Reaction of **2** with $HBF_4{\cdot}Et_2O$ led to a mixture of the nitrido–phosphido cluster $[Ru_5(CO)_{13}(\mu_5\text{-N})\{\mu_2\text{-P(F)N-}i\text{-}Pr_2\}]$ (**3**) and the nitrene–phosphinidene cluster $[Ru_5(CO)_{10}(\mu\text{-CO})_2(\mu_3\text{-CO})(\mu_4\text{-NH})(\mu_3\text{-PN-}i\text{-}Pr_2)]$ (**4**). If the BF_4^- counterion is avoided through use of trifluoromethanesulfonic acid, **4** is the only isolated product. Reaction of **2** with methyltrifluoromethanesulfonate leads to the nitrido–phosphido cluster $[Ru_5(CO)_{13}(\mu_5\text{-N})\{\mu_2\text{-P(OMe)N-}i\text{-}Pr_2\}]$ (**5**), which is structurally analogous to **3**.

Key words: ruthenium, cluster, nitrosyl, nitrene, phosphinidene, phosphido.

Résumé : La réaction du complexe aminophosphinidène $[Ru_5(CO)_{15}(\mu_4\text{-PN-}i\text{-}Pr_2)]$ (**1**) avec du $[PPN][NO_2]$ (PPN = $Ph_3P{=}N{=}PPh_3$) conduit à la formation d'un agrégat complexe nitrosyle–phosphinidène $[PPN][Ru_5(CO)_{13}(\mu_2\text{-NO})(\mu_4\text{-PN-}i\text{-}Pr_2]$ (**2**). La réaction du composé **2** avec du $HBF_4{\cdot}Et_2O$ conduit à un mélange d'agrégat nitrido–phosphido $[Ru_5(CO)_{13}(\mu_5\text{-N})\{\mu_2\text{-P(F)N-}i\text{-}Pr_2\}]$ (**3**) et d'agrégat nitrène–phosphinidène $[Ru_5(CO)_{10}(\mu\text{-CO})_2(\mu_3\text{-CO})(\mu_4\text{-NH})(\mu_3\text{-PN-}i\text{-}Pr_2)]$ (**4**). Si l'on évite la présence du contre-ion BF_4^- en utilisant de l'acide trifluorométhanesulfonique, le produit **4** est le seul à être isolé. La réaction du produit **2** avec du trifluorométhanesulfonate de méthyle conduit à la formation de l'agrégat nitrido–phosphido $[Ru_5(CO)_{13}(\mu_5\text{-N})\{\mu_2\text{-P(OMe)N-}i\text{-}Pr_2\}]$ (**5**) qui est analogue d'un point de vue structural au composé **3**.

Mots clés : ruthénium, agrégat, nitrosyle, nitrène, phosphinidène, phosphido.

[Traduit par la Rédaction]

Introduction

Phosphinidenes (PR) are important and versatile ligands in organometallic chemistry (1). The phosphinidene fragment is isolobal with carbene (CR_2) and there are interesting relationships between the well–established nucleophilic (Schrock type) and electrophilic (Fischer type) carbene complexes and their only recently discovered and highly reactive phosphinidene counterparts (2). The PR group is also, however, a powerful polynucleating ligand in metal cluster chemistry that enhances structural integrity and stability through μ_3- and μ_4-face-capping co-ordination (3). Yet another interesting family of phosphinidene complexes consists of a dimetal fragment bridged by a μ_2–PR ligand. The three membered $\overline{\text{M–M'–P}}$ ring in such molecules is unsaturated and bonding in the ring is partially delocalized owing to the availability of an empty pπ-orbital on the phosphinidene phosphorus atom, resulting in a planar geometry at phosphorus (4).

Over the past several years, we have developed an extensive chemistry based on the transformation of functionalized phosphinidenes on metal clusters (5) including the design of a versatile route to phosphorus monoxide (PO) complexes via the acid-catalysed hydrolysis of P—N bonds in co-ordinated aminophosphinidenes (6–8). Phosphorus monoxide is the heavier congener of NO, and the availability of a range of PO clusters has allowed us to gain some insights, via DFT calculations, into the bonding and electronic structure in these PO clusters for comparison with nitrosyl bonding (9). In pursuing the PO–NO analogy, we were struck by the broader need for a comparison of structure, bonding, and reactivity between pairs of related isolobal phosphorus and nitrogen ligands (phosphinidene (PR), nitrene (NR), phosphide (P), nitride (N)), preferably within the same cluster molecule. There are to our knowledge no examples of PO–NO, PR–NR, or P–N complexes or indeed of clusters bearing any combinations of these in the literature.

In this paper, we report on the formation of the nitrosyl–phosphinidene cluster $[PPN][Ru_5(CO)_{13}(\mu_2\text{-NO})(\mu_4\text{-PN-}i\text{-}Pr_2)]$ (**2**), and its transformation into nitrene–phosphinidene

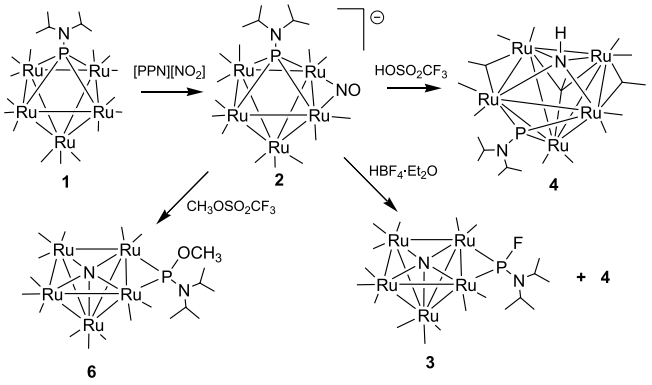
Scheme 1.



and nitride–phosphido clusters via reactions with electrophiles. Portions of this work have been communicated (10).

Formation of a nitrosyl–phosphinidene cluster

After attempts to form nitrosyl–phosphinidene clusters using NO gas or nitrosonium tetrafluoroborate failed owing to cluster decomposition, we turned to the milder reagent $[PPN][NO_2]$ that is effective in the formation of anionic nitrosyl clusters (11, 12). Reactions with the nitrite anion occur via oxidation of a carbonyl ligand and CO_2 elimination. Thus, treatment of the aminophosphinidene complex $[Ru_5(CO)_{15}(\mu_4\text{-PN-}i\text{-Pr}_2)]$ (**1**) with $[PPN][NO_2]$ led to the anionic nitrosyl–phosphinidene cluster $[PPN][Ru_5(CO)_{13}(\mu_2\text{-NO})(\mu_4\text{-PN-}i\text{-Pr}_2)]$ (**2**) in good yield (see Scheme 1).

Compound **2** has been structurally characterized. An ORTEP diagram of the cluster anion is shown in Fig. 1 and selected distances and angles are given in Table 1. The five ruthenium atoms are arranged in a square-based pyramid. The aminophosphinidene ligand caps the square face of the pyramid while the nitrosyl ligand bridges one edge of the square base. The nitrosyl bridged Ru—Ru bond distance (2.7077(4) Å) is significantly shorter than the other Ru—Ru distances in the square base (2.8493(4) – 2.8986(4) Å). Distances to the apical Ru(5) atom range from 2.8345(4) to 2.8583(4) Å. Thirteen carbonyl ligands are terminally bound to the cluster, two to each of the nitrosyl–bound ruthenium atoms and three to each of the other three ruthenium centres. The Ru—N bond lengths to the nitrosyl ligand (Ru(3)—N(9) 1.984(3) Å; Ru(4)—N(9) 2.016(3) Å) indicate a slight asymmetry in the Ru–N–Ru bridge.

The infrared spectrum of **2** shows a weak band at 1543 cm^{-1}, consistent with the stretching frequency of a doubly bridging nitrosyl ligand (13). The ^{31}P NMR spectrum shows a singlet at δ 550.7 for the phosphinidene ligand, a downfield shift of more than 60 ppm compared to the starting cluster **1**.

The formation of **2** involves a loss of two carbonyl ligands and co-ordination of NO in a doubly bridging co-ordination mode as a 3-electron donor, resulting in a overall 74-electron count, consistent with a *nido* M_5 structure or a *closo* M_5P framework if the μ_4-PN-*i*-Pr_2 fragment is considered part of the cluster framework. The octahedral metal–phosphinidene core does not change significantly in the reaction. Compound **2** is the first mixed phosphinidene–nitrosyl cluster.

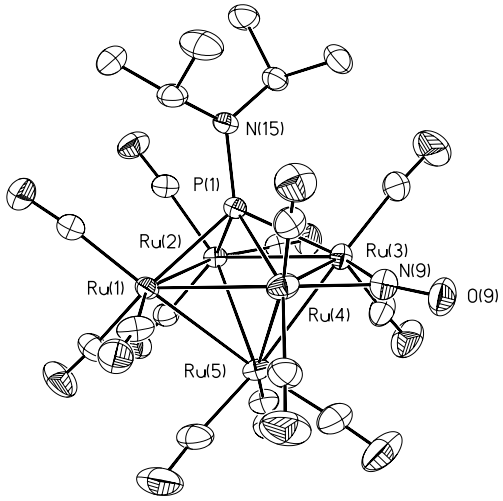
Fig. 1. Molecular structure (ORTEP) of the anion of $[PPN][Ru_5(CO)_{13}(\mu\text{-NO})(\mu_4\text{-PN-}i\text{-Pr}_2)]$ (**2**). Hydrogen atoms have been omitted. Thermal ellipsoids are shown at the 50% probability level.



Protonation of the nitrosyl cluster

In our previous work, we described the acid-catalysed hydrolysis of aminophosphinidenes to form PO clusters. Compound **2** is thus a potential precursor to a PO–NO complex. However, nitrosyl complexes are also known to be reactive towards acid. The reactivity of the aminophosphinidene–nitrosyl cluster towards protonation was therefore examined. Reaction of **2** with $HBF_4{\cdot}Et_2O$ led to two new cluster complexes that were separated by thin layer chromatography.

The first compound isolated from the reaction was the nitrido–phosphido cluster $[Ru_5(CO)_{13}(\mu_5\text{-N})\{\mu_2\text{-P(F)N-}i\text{-Pr}_2\}]$ (**3**). The ORTEP diagram of **3** is shown in Fig. 2 and selected bond distances and angles are shown in Table 2. The molecule consists of a square-based pyramidal arrangement of five ruthenium atoms around the μ_5-nitride ligand. The molecule lies upon a mirror plane with the position of the nitride nitrogen atom N(1) and apical ruthenium atom Ru(3)

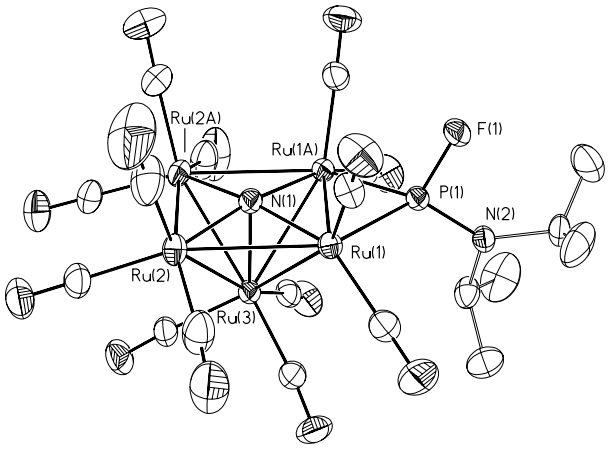
Fig. 2. Structure of $[Ru_5(CO)_{13}(\mu_5\text{-N})(\mu_2\text{-P(F)N-}i\text{-Pr}_2)]$ (**3**). Thermal ellipsoids are shown at the 50% level. Hydrogen atoms have been eliminated.



lying in the plane. The other ruthenium atoms are thus symmetry pairs. Metal—metal distances are 2.8261(4), 2.8687(3), and 2.8447(4) Å between basal ruthenium atoms and 2.8349(3) and 2.7424(3) Å to the apical ruthenium atom. Distances from N(1) to the basal ruthenium atoms are 2.036(2) and 2.010(2) Å, while the distance to the apical ruthenium atom is slightly longer (2.086(3) Å). The nitride atom lies above the plane formed by the basal ruthenium atoms by 0.160(3) Å. The fluoroaminophosphido ligand bridges two of the basal ruthenium atoms, with the phosphorus, nitrogen, and fluorine atoms of the ligand lying on the crystallographic mirror plane. The fluorine substituent is directed towards the basal ruthenium atoms while the amino group is directed towards the apical ruthenium atom Ru(3). The two isopropyl groups are disordered over two symmetry-related positions. The P(1)—Ru(1) distance is 2.2547(7), and the P—F and P—N distances are 1.579(2) and 1.635(3), respectively. The 13 carbonyl ligands are all terminally coordinated, two to each of the phosphorus bound ruthenium atoms and three to the other ruthenium atoms. The nitride ligand contributes five electrons and the phosphido ligand donates three resulting in a cluster electron count of 74. To our knowledge, **3** is the first compound containing a fluoroaminophosphido ligand, although analogous chloro- and bromoaminophosphido ligands have been reported (14).

The structural parameters involving the nitrido ligand and the metal core of **3** are very similar to those of the known anionic nitrido cluster $[Ru_5(CO)_{13}(\mu\text{-CO})(\mu_5\text{-N})]^-$ (15). In fact, the clusters are nearly isostructural, with one doubly bridging carbonyl ligand in $[Ru_5(CO)_{13}(\mu\text{-CO})(\mu_5\text{-N})]^-$ being replaced by the doubly bridging phosphido ligand in **3**. The arrangement of all other ligands in the two is the same, and the electron counts of the two clusters are the same.

The phosphorus NMR spectrum of **3** shows a doublet at δ 391 with a ^1J(PF) of 1087 Hz. The spectrum also reveals the presence of a second, minor isomer with a chemical shift of δ 387 and ^1J(PF) = 1110 Hz. This isomer comprises approximately 10% of the sample and is attributed to the geometric isomer in which the fluorine and amino substituent on the phosphido ligand are interchanged (see Scheme 2). The ratio of the two isomers does not change with temperature and there is no evidence of exchange, suggesting that there is no equilibrium between them. The X-ray crystal structure contains only the major isomer.

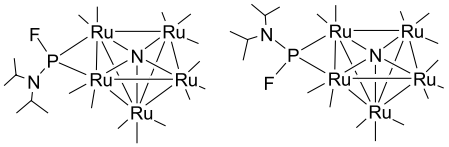
Scheme 2.

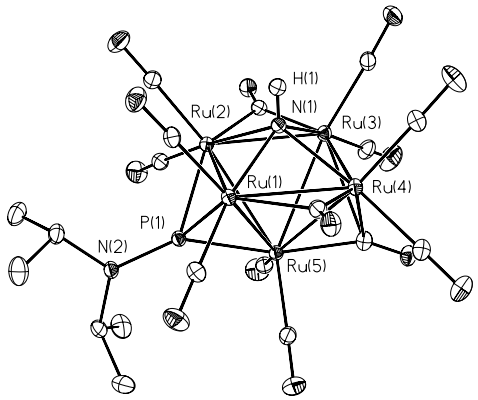


3a (major) **3b** (minor)

The second compound isolated is the nitrene–phosphinidene cluster $[Ru_5(CO)_{10}(\mu\text{-CO})_2(\mu_3\text{-CO})(\mu_4\text{-NH})(\mu_3\text{-PN-}i\text{-Pr}_2)]$ (**4**). An ORTEP diagram of **4** is shown in Fig. 3 and distances and angles are given in Table 3. The cluster consists of five ruthenium atoms arranged in a square-based pyramid. The square face is capped by the NH ligand. The Ru—N distances range from 2.136 to 2.158 Å, comparable to those observed in the very few other known μ_4-NH clusters (16, 17). The hydrogen atom of the nitrene ligand was readily located in the Fourier map and its position and thermal parameters were refined. One of the triangular faces of the metal core is bridged by the phosphinidene ligand. The Ru—P distances of 2.2607(5)–2.2839(5) Å are typical for μ_3-phosphinidene ligands (6, 18). The P—N distance of 1.6295(16) is slightly shorter than a typical P—N

© 2002 NRC Canada

Fig. 3. Structure of $[Ru_5(CO)_{10}(\mu\text{-}CO)_2(\mu_3\text{-}CO)(\mu_3\text{-}PN\text{-}i\text{-}Pr_2)(\mu_4\text{-}NH)]$ (**4**). Thermal ellipsoids are shown at the 50% level. Hydrogen atoms have been eliminated from the isopropyl groups.



single bond and is consistent with the P—N distance in related μ_3-aminophosphinidene ligands (6, 18). The cluster contains 13 carbonyl ligands. One forms a triply bridging interaction at the triangular face opposite to the μ_3-phosphinidene ligand, while two carbonyls doubly bridge at the Ru(2)–Ru(3) and Ru(1)–Ru(4) edges of the square base, adjacent to the uncapped trigonal faces. The remaining carbonyl ligands are terminal, two on each metal. The metal—metal distances of the μ_2-carbonyl-bridged edges are short (2.6929(2) and 2.6978(2) Å). The other distances within the square base are 2.8335(3) and 2.7894(3) Å, while those to the apical ruthenium atom range from 2.8721(2) to 2.9324(2) Å. The nitrene and phosphinidene ligands each contribute 4 electrons, resulting in a cluster electron count of 74, consistent with a *nido* M_5 or *closo* M_5N structure.

The resonance for the hydrogen atom of the nitrene ligand in **4** appears in the ^{1}H NMR spectrum at δ 3.22 as a 1:1:1 triplet with $^1J(^{14}NH)$ = 50 Hz. These values compare well with reported μ_4-NH ligands. The sharpness of the peak, which allows resolution of the coupling, results from the symmetric environment of the quadrupolar nitrogen atom. The phosphorus chemical shift of δ 495.8 is in the expected range for triply bridging phosphinidene ligands and is shifted upfield from that of the μ_4-phosphinidene in **2** by 55 ppm.

The formation of nitrene (NH) ligands via protonation of a nitrosyl ligand was initially observed in the transformation of $\{(\eta^5\text{-}C_5H_4Me)Mn(NO)\}_3(\mu_3\text{-}NO)$ into $[\{(\eta^5\text{-}C_5H_4Me)Mn(NO)\}_3(\mu_3\text{-}NH)]^+$ (19). The present example is of interest because it is the first example of the transformation of a μ_2-NO ligand to a μ_4-NH ligand. Quadruply bridging NH ligands are relatively rare but have previously been produced by protonation of nitrides (17), or via thermolysis or hydrogenation of $NOCH_3$ ligands (16). Also of note in the reaction is the apparent preference for a quadruply bridging nitrene ligand, requiring that the μ_4-phosphinidene ligand of the starting cluster move into a μ_3-coordination mode. This is somewhat surprising given the greater tendency of phosphorus than nitrogen to support hypervalency.

The source of the nitrene hydrogen in **4** was investigated by reaction of **2** with triflic acid-*d*. Deuteration of the nitrene ligand in the resulting product was confirmed by ^{2}H NMR spectroscopy, which showed a broad singlet at δ 3.22 for the ND ligand. Further evidence for the reaction pathway in the conversion of **2** to **4** was provided by the mass spectrometric detection of CO_2 in the gas above the reaction mixture, suggesting that CO acts as a reducing agent in the transformation. Since the number of carbonyl ligands in **2**, **3**, and **4** is the same, cluster decomposition must provide an additional source of CO for co-ordination, consistent with the moderate yields observed.

Table 3. Selected bond distances (Å) and angles (°) for $[Ru_5(CO)_{10}(\mu\text{-}CO)_2(\mu_3\text{-}CO)(\mu_3\text{-}PN\text{-}i\text{-}Pr_2)(\mu_4\text{-}NH)]$ (**4**).

Protonation of the nitrosyl cluster in the presence of excess water results in the formation of the same products with similar yields. In no case was hydrolysis of the aminophosphinidene ligand observed. Clearly, the nitrosyl ligand is the most reactive site in compound **2** towards protonation. The formation of **3** can be avoided by using trifluoromethanesulfonic acid to protonate **2**, leading to **4** as the sole isolated product. However, the yield of **4** in the triflic acid reaction is not significantly better than in the reaction with tetrafluoroboric acid. Reducing the reaction temperature also appears to suppress the formation of **3** in favour of **4**.

The fluorine–substituted phosphido ligand in **3** results from fluoride abstraction from the BF_4^- counterion. We have previously observed such reactivity with BF_4^- in the formation of fluorophosphinidene ligands (7, 20) and difluorophosphido ligands (21). To confirm that BF_4^- is simply acting as a fluoride source, the reaction of **2** with triflic acid was carried out in the presence of excess Bu_4NF. This reaction led to compounds **3** and **4** in roughly the same yields as the reaction with tetrafluoroboric acid.

Characterization of intermediates in the formation of **3** and **4** was attempted by monitoring the protonation reaction at low temperature. The nitrosyl cluster **2** was thus treated with triflic acid at –80°C. Below –40°C, one major species is observed that is tentatively assigned as the hydroxyimido complex $[Ru_5(CO)_{13}(\mu\text{-}NOH)(\mu_4\text{-}PN\text{-}i\text{-}Pr_2)]$ (**5**), which results from protonation of the nitrosyl oxygen. Its ^{31}P chemical shift of δ 558 clearly indicates that the μ_4-phosphinidene ligand is retained. Peaks for the amine isopropyl groups are apparent in the ^{1}H NMR but no peak for the NOH hydrogen was observed. The failure to observe a peak for the NOH ligand could indicate that the proton is rapidly exchanging with acid in solution. Above –40°C, several new species, including compound **4** are formed, but the mixture is too

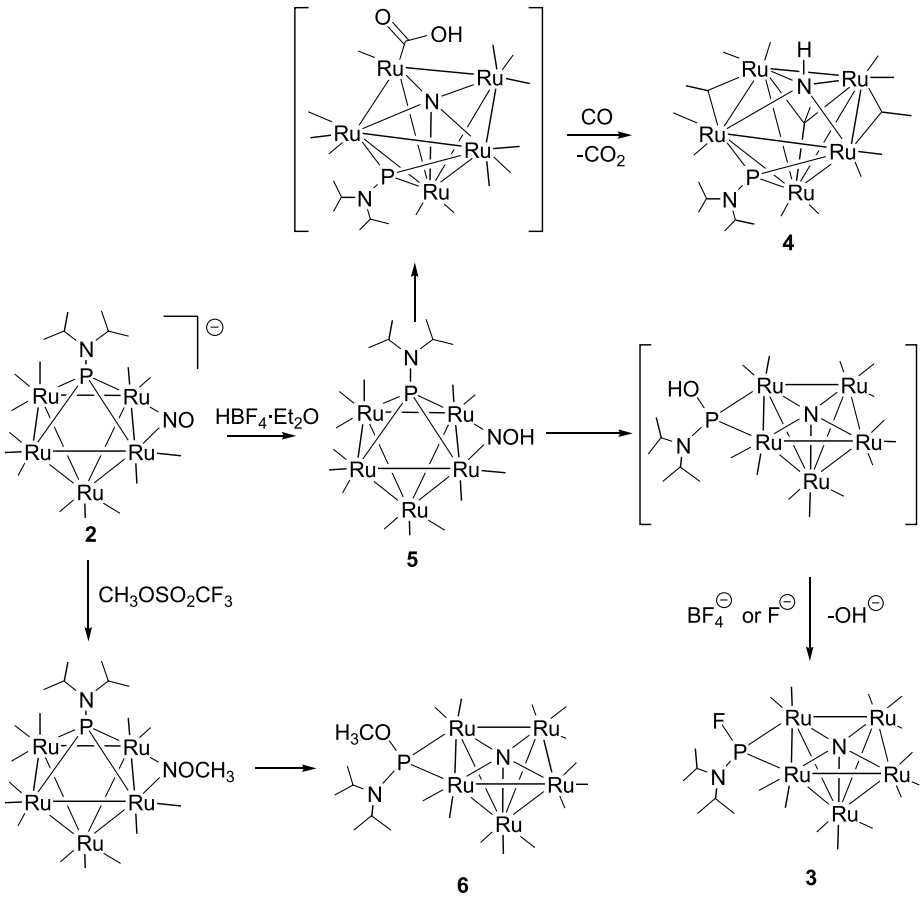
Scheme 3.



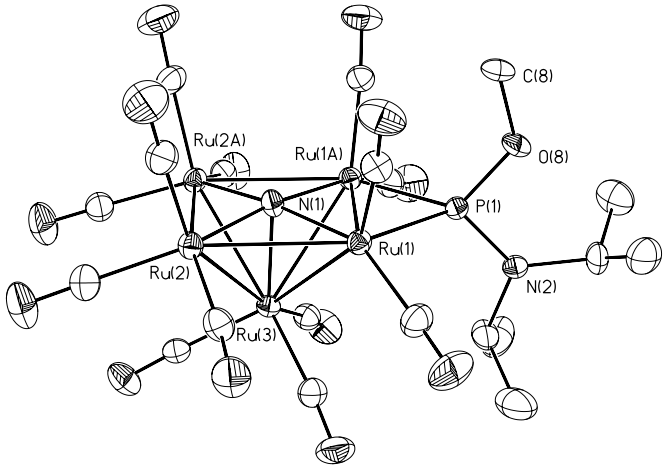
complex to characterize any of the compounds. At higher temperature, compound **4** becomes the predominant species.

Nitrosyl methylation

To expand the chemistry, as well as to help elucidate the mechanism of the protonation reactions, the phosphinidene–nitrosyl cluster was reacted with methyltrifluoromethanesulfonate. One product was isolated from the reaction in moderate yield and identified as the phosphido–nitride cluster $[Ru_5(CO)_{13}(\mu_5\text{-}N)\{\mu_2\text{-}P(OMe)N\text{-}i\text{-}Pr_2\}]$ (**6**). The ORTEP diagram of **6** is shown in Fig. 4 and selected distances and angles are given in Table 2. Compound **6** is structurally analogous to the fluoroaminophosphido cluster **3** except that the fluoro group on the phosphinidene ligand is replaced by an alkoxy group. A comparison of parameters involving the phosphido ligands in the two structures reveals shorter metal—phosphorus distances and a slightly longer phosphido-bridged metal—metal distance in the fluorophosphido complex **3**. The differences reflect the greater π-acceptor ability of the fluorophosphido ligand over the alkoxyphosphido ligand. The other structural parameters of the two clusters are very similar (see Table 2).

The ^{31}P NMR spectrum of **6** shows a singlet at δ 378, close to that observed for the analogous cluster **3**. As for **3**, a minor isomer at δ 376 (13%) is observed and is again attributed to the isomer in which the amino and alkoxy substituents on phosphorus are interchanged. The methoxy group appears in the ^1H NMR spectrum at δ 3.65 (major isomer) or δ 3.47 (minor isomer) with a $^2J(PH)$ of 15 (major) or 18 (minor) Hz.

Fig. 4. Structure of $[Ru_5(CO)_{13}(\mu_5\text{-}N)(\mu_2\text{-}P(OMe)N\text{-}i\text{-}Pr_2)]$ (**6**). Thermal ellipsoids are shown at the 50% level. Hydrogen atoms have been eliminated.



The formation of cluster **6** results from initial methylation at the nitrosyl oxygen to form an $NOCH_3$ ligand. Migration of the alkoxy group from nitrogen to the phosphorus atom of

the phosphinidene ligand leads to the phosphido group and the nitride ligand as shown in Scheme 3. Attempts to observe the methoxyimido intermediate were unsuccessful as elevated temperatures were required to induce reactivity with methyl triflate, and at these temperatures, the reaction proceeds rapidly to the final product. In the reaction, the phosphorus ligand moves from μ_4-coordination to μ_2-coordination, allowing the nitride to occupy the square face of the square-based pyramid. In this reaction, the rearrangement is expected because the three-electron donor phosphido ligand generally prefers a doubly bridging co-ordination mode, while the five-electron donor nitride ligand requires a higher co-ordination number.

Mechanism

A proposed mechanism for the formation of compounds **3** and **4** is shown in Scheme 3. The initial site of electrophilic attack by H^+ is at the oxygen of the nitrosyl ligand forming the hydroxyimido intermediate **5**. This is based on (*i*) characterization of **5** at low temperature, (*ii*) the reactivity with methyl triflate in which the electrophile remains attached to the oxygen in the final product, and (*iii*) literature precedence for electrophilic attack at the oxygen of cluster-bound nitrosyl ligands (22).

Two pathways are available for the decomposition of the hydroxyimido intermediate. The first leads to the nitrene complex **4**, via CO reduction of the NOH ligand and CO_2 loss (detected by GC-MS). This reduction may occur via hydroxide migration to a carbonyl ligand, forming an intermediate nitride–acyl complex, although a concerted mechanism is not ruled out. Formation of the nitride–acyl intermediate requires cluster rearrangement to allow a μ_5 co-ordination mode for the nitride ligand, forcing the phosphinidene ligand into a μ_3 co-ordination mode. A nitride intermediate in the formation of **4** may explain the preference for μ_4-nitrene co-ordination over μ_4-phosphinidene co-ordination in the final product. Carbon dioxide loss and proton migration to the nitride ligand then lead to the final product.

The second pathway for hydroxide migration is to the phosphorus atom of the phosphinidene ligand to form an intermediate hydroxyaminophosphido complex. This migration directly parallels the methoxy migration that leads to the methoxy-amino phosphido complex **6**, and the similar isomer distributions in **3** and **6** suggests a similar mechanism for their formation. In the presence of BF_4^- or fluoride, the hydroxy group is displaced by fluoride leading to **3**. In the absence of fluoride, the hydroxyphosphinidene complex apparently decomposes. Although a mechanism in which fluoride substitution occurs at the nitrogen of the hydroxyphosphinidene cluster **5** leading to a fluoroimido complex can be envisioned, the insensitivity of the yield of **4** to the presence of BF_4^- or F^- suggests that fluoride substitution takes place after differentiation between the two pathways.

Experimental

Unless specified, all procedures were carried out under a nitrogen atmosphere. Solvents were dried and distilled before use. The reagents $HOSO_2CF_3$, $HBF_4{\cdot}Et_2O$, and $CH_3OSO_2CF_3$ were purchased from Aldrich and used as received. The compounds $[Ru_5(CO)_{15}(\mu_4\text{-PN-}i\text{-Pr}_2)]$ (20) and $[PPN][NO_2]$ (11) were prepared according to published procedures. The TLC separations were performed in air using silica gel plates (60 Å F254 5–15 μm). Elemental analyses were carried out by Guelph Chemical Laboratories.

Preparation of compounds

[PPN][Ru$_5$(CO)$_{13}$(μ-NO)(μ$_4$-PN-i-Pr$_2$)] (2)

The cluster $[Ru_5(CO)_{15}(\mu_4\text{-PN-}i\text{-Pr}_2)]$ (78 mg, 0.074 mmol) and $[PPN][NO_2]$ (45 mg, 0.077 mmol) were dissolved in 10 mL of THF resulting in a colour change from dark green to dark red. The solution was stirred for 2 h, the solvent was removed in vacuo, and the residue was extracted with diethyl ether (10 mL) and filtered. Purple crystals were grown from diethyl ether at –30°C. Yield: 54 mg, 47%. IR (CH_2Cl_2 soln) (cm^{-1}) (ν*C*O): 2053 (m), 2005 (vs), 1987 (s), 1949 (vw), 1925 (sh) ν(NO): 1543 (w). ^{1}H NMR ($CDCl_3$) δ: 7.5 (m, Ph), 3.85 (sept, C*H*, ^1J(HH) = 7.0 Hz), 1.15 (d, CH_3, ^1J(HH) = 7.0 Hz). ^{31}P NMR ($CDCl_3$) δ: 550.7 (s, *P*N-*i*-Pr$_2$), 21.7 (s, PPN). FAB-MS (*m*/*z*): 1031 ($[M]^-$), 1003–947 ($[M - nCO]^-$ (*n* = 1–3)). Anal. calcd. for $C_{55}H_{44}O_{14}P_3N_3Ru_5$: C 42.10, H 2.83, N 2.68; found: C 42.17, H 3.02, N 2.22.

Reaction of [PPN][Ru$_5$(CO)$_{13}$(μ-NO)(μ$_4$-PN-i-Pr$_2$)] (2) with HBF$_4$·Et$_2$O

To a solution of $[PPN][Ru_5(CO)_{13}(\mu\text{-NO})(\mu_4\text{-PN-}i\text{-Pr}_2)]$ (**2**) (60 mg, 0.049 mmol) in CH_2Cl_2 (20 mL) was added an excess of $HBF_4{\cdot}Et_2O$ (10 μL, 0.159 mmol) resulting in a colour change from dark red to orange. Then solvent was removed in vacuo, and the resulting residue was purified via thin layer chromatography using hexane–CH_2Cl_2 50:50. Two orange bands were isolated that were characterized as $[Ru_5(CO)_{13}(\mu_5\text{-N})(\mu_2\text{-P(F)N-}i\text{-Pr}_2)]$ (**3**, 9 mg, 23%, two isomers 90:10) and $[Ru_5(CO)_{10}(\mu\text{-CO})_2(\mu_3\text{-CO})(\mu_4\text{-NH})(\mu_3\text{-PN-}i\text{-Pr}_2)]$ (**4**, 12 mg, 31%). Crystals of **3** and **4** were grown from CH_2Cl_2–hexane at –30°C.

^{1}H NMR δ: 3.8 (bm), 1.1 (d, CH_3, ^1J(HH) = 5.8 Hz). ^{31}P NMR δ: 558 (s, *P*N-*i*-Pr$_2$).

[Ru$_5$(CO)$_{13}$(μ$_5$-N)(μ$_2$-P(OMe)N-i-Pr$_2$)] (6)

To a solution of [PPN][Ru$_5$(CO)$_{13}$(μ$_2$-NO)(μ$_4$-PN-*i*-Pr$_2$)] (**2**) (52 mg, 0.033 mmol) in CH_2Cl_2 (20 mL) was added an excess $CF_3SO_3CH_3$ (10 μL, 0.088 mmol). The reaction mixture was heated under reflux for 16 h resulting in a colour change from red to dark orange. The solvent was removed in vacuo. Thin layer chromatography (hexane–CH_2Cl_2 75:25) resulted in the isolation of one orange band. Crystals of [Ru$_5$(CO)$_{13}$(μ$_5$-N)(μ$_2$-P(OMe)N-*i*-Pr$_2$)] (**6**) were grown from CH_2Cl_2–hexane at –30°C. Yield: 10 mg, 29%. IR (CH_2Cl_2) (cm^{-1}) (ν CO): 2079 (m), 2041 (s), 2030 (s), 2020 (vs), 1997 (w), 1986 (w). ^{1}H NMR ($CDCl_3$) δ: 3.57 (sept, ^3J(HH) = 6.2 Hz, CH, **6a**), 3.70 (sept, ^3J(HH) = 6.8 Hz, CH, **6b**), 3.67 (d, ^2J(HH) = 15.2 Hz, OCH_3, **6a**), 3.46 (d, ^2J(HH) = 14.2 Hz, OCH_3, **6b**), 1.45 (d, ^3J(HH) = 6.7 Hz, CH_3, **6a**), 1.53 (d, ^3J(HH) = 6.6 Hz, CH_3, **6b**). ^{31}P NMR ($CDCl_3$) δ: 378 (s, **6a**), 376 (s, **6b**). Anal. calcd. for $C_{20}H_{17}O_{14}PN_2Ru_5$: C 22.97, H 1.64, N 2.68; found: C 22.48, H 1.78, N 2.66.

X-ray crystallography

Crystals of compounds **2**, **3**, **4**, and **6** were mounted on glass fibres. Intensity data were collected on a Siemens SMART CCD diffractometer with the use of graphite-monochromated Mo Kα radiation at 173 K. Unit cells were determined from randomly selected reflections obtained using the SMART CCD automatic search, centre, index, and least-squares routines. Integration was carried out using SAINT and empirical absorption corrections were applied using SADABS. Structure solution was carried out using the SHELXTL 5.1 suite of programs. Initial solutions were obtained by direct methods and refined by successive least-squares cycles. Full matrix least-squares refinements minimized the function $\Sigma_{hkl}w(|F_o|- |F_c|)^2$ where $w = 1/\sigma(F_o)^2$,

© 2002 NRC Canada

$\sigma(F_o) = \sigma(F_o^2)/2F_o$, and $\sigma(F_o^2) = [\sigma(I_{raw})^2 + (0.02I_{net})^2]^{1/2}/Lp$. Crystal data and collection parameters are listed in Table 4.[2]

Conclusions

We have synthesized the first example of a mixed nitrosyl–phosphinidene cluster. Reaction of the nitrosyl–phosphinidene complex with acid leads to nitrogen—oxygen bond cleavage and nitrene or nitride complexes. Amino-phosphinidene hydrolysis is not observed although the phosphinidene is transformed into a phosphido group in one case. Our results suggest that the μ-NO ligand is the most nucleophilic site in these Ru_5 systems, while the μ_4-PN-*i*-Pr_2 group is susceptible to nucleophilic attack at phosphorus. The conversion of NO to nitrene and nitride provides insight into the reduction of nitrosyl ligands on cluster frameworks and the clusters provide an opportunity to compare the properties of related phosphorus and nitrogen ligands. We are currently exploring the generation of μ_n-NO ligands on preformed PO clusters and the comparative chemistry of the four NO–PO–PR–NR combinations.

$SiCl_4$–ethanol as a trimerization agent for organometallics: convenient syntheses of the symmetrically substituted arenes 1,3,5-$C_6H_3R_3$ where R = $(C_5H_4)Mn(CO)_3$ and $(C_5H_4)Fe(C_5H_5)$

Hari K. Gupta, Nada Reginato, Francis O. Ogini, Stacey Brydges, and Michael J. McGlinchey

Abstract: Trimerization of acetylferrocene and of (acetylcyclopentadienyl)tricarbonyl-manganese proceeds efficiently in the presence of ethanol and tetrachlorosilane. The resulting 1,3,5-trisubstituted benzenes have been characterized by X-ray crystallography and compared with the structure of (1,3,5-triphenylbenzene)tris(tricarbonylchromium). The efficacy of EtOH–$SiCl_4$ as a combined reagent for the trimerization of polycyclic ketones is also discussed. Finally, the synthesis and structure of $[CpMn(CO)_2]_2(\mu\text{-}C{=}CHPr)$, derived from the reaction of cymantrene with butyllithium and phenylacetyl chloride at room temperature, is described.

Key words: ketone, condensation, cyclization, organometallics, arenes.

Résume : La trimérisation de l'acétylferrocène et du (acétylcyclopentadiényl)tricarbonylmanganèse se produit de façon efficace en présence d'éthanol et de tétrachlorosilane. Les benzènes 1,3,5-trisubstitués qui en résultent ont été caractérisés par diffraction des rayons X et on a comparé leurs structures avec celle du (1,3,5-triphénylbenzène)tris(tricarbonylchrome). On discute aussi de l'efficacité du EtOH–$SiCl_4$ comme réactif combiné pour la trimérisation de cétones polycycliques. Enfin, on décrit la synthèse et la structure du $[CpMn(CO)_2]_2(\mu\text{-}C{=}CHPr)$ dérivé de la réaction du cymantrène avec le butyllithium et la chlorure de phénylacétyle à la température ambiante.

Mots clés : cétone, condensation, cyclisation, organométalliques, arènes.

Introduction

The use of polycyclic aromatic hydrocarbons as building blocks for discrete nanostructures, such as fullerene (C_{60}) derivatives and extended two- and three-dimensional arrays, is contingent upon the advancement of novel design schemes and facile synthetic approaches (1, 2). In turn, these motifs are rooted in the fact that structure and internal motion are governed by symmetry, sterics, and strain. Diversely functionalized tri- and hexasubstituted (triannulated) benzenes may be widely exploited in these regards, allowing one to amalgamate the topological concepts advanced by Katz (3) and Stang and co-workers (4) with the assembly principles first introduced by Chapman (5). The versatility of these synthons is further enhanced by their general access via cyclotrimerization methods. For example, our recent studies on metal complexes of trindane, **1** (6–8), prepared by the successive dehydration–cyclotrimerization of cyclopentanone, were aided by an efficient route to the $C_{15}H_{18}$ ligand. Whereas early syntheses required concentrated sulfuric acid (9), hydrochloric acid, or sodium ethoxide (10), milder approaches, such as the use of ethanol–tetrachlorosilane, are gaining in popularity (11).

ML_n = $Cr(CO)_3$, $Mn(CO)_3^+$, $(C_5H_5)Fe^+$, $RuCl_2[P(OMe)_3]$, $Mn(CO)_2Br$, *etc.*

Both disilane (12) and transition metal homo- and heterogeneous catalysts (13) have been employed for the oligomerization of symmetrical and unsymmetrical alkynes. In the latter instances, cyclotrimerization generally gives rise to isomeric mixtures, as demonstrated by the conversion of phenylacetylene to 1,2,4- and 1,3,5-substituted benzenes, **2** and **3**, respectively, at elevated temperatures in the presence of Si_2Cl_6 (12*a*). In contrast, acid-catalyzed condensation of ketones of the type $R(CO)CH_2R'$ produces only the threefold symmetric arenes, as exemplified by truxene, **4**, or the triazulenyl system, **5** (14, 15). In this report, we describe the use of EtOH–$SiCl_4$ as a convenient reagent for the trimerization of select acetyl–organometallic complexes and

polycyclic ketones to yield the corresponding 1,3,5-trisubstituted arenes and polyphenylene frameworks, respectively (Scheme 1).

Results and discussion

Syntheses and structures of 1,3,5-$C_6H_3R_3$ where R = $(C_6H_5)Cr(CO)_3$, $(C_5H_4)Mn(CO)_3$, and $(C_5H_4)Fe(C_5H_5)$

Systematic modification of the periphery of C_6R_6 arrays by the introduction of new pendant groups is expected to have static and dynamic stereochemical consequences. In 1987, Katz (3) proposed that 1,3,5-trialkyl-2,4,6-triarylbenzenes could be exploited as rigidly oriented and convergent tridentate metal-binding units. More recently, Stang and co-workers (4) have introduced a supramolecular assembly approach to polycyclic nanostructures from combinations of linear and angular building units capable of metal chelation. Among the latter, 1,3,5-trisubstituted benzenes with both flexible and rigid backbones have been extensively employed. In combining these design principles with our long-standing interest in sterically congested organometallic systems, we eventually hope to construct extended covalent networks from such trimetallic precursors.

Several years ago, we reported the synthesis and single crystal X-ray diffraction analysis of (1,3,5-triphenylbenzene)tris(tricarbonylchromium), **6**, prepared in rather low yield by treatment of the polyaryl ligand with a large excess of $Cr(CO)_6$ (Scheme 2*a*). After initial multiple fractional crystallizations, separation of the trimetallic product from the two monochromium isomers and from the bis-$Cr(CO)_3$ adduct was finally achieved by reverse-phase low-pressure liquid chromatography (16). The solid-state structure of **6** revealed a "two-up, one-down" arrangement of the organometallic moieties. In solution, however, the variable-temperature NMR spectra showed no evidence for slowed rotation of the metal-ligated rings, unlike the case of (hexaphenylbenzene)chromium tricarbonyl, for which the

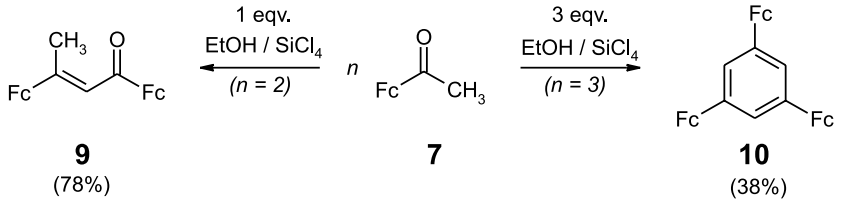
(a)

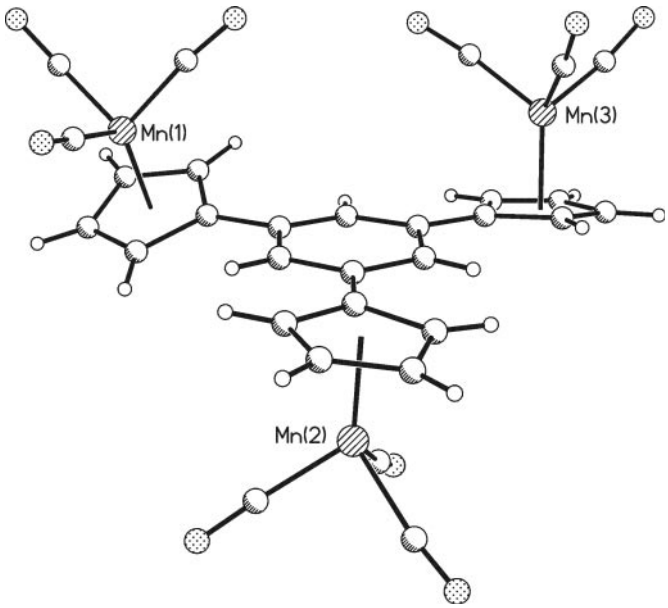


(b)

barrier to rotation of the peripheral $(C_6H_5)Cr(CO)_3$ group was found to be 12.2 kcal mol^{-1} (17).

The preparation of arenes bearing (cyclopentadienyl)ML_n moieties in the 1,3,5 positions cannot parallel the synthetic methodologies exploited for **6**, since the corresponding free polycyclic ligands are not readily available. However, we find that acetylcyclopentadienyl complexes, in particular acetylferrocene, **7**, and (acetylcyclopentadienyl)tricarbonylmanganese, **8**, can be readily trimerized upon treatment with EtOH–$SiCl_4$. In the former case, reaction of acetylferrocene with one equivalent of this reagent at room temperature furnishes (78%) the diferrocenyl complex, **9**, arising from the elimination of a single water molecule. Use of a threefold excess of EtOH–$SiCl_4$ leads directly to 1,3,5-triferrocenylbenzene, **10**, in reasonable yield (40%). The dimer **9** had been described previously by Sasaki and Pittman (18) as the major product (no yield cited) of the reaction of **7** with triethyl orthoformate and dry HCl, and was later isolated by Erasmus et al. (19) as an unexpected by-product (20%) during an attempted preparation of the β-diketone $FcCOCH_2COFc$. A variety of synthetic routes to **10** (20, 21) and its unsymmetrical (1,2,4)-isomer **11** (20, 21*b*, 22, 23) have also been detailed in the literature, although discrepancies regarding reaction conditions and isolable yields exist. The transformation of ethynylferrocene to **10** requires the use of $TaCl_5$ or catalytic amounts of acids, whereas treatment with dicobalt octacarbonyl or the application of thermal and free-radical polymerization methods results in the latter benzene derivative. The current procedure extends the facile process disclosed by Elmorsy and co-workers (11) to organometallic systems, demonstrating a direct, convenient (mild conditions), and rational (stoichiometrically controlled) route to both dimeric and trimeric condensation products (Scheme 2*b*), whose spectroscopic characterizations were previously incomplete.

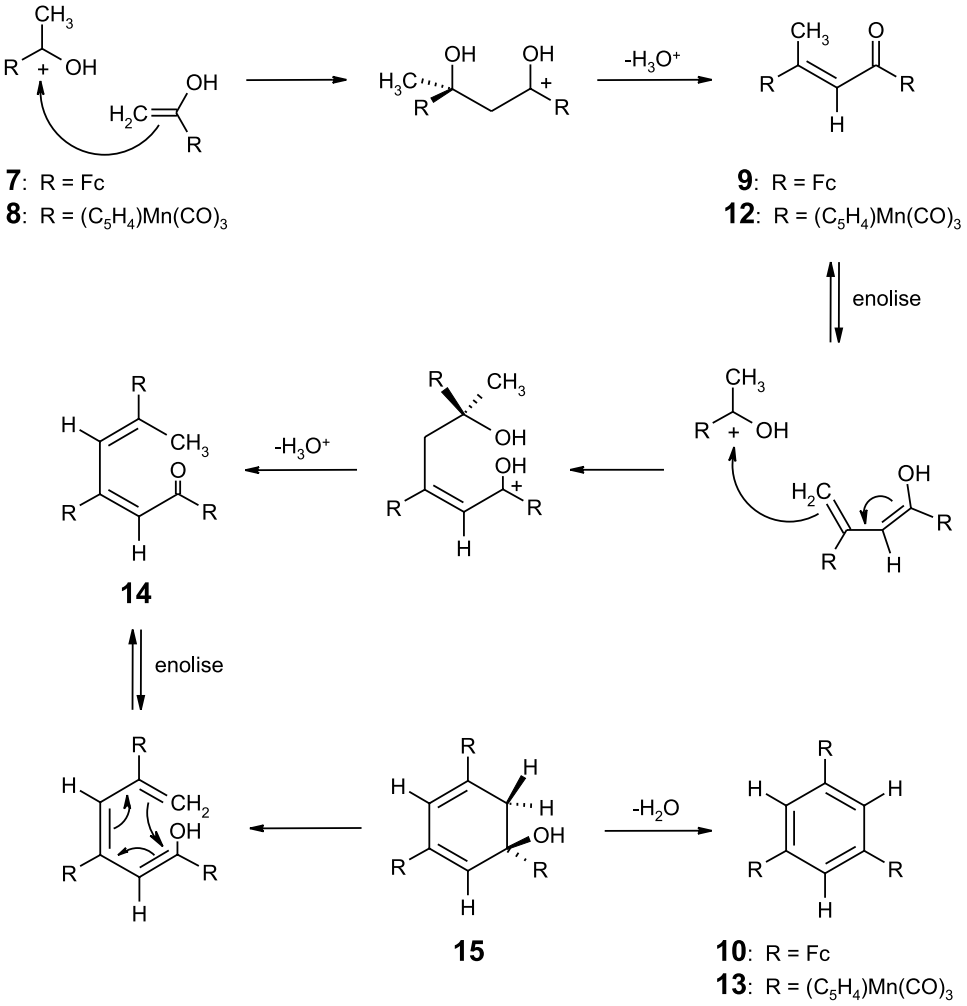
Fig. 1. Perspective view of the molecular structure of 1,3,5-C_6H_3-[(η^5-C_5H_4)$Mn(CO)_3$]$_3$, **13**.



Similarly, (acetylcyclopentadienyl)tricarbonylmanganese, **8**, reacts at room temperature with EtOH–$SiCl_4$ to yield the dimanganese complex **12** (analogous to **9**) and 1,3,5-tris(cyclopentadienytricarbonylmanganese)benzene, **13**, the X-ray crystal structure of which is shown in Fig. 1. In the solid state, the organometallic substituents in the chromium, manganese, and iron trimers **6**, **13**, and **10**, respectively, are each oriented in the now familiar "two-up, one-down" arrangement with dihedral angles between the central and peripheral rings of 152° (up), 67° (up), and 37° (down) for chromium, 24° (up), 11° (up), and 175° (down) for manganese,

© 2002 NRC Canada

Scheme 3. Proposed mechanism for the triple condensation of ketones.



and 153° (up), 14° (up), and 173° (down) for iron. However, the simplicity of the ^{1}H and ^{13}C NMR spectra indicates that, as in the case of **6**, rotation of the $(C_6H_5)Mn(CO)_3$ or $(C_5H_4)FeCp$ substituents is fast on the NMR time scale (298–183 K). To enforce the necessary stereochemistry (i.e., mutually syn orientation) and simultaneously enhance the barrier to aryl—aryl bond rotation in these trimeric units, further derivatization of the benzene framework may be required (vide infra). Very recent X-ray crystal structure determinations of triferrocenylboroxine and -borazine demonstrate that a convergent arrangement of metal-bearing fragments is indeed possible (24).

It has been suggested (18) that these trimerizations proceed via initial formation of a metal-stabilized carbocation, which then reacts with another molecule of the appropriate acetyl complex *in its enol form*. The dimetallic products, typified by **9** and **12**, may then combine, via their enol tautomers, with a third molecule of the protonated acetyl complex to produce the trimetallic arene precursor **14**. Subsequent electrocyclic ring closure can generate the arene hydrate **15** and ultimately the desired 1,3,5-trisubstituted benzene, as depicted in Scheme 3. Although the proposed intermediates are depicted as simple enols, it is likely that they are really silyl enol ethers of presently unknown composition. Moreover, while species of the form $Cl_xSi(OEt)_{4-x}$ most likely serve as a template for the condensation reactions, clarifying the precise nature of the silicon reagent(s) would require extensive mechanistic studies.

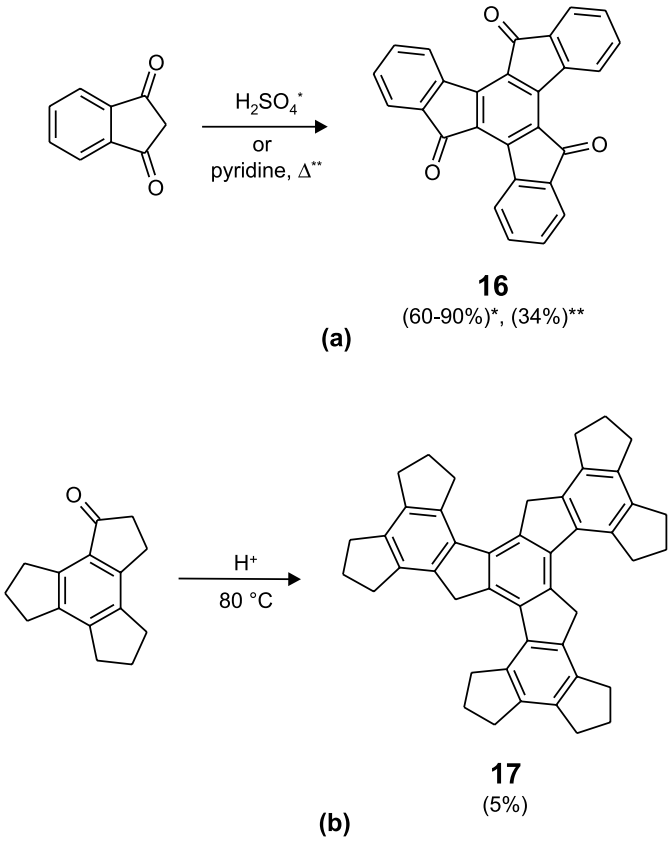
A crucial factor contributing to the ease of these reactions is presumably the enhanced stability of the intermediate carbocations, for which the electron deficiency at the α-carbon is alleviated through overlap of the "vacant *p* orbital" with a filled *d* orbital on the relatively electron-rich metal. NMR spectroscopic, X-ray crystallographic, and computational data of similar organometallic complexes, which could also be viewed as (fulvene)ML_n^+ derivatives, have revealed that the α-carbon bends (by ~25–40°) toward the metal so as to enhance this orbital interaction; the net result is to stabilize the HOMO, destabilize the LUMO, and augment the HOMO–LUMO gap (25).

Attempted trimerisations of polycyclic ketones

As part of the continuing worldwide effort to synthesize curved fragments of fullerenes (Buckybowls) (5), several research groups have based their approaches on threefold symmetric polycyclic precursors such as truxenetrione, **16** (14, 26), and the C_{45} molecule, **17** (27), which are derived from the ketone precursors 1,3-indandione and trindanone, respectively (Scheme 4). Whereas the structure of **16** has been unequivocally established, the existence of **17**, an

© 2002 NRC Canada

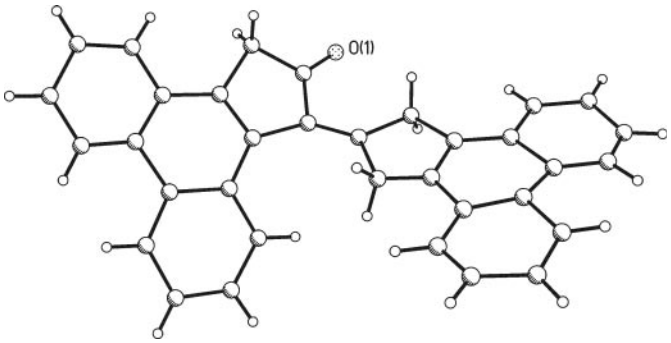
Scheme 4. Acid-catalyzed condensations of (*a*) 1,3-indanone and (*b*) truxenone.



insoluble material, is tentatively based on infrared spectroscopic and mass spectrometric data (27).

In a preliminary investigation of related "tectons" (28), we chose to attempt the trimerization of the tetracyclic ketone **18** with the goal of generating successively the octacyclic and tridecacyclic systems **19** and **20**, respectively (Scheme 5). Treatment of 1,3-dihydro-2H-cyclopenta[*l*]phenanthren-2-one, **18** (29), with either EtOH–$SiCl_4$ or concentrated sulfuric acid yielded two major products. The former, a light yellow crystalline solid, was identified as **19**, but a crystallographic disorder prevented satisfactory refinement of the structure. Figure 2 shows the atom connectivity for **19** and reveals that the structure is decidedly nonplanar because of steric interactions between a peripheral aryl ring in the ketonic half of the molecule and the five-membered ring in the other half. The twist angle between the two five-membered rings linked by the central double bond is approximately 37°. However, the quality of the data is such that we cannot claim accurate bond lengths and angles. The second isolated product, a purple, relatively insoluble solid, yields inconclusive mass spectrometric data and resists all attempts at crystallization. Microanalytical data indicate an empirical formula of approximately $(C_{17}H_{12}O_2)_x$, but at this time, we prefer not to speculate as to its identity. The inability to unambiguously verify products by use of contemporary methods of chemical analysis is an all too common impediment in the preparation of such extended polycyclic hydrocarbons. Enhanced solubility may be achieved by suitable functionalization of the arene periphery, as demonstrated by Plater (28) for related 1,3,5-triarylbenzene fullerene precursors containing more flexible, albeit weaker, aryl–aryl linkages. Regardless, this experiment concurs with earlier evidence (11) that the triple condensation of ketones to yield benzenoids or triarylbenzenes can be inhibited by the steric demands of the substrate.

Fig. 2. Molecular structure of **19** depicting only the atom connectivity.



Reaction of $(C_5H_5)Mn(CO)_3$ with *n*-butyllithium at room temperature

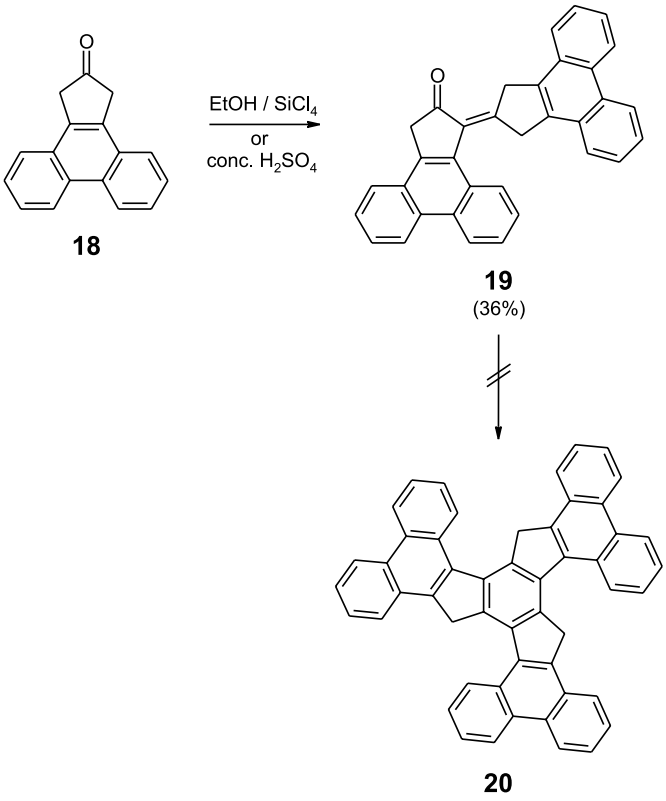
As an extension of our investigations of the ethanol–tetrachlorosilane-induced self-condensation of aryl methyl ketones, we identified the more sterically hindered, hexasubstituted scaffold 1,3,5-tris[(cyclopentadienyl)tricarbonylmanganese]-2,4,6-triphenylbenzene, **22**, as a viable synthetic target (Scheme 6). The successful cyclotrimerization of (phenacetylcyclopentadienyl)tricarbonylmanganese, **21**, would not only yield a topologically attractive organometallic propeller, but it would advance further the scope of this preparative technique.

Acetylation of cyclopentadienyltricarbonylmanganese is known to proceed either via Friedel–Crafts reaction with acetyl chloride – aluminum trichloride (30) or by lithiation of $(C_5H_5)Mn(CO)_3$ at –78°C, prior to treatment with CH_3COCl (31). However, it is also well established that, at higher temperatures, aryl-lithium reagents can attack carbonyl ligands (32), and this is the basis of Fischer's route to carbene complexes.

When $(C_5H_5)Mn(CO)_3$ was treated with *n*-butyllithium at –78°C, allowed to warm to 0°C, and subsequently reacted with phenacetyl chloride (as opposed to acetyl chloride), the purplish red crystalline product afforded a mass spectrum consistent with the formula $(C_5H_5)_2Mn_2(CO)_4(C_5H_8)$. The ^1H and ^{13}C NMR spectra alerted us to the presence of a propyl unit, a vinylic moiety, and two nonequivalent (cyclopentadienyl)manganese(dicarbonyl) fragments, suggesting the bridged vinylidene structure **23**. This assignment was confirmed by X-ray crystallography; the resulting structure is depicted in Fig. 3 and compares favorably with those of previously reported $[(C_5H_5)Mn(CO)_2]_2(\mu\text{-}C{=}CHR)$ systems where R is H, Ph, CHO, or $CH(OCH_2CH_2CH_2O)$ (33). Ultimately, repeated attempts to generate the hexaarylated derivative **22**, even under a variety of conditions, were unsuccessful, presumably because of steric restrictions.

© 2002 NRC Canada

Scheme 5. Attempted trimerization of 1,3-dihydro-2H-cyclopenta[*l*]phenanthren-2-one, **18**.

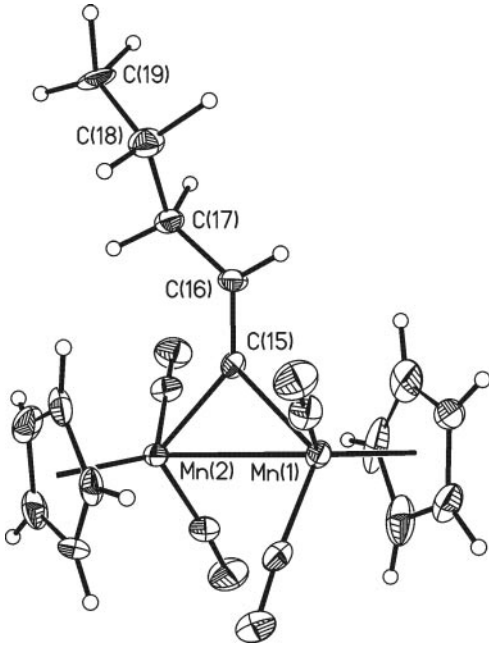


The proposed mechanism for the formation of **23** is shown in Scheme 7 and is suggested to proceed via nucleophilic attack on a carbonyl ligand by the *n*-butyl anion, formation of the organometallic ester **24**, proton abstraction by excess base, and elimination of phenylacetate to produce the vinylidene complex **25**. Vinylidene systems, $RCH{=}C{=}ML_n$, are normally generated either via rearrangement of a coordinated terminal alkyne complex or by the electrophilic protonation or alkylation of the α-carbon atom of an alkynylmetal complex (34). It has already been shown that such monometallic systems react with $(C_5H_5)Mn(CO)_3$ to yield bridged vinylidene species (33). This route to such systems is reminiscent of Hughes' report of the synthesis of $[(C_5H_5)Mn(CO)_2]_2(\mu\text{-}C{=}CH_2)$ by treatment of $(C_5H_5)Mn(CO)_3$ successively with methyllithium, triflic anhydride, and Proton-Sponge (35).

Experimental

All reactions involving organometallic reagents were performed under an atmosphere of dry nitrogen utilizing conventional benchtop and glovebag techniques. Solvents were dried and distilled according to standard procedures (36). Acetyl ferrocene, cymantrene, and phenacetyl chloride were purchased from either Aldrich Chemical Co., Inc. (Milwaukee, Wisconsin) or Strem Chemicals Inc. (Newburyport, MA.) and used as received. Silica gel (particle size 20–45 μm) was employed for flash column chromatography. ^{1}H and ^{13}C NMR spectra were acquired on Bruker AC 300 or AC 200 spectrometers and were referenced to the residual proton or ^{13}C solvent signal, respectively. Direct

Fig. 3. Molecular structure of **23** (30% thermal ellipsoids) depicting the atom numbering scheme.



electron impact (DEI) and direct chemical ionization (DCI) mass spectra were obtained by use of a Finnigan 4500 spectrometer. Infrared spectra were recorded on a Bio-Rad FTS-40 spectrometer. Melting points (uncorrected) were recorded on a Thomas–Hoover melting point apparatus.

Preparation of 1,3-diferrocenyl-2-buten-1-one (9)

To a solution of acetylferrocene (835 mg, 3.66 mmol) dissolved in dry ethanol (25 mL) was slowly added tetrachlorosilane (0.9 mL). The resulting mixture, which was observed to change from a transparent orange to a dark murky purple, was subsequently stirred at room temperature overnight. After quenching with water (10 mL), extracting with dichloromethane (3 × 30 mL), and drying over $CaCl_2$, the residue was chromatographed with 70:30 ethyl acetate – hexanes. The first fraction to elute was 1,3-diferrocenyl-2-buten-1-one, **9** (625 mg, 1.43 mmol, 78%); mp 119–121°C (lit. (37) value mp 118–120°C). IR (KBr) (cm^{-1}): 1633 ($\nu_{C=O}$), 1584 ($\nu_{C=C}$). ^{1}H NMR (200 MHz, CD_2Cl_2) δ: 6.75 (s, 1H), 4.81 (m, 2H), 4.64 (m, 2H), 4.51 (m, 2H), 4.45 (m, 2H), 4.24 (s, 5H), 4.20 (s, 5H), 2.55 (s, 3H). ^{13}C NMR (50 MHz, CD_2Cl_2) δ: 194.8 (C=O), 153.8 (C_5H_5), 119.7 (=*C*H), 86.4 (=*C*-CH_3), 83.6 (Cp C), 72.5, 71.1, 70.4, 70.3 (Cp *C*H's), 69.9, 67.6 (C_5H_5's), 18.9 (=C-*C*H_3). LR-MS (DEI) *m*/*z* (%): 438 ([M$^+$], 100), 373 ([M – C_5H_5]$^+$, 21), 121 ([C_5H_5Fe]$^+$, 57). LR-MS (DCI) *m*/*z* (%): 439 ([M + H]$^+$, 100).

Preparation of 1,3,5-triferrocenylbenzene (10)

To a solution of acetylferrocene (2.00 g, 8.77 mmol) dissolved in dry ethanol (25 mL) was slowly added tetrachlorosilane (4 mL). Upon addition of this reagent, the mixture was observed to change from a transparent orange to a dark murky purple and was stirred at room temperature overnight. After quenching with water (15 mL), extraction with dichloromethane (3 × 30 mL), and drying over $CaCl_2$, the residue was chromatographed with 50:50 dichloromethane–

Preparation of 1,3-dicymantrenyl-2-buten-1-one (12) and 1,3,5-tricymantrenylbenzene (13)

Following the dissolution of (acetylcyclopentadienyl)tricarbonylmanganese (30) (835 mg, 3.39 mmol) in ethanol (20 mL) and the addition of tetrachlorosilane (0.8 mL), the resulting mixture was stirred at room temperature overnight. After addition of water (10 mL), extraction with dichloromethane, and drying over $CaCl_2$, the residue was flash chromatographed with 50:50 CH_2Cl_2–MeOH. The first fraction to elute was 1,3,5-tricymantrenylbenzene, **13** (396 mg, 0.58 mmol, 51%), obtainable as yellow crystals (from dichloromethane–hexane); mp 198°C. IR (CH_2Cl_2) (cm^{-1}): 2024, 1940 (ν_{CO}). ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.24 (s, 3H), 5.22 (m, 6H), 4.82 (m, 6H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 224.4 (Mn-CO's), 134.3 (Ar C's), 123.7 (Ar CH's), 101.4 (Cp C), 82.4, 81.9 (Cp CH's). LR-MS (DEI) *m/z* (%): 684 ([M]$^+$, 14), 600 ([M – 3CO]$^+$, 21), 516 ([M – 6CO]$^+$, 10), 432 ([M – 9CO]$^+$, 20), 377 ([M – Mn – 9CO]$^+$, 43), 322 ([M – 2Mn – 9CO]$^+$, 47), 267 ([M – 3Mn – 9CO]$^+$, 85), 265 (100). Anal. calcd. for $C_{30}H_{15}Mn_3O_9$: C 52.63, H 2.19%; found: C 52.31, H 2.44%.

The second fraction to elute was 1,3-dicymantrenyl-2-buten-1-one, **12** (96 mg, 0.20 mmol, 12%), as a yellow oil. IR (CH_2Cl_2) (cm^{-1}): 2032, 1939 (ν_{CO}). ^{1}H NMR (200 MHz, $CDCl_3$) δ: 6.51 (s, 1H, =CH), 5.44 (m, 2H), 5.18 (m, 2H), 4.83 (m, 4H) (Cp H's), 2.33 (s, 3H, CH_3). LR-MS (DEI) *m/z* (%): 474 ([M]$^+$, 6), 390 ([M – 3CO]$^+$, 29), 336 (13), 306 ([M – 6CO]$^+$, 100), 252 (76), 120 ([C_5H_5Mn]$^+$, 54), 55 ([Mn]$^+$, 100).

Reaction of ketone 18 with tetrachlorosilane and ethanol

To a solution of 1,3-dihydro-2H-cyclopenta[*l*]phenanthren-2-one, **18** (28) (276 mg, 1.19 mmol), dissolved in

ethanol (10 mL) was added tetrachlorosilane (0.5 mL) and the mixture stirred at room temperature overnight. After addition of water (10 mL), extraction with dichloromethane, and drying over $CaCl_2$, the residue was flash chromatographed with 50:50 CH_2Cl_2–MeOH to yield an unidentified purple compound (130 mg) and a pale yellow material, **19** (95 mg, 0.21 mmol, 36%). Repeated chromatographic separations finally yielded crystals of moderate quality that were subsequently identified by an X-ray diffraction experiment.

Reaction of cymantrene with butyllithium and phenacetyl chloride

Cymantrene (1.02 g, 5.0 mmol) was treated with *n*-butyllithium (3.75 mL of a 1.6 M solution) at –78°C and allowed to warm to 0°C over a period of several hours. Phenacetyl chloride (0.9 mL) was added and the solution stirred overnight before being quenched with water, extracted with dichloromethane, and chromatographed over silica gel to give purple–red crystals of **23** (462 mg, 1.1 mmol, 44%). IR (CH_2Cl_2) (cm^{-1}): 2024 (w), 1977 (m), 1939 (s), 1913 (s) (ν_{CO}). ^1H NMR (200 MHz, $CDCl_3$) δ: 7.63 (s, 1H, =CH), 5.33 (s, 5H), 5.30 (s, 5H), 3.22 (m, 2H), 2.26 (m, 2H), 1.72 (t, 3H). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 145.1 (C=*C*H), 88.7, 87.9 (Cp *C*H's), 40.3 (*C*H_2), 24.3 (*C*H_2), 14.3 (*C*H_3). LR-MS (DEI) *m*/*z* (%): 420 ($[M]^+$, 5), 364 ($[M - 2CO]^+$, 8), 308 ($[M - 4CO]^+$, 27), 240 ($[C_{10}H_{10}Mn_2]^+$, 42), 185 ($[C_{10}H_{10}Mn]^+$, 85), 120 ($[C_5H_5Mn]^+$, 100), 55 ($[Mn]^+$, 52). Anal. calcd. for $C_{19}H_{18}Mn_2O_4$: C 54.29, H 4.29%; found: C 54.62, H 4.51%.

X-ray crystal structure determinations of 13, 19, and 23

X-ray crystallographic data[2] were collected from single crystal samples of **13** (0.22 × 0.14 × 0.04 mm^3), **19** (0.24 × 0.22 × 0.05 mm^3), and **23** (0.25 × 0.15 × 0.10 mm^3) mounted on glass fibers. Data were collected using a P4 Bruker diffractometer equipped with a Bruker SMART 1K charge coupled device (CCD) area detector using the program SMART (38) and a rotating anode using graphite-monochromated Mo Kα radiation (λ = 0.71073 Å). The crystal-to-detector distance was 4.987 cm for all samples and the data collection was carried out in 512 × 512 pixel mode utilizing 2 × 2 pixel binning. The initial unit cell parameters were determined by a least-squares fit of the angular settings of the strong reflections collected by a 12 scan in 40 frames over three different sections of reciprocal space (120 frames in total). A hemisphere of data was collected with high redundancy to better than 0.8 Å resolution for **23** (at 195 K), whereas only 1.00 Å resolution was obtainable for **13** and **19** (at 299 and 293 K, respectively). Data reduction was carried out using the program SAINT (39), which applied Lorentz and polarization corrections to the three-dimensionally integrated diffraction spots. The program SADABS (40) was utilized for the scaling of diffraction data, the application of a decay correction, and an empirical absorption correction based on redundant reflections. Structures **13** and **23** were solved by use of the direct-methods procedure in the Bruker SHELXTL program library (41) followed by full-matrix least-squares refinement on F^2 with anisotropic thermal parameters for all nonhydrogen atoms in **23** and only Mn1, Mn2, and Mn3 in **13**. All hydrogen atoms in **13** and **19** and only H1, H6, H7, H8, H9, H10A, and H16A in **23** were added as fixed contributors at calculated positions with isotropic thermal parameters (based on the carbon atom to which they were bonded), whereas the remaining hydrogen atoms in **23** were determined from the least-squares map. Partial decomposition of the crystal sample resulted in poor data quality and hence incomplete refinement of structure **19**.[3]

Conclusion

To conclude, it has been demonstrated that the ethanol–tetrachlorosilane-mediated trimerization of acetyl-organometallics is a convenient and directed route to 1,3,5-trisubstituted arenes. Future reports will detail the preparation of mixed compounds bearing both organic (alkyl, aryl) and organometallic addenda by treatment of dimetallic condensation products, such as **9** or **12**, with a variety of methyl ketones. It is anticipated that the functional versatility of these angular building units will render them ideally suitable to the construction of macro- and supramolecular structures of various sizes and shapes using covalent and noncovalent linkages.

Synthesis of a PennPhos–ruthenium(II) complex: The first crystal structure of a PennPhos–metal complex

Okwado M. Akotsi, Robert McDonald, and Steven H. Bergens

Abstract: The chiral bis(phosphine) ligand *P,P′*-1,2-phenylenebis[(1*R*,2*S*,4*R*,5*S*)-2,5-dimethyl-7-phosphabicyclo-[2.2.1]heptane], [(*R*,*S*,*R*,*S*)-Me-PennPhos] (**1**) reacts with *trans*-$RuCl_2(NBD)Py_2$ (NBD = norbornadiene, Py = pyridine) (**2**) in CH_2Cl_2 at 45°C to form two diastereomers of the triply chloride bridged cation $[\{(\mathbf{1})RuPy\}_2(\mu\text{-}Cl)_3)][Cl^-]$ (**3**) in the ratio 1:3. The isomers were studied by NMR spectroscopy and separated by crystallization from CD_2Cl_2–hexanes mixture. The major diastereomer is one of the *anti*-diastereomers and contains face-sharing bioctahedral diruthenium (Ru(II, II)) molecules with a Ru—Ru distance of 3.289 Å. This diastereomer crystallizes in the monoclinic space group *C*2 (No. 5) with the cell dimensions *a*(Å) = 28.102(2), *b*(Å) = 20.5344(15), *c*(Å) = 12.7692(10), β(°) = 95.7411(16), *V*(Å^3) = 7331.6(9), and *Z* = 4. The Me-PennPhos ligand adopts an unexpected bent, non-*C*2 symmetric conformation upon coordination to ruthenium.

Key words: PennPhos crystal structure, diruthenium complexes, triply bridged complexes, bisphosphine ruthenium complexes.

Résumé : Le ligand chiral bis(phosphine), *P,P′*-1,2-phénylènebis[(1*R*,2*S*,4*R*,5*S*)-2,5-diméthyl-7-phosphabicyclo-[2.2.1]heptane], [(*R,S,R,S*)-Me-PennPhos] (**1**) réagit avec le *trans*-$RuCl_2(NBD)Py_2$ (NBD = norbornadiène; Py = pyridine) (**2**), dans le CH_2Cl_2, à 45°C, pour former deux diastéréomères du cation triplement ponté par des ions chlorures $[\{(\mathbf{1})RuPy\}_2(\mu\text{-}Cl)_3)][Cl^-]$ (**3**) dans un rapport de 1:3. Les isomères ont été étudiés par spectroscopie RMN et séparés par cristallisation à partir de mélanges CD_2Cl_2–hexane. Le diastéréomère principal est l'un des diastéréomères *anti*- et comporte des molécules de diruthénium (Ru(II, II)) bioctaédriques qui se partagent les faces avec une distance Ru—Ru de 3,289 Å. Ce diastéréomère cristallise dans le groupe d'espace monoclinique *C*2 (No. 5), avec *a* = 28,102(2), *b* = 20,5344(15) et *c* = 12,7692(10) Å, β = 95,7411(16)°, *V* = 7331,6(9) Å^3 et *Z* = 4. Lors de sa coordination au ruthénium, le ligand Me-PennPhos adopte une conformation symétrique non *C*2 avec une courbure inattendue.

Mots clés : structure cristalline PennPhos, complexes de diruthénium, complexes triplement pontés, complexes du ruthénium avec une bisphosphine.

[Traduit par la Rédaction]

Introduction

Complexes of ruthenium(II) and chiral bis(phosphines) are the most successful catalyst systems for the enantioselective hydrogenation of prochiral olefins and ketones (1, 2). We recently reported a versatile procedure to synthesize ruthenium–bis(phosphine) catalyst precursors that compliment the existing procedures in the literature (3). We showed that most common chiral bis(phosphine) ligands react with the complex *trans*-$RuCl_2(NBD)Py_2$ (NBD = norbornadiene, Py = pyridine) (**2**) to generate in high yields the crystalline complexes *trans*-$RuCl_2(P\text{-}P^*)Py_2$ (P-P* is the corresponding chiral bis(phosphine)). Examples of *trans*-$RuCl_2(P\text{-}P)Py_2$ and similar compounds have been reported previously by the James group (4). We found that these complexes are active enantioselective hydrogenation catalysts for keto esters and for noncarboxylic olefins in presence of small amounts of HBF_4(aq) (3). Further, reaction of these complexes with 1,2-diphenylethylenediamine (N-N*, either enantiomer) forms in good yields (3) the corresponding compounds developed by Noyori and co-workers (1, 2), *trans*-$RuCl_2(P\text{-}P^*)(N\text{-}N^*)$, which are well-known, extremely active, and selective enantioselective hydrogenation catalysts for simple ketones.

Zhang and co-workers (5) recently reported a rhodium catalyst system containing their ligand *P,P′*-1,2-phenylenebis[{(1*R*,2*S*,4*R*,5*S*)-2,5-dimethyl}-7-phosphabicyclo-[2.2.1]heptane] ([(*R*,*S*,*R*,*S*)-Me-PennPhos] (**1**)) that has achieved the highest enantioselectivities for the hydrogenation

of simple dialkyl ketones. We now report that **1** reacts with the ruthenium precursor **2**, not to form the monomeric dichlorides obtained with most common chiral bisphosphine ligands but rather to form cationic triply chloride bridged dimers. Further, the ligand unexpectedly adopts a bent, non-*C*2 symmetric geometry upon coordination to ruthenium. This is the first reported crystal structure of a PennPhos–metal complex.

Materials and methods

Instrumentation

All ^{1}H and ^{31}P NMR spectra were measured on a Bruker AM-400 spectrometer operating at 400.13 and 161.97 MHz, respectively, or on a Bruker AM-200 spectrometer operating at 200.13 and 80.02 MHz, respectively. ^{1}H NMR chemical shifts are reported in parts per million (δ) relative to tetramethylsilane using solvent as an internal reference. ^{31}P NMR chemical shifts are reported in parts per million (δ) relative to an 85% H_3PO_4 external reference.

Reagents and solvents

The solvents and reagents, *n*-hexanes (K, Ph_2CO), methylene chloride-d_2 (CaH_2), and pyridine (CaH_2) were distilled from drying agents under argon. The argon gas was passed through a bed of Drierite drying agent. Compound **2** was prepared by a published procedure (3).

General methods

Unless stated otherwise, all manipulations were carried out in oven-dried glassware using standard air-sensitive techniques.

[{Ru(Me-PennPhos)Py}$_2$(μ-Cl)$_3$][Cl$^-$] (3)

17.0 mg (0.0474 mmol) of **1** and 20.03 mg (0.0474 mmol) of **2** were weighed in air and charged into an NMR tube. The tube was sealed with a rubber septum and the contents flushed with dinitrogen gas. Zero point five mL of dry degassed methylene chloride-d_2 was added to the tube by cannula and the tube shaken to dissolve the solids. The septum was further wrapped with paraffin film to attach it firmly onto the tube. NMR spectroscopy showed that the reaction was ~70% complete after 20 h at room temperature. The reaction was complete in less than 16 h when carried out at 45°C. The original orange–brown solution of the starting materials gradually turns yellow during this period.

Separation of diastereomers

An NMR tube containing the CD_2Cl_2 reaction mixture was cooled to –78°C (with dry-ice – acetone) and layered with hexanes that were added slowly and dropwise to ensure that the drops flowing down the walls of the tube were cooled before coming into contact with the reaction mixture. The tube was then carefully removed from the cold bath and stored for 5 days at 8°C. The major diastereomer of *anti*-**3** formed as yellow crystals suitable for X-ray analysis. The other isomer of **3** remained in solution. The crystals were recovered by filtration using a cannula with filter paper. NMR spectroscopy showed that the crystals contained only the major *anti*-diastereomer **3**.

NMR data for 3

Isolated major anti-isomer

^{1}H NMR (400 MHz, CD_2Cl_2) δ: 8.25 (m, 4H, Ar), 7.26 (m, 6H, Ar), 6.63 (m, 8H, Ar), 2.98 (d, 2H, $^2J_{PH}$ = 10 Hz, PC*H*), 2.85–2.75 (br m, 4H, PC*H*), 2.52 (d, 2H, $^2J_{PH}$ = 10 Hz, PC*H*), 2.43–1.66 (br m, 12H), 1.51 (d, 6H, $^3J_{HH}$ = 9 Hz, CH_3), 1.46 (d, 6H, $^3J_{HH}$ = 9 Hz, CH_3), 0.76 (d, 6H, $^3J_{HH}$ = 7 Hz, CH_3), and 0.62 (d, 6H, $^3J_{HH}$ = 7 Hz, CH_3). ^{31}P NMR (162 MHz, CD_2Cl_2) δ: 82.8 (d, $^2J_{pp}$ = 32 Hz) and 68.7 (d, $^2J_{pp}$ = 32 Hz).

Minor isomer [3]

^{1}H NMR (400 MHz, CD_2Cl_2) δ: 8.46 (m, 4H, Ar), 7.71–7.35 (br m, 6H, Ar), 7.05 (m, 8H, Ar), 2.75–2.68 (m, 4H, PC*H*), 2.43 (d, 2H, $^2J_{PH}$ = 18 Hz, PC*H*), 2.33–2.15 (br m, 12H), 1.15 (d, 6H, $^3J_{HH}$ = 7 Hz, CH_3), 1.02 (d, 6H, $^3J_{HH}$ = 7 Hz, CH_3), 0.67 (d, 6H, $^3J_{HH}$ = 7 Hz, CH_3), and 0.57 (d, 6H, $^3J_{HH}$ = 7 Hz, CH_3). ^{31}P NMR (162 MHz, CD_2Cl_2) δ: 87.9 (d, $^2J_{pp}$ = 32 Hz) and 62.7 (d, $^2J_{pp}$ = 32 Hz).

X-ray crystallographic studies

Yellow crystals of the major diastereomer of *anti*-**3**·3CD_2Cl_2 were obtained from slow diffusion of hexanes into CD_2Cl_2 as described above. Data were collected on a Bruker P4/RA/SMART 1000 CCD diffractometer[4] using Mo Kα radiation at –80°C. Unit cell parameters were obtained from a least-squares refinement of the setting angles of 5574 reflections from the data collection. The monoclinic diffraction symmetry and systematic absences indicated the space group to be *C*2 (No. 5). The data were corrected for absorption through use of the SADABS (6) procedure. See Table 1 for a summary of crystal data and X-ray data collection information.[5] The structure of the compound was solved using the DIRDIF-96 program system (7), and refinement was completed using the program SHELXL-93 (8). Hydrogen atoms were assigned positions based on the geometries of their attached carbon atoms and were given thermal parameters 20% greater than those of the attached carbons.

Distance restraints were employed to impose an idealized geometry upon one of the solvent CH_2Cl_2 molecules: *d*(Cl(6S)–C(4S)) = *d*(Cl(6S)–C(4S)) = 1.80 Å, *d*(Cl(6S)···Cl(7S)) = 2.95 Å. The final model for the compound refined to values of $R_1(F)$ = 0.0639 (for 8806 data with $F_o \geq 2\sigma(F_o^2)$) and $wR_2(F^2)$ = 0.1993 (for all 12 330 independent data).

[3] NMR data for **3** (minor isomer) were assigned from the spectra of the mixture of the two isomers.

[4] Programs for diffractometer operation, data collection, data reduction, and absorption correction were those supplied by Bruker.

Results and discussion

(*R*,*S*,*R*,*S*)-Me-PennPhos (**1**) reacts cleanly with **2** to generate two diastereomers of the triply chloride bridged cationic dimer **3**, as illustrated in Scheme 1. Related monocationic dimers containing nitrile ligands and mono- or bidentate phosphine ligands have been reported by James and coworkers (4*b*, 9). At room temperature, this reaction proceeds to give two diastereomers of **3** in the ratio ~2:3. The ratio of diastereomers formed is dependent on the reaction temperature. If the reaction is carried out at 45°C, the minor diastereomer formed at room temperature is then formed as the major diastereomer in the ratio ~3:1. The major diastereomer formed at 45°C was identified as one of the *anti*-diastereomers by X-ray diffraction vide infra. If made at room temperature, the ratio of diastereomers (~2:3) converts to the limiting ratio (~3:1) upon heating the reaction mixture at 45°C overnight. These observations suggest that the major diastereomer formed at room temperature is a kinetic product that is thermodynamically less stable than the other formed diastereomer. Further, it appears that the diastereomers interconvert slowly at 45°C. Similar interconversions

Fig. 1. Perspective view (ORTEP) of the major diastereomer of the cation *anti*-**3** (20%) thermal ellipsoids showing the atom-labeling scheme. Hydrogen atoms have been omitted for clarity. The Cl^- counter ion is also not shown.

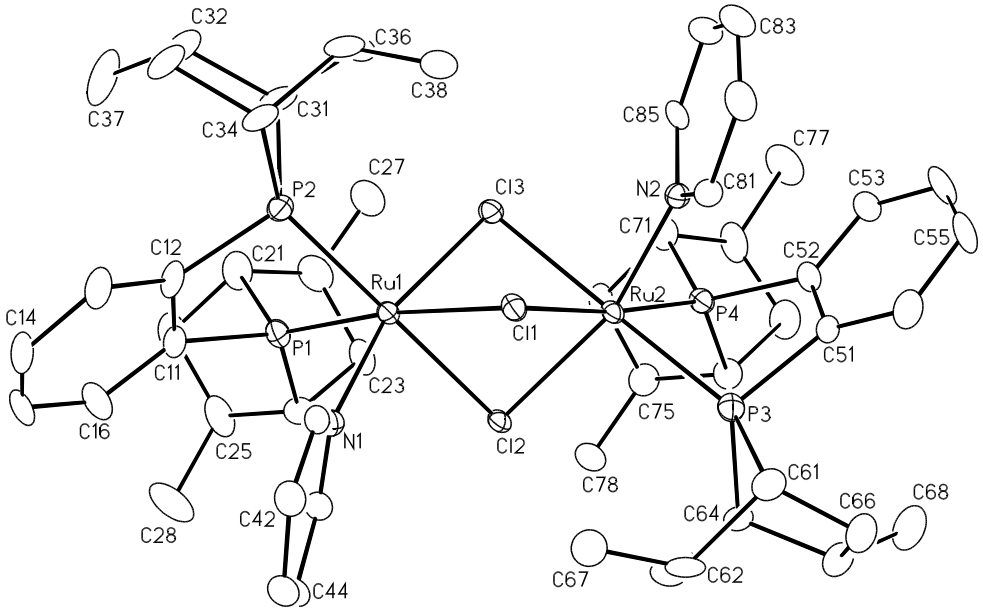

Fig. 2. Spatial distribution within the unit cell of the major *anti*-diastereomer of **3**.

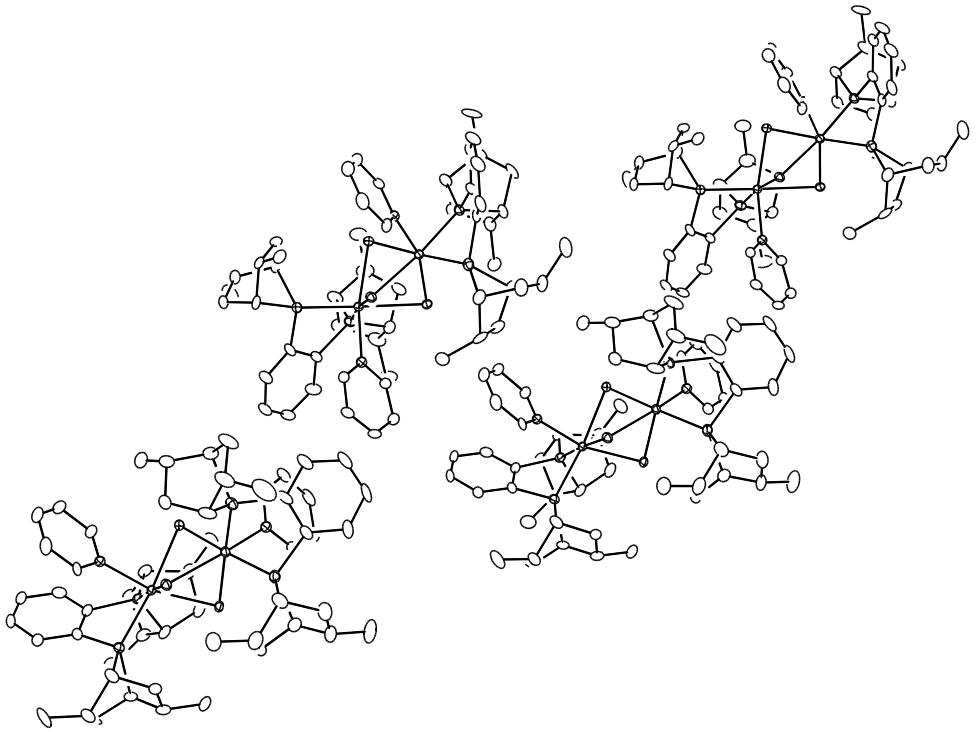

have been observed, for example, with ruthenium bis(phosphine) complexes such as $RuCl_2(dppb)(L)_2$ (dppb = 1,4-bis(diphenylphosphino)butane, L = NH_3, py, 4-NH_2Py, 4-CNPy, 4-MePy, PhPy) (4*b*, 4*c*, 10).

The ^{31}P spectrum of the minor diastereomer of **3** formed at 45°C exhibits an AB pattern with two doublets at $\delta = 87.9$ and $\delta = 62.7$. The major *anti*-diastereomer shows a similar pattern but with peaks at $\delta = 82.8$ and $\delta = 68.7$. There are three possible diastereomers of **3**, two with *anti* relative orientations of the Py rings and one with a *syn* relative orientation.

Scheme 1 shows the *syn*- and the two *anti*-diastereomers. A similar situation was observed by James and co-workers (4*b*, 10) for other Ru(II) triply chloride bridged dimers. As all three diastereomers of **3** have twofold rotation axes, NMR spectroscopy could not be used to distinguish between them.

The dimeric structure of **3** and the identity of the major diastereomer formed at 45°C were confirmed by X-ray crystal studies. Yellow crystals of major *anti*-**3** were obtained upon crystallization by layering hexanes onto a CH_2Cl_2 solution of **3**. Dissolution at low temperature in CD_2Cl_2 and NMR spectroscopy confirmed that these crystals are of the major diastereomer formed at 45°C. The compound crystallizes with three molecules of CD_2Cl_2 per molecule of complex. The structure formed is a distorted octahedral configuration in which the Ru center is surrounded in the equatorial plane by two P atoms and two Cl atoms. The apical positions are occupied by Cl on one side and Py on the other as shown in Fig. 1. There are four molecules of **3** per unit cell arranged as shown in Fig. 2.

The structure of **3** is a triply bridged diruthenium(II, II) face-sharing bioctahedral. Similar X-ray structures for Ru(II, II) dinuclear species have been reported with bis(phosphine) (4*d*, 10) or monophosphine (11) ligands coordinated to the metal center. The Ru—Ru internuclear distance obtained for this compound was 3.289 Å, a distance much longer than a typical Ru—Ru single bond (2.632–3.034 Å) (12). The Ru—Ru distance in this compound is, however, within the range expected for diruthenium complexes with triply bridging Cl atoms. Some examples and their respective Ru—Ru distances are as follows: $[H_2NEt_2][Ru_2Cl_5((R)$-*p*-MeO-BINAP$)_2]$, 3.3 Å (13); $[(\eta^2\text{-}H_2)(dppb)Ru(\mu\text{-}Cl)_3RuCl(dppb)]$, 3.278 Å (4*d*); $[Ru_2Cl_3(PBu_3)_6][BPh_4]$, 3.39 Å (11). The Ru—Cl and Ru—N distances fall within the expected ranges for such Ru(II) complexes (4*a*, 4*c*, 4*e*, 14, 15). Table 2 lists the interatomic distances within major *anti*-**3**.

© 2002 NRC Canada

Table 3 lists some selected interatomic angles for major *anti*-**3**. Of interest is the marked contraction of the Cl-Ru-Cl angle (average 80.9°) from the expected 90° for a regular octahedral. This contraction has been explained by Cotton and Torralba (11) to result from repulsive forces between the two d^6 Ru(II) centers in the molecule with consequent increase in Ru—Ru internuclear distance. The increased Ru—Ru internuclear distances result in contraction of the Cl-Ru-Cl bond angles and expansion of the Ru-Cl-Ru angles. The average value for angles obtained in this compound, 80.9° for Cl-Ru-Cl and 83.6° for Ru-Cl-Ru, fall within the expected respective ranges (77.2–80.9 and 82.9–87.9°) for this type of complex (4*d*, 10, 11, 13).

Unexpectedly, the PennPhos P–aryl–P plane was tilted relative to the P–Ru–P plane. This tilt removes the *C*2 dissymmetry of the ligand. While it is not known whether this tilting is typical of PennPhos compounds, we note that Zhang and co-workers (5) observed that the ^{31}P NMR spectrum of [Rh(**1**)(COD)]$^+$ contained two sets of signals for the phosphorus centers, showing that they were inequivalent. A possible explanation put forward by Zhang and co-workers (5*a*) was that the phosphabicyclo[2.2.1]heptane groups are too bulky to allow the PennPhos to adopt a planar, *C*2-symmetric geometry. The results obtained in the present work appear to confirm this explanation.

Conclusions

The work presented in this paper further illustrates the versatility of compound **2** as a starting material for synthesis of various Ru–bis(phosphine) complexes. The reported crystal structure is the first of a metal complex containing the PennPhos ligand. The formation of dimers upon reaction of **2** with PennPhos rather than the monomeric species formed with most common chiral bis(phosphine) ligands (3) illustrates how the structure of the chiral bis(phosphine) ligand can have unexpected consequences on the structures of their metal complexes. In this case, two methyl groups of PennPhos (in this case, C38 and C27 as well as C67 and C78 of major *anti*-**3**) project into the spatial domain occupied by other ligands on the ruthenium center (5). We propose that it is this projection that favors formation of the cationic dimers **3** rather than the corresponding monomeric bis(pyridine) complex *trans*-$RuCl_2$(PennPhos)Py_2. Inspection of molecular models and the solid-state structure of major *anti*-**3** shows that the methyl groups (e.g., C67 and C38) in *trans*-$RuCl_2$(PennPhos)Py_2 would protrude into the spatial domain occupied by the Py ligands (3, 4*c*). No such steric congestion is present in major *anti*-**3**. Further, since we have shown previously (3) that reaction of (*R*,*R*)-Me-DUPHOS ((–)-1,2-bis((2*R*,5*R*)-2,5-dimethylphospholano)benzene) with **2** generates the monomeric complex *trans*-$RuCl_2$((*R*,*R*)-Me-DUPHOS)Py_2, the present results indicate that it is more the steric requirements and less the electronic requirements of PennPhos that govern formation of the cationic dimers **3**.

Acknowledgements

We thank the Natural Sciences and Engineering Research Council of Canada (NSERC) and the University of Alberta for financial support. We would also like to sincerely thank Prof. Xumu Zhang of the Department of Chemistry, Pennsylvania State University, for his generous donation of the Me-PennPhos used in this work.

Palladium and platinum complexes of L-PhePhos: Acetyl-*p*-(diphenylphosphino)-L-phenylalanine methyl ester — a chiral ligand for transition metal complexation

Vineeth Iyengar, Patrycja V. Galka, Andreas Pletsch, and Heinz-Bernhard Kraatz

Abstract: The crystal structure of the new phenylalanine-based phosphino amino acid L-PhePhos and its reactivity to form the Pd and Pt complexes (L-PhePhos)$PdCl_2$ and (L-PhePhos)$PtCl_2$ is reported. A new platinum hydride was quantitatively formed in the reaction of (L-PhePhos)$PtCl_2$ with $NaBH_4$.

Key words: phosphine, amino acid, hydride, platinum, palladium, structure.

Résumé : On a déterminé la structure cristalline d'un nouvel acide phosphino-aminé à base de phénylalanine, L-PhePhos, on a déterminé sa réactivité à former des complexes de Pd et de Pt, (L-PhePhos)$PdCl_2$ et (L-PhePhos)$PtCl_2$. Un nouvel hydrure du platine se forme quantitativement par réaction du (L-PhePhos)$PtCl_2$ avec le $NaBH_4$.

Mots clés : phosphine, acide aminé, hydrure, platine, palladium, structure.

[Traduit par la Rédaction]

Introduction

Phosphines have proven extremely versatile ligands for a wide range of transition metal catalyzed transformations (1, 2). Chiral phosphines such as the bidentate DIOP, DUPHOS, and others coordinated to late transition metals have allowed asymmetric transformations with high product yield and high enantiomeric excess (3). Despite the success, even commercial success, of many of these chiral phosphine ligands as part of a catalyst, the potential for discovering ligands that result in a more active and more selective catalyst is continuing to fuel interest in the design of novel P-based ligands. In particular, effective and stable chiral ligands that do not require expensive chiral precursors or a laborious multistep reaction are desirable.

In this regard, phosphine-based amino acids offer an exciting opportunity to synthesize both enantiomers of a particular phosphine ligand. Inexpensive optically pure amino acids have been converted to chiral phosphino ligands and have been employed in the laboratory in numerous asymmetric catalytic systems. Chiral phosphine, aminophosphine, and phosphinito ligands based on hydroxyproline (4) have been used for the hydrocarbonylation and hydrogenation of olefins. Recently, Gilbertson reported examples of helical peptides carrying phosphino amino acid donors and described their catalytic behaviour (5).

We recently reported the facile synthesis of enantiomerically pure L-PhePhos, a chiral triphenylphosphine analogue (Scheme 1) (6), by a Pd-catalyzed P–C cross-coupling reaction of L-*p*-iodophenylalanine with Ph_2PH. As part of our ongoing research aimed at exploring the use of P-modified peptides as chiral ligands for transition metal coordination and catalysis, we now report the crystal structure of this new phosphine ligand and our first results of its Pt and Pd coordination chemistry.

Received 2 February 2002. Published on the NRC Research Press Web site at http://canjchem.nrc.ca on 26 November 2002.

Results and discussion

Structure of L-PhePhos

We recently reported the preparation of enantiopure and reasonably airstable L-PhePhos (**1**), a new phosphine amino acid ligand, which has a PPh_2 group attached to the phenyl ring of phenylalanine. The ORTEP plot of compound **1** is shown in Fig. 1(*a*). The P atom in compound **1** exhibits trigonal pyramidal coordination, with both phenyl substituents and the phenyl ring of L-Phe adopting a propeller-like arrangement about the P atom, similar to that in triphenylphosphine (7). Bond distances and angles in L-PhePhos also compare well with those reported by Dunne and Orpen for PPh_3 (7). The average P—C bond length is 1.818 Å (1 Å = 0.1 nm), falling slightly short of the 1.831 Å reported for PPh_3. The C-P-C angle separating the two PPh_2 rings is 103.5°. In the solid state, individual molecules of **1** orient themselves in alternating "up–down–up–down" positions, which aligns their amino acid termini and allows strong N–H···O=CH bonding between adjacent molecules. This results in the formation of linear H-bonded chains, in which the H-bonding distance d(N···O) was found to be 2.867(2) Å

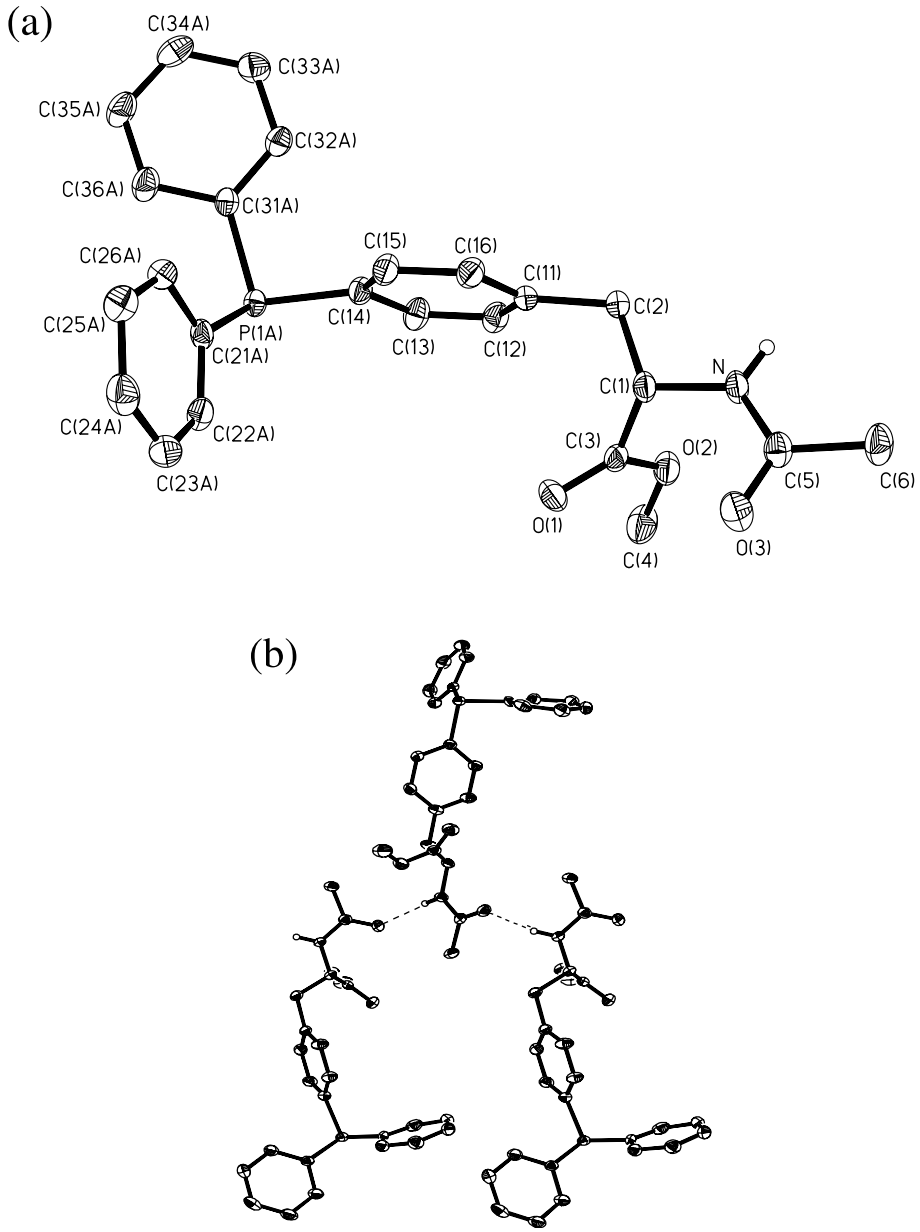
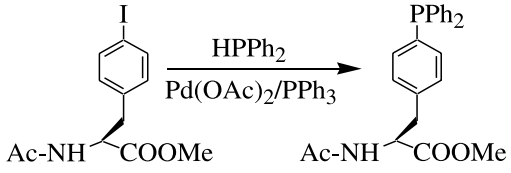
Fig. 1. (*a*) ORTEP diagram of L-PhePhos (**1**) at the 30% probability level. Hydrogen atoms have been omitted for clarity. Selected bond distances: P(1A)—C(21A) = 1.838(11) Å, P(1A)—C(31A) = 1.809(5) Å, P(1A)—C(14) = 1.872(4) Å, C(31A)-P(1A)-C(21A) = 104.7°, C(31A)-P(1A)-C(14) = 101.00(19)°, C(21A)-P(1A)-C(14) = 101.0(4)°. (*b*) Hydrogen-bonding interaction of L-PhePhos molecules d(N···O) = 2.867(2) Å.



Scheme 1. Synthesis of L-PhePhos (**1**) by Pd-catalyzed P–C cross-coupling (6).



(Fig. 1*b*). The H-bonded region is flanked on either side by aromatic phosphine residues of the Ph_3P portion of adjacent amino acids. The aromatic groups of individual one-dimensional chains are pointing towards each other (Fig. 2). The H-bonded chains are stacked 14.5 Å apart, separated by the aromatic phosphine residues. There is no H bonding between adjacent H-bonded planes.

^{1}H NMR resonances of protons involved in H bonding, such as the amide NH in compound **1**, experience upfield shifts as H-bonding strength decreases. Variable temperature (VT) ^{1}H NMR is the tool of choice for evaluating H bonding in solution and has been used before to evaluate the interaction between peptides (8). At high temperatures, H bonding between molecules generally decreases, resulting in a shift closer to the "unperturbed" non-H-bonded signal. To evaluate H bonding in solution, a VT NMR study in $CDCl_3$, a nonpolar solvent widely used to evaluate weak H-bonding interactions, was carried out over a temperature range of

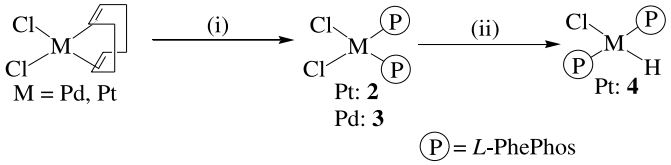
35 K (293–320 K). $CDCl_3$ was chosen as solvent. Absolute NMR shifts larger than 4–5 ppb K^{-1} suggest the presence of H bonding (8). Interestingly, the NH signal of **1** exhibits only a small highfield shift with increasing temperature. The observed temperature dependence is low (–2.8 ppb K^{-1}) and provides no evidence for H bonding in solution.

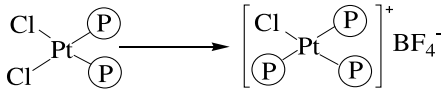
Metal complexes of L-PhePhos

Scheme 2 illustrates the synthetic routes used to prepare Pd(II) and Pt(II) complexes from stoichiometric amounts of (COD)MCl_2 or (PhCN)$_2MCl_2$ (M = Pt, Pd) in the presence of L-PhePhos. The COD and PhCN ligands are both readily replaced by the phosphine, and identical products were obtained from each route. The ^{31}P NMR spectrum of uncoordinated L-PhePhos in $CDCl_3$ shows a single resonance at δ –5.8 (δ –4.6 for PPh_3) (9). Upon coordination to Pt to give *cis*-(L-PhePhos)$_2$PtCl$_2$ (**2**), this signal is shifted downfield to δ 14.5, with a ^{31}P–^{195}Pt coupling of 3665 Hz, characteristic for *cis*-phosphine coordination (9). The Pd analogue *cis*-(L-PhePhos)$_2$PdCl$_2$ (**3**) exhibits a singlet at δ 23.4. The ^{1}H NMR spectra of compounds **2** and **3** show single resonances for the amide NHs, shifted from δ 5.91 in the uncomplexed L-PhePhos to δ 6.14 and δ 5.98 for complexed L-PhePhos in compounds **2** and **3**, respectively (Table 1). The splitting of

Scheme 2. Coordination chemistry of L-PhePhos. (*i*) CH_2Cl_2, L-PhePhos; (*ii*) $NaBH_4$, MeOH.



Scheme 3. Attempted prepatation of [(L-PhePhos)$_3$PtCl][BF_4] in the presence of Ag^+ and L-PhePhos.



the two diastereotopic β-CH_2 proton signals increases upon coordination, which is compatible with a decrease in the mobility of the side-chain. We have observed similar effects in the related serine phosphinito complex (L-SerOPhos)$_2$PtCl$_2$ in which the two diphenylphosphine serine ligands are strongly H bonded (10). Hydrogen bonding, in addition to the steric bulk of the PPh_2 group, is thought of being responsible for this increase. Both complexes are stable in air. We carried out VT NMR experiments on a 4.5 mM solution of compound **2**. Temperature-dependent upfield shifts of the amide resonance of compound **2** from δ 6.092 at 293 K to δ 5.975 at 320 K confirms very weak intramolecular H bonding (–4.4 ppb K^{-1}).

In the presence of one equivalent of $AgBF_4$ and an additional equivalent of L-PhePhos, halide abstraction takes place, as is evident from the precipitation of AgCl from CH_2Cl_2 solution (Scheme 3).

After filtration, the solution exhibits a broad ^{31}P resonance at δ 23.2 ($J_{31P-195Pt}$ = 2425 Hz, $\upsilon_{1/2}$ = 100 Hz) in addition to the resonance of unreacted starting material (δ 14.5). Addition of a second equivalent of $AgBF_4$ results in the decomposition of the complex. These reactions are currently under further investigation.

The reaction of compound **2** with $NaBH_4$ in MeOH solution under basic conditions results in the quantitative formation of the corresponding hydrido complex, *trans*-(L-PhePhos)$_2$PtHCl (**4**). Figure 3 shows the ^{31}P{^{1}H} NMR spectra of the Pt complexes **2** and **4**. Upon borohydride reduction, the ^{31}P signal shifts upfield from δ 14.5 to δ 28.4. At the same time, J_{P-Pt} decreases to a value of 2700 Hz, indicative of a *trans*-coordination of the two phosphine ligands. The ^{1}H NMR spectrum of **4** exhibits a hydride signal as a triplet at δ –15.5 (J_{HP} = 27 Hz and J_{HPt} = 1170 Hz), which unequivocally established the coordination about the Pt cen-

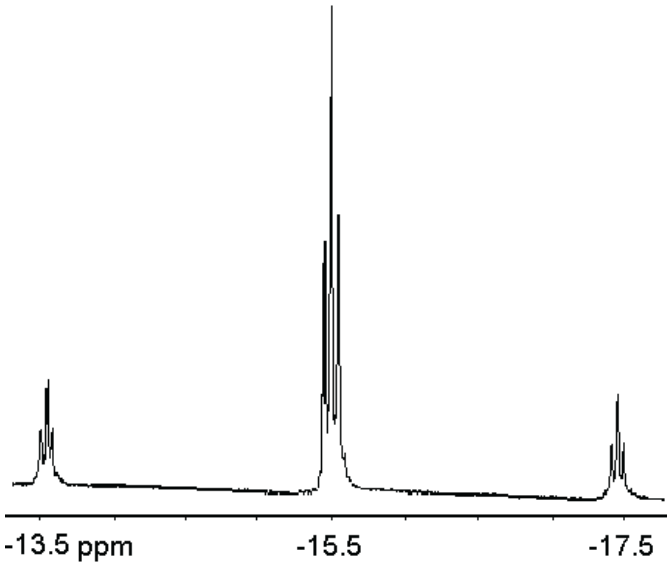
tre as *trans* (Fig. 4). The chemical shift and the coupling constants of compound **4** compare well with other platinum hydride complexes reported in the literature (11). The related reaction of the Pd complex **3** with $NaBH_4$ under identical conditions does not result in any isolable palladium

Experimental

General methods

All manipulations involving air- and-moisture sensitive materials were carried out under an argon or nitrogen atmosphere using a conventional Schlenk line. CH_2Cl_2 (CaH_2), $CHCl_3$ (CaH_2), and benzene (Na, benzophenone) were dried using the appropriate drying agents and distilled under nitrogen prior to use. Diethylamine was refluxed over NaOH, distilled, and stored over 4-Å molecular sieves. ^1H, ^{13}C, and ^{31}P NMR spectra were recorded at 300.135, 75.478, and 121.496 MHz, respectively, on a Bruker AMX 300 NMR spectrometer. All chemical shifts (δ) are reported in parts per million and coupling constants (*J*) in hertz. $CDCl_3$ (Aldrich) was stored over molecular sieves (4 Å). ^1H NMR shifts are referenced to the nondeutero impurity in $CDCl_3$ (δ = 7.24 ppm) or in MeCN-d_3 and are reported relative to tetramethylsilane (δ = 0 ppm). Assignments in the ^1H and $^{13}C\{^1H\}$ NMR were made using J modulation and by ^1H–^1H COSY. All measurements were carried out at 293 K unless otherwise specified. Mass spectrometry was carried out on a VG Analytical 70/20 VSE chromatograph. Elemental analyses were obtained in-house on a Perkin-Elmer 2400 CHN elemental analyzer.

Fig. 4. Hydride region of the ^1H NMR spectrum of *trans*-(L-PhePhos)$_2$Pt(H)Cl (**4**) showing a triplet at δ –15.5 (J_{HP} = 27 Hz, J_{HPt} = 1170 Hz).



Preparation of *cis*-[*N*-Ac-Phe(PPh$_2$)-OMe]$_2$PtCl$_2$ (*cis*-(L-PhePhos)$_2$PtCl$_2$) (2)

To a stirring solution of (COD)PtCl$_2$ (50 mg, 0.14 mmol) in THF (5 mL), a solution of *N*-acetyl-L-(4-diphenylphosphine)phenylalanine methyl ester (113 mg, 0.28 mmol) in THF (5 mL) was added. The mixture was stirred at room temperature overnight and the solvent removed in vacuo and then washed with hexanes (5 mL), leaving an off-white solid. Using (PhCN)$_2$PtCl$_2$ as a starting material resulted in the formation of the identical product.

^1H NMR ($CDCl_3$) δ: 7.01–7.51 (14H, m, Ph), 6.14 (1H, d, *J* = 8 Hz, NH), 4.86 (1H, apparent dd, J^1 = 6 Hz, J^2 = 7 Hz, α-CH), 3.67 (3H, s, OMe), 3.10 (2H, apparent dd, J^1 = 6 Hz, J^2 = 9 Hz, β-CH_2), 1.96 (3H, s, MeC(O)). ^{13}C NMR ($CDCl_3$) δ: 172.0 (C=O), 170.0 (C=O ester), 135.4–128.1 (aromatic), 53.3, 52.7, 38.0, 23.4. ^{31}P NMR ($CDCl_3$) δ: 14.5 (s, $J_{P–Pt}$ = 3660 Hz).

Preparation of *cis*-[*N*-Ac-Phe(PPh$_2$)-OMe]$_2$PdCl$_2$ (*cis*-(L-PhePhos)$_2$PdCl$_2$) (3)

The procedure is identical for that of the Pt analogue. ^1H NMR ($CDCl_3$) δ: 7.72–7.37 (12H, m, Ph), 7.14 (2H, d, *J* = 7.8 Hz, Phe aromatics), 5.98 (1H, d, *J* = 8 Hz, NH), 4.88 (1H, apparent dd, J^1 = 6 Hz, J^2 = 8 Hz, α-CH), 3.66 (3H, s, OMe), 3.12 (2H, apparent dd, J^1 = 3 Hz, J^2 = 6 Hz, β-CH_2), 1.96 (3H, s, MeC(O)). ^{31}P NMR ($CDCl_3$) δ: 23.4 (s). Anal. calcd. for $C_{48}H_{48}Cl_2N_2O_6P_2Pd$: C 58.34, H 4.90, N 2.83; found: C 58.50, H 4.75, N 2.86.

Preparation of *trans*-[*N*-Ac-Phe(PPh$_2$)-OMe]$_2$PtHCl (*trans*-(L-PhePhos)$_2$PtHCl) (4)

125 mg of *cis*-(L-PhePhos)$_2$PtCl$_2$ (0.116 mmol, 1 equiv) was added to 5 mL of methanol and the resulting mixture was dissolved by 1.5 mL of diethylamine. Five milligrams of Na[BH_4] was slowly stirred into the solution and stirring continued for approximately 5 min until the evolution of

pale white gas had ceased. The resulting clear yellow solution was reduced to a greyish brown solid under vacuum. 15 mL of benzene was used to dissolve the material, and any residual solids were removed by filtration. The benzene filtrate was then dried under vacuum giving a white residue. 15 mL of toluene was added and the solution was filtered twice and then vacuumed to dryness. ^{1}H NMR ($CDCl_3$) δ: 7.60–6.90 (14H, m, aromatics), 6.50 (1H, d, NH), 4.88 (1H, apparent dd, J^1 = 6 Hz, J^2 = 14 Hz, α-CH), 3.63 (3H, s, OMe), 3.00 (2H, apparent dd, J^1 = 3 Hz, J^2 = 8 Hz, β-CH_2), 2.05 (3H, s, MeC(O)), –15.50 (1H, t, J_{HP} = 28 Hz, J_{HPt} = 1172 Hz).

X-ray crystallography

Suitable crystals of L-PhePhos (**1**) were obtained by layering a $CHCl_3$ solution of **1** with hexanes. Colourless needles suitable for X-ray crystallography were deposited after 2 days. A single crystal of approximate dimentions 0.60 × 0.36 × 0.11 mm was mounted onto a glass fibre. Data for **1** were measured using a Bruker P4 SMART diffractometer equipped with a rotating anode and a 1000 CCD using Mo Kα radiation (graphite monochromated).[2] The structure was solved using direct methods (12). All non-H atoms were refined anisotropically using full-matrix least squares on F^2 (13). The position of the Ph_2P group was disordered over two positions and was modelled satisfactorily with a 1:1 occupancy for the two positions. The position of the H atoms was found in the difference Fourier map and refined isotropically. The final R value for **1** was R = 0.0390 for 3938 reflection with $I > 2\sigma(I)$ (4455 total reflections). Crystallographic details are summarized in Table 2.

Summary

The P atom in the new phenylalanine-based phosphino amino acid L-PhePhos readily coordinates to Pd(II) and Pt(II) to form the new square-planar complexes *cis*-(L-PhePhos)$_2$PdCl$_2$ and *cis*-(L-PhePhos)$_2$PtCl$_2$. The metal complexes are air stable and exhibit spectroscopic parameters typical of *cis*-coordination of the phosphine ligands to the metal centre. VT NMR gives some indications of intramolecular H bonding between the two amide NH of the L-PhePhos ligands. The rection of (L-PhePhos)PtCl$_2$ with $NaBH_4$ results in the formation of a new platinum hydride (L-PhePhos)PtHCl. We continue to explore the coordination chemistry of L-PhePhos and the chemistry of its Pt and Pd complexes, in particular with reference to their potential application in homogeneous catalysis.

The neutral diradical 5,5′-bis(1,3,2,4-dithiadiazolyl) [SNSNC-CNSNS], the first main group radical to exhibit a dramatic increase in paramagnetism on mechanical grinding

Guillermo Antorrena, Scott Brownridge, T. Stanley Cameron, Fernando Palacio, Simon Parsons, Jack Passmore, Laurence K. Thompson, and Fitri Zarlaida

Abstract: Reduction of $[(CNSNS)_2][AsF_6]_2$ with triphenylantimony and tetrabutylammonium chloride produced the diradical 5,5′-bis(1,3,2,4-dithiadiazolyl) [SNSNC-CNSNS] in high yield as a black solid with widely ranging magnetic susceptibilities (e.g., 0.6 to 2.6 μ_B), which on oxidation with AsF_5 regenerated $[(CNSNS)_2][AsF_6]_2$. The identity of [SNSNC-CNSNS] was established from EPR, vibrational, and mass spectra. Ab initio molecular orbital [MPW1PW91/6-311G(2df)] calculations show the lowest energy structure to consist of two coplanar rings separated by a C—C single bond (1.444 Å), reflected in the comparison of the vibrational spectra of the diradical with that of $[(CNSNS)_2][AsF_6]_2$ and the calculated spectra. Confidence in the calculated [MPW1PW91/6-311G(2df)] structure of the diradical is supported by the excellent agreement between the calculated and X-ray single crystal structure geometries of $[CNSSN]_2$ and $[(CNSNS)_2]^{2+}$ in $[(CNSNS)_2][AsF_6]_2$. The molecular orbitals indicate the diradical is essentially disjoint, confirmed by a very small (0.07 kJ mol^{-1}) GVB-PP(TC-SCF)/6-311G* calculated singlet–triplet energy gap. Accordingly, the EPR spectrum of the diradical (in tetrahydrofuran, 293 K) shows a simple 3-line pattern (g = 2.0043, $a(^{14}N)$ = 1.11 mT) with no observable exchange coupling between the two radical centers. Mechanical grinding of the diradical results in a large increase in paramagnetism (e.g., from 1.03 to 2.55 μ_B) that is unprecedented in main group chemistry. The X-ray diffraction data of the ground and unground powder are consistent with a second order phase change on grinding. Attempts to obtain crystals of the diradical by sublimation led instead to numerous decomposition and rearrangement products, including 4-cyano-1,2,3,5-dithiadiazolyl [NC-CNSSN], monoclinic space group $C2/c$, a = 9.46(2) Å, b = 7.625(5) Å, c = 13.17(2) Å, β = 107.94(4)°, Z = 8. The structure consists of axially symmetric, cofacial, *cis* dimers linked to form strands through two sets of $C{\equiv}N^{\delta-}\cdots S^{\delta+}$ contacts. More efficient and larger scale preparations of [SNS][AsF_6] and $[(CNSNS)_2][AsF_6]_2$ are reported.

Key words: 5,5′-bis(1,3,2,4-dithiadiazolyl), diradical, paramagnetism, mechanical grinding, second order phase change, 4-cyano-1,2,3,5-dithiadiazolyl.

Résumé : La réduction du $[(CNSNS)_2][AsF_6]_2$ à l'aide du triphénylantimoine et du chlorure de tétrabutylammonium fournit le biradical 5,5-bis(1,3,2,4-dithiadiazolyl) [SNSNC-CNSNS], avec un rendement élevé et sous la forme d'un solide noir de susceptibilités magnétiques très variables (par exemple, de 0,6 à 2,6 μ_B) qui, par oxydation à l'aide de AsF_5 régénère le $[(CNSNS)_2][AsF_6]_2$. L'identité du [SNSNC-CNSNS] a été établie par RPE et ses spectres vibrationnels et de masse. Des calculs d'orbitales moléculaires ab initio [MPW1PW91/6-311G(2df)] montrent que la structure de plus faible énergie est formée de deux cycles coplanaires séparés par une seule liaison C—C (1,444 Å) qui se reflète dans la comparaison du spectre de vibration du biradical avec celui du $[(CNSNS)_2][AsF_6]_2$ et du spectre calculé. La confiance dans la structure calculée [MPW1PW91/6-311G(2df)] du biradical est supportée par l'excellent

accord entre les géométries calculées et observées pour $[\overline{CNSSN}]_2$ et $[(\overline{CNSNS})_2]^{2+}$ par diffraction des rayons X d'un cristal unique de $[(\overline{CNSNS})_2][AsF_6]_2$. Les orbitales moléculaires indiquent que le biradical est essentiellement incohérent, ce qui est confirmé par la très faible valeur (0,07 kJ mol^{-1}) de la bande d'énergie triplet–singulet calculée, GVB-PP (TC-SCF)/6-311G*. En conséquence, le spectre RPE du biradical (dans le tétrahydrofurane, à 293 K) présente un diagramme simple de trois raies (g = 2,0043, $a(^{14}N)$ = 1,11 mT) sans couplage d'échange observable entre les deux centres radicalaires. Un broyage mécanique du biradical augmente considérablement son paramagnétisme (par exemple, de 1,03 à 2,55 μ_B), ce qui est sans précédent dans la chimie du groupe principal. Les données de diffraction des rayons X sur les poudres broyées et non broyées sont en accord le fait que le broyage s'accompagne d'un changement de phase du deuxième ordre. Des essais en vue d'obtenir des cristaux du biradical par sublimation ont plutôt conduit à de nombreux produits de décomposition et de réarrangement, y compris du 4-cyano-1,2,3,5-dithiadiazolyle [NC-$\overline{CNSSN}$], groupe d'espace monoclinique, $C2/c$, a = 9,46(2), b = 7,625(5) et c = 13,17(2) Å, β = 107,94(4)° et Z = 8. La structure est formée de dimères *cis*, cofaciaux et de symétrie axiale reliés pour former des brins par le biais de deux ensembles de contacts $C{\equiv}N^{\delta-}\cdots S^{\delta+}$. On rapporte aussi des préparations plus efficaces et à plus grandes échelles de $[SNS][AsF_6]$ et $[(\overline{CNSNS})_2][AsF_6]_2$.

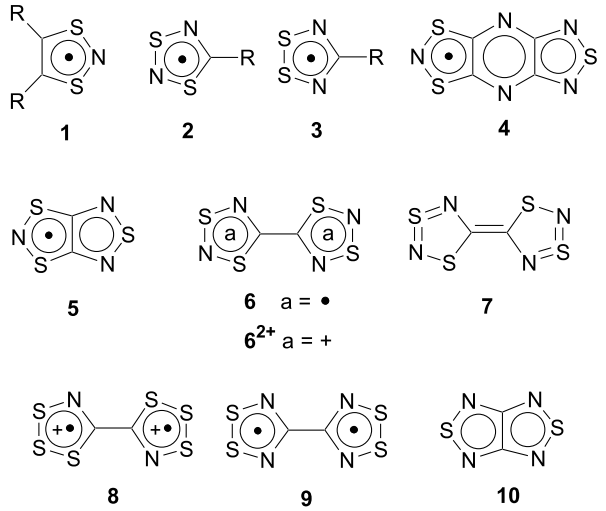
Mots clés : 5,5′-bis(1,3,2,4-dithiadiazolyle), biradical, paramagnétisme, broyage mécanique, changement de phase du deuxième ordre, 4-cyano-1,2,3,5-dithiadiazolyle.

[Traduit par la Rédaction]

Introduction

The synthesis of the soluble $[SNS][AsF_6]$ in high yield on a large scale (1) made possible the extensive quantitative symmetry-allowed cycloaddition chemistry of $[SNS]^+$ (1*b*, *c*). Reactions with a wide variety of alkynes and nitriles gave the respective 1,3,2-dithiazolylium and 1,3,2,4-dithiadiazolylium cations (1*c*), and on reduction the corresponding 7π radicals **1** and **2** (see Fig. 1) (2). Simple derivatives of **1** were not generally isolated as pure materials. Exceptions include 4,5-bis(trifluoromethyl)-1,3,2-dithiazol-2-yl, **1** ($R = CF_3$), a thermally stable but photochemically unstable blue gas over a green paramagnetic liquid at room temperature, which freezes to a diamagnetic solid (2, 3), and **1** (R = CN) prepared by Wolmerhäuser et al. by a different route (4). Some derivatives of the [R-$\overline{CNSNS}$] class of radicals (**2**) have been isolated and characterized (e.g., $R = CH_3$ (5*a*), CF_3 (5*b*), Ph (5*c*), *p*-$O_2NC_6H_4$ (5*c*), 4,4′-$\overline{SNSNCC_6H_4}$-C_6H_4 (5*d*)), as well as [*t*-Bu-$\overline{CNSNS}$] (5*d*, *e*), a paramagnetic liquid that undergoes a concerted photochemical symmetry-allowed rearrangement in solution to a thermodynamically more stable isomer [*t*-Bu-$\overline{CNSSN}$], also a paramagnetic liquid (5*d*, *e*). However, rearrangement of simple derivatives of **2** to the isomeric **3** is the norm and can occur in solution in the dark, although more slowly; and the solid [*p*-C_6H_4-$(\overline{CNSNS})_2$] (6) rearranges on heating. Simple derivatives of the radicals **1**, **2**, and **3** are generally diamagnetic in the solid state with electrons pairing up via weak π*-π* bonding. Banister et al. (7*a*) prepared the α-phase of [*p*-NCC_6F_4-$\overline{CNSSN}$], the first dithiadiazolyl radical that was paramagnetic in the solid state, and Banister et al. (7*a*) and Rawson and co-workers (7*b*, *c*) the β-phase, which surprisingly exhibited weak ferromagnetism below 36 K. Oakley and co-workers (8) showed that the solid state structure of [1,2,5,-thiadiazolo[3,4,*b*]-1,3,2-dithiazolo[3,4,*b*]pyrazin-2-yl] (**4**) undergoes a lateral shift from a paramagnetic slipped π-stack arrangement at 293 K to arrays of dimers at ca. 150 K. The related **5**, first prepared by Wolmerhäuser and Johann (9), undergoes a transition between a purple high-temperature paramagnetic phase consisting of a uniform 1-dimensional slipped π-stack

Fig. 1. Structure legend.



arrangement to a green diamagnetic low-temperature phase with strong dimerization along the stacking direction (10).

The general lability of the simple derivatives of monoradicals of **2** would imply that the preparation of stable diradicals containing a pair of **2** would be problematic. If prepared and isolated, however, it was anticipated that they might well have unusual physical properties based on the behaviour of related compounds (see above). The simplest example of such a diradical is **6**, containing two monoradicals joined by a single C—C bond. However, **6** could adopt the classical Lewis structure (**7**). On the other hand the isolobal **8**, which is a diradical containing a single C—C bond, has been prepared and characterized (11) and has an almost degenerate singlet and triplet ground state. In addition, the isomeric **9** has been prepared by Oakley and co-workers and is also a diradical containing a single C—C bond (12). In the solid state **9** is diamagnetic, forming dimers through π*-π* bonding.

$[(\overline{CNSNS})_2][AsF_6]_2$, containing $\mathbf{6}^{2+}$, the precursor to **6**, had been prepared by the quantitative 2:1 cycloaddition of

© 2002 NRC Canada

$[SNS][AsF_6]$ with dicyanogen (13). There are eight possible derivatives formally obtainable from $\mathbf{6}^{2+}$ by reduction, isomerization, and reoxidation (13*b*). $(CNSNS)_2$ (**6**) represents one of those possibilities formally given by the double reduction of $\mathbf{6}^{2+}$ in $\mathbf{6}\cdot[AsF_6]_2$. The compound **6** is the first example of a non-aryl diradical containing two units of **2**. We present evidence that **6** is a diradical and does not have the classical structure (**7**). In addition we show that **6** is, as far as we are aware, the first example of a main group radical that undergoes a dramatic increase in paramagnetism on mechanical grinding; however, similar cases are well documented for compounds that contain transition metal elements (14, 15). Compounds **6**, **4**, **5**, and **9** are all radicals and members of a class of neutral ternary carbon–sulfur–nitrogen compounds. A great variety of $C_xN_yS_z$ compounds can be envisaged, and the 21 examples whose X-ray structures have been determined and included in the Cambridge database (December 2001, (16)) are included in the Supplemental Material.[5] Compound **6** is one of a small class of main group non-sterically hindered diradicals that are paramagnetic in the solid state, in addition to dioxygen (17). The initial preparation and proposal of a structure for **6** was noted in 1991 (13*a*). Below we present evidence to show that the proposed structure of **6** is correct, although a single crystal X-ray crystal structure has yet to be obtained.

Experimental

General aspects

General techniques and apparatus are described in ref. 18. Unless stated otherwise, all reactions were carried out in a carefully dried one piece apparatus consisting of two Pyrex bulbs (V = 50 cm^3) linked by a glass tube (o.d. 10 mm) incorporating a sintered glass frit (medium porosity). Both bulbs were fitted with 5 mm Pyrex glass valves with PTFE pistons (J. Young, London, U.K.). All glassware was carefully dried prior to use. Light was excluded from reactions by wrapping the reaction vessel in Al foil. Moisture-sensitive materials and all solid products were manipulated in a Vacuum Atmospheres Dri-Lab using dry nitrogen and equipped with a Dri-Train (HE-493) and an internal circulating drying unit containing 1 kg of 3 Å molecular sieves. Sulfur dioxide (Matheson) was vacuum distilled onto and stored over CaH_2. Arsenic pentafluoride (Ozark-Mahoning), cyanogen (Matheson), triphenylantimony (Fluka), and tetrabutylammonium chloride (Eastman Kodak, Lancaster Synthesis) were used as received. Dithionitronium hexafluoroarsenate $[SNS][AsF_6]$ (1) and $\mathbf{6}\cdot[AsF_6]_2$ (13) were prepared as previously described but using modifications that led to increased efficiency at a larger scale ($[SNS][AsF_6]$: 25 g, 85% recovered yield based on S_4N_4; $\mathbf{6}\cdot[AsF_6]_2$: 12.5 g, 96.5% yield based on $[SNS][AsF_6]$); details are described in the Supplemental Material.[5] Elemental analyses were carried out by Beller Mikroanalytisches Laboratorium, Göttingen, Germany. Mass spectra (27 eV, EI) were measured on a Kratos MS50TC spectrometer by the direct inlet method. Density measurements were carried out in a 10 mL pycnometer as described in ref. 19, using acetone in which **6** is insoluble and with which it does not react.

X-ray powder photography

Samples for X-ray powder photography were loaded into 0.5 mm or 0.3 mm glass capillary tubes sealed under nitrogen atmosphere; diffraction photographs were obtained using a Rapide powder diffractometer with nickel filtered Cu Kα radiation with 3 h exposures and calibrated with a Corundum spectrum. The unit cell was extracted with the use of the indexing routines in Jade (20).

Infrared and FT-Raman spectroscopy

Infrared spectra of Nujol and fluorolube mulls of prepared compounds between CsI plates were recorded on a PerkinElmer model 683 grating spectrometer in the range of 4200 to 200 cm^{-1} or on a Bruker IFS66 FT-IR spectrometer in the range 4000 to 400 cm^{-1}. FT-Raman spectra were obtained from neat samples, sealed under nitrogen atmosphere in 5 mm NMR tubes (Wilmad), using an FT-IR spectrometer (Bruker IFS66) equipped with an FT-Raman accessory (Bruker FRA106) incorporating a Nd-YAG laser (emission wavelength: 1064 nm; maximum laser power: 300 mW). Details of data collection have been described previously (21).

EPR spectroscopy

Solution EPR spectra were recorded using a locally modified version of a Varian E-4 spectrometer fitted with an external Bruker B-ST 100/700 temperature control unit. Samples were prepared in a reaction vessel (described above) but incorporating a quartz tube (o.d. 4 mm, i.d. 2 mm), and one thick-walled 10 mL round bottom flask containing the sample (ca. 2 mg), solvent, and a Teflon-coated magnetic stir bar. After the mixture was stirred for 1 h, a portion of the very pale grey solution was poured through the frit into the quartz tube. If an EPR spectrum was not recorded within ca. 1 h of sample preparation, black powder was observed to settle out in the bottom of the tube; the quartz tube was immersed in a sonic bath for 10 min to redisperse **6** into the solvent.

Magnetic measurements

Preliminary magnetic susceptibilities were determined by the Gouy method using a Newport 1.5 in. (1 in. = 0.0254 m) electromagnet in conjunction with a Stanton Instruments Model MC5 microbalance with a sensitivity of 0.02 mg. Variable-temperature magnetic measurements (Memorial University) were made on a fully automated Oxford Instruments superconducting Faraday susceptometer equipped with a Sartorius 4432 microbalance (main solenoid field 1.5 T, gradient field 10 T m^{-1}). Samples were loaded into the sealed sample holder on a Vacuum Atmospheres Dri-Lab.

Reaction	**6**·$[AsF_6]_2$ (g, mmol)	$[NBu_4][Cl]$ (g, mmol)	$SbPh_3$ (g, mmol)	SO_2 (g)	Recovered yield of **6**[a] (g, mmol, %)	Light[b]	Gouy (μ_B)	Purification method[c]	Sublimation products
1	1.975, 3.37	1.940, 6.98	1.237, 3.50	15.93	0.613, 2.941, 87	y	1.21	Static	$C_2N_4S_3$(?)
2	2.002, 3.42	1.916, 6.89	1.217, 3.45	15.69	0.647, 3.107, 91	y	0.99	Static, ΔT	NSNCCNSN (**10**)[d]
3	2.090, 3.57	2.107, 7.58	1.368, 3.87	21.89	0.607, 2.914, 82 (5.453 g byprod)	n	0.71	Static, ΔT	S_4N_4, [NC-CNSSN]
4	1.998, 3.41	1.997, 7.18	1.285, 3.64	13.53	0.662, 3.178, 93	n	1.32	Dynamic, ΔT	S_8

[a]Recovered yield is based on **6**·$[AsF_6]_2$ and assumes complete removal of byproducts. Byprod = recovered weight of reaction byproducts ($SbPh_3Cl_2$ + $[NBu_4][AsF_6]$). Reactions were generally allowed to stir overnight before work up.

[b]Indicates whether the reaction was carried out in the presence (y) or absence (n) of direct, bright incandescent light. The reaction products were protected from direct light exposure by wrapping the reaction vessel with Al foil and by working up the reaction in dim light.

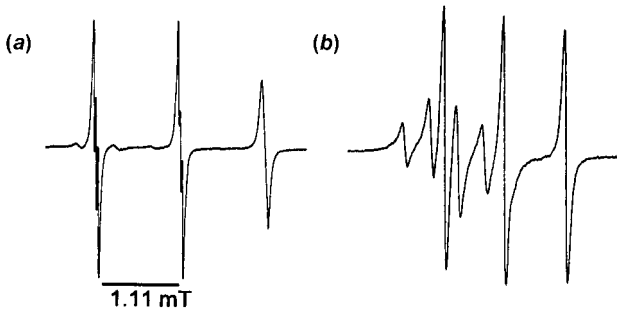
[c]SO_2 indicates prolonged washing and grinding of the product with a 50°C oil bath, as described in the experimental section. Static and dynamic refer to vacuum sublimation, ΔT indicates a temperature gradient was used in heating the reaction tube. See main text for details.

[d]Reference 28.

Variable temperature and variable field magnetic measurements (Spain) were carried out on a Quantum Design MPMS5S SQUID (superconducting quantum interference device) magnetometer equipped with an ac susceptibility attachment, using powdered samples of **6**, which were stored in a drybox in an Ar atmosphere and loaded into the sample holder under Ar atmosphere using a plastic bag.

Samples of **6** were ground, inside a Vacuum Atmospheres Dri-Lab, with a clean and dry agate mortar and pestle, previously cleaned with nitric acid. Samples were handled with glass or Teflon spatulas to minimize contamination with metals. A similar set of grinding experiments and subsequent magnetic measurements were carried out on NaCl and showed that no contaminants had been introduced in the Dri-Lab.

Fig. 2. (*a*) EPR of **6** in THF at 193 K. (*b*) EPR of **6** in THF at 293 K, showing partial rearrangement from -(CNSNS) to -(CNSSN) due to non-rigorously dried glassware.



Preparation of 6

$[SNS][AsF_6]$ was reacted with $(CN)_2$ in SO_2 at 50°C for 5 days to produce **6**·$[AsF_6]_2$ in quantitative yield (13), the purity of which was checked by vibrational spectra of the crystalline product. In a typical reaction, SO_2 (7.036 g) was condensed onto **6**·$[AsF_6]_2$ (1.560 g, 2.66 mmol), $[NBu_4][Cl]$ (1.493 g, 5.37 mmol), and $SbPh_3$ (0.959 g, 2.68 mmol) at –196°C. A black precipitate was immediately observable on melting of the solid SO_2, indicating a rapid reduction to black insoluble **6** (eq. [1]).

$$[1] \quad \mathbf{6}\cdot[AsF_6]_2 + SbPh_3 + 2[NBu_4][Cl] \xrightarrow[SO_2]{} \mathbf{6} + SbPh_3Cl_2 + 2[NBu_4][AsF_6]$$

The reaction was stirred overnight, and the mixture was filtered. The solvent was condensed back into the first bulb; the mixture was stirred for 30 min and refiltered. This procedure was repeated until the colour of the solution had lightened from orange-yellow to a pale yellow. Further separation of the yellow-orange soluble $[NBu_4][AsF_6]$ and $SbPh_3Cl_2$ was accomplished by placing **6** on a sintered glass frit incorporated into a condenser with a pressure-equalizing side-arm joined to a Pyrex bulb (V = 50 cm^3) and closed with a J. Young valve (see Fig. 1 in ref. 22). The soluble products were extracted for up to 3 weeks by refluxing with SO_2 at 50°C, with removal of the SO_2 every few days to break up any large particles with a glass rod. This increased the purity of **6**, as judged by FT-Raman, with an 85% recovered yield (0.466 g, 2.236 mmol) of **6** and reaction byproducts. More extensive washing and grinding did not increase purity and did not afford completely pure material (FT-Raman). Numerous preparations were carried out under varying conditions to establish the reproducibility and quantitative yield of this reduction (Table 1, additional reaction data given in the Supplemental Material) and to reproduce the initial results, which showed the material was paramagnetic, including the exclusion of light to determine if **6** undergoes photochemical rearrangement or decomposition. A large excess of reducing agents was not used owing to the difficulty in separating them and the associated byproducts from **6**. Reaction vessels were rigorously dried otherwise partial rearrangement of the rings to -CNSSN occurred (EPR: Fig. 2*b*); however, if present partially rearranged material could be removed by washing with SO_2 followed by CH_2Cl_2.

Attempts to prepare **6** in acetonitrile, in which **6**·$[AsF_6]_2$ is soluble, using purified $[NBu_4][Cl]$ did not lead to purer **6** (IR and Raman spectra, elemental analysis) (23).

IR and FT-Raman spectral data for **6**·$[AsF_6]_2$ and **6** are listed in Table 2. FT-Raman spectra are shown in Fig. 3; the FT-Raman spectra of **6** from 50–3000 cm^{-1} and the IR spectra of **6** and **6**·$[AsF_6]_2$ are given in the Supplemental

Note: FT-Raman spectra are shown in Fig. 3. Calculated (MPW1PW91/6-311G(2df)) frequencies are scaled as listed. Relative intensities in parentheses, listed as (IR, Raman) for calculated intensities.

[a]Assignments based on visualization of calculated vibrations using HYPERCHEM (37*e*). When two modes are listed, parentheses around the second mode indicate that the first mode is the predominant vibrational mode; a "+" indicates the two modes are of equal importance. See Fig. 6 for atom labelling scheme.

[b]Relative intensities measured as area under the peak.

[c]Unassigned, but are a consistent feature in the spectra of **6**, **6**·$[AsF_6]_2$, and both the solid state and solution spectra of salts of **8** (11*c*).

[d]In addition to peaks assigned to $[AsF_6]^-$, unlisted weak peaks at 1953, 2078, 2156, 2219, 2717, and 2780, and a strong peak at 2876 cm^{-1} are assigned to reduction byproducts.

[e]IR peaks in italics are from a fluorolube mull, all others from a Nujol mull.

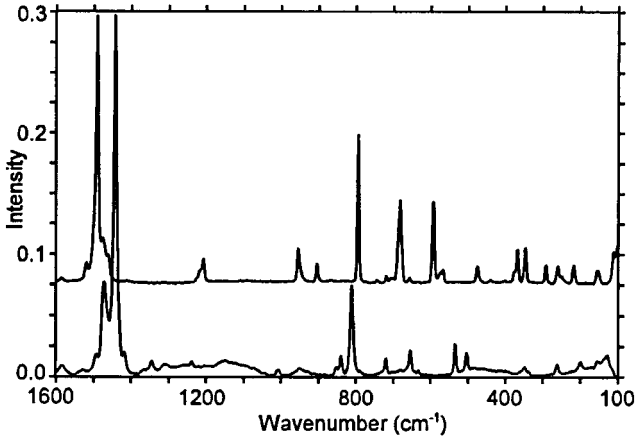
Fig. 3. FT-Raman spectra of $\mathbf{6}^{2+}$ (top: 18 mW, resolution 4 cm^{-1}, 1024 scans, T = 140 K) and **6** (bottom: 60 mW, resolution 4 cm^{-1}, 6000 scans, T = 140 K).



Material. EI-MS data listed below are for **6** (27 eV, I > 5%); data for I > 1% may be found in Supplemental Material.

EI-MS *m/z* (%): 212 ([$C_2N_4{}^{34}S_2{}^{32}S_2$], 6), 210 ([$C_2N_4{}^{34}S^{32}S_3$], 14), 208 ([M]$^+$, 100), 162 ([M – NS]$^+$, 5), 130 ([M – NS_2]$^+$, 36), 80 ([$^{34}SN^{32}S$]$^+$, 8), 78 ([S_2N]$^+$, 71), 64 ([S_2]$^+$, 7). Anal. calcd. for 95% **6** with impurities reasonably assigned as 5% [NBu_4][AsF_6] and $SbPh_3Cl_2$ in a 2:1 ratio (calcd. for pure **6**): C 15.16 (11.53), H 0.60, N 24.37 (26.90), S 55.40 (61.57), Cl 0.84, F 1.32, Sb 1.44, As 0.87; found: C 10.63, H 0.66, N 24.17, S 55.69, Cl < 0.2, F 3.20, Sb 1.16, As 0.77.

The mass spectrum of **6** did not change after up to 3 weeks washing with SO_2 or after storage at –20°C for two years. The EPR spectrum of **6** in THF at room temperature is given in Table 3; no resonance at half field corresponding to the $\Delta m_s = \pm 2$ transition was observed at either room or low temperature, suggesting **6** is not a triplet. Similar spectra were also obtained in SO_2 and CH_2Cl_2 (23).

Compound **6** changes from a black fluffy powder to black graphite-like shiny plates on mechanical grinding, with an apparent large change in volume. The density of **6** (0.035 g of **6** in 8.061 g acetone) was measured to be 1.7 ± 0.1 g cm^{-3} after 1 h of mechanical grinding. A measurement 1.4 g cm^{-3} was obtained for an unground sample of **6**. However, we surmise that this fluffy powder contained empty spaces within the bulk, leading to an erroneously low measured density.

Reoxidation of 6 (26)

Reoxidation of **6** (0.018 g, 0.09 mmol) with AsF_5 (0.130 g, 0.76 mmol) in SO_2 (0.887 g) in the presence of a trace (1 mg) of Br_2 in a 5 mm NMR tube gave a dark brown solution and a very small amount of colourless solid after 10 min at room temperature.

^{13}C NMR δ: 187 (lit (13*b*) value ^{13}C NMR δ: 187 for **6**·[AsF_6]$_2$).

In a larger scale reaction SO_2 (5.686 g), AsF_5 (0.521 g, 3.07 mmol), and Br_2 (6 mg) were condensed onto **6** (0.200 g, 0.96 mmol). The brown mixture was stirred at room temperature for 3 days, filtered, and the reaction volatiles (SO_2, AsF_5 (trace), AsF_3, and SiF_4 (very minor trace)) removed, leaving a black solid (0.550 g, 98% yield) consisting mainly of **6**·[AsF_6]$_2$ with some [$\overline{\text{NSSNC}}$-$\overline{\text{CNSNS}}$][AsF_6]$_2$ and [$\overline{\text{NSSNC}}$-$\overline{\text{CNSNS}}$][AsF_6] (IR: see Table 1 in ref. 13*b*). The IR spectrum also showed bands at 3200 (br), 1723 (w), 1704 (w), 1295 (m), 1076 (w), and 637 (sh) cm^{-1}, which possibly arose from the reaction of AsF_5 with the impurities in **6**. The very low intensity of the band at 1028 cm^{-1} due to SiF_4 in the reaction volatiles precludes hydrolysis as a source of these bands.

Attempts to purify and grow crystals of 6

Various solvents were investigated in an attempt to grow crystals and (or) separate the reaction byproducts from **6**. Compound **6** proved insoluble in $CFCl_3$, CH_3CN, CH_2Cl_2, SO_2, CS_2, AsF_3, benzene, toluene, acetone, and DMSO, as shown by the absence of any black material colouring the solvent after stirring for 24 h and the absence of black material after filtering off the solvent. Although EPR spectra

© 2002 NRC Canada

were obtained in THF (and in SO_2 and CH_2Cl_2) after vigorous stirring or placing the sample in a sonic bath, a black precipitate was observed at the bottom of the sample tube on standing within 1 h, implying **6** is only very sparingly soluble in these solvents.

Sublimation was carried out under static vacuum (10^{-3} mmHg (1 mmHg = 133.322 Pa)) at 90°C in a 14 × 300 mm sealed glass tube (reaction 1 in Table 1), which gave a few black block-like crystals, shown to be [NC-$\overline{\text{CNSSN}}$] by X-ray analysis (see below), and a very few extremely brittle colourless needle-like crystals. Attempts to mount the colourless needle-like crystals were frustrated by their brittleness. EI-MS data for the the colourless crystals (27 eV, I > 5%) is listed below.

EI-MS *m*/*z* (%): 178 ($[C_2N_4{}^{34}S^{32}S_2]^+$, 15), 177 (6), 176 ($[C_2N_4S_3]^+$, 100), 130 ($[C_2N_3S_3]^+$, 32), 104 ($[C_2N_3S_2]^+$, 11), 90 ($[CNS_2]^+$, 5), 78 ($[S_2N]^+$, 19), 46 ($[SN]^+$, 35).

The peak at 176 and the intensity of the ^{34}S-isotopomer peak at 178 suggest $C_2N_4S_3$ as a possible molecular formula. The lack of an abundant ion at 124 ($[S_3N_2]^+$) and the intense $[M - SN]^+$ fragment discounted the structure NC-CNSNSNS, a derivative of the 1,3,5,2,4,6-trithiatriazepine ring system, which has been studied extensively by Rees and co-workers (27).

Another attempt at static vacuum (10^{-3} mmHg) sublimation in a sealed tube with the temperature slowly increased from 30 to 110°C over 5 days (reaction 2 in Table 1) resulted in a few very small black crystals and numerous colourless needle-like crystals after 3 weeks. Crystals were not successfully mounted because of their small size and brittleness. The mass spectrum data of the colourless needles are listed below (27 eV, I > 5%; I > 1% in the Supplemental Material) and were nearly identical to those reported for NSNCCNSN (**10**) (28).

EI-MS *m*/*z* (%): 146 ($[C_2N_4{}^{34}S^{32}S]^+$, 9), 144 ($[C_2N_4S_2]^+$, 100), 78 (S_2N^+, 26), 72 ($[CN_2S]^+$, 31).

Sublimation under static vacuum (10^{-3} mmHg) in a sealed tube with a temperature gradient of 25–80°C for 2 weeks (reaction 3 in Table 1) produced a few large rhombohedral yellow crystals (S_4N_4: FT-Raman spectra (29), see Supplemental Material) and black amorphous material. The mass spectrum of the black material (listed below for 27 eV, I > 5%; I > 1% in the Supplemental Material) and FT-Raman spectrum (strong peak at 2250 cm^{-1} (ν(CN)) and 129 cm^{-1} (indicative of dimer S···S interactions (12), spectrum shown in the Supplemental Material) were consistent with data for [NC-$\overline{\text{CNSSN}}$].

EI-MS *m*/*z* (%): 132 ($[C_2N_3{}^{34}S^{32}S]^+$, 10), 130 ($[C_2N_3S_2]^+$, 61), 84 ($[C_2N_2S]^+$, 23), 80 ($[{}^{34}S^{32}SN]^+$, 11), 78 ($[S_2N]^+$, 100), 72 ($[CN_2S]^+$, 16), 64 ($[S_2]^+$, 38), 58 ($[CNS]^+$, 18).

Sublimation at 50–100°C under dynamic vacuum (10^{-5} mmHg), in a 14 × 400 mm tube capped with a J. Young valve for 2 weeks (reaction 4 in Table 1) was most successful at producing pure **6**, as evidenced by the mass spectrum (data listed below for 27 eV, I > 5%; I > 1% in the Supplemental Material). However, the quantity of sublimed material was extremely small. Sublimation under dynamic vacuum (10^{-3} mmHg, 40–80°C) yielded numerous green-yellow crystals, identified as S_8 (FT-Raman).

Table 4. Crystal data and refinement details for [NC-$\overline{\text{CNSSN}}$].

Characterization and crystal structure of [NC-$\overline{\text{CNSSN}}$]

Several black block-like crystals (from reaction 1 in Table 1) were loaded into rigorously dried glass capillaries and, though of poor quality, were shown to be [NC-$\overline{\text{CNSSN}}$] by single crystal X-ray crystallography. An empirical absorption correction based on azimuthal scans of several reflections was applied, which resulted in transmission factors ranging from 0.82 to 1.00. The data were corrected for Lorentz and polarization effects. A correction for secondary extinction was applied (coefficient = 1.45351×10^{-6}). The structure was solved by direct methods (30) and expanded using Fourier techniques (31); all atoms were refined anisotropically. The full cycle of full-matrix least-squares refinement[6] on F was based on 270 observed reflections [$I > 2.00\,\sigma(I)$] and 65 parameters and converged (largest parameter shift was 0.01 times its esd) with R_1 = 0.069 and wR_2 = 0.074. Neutral atom scattering factors were taken from Cromer and Waber (32). Anomalous dispersion effects were included in $F_{calcd.}$ (33); the values of $\Delta f'$ and $\Delta f''$ were those of Creagh and McAuley (34). The values for the mass attenuation coefficients are those of Creagh and Hubbell (35). All calculations were performed using the teXsan (36) crystallographic software package of Molecular Structure Corporation. Crystal data are summarized in Table 4; full details are given in the Supplemental Material.

Ab initio calculations

Full geometry optimizations and vibrational frequency calculations for **6** (diradical triplet and "quinoidal" closed-

[6] Least-squares function minimized: $\Sigma w(|F_o| - |F_c|)^2$ where w = 1.

© 2002 NRC Canada

shell singlet), $\mathbf{6}^{2+}$, $[(\overline{CNSNS})_2]^{+\bullet}$ ($\mathbf{6}^{+\bullet}$), **9**, and [NC-$\overline{CNSSN}$] were carried out using the GAUSSIAN 98W suite of programs (37*a*) with the 6-311G(2df) basis set and the recently implemented MPW1PW91 HF/DFT hybrid functional (37*b*), which has proved successful in reproducing geometries, vibrational spectra, and energies of heavy-atom containing species (e.g., S_8^{2+} (38) and S_4^{2+} (39)) where other recent high-level calculations (40) did not. The starting geometry for **6**, $\mathbf{6}^{+\bullet}$, and $\mathbf{6}^{2+}$ was the average of the two crystallographically unique cations in the X-ray single crystal structure of $\mathbf{6}\cdot[AsF_6]_2$ (13). Calculated molecular orbitals were visualized with CHEM3D Ultra (37*d*). Calculated vibrational frequencies were animated using HYPERCHEM (37*e*), and assigned by these visualisations. All calculated structures were stationary points (i.e., no imaginary frequencies).

Geometry optimizations on the diradical singlet and triplet states of **6** were also performed at the 6-311G(*d*) level using the GAMESS suite of programs (37*c*) by Goddard and Mawhinney (41); the diradical singlet was calculated by the GVB-PP (TC-SCF) method using the ROHF triplet MOs (41). This method was chosen since electron correlation is required for an accurate energy difference calculation of these two states (42), and the MPW1PW91 method is inadequate for this task. Results are given in the Supplemental Material.

The effects of rotation about the C—C bond for **6** (diradical triplet and "quinoidal" closed-shell singlet **7**), $\mathbf{6}^{2+}$, $\mathbf{6}^{+\bullet}$, and **9** were examined via a series of MPW1PW91/6-31G(*d*) geometry optimizations in which the S-C-C-S dihedral angle (N(1)-C-C-N(1′) for **9**) was held constant in 15° steps from 0° (*cis*) to 180° (*trans*). Vibrational frequencies were not determined in this study.

Results and discussion

Preparation of 6

Double reduction of $\mathbf{6}\cdot[AsF_6]_2$ with $[NBu_4][Cl]$ and $SbPh_3$ gives **6** as an insoluble black powder (eq. [1]). This reaction is almost quantitative (Table 1), as is the preparation of the trisulfide analog $[(\overline{CNSSS})_2][AsF_6]_2$ ($\mathbf{8}\cdot[AsF_6]_2$) from $(CN)_2$ and a mixture of $[S_4][AsF_6]_2$ and (or) $[S_8][AsF_6]_2$ (11), in contrast to the 15% overall yield in the preparation of **9** (12). However, crystals suitable for X-ray structure determination were obtained for the latter two compounds but to date crystals of **6** have been elusive. This is due in part to the insolubility of **6** in numerous solvents. In contrast to the success with **9** (12), numerous attempts at sublimation to obtain crystals and (or) pure **6** resulted only in traces of **6** (mass spectra) and various decomposition products, depending on the sublimation conditions (see Table 1). This suggests that the sublimation and decomposition temperatures for **6** are very similar.

The first Gouy measurement on a sample of **6**, prepared as described above, gave a value of 2.92 μ_B (26) (2.83 μ_B is expected for two strongly coupled unpaired electrons ($s = 1$) and 2.45 μ_B if they are weakly coupled or non-interacting (43)); the second preparation of **6** gave a value of 0.62 μ_B (reaction 2). This drastic difference in magnetic moments led to a search for a correlation between reaction conditions and magnetic moment. Changes in reaction conditions included reaction temperature, reaction time, and method of mixing reagents, some of which are listed in Table 1, and more are given in the Supplemental Material. No obvious correlation was found, but magnetic moments from before and after extensive washing imply that the values are intrinsic to the sample and not the reaction byproducts: complete removal of impurities should lead to an increase in the magnetic moment. There was no obvious benefit to excluding light from the reactions, since there was no evidence that solid **6** rearranged photochemically (EPR, IR, FT-Raman, MS) when purposely exposed to light.

Structure elucidation

In the absence of an X-ray single crystal structure, extensive spectroscopic and computational characterization was carried out to determine the structure of **6**.

Mass spectra

The mass spectra fragmentation pattern of **6** contains a strong parent ion peak with a fragmentation pattern that is in complete agreement with the assigned structure. There are significant differences in the mass spectra of **6** and **9**, in particular the S_2^+ (mass = 64) peak is the most intense peak for **9** but only 8% (70 eV, 7% at 27 eV) for **6**; and a peak at mass = 144 $[M - S_2]^+$ is absent for **6**. These differences imply the rings of **6** do not contain S-S units and therefore **6** does not undergo rearrangement to [NSNSC-CNSSN] or **9** upon reduction.

EPR

The EPR spectrum of **6** in THF at room temperature consists of a triplet of triplets with $g = 2.0043$, $a(^{14}N(2)) = 1.11$ mT and $a(^{14}N(4)) = 0.04$ mT (Fig. 2*a*, Table 3). The differences in line width and intensity of the lines is due to spin-rotation interactions in solution (44). The EPR spectrum of **9** in $CHCl_3$ (Table 3) consists of a pentet ($g = 2.011$, $a(^{14}N) = 0.50$ mT) (12), suggesting there is little or no exchange interaction between the two radical centers for either **9** or **6** (45). For **9**, the onset of exchange coupling between the two rings is observed at 303 K (12*b*), and greater interaction is found in the 1,3- and 1,4-phenylene-bridged bis(1,2,3,5-dithiadiazolyl) species (46, 47), facilitated by the phenyl rings (12*b*), e.g., 5-*tert*-butyl-1,3-bis-(1,2,3,5-dithiadiazolyl)benzene at 240 K shows a simple 5-line pattern with a more complex pattern due to intramolecular exchange observed at room temperature (46).

The absence of a pentet and the similarity of the g and $a(^{14}N)$ values to -$\overline{CNSNS}$ rings rather than -$\overline{CNSSN}$ rings (Table 3) and the good agreement between the calculated and observed $a(^{14}N)$ values indicate the two rings of **6** remain as -$\overline{CNSNS}$ on reduction rather than rearranging to -$\overline{CNSSN}$. The in situ reoxidation of **6** to $\mathbf{6}\cdot[AsF_6]_2$ with AsF_5 in SO_2 showed only $\mathbf{6}^{2+}$ in the ^{13}C NMR and **6** as the main product in a larger scale reaction. The absence of signals attributable to $\mathbf{6}^{+\bullet}$ or $[\overline{NSSNC}\text{-}\overline{CNSNS}]^{+\bullet}$ in the EPR spectrum of **6** (Table 3) suggests the reduction goes to completion.

Theoretical studies

Theoretical calculations were carried out to aid in the assignment of the vibrational spectra (see below) and to use the comparison of the calculated and X-ray structures of $\mathbf{6}^{2+}$

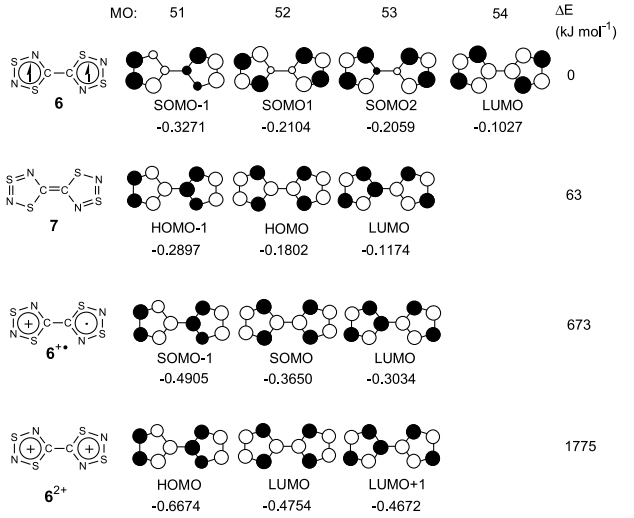
and **9** as a gauge of the quality of the calculated structure of **6**. Tables 5 and 6 show the excellent agreement between the calculated and X-ray crystal structures for both $\mathbf{6}^{2+}$ (in $\mathbf{6}\cdot[AsF_6]_2$ (13)) and **9** (12), respectively, with only the S—S and C—S bond lengths and the S-N-S bond angle slightly outside 3 × (esd) of the experimental data.

Fig. 4. π molecular orbitals 51–54 and MPW1PW91/6-311G(2df) orbital energies (eV) for the $(CNSNS)_2$ series of molecules.



The two rings of **6** were calculated to be coplanar and separated by an sp^2-sp^2 C—C single bond (see Table 5) similar to **9** (12) and the dication in $\mathbf{6}\cdot[AsF_6]_2$ (13). The differences in bond lengths between **6** and $\mathbf{6}^{2+}$ largely reflect the nature of SOMO1 and SOMO2 (see Fig. 4) and the low coefficients on the carbon atoms of **6** (C_5 SOMO1: –0.037, SOMO2: 0.037). Thus the antibonding contributions of the S—N bonds in SOMO1 and SOMO2 with large S (S_1 SOMO1: 0.092, SOMO2: 0.092) and N (N_4 SOMO1: –0.133, SOMO2: –0.133) coefficients lead to S—N bond lengths

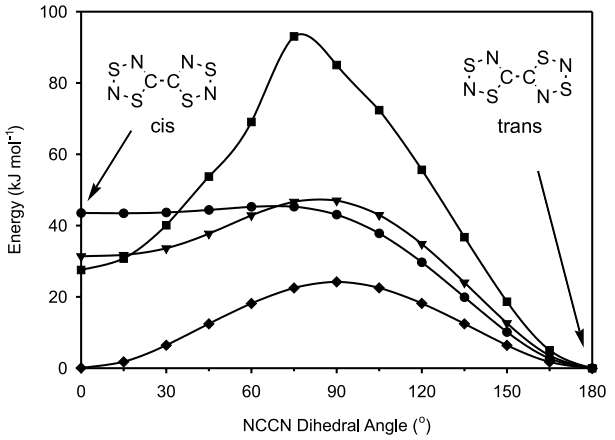
Fig. 5. Calculated [MPW1MPW91/6-311g(2df)] energetics of rotation about the C—C bond for **6** (▼), $\mathbf{6}^{2+}$ (●), $\mathbf{6}^{+\bullet}$ (■), and **9** (▲).



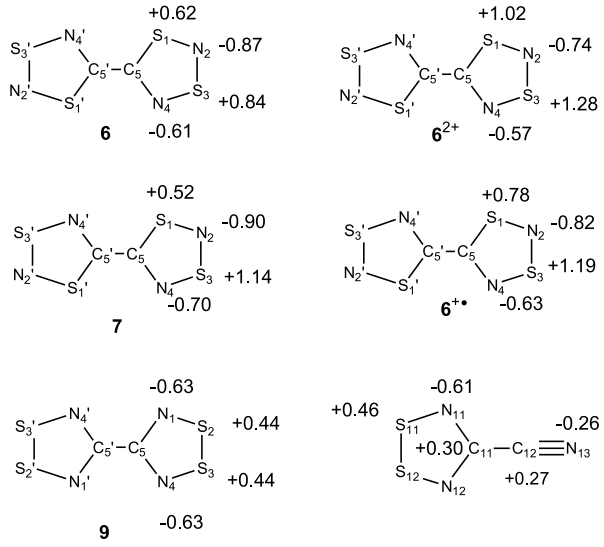
longer in **6** than in $\mathbf{6}^{2+}$. In contrast the C—C and C—N bond lengths in **6** (1.444, 1.282 Å) and $\mathbf{6}^{2+}$ (1.465, 1.298 Å) are rather similar, as directly observed in the vibrational spectra (Table 2), the slight differences being accounted for by inclusion of the differences in the HOMO of $\mathbf{6}^{2+}$ and the corresponding SOMO1 of **6** and the higher carbon and nitrogen coefficients in the HOMO of $\mathbf{6}^{2+}$ (C_5 0.183, N_4 0.127) and the SOMO1 of **6** (C_5 0.115, N_4 0.107). We note that the occupancies of the lower energy orbitals of **6** and $\mathbf{6}^{2+}$ are very similar.

Double occupation of SOMO1 results in a strengthening of the C—C bond, as observed for the calculated closed-shell "quinoidal" singlet **7** (1.358 Å), for which the HOMO is also C—C bonding. The HOMO of **7** is C—N antibonding, resulting in a longer (1.355 Å) C—N bond than that calculated for **6** (1.282 Å).

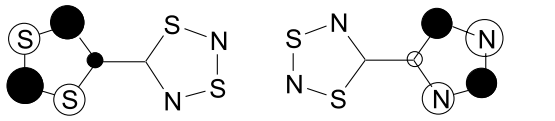
The SOMO1 is occupied (C coefficient: 0.104, see Fig. 4) in the monocation-monoradical $\mathbf{6}^{+\bullet}$, and the C—C distance is therefore intermediate (1.409 Å) to that of the diradical triplet and closed-shell singlet states. Similarly the C—N bond length (1.320 Å) falls between that of **6** and **7**, since the SOMO is C—N antibonding, as is the HOMO of **7**, but only singly occupied.

Rotation about the C—C bond (Fig. 5) confirmed that, in the gas phase, the *trans*-coplanar arrangements of the rings in both **6** and $\mathbf{6}^{2+}$ are the lowest energy conformations. This is in contrast to the previously published ROHF/6-311G* calculations carried out for the diradical triplet **9**, for which the confirmation with the two rings canted at 43.5° was 2.5 kJ mol^{-1} lower in energy than the observed coplanar arrangement in the solid state (12). Our recalculation of **9** at the MPW1PW91/6-311G(2df) level resulted in a lowest energy conformation with the rings twisted 10.5° out of plane, only 0.02 kJ mol^{-1} lower than the coplanar form (Table 6). These differences in ring orientation between the [$(\overline{CNSNS})_2$] series of compounds and **9** is attributed to the $S^{\delta+}\cdots N^{\delta-}$ attractions for **6**, $\mathbf{6}^{2+}$, and **8** vs. the $N^{\delta-}\cdots N^{\delta-}$ repulsions in **9** (see Fig. 6). Similarly, the larger positive charge on the sulfur atoms in $\mathbf{6}^{2+}$ compared with **6** (see Fig. 6) could account for the higher energy of the *cis* orientation in Fig. 5 for $\mathbf{6}^{2+}$ (33.8 kJ mol^{-1}) vs. **6** (27.1 kJ mol^{-1}). The relatively high energy of the twisted geometries of $\mathbf{6}^{+\bullet}$ compared with the other species indicates that the non-planarity prevents electron (and charge) delocalization throughout the

Fig. 6. Atom numbering scheme and calculated (NBO) charges for the $(\overline{CNSNS})_2$ series of molecules, $(\overline{CNSSN})_2$ and [NC-$\overline{CNSSN}$].



Scheme 1.



two rings of $\mathbf{6}^{+\bullet}$. The EPR results for $\mathbf{6}^{+\bullet}$ (Table 3) contradict this, however, since the simple 3-line pattern implies that the electron is localized in one ring of $\mathbf{6}^{+\bullet}$. These differences are possibly due to solvent effects and the inability of the gas phase calculations at this level to correctly model $\mathbf{6}^{+\bullet}$.

The calculated molecular orbitals indicate **6** is in essentially a disjoint diradical state, since the two singly occupied molecular orbitals (SOMOs) of **6** (Fig. 4) consist of linear combinations of the localized orbitals **11a** and **11b** (Scheme 1) (12*b*, 42, 50, 51) even though there is no node at carbon (Fig. 4) to restrict "spin leakage" (47) as there is for **9** (12*b*). The diradical singlet for **9** was calculated (HF/6-311G*) to be lower than the diradical triplet by 2.1 kJ mol^{-1} (12), and recent calculations on tetramethyleneethane determined the diradical triplet to be 4.2–6.3 kJ mol^{-1} lower in energy than the diradical singlet (51). The diradical triplet **6** was calculated (GVB-PP(TC-SCF)/6-311G*) to be lower than the diradical singlet state by 0.07 kJ mol^{-1}, and the calculated bond lengths (see Supplemental Material) were identical to within 0.001 Å (41). Our EPR and magnetic data (see below) are consistent with the expected small exchange interactions between the two unpaired electrons, and the triplet and open shell singlet states of **6** should be essentially degenerate, in agreement with our calculations.

The "quinoidal" closed shell singlet **7**, calculated to be 63 kJ mol^{-1} higher in energy than **6**, is ruled out as a possible product of the double reduction of $\mathbf{6}\cdot[AsF_6]_2$, since **7** would be distinguished by a markedly different vibrational spectra, as expected from the noticeably different bonding (e.g., ν(CC) expected at 1554 cm^{-1} for a bond length of 1.358 Å, see above and Table 5 (calculated spectra listed in

© 2002 NRC Canada

the Supplemental Material)), and since no EPR spectra would be observed experimentally.

Vibrational spectra

For the *trans*-coplanar centrosymmetric (C_{2h} symmetry) **6** and $\mathbf{6}^{2+}$, the 24 expected vibrational modes (12 IR, 12 Raman active) are mutually exclusive owing to the center of inversion present in these species. This is evident in the observed vibrational spectra of **6** (Table 2, FT-Raman shown in Fig. 3, IR in the Supplemental Material), but the high-quality FT-Raman spectrum of $\mathbf{6}\cdot[AsF_6]_2$ shows a few forbidden bands as well (e.g., 751, 437 cm^{-1}). The calculated and observed vibrational frequencies of **6** and $\mathbf{6}^{2+}$ are in excellent agreement with each other (see the values for the more intense vibrations in bold in Table 2) and add significant support to our structural proposal for **6**. For example, the peaks at 1444 and 1239 cm^{-1} in the FT-Raman spectrum of **6** are consistent with C—C single bond stretching heavily mixed with the respective symmetric C–N and C–S stretching modes (see Table 2) and are shifted appropriately from those at 1491 and 1208 cm^{-1} for $\mathbf{6}^{2+}$, considering the differences in C—C and C—N bond lengths between **6** (1.444 and 1.282 Å, respectively) and $\mathbf{6}^{2+}$ (1.454 (15) and 1.298 (10) Å, respectively). These also compare well with those observed (1513, 1230 cm^{-1}) for $\mathbf{8}\cdot[AsF_6]_2$ (d(C—C) = 1.462 (5) Å, d(C—N) = 1.284 (3) Å (11)) and **9** (d(C—C) = 1.488 (7), d(C—N) = 1.331 (7) Å; IR: 1264 (m) cm^{-1}, although peaks due to Nujol at 1460 and 1376 cm^{-1} obscured other expected C—N stretching modes for **9** (12*b*)). Other IR peaks reported for **9** (1244 (s), 1090 (br), 1012 (m), 820 (w), 804 (s), 793 (s), 784 (s), 559 (m), 507 (m), 495 (m), 421 (m) cm^{-1} (12*b*)) were not observed in the vibrational spectra of **6**, supporting the proposal garnered from the MS data (see above) that **6** contains no S—S bonds.

The observed FT-Raman and IR spectra of **6** also indicated the presence of small amounts of the reduction by-products (e.g., $[AsF_6]^-$ (IR: 707 cm^{-1}), C-H (FT-Raman: 2876 cm^{-1})) in agreement with elemental analysis. FT-Raman and IR spectra are given in the Supplemental Material. A lack of change in the vibrational spectra on grinding suggests there is no significant change in geometry to a lower symmetry, e.g., rotomer. This is not definitive, however, since an investigation of the vibrational spectra of the solid (dihedral angle = 0°) and gas phase (42°) of biphenyl yielded negligible differences in the observed spectra (49).

X-ray powder photography

X-ray powder diffraction on samples of **6** was carried out to obtain structural information and observe any possible phase changes in **6** on mechanical grinding. Details are shown in the Supplemental Material. The powder diffraction pattern of **6** did not contain lines attributable to the soluble reaction byproducts (eq. 1: $[NBu_4][AsF_6]$, $SbPh_3Cl_2$), S_4N_4, S_8, or obvious possible products, as well as neutral ternary carbon–sulfur–nitrogen compounds whose X-ray structures have been determined and included in the Cambridge Structural Database (16) as of December 2001 (see Supplemental Material).

A reasonable indexing of the trace and a unit cell were obtained for 54 of 55 reflections from a sample ground for 12 h, and 19 of 20 for an unground sample. The one reflection (d = 2.747 Å) that was omitted was much sharper than the others and probably comes from some other (unidentified) material. However, this reflection is strong, and the results of the indexing should be treated with caution.

Results from an unground sample of **6**: possible space group *Pnma*, a = 10.310 Å, b = 8.210 Å, c = 4.749 Å, V = 401.98 $Å^3$, Z = 4. The probable space group for a sample of **6** ground 12 h is $Pna2_1$, a = 4.817 Å, b = 10.321 Å, c = 8.090 Å, V = 402.2 $Å^3$, Z = 4, and a density of 1.718 g cm^{-3}.

There were subtle, but definite, differences between unground powder samples and those ground for 12 h. The main features stayed the same on grinding, but there were definite changes on grinding. In particular, a shoulder on one of the strong peaks (2θ = 28°) disappeared on grinding, whereas small but definite features elsewhere increased in intensity (see Supplemental Material). These differences coincided with a switch in indexing from centrosymmetric (*Pnma*) to the equivalent non-centrosymmetric ($Pna2_1$) space group. These changes are indicative of a grinding-induced second order phase change consistent with the absence of any significant change in cell volume (52). The sample thus becomes ordered slightly differently on grinding, but with the molecular constituents remaining the same and with very few differences between the phases.

The density of the sample of **6** ground 12 h (1.718 g cm^{-3}) and the density of the unground sample (1.719 g cm^{-3}) are not significantly different and are in the general range of similar planar non-hydrogen atom systems: 1.63 g cm^{-3} for $[CF_3\overline{CSNS}\overline{C}CF_3]^{\bullet}$ (paramagnetic liquid, 22°C; 1.97 g cm^{-3} for the diamagnetic solid) (2), 1.91 g cm^{-3} for diamagnetic [NC-$\overline{C}$NSS$\overline{N}$], 2.26 g cm^{-3} for diamagnetic **9** (12*b*); the low temperature (150 K) less paramagnetic phase of 1,2,5,-thiadiazolo[3,4,*b*]-1,3,2-dithiazolo[3,4,*b*]pyrazin-2-yl (TDP-DTA (**4**)) was ca. 2% higher in density (2.13 g cm^{-3}) than the high temperature (293 K) more paramagnetic phase (2.08 g cm^{-3}) (8). The densities were not reported for the two phases of 1,3,5-trithia-2,4,6-triazapentalenyl (**5**) (10). These are in good agreement with the density of **6** obtained via pycnometer (1.7 g cm^{-3} after 1 h grinding). The density of **6** is significantly lower than that of **9**, implying that the distance between molecules of **6** is greater than that in **9** (intradimer S···S 3.131(2), 3.025(2) Å, interdimer 3.711(2), 3.811(2) Å (12*b*)).

Magnetic measurements: increase in paramagnetism on mechanical grinding

Preliminary room temperature Gouy measurements performed on samples of **6** varied from 2.8 μ_B to as low as 0.6 μ_B. There was no apparent correlation to changes that were made to the procedure for the double reduction of $\mathbf{6}\cdot[AsF_6]_2$ (see Table 1). However, on mechanical grinding with an agate mortar and pestle under a dry nitrogen atmosphere (in a Vacuum Atmospheres Dri-Lab drybox), samples of **6** changed from a black fluffy powder to black graphite-like shiny plates, with a large increase in magnetic moment and no observable changes in the FT-Raman, IR, and mass spectra.

Variable temperature magnetic measurements (4–300 K) were carried out on unground samples and on samples from the same batch ground for periods up to 12 h. The room temperature effective magnetic moments, μ_{eff}, increased on

© 2002 NRC Canada

Fig. 7. Change in effective magnetic moment of **6** on mechanical grinding: (▲) 0 min, (●) 15 min, (▼) 60 min, (■) 720 min grinding time.

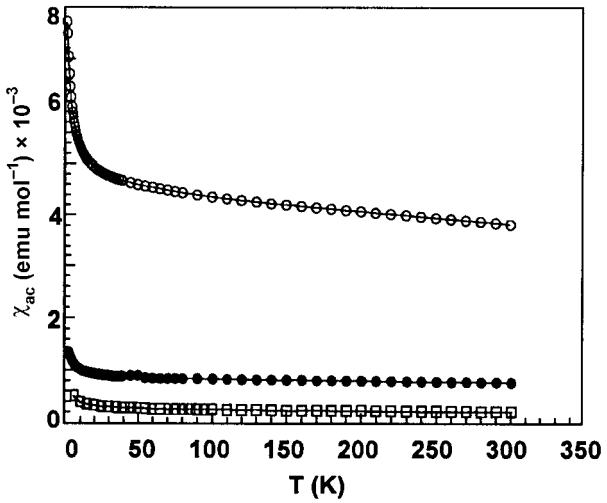
grinding from 1.03 μ_B (unground) to 1.3 μ_B (15 min), 1.38 μ_B (1 h), and 2.55 μ_B (12 h). The effective magnetic moment data as a function of temperature are shown in Fig. 7. The data for **6** clearly show an increase in paramagnetism on grinding. The general decrease in μ_{eff} as the temperature decreases is indicative of the presence of exchange coupling, and it is reasonable to assume that it is antiferromagnetic in nature. None of the magnetic data sets could be fitted successfully to the Bleaney-Bowers equation (53) for a simple S = 1/2 dimer model, suggesting that intramolecular exchange between the unpaired electrons in each of the rings of **6** is unlikely. Given the propensity of systems of this sort to form associated chain-like structures, a simple 1-dimensional chain structure involving associated diradical subunits with interchain interaction corrections was

Fig. 9. Variable temperature AC susceptibility of **6**: (□) unground diamagnetic sample (0.98 μ_B), (●) unground paramagnetic sample (1.39 μ_B), (○) sample ground 720 min (3.02 μ_B at 300 K).



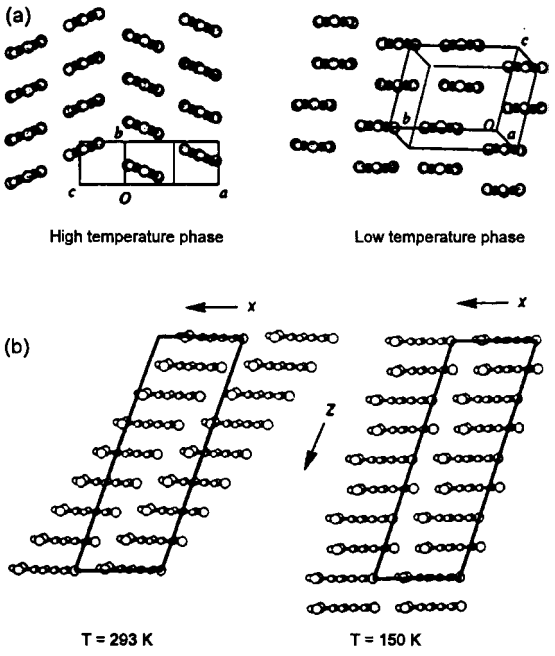
considered as a possible model. However, none of the data sets could be fitted successfully to a Heisenberg 1-dimensional chain model of this sort. Approximate fits were obtained at low temperatures (<150 K, data given in the Supplemental Material), but this was not considered to be rigorous. Notwithstanding the failure to rigorously fit the data, the analysis implies the absence of an intramolecular exchange within subunits of **6**, which is in agreement with the theoretical calculations (calculated $a(^{14}N)$ values, see Table 3) and EPR spectra (e.g., observing only a 1:1:1 triplet), which show that **6** behaves as a disjoint diradical (45, 50).

The change in magnetic behaviour of **6** on mechanical grinding is unique in main group chemistry, although dramatic increases in paramagnetism on grinding are well documented in transition metal chemistry (e.g., refs. 14, 15). Low-temperature (2 K) magnetization vs. field studies (Fig. 8) and variable temperature ac susceptibility measurements (Fig. 9) show that samples of **6** did not display any ferromagnetic character, but exhibited increased magnetization as a function of grinding time, in agreement with variable temperature DC susceptibility studies.

It is reasonable to assume that there must be some association between the disjoint diradical subunits and that it varies in magnitude as a function of grinding. The increase in paramagnetism on grinding suggests that the associations may be disrupted or at least changed by these mechanical forces to induce the second order phase change observed by the X-ray powder diffraction results. We propose that the putative chains form as a result of electrostatic attractions, e.g., between N(2) (–0.87) and S(3) (+0.84) on one molecule with an adjacent S(3)′ and N(2)′ on another, and that these are the strongest intermolecular forces present, as is the case for the tetrameric 4,5-bis(trifluoromethyl)-1,3,2-dithiazol-2-yl $[CF_3\overline{CSNSC}CF_3]^{\bullet}$ in the solid phase (4). The phase change leads to disruption of the π*-π* interactions in the diamagnetic phase, leading to decreased antiferromagnetic coupling, perhaps similar to that observed for **5** (10) (Fig. 10*a*) where a crystallographic phase change on warming decreases

© 2002 NRC Canada

Fig. 10. High- and low-temperature phases of **5**(*a*) and **4**(*b*). Reproduced with permission from: (*a*) W. Fujita et al., Science, **286**, 261 (1999), copyright 1999 American Association for the Advancement of Science; (*b*) T.M. Barclay et al., J. Am. Chem. Soc. **120**, 352 (1998), copyright 1998 American Chemical Society.



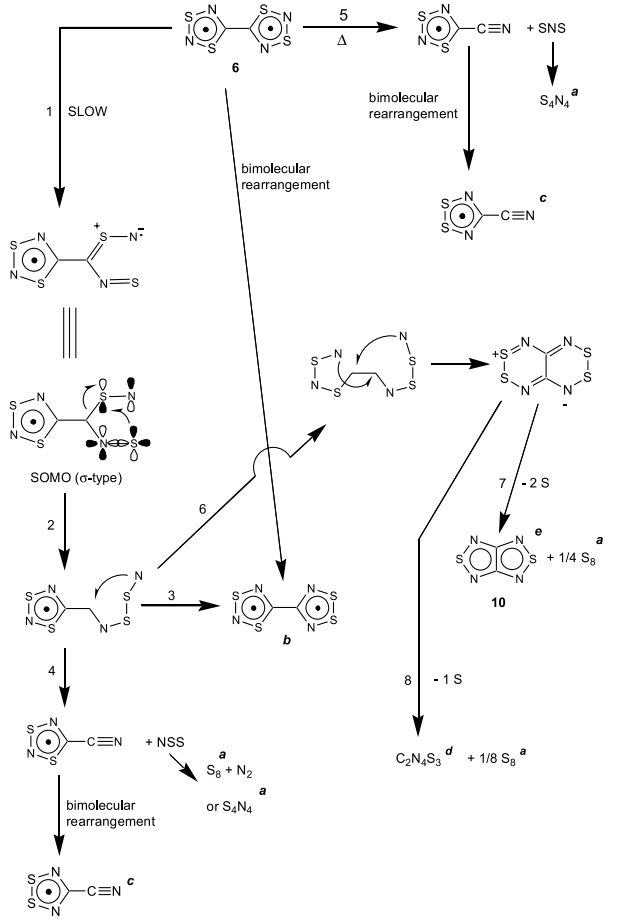
the effect of dimerization along the 1-dimensional stacks, shifting from a stacked dimers phase at low temperature to a phase of evenly spaced slipped π-stacks at high temperature (10). Alternatively, the phase change in **6** may be similar to that observed for TDP-DTA (**4**), shown in Fig. 10*b* (8), where ribbons of TDP-DTA are in slipped π-stacks at room temperature but shift laterally into arrays of dimers at low temperature (8). In contrast to **5**, dimerization of **4** at low temperature does not lead to complete quenching of paramagnetism (8).

We await single crystals of **6** to confirm the associated structural arrangement, which will hopefully allow a fuller understanding of the unique magnetic properties of this diradical species. Thus far suitable crystals have not been produced.

Purity of 6

Despite many attempts to purify **6** we were successful only in preparing **6** in ca. 95% purity by weight, with the impurities reasonably assigned as $[NBu_4][AsF_6]$ and $SbPh_3Cl_2$ in a 2:1 ratio (IR, Raman, elemental analysis). Nevertheless all but one of the major lines in the X-ray powder photographs (see the Supplemental Material) were assigned to **6**, and the calculated density was in good agreement with that determined experimentally. The majority of the bands in the IR and Raman spectra are attributable to **6**, and the features of the EPR and mass spectra were essentially exclusively due to **6**. All these properties were found from samples from all syntheses. The ca. 5% by weight probable impurities are diamagnetic and do not affect the magnetic measurements. It is likely that the impurities are occluded in fragments of the insoluble **6**, severely

Fig. 11. Proposed decomposition pathway for **6**: (*a*) characterized by FT-Raman spectroscopy; (*b*) proposed from EPR spectroscopy in wet glassware; (*c*) X-ray crystal structure; (*d*) proposed from MS; (*e*) characterized by MS (28).



hindering and (or) preventing their removal by repeated grinding and extraction with solvent.

Thermal rearrangement of 6

Explanation of the wide variety of products obtained from attempted crystal growth of **6** by vacuum sublimation may come from work on the ring opening of [H-CNSNS] by Grein (54), together with the known solid state bimolecular rearrangement of 1,3,2,4-dithiadiazolyl rings to 1,2,3,5-isomers (5*d*, 5*e*, 6), the favoured rearrangement process. Figure 11 shows some possible decomposition pathways of **6** in addition to the bimolecular rearrangement. The ring opening of [H-CNSNS] was calculated (HF/3-21G*) to be endothermic by 121 kJ mol^{-1}, i.e., slow but accessible (54), especially on heating. The -NSSN fragment could then close (step 2) to form [NSSNC-CNSNS] (step 3) or lose SSN to form [NC-CNSNS] (step 4). Alternatively [NSSNC-CNSNS] could arise from the bimolecular rearrangement of **6**. [NC-CNSNS] could also be produced directly from **6** (step 5) via the thermal symmetry-allowed loss of SNS•. This loss of SNS• from [Ph-CNSNS] was shown to occur via photolysis (55). [NC-CNSNS] readily rearranges to the more stable isomer [NC-CNSSN] (6), and S_4N_4 could be formed from decomposition of SNS•.

Fig. 12. [NC-CNSSN] packing. Intermolecular contacts: S(12)···N(13) = 3.01 (2) Å, S(11)···N(13) = 3.03(2) Å, S(11)···S(12) = 3.074 (9) Å.

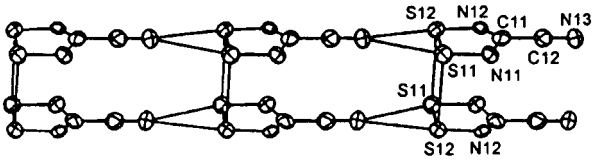

Fig. 13. ORTEP of [NC-CNSSN]. Ellipsoids are 50% probability.

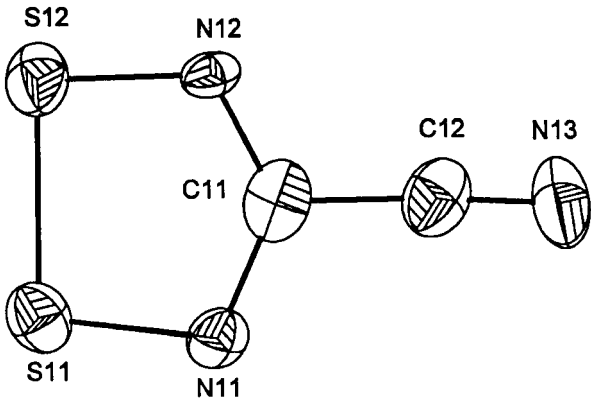

Additionally, a second intramolecular ring opening (step 6) could lead to two fused ring compounds with loss of sulfur: the known **10** (28) from step 7; and $C_2N_4S_3$ (step 8) from observed mass spectra data (see above), which has not been observed hitherto.

Structure of [NC-CNSSN]

Although not well resolved (R_1 = 0.069), the structure of [NC-CNSSN] clearly consists of axially symmetric, cofacial, *cis* dimers of planar [NC-CNSSN] units bound by two long (3.092 (5) Å) S···S π*-π* contacts (55). The dimers are linked to form strands (Fig. 12) via two sets of $N13^{\delta-}$—$S11^{\delta+}$ (2.97 (1) Å) and $N13^{\delta-}$—$S12^{\delta+}$ (2.98 (1) Å) contacts (sum of S and N van der Waals radii: 3.35 Å) per dimer unit; see Fig. 13 for atom-labelling scheme. There are no significant contacts between neighbouring strands, which run in the opposite direction. The average bond lengths within the -CNSSN heterocycles are typical for derivatives of this ring system (56) and compare well with the calculated structure (Table 7). The inter-dimer interaction is due to an in-plane electrostatic interaction between the lone pair on N13 (charge: –0.61 from natural bond order (NBO) analysis) and the positively charged sulfur atoms (+0.46) in a neighbouring dimer (see Fig. 12), similar to that found in cyano-substituted 5-phenyl-2,3,1,4-dithiadiazolium radicals (57). The EPR spectrum of a crystal of [NC-CNSSN] under Freon-11 consists of a broad, featureless band at g = 2.015 (typically g lies between 2.010 and 2.013 for -CNSSN rings, see Table 3) and presumably arises from monomers trapped in the crystal (as for **4**).

Conclusions

Although neither completely pure material nor the single crystal X-ray structure of **6** have been obtained, the identity and the *trans*-planar structure of **6** is supported by EPR and mass spectra, the similarity of the measured density with that calculated from the X-ray powder diffraction data, the re-formation of **6**$(AsF_6)_2$ on oxidation of **6** by AsF_5, the correlation between the calculated and observed vibrational spectra of **6** and $\mathbf{6}^{2+}$, as well as a computational study [MPW1PW91/6-311G(2df)] of **6** and its rotational isomers. Compound **6**, like the isomer **9** and the dication $\mathbf{6}^{2+}$, has a C—C bond order ca. 1 and behaves as a disjoint diradical, even though there is no formal node in the in-plane π SOMOs. Compound **6** does not adopt the classical Lewis structure **7**, which corresponds to a low-lying excited state of **6**.

The structure of **6** can be written as **12a** (Scheme 2), containing two C—N π bonds (1230 kJ mol^{-1}) and one S—N π bond (one half π bond per ring) (335 kJ mol^{-1}). The quinoidal structure **12b** contains one C—C π bond (602 kJ mol^{-1}) and two S—N π bonds (670 kJ mol^{-1}). The difference is 293 kJ mol^{-1} in favour of **12a**, plus energy required to form the polar S^+—N^- bond in **12b**, which is unfavourable.

The synthesis of **6** by reduction of **6**·[$(AsF_6)_2$] led to samples of **6** with room temperature Gouy measurements that

varied between 0.6 to 2.8 μ_B. Variable temperature magnetic measurements show that the material exhibits antiferromagnetic behaviour, undergoing a large increase in magnetic moment on mechanical grinding. The presence of reduction byproducts in the samples of **6** has been taken into account in the form of simple diamagnetic impurities, and the presence of ferromagnetic impurities has been ruled out by variable temperature ac susceptibility measurements. This change in magnetic behaviour of **6** on mechanical grinding is unique in main group chemistry, although well documented for transition metal compounds (e.g., refs. 14, 15). The grinding likely provides the energy needed to overcome the activation energy barrier of the transition from the diamagnetic to the more thermodynamically stable paramagnetic phase. The powder diffraction data for the diamagnetic unground and the paramagnetic ground material are consistent with a second order phase transition between the two phases; i.e., there are only small structural differences between phases with no change in the structure of **6**, as shown by the identical vibrational spectra before and after grinding.

The lability of **6** is illustrated by the variety of dissociation and rearrangement products (e.g., S_8, S_4N_4, [NC-$\overline{\text{CNSSN}}$], $C_2N_4S_2$, and the hitherto unknown $C_2N_4S_3$) obtained on attempted sublimation of **6** to obtain single crystals, the search for which continues.

Compound **6** is the first example of a diradical containing two -$\overline{\text{CNSN}}$S radical groups that is not connected to, or fused to, a phenyl ring (e.g., [*p*-$C_6H_4(\overline{\text{CNSN}}\text{S})_2$] (6)). Compound **6**, like the isomeric **9** (12) and the isolobal **8** (11), is a disjoint diradical. However, unlike **9**, **6** exists in one phase, in which both electrons pair neither by intra- or intermolecular interactions, i.e., as a paramagnetic solid. Compound **6** is one of a small class of non-sterically hindered diradicals that are paramagnetic in the solid state. Other examples include O_2 (17) and **8** (11).

Acknowledgments

We thank Dr. F. Grein for helpful discussions on theoretical aspects and for the ring opening calculations of [H-$\overline{\text{CNSN}}$S], Drs. J. D. Goddard and R. Mawhinney for GVB-PP(TC-SCF)/6-311G* calculations of the diradical singlet and triplet states of **6**, Dr. W.V.F. Brooks for assistance with the interpretation of vibrational spectra, Dr. L. Calhoun for ^{13}C NMR spectra, Dr. D. Wood for the observation that **8**·$[AsF_6]_2$ increases paramagnetism on grinding, Dr. M.A. White for discussions on thermodynamics, Mr. D. Drummond (MS), Mr. R. MacGregor (EPR) and Mr. D. Mitrovic (synthesis and grinding samples of **6** for up to 12 h in the drybox) for technical assistance, and the Natural Sciences and Engineering Research Council Canada (NSERC) for operating grants (T.S.C., J.P., L.K.T.) and a graduate fellowship (S.B.), as well as the Indonesian Government scholarship administered by the World University and Service of Canada (F.Z.). The work in Spain has been supported by CICYT grant MAT2000-1388-C03-03.

Condensed versus open channel structures in cysteic acid coordination frameworks containing d^{10}-d^{10} dimers

Patrick J. Riley, Jennifer L. Reid, Adrien P. Côté, and George K.H. Shimizu

Abstract: Single crystal X-ray structures have been obtained for $[Ag(\text{L-cysteic acid})]_\infty$ (**1**) and $[Ag(\text{L-cysteic acid})(H_2O)]_\infty$ (**2**) These compounds represent the first two structurally characterized complexes of cysteic acid. Network **1** is shown to adopt an infinite two-dimensional structure, describable as one-dimensional ribbons cross-linked into layers. The basic building block is a doubly carboxylate-bridged silver(I) dimer. Compound **1** crystallizes in the monoclinic space group $P2_1$ (a = 5.5066(3) Å, b = 7.5761(4) Å, c = 16.644(1) Å, β = 94.335(1)°). Compound **2**, while differing chemically from **1** by only one water molecule, forms a three-dimensional structure built upon the same core dimer unit as that observed in **1**. In **2**, these units assemble in a different manner via the weak interactions and form a channel structure in which the guest water molecules are included. Compound **2** crystallizes in the monoclinic space group $P2_1$ (a = 8.120(2) Å, b = 9.805(2) Å, c = 9.204(2) Å, β = 98.45(3)°).

Key words: silver, carboxylates, sulfonates, coordination polymer.

Résumé : Faisant appel à la diffraction des rayons X par des cristaux uniques, on a déterminé les structures cristallines de $[Ag(\text{acide L-cystéique})]_\infty$ (**1**) et $[Ag(\text{acide L-cystéique})(H_2O)]_\infty$ (**2**). Ces composés correspondent aux deux premiers complexes de l'acide cystéique à être caractérisés. On a démontré que le réseau de la molécule **1** adopte une structure bidimensionnelle infinie qui peut être décrite par des rubans unidimensionnels reliés entre eux pour former des couches. L'unité de base est un dimère d'argent(I) doublement ponté par le carboxylate. Le composé **1** cristallise dans le groupe d'espace monoclinique, $P2_1$, avec a = 5,5066(3), b = 7,5761(4) et c = 16,644(1) Å, β = 94,335(1)°. Le composé, même s'il ne diffère chimiquement du composé **1** que par une molécule d'eau, forme une structure tridimensionnelle construite sur la même unité dimère de base observée dans la molécule **1**. Dans le composé **2**, celles-ci s'assemblent d'une manière différente par le biais de faibles interactions et forment une structure à canal dans lequel des molécules d'eau invitées sont incluses. Le composé **2** cristallise dans le groupe d'espace monoclinique $P2_1$, avec a = 8,120(2), b = 9,805(2) et c = 9,204(2) Å, β = 98,45(3)°.

Mots clés : argent, carboxylates, sulfonates, polymère de coordination.

[Traduit par la Rédaction]

Introduction

We have been interested in studying the soft coordination networks that result when the interactions between silver(I) and the sulfonate group (RSO_3^-) are employed as the "glue" for the framework (1–4). The sulfonate group, while generally not regarded as a particularly good ligand, can form very stable coordinative interactions when incorporated into an extended structure (5–7). This results from cooperative bonding effects, discussed more typically for hydrogen-bonded solids (8). With silver(I), there appears to be a particularly good hard–soft acid–base match with the sulfonate group as, even from aqueous solution, silver complexes with homoleptic sulfonate coordination are obtainable. In terms of using these interactions to build extended structures, they offer an interesting flexibility not attainable with, for example, metal oxide frameworks (3, 4). The sulfonate group can adopt many different coordination modes, from monodentate to μ^6 (1, 2, 9). Factoring in the roughly spherical shape of the $-SO_3$ moiety, we have employed the analogy of the sulfonate group with a ball of Velcro to describe its coordinative diversity (3).

The present work concerns two coordination frameworks incorporating silver(I) and L-cysteic acid as a ligand. Cysteic acid was chosen as a ligand owing to the presence of three distinct ligating functionalities (10) although, as the structures will show, it readily forms a zwitterionic species negating the Lewis basicity of the amino group. The two structures, 1 and 2, differ chemically only by a single water molecule; however, the structural changes between them are much more significant. The structures contain a mix of strong- and weak-coordination bonding coupled with hydrogen bonding (11). In each structure, the basic building unit, a doubly carboxylate-bridged silver(I) dimer, is the same as

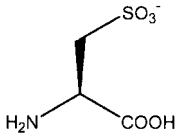
would be expected, since it is sustained by stronger bonds. The one-dimensional assembly of these units is also the same in the two structures. The difference between structures, when water is included or excluded from the system, is in how the one-dimensional columns arrange via weak interactions. For the anhydrous form, **1**, a two-dimensional structure is obtained with extensive interlayer hydrogen bonding. For the hydrated form, **2**, the result is a three-dimensional framework with channels filled with guest water molecules. This compound is fully interconnected by coordinative interactions, albeit weak ones. Compounds **1** and **2** represent the first structurally characterized complexes of cysteic acid.



L-Cysteic acid

Experimental

Silver carbonate, silver nitrate, and L-cysteic acid monohydrate were obtained from Aldrich Chemical Company and used as received. Powder X-ray diffraction data were collected in a capillary mounted on a Nonius Kappa CCD diffractometer using Mo Kα radiation (λ = 0.71073 Å) and visualized using Powderize software. Thermogravimetric analyses were performed on a Netzsch STA449C Simultaneous Thermal analyzer at a scan rate of 5°C min^{-1} under an N_2 flow.

Preparation of X-ray-quality single crystals of 1

A solution of L-cysteic acid monohydrate (0.050 g, 0.267 mmol) in water was added to a solution of Ag_2CO_3 (0.074 g, 0.267 mmol) in water and stirred for 22 h. A portion of this solution (1.5 mL) was filtered into a 15 × 45 mm glass vial, which was placed into a larger 20 mL glass scintillation vial containing EtOH (2 mL), as a diffusion solvent. The larger vial was capped and the filtrate was allowed to stand at room temperature for 1 month. Solvent diffusion yielded colourless single crystals suitable for X-ray data collection. Yield: 0.108 g (0.197 mmol), 73.8%. IR (KBr) (cm^{-1}): 2361.5 (m), 2324.1 (m), 1624.2 (s), 1465.6 (s), 1390.0 (vs), 1320.9 (s), 1236.9 (s), 1171.6 (m), 1134.3 (s), 1031.6 (vs), 966.3 (m), 900.9 (s), 831.0 (s), 742.3 (s), 583.6 (vs), 518.3 (s). Elemental anal. calcd. for **1**: C 13.01, H 2.55, N 5.06; found: C 12.81, H 2.32, N 4.67.

Preparation of X-ray-quality single crystals of 2

A solution of L-cysteic acid monohydrate (0.050 g, 0.267 mmol) in water was added to a solution of $AgNO_3$ (0.046 g, 0.267 mmol) in water and stirred for 26 h. A portion of this solution (1.5 mL) was filtered into a 15 × 45 mm glass vial, which was placed into a larger 20 mL glass scintillation vial containing EtOH (2 mL), as a diffusion solvent. The larger vial was capped and the filtrate was allowed to stand at room temperature for 6 weeks. Solvent diffusion yielded colourless single crystals suitable for X-ray data collection. Yield: 0.105 g (0.184 mmol), 68.7%. IR (KBr) (cm^{-1}): 3459.2 (br), 3180.6 (br), 2361.1 (m), 2333.8 (m), 1612.7 (s), 1470.7 (s), 1394.2 (vs), 1323.2 (s), 1230.4 (s), 1181.2 (m), 1132.0 (s), 1033.7 (vs), 897.1 (s), 820.6 (s), 744.2 (s), 667.7 (s), 580.3 (vs), 514.7 (s). Elemental anal. calcd. for **1**: C 12.60, H 2.82, N 4.90; found: C 12.74, H 2.21, N 4.77.

X-ray data collection and structure determination

Crystals were selected under an optical microscope, coated in oil, and frozen onto a glass fiber. The data for **1** was collected on a Siemens SMART CCD diffractometer at the Steacie Institute of the National Research Council Canada. The data for **2** was collected on a Nonius Kappa CCD diffractometer. Both structures were collected at 173 K using Mo Kα radiation (λ = 0.71073 Å). Both structures were also solved by direct methods and refined by full-matrix least squares, based on F^2, using SHELXTL (12). The structures were refined and hydrogen atoms generated as riding spheres to their parent atoms with the exception of the hydrogen atoms of O11 in compound **2**, in which they were located. The Flack parameters were 0.0065 ± 0.0263 for compound **1** and –0.049 ± 0.023 for compound **2**. A summary of the crystallographic data is given in Table 1. Selected bond distances and angles are shown in Tables 2–5.[2]

Results and discussion

Crystallographic data for **1** and **2** are presented in Tables 1–5.

Structure of Compound 1

The structure of $[Ag(OOCCH(CH_2SO_3)NH_3)]_\infty$ (**1**) is composed of carboxylate-bridged dimers, which are linked by metal sulfonate interactions to form one-dimensional ribbons. These ribbons are further cross-linked by additional metal sulfonate interactions and hydrogen bonding to yield layers. In this structure, L-cysteic acid exists as a zwitterion with the carboxyl and sulfonate groups deprotonated and the ammonium group positively charged. Based upon metal–ligand bonding, this structure is two-dimensional. There is further extensive hydrogen bonding between lamellae to give a three-dimensional architecture considering these weaker interactions.

The core unit of structure **1** is the silver dimer structure; its ORTEP diagram is shown in Fig. 1. The asymmetric unit consists of two types of Ag center and two different molecules of cysteic acid. Two carboxylate groups from two cysteic acid ligands bridge each silver dimer unit (Ag1—O4 = 2.229(3), Ag1—O10 = 2.184(3), Ag2—O5 = 2.225(3), Ag2—O9 = 2.267(3) Å). The carboxylate ligation supports

an Ag1···Ag2 interaction of 2.8011(3) Å, to be discussed in more detail later. The carboxylate–silver dimer is not planar, as illustrated by the torsion angles about the four C–O bonds (C3–O4 = 23.2(5)°, C3–O5 = 0.8(5)°, C6–O9 = –7.6(5)°, C6–O10 = –4.5(5)°). The geometry about Ag1 is six-coordinate and can be described as a basal plane, composed of two *trans*-carboxylate oxygen atoms, one sulfonate interaction (Ag1—O6 = 2.760(3) Å), and the silver–silver contact. Two other sulfonate oxygen atoms complete the coordination sphere. One of these is directed in an axial orientation and forms the linkage to the next dimer unit along the *b*-axis (Ag1—O3 = 2.803(3) Å) to form ribbons, as visible in Fig. 1. The final sulfonate interaction is to O8, from the same SO_3 group as O6 (Ag1—O8 = 2.672(2) Å). This chelating sulfonate group bridges to an adjacent dimer unit, along the *a*-axis to crosslink the ribbons into layers, shown in Fig. 2. Overall, the geometry is a distorted octahedron. Ag2 is a five-coordinate center with very slightly distorted square pyramidal geometry but has very similar features as those of Ag1. The basal plane is again composed of two

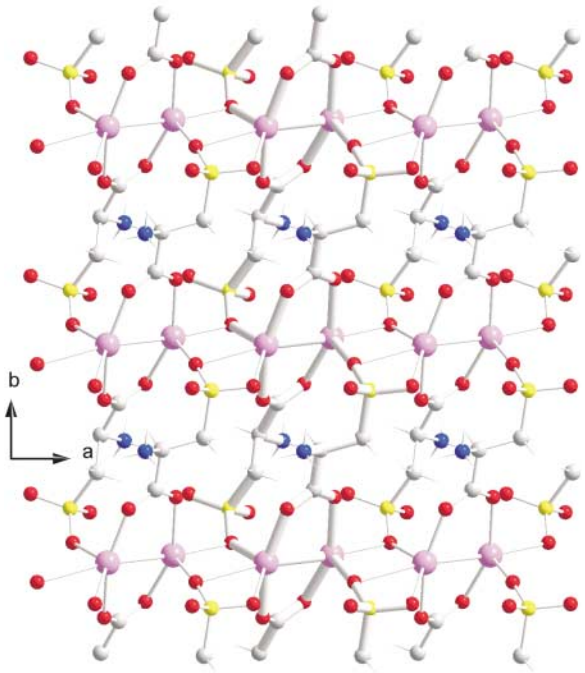
trans carboxylate interactions, the silver–silver interaction and a sulfonate oxygen atom (Ag2—O3 = 2.402(3) Å) that propagates the structure along the *a*-axis. The lone axial site is occupied by a sulfonate oxygen atom (Ag2—O6 = 2.605(3) Å) that serves to link the structure along the *b*-axis.

Fig. 2. View down the *c*-axis of **1**, showing the linking of ribbons into layers. One ribbon unit, extending along the *b*-axis, is depicted with thick bonds. Hydrogen atoms are shown as points for clarity.



The inter-dimer silver···silver distances along the *a*-axis are 3.450(1) Å, longer than the sum of the van der Waals radii (3.42 Å). The layer formation, primarily sustained by the silver coordination of the bridging sulfonate groups, is augmented by charge-assisted ammonium–sulfonate hydrogen bonds (N1—O2 = 2.967(4), N2—O8 = 2.872(4) Å). Thus, by a combination of weak interactions, parallel ribbons, as depicted in Fig. 1, are assembled into layers, shown in Fig. 2. A single ribbon is rendered with thick bonds.

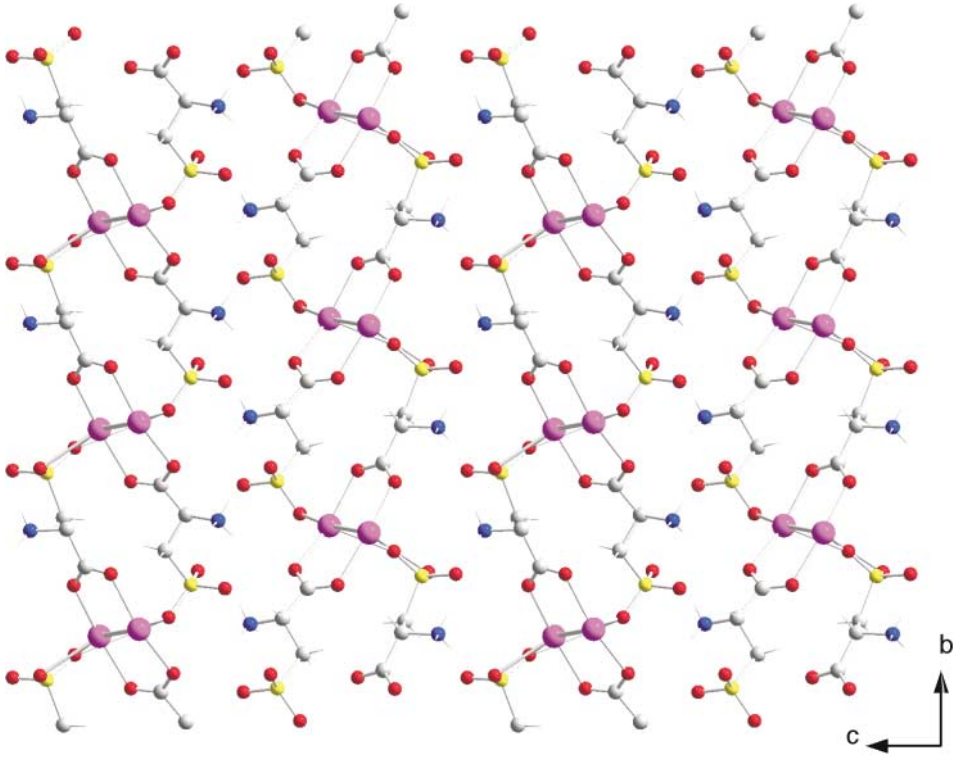
The layers are mutually interacting by a myriad of further ammonium–sulfonate hydrogen bonding. Figure 3 shows a cross section of the layers with the $-NH_3$ and $-SO_3$ groups directed into the interlayer region. Each ammonium group forms hydrogen bonds to two sulfonate oxygen atoms from the adjacent layer (N1—O1 = 2.854(4), N1—O2 = 2.910(4), N2—O7 = 2.823(4), N2—O8 = 2.844(4) Å). Each interlayer is lined exclusively with ammonium groups centered on N1 and sulfonate groups centered on S1, or ammonium groups centered on N2 and sulfonate groups centered on S2. The shortest interlayer Ag···Ag distance is between Ag1 centers at 7.942(2) Å.

Structure of compound 2

As with **1**, the core building unit of compound **2**, $\{[Ag(OOCCH(CH_2SO_3)NH_3)]H_2O\}_\infty$, is the silver(I) dimer bridged by two carboxylate groups. Also as in **1**, these dimeric units assemble via silver sulfonate interactions to form one-dimensional ribbons, and the cysteic acid ligand exists with a protonated ammonium group and deprotonated sulfonate and carboxyl groups. The ribbon motif is depicted in the ORTEP diagram shown in Fig. 4. In contrast to **1**, the silver sulfonate interactions extend into three dimensions

© 2002 NRC Canada

Fig. 3. View down the *a*-axis of **1**, showing four layers as depicted in Fig. 2. Note the interlayer region lined with ammonium groups and sulfonate groups for hydrogen bonding.



rather than layers. Augmented by hydrogen bonding, **2** forms a structure with channels in one dimension, in which are located guest water molecules.

For **2**, the core building unit is again the carboxylate-bridged silver(I) dimer. The two silver centers are distinct. Including the contact to the adjacent silver center, Ag1 has a six-coordinate geometry with a coordination sphere composed of two carboxylate oxygen atoms (Ag1—O4 = 2.295(5), Ag1—O10 = 2.269(5) Å), three sulfonate oxygen atoms (Ag1—O6 = 2.616(7), Ag1—O7 = 2.56(3), Ag1—O8 = 2.81(1) Å), and the silver contact (Ag1···Ag2 = 2.8567(9) Å). The geometry is best described as a square pyramid but where one basal site is bifurcated between two sulfonate oxygen atoms from the same SO_3 group. The coordination to this sulfonate group serves as part of the linking motif to form ribbons in the direction of the *c*-axis. The carboxylate oxygen atoms occupy *trans* sites in the equatorial plane, and a sulfonate oxygen atom, O6, which serves to link the ribbons in the direction of the *a*-axis, occupies the axial site. Ag2 has a five-coordinate, slightly distorted trigonal bipyramidal geometry. The axial sites are occupied by the two carboxylate oxygen atoms (Ag2—O5 = 2.212(5), Ag2—O9 = 2.224(5) Å). Two of the equatorial positions are filled by two sulfonate oxygen atoms from two different SO_3 groups (Ag2—O2 = 2.61(2), Ag2—O3 = 2.63(2) Å) and the remaining site is the previously mentioned Ag–Ag contact. The bond to O3 is involved in forming the ribbon motif along the direction of the *c*-axis. The carboxylate-bridged Ag dimeric unit is, as in **1**, quite distorted from a planar arrangement as indicated by the torsion angles about each of the four C—O bonds (C3—O4 = 31.7(9), C3—O5 = 4.7(9), C6—O9 = –11.5(1), C6—O10 = 31.8(1)°).

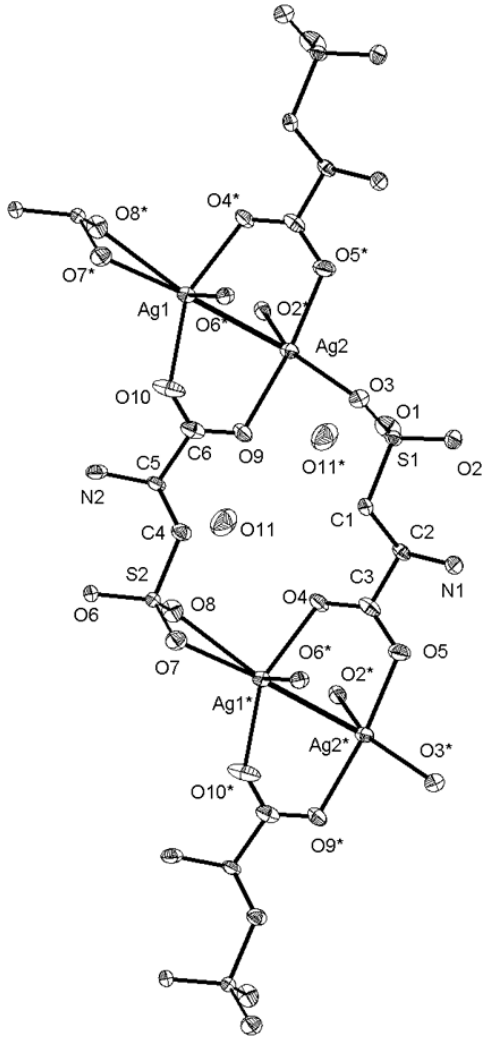
In **1**, the one-dimensional ribbons of silver dimers are linked in a parallel fashion to form layers. In **2**, the same ribbons are arranged to form a three-dimensional assembly. Essentially, each second ribbon undergoes a "turnstile-like" rotation along its primary axis to create space for the guest water molecules. The mutual orientation of adjacent ribbons is shown in Fig. 5. A view perpendicular to the ribbons, as shown in Fig. 6, reveals that the ribbons adopt a herringbone motif. Each ribbon is coordinated to four adjacent ribbons through the Ag1—O6 and Ag2—O2 interactions mentioned above. As in **1**, the silver sulfonate interactions are augmented by hydrogen bonding between ammonium and sulfonate groups (N1—O4 = 3.009(9), N2—O3 = 2.87(1) Å). The reorientation from the layered to the herringbone motif results in the generation of pockets that can accommodate the guest water molecules. These pockets align into channels as shown in Fig. 7.

Metal–metal interactions

One of the notable structural features of the building block for the coordination polymers, **1** and **2**, is the dimeric silver(I) unit (13). There is currently much interest in metal d^{10}-d^{10} interactions, whether they involve copper(I), silver(I), or gold(I) (14). They are of interest at many levels, ranging from a fundamental bonding perspective to their application in the generation of luminescent supramolecular networks. To focus on silver(I) systems, the question that frequently arises is whether a particular compound with a short Ag···Ag contact displays true "argentophilicity" or whether the metal centers are simply at a distance enforced by the remaining ligation (15). An excellent illustration of these interactions was reported by Chivers et al. (16). The Chivers group

© 2002 NRC Canada

Fig. 4. ORTEP diagram of **2**, showing, once again, the Ag dimer motif and its extension to one-dimensional ribbons. Note the additional water molecules (O11). Hydrogen atoms have been omitted for clarity. Thermal ellipsoids of 50% probability are represented.



reported a silver(I) complex of a tellurium diimide ligand with two Ag centers positioned 2.888(2) Å apart. This is a value significantly shorter than the sum of the van der Waals radii for silver, a value of 3.42 Å. In comparison, compounds **1** and **2** contain Ag···Ag distances of 2.8011(3) and 2.8567(9) Å, respectively. The principal difference between these cases is that in the Chivers complex, the two silver centers are displaced towards one another relative to their ideal positions in the absence of any Ag···Ag interaction. This results in a bowing of the 180° bond angle at silver to a mean value of 163.3(5)°. In **1** and **2**, the mean O-Ag-O angles made with the carboxylate oxygen atoms are 159.1(1)° and 155.7(1)°, respectively. However, in these compounds, the silver(I) centers are not displaced towards one another and this bowing at the silver centers is actually away from one another. That said, for the silver centers to align in a linear fashion with the carboxylate oxygen atoms would require an Ag···Ag distance of roughly 2.25 Å, an extremely small value. Thus, the bowing of the metal centers away from each other in this case does also not preclude a possible interaction. This compound is one of numerous examples where the Ag···Ag interaction is not easily distinguishable from the effects of further ligation.

Powder X-ray diffraction (PXRD), thermogravimetric analyses (TGA), and structural interconversion of 1 and 2

PXRD and TGA analyses revealed that structure **1** converts to **2** on hydration. PXRD analyses of bulk samples of both **1** and **2** matched that of the simulation from a single crystal determination, indicating that the single crystal structure was in fact representative of the bulk phase. For **1**, all powders obtained rapidly converted to **2** before a powder analysis was possible. This was also the case with ground single crystalline material. Dehydration of these samples yielded a similar situation where during the powder preparation and analysis, the samples rehydrated. Thermal gravimetric analysis of the anhydrous compound **1** revealed a stable structure below 245°C but at 245°C the sample decomposed. For the hydrate compound **2**, a stable mass was observed below 177°C but at 177°C loss of the included water molecule was observed (3.16% calcd., 3.10% obsd). This compound was then stable up to 245°C at which point decomposition was observed. From the similarities in the thermal behavior, it may be inferred that upon dehydration, **2** converts back to **1**, although we have not been able to show that without variable temperature PXRD.

Chemically, the only difference between the structures of **1** and **2** is the inclusion of one molecule of water per asymmetric unit in **2**. Structurally, however, there are significant changes between the two complexes. This is quite an interesting observation given that the core building unit in the two structures is the same. The difference is in how these units assemble through weak interactions. In these cases, the weak interactions are a combination of silver sulfonate interactions and hydrogen bonding between ammonium and sulfonate groups. The stronger coordinate covalent bonds in the system, the Ag–carboxylate interactions, sustain a dimeric motif observed in both structures (13). Also, in both structures the dimers are linked into ribbons by coordination of silver to a sulfonate group from a neighboring dimer. In **1**, further silver sulfonate interactions serve to link the ribbons into perfect layers that interact via hydrogen bonding. Inclusion of water in **2** disrupts these interribbon contacts via H-bonding and shifts the ribbons into a herringbone motif.

A somewhat perplexing aspect of compounds **1** and **2** is that both structures are obtained from aqueous solutions but only **2** incorporates water. This is made even more puzzling by the fact that the two structures are seemingly interconvertible. The only difference in the preparations of the compounds is that **1** is formed from the carbonate salt of silver(I), whereas **2** results from the nitrate salt. Therefore, it is apparent that the nature of the anion is significant even though it is not incorporated into the final structure. For carbonate, it would have been lost as CO_2. This type of "structure-directing role" of a component in a reaction is not unprecedented and, in fact, likely to occur more frequently than is recognized. Tian et al. (17) have recently reported a porous cobalt imidazolate structure that has a

critical dependence on the presence of piperazine to form, even though piperazine itself is not incorporated as part of the final structure.

The structural flexibility exhibited by this system is exactly the reason for our examining frameworks linked by silver sulfonate interactions. Employed cooperatively, we have shown that these weaker interactions can sustain robust architectures yet, at the same time, offer a degree of flexibility typically not associated with extended inorganic frameworks (3, 4). With L-cysteic acid, there also exists the potential for the generation of porous coordination frameworks for enantioselective guest uptake.

Triply bridged dicopper-bis(trimethylsilyl-chalcogenolates): Synthesis and characterization of the series of helical complexes [$(Me_3SiE\text{-}Cu)_2(\mu\text{-}Ph_2PC{\equiv}CPPh_2\text{-}\kappa^2P)_3$] (E = S, Se, Te)

Andrew I. Wallbank and John F. Corrigan

Abstract: The copper-chalcogenolates [$(Me_3SiE\text{-}Cu)_2(\mu\text{-}Ph_2PC{\equiv}CPPh_2\text{-}\kappa^2P)_3$] (**1**, E = S; **2**, E = Se; **3**, E = Te) have been prepared in good yield from [$(OAcCu)_2(\mu\text{-}Ph_2PC{\equiv}CPPh_2\text{-}\kappa^2P)_3$] and $E(SiMe_3)_2$ at low temperatures. Complexes **1**–**3** contain two pendant -$ESiMe_3$ moieties bonded to copper(I) centres, which are also bridged by three didentate ligands to form helical structures. Complexes **1**–**3** have been characterized by single crystal crystallographic and spectroscopic methods.

Key words: copper, chalcogen, helical, trimethylsilyl groups, phosphinoacetylene.

Résumé : On a préparé les complexes de cuivre-chalcogénates [$(Me_3SiE\text{-}Cu)_2(\mu\text{-}Ph_2PC{\equiv}CPPh_2\text{-}\kappa^2P)_3$] (**1**, E = S; **2**, E = Se; **3**, E = Te) avec de bons rendements à partir de [$(OAcCu)_2(\mu\text{-}Ph_2PC{\equiv}CPPh_2\text{-}\kappa^2P)_3$] et de $E(SiMe_3)_2$ et en opérant à basses températures. Les complexes **1**–**3** comportent deux portions -$ESiMe_3$ pendantes liées à des centres de cuivre(I) qui sont aussi pontés par trois ligands didentates pour former des structures hélicoïdales. On a caractérisé les complexes **1**–**3** par diffraction des rayons X par des cristaux uniques ainsi que par des méthodes spectroscopiques.

Mots clés : cuivre, chalcogène, hélicoïdale, groupes triméthylsilyles, phosphinoacétylène.

[Traduit par la Rédaction]

Introduction

There are now several reports detailing the synthesis of silylated chalcogen complexes of the type $E(R)SiMe_3$, $E(Ar)SiMe_3$, and $E(SiMe_3)_2$ (E = S, Se, Te; R = Me, *n*-Bu, *t*-Bu; Ar = Ph, mes, etc.) (1). In addition to their utility in organic synthesis, Ar–$R(E)SiMe_3$ reagents are well known to react with main group and transition metal salts to yield well-defined polynuclear (cluster) complexes (eqs. [1] and [2]), and these represent a powerful method for metal—chalcogen bond formation (2). These reactions are driven by the formation of the soluble silane Me_3SiX (X = Cl, Br, OAc, etc.) and metal—chalcogen bonds. In such cases, the flexible coordination geometries and bonding ability of the generated chalcogenide (E^{2-}) and chalcogenolate ($E(R)^-$ and $E(Ar)^-$) ligands have resulted in a variety of binary crystalline nanoclusters being synthesized using this strategy (3). Despite the propensity for chalcogenolate ligands to adopt bridging coordination modes, it has been demonstrated that terminal coordination can be promoted by using large substituents (e.g., -$Si(SiMe_3)_3$) (4) about the chalcogen centre, and terminal coordination can be ensured by restricting the number of vacant coordination sites about the metal centres. In this general vein, we are pursuing the synthesis of conjugated bis(trimethylchalcogenide) complexes Me_3SiE-M-spacer-M-$ESiMe_3$ (5), which may potentially be used to "link" metal centres and cluster molecules. Herein, we describe the synthesis and the structural and spectroscopic characterization of [$(Me_3SiE\text{-}Cu)_2(\mu\text{-}Ph_2PC{\equiv}CPPh_2\text{-}\kappa^2P)_3$] (**1**, E = S; **2**, E = Se; **3**, E = Te).

Experimental

General

All manipulations were carried out under an inert atmosphere using standard Schlenk and glovebox techniques. Bis(diphenylphosphino)acetylene (dppa) (6), bis(trimethylsilyl)sulfide (7), bis(trimethylsilyl)selenide (8), bis(trimethylsilyl)telluride (9), and copper(I) acetate (10) were prepared according to literature procedures. All solvents were dried over sodium/benzophenone. NMR spectra were recorded on either an INOVA 600 MHz or INOVA 400 MHz spectrometer at –30°C in C_7D_8. ^1H spectra were obtained at either 599.672 (**2** and **3**) or 399.766 MHz (**1**) and chemical

 DOI: 10.1139/V02-032 © 2002 NRC Canada

shifts are reported in ppm and referenced to internal solvent. ^{31}P chemical shifts are reported in ppm and referenced to external 85% H_3PO_4. ^{77}Se chemical shifts are indirectly referenced to Me_2Se at 0 ppm using $Se(Ph)SiMe_3$ (+82.0 ppm) using an excitation pulse of 2.667 μs at 54 dB with a recycle delay of 3.5 s. Raman spectra were recorded on solid samples on a Bruker RFS 100/S spectrometer equipped with a Nd^{3+}:YAG laser operating at 1064.1 nm and an N_2(l)-cooled Ge detector. The laser power was 80 mW for **1** and **2** and 15 mW for **3** (resolution = 2 cm^{-1}). Chemical analyses were performed by Chemisar Laboratories, Guelph, Ont.

Preparation of [$Me_3SiSCu(\mu$-$Ph_2PC{\equiv}CPPh_2)_3CuSSiMe_3$] 1

Dppa (0.82 g, 2.1 mmol) was added to a stirred suspension of copper(I) acetate (0.17 g, 1.4 mmol) in THF (20 mL). A clear yellow solution resulted after 5 min. The solution was cooled to –55°C and bis(trimethylsilyl)sulfide (0.29 mL, 1.4 mmol) was added dropwise via pipette. The solution was warmed slowly to 5°C. The resultant clear yellow solution was cooled to –40°C and layered with cold hexanes (20 mL). The solution was maintained at –25°C and clear colourless crystals formed after 2 days. At –35°C, the solution was decanted off and the crystals washed with cold pentane (2 × 10 mL) and cold diethylether (2 × 10 mL). The off-white solid was dried in vacuo (0.71 g, 67% yield). mp 114–115°C (decomposes). ^{1}H NMR (–30°C, C_7D_8, ppm) δ: 7.96 (br s, 24H), 6.78 (mult, 36H), 0.55 (s, 18H). ^{13}C NMR (–30°C, C_7D_8, ppm) δ: 7.83 (-Si(CH_3)$_3$). ^{31}P NMR (–30°C, C_7D_8, ppm) δ: –34.1 (br s, $w_{1/2}$ = 38 Hz). ^{29}Si NMR (–30°C, C_7D_8, ppm) δ: 8.3. Anal. calcd. for $C_{84}H_{78}Cu_2P_6S_2Si_2$ (%): C 66.34, H 5.17; found: C 66.23, H 5.43.

Preparation of [$Me_3SiSeCu(\mu$-$Ph_2PC{\equiv}CPPh_2)_3CuSeSiMe_3$] 2

Dppa (0.87 g, 2.2 mmol) was added to a stirred suspension of copper(I) acetate (0.18 g, 1.4 mmol) in THF (20 mL) to yield a clear yellow solution after 5 min. The solution was cooled to –55°C and bis(trimethylsilyl)selenide (0.32 mL, 1.5 mmol) was added dropwise via pipette. The solution was warmed slowly to –5°C. The resultant clear yellow solution was cooled to –30°C and layered with cold hexanes (30 mL). The solution was maintained at –25°C and clear colourless crystals formed after 2 days. At –35°C, the solution was decanted off and the crystals washed with cold pentane (2 × 10 mL) and cold diethylether (2 × 10 mL). The off-white solid was dried in vacuo (0.82 g, 69% yield). mp 112–113°C (decomposes). ^{1}H NMR (–30°C, C_7D_8, ppm) δ: 7.96 (br s, 24H), 6.78 (mult, 24H), 0.64 (s, 18H). ^{13}C NMR (–30°C, C_7D_8, ppm) δ: 7.99 (-Si(CH_3)$_3$). ^{31}P NMR (–30°C, C_7D_8, ppm) δ: –34.8 (br s, $w_{1/2}$ = 75 Hz). ^{29}Si NMR (–30°C, C_7D_8, ppm) δ: 3.9. Anal. calcd. for $C_{84}H_{78}P_6Se_2Si_2Cu_2$ (%): C 62.49, H 4.87; found: C 62.10, H 4.74.

Preparation of [$Me_3SiTeCu(\mu$-$Ph_2PC{\equiv}CPPh_2)_3CuTeSiMe_3$] 3

CuOAc (0.133 g, 1.08 mmol) was combined with dppa (0.64 g, 1.62 mmol) and dissolved with THF (30 mL) at room temperature. After 5 min, a pale yellow solution had formed and stirring was continued for 30 min to ensure complete complex formation. The solution was cooled to –78°C and $Te(SiMe_3)_2$ (0.24 mL, 1.12 mmol) was added dropwise via pipette. A bright yellow solution formed immediately upon addition. The stirred solution was warmed slowly. At –50°C the solution became orange and at –20°C became pale brown. The solution was maintained between –15 and –20°C for 20 min. The pale brown solution was cooled to –40°C and cold pentane (–60°C, 30 mL) was added and the solution was stirred to ensure complete mixing. The stir bar was removed and the flask was maintained at –25°C. Yellow crystals of **3** formed after a few hours. Further cooling to –70°C was used to induce further crystallization. The mother liquor was decanted off and the crystals were washed with cold diethyl ether (–60°C, 2 × 10 mL). The resultant yellow-brown solid was dried in vacuo, 0.25 g (24% yield). mp 96–97°C (decomposes). ^{1}H NMR (–30°C, C_7D_8, ppm) δ: 7.95 (br s, 24H), 6.77 (mult, 36H), 0.78 (s, 18H). ^{13}C NMR (–30°C, C_7D_8, ppm) δ: 8.46 (-Si(CH_3)$_3$). ^{31}P NMR (–30°C, C_7D_8, ppm) δ: –26.8 (br s, $W_{1/2}$ = 161 Hz). ^{29}Si NMR (–30°C, C_7D_8, ppm) δ: –19.5. Anal. calcd. for $C_{84}H_{78}P_6Te_2Si_2Cu_2$ (%): C 58.9, H 4.57; found: C 58.2, H 4.59.

X-ray analyses

Crystals were mounted immersed in cooled mineral oil and placed in a cold stream of N_2 during data collection. A single crystal suitable for X-ray analysis was mounted on a glass fibre. X-ray structural analyses were carried out on STOE IPDS equipped with an imaging plate area detector and a rotating anode (**3**) and Enraf-Nonius KappaCCD single crystal X-ray diffractometers (**1**–**2**) at 200 K (**2**–**3**) or 150 K (**1**). Crystals of **1**, **2**, and **3** all desolvate once removed from their mother liquors, as evidenced by crazing of the crystal faces; this process occurred especially quickly (seconds) for complex **1**. Data were corrected for Lorentz and polarization effects. The SHELXTL (G. M. Sheldrick, Madison, WI) program package was used to solve (direct methods, Cu, E (S, Se, Te) and P) and refine the structures. The weighting scheme employed was of the form $w = 1/[\sigma^2(F_o^2) + (a{\cdot}P)^2 + b{\cdot}P]$ (a, b = refined variables, $P = 1/3\max(F_o^2, 0) + 2/3\ F_c^2$). All non-hydrogen atoms, with the exception of disordered carbon centers, were refined with anisotropic thermal parameters. Hydrogen atoms were included as riding on their respective carbon atoms. The structures solved and refined without complications, with the following exceptions: In **1**, molecule 2 exhibits two-site disorder at both S and Si centres, along with the respective methyl groups, as well as four phenyl rings (C82–C132, C472–C522, C542–C592, C732–C782). These rings were refined as rigid groups (SHELX AFIX command). These atoms refined satisfactorily with 50% occupancies, as did a hexane solvent molecule of crystallization (C1H–C6H). In **2** both Se atoms, one Si site, the methyl carbons on the $SiMe_3$ groups (C79–C84), and ten phenyl rings (C3–C7, C15–C20, C21–C26, C34–C39, C41–C46, C47–C52, C54–C59, C60–C65, C67–C72, C73–C78) exhibited a two-site disorder that refined satisfactorily with 50% occupancies. Tetrahydrofuran molecules of solvation were also disordered over two positions and were refined with 50:50 occupancies. In **3**, two of the phenyl rings (C21–C26; C73–C78) and the methyl substituents about Si2 exhibited two-site disorder and were refined satisfactorily with 60:40 occupancy. The solvent molecule O3S–C12S was refined with 50% site occupancy. A summary of the X-ray determinations is given in Table 1.

Results and discussion

Our on-going interests in the synthesis of bis(trimethylsilyl)chalcogen reagents with a conjugated spacer, prompted us to focus our attention on dinuclear metal complexes bridged by didentate ligands $P(Ph_2)C{\equiv}CPPh_2$ (11). Carty and Efraty (11*r*) first reported the synthesis and spectroscopic characterization of X-Cu(μ-dppa)$_3$Cu-X coordination complexes (**I**), providing evidence for d(π)-d(π) Cu—P interactions, with concomitant reduction in C(pπ)—P(dπ) interactions within the P-C≡C-P linkages (11*q*). We reported recently (12) that the P_3Cu–X tetrahedral coordination geometry about the copper centres, as is observed in the coordination complexes **I**, is suitable for the preparation of tris(trialkylphoshpine)copper(I)trimethylsilylchalcogenolates **II** (eq. [3]). Quintessential to the successful synthesis of the terminal silylchalcogenolate complexes is the sequestering of all additional coordination sites about copper, lest the chalcogenolate ligand adopt a preferred bridging coordination mode (13).

[3] $$CuOAc + 4PR_3 + E(SiMe_3)_2 \rightarrow (R_3P)_3Cu\text{-}ESiMe_3 + AcOSiMe_3 + PR_3$$

II

R = Et, Pr; E = S, Se, Te

In a similar vein, the three didentate ligands in **I** provide the required coordination geometry about two copper centres to force terminal coordination of the formed -E-SiMe$_3$ ligands in **1**–**3**. Thus, when solutions of AcO-Cu(μ-dppa)$_3$Cu-OAc are treated at low temperatures (–55°C) with 2 equiv of S(SiMe$_3$)$_2$, colourless, X-ray quality crystals of **1** form after several days after layering with hexanes and crystallizing at –25°C (Scheme 1). ^{1}H NMR spectroscopic characterization of **1** confirmed the displacement of the -OAc groups from copper and suggested the formation of a Cu–SSiMe$_3$ linkage with, in addition to signals assigned readily to the phenyl rings of the dppa ligands, a high field signal of appropriate integration (δ = 0.55(s) ppm) is observed. A single crystal X-ray analysis provided full structural details and confirmed the formulation of **1**·(THF)$_3$(C$_6$H$_{14}$)$_{0.25}$ as [(Me$_3$SiS-Cu)$_2$(μ-Ph$_2$PC≡CPPh$_2$-κ^2*P*)$_3$]. The molecular structure of **1** is illustrated in Fig. 1 and a selection of bond lengths and angles is

Fig. 1. A perspective view of the molecular structure of $[(Me_3SiS\text{-}Cu)_2(\mu\text{-}Ph_2PC{\equiv}CPPh_2\text{-}\kappa^2P)_3]$ **1** (molecule 1). Thermal ellipsoids are drawn at the 40% probability level and H atoms have been omitted for clarity.

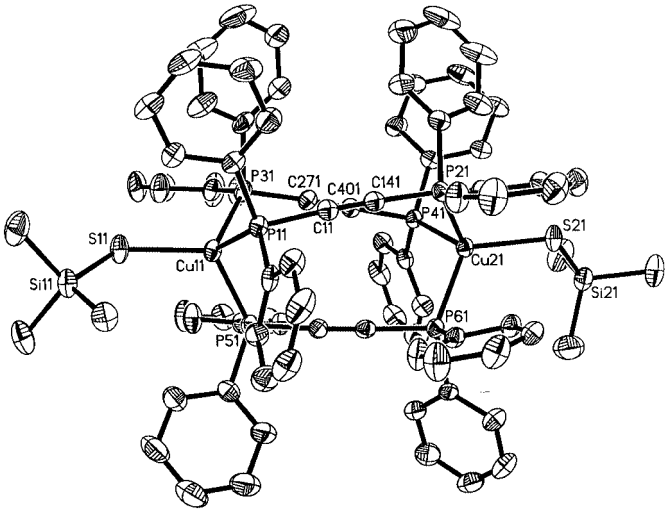

Fig. 2. A perspective view of the molecular structure of $[(Me_3SiSe\text{-}Cu)_2(\mu\text{-}Ph_2PC{\equiv}CPPh_2\text{-}\kappa^2P)_3]$ **2**. Thermal ellipsoids are drawn at the 40% probability level and H atoms have been omitted for clarity.

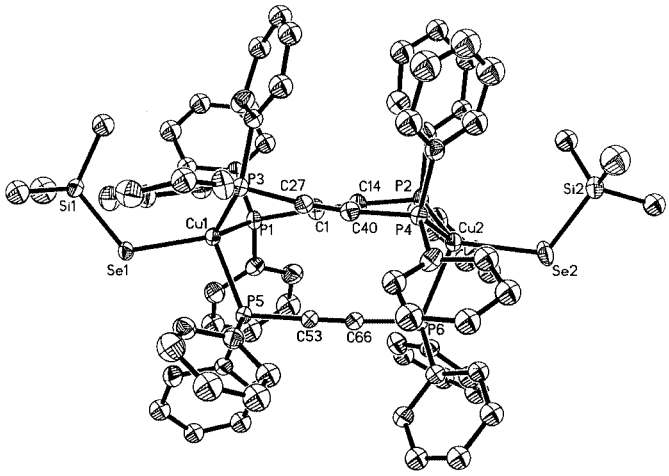

listed in Table 2. Complex **1** crystallizes with two identical yet crystallographically independent molecules in the asymmetric unit, and structural parameters in the text refer to molecule 1. Although stable indefinitely under N_2 atmosphere in the solid state, **1** hydrolyses rapidly in ambient atmosphere and solutions (THF) of **1** need be kept below 5°C to avoid the formation of insoluble unidentified materials.

The molecule consists of two pseudo-tetrahedral copper centres, each bonded to one sulfur and three phosphorus atoms. The two Cu centres are spanned by three dppa ligands, with a Cu···Cu distance of 6.496(1) Å. Of particular interest are the two trimethylsilylthiolate ligands that are bonded terminally (Cu11—S11 = 2.289(2); Cu21—S21 = 2.285(2) Å) to the two copper metals in this dimetallic complex. A similar coordination mode was observed in the related monomeric complexes $(R_3P)_3Cu\text{-}SSiMe_3$ (12). These pendant -$SiMe_3$ moieties represent potential reactive sites for additional sulfur—metal bond formation (12*b*) and complex **1** represents a rare example of a bis(trimethylsilyl)chalcogenolate where two reactive -$ESiMe_3$ moieties are separated by a conjugated spacer group (5,14). The dihedral angle between the two Cu-S-Si is 113.1°, the two S-$SiMe_3$ groups adopting a staggered orientation in the solid state. In solution there is one ^{31}P NMR chemical shift observed at –34.1 ppm; this peak noticeably broadened ($\Delta\nu_{1/2}$ = 38 Hz) owing to quadrupolar coupling to the copper centres (15). An examination of the six Cu—P bonding distances in **1** reveals a pattern of two shorter and one longer Cu—P bonds at each of the copper centres (Cu11—P11 = 2.271(1); Cu11—P31 = 2.336(2); Cu11—P51 = 2.286(2); Cu21—P21 = 2.378(2); Cu21—P41 = 2.286(1); Cu21—P61 = 2.307(2) Å), as was observed for the complexes $(R_3P)_3Cu\text{-}ESiMe_3$ (12). The longest Cu—P contact is that associated with the phosphorus centre *trans* to the S-Si vector (dihedral angle between Si11-S11-Cu11 and S11-Cu11-P31 = 164.1°; between Si21-S21-Cu21 and S21-Cu21-P21 = 177.9°). In addition, the angles P-Cu11-S11 and P-Cu21-S21 are smallest for P31 and P21, respectively (Table 2). These two structural parameters about the Cu centres may suggest steric repulsion between these phosphorus and sulfur centres, as the steric interactions between the -$SiMe_3$ moieties and neighbouring phenyl rings may force a close S11—P31 and S21—P21 contact, which is alleviated by a lengthening of the two Cu—P bonds. The P-C≡C angles are clustered about linear values (177.5(5)–172.4(5)°), the most significant deviations associated with the angles P(61)-C(661)-C(531) and P(51)-C(531)-C(661). As has been observed in other $[M_2(\mu\text{-}Ph_2PC{\equiv}CPPh_2\text{-}\kappa^2P)_3]$ complexes, (11*s*, 11*u*) there is a helical twist about the Cu11—Cu21 vector of approximately 29°, taking the average of the three torsion angles P-Cu11-Cu21-P for the three dppa ligands. Complex **1** crystallizes in the centrosymmetric space group $P\bar{1}$, with both achiral enantiomers present in the unit cell. The resulting magnetic inequivalence of the phenyl rings in the solid state does not manifest itself in solution NMR studies as one type of phenyl ring is observed in the ^1H spectrum, suggesting either fast interconversion of the two enantiomers on the NMR timescale even at low temperatures (–30°C), or that the complex loses its helical structure in solution all together (11s).

The synthesis of the selenium analogue $[(Me_3SiSe\text{-}Cu)_2(\mu\text{-}Ph_2PC{\equiv}CPPh_2\text{-}\kappa^2P)_3]$ **2** from AcO-Cu(μ-dppa)$_3$Cu-OAc and $Se(SiMe_3)_2$ is achieved readily as described for **1**, with virtually identical yields (69% for **2**; 67% for **1**). The ^1H NMR spectrum for **2** also confirmed the presence of -$SiMe_3$ (δ = 0.64 ppm), and the absence of signals assignable to -OAc ligands. X-ray quality crystals of **2**·$(THF)_2$ (space group $P2_1/n$) were grown at –25°C and the molecular structure of **2** is illustrated in Fig. 2, with selected bond lengths and angles listed in Table 2. As for **1**, the structure of **2** consists of two Cu centres bridged by three dppa ligands, each copper also bonded to a trimethylsilylchalcogenolate group (Se) and adopting tetrahedral coordination. A high degree of site disorder was observed in **2**, as all 12

phenyl rings of the phosphine ligands and both -$SeSiMe_3$ moieties were refined using a two-site (50:50) model (see supplementary material).[2] The helical twist (as defined for **1**) in **2** is 20°, and unlike for **1**, in which the two trimethylsilyl groups adopt a staggered conformation (angle = 113.1°), the two -$SiMe_3$ moieties in **2** are best described as being eclipsed (dihedral angle Cu1-Se1-Si1 and Cu2-Se2-Si1 = 11.3°). The solution ^{77}Se NMR spectrum for **2** displays a single resonance at δ = –573.2 (q, $^2J_{PSe}$ = 27 Hz) ppm, and this chemical shift value lies between those reported for $(THF)_2LiSeSi(SiMe_3)_3$ (16) (–825 ppm) and $Se(SiMe_3)_2$, (–334 ppm) (17) and is very close to those reported for the complexes $(R_3P)_3Cu\text{-}SeSiMe_3$ (–570.4 and –565.8 ppm for R = Et and Pr, respectively) (12). As for **1**, only one set of phenyl resonances is observed in the ^{1}H NMR spectrum of **2** (Table 3).

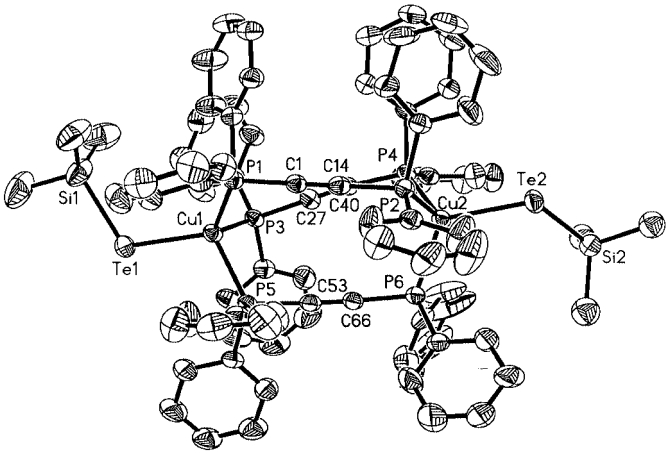
Table 3. Summary of NMR data (δ, ppm) for **1**–**3** at –30°C in C_7D_8.

	$^1H^a$	$^{13}C^a$	^{31}P	^{77}Se
1	0.55	7.83	–34.1	—
2	0.64	7.99	–34.8	–573.2 (J_{PSe} = 27 Hz)
3	0.74	8.46	–26.5	—

[a]Tabulated chemical shift values are those of the -CH_3 groups only.

Fig. 3. A perspective view of the molecular structure of [$(Me_3SiTe\text{-}Cu)_2(\mu\text{-}Ph_2PC{\equiv}CPPh_2\text{-}\kappa^2P)_3$] **3**. Thermal ellipsoids are drawn at the 40% probability level and H atoms have been omitted for clarity.



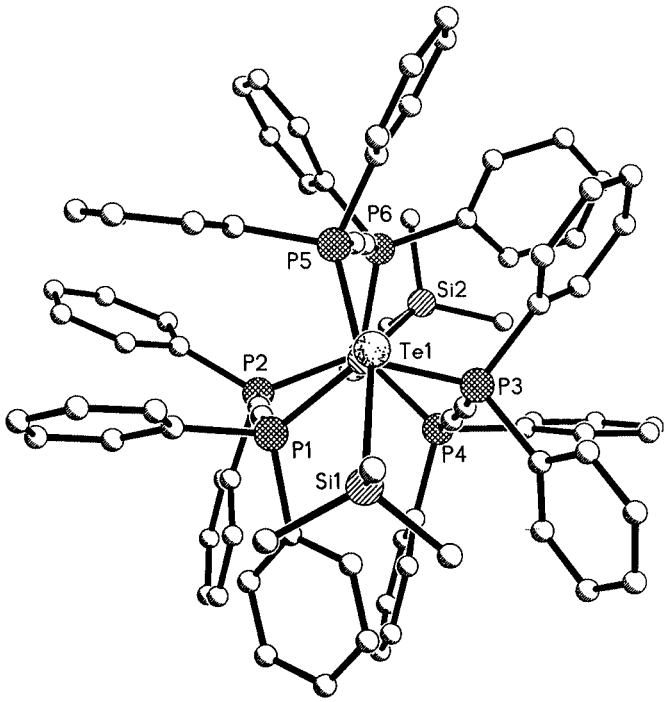
The tellurium analogue [$(Me_3SiTe\text{-}Cu)_2(\mu\text{-}Ph_2PC{\equiv}CPPh_2\text{-}\kappa^2P)_3$] **3** can also be prepared from [$(OAcCu)_2(\mu\text{-}Ph_2PC{\equiv}CPPh_2\text{-}\kappa^2P)_3$] and $Te(SiMe_3)_2$ although the yields are much poorer (25%) than for **1** or **2**. Extremely air- and moisture-sensitive crystals of **3**·$(THF)_{2.5}$ form from concentrated THF–pentane solutions, allowing for crystallographic analysis (Figs. 3 and 4, Tables 1 and 2). The tetrahedral coordination geometries about the two Cu centres in **3** are, expectedly, similar to those observed in the lighter congeners. The helical twist (as defined for **1** and **2**) of the three dppa ligands in **3** is 24°, and the two -$SiMe_3$ groups are staggered (angle = 139.1°, Fig. 4). Unfortunately, the relative instability of **3** in solution has thus far prohibited us from observing a signal in the ^{125}Te NMR spectrum.

The copper—chalcogen bonding distances in **1**–**3** follow the expected trend: Cu—S (2.285(2)–2.356(2) Å) < Cu—Se (2.374(1)–2.381(4) Å) < Cu—Te (2.570(1)–2.593(1) Å). Noteworthy however is that these Cu—E bonding distances are significantly shorter than those reported for complexes **II** (e.g., $(Et_3P)_3Cu\text{-}ESiMe_3$: E = S: 2.4022(5); E = Se: 2.5124(6); E = Te: 2.7126(4) Å)(13). The Cu···Cu distances in this series are longest for **3** (6.454(1) Å) and shortest for **2** (6.442(1) Å).

Spectroscopic characterization

Raman spectra for **1**–**3** each display strong $\nu_{C\equiv C}$, and the position of this peak varies little from **1** (S, 2122 cm^{-1}) to **2** (Se, 2117 cm^{-1}) to **3** (Te, 2116 cm^{-1}). Indeed, the positions of these peaks are similar to those reported for related [$(X\text{-}Cu)_2(\mu\text{-}Ph_2PC{\equiv}CPPh_2\text{-}\kappa^2P)_3$] complexes, and they are markedly (~20 cm^{-1}) shifted to higher energy relative to the free ligand (11*q*). This has been attributed by Carty and Efraty (11*r*) to the decrease in the extent of C(pπ)–P(dπ) interaction in the ligand upon coordination to a metal centre.

Fig. 4. A view of the molecular structure of [$(Me_3SiTe\text{-}Cu)_2(\mu\text{-}Ph_2PC{\equiv}CPPh_2\text{-}\kappa^2P)_3$] **3**, viewed along the Cu···Cu vector and illustrating the helical twist associated with the molecule (H atoms omitted).



Solution NMR spectra for all three complexes were obtained at low temperatures as **1**–**3** decompose rapidly at room temperature in solvent. In the series **1** → **2** → **3**, the ^{1}H resonances of the trimethylsilyl moieties display a stepwise downfield shift (δ = 0.55 (**1**), 0.64 (**2**), 0.78 ppm (**3**)) from S → Se → Te, as has been observed for $E(SiMe_3)_2$ (1*o*, 18) and $(R_3P)_3Cu\text{-}ESiMe_3$ (13*a*) The ^{1}H NMR spectra for **1**–**3** all exhibit one set of phenyl resonances, despite the inequivalence of the aromatic rings in the solid state, as has been described for related $[Ag_2(\mu\text{-dppa-}\kappa^2P)_3]^{2+}$ complexes (11*s*). Thus, complexes **1**–**3** either interconvert between enantiomers rapidly on the NMR timescale (at –30°C), or their helical structure is lost in solution (11*s*). This helical twist is not observed for related bis(diphenylphosphinobutadiynyl) complex [$(PhSe\text{-}Cu)_2(\mu\text{-}Ph_2PC{\equiv}C\text{-}C{\equiv}CPPh_2\text{-}\kappa^2P)_3$] (11*v*).

Conclusions

We have demonstrated that a series of dinuclear tris(phosphine)copper(I) (trimethylsilyl)chalcogenolates (E = S, Se, Te) with terminally bonded -$ESiMe_3$ groups can be prepared from the reaction of 2 equiv of $E(SiMe_3)_2$ and [$(X\text{-}Cu)_2(\mu\text{-}Ph_2PC{\equiv}CPPh_2\text{-}\kappa^2P)_3$] (X = Cl, OAc). The series **1**–**3** represents a rare example of structurally related trimethylsilylchalcogenolate metal complexes and the two pendant -$ESiMe_3$ functionalities are potential sites for metal—chalcogen bond formation. The orientation of three dppa

© 2002 NRC Canada

ligands in these complexes results in triple-strand helicate structures. Although unstable in solution, these complexes are stable indefinitely in the solid state under inert atmosphere at low temperatures.

Acknowledgments

We thank the Natural Sciences and Engineering Research Council of Canada (NSERC) for financial support and The University of Western Ontario's Academic Development Fund (ADF) program and the Canada Foundation for Innovation for equipment funding. We also thank Dr. M. Jennings (UWO) for collecting X-ray diffraction data for complexes **1** and **2** and Professor Y. Huang for assistance in obtaining the Raman data. A.I.W. thanks the Government of Ontario for an Ontario Graduate Scholarship in Science and Technology (OGSST) scholarship.

Bisphosphine ligands containing two *o*-*N*,*N*-dimethylanilinyl substituents at each phosphorus atom

Nathan D. Jones, Patric Meessen, Martin B. Smith, Udo Losehand, Steven J. Rettig, Brian O. Patrick, and Brian R. James

Abstract: The synthesis and complete characterization of the family of tetra(amine)bisphosphine ligands (*o*-$NMe_2C_6H_4)_2P$-(X)-P(*o*-$NMe_2C_6H_4)_2$, where X = CH_2 (dmapm), $(CH_2)_2$ (dmape), and $CH(CH_2)_3CH$ (dmapcp), are described. Crystal structure data are compared with known, analogous bisphosphines containing *o*-pyridyl or phenyl substituents in place of the *o*-dimethylanilinyl groups. Several short, intramolecular C-H···N distances in the anilinyl derivatives may represent the presence of weak hydrogen bonds.

Key words: phosphine, amine, polydentate, hydrogen-bonding to N atoms.

Résumé : On décrit la synthèse et la caractérisation complète d'une famille de ligands tétra(amine)bisphosphine, (*o*-$NMe_2C_6H_4)_2P$-(X)-P(*o*-$NMe_2C_6H_4)_2$, dans lesquels X = CH_2 (dmapm), $(CH_2)_2$ (dmape) et $CH(CH_2)_3CH$ (dmapcp). On a comparé leurs structures cristallines à celles de bisphosphines connues, analogues, contenant des substituants *o*-pyridyle ou phényle à la place des groupes *o*-diméthylanilinyles. Plusieurs distances intramoléculaires C-H···N dans les dérivés anilinyles sont courtes et elles peuvent être le reflet de la présence de faibles liaisons hydrogènes.

Mots clés : phosphine, amine, polydentate, liaison hydrogène avec des atomes d'azote.

[Traduit par la Rédaction]

Introduction

The introduction of an amine moiety into a *mono*phosphine compound for use as a P-N ligand has a long history and dates from the 1940s; early examples include the 2-pyridylphosphines made by Mann and co-workers (1) and *o*-diphenylphosphino-*N*,*N*-dimethyl-aniline [$Ph_2P(o\text{-}C_6H_4NMe_2)$] reported by Venanzi and co-workers (2); we have used the latter extensively in some recent Ru chemistry (3). This aminophosphine is just one example of a wide range of bidentate, chelating P-N ligands (4). The incorporation of an amine functionality into a *bis*(phosphine) ligand is more recent and dates from about 25 years or so, an early example being that of Achiwa who incorporated two PPh_2 moieties into proline derivatives (5). The amino-bisphosphine systems, which have been reviewed (6), have been developed mainly with the aim of surmounting the severe problem in homogeneous catalysis of separating the catalyst from the reaction products. Approaches to solving this problem, including representative literature references, have been: (*i*) to "heterogenize" the homogeneous catalyst by incorporating it into an insoluble polymer via attachment through the N atom (5, 7–9); (*ii*) to solubilize the catalyst in water (in which the reactants and products are only slightly miscible) by quaternization of the N atom via protonation or alkylation (10–16); (*iii*) to water solubilize the catalyst via incorporation of a sulfonate group within an elaborated N-containing functionality (17); and (*iv*) to extract the catalyst post-reaction with aqueous acid in which the product does not dissolve (18, 19).

Our group here has reported extensively on the use of mono- and bis-phosphine ligands containing the *o*-pyridyl moiety, with the goal of developing platinum metal complexes rendered water soluble by protonation of the pyridyl N atom (20); examples include the compound $py_2P(CH_2)_2Ppy_2$ and the related $py_2P(C_5H_8)Ppy_2$, where py = *o*-pyridyl and C_5H_8 is a cyclopentane moiety bridging the two P atoms (cf. Fig. 1). We have now extended this theme by replacing the *o*-pyridyl group by the *o*-dimethylanilinyl group and report here on the synthesis of the new ligands dmapm (1,1-bis(di(*o*-*N*,*N*-dimethylanilinyl)phosphino)methane), dmape (1,2-bis(di(*o*-*N*,*N*-dimethylanilinyl)phosphino)ethane), and dmapcp (*rac*-

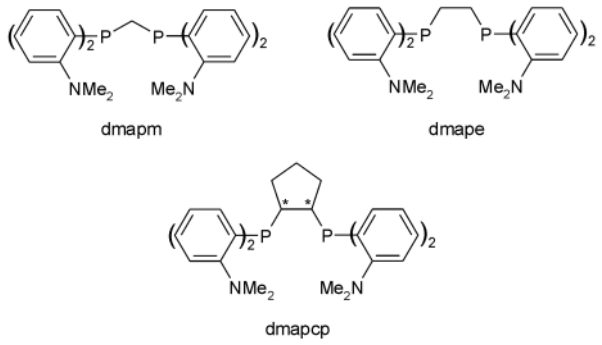
Fig. 1. Tetra(*o*-*N*,*N*-dimethylanilinyl)bisphosphines.



1,2-bis(di(*o*-*N*,*N*-dimethylanilinyl)phosphino)cyclopentane), illustrated in Fig. 1. Tóth and co-workers (11–15) have made related ligands, but bearing *para*-$C_6H_4(NMe_2)$ substituents, including chiral derivatives for catalytic asymmetric hydrogenation in water, once the N atoms have been quaternized; with these systems, simultaneous coordination to the same metal centre by both the P and N atoms of the same ligand is not possible, and there are no reports of bridging by these *para*-substituted ligands. Our new *ortho*-substituted ligands make the N atoms available for coordination to the same metal as the P atoms, as well as for providing convenient μ(P-N) environments; the extensive coordination chemistry of these ligands, particularly within Ru, Pd, and Pt systems, and their applications in catalysis (6, 21) will be published elsewhere. One benefit of excluding coordination chemistry from this article is that the findings presented amount to a contribution in main group chemistry, Tris Chivers's forte!

Experimental

General

Unless otherwise noted, synthetic procedures were performed using standard Schlenk techniques under a dry Ar or N_2 atmosphere. The precursors 1,1-bis(dichlorophosphino)methane and 1,2-bis(dichlorophosphino)ethane were purchased from commercial sources and stored in an N_2-filled glovebox, while 1,2-bis(dichlorophosphino)cyclopentane was made according to a literature procedure (22) and stored in a Schlenk tube under Ar. *N*,*N*-Dimethyl-*o*-bromoaniline was made by reaction of *o*-bromoaniline and dimethylsulfate according to a literature procedure (23); all other reagents were purchased from commercial sources and used as supplied. Solvents were dried and distilled under N_2 prior to use.

NMR spectra were recorded on a Bruker AV300 spectrometer (300.13 MHz for ^{1}H, 75.46 MHz for ^{13}C, 40.56 MHz for ^{15}N, 121.49 MHz for ^{31}P) at 300 K in $CDCl_3$. Residual solvent proton (^{1}H, δ 7.24 relative to external $SiMe_4$), solvent carbon (^{13}C, δ 77.0 relative to external $SiMe_4$), external $MeNO_3$ (^{15}N), or external $P(OMe)_3$ (^{31}P, δ 141.00 relative to 85% aq H_3PO_4), were used as references (*s* = singlet, *d* = doublet, *t* = triplet, *p* = pseudo). Downfield shifts were taken as positive. All *J*-values are given in Hz. Mass spectral and elemental analyses were conducted in the UBC Chemistry Department (B.C., Canada) by G. Eigendorf using a Kratos Concept II HQ mass spectrometer and by P. Borda using a Carlo Erba 1108 analyzer, respectively.

1,1-Bis(di(*o*-*N*,*N*-dimethylanilinyl)phosphino)methane, dmapm

To a solution of *n*-BuLi in hexanes (1.6 M, 16.5 mL, 26.4 mmol), cooled to –40°C on a dry ice – CH_3CN bath, was added *o*-bromo-*N*,*N*-dimethylaniline (5.05 g, 25.2 mmol) in Et_2O (20 mL) via cannula over 20 min. The yellow solution was stirred for 15 min and a white precipitate formed. The slurry was allowed to warm to room temperature (r.t.) and stirring was continued for 1 h. After the solution was cooled again to –40°C, 1,1-bis(dichlorophosphino)methane (1.33 g, 6.09 mmol) in Et_2O (15 mL) was added over 5 min. The resulting orange slurry was stirred for 15 min and then allowed to warm to r.t. Stirring was continued for 1 h and then HCl (~1 M, 50 mL) was added. The organic layer was removed and KOH (~2 M) was added dropwise to the aqueous layer to neutrality. The aqueous fraction was extracted with CH_2Cl_2 (3 × 20 mL) and the combined extracts were dried over $MgSO_4$. After removal of the solvent in vacuo, EtOH (15 mL) was added. The slurry was refluxed for 0.5 h, cooled to r.t., and the mixture filtered to give a white powder that was washed with cold EtOH (3 × 5 mL) and dried in vacuo. Yield: 1.84 g (54%). ^{1}H NMR δ: 2.23 (t, 2H, CH_2, $^2J_{HP}$ = 4.2), 2.68 (s, 24H, NCH_3), 7.02 (pt, 2H, Ar), 7.11 (pd, 4H, Ar), 7.25 (pt, 4H, Ar), 7.40 (pd, 4H, Ar). ^{13}C{^{1}H} NMR δ: 28.0 (t, *C*H_2, $^1J_{CP}$ = 26.2), 45.3 (s, N*C*H_3), 119.7 (s, *C*H), 124.2 (s, *C*H), 128.6 (s, *C*H), 132.3 (s, *C*H), 139.2 (s, *C*N), 157.1 (m, *C*P). ^{15}N NMR δ: –343.7 (s, *N*Me_2). ^{31}P{^{1}H} NMR δ: –36.0 (s). CI-MS *m*/*z*: 557 ([M–H]$^+$). Anal. calcd. for $C_{33}H_{42}N_4P_2$: C 71.2, H 7.6, N 10.1; found: C 71.0, H 7.8, N 9.9. Crystals of dmapm suitable for X-ray diffraction were grown from an acetone solution layered with hexanes.

1,2-Bis(di(*o*-*N*,*N*-dimethylanilinyl)phosphino)ethane, dmape

The synthesis of this compound follows that of dmapm. Thus, reaction of *n*-BuLi (1.6 M, 17.4 mL, 27.8 mmol), *o*-bromo-*N*,*N*-dimethylaniline (5.56 g, 27.8 mmol), and 1,2-bis(dichlorophosphino)ethane (1.61 g, 6.94 mmol) gave 2.44 g (61%) of a white powder. ^{1}H NMR δ: 1.91 (pt, 4H, CH_2, $^2J_{HP}$ = 4.1), 2.62 (s, 24H, NCH_3), 6.94 (m, 8H, Ar), 7.09 (m, 4H, Ar), 7.22 (m, 4H, Ar). ^{13}C{^{1}H} NMR δ: 24.3 (s, *C*H_2), 45.2 (s, N*C*H_3), 119.8 (s, *C*H), 124.1 (s, *C*H), 128.8 (s, *C*H), 132.3 (s, *C*H), 136.9 (pt, *C*N, *J* = 9.5), 157.7 (pt, *C*P, *J* = 6.6). ^{15}N NMR δ: –343.8 (s, *N*Me_2). ^{31}P{^{1}H} NMR δ: –28.9 (s). CI-MS *m*/*z*: 571 ([M – H]$^+$). Anal. calcd. for $C_{34}H_{44}N_4P_2$: C 71.6, H 7.8, N 9.8; found: C 71.0, H 7.6, N 9.5. Crystals of dmape suitable for X-ray diffraction were grown from a CH_2Cl_2 solution layered with EtOH.

Rac-1,2-bis(di(*o*-*N*,*N*-dimethylanilinyl)phosphino)cyclopentane, dmapcp

The synthesis of this compound corresponds to that of dmapm. Thus, reaction of *n*-BuLi in hexanes (1.6 M, 23.0 mL, 36.8 mmol), *o*-bromo-*N*,*N*-dimethylaniline (6.83 g, 34.1 mmol), and 1,2-bis(dichlorophosphino)cyclopentane (2.33 g, 8.57 mmol) at –40°C gave 2.72 g (52%) of a white powder. ^{1}H NMR δ: 1.51 (m, 2H, $C_{(4)}H_2$), 1.70 (m, 2H, $C_{(3/5)}H$H), 2.23 (m, 3H, $C_{(3/5)}H$H, C*H*), 2.55 (s, 12H, NCH_3), 2.60 (s, 12H, NCH_3, obscures C*H* protons), 6.49 (m, 2H, Ar), 6.71 (m, 2H, Ar), 6.96–7.28 (m, 12H, Ar). The ^{13}C{^{1}H} NMR spectrum shows a complicated pattern of signals due to coupling to phosphorus. Chemical shifts are presented

and the number of lines in each signal are given in parentheses following the peak frequencies. $^{13}C\{^1H\}$ NMR δ: 24.6 (1, $C_{(4)}H_2$), 29.9 (3, $C_{(3/5)}H_2$), 40.4 (3, $C_{(1/2)}H$), 45.0 (2, NCH_3), 119.9 (2, *C*H), 124.1 (2, *C*H), 128.5 (1, *C*H), 133.1 (2, *C*H), 137.9 (9, *C*N), 157.8 (7, *C*P). ^{15}N NMR δ: –338.8 (s, NMe_2). $^{31}P\{^1H\}$ NMR δ: –25.6 (s). CI-MS *m/z* 611 ($[M–H]^+$). Anal. calcd. for $C_{37}H_{48}N_4P_2$: C 72.8, H 8.0, N 9.2; found: C 72.9, H 8.1, N 9.1. Crystals of dmapcp suitable for X-ray diffraction were grown from a CH_2Cl_2 solution layered with EtOH. The labelling of the C atoms in the NMR corresponds to that shown in the crystal structure (Fig. 2).

X-ray crystallography of dmapm, dmape, and dmapcp

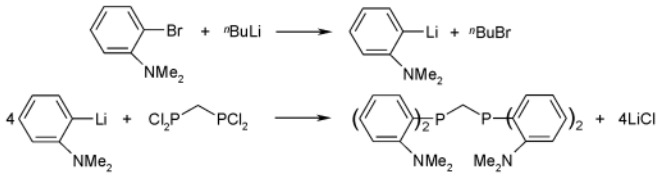
Suitable crystals were selected, mounted on a glass fibre using Paratone-N oil, and the unit frozen to –100°C. All measurements were made on a Rigaku/ADSC CCD area detector with graphite monochromated Mo Kα radiation. Selected crystallographic data appear in Table 1.[5] In each case the data were processed and corrected for Lorentz and polarization effects and absorption (24). Neutral atom scattering factors for all non-hydrogen atoms were taken from the *International Tables for X-ray Crystallography* (25, 26). All structures were solved by direct methods (27) and expanded using Fourier techniques (28). All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were not refined, but were included in calculated positions (with C—H = 0.98 Å) that were updated as the refinement progressed.

Results and discussion

Synthesis

The compounds dmapm, dmape, and dmapcp were prepared in a low-temperature, two-step, one-pot procedure in which *N*,*N*-dimethyl-2-lithioaniline is first generated by reaction of *n*-BuLi with *N*,*N*-dimethyl-2-bromoaniline, and then this is exposed to 0.25 mol equiv of the appropriate tetra(chloro)bisphosphine; Scheme 1 summarizes the method for dmapm. The compounds were isolated from the reaction mixture by extraction with dilute aq HCl and purified after neutralization by recrystallization from boiling EtOH. The syntheses are analogous to those used for syntheses of the related (pyridyl) mono- and bis(phosphine) ligands (20, 29–31). Of note, owing to the activating nature of the NMe_2 groups, the lithium exchange in step one of the synthesis proceeds with higher yields than for the deactivated pyridyl halides in the corresponding tetra(pyridyl)bisphosphine analogues (>50 vs. ~30%) (20). The new ligands are white, microcrystalline powders that are indefinitely air- and moisture-stable in the solid state and for prolonged periods in metal-free solution. They are freely soluble in chlorinated solvents and in dilute aq HCl, partially soluble in alcohols and Et_2O, and insoluble in hexanes.

Scheme 1.



The precursor 1,2-bis(dichlorophosphino)cyclopentane was made by reaction of cyclopentene, white phosphorus, and PCl_3 (22). This procedure results almost exclusively in the *trans* product and, because of this, dmapcp is produced as a racemic mixture of *R*,*R*- and *S*,*S*-enantiomers, as with

[5] Supplementary data (full crystal data and details on data collection and refinement have been deposited, along with tables of atomic coordinates, anisotropic thermal parameters, all bond lengths and angles, and torsion angles) may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada (http://www.nrc.ca/cisti/irm/unpub_e.shtml for information on ordering electronically). CCDC 185016–185018 contain the supplementary data for this paper. These data can be obtained, free of charge, via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge, U.K.; fax +44 1223 336033; or deposit@ccdc.cam.ac.uk).

the 1,2-bis(diphenylphosphino)cyclopentane analogue, dppcp (22); the chirality designators refer to the absolute configurations of the methine C atoms 1 and 2 in the backbone of the ligand (Figs. 1 and 2).

Characterization

The dmapm, dmape, and dmapcp compounds have been fully identified by means of NMR spectroscopy of all the nuclei present (^{1}H, ^{13}C, ^{31}P, and ^{15}N), mass spectrometry, elemental analysis, and molecular structure determination by low-temperature X-ray diffraction.

The compounds show the expected chemical shifts in their ^{1}H NMR signals, but the multiplicity of the backbone protons needs comment. Whereas the CH_2 in dmapm gives the expected triplet due to H–P coupling ($^2J_{HP}$ = 4.2 Hz), the protons in dmape appear as a pseudo triplet, resulting from the overlapping of the expected doublet of doublets, as in the *o*-pyridyl analogue, dpype (30). In the case of the racemic dmapcp, only multiplets were observed for the cyclopentyl protons, and these are assigned by comparison with data for the *o*-pyridyl analogue, dpypcp (20); the assignments of the ^{13}C{^{1}H} signals are tentative and are also based on well-established data for dpypcp (20). The ^{31}P{^{1}H} NMR spectra show singlets at δ –36.0 (dmapm), –28.9 (dmape), and –25.6 (dmapcp); the values for the last two are about 20 ppm to higher fields than those of the *o*-pyridyl analogues (20, 30). The ^{15}N NMR signals for the NMe_2-type ligands appear in the δ –340 region.

It is constructive to consider structural features of dmapm, dmape, and dmapcp along with those of their phenyl analogues: bis(diphenylphosphino)methane, dppm (32), 1,2-bis(diphenylphosphino)ethane, dppe (33), and dppcp (see above) (22), and those we have determined for the pyridyl analogues dpype (20) and dpypcp (20, 34), respectively. As far as we are aware, the pyridyl analogue of dmapm has not been reported. The molecular structures of the three new compounds are, not surprisingly, very similar to those of their phenyl and pyridyl analogues.

Table 2 lists some geometrical parameters for dmapm and dppm, and Fig. 3 shows the molecular structure of dmapm, which shows minor differences to that of dppm. The increased steric bulk of the NMe_2 substituents in dmapm leads to a different rotation of the arene moieties that induces two sub van der Waals contacts between N and H atoms in adjacent *N*,*N*-dimethylanilinyl moieties on each side of the molecule (N1···H23 = 2.65 Å and N4···H14 = 2.50 Å vs. the van der Waals contact of 2.75 Å (35)); the corresponding C···N bond lengths are 3.61 and 3.45 Å (larger than the 3.30 Å value for the sum of the radii), and the corresponding N···C-H angles are about 147 and 163°. These interactions may represent weak C-H···N hydrogen bonds, which do exist (35). This steric hindrance forces the molecule to "stretch", which leads to a 7° wider P-C-P angle (113.9°) and a longer P···P distance (3.099 Å) with respect to dppm. Also, the corresponding C-P-C angles are compressed in comparison to

those of dppm (C1-P1-C17 (95.9°) and C17-P2-C26 (98.9°) vs. 101.7° and 103.2°), which leads to slightly more "pyramidal" P atoms as defined by the sum of the angles at P1 and P2 (av 302.5 vs. av 304.9°). The P—C bond lengths within the two molecules are essentially the same.

The asymmetric unit cell of dmape contains 1.5 crystallographically independent molecules, 1 being in a general position and 1 lying on a centre of symmetry. The main difference (see Fig. 4) is that in the C_S molecule one of the phosphine groups is twisted 180° with respect to the other, whereas in the dissymmetric molecule both phosphine moieties are facing the same side, the *N*,*N*-dimethylanilinyl substituents taking gauche positions with respect to each other. The corresponding bond lengths and angles within each molecule differ only marginally (Table 3). While the centrosymmetric molecule exhibits a planar backbone with a P-C-C-P torsion angle constrained by symmetry to be –180°, the C_S molecule is slightly puckered with a corresponding torsion angle of 173°. The C_S molecule exhibits geometry very similar to that of the also centrosymmetrical analogues dppe and dpype. The pyramidal geometry at the P atom is not affected by the different aromatic substituents, but the average P—$C_{(aromatic)}$ bond lengths are longer in dmape (av 1.844 Å) and dpype (av 1.847 Å) than in dppe (av 1.822 Å), presumably reflecting electronic differences between the *ipso* carbons in the anilinyl and pyridyl moieties compared with those in the phenyl groups (the same difference is seen on comparing data for dmapm and dppm, see Table 2). The C_S molecule shows a short N6···H42 contact (2.53 Å) with C—N = 3.49 Å and an N···H-C angle of 165°, again indicative of a weak H-bonding interaction.

In the case of dmapcp, the backbone is puckered owing to the steric demand of the cyclopentyl ring (P-C-C-P, 168°) (Fig. 2). The four *N*,*N*-dimethylanilinyl moieties lead to steric crowding, inducing sub van der Waals contacts (and possible H-bonding) between two of the N atoms and the closest H atoms of the cyclopentyl backbone (N4···H3b (2.67 Å), C—N (3.49 Å), N···H–C (140.7°); and N1···H2 (2.53 Å), C—N (3.33 Å), N···H–C (136.4°)). These contacts might explain the relatively long P—$C_{(aliphatic)}$ bonds (1.882 and 1.879 Å) and the increased P—P distance (4.505 Å) compared with data for dppcp and dpypcp (Table 4). Accordingly, the P—$C_{(aromatic)}$ bonds of the strained *N*,*N*-dimethylanilinyl moieties are also slightly elongated compared with those of the non-interacting *N*,*N*-dimethylanilinyl groups: P1—C6 (1.852) vs. P1—C14 (1.837 Å) and P2—C30 (1.847) vs. P2—C22 (1.831 Å). The P—$C_{(aliphatic)}$ bonds are about 0.04 Å longer than the P—$C_{(aromatic)}$ bonds.

The unit cell of the dmapcp crystal chosen for the analysis shows that only the *S*,*S* enantiomer is present (chiral space group $P2_12_12_1$), implying a spontaneous resolution has taken place; other crystals must contain only *R*,*R* enantiomers, but no attempt was made to separate these by the Pasteur method of inspection. The analogous dppcp and dpypcp systems crystallize with both enantiomers in the unit cell. Apart from the slight distortions mentioned above, the *S*,*S* enantiomers of the three compounds exhibit a very similar overall molecular geometry (Table 4).

Coordination chemistry

As alluded to in the Introduction, the new ligands have revealed diverse coordination chemistry (6, 21). Established bonding modes include: (*i*) *P*,*P*-, *P*,*N*-, and *P*,*P*,*N*-coordination within d^8 square planar systems, including interconversions

2,6-Diisopropylphenylphosphane: A new, bulky primary phosphane and its mono- and disilylated $Si(CH_3)_3$ and $Si(CH_3)_2$-*t*-Bu derivatives — A synthetic, crystallographic, and dynamic NMR investigation[1]

René T. Boeré and Jason D. Masuda

Abstract: The bulky primary phosphane 2,6-diisopropylphenylphosphane, $DipPH_2$, has been prepared from 1-bromo-2,6-diisopropylbenzene via the reaction of the Grignard reagent with PCl_3. The resulting mixed phosphonous dihalides $DipP(Cl,Br)_2$ are reduced with $LiAlH_4$ to yield the title compound in reasonable yield and on a synthetically useful scale. $DipPH_2$ is also used to prepare the monosilylated derivatives $DipPHSi(CH_3)_3$ and $DipPH\{Si(CH_3)_2$-*t*-Bu$\}$ as well as the disilylated compounds $DipP\{Si(CH_3)_3\}_2$ and $DipP\{Si(CH_3)_2$-*t*-Bu$\}_2$. All products have been fully characterized by IR, mass, and NMR spectroscopy. The crystal structure of $DipPH\{Si(CH_3)_2$-*t*-Bu$\}$ was determined from single-crystal diffraction data: $C_{18}H_{33}PSi$, $P2_1/c$, $Z = 4$, $a = 8.5768(10)$, $b = 28.104(3)$, $c = 8.1102(4)$ Å, $\beta = 93.341(3)°$ ($R = 0.0518$). Changes in the NMR spectrum of $DipPH\{Si(CH_3)_2$-*t*-Bu$\}$ were observed over the temperature range 178–380 K. Barrier heights were determined from the peak separation at low temperature and the coalescence points: $\Delta G^{\ddagger} \approx 40$ kJ mol^{-1} for C(aryl)—P bond rotation and ≈ 72 kJ mol^{-1} for pyramidal inversion at phosphorus.

Key words: crystal structure, 2,6-diisopropylphenyl, bulky substituents, steric congestion, dynamic NMR, primary phosphane, silyl phosphane.

Résumé : On a préparé le phosphane primaire encombré 2,6-diisopropylphénylphosphane, $DipPH_2$, à partir du 1-bromo-2,6-diisopropylbenzène, par le biais d'une réaction de Grignard avec le PCl_3. On a réduit les dihalogénures phosphoneux mixtes qui en résultent, $DipP(Cl,Br)_2$, à l'aide de $LiAlH_4$ pour obtenir le composé mentionné dans le titre avec un rendement raisonnable et à une échelle utile d'un point de vue synthétique. On a aussi utilisé le $DipPH_2$ pour préparer les dérivés monosilylés $DipPHSi(CH_3)_3$ et $DipPH\{Si(CH_3)_2$-*t*-Bu$\}$ ainsi que les produits disilylés $DipP\{Si(CH_3)_3\}_2$ et $DipP\{Si(CH_3)_2$-*t*-Bu$\}_2$. On a caractérisé tous les produits par spectroscopie IR, de masse et RMN. On a déterminé la structure cristalline du $DipPH\{Si(CH_3)_2$-*t*-Bu$\}$ par diffraction des rayons X par un cristal unique; les données pour $C_{18}H_{33}PSi$, $P2_1/c$, $Z = 4$, $a = 8{,}5768(10)$, $b = 28{,}104(3)$ et $c = 8{,}1102(4)$ Å, $\beta = 93{,}341(3)°$ ($R = 0{,}0518$). En faisant varier la température de 178 à 310 K, on a observer des changements dans le spectre RMN du $DipPH\{Si(CH_3)_2$-*t*-Bu$\}$. Les hauteurs de barrières ont été déterminées sur la base de la séparation des pics à basse température et des points de coalescence: $\Delta G^{\ddagger} \approx 40$ kJ mol^{-1} pour la rotation autour de la liaison C(aryle)—P et ≈ 72 kJ mol^{-1} pour l'inversion pyramidale au niveau du phosphore.

Mots clés : structure cristalline, 2,6-diisopropylphényle, substituants volumineux, congestion stérique, RMN dynamique, phosphane primaire, phosphane silylé.

[Traduit par la Rédaction]

Introduction

The chemistry of primary phosphanes has received much attention in recent years, and their utility in both main group chemistry (1–8) and coordination chemistry (9–18) is under active investigation. Aryl phosphanes bearing bulky substituents in the *ortho* positions have been particularly popular, as they have considerably greater stability and more

Received 14 February 2002. Published on the NRC Research Press Web site at http://canjchem.nrc.ca on 29 November 2002.

This work is dedicated to Professor Tristram Chivers in grateful acknowledgment for his constant support and sound collegial advice. Tris has served his Department, University, and Canadian chemistry impeccably and enthusiastically. His efforts have helped put main group chemistry in the forefront of Canadian science.

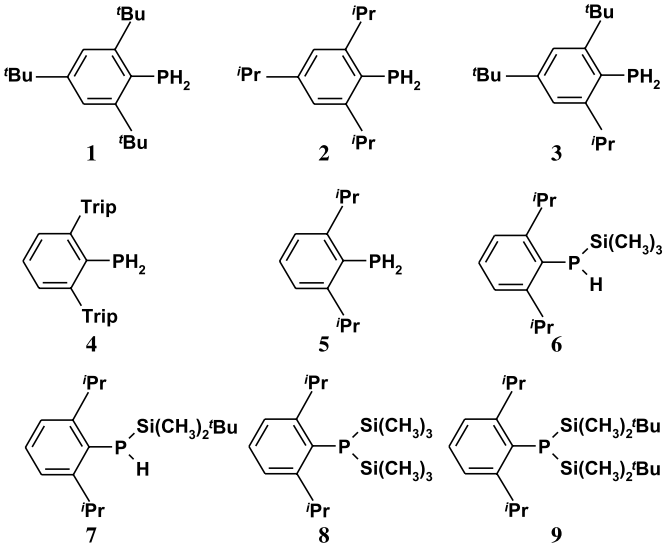
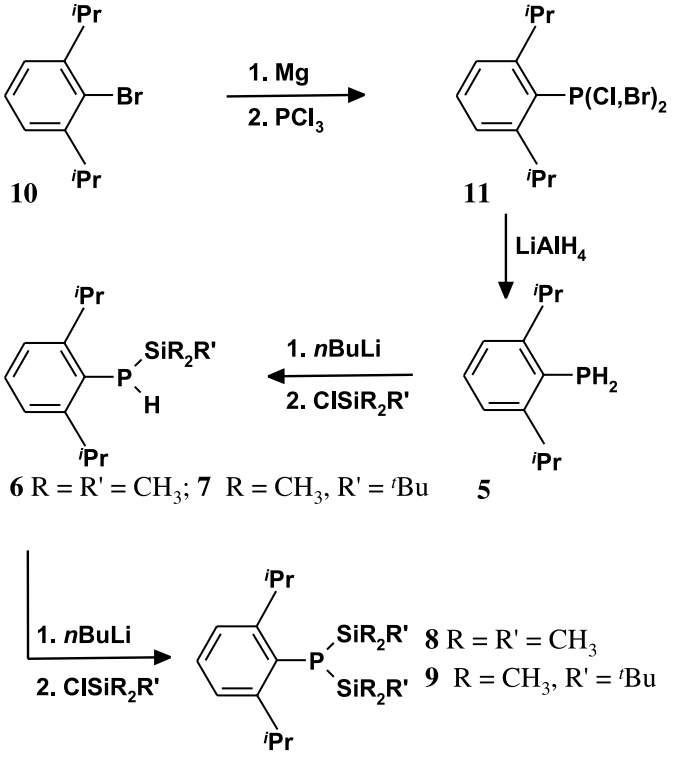
Scheme 1.



controlled reactions (3, 4, 17). The risk associated with the high toxicity of primary phosphanes such as $PhPH_2$ is also mitigated by the bulky substituents, if by nothing more than lowering the volatility of the compounds. The most commonly used bulky primary phosphane (Scheme 1) has undoubtedly been 2,4,6-tri-*tert*-butylphosphane, Mes*PH_2 (**1**) (19). The closely related 2,4,6-triisopropylphenylphosphane, TripPH_2 (**2**) is known, and its chemistry has received some attention (20). A laborious, multi-step, small-scale synthesis of 2,4-di-*tert*-butyl-6-isopropylphenylphosphane, DtbiPH_2 (**3**) has recently been reported (3). The terphenyl compound 2,6-(2,4,6-triisopropylphenyl)-phenylphosphane, TterphPH_2 (**4**) has been prepared and its crystal structure determined (4).

We have been exploiting for some time the 2,6-diisopropylphenyl (Dip) group as a bulky substituent on nitrogen, in particular for the preparation of *N*,*N′*-disubstituted amidines (21, 22) and *N*,*N′*,*N″*-trisubstituted guanidines (23). We are currently in the process of preparing directly analogous phosphorus-containing compounds via primary phosphanes (24) and we were therefore surprised to find that DipPH_2 (**5**) has not been reported heretofore in the literature and indeed there are no reports of the Dip group attached to phosphorus in any compound. At the cost of being slightly less sterically shielding, the use of *ortho* diisopropyl groups imparts to bulky substituents the advantage over *tert*-butyl of providing a wealth of stereochemical information from the ^{1}H NMR signals of the diastereotopic isopropyl groups. The 2,4,6-triisopropylphenyl (Trip) substituent has such groups, but has the disadvantage that the sterically unnecessary *para* isopropyl substituent tends to obscure the often complex and always interesting ^{1}H NMR signals of the sterically essential *ortho* isopropyl substituents. For example, in **2** the chemical shifts of the *ortho* and *para* *i*-Pr CH_3 groups are 1.23 and 1.24 ppm (20). In our experience, the *meta* and the *para* hydrogen atoms on the aromatic backbone of Dip groups tend to be well resolved and can be useful spectroscopic probes in a region of the spectrum removed from the crowded aliphatic regions. There is considerable merit in the use of the Dip substituent, and in this paper we report a practical large-scale synthesis of **5**.

Scheme 2.



Many applications of primary phosphanes either require, or are enhanced by, replacement of one or both hydrides with silyl groups (6, 25–27). We have therefore prepared the silyl compounds Dip$PHSi(CH_3)_3$ (**6**), Dip$PH\{Si(CH_3)_2$-*t*-Bu$\}$ (**7**), Dip$P\{Si(CH_3)_3\}_2$ (**8**), and Dip$P\{Si(CH_3)_2$-*t*-Bu$\}_2$ (**9**). Although the $Si(CH_3)_3$ compounds could be prepared quite easily in sufficient purity to be of synthetic utility, it was difficult to obtain analytically pure samples of these low-melting compounds. The $Si(CH_3)_2$-*t*-Bu derivatives, on the other hand, are easily purified, crystalline solids and have been fully characterized. The strong asymmetry induced by the bulky substituent in **7** induces a dynamic process observable by NMR spectroscopy, and the results of investigations in $C_6D_5CD_3$ are reported over the temperature range 178–380 K. These solution state changes are correlated to the structure found in the solid state by a single-crystal X-ray diffraction study.

Results and discussion

Synthesis and characterization

Our synthetic route (Scheme 2) starts from DipBr (**10**) for which a large-scale synthesis has been worked out starting from the commercially available aniline (28). The Grignard reagent prepared from **10** is added to a cold solution of PCl_3 in THF. This reaction leads consistently to mixtures of all three possible halides, which co-distil as identified by their ^{31}P chemical shifts (Table 1), i.e., DipPCl_2 (**11a**), DipPClBr (**11b**), and DipPBr_2 (**11c**). Typical product distributions of the three are 1.6:2.4:1.0, which by mass balance means that virtually all of the bromide contained in the Grignard reagent ends up on phosphorus, remarkable testimony to the higher nucleophilicity of bromide versus chloride. Mixed

phosphorus halides have been observed previously, for example, in the Grignard preparation of $Mes_2P(Cl,Br)$, where Mes = 2,4,6-trimethylphenyl (32). Reduction of mixtures of **11a–c** with $LiAlH_4$ in THF yielded the phosphane **5**, as a clear, colourless liquid. It has very little odour and is quite easy to handle if stored below room temperature and under nitrogen.

Compound **5** has been fully characterized by ^{1}H, ^{31}P, and ^{13}C NMR spectroscopy, as well as by mass spectrometry and IR spectroscopy. The P–H stretch (recorded as a liquid smear) has a frequency of 2306 cm^{-1}, comparable to 2302 cm^{-1} in CH_2Cl_2 solution reported for $MesPH_2$ (**18**) (17). The ^{31}P NMR spectrum displays the expected 1:2:1 triplet with $^{1}J_{PH}$ = 208 Hz at δ –156.4. As the ^{31}P NMR spectral data for primary phosphanes with bulky substituents and their silyl derivatives are extremely scattered in the literature, we have collected values for as many derivatives as we could locate and compiled them in Table 1. A survey of these data shows that bulky primary phosphanes differ quite widely in ^{31}P chemical shift but that the $^{1}J_{PH}$ values are remarkably consistent and hence diagnostic. The ^{1}H NMR spectrum measured in $CDCl_3$ (Table 2) contains the typical aromatic and aliphatic signals of the Dip group, with the additional aspect that the isopropyl methine septet appears to be split further into doublets with 3.0 Hz coupling to phosphorus. Whether this is four-bond dipolar or through space coupling is yet to be determined. The expected doublet for the PH signal is observed. In addition, almost all the ^{13}C signals are doublets owing to coupling to the single phosphorus nucleus.

After repeated handling of a container of **5**, a new signal was detected in the ^{31}P NMR spectrum at δ –14.6, consisting of a 1:2:1 triplet with $^{1}J_{PH}$ = 477 Hz. We attribute this signal to the phosphane oxide, $DipP(O)H_2$, formed by aerobic oxidation of the phosphane, and base our assignment on the close correspondence of its NMR parameters to those of $Mes*P(O)H_2$: triplet, $^{1}J_{PH}$ = 490.7 Hz at δ –10.0 (33). Saturation of the NMR sample with dry O_2 caused the intensity of this signal to increase, consistent with our hypothesis. We have not attempted to isolate bulk phosphane oxide.

The general procedure for the preparation of the silylated compounds (Scheme 2) was to cleave P—H bonds with *n*-BuLi, then quench the resulting phosphide anions with $R_2R'SiCl$. However, either these reactions do not go to completion, or the base also cleaves P—Si bonds, so that the cleaving and quenching sequences had to be repeated more than once per step. The success of this procedure was greatly assisted by the use of ^{31}P NMR spectroscopy. Aliquots taken directly from the reaction mixture were used to assess the progress of each reaction, and in this way, we were able to prepare phosphanes **6–9** in acceptable yields. Use of the larger *t*-$BuMe_2Si$ group yielded analytically pure samples of **7** and **9**, whereas **6** and **8** always contained some minor impurities. The monosilylated phosphane **7** was

sufficiently stable to allow the investigation of its dynamic behaviour in solution by VT NMR, and this compound yielded crystals suitable for an X-ray diffraction study.

The P–H stretch of **7** (recorded as a KBr pellet) has a frequency of 2330 cm^{-1}, thus considerably higher in energy than the 2301 cm^{-1} value for **5**. ^{1}H, ^{13}C, and ^{31}P data are compiled in Tables 1 and 2. We again note the large variation in phosphorus chemical shift and the consistency of the $^1J_{PH}$ values, which are found between 203 and 212 Hz for all the trivalent P–H compounds listed in Table 1.

Structure of 7 in the solid state

The crystal structure of DipPH{Si(CH$_3$)$_2$-*t*-Bu} (**7**) was determined by X-ray diffraction at –80°C. Crystal data and structure solutions for **7** are given in Table 3, and its selected inter-atomic distances and angles in Table 4. The compound

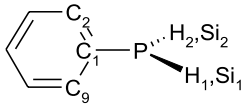
[a]Full geometry optimization and stationary point verification, unless otherwise indicated. Label scheme:



[b]Frequency calculation to verify stationary point fails.

deviations of the phosphorus (0.318(4) Å) and the *ipso* carbon C(1) (0.038(3) Å) atoms from the mean aryl plane defined by the remaining five carbon atoms. Such a deviation for the phosphorus atom has been observed previously in other "secondary" and "tertiary" phosphane structures with bulky *ortho* groups: in **23**, 0.85 Å (25), in Mes*P{OCH_2}$_2$, 0.82 Å (25), and in TripPHPh (**25**), 0.48 Å (35). However, both the structures with *ortho* isopropyl groups have the P atom displaced on the side opposite to that of the "R" substituent, while the Mes*PR_2 structures have the phosphorus pushed out on the same side of the ring as the "axial" substituent.

The sum of angles around phosphorus is only 301.5(26)°, indicative of a highly pyramidal structure at phosphorus. This is commonly observed for secondary phosphanes with bulky Trip or Mes* substituents (**25**, 304° (35); Mes*$PHSiPh_3$ (**26**), 303.9° (27)), values that are statistically indistinguishable from our results.

Calculated (gas phase) structures of 5–9

The structures of **5–9** have been calculated at the B3LYP/6–31G(d) level. Illustrations of the calculated structures are provided in Fig. 2, and some of the core geometric parameters are presented in Table 5. We started our analysis by comparing the calculated structure of **7** with that determined from the crystal structure. There is a remarkable agreement between the two, right down to the conformations adopted by the aryl isopropyl and the triorganosilyl groups. These results serve to confirm that the structure obtained in the solid state is relatively unaffected by intermolecular forces. The calculated bond lengths are 1–2% longer than the measured values, typical for the DFT methodology that we employed. However, the calculated sum of angles at phosphorus was within experimental error of the measured value.

The structures of the symmetrically substituted phosphanes **5**, **8**, and **9** are quite similar, having one substituent at each side of the aryl ring. This is unlike the results from crystallography for Mes*PX_2 derivatives, such as Mes*P{OCH_2}$_2$ or **23** (25), where both substituents are found on the same side of a (distorted) aryl ring. The pyramidal geometry at phosphorus causes a slight distortion of the bond angles, such that the angle $C_{(2)}$–$C_{(1)}$–P (the upper side for each picture in Fig. 2) is in each case somewhat larger than the angle $C_{(9)}$–$C_{(1)}$–P. The unsymmetrically substituted **6** and **7** have significantly twisted isopropyl substituents to minimize steric interactions, whereas the symmetrically substituted compounds have the isopropyl groups symmetrically disposed to the aryl rings and in the "Vee-back" conformation.

Finally, we note the great similarity in the sum of angles at phosphorus calculated for **5–7**, and the agreement of calculated and measured values for **7** (within experimental error). In contrast, when two silyl groups are attached as in **8** and **9**, the sum of angles is greatly increased (by 36–46°). We note that the calculated values of 336.2 and 346.1° are significantly greater than the average measured for Mes_3P (329.0°) from two independent molecules in the unit cell of a single crystal X-ray structure (36). However, these values are comparable to that obtained in a crystal structure for **23**, 343.2° (25)

Solution structures by NMR

The pertinent NMR data for all five phosphanes as determined in $CDCl_3$ solution have been compiled in Table 2. Data from two previously reported compounds, $TripPHCH_3$ (**27**) (35) and $TripPHSiPh_3$ (**21**) (27) have also been included to substantiate the assignment and interpretation of our results. The former is of course a secondary phosphane and hence has a ^{31}P chemical shift that is not comparable to that of ours. However, there is remarkable agreement between the NMR data for **27** and the more symmetrical of our phosphanes $DipPR_2$ (R = H, Si{CH_3}$_3$, and Si{CH_3}$_2$-*t*-Bu). This applies to the ^1H and ^{13}C parameters of the *ortho* isopropyl groups and the ^{13}C parameters of the aromatic rings, for which all the carbon nuclei except the *para* atom C_4 are doublets from coupling to phosphorus. We have also found that the silyl methyl and even the methyl hydrogen atoms of the *t*-Bu groups in **6–9** show evidence of coupling to the phosphorus nucleus.

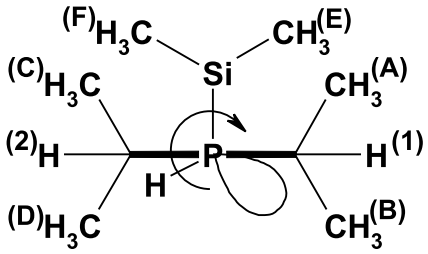
The unsymmetrically substituted phosphanes **6** and **7** have room temperature (RT) ^1H NMR spectra in which there are two isopropyl methyl environments, but only a single CH environment. Similar effects are reported in the literature for the *ortho* isopropyl groups of **21** (27). Additionally, **7** also displays two distinct silyl methyl resonances, which have different degrees of coupling to ^{31}P, i.e., 5.3 and ~1 Hz.

VT NMR study

A variable temperature NMR study of **7** was conducted in $C_6D_5CD_3$ solution. Compound **7** is superior to **6** for this purpose, not only in being a pure crystalline material but also in possessing a pair of diastereotopic methyl groups on silicon which are direct probes for the chirality induced by the asymmetric phosphorus atom in the absence of fast pyramidal inversion. The basic spectral features of the dynamic NMR sample, which was made up in $C_6D_5CD_3$, are very similar to the RT spectrum in deuterochloroform as reported

© 2002 NRC Canada

Scheme 3.



in Table 2. In Scheme 3, the molecule is viewed end-on to highlight the symmetry relationships relevant to solution dynamics (the *t*-Bu group is located in front of the Si atom, and is omitted for clarity). Figure 3 presents several traces selected from the series of spectra that illustrate the key spectral changes; full VT data have been deposited.[3]

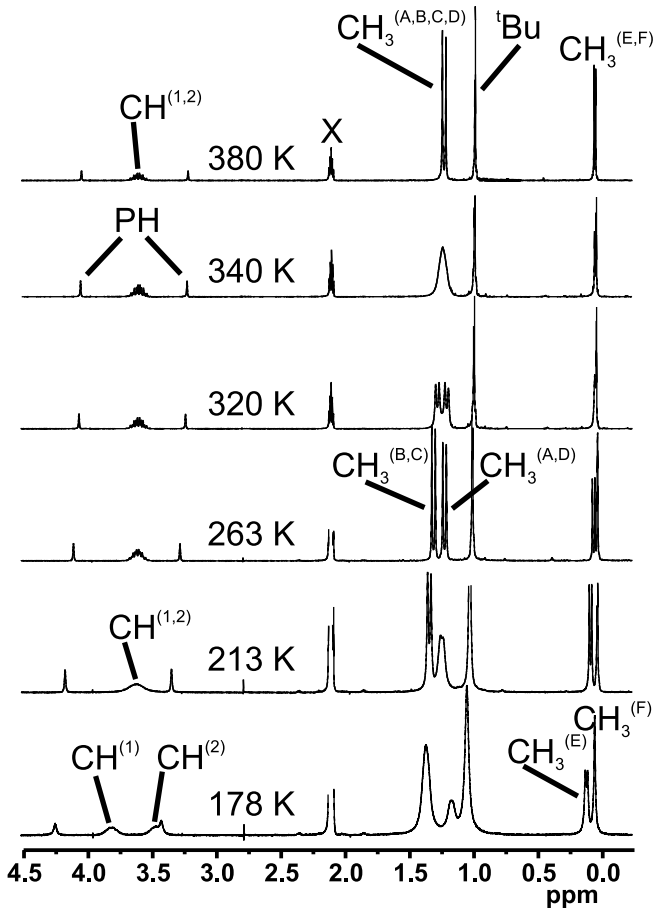
At 380 K, the dynamic processes are in the high temperature limit. Here there is only one kind of isopropyl ($CH^{(1,2)}$ equivalent), one isopropyl methyl ($CH_3^{(A–D)}$ equivalent), and one silyl methyl group ($CH_3^{(E,F)}$ equivalent). This is achieved by a combination of rapid rotation about single bonds and rapid inversion at phosphorus. We note that the $CH_3^{(E,F)}$ signal is a phosphorus-coupled doublet with a coupling constant of ~3 Hz.

On cooling, coalescence of the $CH_3^{(A,B,C,D)}$ as well as the $CH_3^{(E,F)}$ signals occurs, and the coalesced signals become sharp at lower temperature, e.g., as in the 263 K spectrum. Here $CH_3^{(F)}$ appears as a singlet (the splitting of ~1 Hz observed in $CDCl_3$ is not resolved in the more viscous $C_6D_5CD_3$), while $CH_3^{(E)}$ is a doublet with coupling to phosphorus of ~5 Hz. The isopropyl methyl signals break into two distinct sets, labelled $CH_3^{(A,D)}$ and $CH_3^{(B,C)}$, while the $CH^{(1,2)}$ signals remain identical, as in the 380 K spectrum. These changes are consistent with slowed pyramidal inversion at the chiral phosphorus atom. Thus $CH_3^{(E)}$ and $CH_3^{(F)}$ as well as the $CH_3^{(A,D)}$ and $CH_3^{(B,C)}$ pairs become diastereotopic with respect to the chiral phosphorus atom.

Rapid rotation about single bonds has the effect of mapping $CH^{(1)}$ on $CH^{(2)}$, $CH_3^{(A)}$ on $CH_3^{(D)}$, and $CH_3^{(B)}$ on $CH_3^{(C)}$ (Scheme 3), averaging their chemical shifts in the intermediate temperature regime. Below 263 K, this rotational averaging slows down, with coalescence of the methine signals occurring at 213 K. Partial coalescence of the methyl signals is also observed at this temperature. By 178 K we had not reached the low temperature limit of this additional dynamic process, and further cooling of our solution led only to general line broadening. However, at 178 K the methine signals split up into two distinct, though broadened, signals labelled $CH^{(1)}$ and $CH^{(2)}$ (Fig. 3). We attribute this inequivalence to slowed rotation about single bonds. Other workers refer to this as slow rotation about the $C_{(aryl)}$—P bond (27), though several bond rotations are likely coupled in a molecule as sterically congested as **7**.

Using the classical expression of Gutowsky and Holm (37) with Eyring absolute rate theory (38), we can estimate the barrier heights as $\Delta G^{\ddagger}$ ~ 40 kJ mol^{-1} for rotation about single bonds and $\Delta G^{\ddagger}$ ~ 72 kJ mol^{-1} for pyramidal inversion at phosphorus. These numbers are in remarkable agreement

Fig. 3. NMR spectra of **7** at various temperatures as recorded in $C_6D_5CD_3$. Spectra were monitored at 10° intervals over the range 178 to 380 K, and in the intervening spectra to those displayed here, smooth transitions between the peaks were observed. Only the aliphatic region of each spectrum is displayed, including the silyl, the isopropyl, and the PH signals. The residual $C_6D_5CHD_2$ peak (X) is cut short in the low-temperature spectra. Similarly, the *t*-Bu peak is cut short for the middle traces.



with values previously reported in a dynamic study of $TripPHSiPh_3$ (**21**): 39 kJ mol^{-1} for rotation and 71 kJ mol^{-1} for inversion (27). The assignments of the processes in **21** were made by comparison to literature data on phosphorus inversion barriers. The presence of diastereotopic groups $CH_3^{(E,F)}$ on silicon in **7** provides internal corroboration that this is the correct assignment.

Experimental

Starting materials and general procedures

All experimental procedures were performed under a nitrogen atmosphere using modified Schlenk techniques. 2,6-Diisopropylaniline (Aldrich) was distilled from KOH and stored under nitrogen prior to use. PCl_3, $SiMe_3Cl$, $SiMe_2$-*t*-BuCl (Aldrich), and HBr (Merck) were commercial products and used as received. Tetrahydrofuran was dried and distilled under a nitrogen atmosphere from sodium/benzophenone.

[3] Table S1 presents the full VT NMR Data for **7** at ~10 K intervals from 178 to 380 K.

© 2002 NRC Canada

Hexanes and pentane were dried and distilled under a nitrogen atmosphere from $LiAlH_4$. ^1H, ^{13}C, and ^{31}P NMR spectra were recorded on a Bruker AC250/Tecmag Macspect spectrometer operating at 250.13, 101.26, and 62.90 MHz, respectively. The ^1H and ^{13}C chemical shifts of $CDCl_3$ solutions were referenced to TMS and of $C_6D_5CD_3$ solutions to the residual CHD_2 pentet at δ 2.09, while ^{31}P was referenced to external 85% H_3PO_4. Infrared spectra were recorded on Bomem MB-100 or Nicolet Avatar 360 spectrometers as KBr pressed pellets (solids) or as neat liquid smears. Mass spectra were undertaken in the Department of Chemistry, University of Alberta, and elemental analyses were done by MHW Laboratories, Phoenix, Ariz. 1-Bromo-2,6-diisopropylbenzene was prepared from 2,6-diisopropylaniline by the literature method (28).

Preparation of 2,6-diisporopylphenylphosphonus mixed halide, 11

A solution of Grignard reagent was prepared from 60.0 g (247 mmol) of **10** and 6.0 g of activated magnesium turnings in 1150 mL of THF, and transferred via cannula to a solution of 67.0 g (488 mmol) PCl_3 in 200 mL THF held at –15°C. The mixture was allowed to warm to room temperature with stirring (12 h) and then heated to reflux for 2 h. Evaporation of solvent, extraction with 500 mL ether, filtering, and distillation (106–111°C, 0.5 mbar) produced 14.2 g of viscous, colourless oil. Careful integration of the ^{31}P NMR spectrum ($CDCl_3$) showed this to be the mixed phosphonous dihalides $DipPCl_2$ (**11a**) (δ 164.5, 4.5 g), DipPClBr (**11b**) (δ 159.2, 6.9 g), and $DipPBr_2$ (**11c**) (δ 151.9, 2.8 g); total molar yield 38.1%. ^1H NMR ($CDCl_3$) δ: 7.44–7.21 (m, 3H), 4.14–4.11(three sept, each with J_{HH} = 6.8 Hz, 2H), 1.34–1.29 (three d, each with J_{HH} = 6.8 Hz, 6H). ^{13}C NMR δ: 154 (d, $^2J_{PC}$ = 23 Hz), 133.49–133.41 (three d, $^3J_{PC}$ ~1 Hz), 124.97, 124.91 (two s), 31.25, (d, $^3J_{PC}$ = 27.8 Hz), 31.08, (d, $^3J_{PC}$ = 27.8 Hz), 30.89, (d, $^3J_{PC}$ = 27.3 Hz), 24.91–24.81 (three doublets, not resolved). MS (70eV) (calculated on ^{81}Br and ^{35}Cl) *m/z* (%): 354 ($[DipPBr_2]^+$, 5.5), 308 ($[DipPBrCl]^+$, 26.5), 273 ($[DipPBr]^+$, 9.8), 262 ($[DipPCl_2]^+$, 44.9), 227 ($[DipPCl]^+$, 100).

Preparation of 2,6-diisopropylphenylphosphane, 5

A solution of 10.0 g (32.7 mmol) of **11** in 150 mL anhydrous ether was transferred via cannula to a vigorously stirred suspension of 2.78 g (73.2 mmol) $LiAlH_4$ in 150 mL anhydrous ether held at –5°C. After warming to room temperature and heating to reflux for 22 h, the mixture was cooled to 0°C and treated with 53 mL of saturated aqueous NH_4Cl. The organic layer was decanted and the solids washed with 3 × 100 mL degassed ether. The combined ethereal solutions were dried, filtered, and evaporated to a milky oil. Distillation (73–85°C, 0.5 mbar) produced **5** as a clear oil (4.76 g, 24.6 mmol, 75.3% yield). IR (neat) (cm^{-1}): 3056 (w), 2961 (vs), 2868 (m), 2627 (s), 2306 (m), 1572 (w), 1461 (s), 1423 (w), 1383 (m), 1362 (m), 1247 (w), 1181 (w), 1162 (w), 1106 (w), 1086 (m), 1054 (m), 1037 (w), 923 (w), 831 (m), 792 (s), 720 (s), 499 (w). NMR, see Table 2. MS (70eV) *m/z* (%): 194.12306 ($[M]^+$, 100), 193 ($[DipPH]^+$, 44), 179 ($[C_{11}H_{16}P]^+$, 30), 161 ($[C_{12}H_{17}]^+$, 54), 152 ($[C_9H_{13}P]^+$, 44), 151 ($[C_9H_{12}P]^+$, 26), 137 ($[C_8H_{10}P]^+$, 25), 110 ($[C_6H_7P]^+$, 52), 91 ($[C_7H_7]^+$, 26). Anal. calcd. for $C_{12}H_{19}P$ (%): C 74.20, H 9.86; found: C 74.43, H 9.74.

Preparation of DipPHSi$(CH_3)_3$, 6

A solution of 28.4 mL of 1.6 M *n*-BuLi was added slowly by syringe to a vigorously stirred solution of 8.412 g (43.3 mmol) **5** in 80 mL THF held at 0°C. The now red solution was warmed to RT and stirred for 20 min, then cooled again to 0°C, whereupon 5.77 mL (45.5 mmol, 5% excess) $ClSi(CH_3)_3$ was added via syringe, followed by warming to RT and heating to reflux for 2 h. Removal of the volatile components, extraction with 100 mL hexanes, filtering, evaporation, and distillation (110–115°C, 0.5 mbar) of the residue produced 7.39 g of clear oil (29.6 mmol, 64%). NMR, see Table 2. MS (70eV) *m/z* (%): 266.16084 ($[M]^+$, 64), 193 ($[DipPH]^+$, 57), 149 ($[C_9H_{10}P]$, 14), 73 ($[SiMe_3]^+$, 100). Analytically pure material was not obtained, and all samples tended to be contaminated with very small amounts of either **5** or **8**.

Preparation of DipPH{Si$(CH_3)_2$-*t*-Bu}, 7

A solution of 4.00 g (20.6 mmol) **5** in 40 mL THF cooled to 0°C was treated with 13.5 mL (21.6 mmol, 5% excess) of 1.6 M *n*-BuLi. After warming the now yellow solution to RT for 30 min and cooling back to 0°C, 3.10 g (20.6 mmol) $ClSi(CH_3)_2$-*t*-Bu was added by syringe. After warming to RT and then refluxing for 1 h, the solution was shown by ^{31}P NMR to have 70% conversion to **7**. A further 4.5 mL of *n*-BuLi followed by 1.05 g (3.6 mmol) was used in a repeat of the above procedure. NMR indicated complete conversion at this stage. The solids remaining after evaporation of the solvent were extracted with 20 mL hexanes, filtered, evaporated, and the residue sublimed under static vacuum onto a water-cooled cold finger, yielding 3.60 g of colourless crystalline **7** (11.7 mmol, 57% yield, mp 45–51°C). X-ray quality crystals were grown by sublimation under dynamic vacuum in a three-zone tube furnace. IR (KBr pellet) (cm^{-1}): 3050(w), 2958(vs), 2925(vs), 2856(s), 2330(m), 1567(w), 1463(s), 1417(w), 1381(w), 1362(s), 1246(m), 1176(w), 1050(w), 1006(w), 938(w), 839(s), 821(s), 804(vs), 773(w), 737(vs), 680(w), 601(w), 578(w), 444(w), 430(w). NMR, see Table 2. MS (70 eV) *m/z* (%): 308.20866 ($[M]^+$, 53), 251 ($[DipP(Si(CH_3)_2]^+$, 11), 193 ($[DipPH]^+$, 15), 115 ($[(CH_3)_3CSi(CH_3)_2]^+$, 13.7), 73 ($[Si(CH_3)_3]^+$, 100). Anal. calcd. for $C_{18}H_{33}PSi$ (%): C 70.08, H 10.78; found: C 69.84, H 10.62.

Preparation of DipP{Si$(CH_3)_3$}$_2$, 8

A stirred solution prepared from 2.00 g (10.3 mmol) **5** and 20 mL THF held at 0°C was treated with 6.76 mL (10.8 mmol, 5% excess) of 1.6 M *n*-BuLi. After 20 min, the stirred orange solution was treated with 1.37 mL (10.8 mmol) $ClSi(CH_3)_3$, yielding a colourless solution with a white precipitate. ^{31}P NMR indicated that conversion to **7** was incomplete; a further 5.07 mL (8.11 mmol) of *n*-BuLi and 1.03 mL (8.11 mmol) $ClSi(CH_3)_3$ were added following the same procedure as before. ^{31}P NMR analysis indicated 75% **8** and 25% **7**. Again 5.07 mL (8.11 mmol) of *n*-BuLi and 1.03 mL (8.11 mmol) $ClSi(CH_3)_3$ were added following the same procedure and NMR analysis showed complete conversion to **8**. Evaporation of solvent, extraction with 100 mL hexanes, filtration, evaporation, and distillation of the residue (120–130°C, 0.5 mbar) gave 2.20 g of **8**, which cooled to a pasty white solid (6.5 mmol, 63% yield). IR (neat) (cm^{-1}): 3050 (m), 2957 (vs), 2867 (s), 1935 (w), 1861

© 2002 NRC Canada

(w), 1695 (w), 1651 (w), 1633 (w), 1589 (w), 1569 (m), 1557 (w), 1463 (s), 1381 (m), 1361 (m), 1304 (m), 1246 (s), 1177 (m), 1048 (m), 992 (m), 835 (s), 801 (m), 748 (m), 684 (m), 625 (m), 509 (w), 402 (w). NMR, see Table 2. MS (70eV) *m/z* (%): 338.20229 ([M]$^+$, 49), 266 ([DipPHSi(CH$_3$)$_2$]$^+$, 15), 193 ([DipPH]$^+$, 16), 147 ([C$_{11}$H$_{15}$]$^+$, 13.7), 73 ([Si(CH$_3$)$_3$]$^+$, 100). An analytically pure sample was not obtained.

Preparation of DipP{Si(CH$_3$)$_2$-*t*-Bu}$_2$, 9

A solution of 2.00 g (10.3 mmol) **5** in 20 mL THF held at 0°C was treated with 6.43 mL (10.29 mmol) of 1.6 M *n*-BuLi. After warming to RT, the yellow solution was cooled again and treated with 1.55 g (10.29 mmol) ClSi(CH$_3$)$_2$-*t*-Bu. The faint yellow solution was allowed to warm to room temperature over 30 min. Cooling again in an ice bath and treating with another 6.43 mL of 1.6 M *n*-BuLi gave an orange solution. Again 1.55 g ClSi{CH$_3$)$_2$-*t*-Bu} was added after warming the reaction mixture to room temperature and cooling to 0°C. The faint yellow solution was then heated to reflux for 12 h and ^{31}P NMR analysis showed complete conversion to **9**. Evaporation of solvent, extraction into 30 mL pentane, filtering, and evaporation yielded a white solid, which was purified by sublimation under dynamic vacuum onto a water-cooled cold finger to give 2.934 g of a white crystalline **9** (7.7 mmol, 75% yield, mp 57–62°C). IR (KBr pellet) (cm^{-1}): 3047 (w), 2958 (vs), 2929 (vs), 2894 (s), 2857 (s), 2569 (w), 1471 (m), 1460 (m), 1403 (w), 1388 (m), 1380 (m), 1360 (m), 1251 (s), 1245 (s), 1177 (w), 1048 (w), 1024 (w), 1005 (w), 834 (vs), 820 (s), 794 (vs), 760 (s), 742 (m), 681 (w), 670 (m), 660 (w), 575 (w), 470 (w), 408 (w). NMR, see Table 2. MS (70 eV) *m/z* (%): 422.29533 ([M]$^+$, 30), 251 ([M – *t*-Bu]$^+$, 11), 73 ([Si(CH$_3$)$_3$], 100). Anal. calcd. for C$_{24}$H$_{47}$PSi$_2$ (%): C 68.18, H 11.21; found: C 67.99, H 10.94.

X-ray diffraction analysis of DipPH{Si(CH$_3$)$_2$-*t*-Bu}, 7

The crystal structure of **7** was determined using a Bruker instrument fitted with a SMART 1000 area detector. Experimental details are summarized in Table 3. The structure was solved by direct methods using SHELXS-97 (39) and refined by full-matrix least-squares on F^2 against all reflections using SHELXL-97 (40). Neutral atom scattering factors are from *International Tables for X-ray Crystallography*, Vol. C. The weighting scheme used was $w = 1/[\sigma^2(c) + (0.0705P)^2]$, where $P = (F_o^2 + 2F_c^2)/3$. The non-hydrogen atoms were refined anisotropically, and the H atoms on C were refined using a riding model (C—H = 0.95 Å). The H atom attached to P was refined freely. Additional crystallographic details have been deposited.[4]

Electronic structure calculations

The structures of the full geometries of **5–9** were optimized by DFT methods, using the B3LYP hybrid function and the 6–31G(d) basis set, as implemented in the Gaussian98 suite of programs (41) running on AMD K7 computers under Windows 2000 or on four processor Compaq Alpha ES40 or ES45 workstations. Full frequency calculations were performed on all models, and stationary states were confirmed by the absence of imaginary frequencies. In the case of **8** the frequency calculation was unsuccessful, but the strong agreement with the structures of other members of the series provides confidence in the calculated structure.

Conclusions

A new bulky phosphane and two mono- as well as two disilyl derivatives were prepared by routes that provide these materials in synthetically useful quantities. The silyl compounds as well as the phosphane itself are expected to be useful synthons for both main group and transition metal chemistry. We have identified a further example of dynamic effects in compounds of the general class ArPHSiR$_3$ where both the aryl group and silicon bear sterically congested substituents. Studies on the utility of **5–9** as synthons are ongoing in our laboratory.

Acknowledgments

We thank the Natural Sciences and Engineering Research Council of Canada (NSERC) and the University of Lethbridge for financial support (R.T.B.). We thank Dr. Bob Macdonald, Department of Chemistry, University of Alberta, for the collection of the intensity data for the X-ray diffraction study, and Meg O'Shea for performing the DFT calculations. Access to the Multimedia Advanced Computation Infrastructure (MACI) Alpha cluster at the University of Calgary is gratefully acknowledged. We thank Dr. Paul Hazendonk for helpful discussions, and anonymous referees for useful suggestions.

Synthesis and characterization of titanium complexes containing phosphinimido and tropidinyl ligands: Crystal structure of (trop)(*t*-$Bu_3PN)TiCl_2$

Steve J. Brown, Xiaoliang Gao, Matthew G. Kowalchuk, Rupert E.v.H. Spence, Douglas W. Stephan, and John Swabey

Abstract: A new class of titanium complexes containing a tropidinyl (trop) ligand and a phosphinimido (R_3P=N-) or a ketimide ligand (R_2C=N-) were synthesized and characterized. The combination of the cyclopentadienyl equivalent tropidinyl and phosphinimido ligands enables the formation of a group of novel non-metallocene catalysts for olefin polymerization. The crystal structure of (trop)(*t*-$Bu_3PN)TiCl_2$ was determined by single crystal X-ray crystallography. Polymerization of ethylene with this complex was studied in a high-temperature solution process.

Key words: tropidinyl, phosphinimido, ketimide, catalyst, polymerization.

Résumé : On a synthétisé et caractérisé une nouvelle classe de complexes du titane contenant un ligand tropidinyle (trop) et un phosphinimido (R_3P=N-) ou un ligand cétimide (R_2C=N-). La combinaison des ligands phosphinimido et tropidinyle, équivalent du cyclopentadiényle, rend possible la formation d'un groupe de nouveaux catalyseurs non métallocènes pour la polymérisation des oléfines. On a déterminé la structure cristalline du (trop)(*t*-$Bu_3PN)TiCl_2$ par diffraction des rayons X par un cristal unique. On a étudié la polymérisation de l'éthylène à l'aide de ce catalyseur, dans un procédé en solution et à haute température.

Mots clés : tropidinyle, phosphinimido, cétimide, catalyseur, polymérisation.

[Traduit par la Rédaction]

Introduction

Metallocene catalysts ($CpCp'MX_2$, M = Ti, Zr, Hf; with or without a bridge between the Cps) (1–8) and Constrained geometry catalysts ($CpSiR_2NR'TiX_2$) (9–13) have been the subject of intense studies for olefin polymerization in both academia and industrial organizations in the past two decades. Compared to the traditional Ziegler–Natta catalysts, these catalysts have well-defined structures, which makes it possible to control the properties of polymer products through the modification of catalyst structures.

In the past few years, ligands that are considered cyclopentadienyl equivalent in terms of both electronic and steric structures have been synthesized and used to form a variety of single site catalysts for olefin polymerization. For example, the core structure of zirconium complexes with boratabenzene ligands (14–17) is very similar to that of Cp_2ZrCl_2. The activity of the boratabenzene complexes for olefin polymerization was reported to be similar to that of Cp_2ZrCl_2 under the same conditions. Catalysts of the types $(R_3PN)CpTiX_2$ (18–20), $(R_3PN)_2TiX_2$ (21–22), and $(R_3PN)(L')TiX_2$ (23) (where L′ is a heteroatomic ligand) were found to be highly active towards olefin polymerization. The properties of the polymeric products made with these phosphinimido catalysts are similar or superior to those made with conventional metallocene catalysts. Other catalysts or metal complexes with ligands isoelectronic–isolobal with the cyclopentadienyl ligands including the *o*-dicarbollide anions (24), η^3–"nacnac" anions (25), and the $(4\sigma + 2\pi)$ amidinate (26) ligands have also been extensively studied.

A tropidinyl ligand consists of an η^3 4π-electron allylic moiety and a 2σ-electron neutral nitrogen donor. The ligand is considered to be equivalent to a cyclopentadienyl ligand, and $Cp(trop)ZrCl_2$ and $(trop)_2ZrCl_2$ (27–28) were synthesized and were tested for ethylene polymerization. $Cp(trop)ZrCl_2$ exhibited high activity towards ethylene polymerization. $(Trop)_2ZrCl_2$ was only moderately active.

As an extension of our studies of group 4 metal catalysts containing a phosphinimido ligand and a heteroatomic ligand, the synthesis, structures, and polymerization studies of $(trop)(R_3PN)TiCl_2$ were performed, where trop is the N-methyl tropidinyl ligand. Also a titanium complex

(trop)(R_2CN)$TiCl_2$ containing a ketimide ligand (29, 30) and the tropidinyl ligand was synthesized and characterized.

Results and discussion

Synthesis

Tropidine was prepared from dehydration of tropine (31). The 1-trimethyl tin derivative was prepared from the lithium salt of tropidine and trimethyl tin chloride (27). Tropidinyl titanium trichloride, (trop)$TiCl_3$, **1**, was conveniently prepared by the reaction of the 1-trimethyl tin tropidine with $TiCl_4$. The elimination of Me_3Sn-Cl from the reaction of $TiCl_4$ and 1-trimethyltin-tropidine to produce **1** is similar to the syntheses of (Indenyl)$TiCl_3$ (36) and (C_5Me_5)$TiCl_3$ (37) by the elimination of Me_3Si-Cl from $TiCl_4$ and 1-(trimethysilyl)indene and trimethylsilylpentamethylcyclopentadiene, respectively. The reactions again suggest the thermodynamic stability of (trop)$TiCl_3$, **1**, and the equivalence of tropidinyl and the cyclopentadienyl ligands. (Trop)$TiCl_3$, **1**, is an excellent starting material for the preparation of titanium complexes containing the tropidinyl ligand. Thus the reaction of **1** with *t*-Bu_3P=NLi and *i*-Pr_3P=NLi gave (*t*-Bu_3P=N)(trop)$TiCl_2$, **2**, and (*i*-Pr_3P=N)(trop)$TiCl_2$, **3**, respectively. The reaction of **1** with *t*-Bu_2C=NLi resulted in the formation of (*t*-Bu_2C=N)(trop)$TiCl_2$, **4**. Unlike the reactions of $CpTiCl_3$ with anionic ligands, which are usually fast and could be completed within a few minutes even at temperatures below 0°C, the reactions of **1** with the nitrogen-containing anionic ligands are very slow at room temperature. Therefore, heating was found to be necessary to drive the reactions to completion. Scheme 1 summaries the synthesis of the ligand and metal complexes.

Table 1. Crystallographic parameters for **2**.[a]

Formula	$C_{20}H_{39}Cl_2N_2PTi$
Formula weight	457.30
Space group	*Pbca*
Crystal system	Orthorhombic

Goodness-of-fit	1.041
No. of variables	235
R, R_w (%)	5.65, 15.74

[a]All data collected at 24°C with Mo Kα radiation (λ = 0.71069 Å), $R = \Sigma||F_o| - |F_c||/ \Sigma|F_o|$, $R_w = [\Sigma[\omega(F_o^2 - F_c^2)^2]/ \Sigma(\omega F_o^2)^2]]^{0.5}$.

Structure

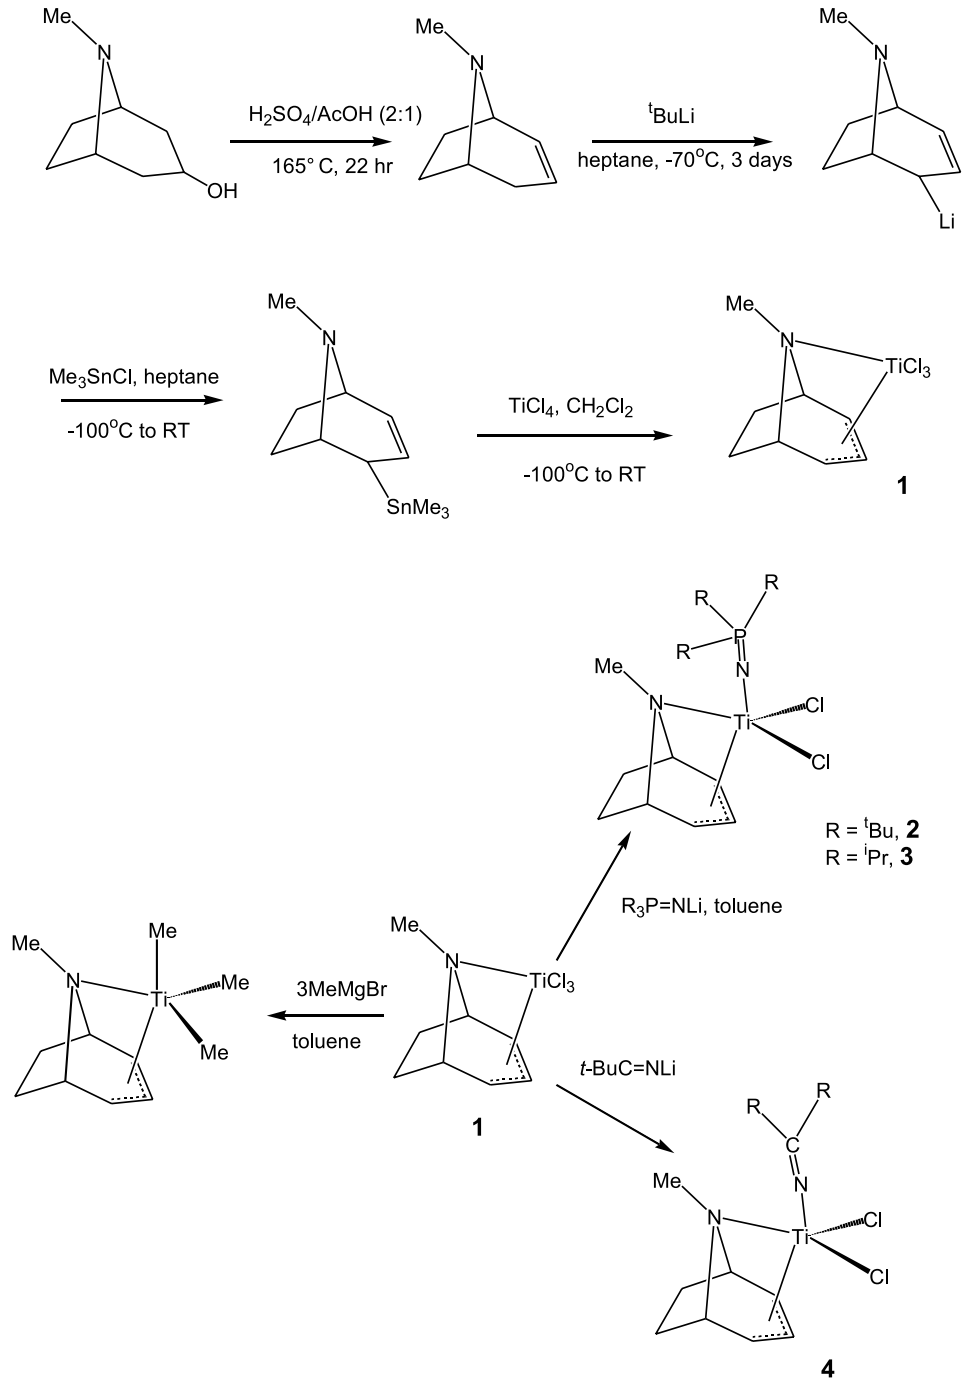
Purple crystals of **2** were grown from a mixture of toluene and heptane. The solid-state structure was determined by X-ray crystallography. The ORTEP diagram of this complex is shown in Fig. 1. Crystal data and selected bond lengths and angles are provided in Tables 1 and 2, respectively. The solid state structure of the molecule shows that the tropidinyl ligand binds to the titanium via a dative bond through the nitrogen atom and an η^3 π bond through the anionic allyl moiety. The tropidinyl ligand is oriented symmetrically with respect to the two Cl ligands. The N—methyl bond in the tropidinyl ligand bisects the Cl-Ti-Cl plane and points to the same direction as the vector from the central titanium to the middle of the Cl ligands (i.e., points to the front of the molecule), which was also seen in the solid structure of Cp(trop)$ZrCl_2$ (28). The average Ti—C bond distance for the allyl moiety in the tropidinyl ligand is 2.37 Å, which is similar to the average Ti—C distance (2.38 Å) found in titanocene dichloride (32, 33). The *t*-Bu_3P=N ligand binds to the titanium center via the nitrogen atom and the geometry of the P-N-Ti moiety is almost linear, as seen from the P-N-Ti angle of 174.50(18)°. This near linear geometry was previously seen in Cp(*t*-Bu_3P=N)$TiCl_2$ (20), Cp(Ph_3P=N)$TiCl_2$ (34), and (*t*-Bu_3P=N)$_2TiCl_2$ (22). The Cl-Ti-Cl angles are 100(1)° in Cp_2TiCl_2 (32, 33), 103.41(12)° in Cp(*t*-Bu_3P=N)$TiCl_2$ (20), and 106.93(7)° in (*t*-Bu_3P=N)$_2TiCl_2$ (22). The Cl-Ti-Cl angle in the complexes increases from Cp, (*t*-Bu_3P=N) to the tropidinyl ligand.

Ethylene polymerization

The dimethylated derivative of **2**, prepared by treatment of **2** with 2 molar equiv of MeMgBr was tested in high-temperature solution polymerization. It showed moderate activity when activated with [Ph_3C][(C_6F_5)$_4$]. The ethylene polymerization rate was 60 L mmol^{-1} min^{-1} at 160°C. For comparative purposes Cp_2ZrMe_2 under the same polymerization conditions has a polymerization rate of 750 L mmol^{-1} min^{-1}.

© 2002 NRC Canada

Scheme 1.



Polymer molecular weight was exceptionally high for both ethylene and ethylene – 1-octene polymerization with a molecular weight of 199 000 g mol^{-1} being produced in co-polymerization at 160°C and a low-ethylene conversion of 68%. The molecular weight distribution (MWD = (weight average)/(number average molecular weight)) for ethylene polymerization was 2.2 indicating single site performance. However, in co-polymerization of ethylene and 1-octene, the MWD for this catalyst was 9.2, indicating non single site catalyst performance with the activation method employed.

Experimental

All preparations, reactions, and manipulations were carried out under a purified nitrogen atmosphere, using both Schlenk techniques and glove boxes. All commercially available chemicals were purchased from Aldrich. Solvents were anhydrous grades, which were first dried through use of a deoxygen catalyst and activated molecular sieve beds and then stored over activated molecular sieves in either Kontes flasks or plastics bottles in glove boxes. R_3P=N-$SiMe_3$

(*R* = *t*-Bu, *i*-Pr) were prepared by reacting the neat phosphines with an excess amount of Me_3SiN_3 at 95°C until no more nitrogen evolution. R_3P=N-H (*R* = *t*-Bu, *i*-Pr) were prepared by reacting R_3P=N-$SiMe_3$ (*R* = *t*-Bu, *i*-Pr) with a catalytic amount of NaOMe in dry methanol followed by removing volatiles and extraction with heptane. NMR spectra were recorded on a Bruker 300 MHz NMR machine. Elemental analyses were obtained from Canadian Microanalytical Services Ltd., Delta, B.C. V4G 1G7. GC–MS analyses were performed at NOVA Chemicals Research and Technology Center, Calgary, AB, T2E 7K7.

Preparation of tropidine

To tropine (25.0 g, 177 mmol) and glacial acetic acid (12 g, 11.5 mL) cooled to 0°C and combined in a 200 mL Schlenk flask was added concentrated H_2SO_4 (46 g, 25 mL) causing fuming. The reaction vessel was fitted with a condenser, and under a slight flow of N_2 the reaction mixture was refluxed for 22 h at 165°C. A 300 mL volume of deionized distilled water was added with stirring and pH adjusted to 13–14 by addition of 50 g (1.25 mol) of NaOH in ~170 mL water. The product was extracted into ether and the organic phase dried over $MgSO_4$. Solids were removed by filtration and the solvent removed in vacuo. The liquid was distilled under ambient pressure at 165–170°C. The distillate was diluted in pentane and the solution was passed through a column of neutral alumina (Brockman Activity I) to remove a small amount of residual starting material. The product was a clear colorless liquid with 99.8% purity as determined by GC–MS ($[M]^+$: 123). The yield was 10.71 g (49.1%).

Preparation of 1-trimethyltintropidine

To a solution of tropidine (10.707 g, 86.9 mmol) in heptane (~300 mL) at –70°C was added *tert*-butyllithium (51.1 mL, 86.9 mmol, 1.7 M in pentane). The reaction mixture assumed a greenish tinge, and within 15–20 min of addition completion a fluffy precipitate was observed in the clear yellow solution. The mixture was maintained at –70°C for 3 days with occasional stirring, at which time the mixture was a combination of an orange supernatant and a yellowish solid.

To the slurry of lithium tropidinide in heptane at –100°C was added trimethyltin chloride (17.3 g, 86.9 mmol) in heptane dropwise over 15–20 min. The color of the reaction mixture gradually became lighter and white solid was observed to have formed. After complete addition, the mixture was warmed to room temperature and stirred for an additional 2.5 h. A 100 mL volume of deionized distilled water was added and the mixture stirred under N_2 overnight. The organic compounds were extracted into heptane–pentane, rinsed vigorously with a solution of brine, and dried over $MgSO_4$. Solids were removed by filtration and the dark liquid passed through a column of neutral alumina (Brockman Activity I), affording a clear liquid with a yellow tinge. The liquid was distilled to give a clear colorless viscous oil with 99.2% purity as determined by GC–MS ($[M]^+$: 286). The yield was 13.65 g (54.9%). ^{1}H NMR (C_7D_8) δ: 5.52 (m, 2H), 3.12 (m, 1H), 3.03 (m, 1H), 2.43 (s, 4H), 2.04 (m, 2H), 1.81 (m, 1H), 1.46 (m, 1H), 0.08 (s, 9H, Sn*Me*$_3$ (further split by 8.7 and 7.7% of ^{119}Sn and ^{117}Sn, respectively), *J* = 25.7 Hz).

Preparation of (tropidinyl)titanium trichloride, 1

To titanium (IV) chloride (0.379 g, 2 mmol) in dichloromethane (15 mL) at –78°C was added dropwise trimethyltin tropidine (0.572 g, 2 mmol) in dichloromethane (20 mL), initiating a dark blue coloration in the reaction mixture. The reaction was warmed to room temperature and stirred overnight under N_2. The solvent was removed under vacuum; the blue solid was slurried in pentane and isolated by filtration. The final product was dried in vacuo and determined to be 99% pure by ^{1}H NMR. The yield was 0.502 g (90.8%). ^{1}H NMR (C_7D_8) δ: 5.14 (t, 1H, *J* = 7.61 Hz), 4.84 (dd, 2H, J_1 = 7.21 Hz, J_2 = 5.01 Hz), 3.10 (br s, 2H), 1.95 (s, 3H, N*Me*), 1.20 (m, 4H, CH_2). Anal. calcd. for $C_8H_{12}Cl_3NTi$: C 34.76, H 4.38, N 5.07; found: C 34.06, H 4.54, N 4.95.

Preparation of (tropidinyl)titanium trimethyl

To a stirred solution of **1** (1 mmol, 0.276 g) in toluene (30 mL) cooled at –70°C was added MeMgBr (4.5 mmol, 3 M in diethyl ether, 1.5 mL). The deep blue solution was allowed to warm to room temperature and was stirred at room temperature for 2 h. The orange slurry was pumped to dryness and the solid was extracted with pentane. The pentane solution was filtered to remove MgClBr and the excess of MeMgBr. The filtrate was pumped to dryness to give pure (trop)(*t*-Bu_3PN)$TiMe_3$ in 47% yield. ^{1}H NMR (C_7D_8) δ: 4.79 (t, 1H, J = 7.50 Hz), 4.69 (dd, 2H, J_1 = 7.20 Hz, J_2 = 5.0 Hz), 2.72 (br s, 2H), 1.91 (m, 2H), 1.62 (m, 2H), 1.50(s, 9H, TiMe3), 1.43 (3H, N*Me*).

(Tropidinyl)(tri-*tert*-butylphosphinimido)titanium dichloride, 2

To (tropidinyl)titanium trichloride (0.502 g, 1.816 mmol) in toluene (15 mL) at –78°C was added a slurry of lithium tri-*tert*-butylphosphinimide (*t*-Bu_3PNLi) (0.405 g, 1.816 mmol) in toluene (25 mL). No apparent reaction was observed. The reaction mixture was heated to 60°C for ~1 h, resulting in a purple colored solution. The solution was filtered to remove LiCl and the product was crystallized after heptane was added to the toluene solution. The yield was 0.669 g (80.6%). ^{1}H NMR (C_7D_8) δ: 5.48 (t, 1H, J = 7.41 Hz), 4.63 (dd, 2H, J_1 = 7.51 Hz, J_2 = 4.61 Hz), 3.61 (br s, 2H), 2.41 (s, 3H), 1.80 (m, 4H, CH_2), 1.22 (d, 27H, N=P-*t*-Bu_3, J = 13.22 Hz). Anal. calcd. for $C_{20}H_{39}Cl_2N_2PTi$: C 52.53, H 8.59, N 6.13; found: C 52.30, H 8.35, N 6.04.

(Tropidinyl)(tri-*tert*-butylphosphinimido)titanium dimethyl

To a stirred solution of **2** (0.325 g, 0.71 mmol) in toluene (~30 mL) cooled at –70°C was added slowly a solution of MeMgBr in dietyl ether (3 M, 0.71 mL, 2.13 mmol, excess). The mixture was left to warm to room temperature and was stirred for 2 h. The dark purple color turned orange. The orange solution was pumped to dryness and the solid was extracted with pentane. After filtration, the pentane filtrate was pumped to dryness and an orange crystalline solid was obtained in 87% (0.26 g) yield. ^{1}H NMR (C_7D_8) δ: 4.73 (t, 1H, J = 7.3 Hz), 4.34 (dd, 2H, J_1 = 7.45 Hz, J_2 = 4.60 Hz), 3.45 (br s, 2H), 2.25 (s, 3H), 2.0 (m, 4H, CH_2), 1.26 (d, 27H, N=P-*t*-Bu_3, J = 12.7 Hz), 0.74 (s, 6H).

(Tropidinyl)(tri-*iso*-propylphosphinimido)titanium dichloride, 3

To (tropidinyl)titanium trichloride (0.442 g, 1.6 mmol) in toluene (20 mL) at –78°C was added a solution of lithium tri-*iso*-propylphosphinimide (*i*-Pr_3PNLi) (0.290 g, 1.6 mmol) in toluene (10 mL). The reaction mixture assumed a dark purple coloration. After warming to room temperature, the solution was stirred an additional 1 h and was filtered. The product, a crystalline purple solid, was crystallized from toluene–pentane with a yield of 0.519 g (72.0%). ^{1}H NMR (C_7D_8) δ: 5.56 (m, 1H), 4.67 (m, 2H), 3.58 (br s, 2H), 2.38 (s, NM*e*), 1.79 (m, 7H, CH_2 and CH(CH_3)$_2$), 0.99 (dd, 18H, J_1 = 15.32 Hz, J_2 = 7.31 Hz). Anal. calcd. for $C_{17}H_{33}Cl_2N_2PTi$: C 49.17, H 8.01, N 6.74; found: C 48.80, H 8.33, N 6.43.

(Tropidinyl)(di-*tert*-butylketimido)titanium dichloride, 4

To (tropidinyl)titanium trichloride (0.449 g, 1.62 mmol) in toluene (15 mL) at –100°C was added a slurry of lithium di-*tert*-butylketimide (*t*-Bu_2C=NLi) (0.239 g, 1.62 mmol) in toluene. No apparent reaction was observed. The mixture was stirred at room temperature for 1 h and then at 55°C for 0.5 h. The solution was filtered and heptane was added to the filtrate. The product, a blue-black solid, was crystallized with a yield of 0.22 g (35.6%). ^{1}H NMR (C_7D_8) δ: 5.35 (t, 1H, J = 7.61 Hz), 4.45 (dd, 2H, J_1 = 7.51 Hz, J_2 = 4.91 Hz), 3.47 (br s, 2H), 2.43 (s, 3H, N*Me*), 1.62 (m, 4H, CH_2), 1.19 (s, 18H). Anal. calcd. for $C_{17}H_{30}Cl_2N_2Ti$: C 53.56, H 7.93, N 7.34; found: C 53.10, H 7.66, N 7.68.

X-ray data collection and reduction

X-ray quality crystals were obtained directly from the preparation as described above. The crystals were manipulated and mounted in capillaries in a glove box, thus maintaining a dry, O_2-free environment for each crystal. Diffraction experiments were performed on a Siemens SMART System CCD diffractometer collecting a hemisphere of data in 1329 frames with 10 s exposure times. Crystal data are summarized in Table 1. The observed extinctions were consistent with the space groups in each case. The data sets were collected ($4.5° < 2\theta < 45–50.0°$). A measure of decay was obtained by re-collecting the first 50 frames of each data set. The intensities of the reflections within these frames showed no statistically significant change over the duration of the data collections. The data were processed using the SAINT and XPREP processing package. An empirical absorption correction based on redundant data was applied to each data set. Subsequent solution and refinement was performed using the SHELXTL solution package operating on a PC. The reflections with $F_o^2 > 3\sigma F_o^2$ were used in the refinements.

Structure solution and refinement

Non-hydrogen atomic scattering factors were taken from the literature tabulations (35). The heavy atom positions were determined using direct methods employing either the SHELXTL or the direct methods routines. The remaining non-hydrogen atoms were located from successive difference Fourier map calculations. The refinements were carried out by using full-matrix least-squares techniques on F, minimizing the function $\omega(|F_o|-|F_c|)^2$ where the weight ω is defined as $4F_o^2/2\sigma(F_o^2)$, and F_o and F_c are the observed and calculated structure factor amplitudes. In the final cycles of each refinement all non-hydrogen atoms were assigned anisotropic temperature factors. Carbon-bound hydrogen atom positions were calculated and allowed to ride on the carbon to which they are bonded assuming a C—H bond length of 0.95 Å. Hydrogen atom temperature factors were fixed at 1.10 times the isotropic temperature factor of the carbon atom to which they are bonded. The hydrogen atom contributions were calculated, but not refined. The final values of refinement parameters are given in Table 1. The locations of the largest peaks in the final difference Fourier map calculation as well as the magnitude of the residual electron densities in each case were of no chemical significance. Positional parameters, hydrogen atom parameters, thermal

parameters, and bond distances and angles have been deposited as supplementary material.[2]

Solution polymerization

All the polymerization experiments described below were conducted on a continuous solution polymerization reactor. The process is continuous in all feed streams (solvent, monomers, and catalyst) and in the removal of product. All feed streams were purified prior to the reactor by contact with various absorption media to remove catalyst poisons such as water, oxygen, and polar materials, as is known to those skilled in the art. All components were stored and manipulated under an atmosphere of purified nitrogen.

All the examples discussed below were from experiments conducted in a reactor of 71.5 mL internal volume. In each experiment the volumetric feed to the reactor was kept constant and as a consequence so was the reactor residence time.

The catalyst solutions were pumped to the reactor independently and there was no pre-contact between the activator and the catalyst. Because of the low solubility of the catalysts, activators, and MAO in cyclohexane, solutions were prepared in purified xylene. The catalyst was activated in situ (in the polymerization reactor) at the reaction temperature in the presence of the monomers. The polymerizations were carried out in cyclohexane at a pressure of 1500 psi (1 psi = 6894.757 Pa). Ethylene was supplied to the reactor by a calibrated thermal mass flow meter and was dissolved in the reaction solvent prior to the polymerization reactor. If a co-monomer (for example 1-octene) was used, it was also premixed with the ethylene before entering the polymerization reactor. Under these conditions the ethylene conversion is a dependent variable controlled by the catalyst concentration, reaction temperature, catalyst activity, etc.

The internal reactor temperature is monitored by a thermocouple in the polymerization medium and can be controlled at the required set point to ±0.5°C. Downstream of the reactor the pressure was reduced from the reaction pressure (1500 psi (1 psi = 6894.757 Pa)) to atmospheric. The solid polymer was then recovered as a slurry in the condensed solvent and was dried by evaporation before analysis.

The ethylene conversion was determined by a dedicated on-line gas chromatograph by referencing to propane, which was used as an internal standard. The average polymerization rate constant was calculated based on the reactor hold-up time, the catalyst concentration in the reactor, and the ethylene conversion and is expressed in L $mmol^{-1}$ min^{-1}.

Average polymerization rate (kp) = $(Q \times (100 - Q)^{-1}) \times [M]^{-1} \times (HUT)^{-1}$, where Q is the percent ethylene conversion, [M] is the catalyst (metal) concentration in the reactor expressed in mM, and HUT is the reactor hold-up time in minutes.

The polymers were characterized by high-temperature GPC in trichlorobenzene using a Waters Instrument.

Conclusions

The elimination of trimethyltin chloride from the reaction of $TiCl_4$ and 1-trimethyltin-tropidine is an excellent synthetic route to tropidinyl titanium trichloride **1**. The facial synthesis of **1** has made it possible for the synthesis of titanium complexes containing a tropidinyl ligand and other nitrogen bearing ligands. The structure of complex (*t*-$Bu_3P{=}N)(trop)TiCl_2$, **2**, suggests that the core structures of $(trop)(R_3PN)TiCl_2$ are similar to those of (L)(L′)TiCl2 where L and L′ are cyclopentadienyl and phosphinimide ligands, respectively. Polymerization studies of the dimethyl derivative of **2** in a high-temperature solution process indicated that the catalyst had low activity compared to that of Cp_2ZrMe_2.

Linear and nonlinear optical responses of a dye anchored to gold nanoparticles dispersed in liquid and polymeric matrixes

Ignacio Vargas-Baca, Andrew P. Brown, Mark P. Andrews, Tigran Galstian, Yuejun Li, Hojatollah Vali, and Mark G. Kuzyk

Abstract: The compound [4-$CH_3C_6H_4$-SS-CH_2CH_2-N(CH_3)$C_6H_4C(C_6H_4N(CH_3)_2)$-4)$_2$]Cl (**1a**) consists of the triarylmethyl chromophore of crystal violet appended to an organic disulfide, to entail direct attachment of this dye to gold surfaces. Addition of **1a** to colloidal dispersions of the metal produced a stable dispersion in methanol–water mixtures. Transmission electron microscopy of Freeze-Fracture sections shadowed with carbon and platinum confirmed that the dispersion remains unaggregated. Local-field effects and coupling to the surface plasmon of gold magnified the interaction of the chromophore with optical fields. A large oscillator strength in the visible spectrum (*f* ca. 35) and a first hyperpolarizability (β ca. 10^{-26} esu, hyper-Rayleigh scattering) were observed as the colloid adsorbed dye molecules. A Hill-type analysis indicated that the adsorption process is cooperative. This combination of organic chromophore and nanoparticle was adapted for incorporation into PMMA-based composite films whose electrooptic coefficient (r_{113} = 2.20 pm V^{-1}) is larger than the sum of the individual contributions of dye and metallic particles.

Key words: chromophores, colloids, gold, local-field effects, nonlinear optical materials.

Résumé : Le composé [4-$CH_3C_6H_4$-SS-CH_2CH_2-N(CH_3)$C_6H_4C(C_6H_4N(CH_3)_2)$-4)$_2$]Cl (**1a**) comprend le chromophore triarylméthyle du cristal violet fixé sur un disulfure organique qui permet d'attacher directement ce colorant sur des surfaces d'or. L'addition du composé **1a** à des dispersions colloïdales du métal conduit à la formation d'une dispersion stable dans des mélanges méthanol–eau. La microscopie électronique de transmission de sections Freeze-Fracture ombragées par du carbone et du platine permet de confirmer que la dispersion dans un état qui n'est pas agrégé. Les effets de champs locaux et le couplage de l'or à la surface plasmonique amplifient l'interaction du chromophore avec les champs optiques. Avec l'absorption de molécules de colorant par le colloïde, on a observé une grande force oscillatoire dans le spectre visible (*f* d'environ 35) ainsi qu'une première hyperpolarisabilité (β environ 10^{-26} esu, diffusion hyper-Rayleigh). Cette combinaison de chromophore organique et de nanoparticule est adaptée à une incorporation dans des films composites à base de PMMA dont le coefficient électrooptique (r_{113} = 2,20 ppm V^{-1}) est supérieur à la somme des contributions individuelles du colorant et des particules métalliques.

Mots clés : chromophores, colloïdes, or, effets de champs locaux, matériaux optiques non linéaires.

Introduction

It is predicted that a third of current electronic technologies for data transmission and processing will eventually be replaced by their faster photonic counterparts. The development of practical electrooptic and photorefractive applications depends on the availability of materials with large nonlinear optical (NLO) responses. Crystals of $LiNbO_3$, KH_2PO_4, and BaB_2O_4 are used to change the wavelength of laser light through parametric processes. Such materials are expensive and cumbersome to tailor into the waveguide configurations that are compatible with optical fibre systems. Because of their processability, polymers and glasses with NLO properties are a convenient alternative to inorganic crystals. Conjugated polymers such as polydiacetylenes have inherent third-order NLO activity but most systems consist of a transparent host-matrix uniformly doped with a NLO-active species. Two kinds of such NLO dopants can be dis-

tinguished: organic chromophores and nanoparticles of semiconductors or metals.

Second- (1, 2) and third-order NLO activity (3) can be induced with organic dyes. The nonlinear response of the composite is in principle proportional to the amount of chromophore present. However, large loadings have an unfavourable effect on mechanical properties, may decrease transparency, and lead to attenuation by dipolar coupling as the inter-chromophore distance decreases. It is therefore desirable to prepare chromophores with the largest hyperpolarizabilities possible. Systematic research during the past two decades has identified features such as a high degree of bond alternation that give organic molecules large hyperpolarizabilities (4). Furthermore, the NLO response of organic species can be augmented up to an order of magnitude when they are organized in orientationally correlated assemblies (5) and chiral supramolecular architectures (6). A remarkable achievement in this field was the preparation of a chromophore that conferred a polymer a high electrooptic coefficient of about 20 pm V^{-1}. This, in turn, led to the fabrication of a 0.1 THz electrooptic modulator operating with a drive voltage of less than 1.0 V (7).

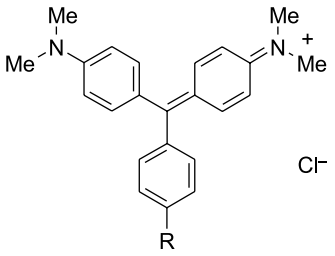
A completely different class of NLO dopants includes small particles of gold, silver, or metal chalcogenides. Because of their inherent symmetry, dispersions of such particles have been considered only as third-order NLO materials (8, 9). A two-wave-mixing device capable of operating as an all-optical switch or gate has been demonstrated (10). The recent discovery of second-order NLO activity for liquid colloidal dispersions of gold (11, 12) opened the possibility of their use in electrooptic devices.

The optical response of metallic colloids arises from the ease with which electromagnetic fields excite electrons at the surface of the particles. Photo-excitation induces charge density oscillations, in particular a collective movement of electrons. This surface plasmon is partially responsible for the intense absorptions at 500–550 and 400 nm, which are characteristic of wine-red gold and yellow-brown silver hydrosols, respectively. It is well known that electronic excitation leads to an electric field redistribution near the metal surface, especially an enhancement in small step sites or protrusions (13, 14) as well as in tiny particles and their aggregates (15, 16). Molecules in the vicinity of such surfaces experience an intense electric field and an increase in their cross-sections for optical interactions. This antenna effect is thought to play an important role in surface enhanced Raman spectroscopy (17). Numerous theoretical calculations have predicted large enhancement factors for luminescence and light absorption of molecules on the surface of small metallic particles (18–20), with further enhancement of absorptivity for systems in which molecular electronic transitions and the plasmon resonance overlap.

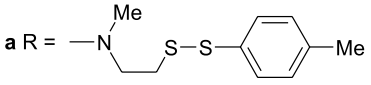
Previous studies of the enhancement of linear optical responses in dye–metal composites have been carried out, depositing dyes on metal island films through sublimation, solvent evaporation, spin coating, or adsorption from liquid solutions (21–26). Those systems indeed exhibited stronger linear optical responses as compared to metal-free controls. Alternatively, dyes have been combined with colloidal dispersions and activated quartz slides have been dipped in the mixtures (27). On such heterogeneous surfaces it is not possible to unambiguously distinguish true local field enhancement from changes of composition due to preferential adsorption of dye on the metal. Thus quantitative conclusions must be drawn cautiously.

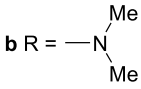
We are specifically interested in theoretical predictions of local field enhancements of the nonlinear response of chromophores (28–30). Experimentally, it has been reported that dispersions of gold clusters in polydiacetylenes induce an enhancement of the third-order susceptibility ($\chi^{(3)}$) by two orders of magnitude in comparison to the polymer alone (31, 32). In addition, strong hyper-Rayleigh scattering (HRS) has been observed for silver colloids in the presence of *para*-nitroaniline (33). Important factors such as particle aggregation, the actual distance of the chromophore to the surface, coupling of electronic excitations, and the particle shape have not been carefully considered.

In this report, we present the synthesis of an NLO active chromophore modified with a disulphide group **1a** (See below) to anchor the molecule to the surface of colloidal gold particles. We observed increases of the linear and nonlinear optical responses as the molecules are adsorbed onto the metal surface and produce stable dispersions of dye-coated metal colloids. We also prepared polymer films doped with these dye–gold particles and observed an enhanced electrooptic coefficient.



1





Experimental

Materials and methods

The manipulation of moisture sensitive materials was carried out under an atmosphere of dry nitrogen using Schlenk and dry box techniques. Organic solvents used for synthesis were purified by distillation over the appropriate drying agent. Most chemicals were obtained from Aldrich and used as received. The disulfide substituted aniline 4-$CH_3C_6H_4$-SS-CH_2CH_2-N(CH_3)-C_6H_5 (**2**) was prepared stepwise; treating N-methyl aniline with ethylene sulfide to obtain $C_6H_5N(CH_3)$-CH_2CH_2-SH and reacting the corresponding lithium salt with 4-$CH_3C_6H_4$-SCl. HPLC grade methanol and Milli-Q™ water were used for the preparation of

colloids. Soda-lime glass slides 1 mm-thick with a 200 Å layer of indium-tin oxide (ITO) were obtained from Delta Technologies and cleaned with acetone and aqueous NaOH.

Instrumentation

All NMR spectra were acquired in a Varian XL200 instrument. IR spectra were recorded in a Brucker IFS-48 FT spectrometer. Raman spectra were collected on a home-built instrument described elsewhere (34); the 514.5 nm line of an Ar^+ laser was used to excite scattering with less than 30 mW of power to minimize sample degradation. Mass spectra were obtained on a KratosMS25RFA spectrometer, FAB was performed with a Xe source (7 kV, 0.4 mA) and an NBA matrix. A diode-array HP-8452A spectrophotometer was adapted with optical-fiber bundles to measure UV–Vis spectra in a custom-built thermostated cell holder with magnetic stirring. Transmission electron microscopy studies were conducted on a Jeol JEM2000FX instrument operating at 80.0 kV. Freeze fracture samples were prepared in a Reichert-Jung KF80 Universal Cryofixation Unit and shadowed in a BALZERS BAF300 Freeze-Etch Unit

Hyper-Rayleigh scattering measurements were performed with a custom-built instrument. A Q-switched Continuum Surelite II Nd:YAG laser provided the fundamental wavelength of 1064 nm in 5 ns pulses with a 10-Hz repetition rate. The laser output, 300–400 mJ per pulse, was reduced to approximately 2 mJ and controlled with the combination of a half-wave retarder, a polarizing cube, and a visible filter as attenuator. This pump beam was focussed onto the sample and the second harmonic signal collected on a photomultiplier with the appropriate sets of lenses. A broad-band infrared filter and an interferential filter were used to prevent all wavelengths but 532 nm from reaching the detector connected to an oscilloscope.

Thin film samples were prepared with a Headway photoresist spin-coater; their thickness was measured using a Dektak 3030ST surface profilometer. Transparent gold electrodes were produced in an Edwards Auto 306 metal-atom evaporator.

The second-order NLO properties of film samples were determined by measuring the Electrooptic coefficient r_{113} in a custom-built set up. The experimental apparatus is shown in Fig. 1. The central element is a Mach-Zehnder interferometer operating with a randomly polarized He-Ne laser (632.8 nm, 8 mW) as the optical source. The input beam was polarized using a 50/50 polarizing beam-splitter and separated into the sample and reference arms using a second beam-splitter. For background measurements, the beam was modulated with a chopper operating 1000 Hz. The test and reference samples had identical structure, which improved the fringe visibility of the interferometer by balancing the light intensity of the arms. The reference arm also contained a glass slide that was rotated by a precision step motor with a controller interfaced to a microcomputer. This slide provided a variable path-length difference (and therefore a phase shift) between the two arms of the interferometer. The beams were recombined and a microscope objective (2O ×) was used to expand the output light beam onto a silicon photodiode detector. The fringe visibility was improved further with the help of a pinhole (d = 400 μm). The detector was connected to a lock-in amplifier, which also provided an internal reference (Ω = 1000 Hz) and oscillation for measurements of the modulated sample. The applied voltage (V_{rms}) was controlled further using an electronic amplifier. Oscillations due to air drafts were minimized by enclosing the optical set-up in a plastic encasing and vibrations were damped using an optical table with pneumatic isolation.

Synthesis of 1a

By adaptation of a technique for the preparation of crystal violet, thionyl chloride (0.55 mL, 6.9 mmol) was carefully added to Micheler's ketone (1.84 g, 6.9 mmol) in 20 mL of toluene at 100°C. After 10 min a brown glassy phase separated from the solvent. Compound **2** (2.61 g, 9.0 mmol) was added with the help of 5 mL of toluene. The mixture was

© 2002 NRC Canada

cooled after 40 min and 1 mL of triethyl amine was added slowly with vigorous stirring. After 16 h the solvent was decanted and the residue was reprecipitated from ethanol-toluene, washed with warm hexane, and dried under vacuum. The crude product was purified by chromatography with a toluene–ethanol gradient of increasing polarity on a cellulose column. The product was obtained as a dark-purple microcrystalline solid with metallic lustre. Yield 11% (0.43 g, 0.7 mmol). UV–Vis (MeOH, MeOH 20%): λ_{max} (ε), 558 (94 000, 70 500), 590 nm (10 400, 68 400 mol^{-1} dm^3 cm^{-1}). FT-IR (KBr) (cm^{-1}): 422, 524, 562, 665, 722, 743, 758, 800, 828, 913, 942, 1063, 1133, 1173, 1227, 1295, 1335, 1363, 1445, 1478, 1522, 1583 (ν). Resonance Raman (MeOH 20%, 2.9×10^{-5} M, 514 nm) (cm^{-1}): 1618, 1586, 1538, 1381, 1306, 1180, 920, 809, 434. ^{1}H NMR (200 MHz, $CDCl_3$) δ: 7.6–6.5 (m, 16H), 4.0–3.5 (m, 19), 2.4–2.1 (broad, 3H). FAB-MS (NBA) *m*/*z* (%): 540 ([M^+], 20), 416 ([$M^+ - HSC_4H_4CH_3$], 10).

Preparation of colloids

Gold dispersions stable in aqueous methanol were prepared by reduction of $HAuCl_4$ in glassware that had been carefully cleaned with aqua regia and rinsed with Milli-Q™ water. All solutions were prepared in methanol 20% (w/v) and filtered through a 0.2 µm PTFE membrane immediately before mixing. In a typical preparation $NaBH_4$ (6.6 mg, 0.17 mmol) was dissolved in 10 mL and added dropwise to $HAuCl_4 \cdot 3H_2O$ (11.0 mg, 2.8×10^{-2} mmol) in 40 g of solvent mixture with vigorous stirring. After 1 h, 10 mL of a 0.4% (w/v) solution of H_2O_2 were added slowly to remove any excess of $NaBH_4$. The next day the sol was diluted to complete 100 mL. Colloids prepared this way were stable for weeks. Each batch was characterized by UV–Vis spectroscopy and TEM.

For adsorption studies, the UV–Vis spectra and (or) hyper-Rayleigh scattering intensity were measured as the gold sol was titrated in a cuvette with small additions of a dilute solution of **1a** under vigorous stirring with delay period of 10 s after each addition for equilibration.

Transmission electron microscopy

Colloid samples for routine particle-size measurements were prepared by solvent evaporation on carbon-coated copper grids (300 mesh). To examine the morphology of a colloid, a drop of the liquid sample was frozen at –142°C (liquid propane). The sample was then cut and etched at –102°C under high vacuum, and a replica was made by shadowing with platinum and carbon (200 V, 100 mA each). The replica was deposited on a plain-copper grid (300 mesh) with distilled water.

Preparation of dye–colloid dispersions in polymer films

A conductive strip was patterned on an ITO slide by acid etching. Films of about 10 µm thickness were cast from a solution of PMMA in *iso*-propanol/toluene (39% w/v) that also contained dodecylamine-coated gold particles (0.22% metal/polymer by weight) (35) and (or) **1a** (0.05 molar ratio to gold). The films were allowed to age in order to remove residual solvents and a thin layer of gold was deposited to serve as a transparent electrode.

Results and discussion

We designed an experiment in which colloidal metallic particles were to be mixed with a NLO dye in solution while their linear (absorbance) and nonlinear (second harmonic scattering) optical responses could be monitored. Guided by published theoretical predictions, we focussed on those factors that would maximize local field effects, namely minimal separation between the chromophore and metal surface and overlap of electronic excitations of dye and metal particle.

The chromophore of crystal violet (**1b**), the tris(*para*-dialkylaminophenyl)methyl cation, was chosen for this study, since it displays (*a*) extensive overlap of its visible absorption (λ_{max} = 590 nm) with the plasma resonance of colloidal gold, (*b*) a large octupolar hyperpolarizability (36), and (*c*) an emission in hyper-Rayleigh scattering that is well separated from multi-photon fluorescence when irradiated at 1064 nm (37).

In recent years, there has been considerable development of self-assembly processes at interfaces. A number of protocols for efficient adsorption of molecules on gold surfaces have been successfully extended to the derivatisation of gold nanocrystals, especially with organosulfur compounds: thiols, disulfides, and sulfides (38–40). We decided to use a disulfide group to directly anchor the chromophore to the surface of gold colloidal particles, using a short chain to maximize interaction with the particle.

It is known that metal colloids in water adsorb many organic molecules, including dyes. However, in some cases it is uncertain whether the molecules are truly in contact with the surface of the particle or sit on top of other adsorbates. The anionic 4,5-benzoindotricarbocyanine builds a multilayered structure onto gold hydrosols stabilized with poly(vinyl alcohol). This is accompanied by a bathocromic shift from 778 to 895 nm but no enhancement of absorbance (41). Silver colloids with adsorbed malachite green (**1c**) require inorganic salts as stabilizing agents. The ions may be a mayor component of the surface structure, since the number and intensity of bands in the visible and Raman spectra are strongly influenced by the salts (42, 43).

Synthesis and properties of 1a

Common methods for the preparation of triarylmethyl dyes involve oxidation steps that are incompatible with some sulfur functional groups. Coupling of the disulfide-containing aniline **2** with Micheler's ketone, activated with thionyl chloride, avoided harsh conditions, but the overall yield was low and repeated chromatographic elutions were necessary to remove impurities. The product was identified by the peak of its cation in the FAB mass spectrum. The ^{1}H NMR spectrum displayed a complex broadened pattern due to dynamic exchange of the conformers defined by different orientations of the disulfide bond. Variable temperature studies confirmed the fluxional nature of the structure but failed to simplify completely the spectrum up to 90°C in DMSO-d_6. The same phenomenon was observed in the disulfide substituted aniline **2**. The purity of the product was assessed by chromatography and UV–Vis spectroscopy. Figure 2 compares its spectrum to that of a commercial sample of crystal violet (95%+ pure). In pure methanol their spectra are virtually identical, with maxima at 590 nm and shoulders

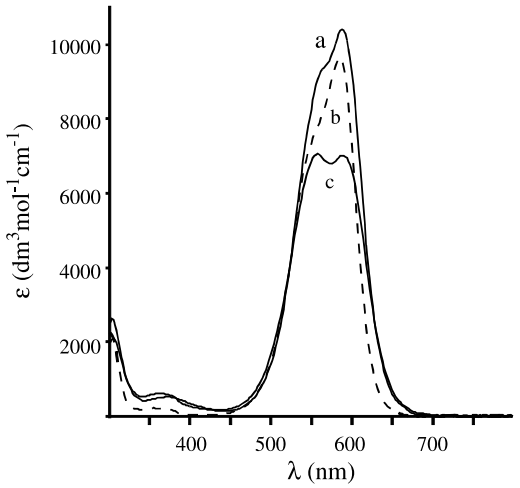
Fig. 2. UV–Vis spectra: (*a*) **1a** in MeOH; (*b*) **1b** in MeOH; (*c*) **1a** in MeOH 20% (w/v).



at 558 nm due to the formation of aggregates. On the basis of the calculated molar absorptivities **1a** was considered pure and used without further treatment. Different from **1b**, **1a** is sparingly soluble in water and solubilization is facilitated by addition of alcohol. In methanol 20% (w/v) the total absorptivity is smaller and the aggregate's band is well resolved. For all adsorption studies, the equilibrium of self-association was neglected, since the two maxima followed the Beer-Lambert law within the range of concentrations employed.

Adsorption of 1a onto gold colloids

Gold colloids prepared in methanol 20% were titrated with **1a** while their visible absorption spectra were monitored. The result of a typical titration is shown in Fig. 3. Upon addition of the dye an intense band appears at long wavelengths; its position depends on the diameter of the particles (λ_{max} = 740 nm for d = 13 ± 5 nm and 676 nm for d = 6 ± 2 nm). The absorbance kept increasing after each addition until a certain amount of dye, characteristic for each size of colloid, was reached. As well, the height of this peak depended linearly on the total concentration of gold for a single size of particle. This behaviour suggests that the new band is due to the dye molecules adsorbed on the surface of the colloidal particles and that the surface is eventually saturated. In the case of 13 nm particles and based on the amount of dye adsorbed by the colloid, the oscillator strength (*f*) was estimated to be close to 35 for this band.

However, the changes observed in the visible spectrum also resemble those due to particle aggregation; thus appropriate control experiments were performed. We noted that addition of NaCl, *p*-tolyldisulfide, and even **1b** as flocculating agents to the 13 ± 5 nm colloid each produced a distinctive maximum always at 704 nm, as shown in Fig. 4. More important, those aggregated colloids were extremely unstable and precipitated within seconds; colloids treated with **1a** did not require any stabilizer and were stable for days provided that all glassware was scrupulously clean, all solutions were filtered to exclude nucleation points, and evaporation was prevented. As the visible spectra alone are not evidence against aggregation, the morphology of colloids treated with **1a** was examined by transmission electron microscopy. Freeze-fracture sections of the same samples used for absorbance measurements were shadowed with carbon and platinum. The micrograph in Fig. 5 displays well-separated metal nanoparticles following a radial distribution of mass with a coefficient practically equal to 2.0; thus the particles are evenly spread in two dimensions. This is in striking contrast with the well-known properties of flocculated metal colloids, whose aggregation proceeds through a mechanism of collisions between clusters and results in highly branched structures with radial distribution coefficients of about 1.75. Because of the non-integer value of this "Hausdorf dimension", such aggregates are usually considered to be "fractal" (44). On the basis of the stability of the **1a**–gold dispersions and the radial distributions in the

Fig. 3. UV–Vis spectra in MeOH 20% (w/v): (*a*) **1a** 19.3 × 10^{-6} mol dm^{-3}; (*b*) gold colloid (d = 6 ± 2 nm, C_{Au} = 2.1 × 10^{-4} mol dm^{-3}, v_0 = 3.045 mL); (*c*) to (*l*) evolution after addition of **1a** (1.2 × 10^{-4} mol dm^{-3}) in 0.025 mL increments. Inset: dependence on the absorbance at 680 nm on the concentration of added **1a**.

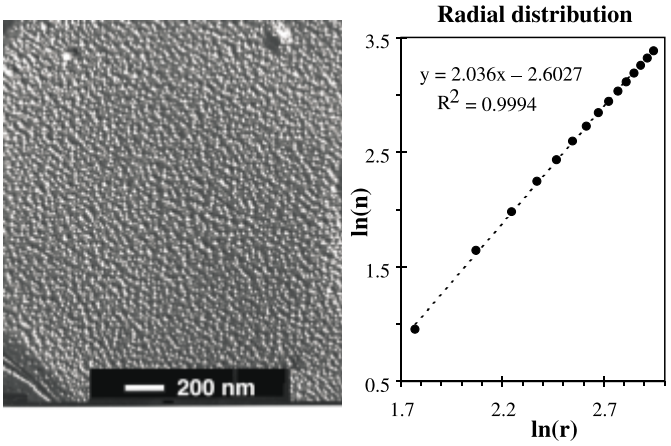

Fig. 6. Hill plot for the colorimetric titration of gold colloid (d = 6 ± 2 nm, $C_{Au} = 2.1 \times 10^{-4}$ mol dm^{-3}) with **1a** from absorbance measurements at 680 nm.

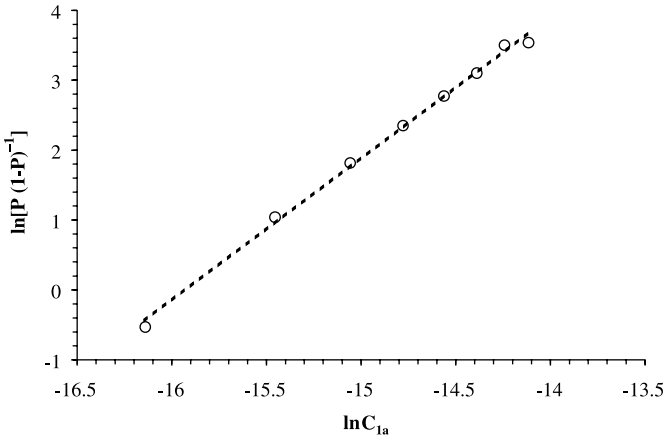


electron micrographs we concluded that colloidal particles treated with **1a** remain in dispersion.

After ruling out aggregation as the cause of the changes in the visible spectra, the absorbance data were used to examine in detail the process of dye adsorption onto the colloid. The inset of Fig. 3 shows the dependence of absorbance, at the maximum of the new band, on the concentration of added dye; it resembles a Langmuir isotherm. However, the corresponding Scatchard plots (45) were highly nonlinear. Figure 6 shows the linear fit that is obtained with eq. [1], which is Hill's model for cooperative adsorption. P is the fraction of occupied binding sites, $C_{\mathbf{1a}}$ the concentration of dye added to the dispersion, K the equilibrium constant, and n_H the Hill coefficient. For several samples of different particle size the correlation coefficients were about 0.99, and n_H values larger than 1.0 (see Table 1). This is consistent with the cooperative character of the process. Similar behaviour is known for the assembly of rotaxanes on functionalised gold nanocrystals (46). Analysis of Hill plots obtained by colorimetric titration of three separate batches of colloid afforded consistent values for the adsorption equilibrium constant, which was temperature insensitive within the experimental error between 15 and 55°C.

$$[1] \qquad \ln\left(\frac{P}{1-P}\right) = n_H \ln C_{1a} + n_H \ln K$$

Raman spectroscopy was used to investigate the orientation of the chromophore with respect to the metallic surface. In solution, the spectrum of the dye was acquired under resonance conditions. Only those modes involving the chromophore were preferentially enhanced for scattering, thus the spectrum of **1a** was virtually identical to that of **1b** (47, 48) without any vibrations from the pendant disulfide branch. Upon adsorption on the gold colloid, a surface-enhanced spectrum with a larger signal-to-noise ratio was obtained, but it did not reveal any new features. Similar spectra were expected because resonance is the dominant effect in surface enhanced Raman spectroscopy of tryphenylmethane dyes (49). A perpendicular orientation of the chromophore with respect to the surface would entail a reduction of symmetry, but none of the anticipated band splittings were observed.

Table 1. Hill analyses for the adsorption of **1a** on colloidal gold at room temperature.

Particle size (nm)	Method	n_H	ln K
6 ± 2	Absorbance, 680 nm	2.0 ± 0.1	15.9 ± 0.1
13 ± 5	Absorbance, 800 nm	1.3 ± 0.5	14 ± 0.1
7 ± 2	Absorbance, 800 nm	2.6 ± 0.1	14 ± 1
7 ± 2	HRS, 532 nm	2.8 ± 0.3	13 ± 2

Therefore a parallel orientation is suggested. This arrangement of the chromophore on the surface provides the minimum distance possible to the metal surface, which is ideal for the enhancement of nonlinear optical properties.

HRS measurements

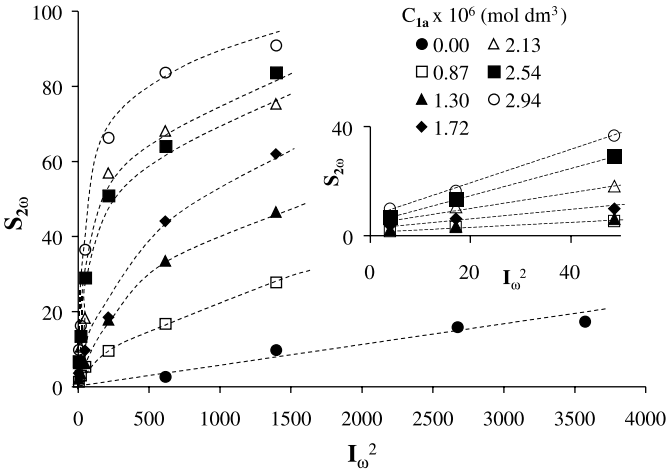
To evaluate its nonlinear optical response, one of the colloids used in the absorbance study (d = 7 ± 2 nm) was excited with the fundamental wavelength of 1064 nm and the scattered light was measured at the frequency of the second harmonic 532 nm. In this technique, the intensity of the signal ($S_{2\omega}$) depends on the square of the pump power (I_0) as modeled by eq. [2] (50). This includes a correction for absorbance (Abs); the constant G is characteristic of the experimental set-up and was evaluated with a standard of *para*-nitroaniline in methanol. The term B^2 contains the sum of the orientational average of β^2 of each component multiplied by its number density N. The initial colloidal dispersions of gold in MeOH 20% produced second harmonic light on their own. Based on the accepted values of hyperpolarizabilities for water and methanol, we found $\beta_{Au} = (2.1 \pm 0.5) \times 10^{-27}$ esu per gold atom, in agreement with a previous report (11, 12).

$$[2] \qquad S_{2\omega} = GB^2 I_0^2 10^{-\mathrm{Abs}}, \quad B^2 = \sum N_i \left\langle B_i^2 \right\rangle$$

Addition of **1a** to the colloid produced unusually strong HRS signals, which deviated from the linear dependence on the square of the pump intensity. As seen in Fig. 7, this was especially true for the samples with larger amounts of dye and may be due to the activation of nonlinear processes of higher order such as three-photon fluorescence and third

© 2002 NRC Canada

Fig. 7. Dependence of the HRS intensity, $S_{2\omega}$, on the fundamental intensity, 1064 nm, of a gold colloid (d = 7 ± 2 nm, C_{Au} = 2.0 × 10^{-4} mol dm^{-3}) upon addition of increasing amounts of **1a**. Inset: Magnification of the response at low pump intensity.

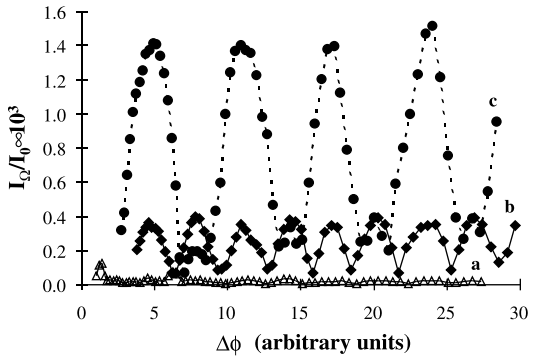


harmonic generation. The magnitude of B^2 was extracted from the initial slopes and used to construct a Hill plot that was consistent with the one obtained from absorbance measurements (Table 1). After subtraction of the contribution from gold and evaluation of the amount of **1a** that saturates the surface of the particles, a value of β ca. 10^{-26} esu was estimated for the chromophore. This is at least one order of magnitude larger than the reported values for the parent dye, **1b**. Since the dye-coated particles absorb strongly at the wavelength of the second harmonic, the apparent increase of hyperpolarizability could be due to resonant enhancement. This interpretation should be approached cautiously. The direct electronic interaction between metal and chromophore cannot be ruled out at this point; the new band in the visible absorption spectrum may arise from a dye–gold charge transfer, in which case the coated metallic particle should be regarded as a new "molecular" entity with its own oscillator strength and hyperpolarizability. Furthermore, the optical properties that were observed are the collective response of a set of colloidal particles with a variety of sizes and shapes; it is known that contributions from only a few "hot particles" may dominate local field effects (51). Measurements under aggregation conditions were not possible because of the instability of such samples.

Electrooptic coefficients of polymer films

To take advantage of the intense NLO activity of the gold–**1a** combination, the dispersion must be incorporated into a suitable matrix. The dye **1a** is very soluble in polar organic solvents, whereas gold colloids are not. Long-chain alkyl amines readily adsorb on gold nanoparticles and render them dispersible in toluene. Such amine coatings are only kinetically stable and can be readily replaced by stronger adsorbates with sulfur functional groups, including **1a**. Concentrated PMMA solutions in toluene–isopropanol mixtures were used to prepare thin films on glass slides. Samples were prepared with and without dodecylamine-coated colloids and (or) **1a** in appropriate proportions. The films were placed between transparent electrodes of ITO and gold

Fig. 8. Electrooptic-experiment interferometer fringe profiles for the measurement of films containing (*a*) gold–amine dispersions, (*b*) **1a**, (*c*) gold–**1a** dispersion.



and were subject to a transversal modulated voltage. This caused a variation of refractive index due to the nonlinear susceptibilities of the material (Pockel's effect). With a Mach-Zender interferometer the phase retardation of a laser beam propagating parallel to the electric field was measured. Measurements were carried out with a variable phase on the reference arm of the interferometer to determine the amplitude of intensity at the modulating frequency. The electrooptic coefficient r_{113} was defined by eq. [3] (52), where λ is the wavelength of the probe laser beam, n the refractive index of the material, V_{rms} the root-mean-square modulating potential, I_Ω and I_0 the intensity out of the interferometer modulated and unmodulated, respectively.

$$[3] \qquad r_{113} = \frac{\lambda}{\pi n^3 V_{rms}} \frac{I_\Omega}{2\sqrt{2I_0}}$$

The fringe profiles from which the EO coefficients were extracted are displayed in Fig. 8. The combined gold–**1a** sample had an EO coefficient (r_{113} = 2.20 pm V^{-1}) larger than those of the films containing only **1a** (0.80 pm V^{-1}) or amine-coated gold particles (0.36 pm V^{-1}) in the same concentrations. The observed coefficient is even larger than the sum of the individual contributions. Current efforts are directed towards maximizing the activity of such composites. Despite the intense harmonic light scattered by dye-coated colloids in liquid dispersion, the observed nonlinear processes are inherently incoherent because of the random distribution of particles. The activity of the polymeric films may be a consequence of anisotropy induced by spin-casting. It can be conceived that more efficient composites will be accessible by tailoring the morphology of the metal dispersion into two- or three-dimensional arrays (53–57).

Conclusions

We have derivatized a triarylmethyl dye by appending a short hydrocarbon arm with a disulfide group to anchor the chromophore to the surface of nanoscopic gold particles. The colloids treated with this dye were stable. Adsorption of the derivatized molecule proceeded by a cooperative process that was followed by monitoring the linear and nonlinear optical responses. TEM demonstrated that aggregation is not a factor in these observations.

© 2002 NRC Canada

Similarly, an enhanced electrooptic coefficient was observed for polymer films that contained both the dye and gold particles. The observed enhancement of optical properties offers opportunities to implement methodologies for chemical analysis and sensors. There is considerable interest in composites containing metal nanoparticles for chemical analysis (58), sensing (59), and nanoscale electronics (60). Local field enhancement of the NLO response of a chromophore will be advantageous for the construction of devices with combined functionality. For example, metallic particles can be grafted on waveguides for an evanescent wave to probe spectroscopically species and chemical processes at the surface (34).

Professor Tristram Chivers, FCIC

This Special Issue of The Canadian Journal of Chemistry honours the outstanding achievements of Professor Tristram Chivers as a scientist, an educator, and an administrator. This collection of papers by his colleagues, friends, and former research students demonstrates Tris' broad influence. He is recognised as a pioneer for Main Group Chemistry, but his passion for science is obvious in all aspects of his career. He has an outstanding reputation as both a lecturer and research mentor and has set new standards for the role of science representative, executive, and ambassador for the chemical community in Canada.

Tristram Chivers was born in Bath, England on 22 August, 1940. He received his B.Sc. (first class honours in Chemistry, 1961), Ph.D. (1964), and D.Sc. (1981) degrees from the University of Durham (U.K.). His Ph.D. thesis with R.D. Chambers involved studies of pentafluorophenylboron compounds, which are now important Lewis acids in the olefin polymerization industry. Following a post-doctoral position (1964–1965) in organometallic electrochemistry with R.E. Dessy at the University of Cincinnati he returned to the U.K. for a two year appointment as a Tutorial Fellow at the University of Sussex. Upon emigration to Canada in 1967, he spent two years at U.B.C. as a Teaching Post-doctoral Fellow with N.L. Paddock, where he developed an interest in inorganic ring systems that later became the foundation of his independent research program. He joined the Department of Chemistry at the University of Calgary in 1969 as Assistant Professor and was promoted to Professor in 1978. He served as Head of the Department from 1977 to 1982.

Tris Chivers and his group have made many seminal contributions to the chemistry of chalcogen compounds. An important early finding was to identify the blue species formed by sulfur in reducing media as the trisulfur radical anion (S_3^-), subsequently shown by R.J.H. Clark to be the blue chromophore in the mineral lapis lazuli. This finding was followed by the discovery of novel acyclic sulfur–nitrogen anions, $SSNSS^-$ and $SNSS^-$, the cyclic $S_3N_3^-$ anion (a 10 π-electron system) and the bicyclic $S_4N_5^+$ cation. The insightful recognition of the isoelectronic relationship between a PR_2 group and an S^+ unit led to the characterization of hybrid PN–SN systems, e.g., $R_2PN_3S_2$ (an 8 π-electron system) and $R_4P_2N_4S_2$ (with a transannular S···S π*-π* interaction). Several of the ring and cage compounds discovered in the Chivers group are now textbook examples and the 1998 edition of "Chemistry of the elements" by N. Greenwood and A. Earnshaw devotes twelve pages to sulfur–nitrogen chemistry that originates from his laboratory. Tris' research is characterized by a creative and imaginative approach to the design and synthesis of unusual compounds. In addition, application of a wide variety of spectroscopic, crystallographic, and electrochemical techniques has led to an understanding of the relationship between the molecular structures and the properties and reactivity of π-electron-rich compounds.

Tris Chivers and his group have also made major contributions to selenium and tellurium chemistry. In collaboration with Risto Laitinen (University of Oulu, Finland) novel acyclic and cyclic selenium imides, e.g., $Se_3(NR)_3$

Professeur Tristram Chivers, MICC

Le présent numéro spécial de La Revue canadienne de chimie rend hommage aux remarquables talents de scientifique, d'enseignant et d'administrateur du professeur Tristram Chivers. Cet assemblage d'articles signés par ses collègues, amis et anciens protégés témoigne de la vaste influence de celui que nous surnommons « Tris ». Si son travail de défrichement de la chimie des éléments des groupes principaux est particulièrement mémorable, sa riche carrière est loin de se limiter à cette seule contribution. Tristram jouit d'une brillante réputation de conférencier et de maître de recherche et, par son exemple, a à jamais resserré les attentes à l'endroit des représentants, directeurs et ambassadeurs de la collectivité des chimistes du Canada.

Tristram Chivers est né à Bath, en Angleterre, le 22 août 1940. Il a reçu un B. Sc. (chimie, mention très honorable, 1961), un Ph.D. (1964) et un D.Sc. (1981) de la University of Durham, au R.-U. Son mémoire de Ph. D., sous la direction de R.D. Chambers, portait sur les composés pentafluorophénylborique, acides de Lewis aujourd'hui largement utilisés dans l'industrie de la polymérisation de l'oléfine. Après un stage postdoctoral dans le secteur de l'électrochimie des composés organométalliques aux côtés de R.E. Dessy à la University of Cincinnati (1964–1965), Tris a regagné sa patrie pour assumer une charge de cours à la University of Sussex. Après avoir émigré au Canada en 1967, il a passé deux ans à la University of British Columbia, à titre de boursier en enseignement postdoctoral auprès de N.L. Paddock. Cette affectation a éveillé chez lui un intérêt pour les systèmes à anneaux inorganiques, futures fondations de son propre programme de recherche indépendant. Il a joint le département de chimie de la University of Calgary en 1969 à titre de professeur adjoint et y a été promu professeur en 1978. Il a assumé la direction du Département de 1977 à 1982.

Tris Chivers et son groupe ont résolument contribué au secteur de la chimie des composés chalcogénés. Un de leurs premiers résultats marquants a été l'identification de l'espèce chimique bleutée formée par le souffre en milieu réducteur : l'anion du radical trisulfure (S_3^-). R.J.H. Clark a subséquemment démontré qu'il s'agissait du chromophore bleu du lapis lazuli. Les travaux de Tris et de son équipe ont donné lieu à la découverte des anions acycliques soufre-azote, $SSNSS^-$ et $SNSS^-$, de l'anion cyclique $S_3N_3^-$ (système à 10 électrons π) et du cation bicyclique $S_4N_5^+$. La judicieuse reconnaissance de la relation isoélectronique entre un groupe PR_2 et une unité S^+ a tracé la voie à la caractérisation des systèmes hybrides, p. ex. $R_2PN_3S_2$ (système à 8 électrons π) et $R_4P_2N_4S_2$ (avec une interaction transannulaire S···S π*-π*). Nombre de composés anneau et cage découverts par le groupe de Chivers font l'objet de manuels de cours. À preuve, N. Greenwood et A. Earnshaw, dans l'édition de 1998 de Chemistry of the elements, consacrent douze pages à la chimie soufre-hydrogène, enfantée par le laboratoire de Tris. Les recherches de Tris se distinguent par une démarche inspirée et originale à l'élaboration et à la synthèse de composés singuliers. De plus, le vaste recours de son laboratoire à la spectroscopie, à la cristallographie et à l'électrochimie a permis de jeter la lumière sur la relation entre les structures moléculaires et les propriétés et la réactivité des composés riches en électrons π.

and $Se_3(NR)_2$, have been characterized. In tellurium chemistry the discovery of the first tellurium(IV) diimides and the polyimido anion $[Te(N\text{-}t\text{-}Bu)_3]^{2-}$, isoelectronic with tellurite $[TeO_3]^{2-}$ represent important landmarks. The creative exploitation of the isoelectronic relationship between imido (NR) and oxo (O) ligands has enabled the Chivers group to open new areas in both inorganic cluster chemistry and coordination chemistry involving polyimido analogues of common oxo-anions with p-block element centres. Significant contributions to this developing field from the Chivers lab include the homoleptic polyimido anions $[C(NR)_3]^{2-}$, $[Si(NR)_4]^{4-}$, $[P(NR)_4]^{3-}$, and $[Se(NR)_4]^{2-}$. These studies have been extended to heteroleptic systems involving both imido and oxo (or thio) moieties attached to the central p-block element, and these anions are attracting interest as novel ligands for catalytic systems. In addition, their metal derivatives form extended structures (coordination polymers or porous materials) in which the mode of aggregation can be controlled by changing the size of the NR group.

Tris Chivers and his group have co-authored more than 300 refereed publications (including reviews and book chapters). Tris has received many awards, most notably the Alcan Lecture Award of the CSC in 1987, the Royal Society of Chemistry Award (U.K.) for Main Group Element Chemistry in 1993, and the E.W.R. Steacie Award of the CSC in 2001. He was elected a Fellow of the Royal Society of Canada in 1991. At the University of Calgary he has been honoured with one of the first Awards of Excellence for Research from the Faculty of Science (1990) and was the first recipient of the University President's Circle Award (2000) in the Faculties of Science and Engineering for achievement in research and creative activity. He has also received Teaching Excellence Awards from the Students' Union (1993 and 1998) and from the Graduate Students' Association (1997) of the University of Calgary.

For more than three decades, Tris has made major contributions to Chemistry in Canada. He was the Senior Editor for the Canadian Journal of Chemistry (1993–1998) and was previously the Inorganic Chemistry Editor (1988–1993). He served on NSERC Chemistry Grant Selection Committees on two occasions (1979–1981 and 1990) and chaired the Committee in 1981. In addition, he performed as group chair for both chemistry GSCs (1996–1999). He was the Chair of the CIC Inorganic Division (1982–1984), Treasurer of the CSC (1990–1992), and President of the CSC (2000–2001). He has also served on a number of international editorial boards, most notably for the Encyclopedia of Inorganic Chemistry. He was Chair of the highly successful 7th International Symposium on Inorganic Ring Systems (IRIS) in Banff 1994. This extensive list of administrative achievements were made possible by Tris' outstanding organizational skills, pleasant manner, boundless energy, and a positive philosophy to achieve the best possible outcome.

Tris Chivers is a strong believer in a balanced approach to work and play. At the University of Durham his activities included contract bridge at which he represented the University team-of-four and became a club master. He also played cricket for Durham City, the B.C. provincial team, and he was selected to represent Canada in the annual test match

Tris Chivers et son groupe ont aussi enrichi les connaissances de la chimie du sélénium et du tellure. Ainsi, en collaboration avec Risto Laitinen (Université de Oulu, en Finlande), ils ont caractérisé des imides de sélénium cycliques et acycliques nouveau genre, notamment $Se_3(NR)_3$ et $Se_3(NR)_2$. Dans l'histoire de la chimie du tellure, la découverte des premières diimides de tellure(IV) et de l'anion polyimide $[Te(N\text{-}t\text{-}Bu)_3]^{2-}$, isoélectronique avec la tellurite $[TeO_3]^{2-}$, constitue un point tournant. L'exploitation innovatrice de la relation entre les ligands imido (NR) et oxo (O) a ouvert de nouveaux horizons en chimie des amas inorganiques ainsi qu'en chimie de coordination des analogues polyimides d'oxoanions communs ayant en leur centre des éléments du bloc-p. De ces premiers efforts du laboratoire de Chivers sont nés les anions polyimides homoleptiques $[C(NR)_3]^{2-}$, $[Si(NR)_4]^{4-}$, $[P(NR)_4]^{3-}$ et $[Se(NR)_4]^{2-}$. Ces études ont été prolongées aux systèmes hétéroleptiques faisant intervenir des groupes imido et oxo (ou thio) liés à un élément du bloc-p central. Ces anions sont actuellement étudiés en raison de leur potentiel en tant que ligands de systèmes catalytiques. De plus, ces dérivés métalliques forment des structures allongées (matériaux poreux ou polymères de coordination) dont le mode d'agrégation peut être contrôlé en modifiant la dimension du groupe NR.

Tris Chivers et son groupe ont cosigné plus de 300 articles dans des publications avérées (y compris des synthèses et des chapitres de livre). Tris a récolté les prix, notamment le Prix de conférence Alcan de la SCC (1987), le prix de la Royal Society of Chemistry (R.-U.) de chimie des éléments des groupes principaux (1993) et le Prix E.W.R. Steacie de la SCC (2001). Il a été reçu membre de la Société royale du Canada en 1991. À la University of Calgary, ses contributions ont été saluées par l'un des premiers prix d'excellence en recherche attribués par la faculté des sciences (1990). Tris a également été le premier lauréat du University President's Circle Award (2000) des facultés des sciences et du génie, prix qui souligne les réalisations et la pensée créative en recherche. Enfin, il peut s'enorgueillir de prix d'excellence en enseignement, adjugés par l'union des étudiants de la University of Calgary en 1993 et 1998 ainsi que par l'association des étudiants diplômés de la University of Calgary en 1997.

Depuis plus de trente ans, Tris est une éminente figure de la chimie au Canada. Il a été directeur scientifique principal de la Revue canadienne de chimie (1993–1998) après avoir été directeur scientifique de Inorganic Chemistry Editor (1988–1993). Il a été membre du Comité de sélection des subventions en chimie du CRSNG à deux reprises (1979–1981 et 1990) et a présidé le Comité en 1981. Il a aussi présidé les deux CSS de chimie (1996–1999). Il a été président de la division de chimie organique de l'ICC (1982–1984), trésorier de la SCC (1990–1992) et président de la SCC (2000–2001). Il a été membre d'innombrables comités éditoriaux internationaux, y compris celui de la Encyclopedia of Inorganic Chemistry. Il a été président du 7th International Symposium on Inorganic Ring Systems (IRIS), qui a eu lieu à Banff en 1994 et qui a obtenu un immense succès. Tris doit un tel bilan à son impeccable sens de l'organisation, à son juste doigté, à son indéfectible énergie et à sa constante visée sur l'excellence.

Tris Chivers a toujours prêché par l'exemple l'équilibre entre le travail et le loisir. Amateur de bridge, il a fait partie de

against U.S.A. in 1969. As a choral singer he has been a member of the tenor section of the Calgary Philharmonic Chorus for almost twenty years. Squash has been (and continues to be) an important influence in his life. He met his wife Sue at a squash club while at the University of Sussex. He credits Sue's support and encouragement for much of his success. Sue and Tris have two children. Peter is an Assistant Professor in the Department of Biochemistry and Molecular Biophysics in the School of Medicine at Washington University and Sally is an SSHRC post-doctoral Fellow in English – Disability Studies at the University of Illinois in Chicago.

Neil Burford

l'Équipe de 4 de la University of Durham et en a été le master. Adroit joueur de cricket, il a été appelé à représenter Durham et l'équipe provinciale de la C.-B. dans ce sport. Il a également porté les couleurs du Canada lors du match préliminaire de cricket au É.-U. de 1969. Choriste d'expérience, il chante la partition de ténor auprès du Calgary Philharmonic Chorus depuis près de vingt ans. Et on ne saurait oublier de mentionner son amour du squash, sport qui a occupé et continue d'occuper une place importante dans sa vie. De fait, c'est au club de squash de la University of Sussex qu'il a rencontré celle qui allait devenir son épouse, Sue. Tris se plaît à dire qu'il doit à Sue la majeure partie de ses réalisations. Le couple a deux enfants. Leur fils, Peter, est professeur adjoint au département de biochimie et de biophysique moléculaire de la faculté de médecine de la Washington University. Leur fille, Sally, est détentrice d'une bourse postdoctorale de perfectionnement du CRSHC et oeuvre au département de littérature anglaise et d'études sur le handicap de la University of Illinois, à Chicago.

AWARD LECTURE / CONFÉRÉNCE D'HONNEUR

Local modes[1]

Bryan R. Henry and Henrik G. Kjaergaard

Abstract: The historical background for the development of the local mode approach is reviewed, including the critical role of the radiation field. The harmonically coupled anharmonic oscillator model is described. Local modes have been used in the interpretation of XH stretching overtone spectra. These spectra can be used as sensitive probes of molecular properties such as bond length and molecular conformation. Examples of these spectral features are discussed. An intensity theory has been developed that permits the accurate calculation of relative and absolute overtone intensities. In molecules with low barriers to methyl rotation, torsional states contribute to the XH stretching band profile. A successful theoretical approach is presented that accounts for these effects and provides insight into the vibrational dynamics. The application of calculated local mode overtone spectra to atmospheric chemistry is discussed.

Key words: local mode, overtone, vibrational intensity.

Résumé : On passe en revue l'historique des origines de l'approche du mode local, y compris le rôle critique du champ de radiation. On décrit le modèle de l'oscillateur anharmonique à couplage harmonique. On a utilisé les modes locaux dans l'interprétation des spectres d'harmonique d'élongation XH. On peut utiliser ces spectres comme sondes sensibles de propriétés moléculaires telles que la longueur de liaison et la conformation moléculaire. On discute d'exemples de telles caractéristiques spectrales. On a mis au point une théorie d'intensité qui permet de faire un calcul précis des intensités relatives et absolues des harmoniques. Dans les molécules avec de faibles barrières à la rotation des méthyles, les états de torsion contribuent au profit de la bande d'élongation XH. On présente une approche théorique qui permet de tenir compte avec succès de ces effets et qui donne un aperçu des dynamiques vibrationnelles. On discute de l'application à la chimie de l'atmosphère des spectres d'harmoniques calculés sur la base du mode local.

Mots clés : mode local, harmonique, intensité vibrationnelle.

[Traduit par la Rédaction]

Introduction and historical perspective

The local mode model was developed in the 1970s to describe highly excited vibrational states of molecules. It has been used to describe XH stretching overtone spectra where X is some heavier atom like C, N, or O. However, the genesis of the model dates back to the 1960s and the work of Siebrand and his collaborators on radiationless transitions in aromatic hydrocarbons (1–3). The most studied radiationless transition in those days was intersystem crossing from $T_1 \rightarrow S_0$ in aromatic hydrocarbons. This radiationless transition converts the electronic triplet-state energy into vibrational energy of the ground electronic state. The resultant highly excited ground vibrational states that accept the electronic energy involve carbon–hydrogen stretching vibrations. Existing theory worked very well in explaining relative rates for these transitions from one molecule to another, but there was a problem with the calculation of the absolute magnitude of these rates. We believed the problem was with the description of the highly vibrationally excited states.

Why should there be a problem? When a small amount of vibrational energy is placed in a molecule, the bonds behave like springs or harmonic oscillators. This behavior is the basis of the traditional normal mode model of molecular vibrations. For example, the normal modes of water consist of a symmetric and an antisymmetric stretch and a bending mode. What happens when more and more vibrational energy is added to the molecule? Eventually the molecule will dissociate, but it is unlikely to do so along one of the normal mode stretching coordinates. Such a process would require the simultaneous breaking of two O—H bonds. It is much more likely that the molecule will seek a low energy pathway for dissociation and break a single O—H bond. In other words it will dissociate along a local coordinate. The higher the vibrational energy is, the less harmonic the vibration. The vibration becomes anharmonic, and not surprisingly, we were able to show that in terms of a normal mode basis most of this anharmonicity is nondiagonal (4). In other words, the

effect of anharmonicity is to mix the symmetric and antisymmetric stretching modes. The sum of these two is a local mode. So, as the vibrational energy increases and anharmonicity becomes more important, we expect the vibrational pattern to become more localized.

Henry and Siebrand used these localization ideas to try to understand XH-stretching overtone spectra (4). The overtone spectrum of benzene had been measured in the liquid phase all the way out to $\Delta v_{CH} = 8$ (8 quanta in CH stretching) by Ellis in 1929 (5). On the basis of the assumption that the six local CH stretching modes were weakly coupled, Henry and Siebrand (4) used a transformation from local to normal coordinates and derived values for CH stretching anharmonicity constants expressed in the normal mode basis. Thus they could calculate the energies of all of the components of the overtone bands expressed in terms of normal modes. For benzene at $\Delta v_{CH} = 6$ there are 462 such components of which 150 are allowed. These are the 75 doubly degenerate E_{1u} states.

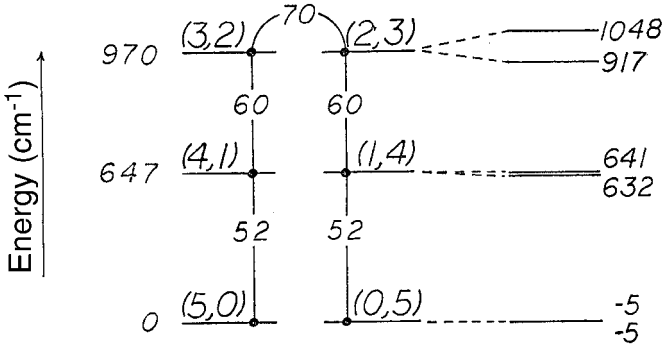
In attempting to generalize this work to other molecules (6), we found that there was little evidence for the involvement of all of the symmetry-allowed normal mode components. In the early 1970s, Hayward and Henry came to the conclusion that the radiation field was selectively exciting only the most anharmonic of the normal mode components (7). This would be a state where all the vibrational energy was effectively localized in one X—H bond (X = C, N, O, etc.). We called such a state a pure local mode state and postulated that it was absorption to these states that accounted for the overtone spectra. It happens that some of these ideas had been published in 1936 in Germany by Mecke and Ziegler (8). However this work seemed to have been largely unknown and after the war appeared to have been totally ignored.

There was some difficulty in getting the initial local mode work published. Referees consistently wanted a description in terms of the conventional normal mode approach to molecular vibrations. After the work appeared in 1975 (7), Albrecht and his collaborators used thermal lensing spectroscopy to look at liquid phase overtone spectra of benzene and other aromatic molecules (9). In referring to the overtone spectrum of benzene, they noted that the local mode model is "an excellent zeroth order description" of the spectroscopically allowed states in the overtone spectrum of benzene. Around the same time, papers by Gelbart and his collaborators (10, 11) confirmed the theoretical basis for a local mode description, and the local mode approach was firmly established.

Thus, in summary, XH stretching overtone spectra can be understood in terms of a local mode model in which the local oscillators are considered to be anharmonic but only weakly coupled. The radiation field selectively excites a state whose components have all of the vibrational energy localized in one of a set of equivalent X—H bonds. Thus in benzene at $\Delta v_{CH} = 6$ the only state that absorbs light is

$$[1] \quad \Psi = N [c_1 \mid 600000 \rangle + c_2 \mid 060000 \rangle + c_3 \mid 006000 \rangle + c_4 \mid 000600 \rangle + c_5 \mid 000060 \rangle + c_6 \mid 000006 \rangle]$$

Fig. 1. Local mode coupling scheme (kinetic energy coupling only) for a two oscillator system in the $v = 5$ vibrational manifold (see text) (from ref. 31).



where the components can be described as products of one-dimensional vibrational wave functions.

$$[2] \quad \mid 600000 \rangle = \mid 6 \rangle \mid 0 \rangle \mid 0 \rangle \mid 0 \rangle \mid 0 \rangle \mid 0 \rangle$$

The individual basis functions $\mid v \rangle$ are anharmonic and, for example, could be taken to be Morse oscillator wave functions. Such a description predicts only a single transition at $\Delta v_{CH} = 6$, in agreement with experiment.

The local mode model is now generally accepted and has been applied in a number of areas (12–15). Because of the localization of energy for spectrally active states in a single chemical bond, XH-stretching overtone spectra are very sensitive to bond properties and have been used to study subtle effects in molecular structure and molecular conformation (9, 13, 16–18). The spectra along with the local mode model have been used to investigate intermolecular forces and nonbonded intramolecular interactions (19–23). The gas phase spectra have also been used in studies of intramolecular vibrational energy redistribution (IVR) (24–30).

The harmonically coupled anharmonic oscillator model

Let us return to the water molecule and assume that the potentials associated with each of the O—H bonds are Morse potentials. We will also assume that the only coupling between the OH oscillators occurs through the kinetic energy. Thus the Hamiltonian takes the form

$$[3] \quad H = T(p_1, p_2) + V(r_1) + V(r_2)$$

where the kinetic energy term is given by

$$[4] \quad T(p_1, p_2) = -\hbar^2\{(\mu_O + \mu_H)[(\partial^2/\partial r_1^2 + \partial^2/\partial r_2^2)] + \mu_O \cos\theta\,(\partial^2/\partial r_1 \partial r_2)\}$$

and the μs are reciprocal atomic masses.

Watson et al. used this Hamiltonian for calculations of the OH stretching overtone spectrum of water (31). Zero order states were taken as simple products of Morse oscillator wavefunctions. Thus the state $\mid 5,0 \rangle$ corresponds to five quanta in one O—H bond and none in the other. Figure 1 shows the interactions between these zero order states in the $v = 5$ vibrational manifold. It turns out that interaction is only large if a given one of the two Morse oscillators differs in excitation by a single quantum. In other words, although

© 2002 NRC Canada

the oscillators are anharmonic, their off-diagonal coupling is well approximated by the rules that govern coupling of harmonic oscillators.

The energy levels in Fig. 1 are shown relative to $|\ 5,0\ \rangle$ and $|\ 0,5\ \rangle$, which occur at 16 886 cm^{-1} (31). The relative zero order energies of the states are given, as well as the significant couplings. On the right are the final energies of the eigenstates after complete diagonalization. Note that the coupling between $|\ 5,0\ \rangle$ and $|\ 0,5\ \rangle$ occurs only indirectly. As v increases the coupling between $|\ v,0\ \rangle$ and $|\ 0,v\ \rangle$ will become more indirect and the two lowest energy final eigenstates will tend toward degeneracy. The two final eigenfunctions are very well approximated by the in-phase and out-of-phase combinations of $|\ v,0\ \rangle$ and $|\ 0,v\ \rangle$. Moreover, early intensity calculations predicted that transitions from the vibrational ground state should have intensity increasingly concentrated in these two lowest states as v increases (9, 31, 32). Thus, as v increases and the splitting between the two lowest eigenstates becomes very small, the spectra become simple and appear as if only a single state is excited.

In 1981, the harmonically coupled anharmonic oscillator (HCAO) model was developed independently by Mortensen et al. (33) and by Child and Lawton (34). The HCAO model was developed to analyze XH stretching overtone spectra in the same spirit as the detailed Morse oscillator calculations for water (31) but with a simpler approach. It is based on the following simple Hamiltonian, which is shown here for two oscillators with local mode frequency ϖ and local mode anharmonicity ϖx.

$$[5]\qquad (H - E_O)/hc = (v_1 + v_2)\varpi - (v_1^2 + v_2^2 + v_1 + v_2)\varpi\, x - (\gamma - \varphi)\varpi\,(a_1^+\, a_2 + a_1\, a_2^+)$$

γ and φ characterize the off-diagonal kinetic and potential energy coupling, respectively.

The a are the familiar step-up and step-down operators, and in the model, coupling is restricted to the harmonic limit. Thus, states are allowed to couple only within a given vibrational manifold, i.e., a given total v, and where oscillator population differs by ±1. All of the parameters of the model, ω, ωx, γ, and φ, are obtained either directly from the spectra or from ab initio calculations. The model works extremely well in accounting for the observed energies of overtone peaks in XH stretching overtone spectra. The model has been generalized to more than two equivalent oscillators and to sets of nonequivalent oscillators (35–37). For the purposes of calculating peak energies, no identification of the wave functions is needed. However, if the component wave functions are taken to be products of one-dimensional Morse oscillators, the HCAO model can be used to generate eigenstate wave functions. Such wave functions have been used successfully along with ab initio calculations of dipole moment functions (simply expanded in local coordinates) to determine overtone intensities (36–45).

Overtone spectra as a sensitive probe of X—H bond lengths

One of the primary reasons for the interest and activity in the local mode field in the last 25 years is that overtone spectra have become accessible in the vapor phase for relatively high values of Δv. XH stretching overtone spectra are already dominated by local modes at around $\Delta v = 3$. However, the spectral resolution of subtle properties such as differences in X—H bond length increases the higher is the overtone. These high energy overtones are extremely weak transitions and are not observable with conventional light absorption techniques. However, a number of laser-based techniques have been developed and successfully applied. One of the most popular of these techniques is intracavity laser photoacoustic spectroscopy (ICL-PAS). This technique has been reviewed in detail elsewhere (46, 47), and here we simply provide a very brief outline. A 20 W Ar ion laser pumps a broad band dye or titanium sapphire laser, and the photoacoustic cell is placed inside the dye or titanium sapphire laser cavity. The molecule absorbs light in an overtone transition, and subsequently the light energy is converted into heat. Since the cell is closed, the pressure of the vapor increases. The pump laser is modulated by a chopper and gives rise to pressure fluctuations that are detected as sound waves by a hearing aid microphone. This very sensitive absorption technique has permitted us to observe vapor phase overtone transitions as high in energy as $\Delta v_{CH} = 9$ (38, 48).

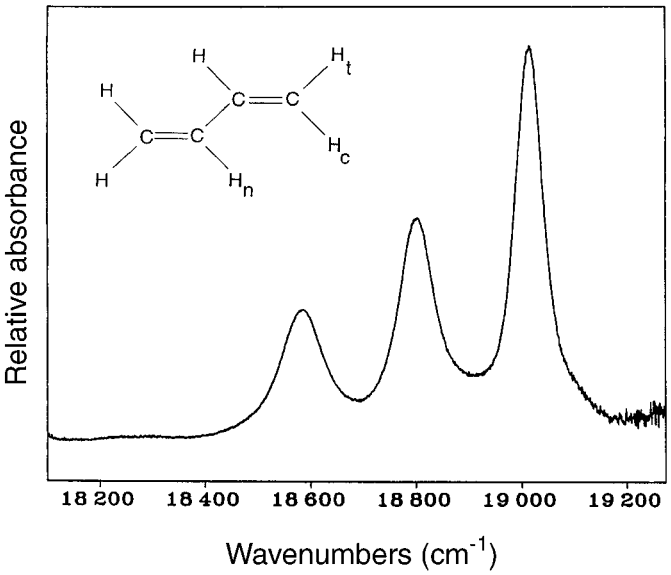


Fig. 2. The gas phase ICL-PAS spectrum of 1,3-butadiene in the $\Delta v_{CH} = 7$ region. The ab initio calculated bond lengths are: C—H_t = 1.0748 Å, C—H_c = 1.0766 Å, and C—H_n = 1.0782 Å (45).

A bond property that is of great interest to chemists is the length. Bond length reflects electronic structure, and we can calculate bond lengths with ab initio electronic structure programs, such as Gaussian (49). For larger molecules these programs calculate bond length differences that are much too small to be verified by standard experimental methods. Do these differences have any physical meaning? Overtone spectra interpreted with the local mode model allow us to resolve small changes in bond length of the order of a thousandth of an Ångstrom (mÅ). Figure 2 shows the spectrum of gas phase 1,3-butadiene at $\Delta v_{CH} = 7$ (45). Even though the bonds are predicted to differ by only milliÅngstroms, they are clearly resolved in the overtone spectrum. The shortest bond, C—H_t, corresponds to absorption at the highest energy.

Fig. 3. The vapor phase ICL-PAS spectrum of naphthalene in the $\Delta v_{CH} = 5$ region.

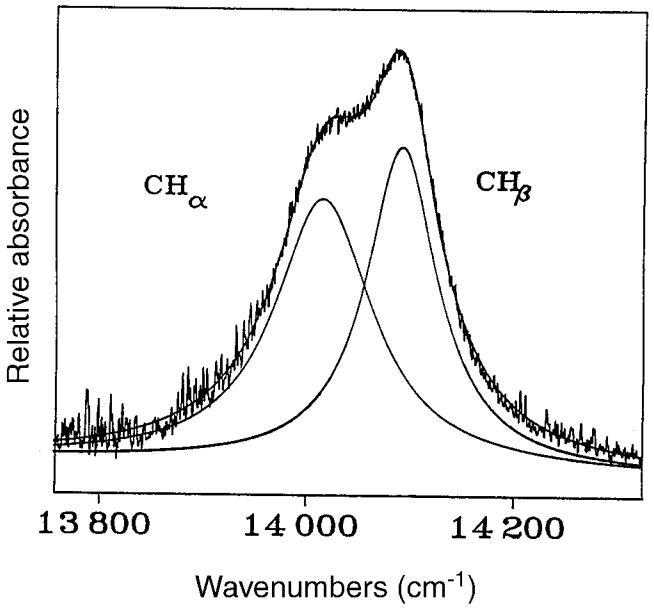

Fig. 4. The vapor phase ICL-PAS spectrum of cyclohexane in the $\Delta v_{CH} = 6$ region.

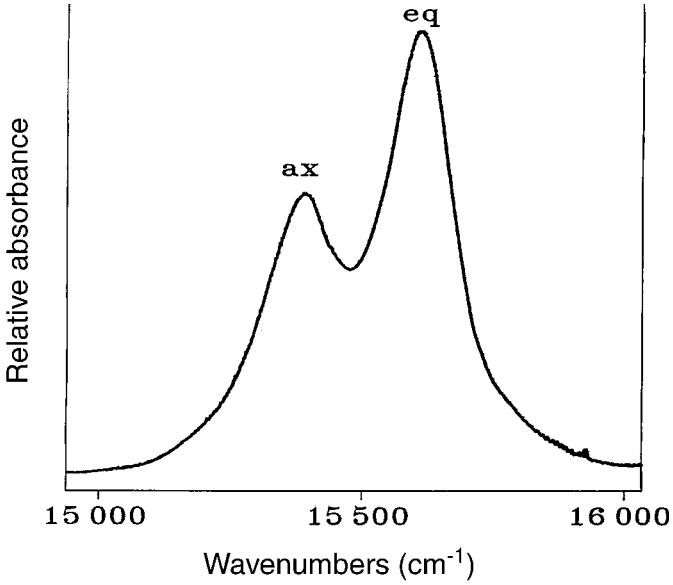

In addition, there are three kinds of bonds and there are two bonds of each type, but these three peaks are of very different intensity. We have developed a theory to calculate overtone intensity that uses ab initio methods to obtain the dipole moment surface of the molecule and the HCAO model to obtain the wave functions (36, 37, 43, 45). These calculations help us to assign the spectra and can successfully account for the intensity differences.

The vapor phase spectrum of naphthalene at $\Delta v_{CH} = 5$ is shown in Fig. 3 (50, 51). Naphthalene represents a more demanding example because the low vapor pressure gives a much lower sample concentration than for 1,3-butadiene, so it is much more difficult to measure the spectrum. Moreover, the predicted bond length difference between the two bond types is smaller, only 0.6 mÅ. This band at $\Delta v_{CH} = 5$ can be decomposed into two Lorentzian components, the high-energy peak for the shorter β-C—H bonds and the low energy peak for the longer α-C—H bonds. We assign these peaks on the basis of the correlation between overtone frequency and bond length — higher frequency corresponds to shorter bond length — and on the basis of our intensity calculations. The assignment can be checked by measuring the spectrum of the molecule where all of the β-Hs have been replaced with deuterium. In the spectrum of naphthalene-β-d_4, the higher energy component disappears (51).

As molecules execute internal motion, the environment of the chemical bonds changes. Because of the short vibrational timescale, overtone absorption spectroscopy can by used to distinguish between these conformationally nonequivalent X—H bonds. For example, as the molecule cyclohexane flips back and forth between equivalent chair conformations, the axial and equatorial bonds are interchanged. Ab initio theory predicts the bond length difference to be 2 mÅ. Figure 4 shows the vapor phase overtone spectrum of cyclohexane at $\Delta v_{CH} = 6$ (43). Peaks due to the axial and equatorial C—H bonds are clearly resolved.

In propane, dimethylether, and acetone, the methyl groups do not rotate freely because of a significant barrier to internal methyl rotation. As a result, there are two types of methyl C—H bonds: one in the plane of the molecular backbone and two out-of-plane C—H bonds that straddle the backbone. Ab initio theory predicts a difference in bond length between the shorter in-plane and the longer out-of-plane bonds of 0.8, 5.2, and 7.6 mÅ for propane, acetone, and dimethylether, respectively (37). Figure 5 shows the vapor phase overtone spectrum at $\Delta v_{CH} = 7$. The spectral splittings scale with the predicted bond length differences.

Catechol is one of the lowest pressure samples for which we have recorded vapor phase overtone spectra (52). The two OH groups form a weak internal hydrogen bond, which elongates the O—H bond of the hydrogen donor by about 2 mÅ. This small change in bond length is clearly visible in the overtone spectrum even in the $\Delta v_{OH} = 3$ region (52), despite the low rotational barrier along the coordinate that breaks the hydrogen bond.

Effects of internal methyl rotation on overtone spectra

If the barrier to methyl rotation is small, the effect on XH stretching overtone spectra is dramatically different than in molecules like propane and acetone. It is no longer possible to associate individual methyl C—H bonds with a specific conformation. However, the methyl C—H bond length still changes as the methyl group rotates. This means that the rotation of the methyl group is coupled to the stretching of the methyl C—H bonds and methyl torsion would be expected to contribute to CH stretching overtone methyl band profiles (23, 26, 53–64).

We were able to account for these effects in detail for the molecule 2,6-difluorotoluene with a model that treated the methyl group as a rigid rotor and the methyl CH oscillators within the HCAO model (57). We introduced terms in the Hamiltonian that accounted for the interaction between

© 2002 NRC Canada

stretching and torsion. In effect the bond length change with methyl rotation implies a dependence of the local mode frequency and the local mode anharmonicity on the methyl torsional angle. We also incorporated our theory for calculating overtone intensities but modified it to introduce rotational angle dependence in the dipole moment operator.

With this approach we were able to simulate successfully the methyl band profiles in the local mode regions of Δv_{CH} = 3 to 6. The parameters that were needed for the model were obtained either from ab initio calculations or directly from the spectra. As a result of the coupling between torsion and stretching, both in the Hamiltonian and through the dipole moment function, a very large number of transitions are predicted to carry intensity and contribute to the overall spectral profile (57).

For toluene, the barrier to methyl group rotation about the benzene ring is essentially zero. Even so the methyl C—H bond length changes by about 3 mÅ as it rotates, and thus we expect torsional involvement in the overtone spectra. We have measured these spectra in the regions of Δv_{CH} = 3 to 6 for toluene and for the toluene-αd_1 and toluene-αd_2 isomers (60–62). Not surprisingly, the methyl regions of the spectra are very different for the three molecules toluene-d_0, toluene-αd_1, and toluene-αd_2.

We used a theoretical approach similar to the one for 2,6-difluorotoluene to analyze the toluene results. The theory could account for the spectral shapes, the change in spectral shapes from toluene-d_0 to -αd_1 to -αd_2, and the change in spectral shape from one overtone to another (62). Figure 6 shows the spectra and our calculated profiles for Δv_{CH} = 4 and 5 for toluene-d_0 and toluene–αd_1, respectively (62).

We can do these calculations in two ways. In the first, the adiabatic approach, we simplify the problem by separating the fast methyl CH stretching motion from the slower motion of methyl rotation. Alternatively, we could combine the two motions and perform the calculation in a basis that includes both the CH stretching and methyl rotation. If we compare these two calculations we get a very interesting result that serves to distinguish between three time scales (62). The fastest time scale involves CH stretching, while methyl rotation is slower. The third time scale is the time it takes all of the CH stretching vibrational energy to transfer from one methyl C—H bond to another. That latter time scale gets longer the higher the vibrational quantum number v, i.e., the more vibrational energy transferred. Recall that the coupling of $|\, v,0\,\rangle$ and $|\, 0,v\,\rangle$ becomes weaker with higher v. When the time for this transfer is slower than the time for coupling of torsion and stretching, the latter dominates. Essentially the CH oscillators do not have time to interact before they are fully mixed with methyl torsional motion. From a CH stretching point of view they become fully localized vibrational modes.

Application of calculated overtone spectra

Earlier calculations of overtone intensities focused on the determination of relative intensities within a given overtone region. As we have noted, these types of intensity calculations are extremely helpful in the assignment of spectra (36, 37, 43, 45). A comparison with exact variational calculations for the water molecule showed that the simple HCAO local mode model provided a vibrational description that was adequate but that improvements in the ab initio dipole moment surfaces were required to achieve accurate absolute overtone intensities (65). Systematic tests of the requirements of the ab initio theory have followed (66–69) to the point where accurate absolute intensities can now be calculated (67, 69, 70–72). All these HCAO calculations rely on local mode parameters that have been derived from observed fundamental and overtone XH stretching transitions. Recently we have developed an approach based on the HCAO local mode model and ab initio calculations that allows overtone spectra of species that have not been measured in the laboratory to be calculated (73, 74). In this method the local mode parameters are determined from ab initio calculations with scaling parameters obtained from known spectra of similar compounds (74).

We have applied these techniques to neutral and charged polycyclic aromatic hydrocarbons (75) and to the water dimer complex (74). The results for the water dimer complex were in excellent agreement with the very few available experimental results. These calculated overtone spectra, combined with estimates of the atmospheric abundance of water dimer, have allowed the atmospheric impact of water

dimer on the absorption of solar radiation to be estimated by radiative transfer calculations (76). Subsequently, we have calculated overtone spectra of a series of mono-hydrated complexes (77, 78) and are currently investigating their impact on absorption of solar radiation (79).

Absorption of solar radiation in OH stretching vibrational overtones in atmospheric trace species can lead to formation of OH radicals. This has been suggested to be an important source of OH radicals at dawn and dusk when the available UV radiation is low (70, 71, 80). Again the local mode model provides a suitable description of the OH stretching vibrations. It then becomes possible to calculate these transitions for various species and to allow their atmospheric impact to be assessed.

Conclusion

An historical perspective has been presented for the development of the local mode model. For XH stretching, anharmonicity appears predominately in off-diagonal terms in a normal mode basis but in diagonal terms in a local mode basis. Thus for vibrations corresponding to XH stretching overtones, the vibrational energy becomes increasingly nondiagonal in a normal mode basis relative to a local mode basis, as the vibrational energy increases. One of the most important elements in the local mode model is the recognition that the radiation field selectively excites states whose components have all of the vibrational energy localized in a single one of a set of equivalent oscillators. Although local modes are anharmonic, the coupling of XH oscillators is well approximated by a harmonic coupling regime, and this characteristic is used in the HCAO model. The HCAO model allows straightforward calculations of state energies for XH stretching overtones and provides simple wave functions that are useful in calculations of overtone intensities. Because of their localized character, XH stretching overtone spectra can be used as sensitive probes of molecular properties such as bond length and molecular conformation. Examples are presented that show the resolution of spectral features for bond length differences less than 1 mÅ. Methyl torsion has a dramatic effect on XH stretching overtone spectra in molecules with a low barrier to internal methyl rotation. A successful theoretical approach is outlined to account for these effects and to provide insight into vibrational dynamics. We have developed an approach based on the HCAO local mode model, ab initio dipole moment functions, and ab initio local mode parameters that can calculate overtone spectra of species for which laboratory spectra have not yet been measured. These calculated spectra facilitate studies of the atmospheric impact of these species.

Antibody-catalyzed formation of a 14-membered ring lactone

Michael D. Pungente, Larry Weiler, and Hermann J. Ziltener

Abstract: Monoclonal antibody (MAb) F123, raised against a macrocyclic phosphonate transition-state analogue, catalyzed an intramolecular transesterification of the corresponding hydroxy ester to give a 14-membered ring lactone. The MAb reaction displayed enzyme-like Michaelis–Menten kinetics with a K_m of 255 μM and a k_{cat} of 0.01 min^{-1} based on *p*-nitrophenol release and calculated on an active-site basis. Substrate specificity and competitive inhibition by a transition state analogue (K_i = 3 μM) demonstrated that the catalytic activity was associated with binding in the antibody-combining site. The lactone product was isolated from a large-scale catalytic experiment through ether extraction and identified by gas chromatography – mass spectroscopy.

Key words: macrocyclization, lactones, catalytic antibodies.

Résumé : L'anticorps monoclonal (AcM) F123, élevé contre un analogue d'état de transition phosphonate macrocyclique, catalyse une réaction de transestérification intramoléculaire de l'ester hydroxylé correspondant pour conduire à la formation d'un cycle lactonique à quatorze chaînons. La réaction de l'AcM présente une cinétique de Michaelis–Menten semblable à celle observée avec les enzymes avec un K_m de 255 μM et un k_{cat} de 0,01 min^{-1} basé sur l'élimination du *p*-nitrophénol et calculé sur une base de site actif. La spécificité du substrat et l'inhibition compétitive par un analogue de l'état de transition (K_i = 3 μM) démontrent que l'activité catalytique est associée à la fixation dans un site de combinaison d'anticorps. La lactone produite lors d'une expérience catalytique à grande échelle a été isolée par extraction à l'éther et on l'a identifiée par spectrométrie de masse liée à un chromatographe en phase gazeuse.

Mots clés : macrocyclisation, lactones, anticorps catalytiques.

[Traduit par la Rédaction]

Introduction

The macrolide antibiotics contain a ring moiety, in many cases represented by a 14-membered lactone. The syntheses of these large-ring compounds pose a challenge for chemists, particularly in controlling the ring-forming step. Attempts to use enzymes in aqueous and organic solvents to catalyze medium to large ring lactonizations have met with limited success, particularly with secondary alcohols (1). Antibodies raised against transition state analogues have offered an alternative class of catalysts for complex reactions, many of which have been highlighted in review articles (2). Indeed, in 1987 Napper et al. (3) reported that an antibody raised against a transition state analogue for an intramolecular six-membered ring cyclization acted as a catalyst for the appropriate substrate to give a δ-lactone. To our knowledge, no antibody-catalyzed macrocyclization has been reported to date. To this end, we extended this antibody methodology to the formation of the 14-membered ring lactone **1**. We therefore synthesized the 14-membered ring transition state analogue **2**, which we subsequently conjugated to a carrier protein for the production of monoclonal antibodies.[4]

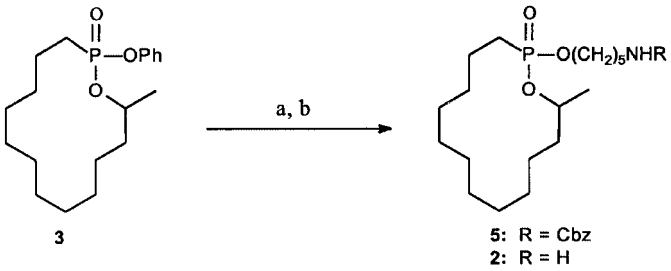
Scheme 1. (*a*) *n*-BuLi, THF, –78°C, $HO(CH_2)_5NHCbz$ (**4**), 59%. (*b*) H_2, 10% Pd/C, EtOH, 85%.



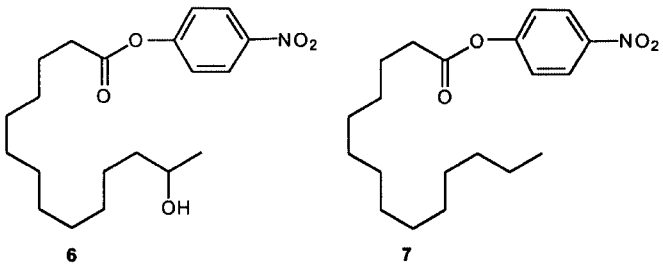
Results and discussion

The synthesis of hapten **2** (Scheme 1) was achieved by substitution of the phenyl moiety of the S*R* diastereomer of phosphonate **3** (4) with the anion of alcohol **4** to give **5** in a 59% yield.

Hydrogenolysis of **5** in ethanol with hydrogen and 10% Pd/C afforded amine **2** in 85% yield.

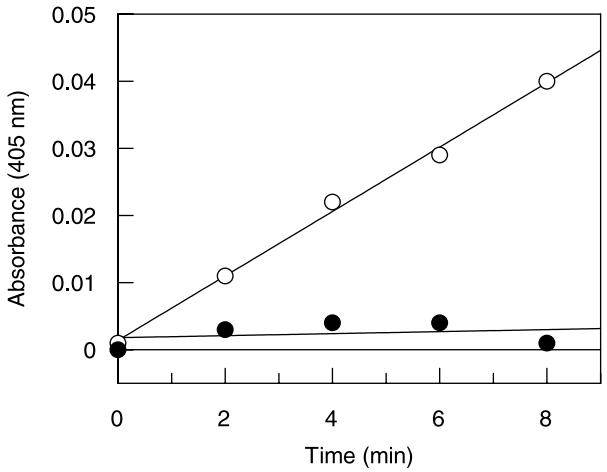
Amine **2** was coupled to carboxyl residues of the carrier protein keyhole limpet hemocyanin (KLH) using the water soluble coupling reagent 1-(3-dimethylaminopropyl)-3-ethylcarbodiimide hydrochloride (EDC), emulsified in Freund's complete adjuvant and used to immunized Balb/c mice. After three subsequent booster injections with KLH·**2** in Freund's incomplete adjuvant, spleens of mice were harvested and MAbs were produced using standard hybridoma methodology (5). Three MAbs (F123, F125, and F150) were selected in an immunoassay based on their selective binding to **2** coupled to bovine serum albumin (BSA). MAbs were purified by sheep anti-mouse affinity chromatography and dialyzed against PBS buffer, pH 7.4. Antibody concentration was determined by measuring optical density at 280 nm (where 1.2 absorbance units correspond to 1 mg mL^{-1} antibody in solution (6)) and using 190 kDa for the molecular weight of IgM monomer.

The three MAbs that showed selective binding to **2** were tested for catalytic activity against substrate **6** while monitoring the release of *p*-nitrophenolate. Of these, only F123 (an IgM monoclonal antibody as determined by isotyping) showed significant activity and was selected for further study. The F123-catalyzed reaction with **6** was shown to obey Michaelis–Menten kinetics with a K_m of 255 μM, and a k_{cat} of 0.01 min^{-1} (based on *p*-nitrophenol release and calculated on an active site basis). The observed rates were corrected for the background hydrolysis in buffer.

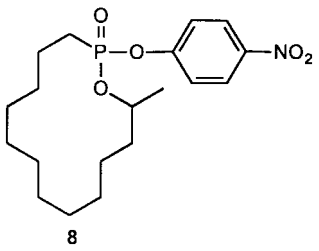


To illustrate that the activity of antibody F123 with **6** is not due to an esterolytic contaminant of the serum, an affinity purified control MAb raised against an unrelated hapten was run in parallel with F123. The control MAb showed no activity with substrate **6**. It should be noted that while this evidence is supportive, it is by no means definitive. In addition, substrate **7**, which lacks the secondary hydroxyl necessary for lactonization, was tested as a substrate for F123 and showed little or no *p*-nitrophenolate release compared with **6** (Fig. 1). This provided strong evidence that the catalytic MAb was not simply behaving as an esterase by hydrolyzing the *p*-nitrophenyl ester moiety. An alternate reason as to why **7** is not processed by F123 could simply be lack of recognition by the antibody. However, these two control experiments together provide substantial evidence that it is indeed the antibody that is carrying out the catalysis.

Fig. 1. Comparison of antibody F123 activity with hydroxy ester substrate **6** (○); with ester **7** (●). In each case, antibody was 0.46 μM; substrates were 100 μM; carried out in PBS buffer (pH 7.4) containing 10% DMSO and 0.5% Triton X-100; total reaction volume was 225 μL.



The 4-nitrophenyl phosphonate derivative **8** was synthesized by base hydrolysis of phenyl phosphonate **3** using refluxing 3 N NaOH–THF, producing the corresponding

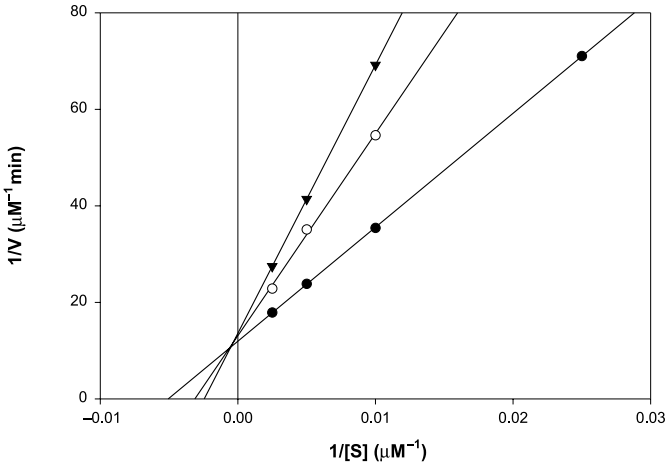


phosphonic acid derivative in a 73% yield. Conversion of the phosphonic acid derivative to the acid chloride with oxalyl chloride, followed by coupling of this phosphoryl chloride intermediate with *p*-nitrophenol, gave a 1.2:1 ratio of diastereomers of **8** in 69% yield.

Owing to a lack of compound **2**, compound **8** was chosen for inhibition studies as we felt it would sufficiently mimic the putative transition state for the cyclization of substrate **6** to give lactone **1**. Inhibition assays with **8** (using a 1:1 mixture of diastereomers) were performed by varying the concentration of **8** at fixed levels of substrate **6** and MAb F123

© 2002 NRC Canada

Fig. 2. Inhibition of the F123-catalyzed macrolactonization of substrate **6** by a mixture of 4-nitrophenyl phosphonate diastereomers of compound **8**. The reactions were performed in PBS buffer (pH 7.4) containing 10% DMSO and 0.5% Triton X-100. The concentrations of compound **8** were: (●) 0 μM; (○) 2 μM; and (▼) 5 μM.



(Fig. 2). Unfortunately, accurate determination of K_i was precluded by the insensitivity of the assay employed. Concentrations of antibody in the same range as the apparent K_i value ultimately determined were needed to get measurable reaction rates. As a consequence the K_i value determined (K_i = 3 μM) can be regarded only as a rough estimate of the true K_i value. However, this result does clearly indicate that binding is tight and is fully consistent with the catalytic activity measured arising from the active site.

Lactone **1** was isolated from pooled catalytic experiments through ether extractions. Unambiguous identification of the lactone was carried out by comparison with authentic **1** (7) by GC, GC–MS, and HR-MS. No lactone was detected in the absence of antibody catalyst.

In summary, we have shown that monoclonal antibody F123, an IgM antibody, has catalyzed macrocyclic lactone ring formation. We feel this preliminary work opens the door for further potential methodology studies toward macrocycle synthesis.

Magnetic properties of some Fe–S six-membered ring compounds

Ping Liu, Jia Cheng Liu, Jian Wang, Jian Kai Cheng, Wen Jie Li, and Xin Huang

Abstract: The Fe_3S_3 cluster is an important component located in the active centres of some iron–sulfur proteins. The magnetic properties of three Fe_3S_3 compounds have been studied for the first time by fitting the temperature-dependent magnetic susceptibilities. The calculated *g* factors and *J* couplings reproduce the magnetic behavior of such compounds very well. There is an antiferromagnetic spin interaction between pairs of magnetic centers in the Fe_3S_3 cluster compounds. The magnetic exchange of Fe-S-Fe model magnetic molecules is discussed.

Key words: Fe_3S_3 compounds, magnetic, antiferromagnetic.

Résumé : L'agrégat Fe_3S_3 est une composante importante de centres actifs des protéines fer–soufre. On a étudié les propriétés magnétiques de trois composés Fe_3S_3 basée sur les susceptibilités magnétiques qui varient avec la température. Les facteurs *g* et les constantes de couplage *J* calculées permettent de très bien reproduire le comportement magnétique de tels composés. Il existe une interaction de spin antiferromagnétique entre les paires de centres magnétiques des composés agrégats Fe_3S_3. On discute de l'échange magnétique de molécules magnétiques modèles de Fe-S-Fe.

Mots clés : composés Fe_3S_3, magnétique, antiferromagnétique.

[Traduit par la Rédaction]

Introduction

Iron–sulfur proteins (including enzymes) exist in most life forms. They are redox proteins and their active centers are the Fe–S clusters in various forms. For example, the Fe–S clusters discovered in nitrogenase are Fe_2S_2, Fe_4S_4, Fe_3S_4, and Fe_8S_7 (1, 2). The Fe_6S_6 clusters have been found in the Fe-hydrogenase (3), and their structures have been determined by X-ray diffraction (1, 2) and spectra (3), respectively. Their schematic structures are shown in Fig. 1. According to structural characteristics of these Fe–S clusters and other Fe–S clusters, they can be divided into two groups; one contains at least one Fe_2S_2 unit, such as Fe_2S_2, Fe_4S_4, or Fe_8S_7; the other contains an Fe_3S_3 unit, such as Fe_3S_4 or Fe_6S_6. Two Fe_2S_2 can re-form an Fe_4S_4, and two Fe_4S_4 can form an Fe_8S_7; one Fe_3S_3 and an S atom can form an Fe_3S_4, and two Fe_3S_3 can form an Fe_6S_6. The Fe_2S_2 unit has been much studied, but the study of the Fe_3S_3 unit is quite rare.

M_3S_3 clusters (M = Fe, Cu, Pd, B, etc.) containing a six-membered ring are very interesting compounds. The six-membered M_3S_3 ring is analogous to benzene in organic compounds, in which electron delocalization is responsible for the molecular aromaticity. The M_3N_3 cluster B_3O_3 (where M = B and N = O) is the anion group of a nonlinear optic material and shows particular properties (4, 5). During the 1990s the study of the magnetic property of transition metal cluster compounds and biological magnetic materials increased dramatically because it overlapped and advanced studies on inorganic and organic magnetic molecules. The study of transition metal cluster compounds (including complex compounds) is a new field of magnetism research that has begun to attract wide attention (6, 7). We hope to infer the magnetic properties of metal active centers of iron–sulfur proteins through a study of the magnetic susceptibility of Fe_3S_3 ring compounds, thus paving the way for the discovery of new advanced biological functional materials.

We have synthesized some Fe_3S_3 ring compounds and determined their crystal structures and molecular structures (8–13). The molecular formulas of compounds **1–3** are as follows:

[1] α-$(Et_4N)_3(Fe_3(PhS)_3Cl_3Br_3)$

[2] $(Et_4N)_3(Fe_3(p\text{-}CH_3PhS)_3Cl_3Br_3)$

[3] $(Et_4N)_3(Fe_3(p\text{-}CH_3PhS)_3Cl_6)$

A perspective view and the conformation of the anion in compound **1** (10) are shown in Fig. 2.

Experimental section

Preparation

Compounds **1–3** have been synthesized in a one-step reaction (10–12). The water and oxygen were removed from the solvents, and the reaction was carried out in an N_2 atmosphere. Molar equivalents of $FeCl_2$, *p*-PhSNa, Et_4NX (X = Cl or Br), and appropriate acetonitrile were added to a

round-bottomed flask, and under magnetic stirring the colour of the reaction solution changed to yellow-green gradually. After the reaction, the reaction mixture was filtered, the filtrate concentrated, and yellow-green crystals were obtained.

Reaction formula:

$$3FeCl_2 + 3R\text{-}PhSNa + 3Et_4NX \longrightarrow (Et_4N)_3(Fe_3(R\text{-}PhS)_3X_3Cl_3)$$

(Compound **1**: R = H, X = Br; compound **2**: R = p-CH_3, X = Br; compound **3**: R = p-CH_3, X = Cl.)

Magnetic measurements

Variable-temperature magnetic susceptibilities in the temperature range 5–300 K were measured on a CF-1 superconducting extracting sample magnetometer at a magnetic field of 5.0 T with the powdered samples kept in capsules filled with N_2 for weighing. The temperature was raised gradually from 5 to 300 K. Data were recorded at an applied field gradient $H(dH/dx) = 1.4 \times 10^7$ Oe·Oe·cm^{-1}. The contribution of diamagnetic susceptibilities of compounds was accounted for.

Result and discussion

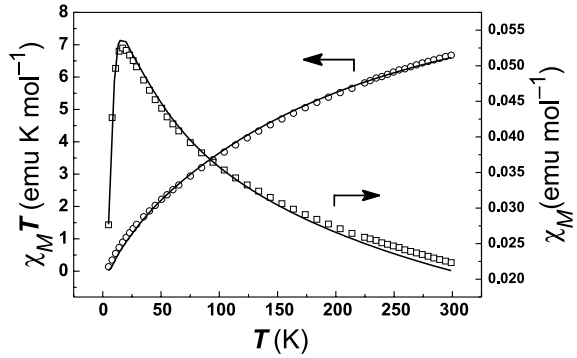
Magnetic properties

The model of Fe-Fe magnetic exchange of Fe_3S_3 six-membered ring compounds was assumed to be as an equilateral triangle with three Fe corners.

The temperature dependence of the molar magnetic susceptibility for clusters **1**–**3** are depicted in Figs. 3–5, respectively, in the form of the product $\chi_M T$ vs. absolute

© 2002 NRC Canada

Fig. 3. Plots of the temperature dependences of $\chi_M T$ and χ_M for compound **1**. The solid lines represent the best calculated curves.



temperature T. The inserts show the thermal dependence of the magnetic susceptibility, where χ_M is the corrected molar magnetic susceptibility per $Fe(II)_3$ cluster unit.

For compound **1**, at room temperature, the value of the $\chi_M T$ product (6.68 emu·K·mol^{-1}) is smaller than the expected high-temperature limit for the three Fe(II) (g = 2.05) unit ($\chi_M T$ = 9.45 emu·K·mol^{-1}). As the temperature decreases, $\chi_M T$ decreases continuously to 0.14 emu·K·mol^{-1} at 5 K, suggesting the presence of an antiferromagnetic exchange interaction. The geometrical model of the Fe_3S_3 six-membered ring compounds based on its structure was assumed to be as an equilateral triangle with three Fe corners. In theory (14) there are 4 nonpair orbitals in the 3d orbit of Fe(II), and it must have high spin S = 2. So the spin-spin coupling Hamiltonian formula using the isotropic Heisenberg model can be written as

$$[4] \qquad \hat{H} = -2\,J\,(S_1 \cdot S_2 + S_1 \cdot S_3 + S_2 \cdot S_3)$$

($S_1 = S_2 = S_3 = 2$ and $J = J_{12} = J_{13} = J_{23}$). Applying the Van Vleck equation (15) gives the following molar susceptibility expression for the equilateral triangle Fe_3 system of **1**:

$$[5] \qquad \chi_M = \frac{2Ng^2\beta^2}{kT} \times \frac{3x^{40} + 25x^{36} + 56x^{30} + 90x^{22} + 110x^{12} + 91}{x^{42} + 9x^{40} + 25x^{36} + 28x^{30} + 27x^{22} + 22x^{12} + 13}$$

in which $x = \exp(-J/kT)$; the other symbols have their usual meanings.

The best fit for both $\chi_M T$ and χ_M for compound **1** leads to the parameters J = –11.09 cm^{-1}, g = 2.11, and $R = 6.67 \times 10^{-4}$ ($R = \Sigma((\chi_M T)_{obsd} - (\chi_M T)_{calcd})^2/\Sigma(\chi_M T)_{obsd}^2$). The result is quite satisfactory. There is no obvious minimum point near the fitting values and convergence in the fitting process is very quick, showing that the result is reliable. The negative J value also illustrates that compound **1** is paramagnetic with an antiferromagnetic coupling of spin.

The Fe_3S_3 ring compound possesses a typical M-S-M structure (M = Fe). The magnetic exchange among Fe atoms is through super-exchange. The distribution of electrons in the sulfur atom and two neighbouring iron atoms could be a merge of the "normal" iron state Fe^{2+}-S^{2-}-Fe^{2+} and the excited state Fe^{1+}-S^{1-}-Fe^{2+}, Fe^{2+}-S^{1-}-Fe^{1+}. When S^{1-} loses a 2p electron, the exchange integral J_{pd} between this sulfur ion and another iron ion will influence the relative direction of the d orbitals in two iron ions. We can say that the super exchange between two iron atoms is realized through a sulfur atom. Based on the fact that compounds containing an M-O-M system have a stronger exchange effect, we note that in Fe_3S_3 the Fe—S distance is short (2.3Å) and the Fe-S-Fe angles are 138° and 141° (between 90° and 180°), which can produce a stronger exchange effect.

Fig. 4. Plots of the temperature dependences of $\chi_M T$ and χ_M for compound **2**. The solid lines represent the best calculated curves.

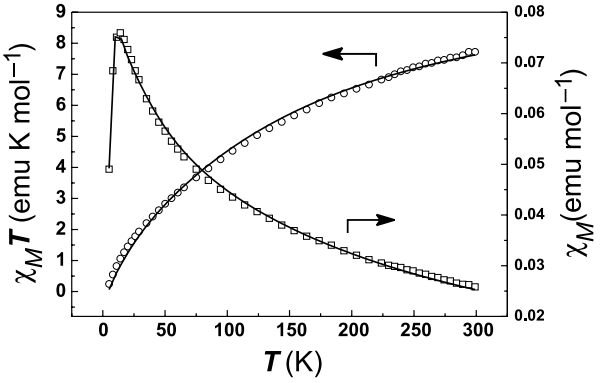


Fig. 5. Plots of the temperature dependences of $\chi_M T$ and χ_M for compound **3**. The solid lines represent the best calculated curves.

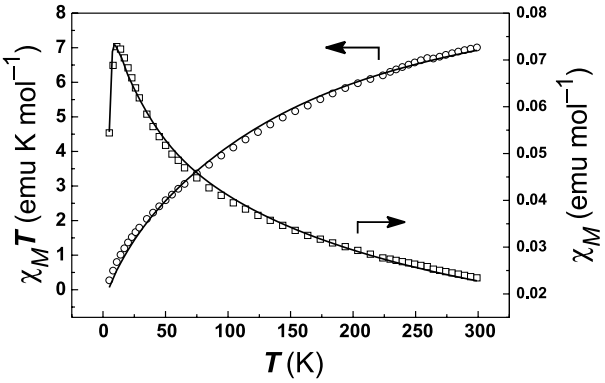

The experimental fitting curves of the temperature dependence of the molar susceptibilities (the product $\chi_M T$ and χ_M) of compounds **2** and **3** are shown in Figs. 4 and 5, respectively.

The curves of $\chi_M T$ and χ_M of compounds **2** and **3** are similar to those of compound **1**. The experimental curves are very flat, and the theoretical curves are fitted satisfactorily. According to the model in Fig. 4, for compound **2**, J = –8.76 cm^{-1} and g = 2.17, which together indicated a paramagnetic compound with antiferromagnetic coupling of spin. For compound **3**, J = –8.57 cm^{-1} and g = 2.06; both belong to paramagnetic compounds with antiferromagnetic coupling of spin.

The J values of compounds **1**–**3** decrease steadily in that order, and the g values are over 2.05. From the molecular structures, the main difference is that there are different *para*-substituted groups in the thiophenol and different halogen coordination in Fe.

Synthesis and structural characterization of binuclear titanium(IV) and tantalum(V) cyclopentadienyl complexes containing bridging phosphinate ligands

Hendrik Dorn, Emira Vejzovic, Alan J. Lough, and Ian Manners

Abstract: The reaction of $Ph_2P(O)(OSiMe_3)$ with $[(\eta^5\text{-}C_5H_5)TiCl_3]$ or $[(\eta^5\text{-}C_5Me_5)TaCl_4]$ in dichloromethane yields the complexes $[\{(\eta^5\text{-}C_5H_5)TiCl_2(\mu\text{-}Ph_2PO_2)\}_2]$ (**1**) or $[\{(\eta^5\text{-}C_5Me_5)TaCl_3(\mu\text{-}Ph_2PO_2)\}_2]$ (**2**), respectively. Structural analysis of **1** and **2** by single-crystal X-ray diffraction revealed the presence of eight-membered metallacycles consisting of bridging–bidentate diphenylphosphinate groups between two metal centers.

Key words: inorganic rings, phosphinate complexes, tantalum, titanium.

Résumé : La réaction du $Ph_2P(O)(OSiMe_3)$ avec le $[(\eta^5\text{-}C_5H_5)TiCl_3]$ et le $[(\eta^5\text{-}C_5Me_5)TaCl_4]$ dans le dichlorométhane conduisent à la formation de $[\{(\eta^5\text{-}C_5H_5)TiCl_2(\mu\text{-}Ph_2PO_2)\}_2]$ (**1**) ou de $[\{(\eta^5\text{-}C_5Me_5)TaCl_3(\mu\text{-}Ph_2PO_2)\}_2]$ (**2**) respectivement. On a déterminé les structures des composés **1** et **2** par diffraction des rayons X; elles révèlent la présence de métallacycles à huit chaînons résultant de l'interaction de groupes diphénylphosphinates bidentates, capables de former des ponts, avec deux centres métalliques adjacents.

Mots clés : cycles inorganiques, complexes de phosphinates, tantale, titane.

[Traduit par la Rédaction]

Introduction

Metal–phosphinate complexes have been extensively investigated because of their interesting structural and chemical properties. Diphenylphosphinate, $[Ph_2PO_2]^-$, is widely used in inorganic coordination chemistry and usually acts as a bridging–bidentate ligand in bi- or polynuclear molecular structures. For example, binuclear complexes are known involving main group metals such as aluminum (1, 2), gallium (3, 4), and indium (3), and involving transition metals such as titanium (5), zirconium (6), vanadium (7, 8), rhenium (9), iron (10), ruthenium (11), rhodium (12), palladium (13), and platinum (13). Polynuclear diphenylphosphinate structures have been prepared incorporating tin (14–18), lead (19), titanium (20), manganese (21), cobalt (21, 22), and copper (23); however, these solid state coordination polymers are often found to dissociate or rearrange in solution.

As part of our interest in inorganic rings and polymers (24–26) we report here the preparation of the binuclear cyclopentadienyl transition metal complexes $[\{(\eta^5\text{-}C_5H_5)TiCl_2(\mu\text{-}Ph_2PO_2)\}_2]$ (**1**) and $[\{(\eta^5\text{-}C_5Me_5)TaCl_3(\mu\text{-}Ph_2PO_2)\}_2]$ (**2**) as well as their spectroscopic and X-ray structural characterization.

Results and discussion

Synthesis and characterization

The reaction between $[(\eta^5\text{-}C_5H_5)TiCl_3]$ or $[(\eta^5\text{-}C_5Me_5)TaCl_4]$ and an equimolar amount of $Ph_2P(O)(OSiMe_3)$ in dichloromethane at room temperature readily gave the binuclear complexes $[\{(\eta^5\text{-}C_5H_5)TiCl_2(\mu\text{-}Ph_2PO_2)\}_2]$ (**1**) and $[\{(\eta^5\text{-}C_5Me_5)TaCl_3(\mu\text{-}Ph_2PO_2)\}_2]$ (**2**), respectively. Compound **1** was isolated in a 78% yield as orange crystals, while compound **2** was obtained in a 60% yield as dark yellow crystals. Both compounds were found to be air and moisture sensitive.

$$2\,[(\eta^5\text{-}C_5R_5)MCl_x] + 2\,Ph_2P(O)(OSiMe_3) \xrightarrow[-2\,SiMe_3Cl]{CH_2Cl_2,\ 25^\circ C} [\{(\eta^5\text{-}C_5R_5)MCl_{x-1}(\mu\text{-}Ph_2PO_2)\}_2]$$

1: M = Ti, R = H, x = 3
2: M = Ta, R = Me, x = 4

The ^{31}P NMR spectra of **1** and **2** in $CDCl_3$ showed singlets at δ 34.5 and 32.0 ppm, respectively, which is consistent with ^{31}P NMR spectroscopic data of other binuclear, bridging–bidentate transition metal phosphinates such as $[\{(\eta^5\text{-}C_5Me_5)TiF(\mu\text{-}F)(\mu\text{-}Ph_2PO_2)\}_2]$ (δ 35.1 and 32.9 ppm) (5) or $[\{PtCl(\mu\text{-}Ph_2PO_2)(PBu_3)\}_2]$ (δ 37.2 ppm) (13). For comparison, the starting material $Ph_2P(O)(OSiMe_3)$ displayed an upfield ^{31}P NMR resonance at δ 23.4 ppm. The ^1H NMR spectra of **1** and **2** exhibited the anticipated

Fig. 1. Molecular structure of [{(η^5-C_5H_5)$TiCl_2$(μ-Ph_2PO_2)}$_2$] (**1**), showing the shape of the $Ti_2P_2O_4$ ring with the boat–boat conformation. Only the ipso carbon atoms of the phenyl rings are shown. Solvent molecules and hydrogen atoms have been omitted.

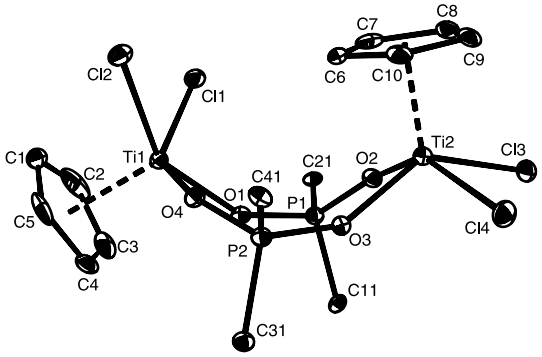

Fig. 2. Molecular structure of [{(η^5-C_5Me_5)$TaCl_3$(μ-Ph_2PO_2)}$_2$] (**2**), showing the shape of the $Ta_2P_2O_4$ ring with the boat–chair conformation. Only the ipso carbon atoms of the phenyl rings are shown. Solvent molecules and hydrogen atoms have been omitted.

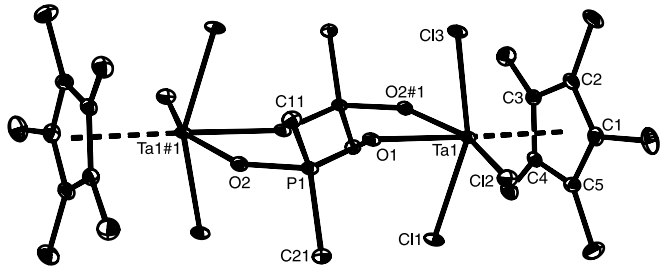

signals in the phenyl region as well as singlets at δ 7.01 (C_5H_5, **1**) and 2.19 ppm (C_5Me_5, **2**), respectively, in the required ratio of integration. The NMR spectra of **1** and **2** suggest a symmetric structure in solution; however, it is unclear whether these complexes are in fact dimeric or perhaps monomeric. The IR spectra of crystalline **1** and **2** were obtained as Nujol mulls between KBr plates and showed several strong νPO_2 absorption bands in the region of 1200–1000 cm^{-1}, which is diagnostic of a bidentate coordination mode of the phosphinate groups (14). The EI mass spectra of **1** and **2** were quite complex and showed many fragments of low intensity; however, peaks corresponding to molecular ions (or their monomeric forms) were not observed, even at lower ionization energies of ~20 eV. Elemental analysis for C and H afforded data consistent with the suggested formulas. The low value for carbon found in compound **2** is most likely due to the presence of dichloromethane in the crystal lattice, which could not be entirely removed under vacuum. A calculation to fit the observed value for carbon (39.2%) gave the approximate formula **2**·1.3CH_2Cl_2.

Detailed structural analysis

The molecular structures of **1**·2$CHCl_3$ and **2**·2CH_2Cl_2 were determined by single-crystal X-ray diffraction and are shown as SHELXTL drawings in Figs. 1 and 2, respectively. X-ray data were collected under the conditions summarized in Table 1. While molecule **1** has no crystallographically imposed symmetry, molecule **2** has a crystallographic inversion center, which relates the halves of the dimer (symmetry code #1: 1–*x*, 1–*y*, 1–*z*).

Both compounds exist as binuclear transition metal complexes with two bridging–bidentate phosphinate groups to form eight-membered $M_2P_2O_4$-rings. In **1**, the eight-membered ring adopts a boat–boat conformation (Fig. 1), while in **2** a boat–chair conformation is observed (Fig. 2). Some important structural features of **1** and **2** are compared in Table 2.

The titanium atoms in **1** possess a 14-electron configuration (if the phosphinate oxygen atoms are considered as two-electron donors) and have a "four-legged piano-stool" geometry with η^5-bound cyclopentadienyl rings. The cyclopentadienyl rings occupy one equatorial (Ti1) and one axial ring position (Ti2), thus reducing the steric interactions between the ligands. The Ti—C_5H_5(centroid) and Ti—Cl distances in **1** (Table 2) are similar to those reported for [(η^5-C_5H_5)$TiCl_3$] (27). Furthermore, all Ti—O and P—O distances as well as O-P-O angles are effectively equivalent (Table 2). This equivalence suggests electron delocalization throughout the bridging diphenylphosphinate groups. The distances are slightly shorter than those reported for the other structurally characterized titanium diphenylphosphinates (5, 20). Analysis of the Ti-O-P bond angles (Table 2) shows an average value of 148.43°, which is significantly larger than the idealized 120° angle expected for a two-electron donating oxygen atom, thus perhaps indicating some Ti—O multiple bond character. Both the O-Ti-O bond angles in **1** (O1-Ti1-O4 82.72(10)°, O2-Ti2-O3 81.58(10)°) are smaller than those in the other binuclear titanium diphenylphosphinate [{(η^5-C_5Me_5)TiF(μ-F)(μ-Ph_2PO_2)}$_2$] (O-Ti-O 155.13(10)°); however, this is a consequence of the different titanium coordination geometry in the latter complex (5).

To our knowledge, compound **2** (Fig. 2) represents the first example of a structurally characterized tantalum phosphinate complex. Both tantalum centers have 16-electron configurations and can be described as having distorted octahedral geometries if the η^5-C_5Me_5 ligands are considered to occupy single coordination sites. The angular distortions from the ideal octahedra are probably due to the steric bulk of the C_5Me_5 ring. Hence, the O-Ta-O angle of 78.48(9)° is compressed relative to the ideal value of 90°. The Ta—C_5Me_5(centroid) distance of 2.435(4) Å and the three Ta—Cl distances ranging from 2.3141(8) to 2.4001(7) Å are normal. It is notable that the Ta—O distances in **2** are quite different. The Ta—O bond *trans* to the C_5Me_5 ring (Ta1—O1 2.329(2) Å) is significantly longer than the other Ta—O distance (Ta1—O2#1 1.978(2) Å), and this feature may be construed as evidence for a strong *trans* influence of the C_5Me_5 substituent. Also, the Ta1—Cl2 bond length of 2.4001(7) Å is longer than the other two Ta—Cl distances (Ta1—Cl1 2.3141(8), Ta1—Cl3 2.3482(8) Å), reflecting a weak *trans* influence of the oxygen atom O2#1. Moreover, the P—O distances show an interesting variation: the P1—O1 bond length (1.648(3) Å) is abnormally long, while the P1—O2 bond length (1.533(2) Å) is within the expected range and comparable to the P—O distances observed in compound **1** (Table 2). This asymmetric bonding arrangement is further reflected by the differing Ta-O-P angles (P1-O1-Ta1 159.43(12), P1-O2-Ta1#1 150.79(16)°) and may also

indicate some Ta—O multiple bond character between Ta1 and O2#1. However, the O-P-O angle of 116.42(12)° is typical for bridging diphenylphosphinate ligands (cf. average O-P-O angle in **1**: 115.63°).

Experimental section

General Information

All reactions were performed under an atmosphere of dry nitrogen. [(η^5-C$_5$Me$_5$)TaCl$_4$] (Strem) and Ph$_2$P(O)(OH) (Aldrich) were purchased and used as received. [(η^5-C$_5$H$_5$)TiCl$_3$] (28) and Ph$_2$P(O)(OSiMe$_3$) (29) were prepared following literature procedures. NMR spectra were recorded on a Varian Gemini or Mercury 300 MHz spectrometer. Chemical shifts are referenced to solvent peaks (^{1}H) or external 85% H$_3$PO$_4$ (^{31}P). Infrared spectra were recorded on a Nicolet Magna 550 FT-IR instrument as Nujol mulls between KBr plates. Mass spectra were obtained with a VG 70-250S mass spectrometer operating in electron impact (EI) mode at 70 eV. Elemental analyses were performed by Quantitative Technologies, Inc., Whitehouse, NJ.

X-ray structural characterization

Crystal data and details of the data collection are provided in Table 1. Diffraction data were collected on a Nonius Kappa-CCD using graphite-monochromated Mo Kα radiation (λ = 0.71073 Å). A combination of 1° ϕ and ω (with κ offsets) scans were used to collect sufficient data. The structures were solved and refined with the SHELXTL-PC V5.1 software package (30). The data frames were integrated and scaled using the Denzo-SMN package (31). Refinement was by full-matrix least-squares analysis on F^2 using all data (negative intensities included). Molecular structures are presented with ellipsoids at a 30% probability level. In all structures hydrogens bonded to carbon atoms were included in calculated positions and treated as riding atoms.[3]

[{(η^5-C$_5$H$_5$)TiCl$_2$(μ-Ph$_2$PO$_2$)}$_2$] (1)

[(η^5-C$_5$H$_5$)TiCl$_3$] (2.50 g, 11.4 mmol) was dissolved in dichloromethane (60 mL) and a solution of Ph$_2$P(O)(OSiMe$_3$)

(3.31 g, 11.4 mmol) in dichloromethane (20 mL) was added at room temperature. After stirring for 16 h the solution was filtered, concentrated under vacuum, and set aside for crystallization. Orange crystals of **1** grew at room temperature over a period of 1 week. Isolated yield 3.56 g (78%). Crystals suitable for an X-ray diffraction study were obtained after storing a solution of **1** in $CHCl_3$ for 1 week at room temperature. IR (Nujol, KBr) (cm^{-1}): 1593 (w), 1146 (s), 1128 (s), 1055 (m), 1037 (m), 1023 (s), 994 (m), 830 (m), 757 (w), 693 (m). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 7.84–7.65 (m, Ph, 4H), 7.42–7.32 (m, Ph, 2H), 7.32–7.15 (m, Ph, 4H), 7.01 (s, C_5H_5, 5H). ^{31}P NMR (121 MHz, $CDCl_3$) δ: 34.5 (s). EI-MS (70 eV) *m/z* (%): 248 ([(η^5-C_5H_5)$_2$TiCl$_2$], 47), 183 ([(η^5-C_5H_5)TiCl$_2$], 100), 148 ([(η^5-C_5H_5)TiCl], 57). Anal. calcd. for $C_{34}H_{30}Cl_4O_4P_2Ti_2$: C 50.9, H 3.77; found: C 50.1, H 3.67.

[{(η^5-C_5Me_5)TaCl$_3$(μ-Ph_2PO_2)}$_2$] (2)

[(η^5-C_5Me_5)TaCl$_4$] (1.00 g, 2.18 mmol) was suspended in dichloromethane (50 mL) and a solution of $Ph_2P(O)(OSiMe_3)$ (0.63 g, 2.18 mmol) in dichloromethane (20 mL) was added. After stirring for 16 h at room temperature the clear, yellow-orange solution was filtered and concentrated under vacuum. Dark yellow crystals of **2** grew over a period of 2 to 3 days at room temperature and were of suitable quality for X-ray diffraction. Isolated yield 0.83 g (60%). IR (Nujol, KBr) (cm^{-1}): 1596 (w), 1269 (m), 1152 (s), 1127 (s), 1113 (s), 1037 (m), 1017 (s), 991 (s), 754 (w), 697 (m). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 8.09–8.01 (m, Ph, 4H), 7.51–7.45 (m, Ph, 2H), 7.40–7.34 (m, Ph, 4H), 2.19 (s, C_5Me_5, 15H). ^{31}P NMR (121 MHz, $CDCl_3$) δ: 32.0 (s). EI-MS (70 eV) *m/z* (%): 503 ([TaCl$_3$(Ph_2PO_2)], 100), 201 ([Ph_2PO], 95), 135 ([C_5Me_5], 41), 77 ([Ph], 53). Anal. calcd. for $C_{44}H_{50}Cl_6O_4P_2Ta_2$: C 41.3, H 3.94; found: C 39.2, H 3.75.

Summary

The reaction of $Ph_2P(O)(OSiMe_3)$ with [(η^5-C_5H_5)TiCl$_3$] and [(η^5-C_5Me_5)TaCl$_4$] is a convenient and selective route for the preparation of the binuclear transition metal phosphinate complexes **1** and **2**. NMR spectroscopic data obtained for **1** and **2** indicated the existence of highly symmetric structures in solution, while solid state characterization by single-crystal X-ray analysis revealed the presence of eight-membered metallacycles incorporating bridging–bidentate diphenylphosphinate groups. Both compounds and, in particular, mononuclear analogs may be suitable catalysts for the polymerization of olefins and experiments in this direction are of interest.

pH-controlled location and metalation of an amphiphilic porphyrin in sodium dodecyl sulfate micelle

Lin Guo and Ying-qiu Liang

Abstract: 5,10,15-Tri(4-hydroxyphenyl)-20-(4-hexadecyloxyphenyl)porphyrin (**P**) was solubilized in sodium dodecyl sulfate (SDS) micelle solutions. Taking advantage of the protonation and deprotonation properties of the amphiphilic porphyrin allowed the study of the pH-controlled transfer process of **P** in SDS micelle by means of UV–vis and fluorescence spectra. In neutral SDS micelle, **P** may be protonated and located at the outer surface of the micelle. In mildly basic conditions the hydrophilic ability of **P** decreases and the porphyrin moiety may transfer to the inner layer of SDS micelle. In strong basic conditions the porphyrin may transfer back to the outer aqueous surface of the micelle. The kinetic study of the porphyrin complexed with Cu(II) shows that the metalation rate of **P** could be controlled by changing the pH.

Key words: porphyrin, location, metalation, sodium dodecyl sulfate, micelle.

Résumé : On a solubilité la 5,10,15-tri(4-hydroxyphényl)-20-(4-hexadécyloxyphényl)porphyrine (**P**) dans des solutions de micelle de dodécylsulfate de sodium (« SDS »). Faisant appel à la spectroscopie UV–vis et à celle de fluorescente et prenant avantage des propriétés de protonation et de déprotonation de la porphyrine amphiphile, on a pu étudier le processus de transfert de **P** à la micelle de « SDS » sous un contrôle du pH. Dans une micelle de « SDS » neutre, **P** peut être protonée et se trouve à la surface externe de la micelle. Dans des conditions basiques, l'habilité hydrophile de **P** diminue et la portion porphyrine peut être transférée vers la couche interne de la micelle de « SDS ». Dans des conditions fortement basiques, la porphyrine peut être éjectée vers la surface extérieure de la micelle. L'étude cinétique de la porphyrine dans laquelle on a incorporé du Cu(II) montre que la vitesse métalatique de **P** peut être contrôlée par un changement de pH.

Mots clés : porphyrine, situation, métalation, dodécylsulfate de sodium, micelle.

Introduction

Biochemical processes occurring in biomembranes are in many cases enabled by the cooperative action of functional molecules (or parts of molecules) in special positions of the matrix membrane. An important example is the porphyrin functional unit, located in the photosynthetic reaction center, which plays an important role in biological processes such as light energy conversion, oxygen transport, and catalysis (1–5). Therefore, special incorporation of porphyrin molecule guests in biomimic membranes and their functions have been of great interest. Porphyrins anchored to lipid bilayers have successfully been applied to the reversible binding of dioxygen in aqueous solutions (6). Incorporation of porphyrins in micelles dramatically influences the aggregation mode and location of these molecules and alters their metalation rate (7–8). It has been suggested that hydrophobic porphyrins can penetrate the lipid regions of membranes and be distributed into the protein-rich membrane domain (9), while highly polar species are supposed to partition mainly in the aqueous compartments (10). The interaction of water-soluble synthetic porphyrins with ionic micelles has been studied intensively (8, 11–12). In the presence of ionic surfactants below their critical micelle concentration (CMC), both tetra-(4-sulfonatophenyl) porphyrin ($TPPS_4$) (13–15) and some meso-tetraaryl-substituted picket fence porphyrins (16) were shown to form aggregates. Above CMC, micelles usually solubilize the aggregates of porphyrin derivatives into monomers (11–13, 17–18).

So far, however, there are still few reports about controlling amphiphilic porphyrin transfer processes in micelle. Although some efforts have been made to study porphyrin aggregation and location in micelle surfactant solutions as well as in aqueous solutions, most of these have concentrated on water-soluble porphyrinic molecules (11–13). Moreover, metalation in microheterogeneous media has been less investigated, although it is a biological phenomenon (19–20). In this work, an attempt is made to gain more insight into the nature of amphiphilic porphyrin interactions with biological structures using the simplest model for membranes and proteinic reaction centers: aqueous ionic micelles. An amphiphilic porphyrin (**P**, shown in Fig. 1) with

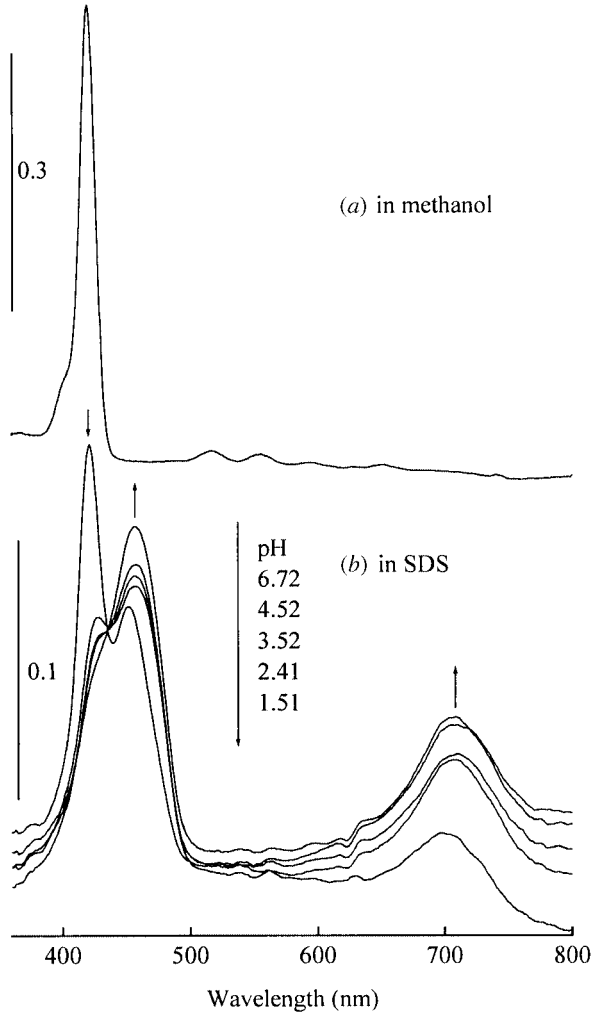
one hexadecyl chain was solubilized in micelle sodium dodecyl sulfate (SDS) solutions. The co-existence of the big hydrophobic porphyrin moiety and the long hydrophobic chain in the same molecule suggests that such a molecule can be solubilized in organic solvents as well as in the nonpolar region of micelles. Furthermore, this kind of amphiphilic porphyrin shows an interesting property: the hydrophilic ability of **P** could be changed with a variation in pH (21). Based on this property, the metalation process of **P** in SDS micelle with the use of a pH-controlled environment will be discussed below.

Experimental

Tetra(4-hydroxyphenyl)porphyrin (THPP) was prepared first (22) and was then hexadecylated by 1-bromohexadecane in an ethanol solution of potassium hydroxide. The products were then separated and purified 4 times by thin-layer chromatography over silica gel C with a solvent mixture of chloroform and with ethanol as the eluant. 5,10,15-Tri(4-hydroxyphenyl)-20-(4-hexadecyloxyphenyl) porphyrin (**P**) was obtained and characterized by elemental analysis, MS, IR, and H NMR spectroscopy (23–24). SDS was the analytical reagent and was recrystallized twice from 90% ethanol. Water was doubly distilled after passing through an ion-exchange resin column. All the organic solvents were analytical-grade pure and used without further purification.

SDS micelle, aqueous, and organic solutions of porphyrin were prepared by injection of a specific amount of a 2.5×10^{-3} mol dm^{-3} dioxane solution of porphyrins into the different solvents to obtained 25 mL solutions. The volume ratio of dioxane and water or other mixture solvents was greater than 1000, so the effects of traces of dioxane on the solution polarity could be neglected. After 20 min of sonication, the UV–vis and fluorescence spectra of the solutions were recorded on a Shimudu UV-3100 spectrophotometer and a PerkinElmer LS50B fluorescence spectrophotometer, respectively, using a 1 cm quartz cell. Excitation wavelength (λ_{ex}) was 423 nm. The pH of the solution was measured by a Leici (Shanghai) pH-250 pH meter, and the pH was controlled by addition of 1.5 mol dm^{-3} NaOH and 1:4 HCl aqueous solutions. The kinetic processes of the porphyrin complexed with Cu(II) were carried out, at room temperature, by adding a specific amount of 0.1 mol dm^{-3} $CuSO_4$ aqueous solution to the pH-variable porphyrin – SDS micelle solutions and then recording the UV–vis spectra of the mixtures at different reaction times.

Fig. 2. UV–vis spectra of **P** in different solutions: (*a*) **P** in methanol; (*b*) acid titration of **P** in SDS micelle solutions. [SDS] = 3.1×10^{-2} mol dm^{-3}; [**P**] = 2.1×10^{-6} mol dm^{-3}.



Results and discussion

Protonization of P in neutral SDS micelle

Figure 2 shows the UV–vis spectra of the acid titration of **P** in SDS micelle solutions. It can be seen that under neutral conditions (pH 6.72) (Fig. 2*b*), **P** shows two split Soret bands at 423 and 455 nm, and four Q bands appear at 519, 562, 602, and 707 nm, respectively. These spectral characteristics are different from those of porphyrin monomer in organic solvent, which include a strong and a narrow Soret band at 419 nm and four Q bands at 518, 556, 595, and 649 nm, respectively (Fig. 2*a*). When pH was decreased to 1.51, The Soret band at 423 nm decreased and eventually disappeared, while the Soret band of **P** at 455 nm increased proportionately. Furthermore, the number of Q bands was observed to change from four to two when the bulk pH

[a][**P**] = 2.1×10^{-6} mol dm^{-3}; [SDS] = 3.1×10^{-2} mol dm^{-3}.

approached 1.51 (Table 1), indicating that **P** has a higher molecular symmetry (D_{4h}) — similar to protonated porphyrin — under this condition (13, 25). The overall absorption characteristics of **P** in pH 1.51 SDS solutions are similar to those of protonated **P** in strong aqueous acid solutions (see Table 1), indicating that **P** may be protonated under this condition. The four Q bands and spilt Soret bands of **P** under neutral SDS conditions indicate that part of **P** was protonated, and the two split Soret bands at 423 and 455 nm may be due to the porphyrin monomer and the protonated porphyrin, respectively.

It should be pointed out that the protonation of porphyrin could take place only under acidic conditions. However, it was found that part of **P** could be protonated in neutral SDS micelle solutions, indicating that SDS micelles could be providing an acid surface microenvironment to **P**, although the bulk pH was not acidic. This function is attributed to the surface-potential effect on the intrinsic pH values near the surface of micelles. The relationship between surface-potential and surface-effective concentration of H^+ (α_H) of micelles is shown by the following equation (26):

$$[1] \qquad \alpha_H{}^i = \alpha_H{}^w \, e^{-F\Psi/RT}$$

where $\alpha_H{}^i$ and $\alpha_H{}^w$ are the effective concentration of H^+ ion in micelle surface and bulk aqueous phases, respectively, F is the Faraday constant, Ψ is the surface potential of the micelle, T is the temperature in Kelvins, and R is the Boltzman constant. Previously, studies have found that the anion surfactant SDS micelle exhibits a negative surface potential ($\Psi < 0$), and the surface potential of the SDS micelle is about –140 mV in the dilute micelle SDS solutions without added electrolyte (27–29); so, according to eq. [1], $\alpha_H{}^i > \alpha_H{}^w$. Drummond et al. (27) studied the acid–base equilibria of azine derivatives and found that the intrinsic pH value decreased 2.4 units at the surface of the SDS micelle compared with the bulk pH value (27). Therefore, it can be understood that a low pH value should exist at the surface layer of SDS micelles — similar to an aqueous acid solution — when the apparent bulk pH approaches 6.72. These phenomena also indicate that **P** may be complexed with SDS micelles rather than just dissolved in the bulk aqueous phase.

Surfactant–dye interaction and dye–dye aggregation are fairly common for oppositely charged dye–detergent pairs and are possible for neutral dyes as well (16, 30). To prevent hydrophobic dyes from undergoing dye–dye aggregation, a high concentration ratio between the surfactant molecules and the solubilized dyes is usually selected to increase the possibility of obtaining only one dye per micelle (26). In this paper, a high concentration ratio of [SDS]:[**P**] was used to decrease any disturbance due to porphyrin aggregation; the bulk pH was the only parameter that was changed. The pH-controlled transfer process of the porphyrin moiety in SDS micelles is discussed below.

pH-controlled transfer process of P in SDS micelle

UV–vis spectra

Figure 3 shows the UV–vis spectra of the base titration of **P** in SDS micelle solutions. It can be seen from this figure that as pH increases from 6.72 to 10.18, the Soret band of the porphyrin monomer at 423 nm obviously narrows and increases, while the band at 455 nm decreases and finally disappears. The four Q bands of **P** shift to 523, 562, 595, and 659 nm, respectively. These spectral characteristics are similar to those of **P** in organic solvent, where it exists as monomers (Table 1). This indicates that with increasing pH the protonated porphyrin may be deprotonized to form a neutral porphyrin in SDS micelle solution. As the bulk pH further increases from 10.18 to 12.06, the Soret band of **P** shows some broadening and decreasing.

It is well known that absorption Soret bands of porphyrins are often sensitive to the nature of local environments in micelle and aggregation forms and to solvent microenvironments (31–32). From the analysis of the spectral parameters such as peak position, intensity, and full-widths at half-height of the Soret band **P** in different solvent environments and in the micelle SDS solutions we can draw further conclusions as to what is happening concerning the site solubilization of **P** in SDS micelles in this pH titration process. It is clear from the data in Table 1 and Fig. 3 that the absorption spectra characteristics of **P** in micelle SDS solutions under neutral conditions are very similar to those of protonated **P** in aqueous acid solutions rather than those of **P** in organic solvent. The protonation of **P** in the neutral SDS micelle solution indicates that **P** may be incorporated into the SDS micelle rather than just dissolved in the bulk aqueous phase. Hence, it can be suggested that the porphyrin moiety of **P** should be located on the outer surface of an SDS micelle within a strong polar microenvironment — similar to aqueous acid solutions — as shown in Fig. 4*a*. Such a solubilization location is thermodynamically stable for the

Fig. 3. UV–vis spectra of **P** in different pH SDS micelle aqueous solutions. [SDS] = 3.1×10^{-2} mol dm^{-3}; [**P**] = 2.1×10^{-6} mol dm^{-3}.

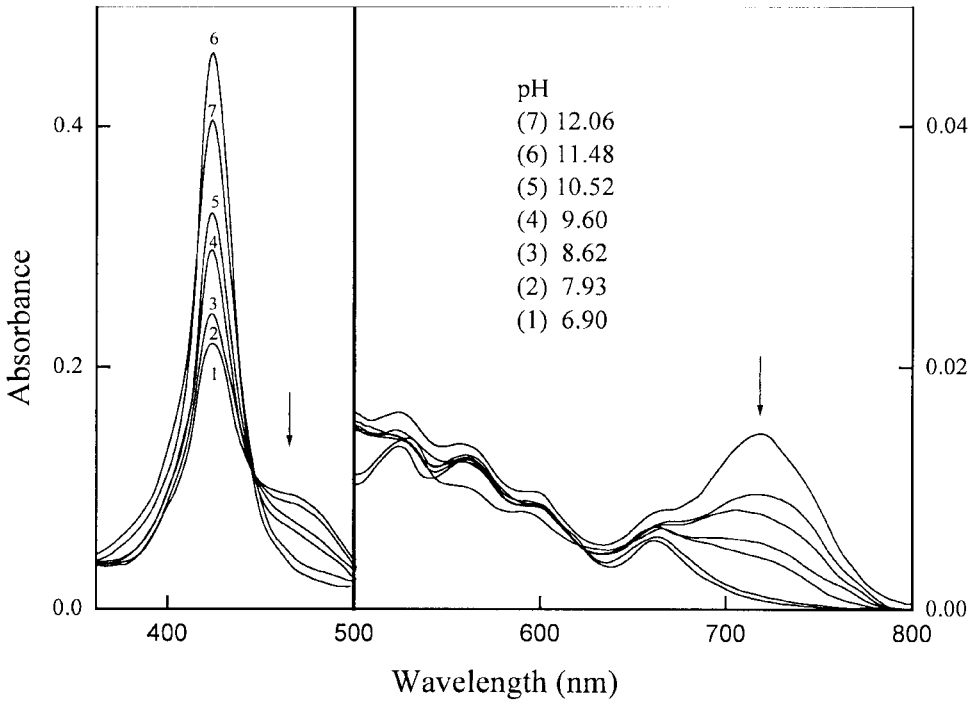

Fig. 4. Scheme of the transfer process of **P** in SDS micelles with increasing bulk pH.

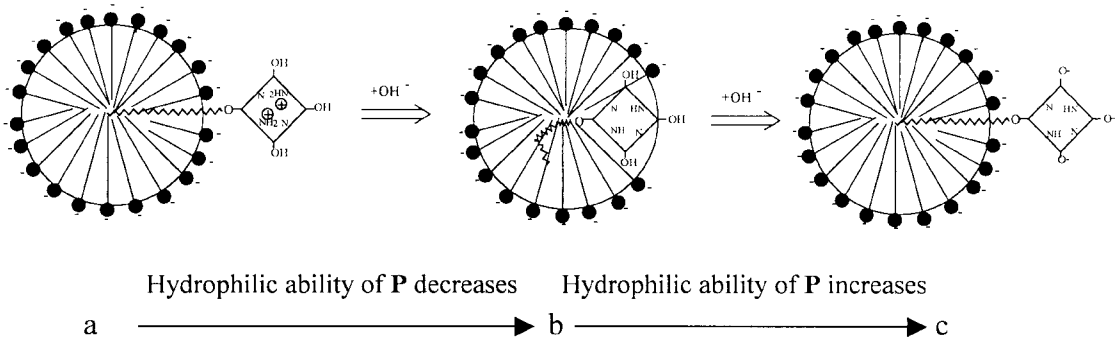

hydrophilic protonated porphyrin moiety and hydrophenyl groups even though there is one hydrophobic hexadecyl chain. However, by increasing the pH, the protonated porphyrin $H_2\mathbf{P}^{2+}$ can be deprotonized to form the neutral porphyrin **P**, and thus reduce the hydrophilic ability of **P**. Consequently, the hydrophenyl groups of **P** can also be deprotonated to form $\mathbf{P}^{1-}$, $\mathbf{P}^{2-}$, and $\mathbf{P}^{3-}$ ions and the hydrophilic ability of **P** increased proportionately. Therefore, the hydrophilic ability of **P** can be adjusted by controlling the pH values. This is the force for the porphyrin macrocycle transferring in or out of the micelles. In fact, when pH is increased up to 10.18, the overall absorption characteristics of **P** are quite similar to those of **P** in organic solvent (Table 1 and Fig. 3). These results infer that **P** may transfer to a weak polar microenvironment in the inner layer of the SDS micelle (Fig. 4*b*). However, when pH is further increased up to 12.06, the decrease of the Soret band intensity as well as the increase of full-widths at half-height of the Soret band suggest that the porphyrin moiety may transfer from the inner layer of the micelle back to the surface layer of the micelle (Fig. 4*c*) for a relatively low value of the Soret band intensity. An increased full-widths at half-height of the Soret band are also observed for **P** in diluted aqueous solutions (33). Figure 4 shows the scheme of this transfer process.

Fluorescence spectra

It is well known that in aqueous media that the microenvironment of many organic or amphiphilic molecules that interact with other macromolecules, micelles, membranes, or adsorption sites is a mixture of hydrocarbon-like and aqueous environments. Generally, the inner core of the spherical micelle has shown low polarity, and the effective dielectric constants of the stern layer are approximately 36–46 (34); the outer surface of the micelle, as well as nearby bulk aqueous phase, exhibit strong polarity. Therefore, the further from the hydrophobic center of the micelle, the greater polarity exhibited by the microenvironment. Hence, the polarity-dependent spectral characteristics are likely to be useful indicators of the nature of microenvironments of molecules in many situations including

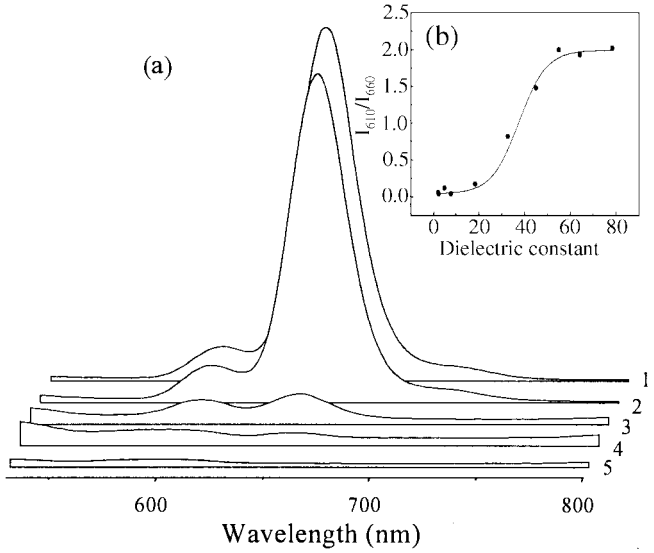
Fig. 5. (*a*) Fluorescence emission spectra of **P** in different solutions: λex = 423 nm; (1) dioxane; (2) 2-propanol; (3) 50% methanol–H_2O; (4) 20% 2-propanol–H_2O; (5) H_2O; (*b*) plot of intensity ratios of 610 nm and 660 nm of **P** against the dielectric constants of different solvents. The solvents and their dielectric constants used in this experiment are, from left to right: dioxane (2.3), chloroform (4.8), tetrahydrofuran (7.6), 2-propanol (18.3), 95% ethanol (26.1), methanol (32.6), 70% MeOH–H_2O (45.0), 50% MeOH–H_2O (54.9), 20% 2-propanol–H_2O (64.1), H_2O (78.5).



solubilization in micelle systems, and the effect of solvents on the fluorescence spectra of porphyrinic molecules has been studied extensively (35–36). Figure 5 shows the emission fluorescence spectra of **P** in different solvents. It can be seen from this figure that the fluorescence emission intensity of **P** is sensitive to the solvent polarity. In low-polar solvents such as methanol and dioxane, **P** exhibits a strong emission band at 660 nm and a relatively weak shoulder band at approximately 610 nm. When the polarity of solvents increases, the fluorescence intensity of **P** decreases rapidly, whereas the fluorescence maximum of **P** at 660 nm is not shifted. In pure aqueous solution **P** shows no obvious emission band within the experimental region. However, the fluorescence emission band at 610 nm is not changed as rapidly as that of the 660 nm band, and it even increases by comparison. Based on this behavior, the polar microenvironment of **P** in different solvents could be represented by the fluorescence intensity ratio of 610 and 660 nm, R (I_{610}/I_{660}). Figure 5*b* shows the plot of the R value of **P** against the dielectric constants of different solvents. It can be seen from this plot that with the increasing dielectric constant of the solvent, the intensity ratio of porphyrin increases proportionately. This may be due to the tendency, in the increase of solvent polarity, to favor face-to-face association of porphyrins, which tends to diminish fluorescence quantum yield.

Figure 6 shows the fluorescence emission spectra of **P** in SDS micelle solutions with different bulk pH. It is clear from this figure that in bulk pH 7.08 solution, **P** has a very low quantum yield of fluorescence, similar to that of **P** in high polar aqueous solutions. With increasing pH, the overall fluorescence intensity increases proportionately, and at pH 10.18 a strong emission band appears at 660 nm and a

Fig. 6. Plot of dielectric constants against the pH values of SDS micelle solutions of **P**.

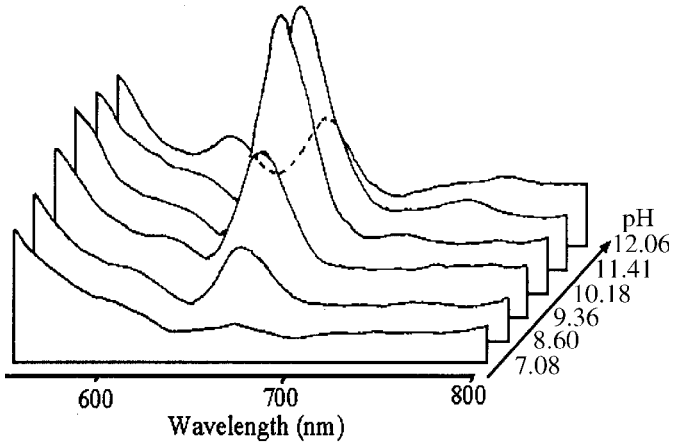


Fig. 7. Fluorescence emission spectra of **P** in different pH SDS micelle aqueous solutions: λ_{ex} = 423 nm; [**P**] = 2.1 × 10^{-6} mol dm^{-3}; [SDS] = 3.1 × 10^{-2} mol dm^{-3}.

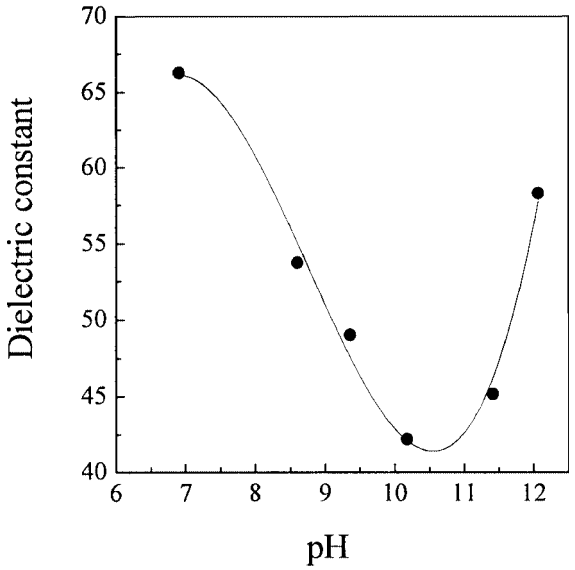

shoulder band at 610 nm. The overall fluorescence spectral characteristics are similar to those of **P** in organic solvent. When the pH value further increases up to 12.06, the fluorescence band of **P** at 660 nm exhibits some decrease. However, the fluorescence emission band at 610 nm does not change as rapidly as that of the 660 nm band. In this paper a high surfactant concentration – porphyrin ratio was used to decrease any disturbance caused by porphyrin aggregation. Consequently, the variation of the fluorescence parameters of porphyrin with bulk pH will now be primarily due to the change in the local microenvironment polarity of **P** in SDS micelle. Based on the R of **P** in different pH values, the corresponding microenvironment polarity of **P** in SDS micelle may be obtained through the information provided by Fig. 5*b*. Figure 7 shows the plot of pH against the corresponding microenvironment dielectric constants of **P** in SDS micelle. It is clear from this plot that the bulk pH is a con-

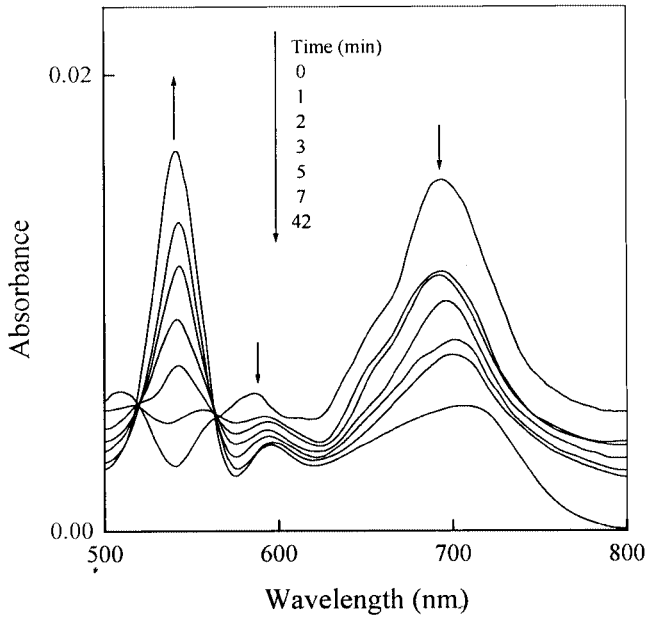
Fig. 8. UV–Vis spectra of **P** complexed with Cu(II) at different reaction times in a pH 6.90 SDS micelle aqueous solution. [**P**] = 2.1×10^{-6} mol dm^{-3}; [Cu^{2+}] = 2.5×10^{-4} mol dm^{-3}; [SDS] = 3.1×10^{-2} mol dm^{-3}.



trolling factor in the transfer process of the solubilizing location of **P** in SDS micelle. Under neutral conditions, **P** may be located in the outer surface of the SDS micelle, which has a strong polar microenvironment with microenvironment dielectric constant (ε) around 66. With the pH of the solution increasing up to 10.18, the porphyrin moiety transfers to the inner layer of the SDS micelle, where there is a relatively weak polar microenvironment (ε ≈ 41). With pH further increased from 10.18 to 12.06, the porphyrin moiety transfers from the inner layer of the SDS micelle back to the outer layer of the SDS micelle (ε ≈ 58). These results correspond to the same results obtained by the UV–vis spectra study (Fig. 4).

pH-controlled metalation rate of P in SDS micelle

It is apparent from the above results that changes in the bulk pH value leads to changes in the hydrophilic ability of the porphyrin and eventually to control of the solubilized location of porphyrin in SDS micelle. By taking advantage of this property, the metalation of porphyrin in SDS micelle could also be controlled by changing the pH, which could be predicted by the kinetics of the porphyrin complexing with Cu(II).

Figure 8 shows the regional UV–vis spectra of **P** complexed with Cu(II) at different reaction times in a pH 6.90 solution of SDS micelle. It can be seen from this figure that the four Q bands of **P** decrease and finally disappear with increasing reaction times, while a new band that increases gradually appears at 542 nm. Furthermore, two isosbestic points appear at 530 and 553 nm. This implies that the solubilized location and polar microenvironment of **P** in SDS micelle are not changed during metalation in neutral SDS solution.

Table 2. The pseudo-first-order reaction rate constant (k_{obs}) of porphyrin complexed with Cu(II) in different bulk pH SDS micelle solutions.[a]

Porphyrin	Micelle	[Cu^{2+}] (mol dm^{-3})	pH	k_{obs} (min^{-1})
P	SDS	2.5×10^{-4}	6.90	1.4×10^{-1}
P	SDS	2.5×10^{-4}	7.71	9.4×10^{-2}
P	SDS	2.5×10^{-4}	8.50	6.9×10^{-2}
P				
P	SDS	6.5×10^{-4}	9.55	4.3×10^{-2}
P	SDS	3.3×10^{-4}	9.55	4.2×10^{-2}
P	SDS	1.6×10^{-4}	9.55	4.2×10^{-2}
P	SDS	0.7×10^{-4}	9.58	3.9×10^{-2}

[a][**P**] = 2.1×10^{-6} mol dm^{-3}; [SDS] = 3.1×10^{-2} mol dm^{-3}.

As the reaction was performed with a great excess of Cu(II), the reaction could be regarded as pseudo-first-order reaction (37). To verify that the pseudo-first-order condition is met in mild basic micelle solution, the apparent metalation rate constants k_{obs}, dependent on a concentration of Cu(II) approximately 10^{-4} mol dm^{-3}, were obtained and listed in Table 2. It is clear from this table that for the pH 9.55 SDS micelle solutions, k_{obs} shows no obvious change when the concentration of Cu(II) is increased from 1.6×10^{-4} to 6.5×10^{-4} mol dm^{-3}. This indicates that, as opposed to aqueous solutions, the precipitation of copper hydroxides in microheterogeneous SDS micelle solutions is so slow that the pseudo-first-order condition is met under mild basic (pH 6.90–9.55) conditions. The pseudo-first-order reaction rate constants of the porphyrins complexed with Cu(II) in SDS micelle solutions with differing pH values (k_Ψ) are listed in Table 1. It can be seen from this table that as the pH increased from 6.90 to 9.58 the metalation rate constants of **P** decreased proportionately.

There are several factors that influence the metalation rate of **P** in SDS micelle when the other experimental conditions are not changed. One of these is the pH of the solutions. Some previous work has suggested that deprotonation is an important process in the complexation of Cu(II) with porphyrin (39). Hence, an increase of pH will eventually lead to an increase of the metalation rate of **P**. However, when the pH of the solution is too high and the concentration of OH^- is too great, the concentration of Cu(II) in solution will decrease and the reaction rate will finally decrease. Another is the solubilizing location of **P** in SDS micelle. It is well accepted that Cu(II) is involved in bonding to porphyrin nitrogen atoms and then promotes a plane structure (39); at the same time the Cu(II) ion is difficult to diffuse into the inner nonpolar core of the micelle (20, 40). Hence, the solubilized location of the porphyrin in SDS micelle influences the metalation rate of porphyrin intensely. If a porphyrin moiety is located at the outer surface of the micelle, the probability of that porphyrin moiety meeting a Cu(II) ion becomes greater, so the metalation rate of porphyrin is greater. When the porphyrin moiety stays at the inner layer of the micelle, although the porphyrin could still form a complex with Cu(II), the metalation rate is relative low.

In this paper, the metalation rates of **P** were measured only in the mildly basic region (pH 6.90–9.58), and the pseudo-first-order condition can be met within this pH

© 2002 NRC Canada

region. Therefore, the variation in the metalation rate of **P** is due mainly to the change of the solubilizing location of **P** in SDS micelles. In the case of neutral SDS solution, the porphyrin moiety stays at the outer layer of the micelle; hence, the matalatic rate is relatively high. As the pH of the solution increases, the porphyrin moiety transfers to the inner layer of the micelle, and the probability of the porphyrin meeting Cu(II) ions becomes lower; hence, the metalation rate of porphyrin decreases proportionately.

Conclusion

By analyzing the UV–vis and fluorescence spectra of the synthesized amphiphilic porphyrin **P** in different solvent environments and the relationship between the solubilizing location of the porphyrin in SDS micelle and the microenvironment polarity, it has been shown that, as the pH is changed, a transfer process exists for the porphyrin moiety of **P** in SDS micelle. In neutral SDS micelle solutions, **P** may be protonated and located at the outer surface of micelle. In mildly basic conditions, the hydrophilic ability of **P** decreases and the porphyrin moiety may transfer to the inner layer of the SDS micelle. In strongly basic conditions the hydrophenyl groups of **P** would be deprotonated; consequently, porphyrin may transfer back to the outer aqueous surface of the SDS micelle. The kinetic study of **P** complexed with Cu(II) shows that the metalation rate could be controlled by changing the pH.

Ryanoids and related compounds — Chemoselective electrocatalytic hydrogenation of alkyl α-pyrrole carboxylates: Selective hydrogenation of ryanodine

Luc Ruest, Hugues Ménard, Vincent Moreau, and François Laplante

Abstract: A study of the electrocatalytic hydrogenation (ECH) process of pyrrole and different alkyl pyrrole-2-carboxylates is presented. Once hydrogenated, the alkyl pyrrole-2-carboxylate becomes an ester of proline, an important natural amino acid. The process is chemoselective to the pyrrole ring. Ryanodine is a natural ryanoid known to be biologically active. The tetrahydroryanodine derivative thus obtained may now represent a molecule of high biological interest. The hydrogenation of ryanodine is possible with electrocatalytic and catalytic processes. In both cases the reaction is not diastereoselective.

Key words: electrocatalytic hydrogenation, proline esters, ryanodine, tetrahydroryanodine.

Résumé : Une étude sur l'hydrogénation électrocatalytique (HEC) du pyrrole et de quelques esters de l'acide pyrrole-2-carboxylique est présentée. Une fois hydrogéné, le pyrrole-2-carboxylate d'alkyle devient un ester de la proline, un acide aminé naturel important. Le procédé est chimiosélectif au cycle pyrrole. La ryanodine est un ryanoïde connu pour son activité biologique. Le dérivé tétrahydroryanodine ainsi obtenu peut maintenant présenter un grand intérêt biologique. L'hydrogénation de la ryanodine est possible par le procédé électrocatalytique et catalytique. Dans les deux cas, la réaction n'est pas diastéréosélective.

Mots clés: hydrogénation électrocatalytique, esters de proline, ryanodine, tétrahydroryanodine.

Introduction

Ryanodine (Fig. 1) is a natural ryanoid extracted from the plant *Ryania speciosa*. This molecule is known to be a potent modulator of the sarcoplasmic reticulum calcium release channel (1). The interesting functional group of ryanodine in the present study is the aromatic pyrrole ring attached to the main polycyclic structure (ryanodol) by an ester function. Once hydrogenated, this heterocycle becomes an ester of proline, a natural amino acid. This tetrahydroryanodine derivative may now represent a molecule of high biological interest. Theoretically, removal of the pyrrole moiety and then esterification of the free hydroxyl group in position 3 with proline could lead to the desired compound, but in fact it has been shown that specific esterification at this endo hydroxyl group is not possible (1*c* and references therein).

We began the present study with simple molecules like pyrrole (**1**), pyrrole-2-carboxylic acid (**3A**), and its methyl (**3B**), ethyl (**3C**), and isopropyl (**3D**) esters (Fig. 1). All these molecules have a pyrrole ring and, except for pyrrole and pyrrole-2-carboxylic acid, an ester group, as seen in ryanodine. With these simple molecules we determined the best conditions (electrocatalyst and electrolyte) for the electrocatalytic hydrogenation (ECH) process of ryanodine.

The ECH process is achieved at room temperature and atmospheric pressure, unlike most of the classical catalytic hydrogenation methods. The classical process often requires a high pressure of hydrogen to reduce an aromatic pyrrole ring (2, 3). Recently, a pressure of 20 bar (1 bar = 10^5 Pa) was used to hydrogenate a compound with a pyrrole ring (4). Previous works in our laboratory used the ECH of phenol, cyclohexanone, and 2-cyclohexen-1-one to develop new electrocatalysts (5–7). The ECH of alkyl pyrrole-2-carboxylate molecules proceeds in acidic medium to prevent the poisoning of the catalyst by pyrrole or its derivatives (8, 9)

The ECH mechanism can be explained by the equations presented in Fig. 2. The electrocatalysts used in an ECH are constituted of a metallic part (M) and an adsorbent part (A). In the first step there is an electroadsorption of hydrogen atoms on the metallic part resulting from the reduction of water (eq. [1]). The alkyl pyrrole-2-carboxylate compound is adsorbed by the adsorbent of the electrocatalyst (eq. [2]). The hydrogenation is possible when the site of adsorption of the molecule is near to the electroadsorbed hydrogen (eq. [3]); this site is called the "triple point" (5). After saturation of the ring, the hydrogenated molecule is liberated by

the adsorbent (eq. [4]). These equations represent the global hydrogenation process of the alkyl pyrrole-2-carboxylate compounds.

Experimental section

Melting points were recorded on a Melter Toledo FP62 hot stage apparatus and are uncorrected. Mass spectra (MS) and peak matching (HR-MS) data were determined at 70 eV on a VG Micromass ZAB-1F spectrometer. The ^{1}H (300 MHz) NMR spectra were recorded on a Bruker AC-300 instrument with CD_2HOD as internal standard centered at 3.30. The usual standard abbreviations have been used to indicate the multiplicity of the proton signals. Column chromatography (flash) was performed with Merck silica gel (200–400 mesh). All the electrocatalysts (5% Pd/Al_2O_3, 5% Pt/Al_2O_3, 5% Rh/Al_2O_3, and 5% Rh/C) were purchased from Sigma-Aldrich. The solvents used for chromatography were HPLC grade. The electrolyte solutions were made with deionized water.

Starting materials

Pyrrole-2-carboxylic acid and pyrrole were purchased from Sigma-Aldrich. Commercial pyrrole was distilled before use. Compounds **3B**, **3C**, and **3D** were synthesized by the following procedure: a solution of *N*,*N*′-dicyclohexylcarbodiimide (4 g, 19 mmol) in distilled CH_2Cl_2 (10 mL) was transferred (cannula) to a solution of pyrrole-2-carboxylic acid (1.9 g, 17 mmol) dissolved in 25 mL of the corresponding alcohol used as solvent (methanol for **3B**, ethanol for **3C**, and isopropanol for **3D**). After the addition of 100 mg of 4-dimethylaminopyridine, the mixture was stirred for 12 h at ambient temperature and under an inert atmosphere. The mixture was filtered on silica gel (40% EtOAc – 60% hexane) before purification by flash chromatography to give esters **3B**, **3C**, and **3D** in 90% yield.

Methyl pyrrole-2-carboxylate (3B)

White crystalline solid; mp 71°C (lit. (10) value mp 72–73°C). ^{1}H NMR (CD_3OD) (ppm): 6.95 (m, 1H, HC5), 6.84 (m, 1H, HC3), 6.18 (m, 1H, HC4), 3.80 (s, 3H, O-CH_3). MS *m*/*e*: 125 ($[M]^+$). HR-MS calcd. for $C_6H_7NO_2$: 125.0477; found: 125.0474.

Ethyl pyrrole-2-carboxylate (3C)

Beige solid; mp 38°C (lit. (11) value mp 40–42°C). ^{1}H NMR (CD_3OD) (ppm): 6.94 (m, 1H, HC5), 6.84 (m, 1H, HC3), 6.17 (m, 1H, HC4), 4.27 (q, 7.1 Hz, 2H, O-CH_2-CH_3), 1.33

(t, 7.1 Hz, 3H, O-CH_2-CH_3). MS *m/e*: 139 ($[M]^+$). HR-MS calcd. for $C_7H_9NO_2$: 139.0633; found: 139.0627.

Isopropyl pyrrole-2-carboxylate (3D)

White solid; mp 41°C. ^{1}H NMR (CD_3OD) (ppm): 6.93 (m, 1H, HC5), 6.82 (m, 1H, HC3), 6.16 (m, 1H, HC4), 5.12 (h, 6.3 Hz, 1H, O-CH-$(CH_3)_2$), 1.31 (d, 6.3 Hz, 6H, O-CH-$(CH_3)_2$). MS *m/e*: 153 ($[M]^+$). HR-MS calcd. for $C_8H_{11}NO_2$: 153.0790; found: 153.0793.

Ryanodine used in the study was purified by a known procedure (1).

Hydrogenated products

All the products obtained by ECH were characterized by ^{1}H NMR and a comparison with authentic samples was done. Pyrrolidine, proline, and proline methyl ester hydrochloride (**4B**) were purchased from Sigma-Aldrich.

Proline ethyl ester hydrochloride (4C)

This material was prepared by a very slow addition of $SOCl_2$ (300 µL, 3.6 mmol) to a solution of proline (244 mg, 2.1 mmol) in ethanol (6 mL) following a known method (12). The mixture was kept at 0°C during the addition. After 5 h, the solvent was evaporated to leave a pure product, an amorphous beige solid (mp 55°C) (99%). ^{1}H NMR (CD_3OD) (ppm): 4.42 (m, 1H, HC2), 4.30 (q, 7.1 Hz, 2H, O-CH_2-CH_3), 3.38 (m, 2H, H_2C5), 2.42 (m, 1H, H_AC3), 2.12 (m, 3H, H_BC3, H_2C4), 1.32 (t, 3H, O-CH_2-CH_3). MS *m/e*: 143 ($[M]^+$). HR-MS calcd. for $C_7H_{13}NO_2$: 143.0946; found: 143.0950.

Proline isopropyl ester hydrochloride (4D)

Synthesis of proline isopropyl ester hydrochloride (4D) was prepared by the previous procedure using isopropanol (99%). The product obtained was a yellowish oil. ^{1}H NMR (CD_3OD) (ppm): 5.12 (h, 6.2 Hz, 1H, O-CH-$(CH_3)_2$), 4.35 (m, 1H, HC2), 3.35 (m, 2H, H_2C5), 2.40 (m, 1H, H_AC3), 2.05 (m, 3H, H_BC3, H_2C4), 1.30 and 1.31 (two d, 6.3 Hz, 6H, O-CH-$(CH_3)_2$). MS *m/e*: 157 ($[M]^+$). HR-MS calcd. for $C_8H_{15}NO_2$: 157.1103; found: 157.1098.

Electrolysis

The electrolysis was carried out in a two-compartment jacketed glass H-cell having a Nafion-324 (E.I. Dupont de Nemours & Co.) membrane as separator. The cell temperature was fixed at 21°C during the ECH by a circulating thermostated bath (VWR 1160A). The working electrode was a reticulous vitreous carbon (RVC) foam (25 × 20 × 6 mm, 80 pores per inch (ppi; 1 inch = 25.4 mm), Electrosynthesis Co.). The electrode was mounted by inserting a glass rod (o.d. 5–6 mm, i.d. 3.5 mm) in the horizontal axis of the piece of RVC. The excess RVC was then removed and a copper wire was inserted into the RVC to be further cemented with silver epoxy (Epoxy Technology). Finally, the electrical contact zone on the RVC matrix was fixed to the glass rod with epoxy to isolate the electrical contact from the electroactive part of the electrode (5).

Both compartments were filled with the 0.1 M NaCl solution whose pH was adjusted to 1.2 with concentrated HCl. The ECH process occurred in the cathodic compartment (filled with 24 mL of the electrolyte) containing the working electrode and the electrocatalyst (200 mg). A platinum counter electrode was used in the anodic compartment. Mechanical stirring was applied during the ECH. When another electrolyte was used, the anodic compartment was filled with 2 M NaOH (5). A constant current of 5 mA was applied during the electrolysis. After passing 50 C of electricity to condition the working electrode, a solution of 0.6 M of starting material in methanol (1.0 mL) was added to the cathodic compartment.

The electrical charge passed through the system was noted in Faraday equivalents. A Faraday equivalent is the minimal amount of electrical charge needed to hydrogenate all the starting material in the cell. The equivalent charge can be calculated by the multiplication of the quantity of starting material by the number of electrons required to complete the reaction and by the Faraday constant (96 485 C per mole of electrons). Thus, 1 Faraday equivalent for 0.6 mmol of a simple alkyl pyrrole-2-carboxylate compound is 232 C, and 1 Faraday equivalent for 0.08 mmol ryanodine is 32 C.

Analysis

The hydrogenation process was tracked by monitoring the consumption of the starting material according to the Faraday equivalent. Aliquots of 500 µL were collected in the cathodic compartment during the ECH and analysed by HPLC (ZORBAX Eclipse XDB-C8 column (4.6 mm (i.d.) × 150 mm)) with an isocratic elution (40% acetonitrile – 60% water). Before the HPLC analysis, the aliquots were filtered on a 0.2 µm syringe filter. The HPLC system was an Agilent 1100 Series. A diode array detector performed the data acquisition. The wavelength was set to 265 nm for **3A**, **3B**, **3C**, and ryanodine; 280 nm for **3D**; and 207 nm for pyrrole.

Recovery of the hydrogenated products

The recovery of the hydrogenated simple alkyl pyrrole-2-carboxylate molecules, except pyrrolidine, was achieved by first evaporating water from the solution on a rotatory evaporator after filtration to remove the electrocatalyst. The product was then recovered by trituration with distilled chloroform. For pyrrolidine, the solution was saturated with K_3PO_4 to adjust the pH to 12. Pyrrolidine was extracted with ether (15 mL). The combined organic phases were dried (Na_2SO_4) and analysed by GC (HP-5890 with DB-1 column (30 m × 0.25 mm (i.d.), J&W Scientific)).

The product obtained after the hydrogenation of ryanodine was recovered with a C-18 SPE cartridge. The pH of the solution was adjusted to 8 for the elution. Distilled methanol was used to recover the product from the cartridge.

Results and discussion

Influence of the electrocatalyst

Figure 3 shows the evolution of the ECH process of **3B** (in 0.1 M NaCl at pH = 1.2 as the electrolyte (saline solution)) with the use of different electrocatalysts. The best results were obtained with the 5% Rh/Al_2O_3 electrocatalyst. The other electrocatalysts (5% Pd/Al_2O_3 and 5% Pt/Al_2O_3) allowed for only a 35% reduction of the starting material for the same Faraday equivalent. These results are consistent with the literature (2–4, 8, 9) where rhodium is the metal that is most effective in the hydrogenation of a pyrrole ring

3A	Phosphate solution	1.4	0

[a]Percentage of starting material (SM) remaining at the indicated Faraday equivalent.

compound in classical catalytic hydrogenation. The stability of the metal in the electrolyte is critical: rhodium and platinum electrocatalysts are resistant to acidic conditions but palladium was observed to dissolve in these conditions. The rhodium electrocatalyst was used for the remainder of the experiment.

Influence of the electrolyte

Several types of electrolyte were tested: phosphate solution (1 M KH_2PO_4 – 1 M NaOH; pH = 7.0), borate solution (0.1 M NaCl – 0.05 M boric acid; pH = 2.5), aqueous methanol solution (0.1 M NaCl in 5% H_2O – MeOH), and saline solution (0.1 M NaCl; pH = 1.2).

A limiting factor in the choice of the electrolyte is its pH. A high pH results in hydrolysis of the ester group of the starting material, giving the pyrrole-2-carboxylic acid and the alcohol residue (ryanodol for ryanodine). At low pH (pH < 0), ryanodine loses water through an important cleavage of the diterpenic skeleton leading to the anhydro series (anhydroryanodine (**6**)) (1).

An ECH of **3C** was performed with each electrolyte, using 5% Rh/Al_2O_3 as the electrocatalyst. The results are shown in Table 1. Aqueous methanol solution was shown to be a relatively poor electrolyte for the reaction. These results suggest a modification in quality of adsorption of the pyrrole ring onto the electrocatalyst (eq. [2]) due to the different solvents used.

The results for the other electrolytes were approximately similar. The difference between them is the stability of the hydrogenated product and its recovery. The hydrogenated products are not stable in the phosphate solution: hydrolysis is rapid, leading to proline, not to ester. The recovery of the hydrogenated product with this electrolyte is also quite difficult owing to the presence of the phosphate salts. All the alkyl pyrrole-2-carboxylate molecules used in this study are stable in this electrolyte. We did not use boric acid (borate solution) in the case of ryanodine owing to the formation of a complex between boric acid and the numerous hydroxyl groups of the molecule (1*c*).

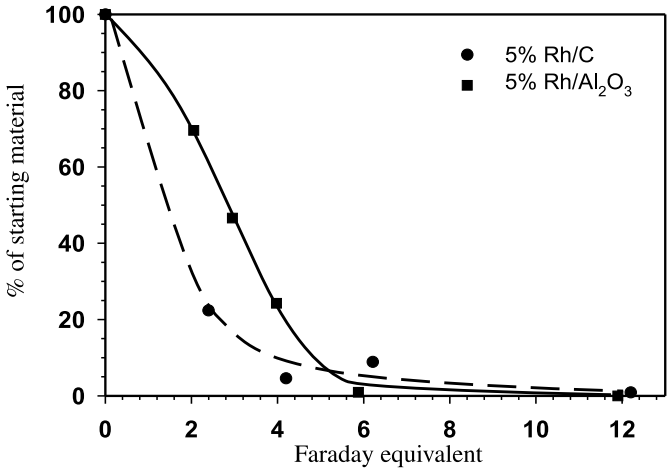
The best electrolyte was the saline solution, and we obtained the best recovery of hydrogenated products with this electrolyte. The ECH process of pyrrole and pyrrole-2-carboxylic acid were more effective with the phosphate solution than with the saline solution (Table 2). These results suggest that the adsorption of the molecule on the electrocatalyst is influenced by the nature and the pH of the electrolyte.

ECH process of the simple alkyl pyrrole-2-carboxylate molecules

Figure 4 shows the ECH of the different alkyl pyrrole-2-carboxylate molecules under the same conditions (5% Rh/Al_2O_3 and saline solution). We can see that the rate of hydrogenation of pyrrole and pyrrole-2-carboxylic acid is very different from that of the other molecules, as mentioned before. The complete ECH of **3B**, **3C**, and **3D** was achieved using from 1.5 to 1.7 Faraday equivalents. Thus, we can

© 2002 NRC Canada

Fig. 5. The ECH process of ryanodine with two different electrocatalysts (5% Rh/Al_2O_3 and 5% Rh/C) in saline solution.



suppose that the differences between these molecules are not large enough to have a significant influence on the ECH process.

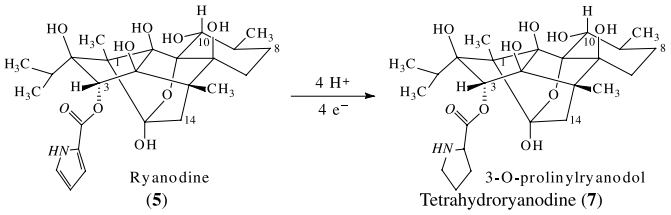
Even if the hydrogenation was shown to be complete, we did not succeed in recovering all of the hydrogenated product. With the techniques used, in the best case, we were able to recover only 59% of the hydrogenated product of **3C** (proline ethyl ester (**4C**)). We recovered 75% of the hydrogenated product of **3B** (proline methyl ester (**4B**)) and 87% of the hydrogenated product of **3D** (proline isopropyl ester (**4D**)). The recovery of the hydrogenated pyrrole-2-carboxylic acid (proline) was difficult owing to the phosphate salts (ECH with phosphate electrolyte). We recovered, in the best case, only 28% of proline. The yield of recovery of pyrrolidine is quite difficult to determine owing to its great volatility. The purity of recovered pyrrolidine was evaluated by GC to be 95%. The SPE technique cannot be used to recover the hydrogenated product of the simple alkyl pyrrole-2-carboxylate molecules.

ECH process of ryanodine

The results of the ECH of ryanodine are presented in Fig. 5. The ECH was attempted with two electrocatalysts, 5% Rh/Al_2O_3 and 5% Rh/C (activated charcoal). With ryanodine more Faraday equivalents are needed to hydrogenate the totality of the starting material owing to the greater dilution (3.2 mM of ryanodine vs. 24 mM for a simple alkyl pyrrole-2-carboxylate molecule). The ECH process with 5% Rh/C electrocatalyst seems to be faster than with 5% Rh/Al_2O_3, but there is stronger adsorption of the hydrogenated product. With 5% Rh/C, we recovered only 7% of the hydrogenated ryanodine vs. 73% with 5% Rh/Al_2O_3 electrocatalyst.

Tetrahydroryanodine (**7**) (hydrogenated ryanodine) (Fig. 6) can be identified by ^1H NMR spectroscopy. The proton supporting the proline moiety (HC(3)) appears at a different position for each diastereomers (D or L). The ^1H NMR spectrum of hydrogenated ryanodine shows an equal amount of the two diastereomers. This reveals the equal accessibility of both sides of the pyrrole ring. These epimers are invisible

Fig. 6. Electrocatalytic hydrogenation of ryanodine.



under UV and are very close in polarity; we did not attempt to separate them.

Tetrahydroryanodine (3-O-prolinylryanodol) (7)

White solid. ^1H NMR (CD_3OD) (ppm): 5.55 and 5.58 (2 × s, 1H, HC3), 3.77 (d, 1H, 10.2 Hz, HC10), 3.73 (m, 1H, HC2′), 3.06 (m, 1H, H_AC5'), 2.86 (m, 1H, H_BC5'), 2.33 (m, 1H, H_AC14), 2.25–2.00 (m, 3H, HC3′, HC13 and $H_{ax}C7$), 2.00–1.70 (m, 5H, HC3′, H_2C4', HC9 and H_BC14), 1.59–1.49 (m, 2H, $H_{eq}C7$ and $H_{ax}C8$), 1.36 (s, 3H, CH_3(C1)), 1.30–1.25 (m, 1H, $H_{eq}C8$), 1.10 (d, 3H, CH_3(C18)), 1.02 (d, 3H, CH_3(C9)), 0.98 (d, 3H, CH_3(C5)), 0.75 (2d, 3H, CH_3(C19)). MS *m/e*: 498 ($[MH]^+$). HR-MS calcd. for $C_{25}H_{40}NO_9$: 498.2703; found: 498.2706.

Catalytic hydrogenation of ryanodine

To our knowledge, the pyrrole ring of ryanodine has never been reduced by a classical catalytic hydrogenation. In our experiments, palladium and platinum catalysts over different supports were not effective in reducing the aromatic ring at atmospheric pressure. The electrocatalytic hydrogenation gave us excellent results. The classical catalytic hydrogenation with 5% Rh/Al_2O_3 in methanol allowed for only 33% hydrogenation of ryanodine after 4 days. When the saline solution (0.1 M NaCl; pH = 1.2) and the same catalyst were used in classical hydrogenation, the reaction was completed after 6 to 12 h. These results can be explained by the difference of adsorption of ryanodine onto the catalyst according to the solvent used. The quantity of solvent, catalyst, and starting material were the same as for the ECH process. All the classical catalytic hydrogenation experiments of this study were done at atmospheric pressure.

Conclusion

The hydrogenation of an alkyl pyrrole-2-carboxylate compound is possible using an electrocatalytic hydrogenation (ECH) process. We have shown that the hydrogenation reaction is specific to the pyrrole ring of alkyl pyrrole-2-carboxylate and does not modify the ester function of the molecule. The ECH of **3B**, **3C**, and **3D** was found to be most effective with rhodium electrocatalyst (5% Rh/Al_2O_3) in saline solution (0.1 M NaCl at pH = 1.2). Pyrrole and pyrrole-2-carboxylic acid ECH gave better results in phosphate solution (1 M KH_2PO_4 – 1 M NaOH; pH = 7.0). All the simple alkyl pyrrole-2-carboxylate compounds were totally hydrogenated after the passage of 1.7 Faraday equivalents of electrical charge.

© 2002 NRC Canada

The ECH process can be used to hydrogenate a complex molecule like ryanodine. Once again, the hydrogenation was complete but there was no diastereoselection in the formation of the reduced compound because of easy access of hydrogen to both sides of the pyrrole ring. The hydrogenation of ryanodine proves that the ECH process can be used efficiently in the selective modification of complex molecules. The biological activity of the new tetrahydroryanodines is currently under study by W. Welch, University of Nevada at Reno, Nevada.

Acknowledgments

We are grateful to Professor W. Welch, Department of Biochemistry, University of Nevada, Reno, who allowed us to do this work with subcontracts of research funded by the National Science Foundation (NSF). We also thank Professor Alan J. Williams, Department of Cardiac Medicine, Imperial College School of Medicine at the National Heart and Lung Institute (NHLI), London, U.K., for a research contract from the British Heart Foundation. The study was also financially supported by the Natural Sciences and Engineering Research Council of Canada (NSERC) and the Fonds FCAR du Québec. We wish to thank Dr. N. Pothier and Mr. G. Boulay, Département de Chimie, Université de Sherbrooke, for their technical assistance (NMR spectroscopy and MS).

Fast, efficient syntheses of linear poly(dipyrromethene)s

Qingqi Chen and David Dolphin

Abstract: The synthesis of three octapyrrolic, **8**–**10**, and four dodecapyrrolic, **15**–**18**, oligomers is reported. They are linear poly(dipyrromethene)s and potential ligands as building blocks for supramolecular architectures through self-assembly. Octapyrrolic oligomers **8**–**10** were prepared in 90–95% yields by condensation of 2 equiv of a tripyrrolic compound **4** with 1 equiv of diformyldipyrrolic compounds **5**–**7**. A similar procedure, involving the condensation of 2 equiv of a pentapyrrolic starting material **13** with 1 equiv of **5**–**7** or **14**, was found to give rise to the corresponding dodecameric systems **15**–**18** in 41–56% yields.

Key words: poly(dipyrromethene), linear polypyrroles, dipyrromethane, dipyrromethene.

Résumé : On rapporte la synthèse de trois oligomères octapyrroliques (**8**–**10**) et de quatre dodécapyrroliques (**15**–**18**). Il s'agit de poly(dipyrrométhènes) linéaires et des ligands potentiels comme blocs pouvant servir à la construction d'architectures supramoléculaires par le biais d'autoassemblages. Les oligomères octapyrroliques **8**–**10** ont été préparés avec des rendements allant de 90 à 95% par le biais de condensations de deux équivalents d'un composé tripyrrolique (**4**) avec un équivalent de composés diformylpyrroliques (**5**–**7**). Une procédure semblable impliquant la condensation de deux équivalents d'un produit de départ pentapyrrolique (**13**) avec un équivalent de composés **5**–**7** ou **14** conduit à la formation des systèmes dodécamères correspondant (**15**–**18**) avec des rendements allant de 41 à 56%.

Mots clés : poly(dipyrrométhène), polypyrroles linéaires, dipyrrométhane, dipyrrométhène.

[Traduit par la Rédaction]

Introduction

Dipyrromethenes (**I**) are yellow colored and fully conjugated flat compounds containing 10-π-electrons and can be precursors of chlorins; expanded, contracted, and isomeric porphyrins (1); bilirubins (2); biliverdin (2); and many other bile pigments (3). They have been extensively used in the synthesis of porphyrins (1) and linear polypyrroles (4). Owing to their stable monoanionic nature, dipyrromethenes have been found to be useful ligands for a variety of metal ions (5). In addition, bile pigments containing dipyrromethene moieties linked by a methylene group such as biladienes-*ac* (**II**) are useful ligands for the formation of well-defined architectures through self-assembly (6). A salient feature of dipyrromethene superstructures is that counterions are not required, since the dipyrromethene unit is a monoanionic ligand and the complex will be neutral when chelated with divalent metal ions. This is in contrast to bipyridine ligands, the standard building blocks for supramolecular assemblies used by Lehn and co-workers (7, 8).

The use of dipyrromethenes as novel ligands to build double helical supramolecules was originally proposed by one of us in 1965 (9), when it was suggested that a 2:2 bis(dipyrromethene) ligand – Co^{II} complex exists in a helical conformation. Since then several crystal structures of 2:2 biladiene-*ac* ligand – M^{II} complexes have been reported where the 2:2 complex existed as a helix (10). Our group re-examined these reactions (6) and explored the use of a 2,2-spacer between dipyrromethene units (such as **III**) and the 3,3′- positions (such as **IV**) and hexapyrins (**V**) (Scheme 1).

Like biladienes-*ac* (**II**), bis(dipyrromethenes) (**III**) and hexapyrrins (**V**) reacted with Zn^{II} to form a double stranded helical complex (5), while the complex of the 3,3′-bidipyrromethene **IV** ($n = 0$) with Zn^{II} showed triangular geometry with the ligand linking the three metal centers in an overlapping progressive fashion. For each ligand one dipyrromethene binding domain lies above the averaged plane of the molecule, while the other dipyrromethene lies below this plane (Scheme 2).

To extend our work, we were interested in linear polydipyrromethenes, which include 2,2′-linked (**A**), 3,3′-linked (**B**), 3,3′- sulfur bridged (**C**), and 2,2- directly linked intermediates (**D**). In this paper we will report on the synthesis and characterization of novel ligands that contain multiple dipyrromethene units.

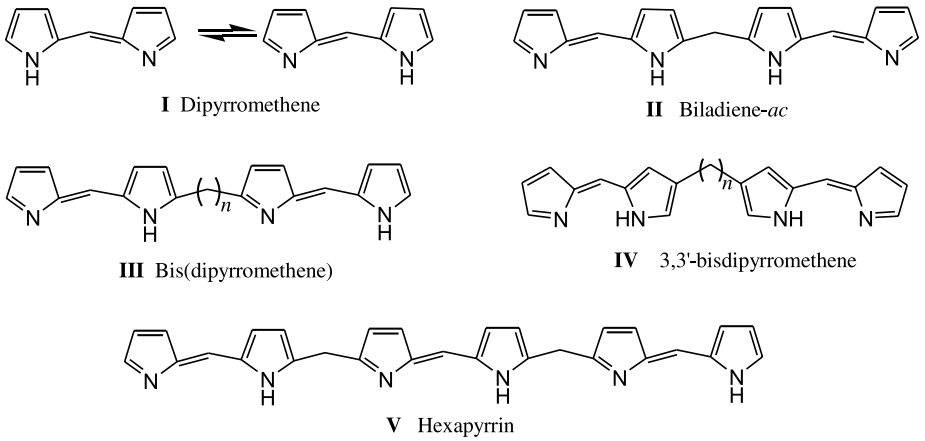
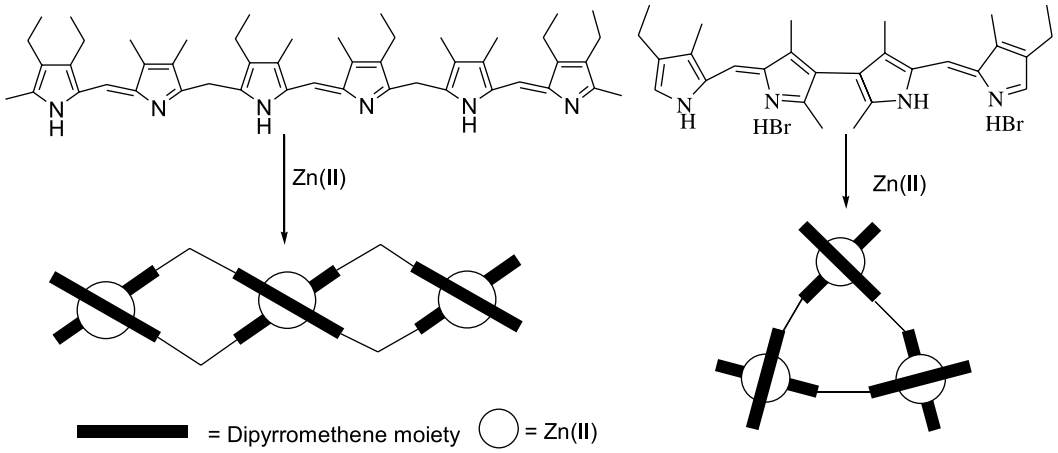
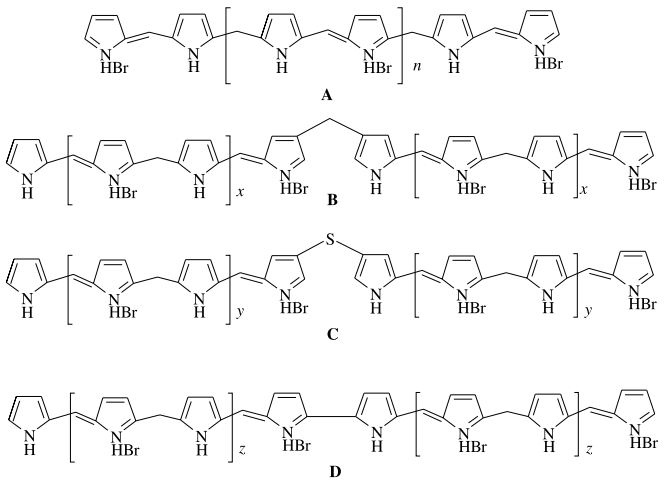
Scheme 1.



Scheme 2.





Linear polypyrroles such as hexanornonapyrrin (11*a*), decahydrohexapyrrin (11*b*–11*d*), and pentapyrrole (11*e*) have been recently reported and characterized. However, synthetic methods for linear oligopyrroles containing more than three dipyrromethene units are not currently available.

The key precursor required for the synthesis of **8**–**9** was tripyrrole **4**. It was synthesized from the known 5-acetoxymethylpyrrole (**1**) via two steps, as shown in Scheme 3. Briefly, the procedure involved first treatment of **1** with pyrrole at reflux in a mixture of *p*-toluenesulfonic acid and dichloromethane or at 40°C in acetic acid, followed by purification of the reaction mixture by direct crystallization from dichloromethane–hexane. The asymmetric dipyrromethane **2** was obtained in 66% yield. Acid-catalyzed coupling of this intermediate with 3,4,5-trimethyl-5-formylpyrrole (**3**) then afforded the requisite hydrobromide salt of tripyrrole **4** in an 86% yield after crystallization.

Once **4** was in hand, the synthesis of the target compounds **8**–**10** proved straightforward. After simple precipitating using anhydrous ether, the acid-catalyzed condensation of 2 equiv of **4** and 1 equiv of **5**–**7** in methanol–dichloromethane was found to give the desired linear octapyrrins **8**–**10** as their corresponding tetrahydrobromide salts, in excellent yields. (detailed in Scheme 3).

Our synthetic procedure for dodecapyrrins **15**–**18** is outlined in Schemes 4 and 5. For this purpose, the key precursor **13** was required; this was prepared from 5-acetoxymethylpyrrole **1a** via two steps. The procedure involved first treating **1** with the 5-unsubstituted 2-formylpyrrole (**11**) at 50°C in acetic acid or at room temperature in a mixture of dichloromethane and *p*-toluenesulfonic acid. Crystallization from dichloromethane–hexane gave the asymmetric dipyrro-

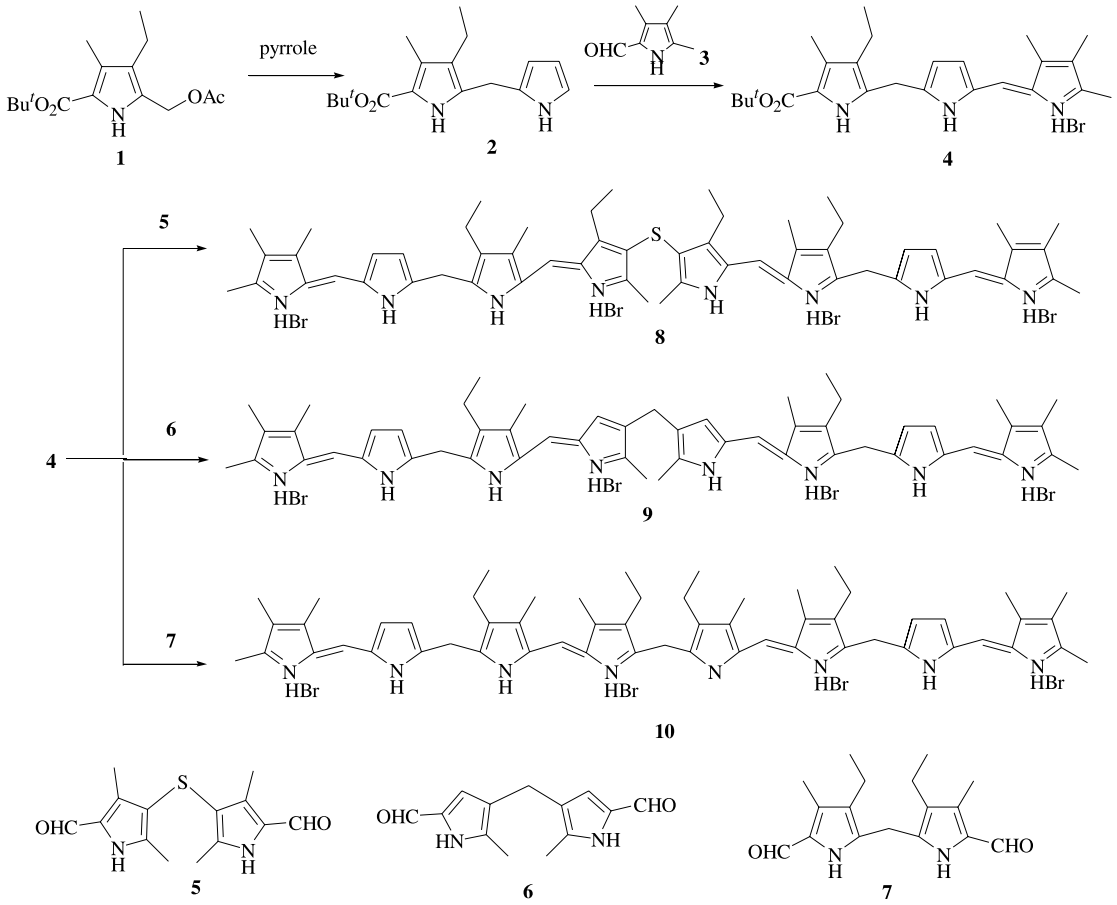
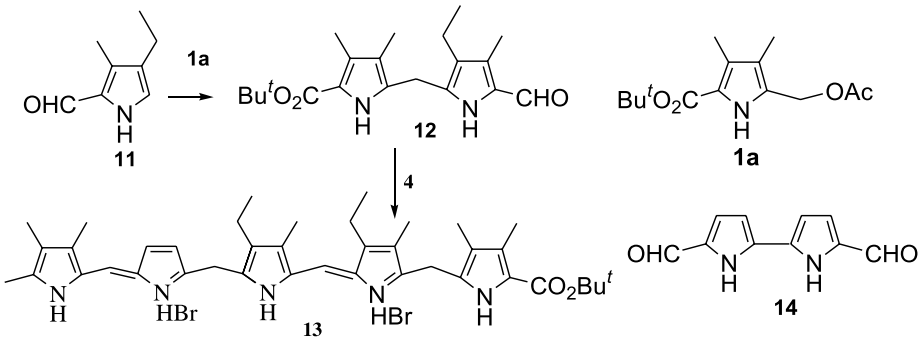


Scheme 4.



methane **12** in 72% yield. Condensation of **12** with tripyrrole acid, generated in situ by treating **4** with trifluoroacetic acid at room temperature for 20 min, afforded the desired intermediate as the dihydrobromide salt **13** in 93% yield after precipitating with anhydrous ether. Acid-catalyzed condensation between **14** and 2 equiv of **13** with 1 equiv of **5**–**7** gave, in good yields, the desired dodecapyrrins **15**–**18** as their corresponding hexahydrobromide salts.

Experimental section

5-Acetoxymethyl-4-ethyl-3-methyl-2-*tert*-butoxycarbonylpyrrole (**1**) (12), 5-acetoxymethyl-3,4-dimethyl-2-*tert*-butoxycarbonylpyrrole (**1a**) (12), 3,4,5-trimethyl-2-formyl-pyrrole (**3**) (13), bis(2,4-dimethyl-5-formyl-pyrrole-3-yl) sulfide (**5**) (14), 5-methyl-2-benzoxycarbonylpyrrole (15), 5,5′-diformyl-4,4′-dimethyl-3,3′-diethyl-dipyrromethane **7** (14), 3-methyl-4-ethyl-2-formylpyrrole (**11**) (16), and 5,5′-diformylbipyrrole (**14**) (15) were synthesized according to the previously reported procedures.

5,5′-Bisethoxycarbony-2,2′-dimethyl-3,3′-dipyrromethane

Paraformaldehyde (1.40 g, 47 mmol, 2.0 mol equiv) was suspended in ethanol (300 mL) containing hydrochloric acid (33%, 5 mL). The mixture was stirred with heating until all

1,2-Bis(5-carboxy-2,4-dimethyl-pyrrole-3-yl)methane

1,2-Bis(5-benzoxycarbonyl-2-methylpyrrole-3-yl)methane (20 g, 63 mmol) was dissolved in tetrahydrofuran (400 mL). Palladium on carbon (10%, 1.0 g) and triethylamine (1 mL) were added to this solution. The mixture was stirred for 20 h under hydrogen at atmospheric pressure and room temperature. The catalyst was removed by filtration. After removal of solvent, the residue was dried under vacuum. The product was obtained as a white powder (16 g, 98%), which was used directly for the next step without further purification. An analytical sample was purified by twice repeating the following procedure: the crude product (100 mg) was dissolved in aqueous saturated sodium bicarbonate (5 mL); the mixture was then filtrated to remove any insoluble materials and carefully adjusted to pH 4 with glacial acetic acid. The white precipitate was collected by suction filtration; mp 220°C (decomposition temperature (dec.)). ^{1}H NMR (200 MHz, DMSO-d_6) (ppm) δ: 2.10 (s, 6H, 3 CH_3), 3.30 (s, 2H, CH_2), 6.40 (s, 2H, 2 pyrr-H), 11.02 (s, 2H, 2 COOH), 11.85 (s, 2H, 2 NH). ^{13}C NMR (50 MHz, DMSO-d_6) (ppm) δ: 9.30 (CH_3), 19.20 (CH_2), 119.90, 127.55, 131.44, 137.55, 161.33 (COO). Anal. calcd. for $C_{13}H_{14}N_2O_4$: C 59.54, H 5.38, N 10.68; found: C 59.33, H 5.28, N 10.39.

5-*tert*-Butoxycarbonyl-4-methyl-3-methoxycarbonylmethyl-2,2′-dipyrromethane (2)

Method A

A 500 mL three-necked, round-bottomed flask equipped with magnetic stirrer bar and a nitrogen inlet was charged with 5-acetoxymethyl-4-ethyl-3-methyl-2-*tert*-butoxycarbonylpyrrole (**1**, 10.0 g, 35.5 mmol) and acetic acid (250 mL). After 20 min of stirring under nitrogen, pyrrole (2.86 g, 42.7 mmol, 1.2 mol equiv) and *p*-toluenesulfonic acid monohydrate (330 mg) were added. The reaction mixture was stirred at 40°C overnight. The solvent was removed under vacuum. The residue was taken into dichloromethane (500 mL) and washed successively by water (2 × 100 mL), aqueous saturated sodium bicarbonate (2 × 100 mL), and saturated brine (100 ml). After drying over anhydrous sodium sulfate and removing solvent under vacuum, the residue was crystallized from dichloromethane–hexane to give the product (3.33 g, 32%).

Method B

A 500 mL three-necked, round-bottomed flask equipped with a magnetic stirrer, nitrogen inlet, and reflux condenser was charged with 5-acetoxymethyl-4-ethyl-3-methyl-2-*tert*-butoxycarbonylpyrrole (**1**, 18.6 g, 66 mmol), pyrrole (4.6 mL, 66 mmol, 1.0 mol equiv), and dichloromethane (200 mL). The mixture was stirred at room temperature for 30 min while nitrogen was bubbled through the solution. *p*-Toluenesulfonic acid monohydrate (250 mg) was then added in one portion. The solution immediately turned yellow-red. The mixture was stirred under reflux for 30 min. TLC then showed the reaction was complete (CH_2Cl_2, 5-acetoxymethylpyrrole R_f = 0.4, product R_f = 0.5, and pyrrole R_f = 0.9). The product dipyrromethane turned yellow-red, pyrrole

© 2002 NRC Canada

turned to brown-black, and the starting 5-acetoxymethyl-pyrrole remained unchanged upon contacting the TLC plate over bromine vapor. After cooling to room temperature, triethylamine (1 mL) in methanol (5 mL) was added to neutralize the acid. Solvent was completely removed under vacuum (first rotovapor, then high vacuum). The yellow semi-solid was mixed with aqueous methanol (90%, 30 mL) and ultrasonicated to aid solidification. The crude material was immediately collected by suction filtration to yield the expected product (11.6 g, 61%), which was pure enough for subsequent use, as judged by ^{1}H NMR. Note that this compound is not very stable and should be stored in the dark and at low temperature. mp 120–122°C. ^{1}H NMR (200 MHz, $CDCl_3$) (ppm) δ: 1.05 (t, J = 7.32 Hz, 3H, CH_3), 1.50 (s, 9H, 3 CH_3), 2.20 (s, 3H, CH_3), 2.30 (q, J = 7.32 Hz, 2H, CH_2), 3.80 (s, 2H, CH_2), 5.80 (s, 1H, pyrrole-H), 6.05 (s, 1H, pyrrole-H), 6.60 (s, 1H, pyrrole-H), 7.60 (s, 1H, NH), 8.60 (s, 1H, NH). ^{13}C NMR (50 MHz, $CDCl_3$) (ppm) δ: 10.23 (CH_3), 14.55 (CH_3), 24.44 (CH_2), 28.33 (CH_2), 29.35 (CH_3), 86.88 ($OCMe_3$), 113.44, 114.55, 116.77, 123.55, 124.56, 125.44, 127.44, 128.33, 161.20 (COO). EI-MS (150 °C) *m/z* (%): 288 ([M^+], 52), 232 (40), 165 (100), 147 (25). Anal. calcd. for $C_{17}H_{24}N_2O_2$: C 70.80, H 8.39, N 9.71; found: C 70.60, H 8.61, N 8.53.

1-*tert*-Butoxycarbonyl-2-methyl-3-ethyl-12,13,14-trimethyl-4,5-dihydro-tripyrrin hydrogen bromide salt (4)

A 250 mL round-bottomed flask equipped with magnetic stirrer bar was charged with 2-*tert*-butoxycarbonyl-3-methyl-4-methoxycarbonylmethyl-dipyrromethane (**2**) (1.0 g, 3.47 mmol), 3,4,5-trimethyl-2-formyl-pyrrole (**3**) (0.48 g, 3.47 mmol, 1.0 mol equiv), dichloromethane (50 mL), and methanol (20 mL). Hydrogen bromide (48% in glacial acetic acid, 3 mL) was added with stirring. The red mixture was allowed to stir for 2 h at room temperature. Anhydrous ether (50 mL) was added and the suspension was allowed to stir for another 30 min. The red solid was collected by suction filtration and washed with anhydrous ether. The crude product was suspended in methanol (50 mL) containing 5 drops of hydrogen bromide (45% in glacial acid) and stirred for 30 min. The solid was collected by filtration (1.46 g, 86%). An analytical sample was obtained as follows: crude product was dissolved in a minimum amount of dichloromethane, and methanol (~1 mL) containing a drop of hydrogen bromide (45% in glacial acid) was added, followed by anhydrous ether to precipitate the product. The red solid was collected by suction filtration; mp 220 (dec.). UV–Vis (CH_2Cl_2) (nm): $\lambda_{max}(\varepsilon)$ = 483 (80 400). ^{1}H NMR (200 MHz, $CDCl_3$) (ppm) δ: 1.05 (t, J = 7.35 Hz, 3H, CH_3), 1.55 (s, 9H, $3CH_3$), 2.00 (s, 3H, CH_3), 2.20 (s, 6H, 2 CH_3), 2.40 (q, J = 7.35 Hz, 2H, CH_2), 2.60 (s, 3H, CH_3), 4.25 (s, 2H, CH_2), 6.30 (s, 1H, pyrrole-H), 7.00 (s, 1H, -CH=), 7.05 (s, 1H, pyrrole-H), 10.05 (s, 1H, NH), 13.10 (s, 1H, NH), 13.20 (s, 1H, NH). ^{13}C NMR (50 MHz, $CDCl_3$) (ppm) δ: 8.89 (CH_3), 10.29 (CH_3), 13.55 (CH_3), 15.55 (CH_3), 17.28 (CH_3), 24.77 (CH_2), 28.71 (CH_3), 30.05 (CH2), 80.20 ($OCMe_3$), 114.93, 119.57, 123.57, 124.13, 125.83, 126.11, 126.39, 127.33, 128.28, 133.13, 144.65, 152.49, 159.68 (C=N), 160.91 (COO). FAB-MS *m/e*: 408 ([M^+ + 1]), 334. Anal. calcd. for $C_{25}H_{33}N_3O_2$·HBr: C 61.47, H 7.02, N 8.60, Br 16.31; found: C 61.58, H 7.10, N 8.32, Br 16.25.

5,5′-Diformyl-2,2′-dimethyl-3,3′-dipyrromethane (6)

5,5′-Dicarboxy-2,2′-dimethyl-3,3′-dipyrromethane (3.0 g, 11 mmol) was suspended in trifluoroacetic acid (15 mL). The mixture was stirred at 40°C until all the solid had dissolved. The mixture was then cooled to –5°C using an ice–salt bath. Trimethyl orthoformate (4.5 mL) was added dropwise over 5 min and the mixture was allowed to stir another 10 min before being poured into a solution of 10% ammonia (100 mL), which was pre-cooled to 0°C. The yellow-brown precipitated was collected by filtration and washed with water. After drying under vacuum and crystallizing from dichloromethane–hexane, the title compound was obtained (2.1 g, 80%); mp 210–212°C. ^{1}H NMR (200 MHz, $CDCl_3$) (ppm) δ: 1.90 (s, 6H, 2 CH_3), 3.30 (s, 2H, CH_2), 6.35 (s, 2H, 2 pyrr-H), 9.40 (s, 2H, 2 CHO), 10.50 (s, 2H, 2NH). ^{13}C NMR (50 MHz, $CDCl_3$) (ppm) δ: 9.50 (CH_3), 19.50 (CH_3), 121.44, 126.78, 130.45, 136.55, 177.55 (CHO). LSIMS *m/e*: 231 ([M^+ + 1]). Anal. calcd. for $C_{13}H_{14}N_2O_2$: C 67.81, H 6.13, N 12.17; found: C 67.51, H 5.90, N 11.89.

General procedure for 8–10

Tripyrrole (**4**, 100 mg, 0.20 mmol) was suspended in trifluoroacetic acid (5 mL), and stirred at room temperature until all solid had dissolved. To this brown-red mixture **5**, **6**, or **7** (0.10 mmol, 0.5 mol equiv) was added under continuous stirring. After 10 min, a mixture of dichloromethane (20 mL), methanol (20 mL), and hydrogen bromide (48% in acetic acid) was added. The red mixture was stirred at room temperature and anhydrous ether (100 mL) was added. The suspension was then allowed to stir for another 30 min. The red solid was collected by suction filtration and washed with anhydrous ether. The crude product was suspended in methanol (50 mL) containing 5 drops of hydrogen bromide (45% in glacial acid) and stirred at room temperature for 30 min. The solid was collected by filtration to afford the expected product. An analytic sample was obtained by repeating the following procedure three times: The crude product (~20 mg) was dissolved in a minimum amount of trifluoroacetic acid. To this red mixture, dichloromethane (1 mL) and methanol (1 mL) containing a drop of HBr (48% in acetic acid) were added, followed by anhydrous ether to precipitate the product. The red solid was collected by suction filtration.

5-*tert*-Butoxycarbonyl-3,4-dimethyl-5′-formyl-4′-ethyl-3′-methyl-2,2′-dipyrromethane (12)

Method A

A 250 mL three-necked, round-bottomed flask equipped with a magnetic stirrer bar and a nitrogen inlet was charged with 5-acetoxymethyl-3,4-dimethyl-2-*tert*-butoxycarbonylpyrrole (3.44 g, 12.5 mmol) and acetic acid (100 mL). Nitrogen was bubbled through the solution with stirring, and after 20 min 2-formyl-3-ethyl-4-methylpyrrole (1.71 g, 12.5 mmol, 1.0 mol equiv) was added. The reaction mixture was stirred at 50°C overnight. The solvent was removed under vacuum (rotovapor). The residue was taken up in dichloromethane (200 mL) and washed successively with water (2 × 100 mL), aqueous saturated sodium bicarbonate (2 × 100 mL), and saturated brine (100 ml). After drying over anhydrous sodium sulfate and removing solvent (rotovapor), the solid was crystallized from dichloromethane–hexane, yielding 0.85 g (20%).

Method B

A 250 mL three-necked, round-bottomed flask equipped with a magnetic stirrer, nitrogen inlet, and a reflux condenser was charged with 5-acetoxymethyl-3,4-dimethyl-2-*tert*-butoxycarbonylpyrrole (1.94 g, 7.30 mmol), 4-methyl-3-ethyl-2-formylpyrrole (1.0 g, 7.30 mmol, 1.0 mol equiv), and dichloromethane (150 mL). The mixture was stirred at room temperature for 30 min while nitrogen was bubbled through the solution. *p*-Toluenesulfonic acid monohydrate (150 mg) was then added in one portion. The solution turned yellow-red immediately. The mixture was stirred under reflux for 30 min. TLC showed the reaction was complete (CH_2Cl_2, 5-acetoxymethylpyrrole R_f = 0.4, product R_f = 0.5, and pyrrole R_f = 0.9). The product dipyrromethane turned red, the pyrrole turned brown-black, and the starting 5-actoxymethylpyrrole remained unchanged upon contacting the TLC plate over bromine vapor. After cooling to room temperature, triethylamine (1 mL) in methanol (5 mL) was added to neutralize the acid. Solvent was completely removed under vacuum (first rotovapor, then high vacuum). The yellow semi-solid was mixed with aqueous methanol (90%, 30 mL) and ultrasonicated to aid solidification. The suspension was kept at 0°C for 4 h. The solid was collected by suction filtration to yield the product (1.80 g, 72%), mp 189–191°C. ^{1}H NMR (200 MHz, $CDCl_3$) (ppm) δ: 1.02 (t, *J* = 7.32 Hz, 3H, CH_3), 1.45 (s, 9H, 3 CH_3), 1.70 (s, 3H, CH_3), 1.75 (s, 3H, CH_3), 1.95 (s, 3H, CH_3), 2.50 (q, *J* = 7.32 Hz, 2H, CH_2), 3.80 (s, 2H, CH_2), 9.25 (s, 1H, CHO), 9.85 (s, 1H, NH), 10.80 (s, 1H, NH). ^{13}C NMR (50 MHz, $CDCl_3$) (ppm) δ: 8.85 (CH_3), 9.00 (CH_3), 10.67 (CH_3), 16.49 (CH_3), 17.35 (CH_2), 28.58 ($OC(CH_3)_3$), 80.18($OCMe_3$), 116.88, 117.35, 119.33, 126.22, 127.55, 127.99, 137.40, 140.53, 161.35 (COO), 176.49 (CHO). General procedure for 15–18

The pentapyrrole (**13**, 100 mg, 0.125 mmol) was suspended in trifluoroacetic acid (5 mL) and stirred at room temperature for 10 min until all the solid had dissolved. To this brown-red solution was added a solution of **5**, **6**, **7**, or **14** (0.0625 mmol, 0.5 mol equiv) in dichloromethane (20 mL) under continuous stirring. After 10 min, a mixture of methanol (20 mL) and hydrogen bromide (2 mL, 48% in acetic acid) was added. The red mixture was stirred for 3 h at room temperature. Anhydrous ether (100 mL) was added and the suspension was allowed to stir for another 30 min. The red solid was collected by suction filtration and washed by anhydrous ether containing a few drops of HBr (48% in acetic acid) to afford the expected product. An analytic sample was obtained by repeating the following procedure three times: the crude product (~20 mg) was dissolved in dichloromethane (1 mL), and methanol (1 mL) containing a few drops of HBr (48% in acetic acid) was added, followed by the addition of anhydrous ether to precipitate the product. The red solid was collected by suction filtration.

Conclusion

In summary, we have developed a fast, highly efficient synthetic methodology that appears to be of versatile utility in terms of allowing for the construction of linear polypyrromethenes. The resulting compounds are stable and exist as the corresponding hydrobromide salts. Self-assembly of those novel ligands with transition metal ions is currently being studied.

Kinetics and mechanism of the oxidation of disaccharides by Cr^{VI}

Viviana Roldán, Juan Carlos González, Mabel Santoro, Silvia García, Nieves Casado, Silvina Olivera, Juan Carlos Boggio, Juan Manuel Salas-Peregrin, Sandra Signorella, and Luis F. Sala

Abstract: The oxidation of D-lactose, D-maltose, D-melibiose, and D-cellobiose by Cr^{VI} yields the corresponding aldobionic acid and Cr^{3+} as final products when an excess of reducing disaccharide over Cr^{VI} is used. The rate law for the Cr^{VI} oxidation reaction is expressed by $-d[Cr^{VI}]/dt = k_H$ [disaccharide][Cr^{VI}], where the second-order kinetic constant, k_H, depends on [H^+]. The relative reactivity of the disaccharides with Cr^{VI} is expressed as follows: Mel > Lac > Cel > Mal, at 33°C. In acid medium, intermediate Cr^V forms and reacts with the substrate faster than Cr^{VI}. The EPR spectra show that five- and six-coordinate oxo-Cr^V intermediates are formed, with the disaccharide acting as bidentate ligand. Five-coordinate oxo-Cr^V species are present at any [H^+], whereas six-coordinate ones are observed only at pH < 2, where they rapidly decompose to the redox products. In the pH 3–7 range, where hexa-coordinate oxo-Cr^V species are not observed, Cr^V complexes are stable enough to remain in solution from several days to several months.

Key words: chromium, saccharides, kinetics, EPR.

Résumé : Lorsqu'on utilise un excès de du disaccharide réducteur par rapport au Cr(VI), l'oxydation du D-lactose, du D-maltose, du D-melibiose et du D-cellobiose par le Cr(VI) conduit à la formation de l'acide aldobionique correspondant et de Cr^{3+} comme produits finaux. La constante de vitesse de la réaction pour la réaction d'oxydation par le Cr(VI) peut être exprimée par l'équation $-d[Cr(VI)]/dt = k_H$ [disaccharide] [Cr(VI)], dans laquelle la constante cinétique du deuxième ordre, k_H, dépend de [H^+]; à 33°C, les réactivités relatives des disaccharides vis-à-vis du Cr(VI) sont les suivantes: Mel > Lac > Cel > Mal. En milieu acide, il se forme du Cr(V) comme intermédiaire qui réagit avec le substrat plus rapidement que le Cr(VI). Les spectres de RPE montrent qu'il se forme des intermédiaires penta- et hexacoordinés d'oxo-Cr(V) dans lesquels le disaccharide agit comme ligand bidentate. Les espèces pentacoordinées oxo-Cr(V) sont présentes à toutes les [H^+] alors qu'on n'observe les espèces hexacoordinées qu'à des pH < 2 et que dans ces conditions elles se décomposent rapidement en produits d'oxydoréduction. À des pH allant de 3 à 7 où on n'observe pas de formation des espèces hexacoordinées d'oxo-Cr(V), les complexes de Cr(V) sont suffisamment stables pour être observés en solution pour des périodes allant de plusieurs jours à plusieurs mois.

Mots clés : chrome, disaccharides, cinétique, RPE.

Introduction

Compounds of Cr^{VI} represent a potential environmental hazard because of their mammalian carcinogenicity and toxicity (1, 2), and they are known to bioaccumulate in flora and fauna, creating ecological problems (3–5). The observation of Cr^V and Cr^{IV} intermediates in the selective oxidation of organic substrates by Cr^{VI} and their implication in the mechanism of Cr-induced cancers (1, 6–7) has generated a considerable amount of interest in their chemistry and biochemistry (8–10).

The major coordination sites involved in Cr binding are hydroxo, alcoholato, carboxylato, and thiolato donor groups (2, 11–12). Five-membered, *O*-donor, chelate ligands, such as 1,2-diols and 2-hydroxy acids, are effective as non-enzymatic reductants (at low pH values) and chelates for high oxidation states of Cr (13–19). Carbohydrates constitute 5–20% (average 10%) of soil organic matter, and they

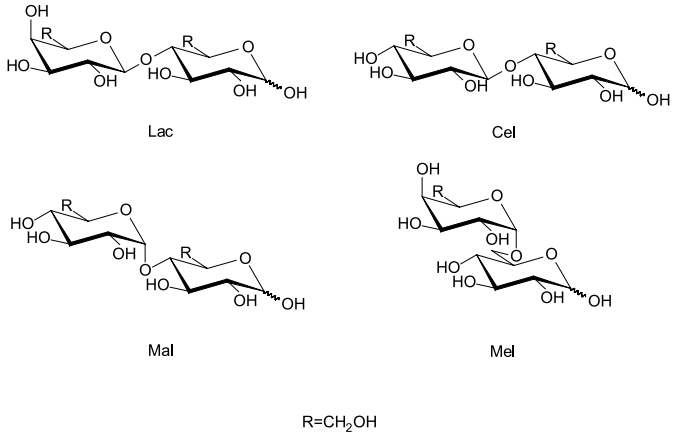
constitute more than 50% of dry matter in plants (20). For this reason, it is interesting to examine the ability of saccharides and their derivatives to reduce or stabilize high oxidation states of Cr, to understand their potential roles in the biochemistry of Cr.

We are studying the possible fate of Cr^{VI} and Cr^{V} in biological systems by examining reactions of Cr^{VI} with low-molecular-weight molecules (21–37). Our studies on the reduction of Cr^{VI} and the intermediate Cr^{V} by aldoses (21–26), deoxyaldoses (27–28), sugar acids (31, 32, 35), and methyl glycosides (29–30) showed that the relative redox reactivities of these saccharides toward chromate are based on the relative rates of the oxidation vs. complexation processes. In view of some preliminary results obtained on the milk–Cr^{VI} system suggesting the formation of long lived lactose–Cr^{V} species generated by direct reaction of Cr^{VI} with lactose (5), we decided to evaluate the kinetics of the reaction of Cr^{VI} with four disaccharides: D-lactose (Lac), D-maltose (Mal), D-cellobiose (Cel), and D-melibiose (Mel), to determine the influence of the glycoside moiety attached to the C^6 or C^4 of glucose (glc) on the chelating and (or) redox reactivity of the saccharide with high oxidation states of chromium.

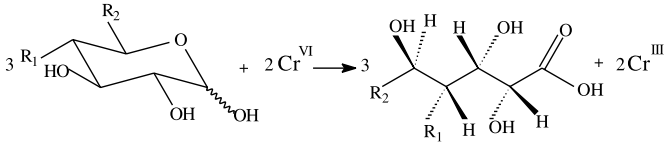


Lac, the most important representative of the β-galactosides, is found in the milk of all mammals up to a concentration of approximately 5% and in some plants in low concentrations. Mal is a product of enzymatic hydrolysis of starch; Mel is a constituent of the trisaccharide raffinose; and Cel is the basic repeating unit of cellulose and lichetin (38). In this work, we study the Cr^{VI} oxidation of these four disaccharides and provide information on the mechanism of oxidation as well as on the structure and stability of the Cr^{V} species formed as redox intermediates.

Experimental

Materials

D-Lactose monohydrate (Anedra, RA-ACS grade), D-maltose monohydrate (Sigma grade, 99%, less than 1.0% of maltotriose and less than 0.3% of D-glucose), D-melibiose



$R_1 = C_6H_{11}O_6$ (Lac, Cel, Mal)
CH_2OH (Mel)

$R_2 = CH_2OH$ (Lac, Cel, Mal)
$C_6H_{11}O_6$ (Mel)

(Sigma grade), D-cellobiose (Pfanshtiehl 99.9%), potassium dichromate (Cicarelli c.a.), potassium chromate (Aldrich grade), glutathione (Sigma grade), acrylonitrile (Aldrich grade), perchloric acid 70% (Merck P.A.), phosphoric acid (Anedra P.A.), and sulfuric acid (Merck P.A.) were used without further purification. Water was purified by deionisation, followed by double distillation from a potassium permanganate solution.

In experiments performed at constant ionic strength (I = 1.0 M) and in different hydrogen ion concentrations, mixtures of sodium perchlorate solutions and perchloric acid solutions were used. Sodium perchlorate solutions were prepared from sodium hydroxide and perchloric acid solutions. The concentration of stock solutions of perchloric acid was determined by titration using standard analytical methods.

The stability of the organic substrate under conditions used in the kinetic studies was tested by paper chromatography and HPLC at given hydrogen ion concentrations.

Caution: Cr^{VI} compounds are human carcinogens, and Cr^{V} complexes are mutagenic and potential carcinogens (39). Contact with skin and inhalation must be avoided. Acrylonitrile is a carcinogen and must be handled in a well-ventilated fume hood (40).

Spectrophotometric measurements

Kinetic measurements were performed by monitoring absorbance changes using a Jasco V-530 spectrophotometer with a fully thermostated cell compartment (±0.2°C). The reactions were followed under pseudo-first-order conditions, using an excess of disaccharide over Cr^{VI}. Reactant solutions were previously thermostated and transferred into a 1-cm pathlength cell immediately after mixing. Experiments were performed at 33°C unless otherwise stated.

The disappearance of Cr^{VI} was followed at 350 nm until at least 80% of the Cr^{VI} was consumed. In the kinetic measurements, the concentration of Cr^{VI} was kept constant at 8.0×10^{-4} M and the disaccharide concentration was varied from 0.08 to 0.36 M. Mixtures of sodium perchlorate and perchloric acid were used to maintain a constant ionic strength (I) of 1.0 M.

The observed pseudo-first-order rate constants (k_{obs}), determined from the slopes of plots of $\ln(A_{350} - A_8)$ vs. time, were averages of at least three determinations and were within ±5% of each other. The first-order dependence of the rate upon $[Cr^{VI}]$ was verified by calculating the k_{obs} values at various $[Cr^{VI}]_0$ ($4.0 \times 10^{-4} - 8.0 \times 10^{-4}$ M) at constant

temperature, initial disaccharide concentration, acidity, and ionic strength.

The formation of Cr^{III} was monitored at 570 nm ($[Cr^{VI}]_o = 8.0 \times 10^{-3}$ M) in the presence of excess disaccharide (0.08 to 0.36 M) in 0.20 M $HClO_4$. Under these conditions, the first-order dependence of the rate upon $[Cr^{VI}]$ was verified and k_{obs} were obtained following the Cr^{III} growth at 570 nm. Initial reaction rates were obtained by fitting the time-dependent data for the absorbance at 570 nm to a polynomial expression (41) and calculating the slope of the tangent at time zero (r_i). First-order rate constants were calculated from these initial rates using the equation $-r_i/(A_o - A_f)$, with average values of the initial rate and calculated estimates of $(A_o - A_f)$. The results at 570 nm are in total agreement with those obtained at 350 nm (Table 1). At the end of the reaction, the two *d-d* bands ascribed to Cr^{III} were observed at λ_{max} = 410 nm (ε = 18 M^{-1} cm^{-1}) and λ_{max} = 570 nm (ε = 15 M^{-1} cm^{-1}). Both visible and UV spectral maxima and intensities are in close agreement with those observed for the $[Cr(H_2O)_6]^{3+}$ ion. These bands are attributable to the octahedral $^4A_{2g} \rightarrow {}^4T_{1g}$ and $^4A_{2g} \rightarrow {}^4T_{2g}$ transitions in O_h symmetry, and are distinctive of the free Cr^{III} aqua complex (42). However, in experiments performed at 20°C the reaction of Cr^{VI} with Lac (33:1 ratio, $[Cr^{VI}] = 12.7 \times 10^{-3}$ M) in 0.2 M $HClO_4$ affords two *d-d* bands at λ_{max} = 409 nm (ε = 26.8 M^{-1} cm^{-1}) and 574 nm (ε = 21.9 $M^{-1}cm^{-1}$) with higher absorbance than expected for $[Cr(OH_2)_6]^{3+}$. These two bands agree closely with those of the acid solutions of the Cr^{III} – aldobionic acid complex, which was independently prepared. The intensity of these *d-d* bands slowly decreases with time toward the two bands with the molar absorption coefficients corresponding to the $[Cr(H_2O)_6]^{3+}$ ion. This behaviour has been observed previously, i.e., when a Cr^{III} complex forms as the final redox product and then hydrolyses to the Cr^{3+} ion (29, 31, 43, 44). The hydrolysis of the Cr^{III} – aldobionic acid complex in 0.2 M $HClO_4$ precludes its separation, and consequently, its structural characterization. At pH > 2, where these kind of complexes are stable enough toward hydrolysis to be characterized (44, 45), the redox reaction between Cr^{VI} and the disaccharide is extremely slow at the temperature used in this work and does not reach completion, even after 1 year. The reaction of chromate with saccharides is completed in shorter periods only when the reaction is allowed to proceed under reflux (44, 45).

Chromate esters were investigated by UV–vis spectrophotometry in the 350–400 nm region in which these esters show characteristic absorption bands. Reactions were performed at pH 4.7, where the redox reaction is slow enough to enable the observation of the ester formation. The instruments were zeroed to both the reference and sample beams passing through matched cuvettes, both containing Cr^{VI} in H_2O at pH 4.7. The solution in the sample cell was replaced with the reaction solution containing 8×10^{-4} M Cr^{VI} and 0.12–0.32 M Lac at pH = 4.7, I = 1.0 M, and T = 33°C. Spectra obtained within 30 min after mixing revealed a distinctive absorption band at 377 nm.

The formation of Cr^{II} was examined by periodic scanning of solutions containing 0.21 M Lac and 0.016–0.09 mM Cr^{VI} in 0.1–0.2 M $HClO_4$ in the presence of dioxygen. Under aerobic conditions if Cr^{II} forms it rapidly converts to CrO_2^{2+}, which has characteristic absorption bands at 290 and 245 nm (33, 46) and can be detected at low $[Cr^{VI}]$. No new bands were detected at these wavelengths in the reaction of Cr^{VI} with Lac. The presence of Cr^{II} was also examined by carrying out experiments with Cr^{VI} and Lac in the presence of $[Co(NH_3)_5Cl]^{2+}$ (a Cr^{II} trapping agent) under anaerobic conditions (8, 47). A solution containing 0.3 M Lac, 4 mM Cr^{VI}, and 4 mM $[Co(NH_3)_5Cl]^{2+}$ in 0.2 M $HClO_4$, I = 1 M and T = 33°C, was left to react, and the Co^{II} content was analyzed after 10-fold dilution with concentrated HCl, centrifuging, and measuring the absorbance at 692 nm (the wavelength expected for the absorption band of $CoCl_4^{2-}$) in the supernatant. No Co^{II} was detected spectrophotometrically. These results suggest that the formation of Cr^{II} in the reaction of Cr^{VI} with Lac can be ruled out.

Product analysis

HPLC was employed to detect the reaction products under the conditions used in the kinetic measurements (excess disaccharide over Cr^{VI}). The chromatograms were obtained on a KNK-500A chromatograph provided with a 7125 HPLC pump. The effluent was monitored with refractive index (ERC-7522, ERMA INC) and UV (115 UV Gilson) detectors. The $[H^+]$ of the standard and the reaction mixture samples was adjusted to 0.1 or 0.2 M by addition of $HClO_4$, and then the samples were filtered through a 0.2 μm membrane prior to injection into the chromatographic system.

Standard solutions of the disaccharides and aldobionic acids were prepared individually in 0.10 M $HClO_4$ and chromatographed separately to determine the retention time of each sample. D-Maltobionic acid, D-cellobionic acid, and D-melibionic acid, used as standards, were synthesized according to the literature methods (48). The stability of the disaccharides and their respective acids was controlled by HPLC. Chromatograms registered after incubation of the standard samples in 0.2 M $HClO_4$ (the highest $[H^+]$ used in the kinetic measurements) at 34°C over 48 h were identical to those of freshly prepared samples.

Experimental conditions and retention times for the disaccharides and oxidation products are given as supplementary material.[3]

EPR measurements

The EPR spectra were obtained on a Bruker ESP 300 E spectrometer. The microwave frequency was generated with a Bruker 04 ER (9–10 GHz) and measured with a Racal-Dana frequency meter. The magnetic field was measured with a Bruker NMR-probe gaussmeter. All of the EPR experiments were carried out at 20°C. Reactions were carried out by direct reaction of $K_2Cr_2O_7$ with 16- to 33-times excess disaccharide at a given pH or by addition of Na_2CrO_4 (8.3 mM) + glutathione (8.3 mM) to solutions of disaccharide (83 mM) at pH 5.0 and 20 ± 1°C.

EPR spectra were simulated using the program PEST WinSIM (49) with 100% Lorentzian lineshapes. The spectral parameters for each Cr^V species were consistent within all simulations, with maximum deviations between g_{iso} values being ±0.0001 units. In the simulations, values for ^1H a_{iso} were included only where the ^1H a_{iso} value was greater than the LW (line width) of the Cr^V species, since the signal is not significantly affected where the ^1H a_{iso} value is ≤LW.

Polymerization test

The presence of free radicals in the reactions of all of the disaccharides with Cr^{VI} was tested by the acrylonitrile polymerization test. In a typical experiment, acrylonitrile in 0.2 M $HClO_4$ (0.5 mL) at 33°C was added to a solution of 2.66×10^{-3} M $K_2Cr_2O_7$ and 0.04 M disaccharide in 0.2 M $HClO_4$ (2.0 mL). After a few minutes a white precipitate appeared. Control experiments (without $K_2Cr_2O_7$ or reductant present) did not show the formation of a precipitate. Possible reactions of Cr^V and Cr^{IV} with acrylonitrile were tested with $Na[Cr^VO(ehba)_2]$ (50) and $[Cr^{IV}O(ehba)_2]$ (ehba = 2-ethyl-2-hydroxybutanoic acid); the latter was generated in solution according to the literature method (51). No precipitation occurred on mixing the Cr^V or Cr^{IV} complexes with acrylonitrile under the same conditions as those used in the Cr^{VI} + disaccharide reactions.

Results

Cr^{VI} oxidation of disaccharides

Over the whole range of perchloric acid concentrations used in the kinetic measurements, UV–vis studies showed that the reaction of each of the studied disaccharides with Cr^{VI} resulted in an absorbance band at 350 nm and a shoulder at 420–500 nm, characteristic of Cr^{VI} in acidic medium. At 350 nm a monotonic decrease in absorbance was observed and it could be described by a single exponential decay. Table 1 summarizes the values of the pseudo-first-order rate constants (k_{obs}), calculated from the slopes of the $\ln(A_{350} - A_8)$ vs. time data, for various concentrations of Lac, Mal, Cel, and Mel, in 0.20 M $HClO_4$. In every case, plots of k_{obs} vs. [disaccharide] show a first-order dependence on [disaccharide] (Fig. 1), and the values of the second-order rate constants (k_H) were determined from the slopes of the straight lines (Table 1, bottom). Consequently, at constant $[HClO_4]$, the rate law is expressed as:

$$[1] \qquad -d[Cr^{VI}]/dt = k_{obs}\,[Cr^{VI}]_T = k_H\,[\text{disaccharide}]\,[Cr^{VI}]$$

where $[Cr^{VI}]_T$ refers to the total Cr^{VI} concentration. For Lac, k_H shows first-order dependence with $[HClO_4]$ (inset of Fig. 1), which may be expressed as $k_H = k\,[H^+]$, with $k = 0.0047(1)$ M^{-2} s^{-1}.

As expected on the basis of the rate law, $-d(\ln[Cr^{VI}])/dt = k_{obs}$, where $k_{obs} = f([\text{saccharide}][H^+])$; k_{obs} was essentially constant with increasing $[Cr^{VI}]_0$.

Fig. 2. Time evolution of the UV–vis spectrum of a mixture of Lac (0.32 M) and Cr^{VI} (8×10^{-3} M). [$HClO_4$] = 0.20 M; T = 33°C, I = 1.0 M over a period of ca. 250 min.

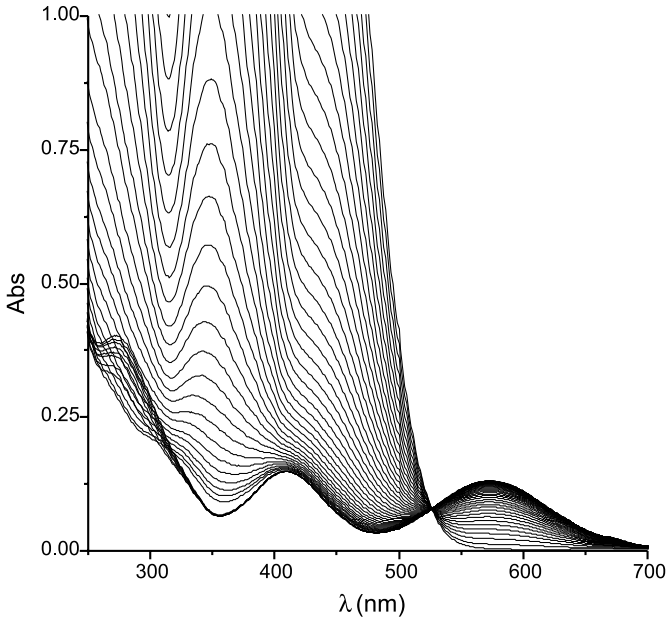

Fig. 3. UV–vis difference spectra of Cr^{VI}–Lac solutions at pH 4.7, showing the increasing band at 377 nm with increasing [Lac]: (*a*) 0.12, (*b*) 0.20, and (*c*) 0.32 M. [Cr^{VI}] = 8×10^{-4} M, T = 33°C, I = 1 M. Spectra taken after 2 min.

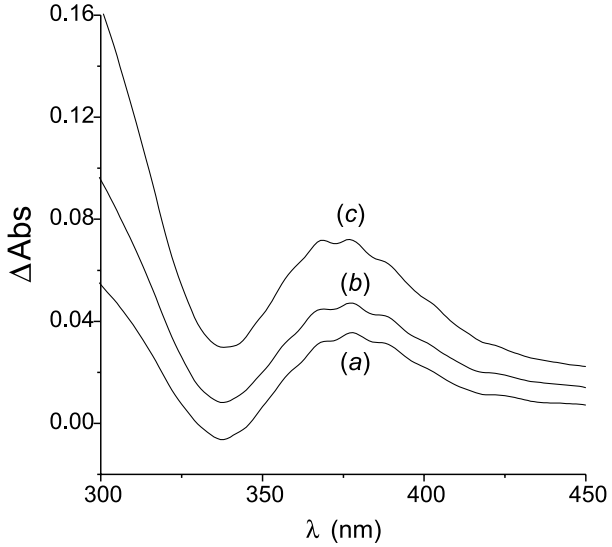
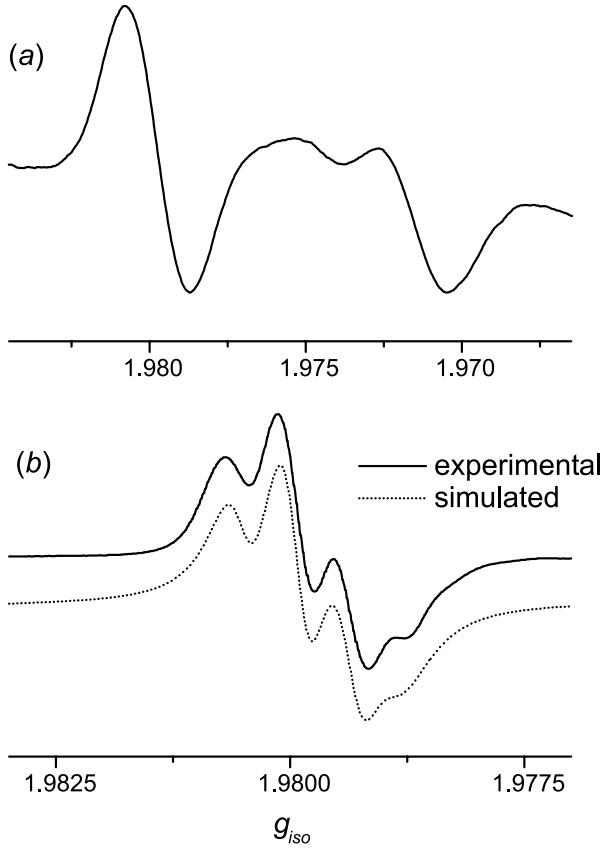


We followed the formation of Cr^{III} at 570 nm for various [disaccharide] in 0.20 M $HClO_4$ to determine the rate of Cr^{III} formation relative to that of Cr^{VI} consumption. The pseudo-first-order rate constants obtained at this wavelength (Table 1) are coincident with those obtained from the Cr^{VI} decay at 350 nm, with the same dependence on [disaccharide]. This means that Cr^{III} forms as fast as Cr^{VI} is consumed; this is consistent with the observation of an isosbestic point at 525 nm (Fig. 2). This result was independently confirmed by following the redox reaction by EPR spectroscopy. The rate

Fig. 4. X-band EPR spectra of mixtures of (*a*) Cr^{VI}–Lac = 1:33, [H^+] = 0.20 M, t = 6 min, modulated amplitude (mod. ampl.) = 4 G; (*b*) Cr^{VI}–Lac = 1:19, pH = 5.0, t = 24 h, mod. ampl. = 0.4 G. I = 1.0 M, T = 20°C, frequency ≈ 9.7 GHz.



constant of the reduction of Cr^{VI} by the saccharide (k_6) was found to be much lower than that of the reduction of Cr^V (k_5). The fact that $k_5 >> k_6$ implies that the slow redox step involves the reduction of Cr^{VI}.

Detection of the intermediate Cr^{VI} ester

Differential UV–vis spectra of mixtures of Cr^{VI} and Lac exhibited an absorption band with λ_{max} = 377 nm (Fig. 3) consistent with that ascribed to Cr^{VI} oxy-esters (52, 53). At pH 4.7, the redox reactions of the studied disaccharides proceed very slowly with negligible reduction of Cr^{VI} within the first hour. Thus, at this pH the ester formation step can be distinguished clearly from the electron transfer reaction. Spectra obtained within 2 min after mixing revealed a distinctive absorption band at 377 nm. Continued scanning for 30 min showed no further change in the spectra. Varying the excess concentration of disaccharide at pH = 4.7 showed that the absorbance at 377 nm increased with increasing concentration of disaccharide (Fig. 3), probably as a result of a shift toward the ester in the esterification equilibrium.

Intermediacy of Cr^V

Using EPR spectroscopy, we have detected the formation of intermediate Cr^V species in the reaction of the disaccharides with Cr^{VI}. The EPR spectra of mixtures of Lac and Cr^{VI} in 0.2 M $HClO_4$ show the formation of several intermediate Cr^V species (Fig. 4*a*). At this [H^+], the EPR spec-

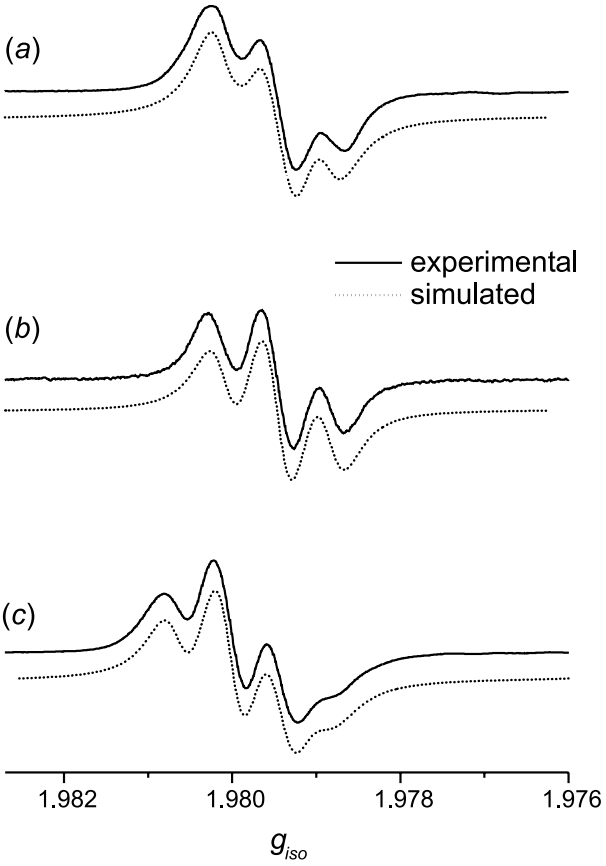
Fig. 5. Experimental and simulated X-band EPR spectra of mixtures of (*a*) Cr^{VI}–Mal = 1:19; (*b*) Cr^{VI}–Cel = 1:16; (*c*) Cr^{VI}–Mel = 1:19. [Cr^{VI}] = 0.015 M, I = 1.0 M, pH 5.0, t = 24 h, T = 20°C, frequency ≈ 9.7 GHz, mod. ampl. = 0.4 G.



tra consist of one signal at g_{iso} = 1.9797, which persists at higher pH, and two additional signals at g_{iso} = 1.9743 and 1.9715. At this [H^+], the EPR signals are not resolved because of the high modulation amplitude required to observe the Cr^V species. The signals at lower g_{iso} are not observed at pH > 2, where the electron transfer reaction becomes extremely slow; by contrast, the Cr^V species with g_{iso} = 1.9797 remains stable in solution for a long time.

At the [H^+] used in the kinetics measurements, the Cr^V EPR signal intensities grow and decay rapidly. For the reduction of Cr^{VI} by Lac ([H^+] = 0.2 M, [Lac] = 0.424 M, $[Cr^{VI}]_0$ = 0.0127 M, T = 20°C), the Cr^V EPR signal grows and decays within 3 h, while the total conversion of Cr^{VI} into Cr^{III} requires 20 h. Under these conditions, changes in the EPR signal intensity give values for the rate constant of the disappearance of Cr^{VI} (k_6), which is ~50-times higher than the corresponding rate constant for the disappearance of Cr^V (k_5). The k_6 values obtained from EPR data agree with the k_{obs} values calculated spectrophotometrically at 570 nm under the same conditions. Thus, the fact that $k_5 > k_6$ means that changes in absorbance at 350 nm reflect changes in Cr^{VI} concentration.

We have also performed the reaction of the disaccharides and Cr^{VI} at a lower [H^+] than was used in the kinetic measurements to obtain information on the structure of Cr^V species formed as intermediates in the reduction of Cr^{VI} to Cr^{III}.

[a] N: number of equivalent protons. ND: not determined.

In the pH 3–7 range and with a Lac–Cr^{VI} ratio of 19:1, the EPR spectrum, taken 24 h after mixing, is composed (signals were deconvoluted by fitting the spectra to Lorentzian derivatives) of two triplets at g_{iso1} = 1.9800 and g_{iso2} = 1.9794 in an ~1:1 proportion. Each of these triplets shows four weak ^{53}Cr (9.55% abundance, I = 3/2) hyperfine peaks at 16.5(3) × 10^{-4} cm^{-1} spacing (Fig. 4*b*, Table 2).

In the pH 5–7 range, the EPR spectrum of a 19:1 Mal–Cr^{VI} reaction mixture affords two triplets at g_{iso1} = 1.9795 and g_{iso2} = 1.9794 in a 1:1 ratio (Fig. 5*a*). In the same pH range, a 16:1 Cel–Cr^{VI} reaction mixture yields one triplet at g_{iso} = 1.9793 (Fig. 5*b*, Table 2).

Mel behaves similarly to Lac. The best fit of the EPR spectrum of a 19:1 Mel–Cr^{VI} mixture in the pH 3–7 range taken 24 h after mixing affords two triplets at g_{iso1} = 1.9802 and g_{iso2} = 1.9798 (Fig. 5*c*, Table 2). These two signals are present in a 1:1 ratio independent of pH.

The ultimate fate of the chromium in these reactions is a Cr^{III} species, and a typical broad Cr^{III} EPR signal, centred at g ~ 1.98, is always observed at later times.

At room temperature and pH 5.0, the reaction of chromate with glutathione (1:1 ratio) in the presence of a 10-times excess disaccharide over Cr^{VI} affords Cr^V EPR spectra identical to those obtained by direct reaction of the disaccharide with Cr^{VI}.

Discussion

Cr^{VI} oxidation of disaccharides

For the ranges of substrate and acid concentrations used in the kinetics measurements, the oxidation of the disaccharides by Cr^{VI} is a complex reaction, yielding $[Cr(H_2O)_6]^{3+}$ and the aldobionic acid as the final redox products. We propose a mechanism that takes into account: (*a*) the kinetic results; (*b*) the polymerization of acrylonitrile added to the reaction mixture; (*c*) the detection of an intermediate Cr^{VI} ester; (*d*) the detection of intermediate of oxochromate(V) species by EPR; and (*e*) the formation of the aldobionic acid as the only organic reaction product.

At the [H^+] and [Cr^{VI}] used in the kinetics studies, Cr^{VI} may exist as $HCrO_4^-$ (54), and this species is proposed as the reactive form of Cr^{VI}, in agreement with the first-order dependence of the reaction rate on [Cr^{VI}]. The chromic oxidation of alcohols and glycols are preceded by the formation of a chromate ester (52, 53). The observation of the

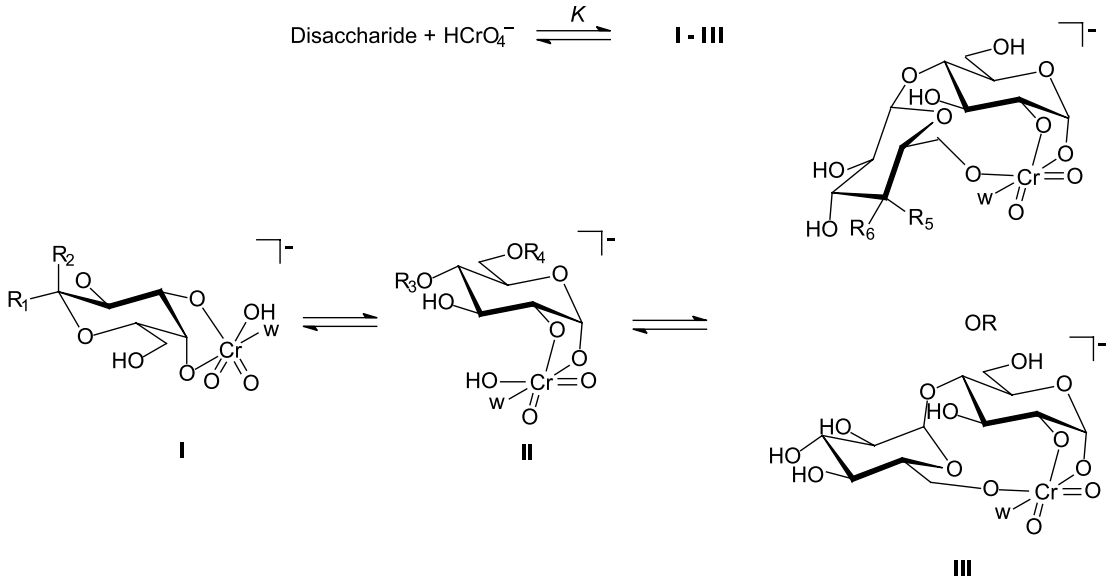
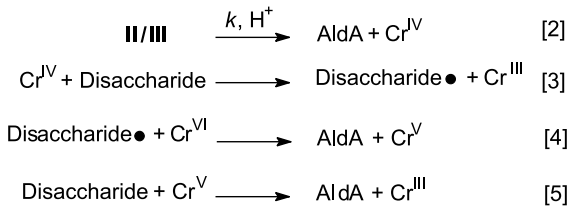
Scheme 1. Cr^{VI}–Mel: $R_1 = O^5$-glc, R_2 = H; Cr^{VI}–Lac: R_1 = H, $R_2 = O^4$-glc. Cr^{VI}–Lac(Mal, Cel): R_3 = glycoside, R_4 = H; Cr^{VI}–Mel: R_3 = H, R_4 = glycoside. Cr^{VI}–Lac: R_5 = OH, R_6 = H; Cr^{VI}–Cel: R_5 = H, R_6 = OH. AldA = aldobionic acid; w = water.





absorbance band, characteristic of chromate oxy-esters, at approximately 377 nm (a few minutes after mixing the disaccharides and Cr^{VI} under conditions where the redox reaction is extremely slow) reveals that such an intermediate Cr^{VI} complex is rapidly formed prior to the redox steps. Thus, the first step of the mechanism proposed in Scheme 1 is the formation of the disaccharide–Cr^{VI} mono-chelate. The disaccharide acts as a bidentate ligand bound to Cr^{VI} via any pair of properly disposed hydroxyl groups. While there is no direct evidence for bidentate chelation of the sugar to Cr^{VI}, it is likely that this is the case, especially since Cr^{VI} chelates have been observed by NMR spectroscopy in the oxidations of another bidentate oxygen donor (18). The chelates proposed in Scheme 1 are those with the ligand bound to Cr^{VI} at the *cis*-$O^{3'}$,$O^{4'}$-diolato (**I**) and *cis*-O^1,O^2-diolato (**II**) moieties of Lac and Mel and the *cis*-O^1,O^2-diolato (**II**) moiety of Mal and Cel. These are proposed on the basis that α-glc forms the Cr^{VI}–glc chelate faster than the β-D-anomer — a fact attributed to the *cis*-1,2-diolato moiety present only in the α-anomer — (21) and the observation of the marked preference of the CrO^{3+} ion for binding to *cis*- rather than *trans*-diol groups of cyclic diols (21, 22, 29, 55). For Mal, Lac, and Cel, **II** is proposed to be in equilibrium with Cr^{VI}–O^1,O^2,$O^{6'}$-disaccharide chelates (**III**). Molecular models show that Lac, Mal, and Cel can afford Cr^{VI}–chelates with the disaccharide bound to Cr^{VI} at O^1,O^2,$O^{6'}$ and with retention of the $^4C_1$ chair conformation of the glycoside moiety. Taking into account that in the redox reaction only the anomeric hydroxyl group is oxidized, it seems reasonable to hypothesize that the complexes with the primary hydroxyl group bound to Cr^{VI} (**II**, **III**) should be the precursors of the slow redox steps.

The slow redox step in the mechanism might take place by either a one-electron or a two-electron transfer (56). The slow step proposed in Scheme 1 involves the intramolecular transfer of two electrons to yield Cr^{IV} and the aldobionic acid (eq. [2]). This is based on the mechanism reported for aldoses, which are also selectively oxidized by Cr^{VI} at the hemiacetalic group with an initial two-electron transfer slow step (21–28). After the slow redox step, Cr^{IV} is predicted to react with excess saccharide to yield Cr^{III} and a disaccharide radical in a fast step (eq. [3]). The latter is supported by the observed polymerization of acrylonitrile when it is added to the reaction mixture. The rapid reaction of the disaccharide radical with Cr^{VI} affords Cr^{V} (eq. [4]), which can further oxidize the disaccharide to yield Cr^{III} and the aldobionic acid as the final oxidation product (eq. [5]).

The k_H in the rate law corresponds to $kK[H^+]$ in this mechanism. This means that the relative reactivity of the disaccharides may be interpreted by taking into account both the rate of formation of the Cr^{VI} ester and its redox rate. Our experimental data show that the disaccharide–Cr^{VI} chelate formation is much faster than the redox steps. For certain aldoses the rate constant for the formation of the aldose–Cr^{VI} chelate (K) in 0.75 M $HClO_4$ has been determined and was found to be 500- to 2000-times higher than the redox

© 2002 NRC Canada

constant (k). Thus, the redox rate should depend, essentially, on the energy barrier the Cr^{VI} chelate has to overcome to attain the five-membered cyclic transition state for the intramolecular H transfer (22). The kinetics data show that the relative reactivity of the disaccharides toward Cr^{VI} is Mel > Lac > Cel > Mal. If we compare the reactivity of these saccharides with glc, which is oxidized by Cr^{VI} with a rate constant of $k_H = 9.9 \times 10^{-4}$ M^{-1} s^{-1} in 0.2 M $HClO_4$ at 33°C (22), we can observe that substitution of the O^4H group of glc by the glycoside moiety results in the retardation of the redox rate, while substitution of the primary O^6H accelerates the redox reaction. The retardation of the redox reaction observed for Mal, Cel, and Lac is probably related to the formation of the Cr^{VI}–O^1,O^2,$O^{6'}$-disaccharide chelates (III). The probability for Mel to act as a tridentate ligand is very low because of the less favourable spatial orientation of the galactoside moiety; therefore, it shows the highest reactivity in the series.

Cr^V intermediates

The most common means of characterizing Cr^V complexes in solution is EPR spectroscopy. The EPR spectral parameters, g_{iso} and A_{iso}, together with the proton superhyperfine (shf) coupling, are useful in determining the binding modes of sugars to the Cr^V center (1, 22, 24, 26, 27, 57, 58). An empirical relationship between the nature and number of donor groups and the EPR spectral parameters of Cr^V complexes has been established (1, 57). Five-coordinate Cr^V species show higher g_{iso} and lower ^{53}Cr A_{iso} values than the corresponding six-coordinate species (57, 59, 60). Thus, the assignment of the structures of new oxo-Cr^V species in solution was made according to the isotropic EPR parameters (g_{iso} and A_{iso} values) and the superhyperfine (shf) pattern of the signal (1, 59).

The EPR spectrum of a Cr^V-diolato species of six-membered ring *cis*-diols yields a doublet, since only one proton is in the plane of the unpaired electron density of the Cr^V ion, while the EPR spectrum of a Cr^V-diolato species of six-membered ring *trans*-diols (with no protons lying in the ligand plane) yields a singlet (55). Consequently, the EPR spectral multiplicity of the bis-chelate Cr^V-diolato$_2$ species formed between Cr^V and pyranosic *cis*- and *trans*-diols will exhibit a triplet and a singlet, respectively, which arise from the orientation of the ring protons of the coordinated diol groups with respect to the basal plane of the complex (1, 55, 57). Based on this, the isotropic EPR parameters g_{iso} and A_{iso} were used to deduce the coordination number and nature of the donor groups of the Cr^V species formed, either for the reaction of Cr^{VI} with the disaccharides or for the reaction of Cr^{VI} with glutathione in the presence of excess disaccharide, according to a described empirical method (1, 57, 59, 60).

The *cis*-diolato moieties of the disaccharides under study are potential binding sites to give five-membered Cr^V species. The five-membered Cr^V chelates are the most thermodynamically favoured, and CrO^{3+} shows a marked preference for binding to *cis*- rather than *trans*-diol groups of cyclic diols (21, 22, 29, 55). Based on this, the EPR spectral features of disaccharide–Cr^V mixtures were interpreted in terms of Cr^V-diolato species involving binding mainly through the *cis*-O^1,O^2-diolato of Mal and Cel and the *cis*-O^1,O^2-diolato and *cis*-$O^{3'}$,$O^{4'}$-diolato of Lac and Mel. The contribution to the EPR signals from other species, involving *trans*-diolato moieties, should be small.

Lactose–Cr^V

The reaction of Cr^{VI} with a 20-times excess of Lac in the pH 3–7 range affords an EPR spectrum dominated by a single detectable signal at $g_{iso} = 1.9797$ with the four weak ^{53}Cr (9.55% abundance, $I = 3/2$) hyperfine peaks at 16.5×10^{-4} cm^{-1} spacing; the product remains in solution from several days to several months. When the modulation amplitude is lowered to 0.4 G, the EPR signal resolves into two triplets at $g_{iso1} = 1.9800$ and $g_{iso2} = 1.9794$ ($A_{iso} = 16.5(3) \times 10^{-4}$ cm^{-1}, ~50:50 g_{iso1}–g_{iso2} ratio) (Fig. 4*b*, Table 2). The g_{iso} and A_{iso} values are consistent with those calculated for five-coordinate oxochromate(V) complexes with four alcoholato donors ($g_{calc} = 1.9800$, $A_{calc} = 16.5 \times 10^{-4}$ cm^{-1}) (1, 57). The shf pattern indicates that the EPR signal is a composite of two oxo-Cr^V-*cis*-diolato$_2$ species with two (one from each chelate ring) carbinolic protons coupled to the Cr^V electronic spin. The two components can be attributed to linkage isomers of the $[Cr(O)(cis\text{-}O,O\text{-Lac})_2]^-$ (61). Even when three different linkage isomers $[Cr(O)(cis\text{-}O^{3'},O^{4'}\text{-Lac})_2]^-$, $[Cr(O)(cis\text{-}O^1,O^2\text{-Lac})_2]^-$, and $[Cr(O)(cis\text{-}O^1,O^2\text{-Lac})(cis\text{-}O^{3'},O^{4'}\text{-Lac})]^-$ (**IV**–**VI** in Fig. 6) are possible, only two species are required to simulate the EPR signal. It seems reasonable to assume that the angles between the carbinolic protons and the Cr^V–ligand plane in two of the linkage isomers of $[Cr(O)(cis\text{-}O,O\text{-Lac})_2]^-$ are very similar, as we cannot distinguish between them.

A more complex EPR spectral pattern is observed in a 0.2 M $HClO_4$ solution. At this $[H^+]$ and a 33:1 ligand–Cr^{VI} ratio, two additional signals at $g_{iso3} = 1.9743$ and $g_{iso4} = 1.9715$ appear, together with the signal at $g_{iso} = 1.9797$ (Fig. 4*a*, Table 2). The shf pattern of these two new signals was not resolved, but the signal at $g_{iso} = 1.9715$ suggests the presence of six-coordinate oxo-Cr^V species, possibly $[Cr(O)(cis\text{-}O,O\text{-Lac})(H_2O)_3]^+$ (**VII**). The calculated g_{iso} value for a six-coordinate oxo-Cr^V species with two alcoholato donors and three water molecules ($g_{clc} = 1.9724$) is in reasonable agreement with the observed g_{iso4} value. The positive charge of this species is also consistent with its appearance at high $[H^+]$. The signal at $g_{iso3} = 1.9743$ may be tentatively attributed to another positively charged six-coordinate oxo-Cr^V mono-chelate $[Cr(O)(O^1,O^2\text{-lactobionato})(H_2O)_3]^+$ (**VIII**, $g_{clc} = 1.9735$), with Cr^V bound to the 2-hydroxyacid moiety of the oxidized product and to three water molecules. Coordination to the oxidized ligand is consistent with the fact that Cr^{VI} is a stronger oxidant in more acidic medium. The six-coordinate oxo-Cr^V mono-chelate **VII** is possibly responsible for the higher rates observed for the Cr^V–disaccharide redox reactions at pH < 2. At higher pH, where Cr^V mono-chelates are not observed, Cr^V complexes are stable enough to remain in solution from several days to several months.

Maltose–Cr^V

For the reaction of Cr^{VI} with Mal, in the pH 5–7 range and with a 19:1 ligand–metal ratio, the EPR spectra (Fig. 5*a*, Table 2) consist of two triplets at $g_{iso1} = 1.9795$ and $g_{iso2} = 1.9794$. The g_{iso} values and the shf pattern indicate these signals may be attributed to two geometric isomers (typical

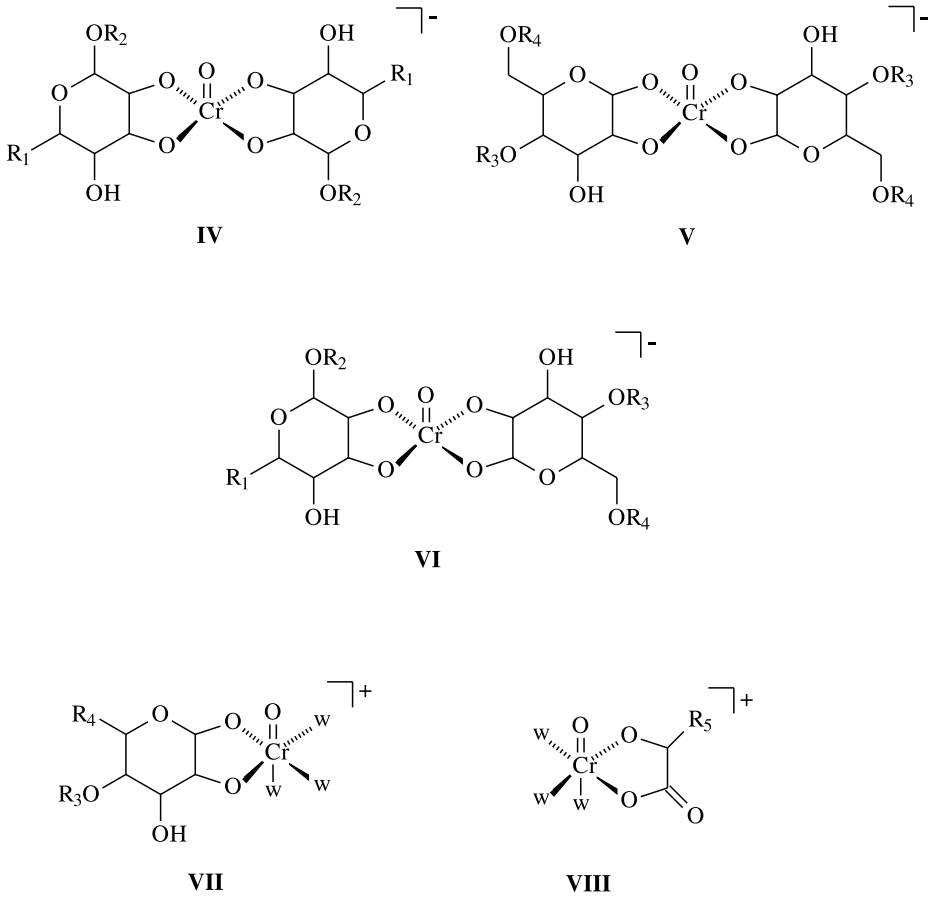
Fig. 6. Structures of Cr^V complexes with disaccharide ligands. R_1 = CH_2OH, R_5 = $C_{10}O_9H_{19}$, w = water. Cr^V–Lac: R_2 = O^4-glc; Cr^V–Mel_2: R_2 = O^6-glc; Cr^V–Lac_2 (Cr^V–Mal_2, Cr^V–Cel_2): R_3 = glycoside, R_4 = H; Cr^V–Mel_2: R_3 = H, R_4 = glycoside.



Δg_{iso} for geometric isomers are $1 \times 10^{-4} - 2 \times 10^{-4}$) (27, 30) of the five-coordinate oxo-Cr^V complex $[Cr(O)(O^1,O^2\text{-Mal})_2]^-$ (**V**), with Mal bound to Cr^V via the 1,2-*cis* diolato moiety.

Cellobiose–Cr^V

Intermediate Cel–Cr^V species formed in the reaction of Cr^{VI} with Cel, in the pH 5–7 range and with a 14:1 ligand–metal ratio, yield EPR spectra (Fig. 5*b*, Table 2) consisting of one triplet at g_{iso1} = 1.9793. The g_{iso} value corresponds to that calculated for a five-coordinate oxochromate(V) complex with four alcoholato donors, and the shf pattern indicates this signal may be assigned to the $[Cr(O)(O^1,O^2\text{-Cel})_2]^-$ chelate (**V**), with Cel bound to Cr^V via the 1,2-*cis* diolato moiety.

Melibiose–Cr^V

In the reaction of Cr^{VI} with Mel at a pH 3–7 range and a 19:1 ligand–metal ratio, the EPR spectra of the intermediate Cr^V species show two triplets at g_{iso1} = 1.9802 and g_{iso2} = 1.9798 (~50:50 g_{iso1}–g_{iso2} ratio). The g_{iso} values and the shf pattern reveal that these signals correspond to different linkage isomers of the five-coordinate oxo-Cr^V complex $[Cr(O)(O,O\text{-Mel})_2]^-$. As in the case of Lac, the three linkage isomers $[Cr(O)(O^{3'},O^{4'}\text{-Mel})_2]^-$ (**IV**), $[Cr(O)(O^1,O^2\text{-Mel})_2]^-$ (**V**), and $[Cr(O)(O^{3'},O^{4'}\text{-Mel})(O^1,O^2\text{-Mel})]^-$ (**VI**) are possible, but only two Cr^V species are required to simulate the EPR signal, probably for the same reasons as for the Lac–Cr^V system.

EPR spectra identical to those shown in Figs. 4*b* and 5*a*–5*c* are obtained when Cr^V is generated by the reaction of Cr^{VI} with glutathione (1:1 ratio) at pH = 5.0 and stabilized by the presence of a 10-times excess of disaccharide over Cr^{VI}. This result indicates that Cr^V species formed at this pH effectively correspond to chelates formed with the disaccharide and not with the oxidized product (aldobionic acid).

Conclusions

Disaccharides form stable high-valent chromium chelates at pH > 2, while at higher $[H^+]$ their oxidation by Cr^{VI} and (or) Cr^V is favoured. The oxidation occurs selectively at the hemiacetalyc C^1OH group, with first-order kinetics for both $[Cr^{VI}]$ and [disaccharide]. The relative ability of the studied disaccharides to reduce Cr^{VI} — Mel > Lac > Cel > Mal — can be attributed to the increasing stability of the intermediate disaccharide–Cr^{VI} chelates formed with Mel through Mal. The redox and complexation chemistry observed for the disaccharide–Cr^{VI} systems parallels that of aldoses. The glycoside moiety can retard the redox rate of the aglycone when additional binding to Cr^{VI} by the glycoside moiety is possible. In the case of Mal, this effect reduces k_H to one half of the value obtained for glc.

© 2002 NRC Canada

At pH 3–7, redox reactions between Cr^V and disaccharides are extremely slow, since once the bis-chelates are formed they are long-lived. A different reactivity pattern is observed at high [H^+], where intramolecular electron-transfer processes take place and mono-chelates are observed. The observation of six-coordinate $[Cr^VO(O,O\text{-disaccharide})(OH_2)_3]^+$ at only high [H^+], together with the selectivity of the redox reaction, suggest that the six-coordinate Cr^V mono-chelate **VII** could be the precursor of the intramolecular electron-transfer reaction step in the redox reactions.

Synthesis, characterization, and X-ray crystal structures of Co(II) and La(III) complexes of a pyridine containing self-assembling system and solution studies of the Co(II) complex

A. Moghimi, M. Ranjbar, H. Aghabozorg, F. Jalali, M. Shamsipur, and Kaj K. Chadha

Abstract: The complexes $[pyda.H]_2[Co(pydc)_2]\cdot H_2O$ (**I**) and $[pyda\cdot H]_2[La_2(pydc)_4(H_2O)_4]\cdot 2H_2O$ (**II**) were prepared from the complexation of a novel pyridine containing self-assembling system $\mathbf{LH_2}$, $([pyda\cdot H_2]^{2+}[pydc]^{2-})$ (pyda = 2,6-pyridinediamine and pydc·H_2 = 2,6-pyridinedicarboxylic acid), with cobalt(II) and lanthanum(III) salts in 82% and 74% yields, respectively. The characterizations were performed using elemental analysis, ESI mass spectroscopy as well as ^1H and ^{13}C solution NMR spectroscopy, and X-ray crystallography. The crystal systems **I** and **II** are monoclinic and triclinic with space groups $P2_1/n$ and $P\bar{1}$, respectively. Coordination number around each Co atom is six with distorted octahedral geometry, while coordination number around each La atom is nine with highly distorted tricapped trigonal prism geometry. The paramagnetic Co(II) and diamagnetic La(III) complexes show ^1H NMR resonances of both anionic $[pydc]^{2-}$ and cationic counter ion $[pyda\cdot H]^+$ in DMSO-d_6. The complexation reactions of the complex **I** in aqueous solution were investigated by potentiometric pH titrations and the equilibrium constants for all major complexes formed are described. The results are presented in the form of distribution diagrams revealing the concentrations of individual complex species as a function of pH. The results revealed that at a pH range 4.0–4.5 the major complex species is $[(pyda\cdot H)]_2[Co(pydc)_2]$.

Key words: self-assembly, X-ray crystal structure, Co(II) complex, La(III) complex, 2,6- pyridinedicarboxylic acid, 2,6-pyridinediamine, hydrogen bonding.

Résumé : On a préparé les complexes $[pyda\cdot H]_2(Co(pydc)_2]\cdot H_2O$ (**I**) et $[pyda\cdot H]_2(La_2(pydc)_4(H_2O)_4]\cdot 2H_2O$ (**II**) par complexation d'une nouvelle pyridine comportant un système d'autoassemblage, $\mathbf{LH_2}$, $([pyda\cdot H_2)^{2+}[pydc]^{2-})$ (pyda = pyridine-2,6-diamine et pydc·H_2 = pyridine-2,6-dicarboxylique) avec des sels de cobalt(II) et de lanthane(III), avec des rendements respectifs de 82% et de 74%. On a caractérisé ces complexes par analyse élémentaire, spectrométrie de masse « ESI », par spectroscopie RMN du ^1H et du ^{13}C en solution ainsi que par diffraction des rayons X. Les systèmes cristallins des composés **I** et **II** sont respectivement monoclinique et triclinique avec des groupes d'espace $P2_1/n$ et $P\bar{1}$. Le nombre de coordination autour de chaque atome de cobalt est de six, avec une géométrie octaédrique déformée, alors que le nombre de coordination autour de chaque atome de lanthane est de neuf, avec une géométrie à prisme trigonal fortement déformée. En solution dans le DMSO-d_6, les complexes paramagnétique du Co(II) et diamagnétique du La(III) présentent des résonances RMN du ^1H tant pour la partie anionique $[pydc]^{2-}$ que pour le contre-ion cationique $[pyda\cdot H]^+$. Faisant appel à des titrages potentiométriques, pH, on a étudié les réactions de complexation du complexe **I** en solution aqueuse et on décrit les constantes d'équilibre de tous les complexes principaux qui se forment. Les résultats sont présentés sous la forme de diagrammes de distribution qui mettent en évidence les concentrations des espèces de chaque complexe individuel en fonction du pH. Les résultats démontrent que dans la plage de pH allant de 4,0 à 4,5, l'espèce complexée le plus important est le $[(pyda\cdot H)]_2[Co(pydc)_2]$.

Mots clés : autoassemblage, structure cristalline par diffraction des rayons X, complexe du Co(II), complexe du La(III), acide pyridine-2,6-dicarboxylique, pyridine-2,6-diamine, liaison hydrogène.

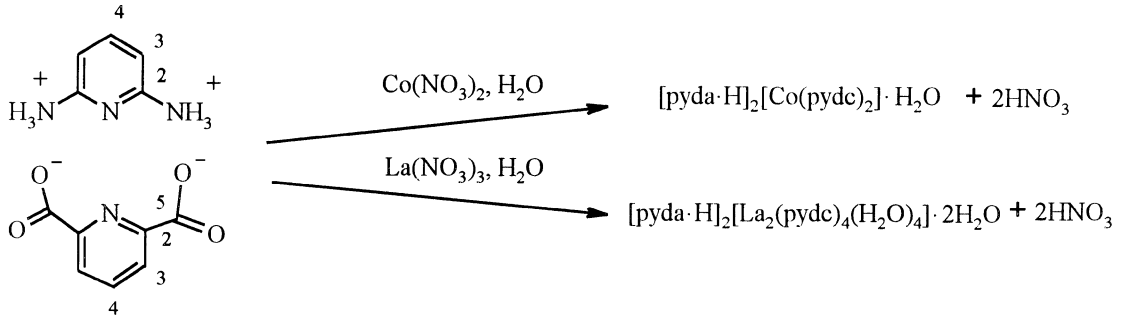
Scheme 1. Synthesis method of ([pyda·H]$_2$[Co(pydc)$_2$]·H$_2$O and [pyda·H]$_2$[La$_2$(pydc)$_4$(H$_2$O)$_4$]·2H$_2$O complexes.



[pyda.H$_2$][pydc]

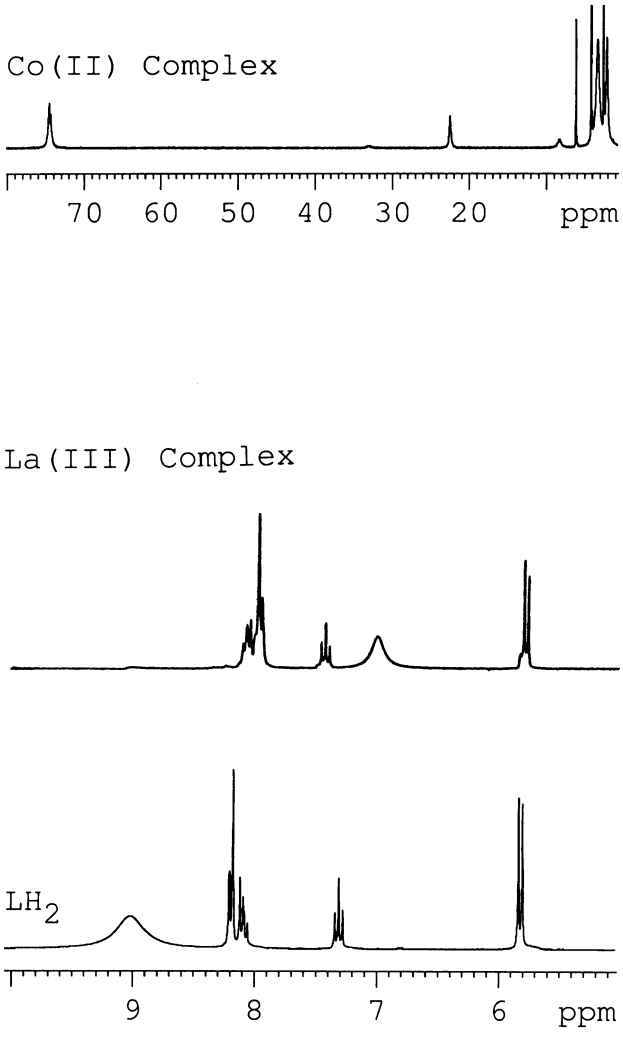
Introduction

Much effort has been made in recent years for the preparation and characterization of self-assembling systems (1). The generation of a self-assembling system that could function in polar solvents such as DMSO and H$_2$O has been a difficult task in this field. This is because of the competitive solvation of donor and acceptor sites by the polar solvents (2). In connection with such stable self-assembling systems in polar solvents, we succeeded in making the water-soluble system, [pyda·H$_2$]$^{2+}$[pydc]$^{2-}$ **LH$_2$**, containing doubly protonated 2,6-pyridinediamine, [pyda·H$_2$]$^{2+}$, and doubly deprotonated 2,6-pyridinedicarboxylic acid, [pydc]$^{2-}$, units (Scheme 1) (3). Recently, Schmuck reported a highly stable self-association of 5-(guanidinocarbonyl)-1H-pyrrole-2-carboxylate in DMSO (4). One of, or a combination of, intermolecular binding forces such as ion pairing, hydrogen bonding, hydrophobic or hydrophilic, host guest, π stacking, and donor–acceptor interactions could stabilize these systems in solution or in solid phase. Zafar et al. have recently tried to control the molecular self-assembly by designing a component containing both carboxylic acid and amino pyridine groups within the same framework (5).

A review of the literature showed that the rigid flat chelates [pydc·H$_2$] and [pyda] can individually form complexes with bivalent and trivalent transition metals (6–14). The La(III) complexes (6) involving [pydc]$^{2-}$ or [pydc·H]$^-$ ligands, [Ag(pydc)(pydc·H$_2$)]·H$_2$O (7), Ni(pydc·H)$_2$]·3H$_2$O (8), [Zn(pydc·H)$_2$]·2H$_2$O (9), [Fe$_2$(pydc)$_2$(OH$_2$)$_6$]·2[pydc·H$_2$] (10), NH$_4$[VO$_2$(pydc)] (11), and [Pd(pydc)(PBu$_3$)]$_2$ (12) are some examples in this regards. Although the solution studies, performed by Platas-Iglesias et al. (13), show that stable triple helical nine-coordinated La(III) complexes are formed from [pydc.H2] derivatives, to the best of our knowledge, no X-ray crystal structure data have yet been reported for the La(III) complex of dipicolinic acid.

Moreover, in a recent publication (15), some coordination complexes that self assemble in two-dimensional supramolecular networks or layers in the solid phase have been reported. These complexes contain bis(imidazolium 2,6-pyridinedicarboxylate) as a ligand. Accordingly, we became interested in investigating the influence of the counter ion [pyda·H$_2$]$^{2+}$ in the complexation process and succeeded in reporting {[BiCl(H$_2$O)(pydc)]$_2$}$_n$ (16), [pyda·H][Zn(pydc)(pydc·H]·3H$_2$O (17), and [pyda·H][Cr(pydc)$_2$]·pydc·H$_2$·0.5H$_2$O (18) complexes from **LH$_2$**. We have found out that a suitable

Fig. 1. ^{1}H NMR spectra of **LH$_2$**, [pyda·H]$_2$[Co(pydc)$_2$]·H$_2$O, and [pyda·H]$_2$[La$_2$(pydc)$_4$(H$_2$O)$_4$]·2H$_2$O complexes in DMSO-d6.



Lewis acid like [pyda] can play an important role in the preparation of anionic M[pydc]$^{n-}$, metal complexes. It also participates in the construction of extensive H-bonding networks within the lattice. In this paper we report the results of the complexation of **LH$_2$** with Co(II) and La(III), characterization of the resulting complexes, and their X-ray crystal structures and NMR data.

Results and discussion

Synthesis and characterization of Co(II) and La(III) complexes of $\mathbf{LH_2}$

The reaction between $Co(NO_3)_2$ and $La(NO_3)_3$ with $\mathbf{LH_2}$ in water leads to the formation of crystalline products (Scheme 1) in 82% and 74% yields, respectively. These complexes displayed distinct mp and elemental analysis consistent with the formula $C_{24}H_{24}CoN_8O_9$ and $C_{38}H_{40}La_2N_{10}O_{22}$, respectively. The presence of $[pyda{\cdot}H]^+$ and $(M + H)^+$ ions in both complexes were confirmed from the expected fragments observed in ESI-MS spectra. This method was selected because of its proper response to the starting ionic ligand $\mathbf{LH_2}$ (3).

The ^1H NMR spectra of the complexes as well as the $\mathbf{LH_2}$ ligand are shown in Fig. 1, and the corresponding ^{13}C NMR data are presented in Table 1. As seen from Fig. 1, the $[pydc]^{2-}$ protons in the paramagnetic Co(II) complex were shifted downfield to 22.5 and 75.0 ppm whereas the resonances of $[pyda{\cdot}H]^+$ were not much disturbed. The upfield shift for NH_3^+ protons can be attributed to the functional group transformation, $-NH_3^+$ to $-NH_2$, upon complexation. From the integration of two characteristic sets of ^1H resonances of both complexes, the $[pydc]^{2-}$:$[pyda{\cdot}H]^+$ mole ratio was found to be 2. A comparison between the NMR data (Fig. 1 and Table 1) indicates that, contrary to the Co(II) complex, the $\mathbf{LH_2}$ resonances are not much shifted upon complexation with La(III).

As a result of complex formation, the strong IR absorptions of $\mathbf{LH_2}$ at 1700 and 1340 cm^{-1} indicative of carboxylate groups are replaced by very strong and broad bands centered at 1660 and 1380 cm^{-1} for the Co(II) complex and at 1600 cm^{-1} and 1420 cm^{-1} for the La(III) complex. The shifts in the position and shape of these bands suggest that both carboxylate groups of $[pydc]^{2-}$ are coordinated to the metal atoms. The two bands at 645 and 420 cm^{-1} that are ascribed to the C—H out of plane bending of the pyridine ring of $[pyda{\cdot}H_2]$ are split and shifted to the higher frequencies due to the pyridine coordination (19). The band at 1580 cm^{-1}, related to the NH of the free ligand, is also shifted to a lower frequency (i.e., 1560 cm^{-1}). This shift may be due to the decreased positive charge in the $[pyda{\cdot}H]^+$ counter ion in comparison with $[pyda{\cdot}H_2]^{2+}$. The new bands in the 360–440 cm^{-1} region result from the new metal–ligand, M—N and M—O, bond formation (20).

X-ray crystallographic structure for Co(II) and La(III) complexes

The numbering schemes and ORTEP diagrams of the Co(II) and La(III) complexes are presented in Fig. 2. A summary of crystallographic data, selected bond lengths and angles for Co(II) and La(III) complexes, and H-bonding data are given in Tables 2 and 3.

An important feature of the crystal structures is the existence of ionic complexes consisting of $[M(pydc)_2]^{n-}$ and $[pyda{\cdot}H]^+$ units (M = Co and La). The cobalt atom is in the

Note: # 1: *–x*, *–y*, *–z*.

center of a distorted octahedral arrangement consisting of six donor atoms of two tridentate ligands of $[pydc]^{2-}$. The two O3-Co-O1 and O7-Co-O5 angles indicate that the four carboxylate groups of the two dianions are oriented in a flattened tetrahedral arrangement around the Co(II) atom. The two dianionic $[pydc]^{2-}$ units are almost perpendicular to each other. The molecular structure of the La(III) complex, $[pyda.H]_2[La_2(pydc)_4[(H_2O)_4]\cdot 2H_2O$, consists of two metal fragments linked *via* the central four-membered La_2O_2 ring. The binuclear self-assembled La(III) complex is built up from two equivalent nine-coordinated lanthanum complex ions. Each of the two La atoms has a highly distorted tricapped trigonal prism geometry and is surrounded by seven oxygen and two nitrogen donor atoms (Fig. 2).

It is worthy to note that, although we started the complexation with $[pyda\cdot H_2]^{2+}[pydc]^{2-}$ ligand, the monocationic $[pyda\cdot H]^+$ counter ion exists in both complexes. The protonated site of the cationic counter ion in both complexes is the pyridine nitrogen. Interestingly, the two protonation sites in **LH_2** are the two -NH_2 nitrogens (3).

The mean of the Co—N and Co—O bond distances (i.e., 2.014 and 2.179 Å, respectively) are different from the corresponding values reported for bis (imidazolium) - 2,6-pyridinedicarboxylate Co(II) complex. For instance, the Co—N1, Co—O2, and Co—O3 distances in the imidazolium complex are 2.157, 2.223, and 2.219 Å, respectively. With respect to the axial N-Co-N angle involving the nitrogen atoms on the two pyridyl ligands, a small deviation (i.e., 3.51°) from linearity is observed. This bond angle is close to the values reported for N-Cu-N than N-Co-N angles in imidazolium carboxylate complexes. The data presented specify that these key bond distances and angles are affected by the nature of the cationic counter ion.

The average La—O (carboxylate) distance, 2.538 Å, in the La(III) complex is comparable with the similar average distance, 2.52 Å, in the $[La_2(C_4H_4O_5)_3(H_2O)_3.5H_2O]_n$ complex

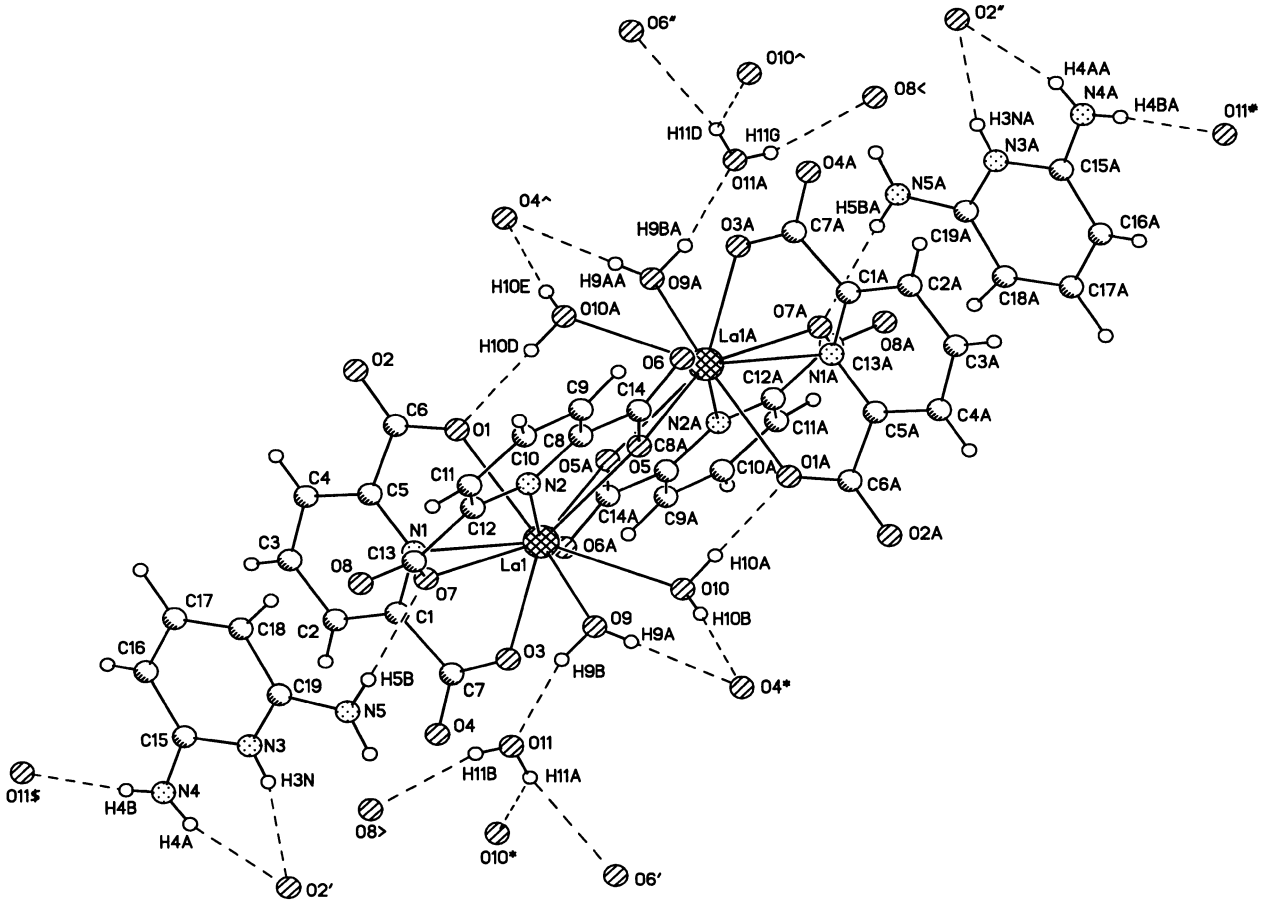
Fig. 3. The hydrogen bonding representation in the $[pyda{\cdot}H]_2[La_2(pydc)_4(H_2O)_4]{\cdot}2H_2O$ complex.



(21), whereas it is larger (2.545Å) in the lanthanum oxalate complexes (22, 23). Also, the average donor–acceptor La—O (water) bond lengths in the present La(III) complex and $[La_2(C_4H_4O_5)_3(H_2O)_3.5H_2O]_n$ are 2.605 and 2.556 Å, respectively (21, 24). The average La—O distances in [La Br_2(diglyme)$_2$][$LaBr_2$(diglyme)] (25), (η^5: η^1: η^1-$C_5H_3(CH_2CH_2NMe_2)_2$-1,3) LaI_2(THF) (26) and $[La_2(C_3H_2O)_3(H_2O)_4].H_2O$ (27) have been reported as 2.58, 2.59, and 2.62 Å, respectively.

As seen in Fig. 3, there are extensive intermolecular H-bondings between coordinated and uncoordinated water molecules, $[pyda{\cdot}H]^+$ and $[pydc]^{2-}$ units in La(III) complex. The D—H and H….A distances and DHA angles in these two complexes indicate that the number of H-bondings in the Co(II) complex is less than those in La(III) complex. The counter ions $[pyda{\cdot}H]^+$ have important role in facilitating the formation of extensive H-bondings in both complexes, particularly in the La(III) complex. Therefore, both ion pairing and H-bonding factors are involved in the construction of the final extended layers that connect to each other to provide self -assembling complexes. As a result, the lattice energy in each case is expected to be large.

By considering some of the $\mathbf{LH_2}$ complexes already reported by this research group (16–18), the two cases under discussion, and the examples provided from the literature (11, 15), one may conclude that in the presence of an amine the ionic metal complex of $[pydc]^{2-}$ should be formed. However, it has to be noticed that this is not necessarily true for all complexes (16).

Solution studies for Co(II) complexes

The equilibrium potentiometric pH titration profiles of $\mathbf{LH_2}$ in (*a*) absence and (*b*) presence of Co^{2+} ion in a 1:2 (Co^{2+}:$\mathbf{LH_2}$) ratio are shown in Fig. 4. The protonation constants ($K_n^H = [H_nL]/[H_{(n-1)}L][H]^n$) were calculated by fitting the potentiometric pH data to the program BEST (28). The abbreviations L, LH, LH_3 and L_2H_2 in Figs 4 and 5 denote to the $\{[pyda][pydc]\}^{2-}$, $\{[pyda{\cdot}H][pydc]\}^-$, $\{[pyda{\cdot}H_2][pydc{\cdot}H]\}^+$, and $\{[pyda{\cdot}H]_2[pydc]_2\}^{2-}$ species, respectively. The results are listed in Table 4, and the species distribution in the absence of metal ion is shown in Fig. 5. As is obvious from Fig. 5, the self-assembling system cannot exist at all at pH>8 and pH<1; at the high pH limits, the partners exist as a neutral amine $[pyda]^{\cdot}$ and a dicarboxylate anion $[pydc]^{2-}$, whereas at the low pH limits, they exist as a diprotonated amine $[pyda{\cdot}H_2]^{2+}$ and a neutral dicarboxylic acid $[pydc{\cdot}H_2]^{\cdot}$. However, maximum amount of the self-assembling system ($[pyda{\cdot}H_2]^{2+}[pydc]^{2-}$), ($\mathbf{LH_2}$) exists (at an about 90% level) at a pH range of about 4.0–4.5, in solution. It is interesting to note that, although both [pyda] and $[pydc{\cdot}H_2]$ exist in three-protonated forms, the pH metric data of their 1:1 mixture cannot be fitted to a six-protonation model. This is obviously in support of the formation of the ion-association compound, in solution.

As is seen from Fig. 4, the potentiometric titration curve of $\mathbf{LH_2}$ system is depressed considerably in the presence of Co^{2+} ion at the metal-to-ligand mole ratio of 1:2. The extent of depression obviously depends both on the stoichiometries

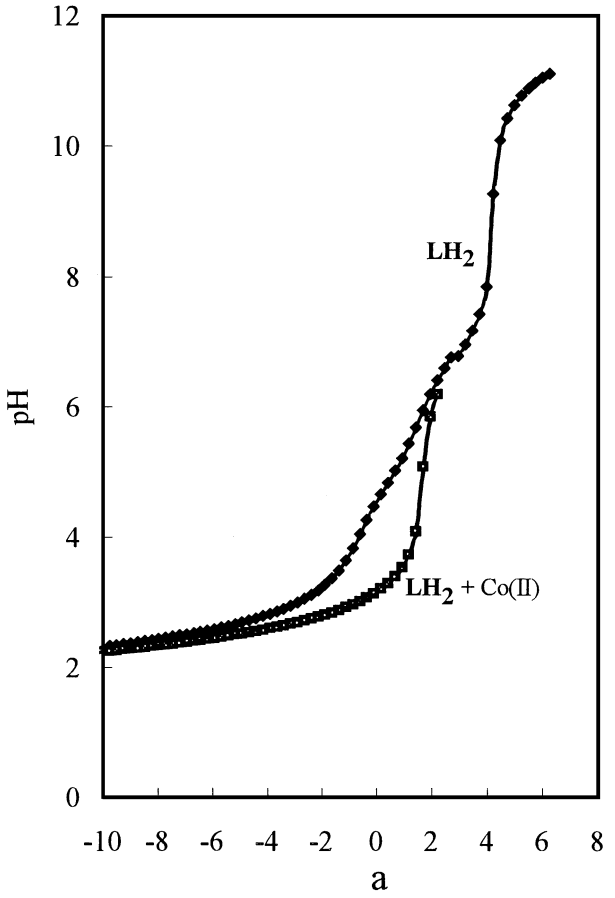
Fig. 4. Potentiometric pH titration curves of $\mathbf{LH_2}$ in the (*a*) absence and (*b*) presence of Co^{2+} ion. Conditions: $[\mathbf{LH_2}] = 1.0 \times 10^{-3}$ M; $[Co^{2+}] = 5.0 \times 10^{-4}$ M; $[H^+] = 0.01$ M; "a" is the molar ratio of $[OH]^-/[LH_2]$, negative values being that of $[OH]^-/[H^+]_{excess}$.



of the resulting complexes and the ability of metal ion to bind to the ligand components. The cumulative stability constants, β_{pqr}, are defined by eq. [1] (charges are omitted for simplicity).

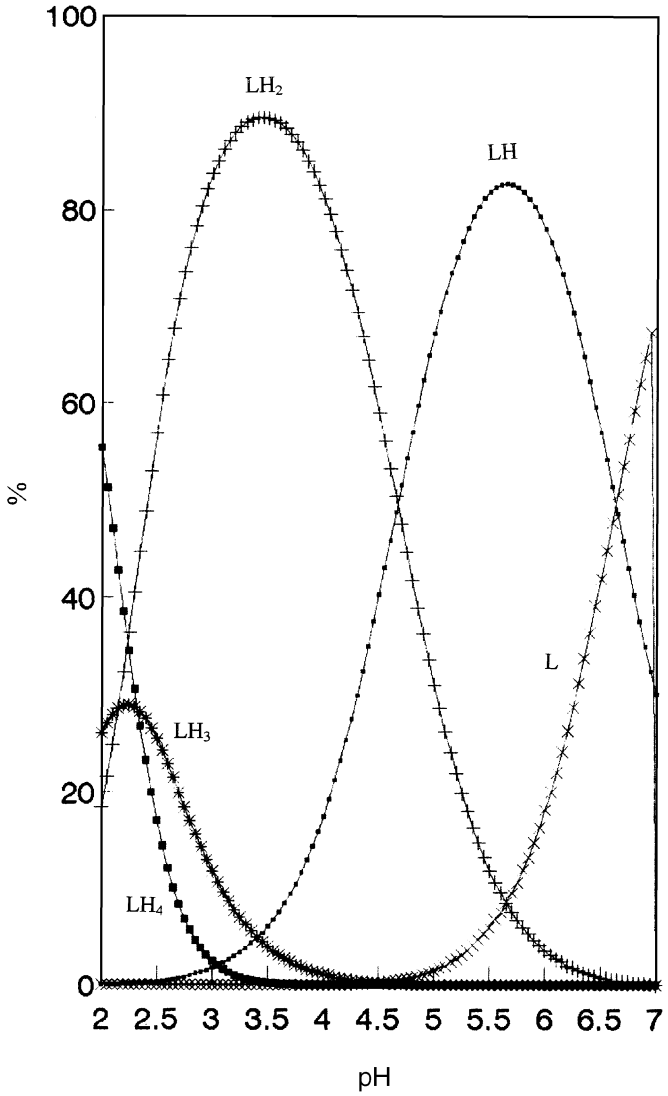
$$[1] \qquad pM + qL + rH \overset{\beta_{pqr}}{\rightleftharpoons} M_pL_qH_r$$

$$\beta_{pqr} = \frac{[M_pL_qH_r]}{[M]^p[L]^q[H]^r}$$

where M is the metal ion, L is the ligand $\mathbf{LH_2}$, H is the proton, and p, q, and r are the respective stoichiometric coefficients. Since the ligand and complex activity coefficients are unknown, the β_{pqr} values are defined in terms of concentrations. The errors are minimized by use of a high constant ionic strength (0.1 M) and low ligand concentration (1.0×10^{-3} M).

The potentiometric pH titration curve of $\mathbf{LH_2}$ in the presence of Co^{2+} ion was fitted to the program BEST, in order to calculate the cumulative stability constants of likely complexed species in solution. The results are included in Table 4, and the species distribution diagram of $\mathbf{LH_2}$ in the presence of Co^{2+} ion is shown in Fig. 6. From Fig. 6, it is obvious that negligible amounts of deprotonated CoL and CoL_2 complexes are formed in solution, over the entire pH

Fig. 5. Distribution curves for L^{2-}, LH^-, $\mathbf{LH_2}$, LH_3^+, and LH_4^{2+} in the self-assembling system in the absence of Co^{2+}.



range of 2.0 to 7.0, while the monoprotonated forms of these species (i.e., CoLH and CoL_2H) show an extent of about 21% (at pH 2.5) and 46% (at pH 7.0), respectively. On the other hand, a CoL_2H_2 complex (i.e., $[(pyda{\cdot}H)]_2[Co(pydc)_2]$) is formed to an extent of about 41% at a pH range of about 4.0–4.5 and decreases in concentration at higher and lower pH values in the expense of increased amount of CoL_2H and CoLH, respectively. Thus, the solution studies strongly support the predominance of the formation of a CoL_2H_2 complexed species with a stoichiometry similar to that of the isolated crystalline complex.

Experimental

Materials

2,6-Pyridinediamine (98%) was purchased from Aldrich and 2,6-pyridinedicarboxylic acid (98%), triethylamine (99%), and tetrahydrofuran (99.7%) were purchased from Merck. Potassium hydroxide, potassium nitrate, potassium hydrogen phthalate, cobalt(II) nitrate hexahydrate 99%, and

lanthanum(III) nitrate hexahydrate were of analytical grade from Merck. Doubly distilled deionized water was used throughout. The synthesis of $\mathbf{LH_2}$ was performed using a previously reported procedure (3).

Instruments

IR spectra were recorded on a Perkin-Elmer 343 and 1720X spectrophotometer using KBr discs. Melting points were determined with a Buchi 520 and were not corrected. ^{1}H NMR and ^{13}C NMR spectra were obtained on a Bruker 250 (250 and 62.5 MHz, respectively) spectrometer. Chemical shifts are reported on the δ scale relative to TMS. Mass spectra were recorded with a MS80RFA spectrometer. Elemental analyses were performed with a Perkin-Elmer 240 apparatus. A Pre-Unicam Spa Philips atomic absorption was used to determine the percentage of Co(II) and La(III) in the complexes. A Jeneway ion analyzer 3045 was applied for quantitative analysis of the NO_3^- anion. All pH measurements were carried out with a model 632 digital pH meter equipped with a combined glass–calomel electrode.

Synthesis of $[pyda{\cdot}H]_2[Co(pydc)_2]{\cdot}H_2O$ complex

To a solution of $Co(NO_3)_2.6H_2O$ (0.26g, 0.9 mmol) in water (20 mL) was added a solution of $\mathbf{LH_2}$ (0.5g, 1.8 mmol) in water (100 mL) and the resulting light brown solution stirred for 15 min. After three weeks, light brown crystals were isolated. The crystals were collected, washed with fresh distilled water, and dried. The pure light brown block shaped crystalline Co(II) complex (0.47g) was prepared in 82.2% yield. mp 285–88°C. IR (KBr) (cm^{-1}): 3520 (s), 3360 (s), 3280 (s), 3160 (s), 1660 (s), 1560 (s), 1480 (w), 1420 (m), 1380 (m), 1320 (m), 1280 (m), 1180 (w), 1130 (w), 1078 (m), 960 (m), 905 (m), 820 (w), 760 (m), 720 (m), 680 (m), 670 (m), 560 (m), 520 (w), 480 (w), 440 (w), 400 (w), 360 (w), 300 (w). ^{1}H NMR (DMSO-d_6) (ppm) δ: H 4.40 (d, 4H, ^3J = 8 Hz, H3,5, pyda·H), 6.31 (t, 2H, ^3J = 8Hz, H4, pyda·H), 22.5 (H4, pydc), 75.0 (H3,5, pydc). (C5). Anal. calcd. for $C_{38}H_{40}La_2N_{10}O_{22}$ (%): C 36.00, H 3.15, N 11.05, La 21.93; found: C 35.81, H 3.19, N 10.99, La 22.00.

Determination of X-ray crystal structure

X-ray crystallographic data were obtained on a Bruker SMART diffractometer equipped with a molybdenum sealed tube and a graphite monochromator at 296 (2) K for the complex **I** and 110 (2) K for the complex **II**. The final cell parameters were determined using the SAINT$^+$ software. It was not found necessary to apply decay or absorption corrections to the data. The data were reduced to give the number of unique reflections.

The structure was solved by automatic direct methods using SHELXTL-PC. The structure was refined by full-matrix least-squares analysis on F^2 with SHELXL. The non-hydrogen atoms were refined anisotropically and all the hydrogen atoms were located from subsequent difference Fourier maps and refined with individual temperature factors to a final R value of 0.0482 for the complex **I** and 0.0442 for the complex **II**.

pH metric titrations

The base used for potentiometric pH titrations was carbonate free potassium hydroxide, which was standardized against primary standard oven-dried potassium hydrogen phthalate. A CO_2-free atmosphere for the base was ensured throughout. The potentiometric apparatus used consisted of a 50 mL glass jacketed cell, a constant temperature bath (MLW thermostat, 25.0 ± 0.1°C), a combined glass electrode, and a 10 mL capacity Metrohm piston burette, for which the tip was sealed in the cap of the titration cell with a clamp and O-rings. Atmospheric CO_2 was excluded from the titration cell with a purging steam of purified nitrogen gas. The electrodes were calibrated in the thermostated cell with standard acid–base to read pH directly (pH = –log $[H^+]$). The value of $K_w = [H^+][OH^-]$ used in the calculations was $10^{-13.78}$ (28). In all experiments, a 1.0×10^{-3} M solution of the ligand was used. The ionic strength was adjusted to 0.1 M with KNO_3. Before an experimental point (pH) was measured, sufficient time allowed for establishment of equilibrium.

Ligand protonation constants and its metal complexes' protonation, stability, and hydrolysis constants were calculated using the program BEST methods described by Martell and Motekaitis (29).

Conclusions

We have demonstrated that the complexation reaction between a novel pyridine containing self-assembling system ligand $\mathbf{LH_2}$ with $Co(NO_3)_2$ and $La(NO_3)_3$ in water leads to the formation of anionic complexes involving $[pyda{\cdot}H]^+$ counter ion. The 2,6-pyridinediamine can serve as a proton acceptor source and the protonated position in the cationic counter ion is the pyridine nitrogen atom while the two protons in the ligand $\mathbf{LH_2}$ are located at the two -NH_2 nitrogen positions. The intermolecular forces existing between anionic and cationic units in the Co(II) and the La(III) complexes consist of both H-bonding and ion-pairing. The solution ^{1}H NMR spectra of the resulting paramagnetic Co(II) and diamagnetic La(III) complexes show the resonances of both cationic and anionic ions $[pyda{\cdot}H]^+$ and $[pydc]^{2-}$ in DMSO-d_6. The results of the potentiometric pH titrations in aqueous solutions also revealed the predominance of the $[pyda{\cdot}H]_2[Co(pydc)_2]$ complex at a pH range 4.0–4.5. The equilibrium constants for all major complexes formed in aqueous solutions are reported. We are now expanding our research to investigate complexes synthesized from Hg, Pd, Pt, Cd, Pb, Tl, V, Sb, Sn, and Zr cations.

Acknowledgments

Teacher Training University and University of Razi financially supported this work. We are grateful to Prof. M. Reza Ghadiri's research group at Scripps Research Institute for X-ray crystallographic data for Co(II) complex. We are also grateful to Dr. G.U. Grintseleu-Knyazev from General and Technical Chemistry Division of Academy of Science of Russia for X-ray crystallographic data for La(III) complex.

Novel terpenoids from the Sea Hare *Aplysia punctata*

John A. Findlay and Guoqiang Li

Abstract: The structures of 23 compounds isolated from the sea hare *Aplysia punctata* have been determined by spectroscopic means. These include four new diterpenes (**1**–**4**): **1**, neoparguerol dione, is a tricyclic diterpene featuring a novel octane-1,5-dione A ring; **2** is deacetylparguerol; **3**, punctatene acetate, shares the same [2:2:1] bicyclic system as dactylomelol from *A. dactylomela*; and **4**, punctatol, has the same skeleton as laurencianol of algal origin. Diastereomeric sesquiterpenes **5** and **6** are similar to some compounds of algal origin, as is **7**, perforatol, which shares the same carbon framework as perforatone from *Laurentia perforata*. In addition we have isolated 16 known compounds comprising 12 sesquiterpenes: perforenone, laurene, α-bromocuparane, α-isobromocuparane, laurinterol, debromoallolaurinterol, laurenisol, isofiliformin, obtusenol, β-snyderol, a dibromochamigrane, a friedosnyderane, two diterpenes: isoconncindiol and parguerol, and two C-15 acetogenins: laurenyne and laurencenyne. These known compounds have been reported previously either from other *Aplysia* species or from *Laurencia* species.

Key words: *Aplysia punctata*, terpenoids, Sea Hare constituents.

Résumé : Faisant appel à des méthodes spectroscopiques, on a déterminé les structures des 23 composés isolés du lièvre de mer, *Aplysia punctata*. Ils comprennent quatre nouveaux diterpènes (**1**–**4**): **1**, la néoparguéroldione, est un diterpène tricyclique comportant un nouveau cycle A formé d'une octane-1,5-dione; **2**, est le désacétylparguérol; **3**, l'acétate de punctatène comporte le même système bicyclo[2.2.1] que le dactylomélol extrait d'*A. dactylomela* et **4**, le puntatol, comporte le même squelette que le laurencianol tiré d'algues. Les sesquiterpènes diastéréomères **5** et **6** sont semblables à quelques composés tirés d'algues et il en est de même pour le composé **7** qui comporte le même squelette carboné que la perforatone isolée de *Laurentia perforata*. On a isolé de plus 16 composés connus, dont 12 sesquiterpènes: perforénone, laurène, α-bromocuparane, α-isobromocuparane, laurintérol, débromoallolaurintérol, laurénisol, isofiliformine; obtusénol, β-snyderol, un dibromochamigrane, un friedosnyderane, deux terpènes (l'isoconncindiol et le parguérol) et deux acétogénines en C-15 (la laurényne et la laurencényne). Ces composés connus avaient été isolés antérieurement d'autres espèces d'*Aplysia* ou d'espèces de *Laurencia*.

Mots clés : *Aplysia punctata*, terpénoïdes, constituants du lièvre de mer.

[Traduit par la Rédaction]

Introduction

The sea hare *Aplysia punctata* is widely distributed from the Atlantic coasts of Greenland, Norway, and the Baltic to the Mediterranean and the Canary Islands (1); its toxic properties have been known since ancient times, and it was reported (2) that the secretion of *A. punctata* was capable of producing urticaria, severe inflammation, and alopecia. Previous chemical studies on this species led to the isolation of uroporphyrin (3), epidioxysterols (4), and seven monocyclic polyhalogenated monoterpenes (5), the latter originating from the red alga *Plocamium collineum*. In addition, data exists concerning the ecological relationship between sea hares (Opistobranch molluscs) and their diet of red algae, mostly of the *Laurencia* and *Plocamium* genera (6). Evidence suggests that many of the terpenoid compounds found in *Aplysia* species (sp.) are of algal origin, and that the animals are capable of modifying some of the terpenoid compounds via metabolic transformations. Thus, the toxic and predator deterrent factors in sea hares may well be due, in large part, to their ability to accumulate and modify compounds of dietary origin.

In our studies, the animals (*Aplysia punctata*, 150 g, wet wt), collected from the northwest coast of Sardinia, Italy, were chopped and extracted with ethanol (95%). The crude extract was subjected to solvent partitioning and repeated chromatographic separation, and 23 compounds were isolated; their structures have been deduced from spectral data. Among these compounds only one, 5-epidioxycholest-6-ene, has been reported from *A. punctata* before (4). The remainder, isolated from this animal for the first time, include four new diterpenes **1**–**4**, three new sesquiterpenes **5**–**7** (see Scheme 1), as well as 16 known compounds comprising 12 sesquiterpenes: perforenone (7), laurene (8), α-bromocuparane, α-isobromocuparane (9), laurinterol (10), debromoallolaurinterol (11), laurenisol (12), isofiliformin (13), obtusenol (14), β-snyderol (15), a dibromochamigrane (16), a friedosnyderane (17), the two diterpenes isoconcinndiol (18)

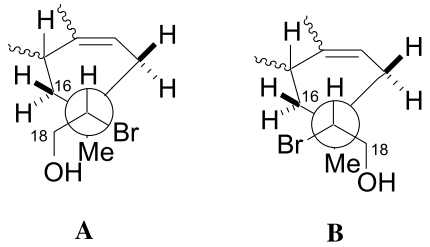
and parguerol (19), and two C-15 acetogenins: laurenyne (20) and laurencenyne (21). These were identified by comparison of spectroscopic and optical rotation data with values in the literature. These known compounds have been previously reported either from other *Aplysia* species or from *Laurencia* species.

Compound **1** was isolated as an optically active semisolid. The ^{13}C NMR and DEPT spectra (Table 1) show a total of twenty carbons, which comprise two methyls, seven methylenes, six methines, and five quaternary carbons. In addition to the two carbonyls and two double bond carbons, four downfield signals correspond to three oxygen-bearing carbons and one bromide methine carbon in view of their proton and carbon chemical shifts. The molecular formula, $C_{20}H_{29}BrO_5$, deduced from these data is supported by EI-MS (found m/z = 412/410 ([$M^+ - H_2O$]) and 411/409 ([$M^+ - H - H_2O$]) and implies the presence of three rings. The proton coupling systems revealed from the ^1H-^1H COSY spectrum show several distinct patterns consistent with structural features in **1**, namely, coupled protons assigned to H-3/H-4/H-5, H-7/H-8/H-9/H-10/H-16, H-13/H-14, and H-17/H-18. Analysis of HMBC data allows the incorporation of these coupling systems into structure **1**. Thus, the features of the C ring are indicated by HMBC correlations Me-19 to C-14, C-15, C-16, and C-17 and the correlations from H-13 to C-10, C-12, and C-15. Ring B is supported by the correlations from Me-20 to C-11, C-12, and C-7. Finally, the correlations of H-5 to C-3, C-4, C-6, and C-7, and of H-1 to C-2, C-7, C-11, C-12, and C-20, and of H-3 to C-2, C-4, and C-5 affirm the novel cyclooctadione A ring system. The bromine is assigned to C-17 on the basis of chemical shifts and is consistent with biogenetically related compounds in the literature such as parguerol and isoparguerol (19).

The stereochemical features of compound **1** were deduced from NOE experiments. The strong NOE enhancements between H_3-20 and H-10 imply these groups are axial. The α configuration of the hydroxyl at C-1 follows from the NOE enhancements between H-1 and H-13 and between H-1 and H_3-20. The β orientation of the hydroxyl group at C-9 is assigned on the basis of the observed NOE between H-9 and H-7. The large J value for H-9 (~11.2 Hz) also indicates that this methine proton is axial. Finally, the Me-19 must possess an α orientation in view of the NOE enhancements between Me-19, H-14 α, and H-16 α. The large NOE enhancements between H-17 and H-10 imply that rotation around the C15—C17 bond is severely restricted, and this allows determination of the orientation of bromine and the relative configuration at C-17. The two possible configurations for bromine at C-17, together with possible side chain conformations based on stereochemical considerations and NOE results, are shown in partial structures A and B (Fig. 1). The NOE enhancements at H-16 β when protons at C-18 were saturated suggested that these methylene protons are close to C-16. This result is consistent only with case A. The lack of significant NOE enhancements between H-18 and H-14 further supports the configuration and conformation in A. Thus, it is possible to assign the relative stereochemistry as shown.

Fig. 1. Configuration of C-17 in neoparguerolidione (**1**).



A global conformational search using MacroModel 4.5 software, MM2 force field (22), and the proposed structure **1** gives a total of 15 conformations in which the energy differs within 3 kcal mol^{-1}. The results indicate a flexible eight-membered ring, with maximum mobility at the C-4 methylene. The rotations of the OH group at C-18 along the C—O bond (energy barrier ~ 2.9 kcal mol^{-1}) and side chain along the C-15—C-17 bond (energy barrier ~ 13.3 kcal mol^{-1}) are restricted owing to steric hindrance. The interatomic distances for the most stable conformation are consistent with NOE data, and in particular, indicate a distance of 2.0 Å between H-16 β and a proton at H-18.

Diterpene **1** possesses a new carbocyclic skeleton, which is a modification of the known pimarane framework. Its

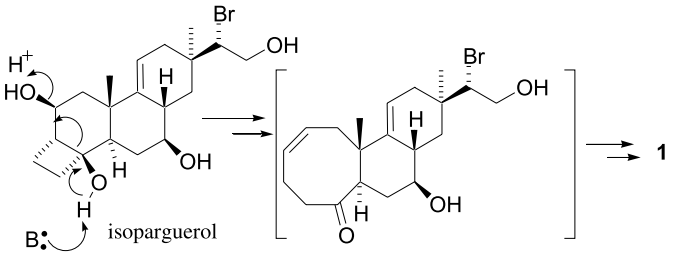
[a]Observed NOE signals when the proton on column 3 is irradiated.

structure is closely related to isoparguerol and parguerol, cytotoxins isolated from the sea hare *Aplysia dactylomela* by Schmitz et al. (19). A possible biogenetic pathway for the formation of **1** from isoparguerol is outlined in Fig. 2. In view of the structural relationship of **1** to isoparguerol we suggest this new carbon skeleton be designated neoparguerane and diterpene **1**, neoparguerolidione.

From the same fraction that contained neoparguerolidione (**1**), two other polar metabolites were isolated, one of which proved to be the known cytotoxic parguerol, while the other was shown to be deacetylparguerol **2**, previously reported only as a hydrolysis product of parguerol (19). Chemical shift assignments are shown in Table 2. The structure and stereochemistry of **2** were established primarily by 1D and 2D NMR experiments. Of special interest are the NOE correlations that support the previously unassigned stereochemistry of the Br at C-17 as shown. Thus, **1** and **2** possess

Fig. 2. Proposed biogenesis of neoparguerolidione (**1**) from isoparguerol.



the same relative stereochemistry in their B, C, and D rings and side chain. Both proved to be unstable, particularly in chloroform, perhaps due to the bromohydrin feature and unfortunately precluded obtaining HR-EI-MS data.

[a]Observed NOE signals when the proton on column 2 is irradiated.

Diterpene **3** was isolated as an optically active oily substance whose composition $C_{22}H_{36}O_3$ was revealed by HR-EI-MS. The strong absorption peaks in the IR spectrum at 1739 and 1240 cm^{-1} indicate the presence of an ester group, and the weak absorption at 1640 cm^{-1} is consistent with the presence of vinyl groups. The ^{13}C NMR and DEPT spectra show a total of 22 carbon signals, which consist of six methyls, seven methylenes, four methines, and five quaternary carbons. Eight downfield carbons are assigned to a carbonyl group, four double bond carbons, and three oxygen-bearing carbons and thus, diterpene **3** has two rings.

Analysis of ^1H NMR, ^1H-^1H COSY, HMBC, and HMQC spectra affords the chemical shift assignments compiled in Table 3. An examination of ^1H NMR and ^1H-^1H COSY spectra reveals several coupled spin systems: an ABX system assigned to the mono-substituted olefin protons at C-1/C-2, and three sequences of $-CH_2CH_2CH-$ assigned to protons at C-4/C-5/C-6, C-8/C-9/C-10, and C-12/C-13/C-14. The bicyclic system was established by the HMBC correlations from H-10 to C-6, C-7, C-8, and C-11. The side chains were located via the correlation of H_3-20 to C-2, C-3, and C-4 and from H_3-18 to C-6, C-10, and C-11. The location of the acetate moiety is confirmed by the C-3 chemical shift. For the oxygen-bridged bicyclic ring system in diterpene **3**, the H-10 proton and H_3-19 must be on the same face of the bicyclo [2.2.1] ring system, allowing for the assignment of

[a]Observed NOE signals when the proton on column 3 is irradiated.

Hα-8, Hβ-8, Hα-9, and Hβ-9 by NOE. The strong NOE enhancement at H_3-18 when H-9 α was irradiated indicates an α methyl group. The absence of NOE observed at H-6 when irradiating H_3-18 is consistent with H-6 having a β conformation.

Diterpene **3** shares the same relative configuration of the bicyclic system as dactylomelol, a related diterpene reported from *Aplysia dactylomela* whose strucure, including absolute stereochemistry, was established by X-ray analysis (23). Dactylomelol differs from **3** by featuring bromine at C-14 and chlorine at C-15 instead of a double bond and a hydroxyl at C-3. We designate **3** punctatene acetate; it is the second example of the novel dactylomelol skeleton in compounds isolated from sea hares, and no similar metabolites have been isolated from algae thus far.

The ^{13}C NMR and DEPT spectra of dibromoditerpene **4** reveal a total of 20 carbon signals comprising five methyls, seven methylenes, four methines, and four quaternary carbons. Seven downfield signals correspond to a double bond, three oxygen-bearing quaternary carbons, and two bromine-bearing methine carbons. The molecular formula, $C_{20}H_{34}Br_2O_2$, is supported by the HR-EI-MS derived ion [M^+ – 2HBr] (*m*/*z* = 304.2414; calcd. 304.24023) and a low-energy EI-MS (27 eV) in which the isotopic pattern of the ions (*m*/*z* = 453, 451, 449, [M^+-CH_3]) indicates the presence of two bromine atoms. Examination of ^1H NMR, ^{13}C NMR, DEPT, HMQC, and HMBC spectra allowed the assignment of proton and carbon chemical shifts, which are summarized in Table 4. Two kinds of coupled spin systems are evident from the ^1H-^1H COSY spectrum. An ABX system involving proton signals at δ 5.80, 5.12, and 4.92 indicates a mono-substituted olefin group while three other separate systems, typical of two adjacent methylene groups further coupled with one methine proton, are assigned to the protons H_2-2/H_2-3/H-4, H-6/H_2-7/H_2-8, and H-10/H_2-11/H_2-12.

Analysis of HMBC correlations allows incorporation of the structural units into a bicyclic diterpene skeleton. Thus, the HMBC correlations from Me-18 to C-1, C-2, and C-6, and the correlations from geminal dimethyl protons Me-19 and Me-20 to C-4, C-5, and C-6 allow the elaboration of

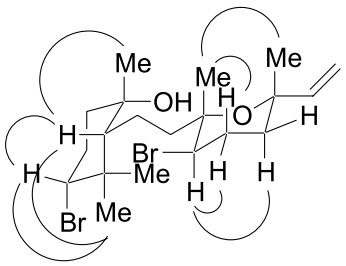
[a]Observed NOE signals when the proton on column 3 is irradiated.

Fig. 3. Significant NOE correlations in 4.



ring A. Furthermore, the HMBC correlations from Me-17 to C-8, C-9, and C-10, and the correlations from Me-16 to C-12, C-13, and C-14 are consistent with the ring B features.

The NOE enhancement data allowed distinction of the structure and stereochemistry of **4** from alternatives. Thus, the NOE enhancements between Me-18 and H-6 is indicative of a *cis* relationship. The equatorial bromine at C-4 follows from the large coupling constant (J = 12.8 Hz) between H-4 and the axial proton at C-3 and is supported by large NOE enhancements between H-4 and H-6. The lack of NOE between Me-17/Me-18 and H-10/Me-17 mitigates against alternative structures featuring an ether bridge from C-1 to C-9 and hydroxyl at C-13. The conformation and relative stereochemistry consistent with NOE data are illustrated in Fig. 3. Compound **4** has the same skeleton as laurencianol, an antibacterial diterpene previously isolated from the alga *Laurencia obtusa*, whose structure was determined by an X-ray diffraction study (24). Laurencianol differs from **4** by featuring a saturated side chain with a hydroxyl at C-14 and chlorine at C-15 and the reverse configuration at C-1. We designate **4** punctatol.

Two diastereoisomers, sesquiterpene alcohols **5** and **6**, were isolated from a polar fraction. Their structures were deduced on the basis of spectral data analysis. Alcohols **5** and **6** possess the same carbon skeleton as several sesquiterpenes such as dactyloxenes, dactylenol, and dactylenol acetate (25), which are quite common in *Aplysia* and *Laurencia* species.

Compound **5** was isolated as an optically active, oily substance whose IR spectrum indicates the presence of hydroxyl (3406 cm^{-1}) and alkenic (1658 and 1649 cm^{-1}) functionalities. The ^{13}C NMR and DEPT spectra indicate a

[a]Observed NOE signals when the proton on column 3 is irradiated.

total of 15 carbon signals comprising four methyls, four methylenes, four methines, and three quaternary carbons. Six downfield carbons are assigned to two double bonds and two oxygen-bearing quaternary carbons in view of their carbon chemical shifts (Table 5). The molecular formula, $C_{15}H_{26}O_2$, is assigned on the basis of spectral data and supported by a mass spectrum (found *m*/*z* = 221 and 220, corresponding to $[M^+ - OH]$ and $[M^+ - H_2O]$, respectively).

The ^1H-^1H COSY spectrum displays three types of coupled spin systems: an ABX system corresponds to H-1/H-2 of the vinyl group, while a system, due to two adjacent methylenes further coupled with a methine proton, is assigned to protons H-4/H-5/H-6. The remaining sequence involves a methyl doublet, one methylene, and two methines corresponding to H-8/H-9/H-10/Me-13. Assembly of these sequences and the remaining structural units follows from HMBC correlations. Thus, the cyclohexenol ring system devolves from the HMBC correlations from Me-14 C-6, C-7, and C-8, and the Me-12 protons to C-10, C-11, and C-6. The side chain is established from the HMBC correlations of Me-15 protons to C-2, C-3, and C-4.

The relative configuration in the cyclohexenol ring is resolved by NOE experiments. Thus, the NOE enhancements at H_3-13 (2.1%) and H_3-12 (2.6%) when H-6 was irradiated suggest the *cis* relationships of these groups. This relative stereochemistry is further supported by correlations between H-6, H_3-12, and H_3-13 in the NOESY spectrum. The relative configuration at C-3 remains unknown.

Sesquiterpene **6** was isolated as an optically active, oily substance whose IR spectrum is nearly identical to that of sesquiterpene **5** indicating the presence of hydroxyl (3416 cm^{-1}) and alkenic (1658 cm^{-1}) functional groups. Its ^{13}C NMR and DEPT spectra are similar to those of sesquiterpene **5** indicating a total of 15 carbon signals comprising four methyls, four methylenes, four methines, and three quaternary carbons. Six downfield carbons are assigned to two double bonds and two oxygen-bearing quaternary carbons in view of their carbon chemical shifts (Table 6). The molecular formula, $C_{15}H_{26}O_2$, is assigned on the basis of spectral data and supported by ions corresponding to $[M^+ - H]$, $[M^+ - OH]$, and $[M^+ - H_2O]$ in EI-MS.

The ^1H–^1H COSY spectrum displays the same three spin systems noted in **5**. The connection of these partial structures and the remaining structural units is completed via analysis of HMBC correlations. The relative stereochemistry of sesquiterpene **6** was revealed by NOE experiments and NOESY correlations. Thus, the NOE enhancement at H-6 (1.9%) when Me-12 was irradiated indicates a *cis* relationship.

The ^{13}C NMR and DEPT spectra (Table 7) of sesquiterpene **7** indicate a total of 15 carbons corresponding to four methyls, four methylenes, four methines, and three

[a]Observed NOE signals when the proton on column 3 is irradiated.

quaternary carbons. Two downfield carbons are indicative of a secondary alcohol and a bromine methine in view of their chemical shifts. The molecular formula $C_{15}H_{25}BrO$ is supported by HR-EI-MS ions $[M^+ - H_2O]$ and $[M^+ - Br]$ (*m/z* = 284.0967, 282.0982, and 221.1896; calcd. for $C_{15}H_{23}{}^{81}Br$, $C_{15}H_{23}{}^{79}Br$, and $C_{15}H_{25}O$: 284.0968, 282.0983, and 221.1905, respectively). The molecular ion was not observed even when using lower electron impact energy (27 eV).

The ^1H-^1H COSY spectrum displays three coupled spin systems consistent with proton sequences H_3-13/H-1/H_2-2/H-3/H-4/H_3-14, H_2-6/H_2-7, and H-9/H_2-10. The assembly of the tricyclic system of **7** is readily achieved by analysis of HMBC correlations. Thus, the cyclohexanol ring is supported by the HMBC correlations from the methine proton H-4 to C-5, C-6, and C-11, and from H_3-12 protons to carbons C-1, C-5, C-10, and C-11. The remaining two rings are established by HMBC correlations from H_3-15 to C-5, C-7, C-8, and C-9.

The relative stereochemistry of **7** is resolved by NOE experiments. Thus, the *cis* cyclohexanol–cyclopentane ring junction is deduced from the large NOE enhancements between H-1 and H-9 and dictates the configuration at C-1, C-5, C-9, and C-11. The *cis* fusion of the cyclobutane–cyclopentane rings is supported by the NOE between H_3-15 and H-9 and between H_3-12 and protons H_2-6 and H_2-7. The α configuration of the H_3-14 is assigned based on the NOE enhancements between H_3-12 and H-4. The hydroxyl group at C-3 is in an α configuration, in view of the NOE between H-3 and H-4.

Sesquiterpene **7** possesses the same skeleton as perforatone, a sesquiterpene previously isolated by Gonzalez et al. (26) from *Laurencia perforata*, whose structure and relative stereochemistry were assigned based on ^1H chemical shift, coupling constant data, and chemical modifications. However, these authors did not offer any evidence for their proposed stereochemistry at C-5, C-8, and C-9, which is opposite to that observed in **7**. We propose the name perforatol for **7**. The absolute configurations of compounds **1**–**7** are unknown.

Experimental section

General

Melting points were determined on a Kolfler hot stage apparatus and are uncorrected. Optical rotations were measured on a PerkinElmer 241 polarimeter. IR spectra were recorded on a Bruker IFS-25 spectrometer using 32 scans at a resolution of 2 cm^{-1}. Mass spectra were taken using a Kratos MS-50 spectrometer and UV spectra were recorded on a Hewlett-Packard 8452A diode array spectrophotometer.

[a]Observed NOE signals when the proton on column 3 is irradiated.

NMR spectra were recorded at room temperature in $CDCl_3$ (unless otherwise specified) on a Varian Unity 400 spectrometer operating at 399.944 MHz for ^1H and 100.575 MHz for ^{13}C. Signal positions were reported on the δ scale in parts per million (ppm) downfield from tetramethylsilane (TMS) as internal standard or reference using the solvent residue peaks. All 2D NMR were recorded (non-spinning) at 25°C using standard Varian software (Version 4.3). Analytical and preparative thin layer chromatography (ptlc) were performed on precoated plates (Kieselgel 60F254, Baker Si500F, and Baker Si-C18F). Substances were made visible on chromatographic plates by viewing under UV light (254 nm), or spraying with phosphomolybdic acid reagent. Vacuum liquid chromatography was carried out on Kieselgel 60G type of silica gel.

Animal material

The animals, *Aplysia punctata* (wet weight 150 g), were collected at Porto San Paolo (Olbia), Sardinia, Italy in April 1993. A voucher specimen was identified and stored by Dr. David G. Reid of the Department of Zoology at The Natural History Museum, London, U.K. under register no. BM(NH) 1994038

Isolation

The sea hares were cut into small pieces and extracted with 95% ethanol (3 × 300 mL). Ethanol was striped off under vacuum at 40°C. The residue was treated with water (250 mL) and re-extracted with methylene chloride (3 × 200 mL) and ethyl acetate (3 × 200 mL). Solvents were evaporated under vacuum below 40°C. The combined methylene chloride and ethyl acetate crude extract (4.4 g) was chromatographed on a short silica gel column (230–400 mesh, 86 g, 7.0 × 6.5 cm) and eluted with hexane containing 10%, 25%, and 50–100% ethyl acetate yielding 4 fractions A, B, C, and D. Fraction A (0.41 g) was rechromatographed on a short column (Kiesegel 60 G, 2.0 × 3.5 cm) and eluted with hexane (60 mL), $CHCl_3$ (80 mL), and EtOAc (30 mL) giving fractions A1 (0.18 g), A2 (0.12 g), and A3 (0.10 g). Fraction A2 and A3 were combined with fraction B for further purification. Fraction A1 was further purified by repeated ptlc and yielded laurencenyne (6.8 mg) (Baker Si-C_{18} F, 0.2 mm, acetone, R_f = 0.63), laurene (16.6 mg) (Baker Si500 F, 0.5 mm, hexane, R_f = 0.49), α-isobromocuparene (4.0 mg) (Baker Si500F, 0.5 mm, hexane, R_f = 0.44), and a mixture of α-bromocuparene and bromolaurene (~1:1) (6 mg) (Baker Si500 F, 0.5 mm, hexane, R_f = 0.56). Fraction B (2.4 g) was purified on a silica gel column (230–400 mesh, 35 g, 4.0 × 4.5 cm) and eluted with an increasing gradient of EtOAc (0 ~ 100%) in hexane, producing 36 fractions (~90 mL each). A combination of fractions 3 to approximately 5 was further purified using silica gel column and ptlc on Kieselgel $60F_{254}$ plates (0.5 mm) giving debromoallolaurinterol (~0.57 g) (hexane–EtOAc = 20:1, R_f = 0.36), laurenisol (~ 0.31 g) (hexane–$CHCl_3$ = 3:1, R_f = 0.32), and laurenyne (4.6 mg) (hexane–$CHCl_3$ = 1:1, R_f = 0.49). Combined fractions 16–19 were further purified by repeated ptlc on Kieselgel 60F254 plates (0.5 mm) giving laurinterol (6.9 mg) (hexane–$CHCl_3$ = 3:1, R_f = 0.55), the dibromo chamigrane derivative (59.0 mg) (hexane–EtOAc = 20:1, R_f = 0.18), and perforenone (9.3 mg) (hexane–EtOAc = 20:1, R_f = 0.07). Fraction C (0.98 g) was separated on a silica gel column (Kieselgel 230–400 mesh, 22 g) using a solvent system of hexane containing increasing portions of EtOAc (0 ~ 100%) yielding 20 fractions (~40 mL each). A combination of fractions 4 to approximately 7 was further

© 2002 NRC Canada

purified via ptlc on Kieselgel $60F_{254}$ plates (0.5 mm) producing the friedosnyderane, 2,3,6-trimethyl-1-(3′-hydroxy-3′-methyl-5′-pentenyl)benzene (3.5 mg) (C_6H_6–CH_2Cl_2 = 3:1, R_f = 0.05), obtusenol (4.2 mg) (CH_2Cl_2, R_f = 0.44), punctatene acetate **3** (4.9 mg) (hexane–EtOAc = 9:1, R_f = 0.38), perforatol **7** (2.8 mg) (C_6H_6–$CHCl_3$ = 3:2, R_f = 0.32), β-snyderol (2.0 mg) (0.25 mm plate, hexane–$CHCl_3$ = 1:1, R_f = 0.12), and punctatol **4** (0.5 mg) (0.25 mm plate, hexane–$CHCl_3$ = 1:1, R_f = 0.08). From the combination of fractions 8 to approximately 19, 5-epidioxycholest-6-ene (3.3 mg) was isolated via ptlc on a Baker Si500 F (0.5 mm) plate using a solvent mixture of hexane–EtOAc = 3:1 (R_f = 0.21). Fraction D (1.5 g) was further separated on a short column (Kieselgel 60G) using solvents $CHCl_3$, $CHCl_3$–MeOH (4:1), and $CHCl_3$–MeOH (3:2), giving three fractions D1 (23 mg), D2 (1.0 g), and D3 (0.31 g). The fraction D3 was partitioned between ether and methanol–water (1:1). Evaporation of the ether phase gave a fraction D3*a* and concentration of the methanol solution resulted in fraction D3*b*. Fraction D2 (1.0 g) was chromatographed on a short column followed by ptlc on Baker Si-C_{18}F (0.25 mm) plate giving isoconcinndiol (13.7 mg) (acetone–H_2O = 4:1, R_f = 0.36) and two diastereoisomers : sesquiterpene **5** (7.8 mg) (MeOH/H_2O = 4:1, R_f = 0.41) and sesquiterpene **6** (4.4 mg) (MeOH/H_2O = 4:1, R_f = 0.28). Fraction D3b (0.25 g) was further purified on a short column (Kieselgel 60G, 2.7 × 3.3 cm, $CHCl_3$ – 0 to 20% MeOH gradient) and yielded 7 subfractions: D3*b*1 through D3*b*7. D3*b*2 (0.14 g), which underwent further purification via ptlc on Kieselgel $60F_{254}$ plates (0.5 mm) using a solvent of hexane–acetone (7:3), afforded neopargueroldione **1** (4.3 mg) (R_f = 0.05). D3*b*3 (0.09 g) was further purified via ptlc on Kieselgel 60 F254 (0.5 mm) using hexane–acetone (7:3) to yield parguerol (3.8 mg) (R_f = 0.03). Fraction D3*b*4 (0.09 g) was purified via ptlc on Baker Si-C_{18}F (0.25 mm) plates using acetone–H_2O (3:2) to give deacetylparguerol **2** (7.9 mg) (R_f = 0.55).

Neopargueroldione 1

Viscous semi-solid, $[\alpha]_D$ = +2.5° (acetone, *c* = 0.0020). NMR data see Table 1. IR (film) (cm^{-1}): 3309, 1696, 732. EI-MS *m/z* (%): 412 ([M^+ – H_2O], 3.6), 411 ([M^+ – H – H_2O], 7.4), 410 ([M^+ – H_2O], 3.2), 409 ([M^+ – H – H_2O], 7.0), 394 (6.1), 393 (3.4), 391 (3.3), 375 (3.3), 373 (3.0), 367 (9.5), 330 (13.0), 312 (28.6), 311 (39.5), 310 (11.4), 294 (9.1), 292 (7.0), 284 (14.0), 266 (14.2), 264 (16.0), 236 (17.8), 213 (26.8), 185 (100), 184 (86.8).

Deacetylparguerol 2

Semi-solid, $[\alpha]_D$ = –18.4° (CH_3OH, *c* = 0.0049). NMR data see Table 2. IR (film) (cm^{-1}): 3355, 2955, 1653, 1457, 1379, 1056, 1018, 668. EI-MS *m/z* (%): 398 (2.8), 396 (3.0), 380 (11.7), 278 (16.3), 363 (21.1), 362 (23.3), 361 (16.3), 360 (19.2), 349 (20.8), 347 (18.2), 346 (16.2), 345 (18.4), 327 (11.8), 299 (18.6), 298 (14.1), 281 (27.6), 273 (24.5), 272 (29.3), 2.57 (10.2), 256 (22.7), 255 (32.6), 254 (40.0), 237 (36.3).

Punctatene acetate 3

An oil, $[\alpha]_D$ = –14.5° ($CHCl_3$, *c* = 0.0024). NMR data see Table 3. IR (film) (cm^{-1}): 2970, 1730, 1454, 1370, 1240, 1002. HR-EI-MS *m/z*: 348.26025 ([M^+]) (calcd. for $C_{22}H_{36}O_3$: 348.26644). EI-MS *m/z* (%): 348 ([M^+], 2.0), 347 (7.8), 305 (1.7), 289 (5.4), 288 (10.3), 287 (18.0), 269 (10.2), 231 (12.9), 219 (18.4), 218 (15.7), 217 (11.1), 205 (52.6), 187 (44.7), 161 (53.1), 147 (92.8), 109 (100), 81 (81.4).

Punctatol 4

Solid, mp = 101–103°C, $[\alpha]_D$ = + 40° ($CHCl_3$, *c* = 0.00015). NMR data see Table 4. IR (film) (cm^{-1}): 3350, 2952, 1456, 1374, 1177, 1072. HR-EI-MS *m/z*: 304.2414 ([M^+ – 2HBr]) (calcd. for $C_{20}H_{32}O_2$: 304.24023). EI-MS *m/z* (27eV) (%): 453 ([M^+ – CH_3], 2.1), 451 (3.9), 450 (1.3), 449(2.5), 436 (1.2), 435 (3.3), 434 (1.5), 433 (5.3), 431 (2.7), 388 (1.6), 387 (5.3), 386 (4.6), 385 (5.1), 384 (6.9), 369 (14.7), 367 (14.4), 275 (18.4), 273 (20.3), 219 (96.1), 217 (100), 193 (79.8), 175 (30.6), 151 (29.9), 135 (62.1), 119 (38.1), 95 (52.3), 81 (56.3).

Sesquiterpene 5

An oil, $[\alpha]_D$ = +31.1° ($CHCl_3$, *c* = 0.0023). NMR data see Table 5. IR (film) (cm^{-1}): 3406, 2973, 1658, 1649, 1452, 1372, 1118, 1077, 919. EI-MS *m/z* (%): 221 ([M^+ – OH], 1.8), 220 ([M^+ – H_2O], 6.0), 205 (3.7), 203 (1.7), 202 (4.9), 187 (5.8), 177 (6.0), 177 (6.0), 152 (36.8), 148 (15.6), 139 (5.4), 137 (16.2), 135 (42.3), 133 (45.1), 121 (61.2), 109 (75.2), 81 (100), 71 (66.8).

Sesquiterpene 6

An oil, $[\alpha]_D$ = +10.4° ($CHCl_3$, *c* = 0.0012). NMR data see Table 6. IR (film) (cm^{-1}): 3416, 2973, 1658, 1452, 1379, 1118, 1043, 921. Lamellar polysilicate nanocomposite materials: Intercalation of polyethylene glycols into protonated magadiite

Marie-Josée Binette and Christian Detellier

Abstract: This paper reports the direct intercalation of organic polymers into the interlamellar spaces of the layered polysilicate magadiite. Poly(ethylene glycols) (PEG 3400 and PEG 1000) were intercalated into acidified magadiite (*H*-magadiite) by displacing a dipolar aprotic solvent (e.g., dimethylsulfoxide (DMSO)) from the *H*-magadiite – DMSO intercalate. This was done directly from the polymer melt at 155°C. The polysilicid acid (*H*-magadiite) was obtained by HCl titration of the sodic form of magadiite obtained by hydrothermal synthesis. Dipolar aprotic solvents (dimethylsulfoxide, *N*-methylformamide, and hexamethylphosphorictriamide) were intercalated in the interlamellar spaces of *H*-magadiite. PEG 3400 and PEG 1000 were then intercalated by dispersing the *H*-magadiite intercalates in a large excess of the polymers heated above their fusion temperature, without any solvent. The resulting polymer intercalated *H*-magadiite nanocomposites were isolated and purified and were shown by chemical analysis to have chemical formulae of $H_2Si_{14}O_{29}(\text{-}OCH_2CH_2\text{-})_{3.1}$ and $H_2Si_{14}O_{29}(\text{-}OCH_2CH_2\text{-})_{2.9}$, respectively, in agreement with a structure in which one unit cell of magadiite corresponds to three oxyethylene units. The dipolar aprotic solvents have been completely removed from the interlamellar spaces. ^{13}C NMR dipolar diphasing techniques show that the polymer chains in the interlamellar spaces of *H*-magadiite are more constrained than in the bulk polymer. ^{29}Si NMR spectra show that the structure of magadiite is unchanged by the two processes of intercalation. The polymer intercalates are characterized by interlamellar spacings of 4.6 and 4.4 Å, as determined by XRD. These values correspond to a flattened arrangement of the polymer chains in the interlamellar spaces. This is also in agreement with DSC data, which demonstrate that the polymer chains are no longer in the aggregation state characteristic of the bulk polymer.

Key words: lamellar polysilicates, polyethylene glycols, nanocomposite materials, polymer intercalation, magadiite.

Résumé : Ce travail décrit l'intercalation directe de polymères organiques dans l'entrecouche du polysilicate lamellaire magadiite. Deux polyéthylène glycols (PEG 3400 et PEG 1000) ont été intercalés dans la magadiite acidifiée (*H*-magadiite) par déplacement d'un solvant aprotique dipolaire (le diméthylsulfoxyde, DMSO) de l'intercalat *H*-magadiite–DMSO. Ceci a été fait directement à partir du polymère fondu à une température de 155 °C. L'acide polysilicique, *H*-magadiite, a été obtenue en titrant avec HCl la forme sodique de la magadiite obtenue par synthèse hydrothermale. Les solvants aprotiques dipolaires (DMSO, *N*-méthylformamide et hexaméthylphosphoramide) ont été intercalés dans l'espace interlamellaire de *H*-magadiite. PEG 3400 et PEG 1000 ont par la suite été intercalés en dispersant les intercalats *H*-magadiite dans un important excès de polymères chauffés au-delà de leur température de fusion, sans l'utilisation de solvant. Les nanocomposites *H*-magadiite intercalés de polymères ayant été obtenus ont, selon l'analyse chimique, les formules chimiques suivantes $H_2Si_{14}O_{29}(\text{-}OCH_2CH_2\text{-})_{3.1}$ et $H_2Si_{14}O_{29}(\text{-}OCH_2CH_2\text{-})_{2.9,}$ respectivement. Ces formules sont en accord avec une structure dans laquelle un unité cellulaire de la magadiite correspond à trois unités oxyéthylènes. Les solvants aprotiques dipolaires ont été complètement expulsés de l'espace interlamellaire. La résonance magnétique nucléaire en déphasage dipolaire du ^{13}C montre que les chaînes de polymère dans l'espace interlamellaire de *H*-magadiite sont moins mobiles qu'à l'état pur. La RMN du ^{29}Si montre que la structure de la magadiite demeure inchangée suite aux deux processus d'intercalation. Les intercalats de polymère sont caractérisés par un espace interlamellaire de 4,6 et 4,4 Å, comme démontré par la diffraction des rayons X. Ces valeurs correspondent à un arrangement en monocouche aplatie du polymère dans les espaces interlamellaires. Ceci est en accord avec les résultats de l'analyse par calorimétrie différentielle à balayage, qui démontre que les chaînes de polymère ne sont plus dans leur état caractéristique du polymère pur.

Mots clés : polysilicates lamellaires, glycols de polyethylène, matériaux nanocomposites, intercalation de polymères, magadiite.

Introduction

Nanocomposite materials are a relatively new class of materials, which are formed when organic and inorganic phases are mixed on a nanometer length scale. In particular, the study of polymer-based nanocomposites has recently attracted considerable attention mainly because this new class of materials represents an alternative to conventionally filled polymers (1). Such nanocomposites have been proven to lead to new and improved properties, compared to that of the pure parent polymer, such as reduced gas permeability (1*y*), increased modulus (1*b*), enhanced ionic conductivity (1*j*), increased solvent and heat resistance as well as decreased flammability (1*d*).

In general, polymers can be intercalated into an inorganic lamellar material by two different approaches: incorporation of a monomer followed by its "in situ" polymerization or by direct insertion of the polymer from solution or from the melt. It has been shown that polymer melt intercalation is the most promising approach to fabricate polymer-based nanocomposites (1*q*, 1*z*). Using this method, several groups studied the intercalation of polyethylene oxide (1*a*, 1*f*, 1*j*, 1*l*, 1*bb*) and polystyrene (1*c*, 1*o*, 1*q*, 1*u*) into lamellar inorganic materials. Several papers describe efforts to incorporate polymers into aluminosilicates, such as smectites, montmorillonite, and hectorite in particular (1*b–d*, 1*f*, 1*i*, 1*l*, 1*n–s*, 1*u*, 1*v*, 1*x*, 1*aa*, 1*bb*), or kaolinite (1*a*), which are used as the inorganic layered phase. Since layered aluminosilicates are rather organophobic, to facilitate the transport of the polymer chains into their interlamellar spaces, it is essential to first modify the silicate. Therefore, in most of the reported inclusions of polymers into aluminosilicate compounds, the interlamellar cations were exchanged with long-chain alkyl ammonium ions prior to polymer insertion (1*c–i*, 2).

In comparison, little work has been done on the preparation of nanocomposite materials derived from polymers and layered polysilicate. The family of crystalline alkali metal polysilicates includes kanemite, makatite, octosilicate, magadiite, and kenyaite. Their structures consist of one or more SiO_4 tetrahedra. Their layers contain terminal oxygen ions that are neutralized by sodium and (or) protons. All are naturally occuring minerals (3) that can also be prepared in the laboratory by hydrothermal synthesis (4). The layered compounds and their silicic acid derivatives are known to be host materials for intercalation and ion exchange (5). They can be used as alternative inorganic components for the formation of nanostructured hybrid-composites. Sugahara et al. (1*g*) prepared a magadiite–polyacrylonitrile intercalation compound and Wang and co-workers reported exfoliation of magadiite in an elastomeric epoxy polymer (1*e*, 1*h*). In both cases, the interlamellar sodium ions of magadiite were first exchanged with long-chain alkyl ammonium ions before the polymers were inserted.

Generally, two types of hybrid structures can be obtained: intercalated, in which one polymer chain is incorporated between the silicate layers; and delaminated, in which the silicate layers are dispersed individually in the organic matrix.

In this work, we report the synthesis of intercalated nanocomposites derived from the silicic acid, *H*-magadiite, and polyethylene glycol. The preparation is done by using the polymer melt intercalation approach. The resulting material has well-ordered multilayers in which inorganic and polymer layers alternate.

Experimental section

Na-magadiite

Na-magadiite was synthesized by the reaction of SiO_2 and NaOH under hydrothermal conditions according to a previously described method (4*b*, 6). SiO_2 (0.537 mol) was added to 80 mL of a solution of 1.25 M NaOH. The reaction mixture was stirred for 1 h and was then heated at autogenous pressure in a stainless steel-lined autoclave to 180°C for 20 h. The Na-magadiite was recovered by filtration, washed with water, and air-dried.

H-magadiite

Titration of Na-magadiite was performed according to the procedure of Lagaly et al. (5*b*). A suspension of 9.6 g of Na-magadiite per 100 mL water was stirred for 1 h. The suspension was then titrated with 0.1 N HCl to a final pH of 2.0. The mixture was stirred for an additional 24 h. The *H*-magadiite reaction product was separated by filtration and air-dried.

Intercalation

H-magadiite (0.5 g), dried at 100°C for 24 h, was dispersed in 20 mL of a polar organic substance (*N*-methyl formamide (NMF), dimethylsulfoxyde (DMSO), or hexamethylphosphorictriamide (HMPA)). For NMF and DMSO, the mixtures were stirred for 24 h at room temperature. In the case of HMPA, a temperature of 50°C was used. The resulting compounds are referred to as H-mag–NMF, H-mag–DMSO, and H-mag–HMPA.

Nanocomposite

The intercalation compound (most reactions were done with H-mag–DMSO) was separated from the organic liquid by centrifugation and was used without removing the adherent liquid for the incorporation of the polymer. Thus, 10 g of PEG 3400 (from Aldrich) was heated to 155°C. To this viscous melt, 2.0 g of *H*-mag–DMSO was added. After 7 days, the reaction was stopped by cooling. The product was worked up by washing and centrifuging in methanol to remove excess polyethylene glycol followed by air-drying and then drying in an oven at 110°C. Polyethylene glycol 1000 (Aldrich) was also used, under the same reaction conditions. These samples are referred to as H-mag–PEG3400 and H-mag–PEG1000.

Physical mixture

A physical mixture of *H*-magadiite and PEG 3400 was prepared by adding 0.9 g of *H*-magadiite to 0.09 g of PEG 3400 dissolved in 30 mL of hot chloroform. The suspension was stirred until total evaporation of chloroform occurred. This sample is referred to as H-mag–PEG3400.

Instrumentation

X-ray diffraction powder patterns were obtained on a Philips PW 3710 diffractometer using a generator voltage of 45 kV and a generator current of 40 mA. Samples were prepared on a circular silicon disk by dispersing 15 mg of

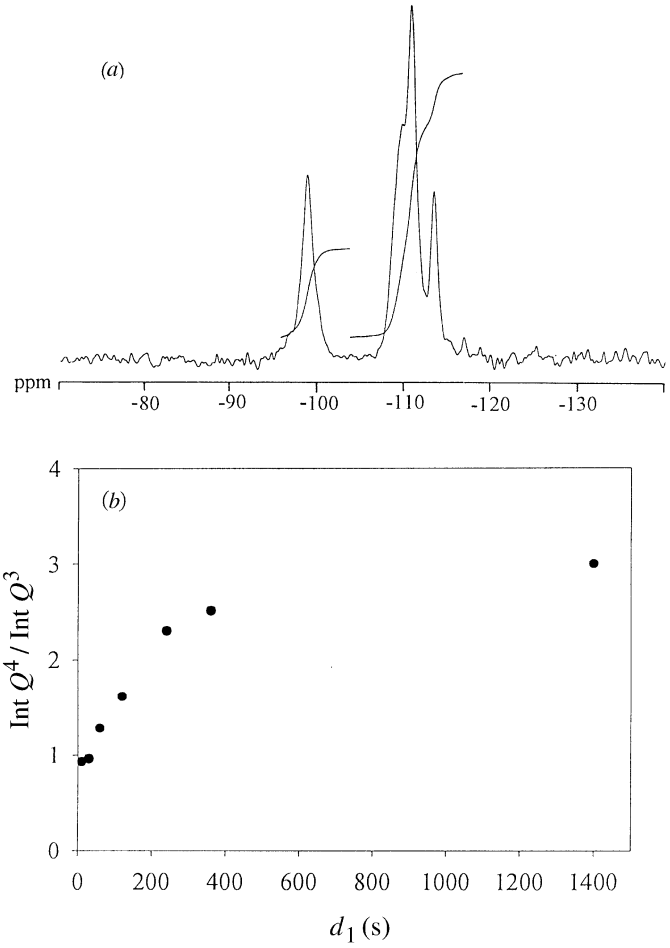
Fig. 1. (*a*) Solid-state ^{29}Si MAS NMR spectra with high-power decoupling and pulse delay of 1400 s for Na-magadiite; (*b*) graph showing the variation of the Q^4/Q^3 ratio as a function of the pulse delay used for the solid-state ^{29}Si MAS NMR analysis with high-power decoupling of Na-magadiite.

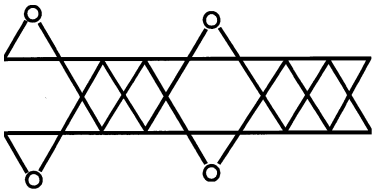


sample with 1 mL of water, followed by sonication for 10 s, and drying on the silicon disk. All DSC (differential scanning calorimetry) analyses were obtained on a thermal analysis controller TAC7/DX from Perkin Elmer. Samples (4–10 mg) were sealed in an aluminum pan and heated at 40°C min^{-1}. All NMR experiments were done on a Bruker ASX-200 spectrometer using a spinning rate of 4 kHz. ^{29}Si MAS NMR with high power decoupling used a pulse of 4 μs and a delay of 240 s, unless otherwise specified. The spectra were referenced to tetramethylsilane. ^{13}C CP-MAS and DD-MAS experiments were performed using a contact time of 0.2 ms and were referenced to hexamethylbenzene.

Results and discussion

Sodium magadiite was obtained by a hydrothermal synthesis following a published method (6), in which a mixture of silica, sodium hydroxide and water, in a molar ratio of 5:1:44, were heated at autogeneous pressure in a stainless steel-lined autoclave to 180°C for 20 h. This procedure avoids possible contamination by Teflon of the resulting product, which can occur when a Teflon-lined reactor is used (6).

Scheme 1. Structural model for magadiite.



The material obtained was characterized by FT IR, XRD, TGA, and ^{29}Si solid-state NMR. All data were in perfect agreement with previously published observations (7), showing that the material obtained was sodium magadiite. Of particular interest for the characterization is the ratio of the Q^4 ($Si(OSi)_4$) and Q^3 ($HOSi(OSi)_3$) peaks which are observed at –112 and –99 ppm, respectively, on the ^{29}Si NMR spectra. A series of spectra was obtained using various pulse delays. The longest delay used was 1400 s, corresponding to a value of $5T_1$ for the Q^4 resonance (8). The integrations give a ratio of 3.0. Figure 1*a* shows the ^{29}Si NMR spectrum obtained under those conditions. Figure 1*b* gives the variation of the Q^4/Q^3 ratio as a function of the delay. It appears that the spectrum of Fig. 1*a*, which gives a Q^4/Q^3 ratio of 3.0, is quantitatively reliable. This result is in agreement with the model previously proposed by different groups for the structure of magadiite (9) (Scheme 1). Combining the results from the thermogravimetric and elemental analysis gives the following chemical formula: $Na_{1.8}Si_{14}O_{30.2}\cdot 6.9H_2O$, which is in agreement with previously reported values (3*e*, 5*a*, 10).

The corresponding polysilicic acid (*H*-magadiite) was obtained by a titration of Na-magadiite by diluted HCl until a pH of 2 was obtained and maintained (11). The material obtained shows less crystallinity than Na-magadiite (Fig. 2); a basal spacing of 11.2 Å was observed corresponding to a collapse of the layers, resulting from a strong H-bond network between the silanol groups. The high-power decoupling ^{29}Si MAS NMR spectra, under high-decoupling conditions, shows that the characteristic Q^4/Q^3 of Na-magadiite is maintained. Under CP-MAS conditions, the Q^3 signal, observed at –101 ppm is strongly enhanced, in agreement with the protonation of the Q^3 sites. The thermogravimetric analysis shows a total weight loss of 5.5%, corresponding to the loss of physisorbed water below 100°C and of condensation of hydroxyl groups in the range 100–500°C.

To succeed in the intercalation of polymeric species in the interlamellar spacing of *H*-magadiite, it was first necessary to intercalate small polar organic molecules (POM) to break the network of H-bonds between the silanol groups (Scheme 2). Three different intercalates were prepared from DMSO, NMF, and HMPA. The corresponding X-ray diffraction patterns are given in Fig. 3 and show basal spacings of 15.6, 15.9, and 21.8 Å, respectively. These values are in good agreement with literature data for the DMSO (11) and the NMF intercalates (11, 12) and are in agreement with an arrangement where the HMPA molecule lies with its PO bond parallel to the interlamellar surfaces (according to the CPK model, HMPA in this orientation would occupy a minimum of 8.7 Å in the interlamellar region). ^{13}C CP-MAS NMR

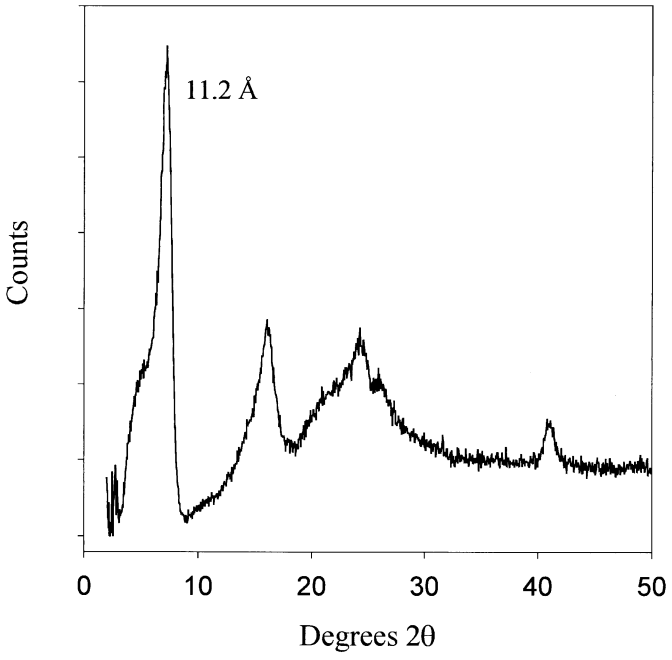
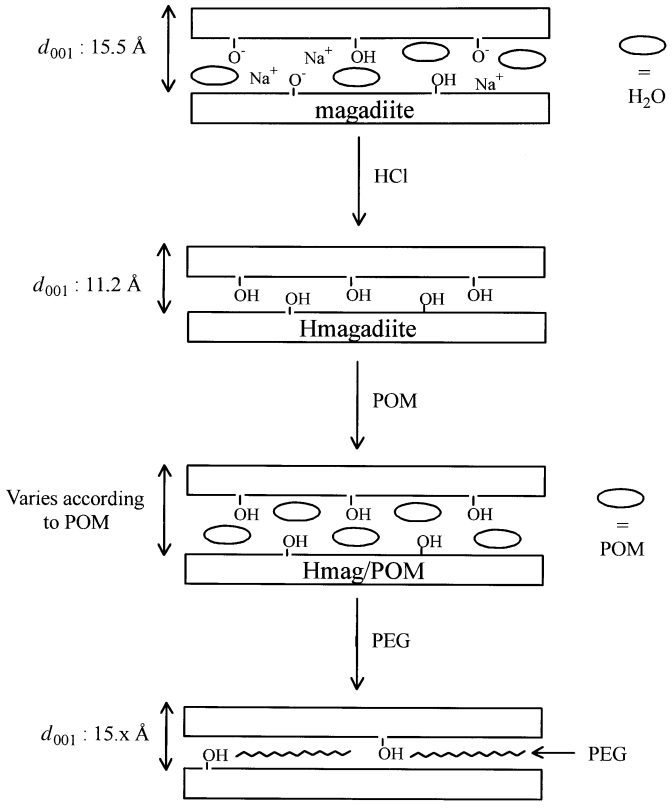
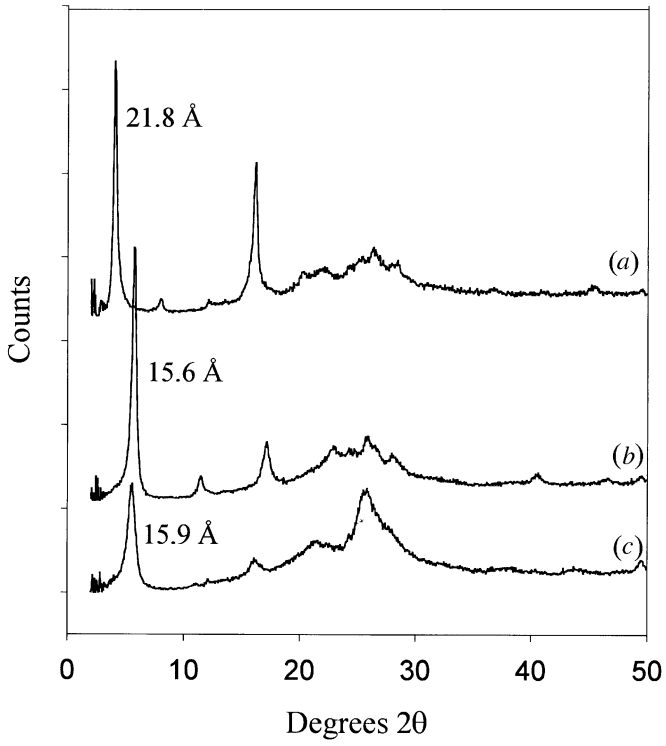


Scheme 2. Schematic representation of the different steps involved in the preparation of nanocomposites from *H*-magadiite.



analyses of the three intercalates show signals at 38.5 ppm (*H*-magadiite–DMSO), 25.6 and 164.1 ppm (*H*-magadiite–NMF), and 36.9 ppm (*H*-magadiite–HMPA). HPD ^{29}Si NMR analysis confirmed that this intercalation process did not modify the characteristic Q^4/Q^3 ratio of the magadiite structure.

Fig. 3. X-ray diffraction patterns (2–50°, 2θ) of: (*a*) H-mag–HMPA; (*b*) H-mag–DMSO; (*c*) H-mag–NMF.

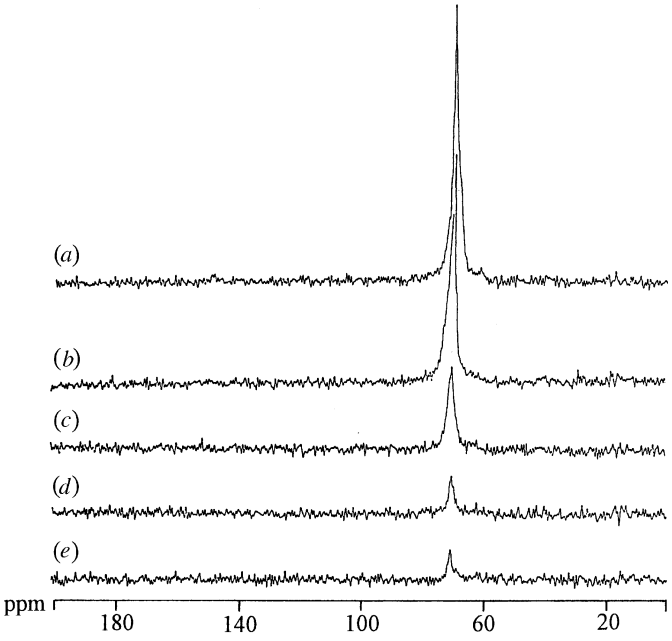


Two polyethylene glycols of molecular weight 1000 and 3400 (PEG 1000 and PEG 3400) were intercalated following a procedure previously described in the case of other lamellar minerals such as montmorillonite (1*q*) and kaolinite (1*a*). The POM-intercalated magadiites were vigorously dispersed in a large excess of the polymers heated above their fusion temperatures, without any solvent. Characterization of the resulting materials was done by XRD, FT IR, ^{13}C and ^{29}Si NMR, DSC, and elemental analysis. These data were systematically compared to those from control samples, consisting of physical mixtures of *H*-magadiite and PEG 1000 and 3400. Most of the intercalation experiments were carried out on the *H*-magadiite–DMSO intercalate.

The resulting polymer-intercalated *H*-magadiite materials (H-mag–PEG1000 and H-mag–PEG3400) were analyzed for their carbon and hydrogen contents. The analysis was done at high temperature (above 1000°C) to insure the total combustion of the organic materials. Percentages of carbon were 7.4 and 7.1, respectively, for H-mag–PEG1000 and H-mag–PEG3400 and the percentages of hydrogen were respectively, 1.6 and 1.7. From these results the chemical formulae of the two compounds were calculated, giving $H_2Si_{14}O_{29}(\text{-}OCH_2CH_2\text{-})_{3.1}$ and $H_2Si_{14}O_{29}(\text{-}OCH_2CH_2\text{-})_{2.9}$, respectively, in agreement with a structure in which one unit cell of magadiite corresponds to three oxyethylene units. The accepted value of the unit cell surface area is 52.8 Å^2 (5*b*). Knowing that the projected surface area of an oxyethylene unit is 14 Å^2, as determined from CPK models, one can estimate a maximum ratio of 3.8 oxyethylene units per magadiite unit cell. This is in agreement with our

© 2002 NRC Canada

Fig. 4. Solid-state ^{13}C CP–MAS NMR spectra for H-mag–PEG3400: (*a*) no dipolar dephasing; with dipolar dephasing: (*b*) τ = 10 μs; (*c*) τ = 30 μs; (*d*) τ = 50 μs; (*e*) τ = 70 μs.



experimental values of 3.1 and 2.9, indicating that the interlamellar region is not fully saturated with oxyethylene units.

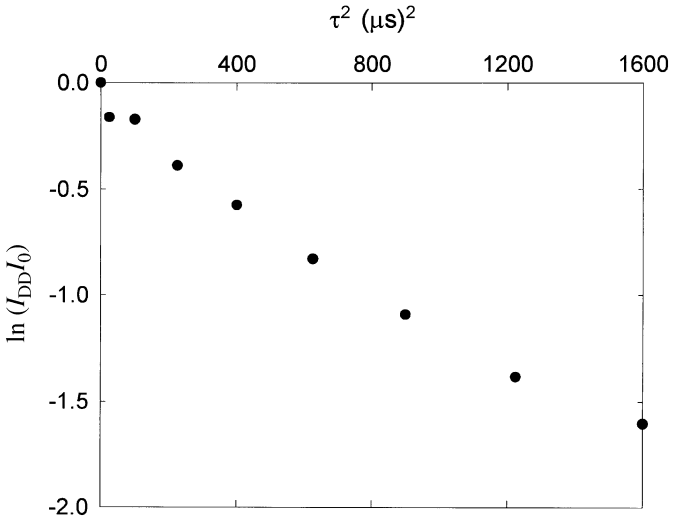
Spectroscopic experimental evidence shows that the DMSO molecules have been completely removed from the interlamellar spaces of magadiite after the intercalation of the polymer; ^{13}C CP-MAS no longer shows the expected band at 38.5 ppm and the FT IR spectra do not show the characteristic bands at 1438, 1417, 1405, and 1318 cm^{-1}. The ^{13}C CP-MAS spectrum gives only one peak at 69.9 ppm in both cases, associated with the ethylene units of the PEG chains. This value is close to that observed at 72.2 ppm for the bulk polymer. The shift to high field could be due to an increase in the number of gauche conformations in the chain when the polymer is intercalated (1*f*). In any case, the observed chemical shift precludes the decomposition of the polymeric chains, since the presence of ethylene glycol units intercalated in magadiite would give a chemical shift at 65 ppm (13). Moreover, this is confirmed by the complete absence of any carbonyl band in the IR spectra of H-mag–PEG1000 and H-mag–PEG3400, which would indicate a decomposition of the polymer into smaller oligomeric chains.

The dipolar dephasing technique is a semiquantitative technique that can assess the mobility of organic groups (1*a,* 17). The ratio of I_{DD}/I_o is a measure of the dynamic state of the molecular group. I_{DD} and I_o are, respectively, the peak intensities of the ^{13}C resonance obtained with and without dipolar dephasing conditions. The signal decay for carbon strongly coupled to protons is described by eq. [1] (14).

$$[1] \qquad I_{DD} = I_0 e^{-\tau^2/(2T_2^2)}$$

where τ is the dipolar dephasing delay time and T_2 is a relaxation time constant. The ratio I_{DD}/I_0 decreases with an increase of the rigidity of the molecular group. The

Fig. 5. Plot of ln (I_{DD}/I_O) vs. the square of the dipolar dephasing time (τ^2) for the ^{13}C DD-MAS spectra acquired for H-mag–PEG3400.



dipolar dephasing time was varied from 0 to 70 μs for both H-mag–PEG3400 and H-mag–PEG1000 (Fig. 4). The results were analyzed on the basis of eq. [1] (Fig. 5). In both cases, a 29% decrease of T_2, the time constant reflecting the mobility of the CH_2 groups, was observed when the polymer was intercalated compared to a simple physical mixture of the *H*-magadiite and the polymer. For both systems, T_2 varied from 28 μs for the physical mixture to 20 μs for the intercalated polymer. These results show that the polymer chains in the interlamellar spaces of *H*-magadiite are more constrained than in the bulk polymer. The T_2 data are comparable to those observed for other constrained systems such as kaolinite–PEG 3400 (15 μs) (1*a*) and diols intercalated in magadiite for which T_2 values ranged from 14–20 μs (15).

The ^{29}Si MAS NMR spectra with high power decoupling are shown in Fig. 6 for *H*-magadiite, H-mag–DMSO, H-mag–PEG1000, and H-mag–PEG3400. The Q^4/Q^3 ratio is constant throughout the intercalation process indicating that the structure of magadiite is unchanged.

Figure 7 shows the X-ray diffraction patterns of H-mag–PEG 1000 and H-mag–PEG 3400. The intercalates are characterized by basal spacings of 15.8 and 15.6 Å, respectively. This corresponds to interlamellar spacings of 4.6 and 4.4 Å since the polysilicate layer is 11.2 Å thick. As mentioned above, from the IR and ^{13}C NMR results, all the DMSO molecules have been expelled from the interlamellar spaces of magadiite during the polymer intercalation process. Consequently, the species responsible for the swelling of magadiite are exclusively the polymeric chains. Similar spacings have been reported for systems in which ethylene glycol or oxyethylene units have been intercalated: ethylene glycol in *H*-magadiite (3.0 Å) (15), ethylene glycol in vermiculite (3.7 Å) (16), polyethylene glycol in lamellar α-zirconium phosphate (2.8 Å), (17) polyethylene glycol in kaolinite (3.7–4.1 Å) (1*a*), and polyethylene oxide in V_2O_5 (4.5 Å) (18). It has to be noted that the X-ray diffraction patterns obtained on the physical mixture of *H*-magadiite and PEG do not show the d_{001} reflection characteristic of an intercalated nanocomposite species.

Fig. 6. Solid-state ^{29}Si MAS NMR spectra with high-power decoupling for: (*a*) *H*-magadiite; (*b*) H-mag–DMSO; (*c*) H-mag–PEG1000; (*d*) H-mag–PEG3400.

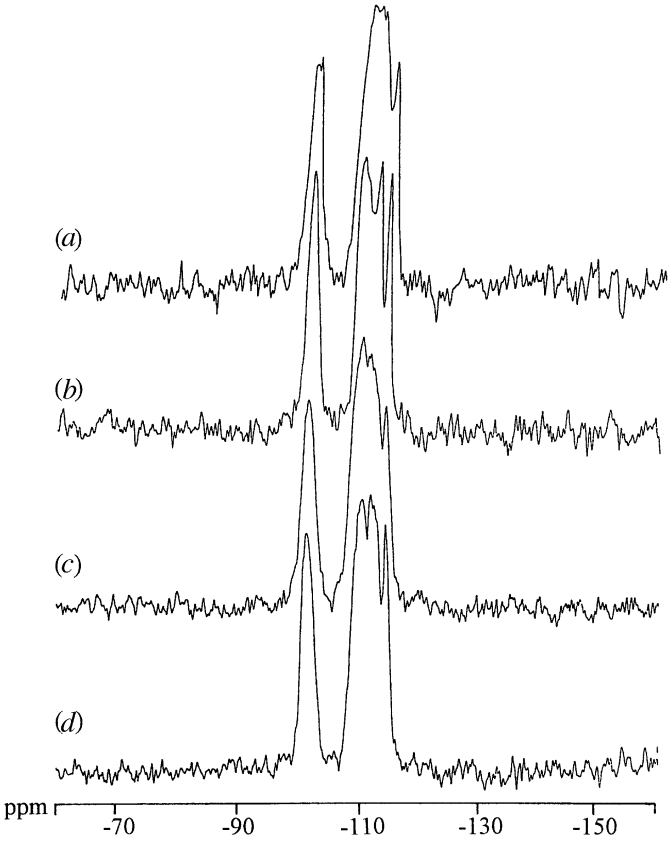

Fig. 7. X-ray diffraction pattern (2–50°, 2θ) of: (*a*) H-mag–PEG1000; (*b*) H-mag–PEG3400.

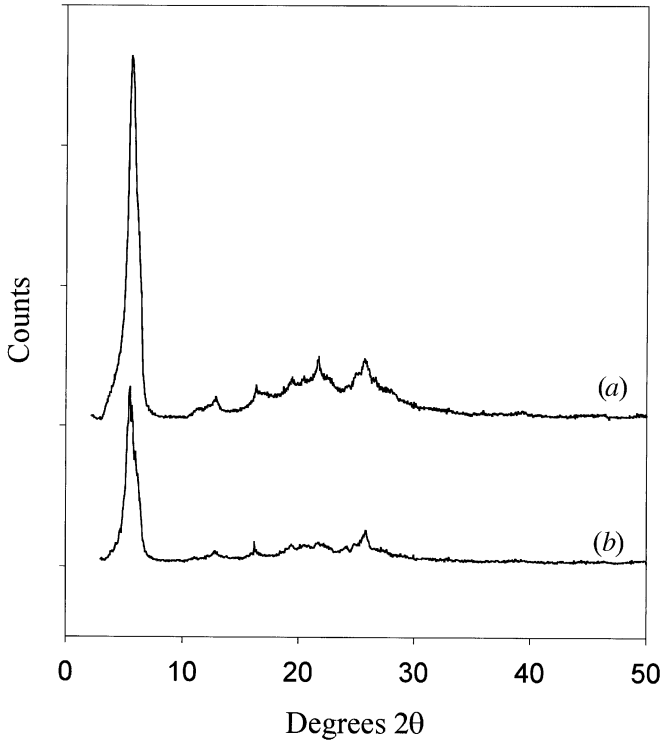

Fig. 8. DSC curves for: (*a*) PEG 3400; (*b*) H-mag–PEG3400 (physical mixture); (*c*) H-mag–PEG3400; (*d*) *H*-magadiite.

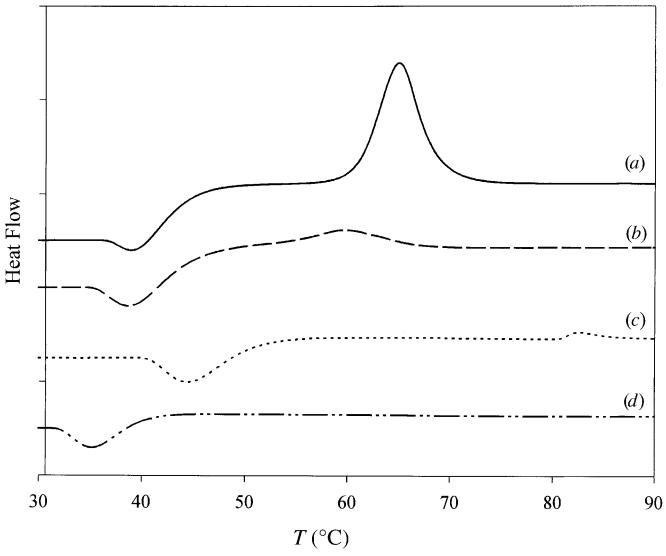

The nanocomposites were also characterized by DSC. The two polymers give endothermic peaks at 59°C (PEG 1000) and 67°C (PEG 3400) corresponding to their melting points. Figure 8 gives the DSC curves for *H*-magadiite, PEG 3400, their physical mixture, and the intercalated nanocomposite. In each case, a starting transient peak is obtained below 50°C. While the endothermic peak corresponding to the polymer melting can still be observed in the case of the physical mixture (as expected, at a lower temperature than for the pure polymer), it is completely absent in the case of the intercalated nanocomposite. This observation is similar to those reported previously in the cases of polyoxyethylene intercalated in montmorillonite (19) and of PEG3400 in kaolinite (1*a*). This is a crucial observation, demonstrating that the polymeric chains are not in an aggregation state characteristic of the bulk polymer. This is consistent with a model in which the polymeric chains interact strongly with the interlamellar surface of magadiite and have lost their bulk properties. Similar results were obtained for H-mag–PEG1000.

This work demonstrates that nanocomposite materials can be prepared from polyethylene glycols and polysilicates. The resulting materials are layered, with alternating organic and inorganic polymeric layers. The inorganic layers have kept the structural characteristics of the parent polysilicate (magadiite) and the organic polymeric monolayers are constrained in a flattened arrangement, resulting from their strong interactions with the interlamellar silicate surfaces of magadiite.

Acknowledgments

The Natural Sciences and Engineering Research Council of Canada (NSERC) is gratefully acknowledged for a research grant (CD). We thank Dr. Glenn Facey (University of Ottawa) for recording the NMR spectra.

ERRATUM

Erratum: The core oligosaccharide component from *Mannheimia* (*Pasteurella*) *haemolytica* serotype A1 lipopolysaccharide contains L-*glycero*-D-*manno*- and D-*glycero*-D-*manno*-heptoses: Analysis of the structure and conformation by high-resolution NMR spectroscopy

Jean-Robert Brisson, Ellen Crawford, Dušan Uhrín, Nam Huan Khieu, Malcolm B. Perry, Wayne B. Severn, and James C. Richards

Ref.: Can. J. Chem. 80(8): 949–963 (2002).

Text in two subsections of the Experimental section was inadvertently omitted in the printed version of this article. The correct text, from the heading "D-*glycero*-L-*manno*-heptose" on page 959 to the paragraph above the heading "Electrospray mass spectrometry" on page 961 should read

D-*glycero*-L-*manno*-Heptose

The heptose was prepared by the condensation of D-galactose with nitromethane in alkaline methanol (76). The crystalline 1-deoxy-1-nitro-D-*glycero*-L-*manno*-heptitol obtained from the aqueous solution of the deionized products (mp 158°C, 21% yield) was converted to its sodium salt. On treatment with dilute sulphuric acid (35°C), followed by deionization with Rexyn 101(H^+) and Amberlite A4(OH^-) ion-exchange resins, the solution was lyophilized to give the heptose as a syrup (80% yield). The product was fractionated by cellulose column chromatography using butan-1-ol–water (1:10 v/v) as the eluant. Fractions containing the heptose were concentrated to dryness under reduced pressure. The D-*glycero*-L-*manno*-heptose having $[\alpha]_D$ –14° (*c* 0.2, water) was pure by paper chromatography and its reduced ($NaBH_4$) and acetylated product on GLC gave a single peak corresponding in retention time with that of authentic hepta-*O*-acetyl-D-*glycero*-L-*manno*-heptitol, establishing its purity.

D-*glycero*-D-*manno*-Heptose

The heptose was prepared from D-altrose via its condensation with nitromethane to yield 1-deoxy-1-nitro-D-*glycero*-D-*manno*-heptitol (mp 109°C, $[\alpha]_D$ –7.0° (*c* 1.1, EtOH), 27% yield)) whose aqueous sodium salt solution on slow dropwise addition to stirred 20% (v/v) sulfuric acid maintained at 0°C was converted to D-*glycero*-D-*manno*-heptose (77). The reaction mixture was neutralized with sat. $Ba(OH)_2$ solution, filtered, passed through Rexyn 101(H^+) and Duolite A4(OH^-) ion-exchange resins to remove residual ionic material, and was concentrated to a syrup (92% yield). The heptose product, as indicated by paper chromatography, was contaminated with altrose and unchanged 1-deoxy-1-nitro-D-*glycero*-D-*manno*-heptitol (ca. 2 to 3%). The product was purified by cellulose column chromatography using butan-1-ol–water (1:10 v/v) as the mobile phase. The D-*glycero*-D-*manno*-mannose had $[\alpha]_D$ +22° (*c* 2, MeOH). A reduced ($NaBH_4$) and acetylated sample on GLC gave a single peak corresponding to authentic hepta-*O*-acetyl-D-*glycero*-D-*manno*-D-heptitol indicating the identity and purity of the synthesized heptose.

ARTICLES

R.J. Dwayne Miller 2000 John C. Polanyi Award Lecture Mother Nature and the molecular Big Bang

Clement Poon and Paul M. Mayer Electron-spin conservation and methyl-substitution effects on bonds in closed- and open-shell systems — A G3 ab initio study of small boron-containing molecules and radicals **25**

David W. Norman, Janet P. Edwards, Christopher M. Vogels, Andreas Decken, and Stephen A. Westcott Synthesis and reactivity of novel Schiff bases containing boronate esters **31**

Michael C. Janzen, Michael C. Jennings, and Richard J. Puddephatt Cationic thiolate and selenolate complexes of platinum(IV) **41**

John G. Cole and Peter Wan Mechanistic studies of photohydration of *m*-hydroxy-1,1-diaryl alkenes **46**

Andreas Decken, Melanie A. Neil, C. Adam Dyker, and Frank Bottomley Iron complexes of the dibenzophospholyl ligand: a synthetic and crystallographic study **55**

E. Haggi, S. Bertolotti, S. Miskoski, F. Amat-Guerri, and N.A. García Environmental photodegradation of pyrimidine fungicides — Kinetics of the visible-light-promoted interactions between riboflavin and 2-amino-4-hydroxy-6-methylpyrimidine **62**

Jintana Meesungnoen, Jean-Paul Jay-Gerin, Abdelali Filali-Mouhim, and Samlee Mankhetkorn Monte-Carlo calculation of the primary yields of H_2O_2 in the $^{1}H^{+}$, $^{2}H^{+}$, $^{4}He^{2+}$, $^{7}Li^{3+}$, and $^{12}C^{6+}$ radiolysis of liquid water at 25 and 300°C **68**

Dirk J. Lefeber, Eneko Aldaba Arévalo, Johannis P. Kamerling, and Johannes F.G. Vliegenthart Synthesis of a hexasaccharide fragment of the capsular polysaccharide of *Streptococcus pneumoniae* type 3 **76**

Y. Chiang, A.J. Kresge, and Q. Meng Kinetics and mechanism of hydrolysis of 3-diazobenzo-furan-2-one and its hydrolysis product (3-hydroxybenzo-furan-2-one) **82**

Celia K. Williams, William C. Galley, and G. Ronald Brown The endothermic nature of the binding of anionic bile salts to a cationic adsorbent **89**

C. Delamere, C. Jakins, and E. Lewars On the generation of oxirene and dimethyloxirene by retro-Diels–Alder reactions, and reactions of dimethyl-oxirene: a computational study **94**

ARTICLES

Kyle L. Fujdala, David W.K. Gracey, Erica F. Wong, and Kim M. Baines The addition of organometallic reagents to tetramesityldigermene **1387**

Maneesh Bahadur, Christopher W. Allen, William E. Geiger, and Adam Bridges Organophosphazenes. 25. The synthesis and electrochemistry of the dicobalt hexacarbonyl complexes of phenylethynylcyclophosphazenes **1393**

Hilary A. Jenkins, Carla L. Dumaresque, Dragoslav Vidovic, and Jason A.C. Clyburne The coordination chemistry of *o*,*o*′-*i*-$Pr_2C_6H_3$-bis(imino)acenaphthene to group 13 trihalides **1398**

Neil Burford, T. Stanley Cameron, Korey D. Conroy, Bobby Ellis, Charles L.B. Macdonald, Robyn Ovans, Andrew D. Phillips, Paul J. Ragogna, and Denise Walsh Sequential dehydrochloride coupling of trichlorophosphine with 2,6-di-isopropylaniline: aminophosphine precursors to phosphetidines **1404**

© 2002 NRC Canada

Mark R.J. Elsegood, Liam M. Gilby, Kathryn E. Holmes, and Paul F. Kelly Sulfimidation of thio-ether crown systems: the X-ray crystal structure of the $\{[9\text{-ane}]S_2S(NH_2)\}^+$, $\{[9\text{-ane}]SS(NH_2)S(NH_2)\}^{2+}$, and $\{[9\text{-ane}]S(NH_2)S_2(\mu\text{-}N)\}^{2+}$ cations **1410**

Vadapalli Chandrasekhar, Venkatasubbaiah Krishnan, Arunachalampillai Athimoolam, and Gurusamy Thangavelu Senthil Andavan New hybrid inorganic-organic polymers containing cyclophosphazenes as pendant groups: Cyclophosphazene ligands containing hydrazone linkages and their conversion to polymers **1415**

Alan Bashall, Felipe García, Gavin T. Lawson, Mary McPartlin, Alexander Rothenberger, Anthony D. Woods, and Dominic S. Wright Formation and decomposition of the Sb(III)/Li cage $[\{Sb(P\text{-}t\text{-}Bu)_3\}_2Li_6\cdot 6THF]$ **1421**

U. Swarnalatha, A. Sivaramakrishna, C.S. Venkatachalam, M.N. Sudheendra Rao, Tomonori Inoue, Tadaharu Ueda, and Masashi Hojo Studies on electrochemical and coordination behaviour of phosphiniminocyclotrithiazenes **1428**

J. Komulainen, R.S. Laitinen, and R.J. Suontamo A theoretical study of the ^{77}Se NMR and vibrational spectroscopic properties of Se_nS_{8-n} ring molecules **1435**

Wolfgang Fraenk, Thomas M. Klapötke, Burkhard Krumm, Heinrich Nöth, Max Suter, Martin Vogt, and Marcus Warchhold Pentafluorophenyl and phenyl substituted azidoborates **1444**

Michael C. Janzen, Michael C. Jennings, and Richard J. Puddephatt Self-assembly using stannylplatinum(IV) halide complexes as ligands for organotin halides **1451**

Kevin S. Jack, John C. Jeffery, Angela P. Leedham, Jason M. Lynam, Michael Niedzwiecki, and Christopher A. Russell Syntheses and structures of bis(imido)organophosphine dianions **1458**

Timothy S. Keizer, Lauren J. De Pue, Sean Parkin, and David A. Atwood Boron halide chelate compounds and their activity towards the demethylation of trimethylphosphate **1463**

Karena Thieme, Sara C. Bourke, Juan Zheng, Mark J. MacLachlan, Fojan Zamanian, Alan J. Lough, and Ian Manners Synthesis, characterization, and structures of zircona- and boracyclosiloxanes with ferrocenyl substituents **1469**

Stephen M. Aucott, Alexandra M.Z. Slawin, and J. Derek Woollins The synthesis of $[\{n\text{-}Bu_2Sn(S_2N_2)\}_2]$ and its use in the preparation of organometallic iridium sulfur nitrogen complexes **1481**

Myrlene Gee, Roderick E. Wasylishen, Paul J. Ragogna, Neil Burford, and Robert McDonald Characterization of indirect $^{31}P\text{-}^{31}P$ spin-spin coupling and phosphorus chemical shift tensors in pentaphenylphosphinophosphonium tetrachlorogallate, $[Ph_3P\text{-}PPh_2][GaCl_4]$ **1488**

Tosha M. Barclay, Robin G. Hicks, Andrew S. Ichimura, and Greg W. Patenaude Synthesis and characterization of a spirocyclic phosphaverdazyl radical – cyclophosphazene hybrid: Evidence for spin transfer from a verdazyl radical to a phosphazene ring **1501**

Andrew D. Bond, Delia A. Haynes, and Jeremy M. Rawson Structural studies of dithiatetrazocines: X-ray crystal structures of the symmetric dithiatetrazocines $p\text{-}XC_6H_4CN_4S_2CC_6H_4X$ [X = NO_2, Br] and the first unsymmetric dithiatetrazocine, $p\text{-}BrC_6H_4CN_4S_2CC_6H_4NO_2$ **1507**

Robert J. Wiacek, Jamie N. Jones, Charles L.B. Macdonald, and Alan H. Cowley Structural interrelationships between the bis(pentamethylcyclopentadienyl)arsenic(III) and antimony(III) cations and their precursor chlorides **1518**

Tianle Zhang, Warren E. Piers, and Masood Parvez Synthesis and characterization of the binuclear diamido titanium chalcogenides $[(Ar)NCH_2CH_2CH_2N(Ar)]_2Ti(\mu\text{-}E)_2$ (E = Se, Te) **1524**

Julio Zukerman-Schpector, Ionel Haiduc, Robinson L. Camillo, João V. Comasseto, Rodrigo Luiz Oliveira R. Cunha, and Alvim Jorge Supramolecular self-assembly through tellurium···halogen secondary bonds: A hexagonal grid of Te_2Cl_2 and Te_6Cl_6 rings in the solid state structure of 1,1,3-trichloro-2,4,5,6-tetrahydro-1*H*-$1\lambda^4$-benzo[b]tellurophene **1530**

Ludmila Scoles, Brian T. Sterenberg, Konstantin A. Udachin, and Arthur J. Carty The synthesis and reactivity of a mixed nitrosyl–phosphinidene cluster of ruthenium: Formation of nitride and nitrene clusters **1538**

Hari K. Gupta, Nada Reginato, Francis O. Ogini, Stacey Brydges, and Michael J. McGlinchey $SiCl_4$–ethanol as a trimerization agent for organometallics: convenient syntheses of the symmetrically substituted arenes 1,3,5-$C_6H_3R_3$ where R = $(C_5H_4)Mn(CO)_3$ and $(C_5H_4)Fe(C_5H_5)$ **1546**

Okwado M. Akotsi, Robert McDonald, and Steven H. Bergens Synthesis of a PennPhos–ruthenium(II) complex: The first crystal structure of a PennPhos–metal complex **1555**

© 2002 NRC Canada

Vineeth Iyengar, Patrycja V. Galka, Andreas Pletsch, and Heinz-Bernhard Kraatz Palladium and platinum complexes of L-PhePhos: Acetyl-*p*-(diphenylphosphino)-L-phenylalanine methyl ester — a chiral ligand for transition metal complexation **1562**

Guillermo Antorrena, Scott Brownridge, T. Stanley Cameron, Fernando Palacio, Simon Parsons, Jack Passmore, Laurence K. Thompson, and Fitri Zarlaida The neutral diradical 5,5′-bis(1,3,2,4-dithiadiazolyl) [SNSNC-CNSNS], the first main group radical to exhibit a dramatic increase in paramagnetism on mechanical grinding **1568**

Patrick J. Riley, Jennifer L. Reid, Adrien P. Côté, and George K.H. Shimizu Condensed versus open channel structures in cysteic acid coordination frameworks containing d^{10}-d^{10} dimers **1584**

Andrew I. Wallbank and John F. Corrigan Triply bridged dicopper-bis(trimethylsilylchalcogenolates): Synthesis and characterization of the series of helical complexes $[(Me_3SiE\text{-}Cu)_2(\mu\text{-}Ph_2PC{\equiv}CPPh_2\text{-}\kappa^2P)_3]$ (E = S, Se, Te) **1592**

Nathan D. Jones, Patric Meessen, Martin B. Smith, Udo Losehand, Steven J. Rettig, Brian O. Patrick, and Brian R. James Bisphosphine ligands containing two *o*-*N*,*N*-dimethylanilinyl substituents at each phosphorus atom **1600**

René T. Boeré and Jason D. Masuda 2,6-Diisopropylphenylphosphane: A new, bulky primary phosphane and its mono- and disilylated $Si(CH_3)_3$ and $Si(CH_3)_2$-*t*-Bu derivatives — A synthetic, crystallographic, and dynamic NMR investigation **1607**

Steve J. Brown, Xiaoliang Gao, Matthew G. Kowalchuk, Rupert E.v.H. Spence, Douglas W. Stephan, and John Swabey Synthesis and characterization of titanium complexes containing phosphinimido and tropidinyl ligands: Crystal structure of (trop)(*t*-Bu_3PN)$TiCl_2$ **1618**

Ignacio Vargas-Baca, Andrew P. Brown, Mark P. Andrews, Tigran Galstian, Yuejun Li, Hojatollah Vali, and Mark G. Kuzyk Linear and nonlinear optical responses of a dye anchored to gold nanoparticles dispersed in liquid and polymeric matrixes **1625**

NOTE OF APPRECIATION / NOTE DE RECONNAISSANCE

The quality of the papers in this journal depends a great deal on the efforts of those who agree to act as critical readers of manuscripts. The editors gratefully acknowledge the following, who helped us between November 1, 2001 and October 31, 2002:

Abbatt, J.
Abramovitch, R.A.
Acree, W.E.
Adlercreutz, P.
Ahnen, D.J.
Almeida, R.M.
Appendino, G.
Argyropoulos, D.S.
Armstrong, D.A.
Armstrong, J.D.
Arnold, J.
Asano, Y.
Ashbaugh, H.S.
Aspinall, G.O.
Auclair, K.
Auger, M.
Auzanneau, F.-I.
Azerad, R.
Backvall, J.-E.
Bain, A.D.
Baines, K.M.
Baker, M.D.
Balch, A.L.
Baldridge, K.
Balfour, W.J.
Bandrauk, A.D.
Banks, J.
Baranski, A.S.
Bardwell, J.
Barra, M.
Barrero, A.F.
Barrett, A.G.M.
Barriault, L.
Bartels, D.M.
Barthel, J.
Bartlett, R.J.
Bayly, S.
Bazan, G.
Beauchamp, A.
Beaulieu, P.
Bell, T.W.
Bennet, A.J.
Benson, G.C.
