Front Cover: (*Concluded*)
Image (A) identifies the heavy atom positions (from the Protein Data Bank, identification code 1BZR) that can be seen at one angle. A second image (B) is visible at different viewing angles that shows the secondary structures outlined as sleeves to depict atom–atom correlations through the protein secondary structure. The computer-generated hologram is constructed from the two single frame images. The physical motion convolved to the iron–oxygen bond-breaking event (as seen in the hologram) is created by several small angle increments in the EF helix according to the structure differences between oxy- and deoxy-tertiary structures and can be observed simply by moving the viewing angle (rotate head or cover). The motion on the cover has been amplified by an order of magnitude to provide clear visibility. See Miller, in this issue, pp. 1–24 on the biomechanics of protein motions and energy transduction of molecular bonds.

To view the hologram properly a directed light is best (e.g., gallery lights, track lighting) or sunlight. Any reasonably collimated light source will provide good visibility as long as it is bright enough.

Page couverture : (*Suite et fin*)
On aperçoit sur l'illustration (A) la position de l'atome lourd (d'après la Protein Data Bank, code d'identification 1BZR), visible sous un angle précis. La deuxième illustration (B), sous un autre angle, révèle les structures secondaires, représentées sous une forme tubulaire et illustrant les corrélations interatomiques dans la structure secondaire de la protéine. L'hologramme généré par ordinateur est élaboré à l'aide de ces deux vues. Le mouvement physique convolutionné de la rupture du lien fer–oxygène (représenté sur l'hologramme) découle de nombreuses petites augmentations d'angle dans l'hélice EF que l'on peut associer aux différences de structure entre les structures tertiaires des formes oxy et déoxy. Il peut être observé par la simple modification de l'ange de vue (rotation du tube ou couvercle). Le mouvement sur le couvercle a été amplifié par facteur décimal afin d'assurer la précision. *Cf.* Miller, dans ce numéro, pp. 1–24, sur la biomécanique du mouvement des protéines et la transduction de l'énergie des liaisons moléculaires.

L'hologramme sera rendu de façon optimale sous faisceau (c.-à-d. projecteurs) ou sous la lumière du soleil. Cela dit, toute source de lumière suffisamment collimatée permettra la visualisation pour autant qu'elle soit assez puissante.

2000 John C. Polanyi Award Lecture
Mother Nature and the molecular Big Bang

R.J. Dwayne Miller

Abstract: Biological molecules are mesoscopic systems that bridge the quantum and classical worlds. At the single molecule level, there are often more than 1×10^4 degrees of freedom that are involved in protein-mediated processes. These molecules are sufficiently large that the bath coordinate convolved to the reaction at an active site is defined by the surrounding protein tertiary structure. In this context, the very interatomic forces that determine the active protein structures create a strongly associated system. Thus, the bath fluctuations leading to reactive crossings involve highly hindered motions within a myriad of local minima that would act to cast the reaction dynamics into the high viscosity limit appropriate to glasses. However, the time scales observed for biological events are orders of magnitude too fast to meet this anticipated categorization. In this context, the apparent deterministic nature of biological processes represents an enormous challenge to our understanding of chemical processes. Somehow Nature has discovered a molecular scaffolding that enables minute amounts of energy to be efficiently channeled to perform biological functions without becoming entrapped in local minima. Clearly, energy derived from chemical processes is highly directed in biological systems. To understand this problem, we must first understand how energy is redistributed among the different degrees of freedom and fully characterize the protein relaxation processes along representative reaction coordinates in relation to these dissipative processes. This paper discusses the development of new nonlinear spectroscopic methods that have enabled interferometric sensitivity to protein motions on femtosecond time scales appropriate to the very fastest motions (i.e., bond breaking or the molecular "Big Bang") out to the slowest relaxation steps. This work has led to the *Collective Mode Coupling Model* as an explanation of the required reduced dimensionality in biological systems. Within this model, the largest coupling coefficients of the reaction coordinate are to the damped inertial collective modes of the protein defined by the strongly correlated secondary structures. These modes act to guide the reaction along the correct seam(s) in an otherwise highly complex potential energy surface. The mechanism by which biological molecules have been able to harness chemical energy over meso-length scales represents the first step towards higher levels of organization. The new insight afforded by the collective mode mechanism may prove important in understanding this larger issue of scaling in biological systems.

Key words: biodynamics, energy transduction, ultrafast spectroscopy, nonlinear spectroscopy, primary processes in biology.

Résumé : Les molécules biologiques sont des systèmes mésoscopiques qui font le pont entre les mondes quantiques et classiques. Au niveau des molécules individuelles, les processus catalysés par les protéines impliquent souvent plus de 1×10^4 degrés de liberté. La taille de ces molécules est suffisamment importante pour que les coordonnées de bain associées à la réaction au niveau d'un site actif soit définies par la structure tertiaire de la protéine avoisinante. Dans ce contexte, les forces interatomiques qui déterminent les structures des protéines active créent un système fortement associé. Il en résulte que les fluctuations du bain qui conduisent à des échanges réactifs impliquent des mouvements fortement empêchés à l'intérieur d'une myriade de minima locaux qui permettrait de fixer la dynamique réactionnelle dans les limites des viscosités élevées apparentées aux états vitreux. Toutefois, les échelles de temps observées pour les ordres d'amplitude des événements biologiques sont beaucoup trop rapides pour être caractérisés de la sorte. Dans ce contexte, la nature apparemment déterministe des processus biologiques représente un défi énorme pour notre compréhension des processus chimiques. La Nature a donc découvert un échafaudage moléculaire qui permet à de faibles quantités d'énergie d'être canalisées de façon efficace afin de pouvoir réaliser des fonctions biologiques sans être piégées dans des minima locaux. Il est clair que, dans les systèmes biologiques, l'énergie provenant des processus chimiques est fortement orientée. Dans le but de comprendre ce problème, on doit avant tout comprendre comment l'énergie est redistribuée entre les divers degrés de liberté et de bien caractériser les processus de relaxation des protéines le long de coordonnées réactionnelles représentatives en relation avec ces processus de dissipation d'énergie. Dans ce travail, on discute du développement de nouvelles méthodes spectroscopiques non linéaires qui ont permis d'associer une sensibilité interférométrique aux mouvements des protéines à des échelles de temps de l'ordre de la femtoseconde appropriées aux mouvements les plus rapides (par exemple, le bris d'une liaison ou du « Big Bang » moléculaire) en présence des mouvements de relaxation les plus lents. Ce travail a conduit au *Modèle de couplage en mode collectif* pour expliquer la dimensionalité réduite requise dans les systèmes biologiques. Dans ce modèle, les coefficients de couplage

les plus grands d'une coordonnée réactionnelle sont introduits pour amoindrir les modes collectifs de la protéine définis par les structures secondaires à forte corrélation. Ces modes agissent pour guider la réaction le long des points de jonction appropriés d'une surface d'énergie potentielle qui est par ailleurs très complexe. Le mécanisme par lequel les molécules biologiques ont pu exploiter l'énergie chimique sur des échelles de longueur méso correspond à la première étape vers des niveaux d'organisation plus élevés. Le mécanisme de mode collectif fournit une approche intuitive qui pourrait s'avérer importante pour la compréhension du sujet plus large qu'est la mise à l'échelle dans les systèmes biologiques.

Introduction

This paper represents a written account of the John C. Polanyi Award Lecture for research in physical chemistry. As such, it will take on a different flavour from a scientific report or review and will attempt to identify an important new direction of chemical research. In particular, the discussion will focus on transition-state processes to keep within the spirit of Polanyi's own pioneering contributions to our current understanding of transition-state processes — albeit with a new direction identified with respect to understanding biological processes from a chemical dynamics perspective.

To make the discussion as general as possible, to the point of being obvious, let me begin by offering a mission statement. Science is arguably the most important human enterprise with respect to its impact on the human condition. It is a social activity within the confines of objective analysis that leads to model building and empowerment through predictable outcomes. There are no boundaries to scientific investigations. The scientific mission can be understated in a simple fashion as: "The quest to understand the Universe". Thus, Science is an intellectual challenge without endpoint and will hopefully engage humanity for the ages to come.

In this quest, there are many length scales and time scales associated with different phenomena that come under examination. On cosmological length scales, one is concerned with an expanding Universe and the defining moment of the Big Bang — the ultimate $t = 0$ boundary condition. With the recent refinement of the Hubble constant, the Universe is now known to be over 8 billion years old and we are able to describe certain events as early as 1×10^{-20} s after the Big Bang (1, 2). This picture and violence to which all of creation has been born stirs everyone's imagination. I would like to draw attention to a much smaller scale of the Universe; one that nevertheless can be envisaged to hold similar defining moments. Figure 1 shows a constellation of star-like objects. It is a representation of the oxygen binding site in heme proteins and is one of my favourite parts of the Universe. I will loosely refer to this as the Proximal Histidine Constellation of atoms. The stars as drawn are the heavy atom positions as determined from X-ray diffraction studies of single crystals. These positions are inspired points as if we were equipped with special glasses that enable us to defy quantum mechanics and observe the core electrons around each carbon emitting X-rays to reveal their positions. At the centre is a giant red star, the iron atom, to which oxygen binds and is transported throughout our bodies. This figure schematically catches a rare event at the defining moment that a new molecule is born — "The Molecular Big Bang". The iron—oxygen bond has just broken as depicted in analogy to a supernova event and the oxygen molecule moves away from the iron atom along a repulsive surface of the product channel appropriate for generating deoxyheme and oxygen. The forces and energy released are depicted as the bright supernova. Chemically, this energy is stored in terms of changes in the charge distribution at the binding site. As opposed to the great distances between stars where the ramifications of a singularity do not affect other points of light, in this part of the Universe there are weak interactions that couple all adjacent points to varying degrees. The Proximal Histidine Constellation will change its location in this part of the sky. The atoms will move to new positions that are lower in energy with the difference in energy being transmitted to the bath (free space in this analogy).

The marvel of this process is that it occurs in a highly directed fashion. To appreciate how magnificent this molecular machinery is requires some calibration to the enormous complexity of proteins — Nature's building blocks. Only a small section of the total protein is shown in Fig. 1 to focus attention on the oxygen binding site. The reaction saddle point requires that the protein move to a region in nuclear configuration space that accommodates the domed porphyrin ring of the deoxyheme (product state). The total available phase space for distinct nuclear configurations is as astronomical as anything contemplated for the heavens. Consider myoglobin as an example of one of the simplest heme proteins. It is a single protein molecule that is responsible for oxygen storage in muscles. This molecule has a primary sequence of 100 amino acids to yield a distinct structure comprised of over 1200 atoms or 3600 degrees of freedom (3). If one considers only the angular coordinate of the amide linkage responsible for the secondary structure, the H-bond potential is relatively shallow and there are three orientations that are approximately degenerate (within kT at room temperature) with respect to nearest-neighbour orientations (4, 5). The number of possible structural permutations for this molecule are 1×3^{100} or 5×10^{47} different configurations, considering only one angular coordinate. This one coordinate gives some feeling of the enormous complexity imbedded in the very structure of biological systems.

Despite this complexity, topological patterns appear in the potential energy landscape of proteins. Again using heme proteins as a representative example, the structure of the oxygen binding site in heme proteins is highly conserved (3). The proximal histidine and associated EF helical sections of heme proteins has evolved into a topological domain that controls oxygen binding. How are proteins able to find these distinct topologically active domains within all the possible

structures available to the system? There is a related question with respect to the chemistry that proteins illicit and regulate. Once an active structure is found, how is the system able to sample the reaction pathway on realistic time scales? Both of these questions are related to the observed time scales or dynamics for protein motions along a small subset of the total coordinate space. The first question pertains to the protein folding problem that was first posed by Levinthal (4). This question has taken on great significance with respect to advancing the frontier of biotechnology. Many proteins can now be synthesized but most are found to be inactive when produced in vitro. The laboratory conditions do not include chaperon proteins that play a critical role in "seeding" the folding process. Nevertheless, there are ample examples of proteins that denature under different conditions and refold to their active state in a seemingly pathway independent manner (5, 6). If such processes were to occur through a random sampling process of all available phase space, it would take geological time scales for proteins to execute even simple functions. It would seem that these systems are poised to find the correct global minima in their structures through a greatly constrained search of configuration space. There must be large numbers of degrees of freedom that are strongly correlated to reduce the sampling process to the relevant time frame.

The question reduces to the factors leading to the correlation of events in either protein-folding or -mediating reactions. This problem has often been stated in terms of Levinthal's paradox: How is it possible for a system with so many degrees of freedom to be able to find the correct path (structure) on the relevant time scales to life? (4–6). This paradox needs to be further defined as one could make similar paradoxical observations with respect to any macroscopic object. For example, one could make the same query with

© 2002 NRC Canada

respect to the time scale for the formation of ice. The difference is that crystals of ice have a periodic structure with a well-defined symmetry. The unit cell is based on only five water molecules arranged in a tetrahedral structure about a central water molecule. This structure is considerably lower in energy than other configurations and subsequent water molecules are strongly driven to form a periodic crystal with this unit cell. Once the crystal structure is formed the crystallization process is seeded and subsequent stages of crystallization ensue rapidly. In each phase of growth, there are only a few degrees of freedom sampling a very coarse grain potential energy surface in comparison to proteins. This distinction brings forward a very important concept. One can rationalize the time scale for protein motions within the same context as ice formation if there is a very deep global minimum. However, in this case, other possible configurations would have very large barriers separating them from the lowest energy structure and the object could be *classified as rigid. It would be inanimate, incapable of supporting life functions.* In order for biological molecules to respond to subtle changes in environment and regulate activity accordingly (i.e., function), there must be nearly degenerate minima imbedded in the structural diversification and there cannot be large barriers separating these structures. Otherwise, the system would either not be able to access an important structure or would become statistically trapped in the deepest minima.

In some sense, the chemically active agents (functionally active proteins, enzymes) in biological systems have to be "alive" at the single molecule level. It is in this context that one should view with marvel how these biological molecules operate and direct relatively minute amounts of chemical energy along the correct pathways to sustain even higher levels of organization among the constituent elements.

The fact that a directionality can be imprinted on such systems is intriguing not only from entropic considerations but also from enthalpic considerations of the driving forces with respect to the operating dynamics. Any molecular system that has numerous degenerate minima with shallow barriers separating the minima operates further from linear response than more rigid systems. The displacements involve larger amplitude motions along pathways interconnecting minima and thus sample more significantly anharmonic components in the many body potential than systems with deep minima (more rigid systems). In this case, one might expect the system should undergo rapid energy redistribution among the relevant degrees of freedom. Once again, one is found asking how such systems can possibly direct a process within the above boundary conditions imposed on living systems. The energetics or enthalpic factors should be randomized too rapidly to impose a directionality to the process.

To restate Levinthal's paradox: Within the constraints of degenerate, readily accessed minima, how is it possible for biological molecules to find their correct structures to perform their functions on the relevant time scales? To further drive home the dilemma, Fig. 2*a* shows a single frame of the protein structure used to computer generate the white light hologram of the structure of sperm whale myoglobin shown on the cover. The positions of all the heavy atoms are retrieved from the highest resolution X-ray structure determination to date (7). In viewing the hologram (stereogram) the atoms should appear floating in space with no apparent rhyme or reason for their particular positions; yet there must be some inherent feature in the structure that yields this particular pattern. This image dramatically drives home the notion of Levinthal's paradox. How does the system find the active subset of structures out of the multitude available to it? Further, once the active structure is adopted for myoglobin, how is it able to sample the correct pathway for oxygen binding and release? (One would expect some degree of correlated motion through the secondary structure. A single frame depicting the helical sections is shown in Fig. 2*b*).

The work to be discussed below will focus on the latter issue, i.e., the mapping problem associated with how biological molecules relax along reaction coordinates to perform functions, somehow steering clear of entrapment in the myriad of local minima. First, it should be noted that in a large number of important biological processes, there is often just a single bond made or broken at an active site. The energy of the reaction is transduced into some higher order function. The transduction process invariably involves structural relaxation along a reaction coordinate towards the product state. Work is done both in relaying the chemical energy into another channel and in relaxation to stabilize the product. The atomic motions in response to the bond breaking and (or) making may be subtle but it must be recalled that these motions are occurring on a backdrop of an enormously complex potential energy landscape. To perform a function (do useful work) the motions must be highly directed; otherwise the system would become trapped in the myriad of local minima. The length scale and time scale of these motions is largely the issue. Crudely speaking, there must be a "director" that imposes a high degree of correlation in the sampling process over the length and time variables. To understand how biological molecules work, we are searching for this director, the ordering element.[1]

Throughout this discussion, heme proteins will be used as model systems to examine this problem. The primary motivations for this selection are that their functionally relevant motions can be optically triggered and a great deal of spectroscopic and structural information is available for this class of proteins. In addition, the structural changes associated with oxygen binding in hemoglobin serve as the cornerstone for our current understanding of molecular cooperativity and allosteric regulation (3, 8).

For background information, the oxygen-binding curve for hemoglobin is shown in Fig. 3 (8, 9). The dependence of oxygen binding on the partial pressure of oxygen shows a rather dramatic change about a critical value. This behaviour is in stark contrast to the purely bimolecular kinetics exhib-

[1] The use of the term director has an analogy to the conductor of an orchestra. The conductor dictates the tempo (time correlation on the different instruments) to the ensemble and enables music to prevail over noise. At the risk of being anthropomorphic, the topological element or director to biological functions must dictate temporal and length scale correlations to enable biological molecules to make "music/life" from the surrounding chaos.

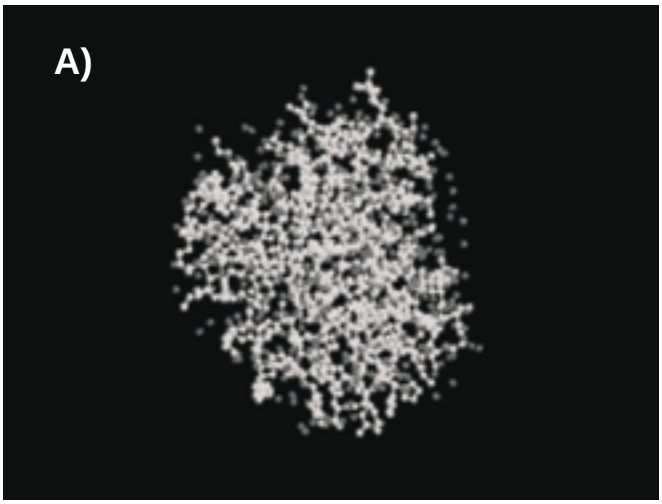
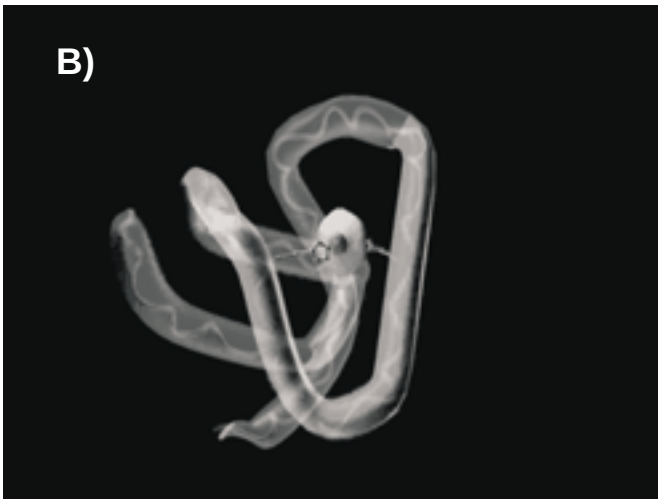
Fig. 2. Single-frame images used to construct the computer-generated hologram on the cover. (*a*) Position of heavy atoms only (from the Protein Data Bank, identification code 1BZR). (*b*) Secondary structures outlined as sleeves to depict atom–atom correlations through secondary structure. The physical motion convolved to the bond-breaking event on the cover is created by several small angle increments in the EF helix according to the structure differences between oxy- and deoxy-tertiary structures (7). The motion on the cover was amplified by an order of magnitude so as to be clearly visible.





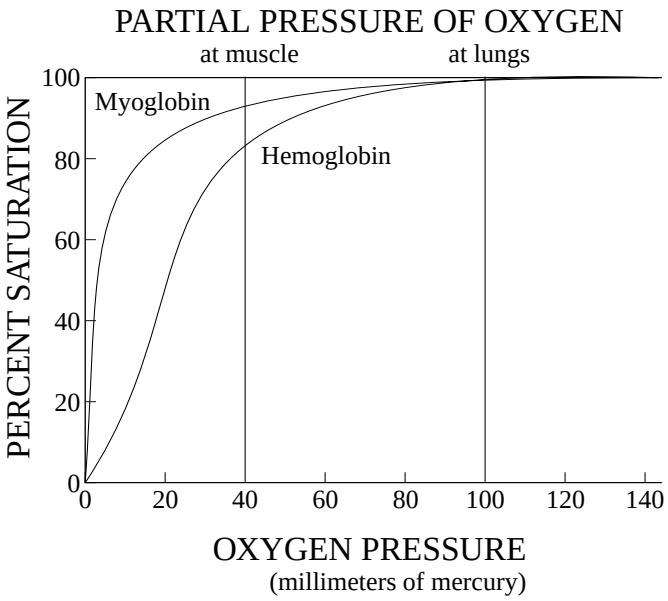
ited by myoglobin that is shown for comparison. Myoglobin is a single heme protein; whereas hemoglobin is comprised of four nearly identical heme proteins (two α- and two β-heme protein subunits) that are very similar to myoglobin. The unusual behaviour of hemoglobin with respect to myoglobin was ascribed to a type of molecular communication between the four subunits with respect to the state of oxygenation that could not be present for the single protein case. Within the Monod model, the oxygen binding curve can be fit assuming there are only two different states for oxygen binding; a high affinity form referred to as the R state and a low affinity form coined the T state (8, 10). This simple two-state description of the oxygen-binding process gained firm footing from the pioneering crystallographic work of Perutz that determined that there were in fact two distinctly different structures for hemoglobin (8). The difference between the fully oxygenated (R) and fully deoxygenated (T) crystal structures depicted a ball-and-socket type motion about the α–β contact region. The motion involves a net 15° rotation and approximately 6 Å translation of the more than 10 000 different degrees of freedom of the protein. Hemoglobin appears to be a "nanomotor", activating a pneumatic switch, that toggles the system between a high- and a low-affinity form through motions dictated along the quaternary coordinate of the protein assembly. Note that the energy powering this nanomotor is simply the four chemical bonds involved in oxygen binding at the heme sites in each protein.

This R to T structural transition is in dynamical equilibrium with its surroundings and becomes most heavily weighted to undergo a transition once the partial pressure of oxygen produces an average loss of more than two oxygens per hemoglobin. The binding affinity for oxygen differs by a factor of 60 for the two structures (11). The system behaves as a nonlinear amplifier with nearly 20 dB gain with respect to changes in the partial changes in oxygen about a critical value. The evolutionary significance of this seemingly simple process should not be under appreciated. The structural transition of hemoglobin acts to hold on to oxygen as long as possible before it delivers the oxygen to deoxygenated areas. In effect, the structural transition increases the diffusion length of oxygen into the tissues while providing a feedback mechanism to provide oxygen to regions undergoing differential metabolic rates. This process was critical to the development of larger more complex organisms. In some sense if it were not for this process, we would have to be more than an order of magnitude smaller (difference in effective diffusion lengths for oxygen transport mediated through myoglobin relative to hemoglobin). To drive this point home further, even clams have evolved a dimeric hemoglobin molecule that exhibits molecular cooperativity of this kind (12). This process is one of the simplest examples of molecular cooperativity; yet was essential to the scaling of multicellular organisms to higher levels of complexity.

The "R-to-T switch" represents an example of coupled reaction coordinates. By some mechanism, the state of ligation at one heme is communicated to neighbouring heme proteins and affects the kinetics of oxygen binding at these remote sites. This process is interesting to contemplate as the distance between heme sites is approximately 30 Å. If this process were to occur in a homogeneous aqueous environment, it would be impossible for a reaction at one site to affect another at these distances. The effective concentration of the hemes is approximately 10 mM. The reaction volume extends only out to the second solvation layer and, at this density, the water rearrangements would completely screen any changes in charge or other forces from affecting an adjacent site. Neither enthalpic nor entropic factors could be modulated at the adjacent site in a purely aqueous environment. The mechanism of communication must involve the surrounding globin to provide a *through space coupling* between reaction sites. The globin has a number of evolutionary features. The primary function is to simply provide a wrapper about each heme porphyrin motif to prevent dimerization. The structure of this globin wrapper has evolved further to pro-

© 2002 NRC Canada

Fig. 3. Oxygen-binding curves comparing myoglobin to hemoglobin (8). The dramatically different dependence on partial pressure of oxygen between myoglobin and hemoglobin is the signature of molecular communication possible in a quaternary protein complex (hemoglobin) that is not possible for a monomeric protein (myoglobin).



vide pH-sensitive activation barriers to O_2 binding and other environmental responses. Higher organization involved the formation of the tetrameric hemoglobin molecules. Close examination of the structural changes between fully oxygenated and fully deoxygenated hemoglobin shows that the largest structural changes are about the quaternary coordinate. It is for this reason that the system is believed to exhibit such a simplified response as described within the Monod two-state model. However, the driving force for the motion about the quaternary contacts must be convolved to the structural changes at the tertiary level. The forces are ultimately derived from the Fe—O_2 bond and this coordinate is directly connected to the tertiary structural fluctuations. So the problem of understanding the large amplitude motions involved in the allosteric regulation of oxygen binding in hemoglobin can be reduced to understanding the coupling of the reaction forces to deterministic structural changes at the tertiary level. The structural changes at the tertiary level are ultimately responsible for modifying the force balance along the quaternary coordinate.

Myoglobin will be used as the model system to understand the tertiary structural changes along the Fe-ligation coordinate. Myoglobin is nearly identical to the heme protein subunits of hemoglobin with the exception that it does not form dimers in solution and thus enables isolation of tertiary motions. The bond-breaking coordinate at the oxygen-binding site leads to structural changes in the surrounding globin. These changes are depicted in Fig. 4. In the ligated- or oxy-form, the iron is hexavalent and resides in-plane within the porphyrin ring. Upon dissociation of the iron—ligand bond, the iron becomes pentavalent, high-spin, and moves out of the porphyrin ring by 0.5 Å. In the process, the porphyrin ring deforms in a puckering motion. These displacements are referred to as the heme-doming coordinate. This motion is thought to focus the reaction forces normal to the heme plane and preferentially couple to the EF helical section through the closest contact point defined by the proximal histidine-94 (13, 14). Until recently, the picture that had emerged from X-ray crystallographic studies was that the heme doming caused a tilting and rotation of the proximal histidine that ultimately led to a small translational motion of the EF helix. It is this helical section that forms a significant fraction of the protein–protein contact at the α–β interface. More recent high-resolution studies have shown that this picture may need to be revised. The iron out-of-plane motion leads to a more subtle "barrel-roll" motion of the EF helix without significant relaxation of the histidine orientation relative to the heme (7). In either case, the doming of the iron is viewed to be the epicentre for the reaction forces leading to differential motion of the EF helix relative to other points in space, to effectively translate the reaction forces from the heme site to the protein–protein contact points (quaternary coordinate) in hemoglobin.

The schematic shown in Fig. 4 gives a "before" and "after" picture for the structural changes. The dynamic pathway connecting the oxy- and deoxy-tertiary structures is required information for understanding the mechanics of this motion. There are two different possible views for the operating length scales of the motion or force/response function of the protein (15). One view is that the motions are *localized*. First, the heme domes. This creates a potential energy gradient that is more localized at the proximal histidine. Small-scale fluctuations along the helix ultimately lead to displacement of the EF helix along the proper coordinate. The whole process can be likened to a series of falling dominos with the length scale on the order of one amino acid. First, one domino falls (heme doming), this action displaces the force to a new location and causes the next domino (proximal histidine region) to fall and then the next, etc. This dynamical picture will be referred to as the Localized Strain Model, where strain is defined as a change in volume element (localized over one amino acid residue in this case). This localized strain process would be distinguishable from other possible mechanisms by the observed dynamics for the protein relaxation. *Given the highly associated nature of proteins, localized motions of this type would involve a diffusive sampling of the protein relaxation and the relaxation would be expected to show stretched exponential behaviour typical of glass-like systems* (16, 17). For the most part, protein-relaxation processes have been characterized to show stretched exponential behaviour such that this view of the mechanics is consistent with a large body of information related to protein dynamics (18–21).

At the opposite extreme, it is possible that the heme doming is coupled to a much more rigid body on the relevant time scale. In this case, the reaction force would be extensively distributed in space (15). The mass displacements in this limit could be reduced to the displacement of a superposition of collective modes involving the whole protein. The relevant length scale would be the effective radius of the protein. This collective mode description of the ensuing relaxation is similar to concepts introduced to understand the

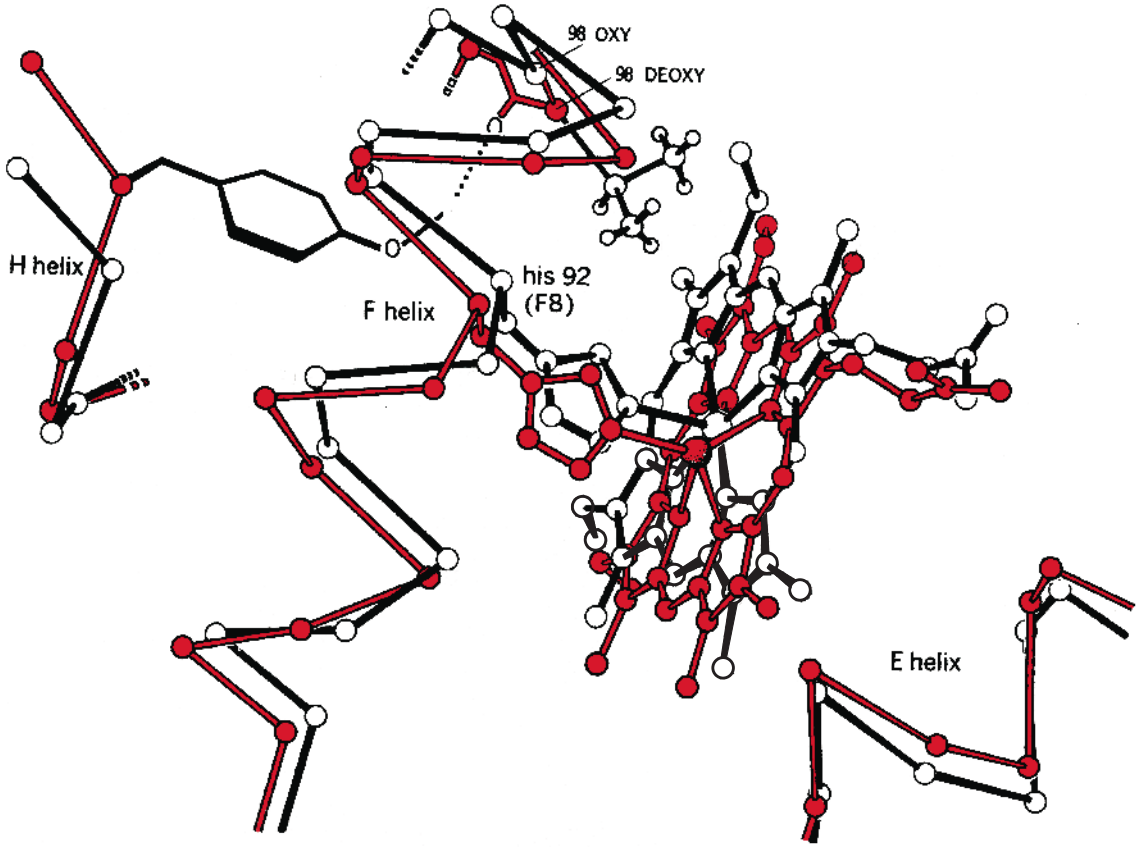
Fig. 4. Expanded view of tertiary structure changes in the vicinity of the heme pocket. In the oxy-state (solid black), the iron resides in plane. Upon breaking of the iron—ligand bond (O_2, CO, NO, etc.), the iron moves out-of-plane and the porphyrin puckers. This motion is coupled to the adjacent helices. The doming of the iron is the epicentre for the forces that ultimately lead to the motion of the EF helix as modulated through the proximal histidine contact, opposite the ligand binding site (modified from refs. 8 and 25).



importance of nondiffusive relaxation processes found in liquids (22, 23). In the case of charge transfer, the liquid reaction and (or) relaxation coordinate convolved to the change in charge density about a solute is found to be dominated by the inertial "free-streaming" collective motions of the liquid that occur on time scales much faster than diffusive relaxation. A modal description of the correlated motion of molecules in the liquid state is somewhat tenuous as these motions in liquids can also be described within a localized basis (23). Individual motions are only instantaneously correlated and have random phase factors. Motions of molecules in the liquid state are also highly damped, such that there in no clear demarcation between nondiffusive and diffusive behaviour. However, in proteins, there is a much stronger degree of correlation of atomic displacements imposed on the system by the covalent bonding, corresponding to the primary sequence and the various forces responsible for the secondary and tertiary structure. After all, these are single molecules and a modal description should be more apt for proteins than liquids. This long length scale view will be referred to as the Collective Mode Model. The true picture will involve some intermediate length scale from these two limiting views in that the forces cannot displace all collective modes of the protein uniformly, otherwise there would be no directionality imposed on the system. *The distinguishing feature of the collective mode description is the modal description of the displacements with a degree of mode selective coupling between the bond making and (or) breaking coordinate and the bath modes* as defined by protein scaffolding surround the heme site.

Functionally relevant protein motions

All mechanisms describing the coupling of the reaction forces to functionally relevant protein motions must take into account how the energy is directed along specific coordinates. The energy must be harnessed specifically to perform the function or do work. As such, the structural changes are deterministic. The reaction energy is expected to be highly directed to perform the function without having the bond energy so highly distributed among the different degrees of freedom that the forces involved do not rise above the thermal noise.

In the case of heme proteins, the functionally important or relevant motions necessarily involve a displacement of the exterior atoms relative to the interior to communicate the state of ligation at the heme site. If there is no relative motion of the exterior atoms, the forces at the protein interface remain unchanged. Thus, there must be a volume change or strain (defined as $\Delta V/V$) at the individual protein level. To be clear, there may be other displacements internal to the protein, however, these will be shielded from the other proteins

© 2002 NRC Canada

unless there is a relative displacement of the exterior residues.[2] Thus, molecular communication is established between proteins through material strain. The strain creates stresses at adjacent protein(s), and thereby modifies the activation barrier for the coupled reaction coordinate at a remote site. This through space coupling provides exponential gain to the control parameter (strain) over the coupled reaction coordinate. In the case of hemoglobin, the strain that develops in the R-to-T transition lowers the barrier for adopting the domed heme configuration. The barrier only needs to be modulated by 0.1 eV at room temperature to cause the deoxygenation rate to increase by two orders of magnitude. Relative to the Fe—O_2 bond energy, this amount of energy transduction amounts to a conversion efficiency of approximately 10%. This efficiency may seem fairly modest, however, it must be born in mind that there are 10 000 degrees of freedom in the protein system. Rather than uniformly exciting all the system modes, the bond energy is extremely well focused along a very narrow subset of configurations. In this light, the degree of directionality imposed on the reaction coordinate by the protein active structure is indeed impressive.

The main point is that the molecular communication pathway is defined by the evolution of protein strain. This is the "talking coordinate" between proteins that indicates the state of ligation at the irons. Concepts of strain are the 3-D equivalents of Hooke's Law for a 1-D spring. Strain is a fourth rank tensor that describes displacements that are both longitudinal (compression and (or) dilation) and tranverse (shear) to the applied stress (reaction force field). Two different kinds of functionally relevant protein motions can be defined: (*i*) motions that lead to a net change in volume; and (*ii*) shear displacements. In the first case, motions of this type would be acoustic in nature and involve longitudinal strain elements. In the second case, the transverse components to the functionally relevant protein motions do not necessarily lead to a change in volume element but rather a change in effective shape.

By studying the protein strain dynamics in real time, one should be able to discern between the aforementioned Localized Strain and Collective Mode Coupling Models. The challenge is to come up with experimental methods that are capable of following these different kinds of motions. In particular, it should be noted that the displacement of the helical sections involve net rms motions of less than 0.1 Å. A very sensitive method is needed to follow such motions with the prerequisite time resolution to follow the structural relaxation from the very fastest events (e.g., bond-breaking event or molecular Big Bang) out to full reequilibration. A type of protein seismology is needed; a method that is sensitive to longitudinal displacements and one that can be related to transverse motions or shear. By measuring the strain dynamics, it is possible to determine if the molecular communication pathway is set up predominantly through localized strain; or alternatively, motions involving the displacement of collective modes or segmental motions of the protein. Specifically, Localized Strain would be characterized by stretched exponential processes; whereas the Collective Mode mechanism would be characterized by nondiffusive relaxation processes occurring on time scales comparable to the inverse frequency of these damped motions. In this latter case, the observed dynamics could be associated with a modal frequency and potentially directly connected to the structural element involved. One last point, of the two classes of functionally relevant protein motions, the shear is most important. For a system such as heme proteins where there is no centre of symmetry, a directed process must necessarily involve anisotropic displacements. The development of anisotropy is most strongly correlated to shear and is the *definitive observation of mode selective coupling* in the reaction coordinate.

Energy redistribution processes in biological macromolecules

The quest as outlined above is to understand how relatively minute amounts of energy can be so highly directed in such complex, metastable, systems such as proteins. In this context, the first line of inquiry should focus on how energy becomes dispersed among the different degrees of freedom. This information can be connected through fluctuation and dissipation theorems to the equilibrium fluctuations along the reaction coordinate (24–27). In 1986, we undertook the first direct time-resolved study of vibrational energy relaxation pathways in proteins (24). This work stemmed from the development of a new spectroscopic method that made it possible to follow the time evolution of vibrational energy relaxation into translational degrees of freedom on ps time scales. This time scale is comparable to the typical lifetimes of vibrational modes (frequencies > 1000 cm^{-1}) such that it was possible to follow even the primary relaxation events.

The experimental concept is shown in Fig. 5. By exploiting the extremely short-lived excited-state lifetimes of deoxyheme proteins and Fe(III) oxidation states, it is possible to selectively deposit a photon of energy at the iron porphyrin site. In the visible part of the spectrum, this amount of energy is approximately the same as the ligand bond energy such that it provides an ideal means to monitor selectively the energy redistribution process originating at the heme porphyrin, as it should occur during the bond-breaking event itself. It should be noted that the heme porphyrin ring is generally attached to the protein through only one covalent bond to the iron at the proximal site. This contact point involves nuclear motions that are largely orthogonal to the porphyrin ring and is decoupled from the majority of the vibrational modes that define the porphyrin. The heme porphyrin moiety approximates a molecule in solution in the sense that the dominant relaxation pathways involve van der Waals contacts with the surrounding bath. For a molecule in solution, the bath would be comprised of solvent molecules executing fluctuations appropriate to the liquid state. In the protein case, the bath is the globin surrounding the heme site in which modulation of the van der Waals contacts would necessarily involve more correlated motions via the primary, secondary, and tertiary structural elements of the protein. Originally, it was felt that the

[2] This statement assumes that the forces are dominated by nearest neighbour interactions. In cases, where there is a charge transfer process, the forces may be more long-range electrostatic forces.

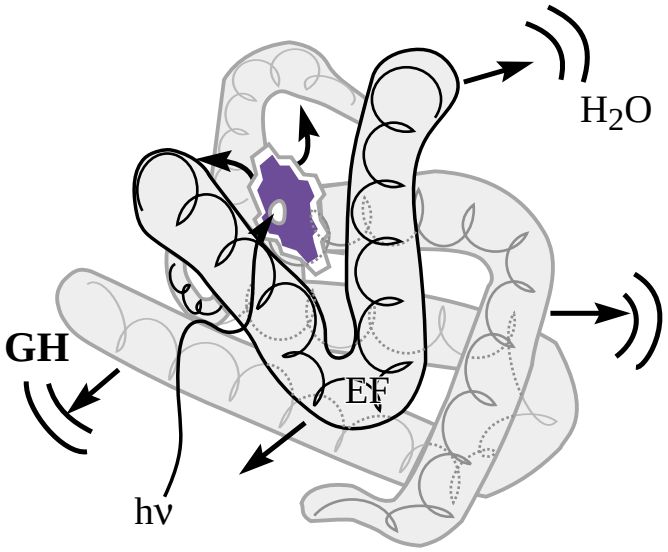
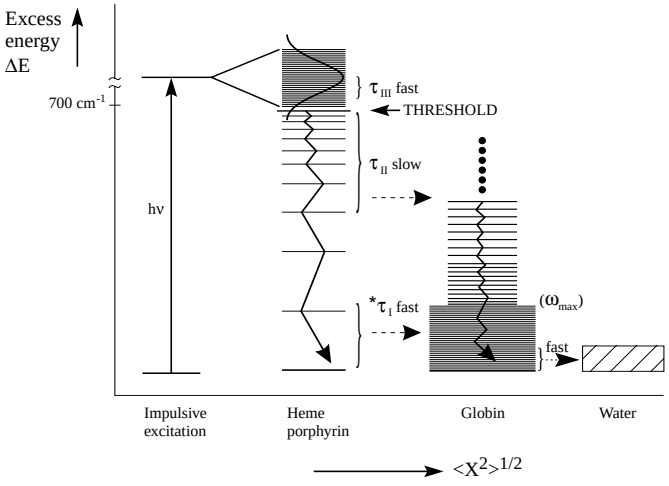
Fig. 5. Schematic of optical excitation of heme proteins to selectively deposit a photon of energy at the heme site and the ensuing of the vibrational energy redistribution dynamics in myoglobin.



protein could serve as a model system for understanding collisional exchange of energy in disordered systems such as solutions but with the distinct advantage that a more microscopic model could be developed from the structural information available on proteins (24). As opposed to solution, all the relative atomic positions of the interacting system were known from X-ray crystallographic studies of the protein structures.

At the time these studies were conducted, very little was known about the energy relaxation processes in proteins. Proteins were and are still considered to be a special subclass of highly associated systems that can be described within a glass description of the operating dynamics. Within this description, one might expect the transfer of vibrational energy into translational energy in the surrounding water to be very slow, i.e., thermal conductivity is generally slow in glasses due to the many scattering sites (mismatch in local density of states). Alternatively, the energy dissipation process could be modeled within the framework of molecular solids. From the foreknowledge that the initially perturbed site is coupled to adjacent residues of the protein by van der Waals forces, it was thought that the energy flow from the heme porphyrin to the globin could be modelled in analogy to the well-studied dynamics of molecular crystals (eg. napththalene or anthracene). In this scenario, the initially hot heme would undergo very rapid intramolecular vibration energy redistribution within the heme porphyrin at excess energies above the statistical limit to the vibrational density of states (region III in the spectral density — see Fig. 6) (26). For typical anharmonic couplings between a normal mode basis, this process leads to a Boltzmann distribution corresponding to an elevated vibrational temperature at the heme site on a 100 fs time scale (27). The subsequent energy exchange process to the surrounding protein matrix would have to go through the low frequency motions that are responsible for modulation of the van der Waals contacts at the heme site (collisional energy exchange). The so-called doorway modes to the vibrational relaxation process would be

Fig. 6. Vibrational density of states diagram (25). The basis states for describing vibrational energy flow are the modes of the heme porphyrin, the surrounding globin, and water. The coupling that leads to energy redistribution between these different degrees of freedom is treated as a weak perturbation. The highest density of accepting modes in both the globin and water is in the lowest energy range such that the lowest frequency skeletal modes of the porphyrin act as doorway modes for energy flow from the heme to the globin and (or) water reservoirs. Note: there is generally a sparse region in the vibrational density of states (region II) that leads to a bottleneck in the energy redistribution.



the high density of state region for modes below 200 cm^{-1} (region I of Fig. 6) (25, 26). The relaxation process can be captured analytically through a first-order time-dependent perturbation treatment. Explicitly, the relaxation for any given mode (i) can be written as,

$$[1] \qquad [2\pi c T_1]^{-1} = \frac{18\pi}{\hbar} \sum_{j=1} \sum_{k=1} \{|\langle i|V^{(3)}_{ijk}|jk\rangle|^2 \, \delta(\omega_i - \omega_j - \omega_k)(n_j + n_k + 1)\}$$

where T_1 is the relaxation time, c is the speed of light, n_j, and n_k are the temperature-dependent probabilities for modes j, k, respectively, and $V^{(3)}_{ijk}$ is the cubic term in the anharmonic coupling of the modes. This equation is essentially a Fermi Golden Rule expression describing the energy flow where the sum is over all possible relaxation pathways that conserve energy (δ term) and momentum. In the overall vibrational cascade to lower and lower frequency motions and spreading of the energy over more and more atoms, there is a region in the vibrational density of states (region II) where this conservation condition can not be met. There is not a corresponding set of acceptor modes in this energy range that enable the decay of a high frequency mode into two lower frequency modes and conserve energy. The threshold between rapid IVR (region III) and this bottleneck (region II) is expected to occur around 700 cm^{-1} (26). If the highest frequency cutoff for the accepting modes of the surrounding protein can be modelled in analogy to the solid state, this cutoff should occur at approximately 200 cm^{-1}. In this case, all the vibrational modes within the spectral region defined between 700 and 200 cm^{-1} will not be able to decay by the

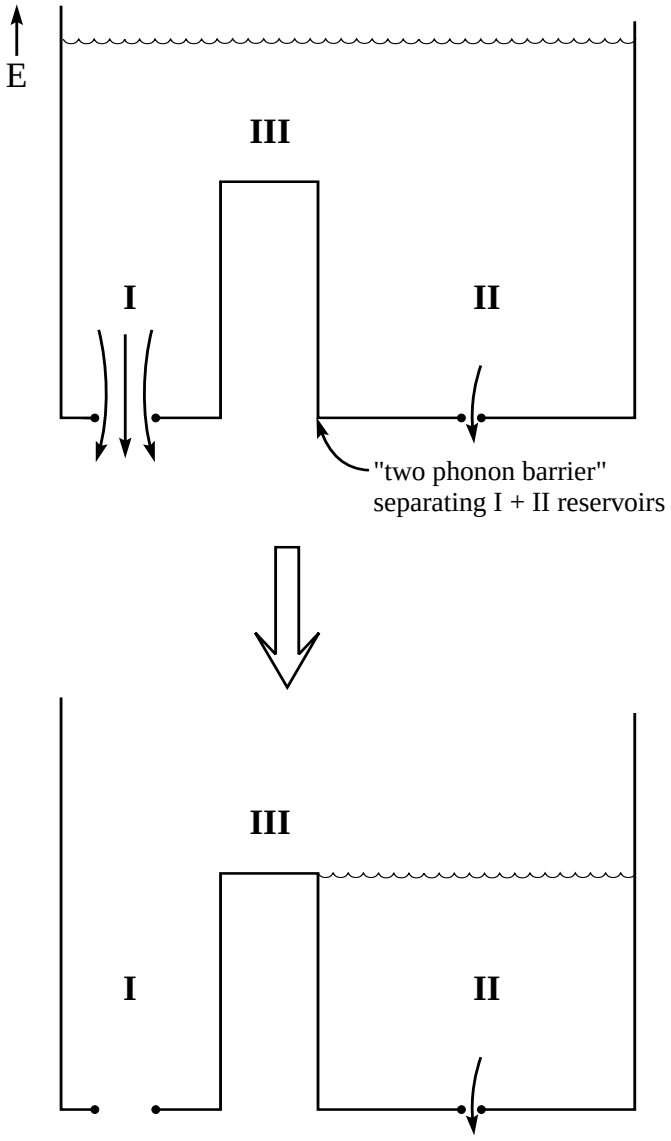
Fig. 7. Hydrodynamic model for vibrational energy flow. At high excess energies (region III), there is very rapid energy redistribution (statistical limit; dynamics determined by average anharmonic coupling). The energy flows out to the surroundings primarily via region I modes. This process is modeled as a larger hole (higher density of accepting modes). As the energy pours out of region III through region I, there is a nonstatistical accumulation in region II. The region I and II modal densities are separated by a barrier to depict the two-phonon barrier that separates the two energy regimes in molecular solids.



emission of one quanta pathways of excess vibrational energy into the surrounding protein. Instead, the relaxation process would require an emission pathway involving at least two vibrational quanta of one accepting mode or combinations. The relaxation would involve higher order terms in the perturbative expansion of the anharmonic potential than just the cubic term needed to describe one quantum transitions to lower frequencies. The smaller magnitude of this perturbative term would lead to much slower relaxation.

A simple hydrodynamic model is shown in Fig. 7 to get across the main concepts of the energy redistribution process. Based on solid-state relaxation processes, the vibrational energy flow from the heme to the protein matrix would be expected to involve a fast initial relaxation process (ps time scales) followed by a much slower process with approximately half the excess energy dissipated into the protein from region II modes on a 100 ps time scale (26). The key prediction is the slow relaxation component that is ascribed to the expected "two-phonon barrier" between the intermediate vibrational spectral density of states of the heme donor modes and surrounding protein acceptor modes (25, 26).

The above treatment requires either experimental or theoretical input with respect to the spatially distinct spectral density of states to be assigned to the heme porphyrin and protein as a starting basis. Molecular dynamics calculations are generally needed to estimate the protein modal density. The relaxation process can also be simulated in MD calculations of this nature by using initial starting conditions in which the heme porphyrin ring modes have excess kinetic energy, corresponding to the excess photon energy, beyond the equilibrated system. A full-blown MD calculation was carried out explicitly modelling the optical excitation process using this approach (27). This study likewise made the prediction that the initial relaxation step should occur on ps time scales with approximately half the energy relaxing within the 40–60 ps time frame. This simulation also made the important prediction that once the energy was transferred from the hot heme to the surrounding protein matrix, it would be extensively distributed throughout the protein by collisional-like coupling of the heme to collective modes of the protein matrix.

The other model that was prevalent at the time that bears mentioning here is the vibrational *soliton model* of Davydov and Scott et al. (28, 29). This model was developed as a potential explanation for how energy is so efficiently directed in biological systems. This particular model is attractive as it offers a potential explanation for the near ubiquitous occurrence of the α-helix in biological systems. This model viewed the helix as the essential topological feature that provides a conduit for transferring energy from one region in space to another without spreading. The mechanical motions along the helix must be decoupled from the surroundings to prevent the energy from spreading, i.e., to create a nondispersive condition on the energy flow. Waves obeying this condition were first observed as canal waves that tended to not damp or spread spatially in the usual manner. This self-sustaining, stationary, character to the wave properties was identified with nonlinear coupling between different propagation modes and is referred to as a soliton wave. The appeal of this model is that it offers an explanation for the highly directional response of biological systems and identifies this property with a topological feature of the right length scale to permit scaling from atomic to the mesoscopic length scales appropriate to biological functions. The occurrence of solitons can be reduced to solving a nonlinear wave equation; in this case the nonlinear Schrodinger equation accorded to vibrational modes of the protein (28, 29). Solutions to this equation produce deformations that involve propagating nondispersing wavepackets that travel along the helix at velocities significantly slower than the speed of sound. The soliton velocity is related to anharmonic terms that necessarily reduce the effective velocity from harmonic

© 2002 NRC Canada

(more rigid) terms in the interaction potential. Within this model, one would also expect the vibrational energy relaxation to be very slow — by definition of the soliton ansatz. There are conceptual problems with respect to exciting such a mode in a biological system and how the soliton could transfer energy to adjacent sites if it is truly a nondispersive mode. These issues aside, this model provides an interesting starting point for discussing the connection between topological features in the protein structure and correlation to energy transduction mechanisms.

Picosecond thermal grating studies of energy redistribution

With the above background, our first experimental observations were surprising. Briefly, the experiment consisted of exciting preferentially a short-lived heme approximately in the centre of the protein and monitoring the evolution of the short-lived electronic excited state into the final energy reservoir — translational energy of the bath. This study was accomplished by using grating excitation to encode a spatially modulated excitation profile in the sample and monitoring the ensuing relaxation of vibrational energy into translational energy by the diffraction of a time-delayed probe pulse off the corresponding modulated index of refraction. The modulation arises from the thermal expansion that results from the relaxation of vibrational energy into translational degrees of freedom.

The most significant developments of this work were: the analytical solution to the thermal elastic equations to connect the temperature-dependent index of refraction and sound fields to molecular relaxation processes; and the achievement of ps time resolution to an effectively photoacoustic approach (24, 30). The appropriate equations defining the experimental observables are governed by the relations (30):

$$[2] \qquad \frac{\partial^2 u}{\partial x^2} - \frac{1}{v^2}\frac{\partial^2 u}{\partial t^2} = \frac{a(3\lambda' + 2\mu)}{\lambda' + 2\mu}\frac{\partial (T - T_0)}{\partial x}$$

$$[3] \qquad \rho C_v \frac{\partial (T - T_0)}{\partial t} - \alpha_{\text{th}} \frac{\partial^2 (T - T_0)}{\partial x^2} = 2Q[1 + \cos(kx)]\gamma e^{-\gamma t}$$

These relations define the material displacement (u) or acoustic field excited in response to a temperature (T) gradient. This is a 1-D analysis along the grating wavevector (k) where a certain amount of heat (Q) is deposited in the material to give a temperature rise as defined by the constant volume heat capacity (C_v), thermal conductivity (α_{th}), and the density (ρ). The amplitude of the displasement is related to the thermal expansion coefficient (a) and the terms λ', μ are material constants related to elasticity. The source term is the RHS of eq. [2]; where γ defines the microscopic relaxation rate constant (vibration to translation and (or) rotation degrees of freedom).

The analytical solution to these coupled equations is:

$$[4] \qquad u(x,t) = A \sin kx \left\{ \frac{1}{b^2 + \omega^2}\left[\frac{b}{\omega}\sin(\omega t) - \cos(\omega t) + e^{-bt}\right] - \frac{1}{\gamma^2 + \omega^2}\left[\frac{\gamma}{\omega}\sin(\omega t) - \cos(\omega t) + e^{-bt}\right]\right\}$$

where b is a constant related to thermal diffusion (decay of grating image) and ω is the acoustic radial frequency at the grating wavevector.

The results are plotted in Fig. 8 for various values for the thermal relaxation rate normalized to the grating acoustic period. The relaxation of energy into translational degrees of freedom (heat) leads the excitation of a standing acoustic wave (the sound field replica of the optical pattern encoded in the material) that beats in and out of phase as the two counterpropagating acoustic waves move past one another. The first maxima in the signal response occurs at one-half an acoustic period from $t = 0$. The most important feature to note is that the effect of finite relaxation processes cause a shift in the acoustic phase. The shift can be directly connected to the relaxation rate. Within typical signal to noise ratios, relaxation times of less than one-twentieth an acoustic period can be determined. The acoustic phase shift and connection to the underlying dynamics (31) is the same as the phase shift exploited in phase modulation fluorescence spectroscopy to determine excited-state lifetimes. The main distinction with this spectroscopy is that it gives a direct observable of the nonradiative relaxation channel and can be used to monitor photodark states.

The highest time resolution is attained by going to the highest possible acoustic (modulation) frequency. By using counterpropagating 355 nm excitation and probe pulse sequences, it was possible to image acoustic frequencies greater than 10 GHz. The grating fringe spacing was less than 120 nm and the effective time resolution was limited by the speed of sound giving rise to expansion over distances comparable to the protein diameter (24, 25). The first data of its kind is shown in Fig. 9. The rise time of the acoustic sound field is convolved to the excitation pulses used in the experiment. From this initial work, it was determined that the vibrational energy relaxed into translational energy of the surrounding bath on a timescale faster than 22 ps (24, 25). Rather than taking greater than 40 ps for the energy to travel *just from the heme to the globin*, the vibrational energy was essentially completely dissipated into translational energy involving acoustic modes of the protein and water. The energy would have to have been extensively delocalized to undergo rapid collisional exchange with the water on the observed time scale.

The qualitative features of these observations were consistent with the MD calculation, however, the dynamics were much faster than predicted. These calculations were conducted with the protein in vacuo. Inclusion of a water layer, found a significant increase in the relaxation rate that brought the calculated results into good agreement with these experiments (25). This work illustrated that there is no effective two-phonon barrier to relaxation processes in proteins. The two-phonon barrier expectation was based on the highest frequency phonon cutoffs in molecular crystals. In proteins, the atoms are covalently bonded such that the gap

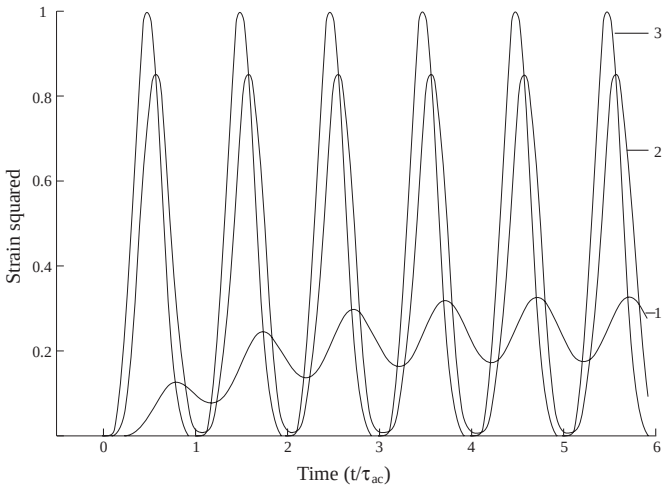
Fig. 8. Calculated thermal grating signals (30). The grating signal is plotted for various nonradiative relaxation times (γ^{-1}) relative to the acoustic period of the grating. Curves 1, 2, 3 correspond to $\gamma^{-1} = 0$, $0.1\tau_{ac}$, τ_{ac}, respectively, where τ_{ac} is the grating acoustic period. The finite relaxation times appear as a phase shift in the acoustic modulation of the signal.

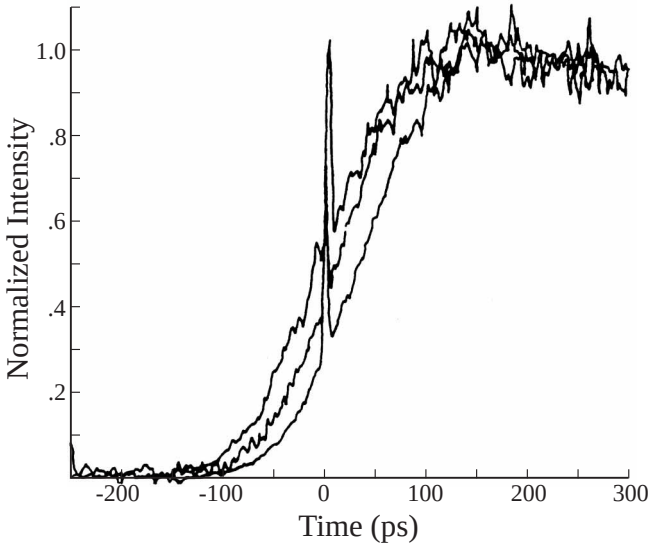


in the spectral density of states is much less pronounced. There may be variations in local density of states for a particular mode but there will also be a pathway enabling a high frequency mode to relax into two lower frequency modes.

Since this initial work, a number of experiments have been conducted using various probes to follow more selectively the relaxation of the excited heme porphyrin modes (32, 33–35). The main body of this work is consistent with the above findings. The only other work that has been able to follow the energy flow to the exterior of the protein used broadening of IR transitions to improve the time resolution (35). This latter work was able to show the expected biphasic relaxation process where half the energy is dissipated into the surrounding water layer within 8 ps and the remaining energy arrives within 15 ps, in good agreement with our earlier studies. Work in this area continues and the most recent picture is consistent with the above description (31, 32, 33–35).

The most important single message that has come from this work is that the energy redistribution processes in proteins are extremely fast. The energy flow all the way from the centre of the protein to the surrounding water layer occurs on time scales comparable or faster than the half period of the lowest frequency breathing mode of the protein. Thus, the collective or spatially extended segmental motions of the protein molecule must be strongly damped. This observation has implications for the vibrational soliton concepts in directing energy in biological systems. Vibration solitons require the nonlinear coupling of all the modes. Based on the rapid damping of the low frequency modes demonstrated by these studies, vibration solitons can not exist in proteins. The effect of water on the coupling has not been included in these theoretical treatments. The collisional exchange with water is too dissipative a process, and the independent collisional events do not lend themselves to the phased excitation required, to support such long-lived states (especially

Fig. 9. Picosecond transient grating studies of vibrational energy relaxation in heme proteins. The upper curve is the instrument response, the middle curve is for met-cyanohemoglobin, and the lower curve is for Malachite Green in ethanol. The rise is instrument response limited by the speed of sound and put an upper limit of 22 ps on the full relaxation process from vibrational energy flow from the heme porphyrin all the way to collisional exchange with the water (25).



over the required spectrum). The bottom line is that energy exchange processes are exceedingly fast in proteins and complete equilibration of excess vibrational energy (mechanical) into translational degrees of freedom occurs on ps to approximately 10 ps time scales.

Architectured phase space models

The fact that proteins undergo extremely rapid energy redistribution is a further challenge to understanding how chemical energy can be directed in biological systems. It was not until the above revelations that my group became earnestly interested in the "directed energy" problem. Once we found that the energy became randomized so rapidly, it became even more difficult to reconcile the observed dynamical processes in biological systems.

In principle, one could treat the directed energy problem in biological systems classically. There are enough degrees of freedom that quantum effects such as phase of the various modes should cancel to give a good approximation to a classical system. We should, then, be able to define a classical Hamiltonian that describes the protein response to a perturbation. There would be a kinetic energy term and a potential energy term defining how the energy of the perturbation is directed. From the above experiments, it is clear that the energy could not be highly directed through kinetic energy terms. Energy being directed as a traveling mechanical deformation would constitute a vibrational wavepacket and would require a nondispersive condition on the vibrational energy propagation (soliton-like character as discussed above). This mechanism for directing the energy can be ruled out. The above experiments demonstrate that the vibrational energy is too quickly randomized. Thus, the energy is

© 2002 NRC Canada

directed through effects mediated through changes in potential energy of the system. Put in another way, the energy must be directed through steric effects. The potential energy landscape of the protein is constructed such that only a relatively small number of pathways are extensively explored through thermal fluctuations, i.e., there exist coordinates that are more labile than others and undergo larger rms fluctuations. These coordinates provide the map for the protein to move from the reactant surface to the product and vice versa.

In chemistry language, the motions are constrained to follow a certain path by steric hinderance. This concept is used repeatedly in chemistry but should be more precisely defined in this problem. In particular, the length scale and time scales need to be defined or this is not a helpful concept. To drive home this point, the sampling process can be likened to particle motion on a slide. I've often made the analogy of the motions along the reaction coordinate to the motion one would experience in a water slide park. There always appears to be one water slide that is straight down. Motion along this potential energy surface from the top of the slide (reaction saddle point) would constitute the path of steepest decent. However, there are generally a great many different slides with meandering pathways from the top to the bottom. The motion of even complex objects with many degrees of freedom (e.g., you) can be constrained to follow a very directed path in such contexts. There is one important distinction to be made in this analogy. We need to consider the net rms motions involved in the protein's functional response relative to those in relation to the background thermal noise. The net displacement of the helical sections about the heme group is on the order of 0.1 Å or less. This value should be compared to the thermal fluctuations inferred from the Debye–Waller factors of the X-ray diffraction pattern of myoglobin that are on the order of 0.03 Å (36, 37). The net displacement is on the same order of magnitude as the background thermal noise. Within the above analogy, one would have to imagine going down a slide during an earthquake! You may start on one slide then midcourse jump to a different slide many times before arriving at the bottom (product state).

In some sense, to state that the directionality of the problem is imposed by the 3-D structure of the protein or steric hinderence is a nonstatement. With the dynamics for energy redistribution now at least qualitatively understood, it is obvious this is so. The real question is what is the length scale and time scale that the reaction proceeds along a particular coordinate. Within the mechanical slide analogy, what is the length scale and time scale of motion along a particular energy gradient? How high is the slide (energetics)? What structure elements are confining the sampling process?

As discussed above, the mechanics of the motion can be separated into a short length scale limit (Localized Strain) or a spatially distributed description (Collective Mode Coupling). This issue of the length scale of the response function is relevant to the degree of directionality and time scales for the structural encoded functions. A useful toy problem to consider is the response of an elastomer to a time-dependent force. In the limit of slowly varying forces, the polymer will deform slowly almost like a liquid. There is distribution of barrier heights. However, the polymers are able to thermally sample different configurations and those that experience larger displacements in the presence of the applied force will lead to a deformation along the applied stress. Now, consider the case of an impulsive force. The same elastomer will behave more like a rigid elastic body. If the area of the applied force is changed and (or) time scale, one would observe different behaviour between highly viscous fluid behaviour to solid-like behaviour. This gendanken experiment simply serves to remind us that all response functions have both a k (length^{-1}) and ω (time^{-1}) dependence. This statement holds true for dielectric functions, magnetic susceptibilty, mechanical response functions, and related many body effects. At the time of our studies, we simply did not know the relevant functional dependence with respect to these two parameters. For the most part, proteins were believed to be "glassy" states such that relaxation along a reaction coordinate should be best described by stretched exponential relaxation processes (short slide and (or) diffusive sampling). However, this view was based primarily on NMR and flash photolysis studies of protein relaxation on relatively long time scales. What if, on the time scale of the bond breaking, there isn't enough time for the protein to sample localized fluctuations, and the strong atom–atom correlations imposed on the system lead to a more spatially extended, rigid-like, response. We were missing key pieces of information related to how the protein responds during the time interval most relevant to the initial curve crossing process at the reaction saddle point, i.e., the very fastest time scales. To fully understand how energy is directed in biological systems, we need to study the mechanical response of the protein on all relevant time scales — from the chemical Big Bang out to full relaxation (over 10 decades in time).

Put in another context, we don't know the coupling coefficient of the reaction coordinate to the various degrees of freedom of the bath. The pathway from the global minima of the reactant to the reaction saddle point and subsequent relaxation to the product global minima involves nuclear fluctuations with contributions from all possible motions. In transition state theory, the rate of passage across the saddle point is dominated by those motions that are the highest frequency and involve the greatest amount of relaxation energy (38). To understand, how the reaction coordinate can be so highly directed into specific motions, the relaxation energetics need to be correlated to various relaxation phases of the protein to determine the dominant pathway or director to the sampling process.

Functionally relevant protein motions probed by four-wave mixing

The challenge, experimentally, is to come up with methods that are capable of observing the functionally relevant protein motions on all pertinent time scales. The motions at the ligation site can be relatively large, as the forces originate at this point. However, the communication pathway must involve the exterior atoms and as pointed out these motions can be exceedingly small if the force is distributed over a large number of atoms. Further, these structural changes constitute an important class of photodark processes. There is no transition moment tied directly to these motions. To probe these exceedingly small, highly correlated motions, an

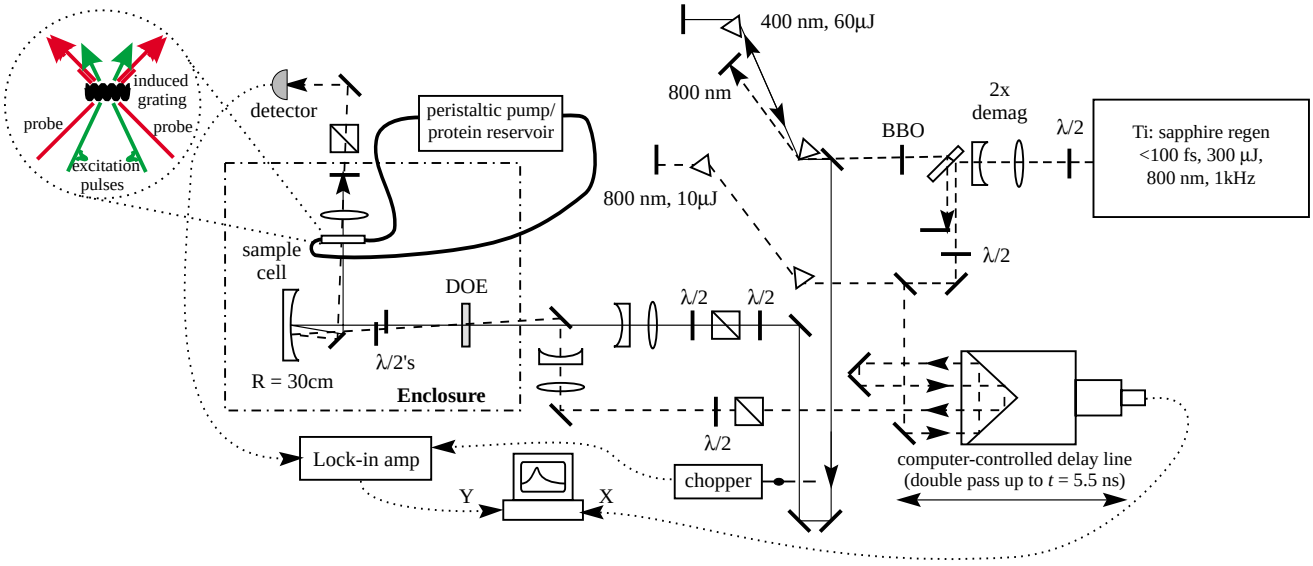
Fig. 10. Transient grating setup with diffractive optic element (DOE) (49).



interferometric approach is needed. Transient grating or four-wave mixing approaches offer this possibility.

The transient grating experimental setup and pulse protocol is shown in Fig. 10. Two excitation pulses are used to write an optical interference pattern in the sample. This image is stored as a periodic modulation of the complex index of refraction that can be probed by diffracting off a probe pulse at the Bragg angle. In essence, this is a single period hologram and the protein sample serves as the holographic storage medium. By choosing the excitation and sample conditions, it is possible to selectively study population dynamics, energy redistribution, or functionally important protein motions. The diffracted signal intensity is given by the relation (38):

$$[5] \qquad \eta(\omega) = \exp\left(\frac{-2.3D_{av}(\omega)}{\cos\Theta_0}\right)\left(\frac{\pi d}{\lambda\cos\Theta_0}\right)^2 [\Delta k(\omega)^2 + \Delta n(\omega)^2]$$

where η is the diffraction efficiency, D_{av} is the average optical density at the probe wavelength λ at the Bragg angle (Θ_0) for diffraction and d is the sample thickness. The terms Δk and Δn refer to excitation induced changes in the *Im* and *Re* components to the complex index of refraction at the probe wavelength. The population terms can be selectively monitored by the periodic modulations in Δk (absorption). However, the protein motions and energetics are detected through changes in the real part of the index of refraction (Δn). Specifically, the relaxation energetics can be monitored through temperature-dependent changes in the index of refraction (Δn_{th} re: thermal expansion and increased linewidths through hot band transitions and collisional broadening). The functionally important protein motions will likewise affect the index of refraction through mass displacements and associated index of refraction changes ($\Delta n_{protein}$). These terms of interest are detected in quadrature with population contributions to the dynamics (Δn_{pop}). The population contribution stems from changes in the optical spectrum and attendant changes in the optical dispersion (index of refraction). This effect can be estimated through a Kraemers–Kronig analysis (31). By using probe wavelengths as far away from either excited state or ground state resonances, it is possible to attain a good degree of isolation of the protein strain dynamics and energetics from what could be considered trivial population effects (in so much as conventional methods can determine this property).

Our studies of the energetics used deoxyheme proteins in which there were no photophysical processes other than vibrational energy relaxation. The proteins have extremely short-lived electronic excited states with out a photolabile ligand bonded to the iron. This work has been discussed above. To probe the functionally relevant protein motions, carboxymyoglobin (MbCO) was used. Photodissociation of the CO ligand can be optically triggered with 100% quantum efficiency by exciting into the either the Q band or Soret band of the heme (33, 39). These excited states are thought to be adiabatically mixed with the deoxy electronic surface (40) and the iron ligand bond found to undergo photodissociation in less than 50 fs (33). Thus, it is possible to photoinitiate the oxy- to deoxy-structure transition on a suitably fast time scale to cover all the possible motions, even those connected to crossing the reaction saddle point, i.e., times during the chemical Big Bang. In these studies, carboxyheme proteins were chosen over oxygen-bound species. The simple reason is that oxygen tends to show complex rebinding kinetics with less than 6% quantum yield for ligand escape; whereas photodissociation of CO from the iron gives a 96% quantum yield for ligand escape (41). The carboxy-forms give access to the full relaxation pathway or full range of functionally relevant protein motions — from the very initial event associated with bond breaking out to ligand escape and finally rebinding.

The original intent of our work in this area was to follow the relaxation energetics subsequent to photodissociation of the Fe—ligand bond. The amount of energy involved in the protein relaxation is an important parameter in understanding the biomechanics of the motion. The very first studies

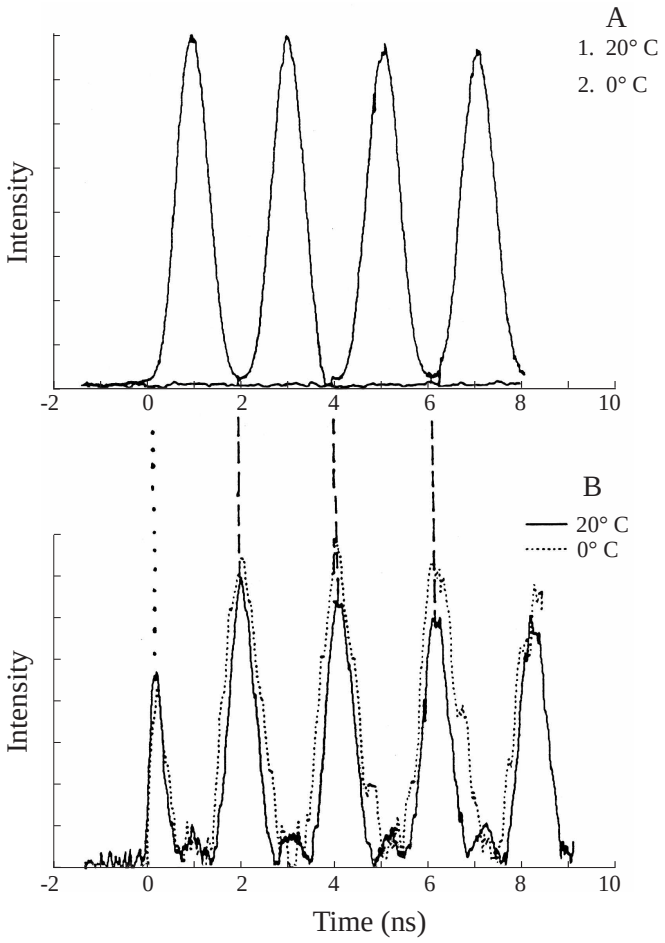
Fig. 11. (*a*) Deoxymyoglobin. The top curve shows the results for 532 nm grating excitation and 1.064 μm probe of deoxymyoglobin. This experiment is the control for a purely thermal process. The lower curve is under identical conditions except the temperature has been reduced to near the thermal expansion point of the medium to illustrate the purely thermal nature of the signal. (*b*) Carboxymyoglobin. The upper curve is at room temperature. The lower curve is under identical conditions except at the zero thermal expansion point. This study illustrates the nonthermal nature of the protein-driven acoustics. The dominant relaxation phase is less than 100 ps (re: Fig. 7 and grating acoustic period) and there does not appear to be significant slower relaxation processes out to 10 ns.



were a major revelation to the process. Rather than observing simple thermally driven sound fields under grating excitation (re: the energetics), we observed large nonthermal sound fields generated by the protein motion in response to the bond dissociation (42). These findings are shown in Fig. 11. The top panel shows the results for deoxymyoglobin (deoxyMb) under the same conditions as carboxymyoglobin (MbCO). The deoxyMb study is the control for a purely thermal process. Note the acoustics are 100% modulated and the first maximum occurs at one-half of an acoustic period from $t = 0$ as expected for thermally excited acoustic grating. Close inspection of the acoustic phase shows that the redistribution of the absorbed photon energy into translational degrees of freedom occurs within 10 ps as discussed above. The thermal nature of the signal is confirmed by going to the zero thermal expansion point of the solution where the signal disappears. In contrast, MbCO shows acoustic modulation that is 180° out-of-phase with the pure thermal response. Most important, the acoustic modulation persists and still dominates the signal near the zero thermal expansion point. This study showed that the protein was undergoing a significant volume change on time scales less than 100 ps. The protein volume changes define the protein strain — one of the key markers of functionally relevant protein motions as defined above. Perhaps the most important observation from this data is that there did not appear to be any significant (<20%) slow component to the protein strain evolution (42, 43). The bond breaking seemed to couple directly the protein strain without any appreciable extended relaxation dynamics (at least out to 10 ns). This observation led initially to the collective mode coupling model for describing the bond energy transduction to protein motions (15).

The above study has some ambiguity with respect to population contributions to the signal and a much more precise determination of the initial dynamics was needed instead of an upper limit. To resolve the dynamics, a counterpropagating grating beam geometry was adopted using 585 nm excitation and probe pulse sequences (31). The larger grating wavevector enabled the coupling of the protein motion to much higher acoustic frequencies and correspondingly higher temporal resolution to the protein strain dynamics. These results are shown in Fig. 12 where the acoustic phase difference between deoxyMb and MbCO are compared directly under identical conditions. This study illustrated that the protein strain was nearly completely developed within 4 ps. In fact, it is apparent from this data that the bond energy is displacing an acoustic mode of the protein faster (by approximately 6 ps) than the energy is becoming randomized into translation energy into the bath (defined by deoxyMb control). This study illustrated that the initial protein strain dynamics involve coupling to collective modes of the protein, i.e., the observed mass displacement corresponds to a strongly damped mode in the 1×10 cm^{-1} range. The significance of these findings should not be lost. The protein is executing functionally relevant motions faster than the energy randomization process discussed in the previous section. The displacement of collective modes in this regard would act to guide the system close to the global minimum of the product distribution before the directionality imposed on the system is lost.

This novel application of grating spectroscopy represents true protein seismology — listening to proteins move by optically monitoring the sound fields produced by the motion. The observed dynamics and connection to the protein strain demonstrates the initial response to be mediated through the coupling of the bond breaking to collective acoustic-like modes of the protein. Other proteins have been studied with nearly identical optical properties and show different amplitudes for the protein-driven acoustic waves. The speed by which all the proteins develop the dominant strain components in the tertiary relaxation is the most interesting observation. There appears to be no evidence for the stretched exponential relaxation processes that might be expected for a more localized strain evolution and glass-like behaviour. It is

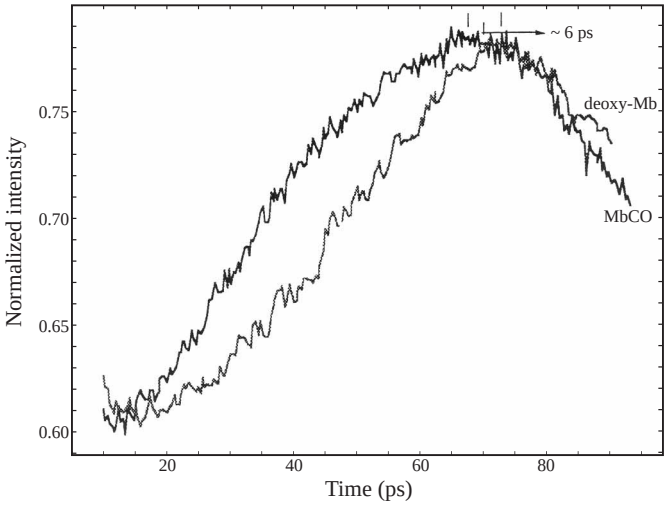
Fig. 12. Counterpropagating grating studies of MbCO at 585 nm. The acoustic phase of the protein-driven sound fields are directly compared to those of the purely thermally driven process. The photodissociation of the ligand leads to protein displacements that are shifted by 6 ps relative to the vibrational to translational energy relaxation process, i.e., the dominant phase of the initial protein relaxation along the dissociation coordinate occurs faster than the energy redistribution process.



important to point that these observations do not dispute previous observations of stretched exponential relaxation behaviour for proteins but rather emphasize the different k and ω dependence of the mechanical response function. Previous measurements were more sensitive to local motions near the heme (via the selection of probe transitions); whereas the protein driven acoustics probe the global relaxation coordinate. It is this coordinate that is sensed by neighbouring proteins such that the grating experiment directly probes the molecular communication coordinate.

The mechanics for this motion involve the coupling of the heme doming, as the epicentre of the reaction force, to the surrounding helical sections that are displaced in a segmental fashion, i.e., the atom–atom correlation is described as the displacement of a collective mode. Whether or not these motions can be ascribed to an imprinted directionality on the reaction coordinate requires a determination of the anisotropic nature of these motions. Since the protein has no centre of symmetry, the reaction forces should lead to highly anisotropic mass displacements on time scales faster than energy redistribution. To observe this effect on the right time scale requires subpicosecond time resolution and higher sensitivity to the index of refraction changes depicting the protein motion.

Diffractive-optics-based nonlinear spectroscopy — Optical analogue of NMR

It has long been appreciated that the signal-to-noise, in any inherently low signal experiment, can be significantly improved by the use of phase-locked heterodyne detection. In NMR, the radiated magnetic field from the cavity is mixed with a reference rf field and detected in quadrature with the reference field. If it were not for the ability to use phase-locked detection for signal processing, NMR would be orders of magnitude less sensitive and would have made far less impact in chemistry. The same methodology can be used in principle to determine multiple time correlations of optical and IR transitions that would access different time regimes and provide structural and (or) dynamical information on strongly correlated many body processes (dynamic structure of liquids, proteins). This detection modality may seem straightforward with respect to its wide implementation in NMR, however, it should be recognized that this approach requires phase stabilities in excess of $\lambda/100$. In NMR, the phase stability between the reference and the signal field emanated from the cavity is not an issue. The effective wavelength is in the meter range. The prospect of keeping paths and phase stable to better than 1 ppm is fairly routine. In contrast, in the optical domain, the signal wavelength is on the order of 500 nm. To achieve $>\lambda/100$ phase stability in this range, path lengths of the different interacting optical beams must be kept constant to within just a few molecular bond lengths (<5 nm variation). This degree of phase stability may seem out of reach considering that acoustical noise introduces micron pathlength fluctuations. Phase-locked signal detection has, however, been accomplished using feedback loops with interferometrically determined reference points. Unfortunately, this approach is cumbersome and is not robust (drifts and requires finding the set points daily). For this reason, there have only been a few reports of phase-locked heterodyne detection in the optical domain.

The quest for improved signal-to-noise is never ending. There is always some experiment that could be conducted — if only one had better signal-to-noise. The possibility of using phase-locked heterodyne detection for four-wave mixing studies has been a long-standing experimental challenge. Rogers and Nelson (44) published a paper outlining the use of a transmission grating to give automatic alignment of transient grating experiments. Similar approaches have been used in the past with respect to using gratings as beam splitters and phase masks are used on a large scale for imaging periodic structures in fibres for the fabrication of fibre Bragg gratings used in wavelength division multiplexing. The distinction of the work of Rogers and Nelson was that the grating generated a "finder" beam. The phase stability of the various beams was not addressed but merely noted that the spatial alignment could potentially be used for heterodyne detection. At the time, we had spent considerable effort on active feedback approaches and had attained as high as $\lambda/300$ phase stability. This limit was only achieved if the beams passed through the same transfer optics after an interferometric reference. It was obvious to us that as long as a diffractive element could be designed to provide a point of symmetry and all the beams passed through the same optics after this reference point, the system would be as stable as active feedback. It was at that point that we realized the best approach would be to specifically engineer a surface relief diffractive optic to provide all the necessary beams at the proper phase matching angle, along with a reference beam, with as large a bandwidth as possible for applications in multicolour fs experiments. This revelation has led to a number of important innovations involving the use of diffractive optics for implementing nonlinear spectroscopies (45–51), from generating tilted phase fronts for true fs time resolution

© 2002 NRC Canada

in a noncollinear beam geometry (less than 200 as broadening) (51) to complex high-order beam geometries (47).

In the case of four-wave mixing, it is fairly straightforward to design an optimized diffractive optic for proper phase matching and multicolour performance. The optic is a simple square-modulated surface relief pattern of the correct height for optimal performance in the desired wavelength range. We have since designed diffractive optics for six-wave, 2-D Raman, experiments that require at least 20 harmonics to generate the required beam pattern and careful attention to the amplitudes of the different Fourier components to enable two-colour experiments with a reference of a predetermined amplitude (48). This novel approach was essential to the first successful determination of the direct $\chi^{(5)}$ response of a liquid that demonstrated the short coherence times of simple fluids (47, 48).

The power of this approach in amplifying small signals can be seen simply by expanding the relations for the detected signal field in the presence of a reference field. The detected signal intensity (I_{OHD}) can be written as (49):

$$[6] \qquad I_{OHD} = \left|E_{ref}\right|^2 + \left|E_{sig}(t)\right|^2 + 2\left|E_{ref}\right|\left|E_{sig}(t)\right|\cos\left(\phi_{sig} - \phi_{ref}\right)$$

Where E_{ref} is the reference field, E_{sig} is the signal field, the φs give the corresponding phase of these fields. The *Re* and *Im* terms to the nonlinear response can be separated by simply changing the relative phase of the reference to the signal field. The *Im* term is related to absorption. In contrast, the *Re* term is related to the modulations in the index of refraction and constructive interference along the signal direction requires a 90° phase shift. Since the two contributions are 90° phase-shifted in their affect on the signal field, it is possible to unambiguously separate the two effects. This feature is not possible with conventional signal intensity measurements and will be a key point below in the discussion of selectively detecting the protein motions. With respect to amplifying the signal, the important point to note is the cross term between the reference and signal field (second term in eq. [6]). This term serves to amplify the signal by several orders of magnitude.

Increased signal amplitude is one issue but really the objective is to increase the signal-to-noise ratio (SNR). If the process amplifies the signal as well as the noise, there is no gain in the detection sensitivity. The SNR for heterodyne detection depends on many factors; the most important are the phase stability and the laser stability (45, 52). Of these two considerations, the single most important criterion is the phase stability between the reference and signal fields. Since the phase of the signal field is determined by the phases of the excitation and probe fields, the phases of all four beams (two excitation, probe, and reference beams) must be stable to within λ/100 (45, 49). It is this requirement that compounds the difficulty in using active feedback. The diffractive optic automatically provides a phase reference through the diffraction process. Any number of beams can be phase-locked or more correctly phase-stabilized using a diffractive optic. Just how good is this diffractive optic approach? Figure 13 shows a schematic of the experimental setup and a demonstration experiment using the $\chi^{(3)}$ response of liquid CS_2 (45). The optical arrangement is a simple 1:1 image relay system using either slightly off-axis spherical mirrors (slight aberration) or off-axis parabolic mirrors. The open arms in the optical relay permit the introduction of various optical elements for independent adjustment of the phase, polarization, and timing of the different beams. The system is very compact. A single optic replaces a plethora of conventional beamsplitters, optical delays, and interferometers that would otherwise be required. The laser used in this study was unamplified and was attenuated to a few mW of average power to conduct a time domain equivalent of Raman scattering to emphasize the sensitivity of the approach. The relative phase of the reference beam is tuned by the simple tilting of a microscope cover slip to adjust the relative phase delay. As can be readily observed, the signal is phase scanned from the *Re* signal component expected for CS_2 (90° phase shift) to the *Im* signal component. The most impressive detail is the observation of the *Im* term. This signal corresponds to the amount of absorption of the excitation fields by stimulated Raman absorption. The effective optical absorption of this process at the excitation levels used would correspond to a change in transmission of the probe of significantly less than 1×10^{-8} (estimated from diffraction efficiency).

The dramatic improvement in SNR is shown in Fig. 14 where detection of the signal intensity using the conventional approach is compared directly to heterodyne detection using diffractive optics. The improvement is quite dramatic for this small signal case. The phase stability is found to be as high as λ/300 for periods of minutes and λ/100 for periods of hours to days (45, 49). This extraordinary phase stability for all four interacting fields is a consequence of the symmetry of the imaging system and optical paths. The symmetry makes the optical imaging immune to beam-pointing noise such that air currents are the primary limitation. This high stability enables signal averaging with phase-locked detection over extensive integration times. The enhancement in the signal-to-noise is typically greater than 100:1 (45) and can be in excess of 1×10^6:1 if done perfectly (38, 52). Previously, transient grating methods were shown to be on par with some of the most sensitive absorption spectroscopies such as cavity ring down, intracavity photoacoustic, and photoacoustic spectroscopies (53). The enhancement factor now possible with the above simple, single optic, approach makes four-wave mixing approaches one of the most sensitive absorption-based methods developed to date. Only FM modulation (side band) spectroscopy has demonstrated greater sensitivity (re: near single molecule detection) (54) and similar modulation methods could be introduced to a high resolution frequency domain analogue of this approach to further enhance the sensitivity. The primary limitation of the heterodyne-detected grating sensitivity is the effective pathlength. The length is defined by the beam interaction region such that this method is confined to small pathlength samples.

Heterodyne detection of protein motions — Observation of mode selective coupling

The development of diffractive-based nonlinear spectroscopy was a key step forward in this problem. With this approach, it was possible to increase the sensitivity and

unambiguously separate the phase from the amplitude terms of the grating signal. The stage was set to fully explore highly directed protein motions and (or) reaction coordinates in biological systems.

In this regard, one would ideally like to have an orientated sample to optically probe the induced birefringence that would develop from anisotropic mass displacements. In solution, it isn't feasible to align the proteins but it is possible to take advantage of the polarized nature of optical transitions to photoselect an orientation. For heme proteins, the relevant transition involve those that are *x*,*y*-polarized in the plane of the heme. In essence, using polarized excitation pulses, it is possible to induce an aligned distribution of excited molecules. The photoselection process induces an absorption anisotropy in the sample or dichroism defined as:

$$[7] \qquad r_{\mathrm{Im}}(t) = \frac{Im\,(\chi_{1111}{}^{(3)}(t)) - Im\,(\chi_{1122}{}^{(3)}(t))}{Im\,(\chi_{1111}{}^{(3)}(t)) + 2\,Im\,(\chi_{1122}{}^{(3)}(t))}$$

The subscripts of the $\chi^{(3)}$ tensor refer (left to right) to the polarizations of the two excitation pulses, probe, and signal field. This relation defines the normalized difference in absorption between parallel and perpendicular polarizations of the probe light relative to the excitation used to induce the anisotropy. For an *x*,*y*-polarized transition, the absorption anisotropy can be shown analytically to have a value of 0.1 (49, 50).

The ability to separate the *Re* and *Im* terms of the $\chi^{(3)}$ susceptibility now makes it possible to define the phase anisotropy (birefringence) in analogy to the absorption anisotropy (dichroism), i.e.,

$$[8] \qquad r_{\mathrm{Re}}(t) = \frac{Re(\chi_{1111}{}^{(3)}(t)) - Re(\chi_{1122}{}^{(3)}(t))}{Re(\chi_{1111}{}^{(3)}(t)) + 2\,Re(\chi_{1122}{}^{(3)}(t))}$$

Fig. 14. Demonstration of signal-to-noise improvement using diffractive optics for passive phase stabilization. The noisy curve is for CS_2 using direct detection of the signal. The other curve is for the same sample, under identical conditions, using the *Im* and *Re* parts of the heterodyne detected signal (data shown in Fig. 13).

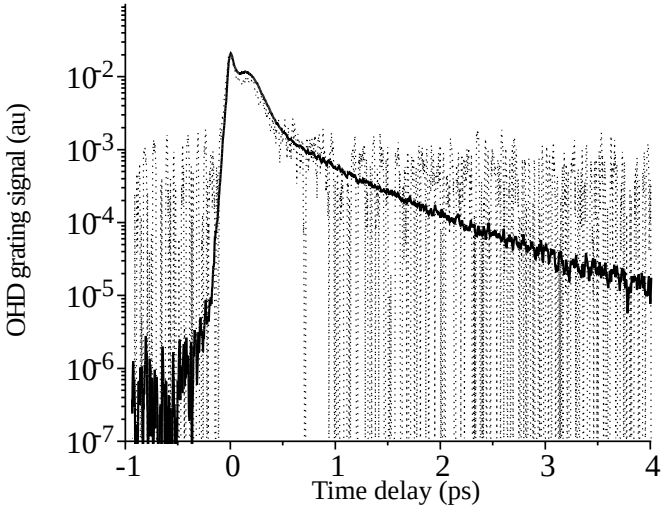

Figure 15 shows the diffractive-optics-based heterodyne detection of both the absorption anisotropy and the phase anisotropy (50). The absorption anisotropy is that predicted for this system at the probe wavelength. The most important feature is the dramatically different behaviour of the phase anisotropy. Rather than a monotonic decay with rotational diffusion, the *Re* part of the signal shows complex behaviour with both rise and decay features that are very distinctive relative to the absorption-based signal. This difference illustrates the significantly different affect the protein motions and relaxation have on the transient absorption relative to the index of refraction changes. The protein relaxation only has a second-order effect on the transient absorption, as manifest in subtle shifts in the spectrum. In contrast, the protein motions directly affect the index of refraction through the differential mass displacements in response to the photoinduced reaction forces. The significantly different dynamics and amplitudes for the observed anisotropy serve as testimony to the affect of the protein motion on the *Re* signal component.

The two most important features of the data shown in Fig. 15 are the amplitude of the phase anisotropy and the dynamics. The amplitude is nearly 0.4 and is far too large for a circular transition to be a simple photoselection effect. The signal components can be transformed to the molecular frame. From this analysis, it was determined that the protein is undergoing differential expansion and compression for directions parallel and orthogonal to the heme plane. In other words, the protein is changing its shape. In this respect, the other interesting feature is that it is doing so within 500 fs. This motion seems to be the dominant relaxation component leading to this unusually large birefringence. There are also ps thermalization components but once this part is separated from the problem by the use of model compounds, it appears the 500 fs component is the primary motion that leads to anisotropic mass displacements.

This motion is the key signature of a directed response for the protein. By going to higher excitation, the strongly

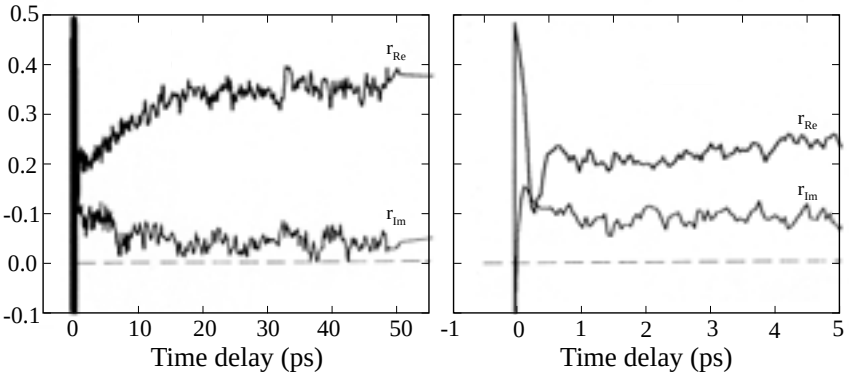
Fig. 15. Diffractive-optics-based heterodyne detection of protein motions. The phase anisotropy is the top curve. The bottom curve gives the absorption anisotropy. Two different time bases are shown to clearly depict the early time protein dynamics. Note: the significantly larger anisotropy in the *Re* part of the signal that develops within 500 fs, distinct from changes in absorption.



damped features of this singular component are more readily observable (50). This time scale may seem unusually fast for a relaxation process, however, these dynamics should be compared to other relaxation phenomena in the condensed phase. It has now been well-established that solvent relaxation involves the significant involvement of free streaming inertial modes (22, 23). In most cases, more than 50% of the solvent relaxation process occurs through these collective librational-like motions. As discussed above, these motions can be described as collective by the short-range order imposed by the weak intermolecular forces and inertial effects that lead to correlations that persist long enough to be categorized as a mode. These motions are not diffusive and generally involve 100 fs components. In protein systems one would expect the correlation to be even stronger and more persistent in both length scale and time scale. So the observed time scale can be rationalized. The most significant distinction of the present work is the observation of anisotropy in the protein relaxation. It has long been speculated that certain motions in the liquid state would be more important in promoting a reactive crossing. Despite fairly exhaustive investigations, there hasn't been an observation of mode selective coupling to the bath modes of liquids. It would appear that the spectral density of states (number of modes available) is all that matters and the coupling coefficient of the reaction to the different bath modes of the liquid state is not strongly varying (22, 23). Clearly, information is being lost in the liquid studies or the different modes are very similar (all involve the motion of a small number of identical solvent molecules). For biological systems, it is anticipated that the protein structure has been highly refined for the expressed purpose of generating mode selective coupling to direct the chemical energy. The above study made this important connection and is the first example of mode selective coupling of a reaction to the bath (in this case the globin surrounding the active site).

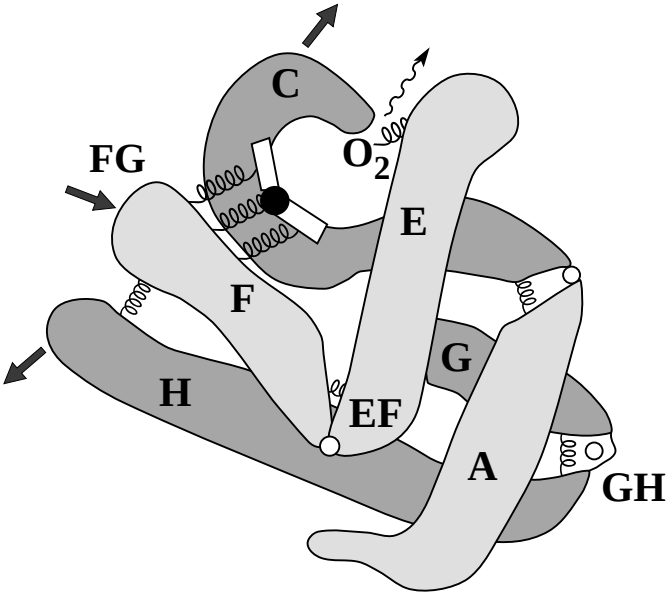
With the identification of this response as an example of mode selective coupling, the observed time scale can be correlated to microscopic processes. From the above treatment, we know that the energy becomes rapidly randomized in biological molecules. Any motions involving frequency components in the 100 to 10 cm^{-1} range should be highly damped. The 500 fs component would correspond to the half period of a highly damped mode of approximately 20 cm^{-1}. From a normal mode analysis of Seno and Go, it was found that the protein structural changes of myoglobin in going from the ligated oxy- to deoxy-tertiary structure can be reconstituted to better than 60% accuracy by the simple displacement of six low-frequency collective modes in the range of 5–20 cm^{-1} (36, 37). The all important mechanical coupling to the EF helical section would involve a mass displacement with a period very close to 20 cm^{-1}. The fact that this topological feature is so strongly conserved, and is the most intimate contact to the largest atomic displacements of the reaction coordinate, projected along the iron motion, support the interpretation of the observed anisotropic mass displacement to the EF helical section. More precisely worded, the largest coupling coefficient of the reaction coordinate is to the collective mode involving segmental motion of the EF helical section. Of course, there will be associated displacements that make up the superposition state defining the motions. Fluctuations of the EF domain would, however, serve to focus the reaction forces and efficiently direct the protein relaxation along the correct seam in a rather complex and tortuous potential energy landscape.

The experimental evidence for the collective mode coupling mechanism of energy transduction illustrates one of the most profound examples of mode selective coupling in chemical reactions. The term profound is not used lightly here as it is meant to convey the importance of these observations with respect to how biological molecules bridge the quantum aspects of chemical reactions to the meso-scale appropriate to biological functions.

The basic features of the collective mode coupling mechanism are shown in Fig. 16. To give this concept a Canadian context, this schematic follows the guiding principle of the famous *Group of Seven* artists who pioneered the portrayal of Canadian landscapes. These artists quickly sketched the scene, then made successive sketches from previous versions, until only the most salient, inspiring, details of the image remained. In some sense, this is what Nature has done to remove complexity, by spatially averaging over various length and time scales to remove fine grain features in the potential energy landscape. To reflect this effect, the individual heavy atoms of myoglobin in Fig. 16 have been replaced by the helical secondary structures that serve to delineate the

© 2002 NRC Canada

Fig. 16. Schematic of the collective mode coupling mechanism. The helical secondary structures are drawn as segments to illustrate the strong atom–atom correlations in these topological regions relative to the larger rms motions at the loop regions that are modeled as hinges for the segmental motion.

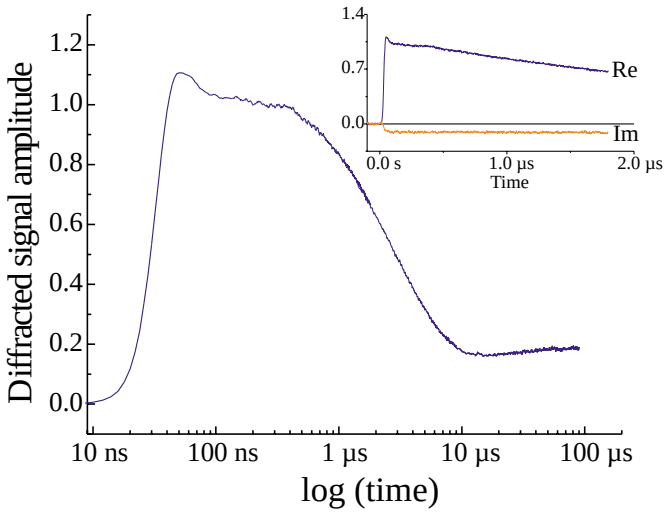


more rigid structure elements in the protein architecture. The rms motions of these regions are much smaller than the loop regions of the globin that serve as hinge points for segmental fluctuations of the helices. The breaking of the Fe—ligand bond creates an epicentre for the reaction forces that lead to the iron motion out of the heme plane and the mechanical coupling to the surrounding helices of the globin. The motions that are energetically favorable with respect to the new charge distribution at the iron will experience a larger displacement than those opposed to the reaction force field. The resultant effect is that the segmental motions of the protein's secondary structure strongly guide the system along the correct seam in the reactive surface with a very coarse grain sampling process. In this manner the system avoids becoming trapped in local minima. Furthermore, the functionally relevant motions become highly directed on a time scale that is competitive with the extremely fast energy redistribution processes discussed above. For example, once the EF helical section samples the low energy path, involving the barrel roll motion, the excess driving force becomes dissipated and the system has been displaced almost completely to the new global energy minimum distribution corresponding to the deoxy tertiary structure. From the energetics of the relaxation process, as discerned from the thermal components to the grating signals, it appears that the system propagates more than 60% of the way towards to this point through the inertial collective mode displacements (15).

Long time dynamics — "It ain't over till it's over"

I have given numerous talks covering the above observations and interpretations of the biomechanics of protein

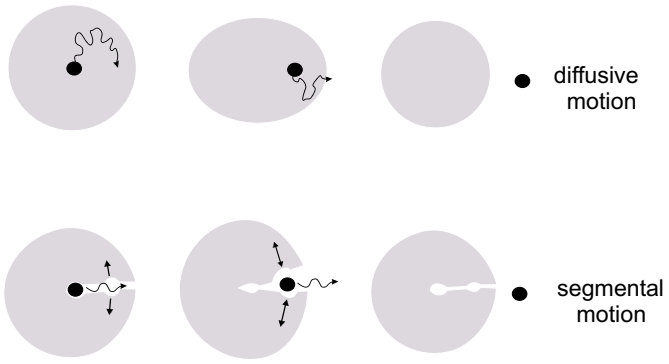
Fig. 17. Protein response to ligand escape. The dynamics for MbCO are shown out to long time to illustrate the strongly two-tiered nature of the protein response at –1.5°C (to eliminate thermal contributions). The *Re* part of the signal shows the initial collective mode response to ligand dissociation, followed by a quiescent period (small amplitude rise due to motion of the CO through the protein) of approximately 400 ns, and then a rather abrupt expansion of the protein (purely single exponential decay; decrease in the index of refraction with expansion). In contrast, the *Im* component shows a flat baseline offset on this time scale and recovers with the expected kinetics for CO recombination on ms time scales. This difference is highlighted in the inset on a linear scale.



functions. Prior to joining the faculty at the University of Toronto (1995), I gave an overview of our work in this area when Professor Ron Kluger questioned the importance of the fs and (or) ps dynamics in biological functions. (A quite lively and enjoyable discussion ensued in which we each questioned how early events led us to be present in the same lecture room.) Basically, it was argued that processes occurring on µs to ms time scales are more relevant to biological functions as these time scales reflect the thermodynamics and kinetics controlling the process. We found ourselves in agreement here. Our work and the above discussion was aimed at how a biological system samples a reaction saddle point and relaxes to the new product state (executes a function) without getting lost in the myriad of local minima, i.e., transition-state crossings of complex systems. Prior to our work, most studies had found that protein relaxation involved glass-like behaviour as depicted by stretched exponential relaxation dynamics extending over several decades in time (16–21). The above work established that the initial protein relaxation phase is dominated by coupling to collective modes of the protein that would act to avoid entrapment in local minima before the onset of the glass-like response. How important is this directional "kick" that is imposed on the system? My group and I had long contemplated extending the dynamical studies to cover the full spectrum of protein motions. We wanted to determine which relaxation mechanism dominated the process, collective modes or glass-like dynamics. This important point could be established by measuring the relaxation energy associated with

© 2002 NRC Canada

Fig. 18. Proteinquakes. The case for fluid-like dynamics is contrasted to segmental sampling of the conformational distribution. The delayed onset and abrupt change in protein volume of opposite sign can be understood if the protein structure remains relatively rigid as the CO samples a discrete number of interconnected void spaces as the ligand escapes to the aqueous phase.



each phase of relaxation (15). This correlation would establish the driving force and response built into the system.

The experimental setup to extend the time base is very similar to the fs setup. A diffractive optic setup was employed with some minor changes. The most significant difference was that a CW laser was used for the probe and reference, with a transient digitizer to provide the time resolution. The diffractive optic was designed to have up to five different fringe spacings so we could measure transport properties and clearly separate thermal contributions to the signal from other contributions. We were originally expecting that we would observe a biphasic response, i.e., the fast collective mode relaxation phase (too fast to be resolved with this setup) followed by a slow stretched exponential relaxation process. Instead, we found, yet again, very different dynamics depicting the long time protein motions. Rather than a stretched exponential component, we observed a dramatic two-step feature to the protein response function (46, 55). These results are shown in Fig. 17 near the zero thermal expansion point to remove the thermal grating components. The two-tier nature of the protein response is most obvious in the log *t* plot where the time scale is compressed. The two most significant features are the initial signal level (collective mode relaxation phase), followed by a quiescent period of several hundred ns, then a large volume change, that is opposite in sign to the original motion, occuring on the μs time scale. By conducting a fringe-spacing dependence, we were able to determine that the solvation of the CO in water creates an index of refraction change (due to the volume excluded to create the cavity in water for the CO) that is 35% of the original signal amplitude. With this information, the μs decay component can be unambiguously assigned to the CO escape from the protein. This feature was then followed by another quiescent period during which the signal decays through bimolecular recombination with the solvated CO to regenerate the ground state and fully reequilibrate the protein system.

Close examination of the dynamics found that the observed protein response actually consisted of a small amplitude exponential rise in the signal followed by a nearly order of magnitude larger exponential component of opposite sign (55). The dynamics could be well-fit to a previous model that used a discrete subset of sites within the protein for the CO and treated the ligand transport as a thermally activated hopping process (56). The observed dynamics are in good agreement with transient IR studies of the shift in the CO vibrational spectrum with escape to the aqueous phase using fixed time delays (57). These comparisons solidify the assignment of the unusual two-tiered dynamical signature to CO transport through the protein. Most important, the rather large change in signal amplitude and most significantly the sign change, demonstrates that the protein relaxation is not a simply monotonic relaxation process along the Fe-ligation coordinate. Stretched exponential relaxation processes are monotonically decaying functions and it is not possible to describe the sign change (reversal) as a glass-like relaxation process. This is an important distinction that merits further consideration.

The CO transport through the protein is not an orthogonal coordinate to the bonding at the active site. This point has been neglected in many treatments and it is obvious from this work that the motion of the CO to the active site must be convolved to the protein relaxation coordinate. In this context, the mechanism of transport of receptor molecules through proteins has been a long debated problem. The protein structure must be rigid enough to maintain functional integrity; yet be fluid enough to permit ready access of receptor molecules to the active site. From phosphorescence quenching studies, it has been inferred that ligands, the size of oxygen, are able to access all possible pathways within protein (58). This statement is based on phosphorescence studies of buried chromophores in which the oxygen concentration dependence is found to be consistent with diffusion limited quenching. In contrast, cryogenic X-ray diffraction studies of myoglobin have found that there are only a few cavities in the protein that can accommodate diatomic ligands (59). All pathways are not accessible. In addition, there is no apparent contiguous pathway that connects the active site to the surface to assist ligand transport in and out of the protein. In fact, if the protein structure was frozen, there would be more than a 100 kcal mol^{-1} barrier to oxygen or CO escape (60). Clearly, protein dynamics are important in creating fluctuating passageways connecting the various void spaces within the protein that act to mediate the transport process. What is the mechanism that enables proteins to conserve structural integrity, yet readily shuttle ligands in and out of buried active sites? To resolve this issue requires real time measurements to fully resolve the dynamics that promote ligand transport. The grating measurements were the first to fully resolve ligand motion through a protein in real time. Based on the above observations, it can be concluded that ligand motion does not involve a completely random, diffusive, walk as inferred from quenching studies. Rather, there appear to be discrete sites within the protein. The essentially single exponential character of the CO final escape step implies that there is either one dominant channel or that the subset of conformations that enable ligand access to the solvent have very similar activation barriers.

The most surprising finding was the much larger volume change of the protein accompanying the final step of CO escape to the aqueous phase. If the protein was sampling a continuous distribution of conformations, akin to a fluid response, there should be a continuous distribution of volumes

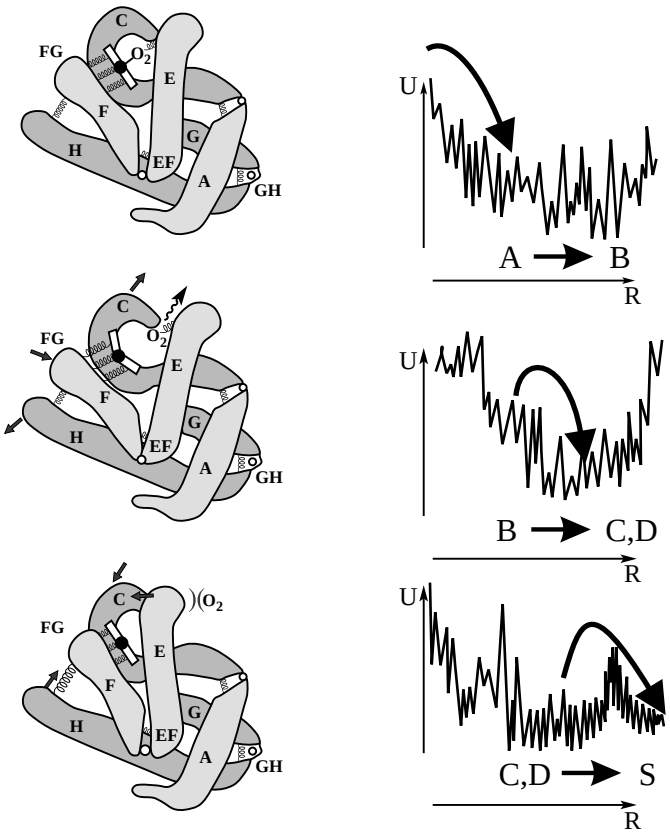
Fig. 19. Collective mode coarse grain sampling of reaction coordinate and (or) functional motions. (*a*) Initial inertial collective mode response. The bond breaking displaces preferentially those modes most strongly coupled to the Fe. This motion is most likely the EF topological domain. This motions constitutes the largest fraction of the driving force (≥6 kcal mol^{-1}) and displaces the system very close to the conformational distribution of the fully relaxed deoxy structure (inset). (*b*) Intraprotein transport. Thermal fluctuations with a small amount of strain energy (2 to 3 kcal mol^{-1}) involved in the structural relaxation as the CO samples discrete void sites within the protein. Inset schematically represents a thermally assisted hopping process near the global energy minimum. (*c*) Ligand escape. The protein executes a change in volume that is comparable or larger to the initial relaxation phase. This process is largely entropically driven. All phases of the protein motion can be understood on the basis of a coarse grain sampling process through segmental fluctuations of the secondary structural elements that form topological domains to guide the system through otherwise extremely complex potential energy surfaces.



corresponding to the two end points as the protein uniformly deforms about the ligand. There should also be a distribution of arrival times characteristic of a diffusive random walk. The delayed onset to this large volume change indicates that the protein is not uniformly deforming to accommodate the ligand but rather undergoing a discontinuous change in structure commensurate with CO escape. Such a process can be rationalized if the protein retains its structural integrity with CO displacement. This phase of the motion would explain the rather small initial change in protein strain or volume; only when the CO leaves the protein does the system exhibit the differential volumes of solvation for CO in the two media (protein and water). The mechanics of this motion are shown schematically in Fig. 18 in which continuous "fluid-like" deformation of the protein about the ligand is contrasted with segmental fluctuations that would conserve the protein volume until ligand escape. The relatively negligible changes in the protein volume as the ligand moves to discrete voids imbedded in the structure demonstrates that the protein is "rigid" in the conformational sampling process. The much larger change in volume with ligand escape to the aqueous phase could then be likened to a quake, i.e., segmental displacement in response to a stress. The terminology "proteinquake" has been used previously as an analogy for understanding the relaxation processes of proteins (61). The above experiment has demonstrated that this analogy is far more appropriate than could have been envisaged prior to these experimental studies. In so far that quake phenomena involve localized strain and relaxation, there is a length scale that needs to be attributed to the process. The strongly tiered (discrete) nature of the protein response suggests that the segmental motions involve fluctuations over the pathlength that connects the void spaces to the surface. This observation clearly illustrates the remarkable degree of molecular engineering that has enabled biological systems to bridge the diffusive properties of liquids with the structural integrity of solids.

Summary

With the above long time studies, we have interferometrically followed protein motions over 12 decades in time to cover the complete range of relaxation phenomena. The general picture that has emerged is summarized in Fig. 19. The main message is that the long-range correlations of atomic motions mediated through the protein secondary structure (and tertiary contacts) greatly reduces the reaction phase space. On short time scales, the relaxation of the protein through a reaction saddle point (reactant to product state) is propagated by the displacement of the inertial collective modes of the protein matrix. The helices move in relation to the less rigid loops in a manner that strongly guides the system along the correct seam. Using the relaxation energetics as the overriding criteria, this motion along the reaction surface is the dominant mechanism. It should be noted that this is the most efficient mechanism possible. By preferential coupling to collective modes of the protein, the reaction forces map the atoms close to the global energy minima corresponding to the product state — at the speed of sound. The importance of the inertial collective phase of the relaxation process is understandable as the very fast energy redistribution processes in these metastable systems would trap the system in local minima otherwise. This work has lead to the proposal that the secondary structures of macromolecules are the director we have been seeking. These topological structural elements have the correct length scale to enable the system to jump from the atomic level, fine grain features, to the mesoscale appropriate to biological functions. In other words, it is the secondary structures such as helices that effectively coarse grain the sampling process.

In this context, Levinthal's paradox is the same as all paradoxes — a misstatement of the problem. Proteins and other biological macromolecules do not have enormous numbers

© 2002 NRC Canada

of *independent* degrees of freedom. There are significant enthalpic factors that lead to secondary structures (and tertiary contacts) that in turn lead to a high degree of correlated motion. In the case of myoglobin, the degree of correlation seems to be so strong that the displacement of less than five modes, as opposed to 1×10^4, can constitute more than 60% of the structural relaxation connecting the oxy to deoxy-tertiary structures (36, 37).

We can now return to the hologram (cover) provided to visually capture this effect. In viewing from right to left, one should see the individual heavy atoms become dressed by a van der Waals surface, like a sleeve, in which the highly directed correlations through the helical secondary structures are depicted (single frame shown in Fig. 2*b*). In moving one's head further from right to left, it should be possible to view what would appear to be the segmental motion of the EF topological domain in response to the heme doming with ligand dissociation. One has to imagine these fluctuations occurring within the background of random thermal fluctuations. The key point is the degree of correlation with respect to length scale.

In order for the secondary structures to satisfy the conditions of imposing the directionality on biological processes, there needs to be a correlation over both length scale and time scale. The correlation over time scales is imposed as a further condition on the problem as most biological processes involve many different intermediates and exhibit functionally relevant kinetics over many decades in time. As observed for CO transport through the myoglobin, there is evidence for a highly simplified response that implicates segmental fluctuations in the sampling process out at least six decades in time relative to the periods of the modes involved. Rigorously speaking, there will be deformations in these secondary structures that appear more localized and impart some liquid-like components to the motion over this time range. However, these localized deformations are likely short-lived and an average structure element showing strong conservation of the secondary structures is inferred from the highly simplified protein response to ligand escape. The concept of secondary structures imposing strong correlations on the sampling process invites a simple mechanical model of how biological systems become highly constrained with respect to their total available configuration space. It is proposed that this type of segmental motion leads to coarse grain sampling over all relevant time scales and fully satisfies the conditions as the director.

Finally, there is one other important point that should be made and emphasized. A great deal of previous work has likened protein dynamics to glass dynamics. This comparison has some merit as both proteins and glasses are highly associated systems. However, glasses are structurally homogeneous, isotropic, systems. In contrast, proteins are highly heterogeneous, being comprised of significantly more rigid structure elements (helices and (or) secondary structures) in relation to strategically placed liquid-like domains (loops). It is the juxtaposition of liquid domains with structurally more rigid domains that enables the system to exhibit coarse grain sampling. In a glass system, a perturbation relaxes through a continuum of different length scales, and associated barriers, to anneal to the lower energy state. This relaxation process exhibits classic stretched exponential behavior. Proteins will exhibit similar trends over short length scales. However, as the perturbation involves longer and longer length scales of motion, eventually the analogy with glasses has to break down. After all, the protein has a well-defined boundary at the aqueous interface. At some point, the discrete nature of the system has to become manifest in the observed response. The present work points to this distinction and highlights the dramatic departure of protein dynamics from glasses once the length scale approaches that appropriate to the biological functions (mesoscale). Thus, proteins and other biological macromolecules are distinct states of matter. The heterogeneity of the structural elements is the key to their amazing properties to retain structural integrity and (or) functionality with fluid-like dynamics — a true hybrid state of matter. We need to properly recognize the global aspects of the reaction coordinate in this regard. Our current inability to strongly influence biological functions with site-directed mutations (save a few examples of charge-transfer processes) is largely a consequence of not treating the global aspects of the reaction coordinate. Future studies of protein dynamics and structure will likely lead to more refined control over biological processes and may give us our greatest insights into chemistry in general.

Acknowledgements

The work discussed above was funded primarily by the Natural Sciences and Engineering Research Council of Canada (NSERC). Supplemental support for the work on diffractive optics was provided by Photonics Research Ontario. Initial funding was provided by the National Institute of Health (U.S.A.). The author has had the privilege to work with a number of dedicated individuals during the course of these studies. In particular, Hui-Ling Chui, Gami Dadusc, John Deak, Laura Genberg, Greg Goodno, Una Marvet, Jennifer Ogilvie, Lynn Richard, and Peter Schulenberg deserve special recognition for their efforts to reveal the intricacies of transition-state processes in biological processes. Special thanks goes to Ron Kluger for stimulating discussion and being the driving force behind a collaboration to use these concepts and (or) spectroscopies to explore chemically modified hemoglobins.

Electron-spin conservation and methyl-substitution effects on bonds in closed- and open-shell systems — A G3 ab initio study of small boron-containing molecules and radicals

Clement Poon and Paul M. Mayer

Abstract: High level ab initio molecular orbital theory calculations have been used to study the geometries and thermochemistry of molecules and free radicals substituted by BH_2, $BHCH_3$, and $B(CH_3)_2$. The heats of formation and RR′B—X bond strengths (RR′ = H, H; H, CH_3; CH_3, CH_3 and X = CH_3, NH_2, OH, F, SiH_3, PH_2, SH, and Cl) together with those for the open-shell systems RR′B—Y· (RR′ = H, H; H, CH_3; CH_3, CH_3 and Y = CH_2, NH, O, SiH_2, PH, and S) have been calculated at the G3 level of theory. The trends observed for the homolytic bond strengths in the closed-shell systems are those expected from electronegativity arguments, i.e., as the difference in electronegativity between the two atoms in the B—X bond increases, the bond strength increases. Methyl substitution on B in the closed- and open-shell species increases the ionic contribution to the bond thereby decreasing the bond strength. The lowest possible homolytic dissociation energy for the free radicals RR′BY· is lower than those of their closed-shell counterparts, yet the B—Y· bonds are shorter. This is due to the demands of spin conservation in the dissociation of the radicals favouring the formation of higher energy products.

Key words: ab initio calculations, bond dissociation energy, organoboron compounds, thermochemistry.

Résumé : Faisant appel à des calculs théoriques d'orbitales moléculaires ab initio à niveau élevé, on a étudié les géométries et la thermochimie de molécules et de radicaux substitués par des groupes BH_2, $BHCH_3$ et $B(CH_3)_2$. On a calculé les chaleurs de formation et les forces des liaisons des composés RR′B—X (RR′ = H, H; H, CH_3; CH_3, CH_3 et X = CH_3, NH_2, OH, F, SiH_3, PH_2, SH et Cl) ainsi que les valeurs correspondantes pour les systèmes à couches ouvertes RR′B–Y· (RR′ = H, H; H, CH_3; CH_3, CH_3 et Y = CH_2, NH, O, SiH_2, PH et S) au niveau G3 de la théorie. Les tendances observées pour les forces homolytiques des liaisons des systèmes à couches ouvertes correspondent à celles auxquelles on pourrait s'attendre sur la base d'arguments d'électronégativité, c'est-à-dire que la force de la liaison augmente avec une l'augmentation dans la différence d'électronégativité entre les deux atomes de B—X. Une substitution du B par un méthyle dans les espèces à couches ouvertes ou fermées provoque une augmentation de la contribution ionique à la liaison accompagnée d'une diminution de la force ionique. L'énergie de dissociation homolytique la plus faible pour les radicaux libres RR′BY· est inférieure à celles de leurs contreparties en couches fermées, mais les liaisons B—Y· sont toutefois plus courtes. Ce fait résulte des demandes de conservation de spin dans la dissociation des radicaux qui favorise la formation de produits d'énergie plus élevée.

Mots clés : calculs ab initio, énergie de dissociation de liaison, composés organiques du bore, thermochimie.

[Traduit par la Rédaction]

Introduction

The strength of a bond between two atoms is one of the most fundamental molecular properties in chemistry. Since few bond strengths (homo- or heterolytic) can be measured directly, estimates are usually derived from molecular and fragment heats of formation (ΔH_f°). Experimental determination of free radical ΔH_f° values (and thus homolytic bond strengths) are inherently difficult and relatively few values are available (1). The two most common methods for deriving free radical ΔH_f° values are by halogen abstraction kinetics and the appearance energy (AE) method (2). A typical approach to the former involves reacting a molecule RH with a halogen atom X· in a very low pressure reactor to form a free radical R· and HX, the halogen concentration being monitored spectroscopically. The enthalpy change of the reaction can be determined by measuring the temperature dependence of the forward and reverse reaction rate constants. If the ΔH_f° values for RH, HX, and X· are known, that of R· can be derived. In the AE technique, molecules RB are chosen so that upon dissociative ionization by photons (for examples see refs. 2 and 3) or monoenergetic electrons (for examples see refs. 4–6) the products R· and B^+ are formed.

In its simplest form, the AE relates the ΔH_f° values of the two products to that of RB, and if ΔH_f° (B^+) and ΔH_f° (RB) are known, ΔH_f° (R) can be determined. Both techniques suffer from limitations, the most significant being that stable molecules RH and RB must be introduced into an apparatus. This poses a problem when the free radicals under study contain functional groups that make the molecules difficult to synthesize or handle.

In light of these difficulties, the development of reliable ab initio molecular orbital methods for estimating molecular thermochemistry has driven a rebirth in the field. In particular, the development of composite techniques such as the G2 and G3 series of methods by Curtiss and Pople and co-workers (7–13) and the complete basis set approach of Petersson and co-workers (14, 15) have allowed researchers to calculate reliable (±10 kJ mol^{-1}) ΔH_f° values for a wide variety of molecules and free radicals. In addition, since theory is not limited by the availability or the handling of compounds, it is possible to exhaustively cover permutations of molecular structures and study substituent effects for a wide variety of properties such as ΔH_f°, proton affinity, electron affinity, gas-phase acidity, bond strength, etc.

A family of compounds that are not amenable to experimental study are the boranes, organoboron compounds involving boron bound to organic substituents. Over the years, there has been extensive experimental study of carbon-containing molecules and the strengths of bonds in hydrocarbons. Boron has not been as widely studied, likely due to the difficulty in handling the compounds as mentioned above. Interest in boron-containing compounds is more than just academic, however, as boron is found in ceramic materials such as boronitrides. Substitution of the boronitride backbone can be used to obtain different properties of the end material and so reliable bond strength and ΔH_f° data are useful.

The homolytic bond dissociation energy (*BDE*), or homolytic bond strength, of a bond in a molecule is defined as the energy change of the reaction that breaks the bond to form two free radicals. Therefore, the homolytic BDE of the B—X bond in BH_2X is the ΔE for the following reaction:

$$BH_2X \rightarrow BH_2\cdot + X\cdot$$

$$BDE = \Delta E = E\ (BH_2\cdot) + E\ (X\cdot) - E\ (BH_2X)$$

In this paper, we calculate the homolytic B—X bond strengths and the heats of formation of BH_2CH_3, BH_2NH_2, BH_2OH, and BH_2F as well as the methyl-substituted analogues $BH(CH_3)CH_3$, $BH(CH_3)NH_2$, $BH(CH_3)OH$, $BH(CH_3)F$ and $B(CH_3)_3$, $B(CH_3)_2NH_2$, $B(CH_3)_2OH$, and $B(CH_3)_2F$. In addition, the second row analogues of these compounds were included for comparison (BH_2SiH_3, BH_2PH_2, BH_2SH, BH_2Cl, $BH(CH_3)SiH_3$, $BH(CH_3)PH_2$, $BH(CH_3)SH$, $BH(CH_3)Cl$, $B(CH_3)_2SiH_3$, $B(CH_3)_2PH_2$, $B(CH_3)_2SH$, and $B(CH_3)_2Cl$). The impact on the B—X bond of a free radical centre on X is also explored in each of the above systems (except for the halogens).

Computational procedures

Standard ab initio molecular orbital calculations (16) were carried out using the GAUSSIAN 98 (17) suite of programs. The geometries of all species were optimized at the HF/6-31G(d) and MP2/6-31+G(d) levels of theory. Vibrational frequencies were also calculated at these levels. A recent assessment of theoretical procedures for treating free radicals concluded that for those with low-spin contamination in the SCF wavefunction, MP2 provided reasonable geometries for subsequent single-point energy calculations (18). All of the radicals presented in this study fall into this category. The MP2/6-31+G(d) geometries were used to obtain G3 (13) total energies. G3 theory approximates the energy of a species at the QCISD(T)/G3large level of theory by a series of additive corrections to a base MP4/6-31G(d) energy. The G3large basis set is a modified version of the standard 6-311+G(3df,2p) basis set in which more polarization functions are added to first row elements (3*d2f*), fewer on second row elements (2*df*), and core polarization functions are incorporated. Details of the properties of the G3large basis set can be found in the original publication by Curtiss et al. (13). G3 incorporates a scaled (by 0.8929) HF/6-31G(d) zero-point vibrational energy (*ZPE*), spin-orbit corrections for atoms, and the use of the MP2(full)/G3large calculation to take into account core-correlation contributions. Finally, an empirical higher-level correction (HLC) accounts for residual basis set errors. The G3 total energies were converted to heats of formation according to the atomization method outlined by Nicolaides et al. (19). Thermal corrections to 298 K employed the scaled HF/6-31G(d) frequencies and known thermal corrections for the elements. Optimized geometries in the form of Gaussian archive entries, are available as supporting information. Copies of material on deposit may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada (http://www.nrc.ca/cisti/irm/unpub_e.shtml for information on ordering electronically). This material has also been deposited with the Cambridge Crystallographic Data Centre. Copies of the data can be obtained, free of charge, on application to the Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, U.K. (Fax: 44-1223-336033 or e-mail: deposit@ccdc.cam.ac.uk).

Results and discussion

Heats of formation

The calculated G3 heats of formation at 0 and 298 K, together with available experimental data at 298 K, are presented in Tables 1 and 2. The only experimental values available for comparison are for the fragmentation products (Table 2), and agreement between theory and experiment is generally good, except for $BH_2\cdot$ which shows a difference of 128 kJ mol^{-1}. The experimental heat of formation for $BH_2\cdot$ (200.83 kJ mol^{-1}) was indirectly derived by Fehlner and Koski (20) from the appearance energy for the formation of BH_2^+ from BH_3 and the ionization energy of $BH_2\cdot$. Both measurements were made with beams of unresolved electrons and are thus, subject to considerable error (6). This example highlights the difficulty of experimentally determining the ΔH_f° values for boron-containing free radicals. Ab initio calculations at a variety of levels of theory result in values ranging from 312 to 322 kJ mol^{-1} (21–25), similar to the present G3 result of 329 kJ mol^{-1}.

[a]All values in kJ mol^{-1}.

The new theoretical values in Table 1 are useful for deriving additivity parameters for estimating molecular heats of formation for boron-containing compounds. Successive methyl substitution on BH_2CH_3 results in decreases in $\Delta H^\circ_{f\,298}$ of 72 and 74 kJ mol^{-1}. This is quite different from the hydrocarbons where methyl substitution lowers the $\Delta H^\circ_{f\,298}$ by 21 kJ mol^{-1} in going from ethane to propane, and by 29 kJ mol^{-1} in going from propane to isobutane (26). The effects of methyl substitution are largely independent of the other groups present, with all of the RR′BX molecules exhibiting decreases in $\Delta H^\circ_{f\,298}$ upon the addition of successive methyl groups of ~70 kJ mol^{-1}. The smallest effect is observed when X is NH_2 (64 kJ mol^{-1}) and PH_2 (67 kJ mol^{-1}). For open-shell systems, the effect of methyl substitution on $RR'BCH_2\cdot$ is similar to that for the closed-shell analogue (68–71 kJ mol^{-1}), while for other RR′BY· species the effect is slightly smaller (63 ± 3 kJ mol^{-1}).

The RR′B—X bond

The trends in the B—X bond length and strength are evident from Table 3. The B—X bond gets shorter in going from a Group 4 to a Group 7 substituent, while the homolytic *BDE* shows an increase across the periodic table (Table 3). This is the same as the trend observed for CH_3—X bonds which has been explained by electronegativity arguments (27–30). As the difference in electronegativity of the two bonded atoms increases, the homolytic bond strength increases. Electronic interactions in these systems will be dominated by the vacant *p*-orbital on boron. The π-donor substituents NH_2, OH, and F all donate electron density from a lone pair to the vacant *p*-orbital on B, resulting in a stabilizing two-electron interaction. The degree of π donation decreases across the first row from NH_2 to F while the inductive effect due to the difference in electronegativity of the atoms increases in the same order. Apparent from the observed trend in bond strengths is that the electronegativity effects outweigh stabilization due to π donation. The pseudo-π orbital on the methyl group in BH_2CH_3 is involved in a weaker hyperconjugation interaction with the vacant *p*-orbital on B. All of these interactions are present (to a lesser extent) with the analogous second row substituents. This is highlighted by the geometries of BH_2NH_2 and BH_2PH_2. The former molecule is a planar C_{2v} structure which maximizes the overlap of the *n*(N) and *p*(B) orbitals, while the latter has a puckered phosphorous centre.

The effect of methyl substitution on the BH_2 group generally (but not universally, see below) decreases the homolytic bond strength, lengthening the B—X bond (Table 3). The effects of methyl substitution in the RR′B—CH_3 and RR′B—SiH_3 series are small, the bond strength decreasing only 2 and 3 kJ mol^{-1} (for CH_3) and 3 and 1 kJ mol^{-1} (for SiH_3) upon the successive addition of two methyl groups on B. When X is a π-donor group the changes in bond strength are more significant. One rationale for the behaviour can be obtained by examining the molecular orbitals in these systems. Of the π-donor substituents NH_2 and OH, the $n(X) \rightarrow p(B)$ molecular orbital is the HOMO only for NH_2. For OH, the HOMO is an antibonding (with respect to the B—O bond) orbital incorporating a B—H (or B—CH_3) group and the O—H bond. The observed trend suggests that methyl substitution enhances the antibonding character of the HOMO, thus weakening the bond. The largest effect is for BH_2NH_2 where successive methyl substitution lowers the B—N bond strength by 10 and 8 kJ mol^{-1}. Another way of rationalizing

[c]Values found in LBLHLM (1).
[d]Based on the reported *IE* of 9.8 eV and $\Delta H_f^\circ(BH_2\cdot)$ of 200.832 kJ mol^{-1}.

the observed trend is from the view point of competing covalent and ionic contributions to the B—X bond:

$$RR'B—X \text{ vs. } RR'B^+X^-$$
$$a \qquad b$$

Methyl substitution lowers the heterolytic bond strength (Table 4), thus increasing the ionic (nonbonding) contribution to the bond. This is most clearly seen in the case of X = F and Cl (Tables 3 and 4). Methyl substitution makes the B—F and B—Cl bonds longer, though the homolytic bond strength increases. The heterolytic bond strengths for the dimethyl-substituted molecules are now closer to the homolytic bond strengths (966 vs. 717 kJ mol^{-1} for X = F and 751 vs. 526 kJ mol^{-1} for X = Cl) indicating that these bonds are influenced to a greater degree by the nonbonding ionic structure *b*.

The RR′B—Y· bond

When the BH_2 moiety is substituted by a free radical group, there is a general decrease in the B—Y· bond length from the closed-shell counterpart (Table 3). There are two possible sets of dissociation products for these RR′BY· radicals:

$$RR'B—Y\cdot \rightarrow {}^2RR'B\cdot + {}^1Y\cdot\cdot$$

$$RR'B—Y\cdot \rightarrow {}^2RR'B\cdot + {}^3Y\cdot\cdot$$

The lowest energy states of CH_2, NH, O, PH, and S are their triplet states. However, Wigner spin-conservation demands that spin be maintained in the unimolecular dissociation (31–33). The shorter B—Y· bonds in the $RR'BCH_2\cdot$, RR′BNH·, RR′BO·, RR′BPH·, and RR′BS· radicals (relative to the corresponding B—X bonds) are consistent with their greater homolytic bond strengths when the products involving the singlet-state Y· groups are formed. While the dissociation to form the lower energy products (incorporating the

triplet state Y· groups) will not strictly be forbidden, the dissociating radicals have equilibrium geometries that are adiabatically connected to the higher energy products. While these homolytic bond strengths are unlikely to be realized in experiment due to avoided crossings with states leading to the lower energy products, they provide a rationale for the observed shorter RR′B—Y· bonds as compared to the corresponding RR′B—X bonds. The BH_2CH_2· radical has a planar structure, allowing a stabilizing one-electron interaction between the occupied *p*-orbital on C and the unoccupied *p*-orbital on B. This interaction is larger than the hyperconjugation that takes place in the closed-shell analogue, resulting in a shorter and stronger bond regardless of the products formed (Table 3). For $RR'BSiH_2$·, the lowest energy products are $^2RR'B\cdot + {}^1SiH_2\cdot\cdot$. In this case, the shortening of the B—Si bond in going from the closed- to open-shell systems is consistent with the formation of the higher energy product pair $^2RR'B\cdot + {}^3SiH_2\cdot\cdot$ (Table 3). Methyl substitution in the RR′B—Y· radicals has a similar effect as observed for the closed-shell molecules, i.e., it lowers the strength of the B—Y· bond by increasing the nonbonding ionic $RR'B^+Y^-\cdot$ contribution.

Summary

The G3 computational method was employed to estimate the heats of formation and bond strengths in a series of organoboron compounds RR′BX and free radicals, RR′BY·. The trends observed for the relative lengths and strengths of the B—X and B—Y· bonds can be understood on the basis of electronegativity arguments and spin-conservation rules. There is a universal decrease in the B—Y· bond length compared to their closed-shell counterparts which corresponds to a tendency to favour higher energy dissociation products rather than the lower energy product pairs. Successive methyl substitution on the boron atom increases the ionic contribution to the B—X and B—Y· bonds thereby increasing the bond lengths.

Synthesis and reactivity of novel Schiff bases containing boronate esters

David W. Norman, Janet P. Edwards, Christopher M. Vogels, Andreas Decken, and Stephen A. Westcott

Abstract: Condensation of 2-aminophenol with boronate ester derivatives of benzaldehyde afforded the corresponding boron-containing Schiff bases, 2-$HOC_6H_4N{=}C(H)C_6H_4R$ (**1a**: R = 2-Bpin; **1b**: R = 3-Bpin; **1c**: R = 4-Bpin; pin = 1,2-$O_2C_2Me_4$). Crystals of **1b** were triclinic, space group $P\bar{1}$, a = 11.9420(6), b = 13.0871(7), and c = 13.2720(7) Å, α = 70.983(1), β = 67.793(1), and γ = 78.380(1)°, Z = 2. Reaction of 2-aminophenol with 2-$HC(O)C_6H_4B(OH)_2$ in EtOH, however, gave a macrocyclic dimer **2** with a OBOBO structural unit. The molecular structure of this dimer has been confirmed by an X-ray diffraction study. Crystals of **2** were monoclinic, space group $P2_1/c$, a = 10.0447(8), b = 21.0894(15), and c = 12.6214(9) Å, β = 105.301(2)°, Z = 4. Further reaction of these Schiff bases with manganese triacetate in toluene afforded 2-arylbenzoxazoles **3a**–**c** via an oxidative cyclization pathway. The molecular structure of the 4-Bpin derivative (**3c**) was characterized by an X-ray diffraction study. Crystals of **3c** were monoclinic, space group $P2_1/n$, a = 6.5392(3), b = 16.3330(8), and c = 16.1942(8) Å, β = 97.9620(10)°, Z = 4.

Key words: boron heterocycles, Schiff bases, arylbenzoxazoles.

Résumé : La condensation du 2-aminophénol avec des dérivés boronates de benzaldéhyde conduit à la formation des bases de Schiff correspondantes contenant du bore, 2-$HOC_6H_4N{=}C(H)C_6H_4R$ (**1a**: R = 2-Bpin; **1b**: R = 3-Bpin; **1c**: R = 4-Bpin; pin = 1,2-$O_2C_2Me_4$). Les cristaux du composé **1b** sont tricliniques, groupe d'espace $P\bar{1}$, avec a = 11,9420(6), b = 13,0871(7) et c = 13,2720(7) Å, α = 70,983(1), β = 67,793(1) et γ = 78,380(1)° et Z = 2. La réaction du 2-aminophénol avec le 2-$HC(O)C_6H_4B(OH)_2$ dans l'éthanol conduit toutefois à la formation du dimère macrocyclique **2** qui comporte une unité structurale OBOBO. La structure moléculaire de ce dimère a été confirmée par diffraction des rayons X. Les cristaux du composé **2** sont monocliniques, groupe d'espace $P2_1/c$, avec a = 10,0447(8), b = 21,0894(15) et c = 12,6214(9) Å, β = 105,301(2)° et Z = 4. Des réactions subséquentes de ces bases de Schiff avec du triacétate de manganèse dans le toluène conduisent à la formation des 2-arylbenzoxaoles (**3a**–**c**) par le biais d'une voie réactionnelle de cyclisation oxydante. La structure moléculaire du dérivé 4-Bpin (**3c**) a été caractérisée par diffraction des rayons X. Les cristaux du composé **3c** sont monocliniques, groupe d'espace $P2_1/n$, avec a = 6,5392(3), b = 16,3330(8) et c = 16,1942(8) Å, β = 97,9620(10)° et Z = 4.

Mots clés : hétérocycles du bore, bases de Schiff, arylbenzoxazoles.

[Traduit par la Rédaction]

Introduction

Compounds containing boronic acids [$RB(OH)_2$] or boronate esters [$RB(OR')_2$] have been used extensively as synthons in the Suzuki–Miyaura cross-coupling reaction for a variety of applications (1–11). Interest in these compounds also arises from their potent biological activities (12–21). For instance, aminoboronic acids are among the most potent inhibitors of serine proteases, a diverse group of proteolytic enzymes responsible for the generation of most disease processes (13–18). The synthesis of aminoboronic acid-containing compounds, however, is often a complicated procedure requiring several complex organic transformations (1, 7). As a result, the range of compounds containing boronic acids is surprisingly small. As part of our investigation into generating novel aminoboron compounds (22–24), we decided to examine the synthesis and reactivity of Schiff bases derived from 2-aminophenol and benzaldehydes containing boronate esters. Results of our study are presented herein.

Results and discussion

Schiff bases are important intermediates in organic chemistry and have been used to prepare a number of pharmaco-

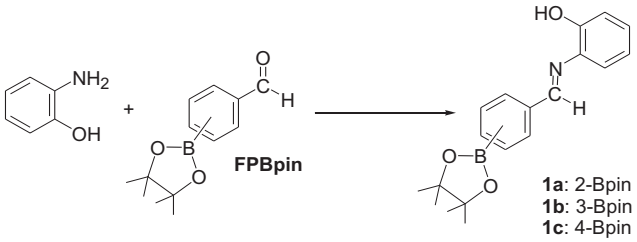
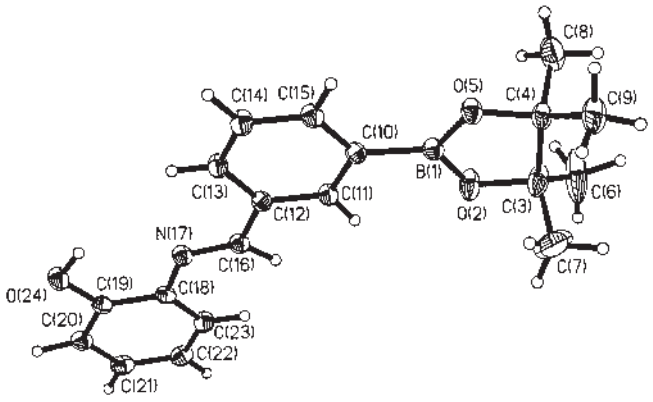
Scheme 1.



logically important compounds (29–34). For instance, Whiting and co-workers (29) have recently used imines containing boronate esters to make enantio-enriched γ-phenyl-γ-amino alcohols. In this study, we found that pinacol-protected derivatives of formylphenylboronic acid [(4,4,5,5-tetramethyl-1,3,2-dioxaborolan-2-yl)benzaldehyde (FPBpin)] add to 2-aminophenol in organic solvents to give crystalline compounds having spectroscopic data consistent with the Schiff bases **1a**–**c** (Scheme 1). As expected, a shift for the methine proton from 10 to 9 ppm is observed in the ^{1}H NMR spectra and a resonance at ca. 160 ppm in the ^{13}C NMR spectra corresponds to the N=CH carbon (25). Likewise, formation of these compounds can be monitored by the diagnostic C=N stretching band in the IR spectra at ca. 1620 cm^{-1} (31). Interestingly, a broad peak at around

Fig. 1. Molecular structure of **1b** with ellipsoids drawn at the 30% probability level. Hydrogen atoms were omitted for clarity.



30 ppm in the ^{11}B NMR spectra indicates that the boron atom lies in a three-coordinate environment (35), even for the 2-Bpin derivative **1a**. This result is somewhat surprising in light of boron's propensity to form coordinative N→B bonds (36).

Although attempts to grow crystals of **1a** suitable for X-ray diffraction studies proved unsuccessful, the molecular structure of the 3-Bpin derivative **1b** (Fig. 1) confirms that no appreciable intermolecular interactions exist between the

Lewis acidic boron atom and the imine nitrogen. Crystallographic data are given in Table 1[3], selected bond distances and angles shown in Table 2, and atomic coordinates are provided in Table 3. The imine C(16)—N(17) bond distances of 1.272(1) (molecule A) and 1.279(1) Å (molecule B) are comparable to azomethine compounds derived from salicylaldehyde and phenylboronic acid (31, 36). The B—O bond distances (av = 1.368(1) Å) are also typical for three-coordinate Bpin groups (25) and significantly shorter than those observed in chelate complexes with diphenylborinic

acid (ca. 1.5 Å), where the boron atom is four coordinate (37).

Compounds **1b** and **1c** could also be prepared in ethanol using a catalytic amount of formic acid. However, we found that reactions of 2-FPBpin with 2-aminophenol in ethanol containing adventitious water gave the novel Schiff base dimer **2** as the only new boron-containing product. It is possible that the formation of **2** proceeds via initial cleavage of the pinacol groups in 2-FBpin to give 2-formylphenylboronic acid. We found that the reaction of this aldehyde with 2-aminophenol in wet ethanol does indeed give condensation product **2** (Scheme 2). Another possible route to this

dimer involves initial formation of **1a** with subsequent cleavage of the pinacol group to give a boronic acid Schiff base. This transient imine could rapidly dehydrate to form **2**. Indeed, we observed that addition of ethanol to preformed **1a** gave bright yellow crystals of dimer **2**.

The molecular structure of **2** is shown in Fig. 2 and crystallographic data are given in Table 1. Selected bond distances and angles shown in Table 2, and atomic coordinates are provided in Table 4. The two fragments form seven-membered rings and are connected via a BOB bridge (B(1)-O(1)-B(2) = 117.8°) with average B—O bond distances of 1.417(2) Å. Interestingly, the two phenolic B—O distances are slightly longer (1.508(2) and 1.516(2) Å) than the bridged BOB bonds. Similar distances and angles have been reported for other BOB ring systems (38–47). The aldimine functionality in **2** is stabilized by N→B interactions with average B—N bonds of 1.651(2) Å. Similar bond distances have been reported in related oxime (48) and salen derivatives (49–51). The ^{11}B NMR spectra of **2** show a peak at 7 ppm, which also suggests that the boron atom remains four coordinate in solution (52). Although blue electroluminescence has been observed in similar organoboron compounds (40–42), this behavior is not observed for **2**.

As Schiff bases are ubiquitous in transition metal chemistry, we decided to investigate the use of these compounds as ligands for biologically active metals (such as Fe, Mo, Cu). Although initial attempts failed in this regard, we found that reaction of these Schiff bases gave the corresponding boron-containing benzoxazoles in varying yields (Scheme 3). Benzoxazoles are an important family of compounds that are found in a variety of natural products with potent biological activities (53–62). As a result, these compounds have attracted a considerable amount of attention for their medicinal and agrochemical uses.

Although the synthesis of benzoxazoles can be accomplished via a number of different methods, oxidative intramolecular cyclization of readily prepared phenolic Schiff bases provides a general route to these important organic compounds (62–67). Indeed, recent work by Varma et al. (61, 62) has shown that manganese triacetate can be used as a relatively benign oxidizing agent for reactions involving

Note: U_{eq} is defined as one third of the trace of the orthogonalized U_{ij} tensor.

sensitive functional groups. We found that $Mn(OAc)_3$ can also be used with **1a**–**c** to give the corresponding boron-containing benzoxazoles **3a**–**c** in low to moderate yield. A proposed mechanism for the manganese promoted intramolecular cyclization of Schiff bases **1a**–**c** is shown in Scheme 4 (61, 62). An alternate mechanism exists whereby initial coordination of the Schiff base to the metal centre occurs via the imine nitrogen atom followed by nucleophilic attack of the oxygen atom to the imine carbon. The formation of these heterocycles can be monitored by the disappearance of the aldimine N=CH functionality in the ^{1}H NMR spectra. The ^{11}B NMR spectra show a broad peak at 31 ppm for the three-coordinate boron atom. The molecular structure of **3c** is shown in Fig. 3 and crystallographic data provided in Table 1. Selected bond distances and angles are shown in Table 5, and atomic coordinates provided in Table 6. Bond distances are similar to those observed for **1b** and **2** and once again no considerable intermolecular interaction is observed between the imine nitrogen and the boron atom. As expected, the imine C(16)=N(24) bond distance (1.341(1) Å) is somewhat shorter than the C(23)—N(24) distance (1.393(1) Å). Unfortunately, attempts to generate the 2-Bpin derivative **3a** using either **1a** or **2** gave only minor amounts of the desired product (by ^{1}H NMR spectroscopy) along with a number of unidentified products.

Experimental

General

All reagents and solvents used were obtained from Aldrich. NMR spectra were recorded on a JEOL JNM-GSX270 FT NMR spectrometer. ^{1}H NMR chemical shifts are reported in ppm and referenced to residual protons in deuterated solvent at 270.1 MHz. ^{11}B{^{1}H} NMR chemical shifts are referenced to external $F_3B{\cdot}OEt_2$ at 86.6 MHz. ^{13}C{^{1}H} NMR chemical shifts are referenced to solvent carbon resonances as internal standards at 67.8 MHz. Multiplicities are reported as singlet (s), doublet (d), triplet (t), quartet (q), multiplet (m), broad (br), and overlapping (ov). Infrared spectra were obtained using a Mattson Genesis II FT-IR spectrometer and reported in cm^{-1}. Melting points were measured uncorrected with a Mel-Temp apparatus. Microanalyses for C, H, and N were carried out at Desert Analytics (Tucson, AZ). The synthesis of pinacolated derivatives of formylphenylboronic acids has been described elsewhere

(25). All reactions were carried out in the air and products are stable indefinitely under such conditions.

*Synthesis of **1a***

2-(4,4,5,5-Tetramethyl-1,3,2-dioxaborolan-2-yl)benzaldehyde (2-FPBpin) (524 mg, 2.27 mmol) was added to a solution of 2-aminophenol (248 mg, 2.27 mmol) in THF (15 mL) and magnesium sulfate (10.0 g). After four days at room temperature the yellow solution was concentrated to 5 mL and stored at 0°C for three days. A brown precipitate was filtered, washed with diethyl ether (3 × 10 mL), and dried under vacuum to give **1a**. Yield: 429 mg (59%) of a brown solid; mp 120–122°C. IR (Nujol) (cm^{-1}): 3413, 3049, 2918, 2858, 1699, 1620, 1587, 1562, 1481, 1462, 1375, 1346, 1317. ^{1}H NMR ($CDCl_3$) δ: 9.04 (s, 1H, C*H*=N), 7.95 (d, *J* = 8 Hz, 1H, Ar), 7.78 (d, *J* = 8 Hz, 1H, Ar), 7.46 (m, 2H, Ar), 7.18 (m, 2H, Ar), 7.02 (d, *J* = 8 Hz, 1H, Ar), 6.92 (ov d of d, *J* = 8 Hz, 1H, Ar), 1.34 (s, 12H, pin). ^{11}B NMR δ: 30 (br). ^{13}C NMR δ: 161.2 (*C*=N), 152.0, 140.1, 136.0, 134.4, 133 (br, *C*-B), 131.0, 130.2, 128.7, 127.9, 120.1, 117.5, 115.4, 83.7 (BO*C*), 24.9 (BOC*C*H_3).

*Synthesis of **1b***

3-(4,4,5,5-Tetramethyl-1,3,2-dioxaborolan-2-yl)benzaldehyde (3-FPBpin) (508 mg, 2.16 mmol) was added to a solution of 2-aminophenol (238 mg, 2.16 mmol) in anhydrous ethanol (10 mL). The clear yellow solution was heated at reflux for 1 h, after which the reaction mixture was stored at 5°C for 2 days. The resultant precipitate was filtered, washed with hexane (2 × 10 mL), and dried under vacuum to give **1b**. Yield: 609 mg (87%) of a pale yellow solid; mp 116–117°C. IR (Nujol) (cm^{-1}): 3408, 2924, 2856, 1626, 1462, 1365, 1252, 1140. ^{1}H NMR ($CDCl_3$) δ: 8.70 (s, 1H, C*H*=N), 8.30 (s, 1H, Ar), 8.05 (d, *J* = 8 Hz, 1H, Ar), 7.95 (d, *J* = 8 Hz, 1H, Ar), 7.51 (ov d of d, *J* = 8 Hz, 1H, Ar), 7.29 (d, *J* = 8 Hz, 1H, Ar), 7.22 (ov d of d, *J* = 8 Hz, 1H, Ar), 7.03 (d, *J* = 8 Hz, 1H, Ar), 6.93 (ov d of d, *J* = 8 Hz, 1H, Ar), 1.37 (s, 12H, pin). ^{11}B NMR δ: 32 (br). ^{13}C NMR δ: 157.2 (*C*=N), 152.3, 138.0, 135.7, 135.5, 135.1, 131.0, 130 (br, *C*-B), 128.8, 128.3, 120.1, 115.8, 115.0, 84.1 (BO*C*), 24.8 (BOC*C*H_3).

*Synthesis of **1c***

4-(4,4,5,5-Tetramethyl-1,3,2-dioxaborolan-2-yl)benzaldehyde (4-FPBpin) (1.01 g, 4.33 mmol) was added to a solution of 2-aminophenol (477 mg, 4.33 mmol) in anhydrous ethanol (25 mL) whereupon the solution was heated at reflux for 2 h. After 12 h at room temperature a bright yellow solid formed from the reaction mixture. The precipitate was filtered, washed with hexane (2 × 10 mL), and dried under vacuum to give **1c**. Yield: 1.27 g (91%) of a bright yellow solid; mp 114–115°C. IR (Nujol) (cm^{-1}): 3371, 2927, 2858, 1622, 1585, 1510, 1462, 1360, 1288, 1234, 1167, 1144, 1086. ^{1}H NMR ($CDCl_3$) δ: 8.64 (s, 1H, C*H*=N), 7.93 (ov m, 4H, Ar), 7.28 (d, *J* = 8 Hz, 1H, Ar), 7.20 (ov d of d, *J* = 8 Hz, 1H, Ar), 7.02 (d, *J* = 8 Hz, 1H, Ar), 6.90 (t, *J* = 8 Hz, 1H, Ar), 1.35 (s, 12H, pin). ^{11}B NMR δ: 31 (br). ^{13}C NMR δ: 156.9 (*C*=N), 152.4, 137.9, 135.3, 135.0, 133 (br, *C*-B), 129.0, 127.8, 120.0, 115.8, 115.0, 84.0 (BO*C*), 24.8 (BOC*C*H_3).

*Synthesis of **2***

2-Formylphenylboronic acid (253 mg, 1.69 mmol) was added to a solution of 2-aminophenol (184 mg, 1.69 mmol) in anhydrous ethanol (15 mL). The clear yellow solution was heated at reflux for 3 h whereupon the solution was allowed to cool to room temperature. After 12 h a bright yellow precipitate formed, which was filtered, washed with hexane (3 × 5 mL), and dried under vacuum to give **2**. Yield: 226 mg (62%) of a bright yellow solid; mp 180°C (dec). IR (Nujol) (cm^{-1}): 2912, 2857, 1628, 1460, 1375, 1270, 1164. ^{1}H NMR ($CDCl_3$) δ: 8.71 (s, 2H, C*H*=N), 7.54 (d, *J* = 8 Hz, 2H, Ar), 7.43 (m, 2H, Ar), 7.25 (ov m, 8H, Ar), 6.95 (m, 4H, Ar). ^{11}B NMR δ: 7 (br). ^{13}C NMR δ: 160.1 (*C*=N), 158.4, 135.9, 134.5, 133.4, 133.0, 132.7, 132.1, 130 (br, *C*-B), 128.0, 118.7, 115.7, 114.4. Anal. calcd. for $C_{26}H_{18}B_2N_2O_3$: C 72.95, H 4.24, N 6.54; found: C 72.49, H 4.20, N 6.37.

*Reaction of **1a** with Mn(OAc)$_3$*

Manganese triacetate (934 mg, 3.48 mmol) was added to a solution of **1a** (563 mg, 1.74 mmol) in toluene (20 mL) and the dark brown solution was heated at reflux for 2 h. The precipitated manganese salts were removed by suction filtration and the toluene was removed under vacuum to afford a dark brown solid. The mixture was analyzed by ^{1}H NMR spectroscopy and showed the presence of minor amounts of **3a** along with a number of unidentified products. Attempts to isolate **3a** proved unsuccessful.

*Synthesis of **3b***

Manganese triacetate (1.36 g, 5.07 mmol) was added to a solution of **1b** (819 mg, 2.54 mmol) in toluene (20 mL) and the dark brown solution was heated at reflux for 2 h. The precipitated manganese salts were removed by suction filtration and the toluene was removed under vacuum to afford a dark red solid. The solid was dissolved in hexane (25 mL), filtered through alumina, and allowed to crystallize at 5°C over 72 h. The resultant solid was filtered, washed with cold hexane (3 × 5 mL), and dried to give **3b**. Yield: 314 mg (39%) of a red-brown solid; mp 131–132°C. IR (Nujol) (cm^{-1}): 2933, 2914, 2856, 2360, 1734, 1587, 1456, 1409, 1367, 1323. ^{1}H NMR ($CDCl_3$) δ: 8.70 (s, 1H, Ar), 8.34 (d, *J* = 8 Hz, 1H, Ar), 7.95 (d, *J* = 8 Hz, 1H, Ar), 7.76 (ov m, 1H, Ar), 7.57–7.53 (ov m, 2H, Ar), 7.35 (ov m, 2H, Ar), 1.37 (s, 12H, pin). ^{11}B NMR δ: 31 (br). ^{13}C NMR δ: 163.2 (*C*=N), 150.9, 142.2, 137.8, 134.0, 133 (br, *C*-B), 130.3, 128.4, 126.6, 125.1, 124.6, 120.1, 110.7, 84.2 (BO*C*), 25.0 (BOC*C*H_3). Anal. calcd. for $C_{19}H_{20}BNO_3$: C 71.04, H 6.29, N 4.36; found: C 71.24, H 6.18, N 4.59.

*Synthesis of **3c***

Manganese triacetate (934 mg, 3.48 mmol) was added to a solution of **1c** (563 mg, 1.74 mmol) in toluene (20 mL) and the dark brown solution was heated at reflux for 2 h. The precipitated manganese salts were removed by suction filtration and the toluene was removed under vacuum to afford a dark brown solid. The solid was dissolved in hexane (25 mL), filtered through alumina, and allowed to crystallize at 5°C over 72 h. The resultant solid was filtered, washed with cold hexane (3 × 5 mL), and dried to give **3c**. Yield: 157 mg (28%) of a pale brown solid; mp 186–188°C. IR

Anal. calcd. for $C_{19}H_{20}BNO_3$: C 71.04, H 6.29, N 4.36; found: C 71.38, H 6.39, N 4.54.

X-ray crystallography

Crystals of **1b**, **2**, and **3c** were grown from methylene chloride solutions at 5°C. Single crystals were mounted using a glass fibre and Paratone-N oil and frozen in the cold stream of the goniometer. Data were collected on a Bruker AXS P4/SMART 1000 diffractometer using ω and φ scans with a scan width of 0.3° and 30 s exposure times. The detector distance was 4 cm. The data were reduced (SAINT) (26) and corrected for absorption (SADABS) (27). The structures were solved by direct methods and refined by full-matrix least-squares on F^2 (SHELXTL) (28). All nonhydrogen atoms were refined anisotropically. Hydrogen atoms were located in Fourier difference maps and refined isotropically. For **2**, one molecule of CH_2Cl_2 was disordered over two positions, generated by an inversion center. For **3c**, a disorder in the oxazole ring (N/O(17) and N/O(24)) was refined by determining the occupancy using an isotropic model and fixed at 50% for consecutive cycles. A disorder in the Bpin fragment was refined by determination of the occupancy using an isotropic model and subsequently fixed at 55% for O(2), C(6), C(7), C(8), and C(9) and 45% for O(2a), C(6a), C(7a), C(8a), and C(9a).

Conclusion

We have prepared new Schiff bases containing boronate ester groups via condensation reactions with pinacolated formylphenylboronic acids (FPBpin) and 2-aminophenol. Reactions of the 2-FPBpin derivative gave a novel dimer containing a seven-membered ring with a BOB bridge. The aldimine functionality in this dimer is stabilized by an intramolecular N→B interaction. Addition of metals to the 3- and 4-Bpin Schiff-bases lead to the formation of boron-containing benzoxazoles which could be isolated in moderate yield. The use of $Mn(OAc)_3$ for these reactions provides a gentle and efficient route to making benzoxazoles that have the potential to be readily functionalized using Suzuki–Miyaura cross-coupling reactions.

Cationic thiolate and selenolate complexes of platinum(IV)

Michael C. Janzen, Michael C. Jennings, and Richard J. Puddephatt

Abstract: The reaction of the adamantanoid compounds $[Hg_4(EPh)_6(L)_4][ClO_4]_2$ (E = S or Se, L = PEt_3 or PPh_3) with $[PtMe_2(bu_2bpy)]$ (bu_2bpy = 4,4′-di-*tert*-butyl-2,2′-bipyridine) occurs easily to give the first examples of cationic thiolate or selenolate derivatives of platinum(IV), $[PtMe_2(EPh)L(bu_2bpy)][ClO_4]$, and the addition is shown to occur with *trans* stereochemistry. The new complexes are characterized by NMR spectroscopy and when L = PEt_3 by X-ray structure determinations. When L = PPh_3, a competitive reaction leads to methyl group transfer from platinum to mercury to give MeHgEPh (E = S or Se).

Key words: oxidative-addition, platinum, thiolate, selenolate, mercury.

Résumé : La réaction de composés adamantanoïdes $[Hg_4(EPh)_6(L)_4][ClO_4]_2$ (E= S ou Se, L = PEt_3 ou PPh_3) avec $[PtMe_2(bu_2bpy)]$ (bu_2bpy = 4,4′-di-*tert*-butyl-2,2′-bipyridine) se produit facilement pour fournier les premiers exemples de dérivés thiolates ou sélénolates cationiques du platine(IV), $[PtMe_2(EPh)L(bu_2bpy)][ClO_4]$ et on a observé que l'addition se produit avec une stéréochimie *trans*. Les nouveaux complexes ont été caractérisés par spectroscopie RMN et, lorsque L = PEt_3, par diffraction des rayons X. Lorsque L = PPh_3, une réaction parallèle conduit à un transfert de groupe méthyle à partir du platine vers le mercure pour donner le MeHgEPh (E = S ou Se).

Mots clés : addition oxydante, platine, thiolate, sélénolate, mercure.

[Traduit par la Rédaction]

Introduction

There is a rich chemistry resulting from reactions of Hg—X bonds from mercury(II) compounds to the organoplatinum(II) centres in complexes $[PtMe_2L_2]$ and related compounds (1, 2). For example, oxidative addition of HgX_2 to $[PtMe_2(bu_2bpy)]$ (bu_2bpy = 4,4′-di-*tert*-butyl-2,2′-bipyridine) (**1**) gives $[PtMe_2(HgX)(X)(bu_2bpy)]$ (X = Cl, Br, O_2CCF_3) (1). However, if the platinum(II) centre is less electron rich or the mercury centre is less electrophilic, the reaction may occur to give a platinum–mercury donor–acceptor bond. This form of reactivity is observed with $[Pt\{CH_2C_6H_4P(o\text{-tolyl})_2\}(S_2CNMe_2)]$ and HgX_2 (X = Br, I) and for the reaction of **1** with $[PtMe_2(HgX)(X)(bu_2bpy)]$ (X = Cl, Br, O_2CCF_3) (2). Further reactions of these products can occur to give overall alkyl–halide exchange reactions, with the formation of $[PtXMeL_2]$ and MeHgX (1*g*). No reactions involving Hg(II)—E (E = S, Se) bonds with organoplatinum(II) complexes have yet been reported. It is known that oxidative addition of the Sn(IV)—E bonds in the ring compounds $[(R_2SnE)_3]$ (R = Me, Ph) to complex **1** occurs easily, giving interesting platinum(IV) complexes containing PtESnESn rings (3). By analogy, it was considered possible that oxidative addition of the Hg(II)—E bonds of the adamantanoid compounds $[Hg_4(EPh)_6(L)_4][ClO_4]_2$ (**2a**–**d**) (Chart 1), might give novel cage complexes containing platinum(IV) centres (4, 5).

It was found that the reactions of **1** with compounds **2a**–**d** occurred easily but with fragmentation of the adamantanoid units to give the first cationic thiolato or selenelato complexes of platinum(IV), as described below. The SE^- ligand (E = S or Se) is reducing in nature and tends to form stable complexes with platinum(II) rather than platinum(IV) (6). Since cationic platinum(IV) complexes are more easily reduced than neutral ones, it is not surprising that the known thiolate or selenolate derivatives of platinum(IV) are all neutral (7). However, it will be seen that cationic REPt(IV) complexes can be prepared and that they may have good thermal stability.

Results

The reaction of complex **1** with $[Hg_4(EPh)_6(L)_4][ClO_4]_2$ (**2**) appeared to occur mostly according to eq. [1].

[1] $$[PtMe_2(bu_2bpy)]\ (\mathbf{1}) + 0.5[Hg_4(EPh)_6L_4][ClO_4]_2\ (\mathbf{2}) \rightarrow [PtMe_2(EPh)L(bu_2bpy)][ClO_4]\ (\mathbf{3}) + Hg(EPh)_2L + Hg(0)$$

For example, when L = PEt_3, a mixture of products was formed from which the corresponding complex $[PtMe_2(EPh)(PEt_3)(bu_2bpy)][ClO_4]$ (E = S (**3a**) or Se (**3b**)) could be crystallized as an air-stable yellow solid. The other products from the reaction were not isolated in pure form and the identity of the proposed product $Hg(EPh)_2L$ (eq. [1]) remains uncertain, as discussed below.

Fig. 1. A view of the molecular structure of complex **3a** roughly down the S—Pt bond, showing the orientation of the phenyl group with respect to the bu_2bpy ligand. Only one component of each of the disordered ethylphosphorus groups is shown for clarity.

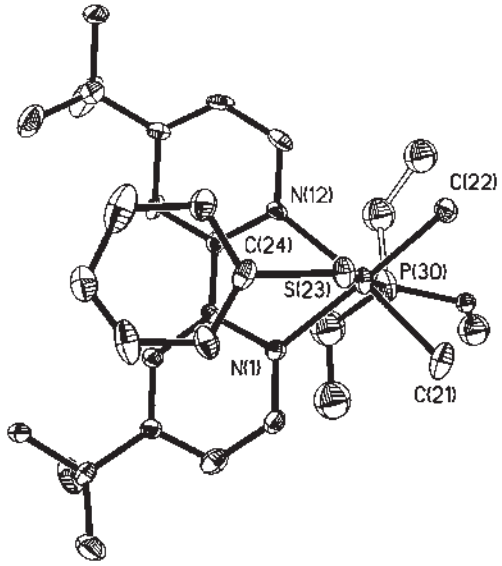

Chart 1. NN = bu_2bpy.

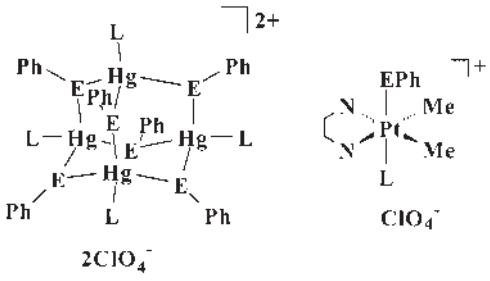
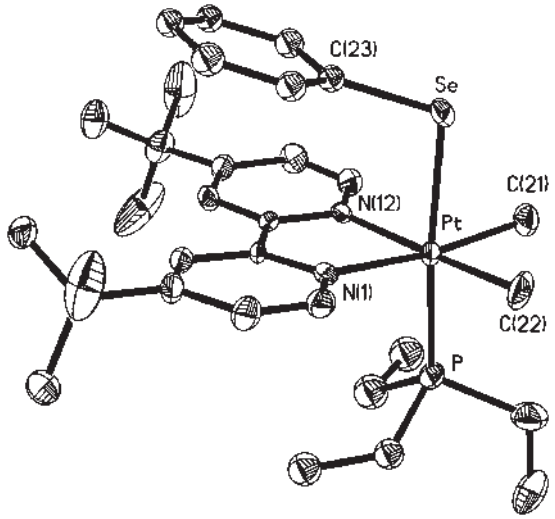


2a, E=S, L=PEt_3 **3a**, E=S, L=PEt_3
2b, E=Se, L=PEt_3 **3b**, E=Se, L=PEt_3
2c, E=S, L=PPh_3 **3c**, E=S, L=PPh_3
2d, E=Se, L=PPh_3 **3d**, E=Se, L=PPh_3

Complexes **3a** and **3b** were characterized spectroscopically and crystallographically. The ^{1}H NMR spectrum of **3a** contained a single methylplatinum resonance, with the coupling constant ($^2J_{Pt,Me}$ = 66 Hz) in the range expected for methylplatinum(IV) complexes with methyl *trans* to nitrogen (8). The presence of a single methylplatinum resonance indicates that the product is formed by *trans* oxidative addition and so supports the structure shown in Chart 1. The mirror symmetry (C_s) of **3a** is also shown by the presence of only three aromatic bu_2bpy peaks and one *tert*-butyl peak in the ^{1}H NMR spectrum. The presence of the triethylphosphine ligand is shown in the ^{31}P NMR spectrum of **3a** by the presence of a singlet resonance at δ = 0.29, with satellites due to the coupling ($^1J_{Pt,P}$ = 1895 Hz) and in the ^{1}H NMR spectrum by the observation of coupling to the methylplatinum protons with $^3J_{P,Pt,Me}$ = 5 Hz. The magnitude of the coupling constant ($^1J_{Pt,P}$ = 1895 Hz) is consistent with the phosphine being *trans* to EPh, but is too high for a phosphine *trans* to a methyl group (9, 10). The resonances in the

Fig. 2. A view of the molecular structure of complex **3b**. Only one component of each of the disordered ethyl and phenyl groups is shown for clarity.



^{1}H NMR spectrum due to the EPh protons appear over the range δ = 6.25–6.52 and are lower in chemical shift than is normal for aryl protons, probably because they lie in the shielding region of the aromatic bu_2bipy ligand (7). The NMR data has thus defined a structure with the phosphine ligand *trans* to the EPh group at platinum(IV). The spectra for complex **3b** are similar and are listed in the *Experimental* section.

The structures of **3a** and **3b** were determined crystallographically and are shown in Figs. 1 and 2, respectively, with relevant bond parameters listed in Table 1. The two compounds are isomorphous and have similar structures, with the EPh and PEt_3 ligands mutually *trans* at platinum(IV). In each complex, the phenyl substituent of the EPh ligand is oriented above the bipyridyl ligand. This leads to π-stacking (11) with intercentroid distances between the phenyl and N(1) pyridyl ring of 3.81 Å for **3a** and 3.64 Å for **3b** and between the phenyl and N(12) pyridyl ring of 4.04 Å for **3a** and 4.45 Å for **3b**. The Pt—P bond lengths are 2.315(5) and 2.291(4) Å for complexes **3a** and **3b**, respectively; comparison with other phosphine complexes of platinum(IV) (12) suggests that these distances are relatively short and, therefore, the EPh ligand has only a moderate *trans* influence. The slightly longer Pt—P bond in **3a** as compared to **3b** may indicate that the SPh ligand has a marginally higher *trans*-influence than SePh. In **3a**, the Pt—S bond distance of 2.398(5) Å and the Pt-S-C angle of 108.9(8)° are unexceptional. The only other structurally characterized arylthiolate complex of platinum(IV) with a two-coordinate sulfur atom is [(η^5-C_5Me_5)$PtMe_2$(S-*p*-C_6H_4Me)], which has Pt—S = 2.344(1) Å and Pt-S-C = 108.4(2)° (13), very similar to the corresponding values in **3a**. The cubane complex [{$PtMe_3$(μ_3-SPh)}$_4$], which contains four-coordinate sulfur atoms with sulfur *trans* to methyl, has a longer Pt—S = 2.506(5) Å and a more open angle Pt-S-C = 118.1(7)° (14). Several arylthiolate complexes of platinum(II) with two-coordinate sulfur atoms have been structurally characterized, and the bond parameters for the Pt-S-C units are similar to those for complex **3a** (15). In complex

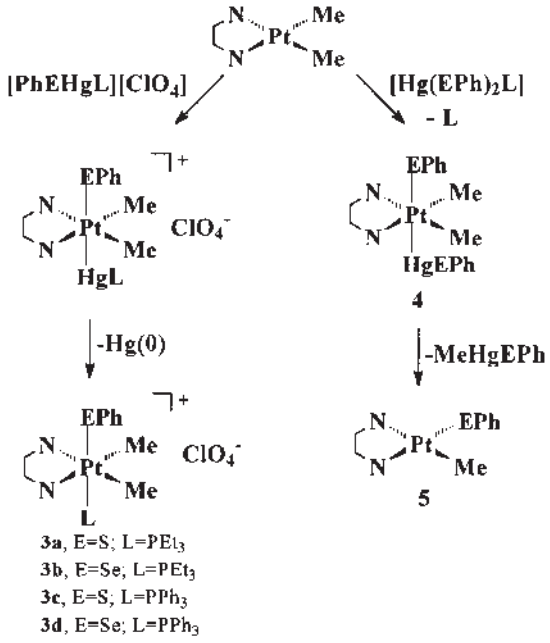
Table 1. Selected bond distances (Å) and angles (°) for complexes **3a** and **3b**.

	3a (E = S)	**3b** (E = Se)
Bond distances (Å)		
Pt—P	2.315(5)	2.291(4)
Pt—E	2.398(5)	2.512(2)
Pt—N(1)	2.14(1)	2.13(1)
Pt—N(12)	2.16(1)	2.12(1)
Pt—C(21)	2.13(2)	2.10(2)
Pt—C(22)	2.05(2)	2.10(1)
Bond angles (°)		
P-Pt-E	176.7(2)	174.9(1)
C-E-Pt	108.9(8)	106.1(8)

Scheme 1. NN = bu_2bpy.



3b, the distance Pt—Se = 2.512(2) Å and angle Pt-Se-C = 106.1(9)° are similar to those in the known neutral Pt(IV)–SePh complexes. For example, corresponding parameters are $[PtMe_2(SePh)_2(phen)]$ (2.4896(9) Å, 103.7(2)°) (7) and $[PtMe_2(SePh)_2(bpy)]$ (2.478(1) Å, 2.498(1) Å, 103.4(4)°, 103.1(3)°) (7).

The reaction of complex **1** with $[Hg_4(SPh)_6(PEt_3)_4][ClO_4]_2$ (**2a**) was monitored by ^1H and ^{31}P NMR spectroscopy in an attempt to identify the other products of eq. [1]. Complex **3a** was readily identified as a major product (ca. 75% based on **1**), and it was shown that one equivalent of **2a** consumed at least 2 equivalents of **1** as required by eq. [1]. A second major product was identified by a resonance in the ^{31}P NMR spectrum at δ = 16.7, with satellites due to the coupling ($^1J_{P,Hg}$ = 2817 Hz). It is tentatively suggested that this complex is $Hg(SPh)_2(PEt_3)$ (eq. [1]), but it was not possible to isolate it in pure form to carry out further characterization. If the formulation is correct, it is likely to form a dimer or oligomer by forming $Hg_2(\mu\text{-SR})$ bridges (4, 16). The formation of trace amounts of metallic mercury was visually evident. In a similar reaction of **1** with **2b**, complex **3b** was identified as the major product, but several mercury(II) phosphine complexes appeared to be formed as indicated by several singlet resonances in the range δ = 5–24 in the ^{31}P NMR spectrum.

[a] $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$; $wR_2 = [\Sigma w(F_o^2 - F_o^2)^2/\Sigma wF_o 4]^{1/2}$.

The reaction of **1** and the triphenylphosphine derivatives $[Hg_4(EPh)_6L_4][ClO_4]_2$ (L = PPh_3; E = S (**2c**) or Se (**2d**)) were somewhat more complex. Again, the complexes $[PtMe_2(EPh)L(bu_2bpy)][ClO_4]$ (E = S (**3c**) or Se (**3d**)) were isolated as yellow solids. They were readily characterized by comparison of their ^1H and ^{31}P NMR spectra with those of the structurally characterized complexes **3a** and **3b**. When the reaction of **1** with **2c** was monitored by NMR spectroscopy, complex **3c** was identified as one major product. In addition, the ^{31}P spectrum contained a resonance at δ = 26.2 ($^1J_{P,Hg}$ = 3215 Hz) tentatively assigned to $Hg(SPh)_2(PPh_3)$. In the ^1H NMR spectrum, the known methylmercury(II) compound MeHgSPh was readily identified (17), present at about half the concentration of **3c**. A similar reaction of **1** with **2d** gave complex **3d** and a compound having $\delta(^{31}P)$ = 29.2 ($^1J_{P,Hg}$ = 3177 Hz), tentatively identified as $Hg(SePh)_2(PPh_3)$, while MeHgSePh was identified by its ^1H NMR spectrum (18).

The stoichiometry of these reactions can be understood by considering that the adamantanoid mercury(II) complexes (**2**) react as if they were comprised of two components: $[Hg_4(EPh)_6L_4][ClO_4]_2$ = 2[PhEHgL][ClO_4] + 2[$Hg(EPh)_2$L] (Scheme 1). The major product **3** is formed by oxidative addition of the fragment [PhEHgL][ClO_4] to **1** with loss of mercury metal. It is not known at which stage the mercury atom is extruded, or even at what stage the adamantane derivative fragments, but Scheme 1 shows one possible route. The oxidative addition probably occurs by a polar mechanism initiated by nucleophilic attack of the electron-rich platinum(II) centre of complex **1** to the electrophilic mercury(II), leading to the observed *trans* addition in the product complex **3**. There are several precedent-setting examples for the loss of mercury(0) from Pt–Hg bonded compounds, such as the reaction of *trans*-$[(2\text{-}Me_2NCH_2C_6H_4)_2Pt]$ with $Hg(O_2CMe)_2$ to yield $[(2\text{-}Me_2NCH_2C_6H_4)_2Pt(O_2CMe)_2]$ and Hg(0) (19).

© 2002 NRC Canada

The minor product MeHgEPh formed in the reactions of **1** with **2c** and **2d** is likely to be formed by the competing oxidative-addition reaction of complex **1** with the fragment $[Hg(EPh)_2L]$ to give intermediate **4** (Scheme 1), which can undergo reductive elimination to yield MeHgEPh and [PtMe(EPh)(bu_2bpy)] (**5**). Complex **5** would then react with more **2** to give additional MeHgEPh. The formed complexes (**3**) are thermally stable, and therefore, cannot be the source of formation of MeHgEPh.

Clearly these reactions are more complex than was envisaged and they did not yield the anticipated platinum–mercury-bonded cage complexes. Nevertheless, they do give a simple route to the first cationic thiolate and selenolate complexes of platinum(IV), and it is shown that these compounds are both air-stable and thermally stable.

Experimental

General

NMR spectra were recorded by using a Varian 300 MHz spectrometer. Chemical shifts are reported with respect to TMS (^{1}H) or external H_3PO_4 (^{31}P) references. Solvents were dried and freshly distilled prior to use. Complexes **2** (4) and [$PtMe_2$(bu_2bpy)] (20) were prepared according to the literature procedures. CAUTION: toxic methylmercury compounds are formed in some reactions; appropriate precautions should be taken.

[($PtMe_2$(SPh)(PEt_3)(bu_2bpy)][ClO_4] (3a)

A mixture of [$PtMe_2$(bu_2bpy)] (80 mg, 0.162 mmol) and **2a** (133 mg, 0.162 mmol) was dissolved in CH_2Cl_2 (5 mL) and the mixture was stirred for 10 min. The yellow solution was filtered through dry Celite, and pentane (40 mL) was added to the filtrate to precipitate the product as a yellow microcrystalline solid, which was isolated by filtration, washed with pentane, and dried in vacuo. Yield: 58%. ^{1}H NMR (CD_2Cl_2) δ: 8.56 (d, $^3J_{6,5}$ = 6 Hz, $^3J_{Pt,H6}$ = 14 Hz, 2H, H6), 7.95 (d, $^4J_{3,5}$ = 2 Hz, 2H, H3), 7.70 (dd, $^3J_{5,6}$ = 6 Hz, $^3J_{5,3}$ = 2 Hz, 2H, H5), 6.52–6.25 (m, 5H, C_6H_5), 1.42 (d, $^3J_{P,Me}$ = 5 Hz, $^2J_{Pt,H}$ = 66 Hz, 6H, Pt-Me), 1.46 (s, 18H, *t*-Bu), 1.38 (m, $J_{H,H}$ = 8 Hz, $J_{P,H}$ = 8 Hz, 6H, CH_2), 0.81 (m, $J_{H,H}$ = 8 Hz, $J_{P,H}$ = 8 Hz, 9H, CH_3). ^{31}P NMR δ: –2.7 (s, $^1J_{Pt,P}$ = 1976 Hz, P-Pt). Anal. calcd. for $C_{32}H_{50}ClN_2O_4PSPt\cdot CH_2Cl_2$: C 43.78, H 5.79, N 3.09; found: C 43.88, H 5.83, N 2.99. Crystals suitable for X-ray crystallographic study were grown over a period of several days by slow diffusion of pentane into a CH_2Cl_2 solution at 22°C.

[($PtMe_2$(SePh)(PEt_3)(bu_2bpy)][ClO_4] (3b)

This complex was prepared similarly, except that **2b** was used instead of **2a**. Yield: 52%. ^{1}H NMR (CD_2Cl_2) δ: 8.52 (d, $^3J_{6,5}$ = 6 Hz, $^3J_{Pt,H6}$ = 14 Hz, 2H, H6), 8.05 (d, $^4J_{3,5}$ = 2 Hz, 2H, H3), 7.59 (dd, $^3J_{5,6}$ = 6 Hz, $^3J_{5,3}$ = 2 Hz, 2H, H5), 6.85–6.42 (m, 5H, C_6H_5), 1.52 (d, $^3J_{P,Me}$ = 5 Hz, $^2J_{Pt,H}$ = 65 Hz, 6H, Pt-Me), 1.46 (s, 18H, *t*-Bu), 1.38 (m, $J_{H,H}$ = 7 Hz, $J_{P,H}$ = 7 Hz, 6H, -CH_2), 0.81 (m, $J_{H,H}$ = 7 Hz, $J_{P,H}$ = 8 Hz, 9H, -CH_3). ^{31}P NMR δ: –5.83 (s, $^1J_{Pt,P}$ = 1966 Hz, P-Pt). Anal. calcd. for $C_{32}H_{50}ClN_2O_4PSePt\cdot CH_2Cl_2$: C 41.68, H 5.50, N 2.94; found: C 41.55, H 5.41, N 2.84. Crystals were grown as described for **3a**.

[($PtMe_2$(SPh)(PPh_3)(bu_2bpy)][ClO_4] (3c)

This was prepared similarly except that **2c** was used instead of **2a**. Yield: 43%. ^{1}H NMR (CD_2Cl_2) δ: 7.88 (d, $^4J_{3,5}$ = 2 Hz, 2H, H3), 7.85 (d, $^3J_{6,5}$ = 6 Hz, $^3J_{Pt,H6}$ = 15 Hz, 2H, H6), 7.46–7.00 (m, 15H, C_6H_5), 6.61–6.30 (m, 5H, SC_6H_5), 1.71 (d, $^3J_{P,Me}$ = 5 Hz, $^2J_{Pt,H}$ = 65 Hz, 6H, Pt-Me), 1.43 (s, 18H, *t*-Bu). ^{31}P NMR δ: –0.2 (s, $^1J_{Pt,P}$ = 1802 Hz, P-Pt). Anal. calcd. for $C_{44}H_{50}ClN_2O_4PSPt$: C 54.80, H 5.23, N 2.90; found: C 54.71, H 5.19, N 2.80.

[($PtMe_2$(SePh)(PPh_3)(bu_2bpy)][ClO_4] (3d)

This was prepared similarly except that **2d** was used instead of **2a**. Yield: 39%. ^{1}H NMR (CD_2Cl_2) δ: 7.93 (d, $^4J_{3,5}$ = 2 Hz, 2H, H3), 7.81 (d, $^3J_{6,5}$ = 6 Hz, $^3J_{Pt,H6}$ = 14 Hz, 2H, H6), 7.50–6.95 (m, 15H, C_6H_5), 6.53–6.20 (m, 5H, SeC_6H_5), 1.75 (d, $^3J_{P,Me}$ = 5 Hz, $^2J_{Pt,H}$ = 66 Hz, 6H, Pt-Me), 1.44 (s, 18H, *t*-Bu). ^{31}P NMR δ: –3.6 (s, $^1J_{Pt,P}$ = 1860 Hz, P-Pt). Anal. calcd. for $C_{44}H_{50}ClN_2O_4PSePt$: C 52.25, H 4.98, N 2.77; found: C 52.07, H 4.79, N 2.69.

X-ray structure determinations

Crystals of **3a** and **3b**, as perchlorate salts, were mounted on glass fibres. Data were collected using a Nonius Kappa-CCD diffractometer using COLLECT software (21*a*). Crystal cell refinement and data reduction were carried out using the Nonius DENZO package (21*a*). The data were scaled using SCALEPACK (21*a*) and no other absorption corrections were applied. The SHEXTL 5.1 program was used to solve the structure by direct methods, followed by successive difference Fouriers (21*b*). Crystallographic details are listed in Table 2.[2] The two compounds are isomorphous, each crystallizing in space group $P2_1$ with one molecule of CH_2Cl_2 of solvation. For complex **3a**, two of the ethyl groups on the phosphorus atom were modeled as isotropic, half occupancy moieties. Only one of each disordered ethyl group is shown in Fig. 1 for clarity. The third ethyl group was also kept isotropic. For complex **3b**, the phenyl ring attached to the selenium atom was modeled as two half-occupancy rings with isotropic carbon atoms. Two of the ethyl groups on the phosphorus atom were also modeled as isotropic, half-occupancy moieties. In Fig. 2 only one of each disordered group is shown for clarity. In both compounds, there was disorder of the CH_2Cl_2 molecule and of the ClO_4^- anion, and they were modeled with geometrical constraints.

Mechanistic studies of photohydration of *m*-hydroxy-1,1-diaryl alkenes

John G. Cole and Peter Wan

Abstract: The photohydration of a variety of *m*-hydroxy-1,1-diaryl alkenes (**8**–**10**) and related systems (**11** and **12**) has been studied in aqueous CH_3CN solution. All of these alkenes photohydrate efficiently in 1:1 H_2O–CH_3CN, to give the corresponding 1,1-diarylethanol (Markovnikov addition) products with high chemical and quantum yields. The aim of this study was to further probe the mechanism of photohydration reported for the parent *m*-hydroxy-α-phenylstyrene (**5**), which has been proposed as consisting of a water trimer-mediated excited state (formal) intramolecular proton transfer (ESIPT) from the phenolic proton to the β-carbon of the alkene moiety to give an observable (by laser flash photolysis (LFP)) *m*-quinone methide intermediate **6**. For this purpose, derivatives of **5** with substituents (methyl or methoxy) on the α-phenyl ring as well as related model compounds were explored. Product studies, quantum yields, fluorescence, and nanosecond laser flash data are reported that are consistent with two distinct mechanisms for photohydration of these compounds: one involving water-mediated ESIPT (**8**, **9**), as observed for the parent compound **5**, and one involving direct protonation of the β-carbon by solvent water (**11** and **12**), with compound **10** possibly operating via both mechanisms.

Key words: photohydration, solvent-assisted excited state intramolecular proton transfer (ESIPT), *m*-quinone methide, diarylmethyl carbocation.

Résumé : Opérant en solution aqueuse de CH_3CN, on a étudié la photohydratation d'une variété de *m*-hydroxy-1,1-diarylalcènes (**8**–**10**) et de systèmes apparentés (**11** et **12**). Tous ces alcènes se photohydratent facilement dans un mélange 1:1 de H_2O–CH_3CN et ils conduisent à la formation des 1,1-diaryléthanols correspondants (addition de Markovnikov) avec des rendements chimiques et quantiques élevés. Le but de cette étude était d'examiner plus à fond le mécanisme de photohydratation proposé pour le *m*-hydroxy-α-phénylstyrène fondamental (**5**) soit une réaction catalysée par un trimère d'eau et caractérisée par un transfert intramoléculaire de proton dans l'état excité (TIPEE) (formel) à partir du proton phénolique vers le carbone β de la partie alcène avec la formation d'un intermédiaire *m*-quinonemétide (**6**) qui peut être observé par photolyse éclair au laser (PEL). À cette fin, on a étudié des dérivés de **5** portants des substituants (méthyle ou méthoxy) sur le noyau α-phényle ainsi que des composés modèles apparentés. Les résultats d'études faites sur la nature des produits et les rendements quantiques ainsi que les données relatives à la photolyse éclair au laser au niveau de la nanoseconde peuvent s'accommoder de deux mécanismes distincts pour la photohydratation de ces composés: l'un implique un TIPEE catalysé par l'eau (**8**, **9**) semblable à celui observé avec le composé fondamental (**5**) et l'autre implique une protonation directe du carbone β par une molécule d'eau du solvant (**11**, **12**); le composé **10** pourrait réagir par une combinaison de ces deux mécanismes.

Mots clés : photohydratation, transfert intramoléculaire de proton dans l'état excité (TIPEE), *m*-quinonemétide, carbocation diarylméthyle.

[Traduit par la Rédaction]

Introduction

Excited state intramolecular proton transfer (ESIPT), a process of wide interest in chemistry, occurs most readily for those molecules whose acidity and basicity of both the proton donor and proton acceptor groups, respectively, are enhanced upon electronic excitation. ESIPT naturally leads to the formation of tautomers that are generally difficult to form via thermal chemistry (1). In almost all cases, the above mentioned proton transfers occur between heteroatoms, and the process is generally reversible. The first cited example of an ESIPT between a phenol and a carbon (alkene) was reported by Kalanderopoulos and Yates (2) in the efficient photohydration of *o*-hydroxystyrene (**1**) (eq. [1]). Photolysis of **1** in aqueous CH_3CN gave the *o*-quinone methide **2**, via

ESIPT from the phenol to the β-carbon. Nucleophilic attack by water at the α-carbon of **2** gives the overall hydration

Received 16 September 2001. Published on the NRC Research Press Web site at http://canjchem.nrc.ca on 15 January 2002.

product **3**. Available evidence suggests that **2** does not return to **1** under the conditions employed, this being an example of an irreversible ESIPT. Recent work from our group (3) on the related compound **4** confirms the formation of an *o*-quinone methide (by laser flash photolysis (LFP) experiments) from these compounds, which is generated within the laser pulse (≈10 ns). Moreover, we have also recently shown that the *meta* isomer (**5**) also photohydrates efficiently, but via a water trimer-mediated ESIPT, to give *m*-quinone methide **6** as the initially formed intermediate (4), as deduced from LFP experiments and the much lower reactivity of **7**, as well as other data (4). The crucial *m*-quinone methide intermediate **6** is formed within the laser pulse. In addition, there is efficient quenching of fluorescence of **5** by added water, concomitant with increased efficiency for the formation of **6**. These data support a mechanism of water-mediated ESIPT from the phenol to β-carbon that is probably concerted (or two very fast steps: deprotonation from the phenol OH followed by protonation of the β-carbon via a proton "relay" mechanism mediated by water). A similar mechanism may also be operative for the *para* isomer, although its intrinsically weak fluorescence emission made detailed mechanistic studies problematic.

The mechanism of the water trimer-mediated ESIPT from phenol to the β-carbon (of the alkene) of *m*-hydroxystyrenes warrants further investigation. In this work, the photohydrations of *m*-hydroxy-α-phenylstyrenes with electron donating substituents (methyl and methoxy) **8**–**10** are investigated. The related dimethoxystyrenes **11** and **12** without an *m*-hydroxy substituent were also studied for additional mechanistic insights.

Results and discussion

Materials

1,1,-Diarylalkenes **8**–**12** were made via dehydration of the corresponding 1,1-diarylethanols **13**–**17**, which in turn were made by the reaction of the corresponding Grignard reagent with 3′-hydroxyacetophenone (for **8**–**10**), 3′-methoxyacetophenone (for **11**), or acetophenone (for **12**). The Grignard reagents were made by standard reaction of the corresponding arylbromides with Mg metal. The isolated yields of the alkenes were generally >60%.

Product studies and quantum yields

Preparatory photolyses of **8**–**12** (argon purged, ~10^{-3} M, 1:1 (v/v) H_2O–CH_3CN, Rayonet RPR-100 photochemical reactor, 254 nm, ~15°C, <5 min) gave the corresponding alcohols (photohydration products) **13**–**17** in essentially quantitative yields (eqs. [2] and [3]). Control experiments showed no reaction in the absence of irradiation. Quantum yields for photohydration (Φ_P, alcohol formation) in 1:1 H_2O–CH_3CN for **8**–**12** were determined relative

to that reported for parent **5** (4) using ^{1}H NMR (Table 1). *m*-Hydroxystyrenes **8**–**10** have Φ_P's significantly higher than **5** (Φ_P = 0.22), whereas styrenes **11** and **12** have comparable values to **5**. The significantly higher quantum yields observed for the *m*-hydroxy-substituted compounds (**8**–**10**) compared to **11** and **12** are suggestive of a different mechanism for photohydration, perhaps similar to that reported for **5**; whereas **11** and **12** can only react via a simple photoprotonatiom pathway.

The photohydrations of **8**–**12** can be monitored readily by UV–vis spectrophotometry, since the alcohol products have much lower extinction coefficients over most of the spectrum (Fig. 1). The change in absorption spectra vs. irradiation time shows a linear relationship until at least 60% conversion, at which point the product may compete for light. Using this method for following the photohydration efficiency of these compounds, the dependence of Φ_P vs. water content (in CH_3CN) are shown in Fig. 2. The quantum yields for **8** and **9** increase rapidly with small additions of water, reaching a plateau at about 7–15 M H_2O. This behaviour is similar to that observed for **5**. However, unlike compounds **5**, **8**, and **9**, the Φ_P's of **10**–**12** have an apparent linear dependence on water concentration in CH_3CN; that is, the Φ_P's increase in a much more gradual fashion. This implies that bulk solvent water is required to accomplish efficient photohydration via photoprotonation for **10**–**12**, whereas a different mechanism requiring much less water content operates for the photohydration of **8** and **9**.

Solvent isotope effects for the photohydration quantum yield ($\Phi_P(H_2O)/\Phi_P(D_2O)$) were determined by comparing the Φ_P in H_2O–CH_3CN and D_2O–CH_3CN solutions (Table 1) using the above UV–vis method. Primary solvent isotope effects for **8** and **9** were evident at low water concentrations ($\Phi_P(H_2O)/\Phi_P(D_2O)$ ~2 at 0.9 M H_2O–D_2O in CH_3CN). At higher water concentrations, no isotope effect was observed ($\Phi_P(H_2O)/\Phi_P(D_2O)$ ~1 at 7.4 M H_2O–D_2O in CH_3CN). This

[a]Quantum yield for photohydration in 1:1 H_2O–CH_3CN, as measured using the reaction of **5** as secondary standard (estimated error, ±10%).
[b]Solvent isotope effect for photohydration (in 0.9 M $H_2O(D_2O)$ in CH_3CN for **8** and **9**; in 7.4 M $H_2O(D_2O)$ in CH_3CN for **10**–**12**).
[c]Fluorescence quantum yield in neat CH_3CN (λ_{ex} = 285 nm; 2-aminopyridine as standard; estimated error, ±10%).
[d]Fluorescence lifetime in neat CH_3CN, as measured by single photon counting. Only lifetimes >1 ns are measurable using the system available.
[e]Lifetime(s) of observed *m*-QM or carbocation in 1:1 H_2O–CH_3CN, as detected by LFP. Biphasic decays observed where two lifetimes are quoted.
[f]Data from ref. 4.

Fig. 1. UV–vis traces for photohydration of **10** in 1:1 H_2O–CH_3CN. Each trace was taken after 20 s photolysis at 254 nm. The final trace is that of the photohydration product **15**.

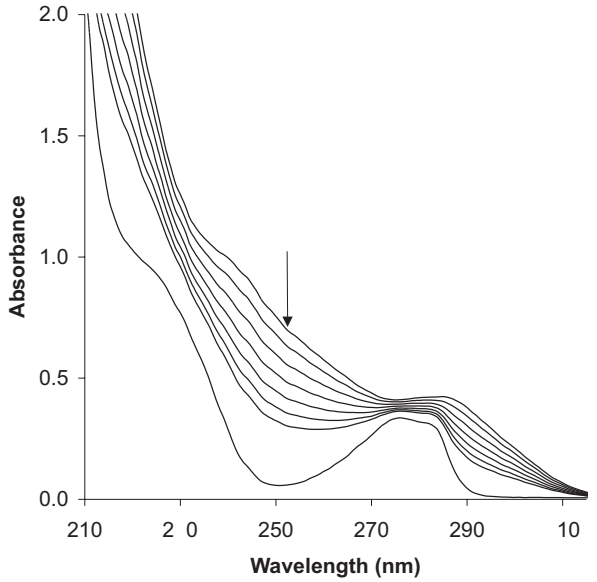

Fig. 2. Plots of quantum yields of photohydration for **8**–**12** vs. water concentration (in CH_3CN).

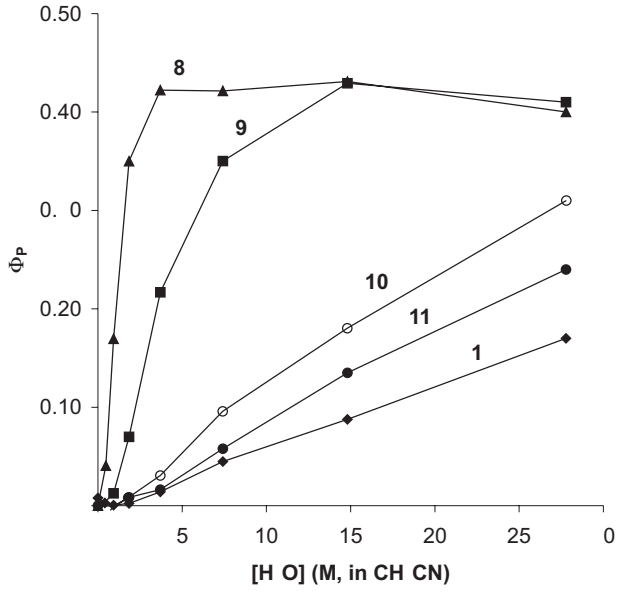

suggests a change in mechanism on going to solutions of high water content, where Φ_P values reach a plateau region (Fig. 2). The solvent isotope effects on the photohydration of **10**–**12** are quite large, with $\Phi_P(H_2O)/\Phi_P(D_2O)$ in the range 3–5. Unlike **8** and **9**, the isotope effects are independent of the concentration of water used (7–15 M H_2O–D_2O).

Steady-state and time-resolved fluorescence studies

Quantum yields of fluorescence (Φ_f) of **8**–**12** in dry CH_3CN were measured relative to 2-aminopyridine (5) (Table 1). The lack of large Stokes shifts in the fluorescence emission spectra indicates that the normal form (i.e., not the phenolate or a tautomeric form) of each compound is responsible for the emission. The addition of methoxy substituents (**9**–**12**) significantly reduces Φ_f, presumably through enhancement of non-radiative decay pathways.

To probe the mechanisms of photohydration further, steady-state fluorescence spectra were taken as a function of water content in CH_3CN. The fluorescence emission of **8** is quenched efficiently with small additions of water, and is essentially quenched by 3.7 M water (Fig. 3). Less efficient quenching was observed when D_2O was used (approximately half as efficient, up to 1.9 M $H_2O(D_2O)$). It is significant to note that at this same water concentration, Φ_P for **8** has essentially reached its maximal value (Fig. 2). Both **9** and **10** exhibit an initial *increase* in fluorescence emission intensity with small additions of water (up to 1.9 M) (Fig. 4*a*), followed by slower quenching by water (relative to **8**), requiring about 50% water to completely quench the emission (Fig. 4*b*). The weaker fluorescence emissions of both **11** and **12** prevented reliable studies of their water-quenching phenomena. However, neither compound exhibited a growth in fluorescence emission on the addition of water. Although the photophysical details are beyond the scope of this study, one possible reason for the observed growths in fluorescence emission intensity with added water (at low water concentrations) for **9** and **10** is associated with hydrogen bonding by added water to the phenol moiety, with the associated changes in structure and intrinsic emission efficiency. Since their Φ_f (in neat CH_3CN) are already low, slight changes to its emission quantum yield would be readily noticeable.

Fig. 3. Fluorescence quenching of **8** by H_2O in CH_3CN.

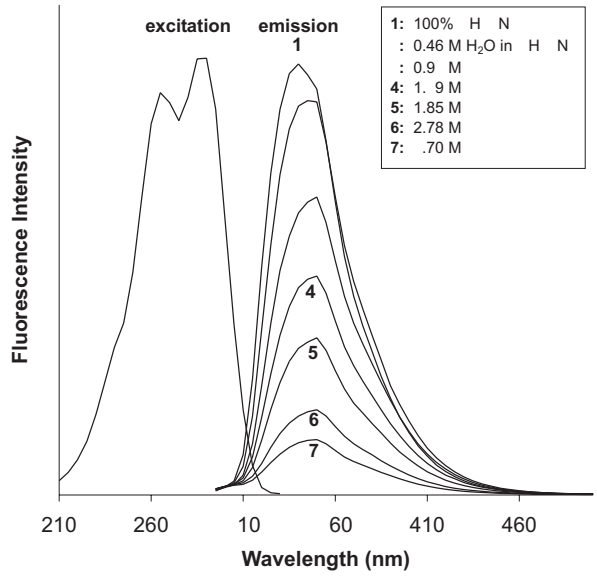

Fig. 4. (*a*) Effect on fluorescence intensity of **9** by added H_2O (in CH_3CN) up to 1.85 M; (*b*) above 1.85 M.

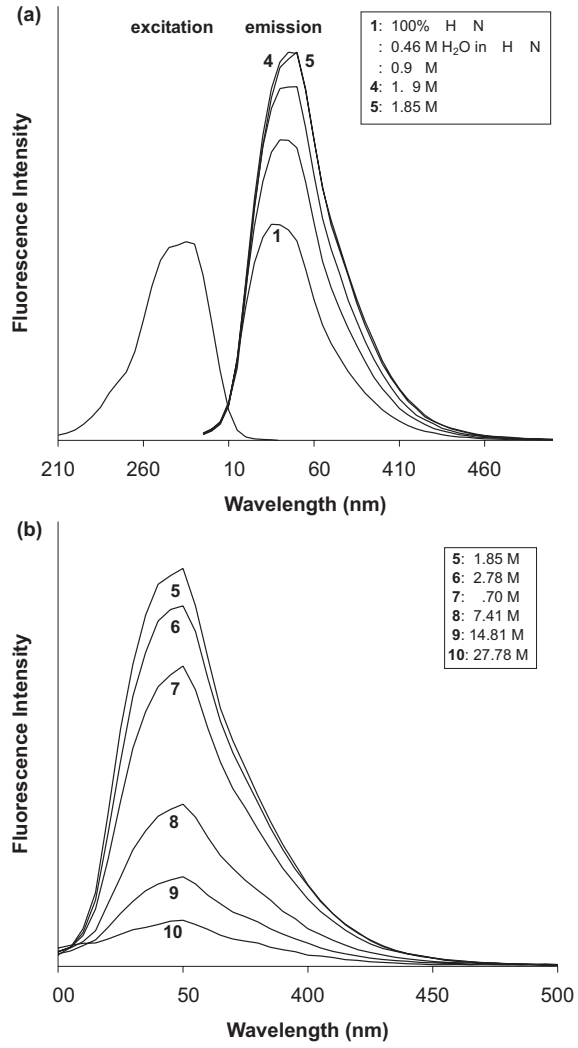

Fig. 5. Stern–Volmer plots of fluorescence quenching of **8** by H_2O (in CH_3CN) using steady-state fluorescence data (H_2O: ■; D_2O: □) and using fluorescence lifetime data (H_2O only: ▲). The solid lines are fits to the square of the water concentration ($[H_2O]^2$).

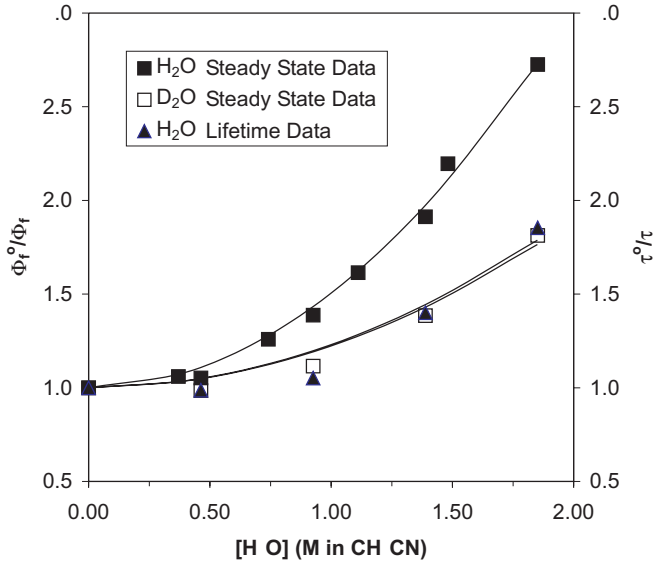

Fig. 6. LFP transients of **8**–**10** in 1:1 H_2O–CH_3CN oxygen-purged solution, 10 ns after laser excitation (266 nm).

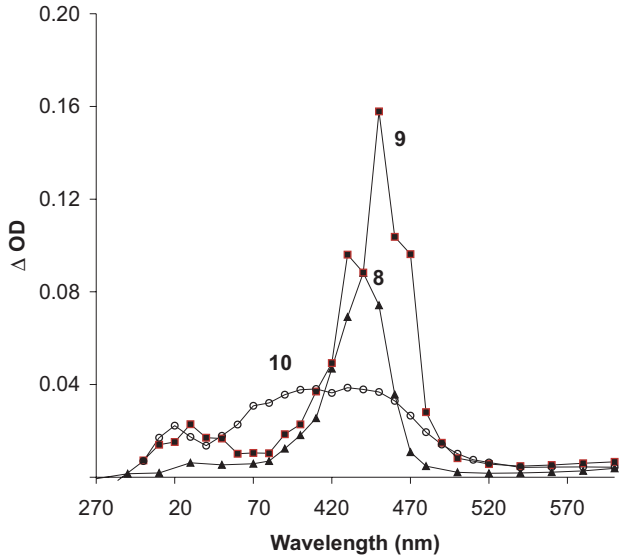
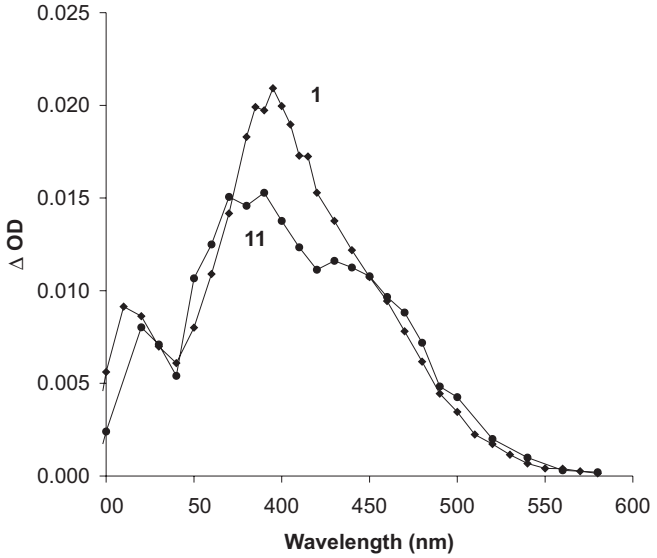


Fluorescence lifetimes (τ_f) were measurable only for **8** (4.4 ± 0.4 ns, neat CH_3CN) (Table 1). Addition of small amounts of water (<2 M) decreased its lifetime as anticipated (4.4, 4.1, 3.1, 2.3 in 0.5, 0.9, 1.4, 1.9 M H_2O, respectively). Stern–Volmer plots of fluorescence quenching by $H_2O(D_2O)$ using steady-state and lifetime data are shown for **8** in Fig. 5. Comparison of the steady-state and lifetime plots show that both static (pre-excitation) and dynamic (post-excitation) quenching of **8** are occurring. The non-linear nature of the plots also suggest that, on average, more than one water molecule is involved with each excited singlet state of

© 2002 NRC Canada

Fig. 7. LFP transients of **11** and **12** in 1:1 H_2O–CH_3CN oxygen-purged solution, 10 ns after laser excitation (266 nm).

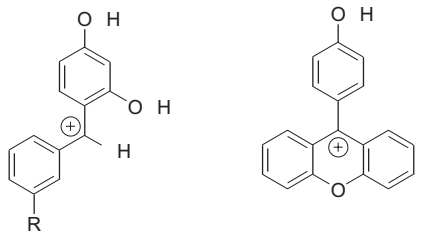


8. Modifying the Stern–Volmer plot so that the concentration of water is squared ($[H_2O]^2$) provides the best fit of the data (Fig. 5). Thus, at low water concentrations in CH_3CN, an average of two water molecules are required to quench the fluorescence, via both the static and dynamic mechanisms.

Laser flash photolysis (LFP)

Nanosecond LFP of **8** and **9** (266 nm; YAG laser; <20 mJ; 20°C) in 1:1 H_2O–CH_3CN resulted in sharp, strongly absorbing transients similar to those previously reported as *m*-QMs (4). LFP of **10** under the same conditions led to a broader transient signal. All three transients appear immediately after the laser pulse (≈10 ns) and are shown in Fig. 6. Purging with oxygen or nitrogen had no significant effect on the profile or lifetime of the transients. The signals decay to baseline in a mono-exponential fashion. Excitation in dry CH_3CN gave no transient signal, thus indicating that water is necessary for the formation of the reactive intermediate. The lifetime of these transients increase with electron-donating substituents on the α-phenyl ring, consistent with an electron deficient species (Table 1).

LFP of the **11** and **12** (lacking a *m*-hydroxy group) in 1:1 H_2O–CH_3CN gave broad transients observed immediately after the laser pulse (Fig. 7) that are insensitive to the presence of oxygen. Excitation of these compounds in the absence of water (dry CH_3CN) did not lead to any transient. Since these compounds lack an *m*-hydroxy group, they cannot form *m*-QMs. Based on their similarity to published data on arylmethyl carbocations (6), they are assigned to diarylmethyl carbocations **18** and **19**, obtained via Markovnikov photoprotonation by water at the β-carbon. Interestingly, both of these diaryl carbocations show a biphasic decay (two pseudo-first-order decays) to baseline across the transient profile (Fig. 8). This suggests the presence of two absorbing species with essentially identical absorption spectra but different reactivity (resulting in two decay rates). A similar biphasic decay was reported for the photo-generated 9-*p*-methoxyphenyl-9-xanthenylium cation (**20**) in aqueous ethanol (7). The short-lived species (≈ 0.1 ms) was assigned to the ion pair (geminate) recombination of the cation and hydroxide ion, while the longer lived species (≈10 ms) was assigned to the reaction of the cation with water. The ratio of the two observed quenching rates of **20** is similar to those obtained for the LFP intermediates **18** and **19**.



18 R = O H
19 R = H
0

The effect of water content (in CH_3CN) on the strength of the LFP transients observed for **8** and **11** are shown in Fig. 9. In dry CH_3CN (as previously mentioned), no signals were observed. However, with small additions of water (<3.7 M in CH_3CN), the transient generated from **8** rapidly grows in, reaching a plateau region at ≈3.7 M H_2O. The carbocation signal of **18** appears only weakly at this water concentration. At much higher water concentrations (5–20 M H_2O), the signal increased in an apparent linear fashion with water concentration. The transient lifetimes observed for both **8** and **11** are shorter at higher water content, consistent with them being carbocation-like species. For **8**, at low water concentrations in CH_3CN the lifetime of the transient is relatively long (14 μs with 0.5 M H_2O). As more water is added, the intermediate lifetime steadily decreases (750 ns in 3.7 M H_2O), reaching 250 ns in 1:1 H_2O–CH_3CN.

It is interesting to note that the two plots observed in Fig. 9 for **8** and **11** are essentially identical to their plots of Φ_P vs. water content (Fig. 2).

Mechanisms of photohydration

Although molecules **8**–**12** photohydrate efficiently in aqueous solution, as shown by the high quantum yields for 1,1-diarylalcohol formation measured in 1:1 H_2O–CH_3CN, it is clear that substantial differences exist with respect to their mechanisms of photosolvolysis. The Φ_P's of **8** and **9** have a water concentration effect that is essentially identical to that observed for **5**. The lifetimes of the transients generated by LFP of **5**, **8**, and **9** are consistent with the increase in the electron donating capability of the *para* substituents on the α-phenyl ring. Most notably, the single-exponential decay of those transients, rather than a biphasic decay, distinguish these intermediates from simple arylmethyl carbocations such as **18**–**20**, indicating that the transients generated from **8** and **9** are most probably *m*-QMs **21** and **22**. It was initially anticipated that the mechanism of photosolvolysis for **8** and **9** would be similar to that reported for **5** involving an excited state (formal) intramolecular proton transfer mediated by a cluster of three water molecules, as shown in **23**. This mechanism was proposed for **5** when it was noted that three water molecules were required to fit the fluorescence quenching data (static and dynamic components). Three water mole-

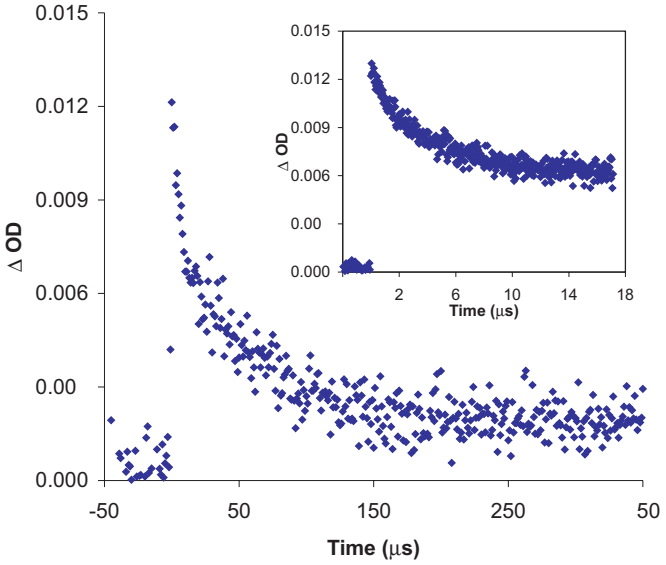
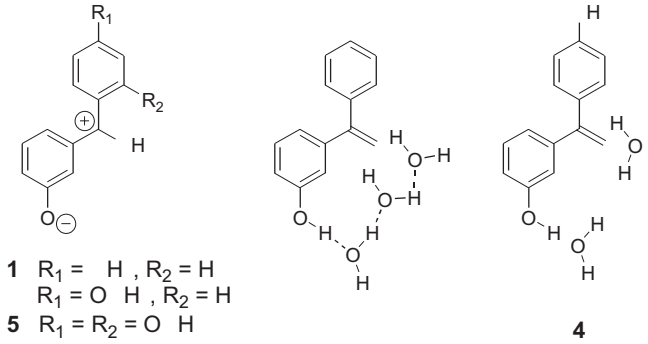
Fig. 8. Biphasic pseudo-first-order decays of the LFP intermediate of **11** monitored at 475 nm in a 1:1 H_2O–CH_3CN oxygen purged solution. Inset: decay at shorter time scales (lifetimes are 4.4 and 55 μs).

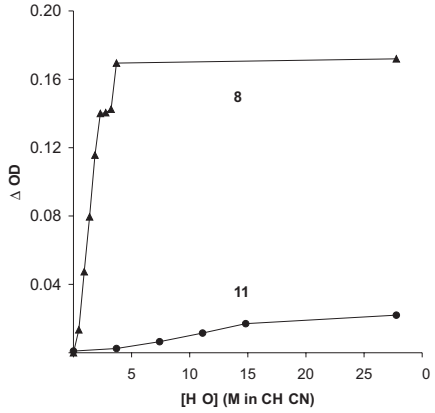


cules hydrogen bonded in a chain could span the distance between the phenol and β-carbon in **23**. However, due to the rapid formation (within the laser pulse) of *m*-QM **6**, it was not possible by LFP to discern whether the proton transfers were concerted or in sequence. The fluorescence quenching data of **8** show that only two water molecules are involved in its proton transfer mechanism. This is insufficient to bridge the distance between the phenol and β-carbon on the alkene. Thus, the intramolecular proton transfer is more likely two excited-state proton transfers with only one water molecule required at each of the acidic and basic sites, as shown in **24**. This would still generate a *m*-QM, although without being a formal intramolecular proton transfer. It appears that the electron donating ability of the *p*-methyl group on the α-phenyl ring of **8** (relative to a hydrogen on **5**) is sufficient in reducing the water requirement of QM formation. Unfortunately, the peculiar fluorescence growth of **9** upon addition of water does not allow for proper Stern–Volmer analysis to determine (on average) how many water molecules are required for quenching of its excited state.



Both **11** and **12** photohydrate to give the corresponding Markovnikov alcohol. Considering the lack of a phenol functionality on these compounds, the reactions must proceed via a diarylmethyl carbocation intermediate. The efficiency of these reactions depend on bulk water concentration, and they have a large primary isotope effect implying that the excited state proton transfers in these cases is not as "early" as for **8** and **9**. The LFP transients show an interesting biphasic decay pattern, similar to that reported for xanthylium cation **20** (7), which was photogenerated by photodehydroxylation of the corresponding alcohol (which generates an initial cation–hydroxide ion pair). In analogy to the assignments made for the kinetic data for **20** (7), the biphasic decay is interpreted as arising from two forms of the carbocation: one being an ion pair with hydroxide ion, and the other the solvent-separated (solvated) carbocation. The shorter-lived species is assigned to the ion pair and the longer-lived species to the solvated carbocation.

Fig. 9. Δ OD vs. water concentration for the transients observed for **8** and **11** (in CH_3CN) immediately after (≈10 ns) excitation by LFP.



The photohydration of **10** shows characteristics of mechanisms involving a *m*-QM as well as those of a simple carbocation intermediate. The dependence of Φ_P on water concentration and solvent isotope effect support the idea that **10** reacts via a carbocation, similar to the mechanism for **11** and **12**. However, evidence that **10** generates a *m*-QM is in the observed decay profile of the intermediate: it lacks a biphasic decay, implying that an ion pair is not formed. Indeed, the intermediate observed for **10** is sufficiently long-lived that a shorter-lived component would have been observable. Since it is clearly mono-exponential, intermediate quenching via ion-pair combination is not occurring, and the species is best assigned to a *m*-QM **25**.

Summary

New insights into the mechanisms of photohydration of 1,1-diarylalkenes have been made. *m*-Hydroxystyrenes **8** and **9** undergo ESIPT to form *m*-QM, followed by reaction with water to form the corresponding 1,1-diarylalcohol. The reaction requires only small volumes of water to be present to reach maximum quantum efficiency. *o*,*p*-Dimethoxystyrenes **11** and **12** undergo ESPT from solvent water to form carbocations **18** and **19**, which then react with either a hydroxide ion or water to yield the alcohol product. The reactions require bulk solvent water to be observable, and do not react in CH_3CN solutions with small amounts of water.

© 2002 NRC Canada

Compound **10**, which is both a *m*-hydroxystyrene and a *o,p*-dimethoxystyrene, shows characteristics of both mechanisms. However, the lifetime of the LFP intermediate shows evidence of a *m*-QM rather than a carbocation intermediate.

Experimental

General

^{1}H NMR spectra were recorded on a Bruker AC–300 (300 MHz) instrument. UV–vis spectra were obtained using Cary 5 UV/Vis, Cary 1E UV/Vis, and Cary 50 Bio scanning spectrophotometers in conjunction with fluorescence, LFP, and Φ_P measurements, respectively. The fluorescence spectra were taken on a Photon Technology International A-1010 (PTI) Quanta Master™ Luminescence Spectrometer. High resolution mass spectra were obtained on a Kratos Concept H (EI) instrument and the uncorrected melting points in a Gallencamp melting point apparatus. IR spectra were recorded on a PerkinElmer Spectrum One FTIR spectrophotometer either as KBr pellets (for solid compounds), or on NaCl plates (as a neat oil). Photolyses were carried out in 100-mL quartz tubes using a Rayonet RPR 100 photochemical reactor with 254 nm lamps (up to 16). The solvents THF, CH_3CN, and CH_2Cl_2 were distilled before use with THF and CH_3CN pre-drying over K and CaH_2, respectively. 3-Hydroxyacetophenone, 3-methoxyacetophenone, acetophenone, 4-bromotoluene, 4-bromoanisole, and 1-bromo-2,4-dimethoxybezene were purchased from Aldrich.

3′-Hydroxy-4″-methyl-1,1-diphenylethene (8)

The Grignard reagent was prepared by adding a solution of 4-bromotoluene (5.5 mL, 45 mmol) in anhydrous THF (25 mL) dropwise to Mg (0.87 g, 35.8 mmol) in anhydrous THF (100 mL) under nitrogen. The resulting mixture was heated at reflux for 2 h, then 3-hydroxyacetophenone (1.82 g, 13.4 mmol) was added dropwise, and then the mixture kept at reflux for more 2 h. Saturated aqueous NH_4Cl was added and the solution was subjected to standard workup (extraction with CH_2Cl_2, washing of the organic with saturated brine solution, drying ($MgSO_4$), filtration, and evaporation to dryness in vacuo), to afford the crude product alcohol 3′-hydroxy-4″-methyl-1,1-diphenylethanol (**13**) (≈70%). Molecule **13** was refluxed in CH_3CN with a catalytic amount of dilute H_2SO_4, to yield the crude oil **8**. Purification by column chromatography in 9:1 CH_2Cl_2–EtOAc yielded pure material (oil). ^{1}H NMR ($CDCl_3$) δ: 2.35 (s, 3H, CH_3), 4.87 (s, 1H, OH), 5.39 (s, 2H, $=CH_2$), 6.78 (m, 2H, Ar), 6.90 (d, J = 8.0 Hz, 1H, Ar), 7.10–7.24 (m, 5H, Ar). HRMS calcd. for $C_{15}H_{14}O$: 210.1045; found: 210.1047.

3′-Hydroxy-4″-methoxy-1,1-diphenylethene (9)

The Grignard reagent was prepared as above using 4-bromoanisole (5.8 mL, 46 mmol), Mg (0.87 g, 35.8 mmol), and 3-hydroxyacetophenone (3.02 g, 22 mmol) to yield the crude product alcohol 3′-hydroxy-4″-methoxy-1,1-diphenylethanol (**14**). Molecule **14** was refluxed in CH_3CN with a catalytic amount of H_2SO_4 (aq) to yield the crude oil **9**. Purification by column chromatography in 4:1 hexanes–EtOAc yielded clean product, which was recrystallized from CH_3Cl and hexanes with an overall yield of 25% (1.35 g, 5 mmol): mp 66–68°C. ^{1}H NMR ($CDCl_3$) δ: 3.81 (s, 3H, OCH_3), 4.73 (s, 1H, OH), 5.35 (d, J = 6.6 Hz, 2H, $=CH_2$), 6.78–6.92 (m, 5H, Ar), 7.16–7.26 (m, 3H, Ar). HRMS calcd. for $C_{15}H_{14}O_2$: 226.0994; found: 226.0994.

3′-Hydroxy-2″,4″-dimethoxy-1,1-diphenylethanol (15)

The appropriate Grignard reagent was prepared from 1-bromo-2,4-dimethoxybenzene (9.0 mL, 62 mmol), Mg (2.12 g, 87 mmol), and 3-hydroxyacetophenone (3.62 g, 27 mmol). The resulting crude oil was washed with benzene to remove the byproduct dimethoxybenzene, resulting in **15** in a 60% yield. Recrystallization from ethanol and hexanes gave pale green cubic crystals in 40% yield): mp 144–146°C. IR (cm^{-1}): 3457 (s), 3310 (s). ^{1}H NMR ($CDCl_3$) δ: 1.77 (s, 3H, CH_3), 3.58 (s, 3H, OCH_3), 3.80 (s, 3H, OCH_3), 4.48 (s, 1H, OH), 4.69 (s, 1H, OH), 6.45 (d, J = 2.9 Hz, 1H, Ar), 6.50 (dd, J = 8.5, 2.5 Hz, 1H, Ar), 6.63 (dd, J = 8.1, 2.6 Hz, 1H, Ar), 6.79 (m, 2H, Ar), 7.09 (t, J = 8.1 Hz, 1H, Ar), 7.30 (d, J = 8.8 Hz, 1H, Ar). HRMS calcd. for $C_{16}H_{18}O_4$: 274.1205; found: 274.1205.

3′-Hydroxy-2″,4″-dimethoxy-1,1-diphenylethene (10)

Molecule **15** (0.40 g, 1.4 mmol) was dissolved in THF (120 mL) and a catalytic amount (one drop) of 10 N H_2SO_4 was added. The solution was heated at reflux for 2 h. Quenching of the reaction with distilled water (100 mL), neutralization with Na_2CO_3 (aq), and general workup (extraction into CH_2Cl_2, drying with anhydrous $MgSO_4$) yielded **10** as on oil. Recrystallization from $CHCl_3$ and hexanes gave light brown cubic crystals with an overall yield of 64%: mp 79–81°C. IR (cm^{-1}): 3445 (s), 3097 (m). ^{1}H NMR ($CDCl_3$) δ: 3.62 (s, 3H, OCH_3), 3.82 (s, 3H, OCH_3), 4.59 (s, 1H, OH), 5.27 (d, J = 1.5 Hz, 1H), 5.63 (d, J = 1.5 Hz, 1H), 6.46–6.51 (m, 2H, Ar), 6.69–6.72 (m, 2H, Ar), 6.88 (d, J = 7.4 Hz, 1H, Ar), 7.11–7.15 (m, 2H, Ar). HRMS calcd. for $C_{16}H_{16}O_3$: 256.1099; found: 256.1101.

2′,3″,4′-Trimethoxy-1,1-diphenylethanol (16)

The appropriate Grignard reagent was prepared from 1-bromo-2,4-dimethoxybenzene (2.4 mL, 17 mmol), Mg (0.41 g, 17 mmol), and 3′-methoxyacetophenone (2 mL, 14 mmol) to afford the crude product alcohol. Purification by column chromatography starting with CH_2Cl_2 and increasing polarity with ethyl acetate yielded the clean product oil **16** (~60%). ^{1}H NMR ($CDCl_3$) δ: 1.79 (s, 3H, CH_3), 3.58 (s, 3H, OCH_3), 3.76 (s, 3H, OCH_3), 3.80 (s, 3H, OCH_3), 4.49 (s, 1H, OH), 6.44 (d, J = 2.2 Hz, 1H, Ar), 6.50 (dd, J = 8.8, 2.2 Hz, 1H, Ar), 6.70 (d, J = 8.1 Hz, 1H, Ar), 6.79 (d, J = 7.4 Hz, 1H, Ar), 6.92 (s, 1H, Ar), 7.13 (t, J = 8.0 Hz, 1H, Ar), 7.30 (d, J = 8.8 Hz, 1H, Ar). HRMS calcd. for $C_{17}H_{20}O_4$: 288.1362; found: 288.1362.

2′,3″,4′-Trimethoxy-1,1-diphenylethene (11)

Molecule **16** (2.21 g, 7.6 mmol) was heated at reflux in a solution of CH_3CN and dilute H_2SO_4. Quenching and workup as for **10** yielded clean **11** in >80% yield. ^{1}H NMR ($CDCl_3$) δ: 3.62 (s, 3H, OCH_3), 3.76 (s, 3H, OCH_3), 3.83 (s, 3H, OCH_3), 5.29 (d, J = 1.5 Hz, 1H, =CH), 5.65 (d, J = 1.5 Hz, 1H, =CH), 6.48–6.52 (m, 2H, Ar), 6.79 (dd, J = 8.1, 1.5 Hz, 1H, Ar), 6.80–6.86 (m, 2H, Ar), 7.12–7.20 (m, 2H,

Ar). HRMS calcd. for $C_{17}H_{18}O_3$: 270.1256; found: 270.1256.

2′,4′-Dimethoxy-1,1-diphenylethanol (17)

The Grignard reaction involving 1-bromo-2,4-dimethoxybenzene (2 mL, 14 mmol), Mg (0.56 g, 23 mmol), and acetophenone (2 mL, 17 mmol) gave the crude product alcohol. Purification by column chromatography in CH_2Cl_2 gave the clean product **17** in 45% yield: mp 84–86°C. IR (cm^{-1}): 3550 (s). ^1H NMR ($CDCl_3$) δ: 1.79 (s, 3H, CH_3), 3.55 (s, 3H, OCH_3), 3.82 (s, 3H, OCH_3), 4.46 (s, 1H, OH), 6.44 (d, *J* = 2.2 Hz, 1H, Ar), 6.50 (dd, *J* = 8.1, 2.2 Hz, 1H, Ar), 7.15–7.29 (m, 6H, Ar). HRMS calcd. for $C_{16}H_{18}O_3$: 258.1256; found: 258.1260.

2′,4′-Dimethoxy-1,1-diphenylethene (12)

Molecule **17** (1.40 g, 5.4 mmol) was heated at reflux in CH_3CN and dilute H_2SO_4. Quenching of the reaction and general workup yielded the clean oil **12** in 90% yield. IR (cm^{-1}): 3081 (m). ^1H NMR ($CDCl_3$) δ: 3.62 (s, 3H, OCH_3), 3.84 (s, 3H, OCH_3), 5.31 (d, *J* = 1.5 Hz, 1H, =CH), 5.68 (d, *J* = 1.5 Hz, 1H, =CH), 6.50–6.54 (m, 2H, Ar), 7.14–7.34 (m, 6H, Ar). HRMS calcd. for $C_{16}H_{16}O_2$: 240.1150; found: 240.1148.

Product studies

In a typical photolysis, 20 mg of substrate in 1:1 (v/v) H_2O–CH_3CN (100 mL) was purged with argon for 10 min before and during irradiation at 254 nm in a Rayonet RPR-100 photochemical reactor equipped with a cooling finger (≈15°C). Representative preparatory photolyses are described below.

Photolysis of 8

Photolysis of **8** in 1:1 H_2O–CH_3CN (~10^{-3} M, 5 min, 16 lamps) followed by standard workup led to the alcohol product **13** (100%). ^1H NMR ($CDCl_3$) δ: 1.89 (s, 3H, CH_3), 2.20 (s, 1H, OH), 2.31 (s, 3H, CH_3), 5.05 (s, 1H, OH), 6.68 (m, 1H, Ar), 6.89–6.93 (m, 2H, Ar), 7.09–7.18 (m, 3H, Ar), 7.25–7.30 (m, 2H, Ar). HRMS calcd. for $C_{15}H_{16}O_2$: 228.1150; found: 228.1149.

Photolysis of 9

Photolysis of **9** in 1:1 H_2O–CH_3CN (as above) gave the alcohol product **14** (100%). ^1H NMR ($CDCl_3$) δ: 1.88 (s, 3H, CH_3), 2.23 (s, 1H, OH), 3.77 (s, 3H, CH_3), 5.26 (s, 1H, OH), 6.68 (m, 1H, Ar), 6.78–6.84 (m, 2H, Ar), 6.89 (m, 2H, Ar), 7.14 (t, *J* = 8.0 Hz, 1H, arom), 7.27–7.32 (m, 2H, Ar). HRMS calcd. for $C_{15}H_{16}O_3$: 244.1099; found: 226.1102.

Quantum yield measurements

Fluorescence quantum yields (Φ_f) for **8**–**12** in neat CH_3CN were measured relative to 2-aminopyridine in 0.1 N H_2SO_4 (Φ_f = 0.60 ± 0.05) (5). Solutions were studied at three concentrations (absorbance ≈ 0.10, 0.07, and 0.04 at λ_{ex} = 285 nm, argon purged) to rule out aggregation effects. Yields were calculated by integrating the emission bands and correcting for the solvent refractive indexes. Weak fluorescence from the solvent was corrected for (by subtraction) by measuring blank samples. Errors are estimated at 10%.

Quantum yields of photohydration (Φ_P) were determined relative to **5** (Φ_P = 0.22) in 100 mL 1:1 H_2O–CH_3CN. Samples (20 mg) of **8**–**12** and **5** were alternately irradiated in a Rayonet photochemical reactor (8 lamps, 2 min, 254 nm). The solutions were then worked up by addition of brine, extraction with CH_2Cl_2 (3 times), washing with distilled H_2O, drying over anhydrous $MgSO_4$, and removal of solvent under vacuum. Samples were analysed by ^1H NMR, with conversion to product being calculated by the relative integration of distinct starting material and product peaks, namely the alkene β-carbon becoming a methyl group. The ratio of known and unknown conversion to product is assumed to be equal to the ratio of their Φ_P. Total conversion to product was kept below 35%. Errors are estimated at ±0.05.

Φ_P at concentrations of water in CH_3CN other than 1:1 H_2O–CH_3CN were determined via UV–vis spectroscopy. A typical experiment involved preparing 8 cuvettes with solutions ranging from neat CH_3CN to 1:1 H_2O–CH_3CN. An equal aliquot (>10 μL) of a stock solution (10–15 mg in 3 mL CH_3CN) was added to each cuvette, and the samples were checked by absorption to be of equal concentration. Shifts in the absorption profile due to added water were not seen. The samples were simultaneously irradiated in a carousel in a photochemical reactor at 254 nm with 4 lamps. Irradiation occurred in 20 s intervals with absorption spectra taken between irradiation periods. The change in absorption at a given wavelength (250 nm) is proportional to the Φ_P for that solution, thus Φ_P for a variety of water concentrations were determined relative to that observed in 1:1 H_2O–CH_3CN. Even though the 1,1-diarylalcohols (**13**–**17**) have ϵ that are much lower than the conjugated 1,1-diarylalkenes at the monitored wavelength, light scavenging by the photoproduct was limited by determining the relative Φ_P at low conversion (~20%). Errors estimated to be ±10%.

Laser flash photolysis (LFP)

All transient spectra and lifetimes were obtained using a Nd:YAG laser (Spectra Physics Quanta-Ray GCR-3 or GCR-11, <20 mJ) with pulse width of ≈10 ns and excitation wavelength of 266 nm. Signals were digitized with a Tektronix TDS 520 recorder. Samples were prepared with OD ≈ 0.3 at 266 nm. Flow cells were used for all spectra obtained. The solutions were purged with nitrogen or oxygen for ≈10 min before excitation. Static cells were used for relative Δ OD experiments, and were purged with oxygen for 5 min prior to analysis. Each static sample was not flashed more than 10 times to limit photodegradation of the sample.

Fluorescence measurements

Steady-state fluorescence was conducted on a Photon Technology Internation A-1010 (PTI) Quanta-Master luminescence spectrometer. All solutions (absorbance ≈ 0.1 at λ_{ex} = 285 nm, except 290 nm for **8**) were purged for 5 min with argon prior to excitation. It was found that the photohydration product was far more fluorescent than the starting material, and prolonged exposure to the excitation lamp would lead to small amounts of product. To minimize this, solutions were allowed to equilibrate to 20°C in the absence of light, and the emission was measured every 5 nm. This method gave reproducible emission bands even after 3 scans,

© 2002 NRC Canada

indicating that no photoproduct was interfering with the fluorescence emission. Fluorescence lifetimes of **8** were measured on a PTI LS-1 instrument using time-correlated single-photon-counting techniques (10 000 counts, λ_{ex} = 290 nm, λ_{em} = 340 nm).

Acknowledgments

We thank the Natural Sciences and Engineering Research Council of Canada (NSERC) for supporting this research in the form of research grants (to PW) and the University of Victoria for a post-graduate fellowship (to JGC).

Iron complexes of the dibenzophospholyl ligand: a synthetic and crystallographic study

Andreas Decken, Melanie A. Neil, C. Adam Dyker, and Frank Bottomley

Abstract: Iron complexes bearing the dibenzophospholyl (DBP) ligand have been prepared. Reaction of DBP-Li with $CpFe(CO)_2Br$ gave $[(\mu_2\text{-DBP})Fe_2Cp_2(CO)_4]Br$ and reaction of DBP-Li with $CpFe(CO)_2I$ gave $[(\mu_2\text{-DBP})Fe_2Cp_2(CO)_4]I$. Reaction of bis(1,1′-dibenzophospholyl) and $[CpFe(CO)_2]_2$ yielded a mixture of *cis*- and *trans*-$(\mu_2\text{-DBP})_2Fe_2Cp_2(CO)_2$. The mixture was also obtained on heating of $[(\mu_2\text{-DBP})Fe_2Cp_2(CO)_4]X$ (X = Br, I). The ligands are σ-bonded through the phosphorus atom in all complexes. The compounds were characterized by ^1H, ^{13}C, and ^{31}P NMR and IR spectroscopies, mass spectrometry, micro analysis, and X-ray diffraction.

Key words: dibenzophospholyl, iron, heterocycle.

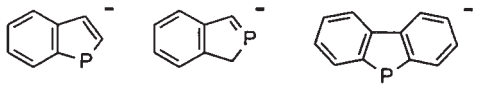
Résumé : On a préparé des complexes du fer portant le ligand dibenzophospholyle (DBP). La réaction du DBP-Li avec le $CpFe(CO)_2Br$ conduit à la formation du $[(\mu_2\text{-DBP})Fe_2Cp_2(CO)_4)]Br$ alors que la réaction du DBP-Li avec le $CpFe(CO)_2I$ conduit à la formation du $[(\mu_2\text{-DBP})Fe_2Cp_2(CO)_4)]I$. La réaction du bis(1,1′-dibenzophospholyle) avec le $[CpFe(CO)_2]_2$ conduit à un mélange des isomères *cis*- et *trans*- du $(\mu_2\text{-DBP})Fe_2Cp_2(CO)_4]X$ (X = Br, I). Dans chacun de ces complexes, les ligands sont liés aux atomes de phosphore par des liaisons σ. Les composés ont été caractérisés par RMN du ^1H, du ^{13}C et du ^{31}P, spectroscopie IR, spectrométrie de masse, microanalyses et diffractions des rayons X.

Mots clés : dibenzophospholyle, fer, hétérocycle.

[Traduit par la Rédaction]

Introduction

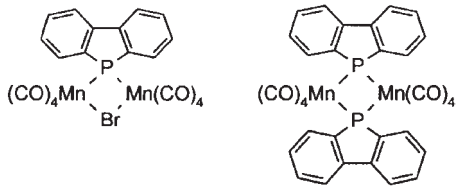
Benzannelated phospholyl ligands such as **1**–**3** have recently emerged as interesting ligands in organometallic chemistry (1). Their hydrocarbon analogues bind primarily through the π-electron system, but **1**–**3** can also ligate metals



1 **2** **3**

through the phosphorus lone pair, resulting in complexes containing ligands with σ-, π-, and mixed-bonding modes. We recently reported the synthesis and characterization of manganese complexes of dibenzophospholyl (DBP, **3**) (2). The ligands were σ-bonded, bridging two metal atoms in the complexes $(\mu_2\text{-DBP})(\mu_2\text{-Br})Mn_2(CO)_8$ (**4**) and $(\mu_2\text{-DBP})_2Mn_2(CO)_8$ (**5**), which is unusual for metal complexes of phospholyl ligands and in contrast to the bonding observed for their hydrocarbon analogues.

We are exploring the chemistry of DBP with emphasis on the differences between its modes of coordination and those



4 **5**

of the fluorenyl analogue and of ligands **1** and **2**. In light of the diverse and controversial chemistry of the fluorenyl complexes $[(\eta^6\text{-}C_{13}H_9)FeCp$ and $(\eta^5\text{-}C_{13}H_9)FeCp]$ (3), we prepared iron complexes of the dibenzophospholyl anion, **3**. The characterization, structures, and properties of the products are reported here.

Results

Synthesis and properties

Compounds **6** and **7** were synthesized from DBP-Li and $CpFe(CO)_2X$ (X = Br, I) in THF at room temperature in high yields (93 and 87%, respectively) (Scheme 1). Heating of **6** or **7** in refluxing xylenes resulted in the formation of trace amounts of **8** with Cp_2Fe as the major product, as well as large amounts of intractable green solids (Scheme 2). Compound **8** was also obtained by reaction of bis(1,1′-dibenzophospholyl) (**9**) and $Cp_2Fe_2(CO)_4$ in refluxing xylenes as a mixture of *cis*- and *trans*-isomers (ratio 1:15) in 75% yield (Scheme 3).

The products were characterized by elemental analysis, IR and NMR spectroscopies, mass spectrometry, and X-ray dif-

fraction. The complexes were either yellow (**6**, **7**) or green (**8**), diamagnetic, crystalline solids. They were mildly air and moisture sensitive; compounds **6** and **7** decompose slowly, especially in the presence of light, while **8** was indefinitely stable under an inert atmosphere, both in solution and in the solid state. Compounds **6**, **7**, and *cis*-**8** were insoluble in nonpolar hydrocarbons and only sparingly soluble in polar organic solvents, while *trans*-**8** was virtually insoluble in all organic solvents. Compound **8** decomposed slowly in $CHCl_3$.

Discussion

Reaction of DBP-Li with either $CpFe(CO)_2Br$ or $CpFe(CO)_2I$ yielded the $[(\mu_2\text{-DBP})Fe_2Cp_2(CO)_4]^+$ cation as the halide salts **6** and **7**, respectively. Crystallographic and spectroscopic data revealed that the structure of the cations in **6** and **7** were identical, both in the solid state and in solution. Formation of the ionic complex was in contrast to the analogous reaction between DBP-Li and $Mn(CO)_5Br$, which yielded the neutral complex **4** (2). The corresponding cation $[(\mu_2\text{-DBP})Mn_2(CO)_{10}]^+$ was not observed. Ring closure of $[(\mu_2\text{-DBP})Fe_2Cp_2(CO)_4][X]$ to give $(\mu_2\text{-DBP})(\mu_2\text{-X})Fe_2Cp_2(CO)_2$ requires the loss of two molecules of CO from the cation and incorporation of the halide atom into the four membered ring. Bond dissociation energies (BDE's) for metal carbonyl bonds have recently been investigated for manganese and iron carbonyl complexes (13). DFT calculations showed that BDE's were significantly higher for Fe—CO bonds in $Cp_2Fe_2(CO)_4$ compared to Mn—CO bonds in $Mn_2(CO)_{10}$ and the Fe—CO bonds in $Fe_2(CO)_9$. If the same trend holds for $CpFe(CO)_2$ and $Mn(CO)_5$ complexes of DBP, loss of carbonyl ligands and ring formation is expected to be more difficult in cyclopentadienyl iron carbonyls compared to manganese carbonyls. This rationale is substantiated by the fact that several complexes of general formula $(\mu_2\text{-PR}_2)(\mu_2\text{-X})Mn_2(CO)_8$ (14) and $(\mu_2\text{-PR}_2)(\mu_2\text{-X})Fe_2(CO)_6$ (15) have been structurally authenticated, while there are no examples of $(\mu_2\text{-PR}_2)(\mu_2\text{-X})Fe_2Cp_2(CO)_2$. Heating of **6** or **7** in refluxing xylenes resulted in the formation of trace amounts of **8** with Cp_2Fe as the major product, as well as large amounts of intractable green solids. There was no evidence for the intermediacy of $(\mu_2\text{-DBP})(\mu_2\text{-X})Fe_2Cp_2(CO)_2$. Compound **8** can be prepared in 75% yield directly from $Cp_2Fe_2(CO)_4$ and **9**. A mixture of *cis*- and *trans*-**8**, was obtained in a 1:15 ratio. No reaction was observed at temperatures below 80°C and the *cis*/*trans* ratio did not change in the 80–144°C temperature range. There was no *cis* → *trans* or *trans* → *cis* conversion in xylenes as determined by ^1H and ^{31}P NMR of the pure isomers as well as mixtures. The *trans* isomer of **8** was highly symmetric in solution as evident by ^1H and ^{13}C NMR spectroscopy which showed 4 peaks in the aromatic C-H region. In contrast, the *cis*-isomer of **8** showed 8 signals in the ^1H and ^{13}C NMR in the aromatic C-H region. The loss

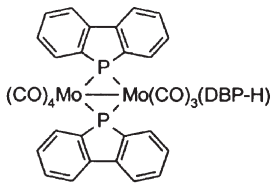
of symmetry is a result of repulsive interactions between the DBP ring systems and the carbonyl ligands (see molecular structure section below) causing the Fe_2P_2 ring to fold. There was no mixing of the hydrogen atom positions as evident by NOESY spectroscopy, which shows no signals due to exchange (0.5 s mixing time).

In complexes **6**–**8** the metal was σ-coordinated by the phosphorus atom of the ligand. There was no involvement of the ligands' π-electrons. This is consistent with the structures of the manganese carbonyl complexes **4** and **5** and in contrast to iron complexes of the fluorenyl ligand ($C_{13}H_9$), where η^6-coordination to the six-membered ring is observed (3*b*, 16). The existence of (η^5-$C_{13}H_9$)FeCp is still controversial and a crystallographic study has not been reported in the literature (3). Compounds **6**–**8** are the first iron complexes of benzannelated phospholyls and to the best of our knowledge the only previous attempt was by Mathey and co-workers (17), who found that reaction between **1** and $FeCl_2$ gave only intractable products.

Molecular structures

A thermal ellipsoid plot of **6** is shown in Fig. 1 (a thermal ellipsoid plot for the cation in **7** has been omitted because it is identical to the cation in **6**). Crystal data and selected interatomic distances and angles of the cations of both compounds are compared in Tables 1 and 2, respectively.



10

The structures are isomorphous and the metric parameters of the cations are almost identical. In each structure, the phosphorus atom is tetrahedrally coordinated with almost equivalent P—Fe interatomic distances (av 2.2904(6) Å for **6** and 2.2955(9) Å for **7**) and P—C (av 1.835(2) Å for **6** and 1.835(3) Å for **7**). The P—Fe distances compare well with those reported for the two known crystal structures of $[(\mu_2\text{-}R_2P)Fe_2Cp_2(CO)_4]^+$ complexes (18, 19). The P—C distances are slightly longer than in the related complexes **4** (av 1.818 (6) Å) (2), **5** (av 1.824(2) Å), and **10** (av 1.79(2) Å) (20). The DBP skeleton is planar and nearly orthogonal to the Fe_2P plane (torsion angle, 88.6°). The cations are skewed with dihedral angles of 76.92(2)° (**6**) and 77.42(2)° (**7**) for the Cp(1)-Fe(1)-Fe(2)-Cp(2) vectors. The Fe(1)-P-Fe(2) angle (124.93(3)° for **6** and 125.41(4)° for **7**) is large in comparison to the M-P-M angles in **4** (102.20(7)°), **5** (102.12(2)°), and **10** (av 76.1(2)°) and is a result of the open

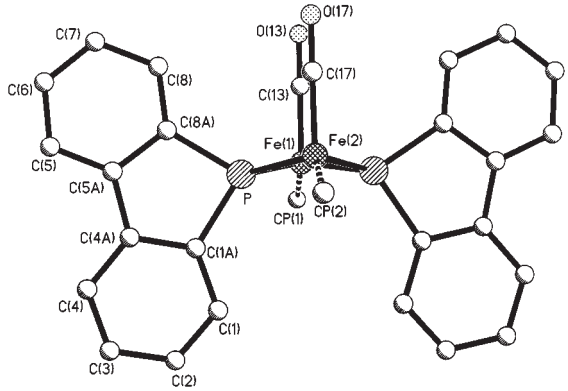
Fig. 3. View of *cis*-**8** showing the folding of the Fe_2P_2 plane. Hydrogen atoms and the cyclopentadienyl rings have been omitted for clarity. Cp(1) and Cp(2) are the centroids of the cyclopentadienyl rings.



M_2P framework. Complexes **4** and **5** consist of M_2PX (X = Br, P) four-membered rings and **9** contains an additional M–M bond; both of these features are missing in **6** and **7**. The Fe···Fe distances are 4.062 Å (**6**) and 4.080 Å (**7**) and there-

© 2002 NRC Canada

fore no direct Fe–Fe interactions are present. The halide anions stack along the *y* axis forming hydrogen bonds, the shortest being 2.912 Å (Br···H(20)) and 2.944 Å (I···H(10)) and there are no additional interionic contacts. Compounds **6** and **7** crystallize as acetone solvates and the solvent molecules are located in channels along the *y* axis. The acetone molecules are hydrogen bonded via the carbonyl oxygen atom (O(26)···H(1) = 2.327 Å for **6** and O(26)···H(8) = 2.456 Å for **7**).

A thermal ellipsoid plot of *cis*-**8** is shown in Fig. 2 and selected interatomic distances and angles are given in Table 3.

Molecules of *cis*-**8** crystallize in the space group $P\text{-}42_1m$ and the $Fe_2(CO)_2$ moiety as well as the centroids of the cyclopentadienyl rings lie on a mirror plane. The phosphorus atom is tetrahedrally coordinated with almost equivalent P—Fe (2.2345(4) Å and 2.2434(4) Å) and P—C (1.8264(16) Å and 1.8253(15) Å) interatomic distances. The P—C distances are shorter than those in complexes **6** and **7**, and are comparable to those in **4** (av 1.818(6) Å) (2), **5** (av 1.824(2) Å) (2), and **10** (av 1.79(2) Å) (20). The four-membered Fe_2P_2 ring displays obtuse angles at the phosphorus atoms (100.576(15)°), which are similar to those in **4** and **5**, and acute angles at the iron centers (77.360(19)°). The Fe···Fe distance is 3.445 Å and therefore no direct Fe–Fe interaction is present. The most intriguing feature of the structure of *cis*-**8** is the orientation of the planar DBP skeleton. Repulsive interactions between the DBP ring system and the carbonyl groups cause a folding of the Fe_2P_2 ring, resulting in a 22.9° angle between the two PFe_2 planes (Fig. 3). The only related structure to *cis*-**8** is that of $(\mu_2\text{-}P(OR)_2)_2Fe_2Cp_2(CO)_2$ ($(OR)_2$ = $OCH_2CMe_2CH_2O$) where a folding of the Fe_2P_2 ring by 18.3° was observed (21). In comparison, the four-membered Mn_2PBr ring in **4** and Mn_2P_2 ring in **5** are planar. The DBP skeleton in *cis*-**8** is almost orthogonal to the Fe_2P planes (torsion angle, 89.6°), which is consistent with the conformation in **4** and **5**. *cis*-**8** crystallizes as a diglyme solvate and the solvent molecules are located in channels along the *z* axis. The diglyme molecules are hydrogen bonded via the peripheral oxygen atoms (O(22)···H(10) = 2.547 Å), each oxygen atom coordinating two molecules of *cis*-**8**. This results in aggregates containing two molecules of *cis*-**8** and one solvent molecule.

Experimental

General

All reactions were carried out under an atmosphere of argon utilizing standard Schlenk techniques. Solvents were dried and distilled according to standard procedures (4). Melting points were measured in open glass capillaries using a Gallenkamp melting point apparatus and were uncorrected. ^1H, ^{13}C, and ^{31}P NMR spectra were recorded on a Varian Unity 400 spectrometer operating at 399.99, 100.6, and 161.31 MHz, respectively. ^1H and ^{13}C spectra were referenced relative to tetramethylsilane and ^{31}P spectra were referenced relative to external triphenylphosphine (δ = –6.0). Electron impact (EI) and fast atom bombardment (FAB) mass spectrometry experiments were performed on a Kratos MS-50 mass spectrometer, with 3-nitrobenzyl alcohol as the FAB matrix and helium as the bombarding gas. Infrared spectra were obtained on a Bruker IFS 25 instrument. Unless otherwise stated, all reagents were obtained from commercial suppliers and used without further purification. $CpFe(CO)_2Br$ (5), $CpFe(CO)_2I$ (6), and bis(1,1′-dibenzophospholyl) (7) were prepared according to literature procedures.

Lithium shavings were obtained from lithium rods (99% under mineral oil). Flash chromatography was carried out using Merck silica gel (330–400 mesh). Elemental analyses were preformed by Galbraith Laboratories, Knoxville, TN.

Preparation of [(μ_2-DBP)$Fe_2Cp_2(CO)_4$]Br (6)

To a solution of 1-phenyldibenzophosphole (0.50 g, 1.9 mmol) in THF (5 cm^3) was added lithium shavings (10-fold excess) and the mixture stirred overnight. The solution was decanted and aluminum trichloride (0.085 g, 0.64 mmol) was added, resulting in a dark brown-red solution (7, 8). The mixture was added dropwise to a solution of $CpFe(CO)_2Br$ (0.99 g, 3.86 mmol) in THF (5 cm^3), producing a dark red solution. Within ten minutes, the solution became yellow-brown and a yellow precipitate formed. The solid was isolated by filtration, washed with hexane, and dried under vacuum to give **6** as a bright yellow solid. Yield: 1.10 g, 1.79 mmol, 93%, mp 184°C (dec.). IR (KBr disk) (cm^{-1}) ν_{CO}: 1978 (m-s), 1988 (m-s), 2026 (m-s), 2040 (m-s). ^1H NMR (acetone-d_6) δ: 8.24 (d, J = 7.6 Hz, 2H), 8.07 (dd, J = 7.6, 7.6 Hz, 2H), 7.65 (m, 2H), 7.60 (m, 2H), 5.30 (s, 10H). ^{13}C NMR (acetone-d_6) δ: 212.33 (*C*O), 212.14 (*C*O), 150.70 (d, $J_{P,C}$ = 27 Hz), 138.84 (d, $J_{P,C}$ = 6 Hz), 131.22, 130.10 (d, $J_{P,C}$ = 14 Hz), 129.64 (d, $J_{P,C}$ = 10 Hz), 123.14 (d, $J_{P,C}$ = 5 Hz). $^{31}P\{^1H\}$NMR ($CDCl_3$) δ: 30. MS-FAB *m*/*z* (%): 608 (0.33) $[C_{34}H_{26}Fe_2P_2]^+$ $[(C_{12}H_8P)_2Fe_2Cp_2]^+$, 366 (12) $[C_{24}H_{16}P_2]^+$ $[(C_{12}H_8P)_2]^+$, 360 (2) $[C_{19}H_{13}FeO_2P]^+$ $[(C_{12}H_8P)FeCp(CO)_2]^+$, 332 (6) $[C_{18}H_{13}FeOP]^+$ $[(C_{12}H_8P)FeCp(CO)]^+$, 304 (43) $[C_{17}H_{13}FeP]^+$ $[(C_{12}H_8P)FeCp]^+$, 248 (8) $[C_{17}H_{13}P]^+$ $[C_{12}H_8PCp]^+$, 183 (45) $[C_{12}H_8P]^+$, 177 (2) $[C_7H_5FeO_2]^+$ $[CpFe(CO)_2]^+$, 128 (4) $[C_{10}H_8]^+$, 121 (42) $[C_5H_5Fe]^+$ $[CpFe]^+$, 65 (18) $[C_5H_5]^+$, 56 (23) $[Fe]^+$.

Preparation of [(μ_2-DBP)$Fe_2Cp_2(CO)_4$]I (7)

In analogy to the preparation of **6**, 1-phenyldibenzophosphole (0.50 g, 1.9 mmol), lithium shavings (10-fold excess), aluminum trichloride (0.085 g, 0.64 mmol), and $Fe(Cp)(CO)_2I$ (1.17 g, 3.85 mmol) gave **7** as a bright yellow solid. Yield: 1.12 g, 1.69 mmol, 87%, mp 208°C (dec.). MS-FAB *m*/*z* (%): 537 (2.5) $[C_{26}H_{18}Fe_2O_4P]^+$ $[(C_{12}H_8P)Fe_2(CO)_4Cp_2]^+$, 481 (1.1) $[C_{24}H_{18}Fe_2O_2P]^+$ $[(C_{12}H_8P)Fe_2(CO)_2Cp_2]^+$, 425 (3) $[C_{22}H_{18}Fe_2P]^+$ $[(C_{12}H_8P)Fe_2Cp_2]^+$, 360 (1.5) $[C_{19}H_{13}FeO_2P]^+$ $[(C_{12}H_8P)FeCp(CO)_2]^+$, 304 (2) $[C_{17}H_{13}FeP]^+$ $[(C_{12}H_8P)FeCp]^+$, 183 (4) $[C_{12}H_8P]^+$, 177 (7) $[C_7H_5FeO_2]^+$ $[CpFe(CO)_2]^+$, 132 (40) $[C_{10}H_{12}]^+$, 128 (12) $[C_{10}H_8]^+$, 121 (7) $[C_5H_5Fe]^+$ $[CpFe]^+$, 85 (47) $[CFeO]^+$ $[Fe(CO)]^+$, 56 (100) $[Fe]^+$. Anal. calcd. for $C_{12}H_8IO_4PFe_2$: C 47.03, H 2.73; found: C 46.85, H 2.88. ^1H, ^{13}C, and ^{31}P NMR and IR data were identical to those reported above for **6**.

Preparation of (μ_2-DBP)$_2Fe_2Cp_2(CO)_2$ (8)

A solution of $Cp_2Fe_2(CO)_4$ (0.29 g, 0.819 mmol) in xylenes (6 cm^3) was added dropwise to a suspension of bis(1,1′-dibenzophospholyl) (0.30 g, 0.819 mmol) in xylenes (7 cm^3) to give a dark red mixture. This was heated to reflux

© 2002 NRC Canada

and within ten minutes the colour of the solution changed to green and a green precipitate formed. After 70 min the dark green mixture was slowly cooled to room temperature. The green precipitate was collected on a sintered funnel, washed with pentane, and dried under reduced pressure to give *trans*-**8** as a green solid. The mother liquor was concentrated to dryness to give a mixture of *trans*- and *cis*-**8**. Flash column chromatography of the mixture using a 2:3 mixture of benzene–pentane gave *cis*-**8** as a green solid. Yield of *trans*-**8**: 0.39 g, 0.581 mmol, 71%, mp 307°C (dec.). IR (KBr disk) (cm^{-1}) ν_{CO}: 1912 (s), 1917 (s). ^1H NMR ($CDCl_3$) δ: 8.72 (d, *J* = 7.6 Hz, 4H), 7.96 (d, *J* = 7.2 Hz, 4H), 7.64 (dd, *J* = 7.8, 7.8 Hz, 4H), 7.52 (dd, *J* = 7.8, 7.8 Hz, 4H), 3.83 (s, 10H). ^{13}C NMR ($CDCl_3$, HMQC) δ: 131, 122, 127, 128, 80. ^{31}P NMR (C_6D_6) δ: –49. MS-EI$^+$ *m*/*z* (%): 664 (46) $[C_{36}H_{26}Fe_2O_2P_2]^+$ $[(C_{12}H_8P)_2Fe_2(CO)_2(C_5H_5)_2]^+$, 636 (13) $[C_{35}H_{26}Fe_2OP_2]^+$ $[(C_{12}H_8P)_2Fe_2(CO)(C_5H_5)_2]^+$, 608 (78) $[C_{34}H_{26}P_2Fe_2]^+$ $[(C_{12}H_8P)_2Fe_2(C_5H_5)_2]^+$, 425 (58) $[C_{22}H_{18}PFe_2]^+$ $[(C_{12}H_8P)Fe_2(C_5H_5)_2]^+$, 366 (73) $[C_{24}H_{16}P_2]^+$ $[(C_{12}H_8P)_2]^+$, 360 (60) $[C_{19}H_{13}FeO_2P]^+$ $[(C_{12}H_8P)Fe(CO)_2Cp]^+$, 304 (72) $[C_{17}H_{13}PFe]^+$ $[(C_{12}H_8P)Fe(C_5H_5)]^+$, 248 (58) $[C_{17}H_{13}P]^+$ $[C_{12}H_8PCp]^+$, 183 (80) $[C_{12}H_8P]^+$, 121 (59) $[C_5H_5Fe]^+$ $[FeCp]^+$, 65 (27) $[C_5H_5]^+$ $[Cp]^+$, 56 (30) $[Fe]^+$, 28 (100) $[CO]^+$. X-ray diffraction experiments

Crystals suitable for diffraction studies were grown from acetone (**6**, **7**) (9) or by vapour diffusion using diglyme–pentane (*cis*-**8**) at –23°C. Single crystals of **6**, **7**, and *cis*-**8** were mounted on thin glass fibers using Paratone-N oil and frozen in the cold nitrogen stream of the goniometer. Data were collected on a Bruker AXS P4/SMART 1000 diffractometer using ω and φ scans with a scan width of 0.3° at 10 s (**6**) and 30 s (**7**, *cis*-**8**) exposure times. A hemisphere of data was collected at a detector distance of 4 cm. Crystal decay was not observed. The data were reduced (SAINT) (10) and corrected for absorption (SADABS) (11). The structures were solved by direct methods and refined by full-matrix least-squares on F^2 (SHELXTL) (12). All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were located and refined isotropically where possible. Hydrogen atoms of the solvent molecule for *cis*-**8** were included in calculated positions and refined using a riding model, while those of the acetone molecules in **6** and **7** were omitted. Crystallographic data are summarized in Table 1 and selected interatomic distances and angles are presented in Tables 2 and 3.[2]

Acknowledgments

Dr. Larry Calhoun (UNB) is thanked for assistance with the NMR experiments and Mr. Gilles Vautour (UNB) for mass spectrometry. We are grateful to the Natural Sciences and Engineering Research Council of Canada (NSERC) and the University of New Brunswick for financial support of this work.

Environmental photodegradation of pyrimidine fungicides — Kinetics of the visible-light-promoted interactions between riboflavin and 2-amino-4-hydroxy-6-methylpyrimidine

E. Haggi, S. Bertolotti, S. Miskoski, F. Amat-Guerri, and N.A. García

Abstract: To clarify the evolution of pyrimidine fungicides under natural aquatic environmental conditions, the visible-light-promoted degradation of the model fungicide 2-amino-4-hydroxy-6-methylpyrimidine (AHMPD) has been studied in air-equilibrated pH 6 aqueous solutions in the presence of riboflavin (Rf), employing time-resolved and stationary kinetic–spectroscopic methods. AHMPD, a compound practically inert towards the attack of singlet molecular oxygen ($O_2(^1\Delta_g)$), quenches excited singlet and triplet states of Rf with rate constants of 2.7×10^9 M^{-1} s^{-1} and 2.7×10^7 M^{-1} s^{-1}, respectively. In the presence of AHMPD, the photodecomposition of Rf, which occurs from the excited triplet state of the pigment, depends on the concentration of the fungicide: at ≥40–50 mM a limited photochemistry occurs due to the quenching of excited singlet Rf, while at ca. 5–10 mM triplet Rf is largely photogenerated and subsequently quenched either by oxygen, giving rise to $O_2(^1\Delta_g)$, or by AHMPD, yielding semireduced Rf through an electron transfer process. Flash photolysis experiments and indirect auxiliary tests confirm the presence of superoxide anion generated by the reaction of Rf anion radical with the dissolved oxygen. The neat result of this intricate scheme of competitive reactions is the photodegradation of both AHMPD and Rf, mainly through a superoxide anion-mediated oxidation, although some contribution of $O_2(^1\Delta_g)$-mediated photooxidations cannot be disregarded.

Key words: photooxidation, pyrimidine derivatives, riboflavin, singlet molecular oxygen, superoxide anion.

Résumé : Dans le but de clarifier l'évolution des fongicides à base de pyrimidine dans les conditions environnementales aquatiques naturelles, on a étudié la dégradation du fongicide modèle 2-amino-4-hydroxy-6-méthylpyrimidine (AHMPD), sous l'influence de la lumière UV–vis, en solutions aqueuses à pH de 6 équilibrées avec l'air, en présence de riboflavine (Rf) et faisant appel à des méthodes spectroscopie résolues dans le temps et de cinétique stationnaire. L'AHMPD, un composé pratiquement inerte vis-à-vis des attaques par l'oxygène moléculaire singulet ($O_2(^1\Delta_g)$), piège les états singulets et triplets excités de la Rf avec des constantes de vitesse de $2{,}7 \times 10^9$ M^{-1} s^{-1} et de $2{,}7 \times 10^7$ M^{-1} s^{-1} respectivement. En présence d'AHMPD, la photodécomposition de la Rf se produit à partir de l'état triplet excité et elle dépend de la concentration du fongicide: à des concentrations ≥ 40–50 mM, la photochimie est limitée en raison du piégeage du singulet excité de la Rf alors que, aux environs de 5–10 mM, la Rf et pratiquement toute photogénérée avant d'être piégée ou par l'oxygène avec formation de $O_2(^1\Delta_g)$ ou par l'AHMPD avec formation de Rf semiréduite par un processus de transfert d'électron. Des expériences de photolyse éclair et des tests auxiliaires indirects confirment la présence de l'anion superoxyde généré par la réaction du radical anion Rf avec l'oxygène dissous. Le résultat net de ce schéma complexe de réactions compétitives est une photogénération à la fois dAHMPD et de Rf, principalement par une oxydation par le superoxyde catalysée par l'anion, même si l'on ne peut pas éliminer complètement des photooxydations catalysées par le $O_2(^1\Delta_g)$.

Mots clés : photooxydation, dérivés de la pyrimidine, riboflavine, oxygène moléculaire singulet, anion superoxyde.

Introduction

Many agricultural chemicals widely present in nature as water and soil contaminants are nitrogen-containing aromatic heterocycles (1), and their thermal and photochemical degradations in water have been topics of growing interest in the last decades (2). Purification of contaminated waters, including the elimination of pathogens, can be cheaply and efficiently carried out by the *lagooning* method, i.e., by the combined action of spontaneous physical, chemical, and bio-

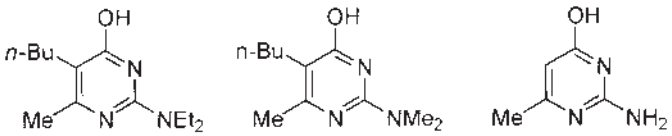
logical processes taken place in lagoons in the presence of oxygen and sunlight (3). In particular, in many cases the photo-induced elimination from the aqueous environment of said *N*-heterocycles has shown to be a potentially applicable procedure, and in some cases the reactions involved have been studied (4). Following this line, in recent papers (5, 6) we have reported the kinetics of the dye-sensitized photooxygenation of several hydroxypyridines, hydroxypyrimidines, and hydroxyquinolines with the basic molecular structures of known *N*-heteroaromatic pesticides (1). The kinetics of the photosensitized oxidation, in aqueous or chloroform solution, of the pyrimidine fungicides ethirimol (5-*n*-butyl-2-diethylamino-4-hydroxy-6-methylpyrimidine), dimethirimol (5-*n*-butyl-2-dimethylamino-4-hydroxy-6-methylpyrimidine), and four analogous pyrimidines, all with structures closely related to that of the model compound 2-amino-4-hydroxy-6-methylpyrimidine (AHMPD), has been previously studied (7, 8).



Ethirimol Dimethirimol AHMPD

In a recent paper (9), we have demonstrated that in the photooxidation of AHMPD in the presence of Rose Bengal — the synthetic xanthene dye most frequently used as a sensitizer (10) — a singlet molecular oxygen-mediated mechanism exclusively operates, with photooxygenation quantum efficiencies ranging from 0.005 in acetonitrile–water (4:1 v/v), to 0.41 in pH 11 water. The reaction sequence, which has been already sufficiently described (4, 11), is depicted in processes [1]–[6], where S is a dye sensitizer responsible for the visible light absorption (RB in the case of ref. (9)), $^1S^*$ and $^3S^*$ are the respective singlet and triplet excited states of S, $O_2(^3\Sigma_g^-)$ is the ground-state molecular oxygen, and $O_2(^1\Delta_g)$ is the singlet molecular oxygen generated by energy transfer from $^3S^*$ to $O_2(^3\Sigma_g^-)$. $O_2(^1\Delta_g)$ can be physically deactivated by collision with solvent molecules (process [4]), or with AHMPD and (or) the sensitizer (process [5]), or can react with the latter compounds giving rise to oxidation products (process [6]). Our results indicated

[1]–[3]

$$S \xrightarrow[[1]]{h\nu} {}^1S^* \xrightarrow[[2]]{} {}^3S^* \xrightarrow[k_{ET}\ [3]]{O_2(^3\Sigma_g^-)} S + O_2(^1\Delta_g)$$

[4] $$O_2(^1\Delta_g) \xrightarrow[k_d]{} O_2(^3\Sigma_g^-)$$

[5] $$O_2(^1\Delta_g) \xrightarrow[k_q]{\text{AHMPD and (or) S}} O_2(^3\Sigma_g^-)$$

[6] $$O_2(^1\Delta_g) \xrightarrow[k_r]{\text{AHMPD and (or) S}} \text{products}-6$$

that the degradation of AHMPD by sensitized photooxidation is efficient only in highly alkaline solutions — a very improbable case in natural waters — and that this procedure could be exclusively applicable in programmed experiments under controlled conditions.

Another more natural alternative route for the photodegradation of water contaminants takes advantage of the presence of some natural dyes in surface waters. In particular, riboflavin (Rf), a well-known natural pigment present in waters of rivers, lakes, and seas (12), has been postulated as a possible sensitizer for the natural photooxidative degradation of some herbicides and related compounds (13–15).

Nevertheless, the role of Rf in the visible-light-promoted decomposition of hydroxy-*N*-heteroaromatic pesticides has been scantily investigated, and only with reference to pyridine derivatives (16, 17), although this information is particularly important for the prediction of the photolysis rates of these contaminants in natural waters. For this reason, the main aim of the present work was to study the behavior of Rf as a sensitizer for the photodecomposition of the model fungicide AHMPD, as well as to gain information on the physical and chemical interactions taking place in this and similar systems.

Experimental

Materials

2-Amino-4-hydroxy-6-methylpyrimidine (AHMPD), 2-aminopyrimidine, 4-hydroxypyrimidine, 6-methylpyrimidine, superoxide dismutase (SOD) from bovine erithrocytes, riboflavin (Rf), Rose Bengal (RB) (all from Sigma), and sodium azide (Aldrich) were employed as received. All irradiated solutions were buffered at pH 6 (NaH_2PO_4–NaOH (18)).

Methods

Static aerobic photolysis of pH 6 aqueous solutions containing AHMPD (either 0.4 to 0.5 mM for the observation of changes in UV spectra or 5 mM for oxygen uptake measurements) and Rf (0.01 to 0.03 mM) or RB (Abs_{560} = 0.4) were carried out in a PTI unit provided with a high pass monochromator and 150 W Xe lamp, irradiating with 440 ± 10 nm (Rf solutions) or 560 ± 10 nm (RB solutions), or in a home-made photolyzer for nonmonochromatic irradiation (150 W quartz halogen lamp). The last photolyzer was only employed in the comparable runs of Rf-sensitized oxygen uptake. In the latter case, a cut-off filter (400 nm) ensured that the light was only absorbed by the sensitizer. The relative rates of oxygen consumption by the system AHMPD–Rf with or without SOD or sodium azide (NaN_3) were obtained from the respective initial slopes of the plots of oxygen consumption vs. irradiation time, under comparable experimental conditions. A specific oxygen electrode (Orion 97–08) was employed. The rates of Rf photodecomposition in nitrogen-saturated solutions, either in the presence or in the absence of AHMPD, were roughly evaluated by the absorbance decrease at 445 nm for a given irradiation time. The stationary quenching of the Rf fluorescence (absorbance at 440 nm = 0.1) was studied with a RF 5301-PC Shimadzu spectrofluorimeter at 25 ± 1°C in air-equilibrated solutions. Fluorescence lifetimes were measured with a time-correlated single photon counting technique on an Edinburgh FL-

© 2002 NRC Canada

9000CD instrument. In both cases, excitation and emission wavelengths were 445 and 515 nm, respectively. Ground-state absorption spectra were registered in a Hewlett-Packard 8452A diode array spectrophotometer.

Nitrogen-saturated aqueous solutions of Rf (0.01 mM) were photolyzed using a flash photolysis apparatus. A ns Nd:YAG laser system (Spectron) at 355 nm was the excitation source, employing a 150 W xenon lamp as analyzing light. The detection system comprised a PTI monochromator and a red-extended photomultiplier (Hamamatsu R666). The signal, acquired and averaged by a digital osciloscope (Hewlett-Packard 54504A), was transferred to a PC via a HPIB parallel interface, where it was analysed and stored.

Results

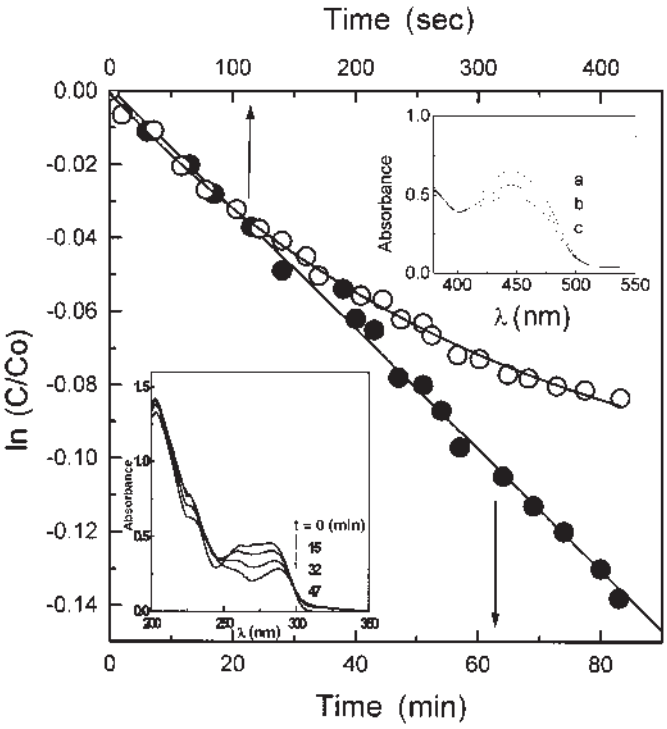
Rf-sensitized photooxygenation of AHMPD

The irradiation of the system AHMPD – Rf – oxygen (air) – pH 6 water with light of wavelength higher than 400 nm — a spectral region in which AHMPD is transparent — produced changes in the UV–vis absorption spectrum of the mixture (Fig. 1, lower inset) that indicate chemical changes in both the pyrimidine and the dye, with simultaneous oxygen consumption. Although the existence of photodegradation pathways that do not consume oxygen cannot be excluded, these processes must not be important, because the irradiation, under comparable conditions, of deoxygenated solutions of AHMPD and Rf produces practically undetectable spectral changes in the 200–300 nm range, where AHMPD absorbs. The same is true for air-saturated solutions of the related compounds 2-aminopyrimidine, 4-hidroxypyrimidine, and 6-methylpyrimidine.

For comparative purposes, 1 mM AHMPD water solutions were irradiated in parallel experiments employing Rf or RB as sensitizers, and the respective rates of oxygen uptake were measured. It is known that with RB as sensitizer an exclusive $O_2(^1\Delta g)$-mediated mechanism operates, with a quantum efficiency of 0.01 in water (9), and, as expected, the first-order plot for oxygen uptake is linear (Fig. 1, main). To the contrary, a similar graphical representation for the experiment with Rf showed a neat curvature (Fig. 1, main), indicating that the Rf-sensitized photooxidation of AHMPD cannot be interpreted through an exclusive $O_2(^1\Delta_g)$-mediated pathway, as with RB, and that other interactions between ground-state AHMPD and ground- and (or) excited (singlet or triplet)-state Rf could also be operative. In addition, the Rf photodegradation rate observed in the irradiation of a nitrogen-saturated water solution of Rf (0.02 mM) in the absence of AHMPD was higher than that found in the presence of 1 mM AHMPD (Fig. 1, upper inset).

Oxygen consumption was observed in the irradiation of the system AHMPD (5 mM) – Rf (absorbance at 445 nm: 0.5) – oxygen – water (relative rate = 1). Under comparable conditions, the rate of oxygen uptake in the former system was greatly reduced in the following cases (Fig. 2): (*i*) irradiating in the presence of 10 μg mL^{-1} of SOD, an enzyme that behaves as a quencher of superoxide anion ($O_2^{\cdot-}$)-mediated photooxidations when used in similar concentrations (19–22) (relative rate = 0.78); (*ii*) irradiating in the presence of 1 mM sodium azide, a well known selective physical quencher of $O_2(^1\Delta g)$ (4) (relative rate = 0.41); and (*iii*) irradiating the system AHMPD–Rf but with a concentration of AHMPD of 40 mM or higher (relative rate for 40 mM AHMPD = 0.61). No oxygen uptake was detected when 5 mM AHMPD was replaced by similar concentrations of 2-aminopyrimidine, 4-hydroxypyrimidine, or 6-methylpyrimidine.

Fig. 1. First-order plots for oxygen uptake upon visible-light irradiation of pH 6 aqueous solutions containing: (●) RB (Abs. at 560 nm = 0.47) plus AHMPD 5 mM, and (○) Rf (Abs. at 445 nm = 0.52) plus AHMPD 0.5 mM. Lower inset: spectral changes upon Rf-sensitized photoirradiation of the mixture Rf (0.02 mM) – AHMPD (0.5 mM) in pH 6 water; numbers on the spectra represent irradiation times in min. Upper inset: absorption spectra of Rf (0.02 mM) in nitrogen-saturated solutions: (*a*) non-photolyzed; (*b*) photolyzed 7 min in the presence of 1 mM AHMPD; (*c*) photolized 7 min (for details see *Experimental section*).



Ground-state association between AHMPD and Rf was not observed by absorption spectroscopy. The difference spectra in the 380–600 nm range, obtained by subtraction of the spectrum of 0.02 mM Rf from those of mixtures 0.02 mM Rf + up to 10 mM AHMPD, were identical to those of the corresponding AHMPD solutions.

Results indicate the operation of a complex mechanism that possibly includes specific interactions of AHMPD with singlet (^{1}Rf*) and triplet (^{3}Rf*) excited states of Rf, represented by processes [7] and [8].

[7] $^1Rf^* + AHMPD \xrightarrow{^1k_q} Rf + AHMPD$ (or products−7)

Fig. 2. Rates of oxygen uptake upon irradiation of air-equilibrated pH 6 aqueous solutions containing Rf (0.02 mM) and: (*a*) AHMPD (5 mM); (*b*) AHMPD (5 mM) and SOD (10 μg mL^{-1}); (*c*) AHMPD (40 mM); and (*d*) AHMPD (5 mM) and NaN_3 (1 mM). Each set of points represents the mean value of four runs.

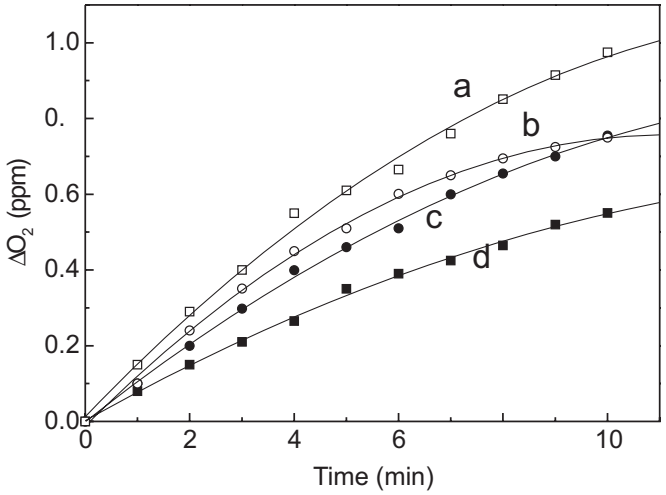

Fig. 3. Transient absorption spectra of Rf (0.01 mM) in argon-saturated aqueous solution, in the absence (●) and in the presence (□) of AHMPD (8 mM) taken at 1 and 20 μs after the laser pulse, respectively. Inset: Stern–Volmer plots for the quenching of ^{3}Rf* (argon-saturated solution) (○) and ^{1}Rf* (air-equilibrated solution) (●) by AHMPD.

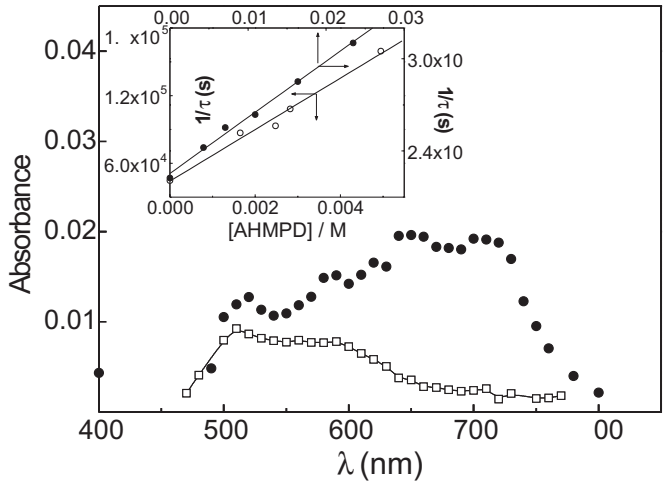

AHMPD ≥ 10 mM produces a detectable quenching of the Rf fluorescence, as determined by either static- or time-resolved fluorescence measurements. Monitoring the fluorescence intensity of Rf in the absence (I_o) and in the presence (I) of different AHMPD concentrations, the classical Stern–Volmer treatment ($I_o/I = 1 + {}^1K_{SV}$ [AHMPD]) allows the determination of the Stern–Volmer constant ($^1K_{SV}$ = 12.5 M^{-1}), which is equal to the ratio $^1k_q/^1k_d$, where ^1k_d is the rate constant for thermal deactivation of ^{1}Rf* (process [9]). Time-resolved experiments yielded a ^1k_d value of 1.9 × 10^8 s^{-1}, corresponding to a Rf fluorescence lifetime in water ($^1\tau_o$) of 5.2 ns, in excellent agreement with reported values (24). Consequently, a ^1k_q value of 2.4 × 10^9 M^{-1} s^{-1} is deduced.

[9] $$^1Rf^* \xrightarrow{^1k_d} Rf$$

On the other hand, ^1k_q values (process [7]) can also be graphically calculated through Stern–Volmer treatment ($1/^1\tau = 1/^1\tau_o + {}^1k_q$ [AHMPD]) by evaluation of the respective $^1\tau$ values in the presence of different concentrations of AHMPD (Fig. 3, inset). The value so-determined (^1k_q = 2.7 × 10^9 M^{-1} s^{-1}) is practically the same, within an estimated error of ±10%, as that obtained by the static fluorescence measurements.

Quenching of ^{3}Rf*

The photodegradation of Rf in water, in the absence of oxygen and under visible light irradiation, predominantly proceeds through the triplet state (25). In our case, ^{3}Rf* was generated by a 355-nm laser pulse, and the ^{3}Rf* disappearance was monitored from the first-order decay of the absorbance at 670 nm, a zone where the interference from other possible species is negligible. ^{3}Rf* lifetime was neatly reduced by the presence of AHMPD. The triplet decay was measured at low Rf concentration (typical 0.02 mM) and at low enough laser energy, to avoid self-quenching and triplet–triplet annihilation effects, respectively. Employing the expression $1/^3\tau = (1/^3\tau_o) + {}^3k_q$ [AHMPD] (where $^3\tau_o$ and $^3\tau$ are the experimentally determined lifetimes of ^{3}Rf* in the absence and in the presence of AHMPD, respectively), a value for the bimolecular rate constant ^3k_q of 2.7 × 10^7 M^{-1} s^{-1} was obtained (process [8], Fig. 3, inset).

The transient absorption spectrum of the Rf solution 1 μs after the laser pulse (Fig. 3, main, upper trace) has been already reported for ^{3}Rf* (17, 26–29). The shape of the spectrum obtained in the presence of 8 mM AHMPD (Fig. 3, main, lower trace) was similar to that already reported (17, 30) to account for electron transfer processes to ^{3}Rf* from different electron-donor substrates of environmental and biological relevance (5, 17, 28, 29, 31), with the concomitant generation of the well-known anion radical $Rf^{\cdot -}$ (28, 29, 32, 33) (process [10]). The radical cation $AHMPD^{\cdot +}$ that simultaneously appears was not detected, likely due to its absorption in a different wavelength range than the observed one, or to its very short lifetime.

[10] $$^3Rf^* + AHMPD \xrightarrow{k_{10}} Rf^{\cdot -} + AHMPD^{\cdot +}$$

Discussion

It is known that many aromatic compounds form relatively stable dark complexes with Rf (34–36). In the case of the system AHMPD–Rf, no ground-state interactions could be detected by absorption spectroscopy. Besides, the excellent concordance between the values of the rate constant ^1k_q obtained for AHMPD by both static-nd time-resolved experiments on the quenching of the fluorescence of Rf (2.4 × 10^9 M^{-1} s^{-1} and 2.7 × 10^9 M^{-1} s^{-1}, respectively) corroborates the absence of said interactions.

The spectral changes in Fig. 1 reveal that the Rf-sensitized aerobic irradiation of 0.4 mM AHMPD produces chemical transformations. Additionally, oxygen uptake experiments (Fig. 2) indicate the participation in the photoprocesses of

© 2002 NRC Canada

reactive oxygen species generated directly or indirectly by ^{1}Rf* and (or) ^{3}Rf*. In spite of the high value of the rate constant for the interaction ^{1}Rf*–AHMPD (^1k_q, process [7]) — close to the diffusion limit — relatively high concentrations of AHMPD are necessary to prevent triplet state population (75 mM, to quench 50% ^{1}Rf*, process [7]).

The competitive pathways represented by processes [3] (and, subsequently, [5] and [6]) and [8] are generated from ^{3}Rf* (37, 38). While processes [5] and [8] can be merely physical events, process [6] can involve the consumption of both Rf and AHMPD. The predominance of a given process will depend on the competition between O_2 and AHMPD for the quenching of ^{3}Rf*. It is known that the quenching of ^{3}Rf* by O_2 occurs with a rate constant $k_{(11)}$ of 9×10^8 M^{-1} s^{-1} (39). Nevertheless, in kinetic terms, and taking into account that the reported quantum yield values for the generation from ^{3}Rf* of $O_2(^1\Delta_g)$ (process [3], with S = Rf) and $O_2^{\cdot-}$ (process [11]) are 0.49 and 0.009, respectively (40), the direct generation of $O_2^{\cdot-}$ by electron transfer from ^{3}Rf* to O_2 can be considered negligible.

$$[11] \quad {}^3\mathrm{Rf}^* + \mathrm{O}_2 \xrightarrow[k_{(11)}]{} \mathrm{Rf}^{\cdot+} + \mathrm{O}_2^{\cdot-}$$

^{3}Rf* is quenched by AHMPD with a global ^3k_q value of 2.7×10^7 M^{-1} s^{-1} (process [8]). As suggested by laser flash photolysis experiments, process [10] would yield the radical anion $Rf^{\cdot-}$. Process [10] does not occur when AHMPD is replaced by 2-aminopyrimidine, 4-hydroxypyrimidine, or 6-methylpyrimidine, as judged by the absence of spectral (UV) perturbations and oxygen consumption in the respective runs. This fact could be a consequence of the enhanced electron donating ability of AHMPD due to the simultaneous presence of amino, hydroxy, and methyl groups in the aromatic ring. Under aerobic conditions, process [10], with [AHMPD] = 5–10 mM, could compete with the generation of $O_2(^1\Delta_g)$ (process [3]). Consequently, under air-saturated conditions, i.e., with a concentration of dissolved oxygen approximately equals to 0.26 mM (41), $O_2^{\cdot-}$ could be formed by electron transfer from $Rf^{\cdot-}$ to O_2 (process [12]). Indirect evidence in support of the participation of $O_2^{\cdot-}$ in the photooxidation of AHMPD was provided by the SOD inhibition of the oxygen uptake (Fig. 2, line b), as well as by the already commented results from flash photolysis experiments.

$$[12] \quad \mathrm{Rf}^{\cdot-} + \mathrm{O}_2 \xrightarrow[k_{(12)}]{} \mathrm{Rf} + \mathrm{O}_2^{\cdot-}$$

$$[13] \quad \mathrm{O}_2^{\cdot-} + \mathrm{AHMPD} \xrightarrow[k_{(13)}]{} \mathrm{products}\text{–}13$$

A rate constant value of 1.4×10^8 M^{-1} s^{-1} has been recently reported (29) for the generation of $O_2^{\cdot-}$ from $Rf^{\cdot-}$ (process [12]), a reaction that at the same time regenerates ground-state Rf. It is well known that $O_2^{\cdot-}$ is a key intermediate in the oxygen redox chemistry of a number of biological and organic substrates (42). Taken into account the former discussion, the oxygen consumption in the Rf-sensitized photooxidation of AHMPD can be explained through an $O_2^{\cdot-}$-mediated mechanism.

As we have demonstrated before (9), AHMPD hardly reacts with $O_2(^1\Delta_g)$ generated with RB as a sensitizer. Hence, the inhibitory effect on the oxygen uptake observed in the irradiation of the system AHMPD–Rf–O_2–NaN_3 (Fig. 2, line d) possibly obeys the known quenching of ^{3}Rf* by the azide anion (29), and (or) the quenching of the photooxidation of Rf via $O_2(^1\Delta_g)$ (process [6], with S = Rf), for which a rate constant k_{rRf} of 6×10^7 M^{-1} s^{-1} has been reported (4).

The species $Rf^{\cdot-}$ could also be generated from ^{1}Rf, especially under relatively high concentrations of AHMPD. The semireduction of Rf from its singlet state has been previously proposed to explain the Rf-photoinitiated vinyl polymerization (28), and the interaction of Rf chromophore radical (from flavin mononucleotide) with ascorbic acid (43). In our case, the lack of photoproducts from this possible pathway, and the decrease of oxygen consumption at high AHMPD concentrations (Fig. 2, line c), could be explained by the existence of a fast back electron transfer reaction in the pair of radical ions so-generated, especially in water, as already suggested by other authors (28, 30).

Concluding remarks

Rf-sensitized irradiation of water solutions of AHMPD produces chemical transformations in both Rf and AHMPD. In air-saturated solution a nonsimple scheme of competitive processes operates, involving triplet Rf. Under sensitizing conditions, i.e., with Rf concentration in the range of 0.02 mM, the photodegradation of the dye and (or) AHMPD depends on the concentration of AHMPD. At AHMPD concentrations ≥ 40 mM, the massive quenching of excited singlet Rf dominates, preventing in practice the whole photoprocess. At AHMPD concentrations ≤ 5–10 mM, excited triplet Rf is formed and, then, is quenched by either oxygen or AHMPD, yielding $O_2(^1\Delta_g)$ and semireduced Rf ($Rf^{\cdot-}$), respectively. Subsequently, $O_2^{\cdot-}$ can be produced from the reaction of $Rf^{\cdot-}$ with dissolved oxygen and, as a result, both AHMPD and Rf are photodegraded. AHMPD disappears mainly by oxygenation. In the absence of oxygen, Rf photodegradation is favored because its regeneration via $O_2^{\cdot-}$ production is precluded.

Finally, it can be said that, in the context of the Rf-sensitized fate of water-soluble contaminants under natural environmental conditions, AHMPD-type compounds are degradable through a photooxidative event.

Monte-Carlo calculation of the primary yields of H_2O_2 in the $^1H^+$, $^2H^+$, $^4He^{2+}$, $^7Li^{3+}$, and $^{12}C^{6+}$ radiolysis of liquid water at 25 and 300°C

Jintana Meesungnoen, Jean-Paul Jay-Gerin, Abdelali Filali-Mouhim, and Samlee Mankhetkorn

Abstract: Monte-Carlo simulations are used to calculate the primary yield of hydrogen peroxide ($G_{H_2O_2}$) of the radiolysis of pure, deaerated liquid water as a function of linear energy transfer (LET) of the incident radiation over the range ~0.3–100 keV μm^{-1}, at 25 and 300°C. The radiations include $^1H^+$, $^2H^+$, $^4He^{2+}$, $^7Li^{3+}$, and $^{12}C^{6+}$ ions with energies from 0.17 MeV to 3.6 GeV. At 25°C, it is found that our $G_{H_2O_2}$ values, calculated with protons of different initial energies, show a monotonic increase as a function of LET, in agreement with the commonly assumed expectation of an increase in molecular yields with increasing LET. Our calculated H_2O_2 yields at 300°C increase significantly faster with LET than do their corresponding 25°C values, showing that the temperature dependence of $G_{H_2O_2}$ at higher LET is less than for low-LET radiation. We also report our results on the temporal variations of the H_2O_2 yields, in the interval ~$1 \times 10^{-13} - 1 \times 10^{-6}$ s, at 25 and 300°C and for the different types of radiation considered. Finally, we find that for incident ions of equal LET > 10 keV μm^{-1}, $G_{H_2O_2}$ decreases as the ion velocity increases, from protons (or deuterons) to carbon ions. These differences produced in $G_{H_2O_2}$ by changing the type of radiation are explained by the greater mean energy of secondary electrons from the higher velocity ions, which penetrate to a greater average distance from the actual particle track, with a corresponding decrease in molecular yields. Our calculated $G_{H_2O_2}$ values compare generally well with the experimental data available from the literature and are also in good accord with the predictions of deterministic diffusion-kinetic model calculations reported earlier.

Key words: liquid water, radiolysis, primary yields, hydrogen peroxide (H_2O_2), linear energy transfer (LET), accelerated protons and heavy ions, temperature, Monte-Carlo simulations.

Résumé : À l'aide des méthodes de simulation Monte-Carlo, nous calculons le rendement primaire de peroxyde d'hydrogène ($G_{H_2O_2}$) produit lors de la radiolyse de l'eau pure désaérée en fonction du transfert d'énergie linéique (TEL) du rayonnement incident, dans la gamme ~0,3–100 keV μm^{-1}, à 25 et 300°C. Les rayonnements ici utilisés sont les ions $^1H^+$, $^2H^+$, $^4He^{2+}$, $^7Li^{3+}$ et $^{12}C^{6+}$ accélérés à des énergies allant de 0,17 MeV à 3,6 GeV. À 25°C, nous trouvons que les valeurs de $G_{H_2O_2}$, calculées pour des protons incidents de différentes énergies initiales, croissent de façon monotone en fonction du TEL, en accord avec ce que l'on attend en général, à savoir que les rendements des produits moléculaires augmentent avec le TEL. Les rendements calculés en H_2O_2 à 300°C augmentent notablement plus vite avec le TEL que leurs valeurs correspondantes à 25°C, montrant qu'à TEL plus élevé la dépendance en température de $G_{H_2O_2}$ est moindre que pour des rayonnements à faible TEL. Nous rapportons aussi les résultats concernant les variations temporelles des rendements de H_2O_2, dans l'intervalle ~$1 \times 10^{-13} - 1 \times 10^{-6}$ s, à 25 et 300°C et pour les divers types de rayonnements étudiés. Nous trouvons enfin que, pour des ions incidents d'égal TEL > 10 keV μm^{-1}, $G_{H_2O_2}$ décroît lorsque la vitesse de l'ion augmente, en passant des protons (ou deutérons) aux ions carbone. Ces différences produites dans $G_{H_2O_2}$ en changeant le type de rayonnement sont expliquées par la plus grande énergie moyenne des électrons secondaires éjectés par les ions de plus haute vitesse, qui pénétrent ainsi, en moyenne, à une plus grande distance de la trajectoire de la particule incidente, entraînant une diminution concomitante des rendements moléculaires. Nos valeurs calculées de $G_{H_2O_2}$ se comparent en général bien avec les données expérimentales disponibles dans la littérature et sont également en bon accord avec les prédictions de calculs modèles diffusionnels déterministes présentés antérieurement.

Mots clés : eau liquide, radiolyse, rendements primaires, peroxyde d'hydrogène (H_2O_2), transfert d'énergie linéique (TEL), protons et ions lourds accélérés, température, simulations Monte-Carlo.

Introduction

The radiolysis of pure deaerated liquid water by low-LET (linear energy transfer, or energy loss per unit track length) radiation (such as ^{60}Co γ-rays, high-energy X-rays, or accelerated electrons) leads principally to the formation of the free radicals and molecular products e^-_{aq}, H·, ·OH, H_2, H_2O_2, and H_3O^+ (for reviews, see refs. 1 and 2). Under usual irradiation conditions, these species are generated nonhomogeneously in widely separated regions of high ionization and excitation densities, commonly referred to as "spurs," along the radiation's path. The so-called "primary" radical and molecular yields (or "escape" yields) $G_{e^-_{aq}}$, $G_{H\cdot}$, $G_{\cdot OH}$, G_{H_2}, and $G_{H_2O_2}$ represent the numbers of species of each kind formed per 100 eV of absorbed energy that remain after spur expansion owing to diffusion. At room temperature, this spur expansion is essentially complete on the time scale of ~1×10^{-6} s after the initial energy deposition. At this time, the species that have escaped from spur reactions are distributed homogeneously throughout the bulk of the solution and available to react with added solutes at moderate concentrations.

For ^{60}Co γ radiation at neutral pH and 25°C (average LET ~0.3 keV μm^{-1}), the normally accepted values of the primary yields (expressed in units of molec./100 eV, molec. = molecules)[3] are the following (1–5):

$$G_{e^-_{aq}} = 2.65 \quad G_{H\cdot} = 0.60 \quad G_{H_2} = 0.45$$

$$G_{\cdot OH} = 2.80 \quad G_{H_2O_2} = 0.68 \quad G_{-H_2O} = 4.15,$$

where G_{-H_2O} denotes, at this stage, the corresponding yield of water molecules decomposed.

A key phenomenon in the radiolysis of water and aqueous solutions is the variation of these primary yields with the type (or LET) of the incident radiation (for example, see refs. 1, 2, and 6–14). With increasing LET, the isolated "spherical" (on the average) spurs of low-LET radiation are formed increasingly closer together and eventually coalesce to form continuous columns of species consisting of a cylindrical track "core" surrounded by a "penumbra" (15, 16). Under those conditions, more free radicals are formed in close proximity with a correspondingly increased probability of reacting with one another to produce the molecular products or to reform water. The radical yields are therefore expected to diminish as the LET increases, whereas the molecular yields increase and the net water decomposition yield decreases. As an exception to this rule, hydroperoxyl ($HO_2\cdot$, or its deprotonated form $O_2^{\cdot-}$, pK_a = 4.8) radicals are produced as primary species, under high-LET irradiation, in yields substantially higher (increasing, typically, from ~0.06 to 0.2 molec./100 eV over an LET range of ~100–650 keV μm^{-1}) (9, 13, 17–21) than the tiny yield observed in low-LET radiolysis (~0.02 molec./100 eV at ~0.3 keV μm^{-1}) (22). Let us also mention the peculiar behavior of $G_{H\cdot}$, which first increases with increasing LET, going from 0.6 molec./ 100 eV at ~0.3 keV μm^{-1} to a maximum of ~0.68 molec./100 eV near 6.5 keV μm^{-1}, and then decreases steeply at higher LET (23).

Hydrogen peroxide is the main oxidizing molecular product in water radiolysis. Because of its high escape yields and its reactivity, H_2O_2 is of great importance in fields such as nuclear engineering (13) and radiation biology (5, 24). Measurements of $G_{H_2O_2}$ by different investigators in water at neutral pH and ambient temperature as a function of LET have been compiled recently by McCracken et al. (13), Meesungnoen et al. (25),[4] and Pastina and LaVerne (26). These latter authors (26) also determined radiation chemical yields of hydrogen peroxide in water at pH 6.5 using protons, helium ions, and carbon ions at energies of a few to 30 MeV. There is a large amount of scatter in the H_2O_2 yields for all LET values above ~5 keV μm^{-1} (13, 25, 26). This uncertainty becomes even greater when temperature effects are considered because H_2O_2 is unstable at elevated temperature, and there is only a relatively small amount of experimental data available for high-LET radiation (12, 13, 27–29). Up to now, the influence of both the LET and temperature on the radiation chemistry of water has been modeled by deterministic (30) and Monte-Carlo (23, 31) calculations over the temperature range 25–300°C. To gain further insights into the effects of varying LET and temperature on the H_2O_2 yield, we performed in the present study Monte-Carlo simulations of the radiolysis of neat, deaerated liquid water to calculate the variations of $G_{H_2O_2}$ with LET, using different types of radiation ($^1H^+$, $^2H^+$, $^4He^{2+}$, $^7Li^{3+}$, and $^{12}C^{6+}$ ions) up to ~100 keV μm^{-1}, at 25 and 300°C. The results were tested against the available experimental data and compared with deterministic diffusion-kinetic modeling calculations reported earlier.

Monte-Carlo simulations

A full description of our Monte-Carlo modeling of the radiolysis of liquid water at ambient temperature has been given elsewhere (32–35). In brief, the energy deposition by the incident radiation (accelerated protons or heavier ions) and by all the secondary electrons that it generates occurs through the slowing down of those particles via a variety of inelastic scattering processes, including ionization, electronic and (or) vibrational excitation of single water molecules, and excitation of plasmon-type collective modes ("physical stage"). The species created during the physical stage reorganize rapidly and produce the "initial" radical and molecular products of the radiolysis, distributed in a highly nonhomogeneous track structure ("physicochemical stage"). The computer codes that we used to cover these two stages are TRACPRO and TRACELE (33). The complex spatial distribution of reactants at ~1×10^{-13} s, which is provided as an output of the program TRACELE, is then used directly as the starting point for the so-called "stage of nonhomogeneous chemistry." This third and final stage, during which the various radiolytic species diffuse and react with one another until all spur and (or) track reactions are complete, was covered by our TRACIRT simulation code (32, 34, 35), using the "independent reaction times" (IRT) method (36) to model the nonhomogeneous reaction kinet-

[3]These units for the radiation chemical yields are used throughout in this paper. For conversion into SI units: 1 molec./100 eV ≈ 1.0364 × 10^{-7} mol J^{-1}.

[4]In the LET range ~0.3–6.5 keV μm^{-1}.

© 2002 NRC Canada

ics.[5] The calculations were performed by simulating short (~5–100 μm) particle track segments, over which the LET remains essentially constant. Typically, ~5000 to 140 000 reactive chemical species are generated in those simulated track segments (depending on the LET), thus ensuring only small statistical fluctuations in the determination of average yields.

As for the calculation of $G_{H_2O_2}$ at 300°C, we used an extended version of our Monte-Carlo computer code, which had recently been developed to include the effects of high temperature on water radiolysis (31, 38). In this version, the thermalization distances (r_{th}) of subexcitation electrons[6] (42, 43) are assumed to decrease linearly with increasing temperature by a factor of 2 between 25 and 300°C (38). This choice was shown to offer the best agreement of the calculated yields $G_{e^-_{aq}}$ and G_{H_2} with experimental data at elevated temperature in the case of low-LET radiation (38). Physically, such a decrease in r_{th} as the temperature increases could be linked to an increase in the scattering cross sections of subexcitation electrons that would account for the corresponding loss of structural order in liquid water owing to the increasing breaking of hydrogen bonds with temperature. Moreover, in accordance with our previous Monte-Carlo calculations (23, 31, 38), $G_{H_2O_2}$ at 300°C was computed at 1×10^{-7} s (rather than 1×10^{-6} s at 25°C) after irradiation, which is the time at which conventional homogeneous chemistry takes over at this temperature.

For incident protons, the influence of the LET on $G_{H_2O_2}$ was investigated at 25 and 300°C over the ranges ~0.3–70 and ~0.25–50 keV μm^{-1}, respectively, by varying the proton energy between ~300 and 0.17 MeV (25). To reproduce the effects of ^{60}Co γ-radiolysis, we used ~300-MeV protons whose average LET value obtained in the simulations was ~0.3 keV μm^{-1}. The effect of LET on $G_{H_2O_2}$ at 25°C was determined for the different radiation types considered by varying the incident particle energy from ~300 to 0.17 MeV/nucleon (~0.3–70 keV μm^{-1}) for $^2H^+$, ~300 to 1.10 MeV/nucleon (~1.3–99 keV μm^{-1}) for $^4He^{2+}$, ~300 to 3.22 MeV/nucleon (~2.9–100 keV μm^{-1}) for $^7Li^{3+}$, and ~300 to 19 MeV/nucleon (~11.6–99 keV μm^{-1}) for $^{12}C^{6+}$. The corresponding average LET values of these various particles over the energy ranges covered were in good agreement with the data reported by Watt (44) and the recommendations of ICRU 49 (45) for liquid water (of density 1 g cm^{-3}).

Results and discussion

Figures 1 and 2 display our calculated values of $G_{H_2O_2}$ as a function of LET for pure, deaerated liquid water, using incident protons as the primary particles, at 25 and 300°C, obtained at homogeneity at 1×10^{-6} and 1×10^{-7} s, respectively. Available experimental data at both temperatures (3, 13, 17, 26, 29, 46–52) are also included in the figures for the sake of comparison. At ~300°C, it should be noted that the only literature data with which a direct comparison can be made are those of Elliot et al. (3) and of Kent and Sims (50) for ^{60}Co γ-rays, and of Sims and co-workers (29) for proton energies in the range 1.2–5.9 MeV. At ambient temperature, our computed $G_{H_2O_2}$ values increase continuously by about 0.44 molec./100 eV from ~0.3 to 70 keV μm^{-1} (Fig. 1; see also Fig. 2*d* of ref. 25).[7] As can be seen from Fig. 2, at 300°C, $G_{H_2O_2}$ is first nearly invariant (at ~0.35 molec./100 eV) with increasing LET from ~0.25 to 2 keV μm^{-1}, and then increases significantly faster than do its corresponding 25°C values (up to ~1.11 molec./100 eV at 50 keV μm^{-1}), showing that the temperature dependence of $G_{H_2O_2}$ is less at higher LET than for low-LET radiation. This result is expected considering the overlapping of the individual spurs along the main particle track as the LET increases, with a resultant increase in the combination of the intervening radical species and hence, in the H_2O_2 yields. Owing to the cylindrical nature of the track structure at high LET, a relatively high portion of these radicals will not escape because as they diffuse along the axis of the track their decay reactions, which are not diffusion controlled for the most part, will be less inhibited by an increase in temperature than those for the isolated spherical spurs of low-LET radiation (12, 27, 30, 31). Despite the relatively large scatter associated with the high-LET $G_{H_2O_2}$ data, the results of our proton track simulations compare well with experiment over the whole LET range studied. In particular, the experimental values of $G_{H_2O_2}$ for ^{60}Co γ-irradiated water at 25 and 300°C (3, 17, 26, 46–49) are well reproduced by our calculated H_2O_2 escape yields for ~300 MeV incident protons; a result that follows from the fact that high-energy protons produce tracks of (on average) isolated spurs, which are very much like those produced by fast electrons in γ radiolysis (14, 25, 26, 33, 34). From Figs. 1 and 2, it should also be noted that our computed $G_{H_2O_2}$ values are quantitatively consistent with the predictions of the deterministic diffusion-kinetic model calculations of Swiatla-Wojcik and Buxton (30) for both 25 and 300°C. Our $G_{H_2O_2}$ results at 25°C are equally close to those calculated by Burns and Sims (17) using the Schwarz diffusion model (47, 53), but they show a monotonic increase in the LET range studied contrary to these authors who found a slight maximum in $G_{H_2O_2}$ around 55–80 keV μm^{-1} (Fig. 1).

These variations of $G_{H_2O_2}$ with LET at 25 and 300°C do not arise from changes in the initial (at ~1×10^{-13} s) yields of hydrogen peroxide, which are essentially constant over the whole LET range covered (see Fig. 3), but rather from the reactions that contribute to the formation or decay of this species in the nonhomogeneous chemical stage. To gain further insights into the origin of the LET dependence of $G_{H_2O_2}$, it is thus of interest to examine the unfolding of the various reactions involving H_2O_2 in the radiation spurs and (or) tracks as they expand by diffusion. This can readily be done with our Monte-Carlo simulations, which enable us to determine quantitatively the LET dependence of each reac-

[5]The IRT simulation methodology has the advantage over deterministic modeling calculations in that, instead of using the "typical, average spur" concept, it correctly incorporates reactants from the same ionization in their actual nonhomogeneous spatial distribution (30, 37).

[6]Subexcitation electrons are those that have kinetic energies less than the first electronic excitation threshold of the medium (~7.3 eV in liquid water) (2, 39–41).

[7]With increasing temperature from 25 to 300°C, it is known that $G_{H_2O_2}$ decreases almost linearly at low LET (see, for example, refs. 3, 27, and 38).

Fig. 1. Variation of the primary hydrogen peroxide yield ($G_{H_2O_2}$) (in molec./100 eV) of the radiolysis of liquid water at 25°C as a function of LET over the range ~0.3–70 keV μm^{-1}. The solid curve represents the results of our Monte-Carlo simulations, using protons as incident particles, obtained at homogeneity at 1 × 10^{-6} s (see text). Experiment: ^{60}Co γ-rays ((+) refs. 3 and 46, (▼) ref. 17, (□) ref. 26, (Δ) ref. 47, (▲) refs. 48 and 49, (●) ref. 50); protons ((★) ref. 17, (■) ref. 26, (▹) ref. 29, (◆) ref. 47, (○) ref. 51, (◇) ref. 52). Absorbed dose-average LET values used for protons are taken from refs. 13, 17, 26, and 44. The dotted line is a least-squares fit to the bulk of H_2O_2 yield data for different investigators at room temperature obtained by McCracken et al. (13) and taken by these authors as being representative of "track-escape" yields for H_2O_2. Comparison is also made with the predictions of the deterministic diffusion-kinetic model calculations of Swiatla-Wojcik and Buxton (30) at 25°C (–◂–) and with the values calculated by Burns and Sims (17) using the Schwarz diffusion model (–•–). Note that a comparison of the results of our proton track simulations at 25°C with the available experimental H_2O_2 yields over the LET range ~0.3–6.5 keV μm^{-1} has been presented previously in Fig. 2*d* of ref. 25.

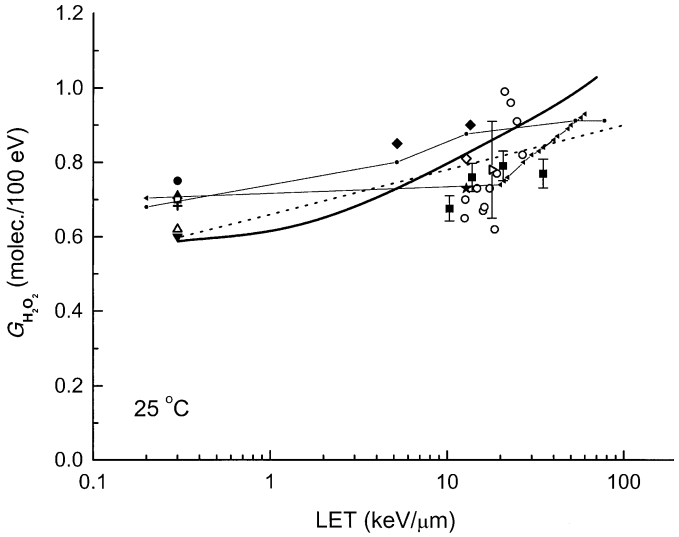

Fig. 2. Variation of the primary hydrogen peroxide yield ($G_{H_2O_2}$) (in molec./100 eV) of the radiolysis of liquid water at 300°C as a function of LET over the range ~0.25–50 keV μm^{-1}. The solid curve represents the results of our Monte-Carlo simulations, using protons as incident particles, obtained at homogeneity at 1 × 10^{-7} s (see text). Experimental data are from Elliot et al. (3) (×) and Kent and Sims (at 270°C) (50) (●) for ^{60}Co γ-rays, and from Sims and co-workers (29) for protons of energies 5.9 MeV (~14.3 keV μm^{-1}) (at 250°C), 2.6 MeV (~23.3 keV μm^{-1}) (at 250°C), and 1 MeV (~34.5 keV μm^{-1}) (at 280°C, extrapolated yield) (▹). Absorbed dose-average LET values used here for protons are taken from refs. 44 and 45. Comparison is also made with the H_2O_2 yield values predicted from the deterministic diffusion-kinetic model calculations of Swiatla-Wojcik and Buxton (ref. 30) at 300°C (–▸–).

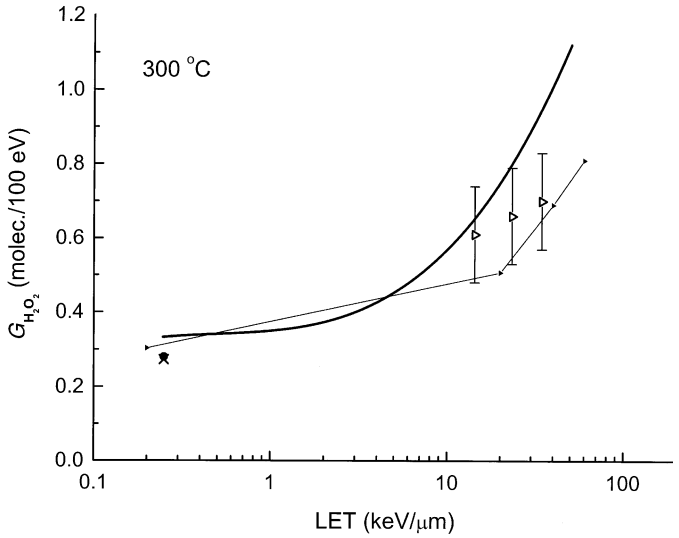

tion. At both 25 and 300°C, the four most important reactions (denoted [R1]–[R4]) that are involved in the primary yield of H_2O_2 in irradiated, deaerated liquid water over the LET range studied, are the following:[8]

[8]For a detailed description of the full reaction scheme considered in our simulations, see refs. 31, 34, and 38.

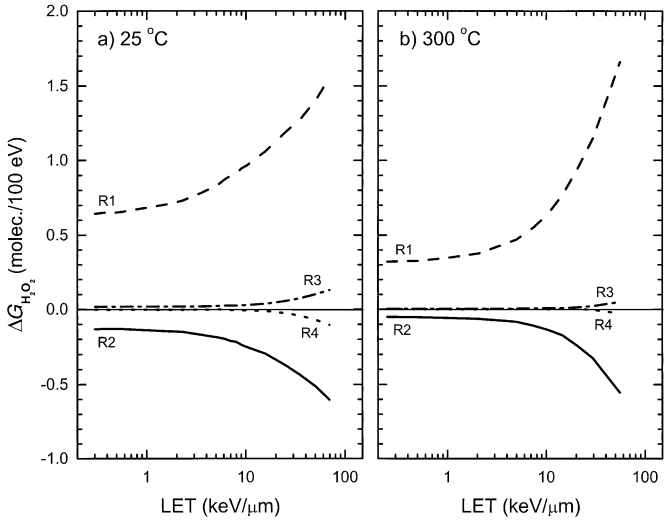
[R4] $H_2O_2 + OH^- \rightarrow HO_2^- + H_2O$

$HO_2^- + H_2O \rightarrow H_2O_2 + OH^-$

Figure 4 compares, at the two temperatures considered, the effect of increasing LET on the extent (expressed as a cumulative $\Delta G_{H_2O_2}$ value) of each of these reactions over the time interval of nonhomogeneous spur chemistry, using protons of different initial energies as incident particles. As one can see in the figure, in the whole LET range covered, hydrogen peroxide is formed mainly by the rxn. [R1] of the ·OH radical with itself, whereas its decay is dominated by rxn. [R2]. At 25°C (Fig. 4*a*), the extent of rxn. [R1] slightly increases as a function of LET in the range ~0.3–2 keV μm^{-1}, and rises much more steeply at higher LET. Rather similarly, the contribution of rxn. [R2] to the removal of H_2O_2 is nearly constant below ~2 keV μm^{-1}, and shows a marked increase,

Fig. 4. Influence of the LET on the extents $\Delta G_{H_2O_2}$ (in molec./100 eV) of the main intra-spur and (or) track rxns. [R1]–[R4] that contribute to the formation and decay of H_2O_2 (see text) in our Monte-Carlo simulations of the radiolysis of liquid water by protons of different initial energies between ~300 and 0.17 MeV: (*a*) at 25°C, over the LET range ~0.3–70 keV μm^{-1} and in the time interval $1 \times 10^{-13} - 1 \times 10^{-6}$ s; and (*b*) at 300°C, over the LET range ~0.25–50 keV μm^{-1} and in the time interval $1 \times 10^{-13} - 1 \times 10^{-7}$ s.



in magnitude, at higher LET, though this increase remains less than about half the corresponding yield variation $\Delta G_{H_2O_2}$ due to rxn. [R1]. As for rxns. [R3] and [R4], our simulation results show that their extents are very small, except at LET values above ~20 keV μm^{-1} where they start to increase somewhat. The overall effect at 25°C is an increase in the hydrogen peroxide yields with increasing LET as shown in Fig. 1. Upon increasing temperature from 25 to 300°C (Fig. 4*b*), the fractions of H_2O_2 either formed by rxn. [R1] or removed by the back rxn. [R2] are decreased by about 50% in the low-LET range (~0.25–2 keV μm^{-1}) (31, 38, 55). Such a decrease can be explained by the fact that these reactions are partially diffusion controlled with rate constants that vary less with temperature than the diffusion in water of the individual species involved (27, 38). At high LET, however, the extents of rxns. [R1] and [R2] show little changes compared to their corresponding values at 25°C, a result attributed to the cylindrical nature of the track structure geometry for which both of these reactions are less inhibited by an increase in temperature (see above). As for the contributions of rxns. [R3] and [R4], they can be regarded at 300°C as negligible over the entire LET range studied ($\Delta G_{H_2O_2}$ = 0.05 and –0.03 molec./100 eV at ~50 keV μm^{-1}, respectively) (Fig. 4*b*). The net effect of LET on $G_{H_2O_2}$ at 300°C is shown in Fig. 2.

Figure 3 shows the influence of LET on the time-dependent H_2O_2 yields at 25 and 300°C, over the range $1 \times 10^{-13} - 1 \times 10^{-6}$ s, obtained from our simulations with protons of various initial energies in the range ~300–0.17 MeV. At 25°C, for LET below approximately 30 keV μm^{-1}, the H_2O_2 yield increases gradually with time to a nearly constant value at ~1×10^{-6} s (Fig. 3*a*). In contrast, above ~30 keV μm^{-1}, the yield of H_2O_2 begins to rise steeply with

Fig. 5. Variations of the primary H_2O_2 yield ($G_{H_2O_2}$) (in molec./100 eV), at 1×10^{-6} s, of the radiolysis of liquid water at 25°C as a function of LET for different types of radiation up to ~100 keV μm^{-1} (see text). The different simulated results are shown as the following lines: (—) protons (or $^2H^+$), (– –) $^4He^{2+}$, (- -) $^7Li^{3+}$, (– - –) $^{12}C^{6+}$. Experiment: $^2H^+$ ((◆) ref. 9, (●) ref. 12), $^4He^{2+}$ ((◇) ref. 9, (Δ) ref. 17, (□) ref. 26, (○) ref. 47, (▽) ref. 51), $^7Li^{3+}$ ((×) ref. 12). Absorbed dose-average LET values used for the various radiations considered are taken from refs. 13, 26, 44, and 47.

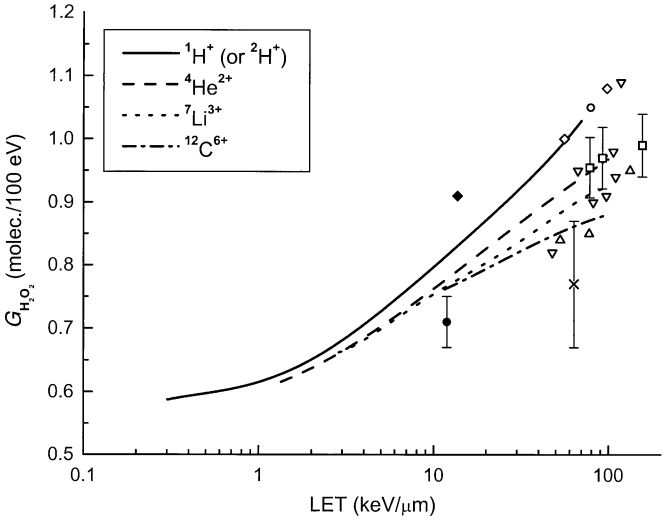

Fig. 6. Time dependences of the H_2O_2 yields (in molec./100 eV) calculated from our Monte-Carlo simulations of the radiolysis of liquid water at 25°C, in the time scale of $1 \times 10^{-13} - 1 \times 10^{-6}$ s, for different types of incident radiation, including $^1H^+$, $^2H^+$, $^4He^{2+}$, $^7Li^{3+}$, and $^{12}C^{6+}$ ions, at the same LET (~30 keV μm^{-1}).

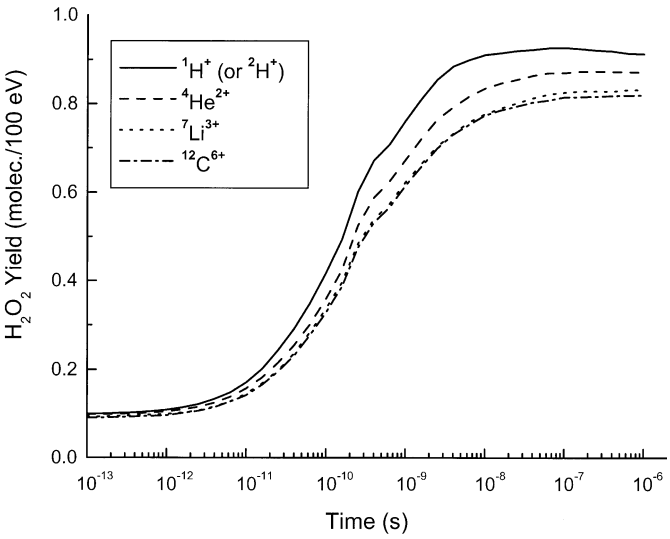

time, then passes through a maximum around 1–10 ns and falls slightly to a plateau region at longer time. These variations in the temporal dependences of the hydrogen peroxide yield mainly reflect, in the LET range studied, the interplay intervening between the time- and LET-dependent spur rxns. [R1] and [R2], which respectively generate and remove H_2O_2. As can also be seen in Fig. 3*a*, our simulation results are in good agreement with the H_2O_2 yields calculated previously by Pimblott and LaVerne (54) using the inverse Laplace transform of best fit to experimental ·OH scavenger data at neutral pH. At 300°C, the calculated time dependence of the H_2O_2 yield at low LET qualitatively resembles that obtained at 25°C (Fig. 3*b*). However, with increasing LET, the maximum observed at 25°C in the 1–10 ns time domain is no longer present at 300°C. In fact, at this latter temperature, the yield of H_2O_2 increases monotonically as a function of time and seems to continue to increase above ~1×10^{-6} s. At present, unfortunately, there are no systematic literature data with which to compare our results on the temporal variation of the H_2O_2 yield at elevated temperatures.

The variations of $G_{H_2O_2}$ as a function of LET for different radiation types up to ~100 keV μm^{-1}, at 25°C, are shown in Fig. 5. These radiations include protons, $^2H^+$, $^4He^{2+}$, $^7Li^{3+}$, and $^{12}C^{6+}$ ions, and their corresponding incident energy and LET ranges are given above. Our calculated $G_{H_2O_2}$ values using protons are identical to those using deuterons of the same LET (or the same velocity), which is in agreement with the experimental observation that protons of energy E and deuterons of energy $2E$ give similar radiation chemical yields (14, 51, 56). Below ~10 keV μm^{-1}, the behavior of $G_{H_2O_2}$ depends very little on the type of radiation. This is expected, since in this region of low LET the track of a charged particle consists, as seen above, of a random succession of spatially isolated spurs, and the observed chemistry of such a particle should therefore be much like that of a fast proton (11, 14). As can be seen in Fig. 5, for incident ions of equal LET > 10 keV μm^{-1}, $G_{H_2O_2}$ decreases as the ion velocity increases, from protons (or deuterons) to carbon ions.[9] This irradiating-ion dependence of the yields of hydrogen peroxide at a given LET is also shown in Fig. 6, which compares the temporal variations of the H_2O_2 yields at 25°C, over the range $1 \times 10^{-13} - 1 \times 10^{-6}$ s, obtained from our simulations using the different incident ions studied here with an equal LET of ~30 keV μm^{-1}. Such results indicate, as it has been frequently noted (for example, see refs. 2, 7, 11, 14, and 59), that LET does not uniquely determine the correct radiation chemical effects of particle track structures. This is explained by the greater mean energy of secondary electrons (the so-called low-LET "short" and "branch" tracks in the terminology of Mozumder and Magee (60), or

[9]For kinetic energies of ions small compared to their rest-mass energy, the nonrelativistic Bethe stopping power equation (57) is well approximated by (in SI units):

$$-\frac{dE}{dx} = \left(\frac{1}{4\pi\varepsilon_0}\right)^2 \frac{4\pi z^2 e^4}{m_0 V^2} NZ \ln\left(\frac{2m_0 V^2}{I}\right)$$

where ze is the charge on the incident ion, V is the ion velocity, m_0 is the rest mass of an electron, NZ is the number of electrons per m^3 of the absorbing medium, and I is the mean excitation and ionization potential of the bound electrons in the absorber (for liquid water, I = 79.7 ± 0.5 eV, see ref. 58). It follows from this equation that for two different ions of equal LET, the one with the higher charge will have the higher velocity (11, 14).

© 2002 NRC Canada

"δ-rays") from the higher velocity ion, which will penetrate to a greater average distance from the main particle track, and lead to a greater dispersion of the initial radical positions around the track (61). In other words, the actual mean initial volume density of free radicals formed in the track will be lower. Under these conditions, a greater fraction of those radicals will be allowed to escape recombination as they subsequently diffuse with consequent tendency for increase in the radical yields measured after track expansion along with decreased molecular product yields (11, 23, 61). As can be seen from Fig. 5, the results of our simulated H_2O_2 escape yields compare generally well with available experimental data. The agreement is remarkably good with the recent experimental $G_{H_2O_2}$ values of Pastina and LaVerne (26) for 5-, 15- and 20-MeV $^4He^{2+}$ ions. As for the temporal variations in the H_2O_2 yields shown in Fig. 6 for protons, $^2H^+$, $^4He^{2+}$, $^7Li^{3+}$, and $^{12}C^{6+}$ ions of the same LET (~30 keV μm^{-1}), there are no literature data with which a direct comparison of our results can be made.

Conclusion

In this paper, we have presented Monte-Carlo simulations of the radiolysis of pure, deaerated liquid water at neutral pH to calculate the variations of the primary yield of hydrogen peroxide with the LET of incident protons over the ranges ~0.3–70 keV μm^{-1} and ~0.25–50 keV μm^{-1} at 25 and 300°C, respectively, and of different radiation types, including $^2H^+$, $^4He^{2+}$, $^7Li^{3+}$, and $^{12}C^{6+}$ ions, up to ~100 keV μm^{-1} at 25°C. The results show that, at both temperatures, $G_{H_2O_2}$ increases monotonically as a function of LET. This increase, which is mainly due to a greater combination of the ·OH radicals formed by the decomposition of water molecules, is significantly faster at 300°C, showing that the effect of temperature at higher LET is less than for low-LET radiation. We also find that, above ~10 keV μm^{-1}, the H_2O_2 yields depend on the type of the irradiating ions. At a given LET, $G_{H_2O_2}$ decreases as the ion velocity increases, from protons to carbon ions, clearly indicating that LET does not uniquely determine the correct radiation chemical effects of particle track structures. Our calculated $G_{H_2O_2}$ values compare generally well with the available experimental data and are also in good accord with the predictions of deterministic diffusion model calculations reported previously.

Acknowledgment

We thank Professor Jay A. LaVerne (University of Notre Dame) for sending us the experimental hydrogen peroxide yield values for protons, helium ions, and carbon ions reported in ref. 26. We also thank Dr. Howard E. Sims (AEA Technology, Harwell, U.K.) for making refs. 29 and 52 available to us. Financial support from the Canadian Institutes of Health Research (Grant No. MT-14617) is gratefully acknowledged.

Synthesis of a hexasaccharide fragment of the capsular polysaccharide of *Streptococcus pneumoniae* type 3

Dirk J. Lefeber, Eneko Aldaba Arévalo, Johannis P. Kamerling, and Johannes F.G. Vliegenthart

Abstract: In the framework of the development of a new generation of neoglycoconjugate vaccines against *Streptococcus pneumoniae*, the synthesis is described of a spacer-containing hexasaccharide fragment related to the capsular polysaccharide of *S. pneumoniae* type 3. Hexasaccharide β-D-Glc*p*A-(1→4)-β-D-Glc*p*-(1→3)-β-D-Glc*p*A-(1→4)-β-D-Glc*p*-(1→3)-β-D-Glc*p*A-(1→4)-β-D-Glc*p*-(1→O-$(CH_2)_3NH_2$) (**1**), comprised of three repeating units, was synthesized via a blockwise strategy employing suitably protected disaccharide building blocks. Carboxylic groups were introduced by selective oxidation with TEMPO (2,2,6,6-tetramethyl-1-piperidinyloxy) in the last reaction steps. Deprotection afforded target hexasaccharide **1**.

Key words: oligosaccharide synthesis, *Streptococcus pneumoniae* type 3, TEMPO oxidation.

Résumé : Dans le cadre du développement d'une nouvelle génération de vaccins néoglycoconjugués actifs contre le *Streptococcus pneumoniae* et faisant appel à une stratégie de synthèse par blocs à l'aide de disaccharides protégés de façon appropriée, on a réalisé la synthèse d'un fragment hexasaccharidique apparenté au polysaccharide capsulaire du *S. pneumoniae* de type 3 et contenant un espaceur, soit le β-D-Glc*p*A-(1→4)-β-D-Glc*p*-(1→3)-β-D-Glc*p*A-(1→4)-β-D-Glc*p*-(1→3)-β-D-Glc*p*A-(1→4)-β-D-Glc*p*-(1→O-$(CH_2)_3NH_2$) (**1**) qui trois motifs. Les groupes carboxyliques ont été introduits en procédant à une oxydation sélective à l'aide de TEMPO (2,2,6,6-tétraméthyl-1-pipéridinyloxy) dans les dernières étapes réactionnelles. La déprotection fournit l'hexasaccharide recherché, **1**.

Mots clés : synthèse d'oligosaccharide, *Streptococcus pneumoniae* de type 3, oxydation par TEMPO.

[Traduit par la Rédaction]

Introduction

Diseases caused by encapsulated bacteria can be prevented by vaccination with neoglycoconjugate vaccines as proven for *Haemophilus influenzae* type b (1), *Neisseria meningitidis* type C (2), and *Streptococcus pneumoniae* serotypes (3). These vaccines are prepared by conjugation of an isolated polysaccharide or a mixture of polysaccharide-derived oligosaccharides to a protein carrier. For a detailed investigation of the immune response to these types of vaccines, neoglycoproteins with a well-defined carbohydrate structure need to be available.

Neoglycoconjugates related to *S. pneumoniae* type 3 have been prepared by coupling di-, tri-, or tetrasaccharide fragments in several carbohydrate–protein ratios to a nontoxic mutant of diphtheria toxin (CRM_{197}) (4). While immunization experiments with these conjugates in mice showed that increasing IgG antibody titres were found with increasing oligosaccharide chain length, no difference was found with respect to the oligosaccharide loading (5).

The use of conjugates that contain larger oligosaccharide fragments than in the study described above might lead to an improved immunogenicity. Furthermore, human antibodies can better recognize larger epitopes on the polysaccharide than do animal antibodies, as shown for neoglycoproteins consisting of synthetic oligosaccharides related to the capsular polysaccharide of *S. pneumoniae* type 23F (6). For these reasons, a program was started for the synthesis of a *S. pneumoniae* type 3 related hexasaccharide fragment (**1**), comprised of three cellobiuronic acid repeating units (Fig. 1).

Received 13 July 2001. Published on the NRC Research Press Web site at http://canjchem.nrc.ca on 21 January 2002.

Results and discussion

The synthesis for tetrasaccharide acceptor **11** was previously described (4). Two disaccharide donors (**6** and **10**, Scheme 1) were tested for the ability to couple with **11** to afford protected hexasaccharide **12** (Scheme 2).

For the synthesis of disaccharide thioethyl donor **6**, first monosaccharide acceptor **4** was prepared by debenzylidenation of **2** (7) using trifluoroacetic acid (→**3**, 88%) and subsequent selective benzoylation using benzoyl chloride

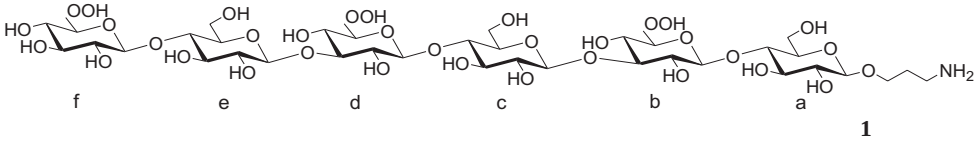
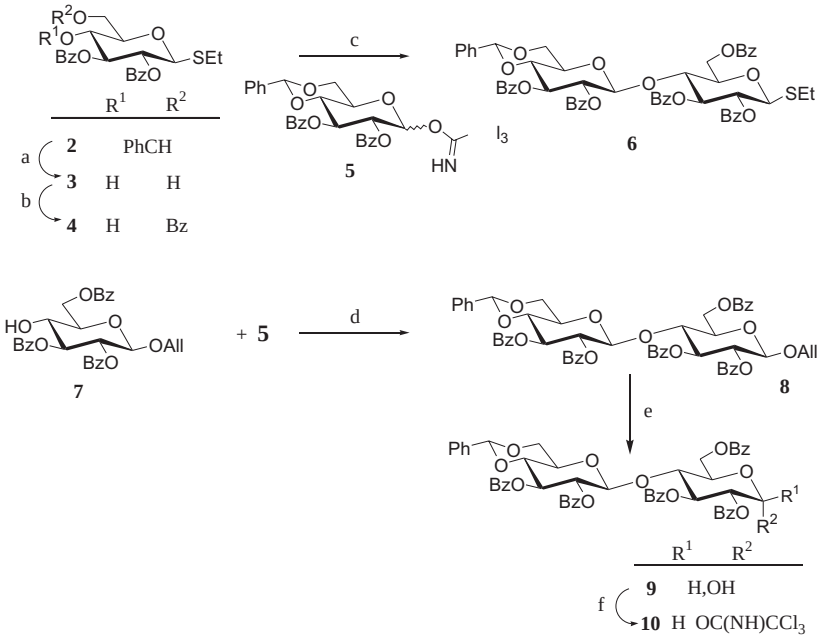
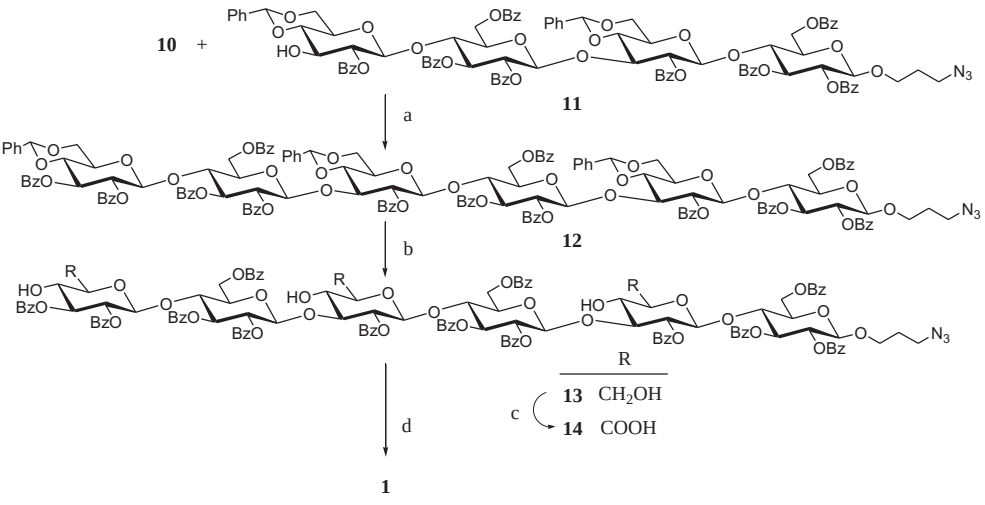
Fig. 1. Target hexasaccharide **1** comprising three repeating units of the capsular polysaccharide of *S. pneumoniae* type 3.



Scheme 1. Synthesis of disaccharide donors **6** and **10**. Reagents and conditions: (*a*) CF_3COOH, H_2O, CH_2Cl_2, 88%; (*b*) PhCOCl, Et_3N, CH_2Cl_2, 50%; (*c*) 10% TMSOTf, CH_2Cl_2, 75%; (*d*) 11% TMSOTf, CH_2Cl_2, 83%; (*e*) (*i*) $(PPh_3)_3Rh(I)Cl$, DABCO, $CH_3C_6H_5$–EtOH–CH_2Cl_2 (10:5:1), (*ii*) NIS, H_2O, THF, 68%; (*f*) Cl_3CCN, DBU, CH_2Cl_2, 86%.



Scheme 2. Synthesis of hexasaccharide **1**. Reagents and conditions: (*a*) 10% TMSOTf, CH_2Cl_2, 63%; (*b*) CF_3COOH, H_2O, CH_2Cl_2, 75%; (*c*) TEMPO, aqueous NaOCl, KBr, Bu_4NBr, aqueous NaCl, aqueous $NaHCO_3$, CH_2Cl_2, 70%; (*d*) (*i*) NaOMe, MeOH (pH 10), (*ii*) $NaBH_4$, 10% Pd/C, 0.05 M NaOH, 61%.



(→**4**, 50%). Coupling of **4** with imidate donor **5** (4) using 10% TMSOTf as a promoter gave **6** in a yield of 75%. For the synthesis of disaccharide imidate donor **10**, first **8** was prepared in 83% yield by coupling of acceptor **7** (4) and donor **5** with 11% TMSOTf as a promoter. Then, deallylation of **8** using tris(triphenylphosphine)rhodium(I) chloride and *N*-iodosuccinimide (→**9**, 68%) and subsequent trichloroacetimidation gave **10** (86%).

For the preparation of protected hexasaccharide **12** (Scheme 2), tetrasaccharide acceptor **11** (4) was coupled

Note: The signals for the 3-aminopropyl spacer are: δ = 4.05 and 3.83 ($OCH_2CH_2CH_2NH_2$), 3.16 ($OCH_2CH_2CH_2NH_2$), 2.01 ($OCH_2CH_2CH_2NH_2$). $J_{1,2}$ couplings are presented in parentheses.

[a]n.d. = not determined.

with donor **6** using *N*-iodosuccinimide and triflic acid as a promoter system. Low yields of product (<8%) were obtained when the reaction was performed at 0°C or lower temperatures. Hexasaccharide **12** could, however, be obtained in a yield of 63% by coupling **11** with disaccharide imidate donor **10** using 10% TMSOTf as a promoter at room temperature. After debenzylidenation of **12** using trifluoroacetic acid (→**13**, 75%), the free primary hydroxyl functions were oxidized. Treatment of **13** with TEMPO and sodium hypochlorite (8) was found to be efficient for the oxidation of the three primary hydroxyl groups in the presence of secondary functions, and **14** was obtained in 70% yield. ^{1}H NMR analysis after methylation with diazomethane showed three singlets at δ = 3.39, 3.30, and 3.23 ($COOCH_3$). Debenzoylation of **14** with sodium methoxide and reduction of the azide using sodium borohydride and 10% Pd/C afforded target hexasaccharide **1** in 61% yield. The identity of the compound was established by ^{1}H NMR spectroscopy (Table 1) and mass spectrometry.

In conclusion, a versatile synthetic route was developed using a block wise strategy for the preparation of hexasaccharide fragment **1**, representing three repeating units of the capsular polysaccharide of *S. pneumoniae* type 3. The carboxylic acids were efficiently introduced by selective oxidation using TEMPO.

Experimental section

General

All chemicals were of reagent grade and were used without any further purification. Reactions were monitored by TLC on Silica gel 60 F254 (Merck); compounds were visualized, after examination under UV light, by heating with 10% (v/v) ethanolic H_2SO_4, orcinol (2 mg mL^{-1}) in 20% (v/v) methanolic H_2SO_4, or ninhydrin (1.5 mg mL^{-1}) in BuOH–H_2O–HOAc (38:1.75:0.25). In the work-up procedures of the reaction mixtures, the organic solutions were washed with appropriate amounts of the indicated aqueous solutions, then dried ($MgSO_4$), and concentrated under reduced pressure at 20–40°C on a water bath. Column chromatography was performed on Silica gel 60 (Merck, 0.063–0.200 mm). Optical rotations were measured in $CHCl_3$, unless stated otherwise, with a PerkinElmer 241 polarimeter, using a 10 cm, l mL cell. ^{1}H NMR spectra in $CDCl_3$ were recorded at 27°C with a Bruker AC 300 spectrometer; the δ values are given in ppm relative to the signal for internal Me_4Si (δ = 0). ^{13}C (APT, 75 MHz) NMR spectra in $CDCl_3$ were recorded at 27°C with a Bruker AC 300 spectrometer; indicated ppm values for δ are relative to the signal of $CDCl_3$ (δ = 76.9). The ^{1}H NMR spectrum of **1** was recorded in D_2O at 32°C with a Bruker AMX 500 spectrometer, and the δ values are given in ppm relative to the signal for internal acetone (δ = 2.225). Two-dimensional TOCSY and ROESY spectra were recorded using a Bruker AMX 500 apparatus (500 MHz) to assign the spectra of compounds **1**, **12**, **13**, and **14**. Residues *a–f* (Fig. 1) were assigned on the basis of interglycosidic ROESY cross-peaks. Matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) spectra were obtained on a Voyager-DE™ mass spectrometer using 2,4-dihydroxybenzoic acid (DHB) in H_2O as a matrix. Elemental analyses were carried out by H. Kolbe Mikroanalytisches Laboratorium (Mülheim an der Ruhr, Germany).

*Ethyl 2,3-di-*O*-benzoyl-1-thio*-β-D-*glucopyranoside (3)*

To a solution of ethyl 2,3-di-*O*-benzoyl-4,6-*O*-benzylidene-1-thio-β-D-glucopyranoside (**2**) (7) (1.37 g, 2.63 mmol) in CH_2Cl_2 (36 mL) were added CF_3COOH (1.5 mL) and H_2O (0.2 mL). The mixture was stirred for 16 h, diluted with CH_2Cl_2, washed with 10% (w/v) aqueous $NaHCO_3$ until neutral pH and 10% (w/v) aqueous NaCl, and the organic layer was dried, filtered, and concentrated. The residue was purified by column chromatography (CH_2Cl_2–MeOH, 98:2) to obtain **3** (1.0 g, 88%). $[\alpha]_D^{20}$ +76 (*c* = 1). R_f = 0.05 (CH_2Cl_2–EtOAc, 9:1). ^{1}H NMR ($CDCl_3$) δ: 7.97–7.93 and 7.53–7.34 (2m, 10H, 2*Ph*CO), 4.74 (d, $J_{1,2}$ = 9.8 Hz, 1H, H-1), 2.76–2.73 (m, 2H, SCH_2CH_3), 1.26 (t, 3H, SCH_2CH_3). ^{13}C NMR ($CDCl_3$) δ: 167.4 and 165.2 (2Ph*C*O); 129.1 and 128.7 (2*Ph*CO, quaternary C); 83.6 (C-1); 79.9, 78.2, 70.1, and 69.9 (C-2–C-5); 62.3 (C-6); 24.3 (SCH_2CH_3); 14.8 (SCH_2CH_3). Anal. calcd. for $C_{22}H_{24}O_7S$ (432.4): C 61.11, H 5.59; found C 60.99, H 5.74.

*Ethyl 2,3,6-tri-*O*-benzoyl-1-thio*-β-D-*glucopyranoside (4)*

To a solution of **3** (0.95 g, 2.2 mmol) in CH_2Cl_2 (50 mL) and Et_3N (0.37 mL) at 0°C was added dropwise a solution of benzoyl chloride (0.27 mL, 2.3 mmol) in CH_2Cl_2 (10 mL). After stirring for 24 h, the mixture was diluted with CH_2Cl_2, washed with 10% (w/v) aqueous NaCl, and the organic layer was dried, filtered, and concentrated. The crude residue was purified by column chromatography (CH_2Cl_2–EtOAc, 95:5) to give **4** (0.6 g, 50%). $[\alpha]_D^{20}$ +60 (*c* = 1). R_f = 0.51 (CH_2Cl_2–EtOAc, 9:1). ^{1}H NMR ($CDCl_3$) δ: 8.05–7.91 and 7.46–7.28 (2m, 15H, 3*Ph*CO), 5.60 and 5.47 (2t, each 1H, H-2,3), 4.82 (d, $J_{1,2}$ = 9.9 Hz, 1H, H-1), 2.82–2.64 (m, 2H, SCH_2CH_3), 1.24 (t, 3H, SCH_2CH_3). ^{13}C NMR ($CDCl_3$) δ: 166.8, 166.7, and 165.2 (3Ph*C*O); 83.4 (C-1); 78.2, 77.2, 70.2, and 69.3 (C-2–C-5); 63.6 (C-6); 24.1 (SCH_2CH_3); 14.8 (SCH_2CH_3). Anal. calcd. for $C_{29}H_{28}O_8S$ (536.5): C 64.92, H 5.26; found C 65.05, H 5.31.

*Ethyl (2,3-di-*O*-benzoyl-4,6-*O*-benzylidene-*β-D-*glucopyranosyl)-(1→4)-2,3,6-tri-*O*-benzoyl-1-thio*-β-D-*glucopyranoside (6)*

A solution of **4** (50 mg, 0.09 mmol) and 2,3-di-*O*-benzoyl-4,6-*O*-benzylidene-D-glucopyranosyl trichloroacetimidate **5** (4) (87 mg, 0.14 mmol) in dry CH_2Cl_2 (2 mL), containing 4 Å molecular sieves, was stirred under Ar for 1 h. Then, TMSOTf (2.5 μL, 14 μmol) was added. After 30 min, the

© 2002 NRC Canada

mixture was neutralized with dry pyridine, filtered over cotton, diluted with CH_2Cl_2, and washed with 10% (w/v) aqueous NaCl. The organic layer was dried, filtered, and concentrated. The residue was purified by column chromatography (toluene–EtOAc, 95:5) to obtain **6** (67 mg, 75%). $[\alpha]_D^{20}$ +41 (*c* = 1). R_f = 0.76 (CH_2Cl_2–EtOAc, 9:1). ^{1}H NMR ($CDCl_3$) δ: 8.05–7.85 and 7.49–7.31 (2m, 30H, *Ph*CH, 5*Ph*CO), 5.74 and 5.61 (2t, $J_{1,2}$ = 9.9 Hz, each 1H, H-2,3), 5.44 (dd, $J_{1',2'}$ = 7.7, $J_{2',3'}$ = 9.5 Hz, 1H, H-2′), 5.42 (t, 1H, H-3′), 5.20 (s, 1H, PhC*H*), 4.83 (d, 1H, H-1′), 4.68 (d, 1H, H-1), 4.49 (dd, $J_{5',6a'}$ = 2.1, $J_{6a',6b'}$ = 12.2 Hz, 1H, H-6a), 4.40 (dd, $J_{5',6b'}$ = 4.8 Hz, 1H, H-6b), 2.70-2.56 (m, 2H, SCH_2CH$_3$), 1.16 (t, 3H, SCH$_2$CH_3). ^{13}C NMR ($CDCl_3$) δ: 136.4 (*Ph*CH, quaternary C); 101.7 and 101.1 (PhCH, C-1′); 83.3 (C-1); 67.5 (C-6′); 62.5 (C-6); 24.2 (SCH_2CH$_3$); 14.8 (SCH$_2$CH_3). Anal. calcd. for $C_{56}H_{50}O_{15}S$ (995.0): C 67.59, H 5.06; found C 67.56, H 5.01.

*Allyl (2,3-di-*O*-benzoyl-4,6-*O*-benzylidene-*β*-*D*-glucopyranosyl)-(1→4)-2,3,6-tri-*O*-benzoyl-*β*-*D*-glucopyranoside (8)*

A solution of allyl 2,3,6-tri-*O*-benzoyl-β-D-glucopyranoside **7** (4) (0.48 g, 0.93 mmol) and 2,3-di-*O*-benzoyl-4,6-*O*-benzylidene-D-glucopyranosyl trichloroacetimidate **5** (4) (1.02 g, 1.64 mmol) in dry CH_2Cl_2 (15 mL), containing 4 Å molecular sieves, was stirred under Ar for 1 h. Then, TMSOTf (35 μL, 0.19 mmol) was added. After 45 min, the mixture was neutralized with dry pyridine, filtered over cotton, diluted with CH_2Cl_2, and washed with 10% (w/v) aqueous NaCl. The organic layer was dried, filtered, and concentrated. The residue was purified by column chromatography (toluene–EtOAc, 95:5) to obtain **8** (0.76 g, 83%). $[\alpha]_D^{20}$ +27 (*c* = 1). R_f = 0.37 (toluene–EtOAc, 9:1). ^{1}H NMR ($CDCl_3$) δ: 8.05–7.85 and 7.50–7.25 (2m, 30H, *Ph*CH, 5*Ph*CO), 5.78–5.65 (m, 1H, OCH$_2$C*H*=CH$_2$), 5.72 and 5.60 (2t, $J_{2,3}$ = 9.6, $J_{2',3'}$ = 9.6 Hz, each 1H, H-3,3′), 5.43 and 5.40 (2dd, $J_{1,2}$ = 7.7, $J_{1',2'}$ = 7.8 Hz, each 1H, H-2,2′), 5.21 (s, 1H, PhC*H*), 5.17–5.10 and 5.08–5.03 (2m, each 1H, OCH$_2$CH=CH_2), 4.83 and 4.72 (2d, each 1H, H-1,1′), 4.49 (dd, $J_{5,6a}$ = 2.1, $J_{6a,6b}$ = 12.1 Hz, 1H, H-6a), 4.39 (dd, $J_{5,6b}$ = 4.5 Hz, 1H, H-6b), 4.27–4.20 and 4.07–3.99 (2m, each 1H, OCH_2CH=CH$_2$), 4.11 and 3.63 (2t, each 1H, H-4,4′), 3.76 (ddd, 1H, H-5), 3.61 (dd, $J_{5',6a'}$ = 4.6, $J_{6a',6b'}$ = 10.6 Hz, 1H, H-6a′), 3.31 (ddd, 1H, H-5′), 2.83 (t, $J_{5',6b'}$ = 10.6 Hz, 1H, H-6b′). ^{13}C NMR ($CDCl_3$) δ: 165.4, 165.2, 165.0, 164.9, and 164.7 (5Ph*C*O); 136.4 (P*h*CH, quaternary C); 117.5 (OCH$_2$CH=*C*H$_2$); 101.7, 101.0, and 99.2 (PhCH, C-1,1′); 69.7 (O*C*H$_2$CH=CH$_2$); 67.4 (C-6′); 62.2 (C-6). Anal. calcd. for $C_{57}H_{50}O_{16}$ (991.0): C 69.08, H 5.08; found C 69.16, H 5.05.

*(2,3-Di-*O*-benzoyl-4,6-*O*-benzylidene-*β*-*D*-glucopyranosyl)-(1→4)-2,3,6-tri-*O*-benzoyl-*D*-glucopyranose (9)*

To a solution of **8** (1.5 g, 1.5 mmol) in absolute EtOH (40 mL), toluene (80 mL), and CH_2Cl_2 (8 mL) were added a catalytic amount of diazabicyclo[2.2.2]octane (DABCO) and tris(triphenylphosphine)rhodium(I) chloride (0.4 g). After stirring at reflux for 4 h, the mixture was concentrated. The residue was dissolved in THF (75 mL), and water (10 mL) and NIS (0.6 g) were added. After 20 min, the mixture was concentrated, diluted with CH_2Cl_2, washed with 10% (w/v) aqueous $NaHSO_3$ (2×) and 10% (w/v) aqueous NaCl, and the organic layer was dried, filtered, and concentrated. The crude residue was purified by column chromatography. Impurities were eluted with toluene–EtOAc (95:5), and **9** was obtained as a light brown syrup by elution with toluene–EtOAc (9:1) (0.99 g, 68%). R_f = 0.17$^{\alpha}$/0.08$^{\beta}$ (toluene–EtOAc, 8:2). ^{1}H NMR ($CDCl_3$) δ: 8.08–7.85 and 7.49–7.23 (2m, 30H, *Ph*CH, 5*Ph*CO), 5.63 (t, 1H, H-3′), 5.46 (dd, $J_{1',2'}$ = 7.7, $J_{2',3'}$ = 9.5 Hz, 1H, H-2′), 5.23 (s, 1H, PhC*H*), 4.89 (d, 1H, H-1′), 4.49 (dd, $J_{5,6a}$ = 2.0, $J_{6a,6b}$ = 12.3 Hz, 1H, H-6a), 4.40 (dd, $J_{5,6b}$ = 3.8 Hz, 1H, H-6b), 3.63 (dd, $J_{5',6a'}$ = 4.9, $J_{6a',6b'}$ = 10.6 Hz, 1H, H-6a′), 3.32 (dt, $J_{5',6b'}$ = 10.4 Hz, 1H, H-5′), 2.94 (t, 1H, H-6b′). ^{13}C NMR ($CDCl_3$) δ: 165.8, 165.4, 165.0 (2C), and 164.9 (5Ph*C*O); 136.5 (*Ph*CH, quaternary C); 101.9 and 101.1 (Ph*C*H, C-1′); 95.5 and 90.1 (C-1$^{\alpha}$,1$^{\beta}$); 67.7 (C-6′); 62.0 (C-6). Anal. calcd. for $C_{54}H_{46}O_{16}$ (951.0): C 68.21, H 4.87; found C 68.16, H 5.02.

*(2,3-Di-*O*-benzoyl-4,6-*O*-benzylidene-*β*-*D*-glucopyranosyl)-(1→4)-2,3,6-tri-*O*-benzoyl-α-*D*-glucopyranosyl trichloroacetimidate (10)*

To a solution of **9** (1.0 g, 1.1 mmol) in dry CH_2Cl_2 (14 mL) were added Cl_3CCN (1.2 mL) and DBU (40 μL). After stirring for 16 h, the mixture was concentrated and the residue was purified by column chromatography (toluene–EtOAc, 88:12) to yield **10** (0.99 g, 86%). $[\alpha]_D^{20}$ +83 (*c* = 1). R_f = 0.32 (toluene–EtOAc, 9:1). ^{1}H NMR ($CDCl_3$) δ: 8.55 (s, 1H, N*H*), 8.08–7.85 and 7.47–7.16 (2m, 30H, *Ph*CH, 5*Ph*CO), 6.68 (d, $J_{1,2}$ = 3.7 Hz, 1H, H-1), 6.12 (dd, $J_{2,3}$ = 10.2, $J_{3,4}$ = 8.6 Hz, 1H, H-3), 5.66 (t, $J_{2',3'}$ = $J_{3',4'}$ = 9.6 Hz, 1H, H-3′), 5.49 (dd, 1H, H-2), 5.48 (dd, $J_{1',2'}$ = 7.7 Hz, 1H, H-2′), 5.25 (s, 1H, PhC*H*), 4.95 (d, 1H, H-1′), 4.54 (dd, $J_{5,6a}$ = 2.0, $J_{6a,6b}$ = 12.2 Hz, 1H, H-6a), 4.44 (dd, $J_{5,6b}$ = 3.8 Hz, 1H, H-6b), 4.30 (ddd, $J_{4,5}$ = 10.0 Hz, 1H, H-5), 4.22 (dd, 1H, H-4), 3.69 (t, $J_{4',5'}$ = 9.5 Hz, 1H, H-4′), 3.64 (dd, $J_{5',6a'}$ = 4.8, $J_{6a',6b'}$ = 10.5 Hz, 1H, H-6a′), 3.34 (dt, $J_{5',6b'}$ = 10.3 Hz, 1H, H-5′), 2.99 (t, 1H, H-6b′). ^{13}C NMR ($CDCl_3$) δ: 165.4, 165.3 (2C), and 164.8 (2C) (5Ph*C*O); 160.3 (O*C*(NH)CCl$_3$); 136.4 (*Ph*CH, quaternary C); 101.8 and 101.1 (Ph*C*H, C-1′); 92.8 (C-1), 67.6 (C-6′); 61.6 (C-6).

*3-Azidopropyl (2,3-di-*O*-benzoyl-4,6-*O*-benzylidene-*β*-*D*-glucopyranosyl)-(1→4)-(2,3,6-tri-*O*-benzoyl-*β*-*D*-glucopyranosyl)-(1→3)-(2-*O*-benzoyl-4,6-*O*-benzylidene-*β*-*D*-glucopyranosyl)-(1→4)-(2,3,6-tri-*O*-benzoyl-*β*-*D*-glucopyranosyl)-(1→3)-(2-*O*-benzoyl-4,6-*O*-benzylidene-*β*-*D*-glucopyranosyl)-(1→4)-2,3,6-tri-*O*-benzoyl-*β*-*D*-glucopyranoside (12)*

A solution of **10** (70 mg, 63 μmol) and **11** (4) (65 mg, 35 μmol) in dry CH_2Cl_2 (1 mL), containing 4 Å molecular sieves, was stirred under Ar for 1 h. Then, TMSOTf (1.1 μL, 6 μmol) was added. After 30 min, the mixture was neutralized with dry pyridine, filtered over cotton, diluted with CH_2Cl_2, and washed with 10% (w/v) aqueous NaCl. The organic layer was dried, filtered, and concentrated. The residue was purified by column chromatography (toluene–EtOAc, 95:5) to obtain **12** (59 mg, 63%). $[\alpha]_D^{20}$ +59 (*c* = 1). R_f = 0.46 (toluene–EtOAc, 9:1). ^{1}H NMR ($CDCl_3$) δ: 5.56 (t, 1H, H-3^a), 5.45 (t, 1H, H-3^f), 5.38 (t, 1H, H-3^e), 5.29 (t, 1H, H-3^c), 5.26 (2H, H-2^a,2^f), 5.16 (1H, H-2^e), 5.15 (1H, H-2^b), 5.14 (1H, H-2^c), 5.12 (2H) and 5.09 (2s, 3PhC*H*), 5.06

3-Azidopropyl (2,3-di-O-benzoyl-β-D-glucopyranosyluronic acid)-(1→4)-(2,3,6-tri-O-benzoyl-β-D-glucopyranosyl)-(1→3)-(2-O-benzoyl-β-D-glucopyranosyluronic acid)-(1→4)-(2,3,6-tri-O-benzoyl-β-D-glucopyranosyl)-(1→3)-(2-O-benzoyl-β-D-glucopyranosyluronic acid)-(1→4)-2,3,6-tri-O-benzoyl-β-D-glucopyranoside (14)

To a solution of **13** (50 mg, 21 μmol) in CH_2Cl_2 (0.22 mL) were added TEMPO (catalytic amount), and 40 μL of a solution of KBr (2.4 mg) and Bu_4NBr (3.2 mg) in saturated aqueous $NaHCO_3$ (0.4 mL). The mixture was stirred vigorously at 0°C, when 122 μL (total) of a solution of saturated aqueous NaCl (0.44 mL), saturated aqueous $NaHCO_3$ (0.22 mL), and aqueous NaOCl (13% Cl active, 0.56 mL) was added dropwise. After 45 min, the mixture was acidified with 4 M HCl (pH 4), diluted with CH_2Cl_2, and the organic layer was washed with 10% (w/v) aqueous NaCl, dried, filtered, and concentrated. The residue was purified by column chromatography. Impurities were eluted with CH_2Cl_2–acetone (8:2), and **14** (35 mg, 70%) was eluted with CH_2Cl_2–acetone–HOAc, (8:2:0.5). R_f = 0.05 (CH_2Cl_2–acetone–HOAc, 8:2:1). MALDI-TOF-MS *m*/*z*: 2490 [M + Na]$^+$, 2512 [M – H + 2Na]$^+$, 2534 [M – 2H + 3Na]$^+$, 2556 [M – 3H + 4Na]$^+$.

A small amount was methylated with diazomethane in methanol for analysis. ^{1}H NMR (CDCl$_3$) δ: 5.55 (t, 1H, H-3^e), 5.54 (t, 1H, H-3^a), 5.39 (t, 1H, H-3^c), 5.36 (2H, H-2^f,3^f), 5.26 (dd, $J_{1,2}$ = 7.8, $J_{2,3}$ = 9.6 Hz, 1H, H-2^e), 5.20 (dd, $J_{1,2}$ = 7.8, $J_{2,3}$ = 9.5 Hz, 1H, H-2^a), 5.15 (dd, $J_{2,3}$ = 9.7 Hz, 1H, H-2^c), 5.08 (2t, each 1H, H-2^b,2^d), 4.83 (d, $J_{1,2}$ = 7.6 Hz, 1H, H-1^f), 4.65 (d, 1H, H-1^e), 4.61 (dd, 1H, H-6^e), 4.53 (d, $J_{1,2}$ = 8.0 Hz, 2H, H-1^b,1^c), 4.52 (d, 1H, H-1^a), 4.48 (d, $J_{1,2}$ = 7.9 Hz, 1H, H-1^d), 4.38 (dd, 1H, H-6a^a), 4.33 (dd, 1H, H-6a^c), 4.28 (dd, 1H, H-6b^e), 4.17 (dd, 1H, H-6b^a), 4.13 (dd, 1H, H-6b^c), 4.10 (t, 1H, H-4^e), 4.04 (t, 1H, H-4^a), 3.91 (H-4^f), 3.90 (t, 1H, H-4^c), 3.81 (H-5^e), 3.78 and 3.44 (OCH_2 CH$_2$CH$_2$N$_3$), 3.76 (H-4^d), 3.74 (H-4^b), 3.69 (H-5^f), 3.63 (t, 1H, H-3^d), 3.57 (t, 1H, H-3^b), 3.56 (H-5^c), 3.55 (H-5^a), 3.51 (d, $J_{4,5}$ = 9.6 Hz, 1H, H-5^d), 3.49 (d, $J_{4,5}$ = 9.6 Hz, 1H, H-5^b), 3.39, 3.30, and 3.23 (3s, each 3H, COOCH_3), 3.09 (OCH$_2$CH$_2$CH_2N$_3$), 1.70–1.59 (m, 2H, OCH$_2$CH_2CH$_2$N$_3$).

3-Aminopropyl (β-D-glucopyranosyluronic acid)-(1→4)-(β-D-glucopyranosyl)-(1→3)-(β-D-glucopyranosyluronic acid)-(1→4)-(β-D-glucopyranosyl)-(1→3)-(β-D-glucopyranosyluronic acid)-(1→4)-β-D-glucopyranoside (1)

To a solution of **14** (20 mg, 8 μmol) in MeOH (3 mL) was added NaOMe until pH 10, and after 5 h, water (1 mL) was added. After stirring for 16 h, TLC (EtOAc–MeOH–H_2O, 12:5:3) showed the formation of a new spot (R_f = 0.1), and the mixture was neutralized with Dowex H$^+$, filtered, and concentrated. A solution of the residue in water was washed with CH_2Cl_2 (3×), and the aqueous layer was concentrated. Then, a solution of the residue in 0.1 M NaOH (0.4 mL) was added dropwise to a suspension of 10% Pd/C (0.8 mg) and $NaBH_4$ (3.5 mg) in doubly distilled water (0.3 mL). After 2 h, when TLC (EtOAc–MeOH–H_2O, 12:5:3) showed the formation of a ninhydrin-positive spot on the baseline, the mixture was acidified with Dowex H$^+$ (pH 4), then loaded on a short column of Dowex 50 W × 2 (H$^+$, 200–400 mesh). After elution of contaminants with water, elution with 1% NH_4OH afforded **1** after concentration and lyophilization from water (2×) (5.4 mg, 61%). $[\alpha]_D^{20}$ = –17 (*c* = 0.4, H_2O). MALDI-TOF-MS *m*/*z*: 1091 [M + H]$^+$, 1112 [M + Na]$^+$, 1134 [M – H + 2Na]$^+$, 1156 [M – 2H + 3Na]$^+$. For ^{1}H NMR data, see Table 1.

Kinetics and mechanism of hydrolysis of 3-diazobenzofuran-2-one and its hydrolysis product (3-hydroxybenzofuran-2-one)

Y. Chiang, A.J. Kresge, and Q. Meng

Abstract: Rates of acid-catalyzed hydrolysis of 3-diazobenzofuran-2-one, measured in concentrated aqueous perchloric acid and hydrochloric acid solutions, were found to correlate well with the Cox–Yates X_o excess acidity function, giving $k_{H^+} = 1.66 \times 10^{-4}$ M^{-1} s^{-1}, $m^{\ddagger} = 0.86$ and $k_{H^+}/k_{D^+} = 2.04$. The normal direction ($k_H/k_D > 1$) of this isotope effect indicates that hydrolysis occurs by rate-determining protonation of the substrate on its diazo-carbon atom. It was found previously that the next higher homolog of the present substrate, 4-diazoisochroman-3-one, also undergoes hydrolysis by this reaction mechanism but with a rate constant 15 times greater than that for the present substrate; this difference in reactivity can be understood in terms of the various resonance forms that contribute to the structures of these substrates. The product of the present hydrolysis reaction is 3-hydroxybenzofuran-2-one, which itself quickly undergoes subsequent acid-catalyzed hydrolysis to 2-hydroxymandelic acid. The acidity dependence of this subsequent hydrolysis is much shallower than that of the diazo compound precursor, and rates of reaction correlate as well with $[H^+]$ as with X_o. This is due in part to incursion of a nonproductive protonation on the hydroxy group of 3-hydroxybenzofuran-2-one that impedes hydrolysis and produces saturation of acid catalysis. Rates of hydrolysis of the hydroxy compound were also measured in dilute $HClO_4$ and NaOH solutions as well as in CH_3CO_2H, $H_2PO_4^-$, $(CH_2OH)_3CNH_3^+$, and NH_4^+ buffers, and the rate profile constructed from these data showed the presence of uncatalyzed and hydroxide ion-catalyzed reactions. This hydroxide-ion catalysis became saturated at [NaOH] ≅ 0.05 M, implying occurrence of yet another nonproductive substrate ionization.

Key words: diazo compound hydrolysis, lactone hydrolysis, Cox–Yates excess acidity, acid catalysis, alcohol protonation.

Résumé : On a observé que les vitesses de réactions d'hydrolyse acidocatalysées de la 3-diazobenzofuran-2-one en solutions aqueuses des acides perchlorique et chlorhydrique donnent une bonne corrélation avec la fonction d'acidité en excès de Cox–Yates, X_o, qui conduit à $k_{H^+} = 1{,}66 \times 10^{-4}$ M^{-1} s^{-1}, $m^{\ddagger} = 0{,}86$ et $k_{H^+}/k_{D^+} = 2{,}04$. La direction normale ($k_H/k_D > 1$) de cet effet isotopique indique que l'hydrolyse se produit par une étape de protonation du substrat cinétiquement déterminante sur l'atome de carbone du diazo. On avait observé antérieurement que l'homologue directement supérieur au substrat étudié, la 4-diazoisochroman-4-one, subit aussi une hydrolyse par ce mécanisme réactionnel, mais que la constante de vitesse de sa réaction est 15 fois supérieure à celle observée avec le substrat étudié ici; cette différence de réactivité peut s'expliquer en termes de diverses formes de résonance qui contribuent aux structures de ces substrats. Le produit d'hydrolyse du produit considéré ici est la 3-hydroxybenzofuran-2-one qui subit rapidement une hydrolyse acidocatalysée subséquente conduisant à l'acide 2-hydroxymandélique. La dépendance de cette hydrolyse subséquente sur l'acidité est beaucoup plus faible que celle sur le diazo précurseur et les constantes de vitesse donnent aussi une bonne corrélation avec $[H^+]$ ainsi qu'avec X_o. Ce résultat est dû en partie à l'incursion d'une protonation non productive sur le groupe hydroxyle de la 3-hydroxybenzofuran-3-one qui inhibe l'hydrolyse et qui produit une saturation de la catalyse acide. Les constantes de vitesse du composé hydroxylé ont aussi été mesurées dans des solutions diluées de $HClO_4$ et de NaOH ainsi que dans des tampons de CH_3CO_2H, $H_2PO_4^-$, $(CH_2OH)_3CNH_3^+$ et NH_4^+ et les profils de vitesses construits à partir de ces données mettent en évidence l'existence de réactions non catalysées et d'autres catalysées par l'ion hydroxyde. Cette catalyse par l'ion hydroxyde devient saturée à [NaOH] ≅ 0,05 M, ce qui implique l'existence d'une autre ionisation non productive du substrat.

Mots clés : hydrolyse de composés diazo, hydrolyse de lactones, acidité en excès de Cox–Yates, catalyse acide, protonation d'alcool.

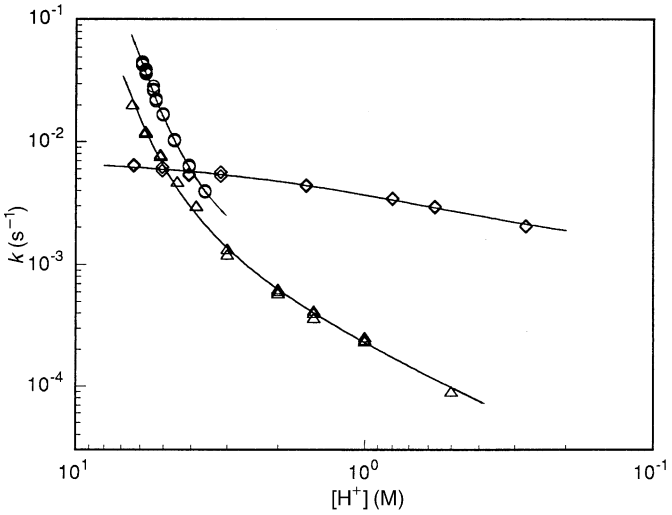
Fig. 1. Comparison of rates of hydrolysis of 3-diazobenzofuran-2-one in concentrated perchloric (O) and hydrochloric (Δ) acids with rates of hydrolysis of 3-hydroxybenzofuranone in concentrated hydrochloric acid (◇).



Introduction

It has been reported that irradiation of 3-diazobenzofuran-2-one (**1**) in low-temperature matrices produces the ketene **2** and the oxocumulene **3** (eq. [1]) (1). To learn whether these interesting molecules are also formed upon irradiation of 3-diazobenzofuran-2-one in aqueous solution at ambient temperature, and, if so, how they react with water, we have undertaken a study of the photolysis of this substance in aqueous media.

[1] 
1 **2** **3**

Diazo compounds such as **1** also undergo acid-catalyzed hydrolysis in aqueous solution, and such hydrolysis could interfere with our photolysis study. To determine whether this would be so, we also examined the hydrolysis reaction. The results proved to be interesting in their own right, and we therefore report them separately here.

The acid-catalyzed hydrolysis of diazo compounds usually produces the corresponding hydroxy derivative, which in the present system would be the hydroxy lactone, 3-hydroxybenzofuran-2-one (**4**) (eq. [2]). We have found that this is indeed the case, but that this product is then quickly hydrolyzed itself, giving 2-hydroxymandelic acid (**5**) (eq. [3]) as the ultimate reaction product. We have measured rates of this second hydrolysis reaction as well.

Experimental section

Materials

2-Hydroxymandelic acid (2) (**5**) was made by sodium borohydride reduction of 2-hydroxyphenylglyoxylic acid, itself prepared by selenium dioxide oxidation of 2-hydroxyacetophenone (2*a*). As reported (2), 2-hydroxymandelic acid could not be obtained completely free of solvent, and it was consequently used as an ethyl acetate solvate. 3-Hydroxybenzofuran-2-one (2*a*) (**4**) was synthesized by treating 2-hydroxymandelic acid with dicyclohexylcarbodiimide. 3-Diazobenzofuran-2-one (3) (**1**) was prepared by converting 2-hydroxyphenylglyoxylic acid into benzofuran-2,3-dione, using refluxing acetic anhydride to effect ring closure, and then making the tosyl hydrazone and cleaving that with sodium hydroxide (3). The spectral and physical properties of these substances agreed with literature values.

All other materials were best available commercial grades.

Kinetics

Rates of reaction were measured spectrophotometrically, using a Cary 220 spectrometer whose cell compartment was thermostatted at 25.0 ± 0.05°C. Rates of hydrolysis of 3-diazobenzofuran-2-one were monitored by following the decrease of its absorbance at λ = 310 nm, where neither 3-hydroxybenzofuran-2-one nor 2-hydroxymandelic acid absorb to any significant extent, and rates of hydrolysis of 3-hydroxybenzofuran-2-one were monitored by following the increase of 2-hydroxymandelic acid absorbance at λ = 278 nm. The data for both reactions conformed to the first-order rate law well, and observed first-order rate constants were determined by least-squares fitting of a single exponential function.

Product analysis

Product compositions were determined by HPLC using a Varian Vista 5500 instrument with a NovaPak C18 reverse-phase column and methanol–water (60/40 = v/v) as the eluent. Products were identified by comparing retention times and UV spectra with those of authentic samples.

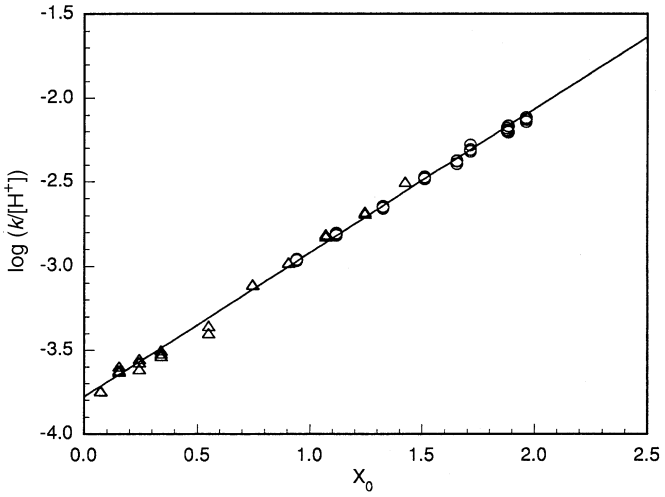
Results and discussion

Product analysis

Rate constants for the hydrolysis of 3-diazobenzofuran-2-one and 3-hydroxybenzofuran-2-one, determined in concentrated acid solutions as described below, are displayed in Fig. 1. It may be seen that both reactions are acid-catalyzed but that the acidity dependences of the two processes are quite different. Because the rates cross one another and have the same value in the vicinity of [H^+] = 4 M, this medium was chosen for product analysis. The reactions are also quite fast at this concentration, with half-lives of the order of 2 min. Samples of reaction mixtures were, therefore, taken

© 2002 NRC Canada

Fig. 2. Rates of hydrolysis of 3-diazobenzofuran-2-one in concentrated perchloric acid (O) and hydrochloric acid (Δ) solutions plotted according to eq. [4].



at short time intervals, were quenched into sufficient sodium acetate solution to give a buffer of pH ≅ 5, and were then immediately analyzed by HPLC.

The reaction mixture formed upon a 1.0 min exposure of 3-diazobenzofuran-2-one to 4 M perchloric acid consisted of, in addition to unreacted substrate, both 3-hydroxybenzofuran-2-one and 2-hydroxymandelic acid in a roughly 2:1 ratio. Another sample taken after 2.0 min exposure showed the same two products but now in approximately comparable amounts. Successive samples taken at later times gave progressively smaller amounts of 3-hydroxybenzofuran-2-one at the expense of increasing amounts of 2-hydroxymandelic acid, until after 15 min only the hydroxymandelic acid was left. This is the behavior expected of two successive reactions and it confirms that 3-hydroxybenzofuran-2-one is first formed by the hydrolysis of 3-diazobenzofuran-2-one and that it then quickly hydrolyzes further to 2-hydroxymandelic acid.

Product analyses were also conducted for the hydrolysis of 3-hydroxybenzofuran-2-one itself. This was done in 0.1 M perchloric acid solution, in an acetic acid buffer of $[H^+] = 3 \times 10^{-5}$ M, in a tris-(hydroxymethyl)methylammonium ion buffer of $[H^+] = 8 \times 10^{-9}$ M, in an ammonium ion buffer of $[H^+] = 5 \times 10^{-10}$ M, and in 0.01 M sodium hydroxide solution. 2-Hydroxymandelic acid was the only product found in the perchloric acid and sodium hydroxide solutions and in the acetic acid buffer as well. 2-Hydroxymandelic acid was also the principle product formed in the tris-(hydroxymethyl)methylammonium ion and the ammonium ion buffers, but a minor amount of a second, unidentified product was also formed in each of these buffers. These minor products could be the corresponding 2-hydroxymandelic acid amides formed by aminolysis of the lactone starting material by the amine buffer components.

3-Diazobenzofuran-2-one

Rates of hydrolysis of 3-diazobenzofuran-2-one were measured in perchloric acid solutions over the concentration range $[HClO_4] = 3.6–5.8$ M and in hydrochloric acid solutions over the range [HCl] = 0.5–6.4 M; the data obtained are summarized in Table S1.[2] Some rate measurements were also made in D_2O solutions of hydrochloric acid-*d* over the range [DCl] = 0.5–6.2 M, and these data are listed in Table S1[2] as well.

The observed first-order rate constants determined in these concentrated acid solutions increased with increasing solution acidity more steeply than in direct proportion to acid concentration. This is commonly the case for reaction rates measured in concentrated acids, and the data in such situations are generally analyzed using an acidity function rather than acid concentration as a measure of acid strength. The X_o scale applied as shown in eq. [4] appears to be the best function available for this purpose (4),

$$[4] \qquad \log (k_{obs}/[H^+]) = \log (k_{H^+}) + m^{\ddagger}X_o$$

and the present data were therefore analyzed using this expression with X_0 values for HCl and $HClO_4$ solutions taken from the literature (5). Figure 2 shows that the data conformed to this relationship well, and that a single correlation sufficed to represent measurements made in the two acids. Least-squares analysis gave the hydrogen ion catalytic coefficient $k_{H^+} = (1.66 \pm 0.03) \times 10^{-4}$ M^{-1} s^{-1} and the slope parameter $m^{\ddagger} = 0.857 \pm 0.007$.

The X_o scale has not been determined for DCl solutions in D_2O, but several other acidity functions have been shown to have the same value in D_2O as in H_2O when the comparison is made at the same molar acid concentration (6). It seems likely that this would be so for the X_o scale as well, and the rate constants determined here for hydrolysis of 3-diazobenzofuran-2-one in DCl were therefore correlated using X_o values obtained on this basis. These data also conformed to the expression of eq. [4] well, and least-squares analysis gave $k_{D^+} = (8.15 \pm 0.12) \times 10^{-5}$ M^{-1} s^{-1} and $m^{\ddagger} = 0.837 \pm 0.008$. Combination of the results obtained in H_2O and D_2O provides the isotope effect $k_{H^+}/k_{D^+} = 2.04 \pm 0.05$.

The normal direction of this isotope effect ($k_H/k_D > 1$) indicates that proton transfer is rate-determining in this reaction (7) and that the process occurs by the standard mechanism for diazo compound hydrolysis in which rate-determining protonation of the diazo-carbon atom is followed by rapid displacement of nitrogen by a molecule of water (eq. [5]) (8). Another mechanism that is sometimes found for diazo compound hydrolysis consists of rapid and reversible carbon protonation followed by rate-determining loss of nitrogen, but such a scheme would give an inverse isotope effect, $k_{H^+}/k_{D^+} < 1$ (7), contrary to the present result.

[5] 
The next higher homolog of the presently examined substrate, 4-diazoisochroman-3-one (**6**), also undergoes

[2] Tables of rate data (Tables S1–S5) have been deposited and may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A OS2, Canada (http://www.nrc.ca/cisti/irm/unpub_e.shtml for information on ordering electronically).

Fig. 3. Rates of hydrolysis of 3-hydroxybenzofuran-2-one in concentrated perchloric acid solutions.

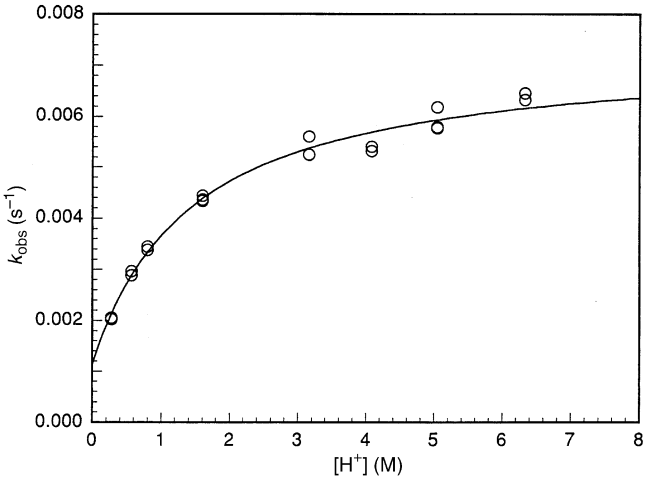

Fig. 4. Rate profile for the hydrolysis of 3-hydroxybenzofuran-2-one in aqueous solution at 25°C.

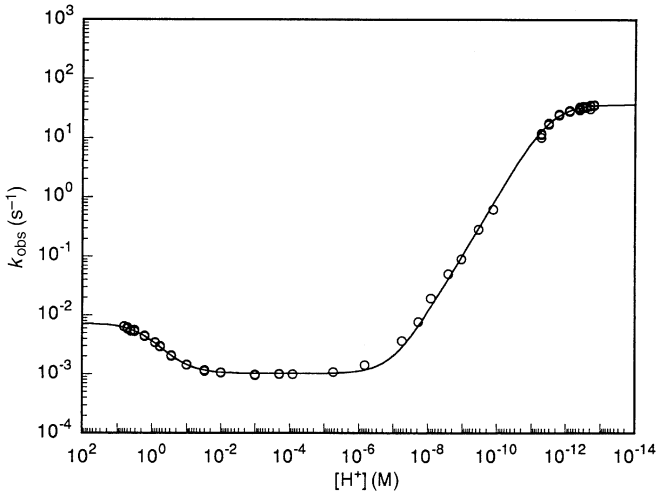
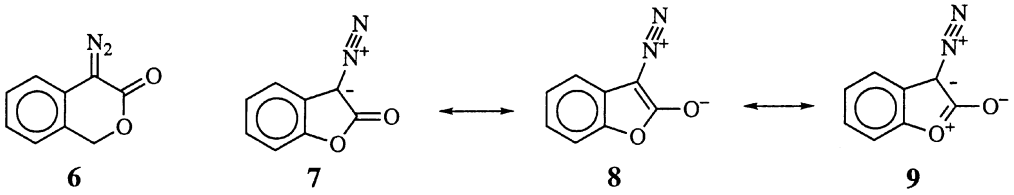
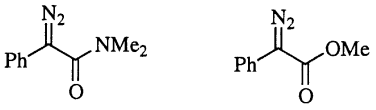


acid-catalyzed hydrolysis by a rate-determining proton transfer mechanism (9); its hydrogen-ion catalytic coefficient, however, is 15 times greater than that for the presently examined substrate. This difference in reactivity can be understood in terms of the various resonance forms that contribute to the structure of these diazo lactones. One of the principle resonance forms of the diazo group puts negative charge on the adjacent carbon atom, as in **7**, and, since this is the site to which the positively charged proton is transferred, the rate of reaction will increase with increasing contribution of this form. This negative charge can also be shifted onto the oxygen atom of the lactone carbonyl group, as in **8**, and, since this removes negative charge from the reactive position, the rate of reaction will decrease with increasing contribution of this form. The lactone carbonyl group, however, is also conjugated with the lactone ether oxygen atom, giving rise to resonance form **9**, which opposes conjugation of the carbonyl with the diazo group, thus raising the contribution of form **7** and increasing the rate of reaction. This opposing conjugation will be stronger in the case of 4-diazoisochroman-3-one than in the case of 3-diazobenzofuran-2-one, because the latter is a phenolic lactone whose ether oxygen atom is also conjugated with its benzene ring. In the isochromanone system, therefore, as compared to the benzofuranone system, the contribution of form **9** will be greater, that of form **8** less, and that of form **7** greater, leading to a greater rate of reaction.



6 **7** **8** **9**

This argument is supported by the fact that *N*,*N*-dimethylphenyldiazoacetamide (**10**) is considerably more reactive toward acid-catalyzed hydrolysis than is the corresponding ester, methylphenyldiazoacetate (**11**) (10). This is in keeping with the greater electron-donating ability of NMe_2 over OMe and the consequent greater contribution to the structure of the amide made by the resonance form corresponding to **9**.



10 **11**

3-Hydroxybenzofuran-2-one (concentrated acids)

Rates of hydrolysis of 3-hydroxybenzofuran-2-one were measured in concentrated perchloric acid solutions over the concentration range $[HClO_4]$ = 0.28–6.3 M. The data obtained are summarized in Table S2.[2]

Figure 1 shows that observed first-order rate constants for this hydrolysis reaction in these concentrated acid solutions increase with acidity much less steeply than do those for the hydrolysis of 3-diazobenzofuran-2-one, and Fig. 3, where the data are plotted on a nonlogarithmic scale, reveals that this is because acid catalysis of the hydroxy substrate becomes saturated at the high concentration end of the range investigated. This saturation of acid catalysis suggests that a nonproductive protonation of 3-hydroxybenzofuran-2-one is taking place, in addition to the productive protonation that

© 2002 NRC Canada

results in lactone hydrolysis; the molecule does, of course, have such a nonproductive protonation site in its hydroxyl group, as shown by the reaction scheme of eq. [6].

[6] 
The presence of this nonproductive protonation requires modification of the simple X_o correlation function of eq. [4]; a term must be added to take this additional reaction into account. A further modification of eq. [4] is required, moreover, by the occurrence of an uncatalyzed lactone hydrolysis reaction (eq. [7]) in addition to the acid-catalyzed process. The presence of such an uncatalyzed reaction is evidenced by the significant rate intercept at zero acid concentration shown by Fig. 3 and, perhaps more convincingly, by the long central horizontal plateau shown by the rate profile for this reaction (Fig. 4), constructed as detailed below. In addition, it seems likely that the acid-catalyzed reaction occurs by a simple A2 mechanism in which water is an active reactant (11). It has been shown in simpler systems that the reaction order in water activity for such a process is two (11) and a term taking this into account should also be added to eq. [4].

The final correlating function incorporating all of these

[7] 
additional features is shown as eq. [8], in which the rate and equilibrium constants are defined by eqs. [6] and [7],

$$[8] \quad \log \{(k_{obs} - k_{uc})/[H^+]\} = \log k_{H^+} + m^{\ddagger}X_o + \log \{K_a^+/(K_a^+ + [H^+]10^{mX_o}\} + 2\log a_{H_2O}$$

a_{H_2O} is the activity of water, supplied here on the mol fraction scale, and $m^{\ddagger}$ and m are the X_o slope parameters for the rate and equilibrium processes, respectively. This expression contains five dependent parameters to be determined by the fit of experimental data (k_{H^+}, k_{uc}, K_a^+, $m^{\ddagger}$, and m), which, unfortunately, proved to be too many: least-squares analysis failed to produce a sensible result. The number of parameters could be reduced to four, however, by supplying a value of k_{uc} (= 0.001 s^{-1}) based on the intercept at zero acid concentration of Fig. 3 and the central plateau of Fig. 4, and this modification of eq. [8] did produce a sensible result. Least-squares analysis gave k_{H^+} = (4.49 ± 0.17) × 10^{-3} M^{-1} s^{-1}, K_a^+ = 1.48 ± 0.17 M, pK_a^+ = –0.17 ± 0.05, $m^{\ddagger}$ = 0.68 ± 0.11, and m = 0.04 ± 0.12.

Very shallow acidity function dependences, similar to the m value obtained here, have been found for the equilibrium protonation of simple alcohols, whereas somewhat steeper dependences, consistent with the present value of $m^{\ddagger}$, occur in the hydrolysis of simple esters (12). The result pK_a^+ = –0.17, on the other hand, makes the conjugate acid of 3-hydroxybenzofuran-2-one somewhat less strongly acidic than oxygen-protonated simple alcohols, for which pK_a ≅ –2.0 (12). This, however, is again as might be expected, inasmuch as hydrogen bonding between the positively charged hydroxyl group and the adjacent carboxyl oxygen atom in the present system will stabilize the undissociated acid and thus, reduce its acid strength.

It is interesting that results similar to those produced by the analysis described above may be obtained by treating the data in a much simpler way, without recourse to an acidity function, using the expression of eq. [9] as the correlating equation.

$$[9] \quad k_{obs} = (k_{H^+}[H^+] + k_{uc})K_a^+/(K_a^+ + [H^+])$$

Least-squares fitting of this expression gives the results k_{H^+} = (5.07 ± 0.84) × 10^{-3} M^{-1} s^{-1}, K_a^+ = 1.44 ± 0.29 M, pK_a^+ = –0.16 ± 0.09, and k_{uc} = (1.12 ± 0.27) × 10^{-3} s^{-1}, which are not significantly different from values obtained by the X_o analysis. This simple treatment is successful in this case because the dependence of K_a^+ and k_{H^+} on X_o are both quite shallow and approximate quite well a simple dependence on [H^+].

3-Hydroxybenzofuran-2-one (dilute solutions)

Rates of hydrolysis of 3-hydroxybenzofuran-2-one were also measured in dilute aqueous perchloric acid solutions over the concentration range [$HClO_4$] = 0.0002–0.1 M, in dilute aqueous sodium hydroxide solutions over the concentration range [NaOH] = 0.003–0.1 M, and in acetic acid, biphosphate ion, tris-(hydroxymethyl)methylammonium ion, and ammonium ion buffers. The ionic strength of these solutions was maintained at 0.10 M by the addition of sodium perchlorate as required. These data are summarized in Tables S3–S5.[2]

The rate measurements in buffers were performed using a series of solutions of varying buffer concentration but constant buffer ratio and, since the ionic strength was constant, also constant hydrogen ion concentration. Observed first-order rate constants determined in each solution series increased linearly with increasing buffer concentration, and the data were, therefore, analyzed using the buffer dilution expression shown in eq. [10]. Least-squares fitting produced zero-buffer-concentration intercepts (k_{int}) which,

$$[10] \quad k_{obs} = k_{int} + k_{cat}[buffer]$$

together with the observed first-order rate constants determined in perchloric acid and sodium hydroxide solutions, were used to construct the rate profile shown in Fig. 4. Hydrogen ion concentrations of the buffer solutions needed for this purpose were obtained by calculation, using thermodynamic acidity constants for the buffer acids from the literature and activity coefficients recommended by Bates (13).

© 2002 NRC Canada

This rate profile shows the hydrogen-ion-catalyzed and uncatalyzed reactions plus saturation of hydrogen-ion catalysis noted above, and it also shows a hydroxide-ion-catalyzed process with saturation of hydroxide-ion catalysis as well. This saturation of hydroxide-ion catalysis implies incursion of yet another nonproductive ionization of the substrate, and a complete rate law formulated by adding this feature to the rate expression of eq. [9] is shown as eq. [11]; Q_a^o is the equilibrium constant for this nonproductive ionization and Q_w is the ionization constant of water.

[11] $$k_{obs} = (k_{H^+}[H^+] + k_{uc})K_a^+/(K_a^+ + [H^+]) + k_{HO^-}\ Q_w/(Q_a^o + [H^+])$$

Least-squares analysis using this expression gave the results $k_{H^+} = (5.42 \pm 0.43) \times 10^{-3}$ M^{-1} s^{-1}, $k_{uc} = (1.01 \pm 0.02) \times 10^{-3}$ s^{-1}, $K_a^+ = 1.33 \pm 0.15$ M, $pK_a^+ = -0.12 \pm 0.05$, $k_{HO^-} = (6.37 \pm 0.17) \times 10^3$ M^{-1} s^{-1}, and $Q_a^o = (2.75 \pm 0.10) \times 10^{-12}$ M, $pQ_a^o = 11.56 \pm 0.02$.[3] These values of k_{H^+}, k_{uc}, and K_a^+ agree well with determinations of these quantities obtained by the other treatments of the experimental data described above; the weighted averages of all results are $k_{H^+} = (4.63 \pm 0.16) \times 10^{-3}$ M^{-1} s^{-1}, $k_{uc} = (1.01 \pm 0.02) \times 10^{-3}$ s^{-1}, and $K_a^+ = 1.40 \pm 0.11$ M, $pK_a^+ = -0.15 \pm 0.03$.

There are two candidates for the nonproductive ionization of 3-hydroxybenzofuran-2-one that could be responsible for saturation of hydroxide-ion catalysis of the hydrolysis of its lactone functional group: (*i*) ionization of the hydroxyl group to give an alcoholate anion (eq. [12]); and (*ii*) ionization of the carbon—hydrogen bond next to the lactone function to give an enolate ion (eq. [13]). Both of these reactions put negative charge near the lactone group and thus, hinder reaction of this group with a negatively charged hydroxide ion.

[12] 
[13] 
It is difficult to choose between these two alternatives. A Hammett–Taft relation correlating acidity constants of secondary alcohols (14) leads to the estimate $pK_a = 12.0$ for the hydroxyl group ionization of eq. [12], which is consistent with the experimentally determined value $pQ_a^o = 11.6$. On the other hand, $pK_a = 12.3$ has been reported for the carbon acid ionization of benzofuran-2-one itself (15) (**12**) (eq. [14]), which again is not inconsistent with the presently determined value.

[14] 
12

The carbon acid ionization reaction of eq. [13] raises the possibility of an alternative lactone hydrolysis route, replacing the traditional attack of hydroxide ion on the lactone carbonyl carbon atom leading to a tetrahedral intermediate. This alternative route (eq. [15]) has the enolate ion (**13**) breaking down to give a ketene (**14**), which then rapidly hydrates to a carboxylic acid enolate ion (**15**), and that ketonizes to the final 2-hydroxymandelic acid product (**16**).

[15] 
13 **14** **15** **16**

The generation of ketenes from ester enolates like this is a well-known reaction (16), and the hydration and ketonization of analogs of **14** and **15** without the *ortho*-phenoxide group are known to be very fast reactions (17). On the other hand, although 3-phenylbenzofuran-2-one (**17**) readily ionizes to its enolate ion (**18**) (eq. [16]), hydrolysis of this lactone is believed to occur by the traditional tetrahedral intermediate route and not through the corresponding ketene (15).

[16] 
17 **18**

[3] This is a *concentration* dissociation constant applicable at the ionic strength (0.10 M) at which it was determined.

The endothermic nature of the binding of anionic bile salts to a cationic adsorbent

Celia K. Williams, William C. Galley, and G. Ronald Brown

Abstract: The binding of a hydrophobic bile salt, sodium chenodeoxycholate, by a polyacrylamide with *N*,*N*,*N*-trimethylammonium dodecyl chloride (QPDA12) pendant groups was studied to evaluate the thermodynamic parameters associated with the binding. The Langmuir equation was used in interpreting the data obtained from HPLC measurements. An increase in binding affinity was observed with increasing temperature indicating that the driving force for binding is derived from an increase in entropy ($\Delta S°$ = 253 J mol^{-1} K^{-1}) despite the positive, or unfavourable, enthalpy change ($\Delta H°$ = 53 kJ mol^{-1}). The positive thermodynamic parameters associated with the binding suggest that the disruption of hydrophobic and (or) ionic hydration associated with the bile salts and cationic polymer is the driving force for the binding.

Key words: bile salts, endothermic binding, polymer sorbents, solvent randomization.

Résumé : La liaison d'un sel biliaire hydrophobe, le chenodeoxycholate de sodium par un polyacrylamide portant des substituants chlorure de *N*,*N*,*N*-trimethydodecylammonium (QPDA12) a été étudiée pour évaluer les paramètres thermodynamiques associés à la liaison. L'équation de Langmuir a été utilisée pour interpréter les données obtenues par HPLC. Une augmentation de l'affinité de liaison a été observée lors de l'augmentation de la température. Ceci indique que la formation de la liaison provient principalement de l'augmentation de l'entropie ($\Delta S°$ = 253 J mol^{-1} K^{-1}) en dépit d'un changement non favourable d'enthalpie positive ($\Delta H°$ = 53 kJ mol^{-1}). Les valeurs positives des paramètres thermodynamiques du processus de l'association suggèrent que la dissolution de la cage d'hydratation associée aux régions hydrophobes et ioniques des sels biliaires et du polymère cationique est le moteur de l'association.

Mots clés : sels biliaires, liaison endothermique, les sorbents polymères, désorganisation de la cage d'hydratation.

Introduction

The ingestion of insoluble cationic polymer resins has been effective as one of the weapons employed in lowering blood cholesterol, hence cardiovascular diseases (1–3). Bile acids are synthesized from cholesterol in the liver, stored in the gallbladder in the conjugated form, and secreted into the duodenum at ingestion of a meal. After the emulsification of the fats in the jejunum by the formation of micellar aggregates (4, 5), more than 99% of the bile salts are reabsorbed and recirculated back to the liver by the enterohepatic circulation. Bile salt binding resins in the gastrointestinal tract can compete with the reabsorption, thereby inducing the liver to consume cholesterol. This leads to a reduction of plasma cholesterol due to the conversion to bile acids as the primary route of the consumption of plasma cholesterol.

[2]Deceased.

Cholestyramine (Questran), a styrene-divinylbenzene copolymer developed in 1959 (6), and colestipol (Colestid), a copolymer of tetraethylene-pentamine and epichlorohydrin (7) are the bile salt sequestering resins currently in wide clinical use. However, they have low efficiency in vivo due to the nonspecific nature of the binding (8–10). To realize significant reduction in cholesterol levels, patients must consume large amounts (up to 24 g/day for cholestyramine).

The development of a clearer understanding of the molecular basis of the binding process is central to the creation of resins that would prove effective in the sequestering of bile salts. The empirical determination of the relative enthalpic and entropic contributions to the binding would prove invaluable in the evaluation of molecular models that can provide direction in the search and creation of more effective resins in the sequestering of bile acids.

The binding of the negatively charged bile salts with cationic resins has most often been considered as a process dominated by the attraction between the oppositely charged ions (11–13). A contribution to the binding due to hydrophobic interactions has been proposed (11–16) based largely on differences observed in binding that were dependent on the hydrophobicity of either the polymer or the bile salt. However, despite the fact that the binding can involve the association of species with large nonpolar moieties, the decomposition of these non-ionic contributions into a van der Waals attraction between the interacting partners and a

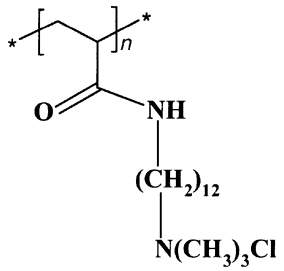
Fig. 1. The chemical structure of *N*,*N*,*N*-trimethylammonium dodecyl chloride (QPDA12) resin.



true hydrophobic association derived from solvent randomization has been lacking.

In the present work, the temperature dependence of the binding affinities for bile salts with a lightly cross-linked polyacrylamide resin functionalized with *N*,*N*,*N*-trimethylammonium dodecyl chloride (QPDA12) (Fig. 1) was studied. The specific goal was to evaluate the relative thermodynamic contributions to the binding process. The somewhat surprising observation that association of the anionic bile salt with the cationic resin is endothermic and entropy driven is discussed in terms of the dominant role played by the changes in solvation that occur in the binding process.

Experimental

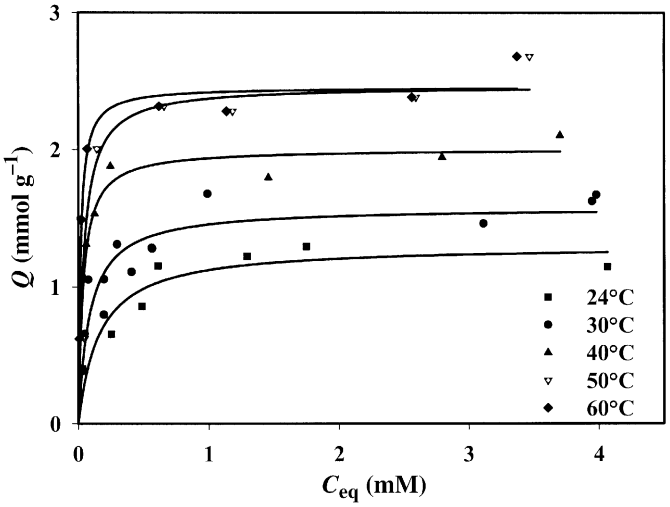
Materials

Sodium cholate (NaC) and sodium chenodeoxycholate (NaCDC) were purchased from Sigma and were used as received. Sodium cacodylate ($(CH_3)_2AsO_2Na$) was from Baker. The QPDA12 resin with chloride as counter-ions was a previously synthesized and quaternized sample (17). The functionality (*f*) was determined to be 2.00 ± 0.07 mmol of trimethylammonium pendant groups per g of dry resin, performed by gravimetric analysis. The chloride counter-ions were precipitated in the form of silver chloride by the addition of 1:1 of 16 M nitric acid and 0.103 M silver nitrate. The precipitate was filtered, washed, dried, and weighed to constant weight.

Adsorption studies

The procedures used for the sorption studies were as described previously (16). The bile salt solutions were prepared in an aqueous 5.0 mM sodium cacodylate buffer, pH range between 7.2 and 7.5. Sodium cacodylate buffer was used in this study to maintain a low ionic strength, which was 5 mM at the concentration employed. A stock bile salt solution (7 mM) was normally diluted with buffer to generate concentrations as low as 0.23 mM. The polymer resin (10 mg) was added to 20 mL of buffer solution containing varying bile salt concentrations. The mixtures were agitated with a mechanical shaker in a constant temperature bath at 120 oscillations per min for more than 18 h at the desired temperature (24–60°C). Reverse-phased high-performance liquid chromatography (HPLC) was used to follow the binding, according to procedures described previously (18).

Fig. 2. Binding isotherms of chenodeoxycholate by QPDA12 at different temperatures.



The bile salt concentrations in the solutions at equilibrium (C_{eq}) and the amount of bile salt bound per g of resin Q (mmol g^{-1}) were calculated, and the binding isotherms were plotted from these results. The isotherms were then analyzed in terms of a Langmuir equation

$$[1] \qquad Q = \frac{Q_m K C_{eq}}{1 + K C_{eq}}$$

with the use of SigmaPlot Software Version 5.00 that yielded the "best-fit" values for *K* and Q_m, the site binding constant, and max *Q* or binding capacity, respectively.

Results

The binding isotherms for sodium chenodeoxycholate with QPDA12 in 5.0 mM sodium cacodylate buffer at pH 7.2 at several temperatures ranging from 24–60°C appear in Fig. 2. The lines through the data points represent the isotherms calculated using the values obtained for Q_m and *K* from the nonlinear fit to eq. [1] and represent the best-fit.

There are two features in the binding isotherms that manifest themselves with an increase in temperature, Q_m and *K*. The value of Q_m at a particular temperature represents the saturation level of the binding, or the binding capacity of the resin. It displays an increase with temperature, and plateaus at 50°C. The values of Q_m divided by the functionality of the resin (*f*), yields the max number (*n*) of bile salt anions bound per functional sites on the resin. Values of *n* are seen in Table 1 to increase with temperature to a limit somewhat in excess of 1:1. This apparent increase in available binding sites on the resin is not accompanied within experimental error, with any indication of either a cooperative form of binding or the presence of more than one binding constant. The resin preparations employed in this work were in the form of aggregated beads. The twofold increase in the available binding sites occurring primarily at lower temperatures appears to arise from a decrease in aggregation with temperature. This influence of temperature on the binding behavior is

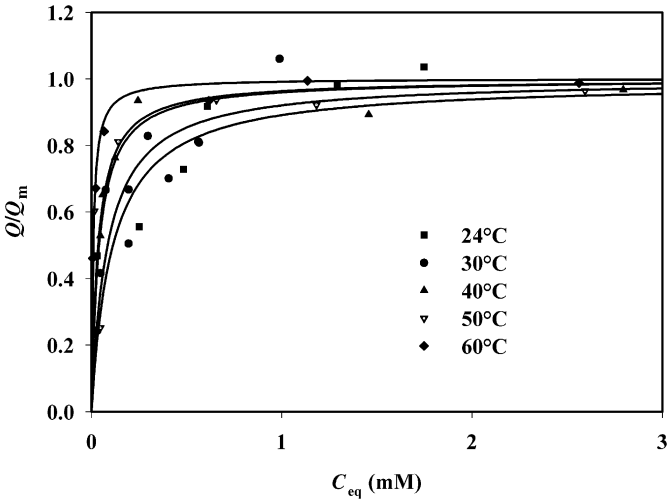
333	103	–32.0	2.47	1.24

Fig. 3. Normalized binding isotherms illustrating the enhancement in binding affinity.



overshadowed by the much larger enhancement in the binding constant over the temperature range of the experiment.

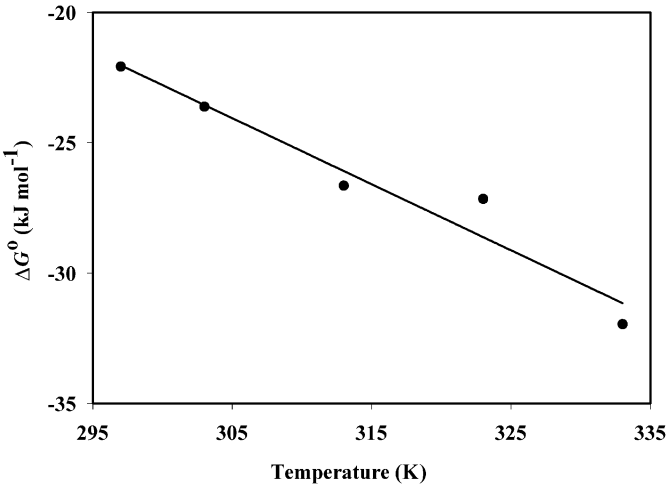
An increase in the strength of the binding, as indicated by increase in K, with rising temperature is also obtained from the analysis of the isotherms in Fig. 2. This enhancement is more apparent in Fig. 3 where the isotherms are represented as Q/Q_m, or have been normalized to the saturation level. The value of C_{eq} required to produce half-saturation clearly is lower as the temperature rises reflecting an increase in K. In accordance with le Chatelier's principle, this increase in K with temperature is indicative of an endothermic process that must therefore, be entropy-driven. The binding capacity of the resin and the site binding constant K, obtained at each temperature appear in Table 1 along with the standard Gibbs free energy of binding which was computed from K.

The increasingly negative $\Delta G°$ as the temperature increased resulted in the linear plot appearing in Fig. 4. The slope based on the fundamental thermodynamic relation

$$[2] \qquad \Delta G_T^o = \Delta H^o - T\Delta S^o$$

represents the standard entropy change ($\Delta S°$) for the binding of sodium chenodeoxycholate with QPDA12 and the y-intercept represents the standard enthalpy change ($\Delta H°$). A linear regression analysis of the relation in Fig. 4 results in a $\Delta S°$ of positive 253 ± 35 J mol^{-1} K^{-1} and a positive $\Delta H°$ of 53 ± 11 kJ mol^{-1}. Alternatively, the data from Table 1 are displayed in the form of a van't Hoff plot (ln K vs. $1/T$) in Fig. 5. The increasing K with temperature manifests itself as

Fig. 4. The standard Gibbs free energy of binding against temperature for chenodeoxycholate by QPDA12.



a slope ($-\Delta H°/R$) that is clearly negative, emphasizing the positive nature of the $\Delta H°$ for the process. The linear regression analysis on this plot results in positive values for $\Delta H°$ and $\Delta S°$ of 53 ± 11 kJ mol^{-1} and 252 ± 34 J mol^{-1} K^{-1}, respectively. As expected, the thermodynamic parameters derived from the two plots are in agreement, albeit with uncertainties weighted somewhat differently.

It can be noted from Table 2 that at 313 K, for example, the value of the change in $\Delta G°$ of –27 kJ mol^{-1} derives from a balance of larger positive $\Delta H°$ and $T\Delta S°$ values. At all given temperatures, the entropic driving force not only contributes to the binding but also is sufficiently large to overcome the endothermic nature of the process resulting in significantly negative standard free energy changes.

Discussion

Binding processes in which favourable charge–charge or charge – polar interactions appear to provide the molecular basis for the spontaneity of the event, can be particularly deceptive. The association of the anionic bile salt with the cationic resin represents an example in which the Coulombic attraction between the charged moieties should appear as a negative enthalpy change that provides the driving force for the process. The observation of an enhancement in the binding affinity of bile acids for the QPDA12 cationic resin with increasing temperature, the signature of an endothermic process, calls for an expansion of the molecular picture in which attraction between two oppositely charged species dominates. Randomization within the system, or a positive $\Delta S°$, is responsible for the binding and is sufficiently large to overcome the positive $\Delta H°$, or unfavourable overall endothermic nature of the binding process that is occurring within the system.

Binding events that are endothermic, and therefore entropy driven, are frequently observed and associated with processes in which changes in solvation, particularly with water as the solvent, are a dominant factor. The binding of Ca^{2+} ion in aqueous solution to thermolysin (19), a calcium-binding protein, represents an elegant example. While favourable charge–charge and ion–dipole interactions appear

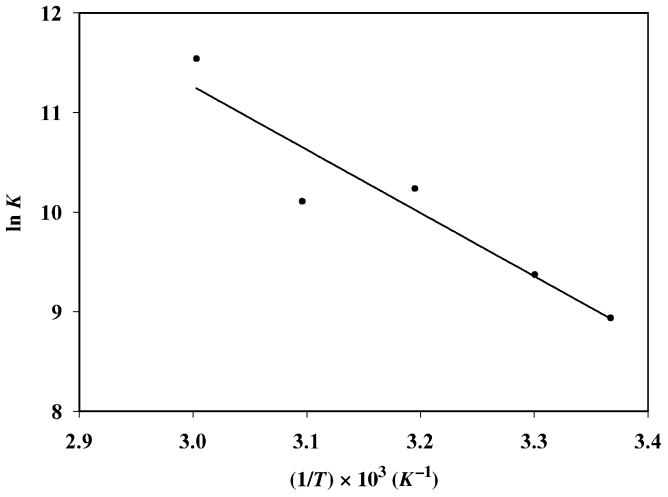
Fig. 5. The van't Hoff plot for the binding of chenodeoxycholate by QPDA12.



in the X-ray structure (20, 21) of the calcium-bound protein, the strongly endothermic nature of the binding points to the stripping off, or liberation, of the water of ionic hydration as the dominant feature of the process. The condensation of the Ca^{2+} ion and the protein into a single entity, is not only accompanied by, but is actually driven by, the disorder produced in the overall solution.

The significant role played by the solvent in self-assembly processes, as well as binding, has appeared in recent years from the evaluation of the thermodynamic parameters associated with the stability of globular proteins. Based on DSC data the spontaneous refolding of "random-coil" polypeptide chains into their native globular structures, at least in the lower temperatures range, is endothermic and entropy driven (22). This is again in contrast with the simple picture that ignores the solvent. This latter example represents a case in which randomization of the hydrophobic hydration associated with nonpolar side chains, rather than ionic hydration, appears to provide the driving force. The binding of bile salts with human serum albumin followed by flow calorimetry is also another example that has been documented to be endothermic and entropy driven (23).

The observation of $\Delta G°$ values arising as a balance between much larger positive $\Delta H°$ and positive $\Delta S°$ values, is frequently encountered with processes occurring in aqueous solution. This is referred to as enthalpy–entropy compensation and can be noted in the binding of the chenodeoxycholate to QPDA12 in this study. The individual positive $\Delta H°$ and positive $\Delta S°$ values that are observed for the binding appear too large in magnitude to be associated with binding as a bimolecular event. They again draw attention to the role that solvent reorganization must be playing in determining the strength of the binding between these ionic components. It should be emphasized, however, that as a consequence of this compensation between the large positive $\Delta H°$ and $\Delta S°$ parameters, smaller exothermic contributions might well be playing a pivotal role in converting the overall $\Delta G°$ from positive to that of a spontaneous process (negative) while retaining the overall endothermic nature of the binding. These essential contributions could exist in the form of direct charge–charge and van der Waals interactions between the binding partners.

Table 2. Thermodynamic parameters calculated from $\Delta S°$ of 253 J mol^{-1} K^{-1} and $\Delta H°$ of 53 kJ mol^{-1} for the binding of chenodeoxycholate by QPDA12.

Temperature (K)	$T\Delta S°$ (kJ mol^{-1})	$\Delta G° = \Delta H° - T\Delta S°$ (kJ mol^{-1})
297	75.5	–22.3
303	77.1	–23.8
313	79.6	–26.4
323	82.1	–28.9
333	84.7	–31.4

Preliminary results of the binding of sodium cholate to the QPDA12 adsorbent in cacodylate buffer also display positive entropy and enthalpy changes, albeit of smaller magnitudes.

In the present work, both the bile salts and the pendants on the resin share the characteristic of being hydrophobic as well as ionic. Irrespective of whether the solvation changes that occur involve ionic or hydrophobic hydration, or both, it is evident that the disruption of ordered water molecules plays an important role in the binding of bile salts with the cationic resin.

Conclusions

The binding of chenodeoxycholate to QPDA12 displayed an endothermic nature in the form of measured binding constants that increased with a rise in temperature. The overall driving force for the binding occurs despite the large unfavourable enthalpy change and is due to an even larger increase in the entropy of binding. The enthalpy–entropy compensation favouring entropy as the net driving force for the binding suggests that the randomization of ordered solvent surrounding the interacting moieties dominates the process. These solvation changes may involve ionic, hydrophobic hydration, or both. Ongoing work centers on the comparison of binding data in the presence of competing anions and solvent perturbations with models that include the solvent as a significant player in the binding process.

On the generation of oxirene and dimethyloxirene by retro-Diels–Alder reactions, and reactions of dimethyloxirene: a computational study

C. Delamere, C. Jakins, and E. Lewars

Abstract: The isomerization of oxirene (oxacyclopropene) (**1**) to ketene, dimethyloxirene (**7**) to dimethylketene via the oxo carbene ("ketocarbene"), and the retro-Diels–Alder extrusion of oxirene and dimethyloxirene from their formal adducts (**9** and **24**, respectively) with benzene were studied computationally. All species were optimized at the MP2(fc)/6–31G(df,p) level; the species involving **1** were also subjected to MP2(fc)/6–31G(df,p) frequency and single-point CCSD(T)/6–31G(df,p) calculations. At the CCSD(T)/6–31G(df,p)//MP2(fc)/6–31G(df,p) level **1** isomerized to ketene in one step with a barrier of 2.8 kJ mol^{-1} and a reaction energy of –320.6 kJ mol^{-1}. The extrusion of **1** from **9** had a late transition state and activation and reaction energies of 264.2 and 214.2 kJ mol^{-1}, respectively, cf. cyclopropene extrusion from its adduct (192.3 and 95.9 kJ mol^{-1}), indicating an antiaromatic destabilization energy of 214.2 – 95.9 = 118 kJ mol^{-1} for **1**. The carbene **8** from ring-opening of **7** lay 10.9 kJ mol^{-1} above **7** (CCSD(T)/6–31G(df,p)//MP2(fc)/6–31G(df,p)), but the transition state could not be found; **8** isomerized to dimethylketene (252.7 kJ mol^{-1} below **7**) with a barrier of 16.4 kJ mol^{-1}, and to *s*-(*Z*)- and *s*-(*E*)-butenone with barriers of 28.5 and 35.4 kJ mol^{-1}, respectively. The UV (TDDFT, B3P86/6–311++G**//MP2(fc)/6–31G(df,p)) spectra of **1** and **7** were calculated. Discrepancies were seen between the calculated IR spectra of **7** (bis(trifluoromethyl)oxirene) and perfluoroethylmethyloxirene, and those attributed to these species in earlier matrix-isolation work.

Key words: oxirene, dimethyloxirene, ab initio, retro-Diels–Alder, Diels–Alder.

Résumé : Faisant appel à des calculs théoriques, on a étudié les réactions d'isomérisation de l'oxirène (oxacyclopropène) (**1**) en cétène et du diméthyloxirène (**7**) en diméthylcétène par le biais de l'oxocarbène (cétocarbène) ainsi que la réaction d'extrusion de rétro-Diels–Alder de l'oxirène et du diméthyloxirène à partir de leurs adduits formels (respectivement **9** et **24**) dans le benzène. Toutes les espèces ont été optimisées au niveau MP2(fc)/6-31G(df,p); les espèces impliquant le composé **1** ont aussi été soumises à des calculs de fréquence MP2(fc)/6-31G(df,p) et ponctuels CCSD(T)/6-31G(df,p). Au niveau CCSD(T)/6-31G(df,p)//MP2(fc)/6-31G(df,p), le composé **1** s'isomérise en cétène en une étape avec une barrière de 2,8 kJ mol^{-1} et une énergie de réaction de –320,6 kJ mol^{-1}. L'extrusion de **1** à partir de **9** implique un état de transition tardif et des énergies d'activation et de réaction de 264,2 et 214,2 kJ mol^{-1}, cf. pour l'extrusion du cyclopropène de son adduit (192,3 et 95,9 kJ mol^{-1}) ce qui implique une énergie de déstabilisation antiaromatique de 214,2 – 95,9 = 118 kJ mol^{-1} pour **1**. L'énergie du carbène **8** provenant de l'ouverture de cycle de **7** est supérieure (CCSD(T)/6–31G(df,p)//MP2(fc)/6–31G(df,p)) de 10,9 kJ mol^{-1} à celle de **7**, mais on n'a pas pu déterminer son état de transition. Le produit **8** s'isomérise en diméthylcétène (énergie de 252,7 kJ mol^{-1} inférieure à celle de **7**) avec une barrière de 16,4 kJ mol^{-1} et en *s*-(*Z*)- et *s*-(*E*)-buténone avec des barrières respectivement de 28,5 et 35,4 kJ mol^{-1}. On a calculé les spectres UV (TDDFT; B3P86/6–311++G**//MP2(fc)/6–31G(df,p)) des composés **1** et **7**. On a observé des divergences entre les spectres IR calculés des composés **7** (bis(trifluorométhyl)oxirène) et perfluoroéthylméthyoxirène et ceux attribués à ces espèces dans un travail antérieur au cours duquel ils auraient été isolés dans des matrices.

Mots clés : oxirène, diméthyloxirène, ab initio, rétro-Diels–Alder, Diels–Alder.

[Traduit par la Rédaction]

Introduction

The C_2H_2O potential energy surface continues to be one of the most intensively scrutinized surfaces, almost 30 years after the first computational studies (1). The realistic synthetic objectives (other structures can be drawn) on this surface are molecules **1** (oxirene), **2** (oxo carbene or "ketocarbene" methanoylcarbene or formylcarbene), **3** (ketene), **4** (oxiranylidene or carbenaoxirane), **5** (hydroxyethenylidene or hydroxyvinylidene), and **6** (ethynol or

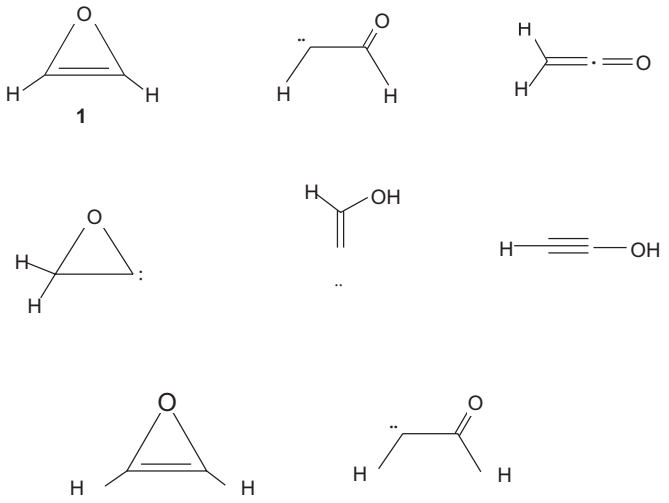
Fig. 1. The more realistic synthetic objects on the C_2H_2O potential energy surface (other species can be drawn) and the dimethyl analogues of **1** and **2** (**7** and **8**).



hydroxyacetylene) (Fig. 1). In this paper our calculations on the reactions of **1** and **7** and on the possibility of generating them by retro-Diels–Alder reactions are presented. Molecules **4** (2), **5** (3), and **6** (4), which are outside the scope of this paper, have been discussed in the literature. Oxirene (**1**) is perhaps, next to the industrially important ketene, the most intensively studied of the species **1**–**6**; the oxirene literature has been reviewed to 1983 (5). Notable subsequent developments have been the reports that: (*i*) monomethyl oxirene (6) but not oxirene (7) can be generated by neutralization of the radical cation in a mass spectrometer. (*ii*) Bachmann et al. (8) observed in a cryogenic matrix an IR absorption that they ascribed to the C—C double bond stretch of dimethyloxirene. This and earlier matrix-isolation work by Torres et al. (9), in which the detection of perfluoroalkyloxirenes was claimed, are apparently the only reports of the isolation of oxirenes. (*iii*) If oxirene is indeed a true intermediate, i.e., a relative minimum on the potential energy surface, its existence is borderline (10, 11), and the barrier to its isomerization to the carbene **2** by ring-opening with C—O bond cleavage is extremely low (12). The existence of **2** is also uncertain (5, 12), and **1** may isomerize directly to ketene **3** without going through **2**. The best computed potential energy surface so far (12) gives **1** → **2** and **2** → **3** barriers heights of 1.3 and 20.2 kJ mol^{-1}, respectively. (*iv*) Disubstitution with groups of widely different electronic natures (from a "periodic scan" of H, BH_2, CH_3, NH_2, OH, and F) destabilizes the putative minimum, except for CH_3 and perhaps F (13). (*v*) Benzoannelation stabilizes the oxirene system (14), but push–pull substitution, effective for other antiaromatic (15) molecules like cyclobutadiene (16), does not seem to work here (17).

The recent assertion (2) that of all of the C_2H_2O species only **3**, **4**, and **6** are likely to be accessible by thermal retro [4+2] reactions (18); the demonstration that, at least among simple "first-row" substituents, only CH_3 appears to distinctly stabilize oxirene (13); and the report (8) of the generation of **7** via the carbene **8**, where experiment was augmented by semiempirical calculations of reaction profiles, prompted us to explore the retro-Diels–Alder extrusion of **1** and **7** and the reactivity of **7**, at reasonably high ab initio levels.

Computational methods

Ab initio (19, 20) geometries and frequencies were calculated with Gaussian 98W[3] on 1 GHz Pentium 3 and 1.5 GHz Pentium 4 computers, with the Windows NT operating system. Geometry optimizations were followed by frequency calculations (21) at the same level to verify that the structure was the desired relative minimum (no imaginary frequencies) or transition state (one imaginary frequency), and to obtain zero-point energies (ZPEs) to correct for the frozen-nuclei energy. Animation of the imaginary frequency of transition states usually served to confirm the nature of the reaction coordinate, i.e., to identify the reactant and product (for the transition state linking **1** and ketene an intrinsic reaction coordinate (IRC) calculation (22) was also done). The correction factor to MP2(fc)/6–31G(df,p) ZPEs is estimated to be in the range 0.96–0.97 (23), and a correction was not used, as its effect on energy differences is negligible (see below). For molecules too large for MP2(fc)/6–31G(df,p) frequency calculations the use of HF/3–21G ZPEs (multiplied by 0.9207 (23)) is shown to be reasonable. The choice of MP2(fc)/6–31G(df,p) geometry optimizations and coupled-cluster (24) CCSD(T)/6–31G(df,p)//MP2(fc)/6–31G(df,p) single-point calculations is discussed below. Absolute total energies, ZPEs, and ZPE-corrected energies are available in the supplementary material tables.[4] Löwdin bond orders (25) were from single-point HF/3–21G calculations with Spartan[5] on Gaussian 98W MP2(fc)/6–31G(df,p) geometries.

Results and discussion

Reliability of the computational methods

The very extensive study of Vacek et al. (11) showed that the curvature of the potential energy surface (i.e., where stationary points exist and whether particular stationary points are minima or saddle points) for C_2H_2O at the geometry of the parent oxirene is quite sensitive to correlation levels and basis sets: the C_{2v} oxirene structure is always a stationary point, but its response to the computational level is some-

Table 1. Calculated relative energies of the species (Fig. 2) on the MP2(fc)/6–31G(df,p) oxirene potential energy surface.

	MP2(fc)/6–31G(df,p)		CCSD(T)/6–31G(df,p)//MP2(fc)/6–31G(df,p)	
Species	With MP2 etc. ZPE	With HF/3–21G ZPE	With MP2 etc. ZPE	With HF/3–21G ZPE
1, Oxirene	0	0	0	0
1t, Transition state	47.8	44.3	2.8	–0.74
3, Ketene	–329.0	–330.5	–320.6	–322.1

Note: MP2 ZPEs are uncorrected (see text), HF/3–21G ZPEs have been multiplied by 0.9207 (23).

what fickle. Hartree–Fock calculations always yield a relative minimum and DFT a transition state, but the result of MP2, quadratic CI (QCISD and QCISD(T)), and coupled cluster (CCSD and CCSD(T)) calculations is basis set dependent. We sought the highest level that would be practical, with our facilities, for the somewhat large molecules (up to 11 heavy atoms) we wished to examine, and which would also give the same potential energy surface curvature for **1** as did the highest levels used by Vacek et al., namely CCSD(T) with triple-ζ basis sets containing several *d* shells and an *f* shell on C and O and several *p* shells and a *d* shell on H. At these very high levels, **1** was a relative minimum with ring-opening vibrational modes of 139–163 cm^{-1}. The lowest correlated level used by Vacek et al. (11), which predicted **1** still is a minimum, was MP2(fc)/6–311G(df,p) with ring-opening mode of 129 cm^{-1}. We find that at the MP2(fc)/6–31G(df,p) level (doubly split rather than triply split valence shell) **1** is still a minimum, with ring-opening mode of 153 cm^{-1}. This is almost the lowest standard ab initio correlated level where **1** is a minimum (omitting the *p* functions on H, **1** still has a minimum, with ring-opening frequency of 148 cm^{-1}) and, therefore, we chose this for all geometry optimizations, and also calculated frequencies at this level for formal adducts of **1** and benzene, and smaller species. To improve relative energies, single-point CCSD(T)/6–31G(df,p)//MP2(fc)/6–31G(df,p) calculations were also done on these smaller MP2(fc)/6–31G(df,p) geometries (our longest calculation, numerical frequencies on a $C_8H_{10}O$ C_1 symmetry species, took 11 days on a 1.5 GHz Pentium 4). We could not use DFT — this always makes oxirene and dimethyloxirene transition states. It should be noted that it has not yet been settled whether oxirene is a relative minimum or a transition state: there is no direct experimental evidence for the parent molecule, and even at the highest levels used so far (11) the results are somewhat quirky as some CCSD(T) calculations with large basis sets gave an imaginary ring-opening frequency. These results should settle the question of the feasibility of generating **1** (assuming it is a minimum) and **7** (which is very likely a minimum (13)) by thermal retro-Diels–Alder reactions, and delineate the intramolecular reactions of **7.**

Oxirene (1), ring-opening

On the MP2(fc)/6–31G(df,p) potential energy surface **1** is a relative minimum that passes through transition state **1t** with a barrier of 2.8 kJ mol^{-1} to form ketene **3**, which lies 320.6 kJ mol^{-1} below **1** (CCSD(T)/6–31G(df,p) single point energies, Table 1 and Fig. 2). The highest-level calculations reported so far for this reaction sequence, CCSD(T)/6–311G(df,p) by Scott et al. (12), are also shown in Fig. 2. They too assign oxirene a low barrier to ring opening, but predict the carbene (**2**) to be a minimum slightly below **1** with a barrier (20.2 kJ mol^{-1}) to the hydrogen migration that transforms it into ketene, whereas at our level carbene **2** is not a stationary point. Scott et al. also find that at the MP2/6–311G(df,p) (triply split) level **2** is not a stationary point and **1** goes to **3** with a barrier of 43.8 kJ mol^{-1}. Our MP2(fc)/6–31G(df,p) barrier is 47.8 kJ mol^{-1}, but this is markedly lowered by a single point CCSD(T)/6–311G(df,p) calculation to 2.8 kJ mol^{-1} (Table 1).

All levels place ketene **3** far below **1**. The MP2(fc)/6–31G(df,p) level, used for all the geometry optimizations in this work, thus concurs with the CCSD(T)/6–311G(df,p) optimizations (12) in finding **1** to be a minimum with a small barrier to ring opening. The activation energy of –0.74 kJ mol^{-1} from the HF/3–21G ZPE correction is probably an artifact of applying a ZPE from one level of calculation to a very small raw energy difference obtained at another level. The use of HF/3–21G ZPEs, where MP2 ZPEs were not routinely feasible, is justified below in the discussion of the data in Table 2; they were calculated in all cases for consistency. Our MP2(fc)/6–31G(df,p) oxirene structure (see below) is similar to the CCSD(T)/6–311G(df,p) structure of Scott et al. (12), and our oxirene-to-ketene transition state **1t** (Fig. 2) resembles their carbene-to-ketene transition state.

Oxirene (1), retro-Diels–Alder extrusion

Four retro-Diels–Alder reactions were examined (Fig. 3; this also shows bond lengths and orders, discussed below). For the formation of **1**, the formal oxirene–benzene adduct **9**, the transition state **10**, and the products **1** and **11**, were optimized at the MP2(fc)/6–31G(df,p) level; the vibrational frequencies were calculated at this level; and single-point CCSD(T)/6–31G(df,p) calculations were performed on the MP2 geometries (MP2(fc)/6–31G(df,p) as well as HF/3–21G ZPE corrections were applied to the MP2 and CCSD(T) energies). For the formation of cyclopropene, **12**–**14** and **11** were optimized at the MP2(fc)/6–31G(df,p) level and single-point CCSD(T)/6–31G(df,p) calculations were performed on the MP2 geometries, but only HF/3–21G ZPE corrections were applied to the MP2 and the CCSD(T) energies. For the extrusion of ethene from the formal adduct with benzene, and for the prototypical retro-Diels–Alder reaction, the conversion of cyclohexene to ethene and 1,3-butadiene analogous calculations were done on **11**, and **15**–**17**, and on **17**–**20**. Benzene was chosen as the "diene" because its stability seems to offer the best chance of obtaining the dienophiles **1** and **7** from a retro-Diels–Alder reaction.

The relative energies for these extrusion reactions are shown in Table 2. The use of ZPEs from HF/3–21G frequencies rather than MP2(fc)/6–31G(df,p) frequencies, a practi-

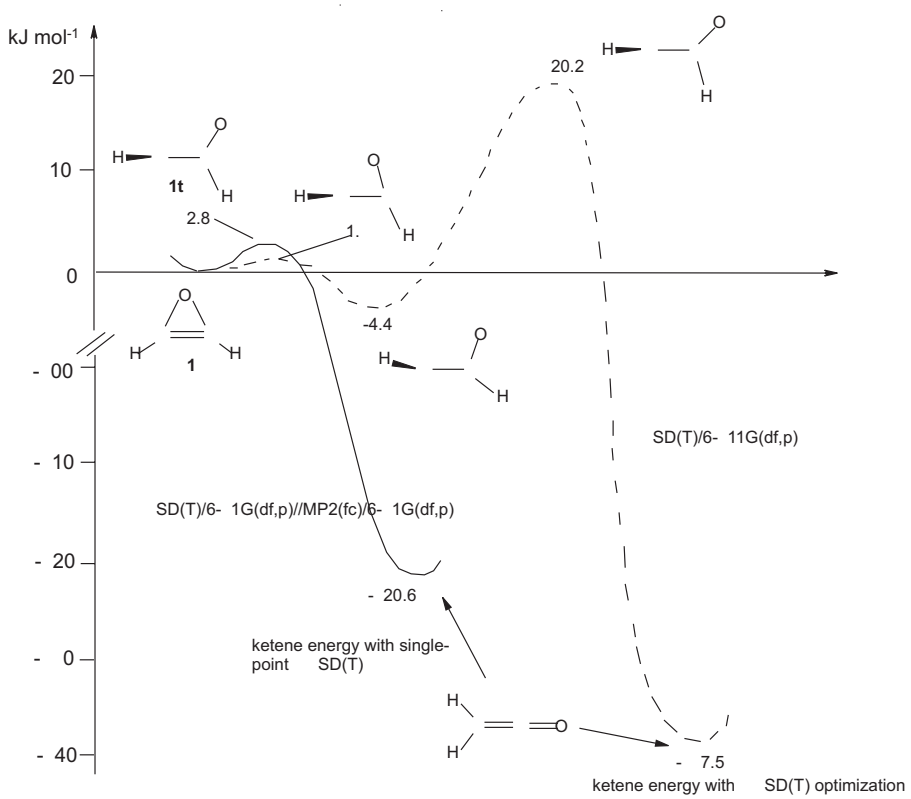
Fig. 2. Reaction profiles for ring opening of oxirene. CCSD(T)/6–31G(df,p)//MP2(fc)/6–31G(df,p) with MP2(fc)/6–31G(df,p) ZPE (see Table 1); the CCSD(T)/6–311(df,p) calculation is from ref. 12. For clarity, the ketene minimum is shown separately for the two routes leading to it.



cal necessity since several formal benzene adducts were examined, makes little difference to the relative energies. In Table 2, where both were calculated for two systems (**10** and **1** + **11**), the HF ZPE gives a relative energy ca. 3 kJ mol^{-1} higher for the transition state (**10**), and ca. 7 kJ mol^{-1} higher for the products (**1** + **11**). In Table 1, where both were calculated for **1t** and for **3**, the maximum discrepancy is 3.5 kJ mol^{-1}. For a comparison of the eight systems, which show a maximum discrepancy of 3.7 kJ mol^{-1} (for **8ta** and **8tb**), see below. Correcting the MP2 ZPEs by 0.96 (the correction factor is estimated to be 0.96–0.97) (23), has practically no effect on the relative energies: 241.7 becomes 242.5, 261.3 becomes 262.1, 216.2 becomes 217.4, and 207.5 becomes 208.7 (cf. Table 2). Because MP2(fc)/6–31G(df,p) frequency calculations on all the benzene adducts were scarcely practical (particularly in the dimethyloxirene series, where we estimate the time for each calculation to vary from a minimum of 22 to up to 44 days), we chose to consistently use HF/3–21G ZPEs. Where MP2 optimizations were not followed by frequency calculations we have assigned the structure the status of a minimum or a transition state by analogy with **9** and **10**. Figure 4 depicts the reaction profiles for the CCSD(T)/6–31G(df,p)//MP2(fc)/6–31G(df,p) (with HF/3–21G ZPE) calculations in Table 2.

For the extrusion of ethene from cyclohexene, the experimental activation and reaction energies have been reported to be 266 and 161 kJ mol^{-1}, respectively (26). Our calculated corresponding energies are 267.7 and 200.7 kJ mol^{-1} for the MP2(fc)/6–31G(df,p), and 273.3 and 176.5 kJ mol^{-1} for the CCSD(T)/6–31G(df,p)//MP2(fc)/6–31G(df,p) levels (Table 2). Bearing in mind that the calculated energy differences are 0 K enthalpy differences, the agreement is good and gives us confidence in the other calculated relative energies. The activation energy for oxirene extrusion is, as expected, much higher than that for oxirene ring-opening (below), and confirms that detecting **1** from a thermal retro-Diels–Alder reaction is probably impossible. Our best value (CCSD(T) single-point with MP2 ZPE) for this retro-Diels–Alder activation energy is 261.3 kJ mol^{-1}.

The main value of these calculations is not so much the demonstration that thermal extrusion of oxirene from **9** is not a feasible route to **1** (which was not in serious doubt), but rather the light they shed on the relative energies and the structures of the species involved. Concerning the energetics of these reactions (Fig. 4), consider the changes seen on going from the prototypical retro-Diels—Alder reaction, the fragmentation of cyclohexene (**18**) to ethene and 1,3-butadiene, to the conversion of dihydrobarrelene (**15**) to ethene and benzene: the increased strain imposed by the etheno bridge, and the formation of the resonance-stabilized benzene, should raise the energy of the reactants relative to that of the products. This will decrease the reaction energy and, considering the transition state on a reaction coordinate diagram as the intersection of reactant and product curves (the Bell–Evans–Polanyi concept (27)), should also decrease the activation energy, and in fact these calculated energies go from ca. 177 to 6 (*sic*) and 273 to 159 kJ mol^{-1}, respectively. Comparing the reaction profile of **12** with that of **15**, there is

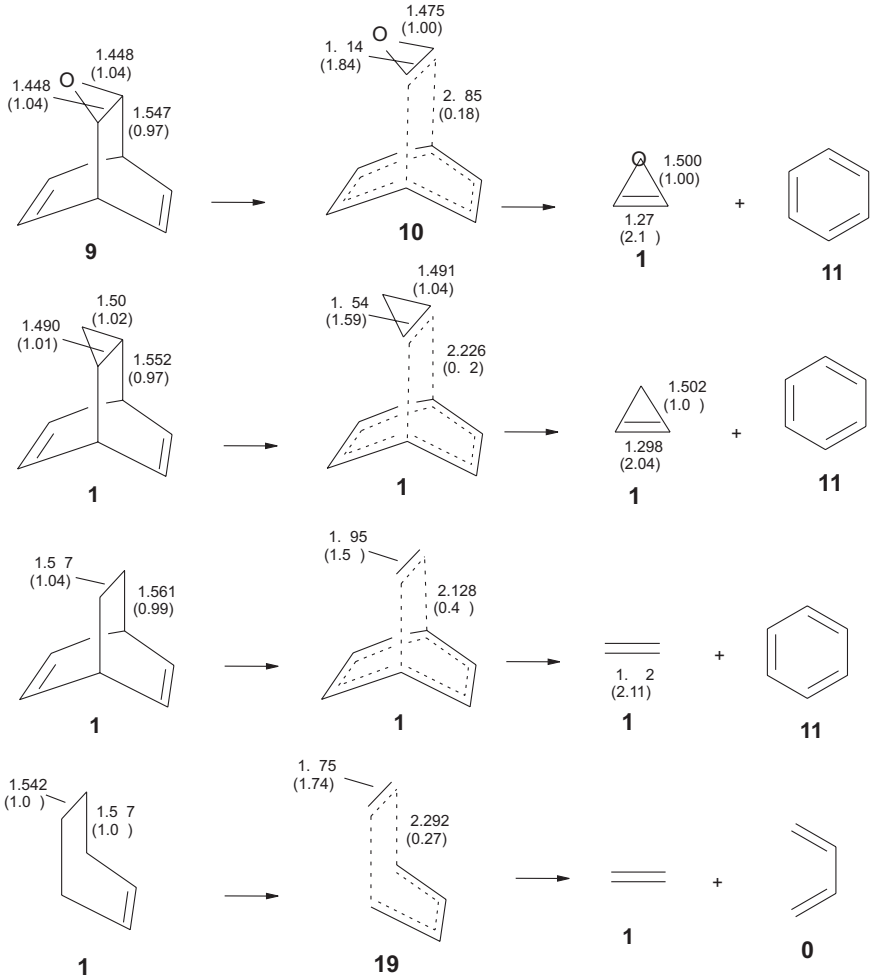
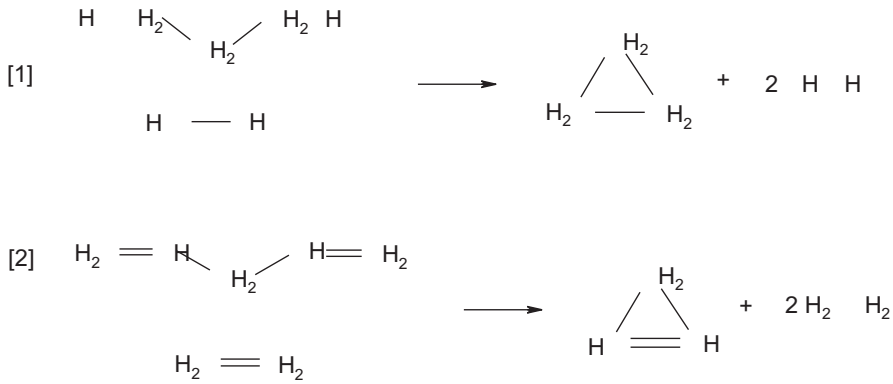
Fig. 3. Retro-Diels–Alder extrusions of oxirene, cyclopropene, and ethene from formal adducts with benzene, and fragmentation of cyclohexene to ethene and 1,3-butadiene. Key bond lengths are shown in Å for MP2(fc)/6–31G(df,p) geometries, and Löwdin bond orders in parentheses for HF/3–21G calculations on the MP2(fc)/6–31G(df,p) geometries.



Scheme 1. Isodesmic reactions for formation of cyclopropane and cyclopropene.



increased strain in both reactant and products caused by the introduction of three-membered rings (benzene is common to both reactions). However, in the reactants an ethano bridge becomes a cyclopropane unit (**15** cf. **12**), while in the products ethene becomes cyclopropene. From the simplest view-point the effect of this depends on the increase in strain on going from ethane to cyclopropane compared to that in going from ethene to cyclopropene, or more precisely, on the isodesmic reaction energies (28) for rxn. [1] compared to rxn. [2] (Scheme 1; these reactions are written to illustrate the concept, and can obviously be simplified by removing a CH_3CH_3 or a CH_2CH_2 from each side). This amounts to the strain energy of cyclopropane vs. cyclopropene (115 vs. 218 kJ mol^{-1} (29)). Our calculations on rxns. [1] and [2] by

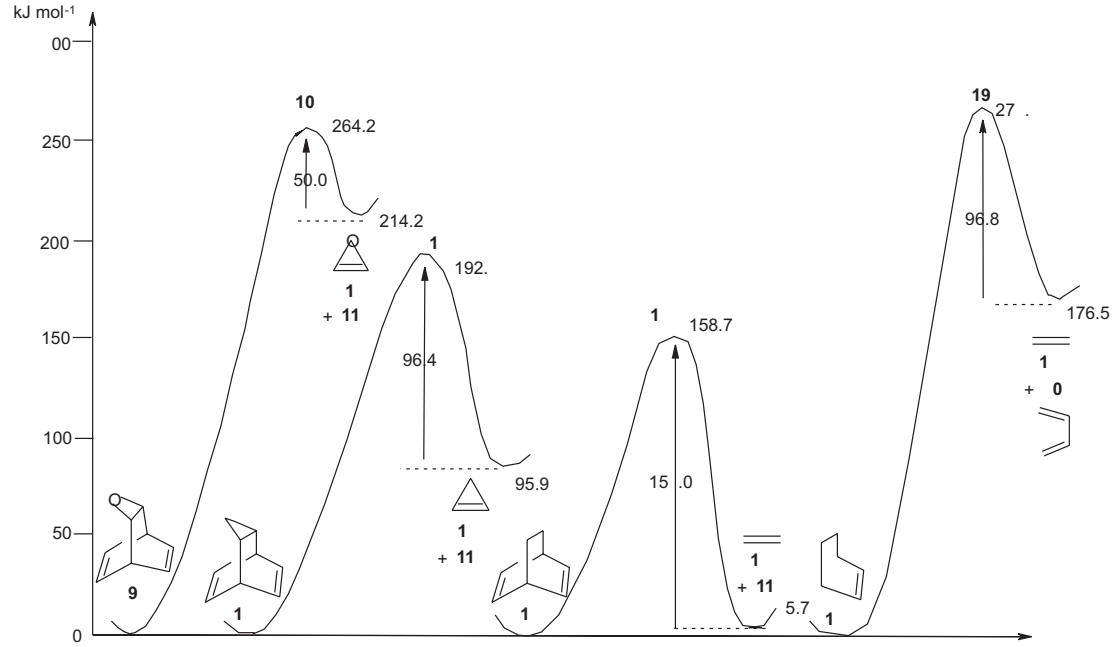
Fig. 4. Reaction profiles for the retro-Diels–Alder extrusions of oxirene, cyclopropene, and ethene from formal adducts with benzene, and fragmentation of cyclohexene to ethene and 1,3-butadiene, calculated at the CCSD(T)/6–31G(df,p)//MP2(fc)/6–31G(df,p) level with HF/3–21G ZPE corrections. Based on the data in Table 2.



the fast but accurate (30) pBP/DN* DFT method (31), as implemented in Spartan, gave 103 vs. 210 kJ mol^{-1} for ΔE. Naively, one would expect the reaction energy to rise by about 100 kJ mol^{-1} and the activation energy by somewhat less: the former is calculated to increase from 5.7 to 95.9 kJ mol^{-1} and the latter from 158.7 to 192.3 kJ mol^{-1} (Fig. 4).

The energetics of the retro Diels–Alder reaction of **12** compared to **9** are particularly interesting. If we assume that replacing a CH_2 group in a three-membered ring by an O has only a small effect on strain energy (and indeed the strain in cyclopropane and oxacyclopropane (oxirane) is similar, 118 cf. 105 kJ mol^{-1}, respectively (32)), then the difference in the reaction energies of these two extrusions directly reflects the antiaromatic (15) destabilization of oxirene. The value for this difference (214.2 – 95.9 = 118 kJ mol^{-1}) compares well with our independent estimate[6] of ca. 124 kJ mol^{-1} for this antiaromatic destabilization (this may be compared with the partly experimental estimate (33) of 201–230 kJ mol^{-1} for the notoriously reactive cyclobutadiene). As expected, the change in activation energy, which only partly reflects the antiaromaticity of oxirene, is smaller

Table 3. Bond order and energetics measures of the lateness of the retro-Diels–Alder transition states **19**, **16**, **13**, and **10**.

Transition state	Bond order measure	Energetics measure
19	1/2(0.74 + 1 – 0.27) = 0.74	273.3/(273.3 + 96.8) = 0.74
16	1/2(0.53 + 1 – 0.43) = 0.55	158.7/(158.7 + 153.0) = 0.51
13	1/2(0.59 + 1 – 0.32) = 0.64	192.3/(192.3 + 96.4) = 0.67
10	1/2(0.84 + 1 – 0.18) = 0.83	264.2/(264.2 + 50.0) = 0.84

Note: See Figs. 3 and 4.

(264.2 – 192.3 = 72 kJ mol^{-1}); nevertheless, this is a large fraction of the increase in reaction energy, and indicates that an oxirene moiety is substantially formed in the transition state. This conclusion is reinforced by examination of the structures of the species in these reactions.

The information from the structures (Fig. 3) in these retro-Diels–Alder reactions complements that from the relative energies, and we will refer to changes in bond order (BO) as these are most readily apprehended (they correlate reasonably with bond length changes). The C-C double bond BOs in the dienophiles (**1**, **14**, **17**) and in the corresponding bond of the pro-dienophile moieties of the reactants are, as expected, close to 2 and 1, respectively. This makes it easy to gauge the lateness of a transition state by comparing the C-C BO of the incipient C-C double bond with the BOs of the corresponding bond in the reactant and product; the case for using BOs in this way has been made by Lendvay (34). These BO changes correspond complementarily with those of the two equivalent bonds (all the reactants are of C_s or C_{2v} symmetry) tethering the diene and dienophile moieties. The sum of the dienophile and tether BOs is always close to 2, varying from 1.91 in **13** to 2.02 in **10**. Consider the prototypical retro-Diels–Alder reaction, **18** → **19** → **17** + **20** (Fig. 3): in **19** the BO of the incipient C-C double bond is 1.74, and comparing this with the corresponding BOs in **18** and **17**, close to 1 and 2, respectively, shows that this reaction has a late transition state, with ethene largely extruded; in agreement with this view, the tether bonds BOs have gone from 1.03 in **18** to only 0.27. For simplicity we can use the extent of C-C double bond formation as the criterion of the lateness of the transition states in these reactions, and thus say that **19** lies 74% of the way along the reaction coordinate. Complementing the structural evidence, the energy profile for this reaction (Fig. 4) shows a transition state much closer in energy to the products than to the reactant, which in accordance with the Hammond postulate (35) likely resembles the products. By the above criteria, the extrusion reaction of ethene from dihydrobarrelene (**15** → **16** → **17** + **11**) has a transition state midway between reactants and products (53% along the reaction coordinate) that is in almost perfect accord with its reaction profile, which places **16** slightly closer to the products than to the reactants. The extrusion reaction of cyclopropene from cyclopropanodihydrobarrelene (**12** → **13** → **14** + **11**) has a transition state slightly more advanced than that of the ethene extrusion (59% along the reaction coordinate), and again this agrees with the reaction profile.

Of special interest is the extrusion of oxirene from barrelene oxide (**9** → **10** → **1** + **11**), which may be profitably compared with the cyclopropene extrusion. The transition state here is considerably later than that for the cyclopropene case (84 vs. 59% along the reaction coordinate), although strain factors should be similar in both cases. This is in essentially perfect accord with the energetics, where the reaction profile shows a transition state far closer in energy to the products than the reactants. Such a late transition state is of course expected from a reaction that requires the formation of an antiaromatic, high-energy molecule.

The quantitative relationship between the lateness of these transition states as measured by bond orders and by energetics is interesting. We choose here as the BO measure the mean of the increase in BO from unity of the incipient C-C double bond and the decrease in BO from unity of the tether bond (Table 3 makes this clear). As the energetics measure we use the activation energy of the forward reaction divided by the sum of the activation energies of the forward and reverse reactions (thus for a degenerate reaction this gives an energetics measure of 0.5 or 50%). The results of these calculations are shown in Table 3. The agreement between the two measures is striking.

We note that lower-energy, possibly ionic, pathways are likely to effectively compete with these pericyclic processes, and indeed although flash thermolysis of a (bis)methoxycarbonyl derivative of **9** intriguingly gave some ketene, the main pathway was isomerization to cycloheptatrienecarboxaldehydes (36).

Dimethyloxirene (7), ring-opening and subsequent reactions

Dimethyloxirene (**7**) is interesting because it is the only substituted oxirene, which high-level calculations have clearly indicated it to be a relative minimum rather than a transition state (13), and in a careful and comprehensive study its infrared spectroscopic detection has been claimed (8). The energetics of our calculations on the ring-opening of **7** to oxo carbene ("ketocarbene") **8** and the reactions of **8** are summarized in Table 4 and Fig. 5.

Carbene **8** is calculated to lie above the oxirene. As is the case with the carbene-like transition state **1t** (Table 1 and Fig. 2) in the ring-opening of the parent oxirene (the parent carbene is not a stationary point at the MP2(fc)/6–31G(df,p) level), the relative energy of **8** decreases significantly on going from the MP2 to the (single-point) CCSD(T) level, i.e., from 33.2 to 10.9 kJ mol^{-1} (Table 4 and Fig. 5). Despite much effort we were unable to locate a properly characterized transition state connecting the oxirene and the carbene. The structure **7t** in Figs. 5 and 6 was obtained by coordinate driving (closing the C-C-O carbene angle in steps of 5° to approach the angle of oxirene) and optimizing each structure, subject to this angle restraint, at the MP2(fc)/6–31G(df,p) level. The highest-energy structure along this path (C-C-O = 110°) was subjected to a single-point CCSD(T)/6–31G(df,p) calculation. Coordinate driving is not guaranteed to find a transition state (37), and the relatively large C-C-O

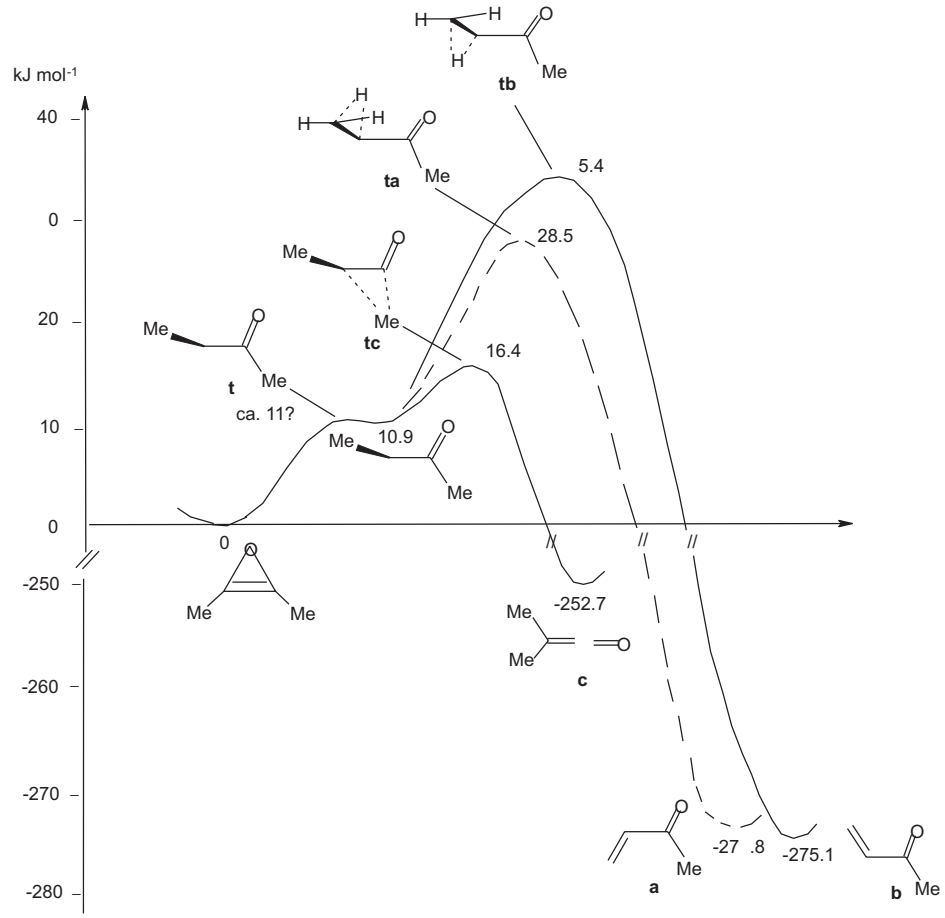
Note: MP2 ZPEs are uncorrected (see text), HF/3–21G ZPEs have been multiplied by 0.9207 (23). The CCSD(T) calculations are at the MP2(fc)/6–31G(df,p) geometry.

[a]Non-optimized structure – see text.

[b]cf. **7** with no ZPE.

Fig. 5. Reaction profiles for ring opening of dimethyloxirene to the oxo carbene and for reactions of the oxo carbene using CCSD(T)/6–31G(df,p)//MP2(fc)/6–31G(df,p) with MP2(fc)/6–31G(df,p) ZPE, except for **7t**, which is from coordinate driving and is not fully optimized. Based on the data in Table 4.



angle of 110° for **7t**, cf. 64.9° and 121.0° for the oxirene and carbene, respectively, suggests that the geometry of this structure may differ significantly from that of the correct transition state; although in accordance with the Hammond postulate (35), the transition state probably does lie closer to the carbene than to the oxirene. Since **7t** was not a properly

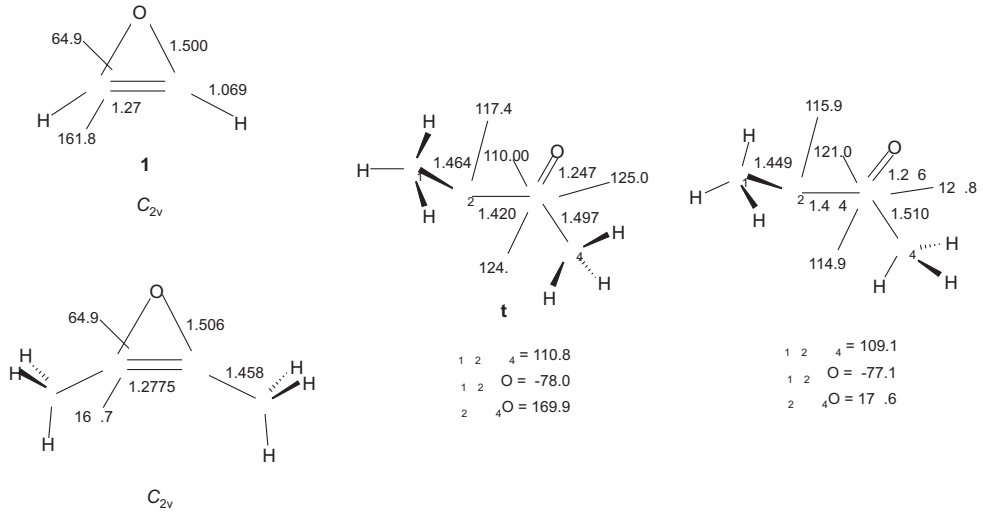
Fig. 6. Geometries of oxirene (**1**), dimethyloxirene (**7**), the oxo carbene (**8**), and the approximate (from coordinate driving) transition state structure **7t** calculated at the MP2(fc)/6–31G(df,p) level. Bond lengths are in Å and angles are in degrees.



optimized, stationary point ZPEs were not calculated for it (38) and the relative energies given for it in Table 4 represent the differences between the raw ab initio energies of **7** and **7t**. If we uniformly compare the energies of **7**, **7t**, and **8** without ZPE corrections, then at the MP2 level **7t** is ca. 2 kJ mol^{-1} *above* **8** but at the single-point CCSD(T) level it is 3 kJ mol^{-1} *lower*, implying that although the coordinate driving structure approximates the true transition state connecting **7** and **8**, this transition state lies only slightly above **8** (Fig. 5). The CCSD(T) dimethyloxirene–carbene energy difference is probably reliable, and places a lower limit on the barrier to ring-opening of this oxirene at about 11 kJ mol^{-1}, compared to 2.8 kJ mol^{-1} (1.3 kJ mol^{-1} for the CCSD(T)-optimized PES (12)) for the opening of the parent oxirene. Our geometries for oxirene **1**, dimethyloxirene **7**, oxo carbene **8**, and the approximate transition state for **7t** are shown in Fig. 6.

The oxo carbene **8** was calculated to readily undergo the standard carbene reactions of hydrogen and alkyl migration to give the butenones **8a** and **8b** (conformers),and dimethylketene (**8c**), with barriers of 35.4 – 10.9 = 17.6, 28.5 – 10.9 = 24.5, and 16.4 – 10.9 = 5.5 kJ mol^{-1}, respectively, (Fig. 5 and Table 4). In thermal processes, dimethyloxirene should drain away via the oxo carbene to give mainly dimethylketene. Our finding of a lower activation energy for the formation of dimethylketene than for butenone is consistent with the observation that in the gas phase collisional deactivation of vibrationally excited carbene **8** increases the ratio of dimethylketene to butenone, suggesting that the latter comes from higher vibrational levels of **8** (39).

We briefly comment on the (primarily experimental) work of Bachmann et al. (8) on dimethyloxirene and on the report by Torres et al. (9) on the preparation of perfluoroalkyloxirenes. Bachmann et al. photolyzed 3-diazo-2-butanone and confirmed by trapping with CO the formation of carbene **8**. Irradiation of **8** in a xenon matrix gave a species, stable below 25 K, that was assigned the structure of dimethyloxirene. An IR band at 2127.6 cm^{-1} from the perdeuterio diazoketone was attributed to the C=C stretch of **7**-d_6, and a band at 2137 cm^{-1} from the nondeuterated precursor was attributed to the C=C stretch of dimethyloxirene. HF/3–21G calculations on **1** and **7** and HF/6–31G** calculations on **1** supported these assignments. Table 5 contains our calculated vibrational spectra of oxirene, dimethyloxirene, and dimethyloxirene-d_6, at the MP2(fc)/6–31G(df,p) level. The correction factor for MP2(fc)/6–31G(df,p) frequencies should be close to 0.94 (23); using this value, the C=C stretch of dimethyloxirene-d_6 is calculated to come at 1969 cm^{-1} and the C=C stretch of dimethyloxirene at 1974 cm^{-1}. Both bands should be very weak or undetectable. On the other hand, the second-strongest band (49%, C—D stretch) in the calculated dimethyloxirene-d_6 spectrum should appear at about 2108 cm^{-1}, quite close to the observed 2127.6 cm^{-1} band. Although the band that was attributed to the C=C stretch of dimethyloxirene-d_6 could have been due to C—D stretch in that molecule, the IR results for undeuterated dimethyloxirene cast doubt on the claim that these two species were observed in the Bachmann et al. work. The only band in the IR spectrum of undeuterated dimethyloxirene that could conceivably appear at 2137 cm^{-1} is the C=C stretch, but our calculations place it distinctly (163 cm^{-1}) lower, and in any case it should be at best very weak. We question the strength of the IR evidence for the observation of dimethyloxirene, although (Fig. 5) this compound is indeed likely to be the proximate product from the carbene **8** in a thermal rearrangement.

Irradiation of the putative dimethyloxirene with broadband light of $\lambda > 230$ nm, but not with monochromatic 457.9 nm light, was reported (8) to lead to dimethylketene. This is consonant with the predicted UV spectrum of **7**, which we calculated on the MP2 geometry by the usually reliable TDDFT method (40) as implemented (41) in Gaussian 98, at the recommended (40) B3P86/6–311++G** level; Table 6 gives the calculated UV spectra of **1** and **7**. The dimethyl compound is predicted to lack absorption above ca. 290 nm (the zero-intensity absorptions are only formally forbidden, e.g., acetone is calculated to have an oscillator strength = 0 band at 290 nm, but in fact shows a very weak ϵ 13 band at 279 nm, a band that initiates a plethora of photo-

	3234 (25) C—H stretch	

Note: Band positions are in cm^{-1} and relative intensities are given in parentheses. All bands of relative intensity ≥ 5% and the ring-opening and C=C stretch bands are listed. None of the spectra have imaginary frequencies. A correction factor has not been applied to the band positions.

Table 6. UV spectra of oxirene (**1**) and dimethyloxirene (**7**), calculated by TDDFT (singlet → singlet), at the B3P86/6–311++G** level, using MP2(fc)/6–31G(df,p) geometries.

Oxirene	Dimethyloxirene
316 (0.0035, 49)	290 (0.0000, 0)
257 (0.0009, 13)	284 (0.0137, 100)
231 (0.0022, 31)	257 (0.0000, 0)
227 (0.0000, 0)	238 (0.0012, 9)
200 (0.0000, 0)	224 (0.0011, 8)
184 (0.0071, 100)	223 (0.0017, 12)

Note: Band positions are in nm and intensities (in parentheses) are given as oscillator strengths and relative intensities, respectively.

chemical reactions). The TDDFT UV of **7** is, thus, at least consistent with the reported (8) photochemical behavior.

The first credible report of the detection of an oxirene was that by Torres et al. (9). They tentatively assigned the bis(trifluoromethyl)oxirene structure (**21**) to one species, and concluded that another species was perfluoroethylmethyloxirene (**22**) by virtue of its formation from isomeric α-diazoketones **23a** and **23b**. We calculated the IR spectrum of **21** at the relatively fast MP2(fc)/6–31G* level after confirming that the calculated IR spectra of **1** and **7** had changed little on going from the 6–31G(df,p) to the 6–31G* basis set: **1** acquires an imaginary ring-opening mode (153 → 39*i* cm^{-1}) and the other bands move ca. 20–50 cm^{-1} to smaller wavenumber (except for C=C stretch, 1801 → 1799 cm^{-1}), whereas the bands of **7** shift (up and down) by up to 33 cm^{-1} (ring-opening mode, 128 → 132 and C=C stretch 2100 → 2090 cm^{-1}). If we realize that **21** may be a potential energy surface relative minimum, rather than the transition state implied by the imaginary frequency, the calculated and (tentative) experimental spectra of **21** may be compared (Table 7). It is not simple to draw a definite conclusion from this comparison, because the experimental intensities were characterized only qualitatively, the calculated intensities are only semiquantitative (42), and matrix effects (43) can cause observed frequencies to deviate somewhat from calculated gas-phase values. If we consider just those bands reported to be medium and strong, and bear in mind that a deviation of about 50 cm^{-1} is quite reasonable, we might correlate (calcd./exp.; Table 7) the 625 (3)/660 m, 1185 (62)/1160 m, and 1228 (100)/1275 s cm^{-1} bands, but the 1325 m cm^{-1} band has no calculated counterpart. For **22**, band positions but not intensities were reported; these might be compatible with other perfluoro-C_5 molecules, although obtaining the same spectrum from **23a** and **23b** clearly supports the assigned structure. It must be noted, however, that in their ma-

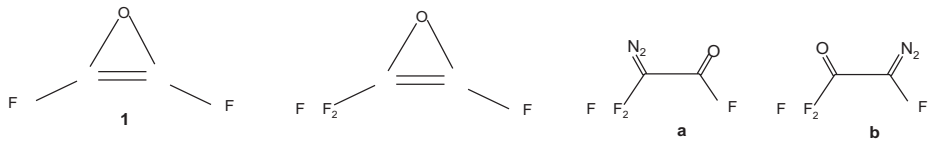

Fig. 7. Retro-Diels–Alder extrusion of dimethyloxirene from its adduct with benzene. Key bond lengths are shown in Å for MP2(fc)/6–31G(df,p) geometries, and Löwdin bond orders in parentheses for HF/3–21G calculations on the MP2(fc)/6–31G(df,p) geometries. The relative energies of reactant, transition state, and products, at the MP2(fc)/6–31G(df,p) level with HF/3–21G ZPE corrections, are given.

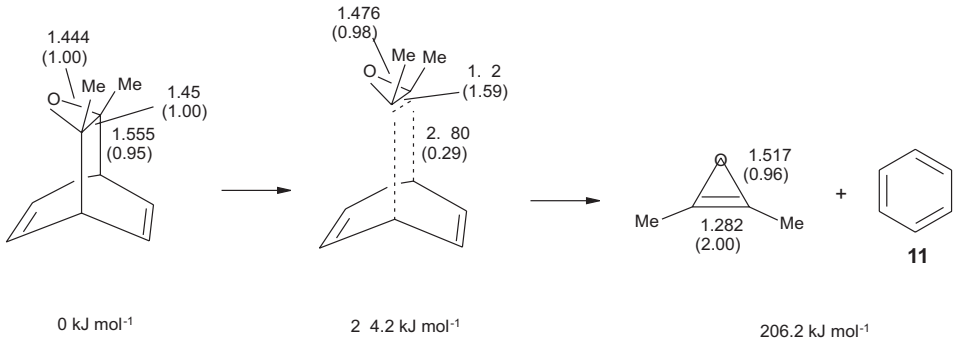

trix isolation study of perfluoro-3-diazo-2-butanone, Laganis et al. (44) were unable to obtain the IR spectrum ascribed (9) to **21**. We conclude that it is doubtful that any oxirene has yet been observed under matrix isolation conditions.

Dimethyloxirene (7), retro-Diels–Alder extrusion

Finally, we briefly summarize our results for the extrusion of **7** from its formal benzene adduct **24** (Fig. 7). Because of the size of **24**, it was studied only by optimization at the MP2(fc)/6–31G(df,p) level with HF/3–21G ZPE corrections; the structural and energetic similarities of **10** and **25** make us confident that **25** is indeed a transition state, and the results with the parent systems (Table 2) indicate that only small changes in relative energies should occur on going to the CCSD(T) level with MP2 ZPEs. Comparison with Fig. 3 shows, concentrating on bond orders, that the dimethyloxirene extrusion transition state **25** is significantly earlier than that for oxirene extrusion. If we say that **10** (Fig. 3) is about 80% (bond orders: 1.84–1 and 1–0.18) along the reaction coordinate, then **25** is only about 60–70% (1.59–1 and 1–0.29) along the way to completion. This is expected if dimethyloxirene is in fact stabilized by the methyl groups, i.e., it should be easier to extrude it. Oddly, this is scarcely reflected in the calculated energetics of the reaction; if we compare at the MP2(fc)/6–31G(df,p) level with HF/3–21G ZPE corrections the dimethyl case (Fig. 7) and the parent system (Table 2), we see that extrusion of **7** has calculated activation and reaction energies of 234.2 and 206.2 kJ mol^{-1}, respectively, while extrusion of **1** has 244.5 and 222.9 kJ mol^{-1} as the corresponding values.

Conclusions

Oxirene was calculated to isomerize directly to ketene with a barrier of 2.8 kJ mol^{-1}; that the carbene was not an intermediate may be an artifact of the CCSD(T)/6–31G(df,p)//MP2(fc)/6–31G(df,p) computational level. At this level the formal oxirene–benzene adduct is calculated to undergo a retro-Diels–Alder reaction with a barrier of 264 kJ mol^{-1}, and so the oxirene, even if a genuine potential surface relative minimum, is likely to be undetectable. Comparison of the extrusion reactions for oxirene and cyclopropene indicated an antiaromatic destabilization energy for oxirene of 118 kJ mol^{-1}. There are discrepancies between our calculations and IR bands reported for dimethyloxirene and for bis(trifluoromethyl)oxirene.

The dimethyloxirene → oxo carbene transition state could not be characterized, but the carbene was a relative minimum 10.9 kJ mol^{-1} above the oxirene (CCSD(T)/6–31G(df,p)//MP2(fc)/6–31G(df,p)). The carbene was predicted to isomerize to dimethylketene with a barrier of 16.4 kJ mol^{-1}, while the two conformers of butenone were calculated to be formed with barriers of about 30 kJ mol^{-1}. Comparing the oxirene and dimethyloxirene extrusions (at the MP2(fc)/6–31G(df,p) level with HF/3–21G ZPEs and bond orders), the dimethyloxirene extrusion involves an earlier transition state as judged by bond orders, yet has only a slightly lower activation energy.

Inhibition de la corrosion de l'alliage d'aluminium 6063 au moyen de composés inorganiques dans une solution de chlorure de sodium à 3 %

L. Bazzi, R. Salghi, E. Zine, S. El Issami, S. Kertit et B. Hammouti

Résumé : L'effet de l'addition de certains composés inorganiques sur le comportement à la corrosion d'un alliage d'aluminium 6063, dans une solution de chlorure de sodium à 3 % est étudié à l'aide des méthodes électrochimique et métallographique. Les composés testés sont les oxo-anions MoO_4^{2-}, CrO_4^{2-}, NO_2^- et les cations métalliques Li^+ et Mg^{2+}. Les résultats obtenus montrent que les composés testés inhibent le processus de corrosion de l'alliage 6063. Le caractère inhibiteur le plus marqué est obtenu en présence des ions Li^+. L'augmentation de la concentration de ces ions a pour effet d'accroître la différence entre le potentiel de piqûration et le potentiel de corrosion. L'efficacité maximale de l'ordre de 85 % est atteinte dès une concentration de 5×10^{-3} M. L'élévation de la température de 25 à 55°C a pour effet d'améliorer la résistance à la corrosion de l'alliage 6063 dans le milieu témoin. Cependant, en présence des ions Li^+, l'efficacité inhibitrice subit une décroissance lorsque la température augmente.

Mots clés : corrosion, inhibition, composés inorganiques, alliage d'aluminium 6063, NaCl 3 %.

Abstract: Some inorganic compounds have been tested as corrosion inhibitors for 6063 aluminium alloy in 3% NaCl by electrochemical and metalographic methods. The compounds were MoO_4^{2-}, CrO_4^{2-}, NO_2^- oxo-anions and Li^+ and Mg^{2+} metallic cations. Results obtained show that these compounds inhibited corrosion of 6063 aluminium alloy, and that the Li^+ cations were the best inhibitors. The difference between pitting potential and corrosion potential increase by increasing the concentration of Li^+. The maximum inhibition efficiency (E% = 85%) was attained at 5×10^{-3} M. Increasing temperature from 25 to 55°C improve corrosion resistance of 6063 aluminium alloy in the absence of Li^+. However, in the presence of these cations, E% decreased at elevated temperature.

Key words: corrosion, inhibition, inorganic compounds, 6063 aluminium alloy, 3% NaCl.

Introduction

L'aluminium et ses alliages acquièrent leur stabilité à travers le film d'oxyde-hydroxyde formé à la surface. Bockris et Minevski (1) ont examiné le mécanisme de passivation de l'aluminium et de ses alliages. Ils ont conclu que pour des valeurs de pH allant de 8 à 11, il y a formation d'une couche poreuse constituée par $Al(OH)_3$ de structure amorphe et par Al_2O_3 cristallisé. Cependant, les ions chlorures sont caractérisés par leur facilité à pénétrer dans ce film et par la formation de complexes solubles. L'inhibition de la corrosion des alliages d'aluminium a fait l'objet de travaux antérieurs. Parmi les inhibiteurs classiques les plus utilisés nous citons les chromates, les silicates et les molybdates (2–6). Des techniques expérimentales telles que les méthodes électrochimiques et les méthodes d'analyse de surface ont pu contribuer à mieux connaître le mécanisme d'inhibition de ces ions. Treverton et al. (7) ont suggéré que les ions chromates pénètrent à travers les défauts et les inclusions du film d'oxyde. Ils réagissent avec les ions métalliques pour former un oxyde mixte Cr_2O_3–Al_2O_3 et par suite empêcher la formation de complexes d'aluminium solubles. Konno et al. (8) ont montré que les ions chromates s'adsorbent à la surface du film d'oxyde. Ils forment une monocouche qui limite l'hydratation du film passif et par suite sa détérioration. Brett et al. (9) ont reporté que l'action des ions chromates dépend du potentiel d'électrode et qu'ils sont fortement adsorbés au voisinage du potentiel de piqûration. Selon d'autres auteurs (10) l'adsorption des ions chromates a pour effet de neutraliser les charges positives à la surface. Ils réduisent de ce fait la pénétration des ions chlorures dans le film d'oxyde et contribuent à la stabilité de la phase oxyde amorphe. Dans des travaux antérieurs (2, 3), nous avons illustré le rôle que peuvent jouer les ions chromates dans

Tableau 1. Composition chimique en poids de l'alliage d'aluminium 6063.

Elément	Al	Mg	Si	Mn	Fe	Zn	Cu	Ti	Ni	Cr
Poids (%)	Balance	0,53	0,44	0,04	0,19	< 0,002	< 0,030	< 0,002	< 0,003	< 0,002

l'inhibition de la corrosion de l'alliage d'aluminium 6063 en milieu neutre non pollué par les ions cuivriques. Le mécanisme de leur action a été expliqué par leur adsorption sur des sites privilégiés pour empêcher le processus de déposition du cuivre à la surface métallique.

Shalaby et al. (11) ont étudié le comportement électrochimique de l'aluminium dans une solution de chlorure de sodium en présence des ions silicates. Ils ont constaté qu'à faibles concentrations (1×10^{-4} M), les ions aluminium réagissent avec le silicate de sodium pour former un film très mince moins soluble et plus compact que la bayérite. Selon ces auteurs, il s'agit de composés cristallins de type $Na_2O{\cdot}Al_2O_3{\cdot}Si_2O{\cdot}H_2O$. Néanmoins, pour des concentrations supérieures, le film passif peut perdre son pouvoir protecteur.

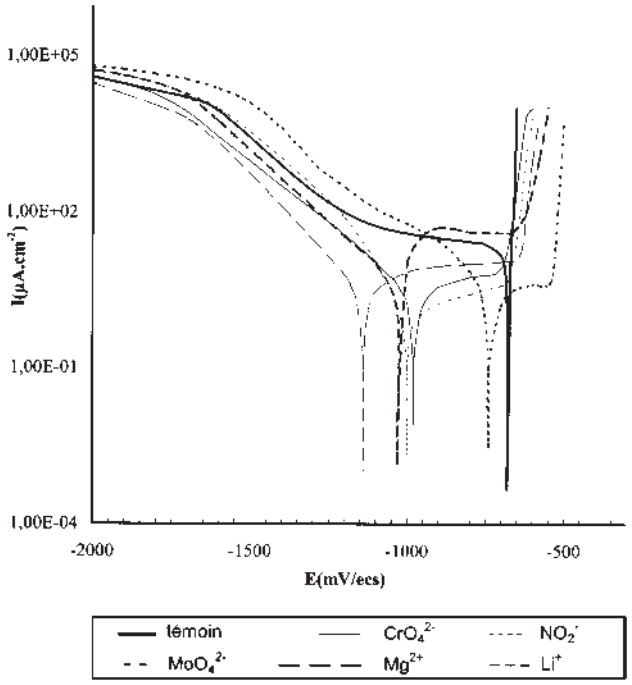
Shaw et al. (12) ont réalisé un prétraitement électrochimique du film passif de l'aluminium dans une solution décimolaire de molybdate de sodium. Ce prétraitement améliore de manière significative la résistance à la corrosion de l'aluminium dans une solution de chlorure de sodium. L'analyse par XPS de ce film indique une prédominance des espèces hydratées de Mo(VI) et Mo(IV) par rapport aux ions chlorures. Cependant, Breslin et al. (13) ont suggéré que la réduction de Mo(VI) en Mo(IV) n'est pas suffisante pour expliquer la performance de l'aluminium en milieu NaCl 0,5 M en présence d'ions molybdates et que ces derniers interviennent par leur pouvoir oxydant dans la croissance de la couche passive. Bazzi et al. (5) ont suggéré que les ions molybdates agissent sur le processus anodique en minimisant la sensibilité à la piqûration de l'alliage d'aluminium 6063.

Fernandes et al. (14, 15) ont examiné l'effet des ions lithium sur le comportement de l'aluminium dans des solutions carbonates. Les résultats obtenus par ces auteurs indiquent la prédominance des ions Li^+ dans le film passif. Rangel et Travassos (16) ont montré qu'en présence des ions chlorures le film riche en ions lithium manifeste une certaine résistance à l'attaque localisée caractérisée par le déplacement du potentiel de piqûration vers des valeurs plus positives. La stabilité de ce film a été mise en évidence par emploi de la voltampérométrie cyclique (16).

Malgré le nombre relativement élevé de travaux consacrés à l'inhibition de la corrosion des alliages d'aluminium, il reste tout de même un certain nombre d'aspects sujets à controverse. Les auteurs ont essentiellement axé leurs recherches sur le comportement anodique, le mécanisme d'action de la plupart des inhibiteurs testés à débattre. D'autant plus que l'action inhibitrice d'un tel inhibiteur peut varier d'un alliage à un autre. Nous nous sommes aperçus également de la rareté des travaux entrepris sur l'inhibition de la corrosion des alliages d'aluminium par les cations métalliques. Nous citons en particulier les ions lithium et magnésium. L'effet inhibiteur des ions lithium est peu étudié dans les milieux chlorurés. La plupart des études ont été réalisées en milieux bicarbonates (14–16).

L'objectif de ce travail est l'étude de l'inhibition de la corrosion de l'alliage d'aluminium 6063 au moyen de composés

Fig. 1. Courbes de polarisation de l'alliage d'aluminium 6063 sans et avec addition d'inhibiteur à 25°C.



suivants : $Na_2CrO_4{\cdot}2H_2O$; $Na_2MoO_4{\cdot}2H_2O$; Li_2SO_4; $MgSO_4$ anhydre et $NaNO_2$.

Partie expérimentale

Nous avons retenu dans cette étude l'alliage d'aluminium 6063 de la classification de l'Association d'aluminium américain. Il est couramment utilisé dans l'industrie agricole et agro-alimentaire. La composition exacte de cet alliage est donnée dans le tableau 1.

La solution corrosive est une solution à 3 % de chlorure de sodium. Le milieu électrolytique est préalablement désaéré pendant 0,5 h par barbotage d'azote. L'homogénéisation de l'électrolyte est assurée par une agitation magnétique. Le pH du milieu est ajusté à la valeur 7,5 par ajout de l'acide chlorhydrique ou de la soude.

Les solutions contenant les composés inorganiques sont préparées, par dissolution dans le milieu témoin, des composés suivants : $Na_2CrO_4{\cdot}2H_2O$; $Na_2MoO_4{\cdot}2H_2O$; Li_2SO_4; $MgSO_4$ anhydre et $NaNO_2$ de marque Merck et de pureté supérieure à 99 %.

L'électrode de travail est un disque de 0,5 cm^2 de surface enrobé dans une résine afin d'avoir une surface d'attaque uniforme. La préparation de l'état de surface de l'électrode de travail comporte une abrasion mécanique successivement à l'aide de papier au carbure de silicium de granulométrie décroissante, suivie d'un rinçage à l'eau bidistillée, puis d'un séchage à l'air comprimé.

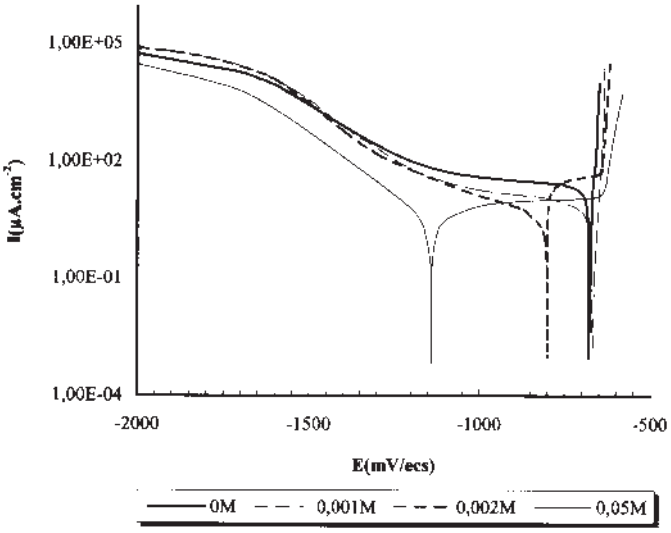
NO_2^{-} (5×10^{-2})	–1000	–640	14	360	35

Fig. 2. Courbes de polarisation de l'alliage d'aluminium 6063 sans et avec addition d'ions Li^{+} à différentes concentrations.



Avant le tracé des courbes de polarisation, l'électrode de travail est polarisée à –2 V s^{-1} pendant 2 min pour réduire les espèces électroactives pouvant exister à la surface métallique (17, 18). On fait ensuite évoluer le potentiel appliqué vers des valeurs croissantes, passant du domaine cathodique au domaine anodique.

Pour tous les essais potentiodynamiques, nous avons adopté une vitesse de balayage de potentiel de 1 mV s^{-1}. Celle-ci nous permet d'obtenir une bonne reproductibilité des résultats et en même temps de nous placer dans des conditions quasi-stationnaires (19–21).

Les échantillons destinés à l'examen métallographique sont découpés sous forme de plaquettes rectangulaires de 1,5 cm × 1 cm de surface et de 1 mm d'épaisseur. Avant chaque essai, les échantillons subissent un polissage mécanique à l'aide de papier abrasif de granulométrie décroissante, suivi d'un polissage chimique dans une solution de composition : H_3PO_4 65 % – H_2SO_4 25 % – HNO_3 10 % pendant 5 min (22), puis un dégraissage à l'acétone, un rinçage à l'eau bidistillée et enfin un séchage à l'air comprimé.

Le montage expérimental utilisé dans l'étude électrochimique est l'ensemble AMEL constitué par un générateur pilote (Amel 568) qui délivre un signal électrique au potentiostat pour faire varier le potentiel avec le temps suivant des vitesses de balayage réglables, un potentiostat (Amel 2049) qui impose un potentiel à l'électrode de travail modulable suivant une vitesse de balayage, une interface (Amel 560/A), qui permet la lecture du courant et sa transformation en potentiel à travers une résistance et un enregistreur (Kipp and Zonen) permettant le tracé automatique des courbes intensité–potentiel.

Les essais de corrosion sont effectués dans une cellule électrochimique à double paroi en verre Pyrex. La cellule est munie d'orifices permettant l'introduction du gaz (azote), de l'électrode de travail, de l'électrode de référence et de l'électrode auxiliaire. L'électrode de référence est une électrode au calomel saturé, positionnée à l'extérieur de la cellule. Le contact avec l'électrolyte est assuré à l'aide d'un capillaire et d'un pont en verre rempli d'une solution de chlorure de potassium saturée. Le rôle du pont est de minimiser la diffusion des ions chlorures de l'électrode de référence vers la solution électrolytique et de maintenir l'électrode de référence à température ambiante lorsqu'on fait varier la température de l'électrolyte. La contre-électrode est un disque en platine placé en face de l'électrode de travail. La cellule électrochimique est reliée à un thermostat à circulation d'eau permettant de maintenir l'électrolyte à la température de traitement (entre 25 et 55°C dans notre travail).

Résultats

Étude comparative

La fig. 1 représente les courbes de polarisation relevées dans une solution à 3 % de chlorure de sodium sans et avec addition de composés inorganiques. Les paramètres électrochimiques sont donnés dans le tableau 2.

Nous remarquons que l'addition des ions Li^{+} (5×10^{-2} M), Mg^{2+} (5×10^{-2} M), CrO_4^{2-} (5×10^{-3} M) et NO_2^{-} (5×10^{-2} M) a pour effet un déplacement remarquable du potentiel de corrosion (E_{cor}) vers des valeurs plus négatives. Le déplacement le plus important est obtenu avec l'addition des ions lithium. L'allure des courbes anodiques montre que l'alliage d'aluminium 6063 présente un phénomène de passivation avec rupture de passivité par attaque localisée. Le potentiel de piqûration reste peu affecté par la présence de ces ions. L'addition des ions molybdates à 5×10^{-2} M au milieu électrolytique conduit à un déplacement du potentiel de piqûration (E_{piq}) vers des valeurs plus nobles.

L'étude comparative de l'effet inhibiteur des ions testés montre que les ions lithium présentent la meilleure action inhibitrice aussi bien dans le domaine anodique que dans le domaine cathodique. En effet l'estimation de la vitesse de corrosion par extrapolation de la pente de Tafel indique que la valeur minimale est obtenue par addition des ions Li^{+}. De plus, la différence entre le potentiel de corrosion et le poten-

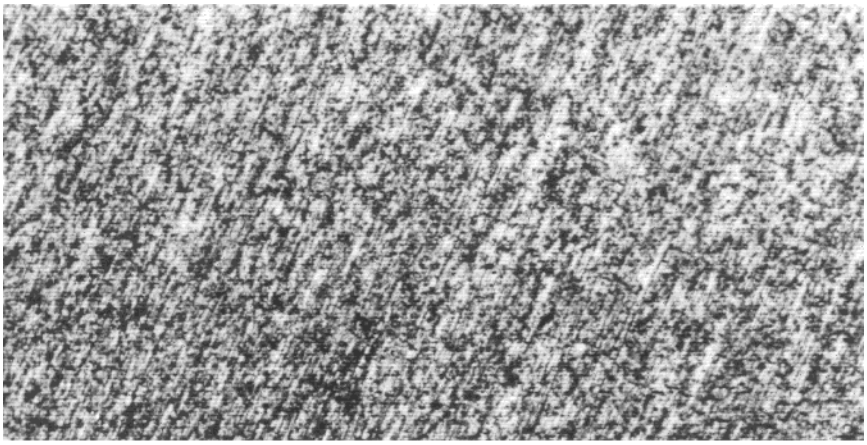
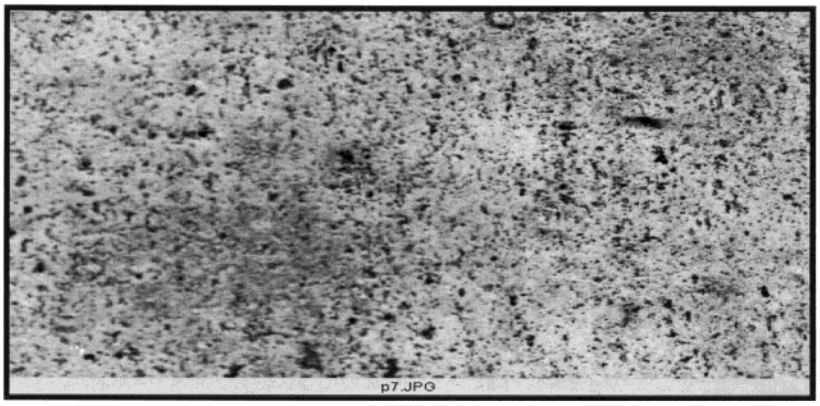
Fig. 3. État de surface de l'alliage d'aluminium 6063 après essai d'immersion de longue durée.



(a) après 15 jours d'immersion dans NaCl 3% (T=25°C) (× 100)



(b) après 15 jours d'immersion dans NaCl 3% contenant les ions Li^+ à 5 10^{-2} M (T=25°C) (× 100)

tiel de piqûration est très élevée en présence des ions Li^+ comparativement aux valeurs déterminées par addition des autres ions étudiés (tableau 2). Compte tenu de ces résultats, nous avons jugé opportun d'effectuer une étude détaillée de l'action inhibitrice des ions lithium sur la corrosion de l'alliage 6063.

Étude détaillée de l'influence des ions lithium

La fig. 2 illustre les courbes de polarisation de l'alliage 6063 dans une solution de NaCl 3 % sans et avec addition des ions lithium à différentes concentrations comprises entre 0 et 5×10^{-2} M. Le tracé de ces courbes est effectué à 25°C. Les différents paramètres électrochimiques déduits de ces courbes sont rassemblés dans le tableau 3.

Au terme des résultats obtenus, les remarques suivantes peuvent être annoncées : (*i*) l'addition des ions Li^+ favorise la passivation de l'alliage 6063. L'étendue du domaine de passivation est d'autant plus marquée que la concentration en ions Li^+ est importante. (*ii*) Les densités de courant cathodique subissent une nette diminution à partir d'une concentration de 1×10^{-2} M en ions Li^+. (*iii*) La densité de courant de corrosion diminue avec l'accroissement de la teneur en ions Li^+ et devient constante lorsque la concentration de ces ions dépasse 5×10^{-3} M. (*iv*) L'addition des ions

Fig. 4. Courbes de polarisation de l'alliage d'aluminium 6063 dans le milieu témoin à différentes températures.

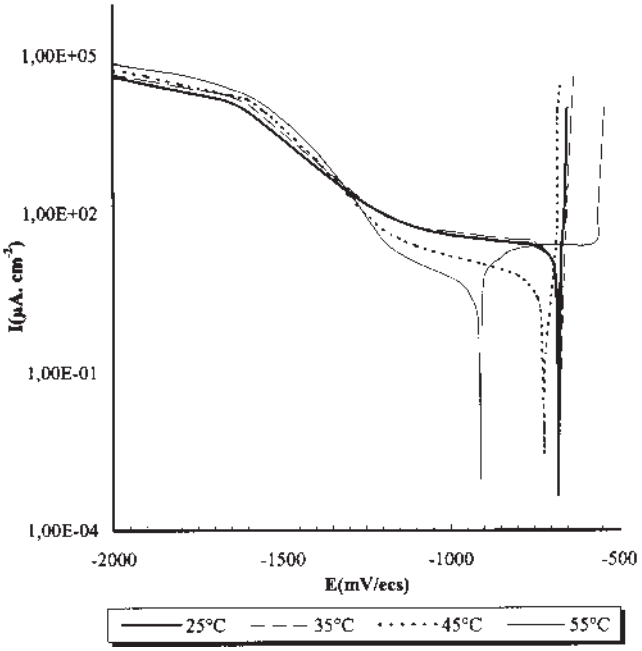

Fig. 5. Courbes de polarisation de l'alliage d'aluminium 6063 dans le milieu contenant 5×10^{-2} M en ions Li^+ à différentes températures.

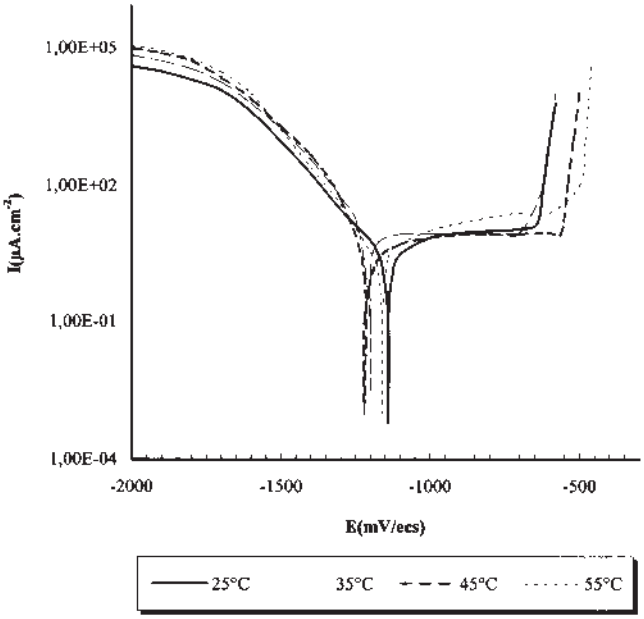

Li^+ au milieu corrosif s'accompagne d'un déplacement du potentiel de corrosion vers des valeurs négatives. Ce déplacement est d'autant plus marqué que la teneur en ces ions est élevée.

L'efficacité inhibitrice des ions Li^+ est définie par l'expression suivante :

$$[1] \qquad E\% = \frac{I^{\circ}_{cor} - I_{cor}}{I^{\circ}_{cor}} \times 100$$

où I_{cor} et I°_{cor} représentent respectivement les densités de courant de corrosion dans le milieu avec et sans inhibiteur. Notons que l'efficacité inhibitrice augmente avec la teneur des ions lithium en solution et atteint une valeur maximale de l'ordre de 84 % à 5×10^{-3} M. Pour des concentrations supérieures, cette efficacité inhibitrice demeure sensiblement constante.

Essais de longue durée

Afin de corréler les résultats des tests électrochimiques accélérés aux phénomènes réels de la corrosion de l'alliage 6063 et de son inhibition, nous avons réalisé des essais d'immersion de longue durée dans une solution de NaCl 3 % sans et avec addition des ions lithium. L'état de la surface après 15 jours d'immersion est illustré par la fig. 3. En absence des ions lithium, on signale une destruction locale du film qui se traduit par l'apparition de piqûres à la surface (fig. 3*a*). En présence des ions Li^+, la surface de l'alliage 6063 reste pratiquement intacte après 15 jours d'immersion (fig. 3*b*); ce qui témoigne de la bonne action de ces ions.

Étude de l'influence de la température

Compte tenu de l'importance du facteur température, une étude électrochimique sur le comportement de l'alliage 6063 dans une solution de NaCl 3 % sans et avec addition d'ions lithium à 5×10^{-2} M pour des températures comprises entre 25 et 55°C a été réalisée. Les courbes de polarisation correspondantes obtenues sont représentées sur les figs. 4 et 5. Les paramètres électrochimiques sont donnés dans le tableau 4.

L'examen de ces résultats permet de faire les constatations suivantes.

En absence des ions Li^+, l'augmentation de la température de 25 à 55°C s'accompagne d'une nette diminution de la densité de courant de corrosion (I_{cor}). Le potentiel de corrosion subit quand à lui un déplacement vers des valeurs plus négatives. Cependant, la différence $\Delta E = E_{piq} - E_{cor}$ n'est significative qu'à la température 55°C. Ces résultats montrent que l'élévation de la température de 25 à 55°C améliore la résistance à la corrosion uniforme et par piqûre de l'alliage 6063 dans NaCl 3 %.

En présence des ions Li^+, la densité de courant de corrosion est très inférieure à celle du témoin pour toutes les températures d'essai. La faible efficacité inhibitrice obtenue à 45 et 55°C est due à la faible vitesse de corrosion enregistrée dans le milieu témoin à ces températures. La différence $\Delta E = E_{piq} - E_{cor}$ est nettement supérieure à celle déterminée dans le milieu témoin et ce pour toutes les températures d'essai. Ce résultat montre la bonne performance de l'alliage 6063 en présence des ions Li^+.

Discussion

L'étude comparative de l'action d'une série de composés inorganiques sur la résistance à la corrosion de l'alliage d'aluminium 6063 a été réalisée en milieu NaCl 3 %. Les résultats obtenus montrent que l'addition des ions Li^+, Mg^{2+}, CrO_4^{2-} et NO_2^- améliorent la résistance à la corrosion de l'alliage d'aluminium 6063. On assiste en effet à une diminution de la densité de courant de corrosion et à un accrois-

sement de l'écart entre le potentiel de corrosion et le potentiel de piquration en présence de ces ions.

L'étude comparative de l'action inhibitrice des ions testés permet de distinguer les ions Li^+ comme meilleur inhibiteur de toute la série examinée; ce qui nous a incité à réaliser une étude détaillée de l'influence de ces ions. Les résultats obtenus dans ce cadre montrent que l'augmentation de la concentration des ions Li^+ en solution provoque un déplacement de E_{cor} vers des valeurs plus négatives. Ce déplacement s'accompagne d'une diminution des densités de courant cathodiques d'autant plus marquée que la concentration des ions Li^+ est élevée. Ces ions ont donc une action cathodique. L'efficacité inhibitrice atteint une valeur maximale de l'ordre de 84 % dès une concentration égale à 5×10^{-3} M et l'écart $\Delta E = E_{piq} - E_{cor}$ s'élargit lorsque la teneur en ions Li^+ croît. Les travaux de Morans et al. (23) sur l'action des ions Li^+ envers la corrosion des alliages d'aluminium 8090 et 2091 corroborent les résultats présentés dans ce manuscrit. Ces auteurs ont montré que la dissolution des alliages 8090 et 2091 décroît avec l'élévation de la teneur en ions Li^+ en solution, ce qui a été expliqué par la participation de ces ions à la formation de la couche de passivation à la surface métallique. Gui et Devine (24) ont mis en évidence la présence du lithium à la surface métallique de l'alliage d'aluminium 6061 par analyse au SIMS du film d'oxyde. Par ailleurs Graig et al. (25) ont attribué l'effet inhibiteur des ions Li^+ à la formation du méta-aluminate de lithium ($LiAlO_2$) à l'interface métal–électrolyte. Ce composé, étant moins soluble, se précipite à la surface métallique et conduit à la stabilité du film d'oxyde.

L'augmentation de la température de la solution corrosive provoque un changement du comportement de l'alliage 6063. La densité de courant de corrosion (I_{cor}) décroît avec l'élévation de la température pour atteindre la valeur minimale à 55°C. Ce phénomène pourrait être attribué à la nature du film d'oxyde-hydroxyde formé à la surface métallique. Selon Vedder et Vermilya (26), le développement du film d'oxyde-hydroxyde se fait en trois étapes : d'abord la formation de l'hydroxyde d'aluminium amorphe ($Al(OH)_3$) suivie par la formation de la boehmite cristallisée (AlOOH). Ces deux étapes sont rapides et engendrent une couche poreuse, identique aux membranes bipolaires. La dernière étape est souvent lente, durant laquelle il y a germination de la bayérite ($Al_2O_3 \cdot 3H_2O$) sous forme d'une couche compacte. L'élévation de la température augmente la cinétique de germination de la bayerite et par suite affaiblit les propriétés électrocatalytiques du film passif. La variation de la température de 25 à 55°C a aussi pour effet de minimiser la sensibilité à la piqûration de l'alliage 6063. Les ions lithium catalysent probablement la croissance du film d'oxyde dans les zones d'adsorption des ions Cl^-. Ils réagissent avec les ions chlorures pour former le chlorure de lithium plutôt que le chlorure d'aluminium (14, 15). Ce dernier est reconnu comme précurseur de la corrosion localisée des alliages d'aluminium (1).

Conclusion

Sur la base des résultats et discussions ci-dessus, les conclusions suivantes peuvent être annoncées : (*i*) Tous les ions testés présentent un caractère inhibiteur plus ou moins marqué vis-à-vis de la corrosion de l'alliage d'aluminium 6063 en milieu NaCl 3 %. (*ii*) L'étude comparative de l'action de ces composés inorganiques montre que les ions lithium sont ceux qui ont la meilleure action. Ils présentent un caractère d'inhibition cathodique et réduisent la sensibilité à la piqûration de l'alliage 6063. Ils améliorent donc les propriétés protectrices du film d'oxyde formé à la surface. (*iii*) L'étude de l'influence de la température révèle que l'alliage d'aluminium devient de plus en plus résistant lorsque la température de la solution témoin croît de 25 à 55°C. (*iv*) En présence des ions Li^+, l'augmentation de la température provoque une décroissance de l'efficacité inhibitrice, mais améliore de manière effective la résistance à la corrosion par piqûre de l'alliage d'aluminium 6063.

Remerciements

1-Propanol hydrate by IR spectroscopy

Jean-Joseph Max, Stéphane Daneault, and Camille Chapados

Abstract: The mid-IR attenuated total reflectance (mid-IR–ATR) spectra of a series of 1-propanol and water mixtures were obtained. Factor analysis (FA) applied to spectra gave the spectra of three principal species and their abundance: pure water, pure propanol, and a 1-propanol hydrate (1:1). When compared to the pure solvents, the hydrate propanol bands were modified which indicated that the valence bonds were perturbed. The assignment of the hydrate IR bands was made by comparing them with those of pure 1-propanol and pure water. No monomer was observed which indicated that all species were associated. The simplest representation of the different associations is by groups of two on which an intermolecular bond (H-bond) can be placed. The exchange between the molecules can be represented by the following equation: $(H_2O\cdots H_2O) + (CH_3CH_2CH_2OH\cdots OHCH_2CH_2CH_3) \rightleftharpoons 2(CH_3CH_2CH_2OH\cdots OH_2)$. The hydrate's formation constant (K_f) is 1.2 (±0.2). This value is less than the one expected from the association of freely moving molecules, indicating that the hydrophobic interactions of the 1-propanol aliphatic chains decrease the strength of the hydrogen bond between water and alcohol in the hydrate.

Key words: IR spectroscopy, ATR spectroscopy, 1-propanol, liquid, aqueous solutions, eigenspectra, hydrate, factor analysis.

Résumé : Nous avons obtenu une série de spectres infrarouges par réflectance totale atténuée de solutions aqueuses de 1-propanol. L'analyse par facteurs des spectres nous a révélé le spectre de trois espèces principales en donnant leur abondance en fonction de la concentration: l'eau pure; le propanol pur et un hydrate de 1-propanol (1:1). En comparant le spectre de l'hydrate avec celui du solvant pur, nous notons que les bandes sont légèrement modifiées ce qui indique que les liaisons de valence du propanol sont perturbées. L'attribution des bandes ir de l'hydrate a été faite en les comparant avec celles du 1-propanol pur et de l'eau pure. Nous n'observons aucune bande que nous puissions attribuer au monomère ce qui indique que toutes les espèces sont associées. Le modèle le plus simple qui représente cette association est par groupe de deux avec liaison hydrogène entre eux. L'échange entre les deux espèces est représenté par l'équation suivante: $(H_2O\cdots H_2O)+(CH_3CH_2CH_2OH\cdots OHCH_2CH_2CH_3) \rightleftharpoons 2(CH_3CH_2CH_2OH\cdots OH_2)$. La constante de formation de l'hydrate, K_f, est 1.2 (±0.2). Cette valeur est plus petite que ce à quoi nous pouvons nous attendre de molécules qui seraient entièrement libres de se déplacer dans la solution. Nous interprétons cette diminution par l'interaction hydrophobique entre l'eau et le 1-propanol dont les chaînes aliphatiques feraient diminuer la force des liaisons hydrogène entre l'eau et l'alcool.

Mots clés : spectroscopie infrarouge, spectroscopie ATR, 1-propanol, liquide, solutions aqueuses, eigenspectra, hydrate, analyse par facteurs.

Introduction

Based on molar volume, refractive index, and density measurements, it was determined that water and methanol mixtures behave as a ternary system and not as an ideal binary one (1, 2). Similar data (3) for the system 1-propanol–water ($PrOH–H_2O$) indicate that this system is not an ideal mixture, although a thorough analysis of it has not been made. IR spectroscopy is a technique capable of identifying the different species that exist in the mixtures and determining their abundance (4–17). Both transmission and attenuated total reflectance (ATR) methods can be used to obtain IR spectra of liquids. Because the OH stretch vibrations are strong absorbers, IR transmission measurements of aqueous solutions are difficult to perform (18). Nevertheless, Zhao and Malinowski (16) used this technique to study methanol–water mixtures in the 1850–2700 cm^{-1} range, where only a combination band is observed. Unfortunately, the CaF_2 cell used superposed strong interference fringes on the spectrum. With a thickness of 104 μm, the other principal bands in the mid-IR region saturated and could not be used for the analysis. However, the ATR configuration can be used to obtain the complete mid-IR spectrum of aqueous systems with high reproducibility and without fringes. Librovich, Maiorov, and co-workers (4), among the earliest users of ATR, showed that aqueous solutions could be studied quantitatively by IR–ATR. However, they did not study the alcohol–water system that is the object of the present study.

We developed an adequate quantitative IR–ATR method that provides consistently reliable results as long as the following basic requirements are met: (*i*) a proper crystal whose refractive index is far from that of the solution (5);

(*ii*) an adequate angle of incidence of the IR beam; and (*iii*) a suitable crystal length. When these conditions are satisfied, the IR–ATR spectra reflect the system's chemical changes (5). We have previously used this technique to study alkali halide aqueous solutions and made several acid–base titrations by IR (6–15, 17). It was found that water combines with ions to form stable clusters when a binary salt (NaCl, KCl, CsCl), a strong acid (HCl), or a strong base (NaOH) is dissolved in it (6–9, 13, 15, 17). We also detected the formation of complexes in aqueous sulfuric and phosphoric acids using this technique (11, 12, 14). Some of these complexes had previously been deduced only from thermodynamic and electrochemical measurements.

In our previous studies, principal factor analysis (FA) was applied to a series of IR spectra, to determine the abundance of the species. This type of analysis is suitable in those cases where some of the species can easily be obtained from the set of experimental spectra. Other methods of applying FA can be used (19), but are more demanding (16, 20). Zhao and Malinowski (16) applied windows factor analysis to a series of spectra obtained from mixtures of water and methanol in the 1850–2700 cm^{-1} range. They determined that a complex made of two water molecules and one methanol molecule is formed.

The purpose of the present study was to analyze the complete mid-IR spectra of mixtures of PrOH and water: (*i*) to determine the number of species present in the mixtures; (*ii*) to determine the abundance of each species; (*iii*) to determine the composition of the species; (*iv*) to obtain the complete mid-IR spectra of any complexes formed; and (*v*) to compare the spectrum of these complexes with that of pure PrOH and pure water.

Experimental and data treatment

Chemicals and solutions

1-Propanol (Omega, HPLC grade, purity > 99.5%, water content < 0.08%) was used without further purification. Deionized water was used to prepare the aqueous solutions. Each sample was prepared by weighing PrOH and water in a 10-mL volumetric flask to the desired concentration. A series of 21 samples ranging from 0 to 797.6 g L^{-1} of PrOH were prepared whose compositions are given in Table 1. Pure D_2O (Aldrich Chemical Co., purity 99.9 atom% D) was used to prepare a mixture of 381.8 g L^{-1} of PrOH and 592.3 g L^{-1} of heavy water.

IR measurements

The IR measurements were obtained using a model 510P Nicolet FT IR spectrometer equipped with a TGS detector. Two KBr windows isolated the measurement chamber from the outside. The samples were contained in a Circle cell (SpectraTech, Inc.) equipped with a ZnSe crystal rod (8 cm long) in an ATR configuration (making 11 internal reflections, the incident beam is at an angle of 45° with respect to the rod's axis). The window region of the ZnSe rod is between 4800 and 650 cm^{-1}. The spectra were taken under nitrogen flow to ensure low CO_2 and water vapor residues in the spectrometer. An accumulation of 200 scans with a resolution of 4 cm^{-1} were obtained for each spectrum. All measurements were made at 26.5°C ± 0.3°C. The cell was carefully washed and dried before each measurement. Since model 510P is a single-beam spectrometer, a background

© 2002 NRC Canada

was taken with the empty cell before the measurement of each sample.

The IR measurements consisted of obtaining the ATR background intensity (R_0) and the ATR sample intensity (R). The ratio of R/R_0 produced intensity I for the spectral range being studied. The 2153 data points ($I(\tilde{\nu})$ vs. $\tilde{\nu}$ (in cm^{-1})) of each spectrum were then transferred to a Microsoft Excel spreadsheet program on a personal computer for numerical treatment. Next, intensity (I) was transformed into ATR absorbance (log (1/I)). A small baseline shift (less than 0.01 ATR Abs) was made to obtain a null mean absorbance in the 4600–4450 cm^{-1} region.

Factor analysis

Considering the set of experimental data, we know that the spectra of water and PrOH are those of pure species (eigenspectra). Therefore, FA can be performed using the following iterative procedure on a personal computer (11, 12): (*i*) water and PrOH are used as principal factors in FA. These are multiplied by the principal spectra and added (Σ (MF × eigenspectra)). Their combined spectra are compared to the experimental spectra to give residual factors that are minimized subject to the restriction that there be no negative band. A least-squares fit procedure is used to monitor best fit; (*ii*) the residues serve to identify another principal factor; (*iii*) the latter is added to the principal factors and step 1 is repeated with the added factor. The iteration is stopped when the residues are at the minimum values; (*iv*) when the final MF values are multiplied by the sample principal spectra concentrations, the species concentrations are obtained.

Results and discussion

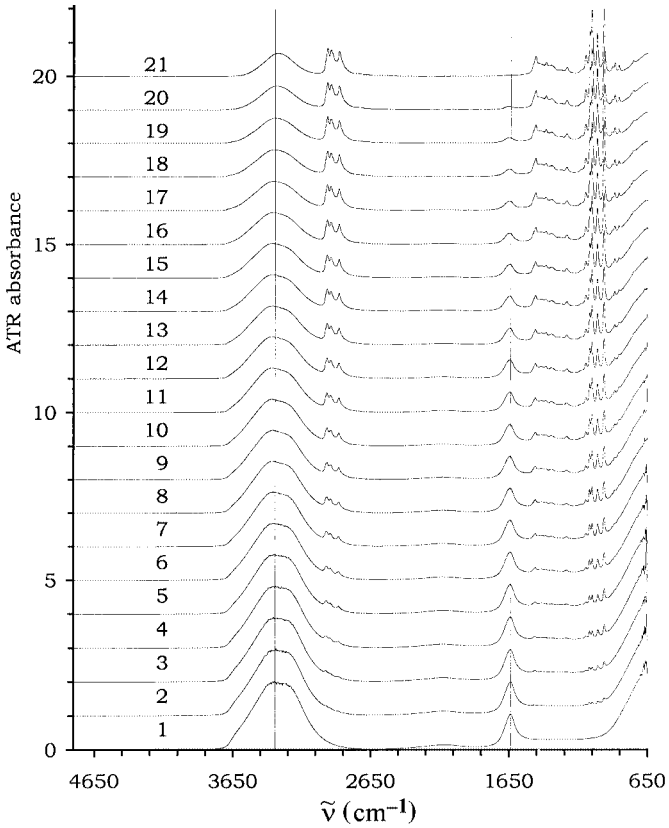
Experimental ATR spectra

The 21 IR–ATR spectra of the water–PrOH mixtures are presented in Fig. 1. This series of spectra presents evolving characteristics with a regular pattern. The water spectrum (bottom spectrum, no. 1) shows the broad intense ν_{OH} (ν_1 and ν_3) band of water from 3600 to 3000 cm^{-1}, the ν_2 band at 1638 cm^{-1}, and the weak broad combination band at 2115 cm^{-1}. The strong libration band, whose max is situated below 650 cm^{-1}, produces a far wing that starts near 1000 cm^{-1}. The spectrum of PrOH is presented at the top of Fig. 1 (trace 21): the C-H stretching bands are situated in the 3000 to 2700 cm^{-1} range; the C-H and O-H deformation bands near 1400 cm^{-1}; and the C-O and C-C stretch bands near 1000 cm^{-1}. Table 2 shows the complete assignment of the bands. Dilution results in a decrease in the intensity of the PrOH bands and in an increase in those of water. Some bands are split or displaced and new bands are observed indicating the presence of other species. These are sorted out by the FA procedure.

Subtraction of the water spectrum

We have previously reported quantitative subtraction of the water spectrum in aqueous systems using the water bands as indicators providing that no negative bands emerge from the process (6–9, 11–15). However, because of the overlapping of the ν_{OH} bands of water and PrOH (Figs. 1 and 2B) the water spectrum subtraction is more difficult than in previous cases. To aid in the water spectral subtraction, we used all of the following indicators: (*i*) the combination band $\nu_2 + \nu_L$ near 2115 cm^{-1} (but being broad and weak this indicator had a large error); (*ii*) the deformation band of water (ν_2) near 1638 cm^{-1} could be used but only in a limited way because it overlapped with the neighboring absorption; (*iii*) the second derivative technique could be used only as a supplementary technique because it was is not very effective in reducing the bandwidth of the water bands because they were too broad (17); (*iv*) the spectrum of a mixture of PrOH and heavy water (1:4.66 molar ratio) was obtained since the D_2O ν_{OD} band was far away from the PrOH ν_{OH} band, with no overlap between the two. For item (*iv*), the heavy water spectrum could be subtracted easily and the information transported to the PrOH water system. The use of all these techniques permitted us to subtract adequately the spectrum of water from those of the mixtures.

Fig. 1. Experimental IR–ATR spectra of 21 mixtures of PrOH and water. The bottom spectrum (no. 1) is that of pure water and is situated on the zero level; the others are successively displaced by 1 au. The top spectrum is that of pure PrOH (no. 21). The composition of the others is given in Table 1. The vertical lines are situated at 3343 and 1638 cm^{-1}.



Factor analysis using two principal factors

The pure PrOH and pure water spectra that are principal and orthogonal spectra (eigenspectra) in the FA procedure are presented in Figs. 2B*a* and 2B*b*, respectively. At the end of step one of the procedure, the MFs are determined (Fig. 2A): that of pure water decreases linearly with increas-

ing PrOH concentration (trace b) while that of PrOH increases regularly but not linearly (trace a). The residues (Fig. 2C) are not null: a pattern emerges with added water that reaches its max at solution 9 whereupon it decreases. This is indicative of at least another species in the solutions. The spectrum of this species, a propanol hydrate, was normalized to 13.27 mol L^{-1} (the concentration of pure PrOH) to allow comparison on an equimolar basis (Fig. 3B).

Factor analysis using three principal spectra

The three principal spectra used in FA procedure are shown in Fig. 3B: **a** (PrOH), **b** (H_2O), **c** (propanol hydrate). The MFs retrieved are given in Fig. 3A and listed in Table 1. The residues from the differences between experimental and calculated spectra are given in Fig. 3C. The strongest residue feature was found to be less than 2% of the strongest band in Fig. 3B situated in the 1000 cm^{-1} region. The other residues' features are much less than 0.5% where bands absorb. Attempts to use more than three species in FA were unsuccessful because the residues could not then be significantly decreased. We found similar results with aqueous NaI solutions (15). From these results, we concluded that three species were sufficient to describe the entire series of 21 mixtures of PrOH and water.

The MFs given in Fig. 3A were converted into total water and PrOH concentration, and the results presented as a function of gravimetry in Fig. 4. The correlation between the experimental results (symbols O and Δ) and the theoretical predictions (full line) is excellent and indicates that the procedure is adequate and that the results are reliable. These results confirm that only pure PrOH, pure H_2O, and one PrOH hydrate are present in the solutions. Consequently, one and only one hydrate is formed over the entire solubility range of the PrOH and water mixtures. The equilibrium existing between the three species in the mixtures is studied in the following section.

1-Propanol hydrate equilibrium formation

Molar ratio of the 1-propanol hydrate

The spectrum of the PrOH hydrate was calculated in the following way. Sample 9 contains 371.34 g L^{-1} of PrOH and 556.10 g L^{-1} of water (Table 1). The spectrum of pure PrOH and that of pure H_2O were subtracted from the spectrum of the sample no. 9 using the MFs 0.150 and 0.481 for pure PrOH and H_2O spectra, respectively. Pure liquid PrOH is 797.6 g L^{-1} and pure H_2O is 997.0 g L^{-1}. Therefore, the PrOH hydrate remaining was composed of 371.34 – 0.150 × 797.6 = 251.70 g L^{-1} (4.188 mol L^{-1}) of PrOH with 556.10 – 0.481 × 997.0 = 76.54 g L^{-1} (4.249 mol L^{-1}) of water giving a molar ratio of 1.000:1.015. According to the IR analysis, the PrOH hydrate is therefore made of one molecule of alcohol and one molecule of water: PrOH–H_2O. This representation of the hydrate is used to indicate the H-bonding between one PrOH molecule and one water molecule. It does not refer to an isolated entity.

The case of ideal mixture

To evaluate the chemical signification of the PrOH hydrate formation, we compare, in this section, the results predicted for an ideal mixture of PrOH and water with the results obtained by FA of the IR–ATR measurements.

Alcohol and water are known to be strongly associated in a polymeric organization through hydrogen bonding in liquid and solid states (21, 22). The resulting molecules have some intermolecular modes that the monomeric molecules do not have (22). Monomeric molecules are rare in liquid water and liquid PrOH. Given the difficulty in dealing with a polymeric organization, a reasonable simplification is to as-

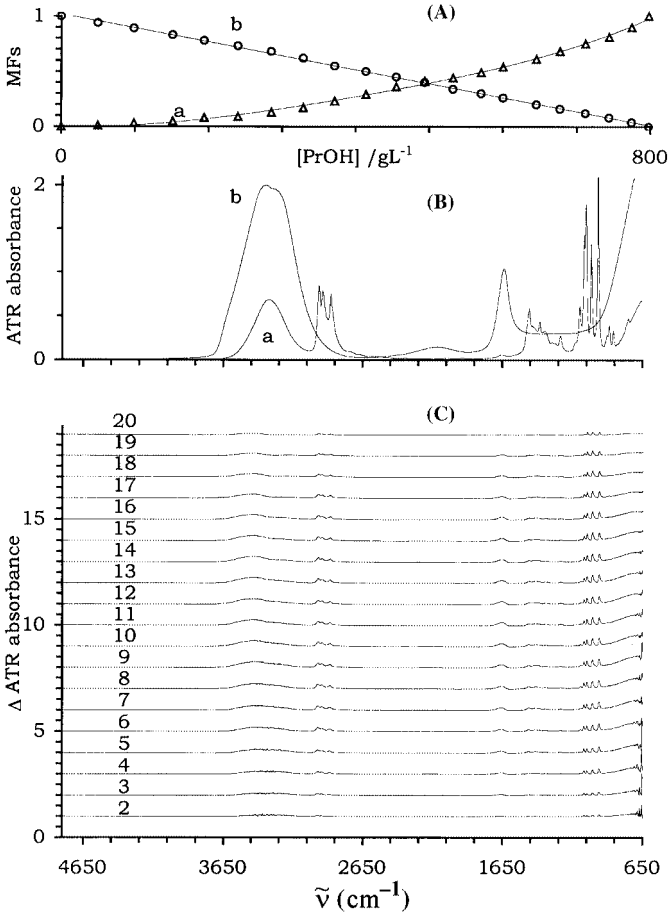

Fig. 3. FA results with three eigenspectra. (A) MFs retrieved for the mixtures: (*a*) PrOH (Δ); (*b*) H_2O (O); and (*c*) PrOH–H_2O (×); (B) IR–ATR spectra of the three eigenspectra; (C) residues in the same order and spacing as in Fig. 1.

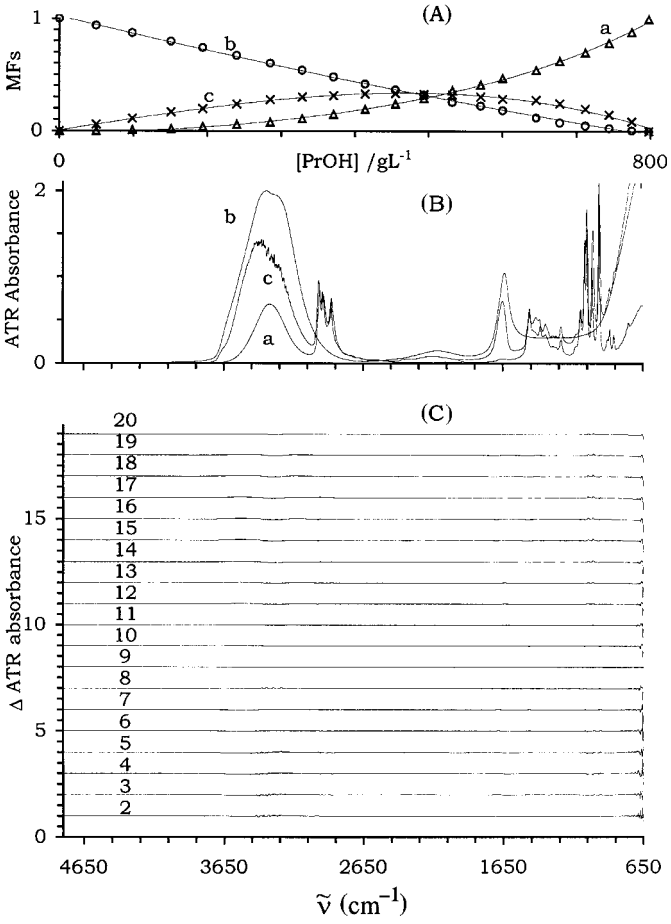


sume that both are made up of dimers. Such a dimer model directly follows the intermolecular interactions observed by IR spectroscopy. Hence, $(PrOH)_2$ and $(H_2O)_2$ indicate a particular strong interaction (hydrogen bond) between two identical molecules. Each molecule in these pairs can also have strong interactions with other molecules. In the following calculations, we will evaluate the transfer of a hydrogen bond between two identical molecules to a hydrogen bond between two different molecules.

In an ideal mixture of these dimers, each molecule of either $(H_2O)_2$ or $(PrOH)_2$ will associate with either H_2O or PrOH with equal probability. An $(H_2O)_2$ dimer may become $(H_2O)_2$ or PrOH–H_2O and a $(PrOH)_2$ dimer may transform into $(PrOH)_2$ or PrOH–H_2O if the hydrogen bonds are assumed to be equivalent in the three situations. Therefore, the probability for a dimer to be $(H_2O)_2$ or $(PrOH)_2$ in an equimolar mixture is 0.25 and that to be a hydrate PrOH–H_2O is $2 \times 0.25 = 0.5$. For a nonequimolar mixture containing *n* mol of water and *m* mol of PrOH, the probability for a particular molecule to be water or PrOH is $n/(m + n)$ and is $m/(m + n)$, respectively. The probability $p_{(H_2O)_2}$ for a particular dimer to be $(H_2O)_2$ is therefore:

$$[1] \qquad p_{(H_2O)_2} = \frac{n}{n+m} \times \frac{n-1}{n+m-1}$$

Because the number of mol is high, eq. [1] can be approximated by:

$$[2] \qquad p_{(H_2O)_2} \approx \left(\frac{n}{n+m}\right)^2 = \left(\frac{1}{1+a}\right)^2$$

where $a = m/n$ is the mol ratio between PrOH and H_2O.

In the same way, the probabilities $p_{(PrOH)_2}$ and $p_{H_2O\cdot PrOH}$ for a dimer to be $(PrOH)_2$ or PrOH–H_2O are given by:

$$[3] \qquad p_{(PrOH)_2} \approx \left(\frac{m}{n+m}\right)^2 = \left(\frac{a}{1+a}\right)^2$$

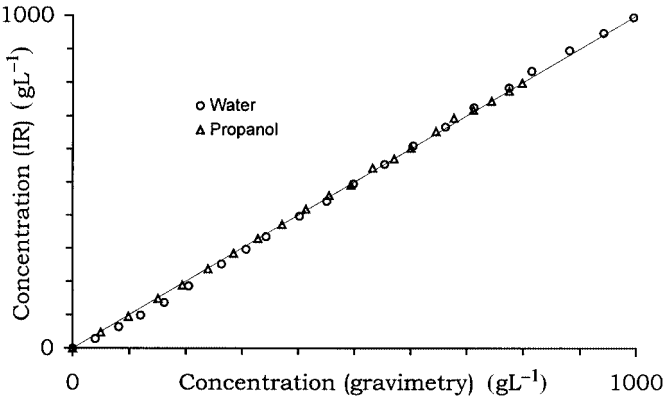
and

$$[4] \qquad p_{H_2O\cdot PrOH} \approx \frac{2nm}{(n+m)^2} = \frac{2a}{(1+a)^2}$$

The values calculated with eqs. [2]–[4] are plotted in Fig. 5A: **a** ($(PrOH)_2$), **b** ($(H_2O)_2$), **c** (PrOH–H_2O). These results were transformed into concentrations by multiplying

© 2002 NRC Canada

Fig. 4. Correlation plot between the concentration retrieved from the IR spectra with that obtained by gravimetry: water (O) and PrOH (Δ).



the above probabilities by the total concentration (in mol L^{-1}), giving the concentrations of water and PrOH in equivalent monomeric species. To follow its PrOH concentration, the values obtained for the PrOH hydrate are divided by 2 because it contains only one PrOH molecule. The results are represented by full lines in Fig. 5B. These results depict an ideal situation where the associated species have the same probabilities: PrOH–PrOH, PrOH–H_2O, and H_2O–H_2O.

Comparison with the concentrations obtained by FA

The concentrations of the three principal species present in the mixtures of PrOH and water retrieved by FA from the IR measurements are given as symbols in Fig. 5B. The PrOH hydrate concentration is counted in PrOH equivalent. Experimental values for pure PrOH and for pure H_2O are greater than the theoretical values (full lines in Fig. 5B). The H_2O values show an apparent smaller deviation than that of PrOH because it is related to a scale four times higher ([H_2O] (left ordinate), [PrOH] (right ordinate)). Experimental values for PrOH–H_2O are smaller than the theoretical values (Fig. 5B*c*). From this we concluded that mixtures of water and PrOH do not behave like ideal solutions. Only part of the polymeric water on the one hand and polymeric PrOH on the other hand break up to produce PrOH hydrate.

The PrOH hydrate formation is governed by the following equilibrium:

$$[5] \quad (H_2O)_2 + (CH_3CH_2CH_2CH)_2 \rightleftharpoons 2(CH_3CH_2CH_2OH{\cdot}H_2O)$$

with the PrOH hydrate formation constant given by:

$$[6] \quad K_f = \frac{[CH_3CH_2CH_2OH \cdot H_2O]^2}{[(CH_3CH_2CH_2OH)_2][(H_2O)_2]}$$

The value of K_f in the ideal mixture situation depicted by eqs. [2]–[4] is 4 (the reciprocal of the squared probability) whereas it is 1.2 ± 0.2 when it is obtained from the concentrations retrieved by FA (Fig. 5C). Large error bars are found at both ends of this figure because the concentration of one type of dimer is very weak there. A K_f value of 1.2 is almost three times less than the ideal mixture value of 4.

Stronger dimer association in liquid PrOH results from van der Waals interactions between the aliphatic groups. Excess PrOH dimers are present because they are not easily broken up by the weaker hydrogen bonding between water and the OH group of PrOH. Hydrogen bonding between water and PrOH being weaker does not easily break the PrOH dimers giving an excess of PrOH dimers. Note that PrOH is soluble in water, while 1-butanol is much less soluble and 1-pentanol is almost insoluble. With linear aliphatic alcohol, with more than four carbons, the hydrophobic interactions are stronger than hydrophilic interactions and cannot be broken by the hydrogen bonding between the OH of the alcohol and water molecules.

These results indicate that the composition of PrOH–water solutions consists of mixtures of only three species: pure PrOH, pure water, and PrOH hydrate (1:1). Except at the extremities where only the pure solvent exist, the molar fraction of the three species varies continuously with the PrOH concentration. From thermodynamic studies on excess partial molar enthalpies, it was found that different mixing schemes exist depending on the molar fraction of PrOH in the sample (23). The authors of these studies discussed the liquid structure changes on the basis of indirect structural information obtained from overall measurements. The IR results of the present study differ from the previous study because they are obtained from the H-bonding variations observed on vibrational modes. Since both methods are related to very different situations, it is not possible at present to make a comparison between the two results. Many IR measurements (around 10) at small PrOH molar fractions (lower than 0.1) would be needed to confirm the existence of a fourth species postulated by the thermodynamic measurements (23).

FA applied to a series of 21 whole spectra (4700–650 cm^{-1}) of aqueous propanol gave better and more complete information than that obtained by considering only the position of individual absorption bands as was done with a recent Raman study of aqueous methanol (24).

The findings of the present study suggest that each molecule tends to associate with like molecules rather than with unlike molecules. Therefore, clusters of water and PrOH coexist in the same solutions producing microheterogeneities. These microheterogeneities were postulated for an acetonitrile–water system studied by IR (25) and by X-ray diffraction and IR (26).

Spectral features of the 1-propanol hydrate

Comparison between PrOH–H_2O and pure PrOH

To compare it adequately with the other spectra, the PrOH hydrate spectrum (Fig. 3B*c*) is presented in Fig. 6 along with that of pure PrOH.

The band positions and assignments are given in Table 2. Looking first at the C-H stretching bands (Fig. 6B), we note that the integrated intensities between 3010 and 2800 cm^{-1} for the two systems are very similar, although the PrOH hydrate C-H bands are blue-shifted by comparison with those of PrOH, and their intensities are slightly modified. Secondly, in the deformation region of PrOH situated between 1500 and 1120 cm^{-1} (Fig. 6C), the increased intensity observed for PrOH hydrate is mostly due to the absorption of

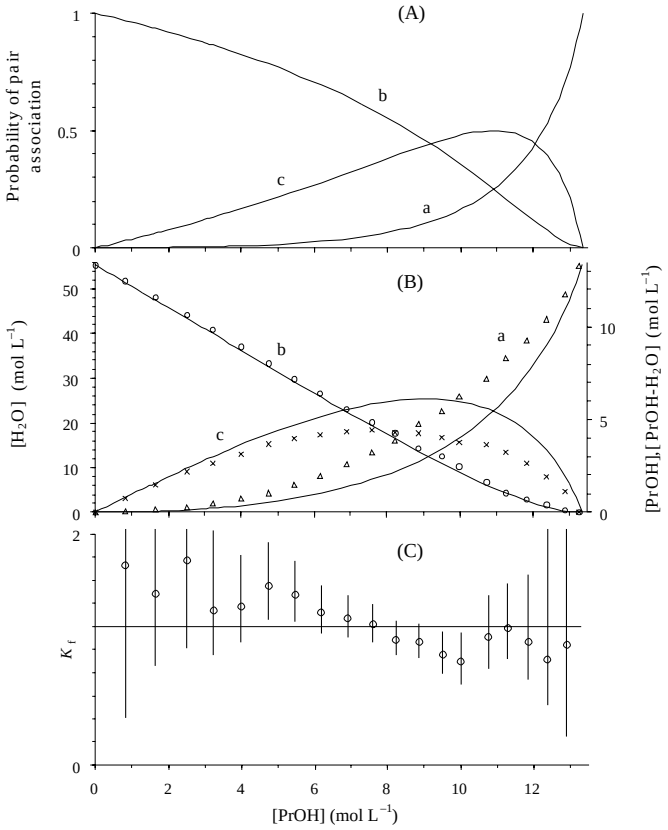

Fig. 6. IR–ATR spectra of pure PrOH (*a*) and PrOH–H_2O (*b*): (A) Complete spectrum; (B) CH stretch region; (C) 1800–1100 cm^{-1} region; (D) 1200–800 cm^{-1} region.

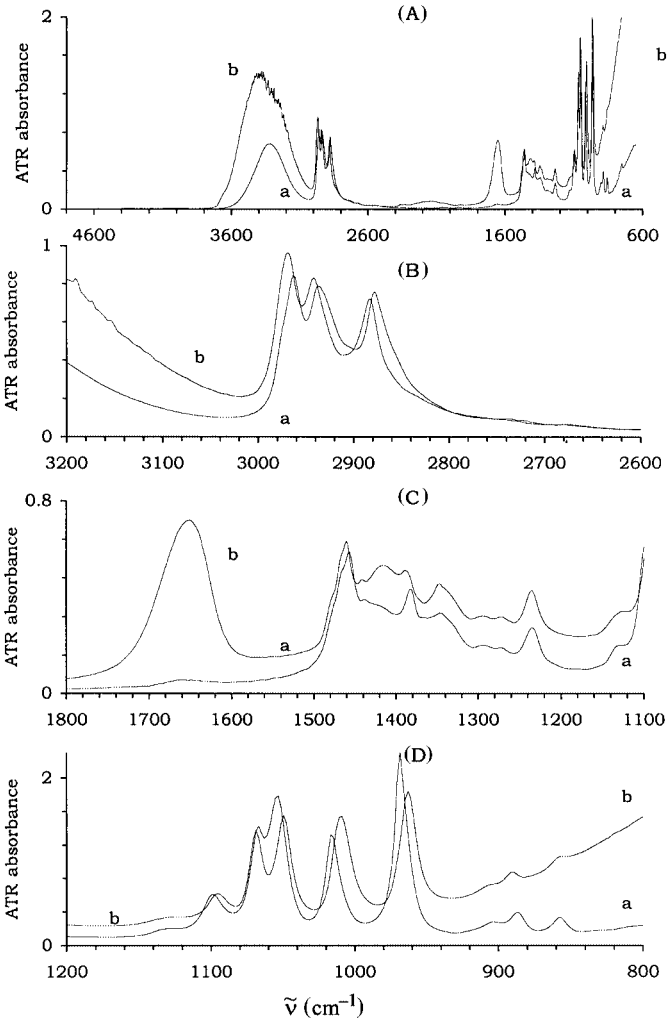


water, although some modifications are observed in the individual components, some of which are blue-shifted, and a new band emerged at 1416 cm^{-1}. Thirdly, the intensity of the PrOH hydrate components in the 1200–800 cm^{-1} region (Fig. 6D) is modified compared to that of PrOH, and the bands are red-shifted. These results indicate that the particular organization of the molecules in the complex PrOH–H_2O perturbs the vibrational modes of PrOH and H_2O.

Assignment of the bands

The position and approximate relative band intensities are given in Table 2. The band assignment listed in the table is based on the normal coordinate analysis work of Fukushima and Zwolinski (27) of PrOH (gas and liquid) and its deuterated analog. Comparing the band positions as given by these authors with that of ours we note that within a few wavenumbers the positions of the pure liquid PrOH are similar. This is acceptable given that the liquid spectra used by Fukushima and Zwolinski come from a data bank (28) and were obtained by transmission measurements, whereas our spectra were obtained by ATR. However, some differences do exist between the two sets of data. The ν_{OH} of liquid PrOH is situated at 3356 cm^{-1} by Fukushima and Zwolinski, whereas we find ν_{OH} at 3320 cm^{-1}. This difference can be explained by the broadness of this band. We have also identified several harmonic and combination bands, some of which are modified in the hydrates.

The 1232 cm^{-1} PrOH band (at 1235 cm^{-1} in Fig. 6C*a*) was assigned by Fukushima and Zwolinski (27) to the COH deformation mode (ν_{18}, Table 2). In the hydrate, a similar band having about the same intensity and shape is situated at the same place (Fig. 6C*b*). However, the presence of water in the hydrate should displace the COH deformation mode. Furthermore, a position of 1232 cm^{-1} for a COH alcohol deformation mode is low. It should, according to Colthup et al. (29), be situated near 1400 cm^{-1}. This is an indication that the assignment of PrOH should be reevaluated.

Fukushima and Zwolinski (27) assigned the 1464 cm^{-1} band of gas and liquid PrOH to ν_9, ν_{10}, ν_{11}, and ν_{12} (Table 2). We observed five components in that region, one of which could be a combination band. The normal coordinate analysis of Fukushima and Zwolinski does not permit greater precision, although these modes are involved in the combination bands in the 2940 cm^{-1} region where they could perturb the C-H absorption bands.

© 2002 NRC Canada

The 1416 cm^{-1} band observed in the hydrate's spectrum is not present in the pure propanol spectrum (Fig. 6C). Since water does not absorb in that region, we tentatively assigned this band to a combination band implying a far-IR band of the hydrate.

Besides verifying the difference band assignment, a new normal coordinate analysis could also verify the assignment of the COH deformation band of PrOH and the other assignment problems mentioned above. Work is in progress on that matter.

Integrated intensity of the O-H stretching vibration in PrOH and water mixtures

The spectrum of the PrOH hydrate was normalized to the concentration of pure liquid PrOH (13.27 mol L^{-1}) to allow comparison on an equimolar basis (Fig. 3B). Since the hydrate is a one-to-one association, the water concentration represented by the spectrum of the hydrate in Fig. 3B is also 13.27 mol L^{-1}. The $\nu_{O\text{-}H}$ intensity of the hydrate has to be compared to that of pure water: 55.35 mol L^{-1}. The pure water spectrum (Fig. 3B*b*) shows an integrated intensity of the O-H stretching band of around 1.6 times higher than that of the PrOH hydrate (Fig. 3B*c*), but with an OH concentration (55.35 × 2/[13.27 × 3]) = 2.8 higher. This indicates that the integrated intensity of the O-H stretching vibration of the PrOH hydrate is greater than that of pure water. As a crude evaluation to sort out the water contribution to the molar integrated intensity of the O-H stretching, we considered the contribution of the $\nu_{O\text{-}H}$ band of the PrOH molecule in the hydrate to be identical to that in pure PrOH and subtracted this contribution from the total integrated intensity in the 3000–3700 cm^{-1} range. The result was estimated to be the contribution of the water molecules to the $\nu_{O\text{-}H}$ band of the hydrate's spectrum. The ratio of the OH stretching integrated intensity of water in PrOH hydrate to that in pure water was found to be 1.6. This indicates that the $\nu_{O\text{-}H}$ integrated intensity of water molecules does not remain constant when the water molecules are in strong interaction with PrOH. To further confirm this result, we evaluated the variation in the integrated intensity of the O-H stretching vibration — in the 3000–3700 cm^{-1} range to avoid any contribution from the C-H vibrations — for each sample. The results are plotted as a function of the sample's water concentration in Fig. 7A (Δ symbols, left ordinate).

Figure 7A also shows that the PrOH concentration in a sample (O symbols, right ordinate) is proportional to the solution water concentration. Therefore, denoting the water and PrOH concentrations by c_w and c_{PrOH}, respectively, we have:

$$[7] \qquad c_{PrOH} = c_0 - ac_w$$

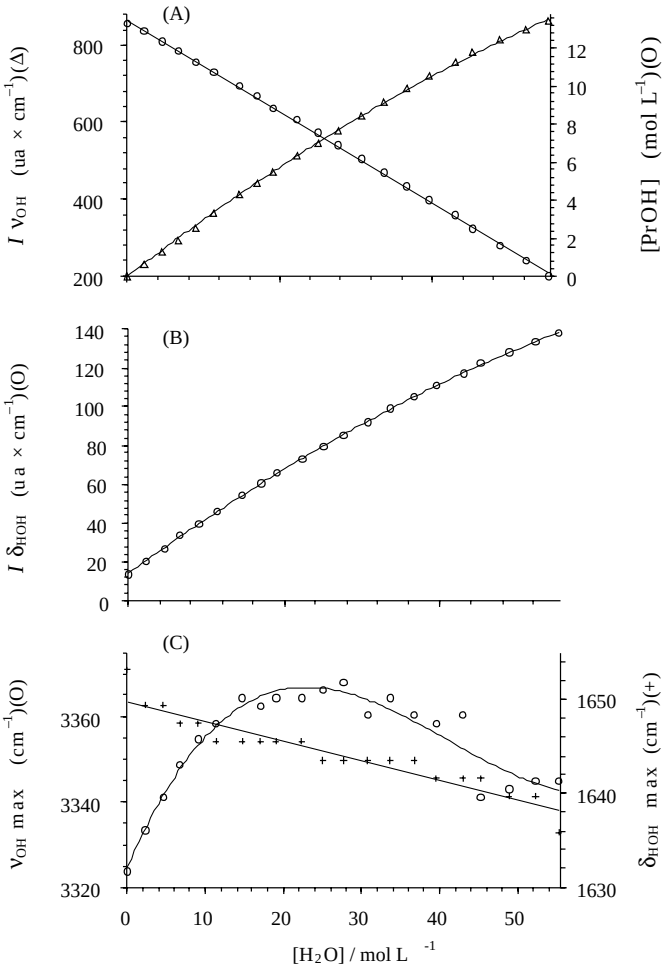
where c_0 is the concentration of pure liquid PrOH and a is the slope observed (= 0.241).

In each sample, the integrated intensity of the O-H stretch band contains the contribution of both water and PrOH, that is:

$$[8] \qquad \int_{\nu_{OH}}^{\text{sample}} I(\nu)d\nu = c_w \int_{\nu_{OH}}^{H_2O} I(\nu)d\nu + c_{PrOH} \int_{\nu_{OH}}^{PrOH} I(\nu)d\nu$$

where the superscript indicates the corresponding contribution. Substituting eq. [7] into eq. [8], one obtains:

Fig. 7. Different parameters of the PrOH–H_2O mixtures are presented as a function of water concentration. (A) PrOH concentration (O, right ordinate) and ν_{OH} integrated intensity (3700–3000 cm^{-1}) (Δ (experimental), (——) calculated: left ordinate); (B) δ_{HOH} integrated intensity (1750–1500 cm^{-1}) (O); (C) ν_{OH} and δ_{HOH} position.



$$[9] \qquad \int_{\nu_{OH}}^{\text{sample}} I(\nu)d\nu = c_w \left\{ \int_{\nu_{OH}}^{H_2O} I(\nu)d\nu - a \int_{\nu_{OH}}^{PrOH} I(\nu)d\nu \right\} + c_0 \int_{\nu_{OH}}^{PrOH} I(\nu)d\nu$$

If the molecular contributions of both water and PrOH to the integrated intensity of the absorption band were unchanged in the hydrate formed, the rightmost term and the term in braces in eq. [9] would be constant. Equation [9] would then represent a linear function of the water concentration c_w, that is, the total $\nu_{O\text{-}H}$ integrated intensity would be proportional to the water concentration. However, Fig. 7A (Δ symbols, left ordinate) clearly shows that such is not the case. Therefore, we must conclude that the molecular contributions of both water and PrOH to the $\nu_{O\text{-}H}$ integrated intensity are changed in the hydrate formed. Furthermore, the slopes observed in Fig. 7A for the total integrated intensity of the O-H stretch band are 14.5 and 8.4 (ATR Abs × cm^2 mol^{-1}) at 0 and 55.35 mol L^{-1} of water, respectively. This indicates that the slope at 0 mol L^{-1} of water (pure PrOH) is nearly twice that at 55.35 mol L^{-1} (pure water). This suggests that

© 2002 NRC Canada

the absorptivity of the O-H stretching vibration of water is multiplied by 2 when the molecule is complexed to one PrOH molecule. This is a new result. It should be noted that the absorptivity of the OH stretching of liquid water is 17 to 19 times stronger than that of water vapor and about half that of ice (21, 30). Therefore, it is not unreasonable that the PrOH–water complex OH stretch absorptivity is twice that of pure liquid water. The above arguments indicate that it is not possible to use the integrated intensities of OH stretching to determine the number of water molecules in the hydrate.

In each sample, the integrated intensity of the O-H stretch band contains the contribution of both water and PrOH and that of PrOH hydrate, that is:

$$[10]\quad \int_{\nu_{OH}}^{\text{sample}} I(\nu)d\nu = c_w \int_{\nu_{OH}}^{H_2O} I(\nu)d\nu + c_{PrOH} \int_{\nu_{OH}}^{PrOH} I(\nu)d\nu + c_{PrOH\ hydrate} \int_{\nu_{OH}}^{PrOH\ hydrate} I(\nu)d\nu$$

where $c_{PrOH\ hydrate}$ represents the PrOH hydrate concentration retrieved by FA. The contributions of both pure water and PrOH are easily obtained using the respective spectra (at the extremity of the curve in Fig. 7A). The results were 15.60 (= 863.1/55.34) and 15.16 (= 201.2/13.27) ATR Abs cm^2 mol^{-1} for water and PrOH, respectively. Note that the former possesses two OH while PrOH possesses only one. This indicates that the integrated intensity of each OH stretching vibration in liquid PrOH is nearly twice that of each of the OH stretching vibrations in liquid H_2O. The integrated intensity due to the PrOH hydrate was obtained by least-squares fitting the experimental values with the right member of eq. [10] calculated using the concentrations retrieved by FA. The molar integrated intensity of the OH stretching in the PrOH hydrate was found to be equal to 41.20 ATR Abs cm^2 mol^{-1}. Therefore, the mean intensity for each of the three OH of the hydrate was estimated to be 13.73 ATR Abs cm^2 mol^{-1}. The latter value is slightly beyond that in pure PrOH while it is near 1.8 times that of pure water. Such a result is fully consistent with the spectrum retrieved for pure PrOH hydrate (Fig. 3B*c*).

Integrated intensity of H_2O deformation vibration in water mixtures

We further evaluated the total integrated intensity of the water deformation band situated near 1638 cm^{-1}. Since PrOH does not have an absorption band in this region, the only contribution to this intensity is due to water. The integrated intensity of each sample was evaluated in the 1750–1500 cm^{-1} range. The results (shown in Fig. 7B), exhibit a nonlinear behavior indicating that the intensity of this vibration of the water molecules is modified when water is associated to PrOH. Therefore, both vibrations (OH stretch and HOH deformation) are enhanced in the PrOH hydrate.

The band position of both the OH stretching and HOH deformation were determined as functions of the sample's water concentration. The results are shown in Fig. 7C. The water deformation (+, right scale) regularly shifts from 1638 to 1650 cm^{-1} as the water concentration decreases. This is consistent with the intensity variation of this absorption band. The variation of the OH stretching position is not monotonic: for pure water it is situated near 3340 cm^{-1}; as the water concentration decreases it slowly shifts to near 3365 cm^{-1} at 25 M H_2O, thereafter it decreases rapidly to 3324 cm^{-1} for pure PrOH. In the mixtures at high water concentration ν_1 and ν_3 of water can be observed (by Gaussian fit) at 3222 and 3389 cm^{-1}, respectively. Below 10 M H_2O, the PrOH OH stretch band is more intense than that of water.

Conclusion

The formation of a PrOH hydrate (PrOH–H_2O) was found by applying FA to the mid-IR–ATR spectra of 21 PrOH–water mixtures. Only one type of hydrate was found over the whole solubility range of the mixtures. This indicates that three species are present in the mixtures: pure H_2O, pure PrOH, and pure PrOH–H_2O hydrate (1:1). The hydrate is formed as soon as PrOH is added to water and reached its peak abundance at 7.57 M PrOH in 25.14 M H_2O. From the IR abundance, the hydrate's formation constant was found to be K_f = 1.2. This is more than three times less than what ideal mixtures would produce and indicates that the hydrophobic interactions of the aliphatic chains in PrOH decrease the association between PrOH and water through hydrogen bonding. This type of interaction would explain the solubility decrease of the alcohols with increasing aliphatic chain length. IR spectroscopy has been used for the first time to evaluate such a decrease quantitatively. The spectrum of the "pure" PrOH hydrate was obtained and the assignment of the bands made. Apart from the water absorption, the spectrum of PrOH–H_2O is similar to that of PrOH with some slight position and intensity changes. Only a small new band appeared in the 1400 cm^{-1} region that we tentatively assigned to a combination of a fundamental mode with an external mode.

Recommandations aux auteurs

Revue canadienne de chimie

La *Revue canadienne de chimie* (Can. J. Chem.) publie, en français ou en anglais, les résultats de travaux originaux, sous forme d'articles ou de communications, dans les divers domaines de la chimie. Un **article** contient les résultats d'une étude définitive terminée. Une **communication** cherche à diffuser rapidement un travail particulièrement important et opportun. Le texte d'une communication ne devrait normalement pas dépasser huit pages dactylographiées à double interligne, y compris les figures et les tableaux, tout en fournissant suffisamment de détails pour que les experts dans le domaine puissent reproduire l'expérience. Un bref énoncé indiquant l'importance des travaux doit figurer dans le paragraphe d'introduction du manuscrit ou accompagner celui-ci sous forme de lettre de couverture. Cet énoncé doit être préparé avec soin, car il peut influer sur la décision des examinateurs. La soumission de **synthèses critiques** est également encouragée. Les manuscrits soumis pour publication dans la *Revue canadienne de chimie* ne doivent pas être soumis en même temps, ni publiés, ailleurs.

Liste de vérification pour les auteurs

Afin d'éviter des délais de publication, les auteurs devraient s'assurer que

1. toutes les sections du manuscrit sont dactylographiées à double interligne, d'un seul côté de feuilles de papier de format standard, avec marges de 1 po (2,5 cm);
2. un original et trois copies claires du texte et les dessins au trait originaux ou des photographies au fini glacé sont soumises;
3. toutes les pages sont numérotées, en commençant par celle du titre, au haut de la page;
4. la page du titre comporte le titre, les noms des auteurs et l'adresse de l'établissement où les recherches ont été effectuées;
5. l'auteur correspondant est identifié et que ses numéros de téléphone et de télécopieur ainsi que son adresse de courrier électronique, si disponibles, sont donnés;
6. la deuxième page comporte le résumé et les mots clés;
7. le format et le style du manuscrit sont conformes à ceux d'articles récents de la Revue;
8. la lettre de couverture indique les noms d'examinateurs potentiels; et
9. un résumé graphique est fourni sur une page distincte.

Il est possible d'éviter les délais de publication en se conformant aux règles décrites ci-dessous.

Manuscrit

Toutes les parties du manuscrit, y compris les notes infrapaginales, les tableaux, les légendes des illustrations et la bibliographie, doivent être dactylographiées à double interligne, d'un seul côté de feuilles de papier de 8,5 sur 11 po (ou ISO A4) avec marges de 1 po (2,5 cm). La première page ne doit comporter que le titre de l'article, les noms des auteurs, le nom ainsi que l'adresse de l'établissement où les recherches ont été effectuées, le nom de l'auteur correspondant, ses numéros de téléphone et de télécopieur ainsi que son adresse de courrier électronique, si disponibles, et toute note infrapaginale qui s'impose. Le manuscrit comprend les résumés (p. 2), le texte principal, puis, dans l'ordre, les remerciements, la bibliographie, les annexes, les tableaux et les légendes des figures. Les textes des légendes doivent être regroupés sur une ou plusieurs feuilles et présentés par ordre numérique. **Chaque page** du manuscrit doit être numérotée, en commençant par celle du titre, au haut de la page. Il importe de rédiger chaque section avec toute la concision qui assurera une clarté adéquate. **Les auteurs devront soumettre l'original et trois copies nettes du texte.** Les titres ainsi que les résumés fournissent l'information utilisée par les **services de repérage de l'information** dans l'élaboration de leurs bases de données. Ceux-ci doivent par conséquent être brefs et informatifs. À la demande du Chemical Abstracts Service, les directeurs scientifiques encouragent tous les auteurs à indiquer leurs prénoms au complet au lieu d'inscrire leurs initiales.

L'**orthographe** doit suivre *Le Grand Robert*. Les auteurs sont responsables de l'uniformité de l'orthographe dans l'ensemble du texte. Les accents doivent être insérés sur les majuscules.

La **nomenclature**, les **abréviations** et les **symboles des unités de mesure** doivent être conformes aux recommandations internationales, entre autres celles de l'Union internationale de chimie pure et appliquée et de l'Union internationale de physique pure et appliquée. Il est recommandé de se servir du **Système international d'unités** ou, tout au moins, de fournir les équivalences en unités SI. Ce système est décrit dans le *Guide de familiarisation au système métrique*, publié en 1989 par l'Association canadienne de normalisation (178, boulevard Rexdale, Etobicoke, ON M6N 3T3, Canada). Pour des raisons pratiques, on permet certaines exceptions à l'utilisation du Système international d'unités. On pourra continuer d'utiliser la molarité, la kilocalorie, le centimètre réciproque (nombre d'ondes) et l'atmosphère. On trouvera dans *Anal. Chem.* **54**, 155 (1982) une liste provisoire des unités de mesure n'appartenant pas au SI mais qui sont acceptables pour les articles de la Revue. Lorsqu'une formule ou le nom d'un composé chimique est signalé par un chiffre, il convient d'utiliser un chiffre arabe gras.

Les abréviations des noms de substances, de procédés, d'organisations, etc., doivent être définis la première fois qu'ils sont utilisés. Les symboles et les caractères grecs ou d'usage peu répandu doivent être identifiés clairement; les indices supérieurs et inférieurs doivent être lisibles et correctement placés ou indiqués.

Les références suivantes pourront être utiles en nomenclature : chimie organique : *Règles de nomenclature pour la chimie organique — Sections A, B et C* (1965), *Compléments à l'édition française des règles de nomenclature pour la chimie organique (Sections A, B et C)* (1974) et *Règles de nomenclature pour la chimie organique — Sections D et E* (1976) (Société chimique de France, 250, rue Saint-Jacques, 75005 Paris, France); *La nomenclature en chimie organique* (Masson et C^{ie}, Paris, 1967); *Chimie organique — Mode d'écriture des noms systématiques*

Also available in English

Can. J. Chem. Downloaded from www.nrcresearchpress.com by China University of Science and Technology on 09/08/12
For personal use only.

(AFNOR, NF T 01-101, 1969); chimie inorganique : *Nomenclature de chimie inorganique* (Bull. Soc. Chim. Fr., numéro spécial, 1975); *Nomenclature de chimie minérale* (AFNOR, NF T 01-003, 1965). Lorsque la nomenclature n'est pas normalisée par accord international, il convient d'adopter celle de la Société chimique de France (voir, entre autres, Bull. Soc. Chim. Fr.). Il n'est pas nécessaire de suivre rigoureusement les règles de nomenclature chaque fois qu'un composé est mentionné dans le manuscrit, mais le nom reconnu doit y figurer au moins une fois, de préférence vers le début du manuscrit.

Tout manuscrit doit être accompagné d'un **résumé**. Les auteurs doivent indiquer entre trois et cinq mots clés directement sous le résumé; ceux-ci seront utilisés par les services de repérage de l'information. Le résumé doit être précédé du titre et des noms des auteurs (une copie, en page détachée, est destinée au traducteur). Il ne doit pas excéder une page et doit être moins long s'il s'agit d'une communication. **Il ne doit comporter aucune abréviation ou référence.** Les auteurs qui peuvent soumettre des résumés dans les deux langues officielles du Canada, c'est-à-dire en anglais et en français courants, sont encouragés à le faire.

La **partie expérimentale** ou les **calculs** doivent être assez détaillés pour permettre une répétition exacte du travail, mais rester concis et éviter les longues descriptions de méthodes déjà connues; ces dernières devraient être signalées par des références appropriées. **Il convient d'attirer l'attention du lecteur sur tout risque nouveau ou particulier du travail expérimental.**

Analyses et spectres — L'apport d'une preuve pleinement convaincante de l'homogénéité et de l'identité de tous les composés présentés comme nouveaux par les auteurs relève de leur responsabilité. La preuve tant de la pureté que de l'identité inclut normalement de bonnes données analytiques relatives aux éléments. Une mesure précise de la masse d'un ion moléculaire est acceptée comme preuve de la composition chimique à la condition d'être accompagnée d'une preuve établissant de façon indépendante la pureté de l'échantillon. En l'absence de ces données, les spectres de RMN ^{13}C et (ou) ^{1}H de certains composés ou d'autres preuves pourront être acceptés sous réserve de l'approbation d'un spécialiste en la matière et de celle du directeur scientifique.

Constantes de vitesse et d'équilibre — Les résultats expérimentaux primaires devraient être mis à la disposition des lecteurs sous forme de tableaux; ils peuvent être intégrés à l'article ou, plus couramment, à la documentation complémentaire. Dans ce dernier cas, quelques exemples de données expérimentales primaires (par exemple, les absorbances) devraient être insérés dans l'article, plus particulièrement si le traitement des données est nouveau ou déroge aux règles établies. En ce qui concerne les expériences de cinétique, les constantes fondamentales de vitesse devraient être présentées, alors que pour la détermination des fonctions d'acidité, les logarithmes *I*, en tant que fonctions des concentrations d'acides, devraient être fournis. À noter que la seconde est la seule unité de temps acceptable pour les constantes de vitesse.

Les **références bibliographiques** doivent être vérifiées auprès des publications originales. Dans la **bibliographie,** qui suit les remerciements, elles doivent être classées par ordre numérique de mention dans le texte. **Chaque référence bibliographique doit être inscrite dans le texte et être signalée par son numéro clé spécifique inscrit sur la ligne entre parenthèses.** Une référence bibliographique de périodique doit respecter la structure suivante : initiales du prénom de l'auteur, nom de famille de l'auteur, titre du périodique (abrégé conformément à *CASSI*, Chemical Abstracts Service, P.O. Box 3012, Columbus, OH 43210, É.-U.), numéro de volume, page initiale de l'article, année de parution entre parenthèses. Une référence bibliographique de livre, de compte rendu de conférence, de thèse, etc. doit indiquer le nom et les initiales de l'auteur (ou des auteurs), le titre de la publication, le chapitre, le nom et les initiales du rédacteur en chef (ou des rédacteurs en chef) le cas échéant, le nom de la maison d'édition, la ville et l'année de publication et la page ou le chapitre d'où est tirée la citation. Voir un numéro récent de la Revue pour des exemples de présentation.

Les **rapports qui ne sont pas encore approuvés pour publication et les communications personnelles** ne font pas partie de la bibliographie et ne doivent être mentionnés qu'en notes infrapaginales ou entre parenthèses dans le texte, en spécifiant les noms de tous les auteurs et leurs initiales. Lorsqu'un document cité dans un article n'a pas encore été publié ou a paru sous une forme qui le rend difficilement accessible dans une bibliothèque scientifique, l'auteur doit faire parvenir deux copies de ce document au directeur scientifique (une copie seulement, dans le cas d'un article sous presse).

Les **notes infrapaginales** ne devraient figurer dans le texte que lorsqu'elles sont inévitables, mais leur utilisation dans les tableaux est encouragée. Lorsque les notes infrapaginales figurent dans le texte, leurs appels devraient être désignés par des chiffres arabes en exposant (sauf dans le cas des tableaux, voir ci-dessous) et numérotés consécutivement à partir de la première note infrapaginale, y compris toute note apparaissant en page titre. Chaque note doit figurer au bas de la page où elle est signalée, **pas dans la bibliographie**.

Les **équations** doivent être dactylographiées clairement, à triple interligne si elles incluent des exposants ou des indices. Les exposants et les indices doivent être lisibles et correctement placés. Il convient de faire une distinction entre la lettre *l* et le chiffre *un*, et entre la lettre majuscule *O* et le chiffre *zéro*. Une lettre ou un symbole ne devrait représenter qu'une seule entité et devrait être utilisé de façon uniforme dans l'article. Chaque variable doit être définie dans le texte ou dans une **liste des symboles** devant apparaître après la bibliographie. Les variables représentant des vecteurs, des matrices, des matrices vectorielles et des tenseurs doivent être clairement définies. Les numéros d'équation doivent être identifiés par des chiffres arabes placés entre crochets et alignés avec la **marge de gauche**. Aucune distinction n'est faite entre la numérotation des formules mathématiques et celle des formules chimiques.

Les **tableaux** doivent être numérotés de façon continue en chiffres arabes, comporter un titre bref et être mentionnés dans le texte. Toute information contenue dans les tableaux doit être dactylographiée à double interligne, sauf les équations mathématiques ou chimiques, les structures chimiques ou les entrées complexes, lesquelles doivent être dactylographiées à triple interligne. Chaque tableau doit être dactylographié sur une page distincte. Les descripteurs et les notes descriptives infrapaginales doivent être brefs. Les tableaux ne doivent pas contenir de lignes horizontales superflues, ni de lignes verticales. Les notes infrapaginales doivent être signalées par des lettres minuscules supérieures en italique. Une note descriptive qui n'est pas introduite par un appel de note peut être inscrite au bas du tableau à titre de **Nota**.

Annexes — Les illustrations et les tableaux en annexe doivent être numérotés différemment des illustrations et tableaux du corps de l'article, p. ex. fig. A1, tableau A1, etc.

Documentation complémentaire—Le Conseil national

Can. J. Chem. Downloaded from www.nrcresearchpress.com by China University of Science and Technology on 09/08/12
For personal use only.

de recherches administre un Dépôt des données non publiées dans lequel la documentation complémentaire peut être versée, à la demande des auteurs ou du directeur scientifique. La documentation complémentaire peut comprendre de grands tableaux, des calculs complexes et des cartes détaillées qui ne sont pas essentiels à la compréhension ou à l'évaluation du document. Les auteurs qui désirent utiliser ce service doivent clairement indiquer les parties dont ils demandent le dépôt dès la soumission de leur article. Les tableaux et les figures doivent être numérotés de façon consécutive, distinctement de ceux destinés à la publication (p. ex. : fig. D1, tableau D1). Toute donnée déposée doit faire l'objet d'une note infrapaginale à la section appropriée du document.

Les auteurs d'articles décrivant la **structure de macromolécules biologiques selon la diffraction des rayons X par un cristal unique** doivent soumettre à la Protein Data Bank (Brookhaven National Laboratory) toutes les données requises pour valider la discussion, y compris les amplitudes et les phases de rayons X et les coordonnées atomiques dérivées. Si les auteurs le désirent, les directeurs scientifiques demanderont à la Protein Data Bank de ne pas diffuser les données jusqu'à une date convenue. Dans le cas des listes de coordonnées, ce délai ne peut pas dépasser une année après la date d'acceptation du manuscrit. Dans le cas des données complètes sur l'amplitude et les phases des structures, la période précédant la diffusion des données ne peut être supérieure à 4 ans. La date de diffusion spécifiée par l'auteur ainsi que l'envoi des données à la Protein Data Bank seront indiqués par une note infrapaginale dans l'article. Si aucune date de diffusion n'est mentionnée, on présumera que les données sont disponibles dès la parution de la Revue.

Dans le cas de la détermination aux rayons X de la structure de cristaux uniques d'autres molécules, des données suffisantes pour une révision adéquate devraient accompagner le manuscrit. Ces données devraient être soumises en format apte à être placé au Dépôt des données non publiées du Conseil national de recherches du Canada. Des recommandations pour la présentation de données cristallographiques ont paru dans le Can. J. Chem. **80** (1), R-6 (2002). Des directives pour la présentation de données d'analyses thermiques ont paru dans *Analyse thermique — Vocabulaire — Présentation de résultats* (AFNOR, NF T 01-021, 1974) et dans *Normes fondamentales — Grandeurs, unités et symboles de thermique* (AFNOR, NF X 02-204, 1985).

Les **instructions supplémentaires à l'usage des auteurs**, dont il est possible de se procurer des exemplaires auprès du directeur scientifique, contiennent de plus amples détails sur la plupart des sujets discutés ci-dessus. Le format de présentation des données physiques, analytiques et spectroscopiques y est également décrit.

Illustrations

Chaque figure ou groupe de figures doit être préparé de manière à occuper, après une réduction appropriée, l'espace d'une ou deux colonnes du texte. Les dimensions finies maximales d'une illustration sur une colonne sont de 8,6 sur 23,7 cm (3,4 sur 9,3 po) et celles d'une illustration sur deux colonnes de 18,2 sur 23,7 cm (7,2 sur 9,3 po). Les figures (y compris les similigravures) sont numérotées en chiffres arabes selon leur ordre séquentiel et doivent être annoncées dans le texte bien que tous leurs éléments doivent être intelligibles en eux-mêmes. Tous les termes, les abréviations et les symboles qui se trouvent dans les figures doivent être les mêmes que ceux apparaissant dans le texte. Seuls les détails essentiels devraient être identifiés; l'information plus détaillée devrait paraître dans la légende. Chaque illustration doit être identifiée, de préférence au bas, à gauche, par le numéro de la figure et les noms des auteurs, suffisamment éloignés de l'espace réservé à l'illustration.

Les **dessins au trait** originaux doivent être en encre noire ou produits par ordinateur en encre noire sur du papier blanc de première qualité ou un matériau comparable. Quant aux graphiques produits par ordinateur, il faut fournir un imprimé au laser de la meilleure résolution disponible. **Les photocopies ne sont pas acceptables.**

L'épaisseur des lignes doit être suffisante (au moins 0,5 point) pour que la reproduction soit nette; tous les symboles, les indices supérieurs ou inférieurs et les signes décimaux doivent être en bonne proportion avec le reste du dessin et suffisamment marqués pour permettre la réduction nécessaire sans perte de détail. Ne pas utiliser de petits symboles ouverts qui ont tendance à se refermer lorsqu'ils sont reproduits. **Le lettrage produit par imprimante à matrice de point ou par machine à écrire, ou à la main, ne sont pas acceptables.** Le même style de police et la même dimension de lettrage doivent servir dans toutes les figures de dimensions semblables d'un article. Toutes les lignes de coordonnées doivent être tracées à la règle. Les enregistrements originaux de **spectres RMN, IR, RPE,** etc., ne peuvent être reproduits et doivent être redessinés.

Dessins de structures — Les structures et schémas à reproduire doivent être soumis sur des pages distinctes (et non pas insérés dans le texte). Il est fortement recommandé d'exploiter un logiciel de dessin tel que ChemDraw ou ChemWindows. La représentation stéréochimique doit préférablement être illustrée par des lignes en gras de largeur simple et des lignes brisées plutôt que par des coins. La police des désignations d'atomes doit être l'Helvetica de 12 points.

La table des matières est ponctuée de **graphiques synoptiques**. Ces graphiques sont un diagramme, une équation ou tout autre petit dessin qui illustre l'objet de l'article. Le graphique doit être un dessin ou un imprimé laser **original**, soumis sur une page distincte, d'une hauteur maximale de 40 mm et d'une largeur maximale de 85 mm, **sans texte** (si ce n'est des annotations essentielles).

Les **photographies** doivent être en *demi-teintes* sur papier glacé. Il faut préparer ces figures dans leurs dimensions de tirage final.

Les **illustrations en couleurs** sont aux frais de l'auteur. On peut obtenir de plus amples renseignements sur les prix auprès de l'agent de publication, Lea Libiseja, aux Presses scientifiques du CNRC (613-990-6965; télécopieur : 613-952-7656; courriel : lea.libiseja@nrc.ca).

Les Presses scientifiques du CNRC préfèrent recevoir la version électronique des graphiques des manuscrits acceptés et l'utiliseront dans la mesure du possible. Quatre copies de la version papier des illustrations doivent être soumises au Bureau de la rédaction, même s'il faut soumettre la version électronique pour la production.

Si les fichiers électroniques ne sont pas disponibles, la version papier des graphiques sera balayée. Toutefois, le lecteur optique reproduit facilement les défauts (p. ex., le liquide correcteur, les maculations). Il est recommandé de ne pas soumettre de photographies tramées, ni des illustrations balayées imprimées au laser, à cause des moirures qui se forment; une moirure est un motif perceptible et non désiré produit par le rebalayage ou le retramage d'une illustration qui contient déjà un motif de points.

Préparation des fichiers de graphiques électroniques

Les auteurs doivent fournir des copies des fichiers

Can. J. Chem. Downloaded from www.nrcresearchpress.com by China University of Science and Technology on 09/08/12
For personal use only.

électroniques originaux (c.-à-d. les fichiers tirés directement du logiciel sur lequel ils ont été créés) et des **épreuves au laser de haute qualité** des images. **Les fichiers électroniques (c.-à-d. le numéro et le contenu de la figure) doivent correspondre aux épreuves au laser.** Sur l'étiquette de la disquette, il faut indiquer (*i*) l'application et la version du logiciel; (*ii*) le(s) noms(s), la dimension et le suffixe du fichier; et (*iii*) si les fichiers ont été importés d'un autre logiciel. Si les fichiers ont été comprimés, il faut indiquer le format de compression. Les versions PC ou Macintosh des polices True Type ou Type 1 doivent être utilisées. **On ne doit pas se servir des polices de caractères en mode points ou non standard.** Les illustrations électroniques sont acceptés sur les disquettes de 3 1/2 po, cartouches Zip de 100 Mo et CD-ROM.

Toutes les illustrations doivent être soumises dans leurs dimensions de tirage final. Quant aux figures comportant plusieurs parties (p. ex., *a*, *b*, *c*, *d*, etc.) créées sur le même logiciel, elles doivent être assemblées dans un seul fichier plutôt que d'être transmises en plusieurs fichiers.

Il faut **garder** les illustrations le plus simple possible afin d'éviter les embûches. Éviter les textures et les fonds grisés compliqués, particulièrement dans les programmes d'illustration vectorielle.

Fichier en mode points — Les fichiers d'images en mode points sont produits sur une grille dans laquelle chaque carré (ou pixel) correspond à une nuance de noir, de couleur ou de gris. Un fichier en mode point est défini par le nombre de pixels ou d'éléments par pouce. Comme le pixel est défini comme un point, on parle aussi de « points par pouce » ou « ppp ». Plus la résolution de l'image est grande, plus le nombre de points sur une surface donnée est élevé.

Les illustrations soumises en mode points doivent être de définition adéquate. Les exigences minimales de définition sont les suivantes : 600 ppp pour les dessins au trait et les lignes fines (les dessins au trait comportant des lignes fines ou un fond grisé), 300 ppp pour les demi-teintes et les couleurs et 600 ppp pour les combinaisons (demi-teintes avec lettrage à l'extérieur de l'espace réservé à la photo).

Tous les fichiers en *couleurs* soumis doivent suivre la base CMJK (cyan, magenta, jaune et noir). Ces couleurs sont utilisées dans l'impression commerciale tout en couleur. Les graphiques RVB (le rouge, le vert et le bleu sont les couleurs utilisées particulièrement pour produire les images sur un écran) ne s'impriment pas correctement.

Fichiers vectoriels — Les fichiers vectoriels sont des fichiers d'images composées d'éléments comme les lignes et les formes. Ce type de fichier convient habituellement aux dessins au trait.

Fichiers vectoriels en mode points — Le mode points peut être importé dans un logiciel vectoriel ou de dessins aux seules fins d'ajouter et de superposer de l'information, des lignes, du texte, etc. Le mode points ne doit pas être redimensionné, recadré, tourné ou manipulé de toute autre façon après avoir été importé.

Les Presses scientifiques du CNRC préfèrent le logiciel CorelDraw! pour créer des images vectorielles. Pour les autres applications possibles, reportez-vous à la liste des programmes graphiques électroniques à http://www.nrc.ca/cisti/journals/elegrapf.html.

Processus de publication

Soumission — Les textes peuvent être remis au directeur scientifique ou à un membre approprié du Comité de rédaction (voir la p. ii de la Revue). Les auteurs doivent confirmer que leurs recherches sont originales et ne sont pas soumises à l'approbation ailleurs, en totalité ou en partie. L'auteur correspondant doit affirmer que tous les auteurs ont lu et approuvé le manuscrit.

Évaluation — Le directeur scientifique sollicite l'avis d'au moins deux lecteurs indépendants choisis en fonction de leur compétence dans le domaine en question; il garde toutefois l'entière responsabilité des décisions relatives au manuscrit. Les auteurs peuvent proposer des lecteurs mais le directeur scientifique n'est pas limité à ces propositions. On s'attend à ce que les lecteurs soient conscients du caractère privilégié du document dont ils évaluent le contenu scientifique et qu'ils fournissent des arguments raisonnables à l'appui de leur évaluation. Leur identité ne sera pas révélée à l'auteur sans autorisation écrite.

Révision — Lorsqu'un manuscrit qui a été renvoyé à l'auteur pour révision n'a pas été retourné dans les 3 mois qui suivent, la rédaction estime que l'auteur a retiré ce manuscrit; toute révision présentée ultérieurement sera traitée comme un nouvel article. Sauf indication contraire, **il faut présenter le texte dactylographié et trois copies lisibles du manuscrit révisé**. Les révisions et les modifications doivent être ajoutées à la machine à écrire; dans la plupart des cas, il convient de retaper la ou les pages corrigées. La version finale de tout article doit être accompagnée du formulaire de **transfer des droits d'auteur** dûment rempli et signé. On obtiendra ce formulaire auprès du directeur scientifique, dans tout récent numéro de la Revue ou sur le site Web des Presses scientifiques du CNRC.

Une fois le text accepté, toute correspondance doit être adressée aux Presses scientifiques du CNRC, Conseil national de recherches du Canada, Ottawa, ON K1A 0R6, Canada.

Soumission du texte en format électronique — Les auteurs sont priés de soumettre **une copie imprimée ainsi qu'une copie sur disquette de la version approuvée de l'article seulement**. Les fichiers de texte et les fichiers d'illustrations devront être soumis sur des disquettes distinctes. Le nom des auteurs doit être indiqué clairement sur chaque disquette soumise. Le **texte** (y compris les tableaux) devrait être soumis en format de traitement de texte (WordPerfect, Microsoft Word ou TeX est préférable, compatible à IBM ou Macintosh). Les macros en TeX et la documentation pour la préparation des soumissions sont maintenant disponibles à ftp://ftp.tex.ac.uk/tex-archive/macros/latex/contrib/supported/nrc/, ftp://ftp.dante.de/tex-archive/macros/latex/contrib/supported/nrc et ftp://ctan.tug.org/tex-archive/macros/latex/contrib/supported/nrc. Il importe d'indiquer le logiciel de traitement de texte utilisé, la version, de même que le type d'ordinateur (IBM ou Macintosh). En ce qui a trait aux **illustrations**, il convient de se reporter à la section « Préparation des fichiers électroniques des illustrations ». Tout article devra être accompagné d'une lettre faisant foi du fait que la version du texte sur disquette reflète exactement la version imprimée soumise.

Droits de reproduction — L'auteur d'un article qui utilise de la documentation (tableaux, figures, schémas, etc.) protégée par les droits d'auteur doit **obtenir une permission écrite du titulaire de ces droits d'auteur** pour permettre la reproduction de l'information **en format imprimé et électronique.** La lettre d'autorisation doit accompagner le manuscrit soumis.

Épreuves en placards — Une épreuve en placard, des épreuves des illustrations, une copie du manuscrit corrigé et un bon de commande de tirés à part sont envoyés à l'auteur. Afin d'en hâter la publication, les épreuves des communications rapides ne seront pas toujours soumises à l'approbation des auteurs. **Les épreuves en placard doivent être relues attentivement, car elles ne sont pas corrigées par les Presses scientifiques du CNRC.** Elles

doivent en outre être retournées dans les 48 heures suivant leur réception. Au stade des épreuves, il n'est plus temps d'apporter des modifications importantes ni de faire des ajouts ou des suppressions. Toutes questions quant aux épreuves en placard devront être adressées à Lea Libiseja (613-990-6965; télécopieur : 613-952-7656; courriel : lea.libiseja@nrc.ca).

Tirés à part — Pour obtenir des tirés à part, il est nécessaire de remplir le bon de commande et de le retourner avec le paiement (chèque, numéro de carte de crédit, numéro du bon d'achat ou pièce de journal interne) en même temps que les épreuves corrigées et le manuscrit ou, dans le cas de communications rapides, dès que possible. Le tarif des tirés à part qui sont commandés après la parution du numéro de la Revue est fortement majoré. **Les tirés à part ne sont pas fournis gratuitement; ils seront envoyés après réception d'un numéro du bon d'achat ou du paiement.**

Transfert des droits d'auteur — Les auteurs doivent compléter un formulaire de transfert des droits d'auteur au CNRC. Toute permission de republication partielle ou intégrale d'un article doit être obtenue auprès des Presses scientifiques du CNRC.

Recommandations aux auteurs d'articles décrivant la détermination de structures cristallines par diffraction de rayons X

Bien que nous demandions aux auteurs d'utiliser un programme checkcif élaboré par l'Union internationale de cristallographie, nous n'appliquons pas à la lettre les normes d'Acta Crystallographica C. Nous croyons en effet que toute structure cristalline doit être évaluée en tenant compte de son importance d'ordre chimique. Nous sommes aussi d'avis que les lecteurs doivent disposer de suffisamment d'information sur la structure pour pouvoir juger d'eux-mêmes de la qualité de la structure. Selon nous, les données sollicitées ci-dessous sont nécessaires à cette fin.

Les données cristallographiques suivantes doivent être fournies. (Toutes les quantités mesurées doivent être accompagnées de l'exactitude de mesure.) : formule chimique; poids formulaire (M_r); couleur; forme; dimensions; système cristallin; symbole de groupe spatial (si les définitions diffèrent des définitions conventionnelles, indiquez les positions équivalentes); dimension de la maille; Z; volume de la maille; densité observée (D_m); densité calculée (D_x); température de travail; paramètre de Flack (le cas échéant); rayonnement utilisé et valeur présumée de la longueur d'onde; solvant de cristallisation.

Il faudra soumettre l'information ci-dessous liée à la mesure des données : diffractomètre utilisé

méthode d'enregistrement et de mesure; région de l'espace réciproque explorée; nombre de réflexions mesurées et nombre de relations indépendantes; nombre de réflexions indépendantes mesurées et critère d'observation; R_{int}; détails touchant toute correction particulière, telle que l'absorption ou l'extinction.

La description de l'affinement doit être suffisamment détaillée pour permettre au lecteur d'évaluer sa qualité et son exhaustivité. La source des facteurs de diffusion doit être spécifiée, de même que toute correction apportée pour la dispersion anormale. En outre, un facteur d'accord final ($R = \sum ||F_o| - |F_c||/\sum |F_o|$) défini à la lumière du traitement des réflexions non observées et un R dûment pondéré ($wR(F)$ ou $wR(F^2)$) doivent être soumis avec la fonction de pondération utilisée. En ce qui a trait à l'affinement par moindres carrés, toute approximation (p. ex. blocs diagonaux) doit être spécifiée tout comme la fonction minimisée. La méthode de pondération doit être décrite et doit inclure les critères qui ont guidé l'attribution d'un poids nul à certaines réflexions. L'exactitude de la structure rapportée devrait être confirmée par une méthode différente de celle utilisée pour l'affinement (p. ex. par une synthèse de Fourier différence) et le résultat de cette vérification doit être brièvement décrit.

L'information exigeant des explications ou des renvois doit être présentée en un court paragraphe expérimental. Ce paragraphe doit comprendre de l'information telle que : facteurs de diffusion tirés de *International Tables for Crystallography* (Vol. C); solution de structure : Xtal3.5 (Hall et al. 1997); programme d'affinement : SHELXL97 (Sheldrick 1997); correction d'absorption : ψ-scans (North et al. 1968); correction d'extinction : SHELXL97 (Sheldrick 1997); fonction de pondération, $w = 1/[\sigma^2(c) + (0.0491P)^2 + 0.6387P]$, où $P = (F_o^2 + 2F_c^2)/3$.

Nous préférons que le reste de l'information ci-dessus soit présentée sous forme de tableau, comme suit :

Données sur le cristal	
$C_{22}H_{20}O_2$	V = 1628,3(2) Å^3
MW = 316,399	Z = 4
Bloc incolore	D_m = non mesuré
0,41 × 0,25 × 0,20 mm	D_x = 1,2907 Mg m^{-3}
Monoclinique	T = 123(2) K
$P2_1/c$	μ = 0,081 mm^{-1}
a = 8,0204(5) Å	Rayonnement Mo Kα
b = 9,0398(10) Å	λ = 0,71073 Å
c = 22,5974(15) Å	Solvant de cristallisation : éther diéthylique/méthanol
β = 96,362(6)°	
Cueillette de données	
Enraf-Nonius CAD-4	θ_{max} = 26.28
ω-2θ scans	$h = -9 \rightarrow 9$
3762 réflexions mesurées	$k = 0 \rightarrow 11$
3286 réflexions indépendantes	$l = 0 \rightarrow 28$
2825 réflexions dont $I > 2\ \sigma(I)$	3 réflexions standards à chaque 200 réflexions
Corr. abs. : T_{min} = 0,96, T_{max} = 1,00	Décroissance d'intensité : aucune
R_{int} = 0,025	
Affinement	
Affinement sur F^2	H atomes contraints
$R[F^2 > 2\sigma(F^2)]$ = 0,038	$(\Delta/\sigma)_{max}$ = 0,001
$R[F^2$, toutes les données] – 0.73	$\Delta\rho_{max}$ = 0,315 e Å^{-3}
$wR(F^2)$ = 0,199	$\Delta\rho_{min}$ = -0,197 e Å^{-3}
218 paramètres	Coefficient d'extinction : 0,0072(13)

© 2002 CNRC Canada

Pour les structures de détecteur de surface, certains des paramètres de cueillette de données doivent être modifiés comme il se doit pour décrire la cueillette de données du détecteur de surface. Lorsqu'il s'agit de structures cristallines multiples, toutes les entrées peuvent être indiquées en une seule colonne pour chaque structure.

Nous publierons normalement un tableau des données cristallines. On pourra soumettre un tableau des distances et angles de liaison choisis si ceux-ci sont nécessaires pour expliquer la chimie. Les autres données, telles que les angles de torsion essentiels, les angles entre les plans et les distances intermoléculaires, seront intégrées au texte seulement si elles sont cruciales du point de vue scientifique. Les tableaux des distances de liaison complètes, des coordonnées atomiques, des paramètres thermiques et des positions des atomes H doivent être inclus dans le CIF. Le CIF sera annexé à la version électronique de la Revue. L'auteur devra soumettre une version électronique ainsi qu'une version imprimée du CIF avec son article. On trouvera ci-dessous des instructions sur le dépôt auprès du CCDC.

En ce qui a trait aux structures ayant des atomes affinés de façon anisotropique, un diagramme ORTEP (ou l'équivalent) rendant compte des ellipsoïdes thermiques doit être soumis.

L'existence d'information déposée est indiquée dans les articles par une note en bas de page respectant le format suivant : « Les données complémentaires de cet article sont consignées dans CCDC XXXXXX. Vous pouvez les commander gratuitement à www.ccdc.cam.ac.uk/conts/retrieving.html (ou auprès du Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, R.-U. (Télécopier : 44-1223-336033; courriel : deposit@ccdc.cam.ac.uk). »

Pour se conformer à ces recommandations, les auteurs devront réunir une quantité imposante d'information, mais il est essentiel que la représentation en soit concise et directe. Il ne doit pas s'agir d'un rapport de progression d'analyse narratif ou d'une discussion de la méthode, à moins que ces éléments n'influent directement les conclusions d'ordre chimique.

Instruction pour le dépôt de données cristallographiques

Ces notes portent sur les données cristallographiques associées aux structures organiques et organo-métalliques.

1. Avant de soumettre son article à la Revue canadienne de chimie, l'auteur déposera auprès du Cambridge Crystallographic Data Centre (CCDC) le CIF visé par la publication (courriel : deposit@ccdc.cam.ac.uk).
2. Avant de soumettre le CIF au CCDC, on en vérifiera l'exactitude à l'aide du programme checkcif de CJC/IUCr (adresse Web : http://www.iucr.org/cjc/checkcif.html) ou à l'aide du programme checkcif IUCr (adresse Web : http://www.iucr.org/iucr-top/journals/acta/c/services/checkcif.html). Lorsqu'on vérifie un CIF aux sites Web ci-dessus, la deuxième ligne du CIF doit être : _publ_suggested_journal 'test'
   Ces programmes checkcif produiront une liste de problèmes à examiner ainsi qu'un formulaire de réponse. Vous devriez corriger le CIF afin de résoudre autant de problèmes que possible et soumettre de nouveau le CIF. Il faudra soumettre avec l'article destiné à la Revue une copie des derniers résultats produits par le programme checkcif accompagnée d'un formulaire de réponse rempli (produit par le programme checkcif). Le formulaire de réponse devra contenir les explications nécessaires.
3. Le CCDC fournit en retour un numéro de dépôt pour chaque structure cristalline signalée dans l'article. Il s'agit d'un numéro de 6 chiffres, p. ex. 100345. L'auteur soumettra à la Revue son article ainsi que tous les numéros de dépôt pertinents.
4. Lorsque l'article sera publié, les notes en bas de page voulues apparaîtront, telles que « Les données complémentaires de cet article sont consignées dans CCDC XXXXXX. Vous pouvez les commander gratuitement à www.ccdc.cam.ac.uk/conts/retrieving.html (ou auprès du Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, R.-U. (Télécopier : 44-1223-336033; courriel : deposit@ccdc.cam.ac.uk)»
5. Les données déposées ne seront pas archivées dans la Cambridge Structural Database avant que l'article ne soit publié. Si, après 15 à 18 mois, l'article n'a toujours pas été publié, le CCDC communiquera avec l'auteur pour déterminer la marche à suivre.

Notes à l'intention des auteurs

On peut obtenir une liste de contrôle du dépôt de données sur la page d'accueil Web du CCDC, à http://www.ccdc.cam.ac.uk/, ou par courriel (à fileserv@ccdc.cam.ac.uk). (Votre message ne devra alors contenir que les mots suivants sendme checklist). Cette liste n'est PAS suffisante pour assurer qu'un CIF soit complet en vue de sa vérification par un programme checkcif.

Pour effectuer une vérification à l'aide d'un programme checkcif, la plupart des champs du CIF doivent être remplis. Les résultats vous permettront de déterminer les champs qui doivent être remplis. Veuillez soumettre au CCDC un CIF complet et non pas un qui ne contient que les paramètres exigés par le CCDC. Le CIF sera annexé à la version électronique de tout article publié par la Revue canadienne de chimie.

Instructions to Authors

Canadian Journal of Chemistry

Can. J. Chem. Downloaded from www.nrcresearchpress.com by China University of Science and Technology on 09/08/12
For personal use only.

The *Canadian Journal of Chemistry* (Can. J. Chem.) publishes reports of original chemical research, in the form of articles or communications, in either English or French. An **article** reports the results of a completed definitive study. A **communication** is intended for the rapid publication of timely and significant work. The manuscript for a communication should not normally exceed eight double-spaced typewritten pages, including any figures and tables, but should contain sufficient experimental detail to allow repetition of the work by those knowledgeable in the field. A brief statement indicating the significance of the work should appear in the introductory paragraph of the manuscript or be indicated in a covering letter. An author should recognize that timeliness and significance are highly subjective qualities; this statement should, therefore, be prepared with some care. The publication of **critical reviews** is also encouraged. Manuscripts submitted to the *Canadian Journal of Chemistry* must not be published or under consideration elsewhere.

Checklist for Authors

To avoid delays in editorial processing, authors should ensure that

1. all sections of the manuscript are typewritten, double-spaced, on one side of standard size paper with 1-in. (2.5 cm) margins;
2. an original plus three clear copies of the text, and original drawings or glossy prints, are submitted;
3. all pages are numbered at top, beginning with title page;
4. the title page includes the title, authors' names, and the names and addresses of the institution at which work was done;
5. the corresponding author is indicated, with telephone number and, where available, facsimile number and e-mail address;
6. page 2 contains the abstract and key words;
7. the format and style conform to that of current articles in the Journal;
8. the cover letter includes the names of possible reviewers; and
9. a graphical abstract is provided on a separate page.

Delays in publication can be avoided by adherence to the instructions below

The Manuscript

All sections of the manuscript, including footnotes, tables, figure captions, and references, should be typewritten, double-spaced, on one side of good quality paper 8.5 × 11 in. (or ISO A4) with 1-in. (2.5 cm) margins. The first page should contain only the title; the authors' names; the names and addresses of the institution at which the work was done; the name and telephone number and, where available, the facsimile number and e-mail address of the corresponding author; and any relevant footnotes. The manuscript will include the abstract(s) (p. 2) and the main body of the text, followed by, in order, acknowledgements, references, any appendices, tables, and figure captions. Figure captions should be typed on a separate sheet in numerical order. **Each page** of the manuscript should be numbered at the top of the page, beginning with the title page. Writing should be as concise as is commensurate with adequate clarity. **The original and three clear copies of the manuscript and supplementary material to be deposited are required.** Both titles and abstracts provide information for contemporary **alerting and information retrieval services**, and should therefore be informative but brief. In compliance with a request from the Chemical Abstracts Service, the Editors urge all authors to use full forenames rather than initials and (or) one forename.

Spelling should follow that of *Webster's Third New International Dictionary* or the *Oxford English Dictionary*. Authors are responsible for consistency in spelling.

Symbols, units, and **nomenclature** should conform to international recommendations such as those of the International Union of Pure and Applied Chemistry and the International Union of Pure and Applied Physics. **SI units** (Système international d'unités) should be used or SI equivalents should be given. This system is explained and other useful information is given in the *Canadian Metric Practice Guide* (1989) published by the Canadian Standards Association (178 Rexdale Blvd., Etobicoke, ON M6N 3T3, Canada). For practical reasons, some exceptions to SI units are allowed. Units such as molarity, kilocalorie, reciprocal centimetre (wave number), and atmosphere may be used for the foreseeable future. An interim list of acceptable non-SI units is reported in Anal. Chem. **54**, 155 (1982). If a formula or name of a chemical compound is referred to by a number, a boldface Arabic number should be used.

Abbreviations for names of substances, procedures, organizations, etc., must be defined the first time they are used. Symbols and Greek letters or little-used characters should be clearly identified; superscripts and subscripts should be legible and correctly placed.

The following references are pertinent in nomenclature: *Nomenclature of Organic Chemistry, Sections A, B, C, D, E, F, and H*, Pergamon Press, London, 1979; *Nomenclature of Inorganic Chemistry*, Butterworth, London, 1971; *Quantities, Units and Symbols in Physical Chemistry*, Blackwell, London, 1987. Tentative recommendations exist for organometallic nomenclature, *IUPAC Information Bulletin* No. 31, 1973; for stereochemical designations, J. Org. Chem. **35**, 2849 (1970); and for steroids, J. Org. Chem. **34**, 1517 (1969). Although tentative IUPAC rules have been published for carbohydrate nomenclature (Biochemistry, **10**, 3983 (1971)), the Editors recommend the use of the British–American nomenclature (J. Org. Chem. **28**, 281 (1963)), until the IUPAC rules become definitive. For nomenclature not covered by international convention, the usage of the American Chemical Society should be followed, e.g., *The Naming and Indexing of Chemical Compounds* (Introduction to Chemical Abstracts Subject Index **56**, IN (1962)). Rigid adherence to nomenclature rules is not expected each time a compound is mentioned in a manuscript, but the approved names should be given at least once, preferably in an early part of the manuscript.

Each manuscript must be accompanied by an **abstract**. Authors should provide three to five key words directly below the abstract for use by the indexing services. The abstract should

be preceded by the title and authors' names so that one copy, on a separate page, can be sent to the translator. The abstract should not exceed one page for articles (shorter for communications) and **should not include abbreviations or references**. Authors who can submit abstracts in both English and French are encouraged to do so.

The **experimental**, or **computational**, material must be sufficiently detailed to permit reproduction of the work, but must be concise and avoid lengthy descriptions of known procedures; the latter should be specified by appropriate references. **A reader's attention should be drawn to any new or unusual hazards encountered in the experimental work**.

Analyses and spectra — It is the responsibility of authors to provide fully convincing evidence for the homogeneity and identity of all compounds they claim as new. Evidence of both purity and identity normally includes good elemental analytical data. An accurate mass measurement of a molecular ion is acceptable as evidence for chemical composition provided that independent evidence for sample purity is given. Where such data are not available, the ^{13}C NMR and (or) ^{1}H NMR spectra of certain compounds, or other evidence, may be acceptable provided that these alternatives are convincing both to an expert in the area and to the Editor.

Rate and equilibrium constants — Primary experimental results should be available to readers in the form of tables, which may be included with the published manuscript or may be treated as supplementary material. In general, examples of the primary experimental data should be included, especially if an innovative or nonstandard data treatment is employed. In papers reporting kinetics experiments, the primary rate constants must be presented, while in papers describing the determination of acidity functions, tables of log *I* as a function of acid concentration should be given. The only acceptable unit of time for a rate constant is the second.

References should be verified by checking the original publications. In the **bibliography**, which follows the acknowledgements, references are numbered and listed in the order in which they are first cited in the text. **Each reference must be cited in the text and designated therein by its unique key number typed on the line in parentheses.** In a reference to the periodical literature, initials precede the surnames of the authors, followed by the name of the periodical (abbreviated in the form used in *CASSI*, Chemical Abstracts Service, P.O. Box 3012, Columbus, OH 43210, U.S.A.), the volume number, initial page number, and year in parentheses. References to books, conference proceedings, theses, etc., should include the name(s) and initials of the author(s), the title of the publication, the name(s) and initials of the editor(s), if any, the name of the publisher, the city and year of publication, and the page or chapter cited. For examples of the appropriate format see a recent issue of the Journal.

Reports not yet accepted for publication and private communications are not acceptable references, and should be included in the text in parentheses or given as a footnote. When citing material that has appeared in a format not readily available in a scientific library, the author must provide the Editor with two copies of the document; for a manuscript "in press," one copy is sufficient.

Footnotes to material in the text should not be used unless they are unavoidable, but their use is encouraged in tables. Where used in the text, footnotes should be cited in the manuscript by superscript Arabic numbers (except in the tables, see below) and should be numbered serially beginning with any that appear on the title page. Each footnote should be typed on the manuscript page on which the reference to it is made; **footnotes should not be included in the list of references.**

Equations should be clearly typed; triple-spacing should be used if superscripts and (or) subscripts are involved. Superscripts and subscripts should be legible and carefully placed. Distinguish between lowercase *l* and the numeral *one*, and between capital *O* and the numeral *zero*. A letter or symbol should represent only one entity and be used consistently throughout the paper. Each variable must be defined in the text, or in a **List of symbols** to appear after the reference list. Variables representing vectors, matrices, vector matrices, and tensors must be clearly identified. Numbers identifying equations must be in square brackets and placed flush with the **left margin**. In numbering, no distinction is made between mathematical and chemical equations.

Tables should be numbered in Arabic numerals in the order cited in the text and each should have a brief title. All information in the tables should be typewritten, double-spaced, except for mathematical or chemical equations, chemical structures, or complicated entries, which should be triple-spaced. Type each table on a separate sheet. Abbreviations may be used in the brief column headings with explanatory footnotes where necessary. Tables should not contain vertical rules or superfluous horizontal rules. Footnotes are indicated by lowercase italic superscript letters. Other descriptive notes may be placed below the table, designated by **Note**.

Appendices — Figures and tables used in an appendix should be numbered sequentially but separately from those used in the main body of the paper, for example, Fig. A1, Table A1, etc.

Supplemental material—The National Research Council of Canada maintains a depository in which supplementary material may be placed, either at the request of the author or suggestion of the Editor. Such material may include extensive tables of data, detailed calculations, and maps not essential for understanding and evaluating the paper. Such material must be clearly marked when the manuscript is submitted. Tables and figures should be numbered in sequence separate from those published with the paper (e.g., Fig. D1, Table D1). The supplemental material should be referred to by footnotes.

Authors of papers describing new **single crystal X-ray diffraction structure determinations** on biological macromolecules must submit to the Protein Data Bank, Brookhaven National Laboratory, all structural data required to validate the discussion, including both X-ray amplitudes and phases and the derived atomic coordinates. If requested by the authors, the Editors will ask the Data Bank not to distribute the information until a specified date. For coordinate lists, this date may not be more than 1 year beyond the acceptance date of the manuscript. For the full structure amplitude and phase data the time interval before distribution may not exceed 4 years. The release date specified by the author will appear in a footnote to the paper along with the statement that the information has been submitted to the Protein Data Bank. In the absence of a specified release date, it will be assumed that the information is available immediately on appearance of the publication.

For single crystal X-ray structure determination of other molecules, sufficient data should be included with the manuscript to allow adequate review. These data should be in a form suitable for deposition in the National Research Council of Canada depository. Recommendations for the presentation of crystallographic data appear in Can. J. Chem. **80** (1), I-5 (2002). Guidelines for the presentation of data from thermal analyses appear in Anal. Chem. **39**, 543 (1967) and **44**, 640 (1972).

Further details on most of these topics are included in the **Supplementary instructions to authors**, copies of which are available from any Editor on request. The format for the presentation of physical, analytical, and spectroscopic data is also described.

Illustrations

Each figure or group of figures should be planned to fit, after appropriate reduction, into the area of either one or two columns of text. The maximum finished size of a one-column illustration is 8.6 × 23.7 cm (3.4 × 9.3 in.) and that of a two-column illustration is 18.2 × 23.7 cm (7.2 × 9.3 in.). The figures (including halftones) must be numbered consecutively in Arabic numerals, and each one must be referred to in the text and must be self-explanatory. All terms, abbreviations, and symbols must correspond with those in the text. Only essential labelling should be used, with detailed information given in the caption. Each illustration must be identified by the figure number and the authors' names on the back of the page or in the left-hand corner, well away from the illustration area.

Line drawings should be made with black ink or computer-generated in black on high-quality white paper or other comparable material. For computer-generated graphics, supply a laser print at the highest resolution available. **Photocopies are not acceptable.**

All lines must be sufficiently thick (0.5 points minimum) to reproduce well, and all symbols, superscripts, subscripts, and decimal points must be in good proportion to the rest of the drawing and large enough to allow for any necessary reduction without loss of detail. Avoid small open symbols; these tend to fill in upon reproduction. **Lettering produced by dot matrix printers or typewriters, or by hand, is not acceptable.** The same font style and lettering sizes should be used for all figures of similar size in any one paper. Any coordinate lines to appear should be ruled in. Original **NMR, IR, and EPR spectra** are often not reproducible and should be redrawn.

Structural drawings — Structures and schemes should be placed on separate pages (not within the text). Use of a computer drawing program such as ChemDraw or ChemWindows is highly recommended. Single-width bold and broken lines are preferred to wedges for stereochemical notation; 12-pt Helvetica font should be used for atom labels.

Graphical abstracts are published as part of the Table of Contents. The graphical abstract may consist of a small structural diagram, equation, or other informative drawing that serves to illustrate the subject of the article. This must be an **original** laser print or drawing, provided on a separate page, of a maximum size of 40 mm high × 85 mm wide, **without text** (except necessary labels).

Photographs should be *continuous tone* on glossy paper. These figures should be prepared in the final published size.

Colour illustrations will be at the author's expense. Further details on prices are available from Lea Libiseja, Managing Editor, NRC Research Press (613-990-6965; fax: 613-952-7656; e-mail: lea.libiseja@nrc.ca).

NRC Research Press prefers the submission of electronic graphic files for accepted manuscripts and will use these electronic files whenever possible. **Four sets of paper versions of figures must be submitted to the Editorial Office** for the review process, even if electronic versions are to be submitted for use in production.

If electronic files are not available, paper versions of the figures will be scanned. Note that the scanner will easily reproduce flaws (e.g., correction fluid, smudges). Submission of noncontinuous (screened) photographs and scanned illustrations printed out on laser printers is not recommended as moirés develop; a moiré is a noticeable, unwanted pattern generated by rescanning or rescreening an illustration that already contains a dot pattern.

Preparation of Electronic Illustration Files

Authors must supply copies of the original electronic files (i.e., the files directly from the software application that they were created in) and **high-quality laser proofs** of the images. **Electronic files (i.e., fig. number and fig. content) should match the laser proofs**. On the disk label, identify (*i*) the software application and version; (*ii*) file name(s), size, and extension; and (*iii*) if the files have been imported from another software. If you have compressed your files, indicate what compression format was used. PC or Macintosh versions of True Type or Type 1 fonts should be used. **Do not use bitmap or nonstandard fonts.** Electronic graphics can be accepted on the following disks: 3 1/2" disks, 100 MB Zip cartridge, and CD-ROM.

All figures should be submitted at their final published size. For figures with several parts (e.g., *a*, *b*, *c*, *d*, etc.) created using the same software application, assemble them into one file rather than sending several files.

Remember that the more complex your artwork becomes, the greater the possibility for problems at output time. Avoid complicated textures and shadings, especially in vector illustration programs; this increases the chance for a poor-quality final product.

Bitmap (raster) files — Bitmaps are image files produced using a grid format in which each square (or pixel) is set to one level of black, colour, or grey. A bitmap (rasterized) file is broken down into the number of pixels or picture elements per inch (ppi). Pixels per inch is sometimes referred to as dots per inch (dpi). The higher the resolution of an image, the larger the number of pixels contained within the rectangular grid.

The proper resolution should be used when submitting bitmap artwork. The minimum requirements for resolution are 600 dpi for line art and finelines (line art with fine lines or shading), 300 dpi for halftones and colour, and 600 dpi for combinations (halftones with lettering outside the photo area).

All *colour* files submitted must be as CMYK (cyan, magenta, yellow, and black). These colours are used in full-colour commercial printing. RGB graphics (red, green, and blue; colours specifically used to produce an image on a monitor) will not print correctly.

Vector files — Vector files are image files produced using elements such as lines and shapes. Typically these files are used for *line drawings*.

Bitmaps inside vector files — Bitmaps can be imported into vector/draw applications only for the purpose of adding and overlaying information, lines, text, etc. Bitmaps should not be resized, cropped, rotated, or otherwise manipulated after importing.

The preferred software application of NRC Research Press for creating vector images is CorelDraw! For other applications that can be used, see electronics graphics list at http://www.nrc.ca/cisti/journals/elegraph.html.

The Publication Process

Submission — A manuscript should be submitted to the appropriate Editor (see p. ii of each issue). The corresponding author must affirm that all of the authors have read and approved the manuscript and that the manuscript represents original work that is not being considered for publication, in whole or in part, elsewhere.

Evaluation — The Editor will seek advice from two or more independent reviewers who are selected for their knowledge of, and their experience in, the subject treated in the manuscript. The Editor retains full responsibility, however, for all decisions regarding the manuscript. Authors are invited to suggest reviewers who are competent to examine their manuscript, but the Editor is not limited to such suggestions. Reviewers are informed that they have received privileged documents for as-

sessment of scientific merit and are expected to provide reasonable arguments to support their evaluations. Identities of reviewers will not be released to authors without the written consent of the reviewer.

Revision — If a manuscript that was sent to an author for revision is not returned within 3 months, the Editors will consider the manuscript withdrawn by the author; any revised version submitted subsequently will be considered as a new contribution. **The typescript and three clear copies of a revised manuscript should be submitted**, unless the Editors specify otherwise. Handwritten revisions and amendments are not acceptable; in most instances the page(s) involved should be retyped. A completed and signed **Assignment of Copyright** form (available from the Editors, in any current issue of the Journal, or on the web site of NRC Research Press) must accompany the final revision of a manuscript.

Once the paper has been accepted, all correspondence should be with NRC Research Press, National Research Council of Canada, Ottawa, ON K1A 0R6, Canada.

Submission of electronic copy — Authors are requested to submit the **final accepted manuscript only, both in hard copy format and on disk**. Text files and figure files should be submitted on separate disks. All disks must be labeled clearly with the authors' names. **Text** (including tables) should be provided in a word-processing format (any form of WordPerfect, Microsoft Word, or TeX is preferable, IBM compatible or Macintosh). TeX macros for preparing papers for submissions are available at ftp://ftp.tex.ac.uk/tex-archive/macros/latex/contrib/supported/nrc/, ftp://ftp.dante.de/tex-archive/macros/latex/contrib/supported/nrc, and ftp://ctan.tug.org/tex-archive/macros/latex/contrib/supported/nrc. Identify the word-processing software, version number, and type of computer used (IBM or Macintosh). For **figures**, see the section "Preparation of Electronic Illustration Files." Include a statement in the letter accompanying the manuscript that the version on the disk **exactly** matches the final hard copy version.

Copyright material — If a manuscript contains material (figures, tables, etc.) that is protected by copyright, the author must submit to the Editor, before publication, **written permission from the copyright holder** to reproduce the material **for both the print and electronic formats**.

Galley proofs — A galley proof, illustration proofs, the copy-edited manuscript, and a reprint order form are sent to the corresponding author. **Galley proofs must be checked very carefully, as they are not proofread by NRC Research Press**, and must be returned within 48 hours of receipt. To expedite publication, proofs of communications are not always sent to the author. The proof stage is not the time to make extensive corrections, additions, or deletions, and the cost of changes introduced by the author and deemed to be excessive will be charged to the author. Questions concerning galley proofs should be addressed to Lea Libiseja, Managing Editor, NRC Research Press (613-990-6965; fax: 613-952-7656; e-mail: lea.libiseja@nrc.ca).

Reprints — If reprints are desired, the reprint order form must be filled out completely and returned with payment (cheque, credit card number, purchase order number, or journal voucher) at the same time the corrected proofs and manuscript are returned or, in the case of a communication, as soon as possible. Orders submitted after the issue has been printed are subject to considerably higher prices. **The Journal does not provide free reprints and reprints are not mailed until a purchase order number or payment is received.**

Copyright transfer — Authors are required to complete a copyright transfer form assigning all rights to NRC. Requests for permission to republish the paper, in whole or in part, should be sent to NRC Research Press.

Revised January 2002

Can. J. Chem. Downloaded from www.nrcresearchpress.com by China University of Science and Technology on 09/08/12
For personal use only.

Notes for Authors of papers presenting the results of X-ray crystal-structure analyses

Although authors are asked to use a checkcif program developed by the International Union of Crystallography (IUCr), the standards of Acta Crystallographica C may not be rigorously applied. Every crystal structure should be evaluated taking into account its chemical significance. Sufficient information about a structure should be available so that readers can make their own judgements about the quality of the structure. The quantities requested in the section below are necessary for this purpose.

The following crystallographic data should be given in the manuscript (all measured quantities should be accompanied by a measure of accuracy): chemical formula; formula weight (M_r); colour; crystal form; crystal dimensions; crystal system; space group symbol (if non-standard setting, give related standard setting); unit cell dimensions; Z; unit cell volume; observed density (D_m); calculated density (D_x); working temperature; Flack parameter (if applicable); radiation used and the assumed value for the wavelength; and the solvent for crystallization.

The following information pertaining to the measurement of data should be given: diffractometer used; method of recording and measurement; the region of reciprocal space explored; the number of reflections measured and number of independent reflections; the number of observed independent reflections and observation criterion; R_{int}; and the details of any special corrections such as absorption or extinction.

The final refinement should be reported in sufficient detail to enable the reader to assess its reliability and completeness. The origin of the scattering factors used should be specified, together with any corrections for anomalous scattering. A final agreement index ($R = \sum||F_o| - |F_c||/\sum|F_o|$) defined with respect to the treatment of unobserved reflections and an appropriate weighted R ($wR(F)$ or $wR(F^2)$) should be given with the weighting function used. For least-squares refinement, any approximation (e.g., block-diagonal) should be specified, as should the quantity minimized. The weighting scheme should be given and should include a statement of any reflections assigned zero weight. The correctness of the reported structure should be checked by a method independent of that used for refinement (e.g., by a difference-Fourier synthesis), and the result of this procedure should be briefly reported.

Information requiring explanations or references should be put into a short experimental paragraph. This paragraph would include information such as the following: scattering factors from *International Tables for Crystallography* (Vol. C); structure solution: Xtal3.5 (Hall et al. 1997); refinement program: SHELXL97 (Sheldrick 1997); absorption correction: ψ-scans (North et al. 1968); extinction correction: SHELXL97 (Sheldrick 1997); weighting function, $w = 1/[\sigma^2(c) + (0.0491P)^2 + 0.6387P]$, where $P = (F_o^2 + 2F_c^2)/3$.

The remainder of the above information should be given in a table, such as:

Crystal data	
$C_{22}H_{20}O_2$	V = 1628.3(2) Å^3
MW = 316.399	Z = 4
Colourless block	D_m = not measured
0.41 × 0.25 × 0.20 mm	D_x = 1.2907 Mg m^{-3}
Monoclinic	T = 123(2) K
$P2_1/c$	μ = 0.081 mm^{-1}
a = 8.0204(5) Å	Mo Kα radiation
b = 9.0398(10) Å	λ = 0.71073 Å
c = 22.5974(15) Å	Crystallization solvent: diethyl ether/methanol
β = 96.362(6)°	
Data collection	
Enraf-Nonius CAD-4	θ_{max} = 26.28
ω-2θ scans	h = –9 → 9
3762 measured reflections	k = 0 → 11
3286 independent reflections	l = 0 → 28
2825 reflections with $I > 2\ \sigma(I)$	3 standard reflections every 200 reflections
Abs. Corr.: T_{min} = 0.96, T_{max} = 1.00	Intensity decay: none
R_{int} = 0.025	
Refinement	
Refinement on F^2	H atoms constrained
$R[F^2 > 2\sigma(F^2)]$ = 0.038	$(\Delta/\sigma)_{max}$ = 0.001
$R[F^2$, all data] – 0.73	$\Delta\rho_{max}$ = 0.315 e Å^{-3}
$wR(F^2)$ = 0.199	$\Delta\rho_{min}$ = –0.197 e Å^{-3}
218 parameters	Extinction coefficient: 0.0072(13)

© 2002 NRC Canada

For area detector structures, some of the data collection parameters should be appropriately modified to describe the area detector data collection. For multiple crystal structures, all entries might be put into a single column for each structure.

The journal will normally publish a Table of Crystal Data. A Table of Selected Bond Distances and Angles may be included if required to explain the chemistry. Publication of other data, such as essential torsion angles, angles between planes, and intermolecular distances can be included in the text if scientifically justified. Tables of complete bond distances, atomic coordinates, thermal parameters, and H-atom positions should be included in the deposited CIF. The CIF will be appended to the electronic version of the journal. Both an electronic and hard copy of the CIF should be submitted with the manuscript. Instructions for deposition with the Cambridge Crystallographic Data Centre (CCDC) are given below.

For structures with anisotropically refined atoms, an ORTEP diagram (or equivalent) displaying the thermal ellipsoids should be presented.

The existence of deposited material is indicated in the printed article by a footnote in the following format: "CCDC XXXXXX contains the supplementary crystallographic data for this paper. These data can be obtained, free of charge, via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, U.K. (Fax: 44-1223-336033 or e-mail: deposit@ccdc.cam.ac.uk)."

The volume of information required for compliance with these notes is formidable, and it is essential that the presentation be concise and relevant. It should not be a narrative account of the progress of the analysis or a discussion of method unless these elements have a direct bearing on the chemical conclusions.

Instruction for deposition of crystallographic data

These notes concern the crystallographic data associated with organic and metal-organic structures.

1. Prior to submitting a manuscript to the *Canadian Journal of Chemistry* (CJC), the author must deposit the corresponding CIF with the Cambridge Crystallographic Data Centre (CCDC). The e-mail address to send a CIF to the CCDC is: deposit@ccdc.cam.ac.uk
2. Before submitting the CIF to the CCDC, it should be tested for errors by using the CJC/IUCr checkcif program (Web site address: http://www.iucr.org/cjc/checkcif.html) or the IUCr checkcif program (Web site address: http://www.iucr.org/iucr-top/journals/acta/c/services/checkcif.html). When checking a CIF at the above Web sites, the second line in the CIF should be: _publ_suggested_journal 'test'
   These checkcif programs will give a list of concerns and a response form. You should correct the CIF to eliminate as many problems as possible and resubmit the CIF. When the manuscript is submitted to CJC a copy of the last output from the checkcif program with a completed response form (from the checkcif program) should accompany the manuscript. Adequate explanations should be given on the response form.
3. The CCDC will provide the author with a deposition number for each crystal structure reported in the manuscript. Each number is a 6-digit integer, e.g., 100345. This deposition number should be included with the manuscript when submitting to the journal.
4. When the paper is published an appropriate footnote will be printed, for example: "CCDC XXXXXX contains the supplementary crystallographic data for this paper. These data can be obtained, free of charge, via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, U.K. (Fax: 44-1223-336033 or e-mail: deposit@ccdc.cam.ac.uk)."
5. The deposited data will not be archived to the Cambridge Structural Database until the paper has been published. If, after 15–18 months, the paper has not been published, the CCDC will contact the depositor to determine what should be done with the data.

Notes for Authors

A checklist of data items for deposition can be obtained from the CCDC Home Page on the World Wide Web (http://www.ccdc.cam.ac.uk/) or by e-mail (to fileserv@ccdc.cam.ac.uk with the one-line message sendme checklist). This list is NOT sufficient to complete a CIF for a checkcif program.

To run a checkcif program, most of the fields on the CIF must be filled. The response will tell you about any fields that require completion. Please submit a complete CIF to the CCDC and not one containing only the parameters listed as required by the CCDC. This CIF will be appended to the electronic version of any paper published by the *Canadian Journal of Chemistry.*

2001 Alcan Award Lecture
From academic research to industrial applications and back again

Douglas W. Stephan

Abstract: This paper reviews our recent research efforts that have taken us from fundamental studies of the reactivity of Ti and Zr complexes to the development of new olefin polymerization catalysts of significant industrial potential. In furthering our understanding of these systems we have probed the unique chemical pathways by which early metal phosphinimide catalysts undergo activation and deactivation.

Key words: titanium, zirconium, dehydrocoupling, polyphosphines, olefin polymerization, catalysis, deactivation.

Résumé : Ce travail présente une revue de nos récents efforts de recherches qui nous ont permis de passer d'études fondamentales sur la réactivité des complexes du Ti et du Zr au développement de nouveaux catalyseurs pour la polymérisation des oléfines qui présentent un potentiel industriel important. En augmentant notre compréhension de ces systèmes, nous avons été amenés à examiner les voies réactionnelles chimiques uniques par lesquelles les catalyseurs métalliques du phosphinimide originaux subissent des activations et des désactivations.

Mots clés : titanium, zirconium, déhydrocouplage, polyphosphines, polymérisation des oléfines, catalyseur, désactivation.

[Traduit par la Rédaction]

Introduction

The public perceives a linear route from fundamental science to commercial application mediated by research funding. However, this is not quite typical. Research funding certainly is essential to garner a deeper understanding of a particular aspect of fundamental science. However, commercial applications often spring from the combination of probing experiments and a broad perspective on the potential implications of the work. This overview succinctly summarizes our efforts.

We have had a continuing interest in the chemistry of the early transition metals. Early work focused on early–late heterobimetallics (1) while more recent efforts have dealt with the chemistry of Ti-sulfur and -thiolate (2) and Zr–phosphorus chemistry (3). Each of these areas has been reviewed. Much of that work centred on the synthesis, structure, and reactivity of these systems. In more recent efforts, we have focused attention on the application of some of these systems in catalytic processes. In this manuscript, we describe the development of novel Zr-hydride based systems, which are capable of catalyzing the oligomerization of primary phosphines. In a strategy designed to improve these catalysts, we discovered a new class of compounds, which are particularly effective, single-site olefin polymerization catalysts. Subsequent collaborative efforts have taken these systems toward commercial-scale applications, while studies of the chemistry of these catalysts have revealed a number of insights regarding catalyst activation, the role of co-catalysts and deactivation pathways.

Zr-hydrides in catalytic dehydrocoupling of P—H bonds

In 1995, we reported the synthesis of the novel potassium salt of the zirconocene trihydride anion (4). Subsequently in 1997, we described the related sequence of reactions involving $Cp^*_2ZrCl_2$ with $LiAlH_4$ followed by treatment with BuLi (Scheme 1) (5). This synthetic route proceeds through the isolable intermediate $[(Cp^*_2ZrH(AlH_4)]_2$, ultimately giving the threefold symmetric species $[(Cp^*_2ZrH_3)Li]_3$ in all but quantitative yield (Fig. 1).

The presence of 1% of this compound effects the catalytic dehydrocoupling of primary phosphines such as $PPhH_2$ to P_5R_5 upon heating to 80–100°C for 24 h. Stoichiometric reactions with phosphines afford the isolation of the complexes $[Cp^*_2ZrH(PPh)_2)Li]$ and $[Cp^*_2ZrH(PPh)_3)Li]$, while transient spectroscopic data support the intermediacy of a phosphinidene-hydride $[Cp^*_2ZrH(PPh))Li]$ (4). These data suggest the partial catalytic cycle for dehydrocoupling as depicted in Scheme 2. What remains unclear are the steps between the triphosphanato anion and the products. Further insertions or alternatively, thermal degradation of $[Cp^*_2ZrH(PPh)_3)Li]$ to $(PR)_3$ and thermal reorganization have been proposed as subsequent steps in the formation of P_5Ph_5.

This chemistry was also applied to the catalytic oligomerization of 1,2-diphosphinobenzene. Quenching of the catalysis after only 30 min revealed the formation of the dimerized species $(C_6H_4P(PH))_2$ (Scheme 3). Allowing the catalysis to continue for 12 h affords complete dehydro-

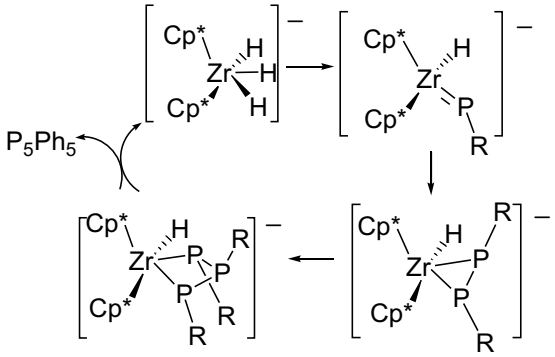
coupling and the formation of the macrocyclic species $(C_6H_4P_2)_8$ (Fig. 2) (6). This species contains 16 contiguous phosphorus atoms in a ring. Although the development of the chemistry of this novel macrocycle is plagued by the insolubility of this species, related work has shown that diphosphinoethane undergoes dehydrocoupling to give the species $(HPCH_2CH_2P)_2$. This species reacts with $AlMe_3$ to give the macrocyclic species $[(PCH_2CH_2PAlMe_2)_2)_4]\cdot 4[AlMe_3]$ (Scheme 4, Fig. 3) (7). This centrosymmetric macrocyclic compound is comprised of four dimeric units that are bridged by two $AlMe_2$ units giving five-membered P_3Al_2 rings. Four additional $AlMe_3$ groups are coordinated to phosphorus, exocyclic to the macrocycle.

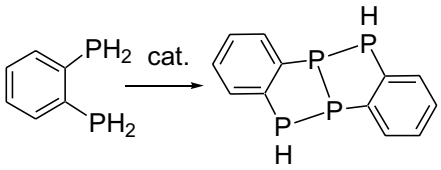
A different approach and a transition point

One of the problems faced in extending the chemistry above is the relatively low activity of the catalysts. Thus in developing an approach, we considered sterically less encumbered catalysts, specifically we sought to develop new

Scheme 2.



Scheme 3.



catalyst systems based on non-metallocene complexes. This approach brought to mind the efforts of Wolczanski and coworkers (8) who described the steric analogy between the tri-*tert*-butylmethoxide and cyclopentadienyl ligands (Fig. 4). Applying a related steric analogy, we focused attention on titanium complexes of bulky phosphinimide ligands. This approach offers several potential advantages. Firstly, the conical nature of phosphinimides approximates the cone occupied by cyclopentadienyl ligands. However, the bulk is more removed from the metal center offering potentially enhanced reactivity. Secondly, the ease of synthesis of phosphinimide ligands from the readily available phosphine precursors provides the flexibility to tune the steric and electronic properties of the ligands. Finally, the inclusion of phosphorus-based ligands permits use of ^{31}P NMR spectroscopy as a convenient spectroscopic handle for monitoring reaction progress.

We recognized that while such species may lead to effective dehydrocoupling catalysts for the oligomerization of phosphines, this strategy has not as yet been probed. Instead, we recognized that this logic may also be effective for the major industrial application of olefin polymerization catalysts. It was at this point that we targeted these species and planned to probe their catalytic utility.

Synthesis of catalyst precursors

The syntheses of phosphinimide ligands of the form $R_3PNSiMe_3$ are well-established processes involving the Staudinger reaction of phosphine with N_3SiMe_3. Subsequent reaction with $CpTiCl_3$ readily affords access to a wide variety of complexes of the form $CpTiCl_2(NPR_3)$ (Scheme 5) (9, 10). Similarly, this synthetic route tolerates considerable flexibility in the range of substituents on either the phosphinimide or the cyclopentadienyl rings. In a similar manner the species $(t\text{-}Bu_3PN)TiCl_3$, $(t\text{-}Bu_3PN)_2TiCl_2$, and $(t\text{-}Bu_3PN)_3TiCl$ (11) are prepared via stoichiometric reac-

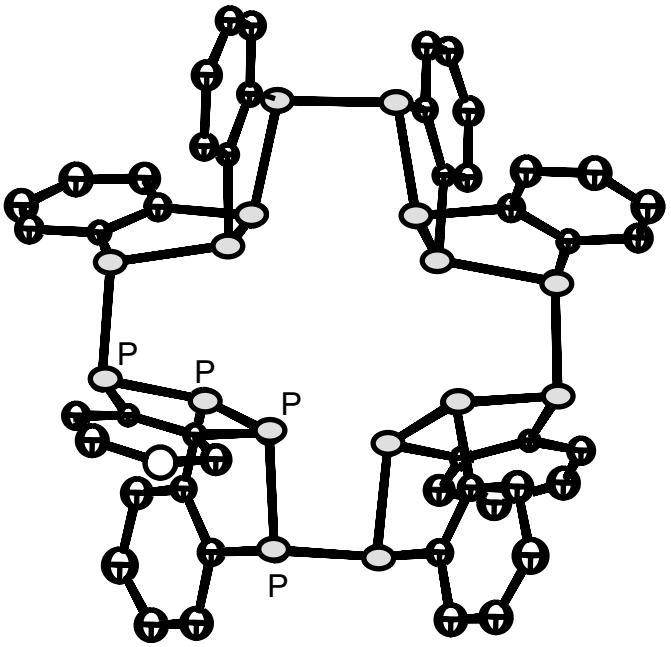
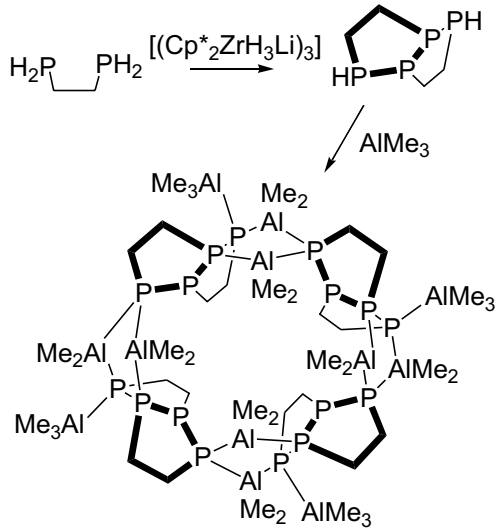


Scheme 4.



tions of the lithium phosphinimide (t-Bu_3PNLi) and $TiCl_4$ (Scheme 5). Subsequent alkylation of both the cyclopentadienyl-titanium halides as well as the cyclopentadienyl-free complexes is achieved in a straightforward manner employing alkyl-lithium or Grignard reagents, providing a large range of derivatives. In a manner analogous to that reported for several metallocenes, the zwitterionic complexes $CpTiMe(NPR_3)(\mu\text{-}MeB(C_6F_5)_3)$ (Fig. 5) (9) and $(t\text{-}Bu_3PN)_2TiMe(\mu\text{-}MeB(C_6F_5)_3)$ were obtained upon reaction of the $CpTiMe_2(NPR_3)$ or $(t\text{-}Bu_3PN)_2TiMe_2$ with $B(C_6F_5)_3$ (Scheme 6).

Ethylene polymerization

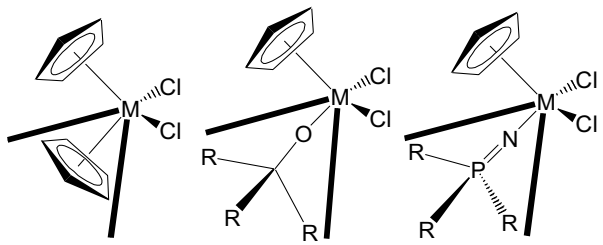
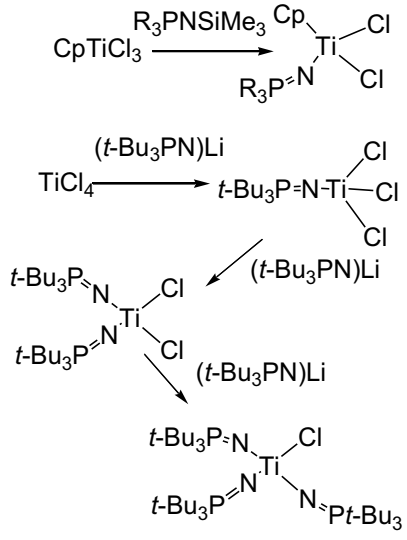


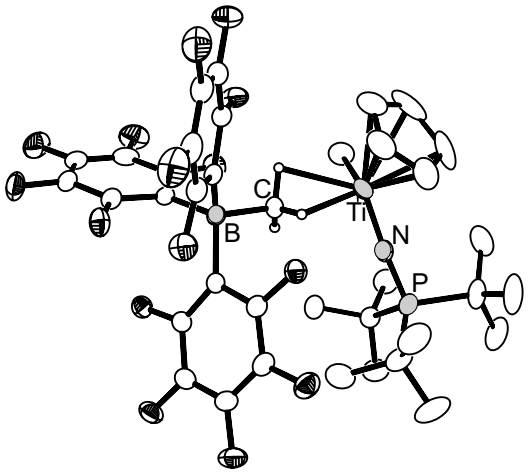
Scheme 5.



alumoxane (MAO), effect the catalytic polymerization of ethylene at 1 atm and 25°C (Table 1) (9, 10). The level of activity varies with the substituents on the phosphorus center as the catalysts derived from $CpTiCl_2(NPCy_3)$ and $CpTiCl_2(NP\text{-}i\text{-}Pr_3)$ and MAO exhibit relatively low activity

© 2002 NRC Canada

Fig. 5. X-ray structure of the zwitterionic complex CpTiMe(NP-*t*-Bu_3)(μ-MeB(C_6F_5)$_3$).



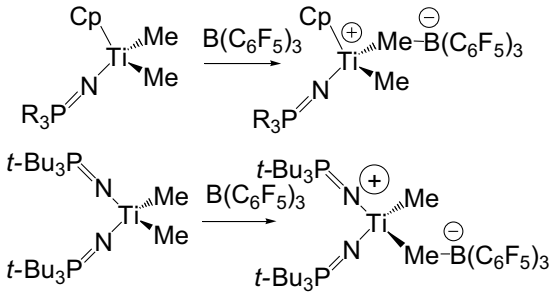
compared to that derived from $CpTiCl_2$(NP-*t*-Bu_3). This latter species with an activity of 652 g PE/mmol/h, approaches that observed from Cp_2ZrCl_2 under the same conditions (895 g PE/mmol/h). It is also noteworthy that the phosphinimide catalyst gives polyethylene of molecular weight 89 000 with a polydispersity of 1.6 consistent with single-site catalysis.

Activation of the analogous dimethyl derivatives of the catalyst precursors with $[Ph_3C][B(C_6F_5)_4]$ results in much higher activity and polyethylene of higher molecular weight (9, 10). While the catalysts derived from $CpTiMe_2(NPCy_3)$ and $CpTiMe_2$(NP-*i*-Pr_3) show a substantial increase in activity giving 231 and 225 g PE/mmol/h, respectively, systems with additional steric crowding such as *t*-$BuCpTiMe_2(NPR_3)$ (R = Cy, *i*-Pr_3, *t*-Bu_3) show significantly higher activity. In these cases, the high activity together with the observation of polydispersities in the range of 7–12 suggest that these screening polymerizations rapidly become diffusion-controlled reactions.

While these results are encouraging, it is clear that for a true commercial potential the catalyst must operate effectively under more demanding conditions of higher temperatures and pressures of ethylene. Such conditions often lead to the degradation of catalysts that are active under the mild conditions of initial laboratory screenings. In collaborative development with researchers at NOVA Chemicals Corporation, the viability of the bis-phosphinimide-based catalyst was demonstrated under commercially relevant solution production conditions (160°C) with the optimization of reagent flows. Under these conditions, Cp_2ZrMe_2 and ($C_5Me_4SiMe_2$N-*t*-Bu)$TiMe_2$ were also tested for comparison. The results demonstrate that the catalyst derived from (*t*-$Bu_3PN)_2TiMe_2$ continues to act as a single-site ethylene polymerization catalyst under these harsh conditions. Polydispersity of 1.9 and good molecular weight of the polymer are achieved with the titanium-phosphinimide catalyst at a remarkably high activity. Our system proved to be almost four times as active as the constrained geometry catalyst under similar conditions (Table 2) (10).

The promising results for the phosphinimide-based catalyst described above clearly warrant further study. This new

Scheme 6.



class of early metal catalysts exhibits unique levels of activity and yet appears to operate in a manner similar to that known for related metallocenes. Thus, from our academic perspective we chose to probe the mechanisms by which these systems were deactivated, in the hopes of garnering a deeper understanding of these catalysts. Such information will also assist in the design of new catalysts and applications.

Catalyst deactivation pathways

Ligand degradation

Some of the data above suggest that sterically demanding ligands are worthy of investigation. In this regard we noted the work of Pringle and co-workers (12) who reported a new class of bulky bidentate phosphine ligands where the P atoms are incorporated in a sterically demanding adamantane-like cage. Molecular modeling suggests titanium complexes of phospha-adamantyl-phosphinimides will exhibit a ligand cone angle significantly larger than that of *tert*-butylphosphinimide and thus offer greater steric protection of the metal center. The "cage-phosphines" $PR(C_6H_4O_3Me_4)$ were conveniently prepared from the reaction of RPH_2 with 2,4-pentanedione and subsequent oxidation gave the corresponding phosphinimine. Complexation by titanium followed the methodologies established above (Scheme 7) (13). These complexes were screened for catalytic activity in ethylene polymerizations in the presence of 500 equiv of MAO or combined with $[Ph_3C][B(C_6F_5)_4]$ and showed surprisingly low activities (<10 g PE/mmol/h). In an effort to understand the poor performance of these titanium complexes the interactions with aluminum reagents were investigated. Reaction of $CpTiMe_2(NPR(C_6H_4O_3Me_3))$ as catalysts, with $AlMe_3$ revealed the generation of a number of products. This suggests that Lewis acid activators attack the titanium complexes. This view was supported by the crystallographic characterization of one of the several products, namely $CpTiMe_2(NPCy(C_6H_4O_3Me_5)(\mu\text{-}AlMe_2)(AlMe_3))$ (Scheme 7) (13). In this species, the aluminum reagent has effected ligand rupture and leads to catalyst deactivation.

Increased Lewis acidity

Another class of sterically demanding phosphinimide complexes have been prepared in which one of the substituents on phosphorus is also a phosphinimide group. These ligands are readily prepared by reaction of lithium-phosphinimide salts with chlorophosphines followed by subsequent oxidation of the P(III) centre (14). In the standard

Table 1. Screening for ethylene polymerization (1 atm, 25°C).

Catalyst precursor	Activator	Productivity (g PE/mmol/h)	MW (Da) (pdi)
$CpTiCl_2(N{=}PCy_3)$	MAO	42	3 590 (1.8)
			336 000 (2.2)
$CpTiCl_2(N{=}P\text{-}t\text{-}Bu_3)$	MAO	652	89 900 (1.6)
Cp_2ZrCl_2	MAO	895	116 353 (2.8)
$CpTiMe_2(N{=}P\text{-}i\text{-}Pr_3)$	$Ph_3C[B(C_6F_5)_4]$	225	163 800 (3.9)
$CpTiMe_2(N{=}P\text{-}t\text{-}Bu_3)$	$Ph_3C[B(C_6F_5)_4]$	401	165 800 (3.4)
$t\text{-}BuCpTiMe_2(N{=}PCy_3)$	$Ph_3C[B(C_6F_5)_4]$	1807	310 200 (7.5[a])

[a]This broader pdi was attributable to the high activity of the catalyst. Narrower pdis were obtained under more dilute conditions.

Table 2. Ethylene polymerization under industrially relevant conditions (160°C).

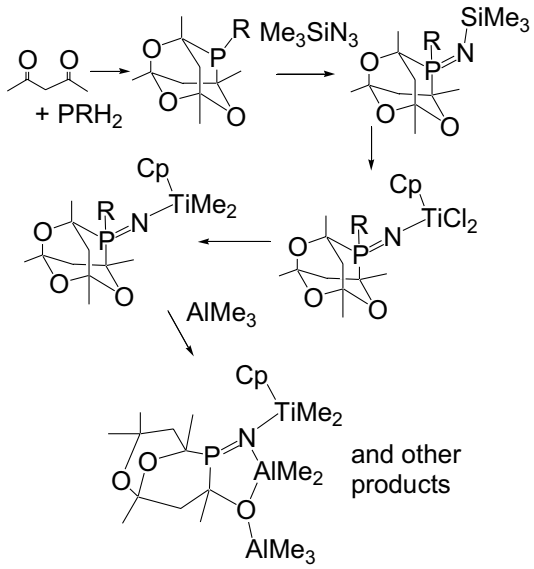
Precursor	Co-catalyst	Productivity (g PE/mmol/h)	MW (Da) (pdi)
$(t\text{-}Bu_3PN)_2TiMe_2$	$[Ph_3C]B(C_6F_5)_4$	62 310	77 500 (1.9)
$(C_5Me_4SiMe_2$ N-*t*-Bu)$TiMe_2$	$[Ph_3C]B(C_6F_5)_4$	16 130	134 500 (2.5)
Cp_2ZrMe_2	$[Ph_3C]B(C_6F_5)_4$	8 850	12 300 (3.8)

manner the corresponding titanium complexes were prepared. The species $CpTi(NPPh_2(NP\text{-}t\text{-}Bu_3))Cl_2$ proved to be a reasonable catalyst precursor yielding a catalyst by activation with MAO which polymerized ethylene with an activity of 300 g/mmol/h. In marked contrast, tests at 1 atm ethylene employing the methyl derivatives and $[Ph_3C][B(C_6F_5)_4]$ showed minimal polymerization activity. Attempts to characterize the cationic species involved the reaction of $CpTi(NPPh_2(NP\text{-}t\text{-}Bu_3))Me_2$ with $B(C_6F_5)_3$. Crystallographic characterization of the product from CH_2Cl_2 confirmed the formulation as $[CpTi(\mu\text{-}Cl)(NPPh_2(NP\text{-}t\text{-}Bu_3))]_2[BC_6F_5)_4]_2$ (Fig. 6) (14). While the mechanism of formation is the subject of speculation, the formation of this species does permit some inferences to be made. While initial interaction of the titanium complex with $B(C_6F_5)_3$ is assumed to involve methyl abstraction, apparently the resulting zwitterion is highly reactive. Clearly the isolation of the chloro-bridged di-cation imply both solvent activation and borate-substituent redistribution. This observation suggests that the electron-withdrawing phosphinimide substituent on the metal-bound phosphinimide ligand results in a highly Lewis acidic Ti species. It is presumably this acidity that prompts deactivation of the catalyst. The activity of the MAO-based catalyst suggests ion-pairing or cation–anion interactions are critical for catalyst stability.

$B(C_6F_5)_3$ as a catalyst poison

While the species $(t\text{-}Bu_3PN)_2TiMe(\mu\text{-}MeB(C_6F_5)_3)$ has been shown above to be an active catalyst for ethylene polymerization, preliminary screening studies showed that the order of addition of the reagents had a dramatic effect on the activity (Table 3) (10). Addition of $(t\text{-}Bu_3PN)_2TiMe_2$ to a solution of $B(C_6F_5)_3$ at 25°C under an ethylene atmosphere gave only a small amount of polyethylene. On the other hand, addition of $B(C_6F_5)_3$ to a solution of $(t\text{-}Bu_3PN)_2TiMe_2$ gave significantly increased activity. These observations prompted NMR studies of the stoichiometric reaction of $(t\text{-}Bu_3PN)_2TiMe_2$ with excess

Scheme 7.



$B(C_6F_5)_3$. In the presence of excess borane, the di-zwitterionic species $(t\text{-}Bu_3PN)_2Ti(\mu\text{-}MeB(C_6F_5)_3)_2$ (Scheme 8, Fig. 7) was obtained (15). This species exhibits negligible polymerization activity, presumably because no formal Ti—C bond remains available for insertion. This observation demonstrates for the first time a dual role for the $B(C_6F_5)_3$ as it acts both as a catalyst activator and a catalyst poison. It is presumably the remote nature of the steric bulk of the phosphinimide ligands that allows access to the metal center by 2 equiv of the borane.

C—H bond activation

The titanium-phosphinimide complexes under discussion are generally active catalysts for polymerization of olefins. However, they also generally show lower activity when activated by MAO. This observation is particularly true for complexes containing sterically less demanding phosphinimide ligands. To probe the root of this observation, reactions of the titanium-phosphinimide complexes with excess $AlMe_3$ were undertaken, in an effort to model the interaction with MAO. In the reaction of $CpTi(NPR_3)Me_2$ with $AlMe_3$, gas evolution was apparent and the resulting product was confirmed crystallographically to be $[CpTi(\mu^2\text{-}Me)(\mu^2\text{-}NPR_3)(\mu^4\text{-}C)(AlMe_2)_3]$ (16, 17). This information confirmed that triple C—H bond activation and the quantitative formation of an unprecedented Ti–Al-carbide cluster occurred (Fig. 8). The Lewis acidity of this complex is evident in the reaction

of this species with donors forming alane-donor adducts. In addition, the Lewis basicity of the central carbide carbon is evidenced by reaction with additional $AlMe_3$ that yields a five-coordinate carbide $[CpTi(\mu^2\text{-}Me)(\mu^2\text{-}NPR_3)(\mu^5\text{-}C)\text{-}(AlMe_2)_3\cdot(AlMe_3)]$ (Scheme 9, Fig. 9) (16). The isolation of these C—H bond activation products, particularly the four- and five-coordinate nature of the central carbon is interesting from an academic perspective. However, the isolation of these species has some implications for the catalyst activity.

Fig. 7. (*a*) X-ray structure of $(t\text{-}Bu_3PN)_2Ti(\mu\text{-}MeB(C_6F_5)_3)_2$. (*b*) Coordination sphere of Ti.

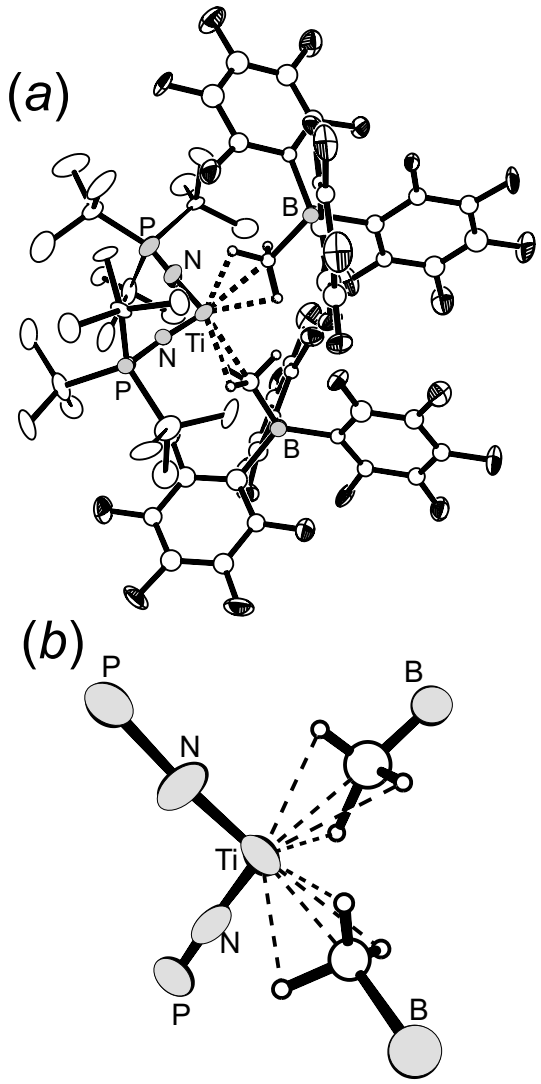

Fig. 8. X-ray structure of $[CpTi(\mu^2\text{-}Me)(\mu^2\text{-}NP\text{-}i\text{-}Pr_3)(\mu^4\text{-}C)(AlMe_2)_3]$.

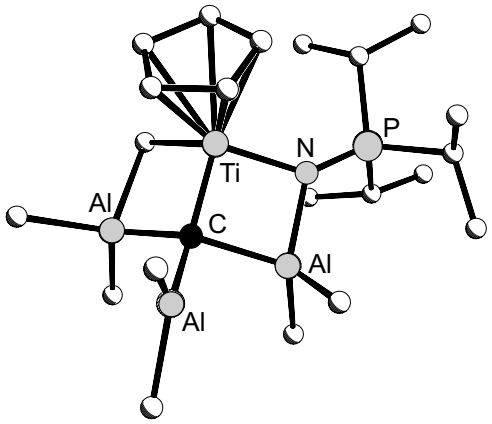

If indeed $AlMe_3$ reacts in a similar manner to MAO, then these observations suggest that C—H bond activation processes may suppress catalytic activity. However, this could

Scheme 9.

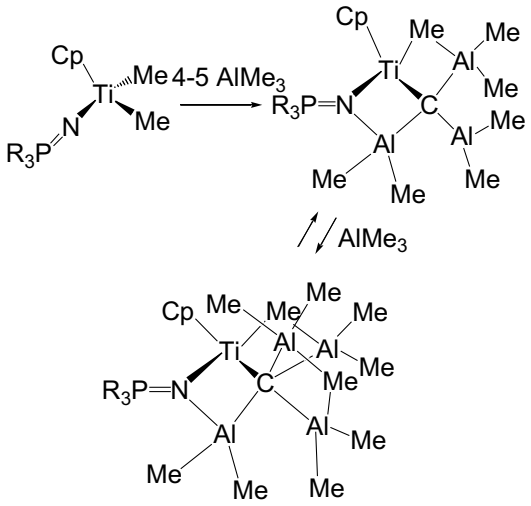

Fig. 9. X-ray structure of $[CpTi(\mu^2\text{-}Me)(\mu^2\text{-}NPPh_3)(\mu^5\text{-}C)(AlMe_2)_3{\cdot}(AlMe_3)]$.

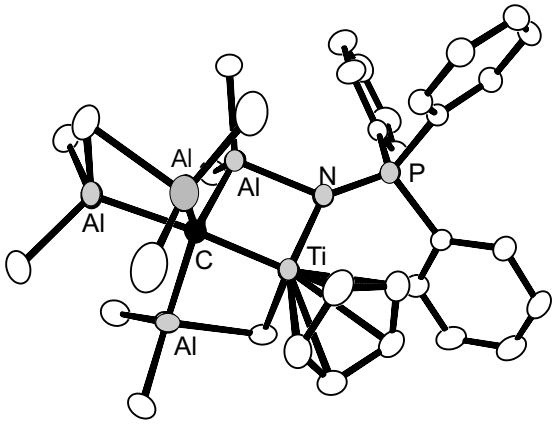
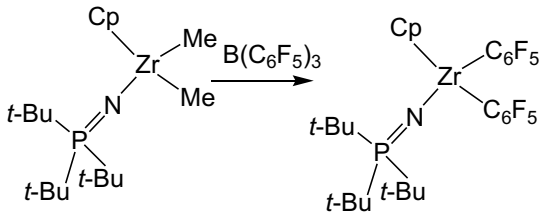


Scheme 10.



be overstated and thus it may be that interaction of the phosphinimide nitrogen atom with an aluminum center of MAO is sufficient to diminish catalyst activity.

C_6F_5 transfer

Zirconium-phosphinimide complexes of the form $Cp'Zr(NPR_3)X_2$ (Cp′ = Cp*, Cp; X = halide, alkyl or aryl) are readily prepared using synthetic methods very similar to that used to obtain the analogous titanium species (18). In general, regardless of the protocol used for activation, the Zr complexes showed uniformly poor catalyst activity for ethylene polymerization. Probing the cause of the poor activity,

Fig. 10. X-ray structure of $(Cp^*Zr)_4(\mu\text{-}Cl)_5(Cl)(\mu\text{-}CH)_2$.

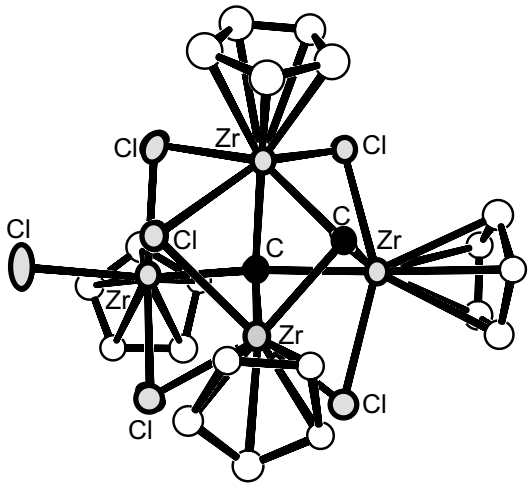


Fig. 11. X-ray structure of $(Cp^*Zr)_5(\mu\text{-}Cl)_6(\mu\text{-}CH)_3$.

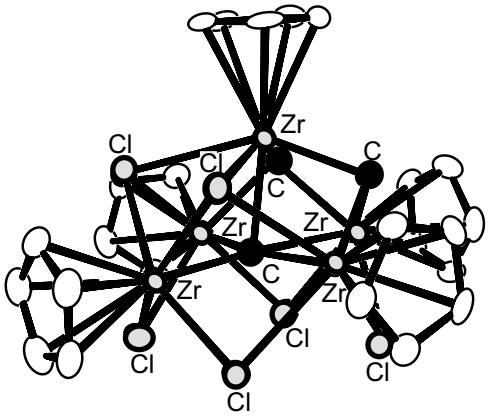

the reaction of complexes of the form $Cp'Zr(NPR_3)Me_2$ (Cp′ = Cp*, Cp) with $B(C_6F_5)_3$ were investigated. Under very mild conditions this reaction was shown by spectroscopic methods to give the species $Cp'Zr(NPR_3)(C_6F_5)_2$ in quantitative yield (Scheme 10) (18). Clearly, this reactivity provides a highly efficient route for the destruction of catalyst activity.

Ligand abstraction and C—H bond activation

Further exploration of the low activity of the Zr analogs prompted reaction of $Cp^*Zr(NP\text{-}t\text{-}Bu_3)Cl_2$ with $AlMe_3$ as a model for the interaction with MAO. While the resulting reaction results in several products as evidenced by ^{31}P NMR spectroscopy, two products were crystallized and structurally characterized. One of the products is the Zr_4 cluster $(Cp^*Zr)_4(\mu\text{-}Cl)_5(Cl)(\mu\text{-}CH)_2$ (Fig. 10) (18). This species is comprised of four Zr atoms bound to a central methine carbon with each Zr atom bonded to a pentamethylcyclopentadienyl ligand and two bridging chloride atoms. One of the Zr atoms also has an additional terminal chloride, while the remaining three Zr atoms are bridged by an additional methine carbon. A second product was identified as $(Cp^*Zr)_5(\mu\text{-}Cl)_6(\mu\text{-}CH)_3$ (Fig. 11) (18). This species, like the previous, is a Zr-cluster comprised of five Cp*Zr fragments about a central methine carbon atom. The Zr atoms form a square-based pyramid

© 2002 NRC Canada

about the central carbon with the basal plane of Zr atoms being bridged by four chloride atoms below the plane. Two chlorine atoms and two pseudotetrahedral methine carbons above the plane bridge the axial Zr center. These two products were obtained in poor yield, nonetheless, these compounds do suggest avenues by which catalyst–co-catalyst interactions can lead to deactivation. Firstly, phosphinimide ligand abstraction clearly occurs which stands in contrast to the related Ti complexes. Secondly, methyl transfer from Al to Zr followed by C—H bond activation is clearly indicated suggesting that C—H bond activation is again involved in catalyst deactivation.

Summary

In summary, our work began addressing very fundamental questions about the reactivity of Ti and Zr complexes. The work on P—H bond activation and catalytic dehydrocoupling of phosphines evolved to a quest for alternative catalyst precursors. In this effort, phosphinimide-based complexes were prepared and it was discovered that these systems provide catalyst precursors that are highly active in ethylene polymerization. In fact, these catalysts rival and in some cases surpass commercial catalysts. While the potential commercialization of these systems is in on-going development in collaboration with researchers at NOVA Chemicals Corporation, our efforts have once again turned to fundamental questions, in this case, deactivation pathways. The study of the unique reactivity exhibited by these systems not only provides a better understanding of these catalysts but also provides insight which could lead to new applications and the design of new catalyst systems.

Acknowledgements

First and foremost, I am grateful for the love and support of Dianne, David, and Katie. I cannot thank them enough. I also wish to acknowledge the administration at the University of Windsor for the provision of a highly supportive environment. My colleagues, in particular Drs. Tuck, Drake, McGarvey, and (the late) Rutherford are acknowledged for establishing a precedent for success. Dr. Steve Loeb is thanked for almost 25 years of friendship and creative discussion. I am indebted to a large group of hard working and talented young scientists that it has been my pleasure to work with over the past 19 years. While a number of these people worked on earlier chemistry not discussed herein, their contributions are very much appreciated. These include the postdoctoral fellows: Yujin Huang, Eva Witt, Peggy McKarns, Nola Etkin, Chris Fermin, Rick Heyn, Zhaomin Hou, Charles Carraz, Luc LePichon, Fred Guerin, Pingrong Wei, and Jim Kickham, as well as the graduate students: Evelyn Kinsch, Graham White, Lucio Gelmini, Hilde Berends, Teresa Wark, Dave Dick, Jianwei Ho, Tim Nadasdi, Tricia Breen, Andrea Firth, Jeffrey Stewart, Chris Ong, Nancy Yue, Silke Courtenay, Aaron Hoskin, Sarah Smith, Emily Hollink, Katie Chan, Chad Beddie, Liam Spencer, Steve Clemens, Ramadan Altwer, and Lourissa Cabrera. In addition, financial support from the University of Windsor, the Natural Sciences and Engineering Research Council of Canada (NSERC), Imperial Oil, Janssen-Ortho, the Petroleum Research Fund, and NOVA Chemicals Corporation is gratefully acknowledged.

Magnetic and structural studies on 1,3-diazolate complexes of cobalt(II) — The characterization of three new cobalt(II) molecule-based magnets

Victor Sánchez, Alan Storr, and Robert C. Thompson

Abstract: The cobalt(II) compounds ($[Co(imid)_2]_x$ (**1**), $[Co(2\text{-}meimid)_2]_x$ (**2**), $[Co(4\text{-}meimid)_2]_x$ (**3**), $[Co(benzimid)_2]_x$ (**4**), and $[Co_3(imid)_6(imidH)_2]_x$ (**5**) (imid = imidazolate, 2-meimid = 2-methylimidazolate, 4-meimid = 4-methylimidazolate, benzimid = benzimidazolate)), have been synthesized and structurally and magnetically characterized. Electronic and vibrational spectroscopy and thermogravimetric studies on all five compounds support structures involving tetrahedrally coordinated cobalt centers with single-bridging 1,3-diazolate ligands forming extended polymeric lattices. Moreover, X-ray powder diffraction studies on **1** and **5** established, through isomorphism with published structures, that the molecular connectivity in these materials is 3-D. Variable temperature and applied field magnetization studies revealed antiferromagnetism as the primary magnetic exchange process in all five compounds. In addition, **1**, **4**, and **5** show magnetic phase transitions to ferromagnetically ordered states below critical temperatures of 16, 13, and 15 K, respectively. Magnetization measurements at 4.8 K as the applied field was cycled between +55 000 and –55 000 G revealed typical hysteresis behavior and gave remnant magnetizations of 334, 257, and 175 cm^3 G mol^{-1} and coersive fields of 6620, 5280, and 4140 G for **1**, **4**, and **5**, respectively. No evidence for long-range magnetic order was obtained for either **2** or **3**. A comparison of the magnetic properties of three pairs of isostructural iron(II) and cobalt(II) molecule-based magnets shows that while the coersive fields are in general larger for cobalt over iron, the magnitude of the difference varies significantly suggesting that one cannot conclude that cobalt analogues will always be harder magnets.

Key words: cobalt(II), 1,3-diazolates, canted spins, molecule-based magnets.

Résumé : On a synthétisé les composés du cobalt(III) suivants, $[Co(imid)_2]_x$ (**1**), $[Co(2\text{-}meimid)_2]_x$ (**2**), $[Co(4\text{-}meimid)_2]_x$ (**3**), $[Co(benzimid)_2]_x$ (**4**) et $[Co_3(imid)_6(imidH)_2]_x$ (**5**) (imid = imidazoles, 2-meimid = 2-méthylimidazolate, 4-meimid = 4-méthylimidazolate et benzimid = benzimidazolate) et on en a fait la caractérisation structurale et magnétique. Les spectroscopies électronique et vibrationnelle ainsi que des études de thermogravimétrie sur ces composés sont en accord avec des structures impliquant des centres de cobalt à coordination tétraédrique et des ligands 1,3-diazolate servant de pont unique pour former des réseaux étendus de polymères. De plus, en se basant sur les structures des composés **1** et **5** déterminées par diffraction des rayons X et l'isomorphisme avec des structures déjà publiées, on peut en déduire que la connectivité moléculaire dans ces matériaux est 3-D. Des études à températures variables et de magnétisation du champ appliqué révèlent que, pour chacun de ces composés, le processus d'échange magnétique primaire résulte d'antiferromagnétisme. De plus, les composés **1**, **4** et **5** donnent lieu à des transitions de phase magnétique conduisant à des états ferromagnétiquement ordonnés à des températures critiques respectivement de 16, 13 et 15 K. Des mesures de magnétisation à 4,8 K alors que l'on faisait varier le champ appliqué de +55 000 à –55 000 G révèlent l'existence d'un comportement d'hystérèse typique qui conduisent à des magnétisations résiduelles de 334, 257 et 175 cm^3 G mol^{-1} et des champs coersifs de 6620, 5280 et 4140 G respectivement pour les composés **1**, **4** et **5**. Pour les composés **2** et **3**, on n'a pas pu observer d'ordre magnétique à longue portée. Une comparaison des propriétés magnétiques des trois paires d'aimants isostructuraux à base de fer(II) et de cobalt(II) montrent que, alors que les champs coersifs sont généralement plus importants pour le cobalt par rapport au fer, l'amplitude de la différence varie de façon significative; ce qui suggère que l'on ne peut pas conclure que les analogues à base de cobalt sont toujours des aimants plus durs.

Mots clés : cobalt(II), 1,3-diazolates, spins penchés, aimants à base de molécules.

Introduction

Recent reviews have documented the ability of diazolate ligands to function as bridging bidentate ligands and to act as relatively efficient mediators of magnetic exchange interactions where paramagnetic metal centers are involved (1–3). Studies on binary pyrazolates of copper(II), cobalt(II), iron(II), nickel(II), and manganese(II) show that the 1,2-positioning of the nitrogen atoms in the ligands leads to 1-D linear chain structures with double azolate bridges and short-range antiferromagnetic coupling between metal centers (4–10). In contrast, as has been discussed (11), in related imidazolate systems, the 1,3-positioning of the donor nitrogens in the ligands results in steric constraints which are likely to prevent the formation of double azolate bridges. These ligands may then be expected to singly bridge metals and form higher dimensional 2-D or 3-D structures with the potential for long-range magnetic interactions. As reported previously, these structural (11, 12) and magnetic (11) characteristics are exhibited by $[Fe_3(imid)_6(imidH)_2]_x$ (where imidH = imidazole), a compound in which iron(II) ions are singly bridged by imidazolate ligands in an extended 3-D lattice. Magnetic studies on this compound revealed antiferromagnetic coupling as the primary exchange interaction. Due, it was concluded, to a canting of the spins, residual spin density remained on the metal centers at low temperatures and this led to long-range order and weak ferromagnetism. We later reported (13, 14) the structure and magnetic characterization of iron(II) complexes of 2-methylimidazolate ($[Fe(2\text{-meimid})_2 \cdot 0.13Cp_2Fe]_x$ (2-meimid = 2-methylimidazolate and Cp = cyclopentadienyl) and 4-azabenzimidazolate ($[Fe(4\text{-abimid})_2]_x$ (4-abimid = 4-azabenzimidazolate). Stoichiometrically and structurally these compounds are distinct from the imidazolate analogue ($[Fe_3(imid)_6(imidH)_2]_x$; nonetheless, they too have single-azolate-bridged 3-D structures and show long-range ferromagnetic order at low temperatures. The magnetic properties exhibited by these three iron(II) systems serve to classify them as molecule-based magnets (15). There is considerable interest in materials such as these from the joint perspectives of understanding factors that generate them and of their potential applications (16).

The noncentrosymmetric M-L-M exchange pathway provided by single-bridging 1,3-diazolate ligands appears to be a key factor in generating spin canting and weak ferromagnetism (14). The phenomenon should not be restricted to iron(II). This fact coupled with the observation that the iron centers involved in the primary exchange pathways in the previously investigated systems are tetrahedrally coordinated (a common geometry for cobalt(II)), prompted us to investigate related cobalt systems. Our studies on $[Co(4\text{-abimid})_2]_x$, a compound which exhibits low-temperature ferromagnetism, have already been described (14). Here, we describe work on five additional cobalt systems: $[Co(imid)_2]_x$ (**1**), $[Co(2\text{-meimid})_2]_x$ (**2**), $[Co(4\text{-meimid})_2]_x$ (**3**), $[Co(benzimid)_2]_x$ (benzimid = benzimidazolate) (**4**), and $[Co_3(imid)_6(imidH)_2]_x$ (**5**).

Some studies on **1**–**4** were reported earlier (17–20) while compound **5** is studied here for the first time. We chose to further examine **1**, in particular, because its structure, as determined by single crystal X-ray diffraction studies (17), involves a 3-D extended lattice, suggesting the possibility of ferromagnetic ordering at low temperatures. Polymeric structures also seemed likely for **2**–**4** and an initial objective of the present study was to establish this through single crystal X-ray diffraction work. Unfortunately, we were unable to obtain crystals of these materials suitable for such studies. Although definitive structures of **2**–**4** remain elusive, we report here spectroscopic and thermal analysis data that attest to their polymeric nature. In addition, **5** is shown here to be isomorphous, and presumably isostructural, with the iron analogue, a compound known to have an extended 3-D lattice structure (11, 12). Previous reports on magnetic properties of these systems are limited to some high-temperature studies on **1** (17, 18*c*) and **4** (19). Variable-temperature and variable-field magnetization studies in the current work reveal that **1**, **4**, and **5** are low-temperature molecule-based magnets. No evidence for long-range ferromagnetic order was obtained for either **2** or **3**.

Experimental

Syntheses

Cobaltocene (from Strem), hexaaquacobalt(II) nitrate and hexaaquacobalt(II) chloride (from Mallinkrodt), imidazole (imidH), 2-methylimidazole (2-meimidH), 4-methyimidazole (4-meimidH), and benzimidazole (from Aldrich) were used as supplied. Acetonitrile and xylenes (from Aldrich) were reagent grade and were dried and distilled under an atmosphere of dry dinitrogen before use.

$[Co(imid)_2]_x$ (1)

Hexaaquacobalt(II) nitrate (7.5 g, 33 mmol) was dissolved in 10 mL of hot water and added dropwise to a solution of imidazole (3.4 g, 50 mmol) in 40 mL of hot water. The mixture was brought to boil and the precipitate was immediately filtered and washed with hot water first, then with acetone. The product was isolated as a microcrystalline purple powder and was dried in vacuo at 100°C. Anal. calcd. for $C_6H_6N_4Co$: C 37.3, H 3.1, N 29.0; found: C 37.6, H 3.0, N 28.7. Samples prepared by this route were examined by X-ray powder diffraction and were employed in the magnetic studies. A small quantity of material of the same composition as **1** was obtained by the removal, via thermolysis, of neutral imidazole from $[Co_3(imid)_6(imidH)_2]_x$ (**5**). This thermal treatment of compound **5** was carried out under a flux of dinitrogen utilizing a TA Instruments TGA 51 unit. A 30 min isotherm at 325°C was programmed into the instrument to completely remove the neutral imidazole. Anal. found: C 37.1, H 3.0, N 28.8.

$[Co(2\text{-meimid})_2]_x$ (2)

Hexaaquacobalt(II) nitrate (1.0 g, 3.7 mmol) was dissolved in 10 mL of ethanol and added dropwise to a solution of 2-methylimidazole (3.0 g, 37 mmol) in 40 mL of ethanol. The purple precipitate which formed immediately was filtered off, washed with ethanol, and dried for 1 h at 115°C. Anal. calcd. for $C_8H_{10}N_4Co$: C 43.4, H 4.6, N 25.3; found: C 43.0, H 4.3, N 24.9.

© 2002 NRC Canada

[Co(4-meimid)$_2$]$_x$ (3)

Hexaaquacobalt(II) chloride (1.0 g, 4.2 mmol) was dissolved in 15 mL of water and added dropwise to a solution of 4-methylimidazole (3.0 g, 37 mmol) in 30 mL of water. NaOH (1.48 g, 37 mmol) was dissolved in 5 mL of water and added dropwise to the mixture to complete the precipitation of a fine purple powder. The precipitate was filtered off, washed with water and then ethanol, and air-dried at room temperature. Anal. calcd. for $C_8H_{10}N_4Co$: C 43.4, H 4.6, N 25.3; found: C 43.6, H 4.5, N 25.0.

[Co(benzimid)$_2$]$_x$ (4)

This compound was prepared as previously reported (19). Anal. calcd. for $C_{14}H_{10}N_4Co$: C 57.3, H 3.4, N 19.1; found: C 57.5, H 3.3, N 19.2.

[Co$_3$(imid)$_6$(imidH)$_2$]$_x$ (5)

This compound was obtained as a purple microcrystalline powder by heating a mixture of excess imidazole (2.0 g, 26 mmol) with cobaltocene (0.2 g, 1.06 mmol) in a sealed and evacuated Carius tube at 150°C for 5 days. Dry xylenes and acetonitrile were used to isolate the product from residual ligand. Anal. calcd. for $C_{24}H_{26}N_{16}Co_3$: C 40.3, H 3.6, N 31.3; found: C 40.8, H 3.6, N 31.2.

Physical characterization

Thermal gravimetric analysis (TGA, 35–800°C) measurements were made using a TA Instruments TGA 51 unit. A Varian Cary 5 UV–vis–near-IR spectrophotometer was used to measure electronic spectra (200–3000 nm) at room temperature on Nujol mulls pressed between quartz plates. Infrared spectra (4000–400 cm^{-1}) were recorded at room temperature using KBr disc samples on a Bomen FT IR spectrophotometer. Magnetic properties were examined using a Quantum Design (MPMS) SQUID magnetometer. Magnetic susceptibilities were measured on finely ground powders at 500 and 10 000 G over the temperature range 2–300 K. Magnetization studies as a function of field strength (0–55 000 G) were made on powders at several temperatures and hysteresis magnetization data were obtained on Nujol mull samples by oscillating the applied magnetic field between +55 000 G and –55 000 G at 4.8 K. A specially designed sample holder, as described previously (5*d*), was used to minimize the background signal. Magnetic susceptibilities were corrected for background and for the diamagnetism of all atoms; corrections of 84×10^{-6} (compound **1**), 110×10^{-6} (compounds **2**, **3**, and **5**), and 140×10^{-6} cm^3 mol^{-1} (compound **4**), were employed. Data reported here are on a per mol of metal ion basis. Powder diffractograms for compound **5** were recorded on a Rigaku Rotaflex RU-200BH rotating anode powder X-ray diffractometer (graphite monochromated Cu Kα radiation). Samples were prepared by applying a hexanes slurry of the compound onto a glass plate and allowing the solvent to evaporate.

Results and discussion

Syntheses and structures

Compounds **1**–**4** were obtained as simple binary azolates, by employing modifications of methods reported in the literature for **1**–**3** (18*a*, 20) or, in the case of **4**, by the method of Goodgame and Cotton (19). The methods used produced the materials in powder form, unsuitable for single crystal X-ray diffraction studies. Previously, we reported that the synthetic pathway in which metallocenes are reacted directly with molten azoles can afford a clean and effective method for preparing divalent metal azolate polymers (9–11, 13). The method has been employed by us in the past to obtain single crystals of iron(II) azolate polymers, suitable for single crystal X-ray studies (11, 13, 21). Unfortunately, attempts to prepare compounds **1**–**4** employing this methodology failed to yield suitable crystals of the desired materials.

The structure of [Co(imid)$_2$]$_x$ (**1**) was determined previously by X-ray crystallography (17). It is a 3-D polymer consisting of fused puckered rings of four tetrahedrally coordinated cobalt(II) ions linked by single-bridging imidazolates. The X-ray powder diffractogram of a sample of **1**, synthesized in this work, agrees well with that calculated (22) from single crystal data reported for the compound (17). Indexing the powder diffractogram (23) of the material prepared here gave calculated lattice parameters of $a = b =$ 22.834 and c = 12.983 Å compared to $a = b$ = 22.872 and c = 12.981 Å, previously reported (17). We conclude that the structure of **1** prepared here is that reported earlier for [Co(imid)$_2$]$_x$ (17).

Although the exact structure of compounds **2**–**4** remain unknown, the polymeric nature of the materials is indicated by their physical properties, which to some extent resemble those determined here for compound **1**. The four cobalt(II) compounds are stable both in air and in contact with moisture. They are insoluble in water and common organic solvents, nonvolatile, and thermally robust. They dissolve with decomposition in concentrated mineral acids. Thermal gravimetric analyses show no mass loss due to thermal decomposition or sublimation below 200°C and at higher temperatures the compounds present similar thermal decomposition behavior with no significant weight loss till temperatures above 400°C are reached (Fig. 1). Compound **4** is the most thermally robust of the four compounds in that there is no indication of thermal decomposition below 600°C.

The electronic spectra we obtained on mulls of compounds **1**–**4** are very similar and are consistent with the spectra previously reported for these materials (18*c*, 19, 20). We observed two broad *d*–*d* transition bands, the first one centered (determined visually) around 1110–1130 (broad and structured), and the second one between 570–590 nm, the latter with a shoulder at about 520–540 nm. These can be tentatively assigned to the $^4A_2 \rightarrow {}^4T_1(F)$ and $^4A_2 \rightarrow {}^4T_1(P)$ transitions, respectively, of (distorted) tetrahedral cobalt(II) (6*b*). Very weak and broad bands, likely due to the $^4A_2 \rightarrow {}^4T_2$ transition, were also detected in the 1500–2200 nm region for **1**, **3**, and **4**. Hence, in agreement with the earlier studies, we conclude that these compounds have structures incorporating tetrahedrally coordinated cobalt(II) centers. That there are no neutral imidazole ligands incorporated in the structures is shown by the microanalytical data as well as the absence of a $\nu_{N\text{-}H}$ stretching vibration (24) in both the electronic spectra as well as the IR spectra of these complexes (see the discussion below concerning the observation of this band in compound **5**).

In summary, concerning structures, the similarities in stoichiometry and physical and spectroscopic properties of

the binary 1,3-diazolates **1**–**4** strongly support the conclusion that, as known definitively for **1**, compounds **2**–**4** also have extended structures with tetrahedrally coordinated metal centers. Moreover, since steric constraints make double-bridging 1,3-diazolates unlikely (11), single azolate bridges and 2-D or 3-D extended structures are more probable structures for these materials than 1-D chains or rings.

The molecule-based magnet ($[Fe_3(imid)_6(imidH)_2]_x$) was prepared earlier in macroscopic crystalline form by the reaction of ferrocene with excess molten imidazole (11). Here, we report that the same reaction employing cobaltocene yields the analogous cobalt compound, $[Co_3(imid)_6(imidH)_2]_x$ (**5**), as a microcrystalline powder. The X-ray powder diffractogram of **5** coincides well with that calculated for $[Fe_3(imid)_6(imidH)_2]_x$ from single crystal X-ray diffraction data (11). Indexing the X-ray powder diffractogram of **5** (23) yields calculated lattice parameters of a = 10.568, b = 12.964, and c = 10.634 Å. These are very similar to those of $[Fe_3(imid)_6(imidH)_2]_x$ (a = 10.591, b = 12.958, c = 10.617 Å) (11). Additional evidence supporting the conclusion that the iron and cobalt compounds are isostructural in addition to being isomorphous comes from spectroscopic studies on **5**. The X-ray determined structure of the iron compound shows the presence of both tetrahedral and octahedral metal centers, the additional coordination sites on the latter being filled by neutral imidazole molecules. The electronic spectrum of compound **5** shows the absorption bands assignable to the $^4A_2 \rightarrow {}^4T_1(F)$ and $^4A_2 \rightarrow {}^4T_1(P)$ transitions of tetrahedrally coordinated Co ions (see previous discussion). Transitions assignable to octahedral cobalt(II) centers are not observable; however, this is not too surprising in view of the fact they would be expected to be an order of magnitude or more weaker than the bands arising from the tetrahedral centers (25). Evidence for the octahedral cobalt centers in **5** comes from the observation of a sharp peak at 2950 nm in the electronic spectrum corresponding to the $\nu_{N\text{-}H}$ stretching vibration of neutral imidazole ligands bound at the octahedral site (11). Finally, we note that the infrared spectrum of **5** and the iron analogue are virtually identical, exhibiting the same vibrational bands at almost the same frequencies. We conclude that **5** has the same structure as the iron analogue (11, 12). In this structure, tetrahedrally coordinated metal ions are connected in chains by singly bridging imidazolate ions. The chains are cross-linked by octahedrally coordinated metal ions. Each tetrahedral center is linked to two others in the same chain and via octahedral centers to two additional chains. Each chain is linked to four different chains via the octahedral centers. A stereoview of a portion of this structure is given as Fig. 3 in ref. 11.

Compound **5** is nonvolatile and does not melt up to the temperature at which its thermal decomposition begins (208°C). Thermal gravimetric analysis of the compound shows that it decomposes in several steps (Fig. 1). Approximately 15% of the initial weight is lost between 208 and 255°C. The next 4% is lost between 255 and 320°C. This total weight loss of 19% corresponds to that expected for the loss of the neutral imidazole ligands. The remaining material has the same composition as compound **1** ($Co(imid)_2$). This is shown by the thermogravimetric data and by the experiment described in the experimental section in which a sample was retrieved from the TA instrument, after heating for 30 min at 325°C, and subjected to elemental analysis. The rest of the thermolysis curve of **5** above 320°C closely parallels that of the authentic sample of **1**.

Magnetic properties

Magnetic susceptibility (χ) and magnetic moment (μ_{eff}) vs. T data over the temperature range 2–150 K in an applied field of 10 000 G are shown in Figs. 2 and 3. Each of the five compounds exhibits a maximum in its χ vs. T plot and a magnetic moment which decreases with decreasing temperature, suggesting the presence of antiferromagnetic exchange. The χ plots for **1**, **4**, and **5**, however, are distinguished from those of **2** and **3** by the presence of a relatively sharp increase in χ as the maximum is reached on cooling. In addition, whereas the magnetic moment plots for **2** and **3** decrease smoothly on decreasing the temperature, the plots for **1**, **4**, and **5** give clear evidence for magnetic anomalies below 20 K. These observations suggested the presence of short-range antiferromagnetic coupling in **2** and **3** and more complex behavior involving the possibility of low-temperature long-range ferromagnetic ordering in **1**, **4**, and **5**. Since saturation effects caused by large applied fields can mask such behavior (14), we examined the magnetic properties of all five compounds at the lower applied field of 500 G. Magnetic susceptibility and moment data at 500 G over the low-temperature region (2–50 K) are shown in Figs. 4 and 5, respectively. While the magnetic properties of **2** and **3** are virtually unchanged at this lower applied field, as expected where only short-range antiferromagnetic interactions are involved, the susceptibility and moment data of **1**, **4**, and **5** are dramatically altered at the lower field below the temperature of the anomaly. Below a critical temperature (T_c = 16, 13, and 15 K for **1**, **4**, and **5**, respectively), the value of the moment increases abruptly to a maximum value (μ_{eff} = 9.4 μ_B at 13 K for **1**, 5.6 μ_B at 10 K for **4,** and 6.0 μ_B at 13 K for **5**) before decreasing again as the temperature decreases to 2 K (Fig. 5). The magnetic transition at T_c is

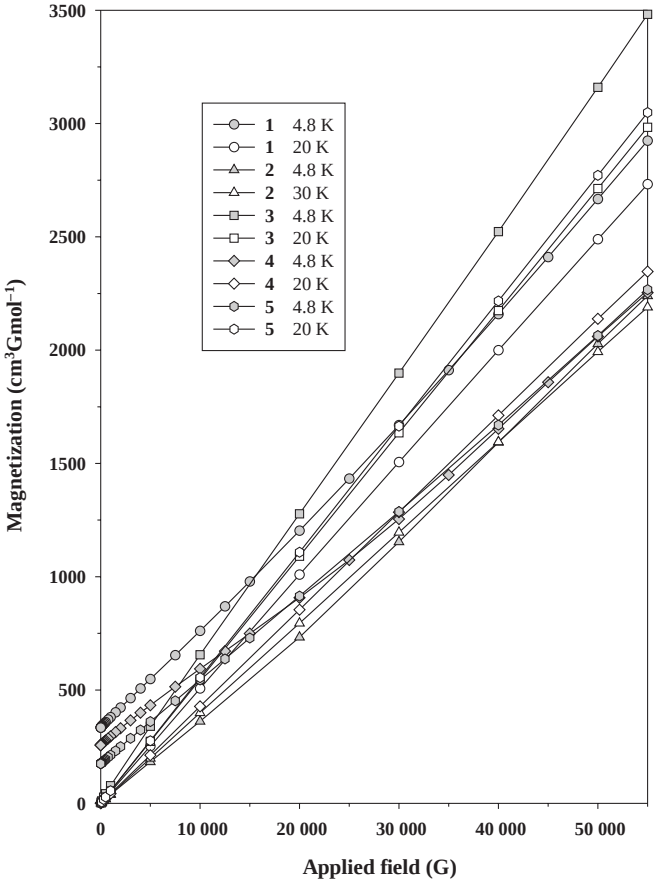

Fig. 7. Field cycled magnetization plots at 4.8 K for **1**, **4**, and **5**.

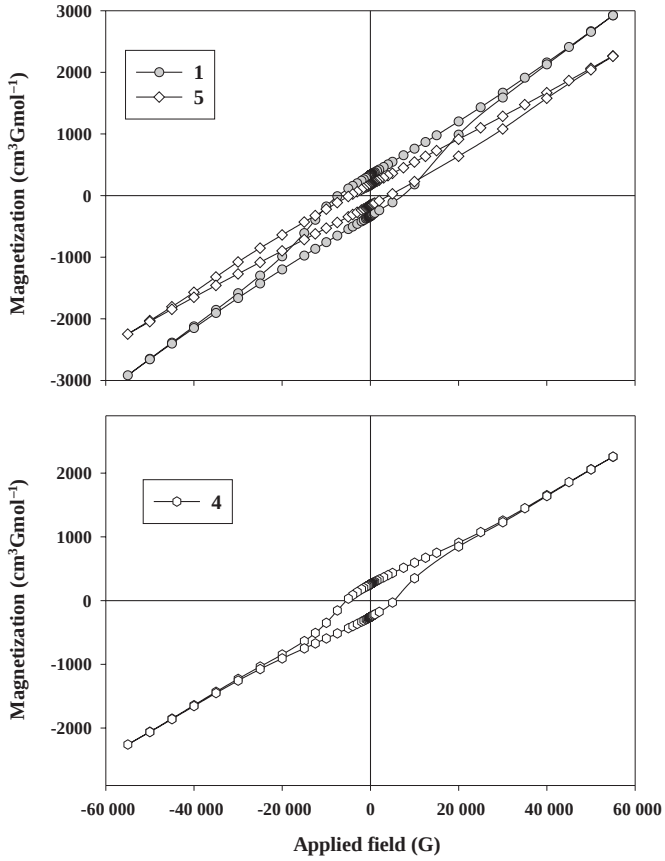

also seen clearly in the χ vs. T plots (Fig. 4) where the abrupt increase in χ below T_c is clearly seen for **1**, **4**, and **5**.

The presence of weak ferromagnetism in **1**, **4**, and **5** is also evident in plots of magnetization vs. applied field (Fig. 6). For these compounds, the plots are linear above T_c and extrapolate to zero magnetization at zero applied field, while below T_c they show extrapolated net magnetization at zero field. That compounds **1**, **4**, and **5** are exhibiting long-range ferromagnetic order and spontaneous magnetization below T_c is further illustrated by hysteresis studies. In these studies, the magnetization was measured at 4.8 K as the applied field was cycled between +55 000 G and –55 000 G. The resulting hysteresis curves are shown in Fig. 7. These plots give remnant magnetizations of 334, 257, and 175 cm^3 G mol^{-1} and coercive fields of 6620, 5280, and 4140 G for **1**, **4**, and **5**, respectively.

The magnetic properties of **1**, **4**, and **5** classify them as molecule-based magnets. In all three compounds, the primary exchange mechanism involves antiferromagnetic coupling between paramagnetic centers and this is combined with a magnetic phase transition to a ferromagnetically ordered state at low temperatures. This behavior is similar to that reported for $[Fe_3(imid)_6(imidH)_2]_x$ (11), $[Fe(2\text{-meimid})_2 \cdot 0.13(FeCp_2)]_x$ (13), and $[Fe(4\text{-abimid})_2]_x$ (14) where, as described in the introduction, it is likely a consequence of spin canting resulting from the noncentrosymmetric M-L-M exchange pathway provided by the single bridging 1,3-diazolate ligands. A spin-canted structure for compounds **1**, **4**, and **5** is supported by the fact that the highest magnetizations measured for these materials were 2924, 2253, and 2267 cm^3 G mol^{-1}, respectively, at 4.8 K and 55 000 G. These values are considerably lower than the theoretical saturation magnetization value of 16 766 cm^3 G mol^{-1} for an $S = 3/2$ system (26).

In contrast to what is observed for **1**, **4**, and **5**, we obtained no evidence for low-temperature ferromagnetic ordering in **2** or **3**. Plots of magnetization vs. applied field extrapolate to zero at zero applied field (Fig. 6) and, moreover, magnetization studies at 4.8 K in which the applied field is cycled between +55 000 and –55 000 G, reveal no evidence of significant hysteresis behavior. Plots of μ_{eff} vs. T decrease smoothly with decreasing temperature (Fig. 3) and χ vs. T plots show only broad maxima at approximately 21 K for **2** and 4 K for **3** (Fig. 2). Paramagnetic impurity in **2** might be the cause of the small increase in magnetic susceptibility at the lowest temperatures studied in the case of this compound (Fig. 2). Unfortunately, we are unable to quantify the magnitude of the antiferromagnetic coupling in **2** and **3** due to the lack of a suitable model for $S = 3/2$ extended 2-D or 3-D lattice systems.

Extensive magnetic data have now been collected on five binary imidazolates of cobalt(II). These are $Co(4\text{-abimid})_2$ (14), and four compounds studied here: $Co(imid)_2$ (**1**), $Co(2\text{-meimid})_2$ (**2**), $Co(4\text{-meimid})_2$ (**3**), and $Co(benzimid)_2$ (**4**). The 4-azabenzimidazolate compound ($Co(4\text{-abimid})_2$) and **1** have similar structures involving single bridging 1,3-

[b]From hysteresis studies at 4.8 K.

diazolate ligands and extended 3-D connectivities and both exhibit weak ferromagnetism at low temperatures. Although the critical temperatures (T_c) are similar for these two compounds, both the coersive fields and remnant magnetizations differ significantly (Table 1). There is no obvious explanation why $Co(4\text{-abimid})_2$ is such a weak (small remnant magnetization) and soft (small coersive field) magnet compared to **1**, although as suggested previously (14), single-ion effects such as zero-field splitting, which could differ significantly between the two compounds, could be a cause. Interestingly, although evidence suggests the structures of the other three binary imidazolates studied here also involve extended structures, only **4** exhibits low-temperature ferromagnetism with a strength and hardness comparable to that of **1** (Table 1), while **2** and **3** give no evidence for ferromagnetic ordering at low temperatures. It is tempting to suggest that **4** has an extended 3-D molecular network like that of **1** while **2** and **3** have structures of lower dimensionality, perhaps 2-D, in which there is less efficient propagation of the 3-D magnetic ordering. X-ray determined structures of **2**, **3**, and **4,** which would clearly help here, remain an elusive goal of this work.

In summary, regarding binary 1,3-diazolates of cobalt(II), this work shows such materials have extended structures with single bridging diazolate ligands. As in related iron(II) compounds, this bridging arrangement can be expected to lead to canted spin antiferromagnetism; however, whether this translates to long-range ferromagnetic order at low temperatures as seen in $Co(4\text{-abimid})_2$ (**1**) and **4** or only short-range antiferromagnetism as in **2** and **3**, depends on factors not yet fully understood.

With the completion, here, of structural and magnetic studies on compound **5** we now have three pairs of magnetically characterized isostructural iron(II) and cobalt(II) molecule-based magnets: $M(4\text{-abimid})_2$, $M_3(imid)_6(imidH)_2$, and $M_2(imid)_4(bipy)$. Comparison of the magnetic parameters (Table 1) of each of these pairs permits an evaluation of the effect of changing the spin state (S = 3/2 for Co(II) and S = 2 for Fe(II)) on the magnet properties. In general, the coersive fields are larger for cobalt over iron; however, the magnitude of the difference varies significantly from pair to pair and clearly one cannot conclude from this that cobalt analogues will always be harder magnets. Regarding remnant magnetizations, these are significantly smaller for cobalt in the case of the $M(4\text{-abimid})_2$ and $M_3(imid)_6(imidH)_2$ pairs and significantly larger for cobalt in the case of the $M_2(imid)_4(bipy)$ pair. Since, as discussed below, the mechanism by which residual spin arises in the case of the $M_2(imid)_4(bipy)$ pair is likely different from that involved with the other two pairs, this suggests such mechanisms have a significant influence on the magnitude of the remnant magnetization in these systems. It was suggested in the earlier work (11) that the primary exchange pathway in $Fe_3(imid)_6(imidH)_2$ occurs via the chains of tetrahedral metal centers and that spin-canted antiferromagnetism produces the residual spin. The same mechanism is possible for the cobalt analogue **5** studied here. Moreover, spin-canted antiferromagnetism has also been proposed as the only likely source of residual spin for the $M(4\text{-abimid})_2$ pair (14). In contrast, as described previously, in addition to spin-canted antiferromagnetism, a form of ferrimagnetism is likely to contribute significantly to the residual spin in the $M_2(imid)_4(bipy)$ complexes (10). This is a consequence of the fact that the structures of these systems involve alternating octahedral and tetrahedral metal centers. As a consequence of the difference in magnitudes of the moments associated with the different chromophores, antiferromagnetic coupling between neighbors gives rise to a net moment on the lattice. It will be interesting to study more examples of isostructural cobalt and iron pairs to further test these ideas.

The syntheses and NMR studies of hexadeca- and octaneopentoxyphthalocyanines

Namrta Bhardwaj, John Andraos, and Clifford C. Leznoff

Abstract: The syntheses of 3,6-dineopentoxyphthalonitrile and 3,4,5,6-tetraneopentoxyphthalonitrile are described. Condensation of these phthalonitriles with nickel chloride in *N*,*N*-dimethylaminoethanol yielded 1,4,8,11,15,18,22,25-octaneopentoxyphthalocyaninato nickel(II) (**3**) and 1,2,3,4,8,9,10,11,15,16,17,18,22,23,24,25-hexadecaneopentoxyphthalocyaninato nickel(II) (**7**). The ^{1}H NMR spectra of these phthalocyanines and the related 2,3,9,10,16,17,23,24-octaneopentoxyphthalocyaninato nickel(II) (**8**) at temperatures from 205 to 330 K in toluene-d_8 exhibited various degrees of restriction of rotation of the neopentoxy groups. Compound **7** exhibited a single atropisomer at 235 K.

Key words: neopentoxy substituted phthalocyanines, variable temperature NMR, restricted rotation.

Résumé : On décrit les synthèses des 3,6-dinéopentoxy- et 3,4,5,6-tétranéopentoxyphtalonitriles. La condensation de ces phtalonitriles avec du chlorure de nickel dans du *N*,*N*-diméthylaminoéthanol conduit à la formation des 1,4,8,11,15,18,22,25-octanéopentoxyphtalocyaninato nickel(II) (**3**) et 1,2,3,4,8,9,10,11,15,16,17,18,22,23,24,25-hexadécanéopentoxyphtalocyaninato nickel(II) (**7**). Les spectres RMN du ^{1}H de ces phtalocyanines et du 2,3,9,10,16,17,23,24-octanéopentoxyphtalocyaninato nickel(II) (**8**), à des températures de 205 à 330 K, dans le toluène-d_8, mettent en évidence des degrés de restriction à la rotation divers pour les groupes néopentoxy. Le composé **7** se présente sous la forme d'un seul atropisomère, à 235 K.

Mots clés : phtalocyanines substituées par des groupes néopentoxy, RMN à température variable, rotation restreinte.

[Traduit par la Rédaction]

Introduction

Phthalocyanines have attracted a great deal of interest due to their unique properties that include extremely high thermal stability and chemical resistivity (1, 2). Traditionally, phthalocyanines have been used as dyes (1, 2) but recently they have found wide applications (3) in fields including liquid crystals (4, 5), chemical sensors (3, 6, 7), photodynamic therapy of cancer (3, 8), and nonlinear optics (9–11). Applications of peripherally unsubstituted phthalocyanines are limited due their insolubility in common organic solvents and water (10, 11). Phthalocyanines possess an extended π-conjugated electron system which permits π stacking (aggregation) between planar macrocycles, provided the distance between the macrocycles is small (10). Adding substituents to the periphery of the macrocycles increases their solubility since these substituents increase the distance between the stacked phthalocyanines and enable their solvation (10, 12). For many years the neopentoxy group has been used as a bulky substituent to enhance solubility (13–15).

Both 3-neopentoxy- (16) and 4-neopentoxy phthalonitriles (13) were available, but these mononeopentoxy phthalonitriles gave phthalocyanines as mixtures of regioisomers (13, 16). Unfortunately, for many applications, it is preferable to have both soluble and symmetric phthalocyanines. With this idea in mind, we set out to synthesize symmetrical polyneopentoxyphthaloniriles, for condensation to very soluble symmetrical multineopentoxy-substituted phthalocyanines. In the course of this work we noticed considerable restricted rotations of the neopentoxy substitutuents on the phthalocyanines as shown by NMR spectroscopy in temperature coalescence experiments.

Results and discussions

Synthesis

Treatment of 2,3-dicyano-1,4-hydroquinone (**1**) with sodium methoxide in methanol at room temperature provided the disodium salt of **1**. This salt reacted with neopentyl tosylate in hexamethylphosphoramide (HMPA) at 110°C for 4 days to give 3,6-dineopentoxyphthalonitrile (**2**) in 62% yield. Condensation (17) of **2** with $NiCl_2$ in 2-*N*,*N*-dimethylaminoethanol (DMAE) at reflux (134°C) gave the symmetrical 1,4,8,11,15,18,22,25-octaneopentoxyphthalocyaninato nickel(II) (**3**) in 22% yield (Scheme 1).

Using a different strategy (11) for the preparation of substituted phthalonitriles, commercially available 3,4,5,6-tetrafluorophthalonitrile (**4**) reacted with excess neopentyl alcohol in *N*,*N*-dimethylformamide (DMF) at 100°C in the presence of potassium carbonate to give 3,4,5,6-tetraneopentoxyphthalonitrile (**5**) in 65% yield. We recently described the preparation of the only other symmetrical neopentoxy-substituted phthalonitrile, namely, 4,5-dineopentoxyphthalonitrile (**6**) (18). Condensation of **5** and **6** as

3 R = $OCH_2C(CH_3)_3$

above gave, respectively, the new 1,2,3,4,8,9,10,11,15,16,-17,18,22,23,24,25-hexadecaneopentoxyphthalocyaninato nickel(II) (**7**) in 15% yield and the previously reported (18) 2,3,9,10,16,17,23,24-octaneopentoxyphthalocyaninato nickel(II) (**8**) (Scheme 2). Phthalocyanines **3**, **7**, and **8** were highly soluble in cyclohexane, benzene, toluene, tetrahydrofuran, and chloroform. The FAB and Maldi mass spectra of **3**, **7**, and **8** (18) all gave parent ion clusters. Comparison of the UV–vis spectra of **3**, **7**, and **8** (18) show the expected red-shifts in **3** and **7** due to the alkoxy substituents at the 1,4-positions. Thus, the λ_{max} of the Q (0.0) band of **3** at 748 nm, **7** at 758 nm, and **8** at 672 nm is consistent with other studies, except that the λ_{max} of **7** at 758 nm is over 13 nm red-shifted compared to another less-hindered, branched hexadecahexyloxy- and hexadeca(2-ethyl)hexyloxy-substituted phthalocyaninato nickel (11). Highly hindered substituents at the 1,4 positions of **3** and even more so of **7** obviously enhances the red-shift of the Q band with the phthalocyanine (Pc) nickel **7** representing one of the most red-shifted alkoxy-substituted Pc nickel known. Although

metal-free **8** had been made (18), some attempts to make metal-free **3** and **7** were unsuccessful.

NMR studies

Examination of the NMR spectra of the two octaneopentoxyphthalocyanines **3** and **8** at room temperature in benzene-d_6 exhibited the expected three singlets for each compound: 7.40, 4.39, and 1.17 ppm for **3** representing the aromatic, alkoxy, and *tert*-butyl protons, and similarly, absorptions at 8.93, 3.88, and 1.26 ppm for **8**. In the NMR spectrum at room temperature (293 K) of the hexadecaneopentoxyphthalocyanine **7**, however, no aromatic protons were present and one would expect two different alkoxy and

© 2002 NRC Canada

tert-butyl absorptions representing the two different positions of the neopentoxy groups. In fact, two different peaks at 1.39 (9 H) and 1.22 ppm (9 H) for the two kinds of methyl signals were apparent but only a single peak at 4.55 ppm (2 H) corresponding to one kind of OCH_2 group could be accounted for. Though one alkoxy group was missing, a faint bulge in the baseline at ~4 to 5 ppm suggested that restricted rotation of the neopentoxy groups was the likely reason for its absence. Thus, **3**, **7**, and **8** were all subjected to temperature-dependent NMR studies to examine this phenomenon, well-known in other related systems including porphyrins (19), neopentylbenzenes (20–22), neopentylnaphthalenes (23), but to the best of our knowledge not phthalocyanines. Table 1 summarizes the relevant thermokinetic parameters obtained from standard lineshape analyses (24–26) for the three phthalocyanines reported in this work.

Pc7

Figure 1 shows the spectral changes observed in the OCH_2 region from 235 to 355 K in toluene-d_8 solvent (27). The spectrum of **7** at room temperature (293 K) exhibited two different *tert*-butyl signals at 1.37 and 1.22 ppm as expected, but only a single OCH_2 peak at 4.57 ppm. Increasing the temperature of the sample during the NMR experiment resulted in the appearance of a new singlet at 4.82 ppm which was still not as sharp as the other OCH_2 peak, now at 4.49 ppm, even at 355 K. In attempts to freeze out rotations of **7**, NMR spectra were recorded at lower temperatures. At 235 K, one OCH_2 signal showed a typical AB splitting pattern giving a unique chemical shift centered at 4.61 ppm, presumably for the 2,3,9,10,16,17,23,24-neopentoxy-OCH_2 group of **7**. The 1,4,8,11,15,18,22,25-neopentoxy-OCH_2 groups showed what at first may be regarded as two widely separated doublets at 6.05 and 3.88 ppm, respectively. Actually, this is a second AB quartet centered at 5.03 ppm. Lineshape analyses of both OCH_2 signals according to a two-site equal population coupled exchange model (24–26) corresponding to two pairs of diastereotopic protons confirms the steric demands imposed by the neopentoxy groups. Nearly identical results were obtained for each OCH_2 group: an enthalpy of activation of about 10 kcal mol^{-1} and a negative valued entropy of activation of about –10 cal K^{-1} mol^{-1} that contribute to a free energy of activation of about 13 kcal mol^{-1} at 298 K. These findings give support for correlated motions in the neopentoxy groups and suggest that all of them are relatively fixed on the NMR time scale at 235 K and **7** occurs as a single atropisomer at 235 K probably with the 16 neopentoxy groups in an alternating configuration as shown in Fig. 2. Another hexadeca substituted Pc was shown to exhibit a non-planar saddle shape in the solid state (28).

Pc3

Figure 3 shows the spectral changes observed in the OCH_2 region from 225 to 300 K in toluene-d_8 solvent. Superimposed on these spectral changes in this region is a curious phenomenon involving the sudden appearance of an anomalous peak at 5.77 ppm at 265 K which becomes prominent at 255 K and disappears by 235 K. We believe this to be water as the total integration of all water peaks remains constant and a temperature-dependent NMR study of the blank pure toluene-d_8 solvent also produced this peak over the same temperature range. A temperature-dependence study of the HOD peak in toluene-d_8 and other solvents has appeared but no mention was made of the sudden appearance of a new HOD absorption in a narrow temperature range (27). A sharp singlet for the OCH_2 peak at 4.38 ppm at a temperature of 310 K remained sharp until 225 K when significant broadening occurred. By 205 K the singlet split into two separate peaks, but at this temperature the two protons still did not split each other as would be expected for diastereotopic protons. The series of spectra in this region were subjected to lineshape analyses according to an equal population uncoupled two-site exchange model (24–26). The resulting thermokinetic parameters were as follows: $\Delta H^{\ddagger}$ = 15.6 ± 0.7 kcal mol^{-1}, $\Delta S^{\ddagger}$ = 25.6 ± 3.5 cal K^{-1} mol^{-1}, and $\Delta G^{\ddagger}_{298}$ = 8.0 ± 0.3 kcal mol^{-1}. By contrast no formal coalescence behaviour was observed in the aromatic and *tert*-butyl regions of the spectrum over the same temperature range. The aromatic peak shifts slightly from 7.37 to 7.17 ppm while the *tert*-butyl protons shift negligibly from 1.21 to 1.23 ppm. However, concomitant with the splitting of the OCH_2 signal as the temperature was lowered, line broadening was also observed in the *tert*-butyl signal suggesting that coalescence phenomena may be observable in this region at much lower temperatures than examined here.

Results for this phthalocyanine indicate that different molecular motions are occurring for **3** than for the sterically congested **7**. The estimated free energy barrier in **3** is about 5 kcal mol^{-1} lower than for **7** (see Table 1). The large enthalpy of activation is offset by a large positive entropy of activation and is consistent with higher degrees of freedom for motion of the neopentoxy groups in **3** than in **7**. In **7** it is unlikely that rotation about the C(Ar)—O or O—CH_2 bonds is facilitated since this will cause the *tert*-butyl groups to interfere with one another. It is known from previous dynamic NMR studies of neopentylaromatics that energy barriers for rotation about C(Ar)—CH_2 bonds are generally at least 5 kcal mol^{-1} higher than about CH_2—$C(CH_3)_3$ bonds (20–23). As noted above it is expected that the hydrogens of the OCH_2 should be diastereotopic as in each of the corresponding groups in **7**. However, resolution was not possible since an estimate of T_2^{-1} for both peaks in **3** at 225 K was nine times larger than the expected value of the coupling constant (J) of 10 Hz as observed in **7**. Reevaluation of the lineshapes for the OCH_2 region including a coupling constant contribution of 10 Hz gave identical thermokinetic parameters.

Pc8

The ^{1}H NMR spectrum of **8** shows the most complicated pattern of the three phthalocyanines examined. Figs. 4*a*–*c* show the spectral changes in the aromatic, OCH_2, and *tert*-butyl regions from 225 to 300 K in toluene-d_8 solvent. At room temperature, three singlets at 8.95, 3.85, and 1.28 ppm for the aromatic, OCH_2, and *tert*-butyl groups, respectively, are observed. At 260 K significant broadening occurs in all peaks to the point where they almost disappear into the baseline. At 225 K two distinct aromatic peaks of unequal intensity are apparent at 9.31 and 8.62 ppm; similarly, two distinct *tert*-butyl peaks are observed at 1.39 and 1.25 ppm.

Fig. 1. ^{1}H NMR spectrum of **7** in toluene-d_8 showing spectral changes in the OCH_2 region from 235 to 355 K.

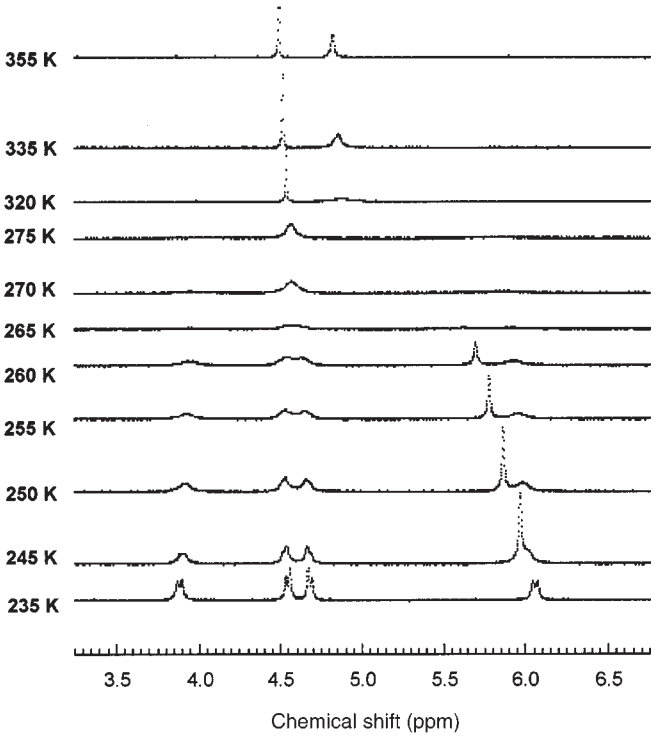

Fig. 2. The suggested atropisomer for **7**.

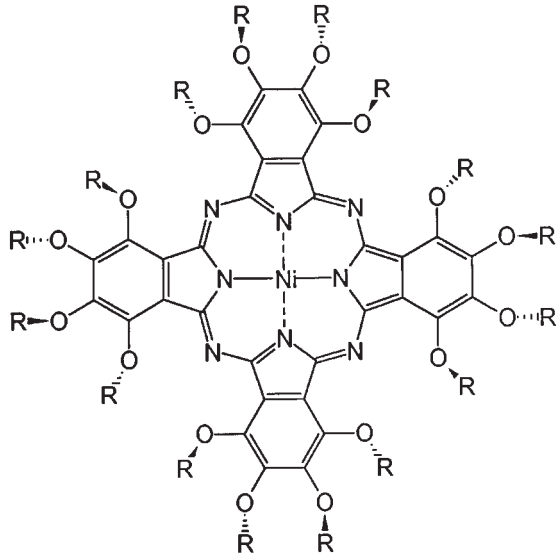
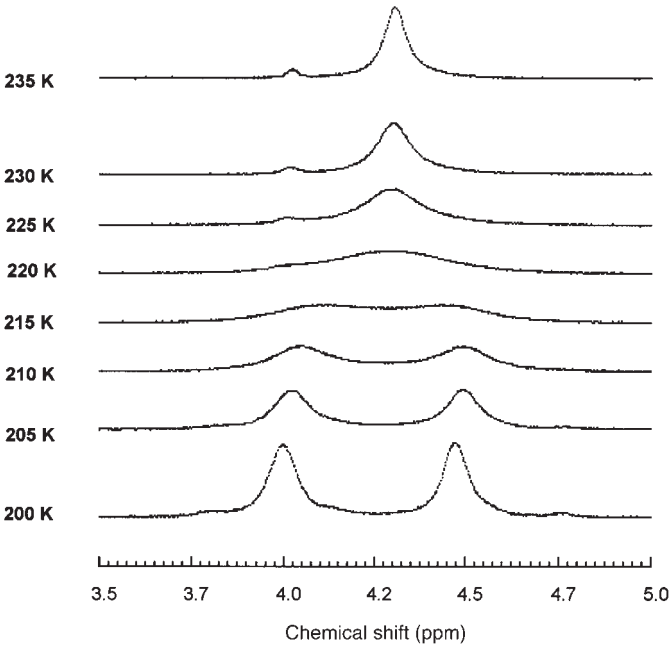


In the OCH_2 region, the singlet at 3.85 ppm becomes an asymmetric triplet as the temperature is lowered. Lineshape analyses according to an unequal population two-site exchange model (26) resulted in a population distribution of p_A = 0.56 and p_B = 0.44 and estimates of free energy barriers of about 12 kcal mol^{-1} for both aromatic and *tert*-butyl regions of the spectrum. These barriers are consistent with those found for **7** as would be expected for interaction between neopentoxy groups ortho to one another. Simulation of the asymmetric triplet for the OCH_2 region is more complex and involves the superposition of *two* unequal population two-site exchange lineshapes. Again, the same population distribution was found as for the aromatic and *tert*-butyl regions with an estimated free energy barrier of about 12 kcal mol^{-1} in each case. The implication of this simulation is that each atropisomer is composed of two different OCH_2 groups: at 230 K a minor conformer has clearly resolvable signals at 3.51 and 4.05 ppm while a major conformer has two very closely spaced signals centered at 3.73 ppm which are not resolvable due to pronounced line broadening. It is expected that the absence of neighbouring neopentoxy groups in the 1, 4, 8, 11, 15, 18, 22, and 25 positions would make these groups more mobile and thus lead to increased broadening of all signals and particularly to complex lineshapes in the OCH_2 region of the spectrum. This is clearly evident when the spectra for **8** are compared with those for **7**. Alternatively, the two distinct aromatic peaks could be due to monomer–dimer equilibria of aggregating phthalocyanines, which is more plausible for the less-hindered **8** than for **3** and **7**. This hypothesis, however, was

© 2002 NRC Canada

Fig. 3. ^{1}H NMR spectrum of **3** in toluene-d_8 showing spectral changes in the OCH_2 region from 200 to 235 K.



ruled out as ^{1}H NMR spectra of **8** run at 235 K at two different sample concentrations resulted in negligible effects on the absorption of the aromatic protons.

Experimental section

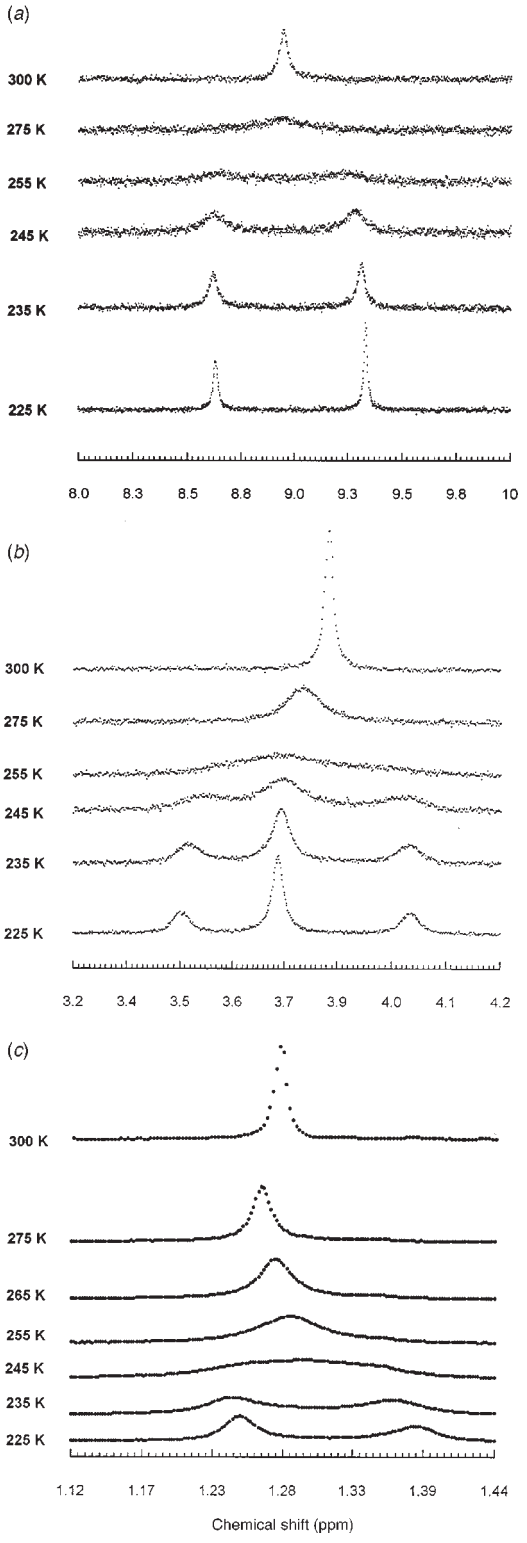
General methods

Inert atmosphere conditions were maintained using Matheson high purity argon. Magnetic stirring methods were utilized during reaction processes. Flash chromatography was performed using silica gel of particle size 40–63 μm. Melting points (mp) were determined using a Kofler hot stage or a Fisher Johns melting point apparatus and are uncorrected.

Nuclear magnetic resonance (NMR) spectroscopy for proton and carbon was performed using a Bruker ARX 400 high-field Fourier transform instrument at room temperature, unless noted otherwise. Chemical shifts are reported in parts per million (δ). The splitting patterns of proton resonances are described as singlets (s), doublets (d), or triplets (t). Coupling constants are reported in Hz for signals that are doublets. Proton-decoupled chemical shifts are reported for the ^{13}C NMR resonances.

Infrared (IR) spectra were recorded on a Unicam Matheson 3000 FT IR spectrometer using KBr discs for solid samples and NaCl discs for liquid samples. Ultraviolet–visible spectra (UV–vis) were recorded on a Hewlett-Packard HP8451A diode array spectrophotometer. Mass spectra (MS) were recorded at 70 eV on a Kratos Profile mass spectrometer in the EI mode for lower molecular weight molecules and in the FAB or MALDI mode for higher molecular weight molecules. Microanalyses were performed by Guelph Chemical Laboratory Ltd., Guelph, Ontario.

Fig. 4. ^{1}H NMR spectrum of **8** in toluene-d_8 showing spectral changes in (*a*) the aromatic region; (*b*) the OCH_2 region; (*c*) the *tert*-butyl region all from 225 to 300 K.



Lineshape analyses: data acquisition

All temperature studies were performed on a Bruker ARX 400 spectrometer using samples prepared in toluene-d_8 solvent. ^{1}H NMR spectra were first recorded at room tempera-

© 2002 NRC Canada

ture and then reacquired at lower or higher temperatures in increments of 5°. Temperatures were read directly from a thermocouple surrounding the probe and are estimated to be within 2 to 3° of the actual temperature of the samples. At each temperature the probe was allowed to equilibrate for about a minute before acquiring data. Test runs at longer equilibration periods (about 10 min) gave spectra identical to those recorded at the above conditions.

Lineshape analyses: data analysis

Digitized spectra were first converted into readable format using [Spec Viewer Free Version] (Advance Chemistry Development). Relevant regions of the spectra were then subjected to lineshape analyses according to expressions given by Sandström (24), Sutherland (25), and Gutowsky and Holm (26) using KaleidaGraph 3.5 (Synergy) software. To account for spectral drift at different temperatures, spectra obtained at higher temperatures were referenced against those recorded at the lowest temperature. Simulated spectra were consistent with two-site exchange systems of either equal or unequal populations. Corresponding estimates of thermokinetic parameters and coalescence temperatures were obtained using standard Eyring expressions given previously (24–26).

3,6-Dineopentoxyphthalonitrile (2)

To 0.151 g (6.56 mmol) of sodium metal dissolved in 5 mL of methanol was added 500 mg (3.13 mmol) of 2,3-dicyanohydroquinone (**1**). This mixture was stirred at room temperature for 2 h. After this time, the methanol was removed under vacuum and to the resulting residue was added 10 mL of HMPA (caution: carcinogen) and 2.27 g (9.38 mmol) of neopentyl tosylate. This mixture was stirred at 110°C for 4 days, cooled to room temperature, and poured into 50 mL of water. The product was extracted using 3 × 50 mL of ether. The combined organic layers were washed with 100 mL of water, followed by 100 mL of brine, and then dried over $MgSO_4$. The ether was removed under vacuum and the crude product was purified by flash silica gel column chromatography using 20% ethyl acetate and 80% hexane as the eluting solvents. The desired product was obtained as a white solid in 62% yield (0.58 g); mp 179–181°C. IR (KBr) (cm^{-1}): 2961, 2229. ^1H NMR ($CDCl_3$) δ: 7.14 (s, 2H), 3.69 (s, 4H), 1.10 (s, 18H). ^{13}C NMR ($CDCl_3$) δ: 155.6, 118.7, 113.0, 105.1, 80.0, 32.2, 26.4. MS *m*/*z* (rel intensity): 300 (M^+, 20), 71 (100). Anal. calcd. for $C_{18}H_{24}N_2O_2$: C 71.97, H 8.05, N 9.33; found: C 72.00, H 8.17, N 9.36.

1,4,8,11,15,18,22,25-Octaneopentoxyphthalocyaninato nickel (3)

A mixture containing 0.300 g (1 mmol) of 1,4-dineopentoxyphthalonitrile (**2**) and 0.0912 g (0.333 mmol) of $NiCl_2$ in 9.9 mL of DMAE was heated to reflux for 48 h. After cooling at room temperature, the reaction mixture was transferred to test tubes. Precipitation of the nickel phthalocyanine was carried out by adding a 90% methanol and 10% water solution. The precipitate was collected by centrifugation and washed twice with methanol. Further purification of the phthalocyanine was carried out by flash silica gel column chromatography using 50% hexane and 50% toluene as the eluting solvents. Final purification involved reprecipitation from toluene–ethanol to give the NiPc as a green solid in 22% yield (69 mg); mp > 300°C. UV–vis λ_{max} (toluene) (log e) (nm): 748 (5.18), 674 (4.58), 444 (4.30), 330 (4.61), 308 (4.66). ^1H NMR (benzene-d_6) δ: 7.40 (s, 1H), 4.39 (s, 2H), 1.17 (s, 9H). FAB-MS *m*/*z*: 1260 (M + 1). Anal. calcd. for $C_{72}H_{96}N_8O_8Ni$: C 68.62, H 7.68, N 8.89; found: C 68.63, H 8.00, N 8.48.

3,4,5,6-Tetraneopentoxyphthalonitrile (5)

To a stirred solution containing 0.50 g (2.5 mmol) of tetrafluorophthalonitrile (**4**) in 15 mL of DMF was added 5.5 g (62.5 mmol) of neopentyl alcohol and 8.6 g (62.5 mmol) of K_2CO_3. The mixture was allowed to stir at 100°C under an argon atmosphere for a period of 24 h. After cooling to room temperature, the reaction mixture was poured onto 50 mL of H_2O and extracted using 3 × 50 mL of ether. The combined organic layers were washed with 100 mL of H_2O followed by 100 mL of brine and then dried over $MgSO_4$. The solvent was removed under vacuum and the crude mixture was purified by flash silica gel column chromatography using toluene as the eluting solvent to give the product in 65% yield (0.76 g); mp 131–133°C. IR (KBr) (cm^{-1}): 2957, 2232. ^1H NMR ($CDCl_3$) δ: 3.81 (s, 2H), 1.10 (s, 4.5H), 1.05 (s, 4.5H). ^{13}C NMR ($CDCl_3$) δ: 153.0, 151.9, 113.3, 104.4, 85.6, 85.2, 32.8, 32.6, 26.7, 26.6. MS *m*/*z* (rel intensity): 472 (M^+, 5), 332 (45), 262 (100). Anal. calcd. for $C_{28}H_{44}N_2O_4$: C 71.15, H 9.38, N 5.93; found: C 71.15, H 9.36, N 6.02.

1,2,3,4,8,9,10,11,15,16,17,18,22,23,24,25-Hexadecaneopentoxyphthalocyaninato nickel (7)

A mixture containing 0.2 g (0.42 mmol) of tetraneopentoxyphthalonitrile (**5**) and 33.5 mg (0.14 mmol) of $NiCl_2$ in 4.2 mL of DMAE was heated to reflux for 48 h. After cooling to room temperature, the reaction mixture was transferred to test tubes. Precipitation of the nickel phthalocyanine was achieved by the addition of water. The precipitate was collected by centrifugation and washed twice with water and once with methanol. The crude phthalocyanine was further purified by flash silica gel column chromatography using 75% hexane and 25% toluene as the eluting solvents. Final purification involved reprecipitation from toluene–ethanol to give the desired NiPc as a green solid in 15% yield (30 mg); mp > 300°C. UV–vis λ_{max} (toluene) (log e) (nm): 758 (5.19), 676 (4.51), 440 (4.25), 386 (4.44), 342 (4.46), 314 (4.69). ^1H NMR (benzene-d_6) δ: 4.55 (s, 2H), 1.39 (s, 9H), 1.22 (s, 9H). FAB-MS *m*/*z*: 1948 (M + 1). Anal. calcd. for $C_{112}H_{176}N_8O_{16}Ni$: C 69.01, H 9.10, N 5.75; found: C 69.02, H 9.29, N 5.51.

6.6 mL of DMAE was heated to reflux for 48 h. After cooling to room temperature, the reaction mixture was transferred to test tubes. Precipitation of the nickel phthalocyanine was carried out by adding a 90% methanol and 10% water solution. The precipitate was collected by centrifugation and washed twice with methanol. Further purification of the phthalocyanine was carried out by flash silica gel column chromatography using 20% hexane and 80% toluene as the eluting solvents. Final purification of the NiPc involved precipitation using toluene–hexane. The desired NiPc was obtained as a green solid in 28% yield (59 mg): mp > 300°C. UV–vis λ_{max} (toluene) (log e) (nm): 672 (5.17), 640 (4.52), 604 (4.46), 416 (4.37), 336 (4.59), 314 (4.73), 288 (4.78). ^{1}H NMR (benzene-d_6) &: 8.93 (s, 1H), 3.88 (s, 2H), 1.26 (s, 9H). FAB-MS *m*/*z*: 1260 (M + 1). Anal. calcd. for $C_{72}H_{96}N_8O_8Ni$: C 68.62, H 7.68, N 8.89; found: C 69.09, H 8.08, N 8.56.

Conclusion

Two different symmetrical octaneopentoxyphthalocyanines and a hexadecaneopentyoxyphthalocyanine were synthesized by three different routes. All of these neopentoxy-substituted phthalocyanines were highly soluble in organic solvents. The highly hindered hexadecaneopentoxyphthalocyanine (**7**) exhibited a highly red-shifted Q-band at 758 nm. Variable-temperature NMR spectroscopy on an octaneopentoxyphthalocyanine (**3**) and particularly, the hexadecanopentoxyphthalocyanine, demonstrated restricted motion of the neopentoxy groups.

The first observed complex of 11-crown-3 ether. X-ray crystal structure and NMR study of (benzo-11-crown-3)$_2$·LiNCS

G.W. Buchanan, M. Azad, and G.P.A. Yap

Abstract: The title complex crystallizes in the monoclinic $P2_1/c$ space group, with a = 7.7397(8), b = 18.287(2), c = 17.4726(19) Å, β = 94.008(2)°, and Z = 4. The coordination geometry around the lithium cation is pseudooctahedral. The effects of lithium complexation on the ^{1}H and ^{13}C solution NMR spectra are discussed. In the solid-state ^{13}C NMR spectrum at 300 K, very long aliphatic proton spin lattice relaxation times are observed along with broadening of the aliphatic carbon resonances. These results are attributed to the dipolar washout phenomenon, where the presence of a low amplitude motion of the same frequency as the ^{1}H decoupler, leads to less effective removal of the ^{1}H–^{13}C dipolar coupling. At 330 K, there is some sharpening of the aliphatic resonances since there is less interference between the motion and the decoupling frequency.

Key words: crown ether analog, lithium complex.

Résumé : Le complexe mentionné dans le titre cristallise dans le groupe d'espace $P2_1/c$ avec a = 7,7397(8), b = 18,287(2) et c = 17,4726(19) Å, β = 94,008(2)° et Z = 4. La géométrie de coordination autour du cation lithium est pseudooctaédrique. On discute des effets de la complexation avec le lithium sur les spectres RMN du ^{1}H et du ^{13}C. En RMN du ^{13}C à l'état solide à 300 K, on observe que les temps de relaxation spin réseau des protons aliphatiques sont très longs et que les résonances des carbones aliphatiques sont élargies. Ces résultats sont attribués au phénomène d'épuration dipolaire dans lequel la présence d'un mouvement de faible amplitude de fréquence égale à celle du découpleur ^{1}H conduit à une élimination moins efficace du couplage dipolaire ^{1}H–^{13}C. À 330 K, les résonances aliphatiques deviennent plus précises parce qu'il y a moins d'interférence entre le mouvement et la fréquence de découplage.

Mots clés : analogue d'éther couronne, complexe de lithium.

[Traduit par la Rédaction]

Introduction

Crown ethers are important and useful compounds, since they complex the salts of the alkali and alkaline earth metals, thereby profoundly altering their properties (1, 2). The Li^+ ion is of immense physiological importance, since lithium carbonate is an effective treatment for the symptoms of bipolar affected disorder (BAD). Although the cavity size of 14-crown-4 ether is ideal for Li^+ complexation, a number of smaller macrocyclic crown systems have also been found to form stable 1:1 complexes with this cation (3–7).

In these laboratories we have embarked on an extensive program to examine the structures and complexation features of novel crown ether anologs. To date, instances of unusual ligand geometries have been found for dibenzo-20-crown-6 ether (8) and bis(*p*-phenylene)-31-crown-9 (9) while a unique complexation mode has been elucidated for the 2:2 sodium iodide complex of dibenzo-15-crown-4 (10).

Recently, we found that Li^+ can be complexed by a 10-crown-3 ether via a 2:1 sandwich-type system (11) and the X-ray crystal structure of this (benzo-10-crown-3)$_2$·$LiClO_4$ complex indicates an interesting quasioctahedral geometry at lithium.

With respect to 11-crown-3 ethers, one would expect that the increased flexibility in the macrocycle might lead to different complexation features than are present in 10-crown-3. There is, however, no information in the literature, other than our recent determination of the X-ray crystal structure of tris(11-crown-3)triphenylene (12). Since benzo-11-crown-3 ether (**1**) is an oil, no X-ray crystallographic studies have been performed. In the present work, we present the results of an X-ray crystallographic study of (benzo-11-crown-3)$_2$·LiNCS (**2**). The complementarity of the X-ray crystallographic method with solid-state ^{13}C NMR spectroscopy is illustrated and the effects of Li^+ ion complexation on the solution ^{1}H and ^{13}C NMR properties are discussed.

Fig. 1. ORTEP for **2a.**

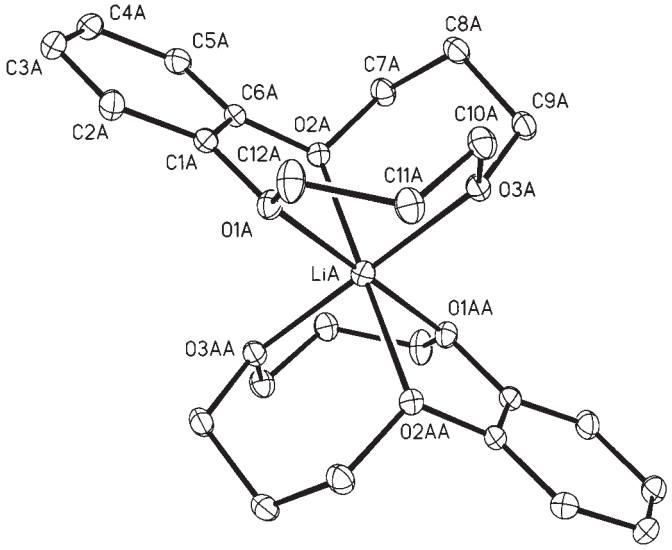

Fig. 2. ORTEP for **2b**.

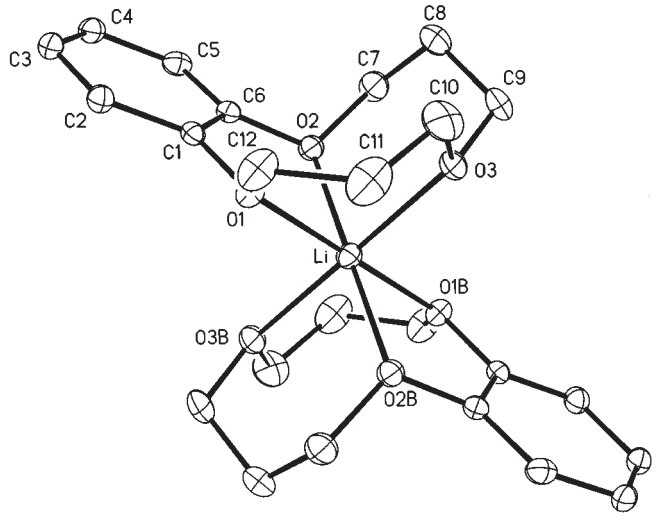

A comparison of the 11-membered ring conformation in the complex is made with that of the free benzo-11-crown-3 in the gas phase as determined via the HyperChem program.

Results and discussion

The ORTEP diagrams for the two crystallographically inequivalent complexes **2** are illustrated in Figs. 1 and 2. The ^{13}C CPMAS NMR spectra recorded at 300 and 330 K are in Fig. 3 and Fig. 4, respectively. Atomic bond lengths are in Table 1, with bond angles collected in Table 2. Torsion angle data are in Table 3 and crystallographic data are in Table 4. Table 5 contains the ^{13}C chemical shifts in solution and in the solid phase. Solution ^{1}H NMR data for **1** and **2** are presented in Table 6.

X-ray crystal structure

The average O-Li-O bond angle involving the six ethereal oxygens is 84.56° with a standard deviation from this mean of 3.97°. This geometry is thus close to the ideal geometry expected for octahedral coordination. The avg Li—O bond length (for the ethereal oxygens) of 2.07 Å is slightly (0.03 Å) shorter than that found in the (benzo-10-crown-3)$_2$·$LiClO_4$ complex (11).

Examination of the torsion angles for the two 11-membered rings of the complex (i.e., **2a** involving O1A, O2A, and O3A vs. **2b**, involving O1, O2, and O3) indicates that the geometries of the two rings are identical. However, the coordination geometry and bond distances from the lithium cation to the ethereal oxygens differs slightly, leading to the two "inequivalent" complexes **2a** and **2b** in the X-ray crystal structure. These differences are small, but larger than the experimental uncertainty and probably arise from crystal packing. For example the LiA—O1A, LiA—O2A, and LiA—O3A bond lengths are 2.059(2), 2.084(2), and 2.091(2) Å, respectively, while the Li—O1, Li—O2, and Li—O3 distances are 2.043(2), 2.039(2), and 2.132(2) Å, respectively.

The two complexes have nearly equivalent ^{13}C solid-state NMR spectra (Figs. 3 and 4), however, there is one additional resonance in the aromatic region of the spectrum between 121 and 127 ppm over that expected from two identical complexes at 300 K and two extra peaks at 330 K.

With respect to the geometry of the 11-membered rings, since 11-crown-3 ether is an oil, there is no X-ray crystal structure available. It is however, of interest to examine the preferred (calculated via HyperChem) gas-phase geometry of benzo-11-crown-3, **1** and compare it with the geometry in the LiNCS complex. These data are presented below. Arbitrarily data for **2b** are used.

Network	Torsion angle in **1** (°)[a]	Torsion angle in **2b** (°)
C1-O1-C12-C11	–148.7	–138.4

[a]For gas phase molecules, using the HyperChem program.

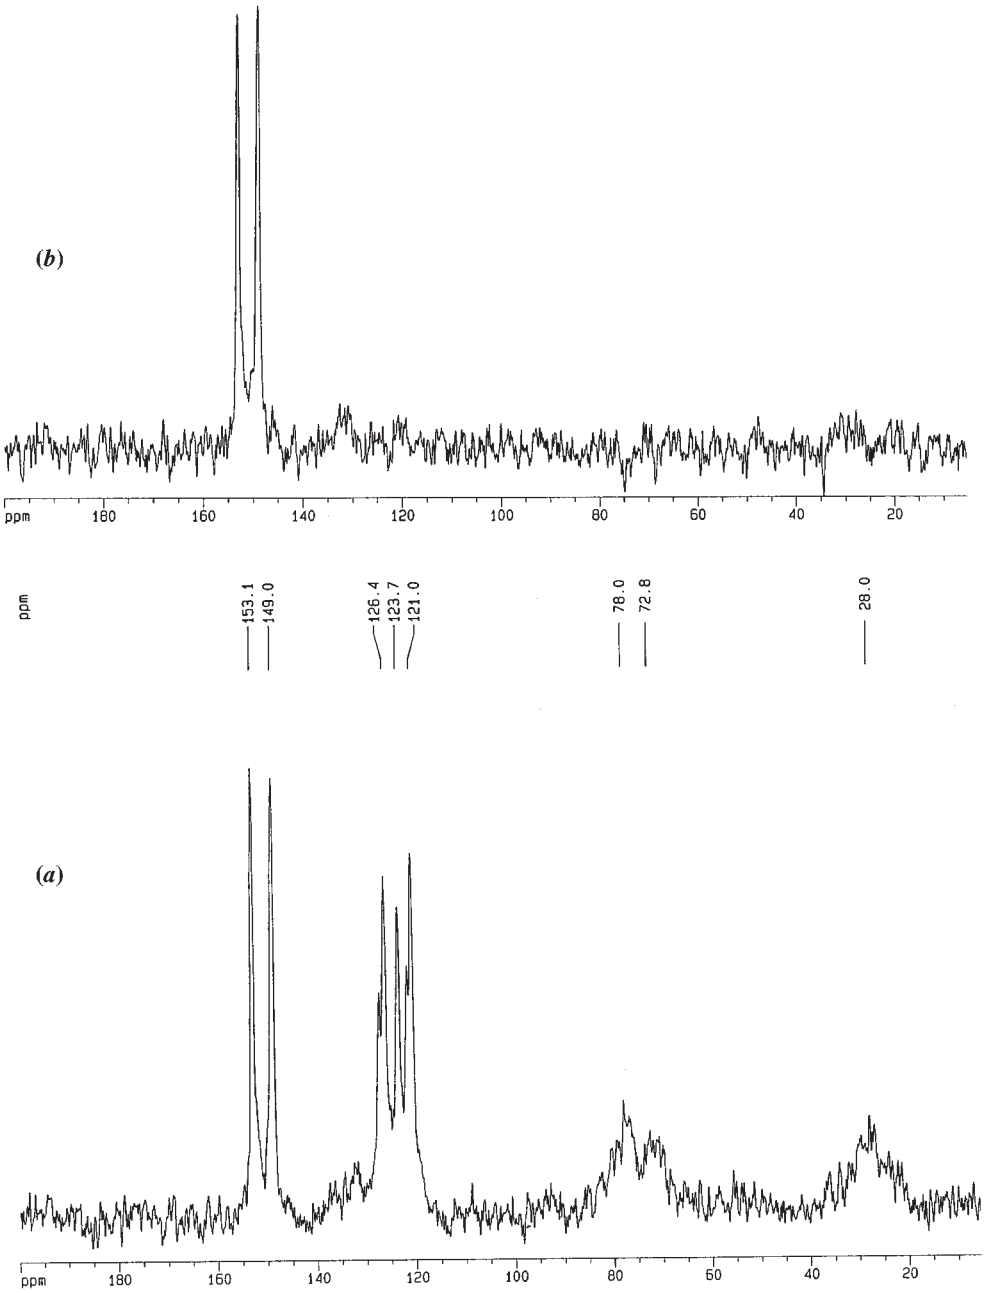
From examination of molecular models, it is clear that the conformational changes which occur upon complexation accompany the reorientation of the oxygen lone pairs on O1, O2, and O3 so that one pair of electrons on each oxygen becomes available for pseudooctahedral coordination to the lithium cation.

NMR studies

The signal assignments in the solution ^{1}H NMR spectrum were made using a combination of COSY and NOSY experiments. For example, for **1**, there is a NOESY correlation between the aromatic protons and the aliphatic peak at 4.119.

© 2002 NRC Canada

Fig. 3. (*a*) 50.3 MHz ^{13}C CP MAS NMR spectrum of **2** at 300 K. (*b*) Dipolar dephased 50.3 MHz ^{13}C CP MAS NMR spectrum of **2** at 300 K.



Hence, the later resonance is assigned to the C7,C12 protons since these are more spatially proximate to the aromatic ring. With these assignments in hand, the carbons directly bonded to protons were identified by the HMQC experiment. Similar methods were employed to assign the solution spectra of **2**.

With respect to the effects of Li cation complexation on the ^{1}H and ^{13}C NMR chemical shifts, there is a general trend of deshielding in both spectra. This is consistent with a loss of electron density around the ethereal oxygens due to complexation.

The solid-state ^{13}C CP MAS spectrum of **2** shows additional multiplicity over that obtained in solution in accord with expectations based on the X-ray crystal structure. As mentioned above, there are seven aromatic carbons observed in the spectrum at 300 K, vs. six expected if there were a single symmetrical complex present in the solid state. Distinction between the quaternary carbon resonances for C1 and C6 was made on the basis of the respective C—O bond lengths. Since the C1—O1 bond is shorter (1.372(3) Å) than the C6—O2 bond (1.381(3) Å), one can conclude that there is more double bond character in the C1—O1 bond, which would be expected to lead to a deshielding effect (13). Hence, the resonance at 153.1 ppm is tentatively assigned to C1, while the C2 resonance is deemed to be at 149.0 ppm.

The appearance of the aliphatic carbon resonances as broad lines at 300 K appears to be due to the "dipolar wash-

out" phenomenon first described about 20 years ago (14) and more recently observed in several 18-crown-6 complexes (15, 16). Apparently, the motion of the C-H vectors of the aliphatic carbons in the solid state is occuring on approximately the same timescale (200 MHz) as the ^1H decoupling rf field. Hence, interference is set up between the motionally generated rf field and the ^1H decoupler. This renders the decoupler less effective resulting in a dipolar-broadened ^{13}C spectrum. When the temperature is increased to 330 K (Fig. 4) the increased motional frequency leads to a situation in which there is less interference with the decoupling field and sharper resonances are observed. Coincident with this phenomenon is the observation of very long ^1H spin lattice relaxation times at these sites, with values of ca. 60 s at 300 K and 120 s at 330 K. These long T_1s dramatically increase the time required to obtain spectra for the attached carbons with reasonable signal-to-noise ratios.

In conclusion, we have found the first complex of 11-crown-3 to be a 2:1 complex of benzo-11-crown-3 with LiNCS. X-ray data show that the complex is rigid, but solid-

state ^{13}C NMR indicates C–H vector motion in the 11-membered rings with a frequency of ca. 200 MHz.

Experimental

Spectra

All solution NMR spectra were recorded using a Bruker AMX-400 spectrometer equipped with a 5 mm inverse probe and an Aspect X32 computer. An Aspect 3000 process controller was employed and all standard microprograms used are in the Bruker Software Library.

For the NOESY experiment, the mixing time used was selected to be consistent with the $1/T_1$ criterion (17) and in the present case it was set to 0.3 s. For the ^{1}H–^{13}C HMQC experiment, the free induction decays were acquired over 1024 data points for each of the 512 values of the evolution time, with a digital resolution of ca. 8 Hz/point in F1 and 4 Hz/point in F2. The raw data were zero filled in F1 prior to transformation using the qsine window function for both F1 and F2. The proton relaxation delays were set to 1 s. Delays were chosen to emphasize J values of 135–140 Hz.

The ^{1}H–^{1}H COSY experiments were run using *N*-type phase cycling with a 45° mixing pulse. The free induction decays were acquired over 1024 data points for each of the 256 values of the evolution time, with a digital resolution of 5 Hz/point. The raw data were zero filled in F1 prior to transformation using the qsine window function for both F1 and F2. The data were symmetrized about the diagonal.

The solid-phase ^{13}C CP MAS spectra were recorded at 50.3 MHz using a Bruker ASX-200 solid-state NMR spectrometer equipped with a Bruker 7 mm triple resonance MAS probe. The magic angle was set accurately (18) using the ^{79}Br resonance of KBr and maximizing the number of rotational echos in the FID. Magic angle spinning rates were ca. 4 kHz. ^{1}H 90° pulses were 3.5 to 3.8 μs with contact times of 2 ms. Chemical shifts were referenced to the ^{13}C

X-ray crystallographic measurement and structure solution

A summary of the crystallographic data is given in Table 4.[2] Diffraction intensities were collected on a Bruker AX SMART 1k CCD diffractometer using Mo Kα radiation at 203 K. 0.3° scans were used at 0, 90, and 180°.

Unit cell parameters were determined from 60 data frames collected at different sections of the Ewald sphere. Semiempirical absorption corrections based on equivalent reflections were applied (19). No crystal decay was noted during the data collection. Unit cell parameters and systematic absences are consistent with the $P2_1/c$ space group. The structure was solved by direct methods, completed with difference Fourier syntheses and refined with full-matrix least-squares procedures based on F^2. All non-hydrogen atoms were refined with anisotropic displacement parameters and hydrogen atoms were treated as idealized contributions. All scattering factors and anomalous dispersion factors are contained in the SHEXTL 5.1 program library.

Materials

The synthesis of **1** has been reported earlier (12). Preparation of **2** was accomplished via mixing **1** (0.400 g, 1.92 mmol) with $LiNCS·2H_2O$ (0.100 g, 0.99 mmol) in hot (340 K) ethyl acetate (10 mL). The solvent volume was then reduced by boiling to ca. 7 mL. After standing overnight, the solution yielded yellow opaque crystals which were collected by suction filtration. Subsequent recrystallization from 1:1 ethyl acetate:acetone yielded 0.72 g (89%) of X-ray grade crystals of **2**; mp 110–113°C.

Substitution reactions at the Ni(III) cation in macrobicyclic complexes — Reaction of metal ion complexes prepared from ligands L^1 (17-oxa-1,4,8,11-tetraazabicyclo[6.5.6]nonadecane) and L^2 (17-oxa-1,4,8,11-tetraazabicyclo[10.5.2]nonadecane) with chloride ion

Alison M. Ingham, Chao Xu, T.W. Whitcombe, Chengtian Xu, J.N. Bridson, and Alexander McAuley

Abstract: The potentially penta-coordinating ligand L^1 has been synthesized by reaction of the bridge bis-(2-(methylsulfonyl)oxyethyl)ether with the tetraazamacrocycle cyclam (cyclam = 1,4,8,11-tetraazatetradecane). The copper(II) complex was characterized initially and subsequent demetallation provided pure L^1. Electrochemical and chemical oxidation of the nickel(II) species yields a Ni(III) ion (low-spin d^7, rhombic, g_{xx} 2.195, g_{yy} 2.189, g_{zz} 2.027) of sufficient stability in acidic solutions for kinetic measurements to be undertaken of substitution reactions at the sixth site. The isomeric ligand L^2, has been synthesized previously, and reactions of the $[Ni(L^1)(solv)]^{3+}$ and $[Ni(L^2)(solv)]^{3+}$ ions with chloride have also been investigated. In both reactions, an unusually high acid dissociation constant is observed, associated with the proposed replacement of the apical ether oxygen by a water molecule that is bound both to the metal centre and hydrogen bonded to the ether. The structure $[Ni(L^2)](PF_6)_2$ (monoclinic, $P2_1/c$, a = 10.699(2), b = 13.244(4), c = 16.603(2) Å, β = 92.10(1)°) converged at R = 0.055 (R' = 0.057) for 325 parameters using 3293 reflections with $I > 2\sigma(I)$. In this complex, the detachment of the ether O donor to yield a square-planar complex is confirmed. Comparisons are made with substitution rates at other Ni(III) macrocyclic ions.

Key words: nickel(III), substitution, macrobicyclic ligand, synthesis, kinetics.

Résumé : On a synthétisé le ligand potentiellement pentacoordinant L^1 par réaction de l'éther ponté bis-(2-(méthylsulfonyl)oxyéthyl)éther avec le cyclame tétraazamacrocyclique (cyclame = 1,4,8,11-tétraazatétradécane). Initialement, on a caractérisé le complexe au cuivre(II) et sa démétallation subséquente a permis d'obtenir L^1 à l'état pur. Les oxydations électrochimiques et chimiques de complexes de nickel(II) conduisent à la formation d'un ion Ni(III) (d^7 de faible spin, rhombique, g_{xx} 2,195, g_{yy} 2,189, g_{zz} 2,077) qui, en solutions acides, sont suffisamment stables pour permettre d'effectuer des mesures cinétiques sur les réactions de substitution au niveau du sixième site. Le ligand isomère L^2 a été synthétisé antérieurement; on a aussi étudié les réactions des ions $[Ni(L^1)(solv)]^{3+}$ et $[Ni(L^2)(solv)]^{3+}$ avec le chlorure. Dans les deux réactions, on a observé une constante de dissociation acide anormalement élevée qui est associée au remplacement de l'atome d'oxygène de l'éther apical par une molécule d'eau qui est reliée par une liaison hydrogène à l'éther et qui est aussi liée au centre métallique. La structure $[Ni(L^2]](PF_6)_2$ (monoclinique, $P2_1/c$, a = 10,699(2), b = 13,244(4) et c = 16,603(2) Å, β = 92,10(1)°) converge à R = 0,055 (R' = 0,057) pour 325 paramètres en utilisant 3293 réflexions avec $I > 2\sigma(I)$. Dans ce complexe, on a pu confirmer le détachement de l'oxygène de l'éther donneur qui conduit à la formation du complexe plan carré. On a fait une comparaison des vitesses de substitution au niveau d'autres ions macrocycliques du Ni(III).

Mots clés : nickel(III), substitution, ligand macrobicyclique, synthèse, cinétique.

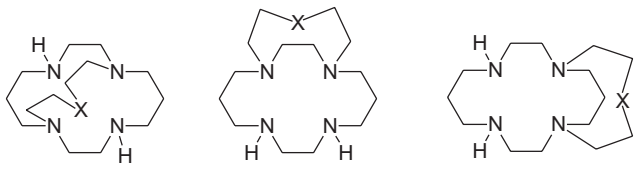
Introduction

Although nickel(III) has been an accessible oxidation state for 30 years (1–6), there have been relatively few studies made of substitution processes at this metal centre. Whilst there are some exceptions, in part, this is owing to a generally strongly oxidizing nature and relatively rapid decomposition of the complex ions. It has been estimated that the nickel(III)-hexaaquo ion would have a redox potential in excess of 2 V (7) and, even when ligated as macrocyclic complexes, E^0 values are close to or exceed 1 V (8–12). In the latter systems, use has been made of strongly acidic media to reduce the rate of (aqueous) solvent decomposition. Only in the cases where deprotonated peptides (13, 14) or cyclic amides (15) surround the metal ion are redox potentials lower. However, in these cases, the rate of axial substitution is substantially greater than that for [Ni(III) cyclam$(H_2O)_2$]$^{3+}$ (cyclam = 1,4,8,11-tetraazacyclotetradecane) (16, 17). Recently, in this laboratory, we described the synthesis of bicyclic ligands in which a cyclam ring is fused to a nine- (18) or 10-membered (19) ring containing an ether donor (L^2 and L^3, respectively), to provide a N_4O donor set with only a single site available for substitution in an octahedral complex ion. Spectroscopic observations are consistent with the formation of nickel(III) species of sufficient lifetimes to permit kinetic measurements. The third isomer (L^1) of the N_4O series is one in which the bridge is made between the 1,8-*trans*-nitrogens of cyclam. Complexes formed by this ligand would have a "hemicryptate" structure. This ligand has been prepared recently (20), using essentially the synthetic route described herein, but the process required selective separation of L^1 from the variety of organic products formed. An alternative route is described where individual components of the product ligand mixture form copper(II) complexes that can be separated chromatographically, and subsequent demetallation permits isolation of the free ligands. In this way, yields of about 50% of L^1 and <10% of L^3 were identified together with amounts of dinuclear copper ions that were not characterized further. Nickel(II) complexes have been prepared and oxidation to Ni(III) achieved both electrochemically and by reaction with oxidants such as $Co(III)^{3+}$(aq). In the spectrophotometric titration of the [Ni(III)(L^2)(solv)]$^{3+}$ ion with acid, a pK_a has been identified consistent with a hydrogen ion dependence observed in substitution reactions with chloride ion.



Results

The crystallographic parameters for each of the complexes are contained in Table 1, with selected bond lengths and angles provided in Table 2. An ORTEP diagram of the cation, [Ni(L^2)]$^{2+}$ is shown in Fig. 1. The ion has a square-planar structure, in a *trans*-I geometry, in marked contrast with the corresponding octahedral ion [Ni$(L^2)(ClO_4)$]$^+$ (22) prepared from perchlorate media and where the ether O donor is coordinated in the solid state. In the present system, the Ni—N bond distances are 2.006, 1.998, 1.976, and 1.981 Å, with the longer two bonds to the tertiary nitrogens of the fused nine-membered ring as observed previously (18, 22). The latter distances are completely consistent with the secondary amine bonds observed for Ni(cyclam)$^{2+}$ (1.975 Å), although they are slightly longer than average Ni(II)—N bond found in a variety of macrocyclic complexes (1.945 Å) (28). In the present system, the apical ether atom (Ni—O = 2.306 Å) indicates that the ether is not bound. Furthermore, the closest fluorine of the PF_6^- counter ion is 2.76 Å from the nickel centre. Curiously, the angle subtended by the ether oxygen to the perpendicular from the N_4 plane is 9.1° suggesting that while the Ni—O distance is stretched to a nonbonding value, the structure-fused ring and apical position of the ether is not altered. This contrasts, for example, with the apical nitrogen observed in Pd([9]ane$N_3)_2^{2+}$ (29) where the ring is observed to undergo inversion removing the nitrogen from the coordination environment entirely. In the present complex, the ether could almost be viewed as representing a nascent interaction with the nickel centre. Presumably, the energy barrier between the four- and six-coordinate species must be very small.

In the ligand synthesis, under the experimental conditions employed, there was predominant formation of L^1, although small amounts of L^3 also formed through reaction across the propylene bridge.

There are three isomeric forms of the N_4O ligand, formed either in the present case, or by bridge formation across the ethylene-(9-N_4O) (L^2) or propylene-(10-N_4O) (L^3) elements of the cyclam. Despite growing well-formed crystals from perchlorate and tetrachlorozincate media for both the copper(II) and nickel(II) complexes of ligand L^1, in each case the material was observed not to diffract. This may be the result of significant fluxionality in the ligand leading to random disorder, even at –90°C. Although there is as yet no crystal structure for a complex of L^1, comparison of the NMR data (supplementary Table S5)[2] shows the bicyclic ligand to differ from the other two that have been synthesized previously (18, 19) and for which structural data have been presented.

Electronic spectra

The UV–vis spectrum of [Cu(L^1)]$^{2+}$ in water shows two broad bands with maxima at 537 nm (ε = 185 M^{-1} cm^{-1}) and 280 nm (ε = 4860 M^{-1} cm^{-1}). The more intense band is assigned to charge transfer, while the lower energy band envel-

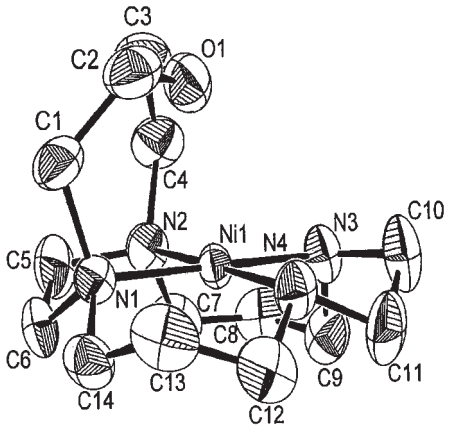
ops the *d–d* transitions. The spectra obtained for $[Ni(L^1)](ClO_4)_2$ in water and acetonitrile are typical of Ni(II) (d^8) complexes in an octahedral environment. A weak transition seen in acetonitrile at 722 nm is believed to be the spin forbidden transition $^1E_g \leftarrow {}^3A_{2g}$. Like other bicyclic species prepared previously, there is a strong field, and the $^3A_{2g} \leftarrow {}^3T_{1g}(F)$ transition (505 nm) is at a fairly high energy for a high-spin Ni(II) system. Comparative values for $[Ni(II)(L^5)]^{2+}$ are 504 nm (30) and $[Ni(II)(L^2)]^{2+}$ 515 nm (22). The spectrum of $[Ni(L^1)]^{3+}$ shows two strong transitions below 400 nm, ascribed to charge transfer transitions.

EPR spectra

The Ni(III) ion complexes are EPR active, yielding spectra characteristic of a low-spin d^7 ion with rhombic symmetry. Details of several complexes, prepared under identical conditions of 0.5 to 1.0 M [H^+], are provided in Table 3 and the spectrum of the sulfato-complex is presented in Supplementary Fig. S4.[2] It is known that tertiary amine – metal ion bond lengths in Ni(II) complexes are longer than those involving secondary amines (31), which may in part explain the origin of the quasi-rhombic structure since the diagonally opposed bonds may differ in the Ni(III) system. However, there may also be distortion induced by the ligand that could lead to the behaviour differing from the comparable spectra for the other isomeric complexes. In an attempt to prepare a disubstituted complex, fluoride ion was added to the perchlorate solution. No evidence is observed that more than one fluoride ion is attached, even at high concentrations of F^-, although as has been pointed out previously (13), the binding of the second ion may be less thermodynamically favoured at the very low temperatures prevailing during measurement.

Fig. 1. ORTEP diagram of the square-planar $[Ni(L^2)]^{2+}$ ion.



Cyclic voltammetry

Two irreversible redox waves are observed for the $[Cu(L^1)](ClO_4)_2$ complex in acetonitrile. The first, corresponding to the Cu(III)/Cu(II) couple, is seen at 1.25 V, approximately the same potential as the complexes $[Cu(II)([L^n)]^{2+}$ (n = 2, 3). Similarly, the Cu(II)/Cu(I) couple of $[Cu(L^1)]^{2+/+}$ at –1.06 V is quite close to that of $[Cu(L^2)]^{2+/+}$ (–1.04 V), but significantly different from $[Cu(L^5)]^{2+/+}$ (–0.85 V) (30) and $[Cu(L^4)]^{2+/+}$ (–1.16 V) (32).

The redox data obtained for $[Ni(L^1)](ClO_4)_2$ in acetonitrile are summarized in Table 4. The Ni(III) macrobicyclic species are strong oxidants and potentials for the Ni(III)/(II) couple are similar to those obtained for the two isomeric N_4O bicyclic species. An additional irreversible redox process was observed at 1.3 V for $[Ni(III)(L^1)]^{3+}$, which may tentatively be assigned to oxidation to produce a ligand radical. As observed previously, the Ni(I) ions are very powerful reductants.

Stability of $[NiL^1)]^{2+}$ and $[Ni(L^1)]^{3+}$ in aqueous acidic solution

The complex $[NiL^1)]^{2+}$ was stable in 1 M $HClO_4$ (T = 25°C) based upon no measurable change in the spectrum at 520 nm over a 12 h period. In the case of $[Ni(L^1)]^{3+}$, studies were made at 395 nm where the rate of decomposition to the

corresponding Ni(II) complex was found to be independent of $[H^+]$ over the range 0.2 to 1 M (I = 1 M). The rate at 20°C was found to be 7.5 (±0.2) × 10^{-4} s^{-1}, and at 10°C, 2.4 (±0.2) × 10^{-4} s^{-1}. At the latter temperature, the half-life of Ni(III) is approximately 50 min, sufficiently long for monitoring of substitution kinetics without significant interference from decomposition. The presence of acid in the solution appreciably reduces the rate of decomposition of the $[Ni(L^1)(H_2O)]^{3+}$ ion, presumably by preventing decomposition via base-catalyzed pathways (33). In the case of $[Ni(L^2)(H_2O)]^{3+}$, the corresponding decomposition rate was found to be 2.2 (±0.1) × 10^{-4} s^{-1} at 25°C, again independent of hydrogen ion concentration. Interestingly, this behaviour differs significantly from that of Ni(III) cyclam, where decomposition increases as $[H^+]$ decreases over the same range used here.

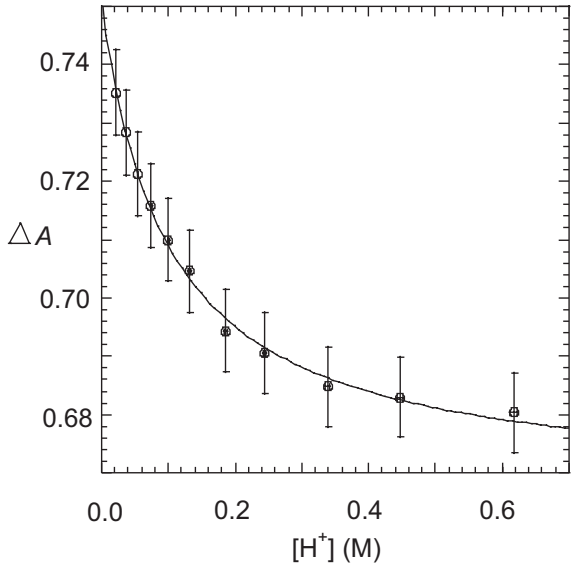
Chloride substitution at $[Ni(L^n)(solv)]^{3+}$

Substitution reactions at Ni(III) centres have been studied previously, with four-coordinate cyclam-based ligands, (15, 16) and peptides (14). Dissociative interchange mechanisms have been suggested for these processes. The rates of substitution at both $[Ni(L^1)(OH_2)]^{3+}$ and $[Ni(L^2)(OH_2)]^{3+}$ were found to be dependent on the concentration of both chloride and hydrogen ion. For $[Ni(L^1)(OH_2)]^{3+}$, an initial spectroscopic investigation identified an equilibrium confirmed by an isosbestic point at 268 nm. The equilibrium constant was determined spectrophotometrically (T = 10°C) at 317 nm at $[H^+]$ = 0.5 M, I = 1 M. For the reaction $[NiL^{3+}] + Cl^- \rightleftharpoons [NiLCl]^{2+}$, (neglecting charges) the equilibrium constant (K = [NiLCl]/[NiL][Cl]) may be determined using the equation:

$$[NiL]_0[Cl]_0/\Delta OD = ([NiL]_0 + [Cl]_0)/(\Delta\varepsilon)l + 1/K(\Delta\varepsilon)l$$

where ΔOD is the observed optical density change, $\Delta\varepsilon$ is the change in extinction coefficient between the reactant and the product, l is the path length in cm, and $[NiL]_0$ (= 2.2×10^{-4} M) and $[Cl]_0$ are the initial concentrations of $[Ni(L^1)(H_2O)]^{3+}$ and Cl^-, respectively. A plot of $[NiL]_0[Cl]_0/\Delta OD$ vs. ($[NiL]_0$ + $[Cl]_0$) displayed good linearity over the range $[Cl^-] = 7 \times 10^{-3} - 8 \times 10^{-2}$ M, from which a value of K = 170 ± 10 M^{-1} was calculated. This value is similar to the values obtained for the reaction of chloride with $[Ni(cyclam)]^{3+}$ (16).

Fig. 2. Spectrophotometric titration of the $[Ni(L^2)(solv)]^{3+}$ ion with hydrogen ions (λ = 390 nm).



Spectroscopic studies with $[Ni(L^2)(H_2O)]^{3+}$ exhibited small differences in absorbance when $[H^+]$ was varied from 0.5 to 0.002 M. Use was made of this feature in determining a pK_a within this acidity range. Absorbance changes (ΔA) were monitored over the range 200–450 nm when μL aliquots of perchloric acid (4.0 M) were added sequentially to a $[Ni(L^2)]^{3+}$ solution starting at $[H^+]$ = 0.002 M. Corrections were made for dilution and also for any decomposition of the Ni(III) species during the periods of measurement. From ΔA_{390} (Fig. 2), K_a = 0.09 ± 0.04. Similar data values were derived at other wavelengths in the 300–359 nm range. Results of an identical experiment on $[Ni(cyclam)]^{3+}$ showed no similar behaviour.

Substitution reaction kinetics for both systems were investigated with chloride concentrations of approximately 10–40 times in excess of that of the [Ni(III)]. Higher concentrations of chloride appeared to show a second reaction, but absorbance changes were too small to permit significant comment. In both instances, the chloride species formed are considerably more stable than the aquo ion, persisting at

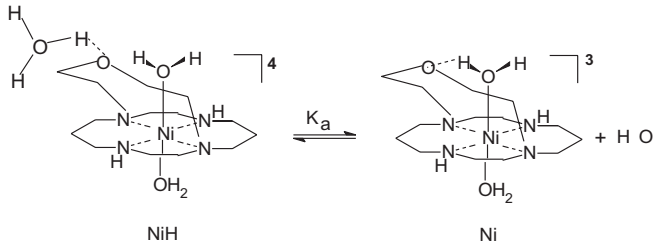
© 2002 NRC Canada

room temperature for several hours. Increased kinetic stability of macrocyclic Ni(III) species has been observed for other Ni(III) macrocyclic complexes with chloride in the axial position (16), and is probably associated with the lower redox potential of these ions. The rate data for the $[Ni(L^1)(H_2O)]^{3+}$ reaction, obtained at λ = 430 nm, are tabulated in Table S6[2] and for the $[Ni(L^2)(H_2O)]^{3+}$ system in Table S7.[2] In general, the scatter of individual values for k_{obs} was in the order of ±5%. For the $[Ni(L^2)(H_2O)]^{3+}$ reaction, measurements were made at λ = 400nm. The observed first-order rate constants (k_{obs}) vary linearly with chloride concentration and plots are provided in Supplementary Figs. S5 and S6,[2] where it is seen that intercepts and slopes vary inversely with $[H^+]$.

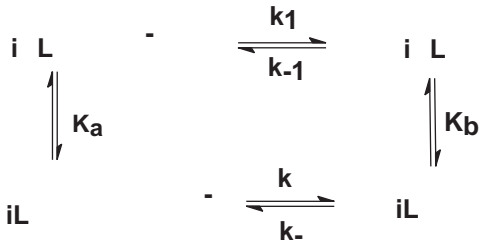
Origin of the protonation equilibria for the substitution reaction

There is a significant difference between the present findings and those for the corresponding $[Ni(cyclam)(H_2O)_2]^{3+}$ species (16), although rate data for Cl^- substitution were collected over approximately the same $[H^+]$ range (0.04 to 0.30 M). In the latter case, there is no evidence of any proton dependence in this range, in keeping with a relatively high (>3) pK_a value for proton dissociation of the first aquo group (12). In the present investigation, an initial acid–base reaction occurs at a much higher acid concentration, consistent with an additional process at the metal centre. If the aquo ion in the sixth site was deprotonated, it is unlikely that the chloride ion would readily replace the resultant hydroxo ion in the inner coordination sphere (the reaction rate increases as the pH rises). The weakness of binding between transition-metal ions and ether oxygen donors is confirmed in the O-donor detachment seen in the structure of the planar $[Ni(II)L^2]^{2+}$ ion. A possible mechanism involves the detachment of the axial O donor and its replacement by a water molecule. The enhanced acidity of coordinated water is well-known, and, at lower acid concentrations, the presence of a lone pair on the ether provides a template for formation of a hydrogen bond with the incoming water molecule as shown. This interaction has the effect of increasing the ability of the coordinated water to donate electrons to the nickel(III) thus labilizing the complex. At higher hydrogen ion levels, the ether group preferentially H-bonds to the H_3O^+ present in solution leaving the isolated water bound to the Ni(III), which in turn, becomes more inert towards substitution.

A mechanistic scheme consistent with the observed acid dependence is described below, where (neglecting charges) $NiHL^n$ and NiL^n represent the complex ions as shown (n = 1 or 2) and $NiH(L^n)Cl$ and $Ni(L^n)Cl$, the corresponding chloro complexes:



Scheme 1.



The rate law derived from this equilibrium set may be represented as:

$$[1] \qquad k_{obs} = (k_1[H^+] + k_2K_a)[Cl^-]/(K_a + [H^+]) + (k_{-1}[H^+] + k_{-2}K_b)/(K_b + [H^+])$$

As can be seen, inverse proton dependences are predicted for both the intercepts and slopes of linear plots of k_{obs} vs. $[Cl^-]$. The uncertainties in the data probably reflect the relative instability of the nickel(III) species, especially at lower proton concentrations and higher temperatures.

For the reaction of $[Ni(L^1)(solv)]^{3+}$, a nonlinear least-squares regression of the data showed large errors particularly for K_b which was seen to be several orders of magnitude lower than K_a. A similar regression was therefore carried out using the equation

$$[2] \qquad k_{obs} = (k_1[H^+] + k_2K_a)[Cl^-]/(K_a + [H^+]) + k_{-1}$$

where $K_b << [H^+]$ and the $k_{-2}K_b$ term is negligible. This resulted in a correlation R^2 = 0.98 with k_1 = 273 ± 16 M^{-1} s^{-1}, k_{-1} = 2.76 ± 0.09 s^{-1}, K_1 = 99 ± 12 M^{-1}, k_2 = 1293 ± 690 M^{-1} s^{-1}, and K_a = 0.022 ± 0.02 M. This value of K_1 agrees reasonably with the equilibrium constant determined spectrophotometrically (170 M^{-1}), although the latter result was obtained at only one hydrogen ion concentration, and within the range where the protonated complex might be expected to persist.

For the reaction of $[Ni(L^2)(solv)]^{3+}$, maintaining K_a = 0.09 M and using eq. [2], a nonlinear least-squares regression of the data yielded (R^2 = 0.98) k_1 = 295 ± 54 M^{-1} s^{-1}, k_{-1} = 4.15 ± 0.77 s^{-1}, K_1 = 71 ± 32 M^{-1}, and k_2 = 705 ± 703 M^{-1} s^{-1}. Details of the rates, parameters, and residuals of correlations of observed and calculated rates are provided in Supplementary Tables S6 and S7.[2] The rate constants may be compared with those of the cyclam complex (16) and $[Ni(L^3)(solv)]^{3+}$. The latter system has been studied previously (19). By use of a treatment of the data similar to that herein, values of k_1 = 17 ± 5 M^{-1} s^{-1}, k_{-1} = 0.083 ± 0.012 s^{-1} (K_1 = 205 ± 70 M), and k_2 = 210 ± 121 M^{-1} s^{-1} with K_a = 0.035 ± 0.03 M, similar to the values published. The most noticeable difference is that although the equilibrium constant for the L^3 complex is similar to that for the other two isomeric species, the individual rate constants are substantially smaller. In all three cases, the acidity profile observed is significantly different from that in $[Ni(III)cyclam(H_2O)_2]^{3+}$, where no hydrogen ion dependence is seen with rates at 6.6° for chloride substitution, k_1 = 168 ± 5 M^{-1} s^{-1} and k_{-1} = 1.15 ± 0.10 s^{-1}. These values may be compared with k_1 = 273, 295, and 17 ± 5 M^{-1} s^{-1} for $[NiHL^n(OH_2)_2]^{3+}$ (n = 1, 2, 3), respectively. The rate constants are quite similar, suggesting a common reaction pathway. The value for L^3

© 2002 NRC Canada

is surprising, since of the three bicyclic ligands, only in the case of complexes of this ligand is the nickel ion known to be coplanar with the macrocyclic donor set, and in this regard, the geometry is closest to the cyclam ion. As predicted, there is an increased lability of the hydrogen-bonded ions. For the isomeric species, there is apparently a greater spread of rates, k_2 = 1293 (L^1), 705 (L^2), and 210 (L^3) M^{-1} s^{-1}, although the errors involved are substantially greater.

Unpublished observations (34) in this laboratory on the much more kinetically stable cobalt(III) ion ($[Co(L^3)(H_2O)]^{3+}$) have identified two pK_a values at 2.2 and 3.8 consistent with H^+ dissociations at both *trans*-disposed sites. In the present study, the first pK_a in each case (≈1.05 for L^1, 1.23 for L^2, 1.45 for L^3) is somewhat lower, possibly associated with the d^7 nickel(III) centre. In comparing the macrobicyclic [Ni(III)(9-ane N_4X)] complexes, where X = S, NH, the equilibrium constants for chloride complex formation are substantially smaller (22), and there is no evidence for behaviour similar to that outlined above where the replacement of the coordinated water by the halide is likely to take place in a manner suggestive of dissociative interchange. Further work on other systems is required to confirm this suggestion.

Conclusions

The rates of chloride substitution at three isomeric nickel(III) complexes containing ether bridges, (L^1–L^3) with a macrocyclic N_4 ring similar to cyclam are compared, and show an unusually high proton equilibrium not observed in the reactions of cyclam. This is related to a H-bonded water molecule displacing the ether in the primary coordination sphere of the complex. In this work, the pK involving $[NiL^2(solv)]^{3+}$ has been determined spectrophotometrically. This detachment is confirmed by a crystal structure of the $[Ni(II)L^2]^{2+}$ ion which is square-planar. In all three cases, the rates of reduction to the corresponding Ni(II) complexes by oxidation of water is invariant of $[H^+]$ in contrast to the Ni(III) cyclam complex which reacts more rapidly at lower acidities.

Experimental

Capping of cyclam was achieved by use of bis-(2-(methylsulfonyl)oxyethyl)ether as the bridging molecule.

Bis-(2-(methylsulfonyl)oxyethyl)ether

Triethylamine (104 mL, 0.8 mol) and bis-(2-hydroxyethyl)ether (23.7 mL, 0.25 mol) were dissolved in 1.5 L dichloromethane under a nitrogen atmosphere. The mixture was cooled to –10°C on an ice and salt bath. Methanesulfonylchloride (46.5 mL, 0.6 mol) in 250 mL dichloromethane was added dropwise over a period of 2 h. The mixture was stirred overnight at room temperature. The organic fraction was washed successively with 100 mL 1 M HCl, 3 × 100 mL water, and 100 mL saturated aqueous sodium carbonate, dried with anhydrous sodium sulfate, and the solvent removed under vacuum. The residue was recrystallized from hot methanol to give white crystals. Yield: 53.8 g (82%). ^{1}H NMR (360 MHz) ($CDCl_3$) δ: 3.05 (s, 3H, CH_3), 3.79, 4.37 (t, 2+2H, CH_2-O). ^{13}C NMR (90.6 MHz) ($CDCl_3$) δ: 37.6 (CH_3), 68.6 (CH_2-OMs), 68.9 (CH_2-O). CI-MS (*m*/*z*): 263 (M + 1).

17-Oxa-1,4,8,11-tetraazabicyclo[6.6.5]tetradecane (L^1)

Sodium carbonate (10 g) in a small volume of THF, dried over molecular sieves, was placed under an atmosphere of nitrogen. To this slurry was added cyclam (21) (1 g, 5 mmol) and bis-(2-(methylsulfonyl)oxyethyl)ether (1.3 g, 5 mmol). The mixture was refluxed for 10 days then filtered. The solvent was removed under reduced pressure to yield a crude ligand mixture. The complexes were prepared by addition of $Cu(ClO_4)_2 \cdot 6H_2O$ (1.85 g, 5 mmol) in acetonitrile to a solution of the ligands and refluxing for 1 h. Following removal of the solvent under reduced pressure, the residue was dissolved in water, and filtered. The copper(II) complexes were purified using a Sephadex CM-C25 column (3 × 30 cm), eluting with 0.1 M $NaClO_4$. The major purple band isolated was identified as $[Cu(L^1)](ClO_4)_2$. Yield: 1.37 g (52%). UV–vis (water) (M^{-1} cm^{-1}): ε_{280} = 4860, ε_{537} = 185. FAB-MS calcd. (found) (*m*/*z*): 333.1 (332.8) ($[Cu^{II}(L^1\text{-}H^+)]^+$ and $[Cu(L1)]^+$), 432.1 (432.2) ($[Cu^{II}L^1(ClO_4)]^+$). ES-MS calcd. (found) (*m*/*z*): 166.6 (166.8) ($[Cu^{II}L^1]^{2+}$), 271.2 (271.2) (L^1H^+), 332.1 (332.3) ($[Cu^{II}(L^1\text{-}H^+)]^+$), 432.1 (432.7) ($[Cu^{II}L^1(ClO_4)]^+$). Isotopic distributions are provided as supplementary material Fig S1.[2] Anal. calcd. for $Cu(L^1)(ClO_4)_2 \cdot H_2O$ (%): C 30.5, H 5.9, N 10.2; found: C 30.5, H 5.4, N 10.7.

A minor bluish-purple band was also eluted that was shown to be identical to the copper(II) complex of L^3 prepared by an independent route (19). FAB-MS (mNBA): 432 = $[Cu(L^3)(ClO_4)]^+$, 332 = $[Cu(H_{-1}L^3)]^+$. Anal. calcd. for $[Cu(C_{14}H_{30}N_4O)](ClO_4)_2$: C 31.56, H 5.67, N 10.51; found: C 31.50, H 5.66, N 10.42. Interestingly, there is no evidence for bridge formation across the ethylene carbons that would lead to L^2. The folding required of the bridging molecule makes this process very unlikely.

Following reaction of $[Cu(L^1)]^{2+}$ with excess Na_2S, the solution was allowed to stand for 30 min, whereupon decolourization and CuS precipitation were complete. After filtration and addition of 2 g NaOH, the free ligand was extracted using dichloromethane and, after drying of the organic layer, and solvent removal, a yellow oil was obtained. Yield: 0.61 g (45%) (based on cyclam). ^{1}H NMR (300 MHz) ($CDCl_3$) δ: 1.38, 1.51 (m, 2+2H, CH_2-C), 2.35 (m, 20H, CH_2-N), 3.20, 3.36 (m, 2+2H, CH_2-O). ^{13}C NMR (75.5 MHz) ($CDCl_3$) δ: 25.5 (CH_2-C), 47.9, 51.0, 53.3, 53.6, 57.6 (CH_2-N), 67.5 (CH_2-O). CI-MS (*m*/*z*): 270 (M^+), 271 (M + 1), 299 (M + 29), 311 (M + 41).

$[Ni(L^1)](ClO_4)_2$

To a solution of the ligand (0.61 g, 0.2 mmol) in 25 mL acetonitrile, was added $Ni(ClO_4)_2 \cdot 6H_2O$ (0.73 g, 0.2 mmol) in 10 mL acetonitrile. The solution was refluxed for 24 h, and evaporated to dryness. The residue was dissolved in water, filtered, and the complex purified by elution with 0.1 M $NaClO_4$ on a Sephadex CM-C25 column. The pale purple complex was recrystallized from sodium perchlorate solution. Yield: 0.44 g (42%). UV–vis (water) (M^{-1} cm^{-1}): ε_{339} = 7, ε_{520} = 4.9, ε_{1077} = 2.5; (acetonitrile) (M^{-1} cm^{-1}): ε_{326} = 17, ε_{498} = 8, ε_{722} = 3, ε_{953} = 4. FAB-MS (*m*/*z*) calcd. (found) for ($[Ni^{II}(L^1\text{-}H^+)]^+$): 327.19 (327.1); ($[Ni^{II}(L^1)(ClO_4)]^+$): 427.1

© 2002 NRC Canada

(427.1). Anal. calcd. for $Ni(L^1)(ClO_4)_2$ (%): C 31.8, H 5.7, N 10.6; found (avg of two independent investigations): C 33.1, H 5.9, N 10.9. We are unable to account for the anomalous C analysis. Mass spectra of the product are shown in Supplementary Figs. S2 and S3[2] including a simulated and experimental segment for the isotopic distribution of the $[Ni(L^1)(ClO_4)]^+$ ion.

The complex $[Ni(L^2)(ClO_4)](ClO_4)$ has been characterized crystallographically (22) and details of the oxidation to Ni(III) provided previously.

$[Ni(L^2)](PF_6)_2$

The exchange of the counter ion was achieved by dissolving ca. 50 mg of the crystallized nickel(II) perchlorate, in a saturated solution of $NaPF_6$, followed by slow evaporation to yield, almost quantitatively, brownish-yellow crystals of X-ray quality.

Solutions of $[Ni(III)(L^1)(OH_2)]^{3+}$ were prepared by oxidation of the nickel(II) ion with Co(III)(aq) in perchloric acid. In the kinetic studies, account was taken of the hydrogen ion content of the cobalt stock solution in preparing solutions for investigation. Titration of a sample of Ni(II) complex with 1 equiv of Co(III) showed an isosbestic point at 340 nm. UV–vis data for the resulting Ni(III) ion (M^{-1} cm^{-1}): $\varepsilon_{317} = 2157$, $\varepsilon_{394} = 1440$.

All high-field ^1H and ^{13}C NMR spectra were recorded on either a Bruker AC300 or AMX360 spectrometer. Chemical shifts are reported relative to tetramethylsilane (TMS). UV–vis spectra were obtained on a dual beam Cary 5 UV–vis–near-IR spectrometer, with the solvent as a background reference. Mass spectra were recorded on either a Finnegan GC330 using standard chemical ionization methods or, for salts, using a Kratos Concept double focusing magnetic instrument (liquid secondary ion mass spectra) with either fast atom bombardment (FAB) (*meta*-nitrobenzylalcohol matrix) or by electrospray (ES) techniques. All spectra were run in the positive ion mode unless otherwise shown. For electrospray, ionization was achieved by volatilizing a 1×10^{-4} M solution of the compound in a $CH_3CN–H_2O$ (1:1) solution.

Electron paramagnetic resonance spectra were recorded at 77 K on either a Varian E6 EPR spectrometer or a Bruker EMX300 instrument, with DPPH ($g = 2.0037$) used as an external standard. Elemental analyses were performed by Canadian Microanalytical Services, Vancouver, BC. A Princeton Applied Research Model 273 potentiostat–galvanostat interfaced to an IBM PC computer was used for electrochemical measurements. Cyclic voltammograms were obtained using the Headstart program (Princeton). A standard three-electrode electrochemical cell was employed, with a Pt microelectrode as the working electrode, a Pt bead as the counter electrode, and a Ag^+/Ag reference electrode, linked to the cell via a salt bridge. All electrochemistry was performed in dry acetonitrile solutions containing supporting electrolyte (0.1 M) (usually 0.1 M *t*-Bu_4NClO_4). Solutions were degassed with argon prior to electrochemical measurement. The ferrocinium/ferrocene (Fc^+/Fc) couple was used as an external standard. $E_{1/2}$ values are reported relative to the Ag^+/Ag couple ($E_{1/2}$ (Fc^+/Fc) = 0.1 V vs. (Ag^+/Ag)).

Kinetic measurements were made using an Applied Photophysics DX-17MV stopped-flow and data acquisition system. The nickel(III) solutions were prepared in situ by oxidation of the nickel(II) species in acidic media using a stoichiometric deficiency of Co^{3+}(aq) in 4.5 M $HClO_4$. Ionic strength was maintained with appropriate concentrations of $Li^+–H^+$-ClO_4. Adjustments were made to account for the effect of the acid added to the solution from the $[Co(H_2O)_6]^{3+}$ solution. Reactions were monitored under conditions where pseudo-first-order kinetics prevailed.

Crystallography

The hexafluorophosphate salt ($[Ni(L^2)](PF_6)_2$) was obtained as irregular brown crystals and mounted on a glass fiber using epoxy resin. All measurements were obtained using a Rigaku AFC6S diffractometer, with graphite monochromated Mo Kα radiation. Cell constants and an orientation matrix for data collection were obtained directly, using a least-squares refinement of 21 centred reflections in the range $34.04° < 2\theta < 39.51°$. The data were collected using the θ–2θ scan technique to a max 2θ value of 50.1°. ω scans of several intense reflections, made prior to data collection, had an average width at half-height of 0.31° with a take-off angle of 6.0°. Scans of $(0.94 + 0.35 \tan\theta)°$ were made at a speed of 8.0°/min (in ω). The weak reflections ($I < 10.0\sigma(I)$) were rescanned (maximum of four rescans) and the counts were accumulated to assure good counting statistics. Stationary background counts were recorded on each side of the reflection. The ratio of peak counting time to background counting time was 2:1. Standards were measured prior to every 150 reflections with no noticeable decay in intensity. Of the 4534 reflections collected, 4294 were unique. The data were corrected for Lorentz and polarization effects. The structure was solved by direct methods, using MITHRIL and DIRDIF (23). The non-hydrogen atoms were refined anisotropically, using a full-matrix least-squares approach. Neutral atom scattering factors were taken from Cromer and Weber (24). Anomolous dispersion effects were included in F_{calc} (25); the values for $\Delta f'$ and $\Delta f''$ were those of Cromer (26). All calculations were performed using the teXsan (27) crystallographic software package of Molecular Structure Corporation. Full details of the structure determination, including bond angles and distances, torsion angles, and intensity data are provided in supplementary Tables S1–S4.[2]

Complexation of the La(III) cation by *p*-sulfonatocalix[4]arene — A ^{139}La NMR study

Yaël Israëli, Christine Bonal, Christian Detellier, Jean-Pierre Morel, and Nicole Morel-Desrosiers

Abstract: The complexation of La(III) by the water-soluble *p*-sulfonatocalix[4]arene was thermodynamically characterized by ^{139}La NMR. The ^{139}La NMR data are consistent with the formation of a 1:1 complex resulting from electrostatic interactions between the sulfonato groups and La(III). The complexation is entropy-driven and is characterized by a positive standard enthalpy ($\Delta_r H° = 11.0 \pm 0.5$ kJ mol^{-1}) and a positive standard entropy ($\Delta_r S° = 108 \pm 2$ J K^{-1} mol^{-1}), which are in very good agreement with the ones determined previously by microcalorimetry. The linear relationship between the ^{139}La NMR linewidth of the free and of the complexed cation, obtained at temperatures ranging from 290 to 340 K, excludes the formation of complexes or aggregates other than the 1:1 complex. It shows also that upon complexation, the effective radius of La(III) undergoes an increase of 50%, related to the replacement of water molecules of the hydrated cation by sulfonato groups of the ligand.

Key words: complexation, water-soluble calixarene, *p*-sulfonatocalix[4]arene, ^{139}La NMR, lanthanum.

Résumé : La complexation du cation lanthane(III) par le calix[4]arène *para* sulfonaté, soluble dans l'eau a été caractérisée thermodynamiquement par RMN du ^{139}La. Les données de RMN ont mis en évidence la formation d'un complexe 1 : 1 résultant de l'établissement de liaisons électrostatiques entre les groupements sulfonate et le cation La(III). La complexation est contrôlée par l'entropie et est caracterisée par une enthalpie standard positive ($\Delta_r H° = 11.0 \pm 0.5$ kJ mol^{-1}) et une entropie standard positive ($\Delta_r S° = 108 \pm 2$ J K^{-1} mol^{-1}). La relation linéaire entre la largeur à mi hauteur du ^{139}La sous sa forme non complexée et celle du ^{139}La sous sa forme complexée, obtenues à des températures variant de 290 à 340 K, exclut la formation de complexes et d'agrégats autre que le complexe 1 : 1. Cette linéarité montre aussi qu'au cours du processus de complexation, le rayon effectif du La(III) subit une augmentation de 50 %, liée à la substitution de molécules d'eau de la couche d'hydratation du cation par les groupements sulfonate du ligand.

Mots clés : complexation, calixarène soluble dans l'eau, calix[4]arène *para* sulfonaté, RMN du ^{139}La, lanthane.

Introduction

Calixarenes are macrocyclic compounds formed by phenolic units bridged by methylenic groups. They are widely studied since they are easily synthesized, functionalized, and present a hydrophobic cavity suitable for guest species (1, 2). Contrary to most of the calixarenes, the *p*-sulfonatocalixarenes are soluble in water. They provide hydrophobic and hydrophilic binding sites.

The extraction of lanthanides and actinides by calixarenes has received considerable attention. The extraction is enhanced in the case of calixarene-bearing phosphate ester groups (3). When the calixarene is substituted by 1,3-acid diethyl amide, the ligand shows a selectivity preference for larger lanthanides (4). This selectivity is interpreted by the formation of dimeric species while for Lu(III), a heavy lanthanide, a monomeric complex is formed. Formation of polymeric species is also mentioned when four (carbamoylmethyl)diphenylphosphine oxide groups substitute the calixarene. But, in this latter case, the presence of water and nitrate ions labilizes the complexes formed with heavy lanthanides (5). On the contrary, water molecules and nitrate ions have no influence on the geometry of the 1:1 complex formed between lanthanide cations, Ln(III), and the calix[4]arenes functionalized by four amide or phosphine oxide groups, as underlined by an NMR study performed in acetonitrile (5). It is reported in the literature that the extraction of heavy lanthanide cations with small ionic radii by calixarene carboxylate derivatives was favoured in the presence of sodium cations. The encapsulation of the sodium cation increases the rigidity of the extractant and consequently the Na-calix[4]arene species act as a preorganised extractant toward Ln(III) ions (6). The (*N*,*N*-diisobutylcarbamoylmethyl)octylphenylphosphine oxide (CMPO) is gener-

ally used as extractant for the actinides. The fixation of CMPO groups to a calixarene increases considerably the extraction efficiency, showing the role played by the calixarene structure toward the selectivity (7, 8).

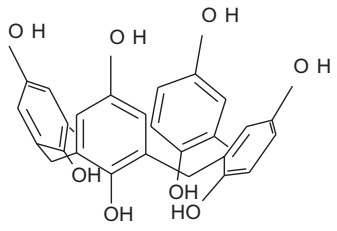
The *p*-sulfonatocalix[5]arene, *p*-sulfonatocalix[6]arene, and their carboxymethoxy derivatives have a pseudo-planar architecture suitable for uranyl complexation. An X-ray study performed on *p*-sulfonatocalix[5]arene shows that the complexation between the calixarene and the uranyl cation involves the phenolic oxygen atoms, while the complexation with the lanthanide cations occurs through the sulfonato groups (9). It was shown recently by X-ray crystallography that the complex formed between the water-soluble *p*-sulfonatocalix[4]arene and La(III) in the solid state results in discrete units with eight La(III) and six calixarene molecules also involving the sulfonato groups (10). Whereas in basic aqueous solution, Shinkai and co-workers (11) underline the formation of a 1:2 complex, the complexation study of lanthanide cations by the *p*-sulfonatocalix[4]arene in acidic medium undertaken by microcalorimetry leads to the determination of the thermodynamic values associated to the formation of a 1:1 complex (12).

In this paper, the complexation of La(III) by the water-soluble *p*-sulfonatocalix[4]arene is thermodynamically characterized by ^{139}La NMR. This technique also leads to information about the structure of the complex.

Experimental

Chemicals

The 25,26,27,28-tetrahydroxy-5,11,17,23-tetrasulfonic calix[4]arene hexahydrate (**1**) and lanthanum(III) chloride heptahydrate (purity 99%) were purchased from Acros Organics and Aldrich, respectively. The lanthanum chloride was used without further purification. The calixarene was purified by recrystallization from an aqueous solution and dried 24 h in an oven at 80–90°C. An amount of 11 ± 1 molecules of co-crystallized water was quantified by ^{1}H NMR using a 1.77 × 10^{-2} mol dm^{-3} solution of dioxane as internal reference.



1

NMR measurements

^{139}La NMR spectra were recorded on a Bruker AMX-500 spectrometer at 70.65 MHz. NMR tubes (5 mm) sealed with parafilm were used. The solvent was a mixture of a 1 × 10^{-2} mol dm^{-3} solution of HCl (pH = 2.0), to avoid hydrolysis of La(III), and D_2O (w/w% D_2O = 5.0). All chemical shifts were referenced against the 1.01 mM stock solution of $LaCl_3$ in 10 mM HCl solution, used throughout this study at 300 K. The chemical shift of the stock solution is –0.22 ppm referenced to a 7.1 mM solution of $LaCl_3$ in 5% D_2O (0 ppm at 300 K). A 90° pulse of 16 μs and a spectral width of 14.3 kHz were used. The acquisition time and the relaxation delay ranged from 15 to 35 ms and 35 to 15 ms, respectively; 10 000 – 87 000 scans were accumulated per spectrum. The temperature was estimated to be reliable at ±0.5 K. The linewidths and chemical shifts were determined by fitting each peak with a Lorentzian line shape.

Results

The evolution of the ^{139}La NMR spectra of 1.01 mM solutions of $LaCl_3$, in 10 mM HCl (pH = 2.0), at 300 K in the absence and in the presence of an increasing amount of *p*-sulfonatocalix[4]arene defined by the ratio ρ (ρ = $[calixarene]_{total}/[La(III)]_{total}$), is shown in Fig. 1. Initially, La(III) was characterized by a peak at –0.22 ppm and a linewidth at half-height of 102 Hz. Upon addition of calixarene, only one peak was observed indicating a fast exchange on the ^{139}La NMR time scale between the free La(III) and the complexed cation. The peak shifted to lower frequency and broadened for ρ values varying from 0 to 3.21. For example, for a ρ value of 3.21, the peak shifted from –0.22 to –6.75 ppm and an increase in the linewidth of 213 Hz was observed. The same experiments were performed at various temperatures, ranging from 290 to 340 K, and similar evolution was observed.

Figure 2 shows the evolution of the chemical shifts of La(III) as a function of ρ at various temperatures. The same trend was observed for each temperature: the chemical shift increased strongly for values of the ratio lower than 1 and reached a plateau at higher values, suggesting the formation of a 1:1 complex between La(III) and the calix[4]arene. In acidic aqueous solution (pH 2.0), the *p*-sulfonatocalix[4]arene (C^{4-}) is a tetra-anion, since the four sulfonic groups are totally dissociated (13). On the basis of a 1:1 stoichiometry, the complexation can be described by eq. [1].

$$[1] \quad La(III) + (p\text{-sulfonatocalix[4]arene})^{4-} = (La\text{–}p\text{-sulfonatocalix[4]arene})^{-} \quad (La, C)^{-}$$

Under fast chemical exchange conditions, the observed chemical shift is the population average of the chemical shift of the free cation (δ_A) and of the complexed cation $(La,C)^-$ (δ_B). It is given by eq. [2].

$$[2] \quad \delta_{observed} = \delta_A \times ([La^{3+}]/[La^{3+}]_{total}) + \delta_B \times ([(La,C)^-]/[La^{3+}]_{total})$$

Since $[La(III)] = [La(III)]_0 - [(La,C)^-]$ and $[C^{4-}] = \rho[La(III)]_0 - [(La,C)^-]$ ($[La(III)]_0$ designates the initial concentration of the cation) and assuming that the solutions are dilute enough to neglect the activity coefficients, the concentration of the 1:1 complex deduced from the expression of the stability constant (K) is given by eq. [3]

$$[3] \quad [(La,C)^-] = 0.5C - (0.25C^2 - \rho D)^{1/2}$$

where $C = [La(III)]_0 + \rho[La(III)]_0 + K^{-1}$ and $D = [La(III)]_0^2$.

Equation [3] combined with eq. [2] led to a non-linear regression (14), which was applied on the observed chemical

Fig. 1. ^{139}La NMR spectra of $LaCl_3$ (1.01 mM in 10 mM HCl) in the presence of various amounts of *p*-sulfonatocalix[4]arene at 300 K (ρ = $[calixarene]_{total}/[La^{3+}]_{total}$).

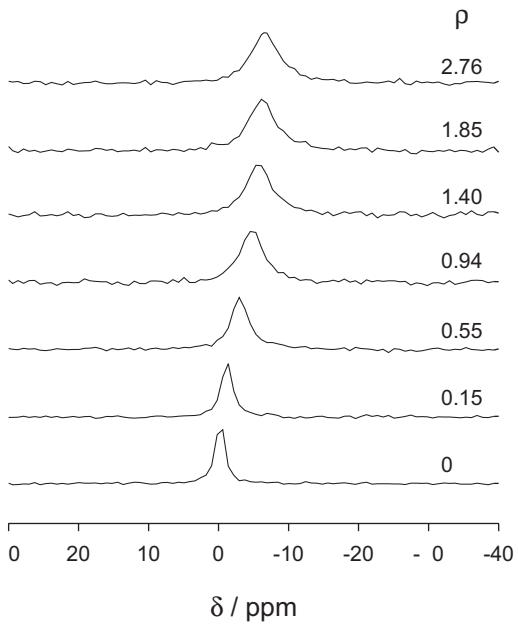

Fig. 2. Variation of ^{139}La chemical shifts of $LaCl_3$ (1.01 mM in 10 mM HCl) as a function of ρ at various temperatures. The points are experimental data and the solid lines are calculated.

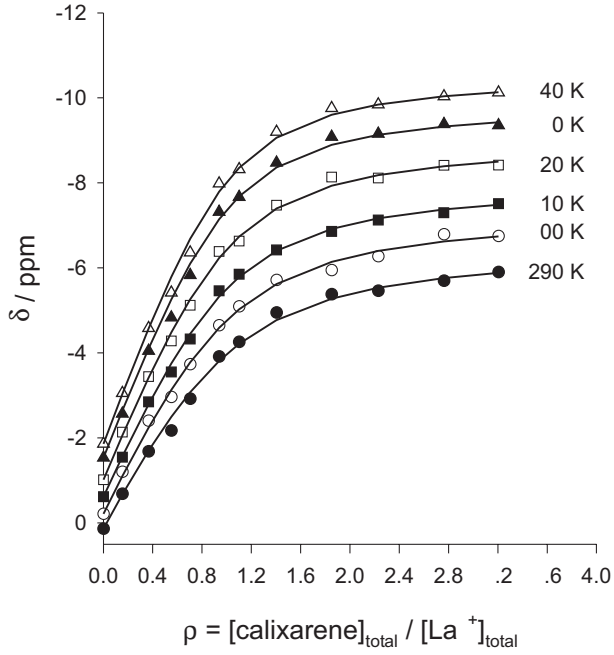

shifts to determine the stability constant of formation of the complex (*K*) and δ_B. The data are reported in Table 1. For example at 300 K, the value of *K* and δ_B obtained are (4.9 ± 0.7) × 10^3 and –7.3 ± 0.2 ppm, respectively. From the van't Hoff plot, a standard enthalpy ($\Delta_r H°$) of 11.0 ± 0.5 kJ mol^{-1} and a standard entropy ($\Delta_r S°$) of 108 ± 2 J K^{-1} mol^{-1} were obtained for the formation of the complex.

The ^{139}La NMR linewidths increased with an increase of the calixarene concentration. For values of ρ higher than 1, it tended to reach a plateau, as shown in Fig. 3. For example, at 290 K, the linewidth varied from 122 Hz (at ρ = 0) to 385 Hz (at ρ = 3.21). Similar to the chemical shift, the observed linewidths are the population average of the linewidth of the two sites, free and complexed La(III) of eq. [1]. They are described by eq. [4].

$$[4] \quad (\Delta\nu_{1/2})_{observed} = (\Delta\nu_{1/2})_A \times ([La^{3+}]/[La^{3+}]_{total}) + (\Delta\nu_{1/2})_B \times ([(La,C)^-]/[La^{3+}]_{total})$$

A non-linear regression, based on a 1:1 stoichiometry model mentioned above, was applied to the observed linewidths. The linewidth of the complex $(\Delta\nu_{1/2})_B$ and the equilibrium constant of formation (*K*) were determined (Table 1). At 300 K, the value of *K* was (11 ± 3) × 10^3, compared to (4.9 ± 0.7) × 10^3 obtained from the evolution of the chemical shift with ρ. This difference can be attributed to the errors characterizing the linewidth, due to the low concentrations of the solutions of La(III) (1 mM), and to the large broadening of the peak. The standard enthalpy and entropy of formation were 10 ± 2 kJ mol^{-1} and 110 ± 5 J K^{-1} mol^{-1}, respectively. These values were similar to those obtained from the chemical shift analysis. The data were also analysed by using the values of *K* obtained from the chemical shift analysis. A good fit was then observed, as shown in Fig. 3, and the linewidths of the complex were in the same order of magnitude as the ones obtained when *K* was varied (Table 1).

Discussion

The ^{139}La NMR data are consistent with the formation of a 1:1 complex between La(III) and *p*-sulfonatocalix[4]arene in acidic medium (pH 2.0). The method leads to the determination of the stability constant *(K)*, the standard enthalpy $\Delta_r H°$), and the standard entropy ($\Delta_r S°$) of complexation. It was reported previously (12) that the counter anion does not actively participate in the complexation process, since the thermodynamic parameters do not depend on the nature of the counter anion (Table 2). Table 2 shows also that the standard enthalpy ($\Delta_r H°$ = 11.0 ± 0.5 kJ mol^{-1}) and entropy ($\Delta_r S°$ = 108 ± 2 J K^{-1} mol^{-1}), obtained by NMR, are in good agreement with the ones measured by calorimetry, 9.2 ± 0.1 kJ mol^{-1} and 112 ± 1 J K^{-1} mol^{-1}, respectively (12).

The complexation of lanthanide cations by *p*-sulfonatocalix[4]arene was studied by Shinkai and co-workers (11) in alkaline media (pH 11.7). It was shown that 1:2 Ln(III)–calixarene complexes are formed. Stability constants were determined from pH-titration methods, giving at 25°C a log *K* value of 19.26 in a 0.1 M ionic strength in the case of La(III). In basic medium (pH 11.7), the complex is formed from covalent bonding between the oxygen atoms of the phenolic groups and La(III), resulting in a high stability constant, while in this study, in acidic medium (pH 2.0), the driving forces are primarily electrostatic between the sulfonato groups and La(III) (12).

The stability constants obtained in this study are in the same order of magnitude as those reported for the complexation of *p*-sulfonatocalix[4]arene with choline derivatives and quaternary ammonium cations, in which case

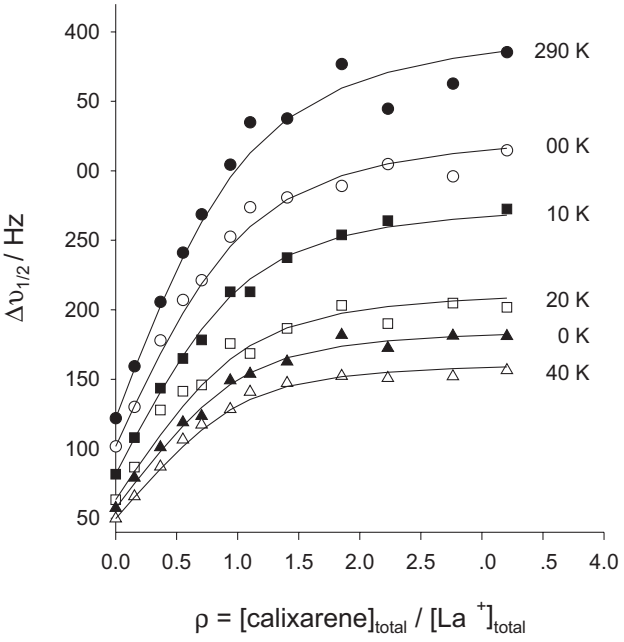
[a]In the non-linear regression, K and $(\Delta\nu_{1/2})_B$ are the parameters.
[b]In the non-linear regression, the values of K are the ones determined from the observed chemical shifts.

Fig. 3. ^{139}La NMR linewidths of $LaCl_3$ (1.01 mM in 10 mM HCl) in the presence of various quantities of *p*-sulfonatocalix-[4]arene at various temperatures. The points are experimental data and the solid lines are calculated. To fit the data, the values of the stability constants have been fixed to the ones obtained from the observed ^{139}La chemical shifts.



log K ranges from 4.0 to 5.6 at pH 7.3 (15) at 296 K. A value of 1.24×10^4 was obtained for the 1:1 complex formation of the *p*-sulfonatocalix[6]arene with the Auramine O dye at pH 7.0 (16).

The values of $\Delta_r H°$ and $\Delta_r S°$ indicate that the complexation is entropy driven. Moreover, the process is endothermic and so it is energetically unfavourable, while the complexation process is exothermic and enthalpy driven with a series of tetraalkyl ammonium cations (12) and with the trimethylanilinium cation and the *N*,*N*-dimethylindoaniline. The corresponding enthalpies are –26 ± 1 kJ mol^{-1} (17) and –29.3 ± 0.8 kJ mol^{-1} (18), respectively. It was reported that these two cations are inserted into the calixarene cavity. In the case of the trimethylanilinium cation, in acidic medium (pH 0.4), the complexation is driven by hydrophobic forces (19*a*), while in neutral medium (pH 7.3) the driving forces are both hydrophobic and electrostatic (19) and both the phenyl and the ammonium moiety can be inserted into the cavity of the calixarene. The complexation with *N*,*N*-dimethylindoaniline (Phenol Blue) involves electrostatic interactions with the sulfonato groups and hydrogen bonding with the OH groups which stabilize the charge separated excited state of the Phenol Blue (20). The complexation of La(III) by ribose (21) and glucitol (14*b*) have been studied also by ^{139}La NMR and negative enthalpy values of –12 and –10 ± 1 kJ mol^{-1} have been found, respectively. With these ligands, the complex results from interaction of the lone pairs of the hydroxyl oxygen atom with the positive charge of the lanthanum cation. In the case of this study, the complex results from electrostatic interactions between La(III) and the sulfonato groups. These interactions are characterized by positive values both of the enthalpy and the entropy. These positive values are mainly related to the partial desolvation of the cation and the sulfonato groups of the ligand, occurring upon complexation and leading to the release of water molecules (12).

The evolution of the ^{139}La NMR linewidth with the concentration of calixarene is similar to the variation of the chemical shifts, indicating also the formation of a 1:1 complex. The linewidth of the complex ($(\Delta\nu_{1/2})_B$) varies linearly with the inverse of the temperature (Fig. 4*a*) indicating the absence of a chemical exchange contribution to the transverse relaxation rate. Since a fast exchange is observed on the ^{139}La NMR time scale, this linear relationship confirms that the observed linewidths are the population average of the linewidths of the two sites, free and complexed La(III), of eq. [1]. A Lorentzian shape, showing that the extreme narrowing conditions are fulfilled, characterized all the observed ^{139}La NMR signals. The relaxation of ^{139}La is purely quadrupolar and the transverse relaxation time is given by eq. [5] (22, 23).

$$[5] \qquad T_2^{-1} = \pi\,(\Delta\nu)_{1/2} = 2\pi^2/49\chi^2\tau_c$$

where χ is the quadrupolar coupling constant and τ_c is the correlation time.

According to the Debye–Stokes–Einstein relationship (24), τ_c is proportional to the volume of the reorienting entity. In aqueous solution, the La(III) cation is coordinated by nine water molecules (25). The molecular volume of $La(H_2O)_9^{3+}$ is 2.68×10^{-28} m^3 (26), which corresponds to an effective radius estimated to be 4 Å. The plot of $(\Delta\nu_{1/2})_B$ as a function of the linewidth of the uncomplexed cation obtained at different temperatures is a linear plot with a slope of 3.37 ± 0.03 (Fig. 4*b*). It is reasonable to assume that the viscosity of the solution in the presence and in the absence of calixarene is in the same order of magnitude, since the initial concentration of La(III) is weak. The χ values are supposed

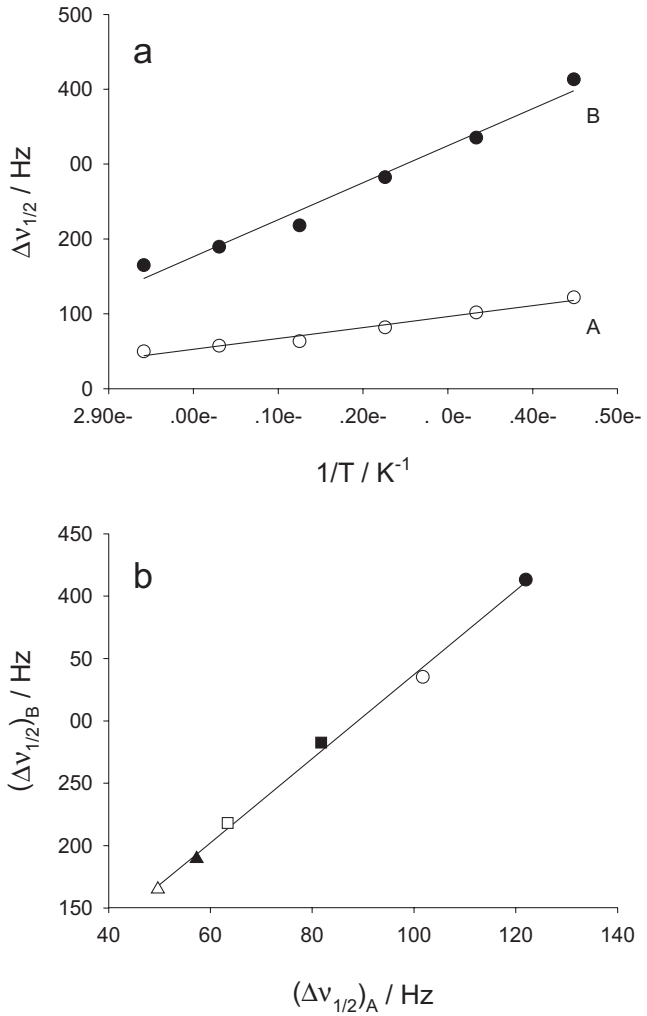
Table 2. Thermodynamic parameters of the complexation of La^{3+} with the *p*-sulfonatocalix[4]arene from NMR and microcalorimetric studies (12) at 300 K.

Compound	Method	log *K*	$\Delta_r H°$ (kJ mol^{-1})	$\Delta_r S°$ (J K^{-1} mol^{-1})
$LaCl_3$	Microcalorimetry[a]	4.23 ± 0.05	9.2 ± 0.1	112 ± 1
$La(NO_3)_3$	Microcalorimetry[a]	4.23 ± 0.09	8.5 ± 0.2	109 ± 2
$LaCl_3$	^{139}La NMR	3.7 ± 0.1[b]	11.0 ± 0.5[b]	108 ± 2[b]

[a]Reference 12.
[b]Obtained from the evolution of the chemical shifts.

Fig. 4. (*a*) ^{139}La NMR linewidths of the uncomplexed (A) and complexed (B) La(III) as a function of 1/*T*. (*b*) ^{139}La NMR linewidths of the complexed La(III) as a function of the ^{139}La NMR linewidths of the uncomplexed La(III) obtained at various temperatures: 290 K (●), 300 K (○), 310 K (■), 320 K (□), 330 K (▲), 340 K (△).



to be similar in the case of the complex and solvated cations. Under these two assumptions, eq. [6] gives the slope of the plot given in Fig. 4*b*.

$$[6] \quad \text{Slope} = ((\Delta\nu)_{1/2})_B / ((\Delta\nu)_{1/2})_A \approx (\tau_c)_B/(\tau_c)_A \approx (a^3)_B/(a^3)_A$$

On the basis of eq. [6], the effective radius of the complex is estimated to be approximately 6 Å, which is in good agreement with the formation of a 1:1 complex and consequently the formation of a 8:6 complex (or of other aggregates) as observed in the solid state (10) can be excluded. The size of the effective radius of La(III) undergoes an increase of 50% upon complexation. The complexation of trivalent lanthanides by CMPO-like calixarenes was studied by ^{1}H NMR in $CDCl_3$ (27). The radii of the uncomplexed calixarene and of the calixarene complexed by La(III) were calculated to be 9.5 and 13.2 Å, respectively, showing an increase of 40%. It is worthwhile to note that the reasonable increase of the radius of La(III) upon complexation confirms the assumption about the similarity between the quadrupolar coupling constant (χ) of the solvated and the complexed cations.

A crystal was obtained from $LaCl_3$ and *p*-sulfonatocalix[4]arene solutions and was analysed by X-ray crystallography (10). Assimilating the calix[4]arene to a sphere, its radius was estimated to be 5.9 Å. This value is similar to that of the radius of the La(III)–*p*-sulfonatocalix[4]arene complex (6 Å) obtained by ^{139}La NMR. This result indicates that the ligand belongs to the inner sphere of coordination of the La(III) cation and that, upon complexation, some molecules of water are replaced by some sulfonato groups.

In conclusion, in acidic aqueous solution, the complex formed between La(III) and *p*-sulfonatocalix[4]arene is a 1:1 complex as shown by ^{139}La NMR and previously by microcalorimetry. The complexation process is characterized by positive enthalpy and entropy values; it is entropy driven. This results from the replacement of water molecules of the hydrated cation by sulfonato groups of the ligand, engaged into electrostatic interactions with La(III). The 1:1 complex formed in aqueous solution can be considered as the first step in the formation of higher stoichiometry complexes leading to the structure observed in the solid state (10).

Acknowledgment

The Natural Sciences and Engineering Research Council of Canada (NSERC) is gratefully acknowledged for a research grant. Dr Glenn Facey is thanked for his help in recording the NMR spectra.

Synthesis of new fluorophores derived from monoazacrown ethers and coumarin nucleus

Ernesto Brunet, Pablo García-Losada, Juan-Carlos Rodríguez-Ubis, and Olga Juanes

Abstract: New ionophores derived from azacrown ethers attached to coumarins have been synthesized and characterized. The alkaline-earth complexes of these new ligands were studied from their UV–vis, NMR, and fluorescence data. Some systems displayed bathochromic shifts and fluorescence decreases upon complexation with Ca^{2+} that may make them useful signaling devices of this metal.

Key words: alkaline earth, emission, molecular modeling.

Résumé : On a synthétisé et caractérisé des nouveaux ionophores dérivés d'éthers aza-couronnes attachés à des coumarines. On a étudié les données de spectroscopie UV–vis, de RMN et de fluorescence des complexes de ces nouveaux ligands avec des métaux alcalinoterreux. Dans quelques systèmes, on observe des déplacements bathochromes et une diminution de la fluorescence lors de la complexation avec du Ca^{2+}; cette propriété peut les rendre utiles dans les appareils de détection de ce métal.

Mots clés : alcalinoterreux, émission, modelage moléculaire.

[Traduit par la Rédaction]

Introduction

The coumarin nucleus has been the focus of our recent research concerning the design of photoactive and luminescence probes (1). Coumarins are interesting heterocycles because of their photochemical and photophysical properties (2), leading to numerous industrial and laser dye applications (3). It is well known that coumarins increase their dipolar moment when excited. Albeit the change can be as large as 6 D in some cases, it has been argued that this is too low a variation to support true internal charge transfer (ICT) species in the excited state. Semi-empirical calculations (4) support that it is more likely that the charge separated resonance forms depicted in Fig. 1 have simply a superior contribution in the excited state. Whatever the reason, excitation of coumarin chromophore increases the electron density of its carbonyl groups, this increase being higher when X (Fig. 1) is an effective electron donor as R_2N. Therefore, the interaction of the carbonyl groups of an excited 3-acylcoumarin with metal cations coupled with the presence of an additional cationic receptor might constitute a good signaling device, provided significant selectivity is attained.

In previous work (5), we investigated the behaviour of 3-aroylcoumarins **1** (Fig. 2) towards alkaline earth cations. While compound **1b** (15-crown-5 derivative) displayed small, similar bathochromic shifts in its UV–vis spectra for the studied cations and, therefore, no selectivity, **1c** (18-crown-6 derivative) and especially **1a** (ethylenedioxa derivative) (6) suffered quite a large red shift (+48 nm) only when complexed to Mg^{2+}.

The conduct of **1a** suggested that the carbonyl groups were paramount for the chelation of the metal, the charge–radius ratio of Mg^{2+} being the best fitted within alkaline earth metals, and that only the 15-crown-5 was able to interfere with them. We thus planned the relocation of crowns relative to the 3-acylcoumarin chromophore for them to cooperate, not compete, to obtain different selectivity in cation recognition (7). In this work we report the synthesis of the ligands **2**–**4** (Fig. 2), in which crown ethers are attached to the 3-position of coumarins through a flexible alkoxycarbonyl spacer. The alkaline-earth complexes of these new ligands were studied from their UV–vis (Table 1), ^{1}H NMR (Table 2), and fluorescence data (Table 3).

Results and discussion

Synthesis precious

Preparation of **2**–**4** were performed in four or five steps from the corresponding 4-substituted salicylaldehyde by means of Knoevenagel condensation with malonic acid as the key step (Scheme 1). This reaction took place with moderate yields except in the case of R = NEt_2, in which it was necessary to use diethyl malonate and hence the additional hydrolysis of the resulting ethyl ester. Subsequent treatment with oxalyl chloride led us to the acyl chloride that then re-

acted with the hydroxyethyl azacrown to afford the final compounds in 45–50% yield.

UV–vis and ^{1}H NMR data

Ligands **2**, **3a**, and **3b** formed complexes of 1:1 stoichiometry with alkaline earth salts as determined by UV–vis and ^{1}H NMR (CD_3CN) titrations. No spectral variations were observed after addition of 1 equiv of metal.

Table 1 and Fig. 3 show that the larger bathochromic shifts occurred for the Et_2N derivatives **4** as expected (vide supra, Fig. 1) but, interestingly, with Ca^{2+} (to a lower extent with Ba^{2+}) and not with Mg^{2+}, in contrast to compounds **1** and other related compounds reported in the literature (8). This sizable red shift indicates that the metal cation closely interacts with the chromophore.

The relatively large deshielding of crown ether NMR proton signals (cf. Table 2) displayed by **4a** when titrated with Ca^{2+}, demonstrates the cation–crown interaction. Besides, the protons of the coumarin ring of **4a** also bear a similar deshielding with Ca^{2+} to that suffered by **1** with Mg^{2+}, where the latter can only interact with the carbonyl groups of the 3-aroylcoumarin. This fact and UV–vis data strongly suggest the carbonyl–crown cooperation in Ca^{2+} binding. Molecular modeling at the ZINDO/1 semi-empirical level predicts relatively stable structures where both the chromen carbonyl and ester groups may participate in the chelation to Ca^{2+} (Fig. 4).

Emission spectra

Only compounds **3** and **4** (**a**, **b**) were fluorescent. Table 3 summarizes the emission parameters of the studied compounds. Compounds **3a** and **3b** showed a slight or moderated increase of fluorescence. The case of complexes **4a** and **4b** with calcium is noteworthy, as they displayed extinction of fluorescence (up to 54%). In general, the presence of the metals should provide new pathways for collisional or static quenching of emission, which might be enhanced if the chromophore and the crown are close and **4b** gives the best host–guest fit.

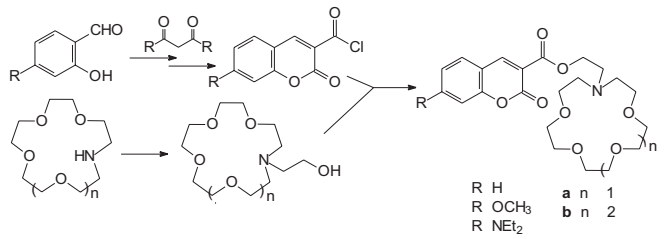
2b	288	+1	+7	+6
3b	345	+2	+9	+6
4b	418	+4	+20	+15

Scheme 1. Reaction pathway.



The variation of Stokes' shifts (SS) upon complexation is even more interesting. This is a manifold phenomenon that has been largely discussed in related compounds (9). After excitation, the molecule relaxes in a lapse of ps to the lowest vibrational level of the first excited electronic state (S_1). This relaxation is so fast that it usually occurs before measurements can be made on the system. (10) The lowest S_1 state generally has a longer lifetime that allows changes in the local environment, which may even involve ample conformational movements. Therefore, if excitation increases the molecular dipole moment, as largely occurs in coumarins (11), both reorganization of the solvent and a conformational change may be involved to stabilize the excited state, hence making SS larger (12). These facts are summarized in Fig. 5.

Ligands **3** displayed larger SS as compared to **4**. Excitation should lead to less stable S_1 species in the case of **3** because the charge-separated resonance forms of Fig. 1 must be less stable when the positive charge develops on an OMe group rather than on a NEt_2 group. This increases the need of solvent relaxation by excited **3**, which thus suffers larger SS. On the other hand, the smallest SS were observed in all cases for the Ca^{2+} complexes, indicating that their excited states have the lowest requirement of extra stabilization either by solvation or conformational changes. This is compatible with the proposed cooperation between the crown and the coumarin, in which the metal plays part of the stabilization role to be performed by the solvent, interacting with the negative end of the charge-separated species. The cooperation between the crown and the coumarin imposes a certain rigidity impeding large conformational changes. The stronger the crown-mediated interaction between the coumarin and the metal, the higher the stabilization of the excited state, and hence, the smaller SS. This occurs for the **4b**·Ca^{2+} complex whose spectroscopic data and molecular modeling suggested the strongest coumarin–metal interaction of the studied compounds.

experimental error. All solvents were purified prior to their use. Alkaline earth perchlorates were purchased from Aldrich and used as received. IUPAC names were obtained from ChemWeb: http://cwgen.chemweb.com/autonom/autonomsearch.html.

Synthesis of alkakine earth complexes and absorption and emission measurements

The complexes were formed by addition of equimolecular amounts of the corresponding alkaline earth perchlorate salt in acetonitrile (1×10^{-2} M) to the coumarin solutions (3.2×10^{-5} M for absorption and 3.2×10^{-7} M for emission). Absorption–emission parameters were analyzed from the same spectroscopic grade solvent.

General methods

Synthesis of the 3-carboxycoumarin derivatives

The corresponding commercial salicylaldehyde (0.25 mmol) and malonic acid (0.25 mmol) were dissolved in 3 mL of ethanol. Aniline (3 drops) was added, and the mixture was stirred at room temperature (r.t.) for 48 h. Filtration of the cooled mixture yielded a solid which was triturated with water and then refluxed in 6 N HCl (5 mL) for 30 min. After cooling, a white solid formed which was filtered and washed with water yielding the 3-carboxycoumarin as analytically pure crystals. 3-Carboxycoumarines, precursors of **1** and **2**, were previously reported (13).

Synthesis of the 3-carbonyl chloride coumarin derivatives

To a mixture of the corresponding 3-carboxycoumarin derivative (1 mmol) and two drops of pyridine in dry toluene under argon was added oxalyl chloride (6 mmol). The reaction compounds were stirred for 48–72 h. The solvent was vacuum evaporated and the residue was triturated with diethyl ether to eliminate the oxalic acid. The solid was filtered off and the filtrate evaporated to yield the 3-carbonyl chloride derivative which was used immediately.

Synthesis of azacrown ethanol derivatives

A solution of 500 mg of the commercial azacrown (15/5 or 18/6) in 25 mL of ethanol, was cooled in an ice bath and 2 equiv of ethylene oxide were bubbled through. The resulting solution was heated to 80°C in an autoclave for 8 h. After vacuum solvent evaporation, the final product was obtained as an analytically pure oil.

Synthesis of the azacrown esters 2–4

To a solution of the azacrown derivative (1 mmol) in dry THF (25 mL) heated under reflux, was added dropwise a solution of the 3-carbonyl chloride (1.5 mmol) during a period of 5 h. The mixture was stirred at r.t. for 1 h. After vacuum solvent evaporation, the final product was isolated in the way indicated in each case.

Synthesis of precursors of compounds 2–4

2-(1,4,7,10-Tetraoxa-13-aza-cyclopentadec-13-yl)-ethanol

It was synthesized following the general method starting from commercial aza-15-crown-5 (2.28 mmol) and ethylene oxide (4.56 mmol). Yield: >98%. It was obtained as an analytically pure yellow oil. ^{1}H NMR ($CDCl_3$) δ: 3.6–3.7 (m, 12H, OCH_2CH_2 O), 3.55 (t, 4H, J = 7.2 Hz, OCH_2CH_2N), 3.50 (t, 2H, J = 7.2 Hz, CH_2OH), 2.75 (t, 4H, J = 7.2 Hz, OCH_2CH_2N), 2.65 (t, 2H, J = 7.2 Hz, NCH_2CH_2OH). ^{13}C NMR ($CDCl_3$) δ: 70.6, 70.3, 70.1, 69.9, 69.7 (OCH_2CH_2O),

59.3 (CH_2OH), 57.9 (NCH_2CH_2OH), 55.5 (OCH_2CH_2N). MS (L-SIMS+): 308.2 ($[M + H]^+$, 52%).

2-(1,4,7,10,13-Pentaoxa-16-aza-cyclooctadec-16-yl)-ethanol

It was synthesized following the general method starting from commercial aza-18-crown-6 (2.28 mmol) and ethylene oxide (4.56 mmol). Yield: >98%. It was obtained as an analytically pure light brown oil. ^{1}H NMR ($CDCl_3$) δ: 3.6–3.7 (m, 16H, OCH_2CH_2 O), 3.55 (t, 4H, J = 7.2 Hz, OCH_2CH_2N), 3.50 (t, 2H, J = 7.2 Hz, CH_2OH), 2.75 (t, 4H, J = 7.2 Hz, OCH_2CH_2N), 2.65 (t, 2H, J = 7.2 Hz, NCH_2CH_2OH).^{13}C NMR ($CDCl_3$) δ: 70.5, 70.2, 70.0, 69.7 (OCH_2CH_2O), 59.0 (CH_2OH), 57.8 (NCH_2CH_2OH), 55.1 (OCH_2CH_2N). MS (L-SIMS+): 264.2 ($[M + H]^+$, 47%).

*7-Diethylamino-2-oxo-2*H*-chromene-3-carboxylic acid ethyl ester*

7-Diethylamine salicylaldehyde (0.52 mmol) and diethylmalonate (0.52 mmol) were dissolved in 20 mL of ethanol. Piperidine (3 drops) was added, and the mixture was refluxed for 24 h. After cooling the mixture, the solvent was evaporated and the residue was purified by column chromatography (hexane–ethyl acetate, 4:1), yielding a yellow oil. Yield: 80%. ^{1}H NMR ($CDCl_3$) δ: 8.45 (s, 1H, H-4), 7.30 (d, 2H, J = 8.9 Hz, H-5), 6.55 (dd, 1H, J = 2.5, 8.9 Hz, H-6), 6.40 (d, 1H, J = 2.5 Hz, H-8), 4.30 (q, 2H, J = 7.0 Hz, $CO_2CH_2CH_3$), 3.40 (q, 4H, J = 7.1 Hz, NCH_2CH_3), 1.30 (t, 3H, J = 7.0 Hz, $CO_2CH_2CH_3$), 1.15 (t, 6H, J = 7.1 Hz, NCH_2CH_3). ^{13}C NMR ($CDCl_3$) δ: 164.2 (C-7), 158.4 (C-2), 158.2 (CO), 152.8 (C-9), 149.1 (C-4), 130.9 (C-5), 109.4 (C-6), 108.9 (C-3), 107.6 (C-10), 96.6 (C-8), 61.1 ($CO_2CH_2CH_3$), 45.0 (NCH_2CH_3), 14.3 ($CO_2CH_2CH_3$), 12.3 (NCH_2CH_3). MS (L-SIMS+): 290.2 ($[M + H]^+$, 24%).

*7-Diethylamino-2-oxo-2*H*-chromene-3-carboxylic acid*

The previous compound (0.23 mmol) was dissolved in water and 0.23 mL of 1 M KOH solution was added. The resulting mixture was stirred for 20 h. After addition of 10% HCl until pH = 2, the solid was filtered and washed with water, yielding the analytically pure carboxycoumarine derivative. Yield: 65%; mp 214 to 215°C. ^{1}H NMR ($CDCl_3$) δ: 8.60 (s, 1H, H-4), 7.45 (d, 2H, J = 8.9 Hz, H-5), 6.70 (dd, 1H, J = 2.3, 8.9 Hz, H-6), 6.50 (d, 1H, J = 2.3 Hz, H-8), 3.50 (q, 4H, J = 7.0 Hz, NCH_2CH_3, 1.25 (t, 6H, J = 7.0 Hz, NCH_2CH_3). ^{13}C NMR ($CDCl_3$) δ: 165.2 (C-7), 164.6 (CO), 157.8 (C-2), 153.7 (C-9), 150.0 (C-4), 131.7 (C-5), 110.7 (C-6), 108.2 (C-3), 104.3 (C-10), 96.2 (C-8), 44.9 (NCH_2CH_3), 12.3 (NCH_2CH_3). MS (L-SIMS+): 261.2 ($[M + H]^+$, 31%). Anal. calcd. for $C_{14}H_{15}NO_4$: C 64.36, H 5.79, N 5.36; found: C 64.32, H 5.78, N 5.40.

*2-Oxo-2*H*-chromene-3-carboxylic acid 2-(1,4,7,10-tetraoxa-13-aza-cyclopentadec-13-yl)-ethyl ester (**2a**)*

It was synthesized following the esterification general method starting from the 15-crown-5 derivative (0.325 mmol) and the corresponding 3-carbonyl chloride coumarin (0.48 mmol). The reaction mixture was dissolved in water and extracted with CH_2Cl_2. The aqueous phase was adjusted to pH 7 with a saturated solution of $NaHCO_3$ and extracted with ethyl acetate. Solvent evaporation of the organic layers yielded **2a** as a light brown oil. Yield: 66%. ^{1}H NMR ($CDCl_3$) δ: 8.55 (s, 1H, H-4), 7.75–7.65 (m, 2H, H-5, H-7), 7.35–7.25 (m, 2H, H-8, H-6), 4.42 (t, 2H, J = 7.2 Hz, CO_2CH_2), 3.65–3.45 (m, 16H, OCH_2CH_2O), 2.95 (t, 2H, J = 7.2 Hz, $CO_2CH_2CH_2N$), 2.85 (t, 4H, J = 7.2 Hz, OCH_2CH_2N). ^{13}C NMR ($CDCl_3$) δ: 162.5 (C-2), 155.1 (C-9), 153.9 (CO), 148.7 (C-7), 129.4 (C-5), 128.6 (C-10), 124.7 (C-6), 122.2 (C-3), 116.8 (C-8), 70.9–70.1 (CH_2O), 64.1 (CH_2CO_2), 54.9 (NCH_2CH_2), 54.0 (OCH_2CH_2N). MS (L-SIMS+): 436.2 ($[M + H]^+$, 21%), 458.2 ($[M + Na]^+$, 4%).

*2-Oxo-2*H*-chromene-3-carboxylic acid 2-(1,4,7,10,13-pentaoxa-16-aza-cyclooctadec-16-yl)-ethyl ester (**2b**)*

It was synthesized following the esterification general method starting from the 18-crown-6 derivative (0.325 mmol) and the corresponding 3-carbonyl chloride coumarin (0.48 mmol). The reaction mixture was dissolved in water and extracted with CH_2Cl_2. The aqueous phase was adjusted to pH 7 with a saturated solution of $NaHCO_3$ and extracted with ethyl acetate. Solvent evaporation of the organic layers yielded **2b** as a brown oil. Yield: 73%. ^{1}H NMR ($CDCl_3$) δ: 8.50 (s, 1H, H-4), 7.65–7.55 (m, 2H, H-5, H-7), 7.35–7.25 (m, 2H, H-8, H-6), 4.40 (t, 2H, J = 7.2 Hz, CO_2CH_2), 3.65–3.45 (m, 20H, OCH_2CH_2O), 2.95 (t, 2H, J = 7.2 Hz, $CO_2CH_2CH_2N$), 2.85 (t, 4H, J = 7.2 Hz, OCH_2CH_2N). ^{13}C NMR ($CDCl_3$) δ: 162.7 (C-2), 156.4 (C-9), 155.0 (CO), 148.7 (C-7), 129.4 (C-5), 128.7 (C-10), 124.7 (C-6), 124.3 (C-3), 116.5 (C-8), 70.6–70.1 (CH_2O), 63.6 (CH_2CO_2), 54.1 (NCH_2CH_2), 53.3 (OCH_2CH_2N). MS (L-SIMS+): 480.2 ($[M + H]^+$, 28%), 502.2 ($[M + Na]^+$, 8%).

*7-Methoxy-2-oxo-2*H*-chromene-3-carboxylic acid 2-(1,4,7,10-tetraoxa-13-aza-cyclopentadec-13-yl)-ethyl ester (**3a**)*

It was synthesized following the esterification general method starting from the 15-crown-5 derivative (0.28 mmol) and the corresponding 3-carbonyl chloride coumarin (0.42 mmol). The reaction mixture was dissolved in water and extracted with CH_2Cl_2. The aqueous phase was adjusted to pH 7 with a saturated solution of $NaHCO_3$ and extracted with ethyl acetate. Solvent evaporation of the organic layers yielded a solid which was triturated with diethyl ether to give **3a** as a light brown oil. Yield: 54%. ^{1}H NMR ($CDCl_3$) δ: 8.50 (s, 1H, H-4), 7.50 (d, 2H, J = 8.6 Hz, H-5), 6.85 (dd, 1H, J = 2.5, 8.6 Hz, H-6), 6.75 (d, 1H, J = 2.5 Hz, H-8), 4.40 (t, 2H, J = 7.2 Hz, $CO_2CH_2CH_2N$), 3.95 (s, 3H, OCH_3), 3.70–3.50 (m, 16H, OCH_2CH_2O), 3.00 (t, 2H, J = 7.2 Hz, $COOCH_2CH_2N$), 2.85 (t, 4H, J = 7.2 Hz, OCH_2CH_2N). ^{13}C NMR ($CDCl_3$) δ: 165.2 (C-2), 163.3 (C-9), 157.5 (CO), 149.7 (C-4), 149.7 (C-7), 128.4 (C-5), 127.6 (C-10), 124.7 (C-6), 122.2 (C-3), 116.5 (C-8), 70.9–70.2 (CH_2O), 64.5 (CH_2CO_2), 55.9 (CH_3O), 54.8 (NCH_2CH_2), 54.2 (OCH_2CH_2N). MS (L-SIMS+): 466.3 ($[M + H]^+$, 26%), 488.3 ($[M + Na]^+$, 4%), 504.3 ($[M + K]^+$, 3%).

*7-Methoxy-2-oxo-2*H*-chromene-3-carboxylic acid 2-(1,4,7,-10,13-pentaoxa-16-aza-cyclooctadec-16-yl)-ethyl ester (**3b**)*

It was synthesized following the esterification general method starting from the 18-crown-6 derivative (0.28 mmol) and the corresponding 3-carbonyl chloride coumarin (0.42 mmol). The reaction mixture was dissolved in water and extracted with CH_2Cl_2. The aqueous phase was adjusted to pH 7 with a saturated solution of $NaHCO_3$ and extracted with ethyl acetate. 3b as a light brown oil. Yield: 52%. ^{1}H NMR ($CDCl_3$) δ: 8.50 (s, 1H, H-4), 7.50 (d, 2H, *J* = 8.6 Hz, H-5), 6.85 (dd, 1H, *J* = 2.5, 8.6 Hz, H-6), 6.75 (d, 1H, *J* = 2.5 Hz, H-8), 4.40 (t, 2H, *J* = 7.2 Hz, $CO_2CH_2CH_2N$), 3.85 (s, 3H, OCH_3), 3.70–3.50 (m, 20H, OCH_2CH_2O), 2.95 (t, 2H, *J* = 7.2 Hz, $COOCH_2CH_2N$), 2.85 (t, 4H, *J* = 7.2 Hz, OCH_2CH_2N). ^{13}C NMR ($CDCl_3$) δ: 165.2 (C-2), 155.8 (C-9), 155.0 (CO), 148.7 (C-4), 134.2 (C-7), 129.4 (C-5), 128.6 (C-10), 124.7 (C-6), 122.2 (C-3), 116.8 (C-8), 70.9–70.1 (CH_2O), 63.5 (CH_2CO_2), 56.0 (CH_3O), 54.9 (NCH_2CH_2), 54.0 (OCH_2CH_2N). MS (L-SIMS+): 510.4 ($[M + H]^+$, 30%), 532.4 ($[M + Na]^+$, 6%), 548.3 ($[M + K]^+$, 8%).

*7-Diethylamino-2-oxo-2*H*-chromene-3-carboxylic acid 2-(1,4,7,10-tetraoxa-13-aza-cyclopentadec-13-yl)-ethyl ester (**4a**)*

It was synthesized following the esterification general method starting from the 15-crown-5 derivative (0.32 mmol) and the corresponding 3-carbonyl chloride coumarin (0.49 mmol). The reaction mixture was dissolved in water and extracted with CH_2Cl_2. The aqueous phase was adjusted to pH 7 with a saturated solution of $NaHCO_3$ and extracted with ethyl acetate. The organic layer was washed with 10% HCl, 20% $NaHCO_3$, and water. Solvent evaporation gave **4a** as a dark brown oil. Yield: 45%. ^{1}H NMR ($CDCl_3$) δ: 8.40 (s, 1H, H-4), 7.30 (d, 2H, *J* = 8.9 Hz, H-5), 6.55 (dd, 1H, *J* = 2.5, 8.9 Hz, H-6), 6.40 (d, 1H, *J* = 2.5 Hz, H-8), 4.40 (t, 2H, *J* = 7.2 Hz, $CO_2CH_2CH_2N$), 3.74–3.51 (m, 16H, OCH_2CH_2O), 3.40 (q, 4H, *J* = 7.1 Hz, NCH_2CH_3), 2.92 (t, 2H, *J* = 7.2 Hz, $COOCH_2CH_2N$), 2.85 (t, 4H, *J* = 7.2 Hz, OCH_2CH_2N), 1.30 (t, 6H, *J* = 7.1 Hz, NCH_2CH_3). ^{13}C NMR ($CDCl_3$) δ: 164.0 (C-7), 158.4 (C-2), 158.1 (CO), 152.8 (C-9), 149.3 (C-4), 131.1 (C-5), 111.6 (C-6), 109.4 (C-3), 104.3 (C-10), 96.8 (C-8), 70.3–70.0 (CH_2O), 63.5 (CH_2CO_2), 55.3 (NCH_2CH_2), 54.1 (OCH_2CH_2N), 44.9 (NCH_2CH_3), 12.3 (NCH_2CH_3). MS (L-SIMS+): 507.1 ($[M + H]^+$, 20%), 529.1 ($[M + Na]^+$, 8%).

*7-Diethylamino-2-oxo-2H-chromene-3-carboxylic acid 2-(1,4,7,10,13-pentaoxa-16-aza-cyclooctadec-16-yl)-ethyl ester (**4b**)*

It was synthesized following the esterification general method starting from the 18-crown-6 derivative (0.32 mmol) and the corresponding 3-carbonyl chloride coumarin (0.49 mmol). The reaction mixture was dissolved in water and extracted with CH_2Cl_2. The aqueous phase was adjusted to pH 7 with a saturated solution of $NaHCO_3$ and extracted with ethyl acetate. The organic layer was washed with 10% HCl, 20% $NaHCO_3$, and water. Solvent evaporation gives **4b** as a dark brown oil. Yield: 51%. ^{1}H NMR ($CDCl_3$) δ: 8.40 (s, 1H, H-4), 7.30 (d, 2H, *J* = 8.9 Hz, H-5), 6.55 (dd, 1H, *J* = 2.3, 8.9 Hz, H-6), 6.40 (d, 1H, *J* = 2.3 Hz, H-8), 4.40 (t, 2H, *J* = 7.2 Hz, $CO_2CH_2CH_2N$), 3.74–3.51 (m, 20H, OCH_2CH_2O), 3.40 (q, 4H, *J* = 7.1 Hz, NCH_2CH_3), 3.05 (t, 2H, *J* = 7.2 Hz, $COOCH_2CH_2N$), 2.95 (t, 4H, *J* = 7.2 Hz, OCH_2CH_2N), 1.30 (t, 6H, *J* = 7.1 Hz, NCH_2CH_3). ^{13}C NMR ($CDCl_3$) δ: 164.0 (C-7), 158.4 (C-2), 158.1 (CO), 152.8 (C-9), 149.3 (C-4), 131.1 (C-5), 111.2 (C-6), 109.4 (C-3), 104.3 (C-10), 96.8 (C-8), 70.3–70.0 (CH_2O), 63.5 (CH_2CO_2), 55.3 (NCH_2CH_2), 54.1 (OCH_2CH_2N), 44.9 (NCH_2CH_3), 12.3 (NCH_2CH_3). MS (L-SIMS+): 551.4 ($[M + H]^+$, 25%), 573.3 ($[M + Na]^+$, 9%).

Conclusion

Several new ionophores derived from coumarins bearing aza-crown ethers attached to the 3-position by means of an ethylenoxycarbonyl spacer have been synthesized. We observed that the systems with strong electron donors at the 7-position displayed the largest bathochromic shifts upon complexation with Ca^{2+} but they were irresponsive to Mg^{2+}. NMR data, molecular modeling, and SS of emission strongly suggest cooperation between the chromen nucleus and the crowns in their binding to Ca^{2+} that was accompanied with a relatively large extinction of fluorescence. These facts may make the **4** compounds as leads for useful signaling devices of Ca^{2+} without interference from Mg^{2+}.

Isentropic compressibility and viscosity of aqueous and methanolic lithium chloride solutions

Abdul Wahab and Sekh Mahiuddin

Abstract: Densities, speeds of sound, and viscosities of aqueous and methanolic lithium chloride solutions were measured as functions of concentration, m (mol kg^{-1}) ($0.3911 \leq m \leq 19.47$) and temperature ($273.15 \leq T \leq 323.15$ K). Measured values of the density, speeds of sound, and viscosity agree well with previously reported data. The isentropic compressibility isotherms for the aqueous solutions converge at a particular concentration, in the temperature range of the study, providing crucial information regarding the solvation behaviour of the ions. However, for the methanol solutions, the isentropic compressibility isotherms decrease smoothly with concentration and converge on extrapolation. Anion solvation controls the viscosity processes at low temperatures whereas cation solvation controls the same at high temperatures. Total primary solvation numbers of lithium chloride in water and methanol were estimated to be 6.0 and 1.9, respectively.

Key words: lithium chloride, speeds of sound, viscosity, isentropic compressibility, solvation number.

Résumé : On a mesuré les densités, vitesses du son et viscosités de solutions aqueuses et méthanoliques de chlorure de lithium en fonction de la concentration, m (mol kg^{-1}) ($0{,}3911 \leq m \leq 19{,}47$) et de la température ($273{,}15 \leq T \leq 323{,}15$ K). Les valeurs mesurées pour les densités, les vitesses du son et les viscosités sont en bon accord avec les données rapportées antérieurement. Dans le domaine des températures étudiées, les isothermes de compressibilité isentrope pour les solutions aqueuses convergent à une concentration particulière, fournissant de l'information cruciale concernant le comportement des ions vis-à-vis de la solvatation. Toutefois, pour les solutions dans le méthanol, les isothermes de compressibilité isentrope diminue de façon régulière avec la concentration et elles convergent par extrapolation. La solvatation de l'anion contrôle les processus de viscosité à basses températures alors que la solvatation de l'anion la contrôle à températures élevées. Les nombres totaux de solvatation primaire du chlorure de lithium dans l'eau et dans le méthanol sont évalués respectivement à 6,0 et 1,9.

Mots clés : chlorure de lithium, vitesses du son, viscosité, compressibilité isentrope, nombre de solvatation.

Introduction

The acoustic and transport behaviour of electrolytes in aqueous and nonaqueous media provide crucial information on the ion solvation in different concentration regions, which are of immense importance to the technologist and theoretician. The structure and existence of free ions, solvated ions, and ion pairs depend on the concentration regions (1).

A number of experimental techniques and theoretical approaches (2, 3) have been employed to study the solvation structure and dynamics of ions in aqueous and nonaqueous media. But the experimental data, obtained by using different techniques, have led to results with large variations regarding solvation number of a particular ion. The reported primary hydration number of lithium ion (2) has a wide distribution between three and seven. Howell and Neilson (4) showed a concentration dependence of hydration numbers, for example, 3.2 at 14 mol kg^{-1} and ~6.5 at 1 mol kg^{-1}, for Li^+ by using the neutron diffraction method. However, the most frequently proposed hydration number of the lithium ion is either 4 obtained from ab initio calculations (3, 5), MD simulations (6), Raman spectra (7, 8), and neutron (9) and X-ray (10) diffraction, or 6 obtained from simulations (11, 12) and X-ray (13) and neutron scattering (4) studies. Recently, Zavitsas (14) made use of freezing point depression to estimate the hydration number of ions and for the Li^+ it is found to be 6.6 ± 0.6. Furthermore, in the system $LiCl{\cdot}nH_2O$, a complete hydration and a direct anion–cation interaction are reported when $n = 6$ and $n = 4$, respectively (15). Tao and Lindsay (16) investigated Brillouin and depolarized Rayleigh scattering of aqueous LiCl solutions and suggested a structural transition at ~9.4 mol kg^{-1}.

X-ray (17, 18) and neutron (19, 20) diffraction techniques showed essentially a hydration number of 6 for Cl^-. But computer simulation (2, 6, 12) results exhibit a wide distribution of primary hydration numbers of Cl^- from 4.9 to 8.5. Cummings et al. (19) observed that the hydration of Cl^- is essentially independent of counter ion by using the neutron diffraction technique. From MD simulations, Tanaka et al. (21) reported comparatively, a rigid geometrical arrangement of hydrated water molecules around Li^+ in contrast to a random distribution of water molecules around Cl^- in an almost saturated solution of LiCl. Yamanaka et al. (17) performed

X-ray diffraction studies and showed that the primary hydration shell of Li^+ becomes ordered at high temperatures whereas Cl^- tends to form a rigid hydration shell at low temperatures. Very recently, femtosecond mid-IR non-linear spectroscopic studies (22) have led to a firm conclusion that the hydration shell of Cl^- is rigid relative to that of the cation. From the above discussion it seems that the temperature and concentration are the decisive parameters for the flexible nature of the primary hydration shells of Li^+ and Cl^-.

From NMR measurements, Vogrin and Malinowski (23) reported a consistent solvation phenomena of LiCl in methanol and water media and found total solvation numbers of 4.5 ± 0.2 and 2.8 ± 0.4, in the respective solvents. Recent theoretical (24, 25) as well as experimental (26) studies suggest strikingly different solvation dynamics in methanol relative to water.

In earlier papers (27, 28), it was reported that the isentropic compressibility isotherms converge at a particular concentration because of the saturation of the primary solvation shell of an electrolyte resulting in a rigid structure. On the other hand, the ion–solvent and ion–ion interactions and equilibria in different concentration regions have an influence on transport properties. Therefore, in this paper, we report speeds of sound and viscosities of aqueous and methanolic lithium chloride solutions as functions of concentration and temperature.

Experimental

Lithium chloride (>99%, E. Merck, Darmstad, Germany) was recrystallized twice from double-distilled water and was kept in a vacuum desiccator over P_2O_5. Finally, lithium chloride was dried by heating at 120°C under vacuum before preparing solutions. Anhydrous methanol was prepared from A.R. grade methanol (>99.5%, Qualigens Fine Chemicals, Mumbai, India) as described elsewhere (29). All solutions were prepared by mass with ±0.2% accuracy. The lithium chloride concentrations were checked by gravimetric analysis using $AgNO_3$.

Densities (ρ) of all solutions were measured with an accuracy of ±0.01% by using a single-stem graduated pycnometer of ~9 cm^3 capacity. The pycnometer was calibrated by using double-distilled water. Speeds of sound (u) in aqueous and methanolic lithium chloride solutions were measured with an accuracy of ±0.1 m s^{-1} by using a variable path interferometer (multifrequency ultrasonic interferometer, M-83, Mittal Enterprises, New Delhi, India) at 2 MHz as described previously (27).

Viscosities (η) were measured with a Schott–Geräte AVS 310 unit equipped with micro Ubbelohde viscometers. Viscometers of different constants of 0.009595, 0.03004, 0.1126, and 0.3099 mm^2 s^{-2} were used to measure the efflux time in different concentration and temperature ranges. An average of five efflux times was used for viscosity calculations at each temperature. The experimental uncertainties in the viscosities were within ±0.5%.

All the measurements were performed as functions of concentration, m (mol kg^{-1}) ($0.3911 \leq m \leq 19.47$ and $0.6812 \leq m \leq 9.684$ for aqueous and methanolic lithium chloride solutions, respectively) and temperature ($273.15 \leq T \leq 323.15$ K). Thermostat types Schott–Geräte CT 1450, Lauda RLS 6D, or Julabo F32 HP was used to control the temperature of all the solutions within ±0.02 K.

Results and discussion

The experimental densities of aqueous and methanolic lithium chloride solutions were found to be linear functions of the temperature at a particular concentration. The values of the parameters of the density equation are given in Table 1. Figure 1 shows the isotherms of ρ vs. m at 298.15 K along with the literature data. The measured densities of aqueous lithium chloride solutions are in good agreement with the literature data (30–32) within ±0.4% at 298.15 K. The density values of methanolic solutions are comparable within ±0.5% with the reported data (33) at 287.65 K.

The measured values of speeds of sound in aqueous and methanolic lithium chloride solutions are collected in Table 1S (*Supplementary materials*).[2] The present values of the speeds of sound in aqueous lithium chloride solutions are comparable within ±0.5% with the reported values (34) at 298.15 K. We could not compare the speeds of sound values for the methanolic lithium chloride solutions because of a lack of literature data. However, the present isentropic compressibilities of methanolic lithium chloride solutions are ~2.6% higher than the reported values (35) at 298.15 K.

The isentropic compressibility (κ_s) values for aqueous and methanolic solutions were calculated by using the relationship

$$[1] \qquad \kappa_s = 1/u^2\rho$$

The isentropic compressibilities against concentration of aqueous and methanolic lithium chloride solutions are plotted in Figs. 2 and 3, respectively, at three temperatures. As earlier, an isothermal equation of the following form (27, 28)

$$[2] \qquad \kappa_s = a_1 + b_1 m + c_1 m^d$$

was used to fit the isentropic compressibilities over the entire concentration range. In eq. [2], a_1, b_1, and c_1 are the temperature-dependent parameters, d is a constant parameter, and m is the concentration in mol kg^{-1}. The least-squares fitted values of the parameters of eq. [2] are listed in Table 2. From Table 2 and Figs. 2 and 3, it is apparent that eq. [2] can reproduce the isentropic compressibilities within ±1.1% for aqueous lithium chloride; for methanolic lithium chloride solutions, it was within ±2.2%. It has been observed that the isentropic compressibility isotherms of aqueous lithium chloride solutions converge in the concentration range of 9.25–13.5 mol kg^{-1} in the temperature range of the study (Fig. 2).

Previous studies (15–17, 21) reveal contradictory views about the nature of the hydration sphere of Li^+ and Cl^-. Tanaka et al. (21) suggested a rigid geometrical arrangement of water molecules around the Li^+ against randomly arranged water molecules around the Cl^-. On the other hand, Yamanaka et al. (17) observed a flexible primary hydration sphere for Li^+ at low temperatures and an ordered arrange-

ment for Cl^- at supercooled and glassy states; they also showed that the hydration number of Li^+ decreases with the decrease in temperature (5.7 at 373 K and 3.5 at 138 K), whereas the hydration number for Cl^- increases with the lowering of temperature. The hydration numbers of Li^+ and Cl^- reported in the literature by several researchers using different techniques, for easy comparison, are summarized in Table 3.

It is evident from Fig. 2 that the lowest concentration of convergence of the isentropic compressibility isotherms is 9.25 mol kg^{-1}, at which the primary hydration shell of the solute is just saturated with $\kappa_{s,h} = 2.548 \times 10^{-10}$ Pa^{-1} (where $\kappa_{s,h}$ is the isentropic compressibility of the hydrated sphere). For the $LiCl{\cdot}nH_2O$ system, a full hydration of Li^+ and Cl^- has been reported (15) at $n = 6$ (9.25 mol kg^{-1}) from the neutron diffraction study. Tao and Lindsay (16) reported a possible structural transition in aqueous LiCl solution at around 9.4 mol kg^{-1} (Fig. 11 of ref. 16) and suggested that the charged ions cause polarization of water molecules in the primary hydration shell. Furthermore, a transition was also observed by Millero et al. (36) at 10.7 ± 0.7 mol kg^{-1} in the plot of $(u - u_0)/m$ vs. $m^{1/2}$, where u_0 is the speeds of sound of pure water and correlated the transition with the hydration structure of the cation. However, we found a transition at 8.8 ± 0.2 mol kg^{-1} in the $(u - u_0)/m$ vs. $m^{1/2}$ plot for the present system.

At 9.25 mol kg^{-1}, over the specified temperature range, all the water molecules were incorporated in the primary hydration shell of lithium chloride resulting in a rigid structure due to the strong and predominant ion–solvent interac-

Fig. 1. Plots of density (ρ) against molality (*m*) at 298.15 K for aqueous and methanolic lithium chloride solutions.

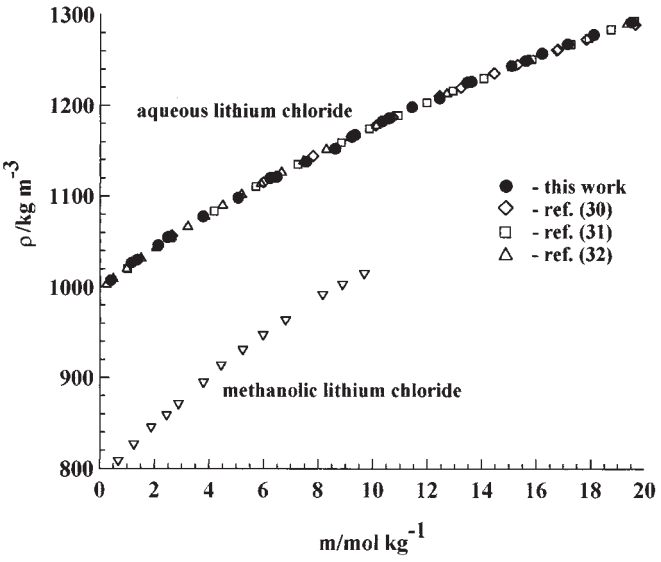

Fig. 2. Variation of isentropic compressibility (κ_s) with molality (*m*) at 273.15 K (○), 298.15 K (□), and 323.15 K (Δ) for aqueous lithium chloride solutions (symbols and solid curves represent experimental and calculated (from eq. [2]) values, respectively).

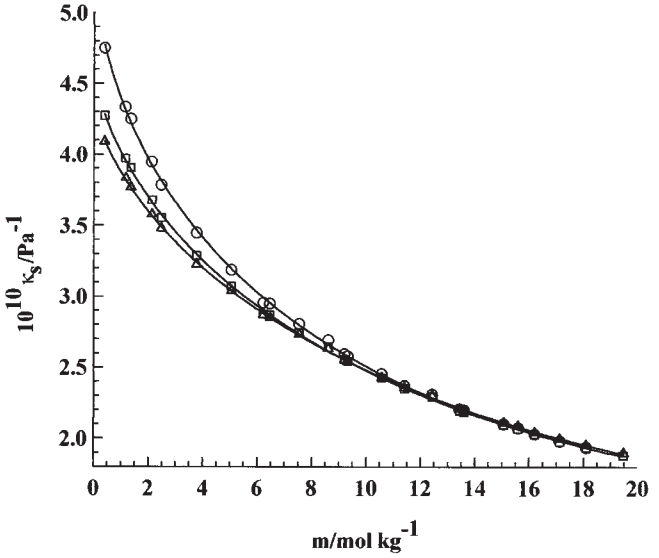
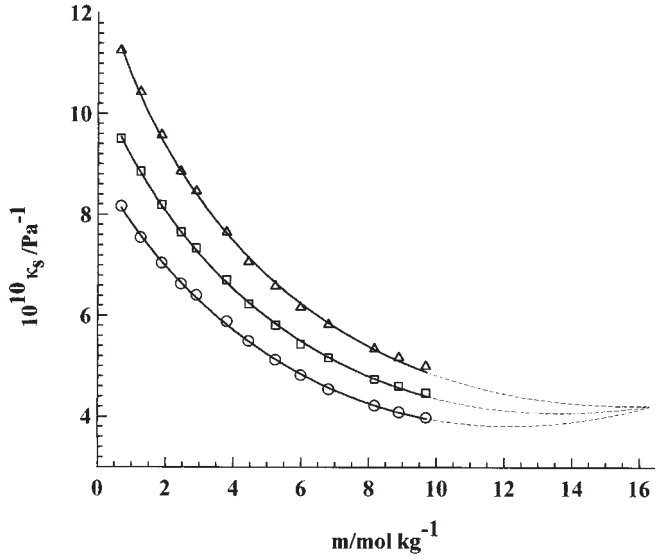


tions. At this critical concentration, the inherent structure and hydrogen bonding of the bulk water are collapsed. The isentropic compressibility value ($\kappa_{s,h} = 2.548 \times 10^{-10}$ Pa^{-1}) at the critical concentration is much lower than that of free water ($\kappa_s = 4.477 \times 10^{-10}$ Pa^{-1}). This indicates that the water molecules are rigidly held in the primary hydration shells of Li^+ and Cl^-. A minimum has been reported at ~9.4 mol kg^{-1} in the dielectric relaxation times (37), which characterize the rotational correlation time of the molecules. This concentration is in good agreement with the critical concentration (9.25 mol kg^{-1}) and indicates a probable correlation with the

Fig. 3. Variation of isentropic compressibility (κ_s) with molality (*m*) at 273.15 K (○), 298.15 K (□), and 323.15 K (Δ) for methanolic lithium chloride solutions (symbols and solid curves represent experimental and calculated (from eq. [2]) values, respectively, and broken curves represent the extrapolated values).



saturation of the primary hydration shell of lithium chloride in water medium.

Beyond 9.25 mol kg^{-1}, the hydration spheres of cations and anions overlap leading to a gradual formation of ion pairs (1) (solvent-shared, solvent-separated, and contact) because of a lesser number of available water molecules around Li^+ and Cl^-. In the entire temperature range of this study, the isentropic compressibility isotherms also converge at 13.5 mol kg^{-1} (Fig. 2). It can be argued that from 9.25 to 13.5 mol kg^{-1}, solvent-separated and (or) solvent-shared ion pairs predominantly exist in the solution; beyond 13.5 mol kg^{-1}, transition to contact-ion pairs is envisaged.

In methanolic lithium chloride solutions, the isentropic compressibility isotherms decrease smoothly with increasing concentration, but do not converge within the experimental concentration and temperature ranges (Fig. 3). On extrapolation, the isotherms converge at 16.30 mol kg^{-1} with $\kappa_{s,h} = 4.20 \times 10^{-10}$ Pa^{-1}. From Figs. 2 and 3, it is clear that the methanolic solution is more compressible in comparison to that of aqueous solution at a particular concentration and temperature. For example, at 0.1 mol fraction of lithium chloride, i.e., at 6.17 mol kg^{-1} aqueous lithium chloride and 3.47 mol kg^{-1} methanolic lithium chloride solutions, the isentropic compressibilities are ~2.9×10^{-10} Pa^{-1} and ~6.9×10^{-10} Pa^{-1}, respectively. This reflects a different solvation behaviour of lithium chloride in methanol than that in water. This difference may be attributed to weak ion–solvent interactions in methanol because of its characteristic structure and as a poor hydrogen bond producer.

The hydration and (or) solvation numbers (n_h) were calculated by using the previously reported empirical equation (27, 28)

$$[3] \qquad n_h = (\kappa_{s,\phi} - \kappa_{s,h} V_\phi)/[V_1(\kappa_{s,h} - \kappa_{s,1})]$$

where $\kappa_{s,\phi}$ is the conventional apparent molal isentropic compressibility (38) of the solution, V_ϕ is the apparent molal volume of the solute, and $\kappa_{s,1}$ and V_1 are the isentropic compressibility and the molar volume of the solvent, respectively. The estimated hydration and (or) solvation numbers of lithium chloride in water and methanol are illustrated in Fig. 4. The primary hydration number for lithium chloride in water was found to be 6.0 at 9.25 mol kg^{-1} and is in excellent agreement with the number of available water molecules per mol of the solute (6.0) at that concentration. The total primary solvation number of lithium chloride in methanol at 16.30 mol kg^{-1} was estimated to be 1.9, which is much smaller than that in water.

To bifurcate the total hydration number of lithium chloride into its individual ionic values, we need the reliable primary hydration number of either Li^+ or Cl^-. Recently, ab initio (39) and quasichemical (3) approaches have established that tetra-coordinated Li^+(aq) is energetically most favored (40). Most attempts (41, 42) to incorporate more than four water molecules in the primary hydration sphere lead invariably to the migration of extra water molecules into the secondary hydration sphere. Hence, by selecting the primary hydration number of Li^+ as 4.0, the primary hydration number of Cl^- is estimated to be 2.0, which is lower than the frequently reported values (2, 17–20) but more or less in agreement with the findings of Yamanaka et al. (17). We could not

Fig. 4. Hydration/solvation number (n_h) vs. molality (m) for (○) aqueous lithium chloride and (□, Δ) methanolic lithium chloride solutions (circles and squares are experimental values and triangles are extrapolated values) at 298.15 K.

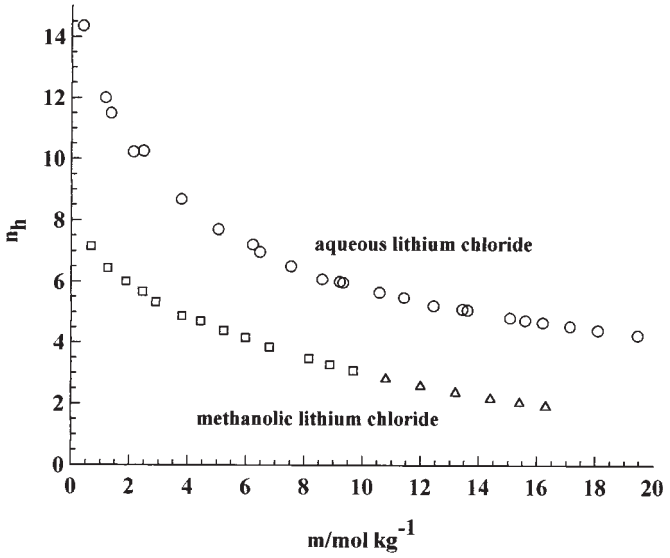

Fig. 5. Variation of viscosities (η) with molality (m) at 273.15 K (●), 298.15 K (■), and 323.15 K (▲) for aqueous lithium chloride solutions.

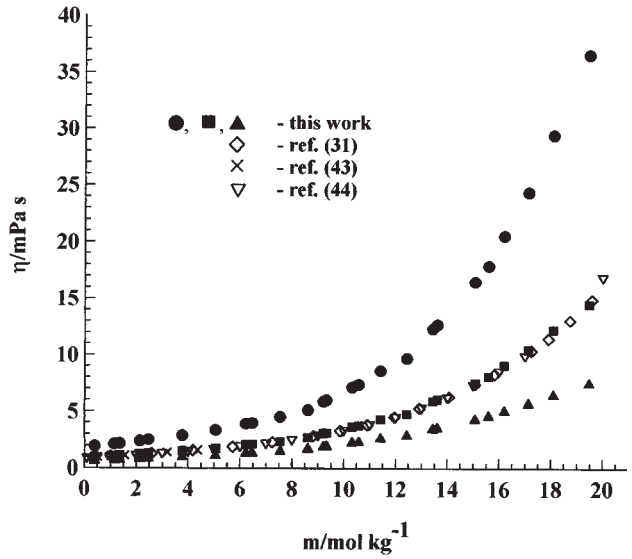

split the total primary solvation number of lithium chloride in methanol because of the lack of reliable literature data.

The experimental viscosities as functions of concentration and temperature for aqueous and methanolic lithium chloride solutions are presented in Table 2S (Supplementary materials).[2] Our viscosity values in water are comparable within ±3.4% of the reported values (31, 43, 44). We could not compare the viscosities of methanolic lithium chloride solutions because of the lack of literature data. Figures 5 and 6 illustrate the η vs. m plots for aqueous lithium chloride along with the literature values and methanolic lithium chloride solutions, respectively.

Fig. 6. Variation of viscosities (η) with molality (m) at 273.15 K (○), 298.15 K (□), and 323.15 K (Δ) for methanolic lithium chloride solutions.

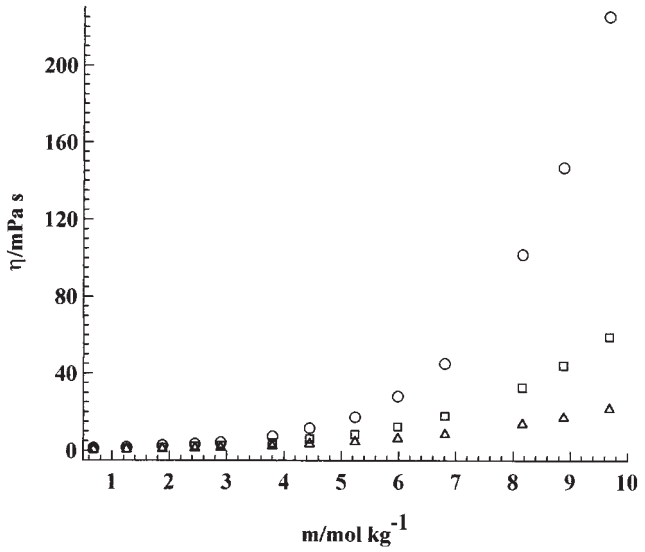

Fig. 7. Dependence of shear relaxation time (τ) with molality (m) at 273.15 K (○), 298.15 K (□), and 323.15 K (Δ) for aqueous lithium chloride solutions.

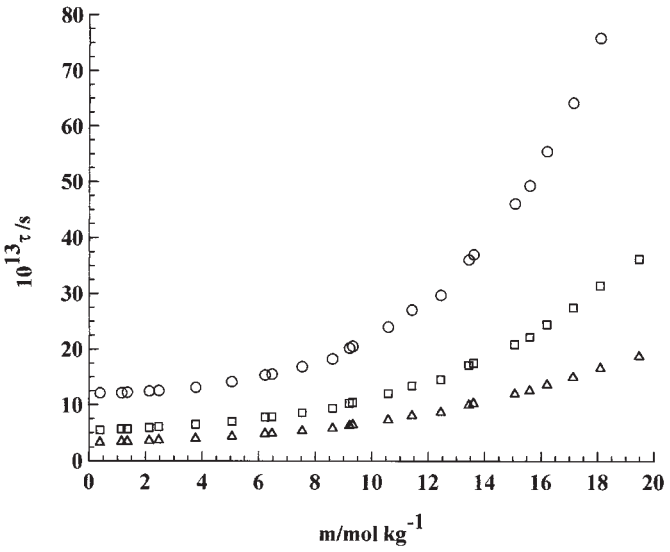

To understand the structure of solutions in different concentration regions, the shear relaxation times (τ) for all the solutions of lithium chloride were determined using the relationship (45)

$$[4] \qquad \tau = 4\kappa_s\eta/3$$

The plots of τ vs. m at different temperatures are shown in Figs. 7 and 8 for aqueous and methanolic solutions, respectively. It is apparent from Fig. 7 that the τ vs. m plots are less exponential at higher temperature. As the temperature decreases the curves become more and more exponential. A similar variation has also been observed for η vs. m plots (Figs. 5 and 6). These trends in τ and η at different tempera-

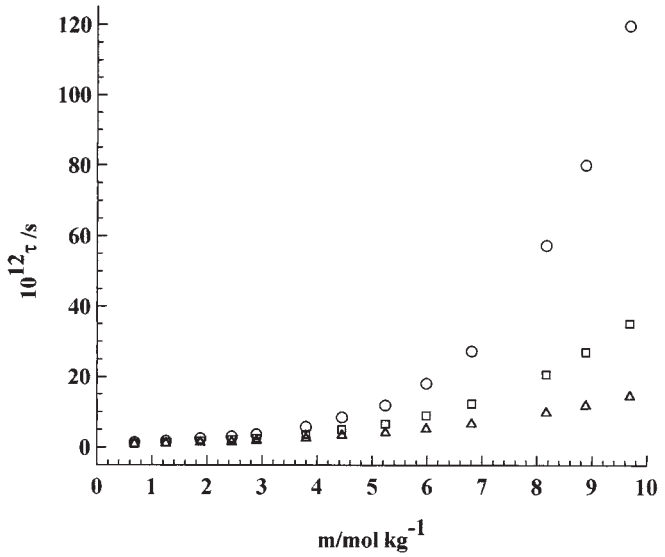
Fig. 8. Dependence of shear relaxation time (τ) with molality (*m*) at 273.15 K (○), 298.15 K (□), and 323.15 K (Δ) for methanolic lithium chloride solutions.



tures (Figs. 5–8) prevail because of the fact that both the normal hydrogen bonds of water (O-H···O) around the cation (46) and the directional hydrogen bonds (47, 48) with anion (O-H···Cl) are reinforced (15, 17) at low temperatures. At room temperature and above, the strong electric field of Li^+ affects the freely moving water molecules to form a rigid hydration shell. Thus, it can be concluded that anion hydration controls the viscosity processes (shear effect) at low temperatures, whereas at high temperatures it is the cation hydration. The same explanation may also hold for the methanolic solutions.

The hydrolysis of an activated ester by a tris(4,5-di-*n*-propyl-2-imidazolyl)phosphine–Zn^{2+} complex in neutral micellar medium as a model for carbonic anhydrase

Terry B. Koerner and R.S. Brown

Abstract: The properties of tris(4,5-di-*n*-propyl-2-imidazolyl)phosphine–M^{2+} complexes (**3**–M^{2+}, M = Zn, Co) in neutral micellar media of Brij-35 and Triton X-100 have been studied in water with respect to their quantitative potentiometric titration, Co^{2+}-visible absorption spectra, and ability of the **3**–Zn^{2+} complex to promote the hydrolysis of the activated ester, *p*-nitrophenyl acetate (PNPA). Potentiometric titration of the **3**–$M^{2+}(ClO_4^-)_2$ complexes in 20 mM Brij-35 media yields a steep titration curve indicative of the cooperative consumption of two hydroxides, with computed pK_1 and pK_2 values of 8.75 and 6.25, respectively, and the midpoint of the titration curve (pK_{app}) being 7.50. A similar titration of the Co^{2+} complex also indicates cooperative consumption of two HO^-, and this is tied to the formation of a 4- or 5-coordinate complex, pK_{app} ~ 7.3–7.4. The cooperativity is explained in terms of sequential replacement of the two ClO_4^- ions associated with the **3**–M^{2+} to eventually yield **3**–M^{2+}–HO^-/($HO^-(H_2O)_n$) having the first hydroxide ligated to the metal ion and the second associated as an ion pair. The **3**–Zn^{2+} complex catalyzes the hydrolysis of PNPA in 20 mM Brij-35 and 40 mM Triton X-100. Plots of the observed second order rate constant (k_2) vs. pH in Brij-35 increase linearly with pH and plateau to a value of k_2^{max} = 0.86 M^{-1} s^{-1}, with a kinetic pK_a of 8.7. These data are analyzed by a process wherein the **3**–Zn^{2+}–HO^- is kinetically active in the rate-limiting step of the reaction, while the ion-paired ($HO^-(H_2O)_n$) exists as a spectator to the slow step, possibly promoting rapid breakdown of a tetrahedral intermediate. Analysis of the kinetic data in terms of a model that accounts for the partitioning of PNPA between water and hydrophobic micellar pseudophase indicates that the second-order rate constant of the micelle-bound ester is augmented by 45-fold due to loading of the PNPA substrate into the micelle.

Key words: Brij-35, TritonX-100, neutral micelle, carbonic anhydrase model, kinetics, potentiometric titrations, catalysis, *p*-nitrophenyl acetate hydrolysis.

Résumé : Opérant dans l'eau, dans un milieu micellaire neutre de Brij-35 et de Triton X-100, on a étudié les propriétés des complexes tris(4,5-di-propyl-2-imidazolyl)phosphine–M^{2+} (**3**–M^{2+}, M = Zn, Co) en relation à leurs titrages potentiométriques quantitatifs, à leurs spectres d'absorption visible du Co^{2+} et l'habilité du complexe **3**–Zn^{2+} à faciliter l'hydrolyse de l'ester activé, acétate de *p*-nitrophényle (PNPA). Le titrage potentiométrique des complexes **3**–$M^{2+}(ClO_4^-)_2$ dans un milieu contenant 20 mM de Brij-35 donne lieu à une courbe de titrage à forte pente qui est une indication de la consommation coopérative de deux ions hydroxydes pour lesquelles on a calculé des valeurs de pK_1 et de pK_2 de 8,75 et 6,25 et un point médian de la courbe de titrage (pK_{app}) de 7,50. Un titrage semblable du complexe de Co^{2+} suggère aussi l'existence d'une consommation coopérative de deux HO^- et ceci est lié à la formation d'un complexe 4- ou 5-coordiné avec un pK_{app} ~ 7,3–7,4. On explique ces coopérations en termes d'un remplacement en séquence des deux ions ClO_4^- associés au **3**–M^{2+} qui conduit éventuellement à **3**–M^{2+}–HO^-/($HO^-(H_2O)_n$) dans lequel le premier hydroxyde est lié à l'ion métallique et le second est associé sous la forme d'une paire d'ions. Le complexe **3**–Zn^{2+} catalyse l'hydrolyse du PNPA dans des milieux contenant 20 mM de Brij-35 ou 40 mM de Triton X-100. Dans un milieu contenant du Brig-35, les courbes de la constante de vitesse du deuxième ordre observé (k_2) en fonction de pH augmentent de façon linéaire avec le pH pour atteindre un plateau à une valeur maximale k_2^{max} = 0,86 M^{-1} s^{-1} et un pK_a cinétique de 8,7. On a analysé ces données par un processus dans lequel le complexe **3**–Zn^{2+}–HO^- est cinétiquement actif dans l'étape cinétiquement limitante de la réaction alors que le complexe sous la forme de paire d'ions ($HO^-(H_2O)_n$) existe sous la forme de spectateur dans l'étape la plus lente et favorisant peut-être une dissociation rapide d'un intermédiaire tétraédrique. L'analyse des données cinétiques en fonction d'un modèle qui tient compte du coefficient de partition du PNPA entre l'eau et la pseudophase micellaire hydrophobe indique que la constante du deuxième ordre de l'ester lié à la micelle est augmentée par un facteur de 45 en raison du chargement du substrat PNPA dans la micelle.

Mots clés : Brij-35, Triton X-100, micelle neutre, modèle de l'anhydrase carbonique, cinétique, titrages, catalyse, hydrolyse de l'acétate de *p*-nitrophényle.

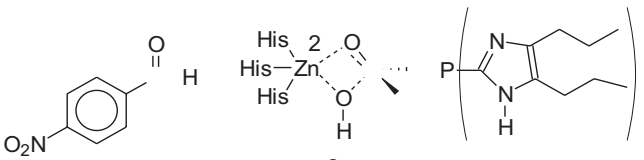
Introduction

Carbonic anhydrases (CA) are ubiquitous metalloenzymes, the active site of which contain an essential Zn^{2+} ion bound by three histidine imidazoles (1). The only known physiological role for the various forms of CA is to facilitate the interconversion of carbon dioxide and bicarbonate in the equilibrium $CO_2 + H_2O \rightleftharpoons HCO_3^- + H^+$, and in doing so these enzymes play important roles in respiration, photosynthesis, calcification, and the control of extracellular pH. Although not its physiological role, the enzyme has also shown catalytic activity toward hydration of aldehydes, hydrolysis of carboxylic esters, phosphoric esters, cyanide, cyanate, and thiocyanate (2, 3). The mechanism of action of CA is among the most completely understood for all enzymes and involves ionization of the active site Zn^{2+}–OH_2 (pK_a~7) to form a nucleophilic Zn^{2+}–OH^-, which subsequently attacks the carbonyl group of the substrate.

Numerous small molecule complexes of Zn^{2+} and other transition metal ions have been offered as models for one or more of the catalytic or spectroscopic features of the enzyme (4–8). Despite the prevalence of such models, none of these shows a catalytic activity toward CO_2 hydration that rivals that of the enzyme where the k_{cat} and k_{cat}/K_m terms are 1.4×10^6 s^{-1} and 1.5×10^8 M^{-1} s^{-1} respectively (1*e*). Rather, the available models shown to react with CO_2 (8) do so with second-order rate constants that are somewhat lower than that for $HO^- + CO_2$ (6000 M^{-1} s^{-1} (9)). CA also catalyzes the easily monitored hydrolysis of *p*-nitrophenyl acetate (PNPA, **1**) with a $k_{cat}/K_m = 2500$ M^{-1} s^{-1} (10). This substrate has been used extensively to test the catalytic ability of some model systems toward ester hydrolysis (7*d*, 11), but again none of these reacts faster than direct nucleophilic attack of hydroxide ion (15 M^{-1} s^{-1} (12)).

It is clear from the above rate data that CA employs some features to enhance the activity of a Zn^{2+}-coordinated HO^- relative to HO^- in aqueous solution. One of the often-invoked ways involves a mechanism having a dual role for the metal ion as in **2**, acting to deliver the nucleophile with simultaneous stabilization of the developing (–) charge on the substrate C=O.



1 **2** **3**

Another factor might involve a medium effect where the hydrophobic environment surrounding the Zn^{2+}–HO^- substantially enhances the nucleophilicity by removing much of the solvation of the hydroxide. The latter possibility has spurred some studies involving encapsulation of Zn^{2+} model complexes into micellar phases, and subsequent investigation of their reactivities toward PNPA and other substrates such as tris *p*-nitrophenyl phosphate and *p*-nitrophenyl-diphenyl phosphate (7*b*, 11*a*, 13).

In the following, we describe our studies of the hydrolysis of PNPA promoted by two neutral micellar systems (14) incorporating the Zn^{2+} complex of tris(4,5-di-*n*-propyl-2-imidazolyl)phosphine (**3**), a complex that we prepared previously (8*b*) as a model for CA. The previous study demonstrated that the complex facilitates the interconversion of CO_2 and HCO_3^- in 80% ethanol–water, the second-order rate constant for attaining equilibrium being 2800 M^{-1} s^{-1}. The study also revealed complications, wherein the complex formed aggregates and also associated with the indicators used for determining the kinetics, suggesting that it might be readily incorporated into a hydrophobic micellar medium. Herein we report that **3**–$Zn^{2+}(ClO_4^-)_2$ can be incorporated into the neutral micellar systems, Brij-35 ($C_{12}H_{25}(OCH_2CH_2)_{23}OH$) and Triton X-100 (*p*-(1,1,3,3-tetramethylbutyl)-phenyl$(OCH_2CH_2)_xOH$, $x = 9.5$, average). Both systems promote the hydrolysis of PNPA as basic forms generated by the formation of what is probably **3**–Zn^{2+}–HO^- having kinetic pK_a values of 8.74 and 8.81, respectively. In addition, we have performed quantitative potentiometric titrations of the Brij-35–**3**–$Zn^{2+}(OH_2)_x$–$(ClO_4^-)_2$ system that reveal a cooperative consumption of two equivalents of OH^- per complex.

Results

There are three observations worth mentioning because they limit the range of study using **3** and Zn^{2+} in the aqueous micellar system. Heterogeneous solutions were observed if the [M^{2+}] was varied above or below the [**3**], suggesting the formation of a micelle-soluble 1:1 ligand–metal complex. The cloudy solutions arise from the free ligand or $M^{2+}(OH^-)_x$, both of which are insoluble in the pH range of this study. Second, at the maximum [**3**–M^{2+}] under which the kinetics were determined, cloudy solutions were observed if the $[surfactant]_t$ was lower than 40 mM for Triton X-100 and 20 mM for Brij-35. This suggests that at high [**3**–M^{2+}] the properties of the micelle are disrupted enough to limit complex solubility, which is known to be a common occurrence in micelle solutions (15). Finally, attempts to control the ionic strength of the Triton X-100 solutions also resulted in cloudy solutions. It has been shown that the aggregation number, the degree of hydration, and the radius of Triton X-100 micelles are all sensitive to the ionic strength and in general these all increase with increasing ionic strength producing micelles that are more diffuse (15*b*). A micelle that is more diffuse and hydrated probably diminishes the solubility of hydrophobic ligands and so limits our studies with Triton X-100 to media in which the ionic strength was not controlled, other than by the presence of the 0.1 M buffers, the upper limit for the ionic strength thus being approximately 0.07 M.

Potentiometric and spectroscopic titrations

At concentrations sufficient for potentiometric pH titration, **3** is not soluble in water, therefore, 20 mM Brij-35 was added to obtain a homogeneous solution. This concentration was much greater than the reported critical micelle concentration (0.04–1.67 mM (15*a*)). In the absence of M^{2+}, **3** in Brij-35 is soluble at low pH (< 4.5) and at high pH (>9.0), but between these values the solutions were cloudy, indicating the fully protonated species **3**–$3H^+$ is soluble in water and is probably not associated with the surfactant to any great extent, while fully deprotonated **3** is soluble in the mi-

© 2002 NRC Canada

celle. However, in the presence of metal ions the solutions are homogeneous at all pH values between 4 and 10.

Shown in Fig. 1 is the potentiometric titration profile for a 1.5 mM solution of **3** and $Zn^{2+}(ClO_4^-)_2$ in the presence of 20 mM Brij-35 at 25°C, I = 0.10 M ($NaClO_4$). A similar curve with $Co^{2+}(ClO_4^-)_2$ (not shown) exhibits the same characteristics. Both profiles indicate complete ligand deprotonation, and thus M^{2+} complexation, by pH 7.0, followed by the consumption of two additional equivalents of hydroxide between 7.0 < pH < 9.0. Attainment of equilibrium was very slow for these titrations, requiring about half an hour between each titration point. A slow attainment of equilibrium for titration of a macrocyclic tetraamine – Zn^{2+} complex in a Triton X-100 micellar system was previously observed by Kimura et al. (13*a*).

The notable aspect of Fig. 1, and the corresponding Co^{2+} titration profile, is the unusually steep consumption of two equivalents of HO^- per **3**–M^{2+} complex exhibited in both the titration curves from 7 < pH < 9. This cannot be explained by a stepwise addition of OH^- or deprotonation of $M^{2+}(OH_2)$, but it can be rationalized by sequential dissociation in a cooperative fashion as represented in eq. [1] for a dibasic acid where $K_2 > K_1$ (16). Given in Fig. 2 are the expanded titration data for the pH 7–9 region of Fig. 1, showing the consumption of 2 equiv. of ^-OH per **3**–Zn^{2+} complex. The line through the data is generated from a NLLSQ fit of the titration data to eq. [2], which was derived for the cooperative dissociation process in eq. [1] with K_1 and K_2 being the first- and second-dissociation constants and K_w being the autoprotolysis constant of H_2O (taken to be 1×10^{-14} M^2). The fit yields computed values are 8.75 and 6.25 for pK_1 and pK_2, respectively (pK_{app} for the midpoint of the titration is 7.50). Similar treatment of the **3**–Co^{2+} potentiometric data gives values for pK_1 and pK_2 of 8.75 and 6.00, respectively (pK_{app}= 7.37).

[1] 
[2] $$\#\,\text{equiv}\,[OH^-] = \frac{K_1[H^+] + 2K_1K_2}{[H^2]^2 + K_1[H^+] + K_1K_2} + \frac{K_w}{[H^+]} - H^+$$

The visible absorption spectra measured between 490–670 nm of a 20 mM Brij-35 solution containing 3.0 mM each of **3** and $Co^{2+}(ClO_4^-)_2$ as a function of pH is given in Fig. 3, along with the pH dependence of the λ_{max} = 575 nm indicating that the pK_{app}, determined by potentiometric titration of the **3**–Co^{2+} complex, is also tied to the formation of an intense purple solution. However, the steepness of the Abs_{575} titration profile from 6.5 < pH < 8.5 is not typical of a single ionization event. The data for the spectroscopic titration best fit to eq. [3][2] with two cooperative ionizations per metal ion, where pK_1 = 8.75, pK_2 = 5.90 (pK_{app} = 7.33), M_a = ([**3**–Co^{2+}][ε_{max}])/2, and K_w is the autoprotolysis constant of water.

[3] $$Abs_{575} = \frac{M_a(K_1[H^+] + 2K_1K_2)}{[H^+]^2 + K_1[H^+] + K_1K_2} + \frac{K_W}{[H^+]} - [H^+] + 0.221\left(\frac{[H^+]}{[H^+] + K_1}\right)$$

Kinetic studies of 3–Zn^{2+} in Brij-35 and Triton X-100 micelle media

The **3**–Zn^{2+} complex catalyzes the hydrolysis of PNPA (0.035 mM) in buffered solutions (0.10 M) in the presence of both Brij-35 (20 mM) and Triton X-100 (40 mM) at 25°C. At each pH the k_{obs} for the hydrolysis of PNPA vs. [**3**–Zn^{2+}] at four concentrations from 0.8 to 4.0 mM gave linear plots with no observable saturation. Second-order rate constants (k_2) for the hydrolysis of PNPA catalyzed by **3**–Zn^{2+} in both Brij-35 and Triton X-100 surfactant were calculated from the slopes of the k_{obs} vs. [**3**–Zn^{2+}] plots at each pH and are given in Tables 1 and 2, respectively. The pH vs. log k_2 profiles for surfactant Brij-35 (Fig. 4) and Triton X-100 (Fig. 5) increase linearly with unit slope as a function of pH and then plateau. Shown in eq. [4] is a mechanism that accounts for the pH dependency of the second-order rate constant, from which can be derived the expression given in eq. [5], where K_a is the kinetic acid-dissociation constant generating the presumed Zn^{2+}–OH^- active species, k_2^{max} is the maximal second-order rate constant for its reaction with PNPA, and (P) indicates the products of the reaction (*p*-nitrophenol(ate) and acetate). NLLSQ fits of the data to eq. [5] generates k_2^{max} (pK_a given in parentheses) values of 0.860 ± 0.099 M^{-1} s^{-1} (8.74 ± 0.06) and 0.023 M^{-1} s^{-1} (8.81 ± 0.11) for Brij-35 and Triton X-100, respectively.

[4] $$\mathbf{3}\text{–}Zn^{2+}(H_2O) \overset{K_a}{\rightleftharpoons} \mathbf{3}\text{–}Zn^{2+}(OH^-) \xrightarrow[k_2\,max]{\text{PNPA}} P$$

[5] $$k_2 = \frac{k_2^{max}K_a}{K_a + [H^+]}$$

Discussion

The system involved in this study comprises M^{2+} complexes of **3**, which are solubilized in neutral micellar media of Brij-35 or Triton X-100. As noted above, homogeneity of the system requires that all components are present: omission of any of M^{2+}, **3**, or micelle agent leads to formation of precipitates. The critical micelle concentration (CMC) for Brij-35 is reported (15*a*) to be between 0.04 and 0.17 mM with an aggregation number (*N*, the average number of surfactant molecules per micelle) of 35–65, while those values for Triton X-100 are 0.08 mM (13*a*) and 79–135 (15*b*). Given a [surfactant]$_t$ of 20 mM for Brij-35 and 40 mM for Triton X-100, one calculates[3] that the actual concentration of micelles is 0.31–0.6 mM and 0.30–0.50 mM, respectively. For the potentiometric titrations in 20 mM Brij-35, we have employed a [**3**] = [Zn^{2+}] = 1.5 mM, while for the spectroscopic titrations the [**3**] = [Co^{2+}] = 3 mM, requiring that each Brij-35 micelle has on average ~2.5–5 **3**–Zn^{2+} com-

[2] This equation is essentially the same as eq. [1], given in ref. 16, with a term to correct the mass balance for an absorbance of the fully protonated species, 0.221([H^+]/([H^+] + K_1)). To undertake the fit, we have the K_1 as the constant ($1 \times 10^{-8.75}$) and K_2 as the variable.

[3] The actual concentration of micelles is given as [micelle] = ([surfactant]$_t$ – CMC)/*N*, where *N* is the aggregation number (see ref. 14, p. 88).

Fig. 1. A titration curve for 1.5×10^{-3} M **3**–$3H^+$ in the presence of equimolar $Zn(ClO_4)_2$ in a 20 mM Brij-35 solution at 25°C, I = 0.10 M ($NaClO_4$).

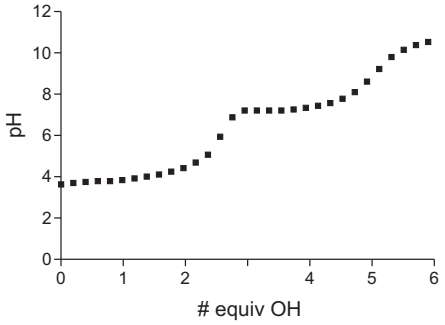

Fig. 2. Potentiometric titration data for the expanded pH 7–9 region of Fig. 1 for **3** in the presence of one equivalent of Zn^{2+}. The line going through the data was calculated from eq. [2] and yields pK_1 = 8.75 and pK_2 = 6.25.

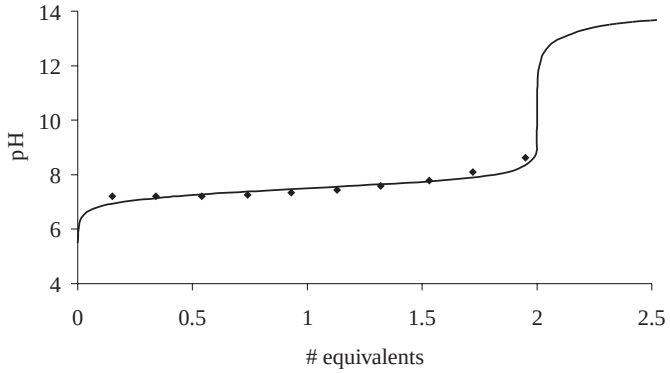

Fig. 3. Visible absorption spectrum of 3 mM **3** in the presence of one equivalent of Co^{2+} in a 20 mM Brij-35 solution as a function of pH (ionic strength not controlled), along with a plot of the absorbance data at λ_{max} = 575 nm vs. pH. The line through the data was calculated using eq. [3]. The dashed line was calculated for a single ionization event with a pK_a = 7.25, ref. 16.

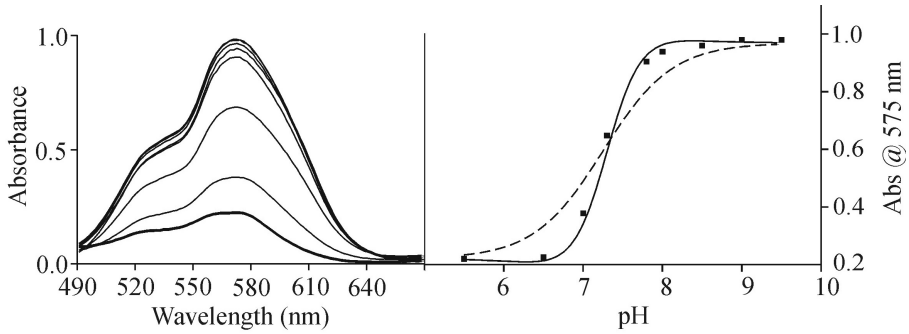
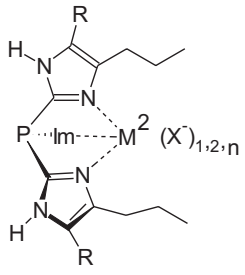


plexes and 5–10 **3**–Co^{2+} complexes. In the case of the kinetic experiments where the [**3**–Zn^{2+}] was varied from 0.8–4.0 mM, the average number of complexes per micelle varies from 1.3–2.6 to 6.4–13 for Brij-35, and 1.5–2.3 to 8–13 for Triton X-100.

Micelles of Brij-35 are described (15*a*) in terms of a spherical model having a central core of radius ~44 Å containing anhydrous and hydrated zones that block solvent flow, and a 7–13 Å thick outer corona, compared to the spines of a sea-urchin, of hydrated poly(oxyethylenes) that permits solvent flow but obstructs the approach of other micelles. That same description suggests that the number of water molecules associated with the poly(oxyethylene) chain ends is about 8 at temperatures from 10–25°C, falling to about 4 at 70°C.

Potentiometric and spectroscopic titrations

The major feature in the potentimetric titration of **3**–$3H^+$ + $Zn^{2+}(ClO_4^-)_2$ or $Co^{2+}(ClO_4^-)_2$ in the Brij-35 medium is the quantitative consumption of five equivalents of hydroxide per **3**–M^{2+} complex, three below pH 7 to form the complex **3**–M^{2+}, and two more between pH 7 and 9 that display a steepness in the titration curve requiring some cooperative process. Accepting the above description of Brij-35 as being largely correct for the conditions employed in our study, and that the inclusion of **3**–M^{2+} does not disrupt the micelle's integrity to any major extent, then under the potentiometric titration conditions each micelle contains on average 2.5–5 **3**–Zn^{2+} complexes or 5–10 **3**–Co^{2+} complexes. Molecular models indicate that when complexed to the three imidazoles, the metal ion is encapsulated by the *n*-propyl groups of the ligand as in **4**, X^- = counterion or H_2O. The exact location and orientation of the complex(es) in the micelle is unknown, but it is likely that they reside in the micellar pseudophase allowing communication between the metal ion core and the various components of the aqueous solvent.



4 Im = (4,5-di-*n*-PrIm)
R = *n*-Pr

It has been suggested that the local dielectric constants (ε_{eff}) of Triton X-100 (17) and Brij-35 (18) micelles are 32 and 38, respectively. The reported dielectric constants are

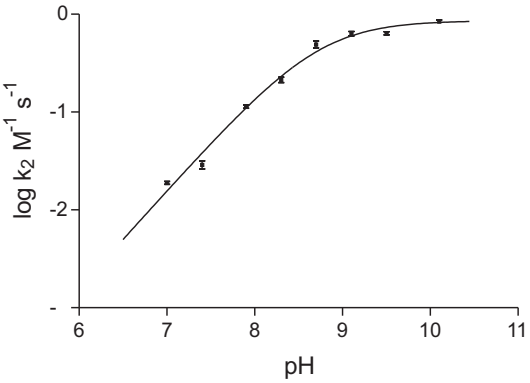

Fig. 5. Plot of log k_2 vs. pH for the **3**–Zn^{2+} promoted hydrolysis of PNPA in 40 mM Triton X-100 at 25°C. The line though the data was calculated using eq. [5].

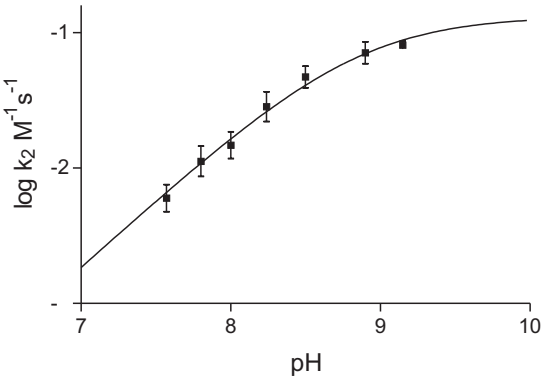

very similar to that of methanol (ε = 31.5) and much lower than that of water (ε = 78.5) (19), which certainly plays an important part in the potentiometric titrations in micellar media which can be understood as M^{2+}–X^- associations.

A highly simplified analysis of the potentiometric titration data considers each micelle to contain a dibasic acid as presented in eq. [1] with $K_2 > K_1$. The mathematical description for this given in eq. [2] nicely fits the pH 7–9 titration data given in Fig. 2, with computed values of pK_1 and pK_2 of 8.75 and 6.25, respectively; the midpoint of the titration (pK_{app}) being 7.5. Because the micelles on average are likely to contain at least two, and up to five, **3**–Zn^{2+} complexes it is probably better to consider the system as a polyprotic acid wherein each dissociation has some influence on the next. Indeed, if the micelle were considered a tetraprotic acid (two complexes, each with two ionizations), one can derive the expression given in eq. [6], to which NLLSQ fitting of the Fig. 2 potentiometric data yields values of pK_1 = 8.75, pK_2 = 6.50, pK_3 = 7.00, and pK_4 = 7.75, argueably giving a better fit to the titration data than does eq. [2]. While expanded fits can be constructed for all possible combinations of ionizations, these do not add to the understanding of the process, so we limit further discussion to the dibasic acid model of eqs. [1] and [2].

[6] $$\#\text{equiv of base} = \frac{K_1[H^+]^3 + 2K_1K_2[H^+]^2 + 3K_1K_2K_3[H^+] + 4K_1K_2K_3K_4}{[H^+]^4 + K_1[H^+]^3 + K_1K_2[H^+]^2 + K_1K_2K_3[H^+] + K_1K_2K_3K_4} + \frac{K_W}{[H^+]} - [H^+]$$

More information about how the association of HO^- affects the metal ion's local environment can be obtained from the spectroscopic titrations of 3 mM **3**–Co^{2+} in 20 mM Brij-35, which also shows the cooperative phenomenon (see Fig. 3). A point of note for the spectroscopic titration is that the consumption of HO^- is tied to the formation of a blue 4- or 5-coordinate Co^{2+} complex (1*f*, 2) and the plot the Abs_{575} vs. pH data given in Fig. 3 can be analyzed in terms of the cooperative consumption of two HO^- by the dibasic acid model (eq. [3]), which yields values for pK_1 and pK_2 of 8.75 and 5.90, respectively (midpoint of titration, pK_{app} = 7.33), values completely consistent with the potentiometric data. The color change promoted by the two hydroxides requires either that they both bind directly to the metal ion, or one does while the other is sufficiently close to perturb the UV-vis spectroscopic properties.

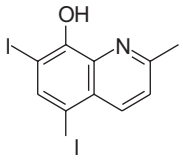
Scheme 1.

$$\underset{\mathbf{a}}{\mathbf{3}-M^{2+}/(ClO_4^-)_2} + 2OH^- \rightleftharpoons \underbrace{\mathbf{3}-M^{2+}-OH^-/(ClO_4^-)+ClO_4^-+OH^-}_{\mathbf{b}}$$

$$\mathbf{3}-M^{2+}-OH^-/(HO^-)+2ClO_4^- \quad (\mathbf{c})$$

Given in Scheme 1 is a process explaining the above data. For neutrality the complex **3**–M^{2+} must initially occupy the reduced polarity micellar pseudophase associated with two ClO_4^- counterions, probably as an ion triplet as in ***a***. In Scheme 1 we have omitted the water molecules associated with the counterions and the metal, but note that these must be present since at pH < 7, prior to the cooperative consumption of HO^-, the Co^{2+} complex is pink, and therefore, octahedral. Although there has been extensive work on ion pairing in cationic micelles, there appears to be relatively little work done with neutral micelle media (14). However, a study by Beltrán et al. (20) shows that the fluorescence of chlorquinaldol (**5**) in a Brij-35 micellar medium under basic conditions correlates with the mole fraction of the Na^+–phenolate ion pair within the micelle microenvironment. Chlorquinaldol does not fluoresce in aqueous solution suggesting the fluorescence is due to ion-pairing within the micelle that is not observed in aqueous solution.



5

Above pH 7, **3**–M^{2+} first consumes a HO^-, probably ligated to the metal, thereby releasing one ClO_4^- to yeild ***b***, which, we suggest, immediately replaces the second ClO_4^- with hydroxide to generate ***c***. The association of the HO^- reduces the coordination of the Co^{2+}, making it 4- or 5-coordinate, which accounts for the color change.

Although cooperative consumption of HO^- by a metal ion seems at first puzzling, there is precedence from the titration of both $Zn(ClO_4)_2$ and $Co(ClO_4)_2$ in methanol (21) that show consumption of two CH_3O^- per metal ion with a steep titration curve suggesting a cooperative process (pK_{app} = 9.75 and 11.35, respectively). Zn^{2+} and Co^{2+} also prefer tetrahedral thiocyanato complexes $[M^{2+}(NCS)_4]$ in the presence of Triton X-100 (22), an interesting observation since a tetrahedral complex is not observed in aqueous solutions. Additionally, Zn^{2+} forms a bis-chloride species in DMSO and methanol with the second halide association constant being larger than the first (23). The driving force for these processes is attributed (23) to reduced charge density at the metal center after binding the first anion, changing the coordination number from six to four or five, and also to an entropy effect resulting from release of coordinating solvent molecules after association of the anion. By analogy the consumption of the first HO^- in the present micellar system to form **3**–M^{2+}–OH^- can reduce both the coordination geometry and the electrostatic attraction of the metal centre for the remaining ClO_4^- in the ion pair so that immediate consumption of the second HO^- ensues. Of course the equilibria shown in Scheme 1 are controlled by a complex balance of enthalpy and entropy effects associated with exchange of ClO_4^- and HO^- between the aqueous and micellar phases, their solvation by associated water molecules in each phase, and their eventual association with the metal ion.

Kinetics of hydrolysis of PNPA promoted by 3–Zn^{2+} in micellar media

The kinetic profiles in Figs. 4 and 5 for the **3**–Zn^{2+} promoted hydrolysis of PNPA in Brij-35 and Triton X-100 suggest a common process where the catalytically active species is generated by consumption of a single HO^- with apparent kinetic pK_a values of 8.74 and 8.81, respectively. The kinetic data must be reconciled with the potentiometric titration data for **3**–Zn^{2+} in Brij-35 that indicates cooperative consumption of two HO^- with pK_1 and pK_2 values of 8.75 and 6.25, respectively, ultimately generating the species **3**–Zn^{2+}–HO^-/(HO^-) proposed in Scheme 1. The kinetic data require a transition state where only one hydroxide is involved in the rate limiting step for the hydrolysis, this probably being the **3**–Zn^{2+}–OH^-. That the kinetic pK_a and first potentiometric pK_1 are identical suggests that the first consumed HO^- generates the active species.

Given in Scheme 2 is a proposed mechanism that accommodates both the kinetic and potentiometric data. Species **A**, **B**, and **C** represent the first association of OH^- with **3**–Zn^{2+}, followed by exchange of ClO_4^- for OH^- accounting for the consumption of 2 equivalents of OH^-. Attack of **3**–Zn^{2+}–OH^- on PNPA might occur in either a concerted fashion to form products directly (24), or in the customary (25) two-step $B_{AC}2$ process via a tetrahedral intermediate (**TI**). In either case we propose that only the **3**–Zn^{2+}–OH^- is kinetically active in the rate-determining step of the reaction with the second OH^- residing in the local environment of the **3**–Zn^{2+}–OH^- as a spectator ion (26). The expulsion of the leaving group could occur spontaneously after the slow step of the reaction, or possibly with trapping of the **TI** by the spectator HO^- as proposed in Scheme 2. Jencks (26*a*, *b*) has termed this "enforced catalysis", which is expected when a proton is transferred to or from an unstable intermediate in order to trap it and limit its return to reactants.

Role of the micelle in catalysis of PNPA hydrolysis by 3–Zn^{2+}

Micelles have been studied for decades as "microreactors", which can compartmentalize and concen-

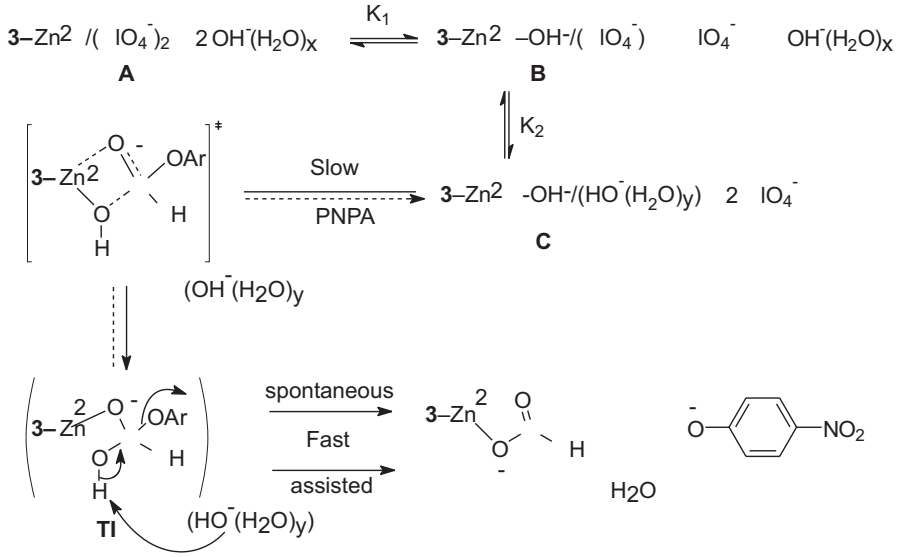
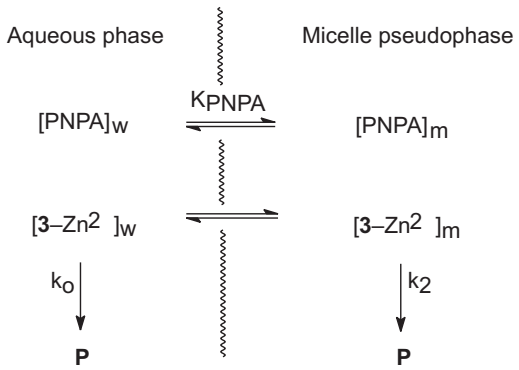
Scheme 2.



trate substrates and reactants thereby altering the rates of chemical reactions (14, 27). The promotion of reactions by cationic or anionic micelles has been discussed in terms of electrostatic and hydrophobic interactions between the surfactant aggregate and substrate, preferential binding of the transition state relative to the ground state reactants (28), and, in some cases, to alterations of the structure of the surrounding water. Less information is available on the methods by which neutral surfactants enhance reactions, but the same general consideration likely apply. In the present case, the neutral surfactant serves first to solubilize the **3**–M^{2+} complex throughout the entire pH region where hydroxide ions associate with the complex, thus preventing the precipitation of **3** or $M^{2+}(HO^{-})_x$, which was seen in our earlier study that did not utilize micelles (8*b*). The maximal reactivity exhibited by **3**–Zn^{2+}–HO^{-}–Brij-35 toward PNPA hydrolysis (k_2 = 0.86 M^{-1} s^{-1}) appears to be the second highest reported for a metal complex, the highest of which we are aware being Kimura's (13*a*) Zn^{2+}–hexadecyltetraazacyclododecane complex (k_2 = 5.0 $M^{-1}s^{-1}$ at pH 10 in 10 mM Triton X-100 and 10% CH_3CN), but both of these are less reactive than free hydroxide in water (k_{HO^-} = 15 M^{-1} s^{-1} (12)). Nevertheless, the present reactivity may be encouraging given the reduced pK_a of the **3**–$Zn^{2+}(H_2O)_x$ complex relative to that of water, (8.75 vs. 15.5) and the usual Brønsted considerations that indicate **3**–Zn^{2+}–HO^{-} should be a poorer nucleophile than hydroxide. Perhaps this suggests the mechanism involves an electrophilic–nucleophilic role for **3**–Zn^{2+}–HO^{-} (illustrated in Scheme 2) as proposed previously (7*b*, 25, 29).

Simple k_2 reactivity data of PNPA hydrolysis promoted by metal complexes in neutral micellar media, as usually presented, (8*b*, 13, 11) generally ignore the important aspect of the micelle increasing the local concentration of substrate in its interior (15, 27, 30). The omission of this renders mechanistic interpretation and rate comparisons incomplete because the real activity is markedly less (31). Given in Scheme 3 is a schematic representation of the partitioning of the PNPA substrate and the nucleophile between the aqueous

Scheme 3.



phase and the micellar pseudophase. The value for the partitioning constant (K_{PNPA}) into Brij-35 was determined in a separate experiment by determining the rate of PNPA hydrolysis at constant pH without **3**–Zn^{2+} complex as a function of Brij-35 surfactant concentration (four values between 3 and 20 mM). The data were fit to eq. [7] (32) where k_o is the pseudo-first-order rate constant in the absence of surfactant, k_2 is the pseudo-first-order rate constant within the micellar pseudophase, and [S] = [total surfactant – CMC]. The determined value at pH = 10.1 is K_{PNPA} = 43 ± 5 M^{-1}.

$$[7] \qquad 1/(k_0 - k_{obs}) = (1/(k_0 - k_2))(1 + K_{PNPA}[S])$$

$$[8] \qquad k_{cat} = \frac{k_2^m K_{PNPA}[\mathbf{3}\text{–}Zn^{2+}]}{V_m(1 + K_{PNPA}[S])}$$

The expression shown in eq. [8], derived on the basis of the process shown in Scheme 3, can be used to determine the second-order rate constant within the micelle where k_{cat} is the observed pseudo-first-order rate constant for catalyzed PNPA hydrolysis (over the background reaction at pH 10.1), V_m is the molar volume of reactive region for Brij-35 given in L mol^{-1} (0.5 M^{-1} for the 20 mM concentration of surfactant used in this study) (31), and k_2^m is the computed second-order rate constant for the reaction promoted by **3**–

© 2002 NRC Canada

Zn^{2+} in the micelle taking account of the loading of PNPA into the latter. In deriving eq. [8], we have ignored the potential **3**–Zn^{2+} catalyzed reaction in water since the complex is insoluble without the micelle. At a complex concentration of 2.5 mM, the computed k_2^m value for the complex in Brij-35 is 0.0186 M^{-1} s^{-1}, far less than the observed value of 0.86 M^{-1} s^{-1}, indicating that a factor of 45 is attributed to the loading of PNPA into the micelle. Interestingly, Scrimin et al. (31) previously applied this analysis to the data of Kimura et al. (13*a*) for hexadecyltetraazacyclododecane–Zn^{2+} catalysis of PNPA hydrolysis in Triton X-100, and have found that the micellar effects are almost wholly attributable to the increasing concentrations of reactants in the small volume of the micellar pseudophase. They conclude that when due attention is paid to the concentration loading, the reactivities of micellized metal complexes do not differ significantly from those of the analogous monomeric complexes in water. In our case, such comparison with the aqueous catalysis of PNPA hydrolysis exhibited by **3**–Zn^{2+} is impossible due to its insolubility.

Experimental

Materials

Unless otherwise stated, all reagents and solvents used were purchased as the highest commercial quality and used without further purification. Tris(4,5-di-*n*-propyl-2-imidazolyl) phosphine (**3**) was prepared according to the procedure previously reported (8*b*). The following buffers were purchased from Sigma–Aldrich: HEPES [4-(2-hydroxymethyl)-1-piperazineethanesulfonic acid, pK_a = 7.4], TAPS [3-{[tris(hydroxymethyl)methyl]amino}-1-propanesulfonic acid, pK_a = 8.4], CAPS [3-cyclohexylamino-1-propanesulfonic acid, pK_a = 10.4]. Neutral surfactants (Triton X-100 and Brij-35) were purchased from Sigma–Aldrich. 4-Nitrophenyl acetate (PNPA) was recrystallized three times from ethyl acetate. All aqueous solutions were prepared from deionized water that was distilled and boiled to remove CO_2.

Potentiometric and spectroscopic titrations

Potentiometric titrations of (**3**) (1.5 mM) in the presence and absence of equimolar amounts of $Zn^{2+}(ClO_4^-)_2$ and $Co^{2+}(ClO_4^-)_2$ were performed using a Radiometer Vit 90 Autotitrator under anaerobic conditions (Ar) at ambient temperature in the presence of 20 mM Brij-35 surfactant. The pH was monitored using a Radiometer GK2322 combination (glass/calomel) electrode calibrated with Fisher certified standard aqueous buffers (pH = 4.00 and 10.00) and recorded as a function of added standardized NaOH solution. The NaOH solutions were made by dilution of an 18 M NaOH stock solution and standardized using potassium hydrogen phthalate. Ionic strength was maintained at 0.10 M ($NaClO_4$).

Spectroscopic titrations were performed by monitoring the absorbance change between 490 and 670 nm of a solution of (**3**) (3.0 mM) as a function of pH in the presence of one equivalent of $Co^{2+}(ClO_4^-)_2$ using an OLIS® modified Cary 17 UV-vis spectrophotometer. Solutions were made similarly to those for the potentiometric titrations except for the exclusion of buffer.

Kinetic measurements

The rate of appearance of the hydrolysis product of PNPA (*p*-nitrophenolate ion) was followed by monitoring the increase in absorbance at 380 nm OLIS® modified Cary 17 UV-vis spectrophotometer at 25.0 ± 0.1°C. Reactions were monitored under pseudo-first-order conditions of excess, but equimolar, **3** and $Zn(ClO_4)_2$ in the range of 0.3–4.0 mM. Reactions were followed to at least four half-lives and displayed good first-order behaviour. The pseudo-first-order rate constants (k_{obs}) were determined by NLLSQ fitting of the absorbance vs. time traces to a standard exponential model. All observed rate constants were determined at least in duplicate and second-order rate constants were determined from slopes of k_{obs} vs. concentration of $[Zn^{2+}]_t$ plots.

In a typical experiment approximately 11 mg (2.3×10^{-5} mol) of **3** was placed in a vial fitted with a rubber septum and flushed with argon. Because of the insolubility of the ligand in water, 0.30 mL of acetonitrile was added along with approximately 0.23 mL (2.3×10^{-5} mol) of a $Zn^{2+}(ClO_4^-)_2$ stock solution (0.10 M). This mixture was sonicated until a homogeneous solution was obtained and then used as the **3**–Zn^{2+} stock solution for the day's experiments. Stock solutions were made up daily because of the instability of the ligand in solution over time. Solutions for the kinetic experiments were made in vials by adding enough **3**–Zn^{2+} stock solution so that after dilution, the concentration was between 0.8–4.0 mM. To this stock solution was added 1.5 mL of a stock surfactant solution (40.0 mM Brij-35 or 80.0 mM Triton X-100) and 1.5 mL of a stock buffer solution (0.20 M, I = 0.20, $NaClO_4$). After dilution this gave solutions containing a ligand–metal concentration ranging from 0.8–4.0 mM, a surfactant concentration of 20.0 mM $Brij_{35}$ or 40.0 mM Triton X-100, a buffer concentration of 0.10 M, and ionic strength of 0.10 M. (The Triton X-100 surfactant solutions were not adjusted for ionic strength because precipitates formed if the ionic strength was adjusted to 0.10 M.) The solutions were then pH-adjusted, put into cuvettes and temperature equilibrated in the spectrophotometer before the start of the reaction. The reaction was initiated by the injection of 10.0 μL of a PNPA stock solution (9 mM).

Studies on the rearrangement of *ortho*-nitrobenzylidenemalonates and their analogues to 2-aminobenzoate derivatives

Elzbieta Lewandowska, Stefan Kinastowski, and Stanislaw F. Wnuk

Abstract: Reaction of the diethyl 2-nitro-4-(trifluoromethyl)benzylidenemalonate with diethylamine in alcohols resulted in the reduction of the nitro group and the oxidation of the vinylic carbon attached to the phenyl ring. Simultaneous migration of the malonic fragment gave the appropriate 2-amino-4-(trifluoromethyl)benzoate esters. The presence of at least two nitro groups, or one nitro group and trifluoromethyl group on the phenyl ring, attached to the α-carbon and strongly electron withdrawing substituents at the β-carbon (CO_2Et, CN) in *ortho*-nitrobenzylidene systems is necessary for this reductive–oxidative rearrangement to proceed. Reaction of nitrocinnamates with thiols in the presence of triethylamine in tetrahydrofuran gave Michael addition products with different regioselectivity of addition. Ethyl 2-nitrocinnamate undergoes standard β-addition of thiols to a carbon–carbon double bond. However, 2,4-dinitro- and 2,4,6-trinitrocinnamates undergo α-addition of thiols, indicating that the presence of two nitro groups on the phenyl ring can reverse polarity of the carbon–carbon double bond in cinnamate acceptors.

Key words: abnormal Michael reactions, aromatic nitro compounds, benzylidene compounds, rearrangements.

Résumé : La réaction du 2-nitro-4-(trifluorométhyl)benzylidènemalonate d'éthyle avec la diéthylamine dans des alcools conduit à la réduction du groupe nitro et à l'oxydation du carbone vinylique attaché au noyau phényle. La migration simultanée du fragment malonique fournit les esters 2-amino-4-(trifluorométhyl)benzoates appropriés. Pour que ce réarrangement d'oxydoréduction se produise, il est requis d'être en présence d'un système *ortho*-nitrobenzylidène comportant au moins deux groupes nitro ou d'un groupe nitro et d'un groupe trifluorométhyle sur le noyau phényle attaché sur le carbone-α et des substituants fortement électroattracteurs sur le carbone-β (CO_2Et, CN). La réaction des nitrocinnamates avec les thiols en présence de triéthylamine, dans le tétrahydrofurane, conduit à la formation des produits d'addition de Michael avec une régiosélectivité d'addition différente. L'addition de thiols au 2-nitrocinnamate d'éthyle conduit à l'addition β normale sur la double liaison. Toutefois, l'addition de thiols sur les 2,4-dinitro- ou 2,4,6-trinitrocinnamates conduisent à des additions α, ce qui indique que la présence de deux groupes nitro sur le noyau phényle peut inverser la polarité de doubles liaisons carbone–carbone des accepteurs cinnamates.

Mots clés : réactions de Michael anormales, composés nitro aromatiques, composés benzylidènes, réarrangements.

[Traduit par la Rédaction]

Introduction

In previous work, we found that treatment of diethyl 2,4-dinitrobenzylidenemalonate (**1a**) with diethylamine (DEA) in MeOH did not lead to the expected Michael addition of DEA to the carbon–carbon double bond. Instead it gave the 2-amino-4-nitrobenzoic acid derivative **2a** (1) (Scheme 1). Such an unusual reductive–oxidative rearrangement selectively yields a variety of 2-aminobenzoic acid derivatives of type **2** when different primary or secondary alcohols (1, 2), thiols (3), or amines (1, 2) were used in place of MeOH. The new ester, thioester, or amide bond is formed at position 1, and a new ether, thioether, or amine bond is formed at the *C*-malonate carbon.

Such a skeletal rearrangement was also effective for heterocyclic π-deficient analogues in which the electron-withdrawing role of the second nitro group on the phenyl ring was replaced by a sp^2-hybridized nitrogen atom in the ring. Thus, nitropyridylidenemalonate 1-oxides bearing nitro and alkenyl substituents in the *ortho* position to each other (e.g., **3**; Scheme 2) underwent rearrangement to the amino-substituted pyridinecarboxylate derivatives (e.g., **4**) (4).

Synthetic methods involving neighboring group interaction in *ortho*-substituted nitrobenzene derivatives have been reviewed (5, 6), and new examples continue to attract interest (7). Such redox processes, which usually involve an intramolecular aldol condensation of the *ortho* substituent with the nitro group acting as the electrophilic center, have been used to synthesize a variety of heterocyclic compounds. These reactions typically occur under basic conditions with or without external reductive reagents and frequently involve thermal transformations (5).

Photochemically induced transfer of oxygen from a nitro group to an *ortho* substituent of nitrobenzene derivatives is

also well known and generates uncyclized nitroso products (5). The latter transformations have been elaborated to employ the *ortho*-nitrophenyl group as a photoremovable protective group for aldehydes and ketones (8) as well as phosphate esters of adenine nucleotides (9). The recent theoretical analysis for the isomerization of 2-nitrotoluene to 2-nitrosobenzyl alcohol is in good qualitative agreement with the available experimental results for the thermal and photoinduced rearrangement of *ortho*-nitrobenzyl compounds (9*c*).

To the best of our knowledge, the transformation of α-phenyl-2-nitrocinnamonitrile to *N*-benzoylanthranilic acid in aqueous–ethanolic alkali (10) is the only analogous example to our rearrangement that exists in the literature. Loudon and Tennant (11) suggested that the possible intermediates in this transformation involved addition of hydroxide ions to the carbon–carbon double bond, followed by an intramolecular aldol-type condensation in which the nitro group provides electrophilic center. We now report selected experiments on the one-step rearrangement of *ortho*-nitrobenzylidenemalonates and their analogues to various 2-aminobenzoic acid derivatives. The scope, limitation, and tentative mechanism of the rearrangement are also presented.

Results and discussion

Effect of the substituted aromatic ring

For the series of nitrobenzylidenemalonates **1a**–**c** reactivity toward rearrangement increased with increasing number of nitro groups on the aromatic ring. Thus, diethyl 2,4-dinitrobenzylidenemalonate (**1a**) undergoes the rearrangement in most cases (1), whereas the 2,4,6-trinitro analogue **1b** rearranges in all cases under the mildest conditions (2, 3). In contrast, diethyl 2-nitrobenzylidenemalonate (**1c**) does not rearrange and forms the stable β-carbonyl Michael adducts of type **9** (R, R′ = H) with amines (1), alkoxides (1), or thiolates (3).

The electron-withdrawing groups influence the rearrangement by (*i*) increasing the acidicity of an α-carbon attached to the aromatic ring, and (*ii*) controlling the oxidative potential of the *ortho*-nitro group. The relative acidities, rates of proton abstraction, and carbanion protonation of 4-nitro-, 2,4-dinitro-, and 2,4,6-trinitrotoluenes in methanolic DMSO have been examined (12). The kinetic ratio for proton abstraction from 2,4-dinitro- and 4-nitrotoluene is 230:1 in DMSO–MeOH (98:2), whereas the ratio for 2,4,6-trinitro- and 2,4-dinitrotoluene is about 100:1 in DMSO–MeOH (60:40). Thus, an increase in kinetic acidity resulting from the introduction of two *ortho*-nitro groups into 4-nitrotoluene is of the order of 2.3×10^4. The corresponding thermodynamic acidities expressed as pK_a values were found to depend strongly on DMSO concentration and are 12.1, 16.6, and 25.7 for 2,4,6-trinitro-, 2,4-dinitro-, and 4-nitrotoluene, respectively (12).

The number of nitro groups also effects the oxidative-reductive properties of these compounds. Bock and Lechner-Knoblauch (13) showed that 1,3,5-trinitrobenzene has the smallest potential for the reduction of the first nitro group (−0.51 V) whereas the reduction potentials of 1,3-dinitrobenzene and nitrobenzene are −0.82 and –1.10 V, respectively. Thus, increasing the number of the nitro groups on the phenyl ring facilitates both formation of the carbanion at the α-carbon (and its subsequent oxidation) and the reduction of first nitro group.

To further study effect of phenyl ring substituents on the rearrangement, 2,6-dinitro- (**6a**), 2-nitro-4-(trifluoromethyl)- (**6b**), and 2-chloro-6-nitrobenzylidenemalonates (**6c**) were prepared in a Knoevenagel condensation ($TiCl_4$–pyridine) (14) between the corresponding aldehydes (**5**) and diethyl malonate (Scheme 3). Reduction of commercially available 2-nitro-4-(trifluoromethyl)benzonitrile with diisobutylaluminum hydride (DIBALH) afforded aldehyde **5b** in 56% yield. This is a substantial improvement on a previously reported synthesis of **5b** when different synthetic approach was used (15). Compound **6a** rearranged under the influence of DEA in ethanol to give **7a** (86%) after 5 days (the rearrangement of **1a** took only a few hours to afford **2a** in 84% yield (1)). It seems that a second nitro group in the *ortho* position in **6a** has some steric influence on the rate of rearrangement.

The 2-nitro-4-trifluoromethyl analog (**6b**) produced under the typical conditions (DEA–EtOH, 24 h at ambient temperature) a stable adduct via ethanol addition to a double bond (**9b**, 51%), plus other by-products including unchanged **6b** and rearranged **7b**. However, prolonged reaction time and elevated temperature (~60°C) led to the expected rearranged product **7b** in 39% yield. Analogous treatment of **6b** with DEA in MeOH gave the rearranged product **8b** (58%) with concomitant transesterification of the malonic moiety. Replacement of the one nitro group by a chloro substituent prevent the rearrangement. Thus, reaction of 2-chloro-6-nitrobenzylidene (**6c**) with DEA–EtOH or amines (DEA, piperidine, or pyrrolidine) under typical conditions resulted in the recovery of **6c**. These results indicate that two strongly electron-withdrawing groups (EWG) must be present in the benzene ring. The data are supported by examination of the Hammett σ values (16) ($\sigma_{NO_2} > \sigma_{CF_3} > \sigma_{Cl}$),

which reflect the interaction of the substituents with the reaction site by a combination of resonance and field effects.

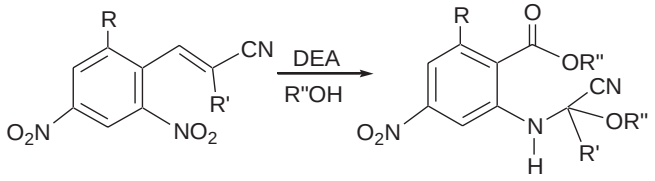
Effect of the substituents on the vinylic carbons

Substituents with strong electron-acceptor properties (CO_2Et, CN) at the β-carbon in *ortho*-nitrobenzylidene substrates also facilitate this rearrangement. Thus, reaction of ethyl α-cyano-2,4,6-trinitrocinnamate (**10**) (17) with DEA–EtOH gave the rearranged product **12** in 66% yield (Scheme 4). 2,4-Dinitrobenzylidenemalononitrile (**11**) rearranges in DEA–EtOH to yield ethyl 2-[*N*-(dicyano)(ethoxy)-methyl]amino-4-nitrobenzoate (**13a**) (56%) in addition to ethyl 2-amino-4-nitrobenzoate (21%). Treatment of **11** with DEA–MeOH gave the methyl ester **13b**.

Ethyl 2,4-dinitrocinnamate (**15a**), which bears only one EWG at the β-carbon, does not undergo this rearrangement (1). The rearrangement also failed with ethyl 2,4,6-trinitrocinnamate (**14**), despite the fact that the aromatic fragment is identical to the most reactive analogue **1b**. This indicated that the number of nitro groups on the phenyl ring, although a significant factor, is not the only force driving this rearrangement.

Interestingly, nitrocinnamates **14** and **15a**,**b** react with ethanethiol in THF in the presence of a catalytic amount of triethylamine (TEA) to give products **16** and **17a**,**b**. Mass spectra of **16** and **17a**,**b**, in addition to the molecular ions, showed peaks for the ions at *m*/*z* (%) 147 (45), 147 (61), and 133 (100) for **16**, **17a**, and **17b**, respectively. Their elemental compositions $C_6H_{11}O_2S$ $[(C_2H_5SCHCO_2C_2H_5)^+]$ for **16** and **17a** and $C_5H_9O_2S$ $[(C_2H_5SCHCO_2CH_3)^+]$ for **17b** were determined by HR-MS. These compounds are formed by the α-addition of the thiol to the α,β-unsaturated carbonyl compounds, a process that is in contrast to the usually observed

Scheme 4.



10 R = NO_2, R' = CO_2Et
11 R = H, R' = CN

13a R = H, R' = CN, R" = Et
13b R = H, R' = CN, R" = Me

β-addition to the carbonyl activated double bond (Michael addition) (18) including cinnamates (19) (Scheme 5). Reaction of **15a** with propanethiol also gave α-addition product **17c** whose structure was confirmed with 2D-NMR experiments. Thus, the heteronuclear multiple bond coherence (HMBC) spectrum showed that aromatic carbons (C6 (135.4) and C1 (140.5)) had a strong coupling to the diastereotopic CH_2 protons at 3.58 and 3.41, whereas no correlation to CH proton at 3.63 was observed. Conversely, the carbonyl carbon at 171.9 shows correlation to the CH proton at 3.63 and only to the one diastereotopic proton at 3.41.

Ethyl 2-nitrocinnamate does not react with propanethiol under similar conditions (TEA–THF). However, treatment of ethyl 2-nitrocinnamate with sodium propanethiolate in EtOH gave the standard β-addition product **18** (Scheme 6). These results indicate that two nitro groups on the phenyl ring reverse polarity of the carbon–carbon double bond in cinnamate acceptors and redirect the regioselectivity of nucleophile addition from the classical β-addition to an abnormal α-addition. Such regioselectivity is controlled by the resonance effect of the nitro groups on the phenyl ring, as opposed to the carboxylate function. Recently, Trost and Dake (20*a*) reported that phosphine-catalyzed reaction of nitrogen nucleophiles with 2-alkynoates also gave α-addition product. Other examples (18*a*) include α-addition of dimethylamine or methanol to methyl 3,3-di(trifluoromethyl)acrylate (20*b*).

Spectral support for the assumption that Michael addition may occur at either the α or β carbon depending on the carbon–carbon double bond polarization was found by comparing the absorption band of the stretching vibration of the double bond in IR spectra of **1a**–**c** (3) and nitrocinnamates. Thus, 2-nitro derivative **1c** displays a medium absorption band at 1641 cm^{-1} (and shows β-addition), whereas the 2,4-dinitro analogue **1a** has only a very weak band at 1642 cm^{-1}. On the other hand, the latter compound shows an active band at 1637 cm^{-1} in Raman spectrum, which points to a symmetrical distribution of π-electron charge density in the carbon–carbon double bond (21). The introduction of the third nitro group resulted in the appearance of a weak absorption band at 1635 cm^{-1} in IR spectrum of **1b**. Analogously, in the cinnamate series 2,4,6-trinitro **14** [1630 cm^{-1} (weak)] and 2,4-dinitro **15a** [1628 cm^{-1} (very weak)] show α-addition, whereas ethyl 2-nitrocinnamate [1634 cm^{-1} (weak to medium)] and ethyl cinnamate [1634 cm^{-1} (medium to strong)] show the β-addition.

The free rotation of the substituents at β-carbon and steric factors seems also to be a factor in rearrangement. Thus,

2,4-dinitrobenzylidene derivative of Meldrum's acid **19** did not yield the rearranged product under standard condition (DEA–EtOH).

Tentative mechanism

The intramolecular nature of this rearrangement was previously proven in experiments using isotopically labelled dimethyl-d_6 malonate and dimethyl-d_6 2,4-dinitrobenzylidenemalonate (1). The possible mechanism might involve the following sequence of steps: (*i*) a classical Michael addition of the alcohol molecule to a π-electron deficient carbon–carbon double bond in **1a** to give **20**; (*ii*) an aldol condensation between carbanion **21** and nitro group to yield the cyclic intermediate **22**; (*iii*) redox processes involving the quinonoid intermediate **23** followed by addition of a second alcohol (or water) molecule that results in regeneration of aromaticity; (*iv*) nucleophilic ring opening of **24** and simultaneous migration of the malonic fragment, which leads directly to the formation of the highly conjugated ester at position 1 and Schiff base at position 2; and (*v*) addition of alcohol to the resulting electron-deficient ketimin of mesoxalic ester **25** at position 2 gives the rearranged product **2a** (Scheme 7). Ketimin **25** would be expected to undergo addition quite readily owing the presence of two EWG at the *C*-malonate carbon in addition to the regular polarization of carbon–nitrogen double bond. A similar mechanism for the conversion of α-phenyl-2-nitrocinnamonitrile to *N*-benzoylanthranilic acid has been suggested (11) (vide supra). In our previous mechanism direct transfer of oxygen from a nitro group to an *ortho*-benzylic position was proposed (1). However, such direct transfers are normally induced photochemically rather than thermally (e.g. in the 2-nitrobenzaldehyde into 2-nitrosobenzoic acid and related rearrangements) (**5b**).

In conclusion, an unusual rearrangement of *ortho*-nitrobenzylidenemalonates (e.g., **1a**,**b** or **6**) and their analogues (e.g., **10** or **11**) in the presence of diethylamine in alcohols produces a variety of 2-aminobenzoate ester derivatives (e.g., **2**, **7**, **8**, **12**, or **13**). The presence of at least two nitro groups, or one nitro group and trifluoromethyl group, on the phenyl ring together with strongly electron-withdrawing substituents at the β-carbon (CO_2Et, CN) in *ortho*-nitrobenzylidene systems, appears to be necessary for this reductive–oxidative rearrangement to proceed. Reaction of nitrocinnamates with thiols in the presence of TEA in THF gave Michael addition products with different regioselectivity of addition. Ethyl 2-nitrocinnamate undergoes the standard β-addition of thiols to the carbon–carbon double bond. However 2,4-dinitro- (**15**) and 2,4,6-trinitrocinnamates

© 2002 NRC Canada

(**14**) undergo abnormal Michael-type α-addition of thiols indicating that the presence of two nitro groups on the phenyl ring can reverse polarity of the carbon–carbon double bond in cinnamate acceptors.

Experimental

Uncorrected melting points were determined with a capillary apparatus. UV spectra were measured with solutions in MeOH. ^{1}H (200 or 400 MHz), ^{13}C (50 or 100 MHz), and ^{19}F (376.5 MHz ($CFCl_3$)) NMR spectra were determined with solutions in $CDCl_3$ unless otherwise specified. Mass spectra (MS and HR-MS) were obtained with electron impact (EI, 20 eV) or atmospheric pressure chemical ionization (APCI) techniques. Merck kieselgel 60-F_{254} sheets were used for TLC and products were detected with 254 nm light. Merck kieselgel 60 (230–400 mesh) was used for column chromatography. Elemental analyses were determined at microanalytical laboratories at Adam Mickiewicz University, Poznan, Poland or Galbraith Laboratories, Knoxville, TN. Reagent grade chemicals were used, and solvents were dried by reflux over and distillation from CaH_2 (except THF–potassium) under argon.

2-Nitro-4-(trifluoromethyl)benzaldehyde (5b)

DIBALH (0.9 mL, 0.71 g, 5 mmol) was added dropwise via syringe to a stirred solution of 2-nitro-4-(trifluoromethyl)benzonitrile (1.08 g, 5 mmol) in dried benzene (20 mL) under N_2 at ambient temperature. After 2 h, reaction mixture was cooled down (ice bath) and 1 M H_2SO_4 (~5 mL) was slowly added. The organic layer was washed ($NaHCO_3$–H_2O, brine), dried ($MgSO_4$) and volatiles were evaporated. Column chromatography (5 → 15% EtOAc–hexane) gave **5b** (0.61 g, 56%); mp 42°C (lit. (15) mp 35°C) with data as reported (15).

Diethyl 2,6-dinitrobenzylidenemalonate (6a)

Procedure A

Titanium(IV) chloride (1.1 mL, 10 mmol) in carbon tetrachloride (2.5 mL) was added dropwise to THF (40 mL) and the mixture was cooled to ~5°C. After 15 min 2,6-dinitrobenzaldehyde (0.98 g, 5 mmol) in THF (5 mL) and diethyl malonate (0.76 mL, 0.80 g, 5 mmol) were added dropwise with stirring. Pyridine (1.6 mL, 20 mmol) in THF (5 mL) was then added dropwise over 20 min. After 24 h, water (8 mL) and diethyl ether (8 mL) were added, the organic layer was separated, and the aqueous layer extracted with ether. The combined ether solution was washed with brine, $NaHCO_3$–H_2O and brine, dried ($MgSO_4$), and concentrated. The precipitate formed on cooling was filtered and recrystallized (EtOH) to give **6a** (1.2 g, 71%); mp 56–57°C. IR ($CHCl_3$) (cm^{-1}): 1720 (C=O). ^{1}H NMR δ: 1.02 and 1.37 (2t, J = 7.4 Hz, 6H, $2CH_3$), 3.98 and 4.34 (2q, J = 7.4 Hz, 4H, $2CH_2$), 7.75 (t, J = 8.3 Hz, 1H, H_{Ar}), 8.10–8.37 (m, 3H, H_{Ar}, CH). EI-MS *m/z*: 338 (5, M^+). Anal. calcd. for $C_{14}H_{14}N_2O_8$: C 49.71, H 4.17, N 8.28; found: C 49.74, H 3.83, N 8.29.

Diethyl 2-nitro-4-(trifluoromethyl)benzylidenemalonate (6b)

Treatment of 2-nitro-4-(trifluoromethyl)benzaldehyde (**5b**; 0.9 g, 4.1 mmol) with diethyl malonate by procedure A gave **6b** (1.2 g, 81%); mp 72°C (EtOH). IR ($CHCl_3$) (cm^{-1}): 1733 (C=O), 1628 (C=C). ^{1}H NMR δ: 1.08 (t, J = 7.1 Hz, 3H, CH_3), 1.38 (t, J = 7.1 Hz, 3H, CH_3), 4.12 (q, J = 7.1 Hz, 2H, CH_2), 4.37 (q, J = 7.1 Hz, 2H, CH_2), 7.61 (d, J = 8.0 Hz, 1H, H_{Ar}), 7.92 (d, J = 7.1 Hz, 1H, H_{Ar}), 8.19 (s, 1H, H_{Ar}), 8.50 (s, 1H, CH). ^{13}C NMR δ: 14.1, 14.5, 62.2, 62.7, 122.7 (q, ^3J = 3.7 Hz), 122.9 (q, ^1J = 273.1 Hz), 130.6 (q, ^3J = 3.3 Hz), 130.8, 131.6, 133.0 (q, ^2J = 34.6 Hz), 134.5, 163.4, 164.6. ^{19}F NMR δ: −63.49 (s). APCI-MS *m/z*: 362 (100, $[M + H]^+$). Anal. calcd. for $C_{15}H_{14}F_3NO_6$: C 49.87, H 3.91, N 3.88; found: C 49.84, H 3.95, N 3.78.

Diethyl 2-chloro-6-nitrobenzylidenemalonate (6c)

The 2-chloro-6-nitrobenzaldehyde (0.93 g, 5 mmol) was treated with diethyl malonate by procedure A to give **6c** (1.3 g, 79%); mp 53°C (EtOH). IR ($CHCl_3$) (cm^{-1}): 1720 (C=O). ^{1}H NMR δ: 1.01 and 1.37 (2t, J = 7.2 Hz, 6H, $2CH_3$), 4.02 and 4.35 (2q, J = 7.2 Hz, 4H, $2CH_2$), 7.43–8.15 (m, 4H, H_{Ar}, CH). EI-MS *m/z*: 329 (1, $M^+(^{37}Cl)$), 327 (3, $M^+(^{35}Cl)$), 292 (100, $[M - Cl]^+$). Anal. calcd. for $C_{14}H_{14}ClNO_6$: C 51.31, H 4.31, N 4.27; found: C 51.30, H 4.28, N 4.27.

Ethyl 2-(*N*-(ethoxy)(diethoxycarbonyl)methyl)amino-6-nitrobenzoate (7a)

Procedure B

DEA (0.2mL, 2.0 mmol) was added to a solution of diethyl 2,6-dinitrobenzylidenemalonate (**6a**; 338 mg, 1 mmol) in EtOH (8 mL) and stirring was continued at ambient temperature for 5 days. The resulting mixture was evaporated and the residue was partitioned (EtOAc, diluted with HCl–H_2O). The organic layer was washed ($NaHCO_3$–H_2O, brine), dried ($MgSO_4$), and evaporated to dryness. Column chromatography (CH_3Cl–CCl_4–EtOAc, 10:5:1) gave **7a** (354 mg, 86%); mp 85°C (EtOH). IR ($CHCl_3$) (cm^{-1}): 3300 (NH), 1720 (C=O). ^{1}H NMR δ: 1.18–1.27 (m, 9H, $3CH_3$), 1.34 (t, J = 7.1 Hz, 3H, CH_3), 3.48 (q, J = 7.1 Hz, 2H, CH_2), 4.22–4.44 (m, 6H, $3CH_2$), 7.14 (dd, J = 7.0, 1.8 Hz, 1H, H_{Ar}), 7.30–7.42 (m, 2H, H_{Ar}), 8.27 (br s, 1H, NH). EI-MS *m/z*: 412 (3, M^+), 265 (100). Anal. calcd. for $C_{18}H_{24}N_2O_9$: C 52.42, H 5.87, N 6.86; found: C 52.38, H 5.82, N 6.86.

Ethyl 2-(*N*-(ethoxy)(diethoxycarbonyl)methyl)amino-4-(trifluoromethyl)benzoate (7b)

Treatment of **6b** (180 mg, 0.5 mmol) by procedure B (~60°C, 24 h) and column chromatography (4 → 15% EtOAc–hexane) gave crude **7b** (~115 mg; purity ~75% (^{1}H NMR) contaminated by **6b** and **9b**). This material was column chromatographed again to give **7b** (85mg, 39%) as a solidified oil. IR ($CHCl_3$) (cm^{-1}): 3300 (NH), 1752, 1739, 1697 (C=O). ^{1}H NMR δ: 1.23 (t, J = 7.2 Hz, 3H, CH_3), 1.25 (t, J = 7.1 Hz, 6H, $2CH_3$), 1.44 (t, J = 7.1 Hz, 3H, CH_3), 3.50 (q, J = 7.1 Hz, 2H, CH_2), 4.27–4.35 (m, 4H, $2CH_2$), 4.43 (q, J = 7.1 Hz, 2H, CH_2), 7.01 (d, J = 8.3 Hz, 1H, H_{Ar}), 7.49 (s, 1H, H_{Ar}), 8.09 (d, J = 8.3 Hz, 1H, H_{Ar}), 9.68 (s, 1H, NH). ^{13}C NMR δ: 14.3 (2C), 14.7, 15.3, 59.7, 61.8, 63.5 (2C), 87.9, 111.9, 114.3, 115.8, 123.9 (q, ^1J = 273.0 Hz),

© 2002 NRC Canada

132.8, 135.9 (q, ^2J = 32.3 Hz), 146.8, 167.6 (2C), 167.6. ^{19}F NMR δ: −64.25 (s). APCI-MS *m/z*: 390 (100, [M + H – EtOH]$^+$). Anal. calcd. for $C_{19}H_{24}F_3NO_7$: C 52.41, H 5.56, N 3.22; found: C 52.62, H 5.41, N 3.33.

Methyl 2-(*N*-(methoxy)(dimethoxycarbonyl)methyl)-amino-4-(trifluoromethyl)benzoate (8b)

Treatment of **6b** (180 mg, 0.5 mmol) by procedure B (~50°C, 24 h; MeOH was used instead of EtOH) and column chromatography (4 → 20% EtOAc–hexane) gave **8b** (110 mg, 58%); mp 128–130°C (MeOH). IR ($CHCl_3$) (cm^{-1}): 3300 (NH), 1740, 1698 (C=O). ^{1}H NMR δ: 3.29 (s, 3H, CH_3), 3.86 (s, 6H, $2CH_3$), 3.98 (s, 3H, CH_3), 7.04 (d, J = 8.1 Hz, 1H, H_{Ar}), 7.34 (s, 1H, H_{Ar}), 8.10 (d, J = 8.2 Hz, 1H, H_{Ar}), 9.68 (s, 1H, NH). ^{13}C NMR δ: 51.5, 52.9, 54.3 (2C), 88.5, 111.4, 114.8, 115.7, 123.8 (q, ^1J = 273.2 Hz), 132.8, 136.3 (q, ^2J = 32.5 Hz), 146.6, 167.2 (2C), 168.1. ^{19}F NMR δ: −64.17 (s). APCI-MS *m/z*: 348 (100, [M + H – MeOH]$^+$). Anal. calcd. for $C_{15}H_{16}F_3NO_7$: C 47.50, H 4.25, N 3.69; found: C 47.63, H 4.32, N 3.62.

Diethyl 2-ethoxy-2-(2-nitro-4-(trifluoromethyl)phenyl)-ethane-1,1-dicarboxylate (9b)

DEA (0.06 mL, 0.6 mmol) was added to a solution **6b** (108 mg, 0.3 mmol) in EtOH (3 mL) and stirring was continued for 24 h at ambient temperature and then at ~35°C for 6 h. Evaporation, work-up (as described in procedure B), and column chromatography (5 → 15% EtOAc–hexane) gave **9b** (62 mg, 51%) as a first eluting product followed by recovered **6b** and **7b**. Compound **9b**: IR ($CHCl_3$) (cm^{-1}): 1751, 1733 (C=O). ^{1}H NMR δ: 1.15, 1.16, 1.30 (3t, J = 7.1 Hz, 9H, $3CH_3$), 3.38–3.59 (m, 2H, CH_2), 3.81 (d, J = 8.3 Hz, 1H, CH), 4.08 (q, J = 7.2 Hz, 2H, CH_2), 4.23–4.31 (m, 2H, CH_2), 5.68 (d, J = 8.3 Hz, 1H, CH), 7.90 (d, J = 8.2 Hz, 1H, H_{Ar}), 7.97 (d, J = 8.2 Hz, 1H, H_{Ar}), 8.17 (s, 1H, H_{Ar}). ^{13}C NMR δ: 14.2, 14.5, 15.4, 59.7, 62.1, 62.3, 66.4, 74.3, 122.0 (q, ^3J = 3.6 Hz), 123.0 (q, ^1J = 272.8 Hz), 129.9 (q, ^3J = 3.2 Hz), 131.1, 131.9 (q, ^2J = 34.3 Hz), 139.7, 149.8, 166.7, 166.8. ^{19}F NMR δ: −63.41 (s). APCI-MS *m/z*: 408 (100, [M + H]$^+$). Anal. calcd. for $C_{17}H_{20}F_3NO_7$: C 50.13, H 4.95, N 3.44; found: C 50.19, H 5.18, N 3.46.

Analogous treatment (8 h, ambient temperature) of **6b** (108 mg, 0.3 mmol) with piperidine (0.06 mL, 0.6 mmol) in EtOH (3 mL) also gave **9b** (83 mg, 68%).

Similar treatment (18 h, ambient temperature) of **6b** (0.25 mmol) with DEA (0.5 mmol) or TEA (0.5 mmol) in MeOH (3 mL) gave analogous adduct of MeOH addition to a carbon–carbon double bond (e.g. **9b**, R″ = OMe, 52%; ^{1}H NMR δ: 3.33 (s, 3H, OCH_3), 3.82 (d, J = 7.8 Hz, 1H, CH), 5.59 (d, J = 7.8 Hz, 1H, CH)) in addition to unchanged **6b** and transmethylation by-products.

Treatment (24h, 50°C) of **9b** (41 mg, 0.1 mmol) with DEA (0.02 mL, 0.2 mmol) in EtOH (2 mL) produced **7b** (17 mg, 40%).

Ethyl 2-(*N*-(cyano)(ethoxy)(ethoxycarbonyl)methyl)-amino-4,6-dinitrobenzoate (12)

Procedure C

Ethyl α-cyano-2,4,6-trinitrocinnamate (17) (**10**; 0.168 g, 0.5 mmol) was dissolved in EtOH (4 mL) and DEA (0.1 mL, 1 mmol) was added at ambient temperature. The mixture was allowed to stand for 6 h and then evaporated to dryness under vacum. The residue was chromatographed (CCl_4–$CHCl_3$–Me_2CO, 10:5:1) and crystallized (EtOH) to give **12** (0.135 g, 66%) as a yellow crystals; mp 120–121°C. UV–vis (MeOH) λ (nm) (ε (M^{-1} cm^{-1})): 367 (3500). IR (KBr) (cm^{-1}): 3100 (NH), 2240 (CN), 1730, 1690 (C=O). ^{1}H NMR δ: 1.20–1.65 (m, 9H, $3CH_3$), 4.00–4.60 (m, 6H, $3CH_2$), 8.45 (d, J = 2.1 Hz, 1H, H_{Ar}), 9.61 (d, J = 2.1 Hz, 1H, H_{Ar}), 10.20 (s, 1H, NH). ^{13}C NMR δ: 13.4, 13.9, 62.9, 64.5, 83.2, 113.4, 114.5, 119.5, 124.5, 138.5, 154.7, 159.6, 163.2. EI-MS *m/z*: 410 (1, M$^+$), 383 (5), 236 (100). Anal. calcd. for $C_{16}H_{18}N_4O_9$: C 46.83, H 4.42, N 13.65; found: C 46.76, H 4.40, N 13.71.

Ethyl 2-(*N*-(dicyano)(ethoxy)methyl))amino-4-nitro-benzoate (13a)

Treatment (18 h) of 2,4-dinitrobenzylidenemalononitrile (17) (**11**; 0.122 g, 0.5 mmol) by procedure C (column chromatography: CCl_4–$CHCl_3$–Me_2CO, 60:10:1) gave ethyl 2-amino-4-nitrobenzoate (22 mg, 21%; mp 90–91°C (lit. (22) mp 89–91°C)) and **13a** (89 mg, 56%) as a second eluting compound; mp 63°C (EtOH). UV–vis (MeOH) λ (nm) (ε (M^{-1} cm^{-1})): 327 nm (2750). IR ($CHCl_3$) (cm^{-1}): 3270 (NH), 2270 (CN), 1720 (C=O). ^{1}H NMR δ: 1.31–1.56 (m, 6H, $2CH_3$), 4.25–4.54 (m, 4H, $2CH_2$), 7.75–8.15 (m, 3H, H_{Ar}), 9.33 (s, 1H, NH). EI-MS *m/z*: 291 (16, [M – HCN]$^+$), 263 (21), 218 (100). Anal. calcd. for $C_{14}H_{14}N_4O_5$: C 52.83, H 4.40, N 17.65; found: C 52.78, H 4.43, N 17.60.

Methyl 2-(*N*-(dicyano)(methoxy)methyl)amino-4-nitro-benzoate (13b)

Treatment of **11** (17) (0.122 mg, 0.5 mmol) by procedure C (18 h, MeOH was used instead of EtOH) and purification (as described for **13a**) gave methyl 2-amino-4-nitrobenzoate (22 mg, 23%; mp 158°C (lit. (23) 154–156°C)) and **13b** (86 mg, 59%; mp 82°C (MeOH)). IR ($CHCl_3$) (cm^{-1}): 3270 (NH), 2270 (CN), 1720 (C=O). ^{1}H NMR δ: 3.92 (s, 3H, CH_3), 4.08 (s, 3H, CH_3), 7.76–8.25 (m, 3H, H_{Ar}), 9.35 (s, 1H, NH). EI-MS *m/z*: 263 (12, [M – HCN]$^+$), 232 (100). Anal. calcd. for $C_{12}H_{10}N_4O_5$: C 49.66, H 3.47, N 19.31; found: C 49.58, H 3.42, N 19.35.

Ethyl (*E*)-2,4,6-trinitrocinnamate (14)

Procedure D

To a stirred solution of 2,4,6-trinitrobenzaldehyde (24) (0.24g, 1 mmol) in anhydrous acetonitrile (15 mL) (carbethoxymethylene)triphenylphosphorane (0.37g, 1.1 mmol) was added in one portion. The resulting cherry reaction mixture was stirred overnight at ambient temperature and then evaporated. The oily residue was chromatographed on silica gel (MeOH–$CHCl_3$, 1:99) and crystallized from MeOH to give **14** (0.202 g, 65%, two crops); mp 52–53°C. UV–vis (MeOH) λ (nm) (ε (M^{-1} cm^{-1})): 234 (21 800). IR (KBr) (cm^{-1}): 1710 (C=O), 1630w (C=C). ^{1}H NMR δ: 1.35 (t, J = 7.0 Hz, 3H, CH_3), 4.29 (q, J = 7.0 Hz, 2H, CH_2), 6.01 (d, J = 16.5 Hz, 1H, CH), 7.99 (d, J = 16.5 Hz, 1H, CH), 9.00 (s, 2H, H_{Ar}). EI-MS *m/z*: 266 (100, [M – OEt]$^+$). Anal. calcd. for $C_{11}H_9N_3O_8$: C 42.45, H 2.91, N 13.50; found: C 42.51, H 2.88, N 13.42.

© 2002 NRC Canada

Reaction of **14** with DEA in ethanol by procedure C did not afford rearranged product and only unchanged **14** was recovered (~81%).

Ethyl (*E*)-2,4-dinitrocinnamate (15a)

Treatment of 2,4-dinitrobenzaldehyde (0.196 g, 1 mmol) with $Ph_3P{=}CHCO_2Et$ by procedure D gave **15a** (181 mg, 68%); mp 91–92°C (lit. (25) mp 94°C). IR ($CHCl_3$) (cm^{-1}): 1705 (C=O), 1628w (C=C). ^1H NMR δ: 1.27 (t, *J* = 7.0 Hz, 3H, CH_3), 4.31 (q, *J* = 7.0 Hz, 1H, CH_2), 6.46 (d, *J* = 16.8 Hz, 1H, CH), 7.84 (d, *J* = 8.5 Hz, 1H, H_{Ar}), 8.11 (d, *J* = 16.8 Hz, 1H, CH), 8.48 (dd, *J* = 8.5, 2.3 Hz, 1H, H_{Ar}), 8.89 (d, *J* = 2.3 Hz, 1H, H_{Ar}).

As a less polar product *Z*-isomer of **15a** (40 mg, 15%) was eluted from the column (^1H NMR δ: 6.24 (dd, *J* = 11.9, 1.8 Hz, 1H, CH), 7.43 (d, *J* = 11.9 Hz, 1H, CH)).

Ethyl 2-ethylthio-3-(2,4,6-trinitrophenyl)propionate (16)

Procedure E

Ethanethiol (0.15 mL, 0.124 g, 2 mmol) and then triethylamine (0.03 mL, 0.022 g, 0.22 mmol) were added to a stirred solution of **14** (0.155 g, 0.5 mmol) in anhydrous THF (5 mL) at ambient temperature. TLC (CCl_4–$CHCl_3$–Me_2CO, 15:5:1) taken after 18 h indicated complete consumption of **14** (R_f = 0.52) with formation of less polar product (R_f = 0.58). After evaporation, the yellowish oily residue was chromatographed ($CHCl_3$) to give **16** (0.159 g, 85%) as a slightly yellow spectroscopically pure oil. IR ($CHCl_3$) (cm^{-1}): 1720 (C=O). ^1H NMR δ: 1.17 (t, *J* = 7.5 Hz, 3H, CH_3), 1.26 (t, *J* = 7.0 Hz, 3H, CH_3), 2.56 (q, *J* = 7.5 Hz, 2H, SCH_2), 3.41–3.85 (m, 3H, CH_2-CH), 4.19 (q, *J* = 7.0 Hz, 2H, CH_2), 8.80 (s, 2H, H_{Ar}). EI-HRMS *m*/*z*: 373.0586 (20, M^+ ($C_{13}H_{15}N_3O_8S$) = 373.0579), 147.0474 (45, ($C_6H_{11}O_2S$) = 147.0479, CH(SEt)CO_2Et).

Compound **16** (as well as **17a**,**b**) was stable when kept at ~5°C for a week. However, significant decomposition (~20%, ^1H NMR) was observed after 3 months.

Ethyl 2-ethylthio-3-(2,4-dinitrophenyl)propionate (17a)

Treatment of **15a** (0.133 g, 0.5 mmol) by procedure E gave **17a** (0.15 g, 91%) as a slightly yellow oil. IR ($CHCl_3$) (cm^{-1}): 1720 (C=O). ^1H NMR δ: 1.22 (t, *J* = 7.4 Hz, 3H, CH_3), 1.29 (t, *J* = 7.0 Hz, 3H, CH_3), 2.68 (q, *J* = 7.4 Hz, 2H, SCH_2), 3.39–3.77 (m, 3H, CH_2-CH), 4.26 (q, *J* = 7.0 Hz, 2H, CH_2), 7.69 (d, *J* = 8.6 Hz, 1H, H_{Ar}), 8.37 (dd, *J* = 8.6, 2.3 Hz, 1H, H_{Ar}), 8.83 (d, *J* = 2.3 Hz, 1H, H_{Ar}). EI-HRMS *m*/*z*: 328.0731 (18, M^+ ($C_{13}H_{16}N_2O_6S$) = 328.0728), 147.0476 (61, ($C_6H_{11}O_2S$) = 147.0479, CH(SEt)CO_2Et).

Methyl 2-ethylthio-3-(2,4-dinitrophenyl)propionate (17b)

Treatment of methyl 2,4-dinitrocinnamate (26) (**15b**; 0.129 g, 0.5 mmol) by procedure E gave **17b** (0.15 g, 93%) as a slightly yellow oil. IR ($CHCl_3$) (cm^{-1}): 1705 (C=O). ^1H NMR δ: 1.23 (t, *J* = 7.4 Hz, 3H, CH_3), 2.75 (q, *J* = 7.4 Hz, 2H, SCH_2), 3.41–3.78 (m, 3H, CH_2-CH), 3.72 (s, 3H, CH_3), 7.68 (d, *J* = 8.4 Hz, 1H, H_{Ar}), 8.39 (dd, *J* = 8.4, 2.3 Hz, 1H, H_{Ar}), 8.82 (d, *J* = 2.3 Hz, 1H, H_{Ar}). EI-HRMS *m*/*z*: 314.0566 (14, M^+ ($C_{12}H_{14}N_2O_6S$) = 314.0572), 133.0328 (100, ($C_5H_9O_2S$) = 133.0323, CH(SEt)CO_2Me).

Ethyl 2-propylthio-3-(2,4-dinitrophenyl)propionate (17c)

Treatment of **15a** (133 mg, 0.5 mmol) with propanethiol (2.0 mmol) by procedure E (column chromatography: $CHCl_3$) gave **17c** (150 g, 88%) as a slightly yellow oil. IR (neat) (cm^{-1}): 1734 (C=O). ^1H NMR δ: 0.97 (t, *J* = 7.3 Hz, 3H, CH_3), 1.26 (t, *J* = 7.1 Hz, 3H, CH_3), 1.59 (septet, *J* = 7.3 Hz, 2H, CH_2), 2.58–2.70 (m, 2H, SCH_2), 3.41 (dd, *J* = 13.3, 6.8 Hz, $1H_A$, from 3-CH_2), 3.58 (dd, *J* = 13.3, 8.1 Hz, $1H_{A'}$, from 3-CH_2), 3.63 (t, *J* = 7.3 Hz, 1H, CH), 4.11–4.25 (m, 2H, CH_2), 7.70 (d, *J* = 8.5 Hz, 1H, H_{Ar}), 8.40 (dd, *J* = 8.4, 2.3 Hz, 1H, H_{Ar}), 8.85 (d, *J* = 2.3 Hz, 1H, H_{Ar}). ^{13}C NMR δ: 13.7 (CH_3), 14.5 (CH_3), 22.9 (CH_2), 34.4 (SCH_2), 35.5 ($3CH_2$), 46.6 (CH), 62.1 (CH_2), 121.0 (C6), 127.3 (C5), 135.4 (C6), 140.5 (C1), 147.4 and 149.6 (C2/4), 171.9 (C=O) (assignments based on DEPT and HETCOR experiments). APCI-MS *m*/*z*: 343 (100, $[M + H]^+$). Anal. calcd. for $C_{14}H_{18}N_2O_6S$: C 49.11, H 5.30, N 8.18; found: C 49.25, H 5.39, N 8.18.

Ethyl 3-propylthio-3-(2-nitrophenyl)propionate (18)

Propanethiol (0.21 mL, 179 mg, 2.35 mmol) was added to a stirred solution of EtONa in EtOH (prepared from Na (50 mg, 2.1 mmol) and EtOH (2.0 mL)) at ambient temperature. After 15 min, ethyl (*E*)-2-nitrocinnamate (27) (130 mg, 0.59 mmol; prepared from 2-nitrobenzaldehyde by procedure D (93%)) dissolved in ethanol (4.0 mL) was added dropwise and the stirring was continued for 2 h. The resulting mixture was evaporated and the residue was partitioned ($CHCl_3$–H_2O). The organic layer was dried ($MgSO_4$), evaporated, and column chromatographed ($CHCl_3$) to give **18** (97 mg, 56%) as an oil. IR (neat) (cm^{-1}): 1740 (C=O). ^1H NMR δ: 0.92 (t, *J* = 7.3 Hz, 3H, CH_3), 1.17 (t, *J* = 7.1 Hz, 3H, CH_3), 1.50–1.57 (m, 2H, CH_2), 2.39 (dt, *J* = 12.6, 7.3 Hz, $1H_A$, SCH_2), 2.50 (ddd, *J* = 12.6, 7.8, 6.6 Hz, $1H_{A'}$, SCH_2), 2.88 (dd, *J* = 15.4, 8.2 Hz, $1H_A$, CH_2), 2.94 (dd, *J* = 15.4, 7.2 Hz, $1H_{A'}$, CH_2), 4.07 (q, *J* = 7.1 Hz, 2H, CH_2), 4.99 (t, *J* = 7.8 Hz, 1H, CH), 7.38 (t, *J* = 7.7 Hz, 1H, H_{Ar}), 7.60 (t, *J* = 7.6 Hz, 1H, H_{Ar}), 7.78 (dd, *J* = 8.0, 1.0 Hz, 2H, H_{Ar}). ^{13}C NMR δ: 13.7 (CH_3), 13.8 (CH_3), 23.0 (CH_2), 34.3 (SCH_2), 39.4 (CH), 42.3 ($2CH_2$), 61.4 (CH_2), 124.5 (C3), 128.4 (C4), 130.1 (C6), 133.4 (C5), 137.4 (C1), 150.1 (C2), 170.3 (C=O) (assignments based on DEPT and HETCOR experiments). APCI-MS *m*/*z*: 298 (100, $[M + H]^+$). Anal. calcd. for $C_{14}H_{19}NO_4S$: C 56.55, H 6.44, N 4.71; found: C 56.46, H, 6.66, N 4.79.

Treatment of ethyl 2-nitrocinnamate (27) (0.5 mmol) with propanethiol (2.0 mmol) by procedure E gave unchanged ethyl 2-nitrocinnamte (91%).

2,2-Dimethyl-5-(2,4-dinitrobenzylidene)-1,3-dioxan-4,6-dione (19)

2,4-Dinitrobenzaldehyde (0.98 g, 5 mmol) was treated with 2,2-dimethyl-1,3-dioxane-4,6-dione (Meldrum's acid) (0.72 g, 5 mmol) by procedure A to give **19** (0.69 g, 43%); mp 138–139°C (EtOH). IR ($CHCl_3$) (cm^{-1}): 1720 (C=O). ^1H NMR δ: 1.82 (s, 6H, $2CH_3$), 7.68 (dd, *J* = 8.4, 0.6 Hz, 1H, H_{Ar}), 8.58 (dd, *J* = 8.4, 2.1 Hz, 1H, H_{Ar}), 8.76 (d, *J* = 0.6 Hz, 1H, CH), 9.12 (d, *J* = 2.1 Hz, 1H, H_{Ar}). Electrocatalytic dechlorination of atrazine

Naomi L. Stock and Nigel J. Bunce

Abstract: Atrazine (2-chloro-4-ethylamino-6-isopropylamino-*s*-triazine), a photosynthetic inhibitor that is used in large quantities for weed control in corn and sorghum, is dechlorinated in aqueous solution upon electrolysis at a reticulated vitreous carbon cathode in the presence of noble-metal catalysts. Electrocatalytic hydrogenolysis to 2-ethylamino-4-isopropylamino-*s*-triazine occurs in quantitative yield, and is most efficient with palladium-based catalysts. Current efficiency increases with atrazine and catalyst concentration, and decreasing current density. A previously unobserved phenomenon with Pd catalysts is that current must be passed for a certain time before dechlorination commences. This lag time is explained in terms of the palladium lattice absorbing a finite amount of hydrogen before catalytically active hydrogen atoms appear on the catalyst surface.

Key words: electrocatalytic hydrogenoloysis, dechlorination, atrazine, palladium catalysts.

Résumé : Soumise à une électrolyse en solution aqueuse, au niveau d'une cathode de carbone vitreuse et réticulée et en présence de catalyseurs de métaux nobles, l'atrazine (la 2-chloro-4-éthylamino-6-isopropylamino-*s*-triazine), un inhibiteur de la photosynthèse utilisé en grandes quantités pour contrôler les mauvaises herbes dans le maïs et dans le shorgo, subit une déchloration. L'hydrogénolyse électrocatalytique en 2-éthylamino-4-isopropylamino-*s*-triazine se produit avec un rendement quantitatif et les catalyseurs à base de palladium sont les plus efficaces. L'efficacité de courant augmente avec les concentrations d'atrazine et de catalyseur et elle diminue avec la densité du courant. Avec les catalyseurs de Pd, il se produit un phénomène qui n'a pas été observé antérieurement; on doit faire passer le courant pour un certain temps avant que la déchloration ne débute. On explique ce décalage dans le temps en fonction d'une absorption dans un premier temps d'une quantité finie d'hydrogène par le réseau du palladium qui précéderait l'apparition d'atomes d'hydrogène catalytiquement actifs à la surface du catalyseur.

Mots clés : hydrogénolyse électrocatalytique; déchloration; atrazine; catalyseurs de palladium.

[Traduit par la Rédaction]

Introduction

Reactions involving electrochemically generated hydrogen adsorbed to a metal catalyst surface (M) have been known since the beginning of the twentieth century (1, 2). Two classes of these reactions are known: electrocatalytic hydrogenation and electrocatalytic hydrogenolysis (both abbreviated ECH). The former involves the addition of hydrogen to π bonds (3–6), whereas the latter involves the reductive cleavage of σ bonds, as in dechlorination reactions (7–11). Both types of ECH reactions involve the electrochemical reduction of a protic solvent to produce adsorbed hydrogen atoms (H_{ads}, eq. [1]) that react chemically with an adsorbed organic substrate $(R\text{-}X)_{ads}$, eq. [3]): see below, which is adapted from ref. 6.

[1] $2H_2O(\text{or } H_3O^+) + 2e^- + M \rightarrow 2H_{ads}M + 2OH^- \text{ (or } H_2O)$

[2] $R\text{-}X + M \rightarrow (R\text{-}X)_{ads}M$

[3] $(R\text{-}X)_{ads}M + 2H_{ads}M \rightarrow (R\text{-}H)_{ads}M + HX$

[4] $(R\text{-}H)_{ads}M \rightarrow R\text{-}H + M$

ECH always competes with the hydrogen evolution reaction (HER), which proceeds via the Volmer-Heyrovsky-Tafel mechanism (6).

[5] $H_2O + e^- + M \rightarrow H_{ads}M + OH^-$ (Volmer reaction)

[6] $H_{ads}M + H_2O + e^- \rightarrow H_2 + M + OH^-$ (Heyrovsky reaction)

[7] $H_{ads}M + H_{ads}M \rightarrow H_2 + 2M$ (Tafel reaction)

The use of ECH for the remediation of chloroaromatic compounds is potentially advantageous compared with traditional techniques such as adsorption on granular activated carbon (GAC) or incineration. As with other electrochemical technologies, ECH is useful as a "front-end" technology for dechlorinating toxic organic compounds prior to biological treatment (12). Comparing ECH with GAC adsorption, the chloro compounds are dechlorinated rather than simply transferred to a different phase; while in comparison with incineration, ECH avoids the possible formation of toxic byproducts such as chlorinated dibenzodioxins and dibenzofurans. As an

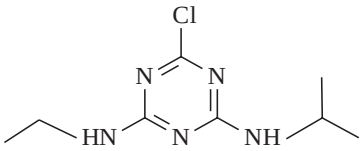
electrochemical process, ECH is a "green" technology, which employs ambient temperatures, aqueous media, and electrons rather than chemical additives to promote chemical change. Provided that high current efficiencies can be achieved, ECH is also cost and energy efficient, technically flexible, and readily allows for the selective dechlorination of many different organic compounds (7).

Atrazine (2-chloro-4-ethylamino-6-isopropylamino-*s*-triazine) is used in large quantities in North America to control broadleaf and grassy weeds, primarily in corn and sorghum, and as a result has become a common contaminant in ground and surface water (13). This is of particular concern, since this herbicide has been identified as a possible carcinogen (14) and endocrine disruptor (15).



In this work we studied electrocatalytic hydrogenolysis (ECH) as a possible remediation method for the dechlorination of atrazine, using various noble-metal catalysts at a reticulated vitreous carbon (RVC) electrode in aqueous solutions. In particular, we examined the influence of substrate concentration, catalyst concentration and reusability, and current density on dechlorination efficiency.

Experimental

Materials

Analytical grade atrazine (99% pure) was purchased from Supelco (Oakville, Ontario). Technical grade atrazine (Aatrex-Nine-O, 90% pure) was generously donated by Peter Smith (Plant Agriculture Department, University of Guelph), and was purified by hot filtration and recrystallization from methanol. An analytical standard of dechlorinated atrazine (DCA) was generously donated by Dr. Nelson Johnson (Novartis, Jonesboro, North Carolina). All catalyst powders were 5% by weight and were obtained from Aldrich (Oakville, Ontario). Sulphuric acid (H_2SO_4), lithium perchlorate ($LiClO_4$), sodium sulphate (Na_2SO_4), and HPLC grade acetonitrile and methanol were obtained from Fisher Scientific (Toronto, Ontario). Nafion-417 membranes and RVC (80 ppi) were obtained from the Electrosynthesis Company (Lancaster, New York). Platinum foil (99.95% pure), platinum wire (99.95% pure, 0.368 mm diameter), and copper wire (99.9% pure, 1.0 mm diameter) were purchased from Alfa Aesar (Ward Hill, Massachusetts). Water used in all experiments was purified using a Millipore Milli-Q Reagent Water System and had a resistivity of not less than 10 MΩ cm.

Apparatus and procedures

Cyclic voltammetry was conducted on unstirred atrazine–acetonitrile solutions (200 ppm) in a 20 mL open-top glass cell. Both the working and counter electrodes were platinum (0.94 and 1.26 cm^2, respectively). In all experiments, 0.15 M lithium chloride was used as the supporting electrolyte and a sweep rate of 200 mV s^{-1} was employed. All CV experiments were conducted on a computer-controlled EG&G Princeton Applied Research Potentiostat (Model 273). Data were acquired using Model 270/250 Research Electrochemistry Software (version 4.10), converted to ASCII-text format and plotted in Microsoft Excel 2000 (version 9.0.2720). A saturated silver–silver chloride electrode, which was calibrated to 200 mV, was used as a reference electrode. Reference potentials were calculated against a standard hydrogen electrode (SHE).

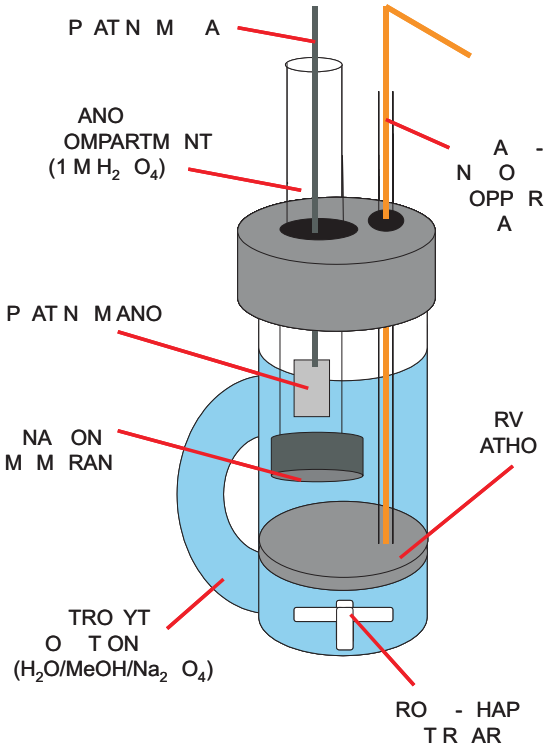
All electrocatalytic hydrogenations were carried out in a flow-through batch cell (Fig. 1) designed by Patrick Dubé (University of Sherbrooke) and fabricated by Yves Savoret (University of Guelph). In this cell, the anode and cathode compartments were separated with a Nafion 417 membrane. In all experiments the cathode was RVC (80 ppi, 5 mm thick and 36 mm in diameter) with a copper wire lead (enclosed in glass tubing for stability) and the anode was platinum foil (16 mm × 12 mm and 0.1 mm thick) with a platinum wire lead. The anolyte solution was 20 mL of sulphuric acid (1 M) and the catholyte solution was water–methanol (75:5 mL), and contained sodium sulphate as supporting electrolyte to a concentration of 0.15 M. Atrazine was dissolved in the methanol aliquot and catalyst powder was added to the cathode compartment. A cross-shaped stir bar was placed in the cathode compartment and upon stirring, the catholyte solution and catalyst powder were forced through the RVC cathode, resulting in the impregnation of catalyst powder in the cathode. The catalyst remained impregnated in the RVC cathode throughout the experiment. When the charge was removed and the magnetic stirrer turned off, the catalyst powder returned to solution. An Amel Instrument General Purpose Potentiostat/Galvanostat (Model 2049) was used for experiments carried out at constant current. A computer controlled EG&G Princeton Applied Research Potentiostat (Model 273), equipped with Model 270/250 Research Electrochemistry Software (version 4.10) was used for experiments carried out at constant potential. A saturated silver – silver chloride electrode, which was calibrated to 200 mV, was used as a reference electrode. All potentials were calculated against a standard hydrogen electrode (SHE). Samples of the pesticide solutions were removed for HPLC analysis at appropriate time intervals during all experiments.

Degradation of the atrazine solutions was monitored using a Waters Model 600 HPLC unit, equipped with a Waters Model 486 variable UV–vis detector, a reverse phase Genesis C_{18} column (4.6 × 250 mm) and a Waters silica precolumn guard. For all analyses, the detector was set at λ = 220 nm and a methanol–water (80:20) mobile phase (1 mL min^{-1} flow rate) was used. Prior to use, solvents were filtered using Supelco Nylon 66 membranes (0.2 μm × 47 mm) to remove microparticles. All injections were done manually using a Rheodyne syringe (Waters), which injected 25 μL of sample into a 5 μL sample loop. Chromatogram generation and peak integration was carried out with Waters Millennium software (version 1.10).

Identification of the dechlorinated product was determined by Perry Martos (University of Guelph) via LC–MS–MS analyses on a VG Quattro II equipped with a quadrapole MS detector and MassLynx software (version 3.5). The samples were ionized using Atmospheric Pressure Chemical Ioniza-

© 2002 NRC Canada

Fig. 1. Schematic of cell used for ECH.



tion (APCI). APCI probe temperatures ranged from 200 to 300°C and cone voltages ranged from 25 to 50 V. Since the samples analyzed by LC–MS contained only single compounds, a column was not required. The mobile phase employed was acetronitrile–water (75:25) (0.6 mL min^{-1} flow rate). The water portion of the mobile phase was spiked with 0.1% formic acid to facilitate ionization of the sample. Prior to use, solvents were filtered to remove microparticles.

Calculations

The apparent current efficiencies for the dechlorination of atrazine were calculated from the number of moles of substrate reacted and the charge passed assuming that two electrons were required for the removal of one chlorine. Changes in volume were taken into consideration due to the removal of samples for analysis.

Results and discussion

The ECH of a 25 ppm solution of atrazine at 50 mA, using as catalyst 50 mg Pd/Al_2O_3, resulted in the rapid production of dechlorinated atrazine (DCA) (2-ethylamino-4-isopropylamino-1,3,5-triazine). The identity of the product was established as DCA by showing that it had the same HPLC retention time and mass spectral properties as authentic material. Following 30 min of ECH treatment, greater than 95% of the atrazine was dechlorinated, and a complete mass balance was obtained (Fig. 2).

Is it really ECH?

Cyclic voltammetry was employed to determine whether the dechlorination of atrazine proceeded via ECH or by direct electroreduction followed by protonation. Ideally the $E_{1/2}$ value for atrazine would have been obtained in the water–methanol solution used for electrolyses, but the reduction of the solvent masked the reduction of atrazine, and so the aprotic solvent acetonitrile was employed instead. In acetonitrile at a platinum cathode, a cyclic voltammogram of 200 ppm atrazine indicated an irreversible reduction process with $E_{1/2}$ = –1.3 V vs. SHE. Upon electrolysis in water–methanol, no reduction was observed at $E = -0.5$ V, and the rate of atrazine reduction was essentially independent of potential at $E \leq -0.8$ V (Fig. 3). Since these potentials are much less negative than $E_{1/2}$ for reduction of atrazine (albeit in acetonitrile) and in the same range as for the reduction of water (–0.83 V (16)), the observed dechlorination of atrazine cannot be as a result of direct electroreduction.

Dechlorination efficiency (Table 1)

The influences of current density, catalyst concentration, variation of the noble-metal catalyst, and initial substrate concentration on the dechlorination efficiency of atrazine were examined. In order to study the effect of current density, a series of 25 ppm atrazine solutions were electrolyzed in the presence of 50 mg Pd/Al_2O_3 at 5, 10, 20, 50, 100, and 200 mA. Applied currents ≥20 mA led to ≥93% loss of the initial atrazine within 30 min (Table 1, entries 1–6). At 10 mA, ECH treatment led to ~65% dechlorination, but at 5 mA dechlorination was negligible. Except for the case of the 5 mA electrolysis, the current efficiency decreased as the applied current increased, and was greatest (16%) at 10 mA (Table 1, entry 2). A decrease in current efficiency with increasing current density was also observed by Yusem and Pintauro (4) upon ECH of soybean oil. The explanation of this effect is that eq. [3], namely electrocatalytic hydrogenation or hydrogenolysis, is in competition with hydrogen evolution, eq. [6]. At high-current densities, the rate of the electrochemical generation of adsorbed hydrogen becomes faster than the rate at which the substrate can migrate to the surface and become adsorbed, eq. [2]. Consequently, a greater proportion of H_{ads} is lost to the unproductive reaction of hydrogen gas evolution, eq. [6].

The influence of catalyst concentration on the dechlorination of atrazine was investigated by employing 0, 25, 50, 100, 200, 400, and 600 mg of Pd/Al_2O_3 catalyst powder in the ECH treatment of 80 mL of a 25 ppm atrazine solution at 50 mA (Table 1, entries 4, 7–13). Catalyst concentrations of 50 mg resulted in the dechlorination of ≥96% of the initial atrazine within 30 min. The control experiment (atrazine without Pd/Al_2O_3) gave negligible reaction, further supporting ECH over the electronation–protonation mechanism. Current efficiency increased with catalyst concentration, with the exception of 600 mg, the maximum catalyst concentration investigated, and the best efficiency (7%) was obtained with a catalyst concentration of 400 mg. We suggest that increasing the amount of catalyst increases the production of *adsorbed* hydrogen (note that at constant current the overall production of hydrogen is independent of the amount of catalyst), thereby promoting hydrogenolysis. At some point, we would expect a further increase in the amount of catalyst to be unproductive, due to clogging the pores of the RVC cathode; this is presumably the explanation for the lower current efficiency observed with 600 mg of catalyst.

[a]Representative experiments were run in triplicate. In these experiments, the average standard deviation was ±0.4%.
[b]Representative experiments were run in triplicate. In these experiments, the average standard deviation was ±6.3%.

The electrocatalytic properties of various noble-metal catalysts — Raney nickel; palladium, platinum, ruthenium, and rhodium on aluminia; and palladium on calcium carbonate — were investigated (Table 1, entries 14–19). Catalysts on carbon powder supports were not included in the study because atrazine rapidly and strongly adsorbed to carbon powder resulting in its removal from solution without a chemical change. Palladium was the most active ECH catalyst (Fig. 4), and current efficiencies of 11 and 6% were achieved with palladium on calcium carbonate and alumina, respectively. This result can be attributed to palladium's ability to both adsorb and absorb hydrogen (17). Similarly, Dabo et al. (18) observed that palladium catalysts offered maximum current efficiencies in the ECH of 4-phenoxyphenol. Palladized carbon felt was found to be an efficient catalyst for the dechlorination of 4-chlorophenol (19) and 2,4-dichlorophenoxyacetic acid (7–9); in the latter studies, current efficiencies for dechlorination reaction followed the sequence Pd > Rh > Ru catalysts.

The influence of the initial substrate concentration on the dechlorination of atrazine was examined using initial atrazine concentrations of 4, 25, and 83 ppm; 50 mA; and 400 mg Pd/Al_2O_3 (Table 1, entries 18, 20, 21). Within 30 min, >80% of the initial atrazine was dechlorinated. Current efficiency increased with increasing initial substrate concentration, a result that can be explained in terms of in-

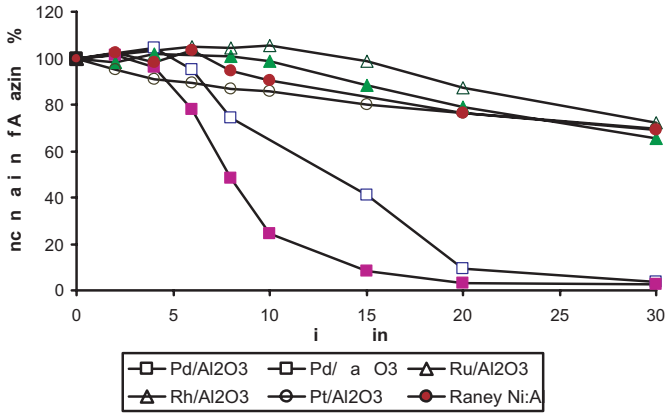

Fig. 5. Concentration of atrazine (A) and dechlorinated atrazine (B) during long-term ECH treatment (20 mA, 50 mg Pd/Al_2O_3) periodically spiked with concentrated atrazine solution.

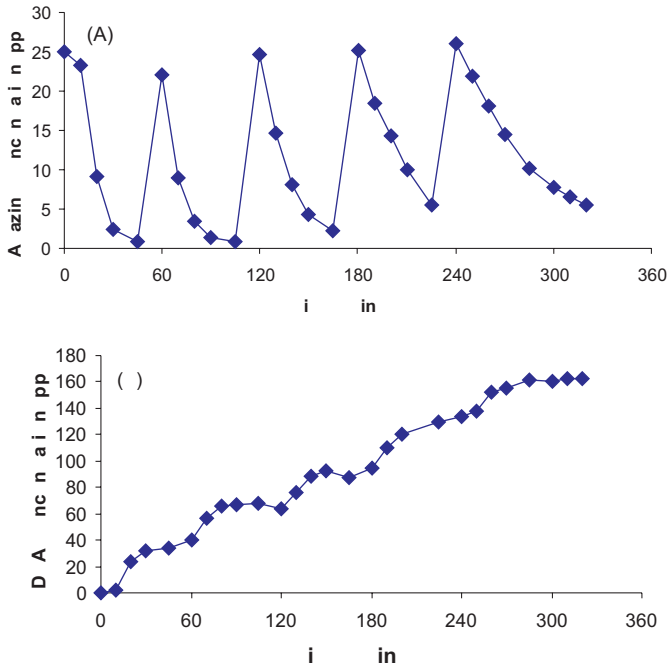

creased adsorption of the substrate on the catalyst (eq. [2]), allowing dechlorination (eq. [3]) to compete more effectively with hydrogen evolution. Previously, Mahdavi et al. (20) found that the current efficiency for the electrocatalytic hydrogenation of cyclohexenone increased with increasing substrate concentration.

Catalyst reusability

Longevity of the catalyst is a critical parameter in any catalytic process. We investigated the reusability of Pd/A_2O_3 for the ECH of atrazine in two different experiments. In the first of these, the Pd/A_2O_3 catalyst (200 mg) was removed by filtration using glass fiber paper after an ECH experiment with 25 ppm of atrazine at 50 mA (catalyst recovery 98 ± 3%). After drying at 80°C, the recycled Pd/A_2O_3 catalyst was used for a second similar ECH experiment; 30 min of electrolysis at 50 mA gave almost complete dechlorination of the starting material, with very similar current efficiency (10% in run 2 compared with 8% in run 1).

Table 2. Current efficiencies and first-order rate constants for the loss of atrazine during long-term ECH treatments (50 mg Pd/Al_2O_3, 20 mA) periodically spiked with concentrated atrazine solution.

Hour	Maximum current efficiency (%)	Rate constant (k) (s^{-1})
1st	5	—
2nd	8	1.23
3rd	6	0.87
4th	4	0.53
5th	3	0.30

In the second experiment, involving Pd/Al_2O_3 catalyst (50 mg), the atrazine solution was electrolyzed continuously at 20 mA, but every 60 min sufficient atrazine was added to restore its concentration to the original value of 25 ppm. The small amount of catalyst for this experiment was chosen so that all of it was trapped in the pores of the RVC and none was inadvertently removed when sampling the solution for analysis. As illustrated in Fig. 5A, the concentration of atrazine rapidly decreased after each addition, although gradual loss of catalyst activity was evident. Figure 5B shows that DCA continuously accumulated in solution during the experiment, eventually reaching a concentration > 160 ppm. Maximum current efficiencies and apparent first-order rate constants for loss of atrazine are listed in Table 2. A first-order plot is illustrated in Fig. 6.

Lag time in dechlorination

The ECH reaction of atrazine, catalyzed by Pd/Al_2O_3, was characterized by a lag time that decreased with an increase of both current density and catalyst concentration (Fig. 7). The lag time (t) was inversely proportional to current density (i) for a fixed catalyst concentration, suggesting that a fixed amount of charge (Q) must pass through the solution before dechlorination of atrazine begins, i.e., $Q = it$. In support of this hypothesis, when atrazine (50 mA, 50 mg Pd/Al_2O_3) was electrolyzed with preactivation of the cathode for 5 min (the lag time observed in Fig. 7A under these conditions) before the introduction of atrazine, the lag time disappeared and the degradation of atrazine was immediate. Furthermore, the maximum current efficiency increased from 4 to 26%. Likewise, in the experiment on long-term catalyst use (Fig. 5A), a lag time was observed only with the initial solution; subsequent additions of atrazine were followed by immediate dechlorination.

We interpret the decreased lag time with higher catalyst concentration in terms of the proportion of the RVC surface that is in contact with catalyst. Since current was constant in the experiments shown in Fig. 7B, the total rate of hydrogen production was the same, but only that produced at Pd was catalytically useful. As noted already, the behaviour of Pd catalysts was unique: no lag time was observed with the other noble metals studied (although it was difficult to determine whether or not a lag time occured with Rh or Ru, because dechlorination was so slow). We therefore hypothesize

Fig. 6. Superimposed first-order kinetic curves for the degradation of atrazine each hour during long-term ECH treatment (20 mg, 50 mg Pd/Al_2O_3) periodically spiked with concentrated atrazine solution.

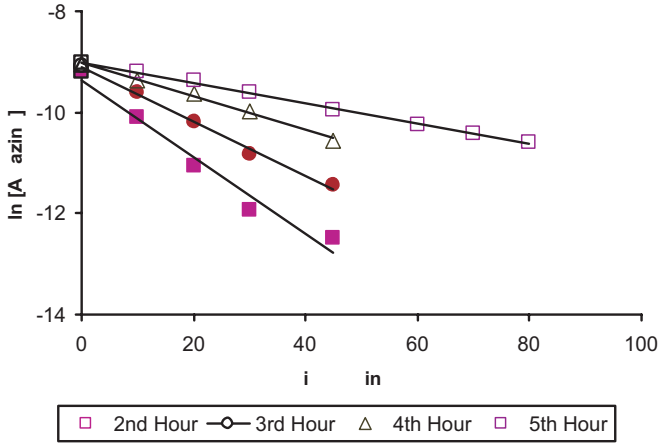

Fig. 7. Occurrence of lag time in the degradation of atrazine. Influence of current density (50 mg Pd/Al_2O_3) (A) and catalyst concentration (50 mA) (B).

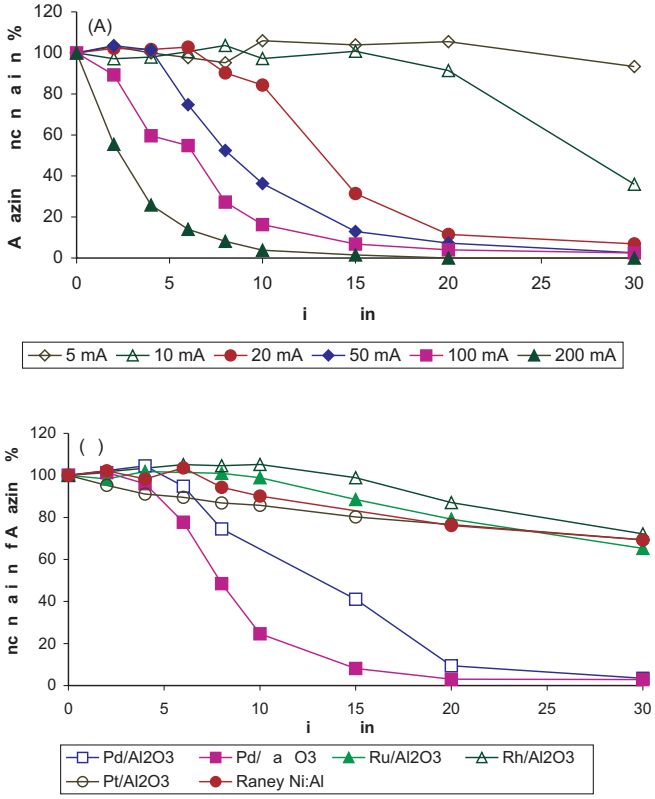

that the unique ability of palladium to both adsorb and adsorb hydrogen (17) accounts for both its superior electrocatalytic properties and the observed lag time. By analogy to a bucket filling with water and then overflowing, we propose that the palladium must first absorb the electrochemically produced hydrogen; once the palladium lattice is "full," hydrogen can be adsorbed at the palladium surface, allowing dechlorination to begin. The following calculation supports the foregoing concept. Consider the experiments in Fig. 7B involving 400 mg of catalyst. We assume that under these conditions the RVC pores are filled with catalyst and hence all the electrolytic hydrogen is formed at a Pd surface. The lag time is 3 min, which at 50 mA corresponds to $Q = 9$ C, or 9×10^{-5} mol H. The mass of Pd (5% on alumina) is 20 mg = 2×10^{-4} mol, i.e., mol H ~ mol Pd. This is consistent with H occupying the interstices of the Pd lattice, but not with Pd merely covering the surface of Pd particles.

In considering why the lag phenomenon had not previously been reported, we noted that most ECH reactions are characterized by reaction times on the order of several hours with samples taken every hour (8) or only at the beginning and end of the experiment (4). In our experiments, complete dechlorination was observed in 30 min and samples were taken every 2 min, making the lag effect easy to observe. Related observations have been reported by Tsyganok et al. (7), in whose dechlorination of 2,4-dichlorophenoxyacetic acid (2,4-D), the electrocatalytic activity of carbon-supported palladium was dramatically enhanced 2 h into the ECH treatment. These authors, who had also noted that preactivation of the cathode resulted in accelerated dechlorination, suggested that preactivation led to the formation of a hydrogen-saturated palladium phase and a change in spatial distribution of the supported Pd-clusters.

Conclusion

We found that electrocatalytic hydrogenolysis is an effective method of dechlorinating atrazine solutions at ppm concentrations. The method may have application to remediation, particularly of waste water streams, though it is not clear whether it has sufficient efficiency to be useful for contaminated ground water. The reaction product, DCA, is formed in quantitative yield. The DCA molecule still retains the *s*-triazine moiety, and it is not clear whether this reaction product will be a photosynthesis inhibitor like the parent molecule. Plant bioassays on the electrolyzed solutions of atrazine are in progress and will be reported separately.

Medium-sized cyclophanes, part 59:[1] Nitration of [3.3]- and [3.3.3]metacyclophanes — Through-space electronic interactions between two or three benzene rings

Takehiko Yamato, Koji Tsuchihashi, Noriko Nakamura, Mai Hirahara, and Hirohisa Tsuzuki

Abstract: The the two *tert*-butyl groups of *anti*-6,15-di-*tert*-butyl-9,18-dimethoxy[3.3]metacyclophane (*anti*-**4**) are both ipso-nitrated even under mild reaction conditions such as copper(II) nitrate in an acetic anhydride solution because of the decreased deactivation of the second aromatic ring by the introduced nitro group. On the other hand, *anti*-5,13-di-*tert*-butyl-8,16-dimethoxy[2.2]metacyclophane (*anti*-**1**) undergoes replacement of only one *tert*-butyl group under the same reaction conditions. The higher yields of the twofold ipso-nitration product *anti*-**7** were obtained in nitration of *anti*-**4** with fuming nitric acid or mixed acid (HNO_3–H_2SO_4). Thus, the number of ipso-nitrations at the *tert*-butyl groups of *anti*-**4** was strongly affected by the reactivity of the nitration reagent. Nitration of the corresponding syn-conformer *syn*-**4** with copper(II) nitrate in an acetic anhydride solution, however, led only to the recovery of the starting compound. The presently developed procedure was further applied to the direct removal of the *tert*-butyl group by electrophilic substitution of the larger-sized ring macrocyclic metacyclophanes, *cone*- and *partial-cone*-tri-*tert*-butyl[3.3.3]metacyclophanes **11**.

Key words: [3_n]metacyclophanes, conformation, ipso-nitration, through-space electronic interaction, crystal structure.

Résumé : En raison de la désactivation plus faible du deuxième noyau aromatique par le groupe nitro introduit en premier, les deux groupes *tert*-butyles de l'*anti*-6,15-di-*tert*-butyl-9,18-diméthoxy[3.3]métacyclophane (*anti*-**4**) sont tous les deux nitrés en position ipso, même dans des conditions aussi douces que le nitrate de cuivre(II) en solution dans l'anhydride acétique. Toutefois, dans les mêmes conditions, la nitration du *anti*-5,13-di-*tert*-butyl-6,18-diméthoxy[2.2]-métacyclophane (*anti*-**1**) ne donne lieu qu'au remplacement d'un seul groupe *tert*-butyle. Les rendements élevés du produit de double nitration ipso, le produit *anti*-**7**, sont obtenus par nitration du produit *anti*-**4** à l'aide d'acide nitrique fumant ou par un mélange d'acide (HNO_3–H_2SO_4). Le nombre de nitration ipso au niveau des groupes *tert*-butyles d'*anti*-**4** sont fortement affectées par la réactivité de l'agent de nitration. La nitration du conformère syn correspondant, *syn*-**4** avec du nitrate de cuivre(II) en solution dans l'anhydride acétique ne conduit toutefois qu'à la récupération du produit de départ. On a aussi appliqué la méthode développée ici pour procéder à l'enlèvement direct du groupe *tert*-butyle par substitution électrophile de métacyclophanes macrocycliques à cycles plus grands, les tri-*tert*-butyl[3.3.3]métacyclophanes (**11**) à *cône*- et à *cône-partiel*-.

Mots clés : [3_n]métacyclophanes, conformation, nitration ipso, interaction électronique à travers l'espace, structure cristalline.

Introduction

Although the replacement of a *tert*-butyl group by a nitro group in electrophilic aromatic substitution has frequently been described in the literature (2, 3), the yields have generally been modest because of the accompanying side reactions (4, 5). Only in activated compounds are better yields obtained. However, there have been only a few investigations on the ipso-electrophilic aromatic substitution of *tert*-butylarenes having more than two benzene rings (6). Recently, we have reported that ipso-acylation (7) and ipso-nitration (8, 9) of internally methyl-substituted di-*tert*-

Scheme 1.

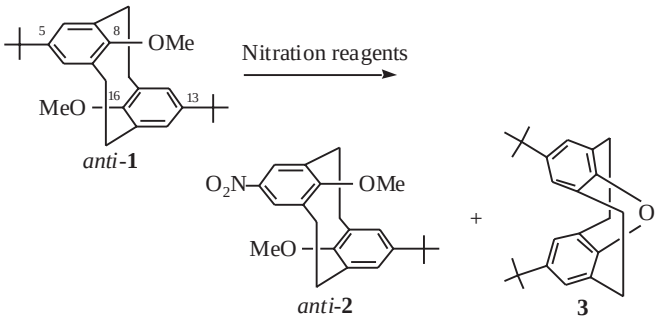

Fig. 1. Two possible through-space electronic interactions of [3.3]MCPs.

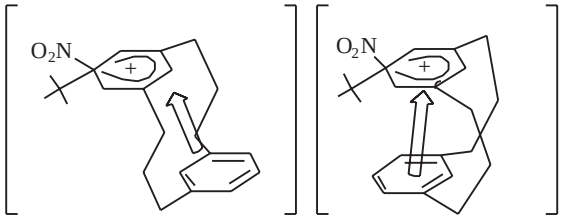
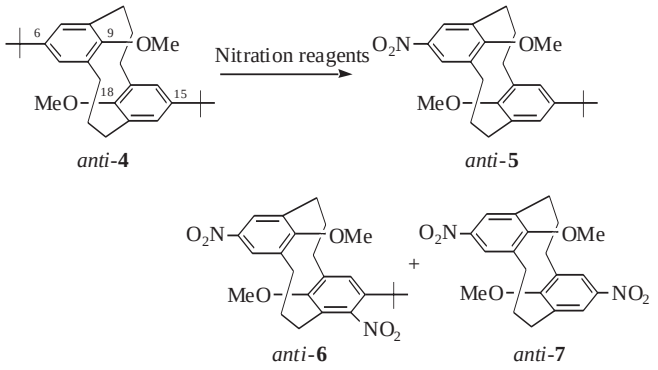


butyl[2.2]- and[3.2]-MCPs (MCP = metacyclophane) leads to the direct introduction of one acyl and one nitro group. However, only one *tert*-butyl group undergoes ipso-acylation under the mild reaction conditions such as acyl chloride in the presence of titanium tetrachloride because of deactivation of the second aromatic ring by the introduced acyl group. Subsequently, we reported (9*b*) that nitration of 5,13-di-*tert*-butyl-8,16-dimethoxy[2.2]MCP (*anti*-**1**) with various nitrating reagents led to mono-ipso-nitration at the *tert*-butyl group to give 5-*tert*-butyl-8,16-dimethoxy-13-nitro[2.2]MCP (*anti*-**2**) as well as the corresponding 17-oxa-[2.2.1](1,3,2)cyclophane **3** arising from intramolecular condensation reaction via *anti–syn*-ring inversion of the nitration intermediate. The latter novel product was obtained owing to the release of the strain in these systems (Scheme 1).

Although the parent [2.2]MCP was first reported as early as 1899 by Pelligrin (10), the synthesis of *syn*-[2.2]MCP was not realized until 85 years later. Mitchell et al. (11) have successfully prepared *syn*-[2.2]MCP at low temperature by using (arene)chromiumcarbonyl complexation to control the stereochemistry. However, *syn*-[2.2]MCP isomerizes readily to the *anti*-isomer above 0°C. Itô and co-workers (12) have also isolated and characterized *syn*-[2.2]MCP without complexation. On the other hand, Mitchell and Boekelheide (13) and Staab et al. (14) succeeded in synthesizing intraannularly substituted *syn*-[2.2]MCPs. However, the internally substituted *anti*- and *syn*-[3.3]MCPs can be easily synthesized and well characterized (15). Thus, the through-space electronic interaction could be achieved through the intraannular positions as in the σ-complex intermediate **A** in the former conformer, but through face-to-face overlapping among the two benzene rings as in the σ-complex intermediate **B** in the latter conformer. Therefore, it is possible to investigate the different behaviour in the nitration of *anti*- and *syn*-[3.3]MCPs and to determine which conformer contributes more strongly to the through-space electronic interaction (Fig. 1).

Scheme 2.



Thus, there is substantial interest in systematically investigating the relationship between neighbouring benzene rings in the ipso aromatic nitrations of larger-sized ring *tert*-butyl-[3.3]MCPs having *anti*- and *syn*-conformations than *tert*-butyl[2.2]MCPs, which might only afford the ipso-nitration product at the *tert*-butyl group because of the formation of the intramolecular condensation product via *anti–syn*-ring inversion of the nitration intermediate (9*b*) being impossible. In this paper we describe the selective introduction of one or two nitro groups by direct replacement of *tert*-butyl groups via the ipso-aromatic nitration of the *meta*-propane-bridged aromatic compounds, *tert*-butyl[3_n]MCPs having more than two arene rings to investigate the through-space electronic interactions occurring among other benzene rings.

Results and discussion

Recently, Vögtle and co-workers (16) reported the preparation of carbocyclic [3_n]metacyclophanes using (*p*-tolylsulfonyl)methyl isocyanide (TosMIC) (17) as the cyclization reagent, which was applied in a new cyclization procedure without phase-transfer conditions (18). However, it has been very difficult to obtain sufficient amounts of the above compounds to investigate their chemical behaviour. Quite recently we described the convenient preparation and conformational properties of [3.3]MCPs as well as the propane-bridged calix[3]arene-analogous macrocyclic MCPs ([3.3.3]MCPs) synthesized by an improved TosMIC method (19) (Scheme 2 and Table 1).

Attempted nitration of *anti*-6,15-di-*tert*-butyl-9,18-dimethoxy[3.3]MCP (*anti*-**4**) (19*a*) with copper(II) nitrate at room temperature for 24 h gave dinitration products *anti*-6-*tert*-butyl-9,18-dimethoxy-5,15-dinitro[3.3]MCP (*anti*-**6**) and *anti*-9,18-dimethoxy-6,15-dinitro[3.3]MCP (*anti*-**7**) in 92% yield as a major product along with mono-ipso-nitrated product *anti*-6-*tert*-butyl-9,18-dimethoxy-15-nitro[3.3]MCP (*anti*-**5**) in 8% yield. Interestingly, both benzene rings are nitrated even in mild reaction conditions such as copper(II) nitrate in an acetic anhydride solution. This result is quite different from the result achieved when only one benzene ring of *anti*-di-*tert*-butyl[2.2]MCP **1** is nitrated under the same reaction conditions because of deactivation of the second aromatic ring by the introduction of the nitro group (9*b*). In

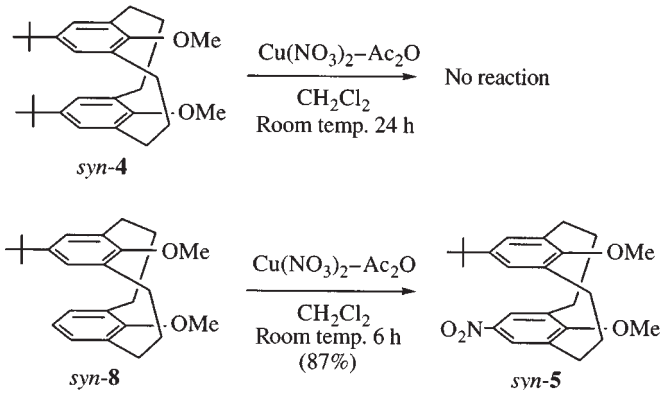
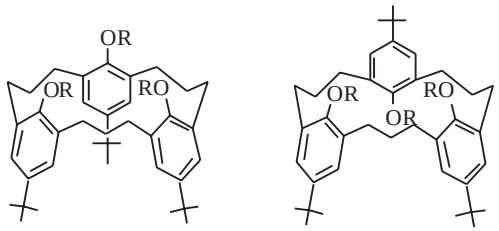
Scheme 3.



contrast, in the case of [3.3]MCP *anti*-**4**, the second nitration occurred because of the decreased deactivation of the second aromatic ring by the introduction of the nitro group.

Interestingly, the higher yields of the twofold ipso-nitration product *anti*-**7** were obtained in the nitration of *anti*-**4** with fuming nitric acid or mixed acid (HNO_3–H_2SO_4). When the nitration reagent was changed from fuming HNO_3 to the more reactive mixed acid (HNO_3–H_2SO_4), the yield of di-ipso-nitrated product *anti*-**7** increased from 55 to 85% yield. Thus, the extent of ipso-nitration at the *tert*-butyl groups of *anti*-**4** was strongly affected by the reactivity of the nitration reagent. By varying the reactivity of the nitrating reagents the ratio of the dinitration products arising from the second nitration at 5-position *ortho* to the *tert*-butyl group or 6-position at the *tert*-butyl group of *anti*-**5** changed. On the other hand, nitration of *anti*-**6** with fuming HNO_3 or copper(II) nitrate resulted only in the recovery of the starting compound. Formation of a twofold ipso-nitration product *anti*-**7** was not observed under the reaction conditions. These results suggest that *anti*-**6** is not the intermediate for the formation of twofold ipso-nitration product *anti*-**7**. Furthermore, nitration of mono-ipso-nitrated product *anti*-**5** with fuming HNO_3 carried out under the same conditions afforded almost the same ratio of dinitrated products *anti*-**6** and *anti*-**7**. This result strongly suggests that in the first step the ipso-nitration at the *tert*-butyl group must occur to afford *anti*-**5**. In the second step, the different regioselectivity was then observed exclusively to compete with the normal nitration at the 5-position *ortho* to the *tert*-butyl group or ipso-nitration at the *tert*-butyl group on the 6-position because of deactivation of the second aromatic ring by the nitro group. Thus, the positional selectivity for the nitration of *anti*-**4** was strongly affected by the reactivity of the nitration reagent, as has been reported for nitration in normal aromatic systems (20).

Fig. 2. Possible conformation of [3.3.3]MCPs.



cone Conformation *partial cone* Conformation

The structures of *anti*-**6** and *anti*-**7** were assigned on the basis of elemental analyses and spectral data. Especially, the mass spectral data for *anti*-**6** (M^+ = 442) strongly supports the dinitration product. The ^1H NMR spectrum of *anti*-**6** in $CDCl_3$ shows three singlets at δ 1.40 for *tert*-butyl protons, at δ 3.14 and 3.33 for methoxy protons, and a set of doublets (J = 2.9 Hz) at δ 7.89 and 7.93 for aromatic protons in a strongly deshielded region due to the nitro group. As a result, *anti*-**6** has been assigned to *anti*-6-*tert*-butyl-9,18-dimethoxy-5,15-dinitro[3.3]MCP.

Attempted nitration of *syn*-6,15-di-*tert*-butyl-9,18-dimethoxy[3.3]MCP (*syn*-**4**) (19*a*) with copper(II) nitrate at room temperature for 24 h failed. Only the starting compound was recovered in quantitative yield. In contrast, as mentioned previously, in the case of *anti*-**4**, ipso-nitration products were obtained. It seems that the *anti*-conformer might be much more reactive than *syn*-conformer in the present ipso nitration. Therefore, the intraannular interaction is much more favourable to stabilize the first σ-complex intermediate than the face-to-face overlapping in [3.3]MCP systems. When the nitration reagent was changed from copper(II) nitrate to the more reactive fuming HNO_3 or HNO_3–H_2SO_4, only a complex mixture of nonvolatile materials was produced. But formation of the desired nitro compound *syn*-**7** was not detected (Scheme 3).

In contrast, nitration of *syn*-6-*tert*-butyl-9,18-dimethoxy-[3.3]MCP (*syn*-**8**) with copper(II) nitrate at room temperature for 6 h afforded only the mononitration product *syn*-**5** in 87% yield. No formation of dinitration products were observed. This result is comparable to the same nitration of *anti*-**8**, which predominantly afforded dinitration products *anti*-**6** and *anti*-**7**. Therefore, the deactivation of the second nitration of *syn*-conformer caused by the other aromatic ring substituted by the nitro group may be larger than that of *anti*-conformer.

It was also found that *anti*-6,15-di-*tert*-butyl-9,18-dimethyl[3.3]MCP (*anti*-**9**) (18*b*) with excess copper(II) nitrate in an acetic anhydride solution at room temperature for 24 h failed. Only the starting compound was recovered in

quantitative yield. When a similar nitration was carried out with fuming HNO_3, it did not afford the desired *anti*-dinitro[3.3]MCP *anti*-**10**, instead only an intractable mixture was obtained. This result seems to indicate that the methoxy group in *anti*-**4** plays an important role in the present ipso-nitration reaction. The ipso-nitration of *anti*-**4** is attributed to the highly activated character of the aryl ring and the increased stabilization of the σ-complex intermediate arising from a dienone-type σ-complex intermediate which is possible in the case of a methoxy substituent.

As mentioned previously, nitration of [3.3]MCP *anti*-**4** with excess copper(II) nitrate in an acetic anhydride solution led to twofold ipso-nitration at the *tert*-butyl groups to give *anti*-**7** in moderate yield along with dinitrated product *anti*-**6**, thus differing from the nitration of 4-*tert*-butyl-2,6-dimethylanisole under the same conditions which afforded only the starting compound. Recently, Cacace et al. (21) reported an intramolecular proton shift, namely, a ring-to-ring proton migration, in (β-phenylethyl)arenium ions during the cationic alkylation of 1,2-diphenylethanes which occurs at a faster rate than the same reaction conducted with toluene in the gas phase. In the present system, an initial σ-complex intermediate would be stabilized by a through-space electronic interaction with the opposing benzene ring, therefore accelerating the reaction, as in the formylation of *tert*-butyl-[*n*.2]MCPs (7).

To study this ipso-nitration reaction in more detail, we investigated the nitration of MCPs having three benzene rings. Recently, we reported in detail on the influence of *O*-substituents on the conformational isomerism of [3.3.3]MCPs (19*a*) having three benzene rings. We established that interconversion between conformers, which occurs by oxygen-through-the-annulus rotation, can be sterically allowed for methyl and ethyl, but inhibited by *O*-substituents bulkier than the propyl group. Furthermore, there are only two possible conformations, "cone" and "partial-cone" in *O*-alkylation products in contrast to four possible conformations in calix[4]arenes (22). Thus, the conformational isomerism is much simpler than that of *O*-alkylated calix[4]arenes. In comparison with the structural characteris-

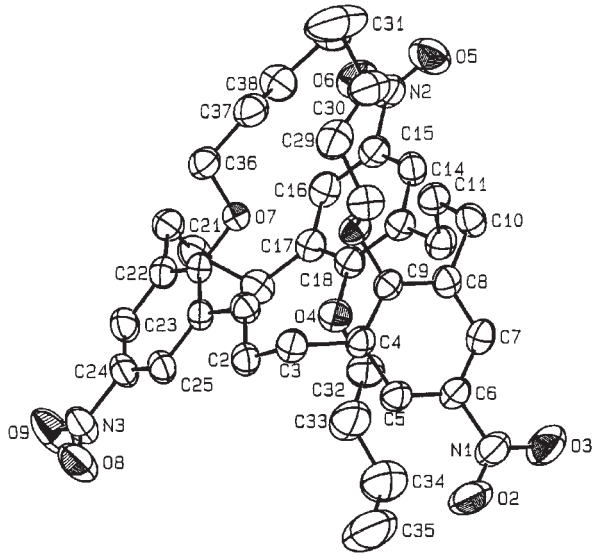
tics of calix[4]arenes, whose cyclophane ring is composed of a 16-membered ring, [3.3.3]MCPs have a cavity composed of an 18-membered ring identical to the corresponding *tert*-butylhexahomotrioxacalix[3]arene (23, 24) (Fig. 2).

In fact, treatment of *cone*-6,15,24-tri-*tert*-butyl-9,18,27-tris[(ethoxycarbonyl)methoxy]-[3.3.3]MCP (*cone*-**11c**) with

Fig. 4. X-ray crystal structure of *partial-cone*-**14b**. Thermal ellipsoids are drawn at 50% probability. Hydrogen atoms have been omitted for clarity.



excess copper(II) nitrate in an acetic anhydride solution for 24 h gave a mixture of the dinitration product *cone*-**13c** and trinitration product *cone*-**14c** in 86 and 14% yields, respectively (Table 2). Interestingly, no mononitration product (*cone*-**12c**) was obtained even under the mild conditions such as those used in the nitration of [3.3]MCP *anti*-**4**. When nitration of *cone*-**11c** with fuming HNO_3 in an acetic acid solution was carried out at room temperature for 30 min, a similar result was obtained. Prolonging the reaction time for 2 h resulted in the increase of the yield of *cone*-**14c** from 25% to quantitative yield. These results strongly suggest that the through-space electronic interaction with the other benzene ring does exist in the [3.3.3]MCPs in spite of a larger ring size than that of the [3.3]MCPs (Scheme 4).

Similarly, introduction of three nitro groups by direct replacement of *tert*-butyl groups by ipso-aromatic nitration of 6,15,24-tri-*tert*-butyl-9,18,27-trimethoxy[3.3.3]MCP (**11a**) (19*a*) with fuming HNO_3 under the conditions of 0.5 h and room temperature has been shown to afford 9,18,27-trimethoxy-6,15,24-trinitro[3.3.3]MCP (**14a**) in 95% yield (Scheme 5 and Table 3).

Similar results are obtained in the case of *O*-butoxy derivative *partial-cone*-**11b**, *O*-(ethoxycarbonyl)methoxy derivatives *cone*-**11c** and *partial-cone*-**11c** to furnish complete threefold ipso-nitration under the reaction conditions used to afford the desired trinitro compounds **14b** and **14c** in almost quantitative yields, respectively. However, an attempted nitration of *O*-(*N*,*N*-diethylacetamide) derivative **11d** failed. Only an intractable mixture was obtained. These results might suggest that the cleavage reaction of more reactive *N*,*N*-diethylacetamide groups has occurred under the reaction conditions used. Interestingly, threefold ipso-nitration of partial-cone conformers was completed within 0.5 h, but it took at least 2 h to complete the reaction in the case of the cone conformer. It seems that partial-cone conformers might be much more reactive than cone conformers in the present ipso-nitration.

Single crystal X-ray diffraction analysis was performed on *cone*-**14c** recrystallized from chloroform and methanol and the ORTEP drawing with the atom numbering system is shown in Fig. 3. The structure was solved by direct methods (SIR 92) (25) and refined using the full-matrix least-squares method and Fourier synthesis. Compound *cone*-**14c** crystallized in the centrosymmetric cubic space group *Ia*-3 (No. 206). This compound is located at the special position (Z = 16) and contains a crystallographic C_3 axis of symmetry, showing that the crystallographically independent moiety is one-third of the full molecule (Table 4). It is clear that the three benzene rings are located on the same side (cone conformer) and thus the through-space electronic interaction among the three benzene rings through overlapping could be possible as discussed above. The dihedral angle of the flattened three aromatic rings is about 43.0°, which is much smaller than that of *p*-*tert*-butylhexahomotrioxacalix[3]arene (65.8°) (26). It is also clear that in the solid state, the carbonyl groups are located sideways, not toward the π cavity, probably to avoid the electronic repulsion with each other.

The X-ray molecular structure of *partial*-*cone*-**14b** recrystallized from chloroform and methanol is shown in Fig. 4 with the atom numbering system. The structure was solved by direct methods (SIR 88) (27) and refined using the full-matrix least-squares method and Fourier synthesis. Compound *partial*-*cone*-**14b** crystallized in the centrosymmetric triclinic space group $P\bar{1}$ (No. 2) and located at the general position (Z = 2). The ORTEP drawing clearly shows that two butoxy groups in the compound point upwards with one of them folded into the π cavity formed by two benzene rings. The dihedral angles of the plane defined by the bridge-chain carbons, C(1)-C(2)-C(3)-C(10)-C(11)-C(12)-C(19)-C(20)-C(21) between three aromatic rings, C(4)-C(5)-C(6)-C(7)-C(8)-C(9) and C(13)-C(14)-C(15)-C(16)-C(17)-C(19), and C(22)-C(23)-C(24)-C(25)-C(26)-C(27) are different values, 77.3°, 33.6°, and 35.0°, respectively.

In the partial-cone conformer, one through-space electronic interaction through face-to-face overlapping with the opposing benzene ring similar to that of *syn*-[3.3]MCP and two through-space electronic interactions through the intraannular interaction like that of *anti*-[3.3]MCP are possible. Thus, in the *partial*-*cone*-[3.3.3]MCP both *anti*-conformation and *syn*-conformation are contained in the molecule. Therefore, both initial and second σ-complex intermediates could also be stabilized by a through-space electronic interaction with other benzene rings not only through the face-to-face overlapping but also through the intraannular interaction like σ-complex intermediates **A** and **B** in [3.3]MCPs, as shown in Fig. 1. Furthermore, the deactivation of the third ipso-nitration caused by the two aromatic rings substituted by nitro groups may be smaller than that of the cone conformer, and thus it could be much faster to complete threefold ipso-nitration than the cone conformer. The stability of multimembered carbon skeletons was found to be an advantage, permiting the interconversion of functional groups without ring-opening side reactions, as opposed to the homotrioxacalix[3]arenes with the ethereal linkages (23).

Experimental

All melting points (Yanagimoto MP-S1) were uncorrected. Proton nuclear magnetic resonance (^{1}H NMR) spectra were recorded on a Nippon Denshi JEOL FT-270 spectrometer. Chemical shifts are reported as δ values (ppm) relative to internal Me_4Si. Mass spectra were obtained on a Nippon Denshi JMS-01SG-2 mass spectrometer at an ionization energy of 70 eV using a direct-inlet system through GLC; *m*/*z* values reported include the parent ion peak. Infrared (IR) spectra were obtained on a Nippon Denshi JIR-AQ2OM spectrophotometer as KBr disks. Elemental analyses were performed by Yanaco MT-5. Gas–liquid chromatograph (GLC) analyses were performed using a Shimadzu gas chromatograph (GC-14A); silicone OV-1, 2 m; programmed temperature rise, 12°C min^{-1}; carrier gas nitrogen, 25 mL min^{-1}.

Materials

The preparation of *anti*-dimethoxy[3.3]MCP *anti*-**4** and *syn*-dimethoxy[3.3]MCP *syn*-**4** was previously described (19*a*). *cone*- and *partial*-*cone*-6,15,24-Tri-*tert*-butyl-9,18,27-trialkoxy[3.3.3]MCPs **11a**–**d** were prepared according to the reported procedure (19*a*).

Nitration of *anti*-4 with copper(II) nitrate in acetic anhydride

To a solution of *anti*-6,15-di-*tert*-butyl-9,18-dimethoxy-[3.3]metacyclophane (*anti*-**4**) (117 mg, 0.289 mmol) in a mixture of CH_2Cl_2 (2.5 mL) and acetic anhydride (50 mL) was added $Cu(NO_3)_2 \cdot 3H_2O$ (150 mg, 0.62 mmol) at 0°C. After the mixture had been stirred at room temperature for 24 h, the reaction mixture was poured into ice water and then extracted with CH_2Cl_2, washed with water and 10% aqueous sodium hydrogencarbonate. The extract was dried over anhydrous sodium sulfate and concentrated. The residue was subjected to silica gel (Wako, C-300, 100 g) column chromatography using as eluents hexane–benzene (1:1) and benzene to give *anti*-**5** (6 mg, 5%), *anti*-**6** (55 mg, 43%), and *anti*-**7** (37 mg, 33%), respectively.

anti-*6*-tert-*Butyl-9,18-dimethoxy-15-nitro[3.3]metacyclophane (*anti-*5)*

Pale yellow oil. ^{1}H NMR ($CDCl_3$) δ: 1.33 (s, 9H), 2.12–2.19 (m, 4H), 2.36–2.48 (m, 4H), 2.56–2.66 (m, 4H), 3.12 (s, 3H), 3.20 (s, 3H), 6.97 (s, 2H), 7.90 (s, 2H). MS *m*/*z*: 397 (M^+). Anal. calcd. for $C_{24}H_{31}NO_4$ (397.52): C 72.52, H 7.86, N 3.52; found: C 72.43, H 7.78, N 3.48.

Nitration of *anti*-4 with fuming nitric acid

To a solution of *anti*-**4** (102 mg, 0.25 mmol) in a mixture of CH_2Cl_2 (2.5 mL) and glacial acetic acid (2.5 mL), fuming HNO_3 (0.83 mL) at 0°C was added. The mixture was stirred at room temperture. After 30 min, the mixture was poured into ice water, extracted with CH_2Cl_2, and washed with water and 10% aqueous sodium bicarbonate. The extract was dried with Na_2SO_4 and concentrated to afford a mixture of *anti*-**6** and *anti*-**7** as a pale yellow solid in a ratio of 45:55 (GLC). The residue was subjected to silica gel (Wako, C-300, 100 g) column chromatography using as eluents hexane–benzene (1:1) and benzene to give *anti*-**6** (33 mg, 30%) and *anti*-**7** (33 mg, 34%).

Nitration of *anti*-4 with mixed acid

To a solution of *anti*-**4** (102 mg, 0.25 mmol) in a mixture of CH_2Cl_2 (2.5 mL) and glacial acetic acid (2.5 mL), mixed acid (a mixture of fuming HNO_3 (1.1 mL) and concentrated sulfuric acid (0.5 mL)) at 0°C was added. The mixture was stirred at room temperture. After 30 min, the mixture was poured into ice water, extracted with CH_2Cl_2, and washed with water and 10% aqueous sodium bicarbonate. The extract was dried with Na_2SO_4 and concentrated. The residue was subjected to silica gel (Wako, C-300, 100 g) column chromatography using as eluents hexane–benzene (1:1) and benzene to give *anti*-**7** (76 mg, 79%).

Nitration of *syn*-8 with copper(II) nitrate in acetic anhydride

To a solution of *syn*-6-*tert*-butyl-9,18-dimethoxy[3.3]-metacyclophane (*syn*-**8**) (88 mg, 0.25 mmol) in a mixture of CH_2Cl_2 (2.5 mL) and acetic anhydride (50 mL) was added $Cu(NO_3)_2 \cdot 3H_2O$ (150 mg, 0.62 mmol) at 0°C. After the mixture had been stirred at room temperature for 24 h, the reaction mixture was poured into ice water and then extracted with CH_2Cl_2, washed with water and 10% aqueous sodium hydrogencarbonate. The extract was dried over anhydrous sodium sulfate and concentrated. The residue was subjected to silica gel (Wako, C-300, 100 g) column chromatography using benzene as the eluent to give *syn*-6-*tert*-butyl-9,18-dimethoxy-15-nitro[3.3]metacyclophane (*syn*-**5**) (87 mg, 87%) as pale yellow prisms (hexane), mp 143–145°C. ^{1}H NMR ($CDCl_3$) δ: 1.06 (s, 9H), 1.83–1.89 (m, 2H), 2.47–2.60 (m, 6H), 3.02–3.18 (m, 4H), 3.50 (s, 3H), 3.57 (s, 3H), 6.57 (s, 2H), 7.48 (s, 2H). MS *m*/*z*: 397 (M^+). Anal. calcd. for $C_{24}H_{31}NO_4$ (397.52): C 72.52, H 7.86, N 3.52; found: C 72.35, H 7.76, N 3.40.

Nitration of 11a with fuming nitric acid

To a solution of 6,15,24-tri-*tert*-butyl-9,18,27-trimethoxy-[3.3.3]metacyclophane (**11a**) (19*a*) (75.0 mg, 0.123 mmol) in a mixture of CH_2Cl_2 (2.0 mL) and glacial acetic acid (2.0 mL), fuming HNO_3 (0.62 mL) at 0°C was added. The mixture was stirred at room temperture. After 30 min, the mixture was poured into ice water, extracted with CH_2Cl_2, and washed with water and 10% aqueous sodium bicarbonate. The extract was dried with Na_2SO_4 and concentrated in vacuo to give a yellow solid (72 mg, 100%). Recrystallization from benzene afforded 9,18,27-trimethoxy-6,15,24-trinitro[3.3.3]metacyclophane (**14a**) (64.0 mg, 89%) as pale yellow prisms, mp 241–243°C. ^{1}H NMR ($CDCl_3$) δ: 1.89–2.00 (m, 6H), 2.58–2.63 (m, 12H), 3.37 (s, 9H), 7.95 (s, 6H). MS *m*/*z*: 579 (M^+). Anal. calcd. for $C_{30}H_{33}N_3O_9$ (579.61): C 62.17, H 5.74, N 7.25; found: C 62.10, H 5.71, N 7.15.

Reaction of *partial-cone*-**11b**, *cone*-**11c**, and *partial-cone*-**11c** with fuming HNO_3 was carried out using the same procedure as described above and details of the products and yields are compiled in Table 3.

partial-cone-*9,18,27-Tributoxy-6,15,24-trinitro[3.3.3]-metacyclophane* (partial-cone-*14b*)

Pale yellow prisms, mp 143–145°C. IR (KBr) υ_{max}: 2958, 2930, 2870, 1585, 1517, 1454, 1379, 1337, 1315, 1263, 1209, 1094, 1063, 1045, 1021, 990, 957. ^{1}H NMR ($CDCl_3$) δ: 0.54–0.62 (m, 3H), 0.83–0.91 (m, 6H), 1.16–2.36 (m, 18H), 2.41–2.52 (m, 4H), 2.65–2.94 (m, 8H), 2.93–3.00 (m, 2H), 3.48–3.58 (m, 2H), 3.65–3.75 (m, 2H), 7.94 (d, *J* = 2.4 Hz, 2H), 7.95 (d, *J* = 2.4 Hz, 2H), 7.96 (s, 2H). MS *m*/*z*: 795 (M^+). Anal. calcd. for $C_{39}H_{45}N_3O_{15}$ (795.8): C 58.86, H 5.7, N 5.28; found: C 58.53, H 5.54, N 5.35.

Attempted nitration of *cone*- (*cone*-**11d**) and *partial-cone*-6,15,24-tri-*tert*-butyl-9,18,27-tris[(*N*,*N*-diethylamino-carbonyl)methoxy][3.3.3]metacyclophane (*partial-cone*-**11d**) with fuming HNO_3 failed. Only an intractable mixture was obtained.

Crystal data for *cone*-14c and *partial-cone*-14b

As a typical procedure, a single crystal was mounted on a quartz fiber and the unit cell constants for *cone*-**14c** were derived from least-squares analysis of the settings of a CAD4 FR590 diffractometer for 25 reflections, in the range of $21.0° < \theta < 22.0°$, $\omega/2\theta$ mode with ω scan width = 0.3 + 0.400 tan θ, scan speed 1.0–20.0 deg min^{-1}, graphite-monochromated Cu Kα radiation; 7402 reflections were measured ($3.50 \leq \theta \leq 65.01°$, $-h$, $-k$, $-l$). Since the maximum values of *h*, *k*, *l* are too large for the program SHELXL-93 (29), only 6883 of reflections whose $(\sin\theta/\lambda)^2 < 0.30$ were used to reduce the maximum values of *h*, *k*, *l*. 2305 unique (merg-

ing R = 0.1502 after absorption correction (max, min transmission factor = 0.9993, 0.7091)), linear and approx. isotopic crystal decay, ca. –5.9% (corrected during the procedure).

The structure was solved by direct methods (SIR 92) (25). Full-matrix least-squares refinement on F^2 with all non-hydrogen atoms, anisotropic and hydrogens in calculated positions with U_{iso} = 1.3 × $U_{(bonded\ atoms)}$ were done. The disorder on C10 and O4 was found and the occupational proportion of C10:C10′ or O4:O4′ was 0.728:0.272. The disorder of C12 and C10 was modeled with isotopic thermal motion and with bond length restraints (C12—C13: 1.52 Å, C12—O5: 1.42 Å), and then refined anisotropically. The occupational proportion of C12:C12′ or C13:C13′ was 0.517:0.483. The weighting scheme is $\omega = 1/(\sigma^2(F_o^2) + (0.1687P)^2 + 26.0206P)$ where $P = (F_o^2 + 2F_c^2)/3$. Final R and R_w values were 0.0921, 0.2228 (refined on F^2). All calculations were performed on a MicroVAX3100 and an IBM RISC System/6000 3100 using MolEN (28) and SHELXL-93 (29).

Similarly, a single crystal was mounted on a quartz fiber and the unit cell constants for *partial-cone*-**14b** were derived from least-squares analysis of the settings of a CAD4 FR 590 diffractometer for 25 reflections, in the range of 24.4° < θ < 26.9°, Enraf-Nonius CAD4 FR586 diffractometer, ω/2θ mode with ω scan width = 0.8 + 0.140 tan θ, scan speed 1.0–7.0 deg min^{-1}, graphite-monochromated Cu Kα radiation; 7194 reflections were measured ($2.31 \le \theta \le 64.92$, $-h$, k, l). 6278 unique (merging R = 0.014, no absorption correction), linear and approx. isotopic crystal decay, ca. –3.8% (corrected during the procedure).

The structure was solved by direct methods (SIR88) (28). Full-matrix least-squares refinement on F with all non-hydrogen atoms, anisotropic and hydrogens isotropic fixed at B_{eq} 4.0 $Å^2$. The weighting scheme was $\omega = 4F_o^2/((\sigma I_o)^2 + 0.0016F_{osup}4)$. Final R and R_w values were 0.073, 0.102 (refined on F). All calculations were performed on a MicroVAX3100 using MolEN (28). Crystallographic data for *cone*-**14c** and *partial-cone*-**14b** are given in Table 4.[3]

Conclusions

We conclude that the selective ipso-nitration of *anti*-di-*tert*-buty[3.3]MCP (*anti*-**4**) led to the direct introduction of one or two nitro group(s) due to a through-space electronic interaction with the opposing benzene ring, similar to the electrophilic aromatic substitution of MCPs. The number of ipso-nitrations of **4** was controlled by the reactivity of the nitration reagent. The current procedure was further applied to the direct removal of a *tert*-butyl group by electrophilic substitution of the larger ring sized macrocyclic metacyclophanes, *cone*- and *partial-cone*-tri-*tert*-butyl[3.3.3]MCPs **11**. Further studies on ipso-nitration are currently in progress in our laboratory.

Organic chemistry and hemoglobin: Benefits from controlled alteration

Ronald Kluger

Abstract: Hemoglobin carries oxygen in circulation within red cells but does not function outside the cells because it fails not only to release oxygen but also dissociates into dimers that make up the tetrameric protein. Bifunctional anionic acylating agents that contain a structurally rigid bridge introduce cross-links that stabilize hemoglobin and alter its oxygen affinity so that it could be used to carry oxygen outside cells. Nitric oxide binds to hemoglobin and in circulation this causes undesirable increases in blood pressure. It had been reported that higher weight collections of hemoglobin do not cause vasoconstriction. Reagents with two pairs of reaction sites joined by a rigid link connect and cross-link two hemoglobins. The resulting bis-tetramers lack the cooperativity of the native protein and bind oxygen too tightly to be useful; occupation by oxygen blocks the sites from nitric oxide. Nitric oxide may be delivered from thionitrosyl groups, which occur in hemoglobin in the red cell. Cross-linked hemoglobin can be specifically nitrosylated. These species can then serve as circulating sources of nitric oxide resulting from an internal electron transfer.

Key words: proteins, hemoglobin, cross-link, red cells, cooperativity, connecting.

Résumé : Dans la circulation sanguine, l'hémoglobine transporte l'oxygène à l'intérieur des cellules rouges, mais à l'extérieur elle ne fonctionne pas parce qu'elle n'est pas en mesure de libérer l'oxygène et, de plus, elle se dissocie en dimères qui forment la protéine tétramère. Les agents acylants anioniques bifonctionnels qui contiennent un pont structuralement rigide permettent d'introduire des liens de réticulation qui stabilisent l'hémoglobine et qui altèrent son affinité pour l'oxygène de façon à la rendre utilisable pour le transport d'oxygène à l'extérieur des cellules. L'oxyde nitrique se lie à l'hémoglobine et dans la circulation ce qui provoque des augmentations indésirables de la pression sanguine. Il a été rapporté que des collections d'hémoglobines de masses moléculaires plus élevées ne provoquent pas de vasoconstriction. Des réactifs avec deux paires de sites réactionnels liés par une jonction rigide permettent de raccorder et de réticuler deux hémoglobines. Les bis-tétramères qui en résultent ne donnent pas lieu à la coopération qui existe dans la protéine naturelle et ils se lient trop fortement à l'oxygène pour être utiles, mais ils ne peuvent donc pas se lier à l'oxyde nitrique. Une extension des raccordements pourrait permettre de résoudre ces problèmes. L'oxyde nitrique peut être obtenu à partir de groupes thionitrosyles que l'on retrouve dans l'hémoglobine des cellules rouges. Il est possible d'effectuer une nitrosilylation spécifique de l'hémoglobine réticulée. Ces espèces servent de sources circulantes d'oxyde nitrique et elles résultent d'un transfert d'électron interne.

Mots clés : protéines, hémoglobine, réticulation, cellules rouges, possibilité de coopération, raccordement.

[Traduit par la Rédaction]

Introduction

Hemoglobin is a protein that is specifically adapted for carrying oxygen in circulation within red blood cells. This enables oxygen-consuming organisms to overcome the low solubility of oxygen in water. Hemoglobin is contained in high concentrations in the red cells where it is protected from destructive oxygen-derived reactive species by detoxifying enzymes. The hemoglobin molecule is a very large tetramer (64 kDa), consisting of two identical α–β heterodimers (1). Each subunit contains a ferrous heme that reversibly binds one equivalent of oxygen. If hemoglobin escapes from the red cell, it ceases to be functional (effectors in the red blood cell lower the affinity of hemoglobin for oxygen) (2). Hemoglobin can also dissociate into dimers, which are excreted through the kidney (3, 4).

Since hemoglobin is a specific chemical entity, it is amenable to alteration through organic chemistry (5). Can hemoglobin be chemically altered so that it can effectively deliver oxygen and remain in circulation outside the red cell? While many chemical approaches have been applied to this prob-

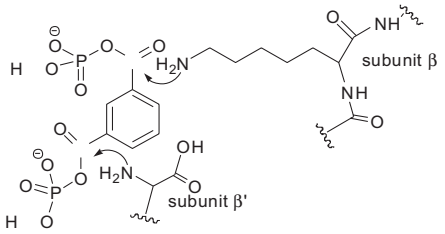
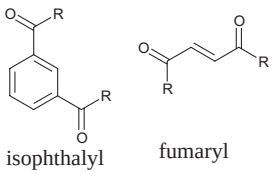
lem (6), this article will focus on those most closely associated with my research.

Designing cross-linkers

Based on studies of chemical modification of hemoglobin, my research group developed reagents that covalently join the subunits in different dimers while reducing the oxygen affinity to match what we believed would be that of an ideal oxygen carrier (7). Acyl methyl phosphates are water-stable anionic acylating reagents, which convert amino groups to amides (7). They selectively react with amino groups of proteins that are in cationic environments of the proteins. In one homologous set of products, the reaction involves an amino group in each of the two β subunits of the protein: the α-amino group of the N-terminal valine of one β subunit and the ε-amino group of Lys-82. These form cross-links that prevent dissociation of the tetramers into dimers (the dimers do not spontaneously dissociate into monomers, see Scheme 1).

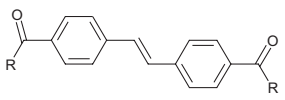


These specifically cross-linked tetramers are stable. They acquire and release oxygen readily and are too large to pass through the kidney in circulation (8). A critical feature of the properties of the altered hemoglobins is that they bind oxygen cooperatively (9) (the successive binding of oxygen to each subunit facilitates binding to another). We introduced cross-links between the β subunits of human hemoglobin with spans of predictable dimensions based on their structures containing unsaturated and aromatic acyl bridge components (9). Examples of these linkages are shown below.



isophthalyl

fumaryl



stilbenedicarbonyl

We were able to make a diverse collection of cross-linked hemoglobin tetramers and correlate their properties to their structures. The altered proteins had oxygen affinities that correlated (inversely) with the length of the cross-link. We were able to show that this arose because the cross-link limited the relative relaxation motions of the protein subunit dimers that occur when oxygen is bound (10). Preliminary in vivo testing revealed that the compounds deliver oxygen efficiently in place of red cells (8).

Cross-linked hemoglobin in circulation

Soon after cross-linked hemoglobins became available, commercial exploitation of some of the materials as red cell substitutes in transfusions began. A number of cross-linked hemoglobins of varying structure began their evaluation in biopharmaceutical and academic laboratories, with a few representative citations given here (11–22). Unfortunately, it was widely noted that unlike red cells, cross-linked hemoglobins in general caused a significant increase in blood pressure of the subject (23–26). This appeared to be the most significant drawback to the use of cross-linked hemoglobin as a red cell substitute. Blood pressure is at least partially controlled by levels of nitric oxide along the inner membranes (endothelia) of blood vessels (27). Nitric oxide signals endothelia to induce contraction of the smooth muscle that surrounds the vessel (28). Since the hemes of native hemoglobin bind nitric oxide more strongly than they do oxygen (29, 30), hemoglobin outside the red cell could cause an increase in blood pressure by binding nitric oxide in place of oxygen at vacant ligation sites (31, 32). If this is the case, then the red cell must be able to exclude or replace nitric oxide.

The effects of specific cross-links within hemoglobin, binding of nitric oxide, and induction of hypertension has previously not been explored, which might have been seen as critical information for rational development of a clinical product. Abdul Alayash, head of the United States Food and Drug Administration section that deals with these products is quoted in TheStreet.com (33):

> In general, attempts over the past 50 years to develop viable blood substitutes have failed because the products have never proven to be as safe as blood. One of the biggest problems: Blood substitutes seem to cause a patient's blood pressure to rise suddenly as capillaries that carry oxygen to various parts of the body constrict. Kidneys are especially susceptible to this so-called vasoconstriction, which starves the organ of oxygen and can lead to failure.
>
> This is a major issue and an obvious concern because we know so little about how these products work. We are going to look extra hard at these products because of their safety profile. We're continuously finding surprises after surprises and discovering new issues.

There is little information available that can be used to correlate specific chemical properties to the unwanted effects. The impression from reports of clinical trials from commercial sources is that cross-linked hemoglobin tetramers in general cause hypertension (34). In cases where nonspecific reagents are used to cross-link hemoglobin, reactions between tetramers occur, creating species with masses beyond 64 kDa. These are multimers of tetramers and are common in materials being developed commercially (35). Some of these are implied to have reduced hypertensive properties.

An important physiological study by Winslow et al. (34) showed that the situation is more complex. They found that some cross-linked hemoglobins (and interconnected mix-

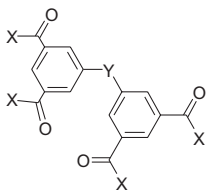
© 2002 NRC Canada

tures) induce more hypertension than others. Some cause a persistent effect, while the effect is transient from others. However, the cross-linked species in those studies included many where the chemical modifications were highly heterogeneous and structurally uncharacterized. The similarity of the binding of the NO and O_2 molecules to hemoglobin suggests that oxygen affinity and nitric oxide affinity would be related to each other in modified hemoglobins. Winslow noted, however, that some examples, which contained hemoglobins connected to one another, as well as internal cross-links, appeared to have a lesser hypertensive effect than the specifically cross-linked tetramers that he studied. Can connecting two hemoglobin tetramers affect the inherent hypertensive properties of the molecule? A trivial source for such a change might be that such a species binds oxygen so tightly that NO is not acquired, or it binds oxygen so weakly, that NO is also not held.

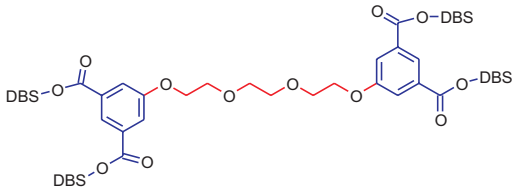
We had already developed a set of cross-linked hemoglobins in which oxygen affinity varies with the length of the cross-link (9). All of these maintain cooperative oxygen binding with a Hill coefficient nearly equal to that of native hemoglobin. So while they were candidates as oxygen carriers, they were also likely to be hypertensive. With these materials, Baines et al. (8) began studies that examine the relationship between vasoactivity and oxygen affinity.

Synthesizing bis-tetramers

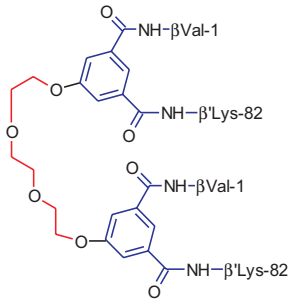
An intriguing question is thus raised by reports that administering cross-linked hemoglobins that are also connected to one another minimizes hypertensive effects (35, 36). No individually characterized species or specific structures were available. All such materials were produced with nonspecific reagents and were used in mixtures after fractionation to remove low and high molecular weight species. There was no reagent known that could not only cross-link proteins with site selectivity but also create a link with a second protein, which it also cross-links. Creating such a reagent is a novel chemical challenge with potential medicinal significance. We considered various strategies that might create the desired entity. We decided that a single reagent with at least four reaction sites would be the most efficient route to connect and cross-link two tetramers. Since we had found that isophthaloyl reagents were efficient cross-linking reagents, we sought the general structure shown below.



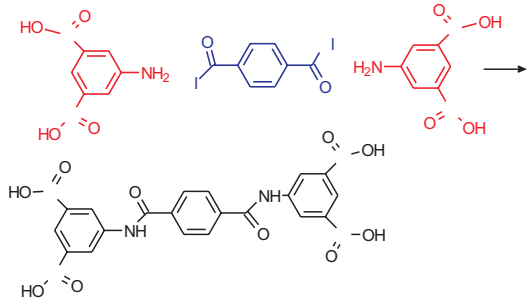
Our first attempt used 3,5-dibromosalicylates as leaving groups (X) and triethylene glycol as a linker (Y) (37). The leaving groups are anionic, although the charge is remote from the site of reaction. The use of modified salicylates was pioneered by Klotz and co-workers (38). My research group made such derivatives for a different purpose (39) and they became popular in the laboratory as skills improved for preparing this class of molecule.



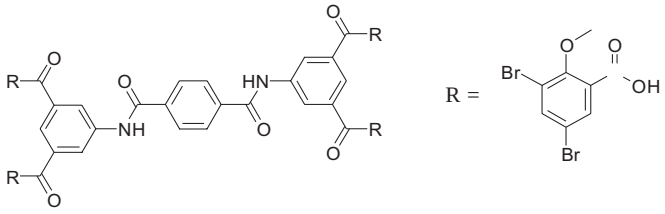
This reagent, however, reacts primarily within one tetramer, probably because it folds onto itself as it reacts (37).



We, therefore, needed a reagent with the same ends but with a different middle, one that keeps the ends apart. A simple synthetic solution for the core of the reagent is



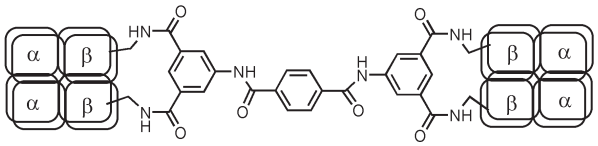
and the resulting tetrakis(3,5-dibromosalicylate) is shown below.



Combining the reagent with hemoglobin gave material that had a molecular weight of about 128 kDa (by size exclusion chromatography based on standards from hemoglobin oligomers) (40). Polyacrylamide gel electrophoresis under nondenaturing conditions also gives the major peak at the same retention time as a 128 kDa standard. SDS capillary electrophoretic analysis (denaturing conditions that separate all subunits) shows that 50% of the material corresponds to a weight of 15 kDa (which would be the unmodified α subunits) and about 33% corresponds to 64 kDa

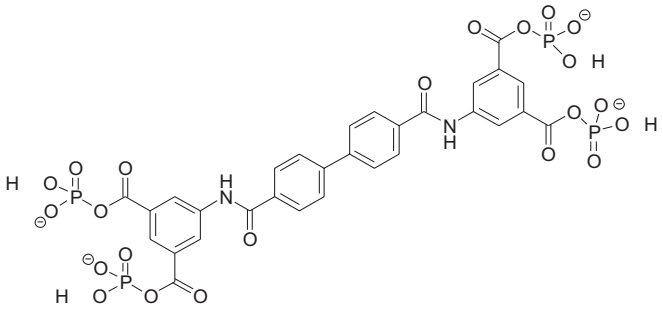
© 2002 NRC Canada

(which would be four linked β subunits). Peptide mapping revealed that the cross-links occur at β-Lys 82. A schematic structure of the proposed cross-linked bis-tetramer is thus:

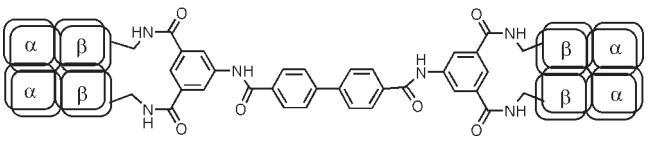


This material has a very high affinity for oxygen (so high that it probably would not dissociate significantly in circulation), and furthermore, the binding of oxygen is not cooperative (n_{50} = 1.2). Therefore, this material probably would not be able to pick up NO since oxygen occupies all sites. This qualifies as the first structurally defined cross-linked bis-tetramer. However, since its binding of oxygen is not cooperative, we made a major change to the environments of both tetramers by placing them in close proximity of each other. Because the tetramer does not release oxygen readily, it would not function well as a red cell substitute. Its low cooperativity would make it even more difficult for oxygen to be released in circulation. One conclusion we reached is that joining hemoglobins can produce a material that may not be vasoconstrictive because it has little capacity for binding nitric oxide once it is oxygenated.

Can the lack of cooperativity and high oxygen affinity in a bis-tetramer be overcome with structural alterations? At the extreme limit, if the link were very long, we would essentially have two independent cross-linked tetramers. Such a product would probably have no functional advantage over the individual cross-linked species. As a result, we next designed reagents with longer connecting spans. Since these have increased hydrocarbon content between reactive ends, lack of solubility in water became a problem with the dibromosalicylates. Fortunately, methyl acyl phosphates are superior activating groups for this purpose and they are readily prepared.

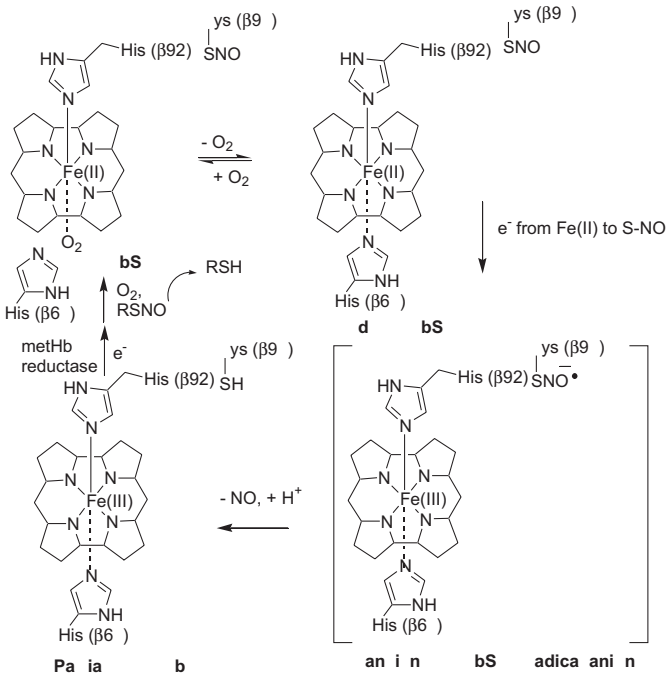


The resulting cross-linked bis-tetrameric product from its reaction with hemoglobin is structurally similar to the product from the smaller reagent in the previous section.



The oxygen-binding properties of this tetramer also showed a very high oxygen affinity and a low degree of cooperativity (n_{50} = 1.2). Based on these results we have created additional reagents that increase the span and also decrease the amount of hydrocarbon in the linker. Preliminary results indicate that these may bind oxygen cooperatively. It appears that these compounds may serve as a basis for investigating the basis of cooperativity in hemoglobin in a general way.

Scheme 1.



Nitric oxide from Cys-NO

To date, there is no obvious structural solution to avoid binding endogenous NO to modified hemoglobins that are effective as oxygen carriers. As an alternative approach, therefore, we considered ways to have a modified cross-linked hemoglobin serve as a source of NO. Gow and Stamler (30) reported that small amounts of hemoglobin within the red cell have the cysteine thiol at position β-93 in a nitrosylated form (RS-NO), which can transfer the NO group. There is some controversy about the physiological significance of this material, since the functional group does not spontaneously release nitric oxide (but it will transfer the nitrosyl group to a Lewis base acceptor). We used nitrosylating reagents to convert a specifically cross-linked hemoglobin into a species where both β-Cys-93 thiol groups are nitrosylated (41).

In measuring the oxygen affinity of this species, we shuttled in through cycles of oxygenation and deoxygenation while recording its spectrum. We noted that upon deoxygenation, NO was released as the ferrous heme oxidized to the ferric state (the fully Fe(III) material, methemoglobin, has a clearly distinct spectrum). We found that the spectral change was such that two of the hemes were converted to the Fe(III) state while two remained in the Fe(II) state. The two β subunits were nitrosylated so we concluded that an

© 2002 NRC Canada

electron transfer reaction occurred. We proposed the following cycle to account for our observations (Scheme 1) (42).

In the red cell, such a process can occur but the resulting metHb is converted to native hemoglobin by an endogenous reductase. Structural models indicate that the β-Cys93 sulfur atom is 12.9 Å from the closest ferrous heme in deoxyHb, permitting an internal electron transfer (42). Furthermore, coordination of oxygen, an electron withdrawing ligand, increases the heme Fe^{III}/Fe^{II} potential, making it a poorer electron donor. Thus, loss of oxygen would permit the internal electron transfer to occur.

The work described shows that the limits of organic chemistry are not exceeded when the target has a molecular weight of over 128 kDa. Of course, by choosing two equivalents of one starting material with a molecular weight of 64 kDa, it does not take many steps to produce novel materials of interest. Our research has led us to the fascinating problem of determining the sources of cooperativity that are lost in coupled hemoglobins. The next steps should be even more interesting.

Acknowledgments

I thank the Canadian Society for Chemistry for selecting me to give the Lemieux Award Lecture, and I am honored to be associated with the memory of Ray Lemieux and his science. My research has been supported by the Natural Sciences and Engineering Research Council of Canada (NSERC). The most recent work reported here has been in active collaboration with my co-workers, in particular John Pezacki and Noam Ship. I thank all my co-workers in this project and especially Professor Richard T. Jones who generously shared his knowledge and joy in the subject of altered hemoglobins.

Electron momentum spectroscopy of the frontier electrons of DABCO does not support an sp^3 hybrid lone-pair description

Saul Wolfe, Zheng Shi, C.E. Brion, James Rolke, Yenyou Zheng, Glyn Cooper, Delano P. Chong, and C.Y. Hu

Abstract: The highest occupied molecular orbital (HOMO) and next-highest occupied molecular orbital (NHOMO) valence orbital electron density distributions of 1,4-diazabicyclo[2.2.2]octane (DABCO) have been investigated by electron momentum spectroscopy, a technique that probes the orbital-like nature of valence (frontier) electron transfer out of a molecule. The experimental results are compared to a range of 6-311++G** calculations to assess the relative merits of three different orbital models that have commonly been used in chemistry. The delocalized (correlated) canonical Kohn–Sham orbitals calculated using the B3LYP or B3PW91 functionals and density functional theory provide near quantitative agreement with the observed valence electron momentum density distributions, and the delocalized canonical molecular orbitals of Hartree–Fock (independent particle) theory are in semiquantitative agreement. In contrast, Pauling's widely used and taught valence bond (hybridization) model, which is equivalent to a localized molecular orbital description, does not correspond at all to the experimental measurements. It follows that, for considerations of electron transfer, the "lone pairs" of DABCO are not localized or hybridized, but rather exist as nondegenerate orbitals that are delocalized differently over the molecular framework. The existence of two different experimental valence orbital electron densities of DABCO provides direct confirmation of the frontier orbital HOMO–NHOMO energy splitting and reordering predicted many years ago by Hoffmann et al. using extended Hückel theory, and interpreted in terms of "through bond" and "through space" interactions.

Key words: orbitals, lone pairs, orbital interaction, hybridization.

Résumé : Faisant appel à la spectroscopie des moments électroniques, une technique qui étudie la nature de type orbitalaire de la valence (frontière) du transfert d'électron à partir d'une molécule, on a déterminé les distributions des orbitales moléculaires haute occupée (« HOMO ») et pratiquement haute occupée (« NHOMO ») de la densité des électrons orbitalaires de valence du 1,4-diazabicyclo[2.2.2]octane (DABCO). On a comparé les résultats expérimentaux à une série de calculs au niveau 6-311++G** afin d'évaluer les mérites relatifs de trois modèles orbitalaires différents qui ont été couramment utilisés en chimie. Les orbitales canoniques délocalisées (avec corrélation) de Kohn–Sham, calculées à l'aide de fonctions B3LYP ou B3PW91 et la théorie de la densité fonctionnelle, correspondent pratiquement de façon quantitative avec les distributions observées pour la densité du moment de l'électron de valence; par ailleurs, les orbitales moléculaires canoniques délocalisées de Hartree–Fock (particule indépendante) présentent un accord semi-quantitatif. Par opposition, le modèle de la liaison de valence (hybridation) de Pauling qui est couramment utilisé et enseigné et qui est équivalent à une description d'orbitales moléculaires localisées ne présente aucune corrélation avec les mesures expérimentales. Il en découle que, pour des considérations de transferts d'électrons, les « paires libres » du DABCO ne sont pas localisées ou hybridées, mais qu'elles existent plutôt sous la forme d'orbitales non dégénérées qui sont délocalisées de façon différente sur le squelette moléculaire. L'existence, dans le cas du DABCO, de deux ensembles expérimentaux différents pour les densités des orbitales électroniques de valence fournit une confirmation directe du dédoublement d'énergie HOMO–NHOMO de l'orbitale frontière et de la réorganisation qui a été prédite il y a plusieurs années par Hoffmann et al. à l'aide de la théorie élargie de Hückel et interprété en fonction d'interactions « par les liaisons » et « à travers l'espace ».

Mots clés : orbitales, paires libres, interaction d'orbitales, hybridation.

Introduction and background

In the commonly used hybridized valence bond (VB) model of Pauling (1), the electron pairs on the nitrogen atoms of 1,4-diazabicyclo[2.2.2]octane (DABCO) are represented as equivalent, degenerate, localized "lone pairs," as shown in Fig. 1. This corresponds to a localized molecular orbital (LMO) treatment in which the degenerate lone-pair orbitals would exhibit a single-valence ionization energy (i.e., one peak in the valence shell photoelectron spectrum). However, it has been known for many years (2, 3) that extended Hückel (i.e., simple delocalized molecular orbital) theory predicts the two highest occupied (frontier) valence orbitals of DABCO to be nondegenerate with a HOMO/NHOMO[3] splitting of 1.63 eV. Hoffmann et al. (2, 3) interpreted this result in terms of "through-space" and "through-bond" interactions, by means of which the nonbonding electrons on the nitrogen atoms communicate with each other. A first-order through-space treatment (2, 3) would predict that the antisymmetric (AS) antibonding combination of 2*p* functions on the nitrogen atoms (in a simple LCAO-MO description) will comprise the HOMO, while the symmetric (S) bonding combination will comprise the NHOMO. However, when the through-bond interaction is turned on, the frontier orbital energy ordering is predicted to be reversed, i.e., the HOMO is bonding (S), and the NHOMO is antibonding (AS). Experimental studies of the binding energy spectrum of DABCO by Heilbronner and coworkers (4) using high-resolution-photoelectron spectroscopy (PES) later confirmed that the HOMO and the NHOMO of DABCO are indeed nondegenerate, with an observed vertical ionization energy splitting of 2.13 eV.

While the ordering of the frontier orbitals of DABCO could not unequivocally be established from the PES measurements (4), a subsequent detailed vibrational analysis of the two PES bands and extended Hückel calculations of overlap populations by Heilbronner and Muszkat (5) supported the orbital ordering predicted by Hoffmann et al. (2, 3).

In the years since Hoffmann's theoretical examination of DABCO, considerable advances have been made in computational chemistry. In particular, the use of Kohn–Sham density functional theory (DFT) has made highly accurate calculations, including the treatment of electron correlation, possible for larger molecules (6). Concurrently, a new experimental technique, electron momentum spectroscopy (EMS) (7–13), has been found to provide effective imaging of the electron momentum density distributions ($|\psi_j(\mathbf{p})|^2$) of individual valence orbitals (j) of target molecules. A recent detailed consideration of what EMS measures, together with related computational studies, has demonstrated (12) that there is an orbital-like nature to electron transfer as it applies to ionization processes and, by extension, to chemical reactivity. In particular, valence electrons are found to be donated (transferred) in a manner that is very well described by the appropriate Dyson orbital density which, in turn, is well approximated by the delocalized Kohn–Sham or canonical molecular orbital density of the initial state molecule.

EMS is a Fourier transform coincidence electron impact spectroscopy that supplies both binding energy and electron momentum information (7, 12, 13). It should be noted that the momentum space orbital wavefunction ($\psi_j(\mathbf{p})$) is the Fourier transform of the much more familiar position space orbital wavefunction $\psi_j(\mathbf{r})$. Using the plane wave impulse approximation, where $\int d\Omega$ implies the spherical average for the randomly oriented gas-phase target molecules, the observed EMS cross section (σ_{EMS}) (i.e., the measured signal) can be well modeled (7, 8, 13, 14) by an expression of the form

$$[1] \qquad \sigma_{EMS} \propto \int d\Omega |\psi_j(p)|^2$$

Thus, EMS provides momentum space "orbital imaging," corresponding to electron donation from an initial state orbital (12). Consequently, the EMS technique can yield definitive information regarding the nature of the valence electrons transferred out of a target molecule. In particular, it should be possible to determine the nature of the electron density distribution and the symmetric and (or) antisymmetric nature of the frontier orbitals of DABCO. Since the measured signal is directly related to the momentum space orbital electron density distribution (eq. [1]), the experimental results for valence electron transfer out of DABCO should provide a straightforward test of the different orbital models commonly used in chemistry. In particular, EMS can be used to evaluate basis sets (wavefunctions) and different quantum mechanical methods such as Hartree–Fock (HF) theory in either the localized molecular orbital model (LMO), corresponding to simple hybridized VB theory (1) or the delocalized canonical molecular orbital (CMO) models (15, 16), as well as the delocalized canonical Kohn–Sham orbital (KSO) model of density functional theory (6, 17).

It should be noted that the KSOs of DFT intrinsically include electron correlation, but the CMOs and LMOs of HF theory are based on the independent particle (noncorrelated) model. Accurate post-Hartree–Fock calculations, such as configuration interaction (CI) methods, which include electron correlation, are restricted to species containing at most two heavy atoms (8, 12, 18, 19). In addition, CI calculations are much more computationally intensive than DFT treatments, so that accurate CI calculations (or other many-body treatments) are not currently feasible for a molecule as large as DABCO.

Although the ability to probe orbital densities or, indeed, even the notion of orbitals as experimental observables has often been questioned (see, e.g., refs. 20–22), in 1977 Fukui (23) wrote:

> In the present status of experimental techniques, no one has been able to observe the orbital pattern experimentally. However, to date, no one can assert that this is totally impossible. If we could only experimentally obtain any knowledge of HOMO and LUMO patterns, chemistry would be profoundly affected. In that event the orbital pattern concept, which is at present of a somewhat unreal nature, will be provided with a certain empirical nature.

Similarly, while Kohn–Sham orbitals have often been described as fictitious mathematical concepts without any correspondence to reality (see, e.g., refs. 6, 14), in a recent commentary on DFT, Stowasser and Hoffmann (24) wrote:

[3] The HOMO is the highest occupied molecular orbital. The NHOMO is the next-highest occupied molecular orbital.

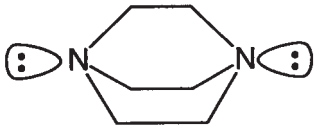
Fig. 1. Simple VB hybridized lone-pair representation of 1,4-diazabicyclo[2.2.2]octane (DABCO).



> …chemists know that orbitals are useful, but the physicists and chemists who use density functional theory so fruitfully have by and large shied away from attributing to Kohn–Sham orbitals the reality that (we think) they deserve.

Recent EMS measurements and computational investigations of electron transfer out of the frontier orbitals of methane (8, 12, 25, 26), ammonia (8, 12, 25, 27), water (8, 12, 19, 25), and methanol (9) have been found to be extremely informative for the evaluation of the different orbital models and the nature of the lone pairs in these molecules. This work has now been extended to a study of the orbital electron (momentum) density distributions and the nature of the lone pairs of DABCO.

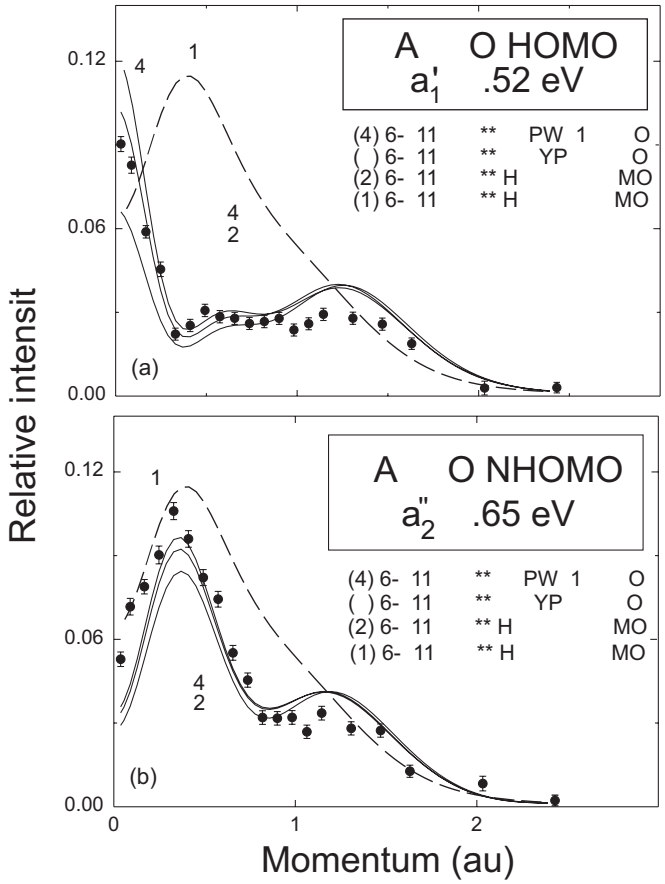
Experimental and computational details

Binding energy spectra for the outer valence region of DABCO were obtained at a series of azimuthal (ϕ) angles using an energy-dispersive multichannel EMS spectrometer. The design and operational details of this instrument, as well as the data reduction procedures, have been described in some detail (28). The impact energy for these measurements was 1200 eV plus the binding energy. The binding energy spectra for DABCO were deconvoluted using peak positions and widths from the high resolution PES data (4, 5), taking into account the EMS coincidence energy resolution of 1.4 eV full width at half maximum (fwhm). This procedure minimizes any cross-contributions from adjacent peaks. The resulting peak areas for the HOMO and NHOMO of DABCO were each plotted as a function of momentum (related to the ϕ angle; see refs. 7, 13, 28) to give the orbital momentum distributions on a common intensity scale. The DABCO sample (purity > 99%) was obtained from Aldrich and used without further purification other than freeze–thaw cycles to remove dissolved air.

A series of HF and DFT calculations was carried out for DABCO using Gaussian 98 (29) and the 6-311++G** basis set, which is sufficiently saturated and contains an adequate number of diffuse functions to provide good modeling at low momenta (large *r*). The B3PW91 (30, 31) and B3LYP (30) gradient corrected functionals were used in the DFT calculations. The theoretical results refer to optimized geometries. The resulting HF CMO and DFT KSO position space wavefunctions of HF and DFT theory, respectively, were transformed into momentum space using the MOMAP software package (32).

The resulting theoretical momentum distributions were then resolution folded using the experimental angular (momentum) resolution parameters and the RESFOLD (32, 33) program. These procedures allow a direct comparison between a theoretical momentum profile (TMP) and an experimental momentum profile (XMP) for each orbital. Localized molecular orbitals (LMOs) were computed by a repartitioning of the total HF wavefunction, using the Boys localization method (34) implemented in MONSTERGAUSS (35).

Fig. 2. Experimental and theoretical electron momentum density distributions for the HOMO and NHOMO orbitals of DABCO. All are at the 6-311++G** level. The dashed curve is the LMO. See text and legend on the figure for details.



Results and discussion

The EMS binding energy spectrum confirms the earlier PES observations (4, 5) that there are two outer valence IPs (7.52 and 9.6 eV, respectively), and not one corresponding to the presence of degenerate nitrogen lone pairs in DABCO. Figure 2 shows the experimental and calculated electron momentum distributions of the electrons transferred out of the two highest occupied orbitals of DABCO. From a comparison of the measured and calculated momentum distributions at these two binding energies, it is immediately apparent that the degenerate 6-311++G** LMO, i.e., the hybrid lone pair (Fig. 2, curve 1) is *incompatible* with the experimental observations at 7.52 and 9.65 eV. In contrast, the 6-311++G** HF delocalized CMO calculation provides a reasonably good semiquantitative description of the measured orbital momentum density distributions. It is noteworthy that significantly better quantitative agreement with the experimental results is provided by the delocalized KSO DFT models. The two DFT functionals give very similar results, with a marginally

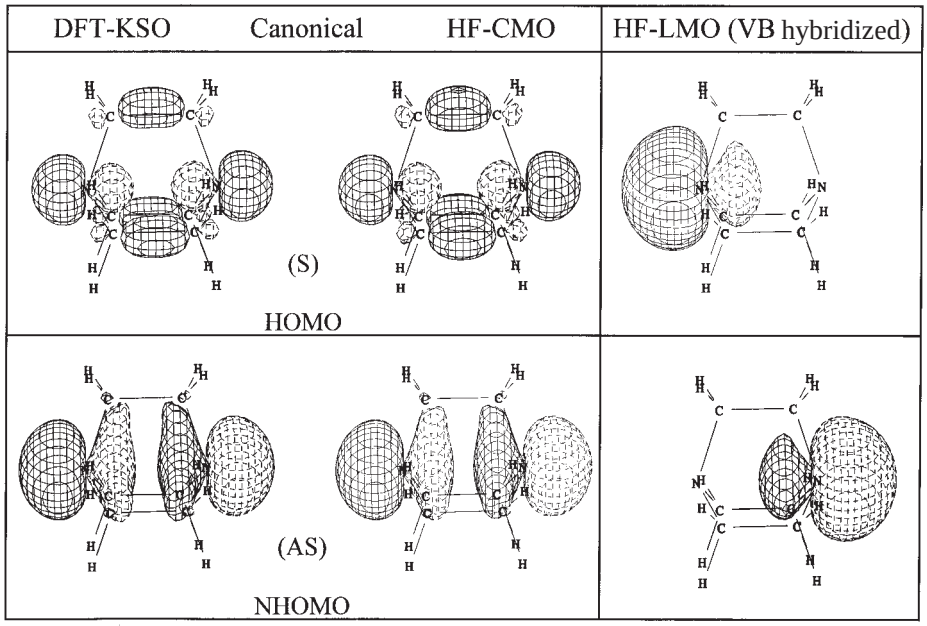
Fig. 3. Different orbital models of the position space electron densities of the HOMO and NHOMO orbitals of DABCO. All calculations are at the 6-311++G** level. The B3LYP DFT method has been employed for the KSOs.



better overall description provided by B3LYP. With the DFT theory and experiment normalized on the HOMO, good agreement is obtained in both shape and intensity for the NHOMO of DABCO.

It is also evident from Fig. 2 that the experimental electron momentum density distribution for the HOMO is predominantly "*s*-type" in character (see, e.g., ref. 36 and Fig. 3 of ref. 37), corresponding to a symmetric (S) orbital, whereas the NHOMO is mainly of "*p*-type" character (see, e.g., ref. 36 and Fig. 4 of ref. 37), i.e., antisymmetric (AS). These experimental findings unequivocally confirm the orbital reordering predicted by Hoffmann et al. (2, 3) for DABCO using a through-space and through-bond rationalization.

The above conclusions regarding the nature of the frontier orbitals of DABCO are entirely consistent with the three-dimensional *position space* representations of the general topographical features of the wavefunction plots of the HOMO and NHOMO shown in Fig. 3, whose KSO (and CMO) plots correspond to the EMS experiments (Fig. 2). At the contour-envelope value shown in Fig. 3 (0.10, i.e., 99% enclosed), the KSO and CMO pictures are very similar, and the S and AS nature of the KSO and CMO HOMO and NHOMO, respectively, predicted by Hoffmann et al. (2, 3) are readily apparent. In contrast, the LMO (hybridized) pictures at the right of Fig. 3, which correspond to equivalent, degenerate, hybridized lone pairs localized on the nitrogens, which do not correspond to experiment, are very different in nature from the KSOs and CMOs.

Preliminary accounts of the present work on DABCO were reported earlier at conferences in Vancouver (38) and Japan (39), and in lectures by one of us (SW) in Japan, Mexico, Israel, and Canada. After our experimental and theoretical work was complete, and as this manuscript was being prepared, another EMS study of DABCO was reported by Takahashi et al. (40). This more limited study compares HOMO and NHOMO measurements for DABCO with several different basis set calculations up to the 6-311++G** level at the delocalized molecular orbital Hartree–Fock level only, with no consideration of Kohn–Sham or localized molecular orbitals. While the experimental results of ref. 40 are qualitatively similar to those reported here, the statistics are not as good, there are fewer data points, and the experimental momentum distributions show significant differences in both shape and intensity from those reported here. These differences probably result from the procedures used by Takahashi et al. (40) to determine the experimental momentum profiles. This was done (40) by setting the spectrometer at two different fixed values of the binding energies and measuring the intensities as a function of ϕ. This type of experimental procedure will almost certainly lead to erroneous cross-contributions from the NHOMO to the HOMO, and vice versa, because of the close energy spacing, and will cause the resulting HOMO and NHOMO intensities to be on different relative intensity scales. As a result, the orbital momentum distributions of ref. 40 will require separate height normalizations to theory. As explained above, these difficulties are avoided in the present work by recording the complete binding energy spectrum in the frontier orbital region at each ϕ angle, with deconvolution of the two peaks. The experimental approach used in the present work therefore minimizes any cross-contributions and also has the advantage of placing the HOMO and NHOMO momentum profiles on a common intensity scale. This permits a more stringent comparison with theory. Although Takahashi et al. (40) show good agreement with their experimental shapes at the 6-311++G** (delocalized) HF level, this finding is likely fortuitous for the reasons stated above (i.e., because of the separate height normalization for each orbital). In this respect their results are at variance with the present work

© 2002 NRC Canada

(Fig. 2) which shows significant quantitative disagreement at the HF level. In fact, reasonable quantitative agreement between theory and experiment is achieved only when electron correlation is included, as seen in the 6-311++G**/B3LYP and B3PW91 DFT calculations of Fig. 2.

In conclusion, the present work for DABCO, in addition to parallel studies of methane, ammonia, water, and methanol (9, 25, 38, 39) all show that (intrinsically correlated) delocalized canonical Kohn–Sham orbitals (KSOs) provide very good quantitative descriptions of the experimentally observed frontier-orbital electron-momentum density distributions. These findings lend strong support to the ideas of Stowasser and Hoffmann (24) regarding the "reality" of Kohn–Sham orbitals. Delocalized HF canonical molecular orbitals (CMOs) provide a good semiquantitative model in which the distribution and location of the valence orbital electron densities are qualitatively correct. In contrast, the still overwhelmingly popular localized (hybrid) VB orbital description *incorrectly distributes and incorrectly locates* the valence orbital electron densities. We believe that the present findings and conclusions regarding the ability of the delocalized KSO and CMO orbital models to describe electron transfer, and the failure of the hybrid orbital model, have profound implications because proper frontier orbital modeling is essential to the understanding of chemistry at the level of valence electron behaviour. These results are likely to be important in areas such as the teaching and practice of chemistry and accurate molecular modeling, as well as for informed input to computer-aided molecular design and reactivity studies where electron transfer is involved.

Ortho substituent effects on transfer of aryl groups from oxygen to carbon in adducts from diaryloxycarbenes and DMAD

Xiaosong Lu and John Warkentin

Abstract: Diaryloxycarbenes, generated by thermolysis of 2,2-diaryloxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazolines in benzene, reacted with dimethyl acetylenedicarboxylate (DMAD) to afford triesters. The triesters arose by aryl-group transfer from oxygen to carbon (ipso substitution). A cyano group in the *para* position had been shown earlier to favour the ipso substitution whereas a *para*-methoxy group disfavoured it. Surprisingly, the *ortho*-methoxy substituent also favoured ipso substitution. As a tentative rationale, we had proposed that a vinylogous diaryloxycarbene intermediate, with dipolar properties, is formed when a diaryloxycarbene attacks at the *sp*-carbon of DMAD and that an *ortho* substituent, with one or more unshared electron pairs, can stabilize the intermediate by donating electron density to the positive site. In the present work, support for that interpretation and for the importance of a steric effect, was provided by examining the competition between (*i*) *p*-tolyl and phenyl; (*ii*) *o*-tolyl and phenyl; (*iii*) *o*-iodophenyl and phenyl; (*iv*) *o*-iodophenyl and *p*-chlorophenyl; and (*v*) *o*-bromophenyl and *p*-chlorophenyl as potential migrating groups.

Key words: aromatic substitution, carbene, ipso, diaryloxycarbene, oxadiazoline.

Résumé : Les diaryloxycarbènes, générés par thermolyse de 2,2-diaryloxy-5,5-diméthyl-Δ^3-1,3,4-oxadiazolines dans le benzène, réagissent avec l'acétylènedicarboxylate de diméthyle («DMAD») pour conduire à la formation de triesters. Les triesters se forment par un transfert de groupe acyle de l'oxygène au carbone (substitution ipso). Il a été démontré antérieurement que la présence d'un groupe cyano en position *para* favorise la substitution ipso alors qu'un groupe méthoxy la défavorise. De façon surprenante, un substituant méthoxy en *ortho* favorise aussi la substitution ipso. Comme explication de ce résultat, on a suggéré que lorsqu'un diaryloxycarbène attaque au niveau d'un carbone sp du DMAD, il y formation d'un intermédiaire diaryloxycarbène vinylogue ayant des propriétés dipolaires et qu'un substituant *ortho* possédant au moins une paire d'électrons non partagée peut stabiliser l'intermédiaire en donnant de la densité électronique au site positif. Dans le présent travail, en examinant la compétition entre divers groupes migrants potentiels ((*i*) *p*-tolyle et phényle; (*ii*) *o*-tolyle et phényle; (*iii*) *o*-iodophényle et phényle; (*iv*) *o*-iodophényle et *p*-chlorophényle; (*v*) *o*-bromophényle et *p*-chlorophényle), on a obtenu des résultats qui appuient cette interprétation et qui mettent en évidence l'importance d'un effet stérique.

Mots clés : substitution aromatique, carbène, ipso, diaryloxycarbène, oxadiazoline.

[Traduit par la Rédaction]

Introduction

Reactions of neutral nucleophiles with Michael acceptors will generally involve dipolar intermediates, as illustrated in Scheme 1 for the attack of an amine on dimethyl acetylenedicarboxylate (DMAD). If the nucleophile is a carbene, such as a dialkoxycarbene, the attack can produce either a dipole or a cyclopropene, depending on whether the reaction is stepwise or concerted. It is not always easy to distinguish between the stepwise addition with subsequent ring-closing and the concerted cyclopropene formation with subsequent ring-opening, but it is fairly clear that, with a few exceptions (1), reactions subsequent to the initial attack often involve the acyclic dipole. The dipolar species may be in equilibrium with the cyclopropenes, many of which are not stable enough at higher temperatures to accumulate to detectable concentrations (2).

We became interested in reactions of methoxyaryloxy- and diaryloxycarbenes with DMAD as a result of the discovery of aryl group transfer, from oxygen to carbon, to produce triester products (Scheme 2) (3, 4).

There was only one prior example of a similar transfer, from the reaction of an aminothiocarbene with DMAD, Scheme 3 (5). The results in Schemes 2 and 3 could be rationalized in terms of a dipolar carbenic intermediate that accomplishes ipso-aromatic substitution, either by nucleophilic attack at the ipso carbon or via cyclopropanation and subsequent reorganization (Scheme 4) as suggested by Capretta (6) for similar reactions of carbenoids. The mechanism involving nucleophilic attack was favoured when it was found that an electron withdrawing group in the *para* position favoured aryl-group transfer whereas an electron donor group disfavoured the transfer (4). For example, *p*-cyanophenyl mi-

grated exclusively when competing with phenyl, *p*-tolyl, or *p*-methoxyphenyl, and phenyl migrated exclusively when in competition with *p*-methoxyphenyl (4). Surprisingly, *o*-methoxyphenyl had a migratory aptitude comparable to that of phenyl (4), suggesting that the *o*-methoxy substituent exerts opposing effects, an electronic effect presumably analogous to that of the *p*-methoxy substituent, disfavouring substitution, and at least one other effect favouring it.

We now report that the *o*-tolyl group has a higher migratory aptitude than the *p*-tolyl group, although both have a lower migratory aptitude than the phenyl group, and that the *ortho* effect is enhanced with the *o*-iodo- and *o*-bromophenyl groups, both of which migrated in preference to the *p*-chlorophenyl group.

Methods, results, and discussion

Oxadiazolines **4** were prepared from appropriate bis(aryl) carbonates (**1**). Diphenyl carbonate is commercially available and di(*p*-chlorophenyl) carbonate was prepared from 1,1′-carbonyl diimidazole by the sequence of reactions shown in Scheme 5 (7).

Diaryloxyoxadiazolines **5** were prepared by exchange reactions of oxadiazolines **4** with the appropriate substituted phenols (7, 8). Thermolysis of **5** in benzene generated carbonates **6** and carbonyl ylides **7** by competing 1,3-dipolar cycloreversions (see Scheme 6). Evidence for the intermediacy of **7** came from the thermolysis-rate constants (7). Although the effects of the substituents on the thermolysis-rate constants are small, the fact that the *p*-cyano substituted oxadiazoline lost N_2 about twice as fast as the parent is consistent with a transition state in which C2 has become more negative, as it would in the carbonyl ylide. In a concerted mechanism, on the other hand, in which N_2 and acetone are extruded simultaneously, as proposed by Smith (9), carbene character would develop at C2. A cyano group, which would destabilize the carbene, should have a rate-retarding effect and not the observed rate-accelerating effect, if carbene formation were part of the rate-determining step.

Diaryloxycarbenes **8**, which presumably arose from fragmentation of carbonyl ylides **7** (10), reacted with DMAD to

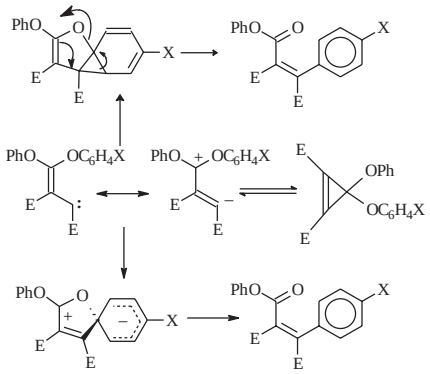
Scheme 4.



form triesters **10** and **11** through migration of an aryl group from oxygen to carbon. In the case of **8a** (Ar = *p*-C_6H_4Me), **10a** was the minor and **11a** the major triester formed (**10a**:**11a** = 1:4.5). Similarly, in the case of **8b**, the yield of **11b** exceeded that of **10b** (**11b**:**10b** = 1.1:1). Thus, the *para*-methyl group retards migration between 4- and 5-fold, whereas the *ortho*-methyl group retards migration by about 10%, both relative to H. However, *o*-iodophenoxy-(phenoxy)carbene (not shown) reacted with DMAD to afford exclusively the triester from migration of the *o*-iodophenyl group. Similarly, the *o*-iodophenyl and the *o*-bromophenyl groups migrated exclusively when in competition with the *p*-chlorophenyl group of **8c** and **8d**. These results are in Table 1, together with some results published earlier.

Identification of the triester formed by ipso-aromatic substitution by means of mass spectrometry was straightforward. For example, esters **10a** and **10b** gave rise to a base peak from loss of the C_6H_5O fragment of the ester; the aryl group that had migrated to carbon was not lost. On the other hand, **11b** lost the fragment $CH_3C_6H_4O$. Esters **10** and **11** were assigned the *E*-configuration on the basis of analogy to a similar compound, the structure of which was secured by means of X-ray diffraction (4).

In each case, the oxadiazoline source fragmented not only to N_2, the carbene, and acetone, but also to 2-diazopropane and the appropriate diaryl carbonate (Scheme 6). The diazopropane was trapped by 1,3-dipolar cycloaddition to DMAD to form known pyrazole **12** (11).

These results can be interpreted as follows: attack on DMAD by the carbenes **8** leads to isomeric dipolar intermediates (**9**), which can also be represented as vinylogous dioxycarbenes (not shown) that are equilibrated by reversible closure to the appropriate cyclopropene. Such equilibration occurs at 80°C in the case of analogous vinylogous dioxycarbenes (2*c*). If equilibration via the corresponding

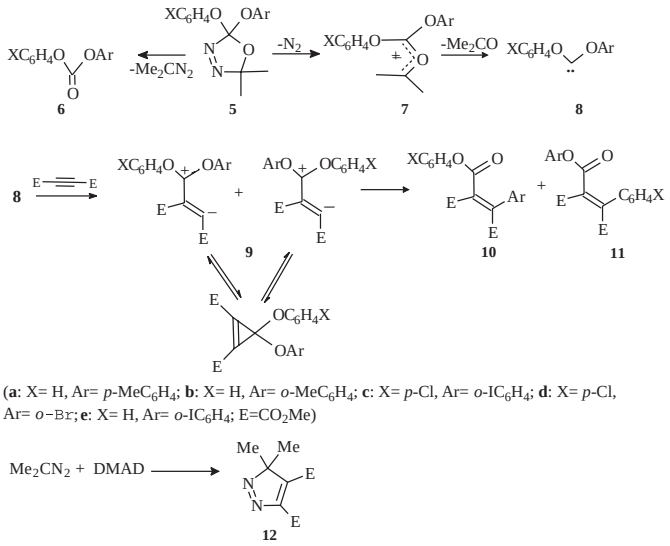
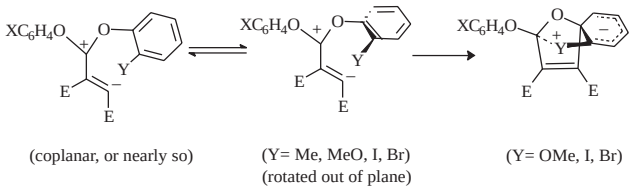
cyclopropenes is rapid compared to aryl group transfer, then the Curtin–Hammett principle (12) applies and the group that is transferred by ipso substitution is selected on the basis of the relative stabilities of the transition states and not the ground states. Given that the principle does apply, it is clear from Table 1 that the *p*-tolyl group is transferred more slowly than the phenyl group, whereas the *o*-tolyl group, although it is also transferred more slowly than the phenyl group, is transferred more rapidly than the *p*-tolyl group. Thus, methyl retards nucleophilic aromatic substitution, as befits its electronic effect, but the retardation is diminished when the methyl group is situated *ortho*. Presumably the *o*-methyl group acts to prevent coplanarity of the aryloxy group with the dipolar fragment tethered to it (see Scheme 7) and that geometry provides an improved orientation of the aryloxy group for attack on the ring. Whether that attack involves formation of one bond, at the ipso position only, or two bonds to the aromatic ring to afford a cyclopropane intermediate (6) is not established.

Both *o*-iodophenyl and *o*-bromophenyl are transferred more rapidly than *p*-chlorophenyl, to the extent that the products of migration of *p*-chlorophenyl were not found. From previous work (4), we know that the *p*-cyano group is

Scheme 6.



Scheme 7.



a strong facilitator of migration whereas a *para*-methoxy group stops aryl migration, both relative to H. Although it was not possible to construct a Hammett plot and to determine the value of ρ, an approximate value can be estimated as follows: if we assume that no more than 2% of a minor product might have been missed, then the migration rate ratios were *p*-CNC_6H_4/C_6H_5 > 37/2 and *p*-$MeOC_6H_4/C_6H_5$ < 2/38 (4). Consequently $k_{p\text{-CN}}/k_H \geq 18.5$ or $\log (k_{p\text{-CN}}/k_H) \geq 1.27$ and $k_{p\text{-OMe}}/k_H \leq 1/19$ or $\log (k_{p\text{-OMe}}/k_H) \leq -1.28$. With $\sigma_{p\text{-Cl}} = 0.63$ and $\sigma_{p\text{-OMe}} = -0.27$, the predicted value of ρ is ca. +3.3. The value of $\sigma_{p\text{-Cl}}$ is 0.23, which, together with the estimated value of ρ, leads to the prediction that the *p*-chlorophenyl group should migrate 5 to 6 times faster than phenyl. Since *o*-iodophenyl and *o*-bromophenyl migrated exclusively when in competition with *p*-chlorophenyl, it is clear that both the *ortho*-iodo and *ortho*-bromo substituents enhance migration, relative to H, even more strongly. The large rate-enhancing effects of *o*-iodo and *o*-bromo, relative to H and to *p*-chloro, cannot be a consequence of relative electron withdrawing abilities, which are very similar ($\sigma_{p\text{-I}} = 0.28$, $\sigma_{p\text{-Br}} = 0.23$, $\sigma_{p\text{-Cl}} = 0.23$).

A likely explanation for the observed effects (*o*-MeO >> H, *p*-MeO < H; *o*-I > *p*-Cl > H; *o*-Br > *p*-Cl > H; *o*-Me < H, *p*-Me < H; and *o*-Me > *p*-Me) focuses on the following factors: (*i*) in a nucleophilic ipso substitution, electron donor groups should raise the transition state energy; (*ii*) *p*-methoxy and *p*-methyl groups are donor groups relative to H and both retard the ipso substitution; (*iii*) methyl retards moderately and methoxy retards more strongly, as expected on the basis of their substituent constants ($\sigma_{p\text{-Me}} = -0.14$, $\sigma_{p\text{-OMe}} = -0.28$);

© 2002 NRC Canada

and (*iv*) *p*-cyano and *p*-chloro are inductively electron withdrawing and cyano also withdraws conjugatively. One therefore expects them to favour ipso substitution on rings bearing those groups, as observed for *p*-cyano. *Ortho* groups, on the other hand, must exert three effects. First, they donate or withdraw electrons, qualitatively like their *para* counterparts. Second, they exert a steric effect that *favours* attack at the neighbouring carbon (ipso attack), as indicated by the effect of *o*-methyl. The fact that *p*-methyl is retarding and *o*-methyl is retarding but less so must mean that the steric effect promotes attack by the dipole–carbene on the aromatic ring. Presumably it does this by increasing the populations of conformers in which the aromatic ring to be attacked is not coplanar with the dipolar–carbenic nucleophile (Scheme 7). Third, the *ortho* substituents bearing unshared electrons (MeO, I, Br) must exert a further effect that reinforces the steric effect; these substituents can donate electron density toward the developing positive site to stabilize the transition state for the formation of the intermediate for nucleophilic-aromatic ipso substitution, illustrated in Scheme 7. A cyclopropanation step would also be facilitated by rotating the aromatic ring as a result of steric hindrance. However, cyclopropanation by a nucleophilic carbene is unlikely to be enhanced strongly by an *o*-OMe substituent.

Thus, the tentative explanation advanced earlier (4), for the electronic effect of the *o*-methoxy substituent, is supported by the findings that the *o*-Br and *o*-I substituents are strongly rate enhancing. That explanation is amplified, on the basis of the results with *o*- and *p*-Me, to include a pure steric effect.

Experimental

NMR spectra were recorded on a Bruker AC-200 or AC-300 NMR spectrometer. Infrared spectra were recorded with a Biorad FTS-40 spectrophotometer, with the sample either in CCl_4 or in a KBr pellet. The IR bands are labeled qualitatively with the symbols br, s, and m for broad, strong, and medium intensities, respectively. Bands from C—H stretching vibrations between 3100 and 2850 cm^{-1} are omitted, as are other weak bands. Melting points were recorded on a Thomas Hoover capillary melting point apparatus; they are uncorrected. Mass spectra of compounds containing Cl, Br, or both list all of the observed molecular ion masses, not only the signals for the most abundant isotope(s). Mass spectra for the oxadiazolines are not reported. 2,2-Dioxy-5,5-dimethyl oxadiazolines do not, in general, afford molecular ion signals and their mass spectra have little diagnostic value. They can be recognized from their ^1H and ^{13}C NMR spectra. The latter typically show C2 between δ 136 and 138 and C5 between δ 118 and 120, if the C2 substituents are alkoxy groups and the C5 substituents are methyl groups (13). Some of the ^{13}C NMR spectra of the products showed fewer signals than were expected and coincidence of some signals in diaryl compounds is suspected. Moreover, some maleate-like methyl esters (**10**, **11**) gave only one ^{13}C OMe signal where two methoxy groups were indicated by ^1H NMR spectroscopy.

General thermolysis method

All thermolyses were carried out by immersing the sealed and vacuum-degassed thermolysis tubes containing the samples in a constant-temperature oil bath at 110.0 ± 0.2°C for 24 h. In a typical procedure a solution containing the oxadiazoline (0.6 mmol) and DMAD (0.8 mmol) in benzene (20 mL) was degassed by means of three freeze-pump-thaw cycles before it was heated in a sealed tube at 110°C for 24 h. A small amount of the solution was used for direct GC–MS analysis. Benzene was evaporated from the rest of the solution and the residue was subjected to flash chromatography with 5% ethyl acetate in hexane as the eluting solvent. The spectroscopic data came from products isolated by means of radial or column chromatography from larger-scale experiments with up to 2.2 mmol of oxadiazoline.

bis-*p*-Chlorophenyl carbonate (1b) (14)

A solution of 1,1′-carbonyldiimidazole (9.7 g, 0.060 mol), *p*-chlorophenol (15.2 g, 0.12 mol), silver nitrate (20.4 g, 0.12 mol), and triethylamine (12.1 g, 0.12 mol) in acetonitrile (100 mL) was heated at reflux for 16 h before it was filtered and cooled to room temperature. Hexane was added until no more precipitate was formed. The colourless needle-shaped crystals (9.6 g, 57%) were removed from the slightly dark solution by vacuum filtration; mp 146–147°C. IR (CCl_4) (cm^{-1}): 1781 (s), 1488 (s), 1278 (m), 1224 (br), 1187 (s), 1163 (m), 1104 (m), 1085 (s), 1013 (s). ^1H NMR (200 MHz, $CDCl_3$) δ: 7.19–7.40. ^{13}C NMR (75 MHz, $CDCl_3$) δ: 122.3, 129.8, 132.0, 149.4, 151.7. EI-MS *m*/*z* (%): 286 (M^+, 10), 284 (M^+, 54), 282 (M^+, 90), 238 (52), 168 (25), 128 (42), 111 (100), 99 (59), 75 (68), 63 (46). CI-MS (NH_3) *m*/*z* (%): 304 ($[M + 18]^+$, 1), 302 ($[M + 18]^+$, 7), 300 ($[M + 18]^+$, 10), 282 (M^+, 27).

***p*-Chlorophenyl hydrazinecarboxylate (2b) (14)**

A stirred solution of bis-*p*-chlorophenyl carbonate (4.0 g, 0.014 mol) in CH_2Cl_2 (30 mL) was cooled with a dry ice bath for 15 min before hydrazine monohydrate (0.71 g, 0.014 mol) was added in one portion. The dry ice was removed to let the solution warm gradually to room temperature and stirring was continued for 20 min. Addition of hexane caused colourless needles to precipitate. Vacuum filtration furnished pure **2b** (1.06 g, 40%); mp 144–145°C. IR (CCl_4) (cm^{-1}): 3458 (m), 3304 (m), 1757 (s), 1549 (s), 1462 (m), 1215 (s), 1010 (m), 978 (m). ^1H NMR (200 MHz, $CDCl_3$) δ: 3.87 (s, 2H, NH_2), 6.35 (s, 1H, NH), 7.07–7.31 (m, 4H, Ar). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 122.9, 129.6, 131.2, 149.3, 156.7.

***p*-Chlorophenoxycarbonyl hydrazone of acetone (3b)**

p-Chlorophenyl hydrazinecarboxylate (3.73 g, 0.020 mol) and anhydrous magnesium sulfate (ca. 6 g) were added to acetone (60 mL). Stirring for 24 h followed by filtration and evaporation of the excess acetone produced pure **3b** as colourless crystals (92% yield); mp 98–102°C. IR (CH_2Cl_2) (cm^{-1}): 3383 (m), 1761 (s), 1482 (m), 1356 (m), 1262 (s), 1201 (m), 1090 (m), 1012 (m). ^1H NMR (200 MHz, $CDCl_3$) δ: 1.88 (s, 3H, CH_3), 2.08 (s, 3H, CH_3), 7.10–7.36 (m, 4H, Ar), 7.97 (s, 1H, NH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 16.4, 25.5, 123.0, 129.5, 131.1, 149.3, 153.1. (37). CI-MS (NH_3) *m*/*z* (%): 229 ([M + 1]$^+$, 32), 227 ([M + 1]$^+$, 100). EI-HRMS *m*/*z* calcd. for $C_{10}H_{11}{}^{35}ClN_2O_2$: 227.0587; found: 227.0575.

2-Acetoxy-2-(*p*-chlorophenoxy)-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (4c)

A solution of lead tetraacetate (LTA, 11.4 g, 2.57 mmol) in CH_2Cl_2 (60 mL) was cooled with dry ice in isopropyl alcohol. Acetone *p*-chlorophenoxycarbonyl hydrazone (4.84 g, 2.14 mmol) in CH_2Cl_2 (20 mL) was added dropwise to the LTA solution, which was then gradually warmed to room temperature and stirred overnight. After three washings with 5% $NaHCO_3$, drying over anhydrous $MgSO_4$, and evaporation of the solvent, flash column chromatography (5% EtOH–hex) gave **4c** in 36% yield as a yellow oil. IR (CCl_4) (cm^{-1}): 2995 (s), 2930 (s), 2873 (m), 1797 (br), 1735 (s), 1588 (m), 1490 (s), 1462 (m), 1434 (m), 1371 (m), 1278 (m), 1231 (br), 1013 (m), 985 (m). ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.40 (s, 3H, Me), 1.67 (s, 3H, Me), 2.08 (s, 3H, COMe), 7.14–7.30 (m, 4H, Ph). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 21.3, 22.7, 24.2, 123.0, 123.8, 129.3, 130.4, 133.0, 150.1, 165.9.

2-(*p*-Chlorophenoxy)-2-(*o*-iodophenoxy)-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (5c)

A solution of **4c** (1.81g, 6.36 mmol) and 2-iodophenol (1.54 g, 7.00 mmol) in CH_2Cl_2 (60 mL) containing catalytic trifluoroacetic acid was heated at reflux for 24 h. Pure **5c** was obtained by means of flash column chromatography (5% EtOH–hex) as a yellow oil, in 43% yield: IR (CCl_4) (cm^{-1}): 1584 (m), 1550 (m), 1486 (s), 1469 (m), 1209 (s), 1155 (s), 1105 (m), 1087 (s), 1014 (m). ^{1}H NMR (200 MHz, $CDCl_3$) δ: 1.34 (s, 3H, Me), 1.37 (s, 3H, Me), 6.80–7.78 (m, 8H, Ar). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 23.5, 23.7, 90.4, 121.4, 122.3, 123.2, 123.8, 126.2, 129.2, 130.5, 135.7, 139.6, 149.9, 151.5.

Thermolysis of 5c in the presence of DMAD

Thermolysis of **5c** (0.28 g, 0.63 mmol) in the presence of DMAD (0.11 g, 0.77 mmol) as described in the general procedure gave carbonate **6c**, aromatic substitution product **10c**, and pyrazole **12**.

***p*-Chlorophenyl *o*-iodophenyl carbonate (6c)**

This compound was obtained in 30% yield as a colourless solid; mp 81–82°C. IR (CCl_4) (cm^{-1}): 1782 (s), 1549 (m), 1488 (m), 1469 (m), 1225 (br), 1190 (s), 1090 (m), 1016 (m), . ^{1}H NMR (200 MHz, $CDCl_3$) δ: 6.99–7.88 (m). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 89.7, 122.3, 128.3, 129.7, 131.9, 139.7, 149.4, 150.8, 151.0. Direct-space analysis of the electronic structure of the $YBa_2Cu_3O_6$ and $YBa_2Cu_3O_7$ crystals

Fausto Cargnoni and Marco Scavini

Abstract: The electronic structure of the $YBa_2Cu_3O_6$ and $YBa_2Cu_3O_7$ crystals is investigated by means of fully periodic-restricted Hartree–Fock LCAO (linear combination of atomic orbitals) pseudopotential calculations. To give a detailed description of the bonding and atomic properties of the materials studied we selected the quantum theory of atoms in molecules approach, and complementary information is obtained from the analysis of the electron localization function in specific cell regions. The main features of the $YBa_2Cu_3O_6$ and $YBa_2Cu_3O_7$ crystals' electron densities are detailed and compared with available experimental data. Since the superconducting transition requires oxidation of the $YBa_2Cu_3O_6$ crystal, we focused on the electronic rearrangements related to the inclusion of oxygen. Cu–O planes, probably responsible for the superconducting transition, exhibit peculiar electronic properties.

Key words: superconducting cuprates, electron density, ab initio calculations.

Résumé : On a étudié la structure électronique de cristaux de $YBa_2Cu_3O_6$ et de $YBa_2Cu_3O_7$ en se basant sur des calculs de pseudopotentiel « LCAO » de Hartree–Fock restreints et totalement périodiques. Afin de pouvoir donner une description détaillée du type de liaison et des propriétés atomiques des matériaux étudiés, on a choisi l'approche de la théorie quantique des atomes dans les molécules et on a obtenu des informations supplémentaires à l'aide de l'analyse de la fonction de localisation de l'électron dans régions spécifiques des cellules. Les détails des caractéristiques principales des densités électroniques dans les cristaux de $YBa_2Cu_3O_6$ et de $YBa_2Cu_3O_7$ sont rapportés et on les compare aux données expérimentales disponibles. Comme la transition de superconduction nécessite une oxydation du cristal de cristaux de $YBa_2Cu_3O_6$, on a porté notre attention sur les réarrangements électroniques apparentés à l'inclusion d'oxygène. Les plans Cu–O, probablement responsables de la transition de superconduction, présentent des propriétés électroniques particulières.

Mots clés : cuprates superconducteurs, densité électronique, calculs ab initio.

[Traduit par la Rédaction]

Introduction

As extensively documented in the literature, one of the common features of cuprates is the dramatic dependence of their electronic structure and transport properties upon oxygen and cation stoichiometry (1, 2).

In particular, $YBa_2Cu_3O_x$ is a nonstoichiometric compound, since the oxygen stoichiometry x can vary from 6 to 7 as a function of the annealing route. $YBa_2Cu_3O_6$ is an insulator; adding oxygen to the structure it becomes metallic, and at low temperatures, it undergoes a transition to superconductor. At the optimal oxygen stoichiometry/concentration ($x = 7$), $T_C = 90$ K (3).

The structure of $YBa_2Cu_3O_x$ (YBCO) also changes as the oxygen concentration changes: $YBa_2Cu_3O_6$ (YBCO6) belongs to the *P4*/*mmm* space group, whereas $YBa_2Cu_3O_7$ (YBCO7) belongs to the *Pmmm* space group.

YBCO6 contains six nonequivalent atoms in the asymmetric unit: Y at (1/2, 1/2, 1/2), Ba at (1/2, 1/2, *z*), Cu1 at (0, 0, 0), Cu2 at (0, 0, *z*), O1 at (0, 0, *z*), and O3 at (0, 1/2, *z*) sites. Concerning YBCO7, eight nonequivalent atoms are present in the asymmetric unit: Y at (1/2, 1/2, 1/2), Ba at (1/2, 1/2, *z*), Cu1 at (0, 0, 0), Cu2 at (0, 0, *z*), O1 at (0, 0, *z*), O2 at (1/2, 0, *z*), O3 at (0, 1/2, *z*), and O4 at (0, 1/2, 0) sites. Passing from YBCO6 to YBCO7, the main structural change is the orthorhombic distortion, which is due to the insertion and ordering of O4 along the *b* axis. Figure 1 shows a stick-and-ball representation of structures YBCO6 and YBCO7; the bonding network represented in the panels will be discussed in the *Results and discussion* section.

Oxidation, coupled with the change in the crystal structure, affects the electronic structure of YBCO giving rise to the dramatic change of its transport properties in the normal state and to the superconducting transition.

Theoretical calculations widely investigated the dependence of the YBCO electronic band structure on the oxygen content (4–10). Minor attention was devoted to the electron density rearrangements induced by oxidation (11). Concerning theoretical electron density studies on superconducting cuprates, Acrivos and Stradella (12) topologically investigated the electron density in CuO_2 lamellas embedded in a point-charge lattice simulating the Nd_2CuO_4 crystal. To the best of our knowledge, no similar investigations on the

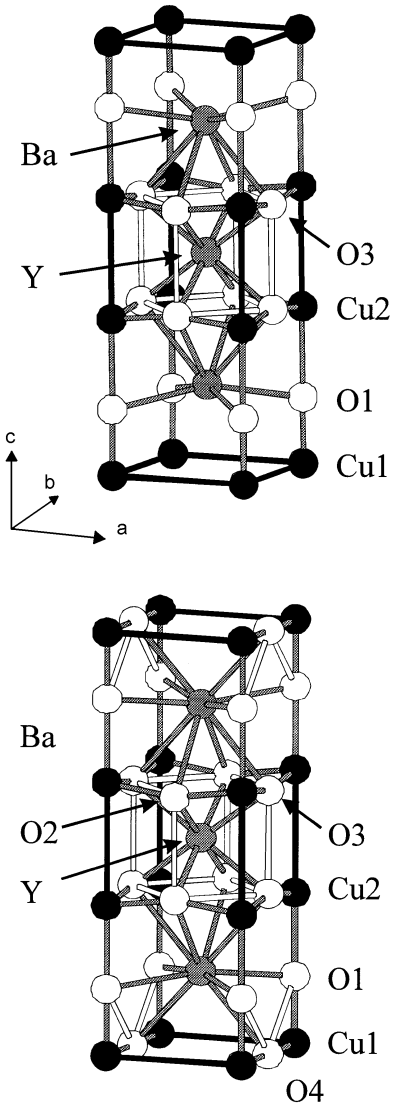
Fig. 1. Stick-and-ball representation of the YBCO6 (top) and YBCO7 (bottom panel) crystals' unit cells and atoms. The bonding network represented in the panels reports all interatomic linkages obtained through the topological analysis of the electron density. Qualitatively different bonds are represented with different colours: black (cation–cation), grey (cation–anion), and white (anion–anion).



YBCO system are available in the literature. The charges of copper atoms at various oxidation states have been calculated by Brown (13) using an empirical approach.

Relatively few experimental electron-density measurements concerning YBCO crystals are available (14–17). All works deal with single crystal X-ray diffraction experiments at room temperature and examine Fourier difference density maps.

Sasaki et al. (14) studied a crystal with $YBa_2Cu_{2.898}Al_{0.102}O_{6.38}$ composition, ascribing the presence of Al to the contamination from the alumina crucible used in the synthesis. At this oxygen concentration, the crystal was found to belong to the *P*4/*mmm* tetragonal space group. Around the Y and Cu1 positions no significant electron density residuals (edr) appear, i.e., electrons are spherically distributed. Cu2 exhibits two positive edr along the *c* axis, directed along the Cu2–O1 and Cu2–Cu2 vectors. These residuals have been ascribed by the authors to the Cu(3*d*) electron configuration, more precisely to the lack of electrons in the $3d_{x^2-y^2}$ orbital. An asymmetrical electronic distribution was found also near the Ba position, and interpreted as a consequence of the anharmonic thermal vibration of barium.

Buttner et al. (15) studied an orthorhombic crystal (space group *Pmmm*). These authors found strong positive residuals along the Cu2–Cu2 vectors. The residual density around Cu1 ions was interpreted as an electron transfer from Cu(3*d*) to Cu(4*s*) states.

Jang et al. (16, 17) studied both oxidized and reduced samples, to make a direct comparison between the different crystals. In the oxidized sample, the authors noted residual electron density around the Cu1 position, and interpreted it as evidence for Cu1—O1 and Cu1—Cu1 bonding. With regard to Cu2, two positive peaks were observed along the *c* axis, while an electron density depletion appeared between Cu2 and O2. Barium was found to be polarized along *c*. In the reduced sample, the authors found a positive edr along the Cu2–Cu2 vector and a negative edr along Cu2–O1. The authors concluded that the introduction of oxygen in the O4 site significantly changed the electron distribution in the whole unit cell.

In this paper, we present fully periodic ab initio restricted Hartree–Fock (RHF) calculations on the YBCO6 and YBCO7 crystals within a pseudopotential LCAO (linear combination of atomic orbitals) scheme, as implemented in the CRYSTAL-98 (18) computational code. The RHF method is much less common in solid-state chemistry and physics than the density functional approach. Actually, apart from the large overestimation of the electronic band gap, wavefunctions of solids obtained from RHF calculations are generally as accurate as density functional calculations (19). Moreover, it was shown that the electron densities obtained from RHF computations in covalent crystals align with the experimental results (20).

The main purpose of the present investigation is the characterization of the bonding and the atomic properties of YBCO6 and YBCO7 as a function of the oxygen content. Whenever possible, the results obtained are compared with available experimental information on the electron density distribution in the crystal unit cell and its rearrangements due to oxidation (14–17). Particular attention is devoted to the Cu–O superconducting planes, since they are presumed to be responsible for the superconducting behaviour of cuprates at low temperatures (21, 22).

To obtain a quantitative and unambiguous insight into the direct-space description of YBCO6 and YBCO7, we adopted the Quantum Theory of Atoms in Molecules (QTAM) (23) approach. Additional information is recovered through the study of the electron localization function (ELF) (24).

Computational details

The wavefunctions of YBCO6 and YBCO7 were obtained by means of fully periodic pseudopotential restricted Hartree–Fock–Roothaan LCAO calculations, as implemented in the CRYSTAL-98 (18) package. The crystallo-

graphic parameters of the crystals studied were taken from the experimental investigations of Jang et al. (16, 17).

In the case of Y, Ba, and Cu atoms we adopted the small-core pseudopotentials developed by Hay and Wadt (25) in conjunction with the Gaussian basis sets suggested by the authors. Small-core pseudopotential for an atom of the *n*th period includes all the electrons up to the $(n - 2)$th row noble gas, that is [Ne] for Cu, [Ar] for Y, and [Kr] for Ba atoms. Oxygen atoms are described within an all-electron formalism.

With regard to the basis set, Gaussian functions with an exponent lower than 0.1 were cut from the corresponding shells, since they lead to linear dependence in periodic Hartree–Fock calculations. This procedure is largely adopted in computational material science (18). Our choice does not reduce the number of atomic orbitals with respect to the original proposal by Hay and Wadt (25). Moreover, the presence of the crystal symmetry and periodicity should balance the approximation due to the cutting of diffuse Gaussian functions, whose contribution is definitely larger in molecules than in periodic calculations (18, 19). In the case of oxygen, we adopted a standard 6–21G plus *d* polarization function basis set (26), giving this atom a comparable number of atomic orbitals with respect to the metallic atoms. We are confident that the approach described is able to reproduce correctly the changes induced in the total electron density of YBCO6 upon oxidation to YBCO7.

The electronic structure of YBCO6 and YBCO7 is carefully investigated within the QTAM approach (23). Although QTAM applications to condensed-matter systems are quite recent (27), they proved to be a very useful tool to characterize the bonding and atomic properties of the studied systems. QTAM is firmly rooted in quantum mechanics, defines subsystems whose properties are determined by physics (28), and, contrary to more conventional methods of analysis, makes no use of any Hilbert space partitioning to extract information from a wavefunction (23). With respect to this study, QTAM represents the ideal candidate to compare calculated and experimental electron density data. A brief introduction to QTAM and to the notation adopted by the authors can be found elsewhere (29). The main concepts adopted in the discussion will be introduced here when necessary.

To obtain a further insight into the direct-space description of YBCO6 and YBCO7, and particularly into the electronic properties of superconducting Cu-O planes, we recovered additional information from the study of the electron localization function (ELF) (24) in specific regions of the crystal cell. ELF analysis is efficient to discriminate the nature of chemical bonding in ionic, covalent, and metallic materials, as pointed out by Savin et al. (30) in a review article and by Silvi and Gatti (31) in a recent ELF investigation on metals, including copper.

The topological analysis of the electron density was carried out with the TOPOND package (32), developed by Carlo Gatti. This program is interfaced with CRYSTAL and implements QTAM for molecules, polymers, slabs, and crystals. The TOPOND code is also able to recover information about the ELF.

The use of QTAM in the case of pseudopotential calculations requires explanation. Since the theory is based on the analysis of the total electron density of a given system $\rho(\mathbf{r})$, the exclusion of core electrons from the calculated wavefunctions leads to an unphysical behaviour of $\rho(\mathbf{r})$ in the core regions. We, therefore, have to (*i*) ignore the topological behaviour of $\rho(\mathbf{r})$ near the nuclei of metals; and (*ii*) assume that the features of $\rho(\mathbf{r})$ in valence regions are reproduced correctly by our approach, since the core electrons are negligibly affected by the chemical surrounding. The use of small-core instead of large-core pseudopotentials is therefore significant, though increases considerably the computational effort required (about one order of magnitude in CPU time), as demonstrated by Vyboishchikov et al. (33). These authors performed an extensive investigation on several molecules containing transition-metal atoms, and compared electron densities obtained through different approaches, namely large core, small core, and all electron computations. They concluded that the use of small core pseudopotentials gives the electron density the correct topological and quantitative behaviour in valence regions, while adoption of large core pseudopotentials is strongly inadequate (33).

Results and discussion

Bonding network and properties

As a first insight into the properties of YBCO6 and YBCO7 crystals, we discuss the bonding network obtained and its changes upon oxidation, as shown in Fig. 1. Within the framework of QTAM, two atoms are linked to each other if their nuclei are connected by a line (*bond path*) where the electron density $\rho(\mathbf{r})$ is a maximum with respect to any lateral displacement from the line. The point $\mathbf{r}_{bcp}$ where $\rho(\mathbf{r})$ attains its minimum value along the bond path is called a *bond critical point* (bcp). It has been shown (34) that the local properties of the electron density at the bcps sum up very concisely the nature of the interaction occurring between the two linked atoms. In the following, the term "X–Y" bond indicates that atoms X and Y are linked by a bond path.

In YBCO6, Y and Ba atoms are eightfold coordinated, and they are linked to oxygen atoms only. O1 atoms present two oxygen–copper bonds (O1—Cu1 and O1—Cu2, both along the *c* axis) and four O1—Ba bonds, approximately laying onto *ab* planes. O3 atoms behave differently with respect to O1, since they have two bonds with Ba, Y, and Cu2 atoms, and five anion–anion bonds along the *c* axis, thus becoming overall eleven-coordinated. Cu1 is linked to the four first neighbouring copper atoms in the *ab* plane, and forms two Cu1—O1 bonds along the *c* axis. Conversely, Cu2 atoms are bonded to the first four neighbouring O3 atoms laying in the *ab* plane, and two bonds along the *c* axis are formed with O1 and Cu2 atoms. As a result, all copper atoms are six-coordinated.

If we consider the oxidation of the material (YBCO7 crystal), significant variations in the atomic coordination of Ba, Cu1, and O1 atoms are observed. Ba atoms raise their coordination from eight to ten, since two Ba—O4 bonds are formed. Cu1 atoms remain sixfold coordinated, since two copper–copper bonds are replaced with Cu1—O4 bonds. O1 atoms increase their coordination number from six to eight, since two O1—O4 bonds are introduced. O4 atoms are ten-coordinated, and they exhibit four O4—Ba and O4—O1 bonds, along with two O4—Cu1 bonds.

© 2002 NRC Canada

The overall crystal network can be summarized as follows. In the YBCO6 crystal, the two-layered Cu2–O3 atoms build up a caged structure consisting of copper–copper, copper–oxygen, and oxygen–oxygen bonds. The cage extends indefinitely along the *ab* plane, and it includes Y atoms and Y—O bonds. The bonding network of Ba, O1, and Cu1 reflects the alternating cation–anion layered structure.

Oxidation of YBCO6 to YBCO7 does not affect the Cu2–O3 caged structure, while changes are found for Ba (which increases its coordination), Cu1 (which reverts two copper–copper bends into copper–oxygen bonds) and O1 (which forms two anion–anion bonds with O4).

The presence of oxygen–oxygen bonds in YBCO6 and YBCO7 could appear questionable and, in particular, they could be ascribed to the cutting of diffuse basis-set functions from metal atoms. However, both theoretical and experimental studies on ionic crystals revealed the presence of bond paths linking anions (35–37), and analogous cases were found in molecules (38–41). While in molecular systems these bonds are interpreted as evidence of the steric crowding between atoms (38–41), in crystals they can be related to the traditional picture of anions building up a lattice whose interstitial cavities are occupied by cations.

A quantitative picture of the bonding properties of YBCO is obtained through the analysis of the electron density at the crystal's bond critical points. The main features of $\rho(\mathbf{r})$ are reported in Table 1 and discussed in the following. Electron density plots in selected crystal planes are reported in Figs. 2–4, along with the corresponding bonding network.

All bonds (except for Cu—Cu) show a strong closed-shell character. In the case of Ba—O (YBCO6 crystal), the electron density $\rho(\mathbf{r})$ at the bcp is significantly depleted, since the two negative eigenvalues of the Hessian of $\rho(\mathbf{r})$ (λ_1 and λ_2) are comparable to each other and much smaller than the positive one (λ_3). This indicates that bonding between Ba and O is assisted by an electronic charge separation in the internuclear region, as typical of ionic bonds (23). Ba—O bond properties do not depend on the oxidation degree of the crystal, suggesting that Ba cations are negligibly affected by this process despite their increase in coordination due to oxygen insertion.

Y—O bond properties are largely similar to the Ba—O case. The only remarkable feature is that the electron density at the Y—O bcps significantly deviates from cylindrical symmetry, as indicated by nonzero ellipticity values (ε). The eigenvectors associated with λ_1 and λ_2 indicate that $\rho(\mathbf{r})$ is preferentially accumulated away from *ab* planes. This effect slightly strengthens as oxidation takes place, and suggests that Y—O bonds are more sensitive to the crystallographic environment with respect to Ba—O. The ionic nature of Ba—O and Y—O bonds is qualitatively shown in Fig. 4, since the electron density appears spherically distributed around the nuclei of Ba, Y, and O atoms.

The features of Y—O and Ba—O bonds are transferable to O—O, notwithstanding the difference due to atomic charges (Ba—O and Y—O bonds link atoms with opposite charges, at variance with O—O). This result is not contradictory but, on the contrary, grants a large degree of universality to the properties of $\rho(\mathbf{r})$ at the bcp in the case of ionic closed-shell interactions. At variance with respect to the Ba—O case, in YBCO6, O—O bonds exhibit negligible ellipticity values. Analogous with the Y—O case, these linkages are therefore sensitive to the crystal structural and chemical anisotropy. The O3—O3 linkages directed along the *c* axis preferentially distribute charge away from Cu2 first neighbours ($\varepsilon = 0.18$), while an opposite and more marked behaviour is observed in the case of O3—O3 bonds placed onto *ab* planes ($\varepsilon = 0.33$). The picture is substantially maintained when the oxidation of YBCO6 to YBCO7 is considered. In YBCO7, O1—O4 bonds preferentially distribute $\rho(\mathbf{r})$ along *bc* planes (i.e., towards first neighbouring Cu1 atoms).

Copper–copper and copper–oxygen bonds require much more attention, due to their presumed role in the control of the superconductivity properties (21, 22). Cu—O bonds have a strong ionic character, whatever the degree of oxidation of the material and the atoms considered. In fact, similarly to the case of Ba—O, Y—O, and O—O bonds, λ_1 and λ_2 are much smaller (in absolute value) with respect to λ_3, giving $\nabla^2\rho(\mathbf{r})$ a large and positive value.

Despite the similarities between all metal–oxygen bonds, copper atoms present a fundamental difference with respect to the other cations of the crystal. While barium and yttrium assume a nearly spherical valence shell electron density distribution upon bonding with oxygen, copper atoms exhibit a large polarization of their valence shell. More precisely, $\rho(\mathbf{r})$ is depleted along the Cu—O bonding directions and locally concentrated in nonbonding regions, as typical of atoms forming bonds with partial ionic character (29). The above is true for all copper–oxygen bonds (Cu1—O1 and Cu2—O3, see Fig. 3 and 4; Cu1—O4, see Fig. 2) except for Cu2—O1. In fact, no charge depletion in the valence shell of copper is observed along the Cu2—O1 bond path (see Fig. 3), suggesting that this bond is weaker with respect to the other Cu—O bonds. This observation will be quantitatively confirmed below.

Concerning bond ellipticities, in the case of Cu2–O3, a preferential charge accumulation in the *ab* planes is observed, whereas no significant deviation from cylindrical symmetry is observed for Cu2–O1 and Cu1–O1. CuO_2 *ab* layers represent planes of preferential electron density accumulation for Cu—O and O—O bonds. Cu1—O4 bonds (YBCO7) preferentially place electron density onto the two-dimensional copper–oxygen *bc* arrays.

The main structural effects due to oxidation onto Cu—O bonds are: (*i*) the Cu1—O4 bond formation; and (*ii*) the shortening of the Cu2—O1 internuclear distance. As Cu2—O1 changes from 2.47 Å (YBCO6) to 2.31 Å (YBCO7), the electron density and its laplacian significantly increase at the bcp ($\rho(\mathbf{r})$: 0.028 au in YBCO6, 0.041 au in YBCO7; $\nabla^2\rho(\mathbf{r})$: 0.23 au in YBCO6, 0.36 au in YBCO7). These bonds thus approach, without reaching, the values observed at the Cu2—O2 and Cu2—O3 bond critical points ($\rho(\mathbf{r})$ is about 0.1 au and $\nabla^2\rho(\mathbf{r})$ 0.65 au). In conclusion, Cu2—O1 strengthens upon oxidation, but remains weaker than Cu2—O2 and Cu2—O3 bonds. Finally, Cu1—O1 bonds are not significantly affected by oxidation.

Both YBCO6 and YBCO7 exhibit Cu1—Cu1 and Cu2—Cu2 bonds. The analysis of their properties in YBCO6 clearly indicates that they completely differ with respect to all the others present in the crystal. In fact, both in the case of Cu1—Cu1 and Cu2—Cu2, the negative curvatures of the

Note: For each bond, we report the internuclear distance (*R*), the electron density value at the bcp (ρ_{bcp}), its laplacian ($\nabla^2\rho_{bcp}$), and the Hessian eigenvalues (λ_i). Apart from *R* (expressed in Å), all other values are in atomic units. The ellipticity (ε) is dimensionless and is defined as $\varepsilon = \lambda_1/\lambda_2 - 1$. In the case of the YBCO6 system, O3—O3 bonds lying onto the *ab* plane are reported in the upper line, while the bonds directed along the *c* axis are in the lower line.

Hessian of $\rho(\mathbf{r})$ at the bcp are smaller but comparable to the positive one. Consistently with the larger internuclear distance (3.860 Å, compared with 3.292 Å), the electron density at the Cu1—Cu1 bcp is about 40% smaller than for Cu2—Cu2. $\rho(\mathbf{r})$ is slightly less concentrated onto the internuclear axis (Cu1—Cu1: $\lambda_1 \cong \lambda_2 \cong -2.5 \times 10^{-3}$ au; Cu2—Cu2: $\lambda_1 \cong \lambda_2 \cong -2.9 \times 10^{-3}$ au), and λ_3 is larger for Cu1—Cu1 than for Cu2—Cu2, despite the larger $\rho(\mathbf{r})$ value of the latter. $\nabla^2\rho(\mathbf{r})$ at these bcps is always positive, but at least one order of magnitude smaller with respect to the other bonds present in YBCO6 and YBCO7. The features of Cu—Cu bonds substantially agree with analogous results obtained in the case of bonding between transition-metal atoms in the oxidized state (see, for example, experimental and theoretical investigations concerning Co–Co in coordination complexes (42, 43)). Cu1—Cu1 appears definitely weaker than Cu2—Cu2, since the electron density at the bcp is smaller and less efficiently concentrated. As our analysis of the ELF will show, there is a definite difference between the nature of Cu1—Cu1 and Cu2—Cu2.

Oxidation of YBCO6 to YBCO7 induces a significant decrease in $\rho(\mathbf{r})$ at all copper–copper bcps (Cu1—Cu1: from 7.4×10^{-3} to 4.2×10^{-3} au; Cu2—Cu2: from 9.6×10^{-3} to 5.9×10^{-3} au), suggesting that insertion of O4 gives rise to the depletion in the valence electron density distribution of all copper atoms, though no Cu2—O4 bonds are formed.

The investigation of the ELF confirms the bonding analysis reported above; a qualitative picture of the ELF is reported in Figs. 2 and 3. The ELF is a local measure of the Pauli repulsion; in the analytical definition given by Becke and Edgecombe (24), it assumes values close to 1.0 in the regions dominated by an antiparallel electron coupling (as happens for covalent interactions or nonbonding electron pairs), while it has near 0.0 values where small coupling between antiparallel electrons occurs (such as the case of closed-shell interactions).

Ba—O and O—O show very low ELF values at the bcps (about 0.02 and 0.03, respectively) confirming their complete ionic character. Slightly greater ELF values are found at Y—O and Cu—O bcps (0.09 for Y—O and 0.08 for Cu—O), indicating a slightly increased shared nature with respect to Ba—O and O—O. Definitely larger ELF values are found only at Cu2—Cu2 bcps, confirming their significant shared character as inferred from the electron density analysis. In YBCO6, the ELF at Cu2—Cu2 bcps assumes a value (0.32) close to the case of metallic copper (0.38) (31) while at

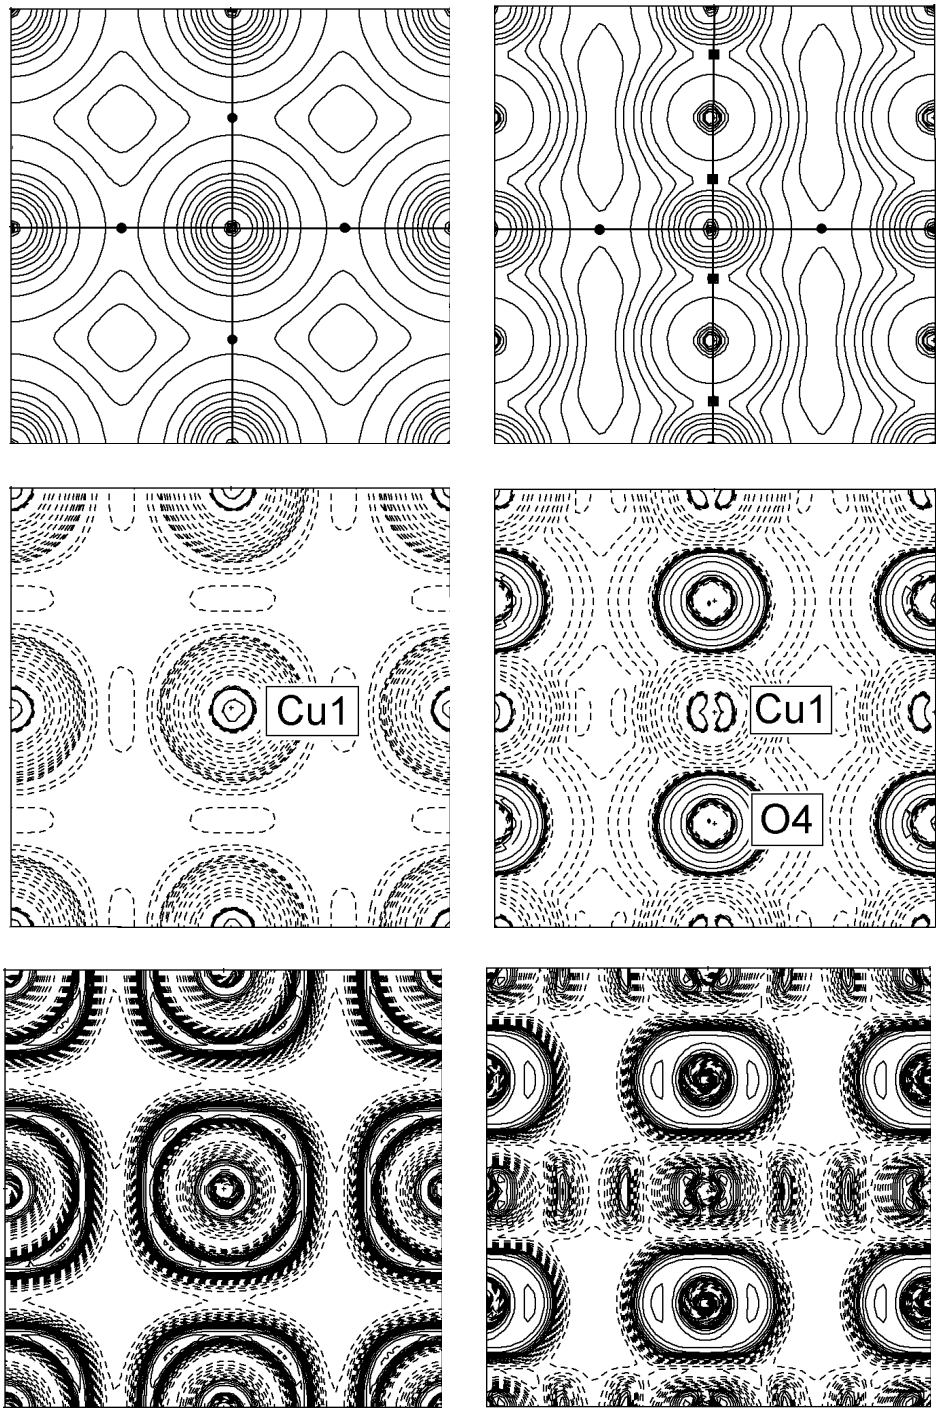
Fig. 2. Isovalue contours of $\rho(\mathbf{r})$ (top), $\nabla^2\rho(\mathbf{r})$ (middle), and ELF($\mathbf{r}$) (bottom panels) for the YBCO6 (left) and YBCO7 (right panels) crystals. Plots represent *ab* planes containing Cu1 atoms. $\rho(\mathbf{r})$: the molecular graph is superimposed to the electron density isovalues lines. Bond paths are traced as heavy lines; bcps are marked with dots. $\nabla^2\rho(\mathbf{r})$: negative (positive) contour values are traced with full (dashed) lines. ELF($\mathbf{r}$): contour values greater (smaller) than 0.5 are traced with full (dashed) lines.



Cu1—Cu1 bcps, it is significantly smaller (0.06), and indicates that a weak coupling between bonding electrons occurs. In the oxidized material (YBCO7) minor changes are observed. The ELF increases to 0.09 at Cu1—Cu1 bcps (see bottom panels of Fig. 2), while in the case of Cu2—Cu2 it undergoes a minor decrease (ELF = 0.30) in spite of the observed large lowering of the electron density (see Fig. 3).

In conclusion, the ELF analysis indicates that the properties of Cu1—Cu1 bonds have a nearly closed-shell character. On the contrary, Cu2—Cu2 bonds are similar to the limiting case of metallic copper (31), notwithstanding the net and large positive charge assumed by Cu2 in YBCO (see next section).

In cuprate superconductors, the superconducting transition temperature usually increases with the number *n* of neighbour-

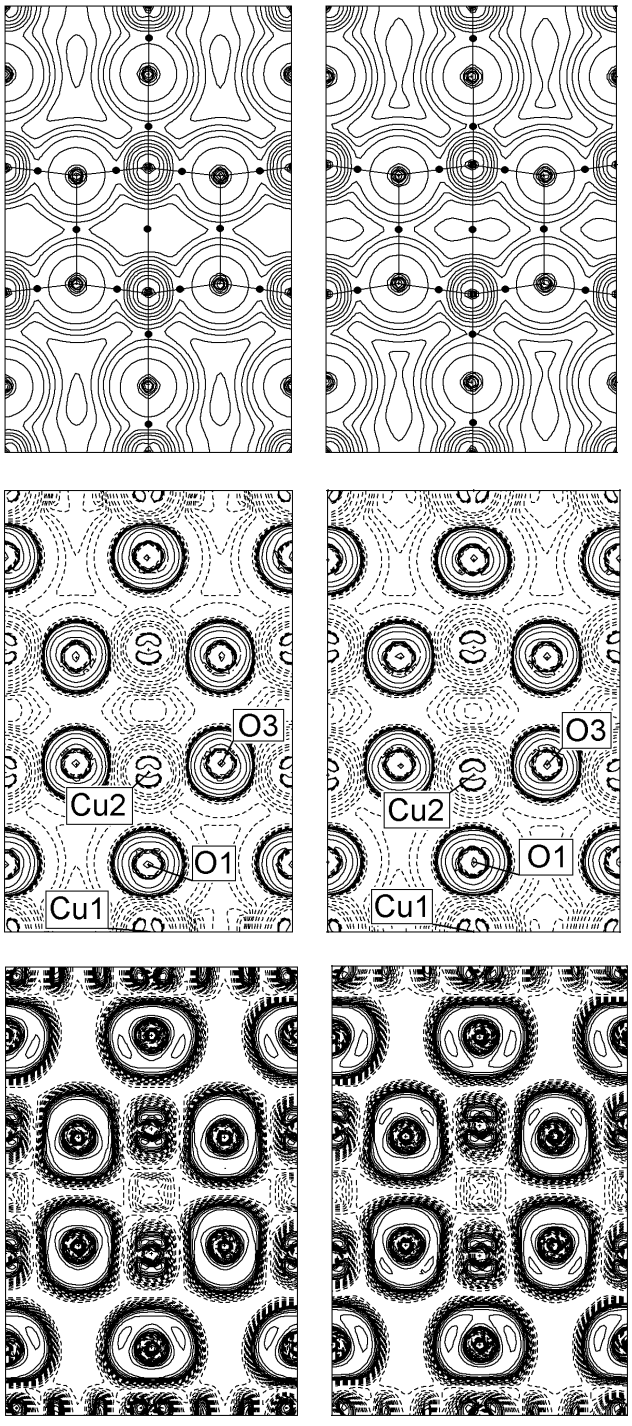
Fig. 3. Isovalue contour plot of $\rho(\mathbf{r})$ (top), $\nabla^2\rho(\mathbf{r})$ (middle), and ELF($\mathbf{r}$) (bottom panels) for the YBCO6 (left) and YBCO7 (right panels) crystals. Plots represent *ac* planes. See the caption to Fig. 2 for notation.



ing CuO_2 *ab* planes. As an example, in $Bi_2Sr_2Ca_{n-1}Cu_nO_y$ the critical temperature T_C is 10, 90, and 110 K for n = 1, 2, and 3, respectively (44). The copper–copper covalent bonds along *c* could support the delocalization of charge carriers in neighbouring superconducting planes, and play a role in the mechanism of charge transport both in the normal and superconducting states.

Atomic properties

QTAM performs an unambiguous partitioning of the physical space in disjointed regions (usually including just one nucleus) termed *atomic basins* and indicated with Ω (23). An important consequence is that many observables can be partitioned in *atomic* contributions that sum up to the system expectation value. In the present investigation, we will focus on: (*i*) the electron population of each atom; and (*ii*) the polarization of their basin electron density. The atomic polarization is rationalized and quantified through the analysis of the first- and the second-electronic moments of each basin, that is, the dipole vector μ (45) and the quadrupole tensor $\mathbf{Q}$ (46, 47), whose components are defined (in Cartesian coordinates) by the following equations:

$$[1] \qquad \mu_i = -\int_{\Omega} \rho(\mathbf{r}) x_i \mathrm{d}\tau$$

$$[2] \qquad Q_{ij} = -\int \rho(\mathbf{r})(3x_i x_j - \delta_{ij} r^2)\mathrm{d}\tau$$

where x_i stands for x, y, and z or, equivalently in the case of the systems studied here, coordinates expressed in the crystals unit cell vectors a, b, and c, respectively. Electron density distributions with spherical symmetry have zero Q_{ii} terms; negative Q_{ii} values indicate an accumulation of charge in the x_i direction at the expense of the directions associated with positive Q_{jj} components.

In YBCO6 and YBCO7, the only significant components of the atomic dipoles are directed along the *c* axis, while generally only the diagonal terms (Q_{aa}, Q_{bb}, and Q_{cc}) of the quadrupole tensors have nonzero values. This means that in this study the eigenvectors of $\mathbf{Q}$ are rigorously (YBCO6) or nearly (YBCO7) placed along the three cell axes *a*, *b*, and *c*. The relevant data of the atomic charge (q) and the atomic first- and second-electronic moments are reported in Table 2. Atomic first-moment values refer to atoms lying in the lower part of the cell represented in Fig. 1.

To get a qualitative picture of the present analysis, in Figs. 2–4 we report plots of the electron density $\rho(\mathbf{r})$ and its laplacian $\nabla^2\rho(\mathbf{r})$ in selected crystal planes. The $\nabla^2\rho(\mathbf{r})$ scalar field is related to the atomic electron density polarization, as it assumes negative values in regions where $\rho(\mathbf{r})$ is locally concentrated and vice versa (23).

We first examined the atomic electronic populations (see Table 2). In YBCO6, the largest positive charge is observed for Cu2 (+2.36e); similar values are found for Y (+2.11e) and Ba (+2.04e), whereas Cu1 atoms exhibit a definitely smaller oxidation degree (+1.17e). The average charge of oxygen atoms is –2.01e, O1 and O2 atoms being respectively "overcharged" and "undercharged" of about 0.1e with respect to the ideal ionic value of –2e. Taking into account the oxidation of the material, all cations increase their positive charge. This additional charge transfer from metallic atoms to oxygen is strongly selective with respect to the different cations. Cu1 loses 1.12e, whereas Y, Cu2, and Ba only lose small amounts (0.13, 0.09, and 0.04e, respectivey); the average oxygen charge decreases to –1.95e. It is worth noting that yttrium atoms are more sensitive than barium atoms with respect to the crystal oxygen content, although Ba is much closer than Y to O4 sites, and no Y—O4 bond is formed. This agrees with the observed dependence of the

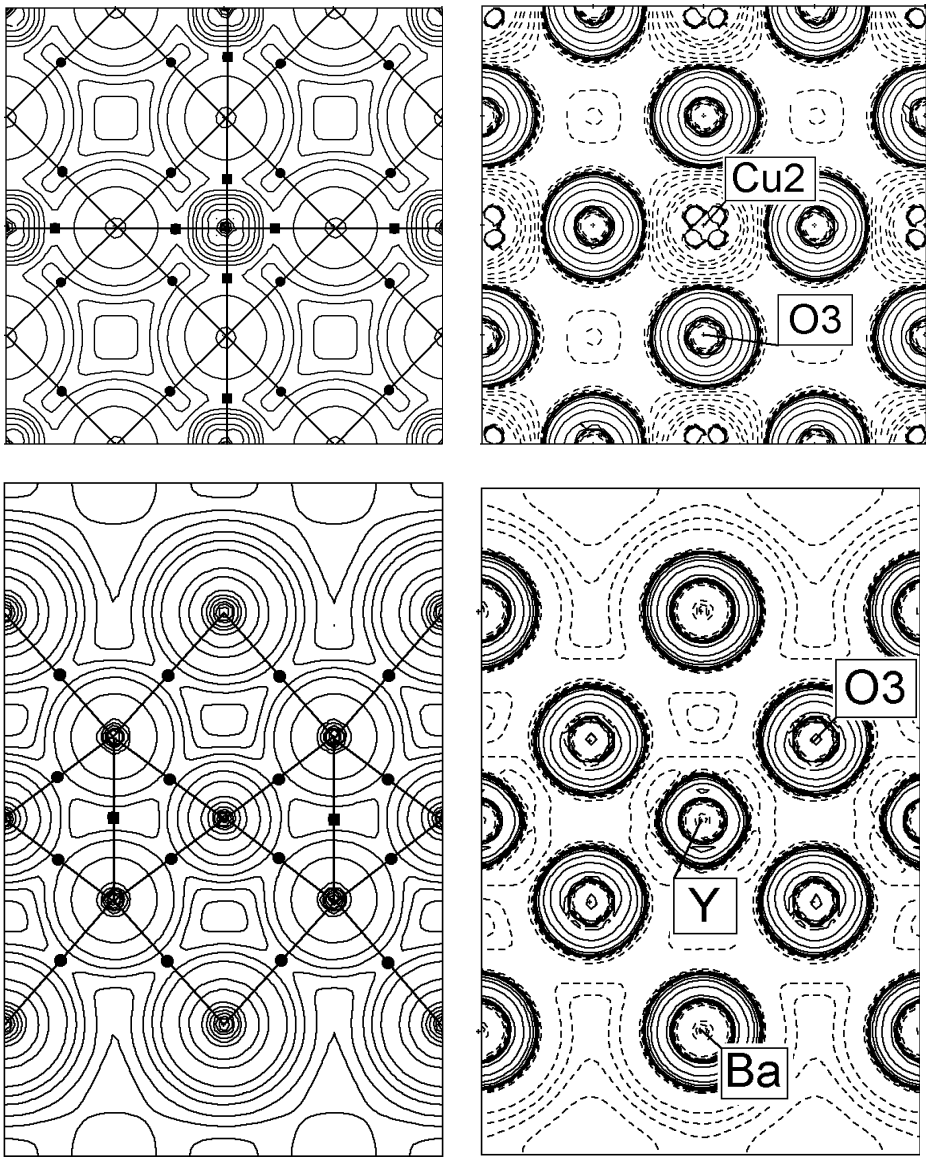
Fig. 4. Isovalue contour plot of $\rho(\mathbf{r})$ (left) and $\nabla^2\rho(\mathbf{r})$ (right) for the YBCO6 crystal. Plots refer to *ab* (top) and *ac* (bottom) planes. Top left panel: the Cu2—O2 molecular graph is projected on the plot plane. Left panels: bcps are marked with dots. Right panels: see the caption to Fig. 2 for notation.



cuprates electronic properties on the rare earth metal placed at the Y site (2).

Focusing on CuO_2 *ab* planes, upon oxidation the overall electron population of Cu2, O2, and O3 undergoes a decrease of 0.16e/plane. This finding is in accordance with the increase of electronic holes in CuO_2 *ab* planes observed upon oxidation.

Comparing the atomic charges of copper atoms with the empirical estimates given by Brown (13), we obtain a good quantitative agreement (i.e., within 0.1e) in the case of Cu1, whatever the oxidation degree of the material considered. In the case of Cu2, QTAM and empirical values are similar in YBCO7, but significantly differ in YBCO6 (QTAM, +2.36e; empirical, +1.9). Both approaches predict that oxidation of YBCO6 increases the positive charge of Cu1 and Cu2. Brown (13) found that Cu2 is more charged than Cu1 in YBCO6 (Cu1, +1.2e; Cu2, +1.9e), the picture being reversed in YBCO7 (Cu1, +2.4e; Cu2, +2.3e); conversely, QTAM data indicate that Cu2 is more charged than Cu1 whatever the oxygen content considered.

The picture given by QTAM agrees with the experimental estimates of copper atom charges given by Akase et al. (48). These authors studied a crystal of $YBa_2Cu_3O_{6.90}$ composition by means of convergent-beam electron diffraction, and assigned to Cu1 and Cu2 a charge of +2.0 and +2.2e, respectively.

The analysis of the first and second electrostatic moments of cations agrees with the rank of ionic behaviour suggested from the previous analysis, and confirms the qualitative observations on the polarization of the valence shell electron density distribution reported in the previous chapter. Ba has the smallest dipole and quadrupole moment components: in the YBCO6 crystal its electronic population is accumulated preferentially along the *c* axis ($Q_{cc} = -0.88$ au), while the *ab*

O2	–1.89	–0.02	+1.27	–0.04	–1.23
O3	–1.90	–0.02	+0.03	+1.07	–1.10
O4	–1.96	0.00	–1.74	+1.68	+0.06

Note: For each atom we report the atomic charge (q), the c axis component of the atomic first moment (μ), and the three relevant components of the atomic quadrupole moment tensor (Q_{aa}, Q_{bb}, and Q_{cc}). All values are in atomic units. Dipole moments: 1 au = 2.542 D. Quadruple moments: 1 au = 1.345 B.

plane depletion is isotropic ($Q_{aa} = Q_{bb}$). Barium μ_c is positive (+0.21 au), as the Ba atoms' electron density is preferentially distributed towards Cu1. In YBCO7, the c axis electron density accumulation is less intense ($Q_{cc} = -0.52$ au) and nearly symmetric with respect to the Ba nucleus ($\mu_c = +0.03$ au). The anisotropy of the barium electron density along the c axis is consistent with previous experimental findings (14, 16), and should, therefore, not be entirely attributed to its anharmonic thermal motion.

Y atoms have a zero c component of the atomic dipole due to crystal symmetry. The analysis of **Q** indicates that in the YBCO6 crystal Y places electron density preferentially onto *ab* planes ($Q_{aa} = Q_{bb} = -0.74$ au; $Q_{cc} = +1.46$ au). Surprisingly, the picture is completely reversed in YBCO7, where the *ab* planes appear to be slightly depleted ($Q_{aa} = +0.49$ au; $Q_{bb} = +0.17$ au) in favour of a c axis accumulation ($Q_{cc} = -0.66$ au).

The large atomic polarization of copper atoms confirms their lower ionic behaviour with respect to Y and Ba atoms. In YBCO6 the valence shell of Cu1 is deprived along the c axis ($Q_{cc} = +6.91$ au, see Fig. 3) and accumulated onto *ab* planes ($Q_{aa} = Q_{bb} = -3.46$ au, see Fig. 2). As O4 is introduced, nearly equivalent $\rho(\mathbf{r})$ depletions along c and b are observed ($Q_{bb} = +1.56$ au; $Q_{cc} = +1.84$ au), the Cu1 electron density is preferentially accumulated along the a direction and points towards nearest neighbouring Cu1 atoms. Contrary to our findings, and to the investigation of Buttner et al. (15), which indicate a charge depletion along the Cu1–O1 vectors, Sasaki et al. (14) obtained a spherical electron density distribution for Cu1 atoms.

Concerning Cu2, in YBCO6 its valence shell electron density is depleted along the first neighbour Cu2—O3 directions ($Q_{aa} = Q_{bb} = +1.02$ au), while Cu2—O1 bonds are not strong enough to induce an electron density depletion along the c axis (see Figs. 3 and 4). The c axis electron density accumulation is more marked in the Cu2—Cu2 internuclear region ($\mu_c = -0.11$ au), in agreement with the shared nature of this bond. In an atomic orbital picture, we could state that Cu2–O interactions preferentially deprive of electronic population the orbitals with a and b components such as the $3d_{x^2-y^2}$ one, as suggested by Sasaki et al. (14) and by Jang et al. (17). Concerning oxidation to YBCO7, no qualitative changes in the valence shell arrangement of Cu2 are observed. Quantitatively, oxidation induces minor changes in the atomic polarization of copper (μ_c decreases from +0.11 to +0.10 au; Q_{aa} and Q_{bb} change from +1.02 to +0.90 and +0.81 au, respectively; Q_{cc} varies from –2.04 to –1.71 au). Finally, the preferential c axis electron density accumulation of Cu2 is consistent with X-ray experimental investigations (14–17).

The behaviour of oxygen can be summarized as follows. First, O atoms present atomic polarization terms comparable with respect to Y and Ba atoms (μ values close to 0.01 au and **Q** components close to 1.00 au). Second, the polarization of O atoms is dominated by the surrounding Y and Ba atoms, since the electron density is preferentially polarized along Ba—O and Y—O directions. Oxidation does not induce significant changes in O2 and O3, and in YBCO7 these atoms remain thus similar to each other, in agreement with other theoretical investigations (10). Conversely, insertion of O4 induces a significant change in the polarization of O1. While in YBCO6 these atoms equally accumulate electron density along the a and b directions, in YBCO7 the proximity of O4 induces a preferential polarization along a, away from O1—O4 vectors.

Conclusions

We calculated the wavefunctions of YBCO6 and YBCO7 by means of ab initio fully periodic restricted Hartree–Fock pseudopotential LCAO calculations. The electronic structure of the crystals were then investigated by means of a density based (i.e., direct space) approach, namely the quantum theory of atoms in molecules (23).

The analysis of the bonding properties reveals the presence of an extended O2-O3-Cu2 caged structure that includes Y cations. The structure presents O—O bonds with strong closed-shell character, as found for Y—O and Ba—O, while a larger shared nature is found for Cu—O. Cu1—Cu1 bonds are weak, and their properties suggest a nearly closed-shell nature. Contrary to all the other bonds present in the crystals, Cu2—Cu2 bonds have a marked shared (i.e., covalent) character, confirmed by the proximity of the ELF value at the bcp to the case of metallic copper. Since Cu2—Cu2 bonds bridge neighbouring superconducting planes, it is likely that they play an important role in the delocalization of charge carriers in superconducting cuprates.

The analysis of atomic properties indicates that both in the YBCO6 and YBCO7 crystals Ba cations have a nearly +2e charge, while the other cations' electronic populations significantly depend on the oxidation degree considered. Inclusion of O4 in the structure induces a large oxidation of Cu1, but also Y and Cu2 atoms undergo an electron population decrease. Contrary to Ba, Y is sensitive to the crystal structure and oxygen content, in agreement with the dependence of the superconducting properties of cuprates on the rare earth element inserted.

© 2002 NRC Canada

The study of atomic polarization indicates a small anisotropy of the electron density around Ba cations, insofar that there is a preferential accumulation along the *c* axis. Analogous experimental findings suggest that this is a proper electronic effect, and not (only) the result of the anharmonic thermal motion of barium (14, 16).

Concerning copper, in YBCO6 the Cu1 valence charge density is depleted along the Cu1–O1 directions, while in YBCO7 the same is true for the Cu1–O4 vectors also. The valence shell polarization of Cu1 largely depends on the oxygen content.

Cu2 is significantly polarized along the *c* axis, in accordance with experimental data (14, 15, 17). O1 does not deplete the valence shell of Cu2 in both YBCO6 and YBCO7, since Cu2—O1 bonds are weaker than Cu2—O2 and Cu2—O3 bonds. Copper atoms share a significant amount of electron density along the Cu2–Cu2 internuclear region.

Oxygen atoms are weakly polarized, and preferentially place electron density towards Ba and Y atoms.

Conformational analysis of the bicyclo-[4.4.1]undecan-11-one ring system

Masood Parvez, Ted S. Sorensen, and Fang Sun

Abstract: The first conformational analysis of a bicyclo[4.4.1]undecan-11-one system (**1**) is presented. Based on low-temperature ^{13}C NMR line-broadening measurements and an X-ray structure of the 1,6-dibromo derivative (**2**), this ketone adopts a chiral conformation with approximate C_2 symmetry about an axis containing the >C=O bond. The observed NMR line-broadening results are consistent with a dynamic interchange of *M* and *P* enantiomeric C_2 conformations, or expressed another way, the "effective" development of an additional C_s symmetry plane bisecting the molecule at right angles to the plane containing the one carbon bridge (overall average C_{2v} symmetry). This process has a $\Delta H^{\ddagger}$ barrier of 42 kJ mol^{-1} for ketone **1** (43 kJ mol^{-1} for **2**).

Key words: bicyclo[4.4.1]undecan-11-one, conformational analysis, NMR line broadening, X-ray structure, enantiomers.

Résumé : On présente la première analyse conformationnelle d'un système bicyclo[4.4.1]undécan-11-one (**1**). Sur la base de mesures à basse température de l'élargissement des raies de RMN du ^{13}C ainsi que sur la structure de son dérivé 1,6-dibromé (**2**) telle que déterminée par diffraction des rayons X, cette cétone adopte une conformation chirale de symétrie approximative C_2 autour d'un axe qui comprend la liaison >C=O. Les résultats observés pour l'élargissement des raies en RMN sont en accord avec un échange dynamique des conformations C_2 énantiomères *M* et *P* ou, exprimé d'une autre façon, avec le développement "effectif" d'un plan de symétrie C_s additionnel qui divise la molécule à angles droits par rapport au plan contenant le carbone du pont (symétrie globale moyenne C_{2v}). Dans la cétone **1**, la barrière d'énergie, $\Delta H^{\ddagger}$, est de 42 kJ mol^{-1} (43 kJ mol^{-1} dans **2**).

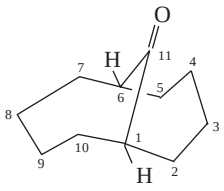
Mots clés : bicyclo[4.4.1]undécan-11-one, analyse conformationnelle, élargissement de raies en RMN, diffraction des rayons X, énantiomères.

[Traduit par la Rédaction]

Introduction

Out-out-bicyclo[4.4.1]undecan-11-one (**1**) was synthesized in the expectation that ring-expansion reactions of the one-carbon bridge might yield efficient routes to larger ring systems. For example, such approaches have been used to prepare the bicyclo[3.3.3]undecane ring system from bicyclononan-9-one (1), but unfortunately ketone **1** proved to be resistant to nucleophilic addition reactions, e.g., dimsyl anion.

In characterizing **1**, however, we became interested in the



1

conformational behavior of this simple ketone, since the room temperature ^{13}C NMR spectrum clearly showed one broadened peak, which is indicative of a relatively high barrier for a conformational interchange process. Unlike the well-studied bicyclo[3.3.1]nonane ring system (2), there have been no studies of the larger [4.4.1] skeleton. There was also a possibility that the nonreactivity of **1** might be related in some way to its conformation, although this turns out not to be the case.

This paper reports a variable temperature NMR conformational study of **1** and of the 1,6-dibromo derivative (**2**). We also obtained a single crystal X-ray structure of the latter.

Results and discussion

Ketone **1** was prepared by hydrogenation of the known [6+4] cycloadduct of tropone and butadiene (3, 4). Alternative approaches from 2-carboethoxycycloheptanone and 1,4-dialkylating agents (single pot or two-step) were unsuccessful as preparative-scale reactions (low yields, complex mixtures). The room temperature 400 MHz NMR spectrum of **1** shows four complex multiplets, a symmetrical multiplet (2H) at δ 2.78 (H1 and H6), and multiplets at ca. 1.8 (8H), 1.62 (4H), and 1.45 (4H). The 100 MHz ^{13}C NMR spectrum shows four peaks at δ 219.8 (C=O), 55.0 (CH), 28.7 (CH_2), and 26.8 (CH_2). The peak at δ 28.7 (25°C) was noticeably broader than the other three. The ^{13}C NMR peaks at δ 26.8

and 28.7 can be assigned to the 3,4,8,9 and 2,5,7,10 carbons, respectively, based on low-temperature ^{1}H–^{13}C HETCOR and ^{1}H COSY spectra, together with coupling constant data. The presence of only four ^{13}C NMR peaks for **1** at 25°C (from a total of eleven carbons) requires at least two separate elements of molecular symmetry (or conformationally averaged symmetry).

Variable temperature NMR spectra of 1

A series of low-temperature ^{1}H (400 MHz) and ^{13}C (100 MHz) NMR spectra were run at 10°C intervals from 25 to –115°C in CD_2Cl_2. In the ^{1}H NMR spectrum, the peak at δ 2.78 is unchanged except for loss of resolution. Changes in the high-field peaks, however, are readily apparent, the most notable being the extreme broadening of the 4H δ 1.45 multiplet, and eventual decoalescence into a 2H quartet at ca. δ 1.1 (J = 12.8 Hz). The other half of this system is buried in a complex series of peaks from δ 1.4 to 2.0.

In the ^{13}C NMR spectrum, the 2C peak at ca. 55 ppm and the >C=O peak are unchanged, but both high-field carbon peaks broaden and eventually devolve into two peaks: δ 28.7 into 24.2 and 30.7; δ 26.8 into 25.1 and 26.4 (the chemical shifts are somewhat temperature dependent).

These low-temperature NMR results (six ^{13}C peaks present, 1:2:2:2:2:2 relative area) are consistent with **1** having essentially a single conformation in which pairs of carbons *remain equivalent even at –115°C*. A structure in which this symmetry is generated by either of two symmetry planes (*X* or *Y*) or a two-fold rotation axis, could be consistent with the low-temperature NMR results, as shown in Fig. 1.

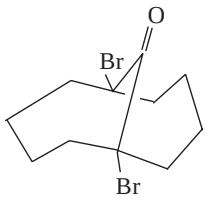
Since, however, the 2C bridgehead carbon peak remains unbroadened, a structure in which the symmetry is generated by either the symmetry plane *X* or the two-fold rotation axis would be more consistent with the low-temperature NMR results. The third possibility involving the *Y* symmetry plane would require concomitant accidental equivalence of the bridgehead-carbon chemical shifts, which in the case of ^{13}C NMR spectroscopy in particular is obviously a less-likely scenario.

The symmetry plane (*X*) model requires different conformations in the two rings, whereas the rotational axis model implies that both rings have the same conformation.

The dynamic NMR line-broadening results noted in this study were quantified by modeling the observed ^{13}C NMR spectra with calculated lineshapes (two-site exchanges). Useable data were obtained from +5 to –75°C (10°C intervals), employing either or both of the averaged ^{13}C peaks. The lower field averaged peak was used from +5 to –35°C, the higher field averaged peak from –35°C to –55°C. At –55°C, broadened decoalesced peaks from the original "δ 28.7 averaged peak" were evident, and at –65°C both sets of broadened decoalesced peaks were present. A plot of the measured rate constants vs. $1/T$ gave a good linear plot: $\Delta H^{\ddagger} = E_a - RT = 42 \pm 1$ kJ mol^{-1} and $\Delta S^{\ddagger} = -2 \pm 2$ J mol^{-1} K^{-1}.

The dynamic conformational process responsible for these line-broadening results can be accommodated by assuming that either of the previously discussed conformations for **1** represent the "frozen-out" structure, and that the dynamic NMR line broadening is caused by a conformational interchange process that generates an additional element of symmetry, i.e. C_2 (ground state) $\overset{C_s}{\rightarrow}$ effective C_{2v} symmetry or C_s (ground state) $\overset{C_2}{\rightarrow}$ effective C_{2v} symmetry. For example, the latter possibility could be envisaged as shown below:

[1] 
Since either of the above processes seemed possible, we felt that an X-ray structure of the **1** system might provide a more definitive answer to this ambiguity. Ketone **1** is a liquid, but the 1,6-dibromo structure **2**, prepared from **1** using free radical bromination conditions, is a white crystalline solid. Since the bromine presence in **2** could conceivably influence the conformational behavior of the [4.4.1] system, we first carried out ^{1}H and ^{13}C NMR studies on **2**.



2

As for **1**, both the ^{1}H and ^{13}C NMR spectra of **2** showed dynamic NMR line broadening. At ambient temperature four ^{1}H multiplets were observed at δ 2.55, 2.4, 1.9, and 1.7 (all 4H). The more deshielded pair were both dddd patterns, but the more shielded pair were more complex. On cooling to –77°C, five multiplets were produced at ca. δ 2.45 (6H), 2.1 (2H), 1.9 (2H), 1.72 (4H), and 1.35 (2H). Except for the peak at δ 1.35 (q, J = 12.2 Hz) these multiplets were complex. The presence of the high field quartet in the decoalesced spectrum is a similar result to that observed for **1**.

The ambient ^{13}C NMR spectrum of **2** was also similar to that of **1**, δ 200.7 (CO), 82.0 (Cq), 41.1 (CH_2, C2,5,7,10), and 25.8 (CH_2, C3,4,8,9). The peak at δ 41.1 decoalesces into peaks at δ 43.8 and 36.6, the peak at δ 25.8 into peaks at δ 26.4 and 23.8; the two less-shielded ^{13}C peaks remain

unchanged. Although the individual ^{13}C NMR chemical shifts in **2** are quite different from **1**, due to the bromine influence, the dynamic NMR behavior is very similar to **1**. Useable line-broadened ^{13}C NMR spectra were obtained at 5°C intervals over the temperature range of +35 to –55°C. As in the case of **1**, one or the other (or both) of the two high field peaks in **2** could be used for the modeling, giving $\Delta H^{\ddagger}$ = 43 ± 1 kJ mol^{-1}, $\Delta S^{\ddagger}$ = 1 ± 2 J mol^{-1} K^{-1}.

The similar transition-state barrier size for the conformational interchange in **2** compared to **1**, together with the similar high field ^{1}H NMR quartet in the decoalesced spectra of both **1** and **2** strongly argues for conformational correspondence in both structures.

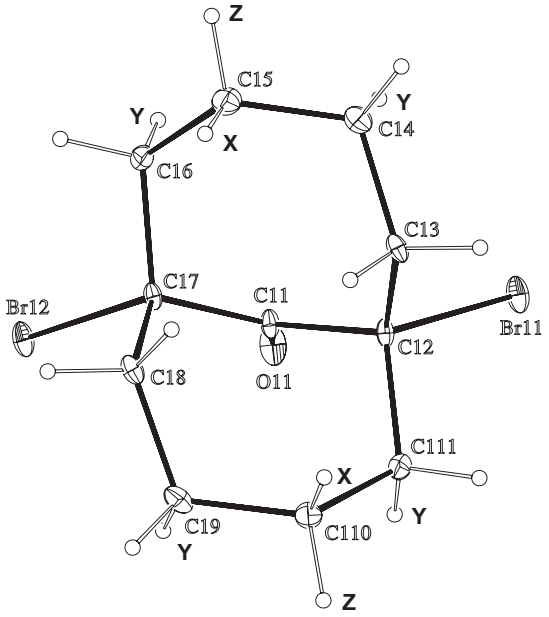
X-ray structure determination of 2

After considerable experimentation, suitable crystals of **2** were obtained for the single crystal X-ray studies (Table 1).

All four of the unique molecules of **2** have a quite similar conformation, and one of these is shown in Fig. 2. In this structure *both rings* have nearly identical conformations, and the molecule as a whole has near C_2 symmetry about an axis through the >C=O bond. This is most clearly shown by a comparison of the C18-C19-C110-C111 (–69.2°) and the C13-C14-C15-C16 (–71.7°) dihedral angles.

There is also evidence that this crystal structure is in agreement with the solution NMR results. For example, one can now assign the highly shielded quartet ($J \approx$ 12–13 Hz) seen in the low-temperature ^{1}H NMR spectrum of both **1** and **2** to the "axial" hydrogens on carbons C15 and C110 in Fig. 2 (labeled X). These hydrogens are unique in having two vicinal hydrogen neighbors (Y) with dihedral angles approaching 180° (hence large J values). A sizeable geminal coupling is also assumed here (Z). Analysis of the low-temperature COSY and HETCOR spectra (see *Experimental*) is fully consistent with this assignment.

Fig. 2. ORTEP plot of 1,6-dibromobicyclo[4.4.1]undecan-11-one (**2**), showing one of the *M* configuration conformational enantiomers.



CP MAS ^{13}C NMR spectrum of ketone 2

Another possible correlation between the single crystal X-ray results and the solution-phase NMR data would involve a comparison of the solid state ^{13}C NMR shifts with the respective solution-phase values. In the crystal we expect to see the frozen-out conformation even at 20°C.

There are 16 molecules in the unit cell of **2**, corresponding to eight *M* and eight *P* enantiomers (5), of which four of each are unique. Each of the unique molecules has a similar conformation, but in no case do they have a perfect C_2 axis; therefore, the ^{13}C NMR equivalences seen in the low-temperature solution spectrum of **2** are not totally operative.

^{13}C NMR peaks were observed at δ 202.0, 84.1, 45.1, 36.7 and 26.2, with area ratios ca. 1:2:2:2:4. Linewidths at half height were 160, 470, 234, 215, and 265 Hz, respectively (±10 Hz). The peak at δ 26.2 shows some line-shape evidence for being an overlap of two fairly closely spaced peaks ca. δ 26.5 and 25. The corresponding solution chemical shifts (–77°C) are δ 200.7, 82.0, 43.4, 36.2, 26.1, and 23.5; an agreement of ±2 ppm with the solid-state data and further evidence, therefore, that solid and solution conformations of **2** are similar.

Conclusion

The symmetrization process described in the NMR part of this study ($\Delta H^{\ddagger}$ = 42 and 43 kJ mol^{-1} for **1** and **2**, respectively) can now be rationalized as the interchange of *M* and *P* (C_2) enantiomers of **1** and **2** via an intermediate or transition state of average C_{2v} symmetry. This interconversion can be most easily pictured as a concerted motion of the molecule as a whole, and this process resembles that found in *cis*-decalin interconversions (see eq. [2]). The $\Delta H^{\ddagger}$ conformational barrier in the latter is about 52 kJ mol^{-1} (6), about 25% higher than in our [4.4.1] systems.

[2] 
Experimental

The [6+4] adduct of tropone and butadiene was prepared as described (3) and partially purified (ca. 92%) by flash chromatography (SiO_2, hexane). This material (3.6 g, 0.022 mol) and 10% Pd/C (0.8 g) in absolute ethanol (80 mL) was hydrogenated (2) (60 psi H_2, 4.5 h) (1 psi = 6.894 kPa). The mixture was filtered twice through a celite bed and the solvent evaporated under pressure (0.1 mm Hg) to give 3.72 g of an oily liquid. GC–MS analysis showed three impurity peaks with slightly shorter retention times than for **1** (total <10%). For **1**: MS *m/z* (%): 166 (M^+, 95), 111 (68), 98 (72), 96 (76), 95 (78), 82 (78), 81 (93), 55 (80), 67(100). HRMS calcd. for $C_{11}H_{18}O$: 166.1347; found: 166.1358.

1,6-Dibromobicyclo[4.4.1]undecan-11-one (2)

Ketone **1** (1.0 g, 6.0 mmol) and Br_2 (3 equiv) in CCl_4 (200 mL) were irradiated with a 275-watt sunlamp (30 cm) for 5 h. The resulting solution was washed with a Na_2SO_3 solution, $NaHCO_3$ solution, brine, and dried over $MgSO_4$. The residue was crystallized from CH_2Cl_2–hexane (1:10), yielding 1.12 g (58%) fo the product. The NMR data for **2** are described in the *Results and discussion* section. Ketone **2** was recrystallized from various solvent systems, mp 183–184°C. HRMS calcd. for $[M - Br]^+$: 245.03641 (^{81}Br); found: 245.03693.

NMR spectroscopy

Variable-temperature ^1H and ^{13}C NMR spectra were obtained on a Bruker AM-400 spectrometer, using dichloromethane-d_2 solvent. Although the freezing point of CH_2Cl_2 is –97°C, our solutions did not freeze down to –115°C. Temperatures were calibrated using a methanol standard. Line-broadening peaks in the ^{13}C NMR spectrum were modeled using a standard two-site exchange mechanism as applied to two sets of exchanging ^{13}C peaks (modified DNMR-5 program (7)).

NMR analysis of the high field "quartet" in 2

This 2H area feature appears in the frozen-out low-temperature ^1H NMR spectra of **2** (and **1**). The coupling constant is ca. 12–13 Hz, but the individual lines are broadened, suggesting that each of the three *J* values is slightly different. A low-temperature COSY and HETCOR spectrum were obtained, and as identified from the ORTEP drawing in Fig. 2, the quartet for **2** is assigned to the H_X hydrogen on C15 and C110. The COSY spectrum shows this quartet strongly coupled to hydrogens at ca. δ 1.7, 1.9, and 2.45. In each case, these ^1H peaks are featureless or overlapped in the 1D spectrum. In the HETCOR spectrum, each of these "other" ^1H peaks is connected to different carbons; δ 1.9 is the geminal partner of the ^1H assigned as the quartet peak, δ 1.7 is connected to C14 (C19), and δ 2.45 is connected to either C13 (C18) or C16 (C111) (see Fig. 2). In Fig. 2, the vicinal hydrogens having dihedral angles of ca. 160–180° are shown as H_Y and the geminal hydrogen as H_Z. The assumption in this analysis is that the high field quartet can be uniquely assigned to H_X on the basis of three large coupling constants. In this analysis, we show that the COSY and HETCOR information is fully consistent with this assumption. In the case of ketone **1**, the quartet (–100°C) at δ 1.11 ($J \approx 13$ Hz) is well-separated from an overlapped series of peaks from δ 1.5–2. The low-temperature HETCOR spectrum shows that the high field ^1H quartet peak is correctly connected to one of the β-carbon peaks, but the COSY spectrum shows only two correlations, likely because of peak overlaps.

CP MAS spectrum

A CP MAS ^{13}C NMR spectra (140 000 scans) was obtained on a Bruker AMX-300 at 75.48 MHz, spinning rate 8 KHz, 4mm rotor, at 27°C. Peaks were referenced relative to glycine carbonyl (δ 176.3).

X-ray crystal structure determination

Pertinent experimental parameters concerning this determination are given in Table 1. Details of bond lengths, angles, and dihedral angles are provided as *Supplementary material*.[2]

Data collection and structure solution

A colorless plate crystal of $C_{11}H_{16}Br_2O$ was mounted on a glass fiber. All measurements were made on a Nonius Kappa CCD diffractometer with graphite monochromated Mo Kα radiation. Cell constants obtained from the refinement (8) of 11 218 reflections in the range $1.0 < \theta < 28.3°$ corresponded to a primitive monoclinic cell; details of crystal data and structure refinement have been provided in Table 1. The space group was uniquely determined from the systematic absences. The data were collected (9) at a temperature of 173(2) K using the ω–φ scans to a maximum θ value of 28.3°. The data were corrected for Lorentz and polarization effects and for absorption using a multiscan method (8). Since the crystal did not show any sign of decay during data collection a decay correction was deemed unnecessary.

The structure was solved by the direct methods (10) and expanded using Fourier techniques (11). The nonhydrogen atoms were refined anistropically. Hydrogen atoms were included at geometrically idealized positions and were not refined. The final cycle of full-matrix least-squares refinement using SHELXL97 (12) converged (largest parameter shift was <0.001 times its esd) with unweighted and weighted agreement factors, $R = 0.087$ and $wR = 0.248$ (all data), re-

The redox properties of ferrocenyl-substituted aryl azines

Vittorio A. Sauro and Mark S. Workentin

Abstract: A series of ferrocenyl substituted azines (**1**-Fc/Ar, where Ar = 4-$NO_2C_6H_4$, 4-CNC_6H_4, 4-$OCH_3C_6H_4$, C_5H_4N, ferrocene, anthracene, and pyrene) were investigated by electrochemical and photochemical techniques. All the **1**-Fc/Ar exhibited oxidation waves within 60 mV of each other, consistent with the expected oxidation of the ferrocene moiety. The reduction properties of **1**-Fc/Ar is governed by the nature of the Ar substituent. The standard reduction potentials suggest that ferrocene has comparable electron donating abilities as a 4-methoxyphenyl and 4-dimethylaminophenyl group. The anthracenyl azines exhibit one-electron reversible reduction followed by dimerization of the radical anion resulting in dimerization rate constants (k_d) between 5.1×10^4 and 1.5×10^5 M^{-1} s^{-1}. **1**-Fc/Anth and related azines undergo photochemical *E*/*Z* isomerization of the C=N bonds to produce *E*/*Z* and *Z*/*Z* isomers from the thermodynamically most stable *E*/*E* form. Fluorescence at 77 K, was observed for these compounds only after long-wavelength irradiation to produce a mixture of *E*/*E*, *E*/*Z*, and *Z*/*Z* isomers. Fluorescence quantum yields of 0.042, 0.090, and 0.176 were determined for **2**-Anth/H, **2**-Anth/Anth, and **1**-Fc/Anth, respectively. The electrochemical, photochemical, and X-ray data suggest that the azine unit is a conjugation "limiter" and may be a general characteristic of azine molecules.

Key words: azines, electrochemistry, cyclic voltammetry, reduction, electron transfer.

Résumé : Faisant appel à des techniques électrochimiques ainsi que photochimiques, on a étudié une série d'azines de ferrocényles substitués (**1**-Fc/Ar dans lesquels Ar = 4-$NO_2C_6H_4$, 4-CNC_6H_4, 4-$OCH_3C_6H_4$, C_5H_4N, ferrocène, anthracène et pyrène). Tous les **1**-Fc/Ar présentent des vagues d'oxydation à moins de 60 mV les uns des autres, ce à quoi on peut s'attendre pour l'oxydation de la partie ferrocène. Les propriétés de réduction des **1**-Fc/Ar sont définies par la nature du substituant Ar. Les potentiels de réduction standards suggèrent que les propriétés du ferrocène en ce qui a trait à ses possibilités de donner des électrons sont semblables à celles des groupes 4-méthoxyphényle et 4-diméthylaminophényle. Les azines dérivés de l'anthracène donnent lieu à une réduction réversible à un électron suivie d'une dimérisation de l'anion radical avec des constantes de vitesse de dimérisation (k_d) qui vont de $5{,}1 \times 10^4$ à $1{,}5 \times 10^5$ M^{-1} s^{-1}. La **1**-Fc/Anth et les azines apparentées subissent des isomérisations photochimiques *E*/*Z* des liaisons C=N qui conduisent à des mélanges d'isomères *E*/*Z* et *Z*/*Z* à partir de la forme *E*/*E*, thermodynamiquement la plus stable. Ces composés ne donnent lieu à de la fluorescence à 77 K qu'après avoir été soumis à une irradiation à grande longueur d'onde qui permet de produire un mélange des isomères *E*/*E*, *E*/*Z* et *Z*/*Z*. On a déterminé des rendements quantiques de fluorescence de 0,042, 0,090 et 0,176 respectivement pour les **2**-Anth/H, **2**-Anth/Anth et **1**-Fc/Anth. Les données électrochimiques, photochimiques ainsi que celles relatives à la diffraction des rayons X suggèrent que l'unité azine « limite » la conjugaison et que cette propriété est peut-être une caractéristique générale pour les molécules d'azine.

Mots clés : azines, électrochimie, voltampérométrie cyclique, réduction, transfert d'électron.

Introduction

Ferrocene and its derivatives have been investigated for their use in a variety of applications, including in organic synthesis (1), in applications tied to their electrochemical properties (1–5), in biological systems (6), as molecular wires and in other nanoelectronic devices (7), and in anion recognition applications (8). Due to the special chemical, stereochemical, and electrochemical properties (1) of ferrocene, there is great interest in ferrocene based ligands for the production of multi-metal containing organometallic complexes that can be used for a variety of applications (9, 10). Ferrocene-containing compounds have also been investigated for their second-order non-linear optical (NLO) properties (3, 11–13).

Ferrocene and its derivatives have been studied extensively using electrochemical techniques (1) and generally show a single one-electron reversible oxidation whose potential varies depending on the substituent attached to the cyclopentadienyl ring (3, 5, 10, 13, 14). The redox properties of the ferrocene group have been exploited to produce molecules that may have potential applications as molecular switches and molecular sensors (15, 16).

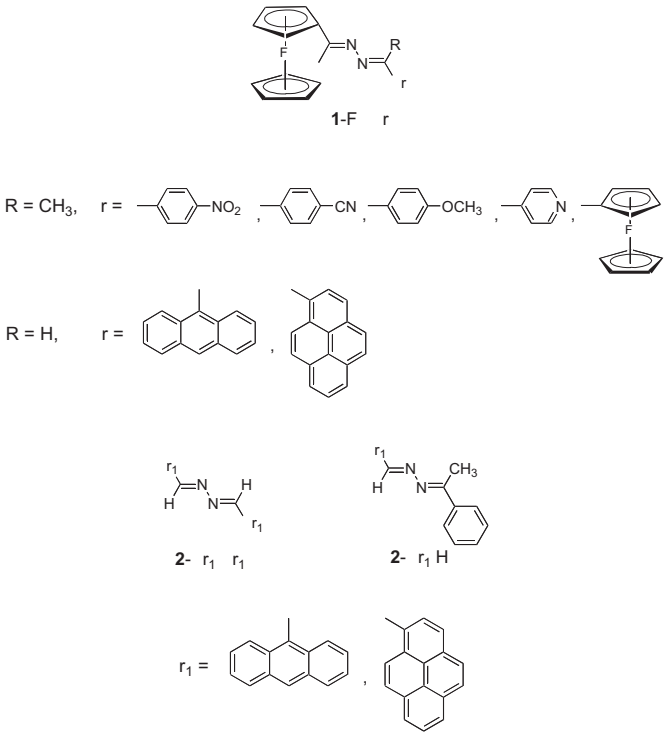
Azines (>C=N-N=C<) appear to have the structural elements necessary to allow for complete conjugation between the substituents used to make up its structure, although there is now general agreement that the azine unit stops, or at the very least limits, conjugation. The question of conjugation through the azine unit has been investigated both theoretically and experimentally (17–29). Glaser and co-workers (20–29) examined the solid-state structures of a large number of structurally related aryl azines, paying particular attention to the structural consequences of conjugative interactions that manifest themselves in the solid-state structures. As a result of their extensive X-ray analyses, including the conformational properties about the N–N and Ar–C bonds, bond length analysis, and theoretical studies, Glaser and co-workers (25, 27) conclude that the azine unit is a "conjugation stopper," at least in the solid state.

Early and recent electrochemical investigations (2, 30–38) of azines have suggested that they do not exhibit extensive electronic communication through the azine unit. In a more recent study, we reported (39) the redox behavior of an extensive series of substituted acetophenone azines with emphasis on their extent of conjugation. The standard reduction potentials ($E°$) were found to vary as a function of substituent, with electron donating substituents causing the molecules to reduce at more negative potentials than those containing electron withdrawing groups. The azines were found to preferentially reduce at the C=N bond closest to the aryl group substituted with the most electron withdrawing substituent. Based on our extensive substituent-effect study, in this investigation (39) the azine unit was found to impede conjugation, and the limited electronic effects measured could have been purley inductive, supporting the notion of Glaser (20–29).

The electrochemical behavior of ferrocenyl azines has been previously investigated in a few cases (2, 4). Xu-Bing et al. (4) report the redox behavior of ferrocene coupled to bipyridine by an azine linkage, and the cyclic voltammetry (CV) plot shows the expected one-electron reversible oxidation typical of ferrocene-containing molecules. In addition, two-reduction processes were reported by the authors and attributed to the reduction of the -CHNNC($C_{10}H_6N_2$) group, which is consistent with the reduction of other types of azines (30, 35–39). Osborne et al. (2) report the electrochemistry of several azines and related compounds that contain one or two ferrocene groups. The single ferrocene compounds exhibit the expected one-electron reversible oxidation with standard oxidation potentials in the range of +0.38 to +0.67 V vs. SCE in 0.2 M tetrabutylammonium perchlorate – CH_2Cl_2. For compounds containing two ferrocenyl groups, including the azine **1**-Fc/Fc in Scheme 1, the CV show two almost overlapping reversible one-electron oxidations. This indicates that the electronic communication between the two ferrocene subunits through the azine moiety is small. No reduction processes were observed up to –0.5 V vs. SCE in 0.2 M tetrabutylammonium perchlorate – CH_2Cl_2 solution.

To extend our study into the electronic nature of azines, a series of azines containing a ferrocene group were investigated by cyclic voltammetry (CV). Ferrocene was chosen as a substituent because it is an excellent electron donor (1) and when coupled to a substituted aryl azine containing an electron acceptor, the resultant compound could potentially exhibit the NLO response seen in other azines (24, 25) and ferrocene-containing molecules (11–13). Each ferrocene containing molecule investigated for the various applications listed above took advantage of the same general strategy, mainly, to produce molecules where electronic communication between ferrocene and a second group was realized usually by the use of a conjugated bridge. For this reason, the azine unit is synthetically simple to incorporate and could serve as an ideal linkage to allow for the electronic communication between ferrocene and an aryl group; results with other azines, however, show that the azine unit will not allow for conjugative interaction. In the absence of any conjugative effects, the versatility of the azine unit as a linker and the ease in which azines can be synthesized makes them ideal synthons for coupling electron donating and acceptor groups for many applications. An important aspect of any application is an understanding of their electronic properties and that is what we describe here. The various compounds examined are illustrated in Scheme 1, along with a shorter notation used within the text to quickly identify each molecule. The terms Fc, Ar, Anth, Py, and Pyrd refer to ferrocene, aryl, anthracene, pyrene, and pyridine, respectively. In addition, nitro, cyano, and methoxy substituted phenyl rings will be denoted by 4-NO_2, 4-CN, and 4-OCH_3, respectively, where the number four refers to *para* substitution of the phenyl rings. An unsubstituted phenyl ring will be denoted by H (e.g., **2**-Anth/H).

Scheme 1.



Results and discussion

The electrochemical behavior of the series of ferrocenyl azines (**1**-Fc/Ar) was studied in *N*,*N*-dimethylformamide (DMF), using cyclic voltammetry (CV). The electrochemical characteristics depend on the structure of the aryl

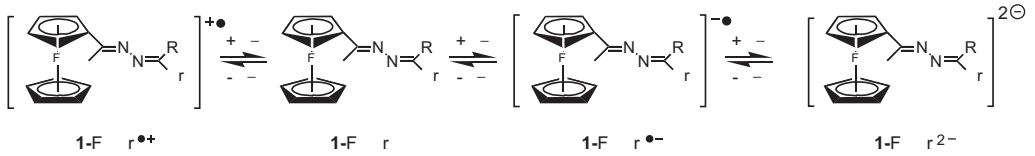
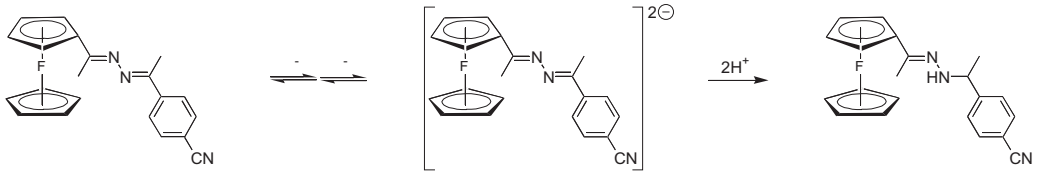
Scheme 2.



Scheme 3.



substituent. Ferrocenyl azines that contain a *para*-substituted aryl group exhibit electrochemical behavior similar to that observed for the acetophenone azines (39). Figures 1*a–e* shows a series of cyclic voltammograms for acetylferrocene-4-cyanoacetophenone azine (**1**-Fc/4-CN) in 0.1 M TEAP–DMF using various scan directions and switching potentials. A characteristic voltammetric feature is a single electron anodic wave at positive potentials that is reversible at all scan rates investigated (the wave labeled A in Fig. 1*e*) and is common to all of the **1**-Fc/Ar investigated. The anodic waves are due to formation of the azine radical cation (**1**-$Fc^{\bullet+}$/Ar) and the position of the oxidation is typical for ferrocene-containing molecules, representing the oxidation of the iron core from the Fe^{II} to the Fe^{III} state and vice versa (2). Other voltammetric features include a cathodic wave at negative potentials that is reversible at all scan rates investigated (wave B in Fig. 1*e*), followed at more negative potentials by a second single electron cathodic wave (wave C in Fig. 1*e*). The two reduction waves represent the successive reduction of the corresponding azine to its radical anion (**1**-Fc/$Ar^{\bullet-}$) and then its dianion (**1**-Fc/Ar^{2-}), respectively. This series of events is shown schematically in Scheme 2.

When the CV is scanned in the negative potential direction and goes through the formation of dianion, minor oxidation waves are observed on the reverse scan. These processes are evident only when the scan goes through the formation of **1**-Fc/Ar^{2-} and result from the protonation or some other reaction of **1**-Fc/Ar^{2-}. The dianion is sufficiently basic to be protonated by solvent molecules or, more likely, residual H_2O. Reduction and protonation most likely occur at the C=N moiety adjacent to the substituted aryl group to give a hydrazone (Scheme 3) similar to that observed in the reactions of acetophenone azine radical anions and dianions with trifluoroethanol (TFE) (39). Reduction of the azomethine bond adjacent to the ferrocenyl group occurs at much more negative potential as evidenced by the irreversible reduction at –2.303 V vs. SCE for **1**-Fc/Fc (see below). The identity of the minor products were not determined.

Azines **1**-Fc/Pyrd, **1**-Fc/4-OCH_3, and **1**-Fc/4-NO_2 showed similar voltammetric features as **1**-Fc/4-CN described above. In the cases of **1**-Fc/4-CN, **1**-Fc/Pyrd, **1**-Fc/4-OCH_3, and **1**-Fc/4-NO_2 (Figs. 1*e–h*) the formation of **1**-Fc/$Ar^{\bullet-}$ is completely chemically reversible (dashed line). For this series, standard reduction potentials ($E^{\circ}_{0/\bullet-}$) vary as a function of the electronic properties of the substituent and are summarized in Table 1. The reduction potentials of **1**-Fc/Ar exhibit a significant substituent effect with values differing by more than 1.2 V between **1**-Fc/4-NO_2 and **1**-Fc/4-OCH_3. The more electron withdrawing the substituent the easier the azine is to reduce and the more positive the $E°$ value. The $E^{\circ}_{0/\bullet-}$ are comparable to the $E°$ of the similarly substituted acetophenone azines but with a 4-methoxyphenyl or 4-dimethylaminophenyl group in place of the ferrocene unit (39). This illustrates that ferrocene has similar electron donating characteristics as the two aryl groups, as has been previously suggested by other researchers (10, 12). The reductions of **1**-Fc/Ar are single electron based on the $i_p/\sqrt{\nu}$ values in comparison with the Fe^{II}/Fe^{III} couple.

The dianions of **1**-Fc/4-CN, **1**-Fc/Pyrd, **1**-Fc/4-OCH_3, and **1**-Fc/4-NO_2 are not reversible on the CV timescale up to 50 V s^{-1} in DMF. Typical CVs at low scan rates are also illustrated in Figs. 1*e–h*. The potentials ($E_{p\bullet-/2-}$) for the second reduction follow the same trend with substituent donating and withdrawing ability (see Table 1) and become easier to reduce when electron withdrawing substituents act to reduce the electron density from the radical anion. The substituent effect is slightly smaller for the second wave with potentials differing by 0.8 V through the series **1**-Fc/4-NO_2 to **1**-Fc/4-OCH_3. Once again, the $E_{p\bullet-/2-}$ values indicate that ferrocene has comparable electron donor capabilities as 4-methoxyphenyl and (or) 4-dimethylaminophenyl in comparison to the appropriate acetophenone azines (39). The second reduction wave observed for **1**-Fc/4-OCH_3, however, may not be due to dianion formation but may result from reduction of the azomethine bond adjacent to the ferrocenyl group since the $E_{p\bullet-/2-}$ is comparable to that observed for the first reduction of **1**-Fc/Fc to **1**-$Fc/Fc^{\bullet-}$. The exact nature of this reduction process could not be investigated because it occurs at very negative potentials and into the solvent discharge.

The reduction of the nitro containing ferrocenyl azine warrants further discussion. We previously reported (39) that the reduction of all the nitro containing acetophenone azines occurs at almost identical potentials (~ –1 V vs. SCE). This was attributed to the fact that the reduction appears to be that of azine substituted nitrobenzene molecules and not an aryl-nitro substituted azine. Similarly, reduction of **1**-Fc/4-NO_2 occurs at –0.956 V vs. SCE and supports our earlier suggestion that reduction is occurring at the Ar-NO_2 group and not at one of the azine C=N imine bonds. The reduction

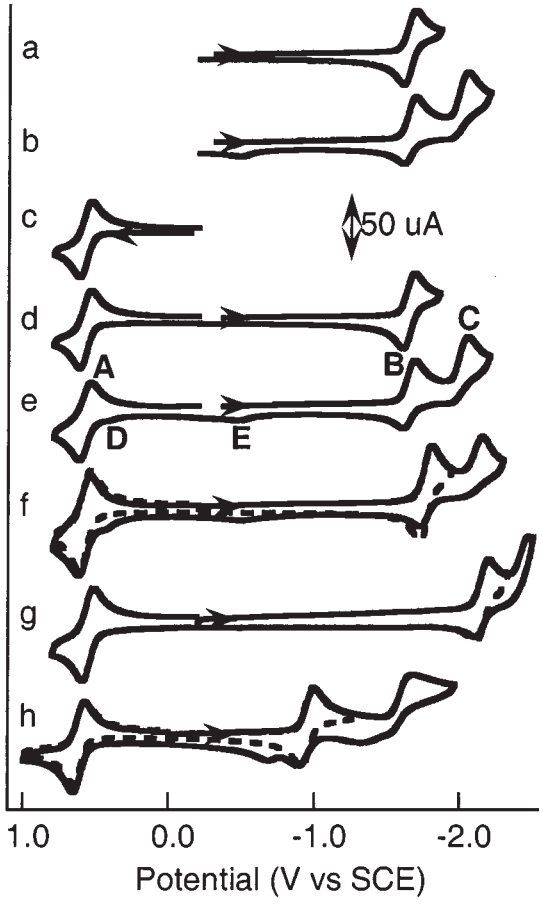
Fig. 1. Cyclic voltammograms of selected azines measured in 0.1 M TEAP–DMF at 0.2 V s^{-1}. Arrows indicate the scan direction. Parts *a–e* are of **1**-Fc/4-CN; (*a*) CV starting at 0 potential and switching after the appearance of wave B. (*b*) CV starting at 0 potential and switching after the appearance of wave C. (*c*) CV starting at 0 potential and switching after the appearance of wave A. (*d*) CV starting at 0 potential and switching after the appearance of wave B and continuing into the positive potential region and switching again after the appearance of wave A. (*e*) CV starting at 0 potential and switching after the appearance of wave C and continuing into the positive potential region and switching again after the appearance of wave A. Parts *f–h* are the CVs of **1**-Fc/Pyrd, **1**-Fc/4-OCH_3, and **1**-Fc/4-NO_2, respectively. Solid lines are the CV going through radical anion and dianion formation and continuing into positive potentials where the radical cation is formed. Dashed lines are the CV when the potential is reversed after formation of the radical anion and continuing into positive potentials where the radical cation is formed.



potentials of the nitro containing azines all occur within 44 mV of each other and their values are all approximately equal to –1 V vs. SCE, roughly the same potential as nitrobenzene in the same solvent (–1.1 V vs. SCE). **1**-Fc/4-NO_2 also shows a second less well-defined cathodic wave (Fig. 1*h*) that is due to further reduction of the aryl nitro group, presumably to form hydroxylamines, which are known to result from reduction of aryl-NO_2 compounds (40). The second cathodic wave is not completely reversible and includes other electrochemical processes that make it appear oddly shaped in comparison with other waves due to dianion formation in Fig. 1. Scanning to even more negative potentials (past the formation of dianion) produces two multi-electron waves that are due to further reduction of the protonated **1**-Fc/4-NO_2 dianion to ultimately form amines.

1-Fc/Py shows a one-electron reversible oxidation due to formation of a radical cation, similar to the other ferrocenyl azines discussed thus far (A in Fig. 2*a*). However, **1**-Fc/Py was the only ferrocenyl azine that exhibits a reversible cathodic reduction for the formation of the both the radical anion and dianion and provides values for $E^{\circ}_{0/\bullet-}$ = –1.549 V vs. SCE and $E^{\circ}_{\bullet-/2-}$ = –1.995 V vs. SCE, respectively. This is typical for pyrene-containing molecules (41). Reversing the potential after the formation of the radical anion (B) results in a completely reversible wave. Continuing into the positive potential region results in the CV showing two one-electron reversible waves for the reduction and oxidation of **1**-Fc/Py (dashed line in Fig. 2*a*). No oxidation waves were observed for **2**-Py/H or 1-pyrenecarboxaldehyde up to +1 V whose electrochemical behavior were examined for comparison to **1**-Fc/Py. Formation of the azine (i.e., **1**-Fc/Py and **2**-Py/H) results in a negative potential shift for the formation of the pyrene radical anion in comparison to 1-pyrenecarboxaldehyde. It must be noted that in the case of the azines, it is the C=N bond that is reduced, but the C=O bond is reduced in 1-pyrenecarboxaldehyde. In general, the azomethine group is more easily reduced than the carbonyl group from which it is derived (40). Thus a shift to more positive reduction potentials is expected by replacing the oxygen of a C=O bond with a nitrogen. In the case of the azines, the observed shifts relative to the parent carbonyl compounds is to more negative potentials, suggesting that the effects of replacing the C=O with C=N are offset by the conjugative or inductive effects of the azine unit and its second substituent. For **1**-Fc/Py, the negative shift in reduction potential indicates that there is some electronic communication through the azine moiety with the electron donating ferrocenyl group of **1**-Fc/Py having a larger effect (shift of –0.2 V) than the phenyl ring of **2**-Py/H (shift of –0.12 V). Reduction to the dianion shows only a small effect due to azine formation.

An additional process is also observed in the CVs of the pyrene-containing molecules. The wave for the formation of the dianion is followed very closely by a third reversible reduction wave that can be clearly identified in the CV of **2**-Py/H (Fig. 2*b*). In the cases of **1**-Fc/Py and 1-pyrenecarboxaldehyde, the formation of dianion is coincidental with the third reduction process. This results in a wave that appears as a single reversible reduction wave (at approximately –1.9 V), but it is not completely reversible since the cathodic and anodic peak-current ratios are greater than unity. At faster scan rates, the peak-current ratio does approach unity, indicating that the rate of the third reduction process is slow enough to be outrun by the scan rate. It was noticed that the appearance of the third reduction process was dependant on the quality of the solvent used for the experiment (i.e., [H_2O]). In meticulously dried solvent, the third reduction process for **2**-Py/H was almost not observable. As well, addition of an acid (TFE) to the electrochemical solution of **2**-Py/H, caused an increase in the current for the third reduction. This third reduction process is due to the reduction of the product derived from protonation of the dianion by solvent molecules or any residual water present. The formation of this

protonated product is also responsible for the minor anodic peaks on the return scan (between –0.5 and –0.8 V, depending on scan rate) due to oxidation of the formed conjugate base for each of the pyrene containing azines. As well, the protonated product is also responsible for the minor peak preceding wave A for **1**-Fc/Py (Fig. 2*a*), which is not observed unless the scan goes through the formation of a dianion. Protonation would interrupt any conjugation that may exist and result in a minor ferrocenyl-containing product that is easier to oxidize than the original azine.

The anthracenyl-containing molecules exhibit different electrochemical behavior compared with the others. Fig. 3*a* shows the CV of **1**-Fc/Anth, which features a completely reversible one-electron wave (A) at positive potentials, as well as an irreversible one-electron cathodic wave (B) at slow

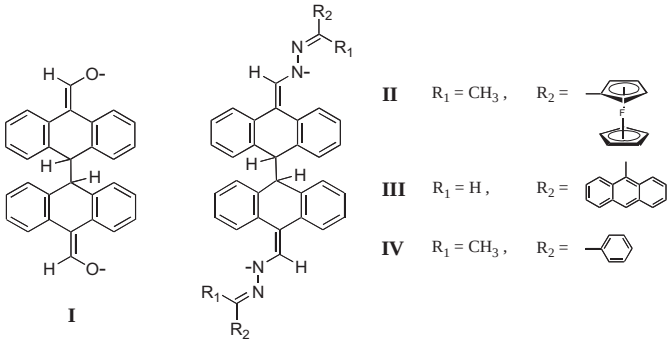
Scheme 4.



scan rates (i.e., 0.1–0.5 V s^{-1}) that becomes quasi-reversible at faster scan rates (i.e., 15–65 V s^{-1}). The E_p shifts to more negative potentials with increasing scan rate and does not vary linearly with the logarithm of the scan rate (log ν). Also present in the CV for **1**-Fc/Anth is an anodic wave (C) with an E_p at approximately –0.9 V whose intensity decreases relative to the peak current of the irreversible wave as the scan rate is increased. The E_p of wave C shifts towards more positive values with increasing scan rate. This suggests that the anodic wave C is due to a product formed during the reduction process at wave B. The decrease of relative intensity of wave C compared with wave B with increasing scan rate indicates that the formation of the new species is outrun at faster scan rates. Reversing the scan direction towards more negative potentials after the appearance of oxidation wave C results in a CV that is identical to the one obtained on the initial scan, indicating that the product formed upon azine reduction is oxidized back to the original azine. This electrochemical behavior of **1**-Fc/Anth is consistent with electrochemically reversible reduction followed by rapid dimerization. The formed dimer can then be oxidized back to starting azine. Digital simulation of the CV of a reversible reduction followed by dimerization produces similar features (i.e., E_p shifts to more negative values and non-linear E_p vs. log ν) as are observed for the experimental data. Similar voltammetric features are observed in the CVs for other anthracenyl-containing model compounds (Figs. 3*b*–*d*) **2**-Anth/H, **2**-Anth/Anth, and 9-anthraldehyde, which do not show any oxidation processes up to +1 V.

The reduction of 9-anthraldehyde (used as a model compound to examine substituted anthracene reduction, Fig. 3*d*) was examined in 0.1 M TEAP–DMF solution by Lasia and Rami (42). It exhibits similar voltammetric features upon reduction as **1**-Fc/Anth and the other anthracenyl azines. The one-electron cathodic wave results from the formation of the 9-anthraldehyde radical anion that quickly couples (k_d = 1 × 10^5 M^{-1} s^{-1}) (42) with a second radical anion to form a dianionic dimer (I in Scheme 4) and results in the observed one-electron irreversible reduction wave. The anodic wave at ~ –0.5 V on the reverse scan results from the oxidation of the dimer back to 9-anthraldehyde (42) and is not reversible upon switching the scan direction once again. In the case of **1**-Fc/Anth, **2**-Anth/Anth, and **2**-Anth/H, the corresponding dimers II, III, and IV (Scheme 4) are proposed to account for the oxidation waves observed at –0.927, –0.614, and –0.772 V vs. SCE at 0.1 V s^{-1}, respectively. Rate constants for dimerization (k_d) can be calculated using known procedures (43) and appear in Table 2. The k_d value for **1**-Fc/Anth suggests that the electron donating abilities of the ferrocenyl group act to hinder dimer formation. The rates are approximately equal for the remaining anthracenyl azines.

Table 2. Electrochemical data and dimerization rate constants for anthracene containing azines.

Compound	E_p (at 0.2 V s^{-1})[a]	E^{o} [a]	k_d (M^{-1} s^{-1})
1-Fc/Anth	–1.445	–1.437	5.1 × 10^4
2-Anth/H	–1.397	–1.403	1.5 × 10^5
2-Anth/Anth	–1.224	–1.232	3.3 × 10^5
9-Anthraldehyde	–1.203	–1.207	1.8 × 10^5

[a]In V vs. SCE.

For **1**-Fc/Anth, the electrochemical behavior is governed by two independent moieties, namely the ferrocene and the anthracene groups. The ferrocene moiety has the effect of making the anthracenyl unit more difficult to reduce as evidenced by a shift of 0.24 V to more negative potentials relative to 9-anthraldehyde. This indicates that some electronic communication must be occurring through the azine unit. A similar situation is observed for **2**-Anth/H. The reduction of **2**-Anth/Anth also shows evidence for electronic communication. Although the reduction potential of **2**-Anth/Anth occurs at the roughly same potential as 9-anthraldehyde, only one electron is involved in the process. One might expect a two-electron wave for **2**-Anth/Anth if the azine moiety prevented any communication between the two anthracene units (i.e., reduction of both anthracene units simultaneously, similar to the situation previously observed for 4,4′-dinitroacetophenone azine (39)).

The electrochemical behavior of acetylferrocene and acetylferrocene azine (**1**-Fc/Fc) was also examined for comparison with the results obtained for the other **1**-Fc/Ar. **1**-Fc/Fc shows an anodic wave that consists of two one-electron reversible oxidations that have slightly different oxidation potentials (Fig. 4*b*). This results in an oxidation wave that is approximately twice the magnitude of the other one-electron oxidations (Fig. 5) and appears to have a shoulder on the leading edges of the waves. This is consistent with the electrochemistry observed for **1**-Fc/Fc by Osborne et al. (2) who estimates the oxidation potentials of the two ferrocene units to be +0.47 V and +0.56 V vs. SCE in 0.2 M TBAP–CH_2Cl_2. **1**-Fc/Fc also shows a reduction wave at very negative potential caused by the reduction of the C=N bond of the azine unit. This reduction occurs into the solvent discharge, which makes determining the standard potential difficult. Reduction of a C=N bond at such negative potentials results in the formation of minor electroactive species, which are oxidized on the reverse scan and have similar structure to the parent azine. These products most likely result from reaction of the azine radical anion with H_2O or electrolyte or some reduced form of the electrolyte. Figure 4 illustrates the CVs of **1**-Fc/Fc as well as the reference compound, acetylferrocene. The reduction that occurs in the CV of acetylferrocene is the one-electron reduction of the carbonyl group. All electrochemical data is summarized in Table 1.

The Fe^{II}/Fe^{III} couple in the **1**-Fc/Y is subject to a substituent effect as indicated by the oxidation potentials of the two model compounds, ferrocene and acetylferrocene (+0.470 V and +0.691 V vs. SCE in DMF, respectively). The

Fig. 4. Cyclic voltammograms of (*a*) acetylferrocene and (*b*) **1**-Fc/Fc measured in 0.1 M TEAP–DMF at 0.2 V s^{-1}. Arrows indicate scan direction. Dashed line is the CV in the positive potential region only.

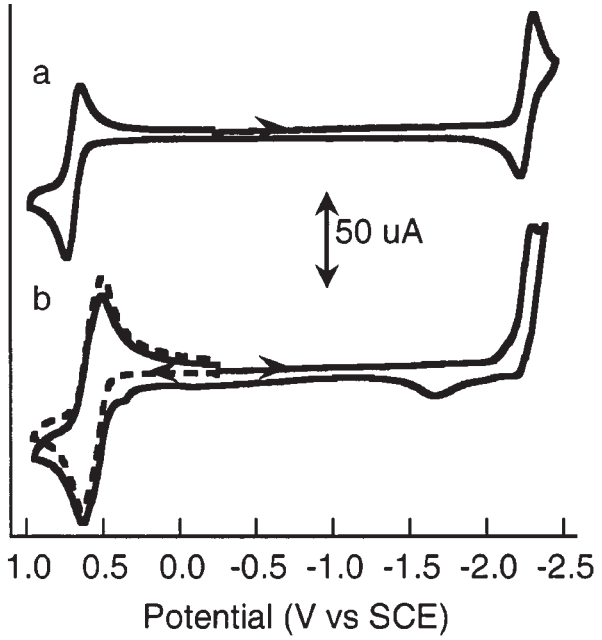

Fig. 5. Cyclic voltammograms of the reversible oxidation waves for the ferrocenyl azines measured in 0.1 M TEAP–DMF at 0.2 V s^{-1} scan rate: (*a*) **1**-Fc/Fc; (*b*) **1**-Fc/4-NO_2; (*c*) **1**-Fc/Anth; (*d*) **1**-Fc/Py; (*e*) **1**-Fc/4-CN; (*f*) **1**-Fc/Pyrd; and (*g*) **1**-Fc/4-OCH_3.

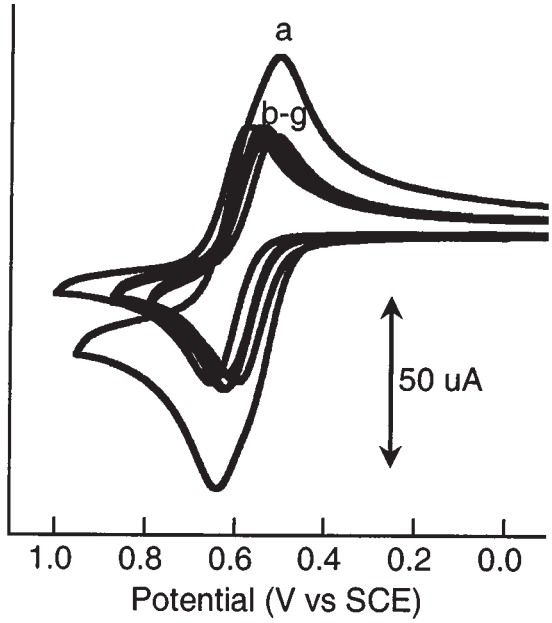

oxidation potentials of the ferrocene unit can be used to probe the effects of adding an azine unit and any possible contribution from the aryl group to the electrochemical behavior of the iron core. The CVs showing the reversible oxidation of **1**-Fc/Ar to **1**-Fc/$Ar^{\bullet+}$ at 0.2 V s^{-1} are shown in Fig. 5. As expected, the ferrocenyl unit becomes easier to oxidize (less positive potentials) with more electron donating substituents and vice versa. All $E^{\circ}_{\bullet+/0}$ are within 59 mV of each other, indicating only a modest substituent effect on the oxidation. This reinforces the notion of little to no conjugation through the azine unit, producing only small substituent effects, particularly on the Fe core. A more illustrative example of the extent of communication through the azine unit is the oxidation of **1**-Fc/Fc that shows two oxidation processes that occur at slightly different potentials. If there was no conjugation through the azine unit, we would expect that the oxidation potentials would be coincidental and that the observed wave would appear as if it were a completely reversible two-electron reduction process. That is, both ferrocene units would be oxidized simultaneously. Thus the oxidation of **1**-Fc/Fc would be similar to the simultaneous double one-electron reduction of 4,4′-dinitroacetophenone azine (39). Since the oxidation of **1**-Fc/Fc appears as two processes at slightly different potentials, there must be some electronic communication through the azine moiety that results in the second oxidation being slightly harder to accomplish (i.e., occurs at more positive potential) than the first.

The heterogeneous rate constants (k_{het}) for electron transfer can be calculated (43, 44) for the compounds investigated and are listed in Table 3. The calculated k_{het} are within the expected range (10–10^{-3} cm s^{-1}) for reversible or quasi-reversible electrode kinetics. Rate constants for compounds **1**-Fc/Fc, **2**-Anth/Anth, **2**-Anth/H, and 9-anthraldehyde could not be determined in this way because they do not exhibit suitable reversible waves, a requirement for the calculation.

The **1**-Fc/Ar compounds offer the opportunity to calculate the HOMO–LUMO energy gap (listed in Table 3). The energy difference between oxidation and reduction potentials is the HOMO–LUMO energy gap and is an indication of the electron donor–acceptor properties of the compound. The variation of $\Delta E_{HOMO-LUMO}$ as a function of the substituent (values differ by more than 30 kcal mol^{-1}) illustrates the "fine tuning" possible for azine electronic properties simply by changing the substituent(s) attached to the azine unit.

To further our examination of the electronic nature of azines, the photochemical behavior of a series of azines containing a chromophoric group (specifically anthracene) was investigated. This allowed for the evaluation of the effect of the ferrocene group on the photochemical characteristics of these azines. Azine photochemistry is governed by *E*/*Z* isomerization of the azomethine bonds (45–51), which has been shown to be a general property of the 2,3-diaza-1,3-butadienes. The photochemistry and photophysics of **2**-Anth/Anth has been thoroughly investigated by Appenroth et al. (48–51). **2**-Anth/Anth can exist as three isomers, *E*/*E*, *E*/*Z*, and *Z*/*Z*, where the *E*/*Z* and *Z*/*Z* isomers can be selectively produced, starting from the thermodynamically stable *E*/*E* form, by irradiation with wavelengths λ = 488 and 436 nm, respectively. It was found that neither of the three isomers fluoresce at room temperature and only the *Z*/*Z* isomer fluoresced at 77 K (51). The fluorescence spectrum of (*Z*/*Z*)-**2**-Anth/Anth contained the same structural features as anthracene and its quantum yield of fluorescence in ethanol was determined to be Φ_f = 0.090 using an excitation wavelength of 350 nm at 77 K.

To investigate the luminescent properties, the fluorescence spectra of the anthracenyl-containing azines were recorded

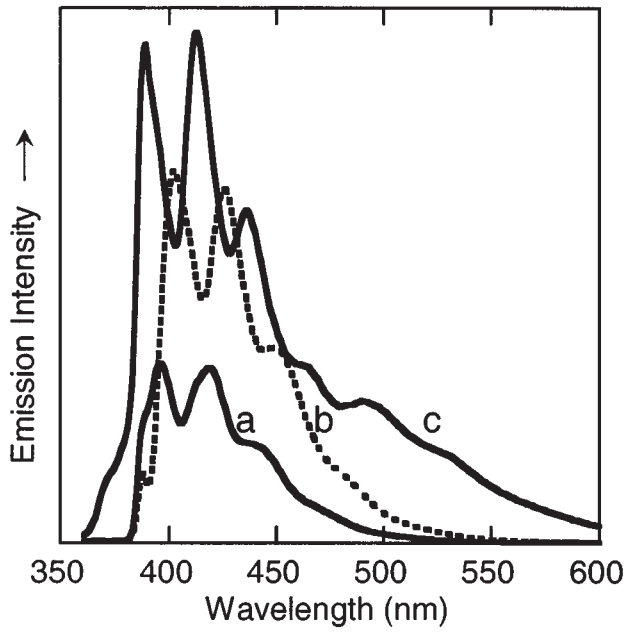
Fig. 6. The emission spectra of **1**-Fc/Anth, **2**-Anth/H, and **2**-Anth/Anth in EPA at 77 K using a 350 nm excitation wavelength: (*a*) **2**-Anth/H; (*b*) (dashed line) **2**-Anth/Anth; (*c*) **1**-Fc/Anth.



in EPA both at room and low temperature (77 K). Figure 6 shows the fluorescence spectra of **1**-Fc/Anth, **2**-Anth/H, and **2**-Anth/Anth at 77 K. None of the azines showed fluorescence at room temperature, and only weak fluorescence at low temperature when an excitation wavelength of 350 nm was used. Such behavior was observed previously for several different azines including **2**-Anth/Anth (48, 51), where the *E*/*E* isomer was shown to be non-fluorescent. The samples were then exposed to radiation of wavelength 410–490 nm to induce isomerization to the *Z*/*Z* isomer and the fluorescence was reexamined. Once again, little to no emission was observed at room temperature. In contrast, the emission intensity at 77 K was dramatically increased, approximately 12–70 times relative to the samples before irradiation. The low-emission intensity at room temperature can be attributed to efficient energy dissipation in the excited state via *E*/*Z* isomerization of the azomethine bonds. This isomerization process becomes less important at 77 K with a concomitant enhancement of fluorescence since the azine molecules are now contained in the solid glass of the frozen EPA solution. The emission observed for **1**-Fc/Anth, **2**-Anth/H, and **2**-Anth/Anth contains similar structural features as that of anthracene (52).

Appenroth et al. (51), attributed the observed emission of (*Z*/*Z*)-**2**-Anth/Anth to the anthracene chromophore that is twisted out of the molecular plane of the azine moiety in the *Z*/*Z* isomer (53, 54). The twisting results from steric interactions between the azine nitrogen and the anthracene unit. This results in an interruption of any conjugation that may be occurring. The *E*/*Z* isomer of **2**-Anth/Anth did not show any emission at either temperature despite twisting of one of the anthracene units. The situation is very similar for **1**-Fc/Anth and **2**-Anth/H. The need for irradiation at 410–490 nm prior to the observation of any emission suggests that the *E*/*E* isomers of **1**-Fc/Anth and **2**-Anth/H, the thermodynamically most stable and initial structures, do not fluoresce and any fluorescence must come from one of the other two isomers. Similar to **2**-Anth/Anth, long-wavelength irradiation induces isomerization of the C=N bonds and results in fluorescence not observed for the *E*/*E* isomers. Emission from the *E*/*Z* or *Z*/*Z* isomers of **1**-Fc/Anth and **2**-

Table 4. Quantum yields (Φ_f) and total normalized fluorescence intensities of **1**-Fc/Anth, **2**-Anth/H and **2**-Anth/Anth in EPA at room temperature and 77 K.

		Before irradiation		After irradiation	
Azine	Φ_f [a]	r.t.	77 K	r.t.	77 K
1-Fc/Anth	0.176	0.3	3.4	20	242.1
2-Anth/H	0.042	0.08	5.1	1	58.4
2-Anth/Anth	0.090	0.14	7.2	1.7	123.7

Note: Fluorescence intensities are normalized relative to the area under the room temperature emission curve of **2**-Anth/H after irradiation at 410–490 nm.

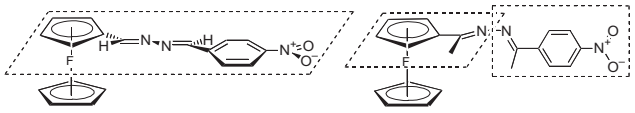
[a]Quantum yields in EPA at 77 K using 350 nm excitation wavelength relative to that of **2**-Anth/Anth (51). The concentrations of the fluorescence samples were adjusted so that absorption at 350 nm was equivalent.

Anth/H cannot, however, be distinguished since it is unclear whether both C=N bonds need to be in the *Z* configuration or only the C=N bond nearest the anthracenyl group.

The fluorescence quantum yields (Φ_f) of **1**-Fc/Anth and **2**-Anth/H were determined by comparison to the Φ_f previously determined for **2**-Anth/Anth (51) under similar experimental conditions. The determined quantum yields at 77 K are listed in Table 4 along with the normalized fluorescence intensities. Table 4 shows that, in frozen solution where the isomerization is prevented, the fluorescence of **1**-Fc/Anth is twice that of **2**-Anth/Anth and four times that of **2**-Anth/H. The emission intensity of **2**-Anth/Anth is approximately twice that of **2**-Anth/H under all conditions owing to the two anthracenyl groups in **2**-Anth/Anth compared with one in **2**-Anth/H. The fluorescence intensity of **1**-Fc/Anth at room temperature after irradiation was significantly higher than the other two azines. This suggests that radiationless deactivation processes are less favoured for **1**-Fc/Anth than for **2**-Anth/H and **2**-Anth/Anth in fluid solution, and that the ferrocene group may in fact hinder the *E*/*Z* isomerization that is the main deactivation mechanism at room temperature. In addition, fluorescence quenching by ferrocene does not appear to dominate, either at room temperature or 77 K, in comparison to the observed fluorescence of **2**-Anth/H and **2**-Anth/Anth. This suggests that (*Z*/*Z*)-**1**-Fc/Anth (or (*E*/*Z*)-**1**-Fc/Anth) does not exhibit significant electronic communication between the two azine substituents either by through-bond or through-space interactions since ferrocene is known to be a good fluorescence quencher (15, 55). Any fluorescence observed before irradiation presumably results from minor amounts of *E*/*Z* or *Z*/*Z* isomers that may be present in the initial solution, formed by thermal processes.

To extend the solid-state analysis of azines, crystals of **1**-Fc/4-NO_2, **1**-Fc/4-CN, **1**-Fc/Pyrd, and **1**-Fc/Anth suitable for X-ray analysis were grown by slow evaporation of a solution of the azine in an appropriate solvent. All C=N bonds are in their *E* configurations as expected. The average Fe—C bond distances of the ferrocene moiety are all similar (2.030–2.040 Å) and fall within the range commonly found for ferrocene compounds (2, 4, 56) but are shorter than those found in ferrocene itself (2.045 Å) (57). This may be due to any of the conjugative effects of the attached azine, which pulls electron density from the cyclopentadienyl ring and results in the shortening of the average Fe—C bond lengths. All the cyclopentadienyl rings are planar (mean deviation of 0.0002–0.0025 Å) and parallel to each other (angle between rings of 0.9–3.5°). The C—C of the cyclopentadienyl rings, N—N, and C=N bond lengths are similar to those determined for other ferrocenyl azines (2, 4, 12).

Scheme 5.



1-Fc/4-NO_2

One striking feature of the determined **1**-Fc/Ar structures is the twisting of the molecules through the azine moiety as indicated by >C=N-N=C< dihedral angles of 99.1–160.9° (see *Supplementary material*). This is in complete contrast with the structure of ferrocenealdehyde-4-nitrobenzaldehyde azine, reported by Houlton and co-workers (12), illustrated in Scheme 5, whose X-ray structure shows an almost complete planarity of the $C_5H_4CHNNCHC_6H_4NO_2$ fragment to produce an extended π system. The similar azine **1**-Fc/4-NO_2 (Scheme 5), which differs only by the addition of two methyl groups, produces a significantly different orientation. This suggests that **1**-Fc/Ar should not exhibit any conjugation through the azine unit. The electrochemical results suggest, however, that there is significant conjugative interactions in the **1**-Fc/Ar in solution. The twisting of the molecules observed in the solid state, therefore, may not be a good reflection of their orientation in solution and may be caused by packing effects in the solid. The same argument was proposed by Glaser and co-workers (22, 25) to explain the nonplanarity of the acetophenone azines in the solid state.

Conclusions

The electrochemical behavior of the **1**-Fc/Ar is governed by the ferrocenyl and aryl group attached to the azine moiety. All the **1**-Fc/Ar showed a reversible oxidation between +0.62 and +0.55 V vs. SCE as a function of the aryl substituent. Electron withdrawing groups resulted in more positive oxidation potentials with only a slight substituent effect on the Fe^{II}/Fe^{III} oxidation, as evidenced by the small variation (59 mV) in potentials. The reduction potentials of **1**-Fc/Ar were determined and electron donating groups showed more negative reduction potentials, whereas less negative potentials were observed for electron withdrawing substituents. For **1**-Fc/Ar, where the aryl group was a substituted benzene ring, the effect of introducing an electron donating ferrocenyl group on azine reduction results in the ferrocene having similar electron donating characteristics as a methoxyphenyl or dimethylaminophenyl group compared with the reduction potentials determined for similar systems (39). The reduction and oxidation potentials determined for **1**-Fc/Ar suggest that there is some electronic communication between the two substituents of the azine moiety in comparison with model compounds. Therefore, we suggest that the azine unit does allow for limited conjugation in the **1**-Fc/Ar as it did for the acetophenone azines (39). The nonplanarity of the **1**-Fc/Ar observed in the solid-state structures, suggest-

© 2002 NRC Canada

ing no conjugation, may not be an accurate reflection of their orientation in solution.

The photochemistry of **1**-Fc/Anth, **2**-Anth/Anth, and **2**-Anth/H is governed by *E*/*Z* isomerization processes and no emission is observed for these compounds either at room temperature or at 77 K. Fluorescence at 77 K is observed after long wavelength irradiation where the thermodynamically most stable *E*/*E* isomer is converted to the *E*/*Z* and *Z*/*Z* isomers from which emission occurs. Any conjugative interactions in the *E*/*E* isomer is interrupted upon formation of the *E*/*Z* or *Z*/*Z* isomer, allowing for fluorescence of the anthracenyl group. The ferrocenyl group in **1**-Fc/Anth has only a slight effect on the anthracenyl fluorescence, enhancing it relative to **2**-Anth/Anth and **2**-Anth/H, and no evidence for intramolecular or inductive quenching by ferrocene was observed under the experimental conditions. The donor–acceptor properties of ferrocenyl azines, however, can be easily manipulated by altering the aryl substituent on the azine unit, making them good candidates for materials applications.

Experimental

Materials

All chemicals used were purchased from Aldrich and used as received unless otherwise stated. For electrochemical experiments only, acetylferrocene, 9-anthraldehyde, and 1-pyrenecarboxaldehyde were recrystallized from suitable solvents prior to use. *N*,*N*-dimethylformamide(DMF) was distilled under reduced pressure over calcium hydride prior to use. Argon was flushed over the DMF during the transfers into the electrochemical cells. Tetraethyl ammonium perchlorate (Kodak) was recrystallized three times and dried under vacuum at 60°C prior to use and stored in a vacuum dessicator. Ferrocene was sublimed once before use. NMR spectra, recorded on a Varian Gemini 300 MHz (300.075 MHz for ^{1}H and 75.462 MHz for ^{13}C) or Varian Mercury 400 MHz instrument (400.0854801 MHz for ^{1}H and 100.6015500 MHz for ^{13}C), are herein referred to as 300 or 400 MHz for ^{1}H and 75 or 100 MHz for ^{13}C. All chemical shifts are reported in parts per million downfield from tetramethylsilane. Melting points were recorded using a Gallenkamp melting point apparatus and are uncorrected. IR data was recorded on a PerkinElmer System 2000 FT-IR. Mass spectra analysis was performed with a Finnigan MAT 8200 mass-data system. Gas chromatography analysis was performed on a Hewlett–Packard 5890 Series II gas chromatograph equipped with a 10 m HP5 column and an FID detector. UV–vis data were collected on a Varian Cary 100 spectrometer. Fluorescence spectra were recorded using an ISA Spex 3 Fluorimeter.

Electrochemistry — cyclic voltammetry

Experiments were performed using either a Princeton Applied Research (PAR) 283 or 263 potentiostat interfaced to a personal computer. PAR M270 software was used to conduct the experiments as well as analyze the derived data. Measurements were conducted in an all-glass cell kept at 25°C. All glassware was predried in an oven and assembled, hot while flushing with argon. The working electrode was glassy carbon (Tokai) and the counter electrode was a platinum flag. The reference electrode was a silver wire housed in a glass tube sealed with a porous ceramic tip and filled with a 0.1 M solution of tetraethylammonium perchlorate (TEAP). The same reference electrode was used in all experiments. Concentrations of 2 mM of azine in 0.1 M TEAP in DMF were used. Ferrocene, tetracyanoethylene, or 4-nitroacetophenone azine (39) were used in all experiments as internal references to a saturated calomel electrode ($E°$ = 0.470, –0.319, and –0.973 V vs. SCE in DMF, respectively). Positive feedback IR compensation was used in all experiments to minimize the effects of uncompensated solution resistance.

Fluorescence

Fluorescence spectra were recorded on an ISA Spex 3 Fluorimeter interfaced to a personal computer. EPA (2:5:5 mixture of ethanol – diethyl ether – isopentane) was prepared from spectroscopic grade solvents and stored in a tightly sealed bottle. Azine solutions were prepared by dissolving the appropriate amount of azine in EPA so that the UV–vis absorbance at 350 nm was the same for all samples and kept below 0.07. Samples were kept in the dark as much as possible during preparation, transport, and storage. Azine solutions were then placed in quartz tubes, purged with argon gas to remove oxygen and sealed with a rubber septa. The samples were placed in the fluorimeter inside a low-temperature sample holder filled with liquid nitrogen (the same samples and apparatus was used for room temperature spectra but without the liquid nitrogen). The samples were checked for any cracks in the frozen solvent and the fluorescence or excitation spectra were recorded. Samples were removed from the liquid nitrogen and allowed to warm to room temperature between runs. Any condensation that accumulated on the tubes during the warming process was removed before immersing into the liquid nitrogen again. The liquid nitrogen was frequently changed in the sample holder to remove interference from ice particles which form at the nitrogen-air interface. Photolysis with light of wavelength 410–490 nm was performed using the setup described below for the long wavelength photolysis. The fluorescence samples were irradiated in the same quartz tubes used for recording the spectra and placed back in the fluorimeter. The samples were irradiated until no increase in the cold emission intensity was observed, approximately 4 h.

Long wavelength photolysis

Photolysis with light of wavelength 410–490 nm was performed using a high-pressure mercury lamp surrounded by a filter solution of $CuSO_4 \cdot 5H_2O$ (2.7 M NH_3) and $NaNO_2$ (58) in a quartz reaction chamber. Photolysis was performed on the fluorescence samples whose preparation is described above.

Synthesis of acetylferrocene azines (1-Fc/Ar)

The symmetric azines **1**-Fc/Fc and **2**-Anth/Anth were synthesized according to a prescribed procedure and the spectral characterization and other physical data matched that previously reported (2, 59). The asymmetrical azines were synthesized by adding the appropriate substituted ketone or aldehyde (1 equiv) to the corresponding acetylferrocene (diethoxyphosphinyl) hydrazone (1 equiv) in benzene–NaH (1.3 equiv). Both the preparation of the acetylferrocene

© 2002 NRC Canada

(diethoxyphosphinyl) hydrazone and azine were prepared according to the published procedures (22, 39).

Preparation of diethyl phosphorohydrazidate

Hydrazine hydrate (20 equiv) was added dropwise to a stirred solution of anhydrous K_2CO_3 (15 equiv) and triethylbenzyl ammonium chloride (0.1 equiv) in CCl_4–CH_2Cl_2 (4:7) at 20–25°C. A solution of diethylphosphite (1 equiv) in CH_2Cl_2 was then added at 20–30°C. The stirring was continued for 6 h after which the K_2CO_3 crystals were filtered off and rinsed with CH_2Cl_2. The solvents were removed and the residue was kept under high vacuum for several hours. The resultant pale yellow liquid was used without further purification.

Preparation of acetylferrocene(diethoxyphosphinyl)-hydrazone

Diethyl phosphorohydrazidate (1 equiv) and acetylferrocene were dissolved in benzene and heated at reflux for 5 h. The benzene was removed by rotary evaporation to yield a crystalline sample. The solid was then purified by recystallization from hexanes–benzene (2:1). The purity of the sample was verified by GC and NMR.

X-ray crystallography

Single crystals of **1**-Fc/4-NO_2, **1**-Fc/4-CN, **1**-Fc/Pyrd, and **1**-Fc/Anth were grown by slow evaporation of a concentrated solution of the azine in an appropriate solvent. Crystals were mounted on a glass fibre. Data were collected on a Nonius Kappa-CCD diffractometer using COLLECT (Nonius, 1998) software. The unit cell parameters were calculated and refined from the full data sets. Crystal cell refinement and data reduction was carried out using the Nonius DENZO package. The data were scaled using SCALEPACK (Nonius, 1998) and no other adsorption corrections were applied. The SHELXTL 5.1 (Sheldrick, G.M., Madison, WI) program package was used to solve the structures by direct methods, followed by successive difference Fouriers. All non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were calculated geometrically and were riding on their respective carbon atoms. The crystal data for the structures determined in this report are reported in the *Supplementary material*.[2]

Low temperature interface-mineralizing route to hollow CuS, CdS, and NiS spheres

Xuchuan Jiang, Yi Xie, Jun Lu, Liying Zhu, Wei He, and Xianming Liu

Abstract: Submicrometer hollow CuS, CdS, and NiS spheres with diameters between 400 and 1300 nm were successfully prepared through an interface-mineralizing reaction in a $NH_3 \cdot H_2O$–CS_2 solution at low temperature. Several techniques were applied to characterize the interesting self-assembled structures. The compositions of the prepared CuS, CdS, and NiS materials were confirmed by X-ray powder diffraction (XRD), the surface atomic ratios and the valence state of ions were examined by X-ray photoelectron energy spectroscopy (XPS), and the morphologies of products by transmission electron microscope (TEM). The optical properties, including absorption and emission, were recorded by UV–vis absorption and fluorescence spectroscopy, respectively. In this approach, ethylenediamine (en) was substituted by aqueous ammonia ($NH_3 \cdot H_2O$) to avoid violent reactions with carbon disulfide (CS_2). The main advantage to this approach is that both ammonia and CS_2 played multi-functional roles in the assembly of hollow-sphere structures. The reaction sources themselves (CS_2) served as the reaction template and required no other templates to support it. The proposed interface-mineralizing mechanism is discussed, and the hollow-sphere structures obtained are envisioned to have applications in area of materials science.

Key words: hollow-sphere structure, $NH_3 \cdot H_2O$–CS_2, metal sulfides

Résumé : Faisant appel à une réaction de minéralisation à l'interface, dans une solution de $NH_3 \cdot H_2O$–CS_2, à basse température, on a préparé avec succès des sphères creuses de CuS, CdS et de NiS de dimensions sous micrométriques, ayant des diamètres allant de 400 à 1300 nm. On a appliqué plusieurs techniques pour caractériser ces structures intéressantes qui donnent lieu à de l'autoassemblage. Les compositions des produits CuS, CdS et NiS qui ont été préparés ont été confirmées par diffraction de rayons X par des poudres; les rapports de surface atomique et l'état de valence des ions ont été évalués par spectroscopie de l'énergie photoélectronique des rayons X et les morphologies des produits ont été étudiées par microscopie de transmission électronique. Les propriétés optiques, y compris l'absorption et l'émission, ont été enregistrées respectivement par le biais des spectres d'absorption UV–visible et de fluorescence. Dans cette approche, on a substitué l'éthylènediamine (en) par de l'ammoniac aqueux ($NH_3 \cdot H_2O$) afin d'éviter les réactions violentes avec le disulfure de carbone (CS_2); les principaux avantages de cette substitution sont que l'ammoniac et le CS_2 jouent tous les deux plusieurs rôles dans l'assemblage des structures sphériques creuses. De plus, les sources de réaction servent aussi de gabarit pour la réaction, éliminant la nécessité d'avoir d'autre support. On discute du mécanisme proposé pour la réaction de minéralisation à l'interface. On croit que les structures sphériques creuses obtenues ici auront des applications dans le domaine des sciences des matériaux.

Mots clés : structure sphérique creuse, $NH_3 \cdot H_2O$–CS_2, sulfures métalliques.

Introduction

Nanomaterials with different morphologies exhibit dissimilar properties (1). Metal chalcogenides have gained much more attention in the field of material science (2) because of their unusual electronic properties and interesting chemical behaviors (3). Nanoparticles, intermediate in size between bulk solids and molecular entities, have been the subject of numerous investigations (4–7), and such nanoparticles can undergo self-assembly into superlattices or special nanostructures (7–11). The future design of functional nanodevices will most likely rely on the principles of molecular self-organization. Many of examples of such compounds with interesting morphologies or special structures have been reported in the literature, including nanostructural rods, wires, cables, or spheres (12–15). Recently, Stupp and Braun (11) constructed semiconductor CdS nanomaterials with three different morphologies: hexagon-pore arrays, layers, and hollow spheres. These nanomaterials were prepared by the reaction of H_2S and Cd^{2+} ions in a lyotropic liquid-crystal template, and were the first reported examples of inorganic non-oxide semiconductor materials. Caruso et al. (16) reported the nanoengineering of silica and silica-polymer spheres by colloid-templated electrostatic layer-by-layer self-assembly. Volkmer et al. (17*a*) reported the spontaneous self-assembly and the resulting superstructures of discrete nanoporous surfactant-encapsulated clusters, mono-

layers, and LB films of $(DODA)_{40}(NH_4)_2[(H_2O)_n \subset Mo_{132}O_{372}(CH_3CO_2)_{30}(H_2O)_{72}]$ ($n \approx 50$). Xie and co-workers (18) fabricated submicrometer hollow CdS spheres through self-assembly in the ethylenediamine (en) – carbon disulfide (CS_2) – water system, as well as self-organized peanut-like CdS and ZnS nanostructures in the interface region of organic and inorganic phases. Imhof and co-workers (19) discuss an emulsion templating scheme that employs monodisperse liquid droplets instead of solid particles as the colloidal template,which can be used to produce porous rutile titanium dioxide. The above-mentioned self-organized micro- and nanoparticles have different surface chemical compositions, increased stability, higher surface areas, and different magnetic and optical properties (20), thus making them attractive from both a scientific and a technological viewpoint. The self-organized hollow spheres including composite materials and coatings have diverse applications, such as capsule agents for drug delivery, catalysis, and protecting sensitive agents. To understand the mechanism of self-organization, we report here on the self-organization of the en–CS_2 system to form transitional-metal hollow-sphere structures.

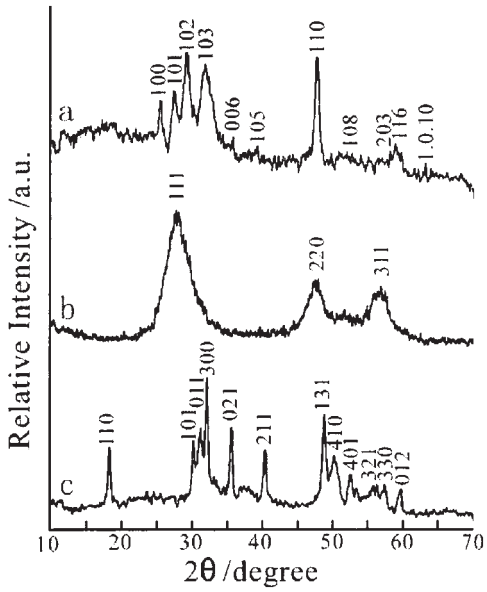
It is known that the properties of aqueous ammonia (the NH_3 content is ~28%) are similar to those of en ($H_2NCH_2CH_2NH_2$). Aqueous ammonia, however, has more advantages than en such as lower price, lower toxicity, and the avoidance of violent reactions with CS_2. More importantly, $NH_3 \cdot H_2O$ reacts softly with CS_2 without any buffers and can lead to self-assembled sulfide nanomaterials with interesting or unique structures. In this paper, we report the self-assembly of hollow CuS, CdS, and NiS spheres with diameters of 400~1300 nm via the interface-mineralizing reaction in a $NH_3 \cdot H_2O$–CS_2 system at low temperature. One obvious advantage of this strategy is that both $NH_3 \cdot H_2O$ and CS_2 play various roles in the formation of the hollow spheres. $NH_3 \cdot H_2O$ acts as the ligand, nucleophile agent, and reaction buffer between NH_3 and CS_2. Meanwhile, in the oil phase, CS_2 serves as the sulfur source and architecture template. This may offer more evidence to support the reaction mechanism proposed in our previous work.

Experimental

Procedure

Based on our strategy, the following one-pot reaction route was designed to prepare hollow metal-sulfides spheres. Carbon disulfide (CS_2) (2.0 mL, ~0.034 mol) was added into aqueous ammonia solution (20.0 mL, the content of NH_3 is 28 wt%), followed by dropwise addition (ca. 30 min) of Cu^{2+}, Cd^{2+}, or Ni^{2+} ions in solution (0.1 mol dm^{-3}, 10.0 mL). The mixture was stirred slowly at room temperature. After the addition of M^{2+} ions, the reaction systems were heated for 1 h at 50°C under vigorous stirring until brown-black precipitates formed. The mixtures were then cooled to room temperature, and the precipitates were filtered, washed with dilute hydrochloric acid solution (0.1 mol dm^{-3}), distilled water, and ethanol for three or more times. The final products were dried in vacuum at 40°C for 4 h, and stored for further investigation.

Fig. 1. The XRD patterns of the prepared samples. (*a*) Hexagonal CuS phase; (*b*) cubic β-CdS phase; (*c*) hexagonal NiS phase.



Characterization

Three samples were characterized as follows. The constituents of the final products were confirmed by X-ray powder diffraction (XRD) analysis, carried out with a Japan Rigaku D/max-γ rotation anode X-ray diffractometer, using Ni-filtered Cu Kα radiation at 25°C. A scanning rate of 0.05° s^{-1} was applied to record the patterns in the 2θ range of 10~70°. The morphologies of products were observed with a Hitachi H-800 transmission electron microscope (TEM) at the acceleration voltage of 200 kV, and the high-resolution transmission electron microscopy (HRTEM) images of the products were obtained on a JEOL-2010 transmission electron microscope. A small amount of CuS, CdS, or NiS powder was ultrasonically dispersed in ethanol, followed by adsorption of one droplet of its suspension onto a copper grid for measurement. The electronic binding energy was examined on an X-ray photoelectron spectroscope (XPS), model VGESCALAB Mg Kα ($h\upsilon$ = 1253.6 eV), with a pressure of 1.0×10^{-4} Pa and a revolution of 1.0 eV. Their optical properties were recorded by a UV–vis absorption and fluorescence spectrophotometer. The UV–vis spectra of samples were recorded on a UV–vis Spectrophotometer Specord 200 (Analytik Jena AG) absorption diode array spectrometer using 1-cm quartz curettes. The photoluminescence (PL) spectra of products were performed on a Hitachi 850-fluorescence spectrometer with a Xe lamp at room temperature with an excitation wavelength of 320 nm.

Results and discussion

Figure 1 displays the XRD patterns of products, and the narrow Bragg reflection peaks of the crystalline metal sulfides are all indexed. All of the relative information on the hollow CuS, CdS, and NiS sphere structures are listed in Table 1. Each of the XRD patterns shows a pure-phase compound. From the broaden peaks, the size of the small crystalline particles, estimated roughly by Scherrer's for-

mula (21), is less than 15 nm, which is also confirmed by transmission electron microscope images.

The electronic binding energy values of products were authenticated by XPS spectra. The general scan spectra show the presence of the principle C(1*s*), S(2*p*), and metallic core levels, with no evidence of impurities for all three samples. The binding values, 933.1 eV for Cu(2*p*), 917.8 eV for Cu (LMM), and 162.3 eV for S(2*p*), were identical to the hexagonal CuS phase (405.2 eV for Cd($3d_{5/2}$), 381.0 eV for Cd(MNN), and 161.8 eV for S(2*p*)). The values of 855.3 eV for Ni($2p_{3/2}$) and 162.5 eV for S(2*p*) are also in good agreement with NiS. All the results are in accordance with the published values (22).

The TEM images of hollow metal-sulfides spheres are shown in Figs. 2–4. Figure 2 displays the TEM images of hollow CuS spheres. Figures 2*a* and 2*b* display the hollow spheres with diameters of 400~1300 nm, and the spherical walls are comprised of many small particles with diameters of ca. 10 nm. The strong contrast between the dark edge and pale center of some mineralized hollow CuS spheres is evidence for its hollow nature. In Fig. 2*a*, about 40% of the hollow spheres are filled with small particles. A broken hollow CuS sphere with a diameter of 1000 nm is shown in Fig. 2*c*, in which the open section can be clearly observed. The thickness of sphere walls is about 13~40 nm (Figs. 2*b* and 2*c*). Figure 2*d* shows the electron diffraction (ED) pattern of the CuS particles with Bragg diffraction rings indexed at the 100, 101, 102, 220, and 103 planes, which is in agreement with the XRD pattern (Fig. 1*a*). Meanwhile, the HRTEM image of the hollow CuS sphere is shown in Fig. 2*e*; the lattice spacing distance is ca. 3.05 Å, which is consistent with the 102 plane in the XRD pattern (Fig. 1*a*).

Figure 3 displays the morphology (Fig. 3*a*), ED pattern (Fig. 3*b*), and HRTEM image (Fig. 3*c*) of the hollow CdS spheres. The sphere wall is composed of many nanocrystals with average diameters of 15 nm. About 60% of the structures are hollow spheres, 20% of hollow spheres are filled with small particles, and the others are in an agglomerated disorganized state, which can also be seen from a histogram (Fig. 3*d*). The thickness of hollow CdS spheres is about 50 nm. Three strong ED rings are indexed at the 111, 220, and 311 planes, whereas the two other weaker ED rings are indexed at the 400 and 420 planes for the cubic β-CdS phase. From the HRTEM image, the lattice spacing distance of CdS nanocrystals is ca. 3.35 Å (Fig. 3*c*), which corresponds to the 111 plane in the XRD pattern of CdS (Fig. 1*b*). Similarly, the morphology of the hollow NiS spheres is shown in Fig. 4*a*. The dispersion of the spheres are well separated, showing just a small amount of aggrega-

Fig. 3. The (*a*) TEM image; (*b*) ED pattern; and (*c*) HRTEM image of hollow CdS spheres; and (*d*) a histogram of the data.

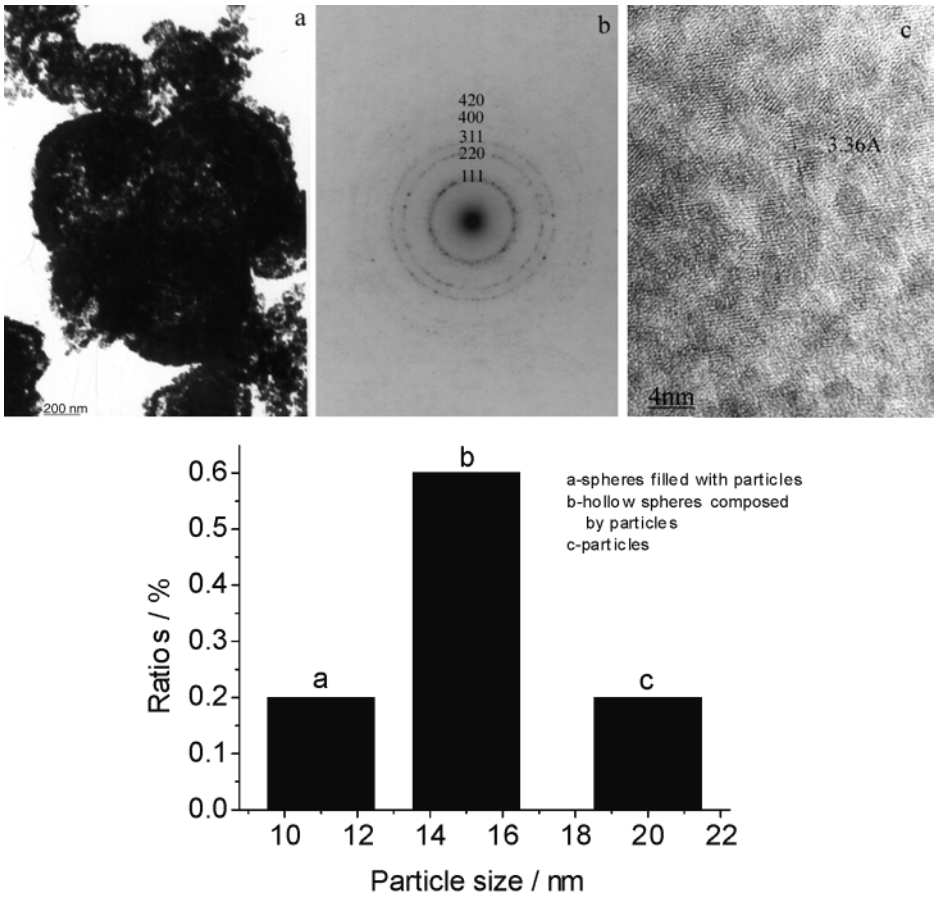

Fig. 4. The (*a*) TEM image; (*b*) ED pattern; and (*c*) HRTEM image of hollow NiS spheres.

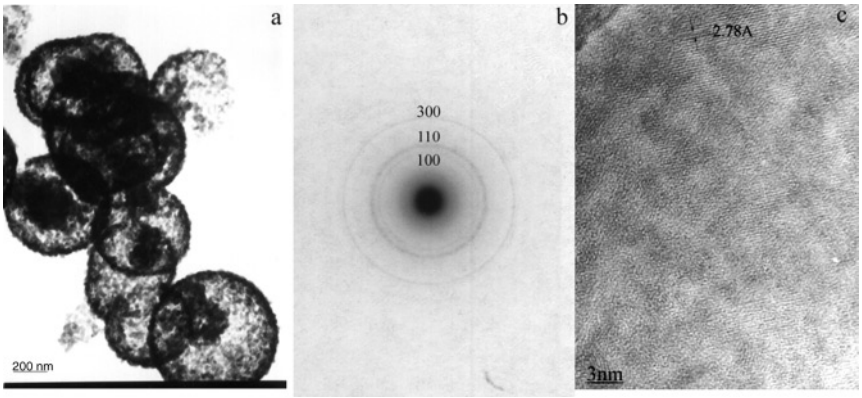

tion. The spherical walls consist of a large amount of particles with average diameters of 12 nm that self-assemble and mineralize on the surface of CS_2 droplets. The ED rings (Fig. 4*b*) are indexed at the 110, 021, and 300 planes for the hexagonal NiS phase, which corresponds to the reflection peaks in the XRD pattern (Fig. 1*c*). Here most parts of NiS are hollow spheres and the thickness of walls are between 13~30 nm. The lattice spacing distance of NiS nanocrystals that comprise the spherical walls is ca. 2.76 Å, corresponding to the 300 plane in the XRD pattern (Fig. 1*c*). All of the above-prepared hollow-sphere structures were heated at 50°C for 12 h, and apart from a little condensation, the hollow spherical structures remained stable. When heated at higher than 120°C for 3 h, the hollow spherical structures were broken and condensed into solid bulk-like materials.

The proposed formation processes of the hollow CuS, CdS, and NiS spheres can be described diagrammatically (Scheme 1).

From Scheme 1, liquid CS_2 added into aqueous ammonia formed small oil droplets due to its sparing solubility (23); they dispersed into a homogeneous solution under a stirring. This was supported by the observations that when stirred, the liquid–liquid heterogeneous $NH_3{\cdot}H_2O$–CS_2 system became opalescent and finally clear, followed by the Tyndall

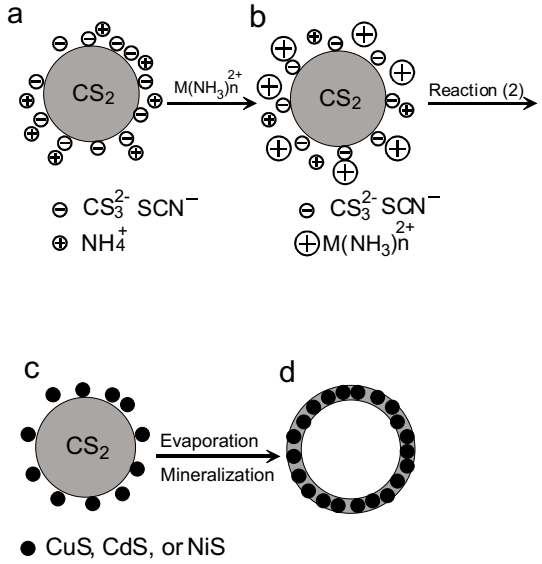
Scheme 1. Illustration of the interface-mineralizing reaction used to prepare hollow CuS, CdS, and NiS spheres. (*a*) CS_3^{2-} and SCN^- ions formed at the interface of CS_2 oil droplets and the electrostatic attraction with NH_4^+; (*b*) M^{2+} ions were added to $NH_3{\cdot}H_2O$–CS_2 system and $M(NH_3)_n^{2+}$ aggregating around the CS_2 droplets; (*c*) $M(NH_3)_n^{2+}$ ions decomposed, and MS (M = Cu, Cd, or Ni) precipitates simultaneously form at the surface of CS_2 droplets via rxn. [2]; (*d*) the metal sulfides mineralized to form stable MS sphere walls after unreacted CS_2 was evaporated upon heating at 50°C for 1 h.



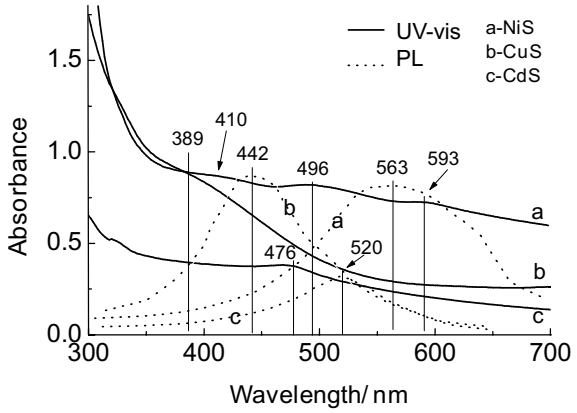
effect observed using a He–Ne laser beam. After about 5 min, the color of the mixed solution turned red. Some freshly formed S^{2-} ions (eq. [1]) aggregated around the unreacted CS_2 droplets, and hence the ammonia complex $M(NH_3)_n^{2+}$ (n = 4 for Cu^{2+} or Cd^{2+} and n = 6 for Ni^{2+}) ions gradually gathered around the surface of droplets of CS_2 because of both electrostatic attractions and additional chemical reactions (eq. [2]). The decomposition of $M(NH_3)_n^{2+}$ ions and the nucleation of nanocrystallites occurred simultaneously on the interface of CS_2 oil droplets with aqueous ammonia (eqs.[2] or [4]). Heating accomplished various roles for the formation of the hollow CuS, CdS, and NiS sphere structures, such as the promotion of the reactions (eqs. [1]~[4]), the evaporation of the unreacted CS_2 oil droplets (the boiling point of CS_2 is 45°C (24)), and the mineralizing of nanoparticles on the surface of droplets. The diffusion of CS_2 may lead to many small holes on the sphere walls, which can be observed by TEM. In addition, if the diffusion of the surrounded CS_2 molecules is homogeneous in all directions, the closed spheres have small holes on the sphere wall (Fig. 2*b*); broken wall or unclosed spheres (Fig. 2*c*) may also be obtained from heterogeneous diffusion of the CS_2 molecules.

The above-mentioned formation mechanism of the hollow-sphere structures may be supported by the following reactions:

[1] $4NH_3 + CS_2 \rightarrow NH_4SCN + (NH_4)_2S$

[2] $M^{2+} + (NH_4)_2S \rightarrow MS\downarrow + 2NH_4^+$

Fig. 5. The UV–vis absorption (solid line) and photoluminescence (dotted line) spectra of the products. They are (*a*) NiS; (*b*) CuS; and (*c*) CdS.



[3] $M^{2+} + 7NH_3 + 2CS_2 \rightarrow M(NH_3)_3(CS_3) + NH_4SCN + 2NH_4^+$

[4] $M(NH_3)_3(CS_3) \rightarrow MS\downarrow + 3NH_3\uparrow + CS_2\uparrow$

where the reaction of CS_2 with a nucleophile in the presence of base (eq. [1]) is a very general one (18*a*). Fackler et al. (25*a*, *b*) have investigated in detail the reactions between NH_3 and CS_2. In these reactions the N atom of NH_3 is nucleophilic, and in basic solutions (pH = ~9.2) is prone to attack CS_2. In our work, the formation of SCN^- ions or $M(MH_3)_3(CS_3)$ was identified by IR spectroscopy. The M^{2+} ions initially formed $M(NH_3)_n^{2+}$ ions or $M(NH_3)_3(CS_3)$ complexes, which are favorable for the slow nucleation and self-assembly of MS nanocrystals around the unreacted CS_2 droplets. With respect to the formation mechanism of the hollow spheres, Imhof and co-workers (19) have stated that the emulsion template formed by surfactant molecules with long chains is favorable for the formation of materials with holes after the surfactants have been removed. Here we prepared hollow MS spheres without the use of any pre-existing templates.

In contrast to the above procedure, when Cu^{2+}, Cd^{2+}, or Ni^{2+} ions were added to the pre-reacted (30 min) mixture of aqueous ammonia with CS_2 at 50°C, the reaction rate of precipitation increased under the similar conditions. Most of the final products were spherical nanoparticles rather than the desired hollow spheres, probably caused by the rapid nucleation of the nanocrystals and the tiny crystals having not enough time to self-assemble. This is because the CS_2 molecules had completely reacted within 30 min. The above-mentioned results indicate that the competitive reactions between the decomposition of $M(NH_3)_n^{2+}$ and the formation of MS nanoparticles were favorable for the formation of hollow-sphere structures.

To examine the importance of the sulfur source (CS_2) in the formation of hollow metal-sulfides spheres, other sulfur sources (Na_2S and $Na_2S_2O_3$) were tested. Unfortunately, only solid particles were prepared from these alternative sulfur sources, because of random release of S^{2-} ions and rapid precipitation, neither of which are suitable for the orderly self-assembly of nanoparticles. Moreover, no stable architectures provided by CS_2 droplets were suitable for the self-

© 2002 NRC Canada

organization of nanocrystals. This indicates that the existence of CS_2 oil droplets is important for the formation of hollow spheres.

To understand the effects of quantum-size "bricks" (which are formed on the sphere walls) on the optical properties, the UV–vis absorption (solid line) and photoluminescence (PL) (dotted line) properties of the hollow-sphere structural sulfides were measured; the results are shown in Fig. 5. Three absorption peaks for hollow NiS spherical materials are seen at 410, 496, and 593 nm (Fig. 5*a*). We speculate that these may be caused by the various structures of NiS bricks that form the NiS sphere walls but the essential causes are unclear and require further investigation. The maximum absorption at 389 nm for CuS nanocrystals (Fig. 5*b*) may be assigned to the optical-band edge–edge transition. Similarly, the maximum absorption at 476 nm for CdS (Fig. 5*c*) is attributed to the optical-band edge–edge transition, although a splitting of the energy bands into discrete, quantized levels occurs (26). The obvious blue shift of the absorption peak may be attributed to the small dimensional bricks that make up the hollow CdS sphere walls, similar to the data reported in ref. 18*a*. In addition, the particles' sizes are calculated and estimated by the absorption edge in the UV–vis spectra; they are calculated to be around 12 nm for CuS, 16 nm for CdS, and 10~35 nm for NiS, (27), which are in agreement with the TEM observations.

The PL excitation spectra (dotted line) of the samples (λ_{ex}= 320 nm) were recorded as follows. The hollow NiS spheres photoluminesce at ca. 563 nm (Fig. 5*a*), while the hollow CuS spheres emit at 442 nm (Fig. 5*b*), and the hollow CdS spheres emit at the maximum of 520 nm (Fig. 5*c*). The differences in emitting wavelengths for metal sulfides maybe caused by the quantum-size bricks that compose the sphere walls. The highly structured shape of the emission suggests that the interaction is not of an excimer (28), but rather a consequence of intermolecular exciton interactions (29).

Conclusion

Hollow CuS, CdS, and NiS spheres with diameters of 400~1300 nm were successfully self-assembled through the interface-mineralizing reaction route in $NH_3{\cdot}H_2O$–CS_2 at 50°C. In this approach, it was worth noting that both ammonia and CS_2 played important multi-functional roles in the formation of hollow-sphere structures. The CS_2 source itself served as the self-organization template for nanoparticles and required no pre-existing templates. This method could be expanded to the self-assembly of hollow spherical structures in material fields.

Reaction of the tamoxifen cation and the bis-(4-methoxyphenyl)methyl cation in aqueous solutions containing 2′-deoxyguanosine

Robert A. McClelland, Cristina Sanchez, Effiette Sauer, and Sinisa Vukovic

Abstract: The competition between 2′-deoxyguanosine (**dG**) and water has been quantitatively evaluated for the allylic carbocation derived from tamoxifen and for the stabilized diarylmethyl cation (bis-(4-methoxyphenyl)methyl). Both systems were examined by the competition kinetics method, in which the products were quantitatively analyzed after the S_N1 solvolysis of the corresponding acetate esters in aqueous solutions containing the nucleoside. The principal product of the reaction of both cations with **dG** is the adduct at the NH_2 group, a characteristic of delocalized carbocations. The tamoxifen cation was also examined by laser flash photolysis, with absolute rate constants for the reaction with **dG** and water being obtained and converted into rate constant ratios. The principal result of this study is that there is a three orders of magnitude difference in the reactivity of these cations towards the neutral form of **dG** and its conjugate base. Under acidic conditions where the reaction occurs with neutral **dG**, the guanine–water selectivity is low. Even at relatively high concentrations of **dG**, the majority of the product is alcohol derived from the water reaction. At pH 10 to 11, in contrast, **dG** is present as the anion and this is highly competitive. Yields of adduct as high as 90% can be attained. A consequence of the large difference in reactivities is that at neutral pH the majority of the reaction of the cation with **dG** is actually occurring via the small amount of conjugate base present. A further feature of the results is that the NH_2 adduct is the predominant stable product from the anion. To explain the high rate constant for the reaction forming this product, a mechanism is proposed whereby one of the protons of the NH_2 group is transferred to N1 as the N2–cation bond is forming.

Key words: guanine, DNA adduct, carbocation, tamoxifen.

Résumé : On a évalué de façon quantitative la compétition entre la 2′-désoxyguanosine (**dG**) et l'eau pour le carbocation allylique dérivé du tamoxifène et pour le cation diarylméthyle stabilisé, bis-(4-méthoxyphényl)méthyle. On a examiné les deux systèmes par la méthode des cinétiques en compétition dans laquelle les produits sont analysés de façon quantitative après une solvolyse S_N1 des esters acétiques correspondants en solutions aqueuses contenant le nucléoside. Le produit principal de chacune des réactions des deux cations avec la **dG** est un adduit au niveau du groupe NH_2, une caractéristique des carbocations délocalisés. On a aussi étudié le cation du tamoxifène par photolyses éclairs au laser à partir desquelles on a obtenu des constantes absolues de vitesse pour la réaction avec la **dG** et l'eau, celles-ci étant transformées en rapports de constantes de vitesses. Le principal résultat de cette étude est qu'il y a trois ordres de grandeur de différence dans la réactivité de ces cations vis-à-vis de la forme neutre de la **dG** et de sa forme conjuguée. Dans les conditions acides où la réaction se produit avec la **dG** neutre, la sélectivité guanine–eau est faible. Même à des concentrations élevées de **dG**, la plus grande partie du produit est l'alcool qui provient de la réaction avec l'eau. Par ailleurs, à des pH de 10 à 11, la **dG** est présente sous la forme d'anion qui est fortement compétitif. On peut alors obtenir des rendements d'adduit pouvant atteindre 90%. Une conséquence de la grande différence dans les réactivités est que, au pH neutre, la plus grande partie de la réaction du cation avec la **dG** se produit par le biais de la faible quantité de la base conjuguée qui est présente. Une caractéristique additionnelle des résultats est que l'adduit avec le NH_2 est le produit stable prédominant à partir de l'anion. Pour expliquer la constante de vitesse élevée pour la réaction conduisant à la formation de ce produit, on propose un mécanisme dans lequel un des protons du groupe NH_2 est transféré vers N1 alors que la liaison N2–cation se forme.

Mots clés : guanine, adduit avec l'ADN, carbocation, tamoxifène.

Introduction

A common property of chemical carcinogens is the formation of DNA adducts (1). These adducts arise from chemical reactions in which DNA reacts with an electrophile, often an electrophile resulting from metabolism of the parent compound. Tamoxifen **1** (Scheme 1), an antiestrogen used in the treatment and control of breast cancer, is a hepatocarcinogen in the rat (2–4) and causes a small number of endometrial cancers in women (5–7). DNA adducts have been observed in both the animal models (8, 9) and in women treated with the drug (10–14). These are explained by the pathway of Scheme 1 (15–22), whereby an allylic carbocation **3** forms in an S_N1 ionization of a sulfate ester **2b**. The latter is derived from metabolic α-hydroxylation of the parent drug to α-hydroxytamoxifen **2a** followed by sulfate transfer. The principle DNA adducts **4** are isomers (see below) where the the α-carbon of the tamoxifen is attached to the NH_2 group of guanine residues (20–22). This position of attachment to guanine is characteristic of delocalized carbocations (1).

We have described experiments where the cation **3**, the "tamoxifen carbocation," was observed with laser flash photolysis (LFP) (23). The LFP approach has now been employed to study a number of carbocations (24). These are ground-state cations, identical to ones formed in S_N1 solvolyses. The significant advantage of the LFP method is that it is capable of providing direct information on reactivity, both towards the solvent (i.e., water) and to added nucleophiles. A nucleophile of interest because of the relation to carcinogenicity discussed above is guanine or a guanine derivative such as 2′-deoxyguanosine (**dG**). Our previous study (23) showed that the tamoxifen cation is quenched by **dG** in an aqueous solution. However, the selectivity over the reaction with solvent is poor, so that even at the highest concentrations of **dG**, the majority of the cation reacts with solvent. This behavior is typical of carbocations in water (25), but it contrasts dramatically with arylnitrenium ions, the DNA-binding electrophiles derived from carcinogenic amines. Both LFP studies (25, 26) and product analyses (27, 28) show that guanine derivatives are excellent nucleophiles for arylnitrenium ions, even in water.

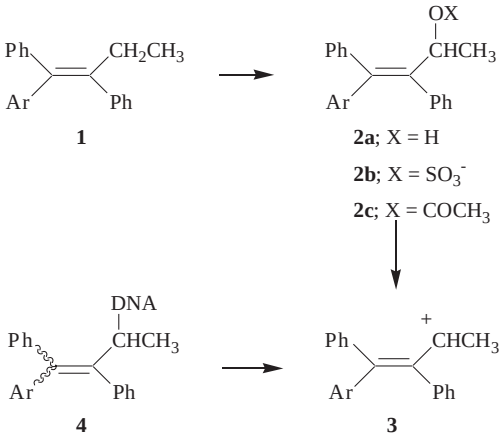
We have now performed a detailed study of the reaction of the tamoxifen cation with **dG**, employing LFP to measure absolute rate constants and product analyses (competition kinetics) for relative rate constants. Competition kinetic experiments have also been carried out with a diarylmethyl cation, the bis-(4-methoxyphenyl)methyl cation, which has a similar lifetime in water to the tamoxifen cation (29). These studies show that there is very pronounced effect of pH on the **dG** reaction. The neutral form of **dG** is quite unreactive as previously found (25). Its conjugate base, however, is far more reactive, so much so that at pH 7 the principal species that is reacting with the cations is the anion. The difference between the two forms of guanine has been recognized (30), but we are not aware of a detailed kinetic study demonstrating the magnitude of the effect, especially for short-lived carbocations.

Results and kinetic analysis

Rate pH-profiles in 100% aqueous solutions

In our original paper, the sulfate ester **2b** was employed as the precursor in the LFP experiments (23). A transient with

Scheme 1. Ar = C_6H_4-4-$OCH_2CH_2N(CH_3)_2$.



λ_{max} at 460 nm was identified as the tamoxifen cation on the basis of several criteria employed to assign carbocation intermediates (24). A key observation was the quenching by azide ion, in particular, the identity of the azide:water rate constant ratio with one obtained by competition kinetics (product analysis) for the ground-state solvolysis of the sulfate in aqueous solutions containing azide ion.

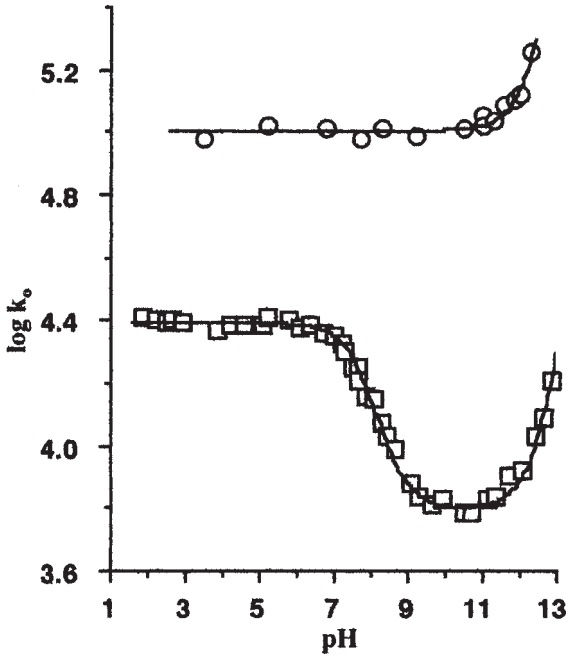
The sulfate ester has a high reactivity towards solvolysis in the ground state. This limits LFP experiments to solutions with considerable organic component (i.e., 40% acetonitrile) where the lower ionizing power slows the S_N1 reaction. Since acetate esters have been successfully employed as precursors of carbocations in LFP experiments (24), we investigated the appropriate tamoxifen derivative **2c**. This also produces the tamoxifen cation upon irradiation in aqueous solutions. This was established by comparing LFP results with the acetate and the sulfate in 40% acetonitrile. The two gave the same transient with the same decay kinetics.

The acetate is much more stable towards ground-state solvolysis, with a half-life in 100% water of 2 h. We therefore started by carrying out a detailed kinetic study of the decay of the tamoxifen cation in 100% aqueous solutions. Since the buffers accelerated the decay, experiments were performed with serial buffer dilutions at constant buffer ratio (and constant pH), and the rate constant obtained as the intercept of the plot of k vs. buffer concentration. These rate constants, along with ones obtained in solutions of perchloric acid and sodium hydroxide, are plotted as log k_o vs. pH in Fig. 1. Also plotted in this figure are rate constants obtained in a similar manner for the other cation of this study, the bis-(4-methoxyphenyl)methyl cation.

The profile for the latter cation is straightforward. There is a pH-independent region from acidic pH to a pH of about 11 that corresponds to the reaction of the cation with solvent water molecules. The rate constant is 1.0×10^5 s^{-1}. (Table 1 provides a summary of all rate and equilibrium constants measured in this work, along with their errors provided as one standard deviation.) At pH 11, there is a break to a reaction that is first order in hydroxide ion. This obviously represents the cation–hydroxide combination; the second-order rate constant is 3.8×10^6 M^{-1} s^{-1}. One noteworthy feature is the relatively little difference (a factor of 13) between k_w and k_{OH}, typical of short-lived cations in aqueous solutions (31–33).

© 2002 NRC Canada

Fig. 1. pH dependence of the logarithm of the rate constants for the decay of the tamoxifen cation (squares) and the bis-(4-methoxyphenyl)methyl cation (circles) in aqueous solutions. Temperature is 20°C and k_o has units of s^{-1}. The data for the tamoxifen cation have been obtained at a constant ionic strength of 0.10 M maintained with $NaClO_4$. The data for the bis-(4-methoxyphenyl)methyl cation were obtained in solutions with ionic strength less than 0.01 M. The cations were generated by LFP of acetate precursors with irradiation at 248 nm and detection at 460 nm (tamoxifen cation) and 500 nm (bis-(4-methoxyphenyl)-methyl cation). Rate constants in the region pH 3–11 were obtained in buffer solutions, and are based upon extrapolation to zero buffer concentration. The points are experimental. The line for the tamoxifen cation has been drawn on the basis of eq. [2] and the parameters given in the text.



The profile for the tamoxifen cation can be explained by recognizing that there is a side-chain amine. This means that there are two carbocations, a dication $\mathbf{T}^{2+}$ where the amine is protonated and a monocation $\mathbf{T}^{+}$ where the amine is neutral (Scheme 2). Both, in principle, can react with water and hydroxide, giving rise to eq. [1], where K_w is the autoprotolysis constant of water.

$$[1] \qquad k_o = \frac{k_w^{2+}[H^+] + k_{OH}^{2+}K_w + k_w^{+}K_a(\mathbf{T}) + \dfrac{k_{OH}^{+}K_wK_a(\mathbf{T})}{[H^+]}}{[H^+] + K_a(\mathbf{T})}$$

This takes the form of a four-parameter equation (eq. [2]) where $y = k_o$ and $x = [H^+]$.

$$[2] \qquad y = \frac{ax + b + c/x}{x + d}$$

The experimental data were fit to eq. [2] to provide the four parameters. Parameter d (1.34×10^{-8}) is the acidity constant, corresponding to a pK_a of 7.87. This means that the ammonium group in $\mathbf{T}^{2+}$ is one log unit more acidic than in the parent drug. This reflects the electron withdrawing influence of the delocalized positive charge associated with the allylic cation. Parameter a (2.5×10^4 s^{-1}), is equal to k_w^{2+}, the rate constant for water addition to the dication. In terms of the pH profile, this reaction dominates from acidic pH to a pH just before 9; the downward break between pH 7 and 8 is a reflection of the changing acid–base equilibrium. Parameter c ($k_{OH}^{2+}K_wK_a(\mathbf{T}) = 2.2 \times 10^{-17}$) explains the increase in base. This must be due to a reaction of the monocation $\mathbf{T}^{+}$ with hydroxide ion. With $K_a(\mathbf{T})$ known, the rate constant k_{OH}^{+} can be calculated; the value is 1.6×10^5 M^{-1} s^{-1}.

Parameter b (8.4×10^{-5}) accounts for the pH-independent region between pH 9 and pH 11. There are two kinetically equivalent processes that could be responsible, the reaction of hydroxide ion with the dication $\mathbf{T}^{2+}$ and the reaction of water with the monocation $\mathbf{T}^{+}$. The former can be ruled out, since it requires a value of k_{OH}^{2+} of 8.4×10^9 M^{-1} s^1, several orders of magnitude greater than expected. As noted above, hydroxide would not react with a cation of the aqueous lifetime of $\mathbf{T}^{2+}$ at anywhere near this rate. Our conclusion, therefore, is that the pH-independent region in weakly basic solution represents water reacting with the monocation $\mathbf{T}^{+}$. The rate constant for this process (k_w^{+}) is 6.3×10^3 s^{-1}, fourfold smaller than the rate constant k_w^{2+} for the reaction of water with $\mathbf{T}^{2+}$. This greater reactivity of the dication is not surprising. There is undoubtedly a significant stabilization in both cations by the π-interaction with the oxygen of the dimethylaminoethoxy group. This interaction will be stronger when that group is neutral as opposed to where the amine is protonated. In other words, the $(CH_3)_2NCH_2CH_2O$- group must be a better π donor than the $(CH_3)_2HN^+CH_2CH_2O$- group.

Analysis of the rate constants associated with the buffer revealed that the rate accelerations were due to the basic component of the buffer, the terms in (B) that appear in Scheme 2. As with water and hydroxide, reaction in principle could occur with both $\mathbf{T}^{2+}$ and $\mathbf{T}^{+}$, although of the four buffers employed, only tris resulted in rate constants for both the dication and cation that were statistically significant (Table 1). The actual reaction occurring with the buffer is not known. The most likely scenario is a cation–nucleophile combination. However, a reaction where the buffer base acts as a general base to assist the addition of water to the cation is also possible. Arguments have been made that the water reaction itself is generally base-catalyzed, with a second water molecule acting as the base (29).

Decay of the tamoxifen cation in the presence of 2′-deoxyguanosine

These experiments were carried out in 20% acetonitrile for solubility reasons. LFP experiments with **dG** as the trapping nucleophile require irradiation, at 308 nm, with our equipment where the **dG** does not absorb. While **2c** does have absorbance at this wavelength, it is weak. Thus, more concentrated solutions of the precursor were required. These concentrations could not be achieved in 100% aqueous solutions, especially solutions of higher pH where the side-chain amine of **2c** is not protonated. The use of 20% acetonitrile also meant that the solubility of **dG** was increased. Solutions with a **dG** concentration of 20 mM were possible, in contrast to 100% aqueous where 8 mM is about the maximum concentration.

Figure 2 provides the results. The rate constants for the solvent reaction were obtained as described in the previous

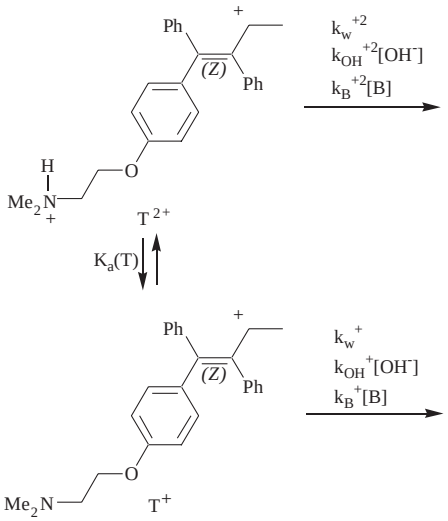
Scheme 2.



section, with (where appropriate) serial buffer dilutions providing the rate constants at zero buffer concentration. The rate constants for the reaction with **dG** were obtained using dilute buffers, with 5 to 6 concentrations of **dG** ranging from [**dG**] ~ 0.02 M to [**dG**] = 0 at each pH. The rate constants increased in the presence of **dG**. This acceleration was modest in the solutions with pH 4–6, with only about a 15% increase from the solution with no **dG** to the solution with the highest concentration. As the pH increased, however, the effect of **dG** became much more pronounced, and by pH 9 it was possible to triple the rate constant over that in the absence of **dG**. The observed rate constants were plotted against the concentration of added **dG**. These plots were linear. Their slopes, defined as k_{dG}, are plotted as the circles in Fig. 2.

The solvent reaction was analyzed as in the previous section. Values of the parameters so obtained were $K_a(\mathbf{T}) = 5.5 \times 10^{-8}$ (p$K_a(\mathbf{T}) = 7.27$), $k_w^{2+} = 3.2 \times 10^4$ s^{-1}, and $k_w^{+} = 8.2 \times 10^3$ s^{-1}. The two rate constants are slightly larger than the ones obtained in the study in 100% aqueous solutions. This is a typical observation for carbocation–water reactions as acetonitrile is added (29). There is also a difference in the pK_a(**T**) value. This is likely also a solvent effect. Our previous study in 40% acetonitrile resulted in an even lower value of pK_a(**T**) (6.6) (23).

An interesting feature of the reaction with **dG** is that at about the point where the curve for the solvent reaction breaks downward, the profile for the **dG** reaction breaks upward. The reasons for this must be different. The downward break in the solvent profile occurs because of the conversion of $\mathbf{T}^{2+}$ to $\mathbf{T}^{+}$. The upward break in the **dG** profile must represent the onset of a new reaction, the reaction of the cation with the conjugate base of **dG**. This leads to the kinetic model of Scheme 3, which shows the nucleoside reaction occurring in four ways. Both the neutral form of **dG** (**dG-H**) and its conjugate base ($\mathbf{dG}^-$) are nucleophiles, and each, in principle, reacts with $\mathbf{T}^{2+}$ and $\mathbf{T}^{+}$.

The kinetic system of Scheme 3 gives rise to eq. [3] for k_{dG}.

$$[3] \qquad k_{dG} = \frac{(k_n^{2+}[H^+]^2 + \{k_a^{2+}K_a(\mathbf{G}) + k_n^{+}K_a(\mathbf{T})\}[H^+] + k_a^{+}K_a(\mathbf{G})K_a(\mathbf{T}))}{([H^+] + K_a(\mathbf{T}))([H^+] + K_a(\mathbf{G}))}$$

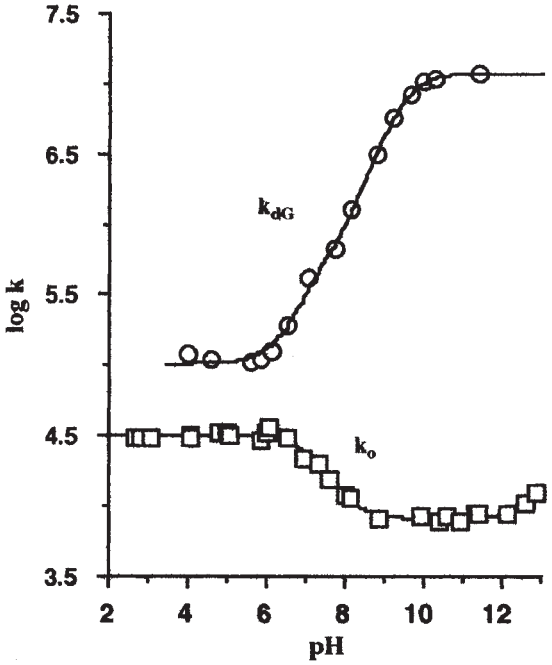
Fig. 2. pH dependence of the logarithm of the rate constants for the decay of the tamoxifen cation in solvent (squares) and the quenching by 2′-deoxyguanosine (**dG**) (circles). Temperature is 20°C, and the solvent is 20:80 (v:v) acetonitrile–water with ionic strength maintained at 0.10 M with sodium perchlorate. Units of k are s^{-1} (solvent reaction) and M^{-1} s^{-1} (**dG** reaction). The cation was generated by excitation of **2c** at 248 nm (solvent data) and 308 nm (**dG** data). The points are experimental. The lines have been drawn on the basis of eq. [2] (solvent reaction) and eq. [4] (**dG** reaction).



This equation contains two acid acidity constants (K_a(**T**) and K_a(**G**)) referring, respectively, to the ammonium group of the tamoxifen cation and the N1-H proton of **dG**. The rate constants are identified with superscripts "2+" and "+" to differentiate reactions with $\mathbf{T}^{2+}$ and $\mathbf{T}^{+}$ and with subscripts "n" and "a" to differentiate reactions with the neutral and anionic forms of the nucleoside. This equation takes the form of eq. [4], with five adjustable parameters.

$$[4] \qquad y = \frac{ax^2 + bx + c}{(x + d)(x + e)}$$

The experimental data were fit to this equation with the parameter $d = K_a$(**T**) fixed at the value of 5.5×10^{-8} obtained from the analysis of the water reaction. The other four were allowed to vary to values providing the best fit.

The parameter e (5.3×10^{-9}) is the acidity constant for **dG**, and corresponds to a pK_a value of 9.27. We also measured this value spectroscopically under the same solvent conditions, and obtained a value of 9.37. Within the experimental error (Table 1), the value obtained from the kinetic fit is identical. The parameter $a = k_n^{2+} = 1.0 \times 10^5$ M^{-1} s^{-1} is the rate constant for the reaction of the neutral form of **dG** with the dication $\mathbf{T}^{2+}$. The parameter c (3.4×10^{-10}) is equal to $k_a^+ K_a$(**T**)K_a(**G**) and represents the reaction of the conjugate base of **dG** with $\mathbf{T}^{+}$. With values of the acidity constants known, k_a^+ is calculated as 1.2×10^7 M^{-1} s^{-1}. The parameter b (3.4×10^{-2}) represents two kinetically equivalent processes, neutral **dG** reacting with $\mathbf{T}^{+}$ (the k_n^+ process) and anionic **dG** reacting with $\mathbf{T}^{2+}$ (the k_a^{2+} process). The latter must be the major contributor. If the former is responsible, $b = k_n^+ K_a$(**T**), which requires k_n^+ to be 6.2×10^5 M^{-1} s^{-1}. This is a sixfold greater than k_n^{2+}, the rate constant for the reaction of neutral **dG** with the dication. This makes no sense since the dication is the more reactive species. Based upon results for other nucleophiles, k_n^+ will lie in the range $1.5–3 \times 10^4$ M^{-1} s^{-1}, a factor of three to six times smaller than k_n^{2+}. We therefore conclude that the k_n^+ process could contribute about 3% to the term in b. However, 97% of this term must be due to the process in k_a^{2+}. Using this 97% factor, k_a^{2+} is calculated as 6.4×10^7 M^{-1} s^{-1}. It can be seen that this is consistent with the greater reactivity of the dication — k_a^{2+} is fivefold larger than k_a^+.

Scheme 3.

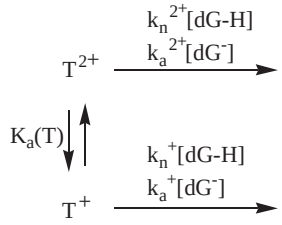


Figure 3 shows how the observed rate constants for the reaction of the tamoxifen cation and **dG** are broken down into the contributions from the four reactions. The curves in this figure were calculated using the rate constants provided in the previous paragraph (with an estimate for k_n^+ of 2×10^4). It can be seen that under acidic conditions the reaction that occurs involves $\mathbf{T}^{2+}$ and the neutral form of **dG**, while under basic conditions, $\mathbf{T}^{+}$ reacts with the anion of **dG**. The principle contributor at pH 7 is the reaction of $\mathbf{T}^{2+}$ with the conjugate base.

Tamoxifen cation and deoxyguanosine — competition kinetics

The experiments described in this section were performed to determine if the pH effect is also observed in the products. The principle adduct of the tamoxifen cation and **dG** has been isolated and characterized previously as compound **TdG** of Scheme 4 (22). This is formed as four diastereomers, arising from the combinations of the (*R*) and (*S*) forms at the α stereocenter and (*E*) and (*Z*) forms about the C=C. The latter arise because the cation undergoes rapid rotation about this bond before capture by nucleophiles. HPLC analysis of this mixture then provided retention times for the four isomers under our HPLC conditions.

Experiments were then performed in which the acetate **2c** was added to solutions of 20% acetonitrile containing 2′-deoxyguanosine, and the ground-state solvolysis reaction allowed to proceed to completion overnight. The products were analyzed by HPLC. With appropriate correction for relative HPLC sensitivities, this provided the ratio of the sum of the concentrations of the four adducts [**TdG**] to the sum of the concentrations of the (*E*) and (*Z*) alcohols [**TOH**]. This ratio was then converted to a competition-kinetic ratio according to eq. [5], where [**dG**] was the concentration of the nucleoside in the solution.

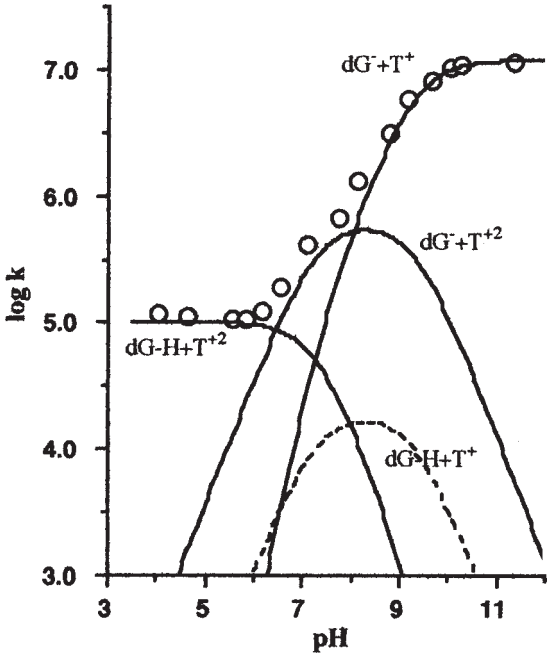
Fig. 3. Breakdown of the reaction of 2′-deoxyguanosine and the tamoxifen cation into components.



[5] $k_{\mathbf{dG}}/k_o = (1/[\mathbf{dG}])([\mathbf{TdG}]/[\mathbf{TOH}])$

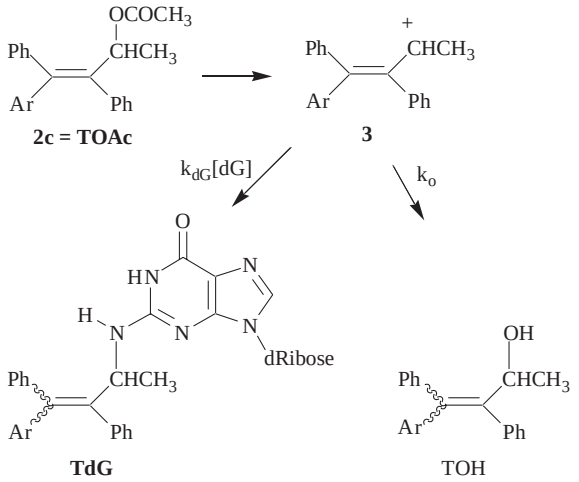
The results are plotted in Fig. 4, and show the same trend as observed in the absolute rate constants, with a significant increase in the selectivity ratio at higher pH. In terms of the analysis of the previous sections, this ratio is given by eq. [6] (see below), obtained by dividing eq. [3] by eq. [1].

The line drawn through the experimental points in Fig. 4 is based on a fit to this equation. Because of the number of parameters involved, the fitting was performed by fixing the values of $K_a(\mathbf{T})$, $K_a(\mathbf{G})$, and $k_w^+:k_w^{2+}$ at the values obtained previously, 5.5×10^{-8}, 5×10^{-10}, and 0.256, respectively. This left the three rate constant ratios as variables; values are provided in Table 1. Also given in this table are values of the same ratios calculated from the absolute rate constants measured with LFP. The values of $k_n^{2+}:k_w^{2+}$ obtained by the two methods are not outside of experimental error. The two values of $k_a:k_w$ are, however, statistically different, with the LFP ratio greater than the product ratio in both cases. A possible explanation is provided in the *Discussion*.

Bis-(4-methoxyphenyl)methyl cation and deoxyguanosine — Competition kinetics

These experiments were performed following the same procedure described in the previous section, with the cation (designated as $\mathbf{D}^+$) being obtained by solvolysis of the acetate ester in solutions of 20% acetonitrile containing **dG**. The HPLC traces showed the peak for the alcohol product **DOH** and three peaks associated with a reaction with **dG**. Since this cation does not generate a new stereocenter (or C=C isomers), each of these peaks must represent a product derived from a different position of attachment to the **dG**.

Scheme 4.



This means that there are four reactions occurring in parallel, one forming alcohol and three forming different **dG** adducts (Scheme 5). These adducts are designated as **DdG1**, **DdG2**, and **DdG3** in order of increasing HPLC retention times.

Figure 5 shows how the areas of the peaks for the four products vary with pH for experiments performed with constant concentrations of **dG** and acetate ester. Under acidic conditions (pH 3–5) the areas are constant. The alcohol is the major product, with only small peaks for the three adducts (note the scale in Fig. 5 is logarithmic). As the pH increases, the alcohol peak decreases significantly, the peaks for **DdG1** and **DdG2** grow, and the peak for **DdG3** disappears. Under basic conditions there is another constant region, with the major peak corresponding to **DdG1**.

A sample of **DdG1** was isolated from a scaled-up reaction at high pH. The NMR spectra in DMSO-d_6 clearly established that this is the N2-adduct. Features of the NMR leading to this assignment were the down-field proton (10.4 ppm) integrating as 1H characteristic of N1H of guanine derivatives, the proton at C8 in its characteristic position near 7.8 ppm, and a proton at 7.4 ppm integrating only as 1H for N2H. The attachment N2H was most clearly seen by the coupling of this proton and the methine proton of the diarylmethyl group (6.0 ppm). This coupling was verified by a 2D COSY experiment.

With a sample of **DdG1** available, the HPLC area ratio for this peak relative to the alcohol was converted to a concentration ratio, and then, with eq. [7], into a ratio of rate constants.

[7] $k_{\mathbf{dG1}}/k_o = (1/[\mathbf{dG}])([\mathbf{DdG1}]/[\mathbf{DOH}])$

The pH dependence of this ratio is shown in Fig. 6. As with the tamoxifen cation the selectivity is modest in acidic solutions, but becomes much more significant at higher pH.

Figure 6 can be explained by a kinetic model where the cation reacts with water in a pH-independent manner to form

[6] $$k_{dG}/k_o = \frac{(k_n^{2+}/k_w^{2+})[H]^{2+} + (k_a^{2+}/k_w^{2+})K_a(\mathbf{G})[H^+] + (k_a^+/k_w^+)(k_w^+/k_w^{2+})K_a(\mathbf{G})K_a(\mathbf{T})}{([H^+] + (k_w^+/k_w^{2+})K_a(\mathbf{T}))([H^+] + K_a(\mathbf{G}))}$$

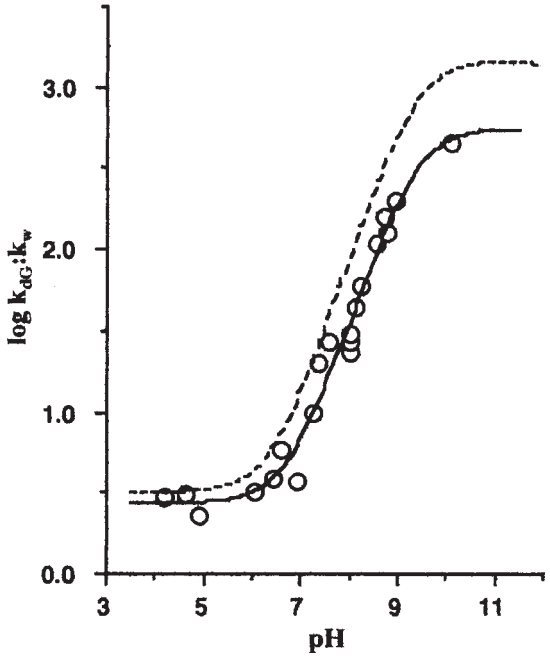
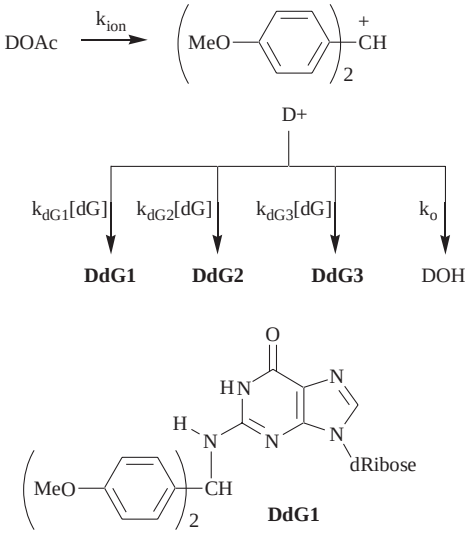
Fig. 4. pH dependence of the logarithm of the ratio of rate constants k_{dG}:k_w for the competition for the tamoxifen cation between 2′-deoxyguanosine and water. Temperature is 20°C, and the solvent is 20:80 (v:v) acetonitrile–water with ionic strength maintained at 0.10 M with sodium perchlorate. The circles are the experimental data obtained by analysis of the products of the ground-state solvolysis of the acetate **2c**. The solid line was obtained by fitting the data to eq. [6] as described in the text. The dashed line is the ratio of the absolute rate constants measured by LFP; this line was calculated as the difference between the two lines drawn in Fig. 2.



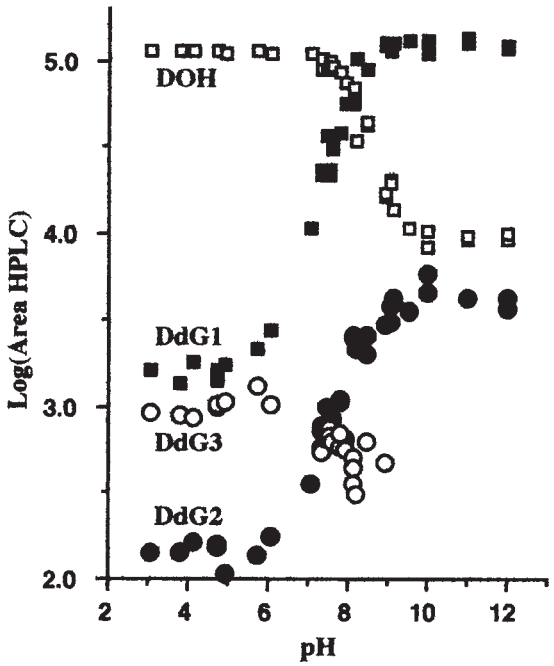
Scheme 5.



the alcohol, while adduct **DgD1** is formed from both neutral **dG** and its anionic conjugate base. This leads to eq. [8],

$$[8] \qquad k_{\mathbf{dG1}} / k_o = \frac{(k_n^1/k_w)[H^+] + (k_a^1/k_w)K_a(\mathbf{G})}{[H^+] + K_a(\mathbf{G})}$$

Fig. 5. pH dependence of the logarithm of the HPLC areas for the four products observed in the reaction of the bis-(4-methoxyphenyl)methyl cation in 20% acetonitrile in the presence of 2′-deoxyguanosine. The cation was obtained from the solvolysis of bis-(4-methoxyphenyl)methyl acetate. The experiments were performed with a constant concentration of **dG** (0.0096 M) and a constant concentration of the acetate (100 μM).



where $K_a(\mathbf{G})$ is the acidity constant of **dG**, k_w is the rate constant for the reaction with water, and k_n^1 and k_a^1 are the rate constants for reactions forming adduct **DgD1**. As above, the subscripts "n" and "a" represent reactions of the neutral and conjugate base forms of **dG**. The superscript "1" indicates that these are reactions forming **DdG1**. Equation [8] contains three variables, two rate constant ratios, and the acidity constant. The experimental data were fit to this equation with all three parameters as adjustable parameters. The results are provided in Table 1. It can be seen that the value of the acidity constant is within experimental error the same as values obtained by a spectroscopic analysis and a kinetic analysis of the tamoxifen system.

The other two **dG** adducts have not been identified. Under acidic conditions where the neutral form of **dG** is reacting, the area of the peak for **DdG3** is 60% of that for **DdG1**. However, both are minor components of the reaction mixture. With the assumption that the HPLC sensitivity for **DdG3** is the same as that of **DdG1**, the ratio k_n^3:k_w is only 0.7 M^{-1}. This means that even at the highest concentrations of **dG** attainable (~20 mM), the yield of **DdG3** is only around 1%. The peak for this adduct is not observed in the basic solutions where the anion of **dG** is reacting. Either this adduct is not formed by the reaction with the anion, or its yield is very small in comparison with the other products.

DdG2 follows the pattern of the major adduct with a significant increase relative to alcohol when the **dG** reacts as the anion. The assumption of the same HPLC sensitivity results in ratios k_n^2:k_w = 0.1 M^{-1} and k_a^2:k_w = 45 M^{-1}. While the latter shows relatively good selectivity over the alcohol,

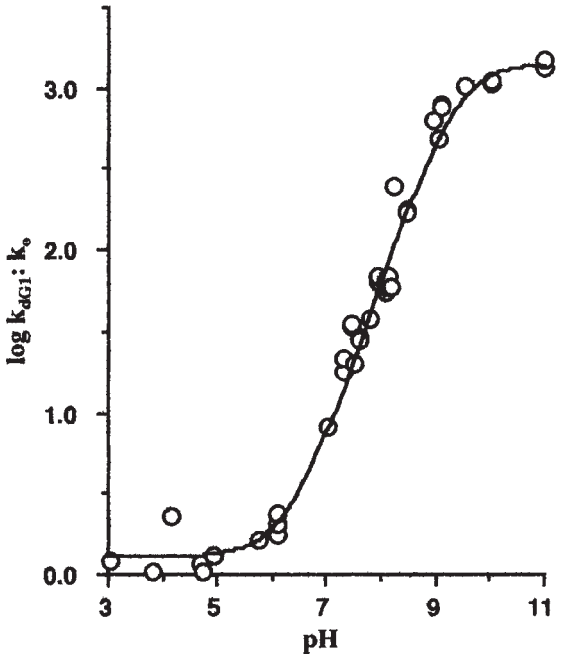
Fig. 6. pH dependence of the logarithm of the ratio of rate constants k_{dG}:k_w for the competition for the bis-(4-methoxyphenyl)-methyl cation between 2′-deoxyguanosine and water. Temperature is 20°C, and the solvent is 20:80 (v:v) acetonitrile:water. The circles are the experimental data obtained by analysis of the products of the ground-state solvolysis of the bis-(4-methoxyphenyl)methyl acetate. The line was obtained by fitting the data to eq. [8].



k_a^2:k_a^1 is only 0.03. Thus the yield of **DdG2** is never greater than 3%.

Finally, we note the evidence that the reaction has proceeded via S_N1 solvolyses. This takes the form of experiments where the first-order rate constant for the disappearance of **DOAc** was measured by HPLC. In 20% acetonitrile with the pH at 9.5, rate constants of 0.0018 s^{-1} and 0.0017 s^{-1} were measured for solutions with [**dG**] = 0 and [**dG**] = 0.0096, respectively. The products in the latter are around 90% adducts. The observation that the rate constant is unchanged, within experimental error, shows that the product-determining step has occurred after the rate-determining step; i.e., the reaction is S_N1. A similar experiment was not necessary with the tamoxifen system. The observation of C=C isomers in the products shows that there must have been a cationic intermediate.

Discussion

An attractive approach to model DNA–electrophile interactions is to investigate the reaction with a monomer such as 2′-deoxyguanosine. In this study electrophiles were two delocalized carbocations, the allylic cation derived from the carcinogen tamoxifen, and the bis-(4-methoxyphenyl)methyl cation. Lifetimes of these electrophiles in aqueous solution are 10–200 ms. By carbocation standards, these are relatively long-lived (24). Some relevant comparisons are the benzylic cations derived from ring opening of the diol epoxides of the carcinogen benzo[*a*]pyrene — lifetimes of the order of 50 ns in water (34, 35) — the *p*-methoxybenzyl cation, a benzylic system that has been studied with guanine in the past (36–38) — lifetime of 5 ns (39) — and the diphenylmethyl cation — lifetime of 800 ps (40). The parent benzyl cation is too short-lived to exist in water (41).

The cations of this study clearly show significant differences in reactivity towards the neutral form of 2′-deoxyguanosine and its conjugate base. This difference is seen in the guanine:water selectivities obtained by analyzing products of solvolysis reactions. It is also seen in the absolute rate constants measured with LFP. A greater reactivity of the conjugate base form of a nucleophile is hardly surprising. Previous studies of guanine–electrophile interactions have commented on this in qualitative terms (30, 36–38). We are not aware of a quantitative study, particularly one where rate constants and rate constant ratios were obtained for intermediate carbocations.

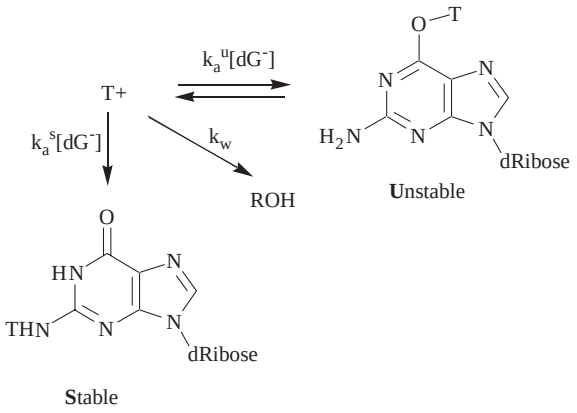
For the cations of this study, the difference between the rate constants for the neutral form of **dG** and the conjugate base is about three orders of magnitude. This results in very different selectivities over the solvent reaction. Under acidic conditions where it is the neutral form of **dG** that reacts, the cations preferentially react with water even at the highest concentrations of **dG**. Arylnitrenium ions, the reactive electrophiles derived from arylamine carcinogens, provide an interesting contrast here. These cations react very efficiently with **dG**, with a high selectivity over the water reaction (25–28). This reaction involves the neutral form of **dG**, since the rate constant is unchanged over the pH range 3.5–8.0 (25). (Studies of arylnitrenium ions with anionic **dG** are currently in progress). The following comparison shows how dramatic the difference is. When the tamoxifen cation (as the $\mathbf{T}^{2+}$ form) reacts in acidic solutions containing 1 mM **dG**, only 0.3% of the products are derived from the nucleoside, 99.7% being the alcohol obtained from capture by solvent. The percentage of adducts is even lower for the bis-(4-methoxyphenyl)methyl cation under the same conditions. The 2-fluorenylnitrenium ion has an aqueous lifetime that is identical to that of $\mathbf{T}^{2+}$. When this cation reacts in 1 mM **dG**, 96% of the products are derived from the nucleoside and only 4% from the solvent (24).

Changing to basic conditions where the **dG** has been converted to its conjugate base results in much higher selectivities towards the nucleoside. For example, the bis-(4-methoxyphenyl)methyl cation reacting at pH 11 in the presence of 1 mM **dG** will form 60% **dG** adduct. This is obviously an attractive method for the preparation of adducts for the purpose of structural characterization. The difference between the two forms of **dG** is such that by pH 7 to 7.5, the majority of the reaction that does occur with the nucleoside is the reaction with the small fraction of anion that is present. This is also reflected in an improved selectivity over the solvent reaction. As one example, the **dG**:water selectivity for the bis-(4-methoxyphenyl)methyl cation at pH 7.3 has increased to 13 from its acidic value of 1.2. This increase occurs since 91% of the reaction with **dG** at pH 7.3 is occurring via the conjugate base.

In the tamoxifen system, a comparison was made between ratios of rate constants for the **dG** and water reactions obtained by product analysis and ratios calculated from the absolute rate constants measured with LFP. The two ratios for

© 2002 NRC Canada

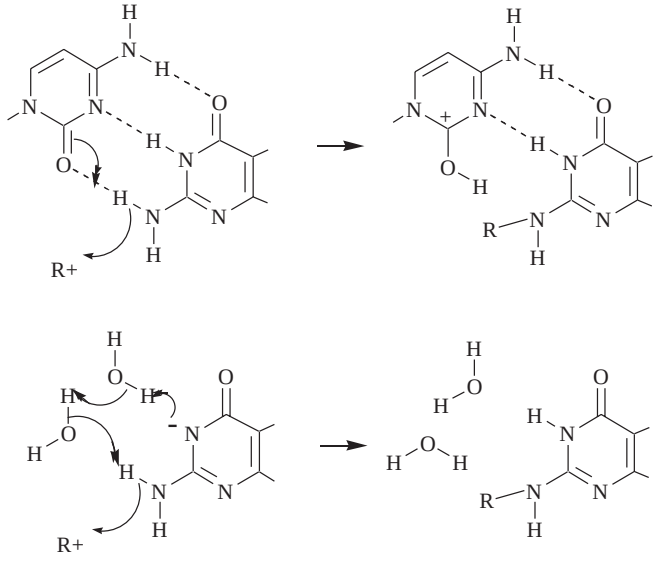
Scheme 6.



the competition involving the neutral form of **dG** and water were not outside of experimental error (although this error was quite large). On the other hand, the ratios for the anion of **dG** vs. water were statistically different, with a greater ratio being obtained by the LFP experiments. The difference is almost a factor of three. There is a very large difference in the time scales of the two experiments. The LFP measurements occurred on the microsecond time scale. The product analyses, on the other hand, were carried out after 16–24 h, the time required for complete solvolysis of the acetate. This leads to an explanation whereby the reaction of the cation with **dG** anion proceeds reversibly to an unstable adduct in addition to its irreversible reaction forming the stable product, the N2 adducts (Scheme 6). The quenching by the **dG** anion measured as the second-order rate constant in the LFP experiment would then correspond to the sum of the rate constants for the formation of the unstable and stable products ($k_a^u + k_a^s$). The rate constant in the competition experiment would only refer to the latter (k_a^s). Thus, the ratio for the latter would be smaller.

This scenario requires that the unstable adduct be "stable" on the time scale of the LFP experiment, i.e., that it last at least half a millisecond. On the other hand, it must have completely reacted before the products were analyzed. A structure that would satisfy these requirements is the adduct at O6 shown in Scheme 6. Such an adduct is an obvious product of the reaction of a carbocation and the anion of guanine, since it is at O6 that the majority of the negative charge will reside. O6-(*p*-methoxybenzyl)guanosine, the analog derived from the *p*-methoxybenzyl cation, has been shown to be unstable in aqueous solution (36). Its decomposition was pH independent at high pH, and the reaction was proposed to involve ionization to the *p*-methoxybenzyl cation and the guanosine anion. The half-life for this ionization was about 0.5 h. Both the tamoxifen cation and the bis-(4-methoxyphenyl)methyl cation are more stable than *p*-methoxybenzyl, and thus ionizations that result in these cations will be considerably faster. This can be seen in the observation that the acetate esters derived from the two solvolyze at a reasonable rate in water, while *p*-methoxybenzyl acetate is very stable under these conditions. Thus, an O6 adduct formed with the tamoxifen cation (or the bis-(4-methoxyphenyl)methyl cation) is expected to be quite short-lived. It could well survive the time scale of the LFP experiment, but it would not be around after several hours.

Scheme 7.



Despite the fact that the negative charge in the **dG** anion is at O6 (and N1), there is still a remarkably large rate constant for the reaction that forms the N2 adduct. This effect is best seen in the competition kinetic experiments with the bis-(4-methoxyphenyl)methyl cation where a single carbocation was involved and the N2 adduct:water product ratio was measured and converted to a rate-constant ratio. The latter changes from 1.2 (k_n^1:k_w) for neutral **dG** to 1500 (k_a^1: k_w) for the anion. The rate constant k_w is the same in the two ratios, with a value of 1.3×10^5 s^{-1} in this solvent (29). Thus, the rate constant k_n^1 for the formation of the N2 adduct with neutral **dG** is 1.6×10^5 M^{-1} s^{-1}, and k_a^1 for the anion is 2.2×10^8 M^{-1} s^{-1}, over three orders of magnitude greater.

Observations of enhanced formation of N2 adducts in the anion of guanine have been made previously (36–38), although it is not clear if free carbocations were involved in all cases. The N2 adduct is also the principle product of the reaction of DNA with the tamoxifen carbocation (20–22), as well as a number of other electrophiles (1). In DNA one of the NH_2 protons is involved in hydrogen bonding to the complementary cytosine. This has led to the recent proposal (42) of a mechanism whereby the proton in the hydrogen bond transfers to the neighboring cytosine as the nitrogen–electrophile bond is forming (top reaction of Scheme 7). In other words, the neighboring cytosine acts as a base to assist the reaction of the NH_2 group by removing one of its protons as the reaction proceeds.

A similar mechanism would explain the high reactivity of the NH_2 group in the guanine anion. Here the base would be the adjacent partially negatively charged nitrogen at N1. The proton at NH_2 could be transferred directly to N1 through a four-center transition state or, perhaps, through the intervention of surrounding water molecules, as shown in the bottom mechanism in Scheme 7. In any case the reaction would lead directly to the product, and there with little or no build-up of positive charge at N2.

Experimental section

α-Hydroxytamoxifen and α-acetoxytamoxifen ((*E*)-1-[4-[2-(dimethylamino)ethoxy]phenyl]-1,2-diphenyl-1-buten-3-ol and its acetate ester) were available from a previous study (43) as were bis-(4-methoxyphenyl)methanol and bis-(4-methoxyphenyl)methyl acetate (44).

*N*2-Bis-(4-methoxyphenyl)methyl-2′-deoxyguanosine was isolated from a scaled-up reaction. 2′-Deoxyguanosine (286 mg, 1 mmol) was added to a mixture of 20 mL acetonitrile and 30 mL of water, and 0.9 mL (0.9 mmol) of sodium hydroxide was added. A solution of bis-(4-methoxyphenyl)methyl acetate (200 mg, 0.7 mmol) in 5 mL of acetonitrile was then slowly added over 8 h, and the mixture left to stand at room temperature, with periodic monitoring by HPLC. When, after 3 days, this indicated that there was no ester remaining, the pH was adjusted to about 5 by the addition of a small amount of 1 M HCl, and the mixture concentrated with a rotary evaporator until only water remained. At this point, a precipitate had formed, which was isolated by filtration. This solid was purified by column chromatography on silica gel with 100% ethyl acetate as the eluting solvent. Fractions were analyzed by HPLC and the fractions containing the adduct were combined and the solvent removed. The solid obtained was purified by dissolving it in a small amount of methanol and then induction of precipitaton by the addition of water. The solid showed only a single peak on HPLC corresponding to the adduct identified as **DdG1**. This was characterized as *N*2-bis-(4-methoxyphenyl)methyl-2′-deoxyguanosine by ^{1}H NMR, with coupled protons being identified by gCOSY experiments. ^{1}H NMR (500 MHz, DMSO-d_6) δ: 2.05–2.10 (m, 1H, H2$_a$′), 2.55–2.6 (m, 1H, H2$_b$′), 3.40–3.45 (m, 1H, H5$_a$′), 3.55–3.60 (m, 1H, H5$_b$′), 3.70 (s, 6H, OCH_3), 3.80 (m, 1H, H4′), 4.30 (m, H3′), 4.83 (t, 1H, C5′-OH), 5.22 (d, 1H, C3′-OH), 6.02 (d, 1H, C_α-H), 6.08 (t, 1H, H1′), 6.94 (d, 4H, Ar-H), 7.21 (d, 4H, Ar-H), 7.36 (d, 1H, N2-H), 7.84 (s, 1H, H8), 10.35 (s, 1H, N1-H). Mass spectra of this material, even with soft ionization techniques, showed only a very small peak for the molecular ion (m/z = 492).

LFP experiments involved ca. 20 ns pulses at 248 or 308 nm (60–120 mJ per pulse) from a Lumonics excimer laser. A pulsed xenon lamp provided the monitoring light. After passing through a monochromator, the signal from the photomultiplier tube was digitized and sent to a computer for analysis. Stock solutions of the acetates (α-acetoxytamoxifen and bis-(4-methoxyphenyl)methyl acetate) of concentration 20–50 mM were prepared in acetonitrile. Immediately before irradiation a small volume was added to the solution of interest (usually in a 25 mL volumetric flask). Final concentrations of the acetates were 50 μM (α-acetoxytamoxifen in water) and 200–300 μM (α-acetoxytamoxifen in 20% acetonitrile and bis-(4-methoxyphenyl)methyl acetate). The solutions were irradiated with laser light at 248 nm (when studying the reaction with the solvent) and at 308 nm (α-acetoxytamoxifen in the presence of 2′-deoxyguanosine). The signals of the transient carbocations were monitored at 460 nm (tamoxifen cation) and 500 nm (bis-(4-methoxyphenyl)methyl cation). These showed excellent first-order decays. Observed first-order rate constants were obtained by fitting the experimental data of absorbance vs. time to the exponential equation. Rate constants for the solvent reaction were obtained as the average of five to eight kinetic runs. For the decay of the tamoxifen cation in the presence of 2′-deoxyguanosine, 12–16 kinetic runs were averaged. The pH of the solutions was established by the use of perchloric acid (pH < 3), sodium hydroxide (pH > 11) with acetate, phosphate, tris, and carbonate buffers in between. When a buffer was employed, serial dilutions were performed to provide four to five solutions of the same pH (as verified by recording the pH with a pH meter). The observed rate constants were linear in the buffer concentration, and the value of k_o, the rate constant in the absence of the buffer, was obtained as the intercept at zero buffer concentration. The experiments with **dG** present were performed with dilute solutions of the buffers (total concentration less than 0.01 M) with four to five concentrations of **dG** ranging up to 20 mM. The rate constants $k_{\mathbf{dG}}$ were obtained by linear regression of the plot of the observed rate constants against the added concentrations of **dG**.

The value of the acid dissociation constant of 2′-deoxyguanosine was measured in 20% acetonitrile, ionic strength = 0.1 M, 20°C by preparing a series of buffer solutions to which had been accurately added the same constant concentration (100 μM) of the nucleoside. Spectra were recorded with a HewlettPackard diode array spectrometer, and titration curves of absorbance vs. pH constructed at several wavelengths. These were fit to the equation $A = (A_{acid}[H^+] + A_{base}K_a)/([H^+] + K_a)$, A_{acid} and A_{base} are the plateau absorbances at low pH and high pH, respectively.

HPLC experiments were performed with a Waters HPLC system comprising a Waters 600E system controller, a Waters 486 tunable absorbance detector set at 238 nm, a Waters 746 data module, and a Waters U6K injector. The column employed was a Waters Symmetry C18 column of 5 μm particle size and dimensions 4.6 mm × 150 mm; the eluting solvent was first passed through a guard column of the same packing material and 4.6 × 25 mm dimensions. Solvents were sparged with helium.

Solutions of α-acetoxytamoxifen and bis-(4-methoxyphenyl)methyl acetate were prepared as described above, by adding the concentrated stock solution in acetonitrile to a solution of 20% acetonitrile. The entire set of experiments with each acetate were performed with the same stock solution to ensure that the final solutions were all of the same concentration, around 100 μM. The solutions were allowed to stand at room temperature for a period of 16–24 h, sufficient time that the signal of the acetate in the HPLC had disappeared.

The products from the α-acetoxytamoxifen were analyzed at 260 nm. Elution at 1 mL min^{-1} involved: (*i*) an initial 0.5 min isocratic run at 25% acetonitrile – 75% acetate buffer (pH 4.5, 0.05 M); (*ii*) a linear gradient to 85% acetonitrile – 15% acetate buffer over 13.5 min; (*iii*) a 3 min isocratic run at 85% acetonitrile – 15% acetate buffer. Peaks were observed at 1 to 2 min (**dG**), 10.5, 10.6 (overlapping (*E*)-**TdG** isomers), 11.8, 11.9 (overlapping (*Z*)-**TdG** isomers), 12.8 ((*E*)-**TOH**)), and 13.5 ((*Z*)-**TOH**). The areas for these peaks were converted into concentration ratios as follows:

$$[9] \qquad [\mathbf{TdG}]/[\mathbf{TOH}] = (1/RF)(\text{Area}(\mathbf{TdG})/\text{Area}(\mathbf{TOH}))$$

© 2002 NRC Canada

where [**TdG**], [**TOH**], Area(**TdG**), and Area(**TOH**) are the sums of the concentrations and HPLC areas of the four **dG** adducts and the two alcohols, respectively, and *RF* is the relative HPLC response factor. The latter was obtained as follows. For a series of solutions of the same total concentration of products, eq. [10] applies:

$$[10] \quad [\mathbf{TdG}] + [\mathbf{TOH}] = \text{Area}(\mathbf{TdG})/F(\mathbf{TdG}) + \text{Area}(\mathbf{TOH})/F(\mathbf{TOH}) = [\mathbf{TOAc}]_o$$

where F(**TdG**) and F(**TOH**) are the HPLC sensitivities of the adducts and alcohols, respectively, and $[\mathbf{TOAc}]_o$ is the constant total concentration of products determined by the initial concentration of acetate ester. Rearrangement gives eq. [11]:

$$[11] \quad \text{Area}(\mathbf{TdG}) = -(F(\mathbf{TdG})/F(\mathbf{TOH}))\text{Area}(\mathbf{TOH}) + F(\mathbf{TdG})[\mathbf{TOAc}]_o$$

where F(**TdG**):F(**TOH**) is equal to *RF*. A plot of the total area of the adducts was indeed linear in the sum of the area of the two alcohols. The slope (–2.2) was the negative of *RF*. It should be noted that there are two assumptions in this treatment: **TdG** and **TOH** account for the products and the HPLC sensitivities of the four forms of **TdG** are equivalent, as is also the case for the two forms of **TOH**. The former is true to at least 95%. There were other small peaks in the HPLC chromatogram (including the cyclic indenes (43)) but these never amounted to more than 5% in total. The identical sensitivities of the two alcohols was seen in the previous study. Further confirmation that this *RF* is reasonable is evident from the observation that the sum of the extinction coefficients measured at 260 nm for 2′-deoxyguanosine and α-hydroxytamoxifen divided by the extinction coefficient for α-hydroxytamoxifen is 2.3. The latter is a relative response factor calculated with the assumption that the two chromophores in the adducts are independent and can be modeled by the chromophores in **dG** and the alcohol.

The products from bis-(4-methoxyphenyl)methyl acetate were analyzed at 230 nm. Elution at 2 mL min^{-1} involved: (*i*) an initial 2.0 min isocratic run at 25% acetonitrile – 75% phosphate buffer (pH 7, 0.02 M); (*ii*) a linear gradient to 50% acetonitrile – 50% phosphate buffer over 8 min; (*iii*) a 5 min isocratic run at 50% acetonitrile – 50% acetate buffer. Peaks were observed at 1 min (**dG**), 5.3 min (**DdG1**), 6.2 min (**DdG2**), 6.4 min (**DdG3**), and 9.0 min (DOH). The ratio of the concentration of the NH_2 adduct **DdG1** to alcohol was obtained with eq. [12] using a relative response factor of 1.25 obtained by coinjecting authentic samples of the two products.

$$[12] \quad [\mathbf{DdG1}]/[\mathbf{DOH}] = (1/RF)(\text{Area}(\mathbf{DdG1})/\text{Area}(\mathbf{DOH}))$$

First-order rate constants for the solvolysis of bis-(4-methoxyphenyl)methyl acetate were obtained by repeat injections starting immediately after preparation of the solution. The area of the peak for the acetate vs. time was fit to the exponential equation.

A novel metal-chain extension reaction: synthesis of $(X)[Os(CO)_3(CN\text{-}t\text{-}Bu)]_nMn(CO)_5$ (X = Cl, Br, I; *n* = 1, 2, 3)

Faming Jiang, Hilary A. Jenkins, David F. Green, Glenn P.A. Yap, and Roland K. Pomeroy

Abstract: Complexes of formula $(X)[Os(CO)_3(CN\text{-}t\text{-}Bu)]_nMn(CO)_5$ (X = Cl, Br, I; *n* = 1, 2, 3) have been prepared by the reaction of $Os(CO)_4(CN\text{-}t\text{-}Bu)$ with $Mn(CO)_5(X)$ in hexane at room temperature. The characterization of the complexes included the crystal structures of compounds with X = I, *n* = 1, 3 and X = Cl, Br, *n* = 2 (**2ClA** and **2BrB**). The trinuclear products were isolated as two isomers. The major isomer (**2XA**) has an isocyanide ligand attached to each osmium atom, whereas the minor isomer (**2XB**) has both of these ligands bound to the terminal Os atom. The structures contain Os_nMn chains with unbridged Os—Mn bonds (range of lengths are 2.870(1)–2.9245(8) Å) and for compounds with *n* = 2 or 3 Os—Os bonds (range of lengths are 2.8812(4)–2.8928(5) Å). The mechanism of formation is believed to involve replacement of a CO ligand with the $18e^-$ ligand $Os(CO)_4(CN\text{-}t\text{-}Bu)$ at the metal with the coordinated halide, followed by a rearrangement in which the halide ligand migrates to the donor Os atom with concomitant migration in the reverse direction of a carbonyl ligand. The preparation of $(OC)_4(t\text{-}BuNC)OsMn(CO)_4(Cl)$ with an Os–Mn dative bond is also reported along with the $(OC)_4(t\text{-}BuNC)OsRe(CO)_4(X)$ analogues.

Key words: manganese–osmium, rhenium–osmium, dinuclear, metal chain, dative metal–metal bond.

Résumé : On a préparé des complexes de formule $(X)[Os(CO)_3(CN\text{-}t\text{-}Bu)]_nMn(CO)_5$ (X = Cl, Br, I; *n* = 1, 2, 3) par réaction du $Os(CO)_4(CNB\text{-}t\text{-}Bu)$ avec du $Mn(CO)_5(X)$, dans l'hexane, à la température ambiante. La caractérisation des complexes a impliqué la détermination des structures cristallines des composés pour lesquels X = I avec *n* = 1 ou 3 et X = Cl ou Br et *n* = 2 (**2ClA** et **2BrB**). On a isolé deux formes isomères des produits trinucléaires. L'isomère principal (**2XA**) comprend un ligand isocyanure attaché à chaque atome d'osmium alors que, dans l'isomère minoritaire (**2XB**), chacun de ces deux ligands est attaché à l'atome d'osmium terminal. Les structures comportent des chaînes Os_nMn dans lesquelles on retrouve des liaisons Os—Mn qui ne sont pas pontées (longueurs des liaisons allant de 2,870(1) à 2,9245(8) Å) et, dans les cas où n est égal à 2 ou 3, on rencontre aussi des liaisons Os—Os (longueurs des liaisons allant de 2,8812(4) à 2,8928(5) Å). On croit que le mécanisme de formation implique premièrement le remplacement, au niveau du métal coordiné à l'halogène, d'un ligand CO par le ligand à $18e^-$ $Os(CO)_4(CN\text{-}t\text{-}Bu)$, suivi d'un réarrangement dans lequel le ligand halogène migre vers l'atome d'osmium donneur avec une migration concomitante d'un ligand carbonyle dans la direction inverse. On rapporte aussi la préparation du $(OC)_4(t\text{-}BuNC)OsMn(CO)_4(Cl)$ comportant une Os–Mn liaison dative ainsi que celles de ses analogues $(OC)_4(t\text{-}BuNC)OsRe(CO)_4(X)$.

Mots clés : manganèse–osmium, rhénium–osmium, dinucléaire, chaîne de métaux, liaison dative métal–métal.

[Traduit par la Rédaction]

Introduction

Much of the past work from this laboratory has described complexes in which an 18-electron organometallic compound acts as a 2-electron donor ligand to a 16-electron organometallic fragment in much the same way as a conventional ligand such as PPh_3 (1–7). Typical examples of molecules of this type are $(OC)_5OsOs(CO)_3(GeCl_3)(Cl)$ (1), $(L)(OC)_4OsM(CO)_5$ (M = Cr, Mo, W; L = PR_3 (2), CN-*t*-Bu (3)), and $(R_3P)(OC)_4M'Ru(CO)_3(SiCl_3)_2$ (M′ = Ru, Os, but not Fe) (4). These complexes contain an unbridged dative bond between two transition metal atoms and are rare (8); complexes with dative metal–metal bonds supported by bridging ligands are, however, more common (9). There has also been renewed interest in complexes with unbridged dative bonds between a transition metal and a main-group metal (10).

In some of our earliest studies, it was observed that isomerization often occurred for complexes with unbridged dative metal–metal bonds that also contained a halide or (especially) a hydride ligand coordinated to the acceptor metal atom (11, 12). The isomerization involved migration of the halide (or hydride) ligand to the donor atom with

concomitant migration of a carbonyl ligand to the acceptor atom (Scheme 1; in this and other schemes presented here the carbonyl ligands not involved in the isomerization have been omitted.) If the halogen ligand is considered a one-electron donor ligand, then the isomerization process results in the conversion of the dative metal–metal bond to a nondative bond.

It is well-known that the presence of a halide ligand in a metal-carbonyl complex often labilizes the carbonyls to ligand substitution (13, 14). The possibility, therefore, exists for further substitution–isomerization reactions on the binuclear compound to yield complexes with extended metal chains. Several previous attempts to exploit this strategy to the synthesis of polynuclear compounds were unsuccessful. Here we report the partial realization of the method in the synthesis of $(X)[Os(CO)_3(CN\text{-}t\text{-}Bu)]_nMn(CO)_5$ (X = Cl, Br, I; n = 1, 2, 3) complexes that contain chains of up to four metal atoms. The tetranuclear complex has been the subject of a communication (15).

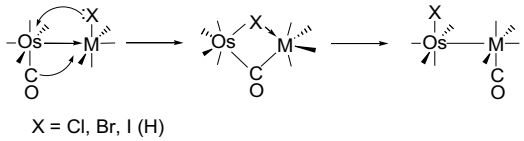
Experimental

Unless otherwise stated, manipulations of starting materials and products were carried out under a nitrogen atmosphere with the use of standard Schlenk techniques. Hydrocarbon solvents were heated to reflux over potassium, distilled, and stored over molecular sieves before use. Dichloromethane was dried in a similar manner except that P_2O_5 was employed as the drying agent. The precursory compounds $Mn(CO)_5(X)$ (X = Cl, Br, I) (16), $[Re(\mu\text{-}X)(CO)_4]_2$ (17), and $Os(CO)_4(CN\text{-}t\text{-}Bu)$ (3) were prepared by literature procedures. The reaction vessels were Carius tubes of volumes between 25–50 mL and each were fitted with a Teflon valve. NMR spectra were recorded on a Bruker AMX 400 spectrometer at the appropriate operating frequencies for the ^1H, $^{13}C\{^1H\}$, and $^{31}P\{^1H\}$ NMR spectra. Samples of the complexes used for $^{13}C\{^1H\}$ NMR spectra were enriched to ~30% ^{13}CO. The samples were prepared from more highly ^{13}CO-enriched $M(CO)_5(X)$ (M = Mn, Re), which in turn was prepared by stirring the $M(CO)_5(X)$ in hexane (or toluene) under ^{13}CO (99%; 2 atm) at room temperature for 24 h (13). It was found that the ^{13}CO was scrambled equally over all CO sites in the products. Analytical and spectroscopic data for the new compounds are given in Tables 1–3.

Preparation of $(OC)_4(t\text{-}BuNC)OsMn(CO)_4(Cl)$ (1)

A solution of $Os(CO)_4(CN\text{-}t\text{-}Bu)$ (30 mg, 0.078 mmol) and $Mn(CO)_5(Cl)$ (17 mg, 0.074 mmol) in hexanes (15 mL) was cooled to –196°C and the solution was degassed with three cycles of freeze-pump-thaw; the vessel was covered with aluminum foil. The mixture was stirred under vacuum at room temperature for 20 h. A bright yellow precipitate resulted. The solvent was removed from the precipitate, which was washed with hexane (3 × 2 mL) and then dried on the vacuum line. The product was analytically pure; further purification was prevented by its instability in solution at room temperature. Reaction of $Mn(CO)_5(X)$ (X = Br, I) under similar conditions gave the isomerized products (**1X**; see below).

Scheme 1.



Preparation of $(OC)_3(t\text{-}BuNC)(I)OsMn(CO)_5$ (1I)

To a Carius tube was added $Os(CO)_4(CN\text{-}t\text{-}Bu)$ (39 mg, 0.10 mmol), $Mn(CO)_5(I)$ (32 mg, 0.10 mmol), and hexanes (10 mL); the solution was degassed as before and the reaction tube covered with aluminum foil. The mixture was stirred under vacuum at room temperature. An IR spectrum after 2 days indicated the starting compounds were still present. The vessel was resealed and the solution degassed as before. After a further 5 days of stirring an IR spectrum indicated that only $(OC)_3(t\text{-}BuNC)(I)OsMn(CO)_5$ (**1I**) was present. The resulting yellow solution was transferred into a Schlenk tube, concentrated, and stored at –27°C to give **1I** as yellow crystals (49 mg, 73%). A second preparation under ambient light resulted in the same product plus traces of **2IA** that were separated by chromatography as described below. The chloro and bromo analogues (**1Cl** and **1Br**) were prepared in a similar manner, that is, under ambient light with a reaction period of 5 days.

Preparation of $(OC)_6(t\text{-}BuNC)_2(I)Os_2Mn(CO)_5$ (2IA and 2IB)

A solution of $Os(CO)_4(CN\text{-}t\text{-}Bu)$ (60 mg, 0.15 mmol) and $Mn(CO)_5(I)$ (24 mg, 0.075 mmol) in hexanes (10 mL) was degassed as described above and the reaction vessel sealed under vacuum. The mixture was stirred at room temperature. Compounds $Os(CO)_4(CN\text{-}t\text{-}Bu)$ **1I** and **2I** were present after 2 days as indicated by IR spectroscopy. An IR spectrum of the reaction solution after 7 days indicated the presence of the desired product plus traces of **1I.** The resulting yellow solution was concentrated and subjected to chromatography on a silica gel column (12 × 1 cm). Elution of the column with hexanes–CH_2Cl_2 (8:1) gave two yellow bands; the first contained **1I**, the second **2IA.** The second fraction was collected, concentrated, and stored at –27°C to give **2IA** (41 mg, 53%) as yellow crystals. Further elution of the column with hexanes–CH_2Cl_2 (4:1) yielded a third yellow band from which **2IB** (5 mg, 6%) as yellow crystals was isolated in a manner similar to that for **2IA**. The chloro (**2ClA** and **2ClB**) and bromo (**2BrA** and **2BrB)** analogues were synthesized in an analogous fashion; yields are given in Table 1. It was verified on a small scale that the trinuclear complexes could be also prepared from similar reactions of $Os(CO)_4(CN\text{-}t\text{-}Bu)$ and **1X** in a 1:1 molar ratio.

Preparation of $(OC)_9(t\text{-}BuNC)_3(Br)Os_3Mn(CO)_5$ (3Br)

A degassed solution of $Os(CO)_4(CN\text{-}t\text{-}Bu)$ (58 mg, 0.15 mmol) and $Mn(CO)_5(Br)$ (14 mg, 0.05 mmol) in hexanes (8 mL) was stirred under vacuum at room temperature for ~40 h, during which time a yellow precipitate formed. The IR spectra revealed the solution contained small amounts of **2Br**, whereas the solid was mainly **3Br**. The solution was removed from the solid, which was then recrystallized from toluene–hexanes to furnish **3Br** (28 mg,

41%) as a yellow crystalline solid. The chloro (**3Cl**) and iodo (**3I**) congeners were synthesized similarly. It was also verified that the **2X** complexes react with excess $Os(CO)_4$(CN-*t*-Bu) under the same conditions to give the corresponding **3X** compounds.

Preparation of $(OC)_4$(*t*-BuNC)$OsRe(CO)_4$(Cl)

A degassed solution of $Os(CO)_4$(CN-*t*-Bu) (44 mg, 0.11 mmol) and $[Re(\mu\text{-}Cl)(CO)_4]_2$ (36 mg, 0.054 mmol) in toluene (15 mL) was stirred under nitrogen at 45°C for ~20 h, during which time a yellow precipitate formed. The mother solution was removed and the precipitate washed with hexanes; the precipitate was then recrystallized from toluene–hexanes at –40°C to afford yellow crystals of (*t*-BuNC)$(OC)_4OsRe(CO)_4$(Cl) (30 mg, 39% yield). The bromo and iodo analogues were prepared in a similar manner.

X-ray structural determination of 1I, 2ClA, 2BrB, and 3I

The structures of **1I**, **2ClA**, and **2BrB** were determined at St. Mary's University, whereas that of **3I** was carried out at the University of Ottawa. The determinations followed the same general procedure. A single (yellow) crystal of suitable size was grown from hexane or hexane–CH_2Cl_2, and mounted on a glass fiber. Data were collected at –50°C for **1I**, **2ClA**, and **2BrB**, and at –70°C for **3I**; a Bruker (Siemens) SMART/CCD diffractometer was used in each case. Crystal data refinement parameters are summarized in Table 4, and selected interatomic distances and angles are

given in Tables 5–7.[2] Unit-cell parameters were calculated from reflections obtained from 60 data frames collected at different sections of the Ewald sphere. A statistical measurement of intensity data indicated the space group, and this was borne out by successful refinement of the structure. Semiempirical absorption corrections were applied using redundant data. Full-matrix least-squares refinement on F^2 was performed after solving using Patterson methods and the solution package SHELXTL v. 5.10 (18). Anisotropic thermal parameters were applied to all non-hydrogen atoms; hydrogen atoms were generated at ideal positions and their positions were updated with each refinement cycle. The following disorders in the structures were encountered: (*i*) for **1I**: O(2), O(11), and O(13) were each disordered over two positions; all were refined satisfactorily with 0.5 occupancy factors. (*ii*) For **2ClA**: CO(15) and Cl were disordered and modeled with occupancy factors of 53:47. (*iii*) For **2BrB**: CO(22) and Br were disordered with an occupancy factor of 88:12. Rotational disorder (50%) was also observed for the methyl groups within the *t*-BuNC ligands of **2BrB**.

Results and discussion

Binuclear OsMn complexes

A bright yellow precipitate resulted when $Os(CO)_4$(CN-*t*-Bu) and $Mn(CO)_5$(Cl) in a 1:1 molar ratio in hexanes was stirred in the dark overnight. From its ^{13}C NMR spectrum at –40°C in CD_2Cl_2 and its IR spectrum it is formulated as $(OC)_4$(*t*-BuNC)OsMn$(CO)_4$(Cl) (**1**) with a donor–acceptor OsMn bond and with both noncarbonyl ligands *cis* to the metal–metal bond (eq. [1]).

[1] $Os(CO)_4(L) + Mn(CO)_5(Cl) \xrightarrow[\text{hexane}]{25°C} -Os(L)-Mn(Cl)- + CO$

L = $CNBu^t$ **1**

In **1** the 18e⁻ compound $Os(CO)_4$(CN-*t*-Bu) acts as a two-electron donor ligand towards the 16e⁻ $Mn(CO)_4$(Cl) moiety. The ^{13}C NMR spectrum of **1** has a 1:2:1 pattern in the Mn–CO region around δ 220, and a 2:1:1 pattern in the Os–CO region (δ 160–185). The latter pattern is typical of complexes such as $(OC)_4$(*t*-BuNC)OsCr$(CO)_5$ in which the 18e⁻ $Os(CO)_4$(CN-*t*-Bu) compound acts as a ligand (3). In particular, the high field resonance in the spectrum of **1** at δ 163.0 is characteristic of this type of complex and is assigned to the carbonyl *trans* to the dative metal–metal bond (1–3, 7). The chemical shift of this resonance in $(OC)_4$(*t*-BuNC)Os[Acc] (Acc = 16e⁻ acceptor fragment) complexes may be a measure of the acceptor strength of the 16e⁻ fragment (19). The shift of this resonance in **1** may be compared with δ 165.1 and 159.3, the shifts found in $(OC)_4$(*t*-BuNC)OsCr$(CO)_5$ and $(OC)_4$(*t*-BuNC)OsOs$(CO)_3(GeCl_3)$(Cl), respectively (3, 19).

Scheme 2.

$Os(CO)_4(L) + Mn(CO)_5(X) \xrightarrow[\text{hexane}]{25°C,\ 7\ d} (OC)_3(X)(L)OsMn(CO)_5 + CO$

L = $CNBu^t$, X = Cl, Br, I → **1** → **1X**

Compound **1** was insoluble in hexane at room temperature; warming **1** in hexane caused it to decompose. Although **1** was stable in CD_2Cl_2 at –40°C, it decomposed in CH_2Cl_2 at room temperature over ~90 min. Two decomposition

products were identified as $Os(CO)_4(CN\text{-}t\text{-Bu})$ and $Mn(CO)_5(Cl)$ by IR spectroscopy. Dissociation in solution of complexes with weak dative metal–metal bonds has been observed previously (6, 11). Furthermore, in some cases these complexes react with CH_2Cl_2 (20).

When the reaction of $Os(CO)_4(CN\text{-}t\text{-Bu})$ and $Mn(CO)_5(Cl)$ in hexanes was carried out for 7 days in ambient light under vacuum, a second product, which was also analyzed as $MnOs(CO)_8(CN\text{-}t\text{-Bu})(Cl)$ (**1Cl**), was obtained. The reaction with $Mn(CO)_5(X)$ (X = Br, I) and $Os(CO)_4(CN\text{-}t\text{-Bu})$ gave the corresponding $MnOs(CO)_8(CN\text{-}t\text{-Bu})(X)$ (**1Br**, **1I**) derivatives; there was no evidence in the latter reactions for a complex analogous to that of **1**. The crystal structure of **1I** (reported below) revealed that these compounds should be formulated as $(OC)_3(t\text{-BuNC})(X)OsMn(CO)_5$ (X = Cl, Br, I) (Scheme 2). Since the $Mn(CO)_5$ and $Os(CO)_3(CN\text{-}t\text{-Bu})(X)$ fragments are $17e^-$ species, the Mn–Os bonds in these molecules are considered nondative metal–metal bonds.

A view of **1I** is shown in Fig. 1; selected bond lengths and angles for the molecule are listed in Table 5. As can be seen from the figure, the Mn–Os bond is unbridged. There do not appear to be any structures of complexes with unbridged Mn–Os bonds with which to compare the Mn—Os length in **1I** of 2.9245(8) Å. In $CpMnOs_3(\mu_2\text{-CHCHPh})(\mu\text{-H})(\mu\text{-CO})(CO)_{11}$ the Os—Mn length is 2.765(4) Å (21); in the $MnOs_3(\mu_4\text{-C})(CO)_{13}$ the Os—Mn lengths range from 2.7797(9) to 2.8271(7) Å (22). From the (unbridged) metal–metal bond lengths reported for $Mn_2(CO)_{10}$ (2.9038(6) Å) (23) and $Os_3(CO)_{12}$ (average = 2.887 Å) (24) one can estimate the length of an unbridged Mn—Os bond to be ~2.895 Å. The Os–Mn distance in **1I** is, therefore, somewhat longer than expected; it is also significantly longer than the three other Os–Mn lengths reported below.

The formation of complexes of type **1X** involves an isomerization in which the halide X migrates from the Mn to the Os atom in $(OC)_4(t\text{-BuNC})OsMn(CO)_4(X)$ with concomitant migration of a carbonyl ligand from Os to Mn as shown in Scheme 2. As mentioned in the *Introduction*, we have previously observed this type of migration in $(Me_3P)(OC)_4OsRu(CO)_3(SiCl_3)(Br)$ (11). A similar migration is presumably also involved in the formation of $(Me_3P)(OC)_3(H)OsRe(CO)_5$ from $Re(CO)_5(H)$ and $Os(CO)_4(PMe_3)$, although the intermediate with a dative Os–Re bond is not observed (12).

Because of the donor–acceptor character of the metal–metal bond in molecules such as **1** there is expected to be a greater charge separation in these molecules compared with the isomerized derivatives (e.g., **1Cl**). Consistent with this view is that the C—O stretches in **1** (with a dative Os—Mn bond) span the range 1924–2118 cm^{-1}, whereas in **1Cl** the range is 1970–2099 cm^{-1}. It may be the relief of this charge separation that is the driving force for the isomerization. The nondative Os–Re bond in $(Me_3P)(OC)_3(Br)OsRe(CO)_5$ is slightly shorter than the dative Os–Re bond in the closely related $(Me_3P)(OC)_4OsRe(Br)(CO)_4$, an observation consistent

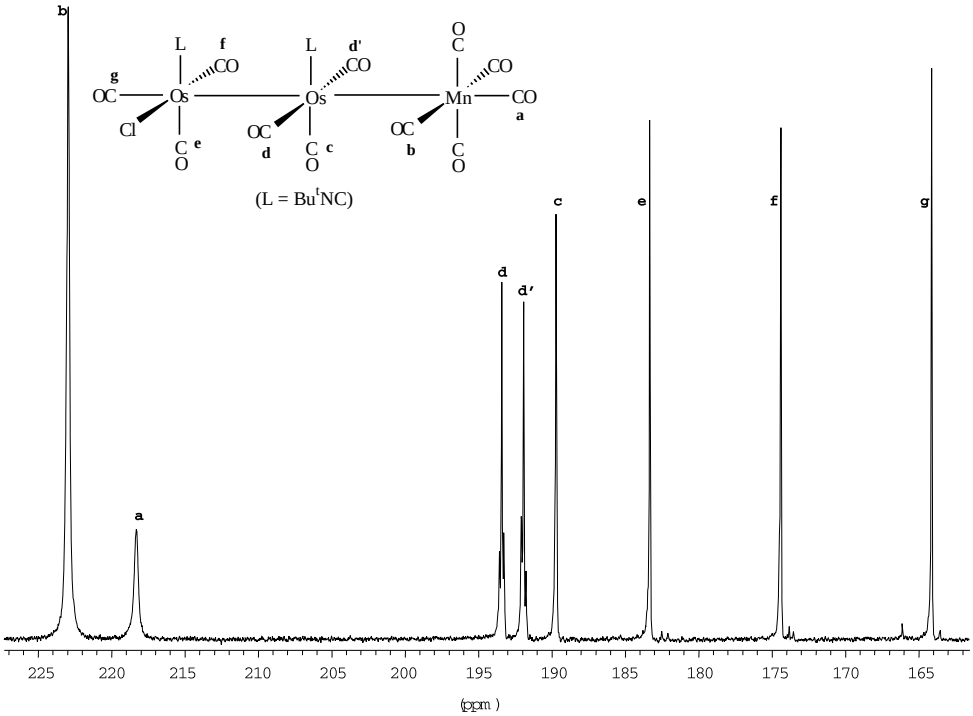
Fig. 3. The ^{13}C NMR spectrum (CO region) of **2C1A** (^{13}CO enriched) in CH_2Cl_2–CD_2Cl_2 (4:1) at – 40°C. The assignment of the signals is given in the inset.



with the view that nondative metal–metal bonds are somewhat stronger than similar dative metal–metal bonds (4, 12, 25).

Trinuclear OsMn complexes

Halide ligands in metal carbonyl complexes such as $M(CO)_{6-n}(X)_n$ (M = Mn (26), Re (27), n = 1; M = Fe (28), Ru, Os (29), n = 2; X = Cl, Br, I) usually activate the complex to carbonyl substitution. It was, therefore, reasoned that the **1X** complexes might undergo further carbonyl substitution by $Os(CO)_4$(CN-*t*-Bu) at the osmium atom and this possibility was found to be correct.

Reaction of **1X** with $Os(CO)_4$(CN-*t*-Bu) in a 1:1 ratio, or the reaction of $Mn(CO)_5(X)$ and $Os(CO)_4$(CN-*t*-Bu) in a 1:2 ratio, readily affords complexes of formula $MnOs_2(CO)_{12}$-(CN-*t*-Bu)$_2$(X) (**2X**) according to Scheme 3. Two isomers of this formula were isolated by column chromatography. The major isomer in each case (**2XA)** is formulated with an $MnOs_2$ backbone with an isocyanide ligand coordinated to each osmium atom. The halide ligand is placed on the terminal Os atom at a site that is both *cis* to the Os–Os bond and the *t*-BuNC ligand (Scheme 3). This is based on the crystal structure and the ^1H and ^{13}C NMR data of **2ClA.** The bromo and iodo analogues have similar ^1H NMR and IR spectra to **2ClA.**

A view of **2ClA** is shown in Fig. 2; selected bond lengths and angles are given in Table 6. The Os—Mn length in **2ClA** of 2.900(1) Å is significantly shorter than the Os—Mn length in **1I** (2.9245(8) Å). This is unexpected because in **1I** the ligands *trans* to the Os–Mn bond are π-acceptor carbonyl ligands, whereas in **2ClA** one of the *trans* ligands is $Os(CO)_3(L)(Cl)$, which is probably a π-donor ligand (7). The latter property would be expected to increase the *d*π–*d*π interactions across the metal–metal bond and hence weaken the Os–Mn bond (see below). The apparent strengthening of the Os–Mn bond in **2ClA** compared with that in **1I** is tentatively assigned to more extensive delocalization and hence stabilization of the metal–metal bonding electrons in **2ClA**.

The Os—Os distance in **2ClA** of 2.8812(4) Å, may be compared with the average Os—Os length (2.887(3) Å) in $Os_3(CO)_{12}$ (24). The Os–Os distances in linear Os_3 chains are, however, somewhat longer than the distance in the triangular cluster. For example, the Os—Os lengths in $Os_3(CO)_{12}(I)_2$ (30), $Os_3(CO)_{12}(SiCl_3)_2$ (31), and $Os_3(CO)_{10}$-$[P(OMe)_3]_2(Br)_2$ (32) are 2.935(2), 2.912(1), and 2.916(2) Å, respectively. In $(OC)_3[MeC(CH_2O)_3P]_2OsOs(CO)_4W(CO)_5$ (33), $(OC)_4$(CN-*t*-Bu)$OsOs(CO)_3$(CN-*t*-Bu)$W(CO)_5$ (34), and $(Ph_3Sb)(OC)_4OsOs(CO)_4Os(CO)_3(Br)_2$ (35), the Os—Os (dative) bond lengths are 2.940(1), 2.907(2), 2.8882(5), and 2.9308 Å, respectively. The Os–Os length in **2ClA**, therefore, appears to be significantly shorter than most comparable unbridged Os–Os distances in noncluster complexes reported in the literature.

The ^{13}C NMR spectrum of **2ClA** in the CO region (Fig. 3) has the expected 1:4 pattern in the Mn–CO region due to the axial and radial carbonyls of the $Mn(CO)_5$ unit; these signals are broadened due to the quadrupole moment of 5/2 of ^{55}Mn. There are six resonances each of intensity 1 in the δ 160–195 region (the region where the resonances of Os–CO groupings normally appear (2, 3, 7, 36)). Such a spectrum is consistent with the solid-state structure when it is realized that the terminal Os atom is chiral because it has four different ligands with three unique ligands occupying a face of the octahedron. The *trans*-carbonyl ligands attached to the central Os atom (labeled d/d′ in Fig. 3) are, therefore, chemically distinct. This is similar to the AB pattern exhibited by protons of a CH_2 unit adjacent to a chiral center in organic

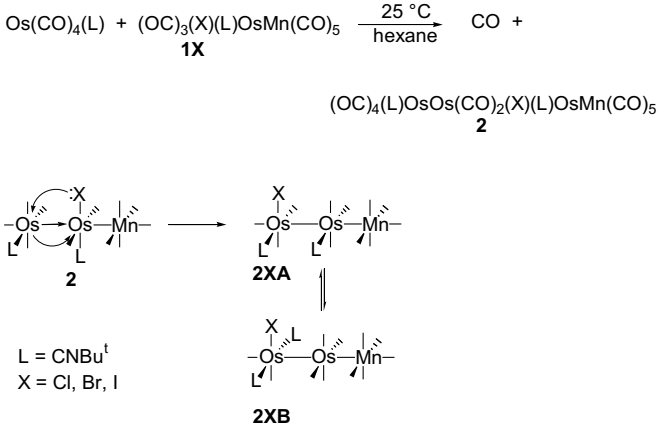
Scheme 3.



molecules (37). The signals due to these carbonyls also exhibit ^{13}C–^{13}C coupling as expected for chemically different carbonyls that are mutually *trans* to each other (38) and the level of ^{13}C enrichment of the sample (~30%).

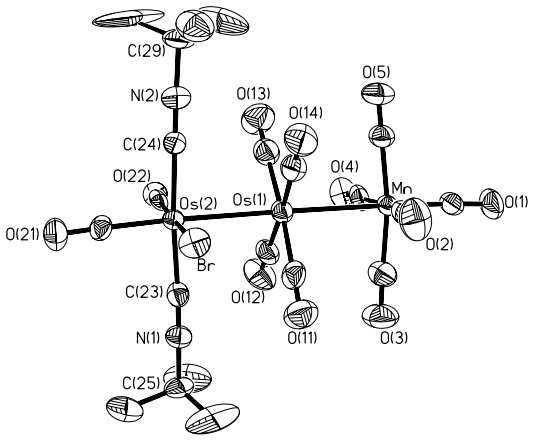
From their spectroscopic properties, the minor isomers (**2XB**) are formulated with a similar structure to **2XA**, but with both isocyanide ligands on the terminal osmium atom in a mutually *trans* orientation (Scheme 3). In each case, the ^1H NMR spectrum consists of a singlet that indicates, in the absence of chemical exchange, that both isocyanide ligands are chemically equivalent. The IR spectrum has one very weak and one strong C–N stretch consistent with the view that these ligands are in mutually *trans* sites on the same osmium atom. The ^{13}C NMR spectrum of **2ClB** in CH_2Cl_2–CD_2Cl_2 exhibits two signals in a ratio of 4:1 in the Mn–CO region and three signals in a 4:1:1 ratio in the Os–CO region, as expected.

The structure of **2BrB** was confirmed by X-ray crystallography. A view of the molecule is given in Fig. 4; selected bond lengths and angles are presented in Table 6. The Os—Mn and Os—Os lengths are 2.884(1) and 2.8895(4) Å, respectively, and may be compared with the other Os–Mn and Os–Os lengths discussed above. That the Os–Mn length in **2BrB** is somewhat shorter than that in **2ClA** may reflect fewer steric interactions between the radial ligands on the Mn and Os(1) atoms in **2BrB**.

A solution of pure **2IA** in hexane was stirred under vacuum at room temperature for 90 h. An IR spectrum of the solution at this stage indicated the presence of **2IA**, along with significant amounts of $Mn_2(CO)_{10}$ and trace amounts of **2IB**. Likewise, a solution of **2BrB** in hexane was stirred under vacuum at room temperature for 90 h and an IR spectrum then taken of the solution. The spectrum indicated the presence of **2BrA**, significant amounts of $Mn_2(CO)_{10}$, but little or no starting complex (**2BrB**). In each case there were C–O stretching bands due to unidentified products. These preliminary results indicate that the **A** and **B** forms of **2X** are present in equilibrium in hexane at room temperature. They also show that the complexes are unstable under these conditions and decompose to $Mn_2(CO)_{10}$ and other unidentified products. It may be that decomposition proceeds mainly via form **B**.

There is ample evidence that migration of carbonyl ligands across dative metal–metal is facile (2, 3, 5, 6). For example, the sample used for the spectrum shown in Fig. 3 was prepared from ^{13}CO-enriched $Mn(CO)_5(Cl)$ and unenriched $Os(CO)_4(CN\text{-}t\text{-}Bu)$. It is evident from the spectrum that the label is scrambled over all carbonyl sites in the molecule. Similar isomers to **2A** and **2B** are found for $Os_2(CO)_7(CN\text{-}t\text{-}Bu)_2W(CO)_5$, but in this case the isomers are not in equilibrium in solution at room temperature (34). The migration of the noncarbonyl ligand to the terminal osmium atom in **2BrB** is also reminiscent of the migration observed in the formation of $(OC)_3[MeC(CH_2O)_3P]_2OsOs(CO)_4OsW(CO)_5$ from the addition of $Os(CO)_4[P(OCH_2)_3CMe]$ to $[MeC(CH_2O)_3P](OC)_4OsW(CO)_5$ at 90°C (33). The trinuclear complex in this case contains two dative metal–metal bonds in tandem and has both P ligands coordinated to the terminal Os atom, in a *trans* configuration. This type of migration results in the more bulky noncarbonyl ligand moving to a less sterically hindered site, although the radial site on the terminal Os atom is even less sterically hindered. The *trans* arrangement of the noncarbonyl ligands, which are poorer π-acceptor ligands than CO, would not be expected to be the electronically preferred structure. It is usually found that poor π-acceptor ligands prefer sites *trans* to carbonyl ligands. We have recently argued that there is an electronic preference to have a strong π-acceptor ligand (e.g., CO) *trans* to the metal–metal bond in binuclear complexes. This is because it will reduce the repulsive $d\pi$–$d\pi$ interactions across the metal–metal bond (7).

Fig. 4. Molecular structure of $(OC)_2(Br)(CN\text{-}t\text{-}Bu)OsOs(CO)_4OsMn(CO)_5$ (**2BrB**).



Tetranuclear OsMn complexes

Reaction of $Mn(CO)_5(X)$ and $Os(CO)_4(CN\text{-}t\text{-}Bu)$ in a 1:3 ratio in solution at room temperature readily gave products that analyzed as $MnOs_3(CO)_{14}(CN\text{-}t\text{-}Bu)_3(X)$ (**3X**; eq. [2]); it was also established on a small scale that the same products could be formed from **2X** and with an excess of $Os(CO)_4(CN\text{-}t\text{-}Bu)$ under the same conditions. The X-ray crystal structure of **3I** was determined at –70°C and a view of the molecule is given in Fig. 5; structural parameters are listed in Table 7. The structure consists of an essentially linear Os_3Mn chain with an isocyanide ligand attached to each Os atom. The halide is coordinated, once again, to the terminal Os atom in a site that is *cis* to both the Os–Os bond and a *t*-BuNC ligand.

Fig. 5. Molecular stucture of $(OC)_3(I)(CN\text{-}t\text{-}Bu)OsOs(CO)_3(CN\text{-}t\text{-}Bu)Os(CO)_3(CN\text{-}t\text{-}Bu)OsMn(CO)_5$ (**31**).

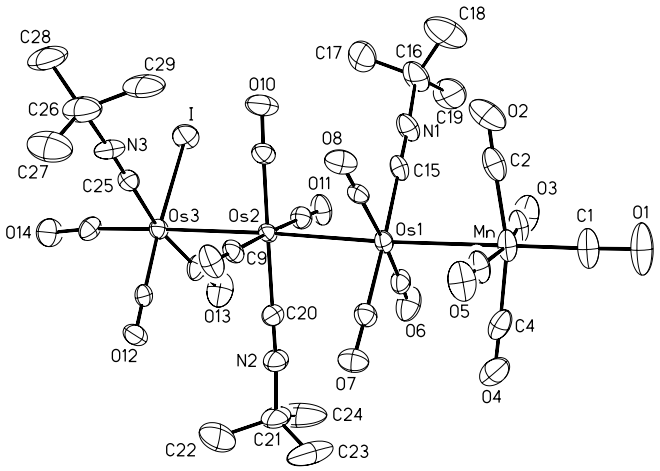

Fig. 6. The ^{13}C NMR spectrum (CO region) of $(OC)_4(t\text{-BuNC})OsRe(CO)_4$ (Br) (^{13}CO enriched) in CH_2Cl_2–CD_2Cl_2 (4:1) at −40°C. The assignment of the signals is given in the inset (L = *t*-BuNC).

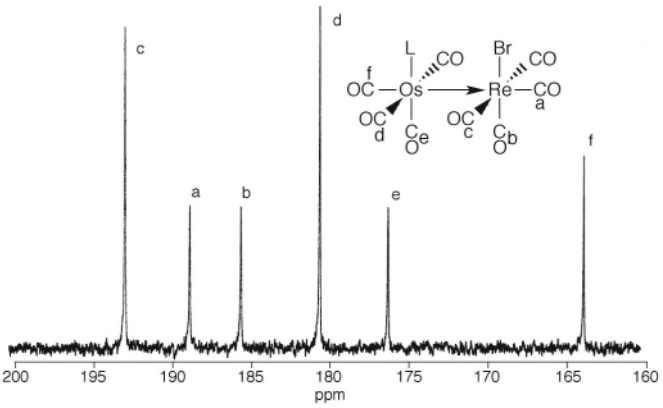


[2] $3Os(CO)_4(L) + Mn(CO)_5(X) \xrightarrow[\text{hexane}]{25\ °C} \underset{\mathbf{3X}}{X\text{–}Os(L)\text{–}Os(L)\text{–}Os(L)\text{–}Mn\text{–}} + CO$

(or **2X**)

$L = CNBu^t$

X = Cl, Br, I

The Os—Mn distance in **3I** at 2.870 (1) Å is the shortest of the four Os—Mn lengths determined in this study and some 0.05 Å shorter than that in **1I**. The Os—Os lengths 2.8894(5) and 2.8928(5) Å in **3I** are not significantly different from the Os—Os lengths in **2ClA** and **2BrB**, and comparable to the Os—Os lengths in $Os_3(CO)_{12}$. From a ground state point of view, therefore, the metal–metal bonds in **3I** appear strong.

The ^{13}C NMR spectrum of ^{13}CO-enriched **3Cl** (Table 3) has two signals in a 4:1 ratio to low field of δ 215 assigned to the carbonyls on manganese, and eight signals to high field of δ 195 assigned to the carbonyls attached to the osmium atoms. The latter signals are of intensity 1 except that at δ 194.8, which is of intensity 2. The spectrum is consistent with the view that **3Cl** has the same structure as found for **3I** in the solid state if two of the resonances are degenerate. As in the spectrum of **2ClA**, because the terminal osmium atom is chiral each carbonyl attached to an osmium atom is chemically different. The methyl resonances in both the ^1H NMR spectra of **3X** (and in ^{13}C NMR spectrum of **3Cl**) show two resonances in the ratio of 2:1. It is probable that the signals due to the methyl groups of the CN-*t*-Bu groups coordinated to the two internal osmium atoms are degenerate.

Only one isomer of **3X** was isolated and it can be assumed to be the result of addition of $Os(CO)_4(CN\text{-}t\text{-}Bu)$ to the major isomer of **2X** (i.e., **2XA**). The substitution of a carbonyl ligand of the $Os(CN\text{-}t\text{-}Bu)_2(X)(CO)_2$ unit in **2XB** would be expected to be slower than in **2XA** for both steric and electronic reasons. The presence of an additional CN-*t*-Bu ligand on the terminal Os atom would block the substitution and increase the strength of the remaining Os–CO bonds.

Attempts to prepare complexes with still longer metal chains have so far been unsuccessful. Stirring $Mn(CO)_5(X)$ in solution with a large excess of $Os(CO)_4(CN\text{-}t\text{-}Bu)$ resulted in only **3X** being formed. Carrying out the same reactions at elevated temperatures resulted in decomposition.

Binuclear OsRe complexes

Complexes of formula $(OC)_4(t\text{-BuNC})OsRe(CO)_4(X)$ (i.e., with dative Os–Re bonds) were synthesized according to eq. [3] as air-stable, yellow crystals. (It was found that the dimeric rhenium precursor gave purer products than the

[3] $2Os(CO)_4(L) + [Re(\mu\text{-}X)(CO)_4]_2$

X = Cl, Br, I

$\xrightarrow[\text{toluene}]{45°\ C} 2(OC)_4(L)OsRe(CO)_4(X)$

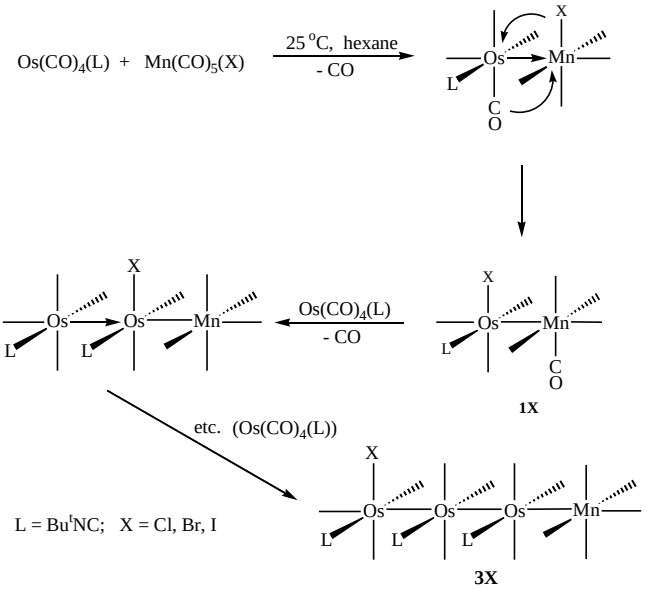
1ReX

corresponding $Re(CO)_5(X)$ complexes.) The formulation of the products with a dative metal–metal bond is clearly indicated by ^{13}C NMR spectroscopy (e.g., Fig. 6). In particular, the complexes exhibit three resonances in a 2:1:1 ratio in the region δ 184–194 attributed to the carbonyls of the $Re(CO)_4(X)$ moiety (Table 2). These signals show little quadrupolar broadening presumably because of the large field gradient through the molecule arising from the polar nature of the dative Os–Re bond causing rapid quadrupolar relaxation.

Attempts to isomerize the $(OC)_4(t\text{-BuNC})OsRe(CO)_4(X)$ complexes by heating them in solution at 60°C only resulted in decomposition. It has previously been found that, like nondative metal–metal bonds, dative metal–metal bonds appear strongest when both metals are third-row transition elements (2, 4, 25). The increased strength of the Os–Re bond would contribute to the barrier to the isomerization of the **1ReX** complexes compared with that of the Mn analogues. We point out here that although $(Me_3P)(OC)_4(Br)OsRe(CO)_5$ is known it was not prepared by isomerizarion of

© 2002 NRC Canada

Scheme 4.



$(Me_3P)(OC)_4OsRe(Br)(CO)_4$, but rather by reaction of $(Me_3P)(OC)_4(H)OsRe(CO)_5$ with CBr_4 (12).

Conclusions

We have previously observed the isomerization of $(Me_3P)(OC)_4OsRu(CO)_3(SiCl_3)(Br)$ with a dative Os–Ru bond to $(Me_3P)(OC)_4(Br)OsRu(CO)_3(SiCl_3)$ with a nondative Os–Ru bond (11). This type of migration has been exploited for the synthesis of $(X)[Os(CO)_3(CN\text{-}t\text{-}Bu)Os]_nMn(CO)_5$ complexes with n = 1, 2, 3. It is believed that there is initial replacement of CO in the $Mn(CO)_5(X)$ or $Os(CO)_3(CN\text{-}t\text{-}Bu)(X)$ unit by the $18e^-$ ligand $Os(CO)_4(CN\text{-}t\text{-}Bu)$. This is followed by rearrangement to the isomer with a nondative metal–metal bond by migration of the halogen ligand to the donor Os atom with concomitant migration in the reverse direction of a carbonyl ligand. This is summarized in Scheme 4.

There are a number of factors involved in the successful synthesis of the Os_nMn complexes. The $18e^-$ $Os(CO)_4(L)$ must be sufficiently basic to form the initial donor–acceptor complex ($Os(CO)_5$ does not undergo these reactions). The noncarbonyl ligand (L) must be sterically undemanding so that it does not block entry of an additional $Os(CO)_4(L)$ ligand. With one exception, this reaction stops at the binuclear derivative for $Os(CO)_4(PR_3)$ ligands (2, 33). Furthermore, in complexes such as $(Me_3P)(OC)_4OsW(CO)_5$ and $(Me_3P)(OC)_4OsRu(CO)_3(SiCl_3)(Br)$ the major isomer has the P ligand *trans* to the dative metal–metal bond (2, 12).

An additional requirement for the formation of the tri- and tetranuclear species is that the dative bond in the intermediates should not be too strong. For example, the $(OC)_4(t\text{-}BuNC)OsRe(CO)_4(X)$ complexes do not isomerize. In addition, the $1e^-$ ligand on the acceptor atom should readily allow the formation of the bridged intermediate. In previous work, we have shown that for $(Me_3P)(OC)_4OsRu(CO)_3(SiCl_3)(X)$ compounds isomerization occurs immediately for X = H and slowly for X = halide. On the other hand, $(Me_3P)(OC)_4OsRu(CO)_3(SiCl_3)_2$ does not undergo this rearrangement (11). Attempts to further exploit this reaction for the preparation of complexes with still longer metal chains are planned.

Molar excess enthalpies for some systems containing the OH and (or) O groups in the same or in different molecules

Jose Carlos Cobos, Isaias Garcia de la Fuente, and Juan Antonio Gonzalez

Abstract: In this work, H_m^E data at 298.15 K for the systems 1-nonanol + *n*-C_{12}; 1-nonanol + *n*-C_{14}; 1-hexanol + 3,6,9-trioxaundecane; and 2-(2-butoxyethoxyethanol) + *n*-C_7 are reported. Measurements were carried out with a standard Calvet-type microcalorimeter. Molar excess functions, including enthalpies and entropies, are carefully examined to report on the main features of the studied solutions. Dipole–dipole interactions between ether molecules are, therefore, of great importance in both 1-alkanols + polyoxaalkanes mixtures and between hydroxyether molecules in alkoxyethanols + *n*-alkanes systems. In the second case, it has been attributed to the existence of intramolecular H-bonds in alkoxyethanols as well as to their higher effective-dipole moment in comparison to that of homologous 1-alkanols. DISQUAC is the only model that can be used to accurately represent thermodynamic functions (except molar excess volumes, V_m^E) of all of the solutions under study. UNIFAC underestimates dipole–dipole interactions in 1-alkanols + polyoxaalkanes and alkoxyethanols + *n*-alkanes systems. In exchange, the self-association of the alcohol is overestimated in mixtures of 1-nonanol with *n*-alkanes. Currently, the ERAS model can only be used to examine these solutions. The variation of the V_m^E with the size of the *n*-alkanes is well described.

Key words: excess functions, OH group, O group, interactions, models.

Résumé : Dans ce travail, on rapporte des données de H_m^E, à 298,15 K, pour les systèmes 1-nonanol + *n*-C_{12}; 1-nonanol + *n*-C_{14}; 1-hexanol + 3,6,9-trioxaundécane et 2-(2-butoxyéthoxyéthanol) + *n*-C_7. On a effectué les mesures à l'aide du microcalorimètre de type Calvet standard. Dans le but de bien redélimiter les caractéristiques principales des solutions étudiées, on a examiné en détail les fonctions d'excès, tant les entropies que les enthalpies. Ainsi, les interactions dipôle–dipôle entre les molécules d'éther sont de la plus grande importance dans les mélanges 1-alkanols + polyoxaalcanes et c'est aussi le cas entre les molécules d'hydroxyéthers dans les systèmes alkoxyéthanols + *n*-alcanes. Dans ce cas, on l'attribue à l'existence de liaisons hydrogènes intramoléculaires dans les alkoxyéthanols ainsi qu'à leur moment dipolaire effectif plus élevé par comparaison avec les 1-alkanols homologues. Le modèle DISQUAC est le seul qui peut être utilisé pour représenter de façon adéquate les fonctions thermodynamiques (à l'exception des volumes molaires en excès, V_m^E) de toutes les solutions étudiées. Le modèle UNIFAC sous-estime les interactions dipôle–dipôle dans les systèmes 1-alcanols + polyoxaalcanes et alkoxyéthanols + *n*-alcanes. Par ailleurs, l'autoassociation de l'alcool est surestimé dans les mélanges de 1-nonanol avec les *n*-alcanes. Actuellement, le modèle ERAS ne peut être utilisé que pour traiter ces solutions. On décrit aussi les variations dans les valeurs de V_m^E avec la taille des *n*-alcanes.

Mots clés : fonctions d'excès, groupe OH, groupe O, interactions, modèles.

[Traduit par la Rédaction]

Introduction

Mixtures containing oxygenated compounds, such as ethers (-O- group) and alkanols (-OH group) are of great importance from a practical point of view because they are increasingly used as additives to gasoline owing to their octane-enhancing and pollution-reducing properties (1, 2). Both groups may belong to the same molecule used to build hydroxyethers, which are nonionic amphiphile molecules, and consequently are very effective surfactants with a large number of applications (3–6). From this point of view, it is remarkable that they are considered as priority compounds by the Canadian Enviromental Protection Act in 1999 (www.ec.gc.ca).

Theoretically, solutions involving oxaalkanes are of high interest because of the possibility of studying of a number of effects (e.g., steric or proximity effects, cyclization) on the interactions present in the mixture. Binary systems of oxaalkanes and 1-alkanols are particularly interesting due to their complexity, resulting from the partial destruction of the self-associating alcohols by the active molecules of ethers, and of the new OH—O bonds created. The treatment of this class of systems is, therefore, is a strong test for any theoretical model. Moreover, it is a necessary step to study mixtures containing hydroxyethers, where the intramolecular effects between their -OH and -O- groups is of great importance (7–9).

The OHO project is part of a general program, the "TOM project" (thermodynamics of organic mixtures) (10, 11), in

which mixtures containing the -O- and (or) -OH groups are investigated to determine and characterize the interactions where these groups participate.

We have contributed largely to the OHO project, reporting a large quantity of measurements on the vapor–liquid equilibria (VLE), liquid–liquid equilibria (LLE), solid–liquid equilibria (SLE), molar excess enthalpies (H_m^E), molar excess heat capacities at constant pressure (C_{pm}^E), and molar excess volumes (V_m^E) (see refs. 12–28).

Moreover, in terms of DISQUAC (10,11), a purely physical model based on the rigid lattice theory of Guggenheim (29), we have developed a detailed theoretical study of interactions, where some of the mentioned groups are involved. One of the most important conclusions from these studies is that DISQUAC can be applied to any type of mixtures assuming structure-dependent interaction parameters. DISQUAC, therefore, can be applied to systems where intermolecular H-bonds are present between the same class of molecules (homocoordination in, e.g., 1-alkanols + *n*-alkanes mixtures (30)) or between different molecules (heterocoordination, as in 1-alkanols + amines (31, 32); 1-alkanols + propanal (33); or oxaalkanes + $CHCl_3$ (34)). We have recently shown that DISQUAC is very useful in analyzing those systems where intramolecular H-bonds are also of great relevance (i.e. alkoxyethanols + alkanes mixtures (9)).

The Dortmund version of UNIFAC (35, 36), which ignores proximity or steric effects, fails to describe properties such as H_m^E or C_{pm}^E, which are very sensitive to the molecular structure for the complex mixtures mentioned above (for examples, see refs. 31, 37). Unfortunately, both the DISQUAC and UNIFAC models are based on rigid-lattice theories and $V_m^E = 0$.

The model more widely applied to simultaneously represent H_m^E and V_m^E is the so-called ERAS model (38), which combines the real-association solution model (39–42) (chemical contribution) with the physical contribution, expressed by the Flory equation of state (43). ERAS has been sucessfully applied to solutions such as 1-alkanols + alkanes (44); 1-alkanols + amines (31, 32,45); 1-alkanols + monooxalkanes (46, 47); or amines + *n*-alkanes (45). The lack of a systematic treatment in the framework of this model of 1-alkanols + polyoxaalkanes mixtures underlines the difficulty in studying such solutions. Indeed, only mixtures of 1-propanol with 2,5,8,-trioxanonane or 2,5,8,11-tetraoxadodecane have been studied, assuming that the polyethers are self-associated (48). On the other hand, ERAS can only be applied to those systems where association is expected and is not useful in treating, e.g., monooxalkanes + alkanes mixtures.

The purpose of this paper is to report H_m^E measurements at 298.15 K for the following mixtures: 1-nonanol + *n*-dodecane; 1-nonanol + *n*-tetradecane; 1-hexanol + 3,6,9-trioxaundecane; and 2-(2-butoxyethoxyethanol) + *n*-heptane. These systems will be also analyzed, when possible, in terms of DISQUAC, UNIFAC, and ERAS models.

Experimental

Materials

All the chemicals were from Fluka. Dodecane, 3,6,9-trioxaundecane, and 1-nonanol (purum > 98 mol%); and heptane, tetradecane, and 1-hexanol (puriss p.a., with purity > 99 mol%) were used without further purification. 2-(2-Butoxyethoxy)ethanol (stated purity > 98 mol%) was fractionally distilled many times in a glass 100-theoretical plates column, at a reflux ratio of approximately 25:1 at 1.6 kPa of reduced pressure, until no measurable impurities were observed in a vapor-phase chromatography trace analysis. The final purity was estimated to be 99.9%. Prior to the experimental measurements, all liquids were carefully dried over molecular sieve beads (Union Carbide type 4Å) from Fluka.

Densities of pure compounds at 298.15 K are in good agreement with literature values (49–51) and are equal to those found in previous works (see refs. 16, 18, 19).

Apparatus and procedure

A standard Calvet-type microcalorimeter, equipped with a batch mixing cell with a small (<2%) gas phase, and the experimental technique of Paz Andrade et al. (52) were used to determine H_m^E over the entire mol fraction range. Details of the experimental technique and of the accuracy attained have been described elsewhere (53–55). The calorimeter was thermostated to ±0.005 K and measurements were carried out at 298.15 K.

Binary mixtures were prepared by mass. All weighings were corrected for buoyancy effects, and the error on the final mol fraction is estimated to be less than 0.0001. Conversion to molar quantities is based on the relative atomic mass table issued by IUPAC (56).

Experimental results

The experimental results are listed in Tables 1–4. There are no data in literature for comparison. H_m^E (J mol^{-1}) measurements were fitted using equations of the type represented below.

$$[1] \qquad H_m^E = x_1(1-x_1)\sum_{i=0}^{k} A_i x_1^{i/2}$$

$$[2] \qquad H_m^E = x_1(1-x_1)\sum_{i=0}^{k} A_i (2x_1-1)^i$$

Coefficients in eqs. [1] and [2] were determined by least-squares regression with all points weighted equally. They are given in Table 5, together with the corresponding standard deviations (σ).

Theories

DISQUAC

Assessment of geometrical parameters

The total relative molecular volumes (r_i), surfaces (q_i), and the molecular surface fractions (α_{si}) of the compounds present in the mixture are usually calculated additively on the basis of the group volumes (V_G) and surfaces (A_G), as recommended by Bondi (57) and Kehiaian et al. (58). The geometrical parameters of the groups referred to in this work are given elsewhere (30, 58, 59).

Equations

The equations used to calculate G_m^E and H_m^E are the same as in other applications (30). The interactional terms in the excess thermodynamic properties G_m^E and H_m^E contain a DIS (dispersive) and a QUAC (quasichemical) contribution, which are calculated independently by the classical formulas and then simply added. The degree of nonrandomness is thus expressed by the relative amounts of dispersive and quasichemical terms.

$$[3] \qquad G_m^E = G_m^{E,COMB} + G_m^{E,DIS} + G_m^{E,QUAC}$$

$$[4] \qquad H_m^E = H_m^{E,DIS} + H_m^{E,QUAC}$$

where $G_m^{E,COMB}$ is the Flory–Huggins combinatorial term (58, 60).

For the QUAC term, as coordination number the reference value was chosen, i.e. $z = 4$.

The temperature dependence of the interaction parameters g_{st}, h_{st}, and c_{pst} has been expressed in terms of the DIS and (or) QUAC interchange coefficients (30) $C_{st,1}^{DIS}$ and $C_{st,1}^{QUAC}$, where s and t are two functional groups present in the mixture (e.g., OH and O); and l = 1 (Gibbs energy: $C_{st,l}^{DIS/QUAC} = g_{st}^{DIS/QUAC}(T_0)/RT_0$); l = 2 (enthalpy: $C_{st,2}^{DIS/QUAC} = h_{st}^{DIS/QUAC}(T_0)/RT_0$) and l = 3 (heat capacity: $C_{st,3}^{DIS/QUAC} = c_{pst}^{DIS/QUAC}(T_0)/R$). $T_0 = 298.15$ K is the scaling temperature.

Modified UNIFAC (Dortmund version)

Modified UNIFAC (35) differs from the original UNIFAC (61) by the combinatorial term and the temperature dependence of the group interaction parameters (a_{nm}, b_{nm}, c_{nm}).

The equations used to calculate G_m^E and H_m^E are obtained from the fundamental equation for the activity coefficient γ_i of component,

$$[5] \qquad \ln \gamma_i = \ln \gamma_i^{COMB} + \ln \gamma_i^{RES}$$

where $\ln \gamma_i^{COMB}$ is the combinatorial term and $\ln \gamma_i^{RES}$ is the residual term.

Assessment of geometrical and interaction parameters

In modified UNIFAC, main groups are defined to improve correlations. Generally, they are divided in several subgroups, which have different geometrical parameters. The subgroups within the same main group, however, are assumed to have identical group energy-interaction parameters. The geometrical parameters, the relative van der Waals volumes, and the relative van der Waals surfaces of the different subgroups are not calculated from molecular parameters (as in the original UNIFAC) but fitted together with (a_{nm}, b_{nm}, c_{nm}) to the experimental values of the thermodynamic properties considered. The geometrical and interaction parameters are taken from literature (35, 36) and used without modification.

The ERAS model

This model combines the real association solution model (39–42) with Flory's equation of state (43). The excess functions are written as

$$[6] \qquad X_m^E = X_{m,phys}^E + X_{m,chem}^E$$

where X = G (Gibbs energy), H (enthalpy), V (volume). In eq. [6], $X_{m,chem}^E$ is the chemical contribution, mainly due to association reactions, and $X_{m,phys}^E$ represents the physical contribution, resulting from the physical interactions between molecules.

The chemical contribution to the excess properties arises from the chemical interactions between the molecules, in particular hydrogen bonding. Thus, alcohol molecules (A) build linear chains of associated multimers

$$[7] \qquad A_n + A \overset{K_A}{\leftrightarrow} A_{n+1}$$

where n is the degree of self association, ranging from 1 to ∞.

The association constants are assumed to be independent from the chain length. Their temperature dependence is given by

$$[8] \qquad K_A = K_0 \exp[-(\Delta h_A^*/R)(1/T - 1/T_0)]$$

where K_0 is the equilibrium constant at the standard temperature T_0, and Δh_A^* is the enthalpy variation for eq. [7], which corresponds to the hydrogen bonds energy. Reaction [7] is also characterized by the volume change (Δv_A^*) related to the formation of the linear chains.

$X_{m,phys}^E$ is derived from Flory's equation of state (43), which is assumed to be valid not only for the pure components but also for the mixture

$$[9] \qquad \tilde{P}_i\tilde{V}_i / \tilde{T}_i = [\tilde{V}_i^{1/3} / (\tilde{V}_i^{4/3} - 1)] - 1 / (\tilde{V}_i\tilde{T}_i)$$

where i = A, B (second compound), or M (mixture). In eq. [9], $\tilde{V}_i = V_i/V_i^*$, $\tilde{P}_i = P_i/P_i^*$, and $\tilde{T}_i = T_i/T_i^*$ are the reduced parameters for volume, pressure, and temperature, respectively. The reduction parameters for the pure components V_i^*, P_i^*, T_i^* are calculated previous determination of density, thermal expansion coefficient, and compressibility, which can be obtained from experimental *P-V-T* data; they also depend on K_i, Δh_i^*, Δv_i^* (62, 63). The reduction parameters for the mixture P_M^* and T_M^* are calculated via certain mixing rules (44, 62, 63), where X_{AB}, the energetic interaction parameter characterizing the difference of dispersive intermolecular interactions between molecules A and B in the solution and in the pure components, is introduced. It is the only adjustable parameter of the physical part of H_m^E and V_m^E.

As in DISQUAC, the surface and volume of molecules are calculated using Bondi's method (57).

Discussion

1-Nonanol + *n*-alkanes mixtures

DISQUAC properly represents the H_m^E of these systems (Figs. 1–3) using the interaction parameters available in the literature (Table 6, refs. 30 and 79). The results are independent of the size of the of *n*-alkane. In exchange, discrepancies are observed for solutions of the shorter 1-alkanols with long chain *n*-alkanes. This has been attributed to a supplementary endothermic contribution to H_m^E resulting from the breaking of the orientational order of the longer *n*-alkanes (64, 65), which must be added to the main contributions of H_m^E including (*i*) that from the breaking of the H-bonds between alkanol molecules upon mixing; and (*ii*) dipole–dipole interactions between alkanol molecules. The effect of this supplementary contribution is to decrease the number of broken H-bonds in comparison to the case of a shorter *n*-alkane. The experimental H_m^E is, therefore, not as high as one could expect and consequently DISQUAC overestimates, e.g., H_m^E of the 1-propanol + *n*-pentadecane system (30). For longer 1-alkanols, however, the mentioned supplementary contribution vanishes, and DISQUAC correctly predicts the variation of H_m^E with the size of *n*-alkane.

ERAS parameters for these solutions and for pure compounds are listed in Table 7. Results of H_m^E are similar to those obtained using DISQUAC (Figs. 1–3). We must remark that the applied values of Δh_A^* (–25.1 kJ mol) and Δv_A^* (–5.6 cm^3 mol^{-1}) are common for all the 1-alkanols and widely used (44–47, 62, 63).

ERAS represents, rather accurately, V_m^E (Figs. 4 and 5). It is well-known that this magnitude in 1-alkanols + *n*-alkanes systems is the result of several opposing effects: changes in self-association and in physical interactions (dipole–dipole) between alkanol multimers and monomers leads to an increase in volume; a decrease in volume is due to changes in free volume and interstitial accomodation (66). The sign and magnitude of these contributions are sensitive to the lengths of the component molecules (67). For the 1-nonanol + *n*-heptane system, $V_m^E < 0$, except at very low mol fraction of the alcohol, since the fitting of the alkane into the alkanol multimer structure predominates. In constrast, in the 1-nonanol + tetradecane system $V_m^E > 0$, this negative contribution to V_m^E vanishes and the interactional contribution to V_m^E is more relevant.

This complex behaviour is well-described by ERAS decreasing the X_{AB} parameter with the size of the *n*-alkane (Table 7). The same behaviour is observed, for example, in ethanol + *n*-alkanes mixtures (44).

In UNIFAC, alkanols are characterized by the two main groups: OH and CH_3OH (35). The former is subdivided in

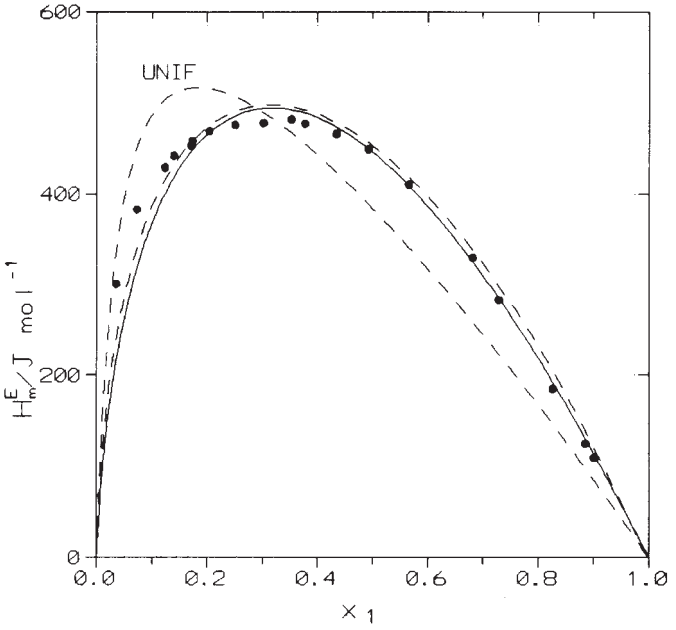

Fig. 2. H_m^E at 298.15 K for the 1-nonanol + *n*-dodecane system. Points, experimental results (this work); solid line, DISQUAC calculations; dashed lines, UNIFAC (UNIF) and ERAS calculations.

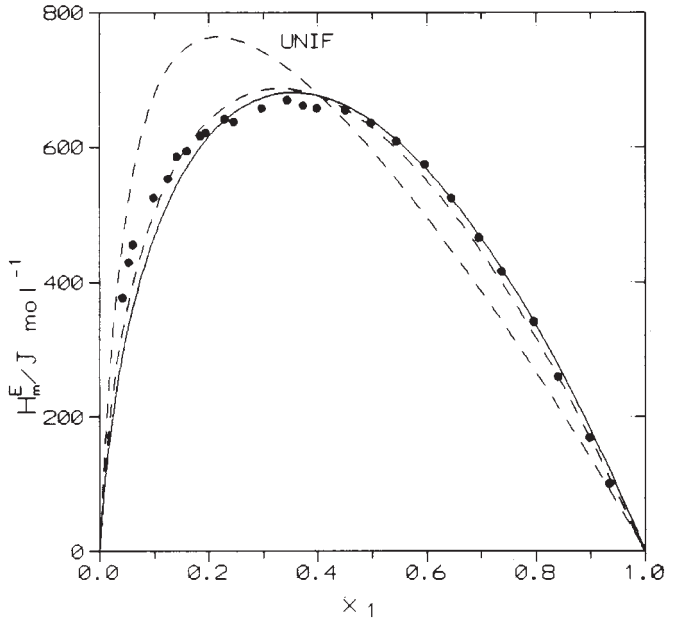

three subgroups: OH(p), OH(s), and OH(t), which represent the hydroxyl group in primary, secondary, and tertiary alkanols. CH_3OH is a group by itself that characterizes methanol. In this framework, UNIFAC provides H_m^E curves that are much more asymmetric than the experimental ones (Figs. 1–3). UNIFAC, therefore, overestimates the self-association of the alkanol.

Fig. 3. H_m^E at 298.15 K for the 1-nonanol + *n*-tetradecane system. Points, experimental results (this work); solid line, DISQUAC calculations; dashed lines, UNIFAC (UNIF) and ERAS calculations.

1-Hexanol + 3,6,9-trioxaundecane

We have previously reported H_m^E of systems containing 1-propanol, 1-butanol, 1-pentanol, 1-heptanol, or 1-decanol and the same triether (16). H_m^E (x_1 = 0.5) increases with the size of the alkanol (Fig. 6). The H_m^E variation is parallel to that in diethers or triethers + *n*-alkanes mixtures when the length of the alkane increases (Fig. 6, ref. 59). The H_m^E dependence with respect to mol fraction is nearly symmetrical (Fig. 7). Moreover, $G_m^E < H_m^E$ and TS_m^E is mainly positive (Ta-

ble 8). All this contrasts with the behaviour of 1-alkanol + monoether systems, where, from 1-propanol, H_m^E varies very little with the chain length of the alkanol (Fig. 6, refs. 20 and 37) and is skewed towards low mol fractions of 1-alkanols. In addition $G_m^E \approx H_m^E$ and TS_m^E is s-shaped or slightly positive (Table 8). These features suggest that in mixtures containing polyoxaalkanes, dipole–dipole interactions between ether molecules play a major role.

In terms of group contributions, there are three different groups in 1-alkanols + oxaalkanes systems (OH, O, and CH_2 (aliphatic)) and three different contacts (OH–CH_2 (30, 79), O–CH_2 (59), and O–OH (37)). DISQUAC accurately represents the H_m^E of these solutions using structure-dependent interaction parameters. It is noteworthy that the OH–O contacts in mixtures of 1-alkanols with 3,6,9-trioxaundecane or other higher oxaalkanes are characterized by interchange coefficients (Table 6), which are derived, following simple rules, from those for the OH–O contacts in systems containing 2,5-dioxahexane or 3,6-dioxaoctane (37).

Table 7. ERAS parameters at 298.15 K for pure compounds in 1-nonanol + *n*-alkanes mixtures.

Compound	V_m (cm^3 mol^{-1})	V^* (cm^3 mol^{-1})	P^* (J cm^{-3})	T^* (K)
1-Nonanol[a]	174.92	146.78	424.4	6258

UNIFAC predicts lower H_m^E than DISQUAC. To some extent, it may be due to UNIFAC failing when representing proximity effects in polyoxalkanes + solvents mixtures (68, 69).

At present, there is no treatment in terms of ERAS for these types of solutions.

2-(2-Butoxyethoxyethanol) + *n*-heptane

The H_m^E term arises from: (*i*) the breakening of inter- and intramolecular H-bonds and; (*ii*) the dipole–dipole interactions between alkoxyethanol molecules.

At equimolar composition, the studied systems show $G_m^E > H_m^E$ and large values of C_{pm}^E (9). This is typical behaviour for solutions including a self-associated compound, and thus it occurs in 1-alkanols + *n*-alkanes mixtures. As already mentioned, this self-association is produced via both inter- and intramolecular H-bonds (7–9).

The effective polarity of a molecule with a given dipole moment (μ) can be defined through the effective dipole moment ($\bar{\mu}$) an useful magnitude to examine the impact of polarity on bulk properties (9, 31, 32, 68, 70, 71). It is known that increasing the polarity of molecules leads to miscibility gaps when they are mixed with *n*-alkanes. For example, for the acetonitrile (μ = 3.5 D (49); $\bar{\mu}$ = 1.86) + *n*-C_6 system, the upper critical solution temperature (UCST) is 350.15 K (72), while for the 2-propanone (μ = 2.8 D (49), $\bar{\mu}$ = 1.2) + *n*-C_6 it is 238.15 K (73).

Alkoxyethanols (1) + *n*-alkanes (2) systems show higher UCSTs than the corresponding mixtures with homologous 1-alkanols[2] (25, 26). Because $\bar{\mu}$(alkoxyethanol) > $\bar{\mu}$(homomorphic 1-alkanol) (9), it implies that initial dipole–dipole interactions are more important in systems with alkoxyethanols than in alcoholic solutions.

For a given *n*-alkane, H_m^E (alkoxyethanol) > H_m^E (homologous 1-alkanol) (Table 8), indicating that intermolecular H-bonds are now less important. This may be due to (*i*) the presence of intramolecular H-bonds, which reduces the number of possible intermolecular H-bonds; and (*ii*) the major relative weight of the mentioned dipole–dipole interactions. Moreover, it should be noted that $H_m^{E,\infty}$ (alkoxyethanol (1) + *n*-alkane (2)) < $H_m^{E,\infty}$ (1-alkanol (1) + *n*-alkane (2)), as this magnitude, independent of the *n*-alkane (30, 74), is 23.4 kJ mol^{-1} at 303.15 K for 1-hexanol (75) and 21.8 kJ mol^{-1} for 1-octanol (76). In mixtures with *n*-heptane at 298.15 K, $H_m^{E,\infty}$ = 15.5 and 14.4 kJ mol^{-1} for 2-propoxyethanol and 2-butoxyethanol, respectively (9, 77). The lower $H_m^{E,\infty}$ values in alkoxyethanols mixtures have been interpreted assuming that the hydroxyether molecules become free through the destruction of the intermolecular H-bonds by the addition of the solvent molecules, and that each alkoxyethanol molecule forms an intramolecular H-bond between the -O- and OH- groups of the same molecule and thus stabilizes itself (77). For such reasons, the H_m^E curves are more symmetrical than those for alcoholic solutions, which are strongly shifted towards lower concentrations of the self-associated compound (Fig. 8).

The decreased importance of intermolecular H-bonds in alkoxyethanol mixtures is also supported by their higher TS_m^E values when they are compared with those of systems involving 1-alkanols (Fig. 9, Table 8).

[2]For example, other homologous molecules considered are 2-ethoxyethanol, 1-pentanol, 2-(2-butoxyethoxyethanol), and 1-decanol.

Fig. 8. H_m^E at 298.15 K for the systems 1-decanol + *n*-hexane (■, 83); and 2-(2-butoxyethoxyethanol) + *n*-heptane (●, this work). Solid lines, DISQUAC calculations; dashed line, UNIFAC results for the mixture including 2-(2-butoxyethoxyethanol).

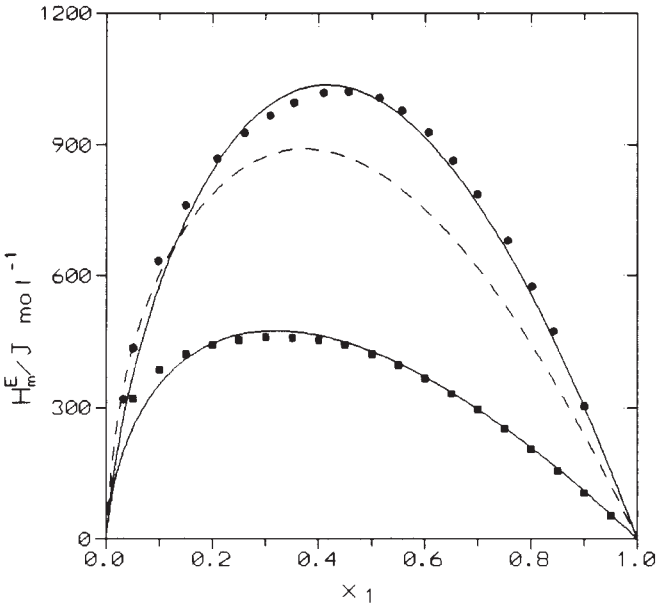

Fig. 9. TS_m^E at 298.15 K for the systems 1-decanol + *n*-hexane (●) and 2-(2-butoxyethoxyethanol) + *n*-heptane (—) (for references, see Table 8).

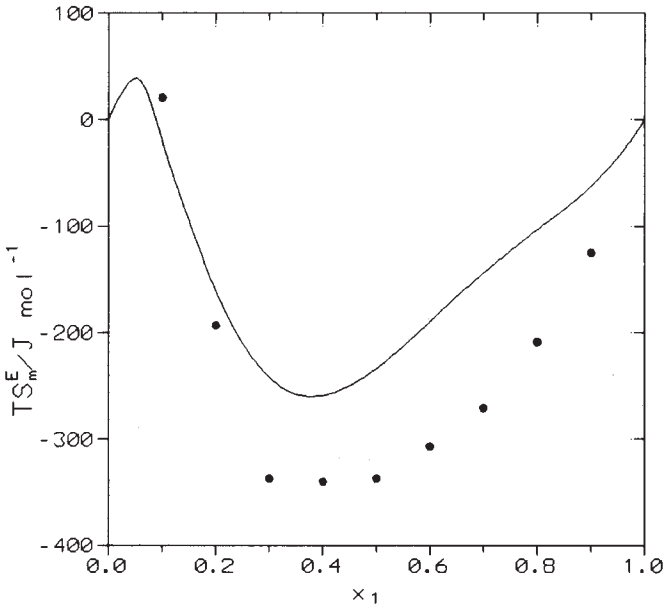

All these features underline the decreased importance of intermolecular H-bonds in alkoxyethanol solutions. DISQUAC accurately represents H_m^E of alkoxyethanols + alkanes mixtures (Fig. 8, ref. 9). The interaction parameters for the OH–O contacts in $CH_3(CH_2)_mOCH_2$ $CH_2OCH_2CH_2OH$ + *n*-C_n systems are practically independent of the hydroxyether (9). Only the first dispersive parameter is different for 2-(2-methoxyethoxyethanol) (9), due to the very high UCSTs of solutions formed by this alkoxyethanol and alkanes (25).

UNIFAC H_m^E results are lower than those from DISQUAC (Fig. 8), implying that dipole–dipole interactions are underestimated, since the UNIFAC interaction parameters used are derived from data on 1-alkanols + oxaalkanes mixtures. The same result occurs in terms of DISQUAC when intramolecular effects are neglected (i.e., when using interaction parameters for the OH–O contacts determined as in UNIFAC) (78). Note that dipole–dipole interactions are actually more important in alkoxyethanols + alkanes mixtures than in 1-alkanols + ethers mixtures. For example, 2-methoxyethanol + *n*-C_7 at equimolar composition (9) is not miscible at room temperature, whereas this is not the case for the 1-butanol (1-alkanol homologous to 2-methoxyethanol) + methylpropylether (oxaalkane homologous to 2-methoxyethanol) system.

Conclusions

Measurements of H_m^E at 298.15 K for 1-nonanol + *n*-C_{12}, 1-nonanol + *n*-C_{14}, 1-hexanol + 3,6,9-trioxaundecane, and 2-(2-butoxyethoxyethanol) + *n*-C_7 have been reported.

Dipole–dipole interactions between ether molecules are of great importance in 1-alkanols + polyoxaalkanes mixtures and between hydroxyether molecules in alkoxyethanols + *n*-alkanes systems. In the second case, the importance of dipole–dipole interactions are due to not only the existence of intramolecular H-bonds in alkoxyethanols but also the higher effective dipole moment compared with that of homologous 1-alkanols.

DISQUAC is the only model that can be used to accurately represent the thermodynamic functions (except V_m^E) of the solutions examined. UNIFAC underestimates the dipole–dipole interactions in 1-alkanols + polyoxaalkanes and alkoxyethanols + *n*-alkanes systems. In exchange, the self-association of the alcohol is overestimated in mixtures of 1-nonanol with *n*-alkanes. The ERAS model only can be used, at present, to treat these solutions. The variation of the V_m^E with the size of the *n*-alkane is well described.

A theoretical study of the mechanism of 1,2-migrations in methoxysiloxycarbene

Paul G. Loncke, Timothy A. Gadosy, and Gilles H. Peslherbe

Abstract: Intramolecular rearrangements of methoxysiloxycarbene ($CH_3OCOSiH_3$) have been investigated by means of ab initio molecular orbital theory and hybrid density functional theory calculations. Particular attention was paid to 1,2-silyl migration from oxygen to the carbene carbon, and to the analogous 1,2-methyl migration for comparison. A combination of frontier molecular orbital (FMO) theory, natural bond orbital (NBO) analysis, and the theory of atoms in molecules (AIM) were used to shed light on the mechanistic details of these rearrangements. The present analyses clearly indicate that 1,2-silyl migration involves nucleophilic attack by the carbene lone pair at silicon, whereas 1,2-methyl migration seems to involve an anion-like shift of the methyl group from oxygen to the "vacant" carbene *p*-orbital. Finally, based on the computed relative Gibbs free energy barriers, it is apparent that 1,2-silyl migration is much more favorable than 1,2-methyl migration, in keeping with experimental observations.

Key words: carbenes, oxycarbenes, intramolecular rearrangements, 1,2-migrations, quantum chemistry, theory of atoms in molecules, natural bond orbital analysis

Résumé : On a étudié les réarrangements moléculaires du méthoxysiloxycarbène ($CH_3OCOSiH_3$) en faisant appel à des calculs ab initio basés sur la théorie des orbitales moléculaires et sur la théorie de la densité fonctionnelle hybride. On s'est intéressé particulièrement à la migration 1,2 du silyle de l'oxygène vers le carbone du carbène et, pour fins de comparaison, à celle de la migration analogue 1,2 du méthyle. On a utilisé une combinaison de la théorie de l'orbitale moléculaire frontière (OMF), à une analyse de l'orbitale de liaison naturelle (OLN) et à la théorie des atomes dans les molécules (ADM) pour comprendre les détails mécanistiques de ces réarrangements. Les analyses présentées indiquent clairement que la migration 1,2 du silyle implique une attaque nucléophile de la paire libre du carbène sur le silicium alors que la migration 1,2 du méthyle semble impliquer un déplacement semblable à celui d'un anion du groupe méthyle de l'oxygène vers l'orbitale p vacante du carbène. Enfin, sur la base des barrières relatives d'énergie libre de Gibbs, il est apparent que la migration 1,2 du silyle est beaucoup plus favorable que celle de la migration 1,2 du méthyle; ce qui est en accord avec les observations expérimentales.

Mots clés : carbènes, réarrangements intramoléculaires, migrations 1,2, chimie quantique, théorie des atomes dans les molécules, analyse de l'orbitale de liaison naturelle.

[Traduit par la Rédaction]

Introduction

Intramolecular 1,2-migrations from carbon atoms to the carbene centre in alkylcarbenes are fairly well understood (1–3). Extensive experimental and theoretical studies indicate that these rearrangements involve species migrating with anion-like character to the "vacant" carbene *p*-orbital. La Villa and Goodman (4), Bonneau et al. (5), and Moss et al. (6) have shown that alkyl substitution at the migration origin enhances 1,2-H migration rates in alkylhalocarbenes. Liu and Bonneau (7) have also reported that electron donating *p*-substituents accelerate 1,2-H migrations in *p*-substituted benzylchlorocarbenes. Moreover, density functional theory calculations by Keating et al. (8) indicate that electron donating substituents attached to the migration origin of singlet alkylchlorocarbenes lower the activation barriers for 1,2-H and 1,2-Ph migrations. These findings are all consistent with a mechanism involving anion-like migrating species, where the positive charge developing at the migration origin is stabilized by electron donating groups. On the contrary, electron donating substituents attached to the carbene carbon tend to decelerate 1,2-shifts from the migration origin. For instance, Moss et al. (6) have shown that 1,2-H and 1,2-C migrations in alkylfluorocarbenes are slower than those in the corresponding alkylchlorocarbenes. Similarly, La Villa and Goodman (9) found that the 1,2-H shift in methylchlorocarbene is slower than that in methylbromocarbene. Furthermore, ab initio calculations by Evanseck and Houk (10) suggest that 1,2-H migration barriers in alkylcarbenes are raised by electron donating substituents attached to the carbene carbon. These observations seem to suggest that the increased negative-charge density at the carbene carbon due to the presence of electron donating substituents has a net stabilizing effect, which results in decreased reactivity. Furthermore, the transition states for 1,2-

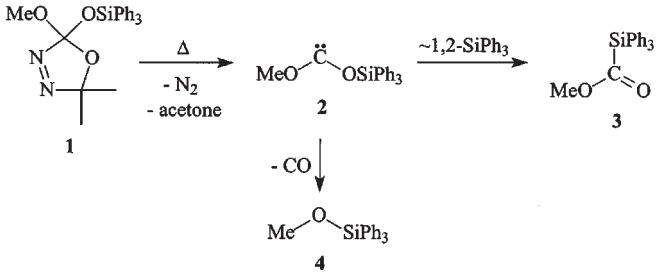
Scheme 1.



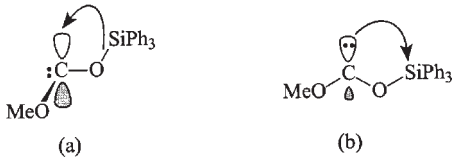
migrations may be destabilized as a result of the increased negative-charge density at the carbene carbon.

In contrast to 1,2-migrations from carbon atoms to the carbene centre, 1,2-migrations from oxygen atoms to the carbene carbon in oxy- and dioxycarbenes are relatively rare and more convoluted. Moss et al. (11) have shown that 1,2-acyl migrations in phenylacyloxycarbenes involve nucleophilic attack by the carbene lone pair at the acyl carbon, whereas Suh et al. (12) have found evidence for a mechanism involving anion-like migrating species in gas-phase 1,2-alkyl migrations in dialkoxycarbenes. On the other hand, Venneri and Warkentin (13) have reported experimental evidence indicating that methoxyallyloxycarbene rearrangements, including 1,2-allyl migrations, occur by a fragmentation–recombination mechanism involving methoxycarbonyl and allylic radicals. Investigations of intramolecular rearrangements in *p*-substituted benzyloxymethoxycarbenes (14) and benzyloxy(benzyloxy)carbenes (15) also support a fragmentation–recombination mechanism involving radicals. In addition, ab initio and density functional theory calculations by Reid and Warkentin (16) suggest that a fragmentation–recombination mechanism involving radicals is energetically feasible for rearrangements of ground-state singlet allyloxyhydroxycarbene.

Methoxytriphenylsiloxycarbene (**2**), generated by thermolysis of 2-methoxy-2-triphenylsiloxy-5,5-dimethyl-Δ^3–1,3,4-oxadiazoline (**1**), was recently reported to undergo 1,2-triphenylsilyl migration from oxygen to the carbene carbon and decarbonylation, affording the methyl triphenylsilylformate (**3**) and methyl triphenylsilyl ether (**4**), respectively, as illustrated in Scheme 1 (17). The reaction was carried out in benzene at 110°C, and the product ratio of ester **3** to ether **4** was found to be 1:3. Moreover, when oxadiazoline **1** was heated in toluene and in the presence of TEMPO, no evidence for products of radical trapping was found. This latter observation suggests that unlike the other dioxycarbene rearrangements (13–15) discussed in the previous paragraph, the rearrangements of carbene **2** do not occur via a pathway involving radicals. Thus, in the case of 1,2-triphenylsilyl migration, there could be two possible mechanisms. The triphenylsilyl group could migrate with anion-like character from oxygen to the vacant carbene *p*-orbital, as illustrated in Scheme 2*a*. Alternatively, the rearrangement could proceed via nucleophilic attack by the carbene lone pair at silicon, as shown in Scheme 2*b*.

To gain insight into the actual mechanisms for the intramolecular rearrangements of methoxytriphenylsiloxycarbene

Scheme 2.



(**2**), we have performed ab initio molecular orbital theory and hybrid density functional theory calculations on methoxysiloxycarbene ($CH_3OCOSiH_3$) as a model system. A preliminary account of our calculations has been recently reported (17). In this article, we report a thorough investigation of 1,2-silyl migration in methoxysiloxycarbene, while we defer the study of other possible carbene rearrangements such as the decarbonylation pathway to a future publication (18). We pay particular attention to the actual mechanism of 1,2-silyl migration, which we shall contrast to that of 1,2-methyl migration.

Computational methods

Standard ab initio molecular-orbital calculations at the Hartree–Fock (HF) and second-order Møller–Plesset (MP2) levels of theory (19) and hybrid density functional theory calculations at the Becke3 Lee–Yang–Parr (B3LYP) level (20), together with 6–31+G* and 6–311+G(2d,p) basis sets (19) were carried out with the Gaussian 98 suite of programs (21). Ground-state minimum-energy structures were optimized with the Berny algorithm (22), while transition-state optimizations were performed using the eigenvector-following method (23–25). Frequency calculations were performed for stationary-point characterization and thermochemical data was obtained within the rigid rotor-harmonic-oscillator approximation using standard statistical mechanical methods implemented in Gaussian 98 (26). Natural bond-orbital (NBO) analysis (27) was also carried out using the NBO program, Version 3.1 (28) available in the Gaussian 98 suite.

A topological analysis of the gradient field of the electron density ($\rho(r)$) was carried out with the AIMPAC series of programs (29, 30), which is based on the theory of atoms in molecules (AIM). AIM provides a simple but rigorous means of partitioning the molecular electronic density into sub regions called basins, each belonging to a given nucleus (31). Each basin can be integrated affording properties usually ascribed to atoms.[2] A maximum, minimum, or saddle point in the topology of $\rho(r)$ is associated with critical points, where the first derivative $\nabla\rho(r)$ is zero. Critical points are classified according to their rank (ω) and signature (σ) as (ω, σ). ω refers to the number of nonzero curvatures of $\rho(r)$ at the critical point, and σ is the sum of the signs of the curvature at the critical point. For example, at a (3, –3) critical point or *attractor,* all three curvatures are negative and at a (3, –1) point or *bond critical point* two curvatures are negative and one is positive. The bond ellipticity ($\varepsilon = \lambda_1/\lambda_2 - 1$), where λ_1 and λ_2 are the two associated (negative) curvatures

[2] The numerical integration parameters used for integration over the atomic basins were 64 ϕ-planes, 48 θ-planes, and 96 radial points per integration within the β-sphere around the nucleus.

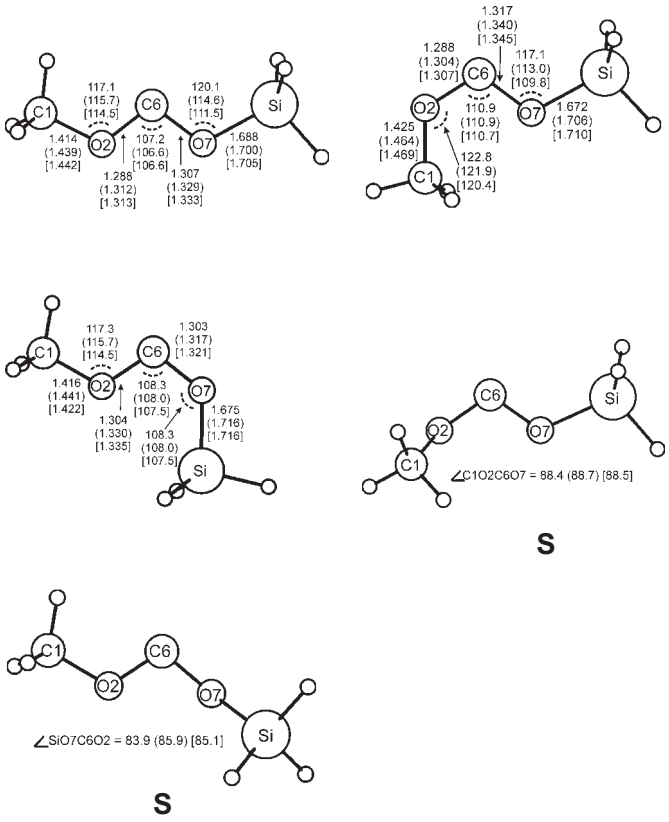
Fig. 1. Computed geometries for *trans-trans* **A**, *cis-trans* **B**, and *trans-cis* **C** conformers of methoxysiloxycarbene and rotational transition states, $\mathbf{TS_{AB}}$, and $\mathbf{TS_{AC}}$. Bond lengths are in angstroms and bond angles in degrees. HF, B3LYP (parentheses), and MP2 [brackets], parameters obtained with the 6–311+G(2d,p) basis set are listed.



of ρ at a bond critical point directed along axes perpendicular to the bond path, defines a measure of the extent to which charge is preferentially accumulated in a given plane (31). Thus, in a bond with cylindrical symmetry, the ratio λ_1/λ_2 is one and ε is zero. On the other hand, when charge preferentially accumulates in a given plane, as one would expect for a π bond, the associated curvature λ_1 is larger than the curvature λ_2 in the perpendicular direction and thus ε is greater than zero.

Results and discussion

Methoxysiloxycarbene conformers

Geometric conformers computed for methoxysiloxycarbene are shown in Fig. 1. They include a *trans-trans* conformer (**A**), a *cis-trans* conformer (**B**) and a *trans-cis* conformer (**C**). Also shown, are transition-state geometries for *trans-trans* to *cis-trans* isomerization ($\mathbf{TS_{AB}}$), and *trans-trans* to *trans-cis* isomerization ($\mathbf{TS_{AC}}$). Selected geometric parameters are listed in Fig. 1, along with atom labels for identification in this discussion. From the relative Gibbs free energies given in Table 1,[3] it is apparent that **A** is the most stable carbene conformer. It should be mentioned that all calculations were carried out on the closed-shell singlet (S_0) state of the carbene since oxy- and dioxycarbenes are known to have large $S_0 \rightarrow T_1$ and $S_0 \rightarrow S_1$ energy gaps (32–34). For instance, Moss et al. (34) reported that the lowest triplet states of *trans-trans* and *cis-trans* dimethoxycarbene are 76.3 and 76.7 kcal mol^{-1}, respectively, above their corresponding singlet ground-state conformers, based on MP2/6–31G*//HF/6–31G* calculations. Furthermore, the open-shell singlet (S_1) states of these carbenes are reported to lie 104 and 109 kcal mol^{-1}, respectively, above their corresponding singlet S_0 states, according to CIS/INDO/S//HF/6–31G* calculations (34). Feller et al. (32) calculated vertical $S_0 \rightarrow T_1$ gaps for dihydroxycarbene at various levels of theory and found values ranging from 43.4 to 66.3 kcal mol^{-1}, while the lowest energy triplet carbene was found to be 26.4 to 50.0 kcal mol^{-1} above the lowest energy singlet carbene. In the case of methoxysiloxycarbene, the vertical $S_0 \rightarrow T_1$ gaps for **A**, **B**, and **C** computed at the CIS/6–31+G*//MP2/6–31+G* level are 57.8, 56.8, and 55.1 kcal mol^{-1}, respectively, while the $S_0 \rightarrow S_1$ gaps are 116.0, 118.1, and 118.4 kcal mol^{-1}. Moreover, optimization of triplet methoxysiloxycarbene at the MP2/6–31+G* level afforded two conformers that were 55.2 and 55.8 kcal mol^{-1} above the lowest singlet (S_0) state carbene conformer **A**.

Interestingly, the barrier for *trans-trans* **A** to *cis-trans* **B** isomerization (via $\mathbf{TS_{AB}}$) is considerably higher than that for *trans-trans* **A** to *trans-cis* **C** isomerization (via $\mathbf{TS_{AC}}$), as can be seen from the relative Gibbs free energies given in Table 1. This suggests that in conformer **A**, the methoxy oxygen O2, is a better π-electron donor than the siloxy oxygen O7, and consequently O2–C6 has more double-bond character than C6–O7. NBO perturbation-theory energy analysis (27) reveals that the stabilization energy due to $n_{O2} \rightarrow p_{C6}$ delocalization is generally greater than that for $n_{O7} \rightarrow p_{C6}$ interaction (Table 2), while AIM analysis (28–30) indicates that the electron density at the bond critical point ($\rho(r_c)$) between O2 and C6 is greater than that between C6 and O7 (Table 3). These findings are clearly in keeping with the greater double-bond character of the O2–C6 bond. In addition, both NBO and AIM atomic charges show that there is less negative charge on O2 than there is on O7, further supporting the idea that the methoxy oxygen O2 is a better π-electron donor than the siloxy oxygen O7. Moreover, the O2–C6 bond is found to be slightly shorter than the C6–O7 bond (Fig. 1), again supporting the greater double-bond character of O2–C6. Indeed, both the O2–C6 and C6–O7 bonds are expected to have π-type character, which is verified by the fact that the bond ellipticity (ε) is noticeably larger than zero for the two bond paths (Table 3). Notice that the O7–Si bond is virtually aligned with the vacant carbene *p*-orbital in $\mathbf{TS_{AC}}$, whereas the C1–O2 bond is better aligned with the same *p*-orbital in $\mathbf{TS_{AB}}$ (Fig. 1). These features may lead one to believe that stabilization due to $\sigma_{O7-Si} \rightarrow p_{C6}$ cation-like hyperconjugation in $\mathbf{TS_{AC}}$ is greater than that due to $\sigma_{C1-O2} \rightarrow p_{C6}$ hyperconjugation in $\mathbf{TS_{AB}}$, consequently resulting in a lower isomerization barrier via $\mathbf{TS_{AC}}$. According to our NBO perturbation-theory energy analysis, the stabiliza-

$n_{C6}\rightarrow RY^{*}_{Si}$. (total)	28.3	27.7	14.1	14.6

Note: The energetic importance of interactions between filled (donor) Lewis-type NBOs and empty (acceptor) non-Lewis NBOs are estimated via second-order perturbation theory analysis of the Fock matrix in the NBO basis, as discussed in ref. 27. The $n_{C6}\rightarrow RY^{*}_{Si}$ (total) denotes the stabilization energies resulting from interaction of n_{C6} with all RY^{*}_{Si} NBOs. The polarization coefficient on Si of the σ^{*}_{O7-Si} NBO about 85% for **A**, **B**, and **C**, and between 90 and 95% in $\mathbf{TS}_{AD}$ and $\mathbf{TS}_{BE}$.

tion energy resulting from $\sigma_{O7-Si} \rightarrow p_{C6}$ hyperconjugation in $\mathbf{TS_{AC}}$ appears to be negligible. We found, however, that $\sigma_{C1-O2} \rightarrow p_{C6}$ hyperconjugation in $\mathbf{TS_{AB}}$ yields a stabilization energy of 6.51 and 7.08 kcal mol^{-1} at the RHF level of theory with 6–31+G* and 6–311+G(2d,p) basis sets, respectively, and 2.23 and 2.05 kcal mol^{-1}, respectively, at the B3LYP level of theory with the same basis sets. Thus, it appears that cation-like hyperconjugation only plays a minor role, if any, in the determination of barrier heights for isomerization.

Silyl migration

We now focus on the mechanism for 1,2-silyl migration in methoxysiloxycarbene. Since no evidence was found for radical-based mechanisms in the rearrangements of methoxytriphenylsiloxycarbene (17), we considered two mechanistic possibilities for 1,2-silyl migration in methoxysiloxycarbene, as proposed earlier for 1,2-triphenylsilyl migration in methoxytriphenylsiloxycarbene (Scheme 2). One of the possibilities involves the silyl group migrating with anion-like character from oxygen to the vacant carbene *p*-orbital located essentially perpendicular to the carbene valence plane, similar to that illustrated in Scheme 2*a*. The other possibility involves nucleophilic attack by the carbene lone pair at silicon in the carbene valence plane, analogous to that shown in Scheme 2*b*.

In terms of frontier molecular orbital (FMO) theory, nucleophilic attack by the carbene lone pair at silicon ap-

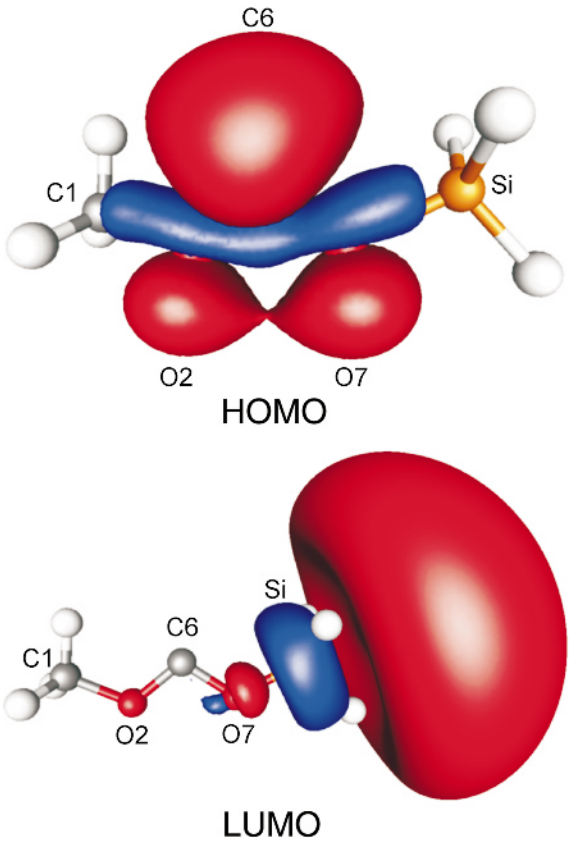
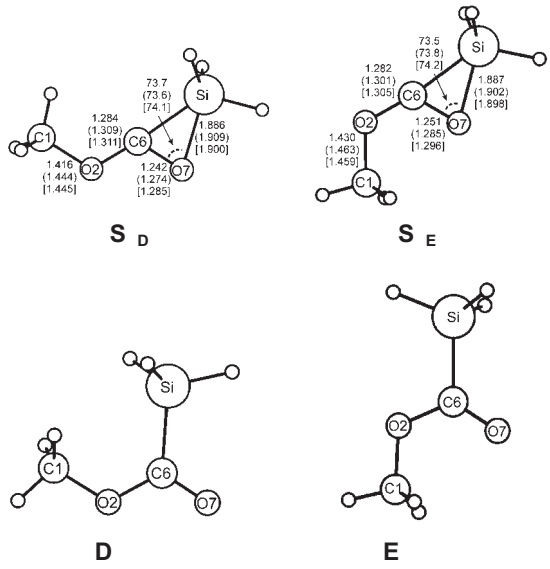
Fig. 2. Plots of the highest occupied molecular orbital (HOMO) and the lowest unoccupied molecular orbital (LUMO) for conformer **A** of methoxysiloxycarbene obtained at the HF/6–311+G(2d,p) level.



pears to be favored. The HF/6–31+G* orbital energies for conformer **A** are –10.2 eV (HOMO) and 1.82 eV (LUMO). Similar values were obtained for conformers **B** and **C**. For comparison, HF/6–31G* orbital energies reported for *trans-trans* dimethoxycarbene (34) are –10.6 eV (HOMO) and 4.34 eV (LUMO), while those computed at the HF/4–31G level for *trans-trans* methoxyphenoxycarbene (35) are –10.8 eV (HOMO) and 3.33 eV (LUMO). In these two dioxycarbenes, the HOMO is primarily made up of lone pairs on the carbene carbon and its two flanking oxygen atoms, while the LUMO is essentially the vacant carbene *p*-orbital. These dioxycarbenes are not particularly known for their intramolecular reactivity, and this may be due to the large HOMO–LUMO gaps they possess, as well as geometric constraints, which make the interaction between high-lying molecular orbitals (MO) such as the σ_{CO} orbital of the methoxy group and the vacant carbene *p*-orbital difficult. The LUMO energy of conformer **A**, **B**, and **C**, however, is considerably lower than those reported for dimethoxycarbene and methoxyphenoxycarbene, which should facilitate intramolecular rearrangement. Moreover, the orbital energies obtained for **A**, **B**, and **C** are comparable to those reported for phenylacyloxycarbenes, which are known to undergo 1,2-acyl migration (11). For example, the HF/4–31G orbital energies of phenylacetoxycarbene are –10.1 eV (HOMO) and 1.61 eV (LUMO). In this latter carbene, the LUMO is essentially the carbonyl π^*-orbital. Further analysis of the FMOs for conformers **A**, **B**, and **C** reveals that the largest MO coefficient for the LUMO is on Si instead of the carbene carbon C6. For the HOMO, sizeable MO coefficients are found on the methoxy oxygen O2, the carbene carbon C6, and the siloxy oxygen O7. Moreover, it is evident from the FMOs plots shown in Fig. 2 that the LUMO is primarily the σ^*_{O7-Si} orbital, while the n_{O2}, n_{C6}, and n_{O7} nonbonding orbitals almost exclusively make up the HOMO. Thus, in conformers **A** and **B** where the n_{C6} orbital (HOMO) is aligned with the σ^*_{O7-Si} orbital (LUMO), interaction between these two orbitals and hence nucleophilic attack by the carbene lone pair at silicon appear to be favorable.

Fig. 3. Geometries of the transition states for 1,2-silyl migration, $\mathbf{TS_{AD}}$ and $\mathbf{TS_{BE}}$, and the corresponding products *anti*-methyl silylformate **D** and *syn*-methyl silylformate **E**. Bond lengths are in angstroms and angles in degrees. HF, B3LYP (parentheses), and MP2 [brackets] parameters obtained with the 6–311+G(2d,p) basis set are given.



The computed transition-state geometries for 1,2-silyl migration from oxygen to the carbene centre in **A** and **B** are shown in Fig. 3, along with the corresponding products, *anti*-methyl silylformate **D** and *syn*-methyl silylformate **E** (the transition states are simply labeled $\mathbf{TS_{AD}}$ and $\mathbf{TS_{BE}}$, respectively). Relative to the parent carbene conformers (Fig. 1), the dissociating O7–Si bond lengthens considerably, the developing C6–O7 double bond shortens significantly, and there is substantial shrinkage of the C6-O7-Si angle in

Turning our attention to the computed atomic charges, we note that both NBO and AIM atomic charges for the methoxysiloxycarbene conformers listed in Table 4 indicate that the largest positive charge is on Si, which means that this site is most susceptible to nucleophilic attack. In addition, the carbene carbon C6 has a fairly sizeable positive charge, and this may lead one to believe that the carbene carbon is a poor nucleophile. The nucleophilicity of the carbene carbon, however, may actually arise from back donation by lone pairs on the two flanking oxygen atoms that are capable of stabilizing the developing transition state, and this is not necessarily reflected in the atomic charge of the carbene carbon.

the two transition states (Fig. 3). Moreover, the geometries of the transition states are planar, indicating that the silyl group migrates in the plane of the carbene lone pair. These geometric features are consistent with nucleophilic attack by the carbene lone pair at silicon, together with C6–O7 double-bond formation, and are reminiscent of the mechanism proposed by Moss et al. (11) for 1,2-acyl migrations in phenyl(acyloxy)carbenes.

In an effort to monitor the electronic structure changes in going from **A** and **B** to $\mathbf{TS_{AD}}$ and $\mathbf{TS_{BE}}$, respectively, NBO and AIM analyses were also performed on the transition states. NBO perturbation-energy analysis indicates that the

negative hyperconjugative $n_{C6}\rightarrow\sigma^*_{O7-Si}$ and $n_{C6}\rightarrow RY^*_{Si}$ interactions in **A** and **B** increase tremendously in $\mathbf{TS_{AD}}$ and $\mathbf{TS_{BE}}$, as can be seen from the stabilization energies in Table 2. It is important to note that the σ^*_{O7-Si} orbital is heavily polarized towards Si (the NBO polarization coefficient is about 85–95% on Si). In addition, there is considerable strengthening of the $n_{O7}\rightarrow p_{C6}$ interaction in $\mathbf{TS_{AD}}$ and $\mathbf{TS_{BE}}$ relative to **A** and **B**. Moreover, the NBO charge differences given in Table 5 reveal that there is significant positive charge build-up on Si, considerable positive charge build-up on O7, while the change in charge on C6 appears to be insignificant. These observations are in keeping with nucleophilic attack by the carbene lone pair at silicon, together with simultaneous C6–O7 double bond formation. In addition, there generally appears to be a small build-up of positive charge on O2, which may be a reflection of π-electron stabilization of the two transition states. This is further supported by a small increase in the strength of the $n_{O2}\rightarrow p_{C6}$ interaction at the B3LYP level of theory, but not at the HF level of theory where the reverse is observed (Table 2).

AIM analysis reveals that the electron density at the bond critical point ($\rho(r_c)$) along the O7–Si bond path decreases, while it increases along the C6–O7 bond path in going from **A** and **B** (Table 3) to $\mathbf{TS_{AD}}$ and $\mathbf{TS_{BE}}$ (Table 6). Meanwhile, a new C6–Si bond path with low $\rho(r_c)$ appears in the two transition states. According to the AIM charges, there is sizeable positive charge build-up at the carbene carbon C6, significant positive charge development at O7, and modest positive charge build-up at Si, in the two transition states as indicated in Table 5. These findings are in agreement with nucleophilic attack by the carbene lone pair at silicon, along with simultaneous C6–O7 double-bond formation and O7–Si bond dissociation. There is generally a small build-up of positive charge on O2, which is accompanied by a meagre increase in $\rho(r_c)$ between O2 and C6 in the transition states (Table 6). These latter observations are consistent with modest stabilization of the two transition states by back donation from the O2 lone pairs. The bond ellipticities (ε) of the C6–Si and O7–Si bond paths are fairly large for reasons which may not be immediately obvious, but such occurrences are usually associated with the apparition of three-membered ring structures (31).

The Laplacian of the electron density ($\nabla^2\rho(r)$) allows identification of regions of local charge concentration ($\nabla^2\rho(r) < 0$) and local charge depletion ($\nabla^2\rho(r) > 0$) in the topology of the electron density of a molecule (31). Regions of charge concentration can be mapped to localized electron pairs of the Lewis and VSEPR models. Contour plots of $\nabla^2\rho(r)$ for **A** and $\mathbf{TS_{AD}}$, generated from MP2/6–311+G(2d,p) wavefunctions are shown in Fig. 4. These plots clearly show that the charge concentration corresponding to the carbene lone pair in **A** becomes distorted toward silicon in $\mathbf{TS_{AD}}$, consistent with a mechanism involving nucleophilic attack by the carbene lone pair at silicon. At the same time, the

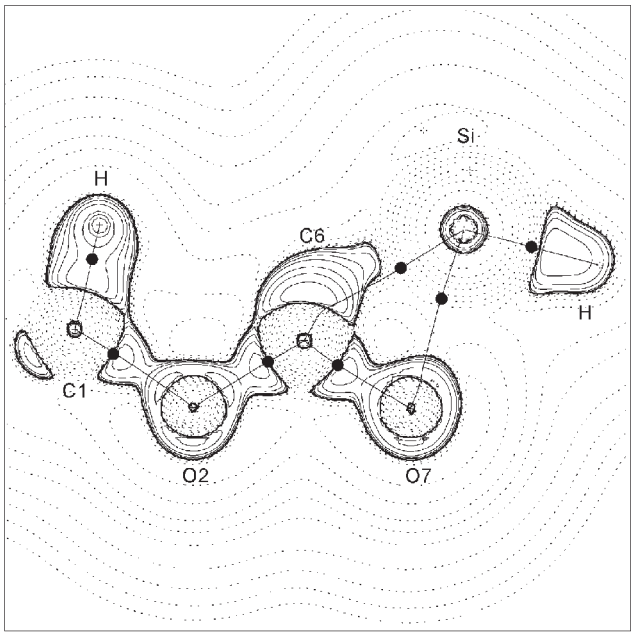
A



$\mathbf{TS_{AD}}$

charge concentration that appears as a small projection along the O7–Si bond path in **A** disappears in $\mathbf{TS_{AD}}$, reflecting the weakening of the bond during silyl migration.

The relative Gibbs free energy barriers computed for 1,2-silyl migration (via $\mathbf{TS_{AD}}$ and $\mathbf{TS_{BE}}$) at the HF level of theory appear to be overestimated when compared to experimentally determined barriers reported for similar rearrangements (Table 1), as is commonly the case (36–38). However, the B3LYP and MP2 computed barriers seem to be quite reasonable. Relative Gibbs free energy barriers computed at the HF level of theory are between 20.0 and 22.0 kcal mol^{-1}, whereas at the B3LYP and MP2 levels of theory, they are around 8.0 to 11.0 kcal mol^{-1} (Table 1). The latter numbers are consistent with barriers measured for similar rearrangements. For example, the experimentally determined Gibbs free energy barrier for 1,2-acyl migration in phenylbenzoyloxycarbene is 9.9 kcal mol^{-1} (11). For other rearrangements, the barriers are generally lower. Barriers determined experimentally for 1,2-H shifts in *p*-trifluorobenzylchloro-, *p*-chlorobenzylchloro-, and cyclobutylchlorocarbenes are 4.9, 4.5, and 2.3 kcal mol^{-1}, respectively (6,7). For 1,2-C migration in cyclobutylchloro-, cyclopropylchloro-, cyclopropylfluorocarbenes the barriers are 3.8, 3.0, and 4.2 kcal mol^{-1}, respectively (6).

Comparison with methyl migration

For comparison and further mechanistic insight, we now focus on the mechanism of 1,2-methyl migration from oxygen to the carbene carbon in methoxysiloxycarbene. Initially, we will examine the possible rearrangement mechanisms in terms of FMO theory. First, let us consider the requirements that would favor nucleophilic attack by the carbene C6 lone pair at the methyl carbon C1. For this mechanism to be favored, sizeable coefficients for the HOMO and LUMO must be located on the C6 and C1 atoms, respectively. Indeed, there is a sizeable coefficient for the HOMO on the C6 atom, but the coefficient for the LUMO on the C1 atom appears to be negligible (Fig. 2).

Note: $\rho(r_c)$, $\nabla^2\rho(r_c)$, and ε represent the electronic charge density, the Laplacian of the charge density, and bond ellipticity, respectively.

Thus, even though the n_{C6} orbital may be well aligned with the σ^*_{C1-O2} orbital in conformers **A** and **C**, nucleophilic attack by the carbene lone pair at the methyl carbon is expected to be unfavorable. In the case of an anion-like shift of

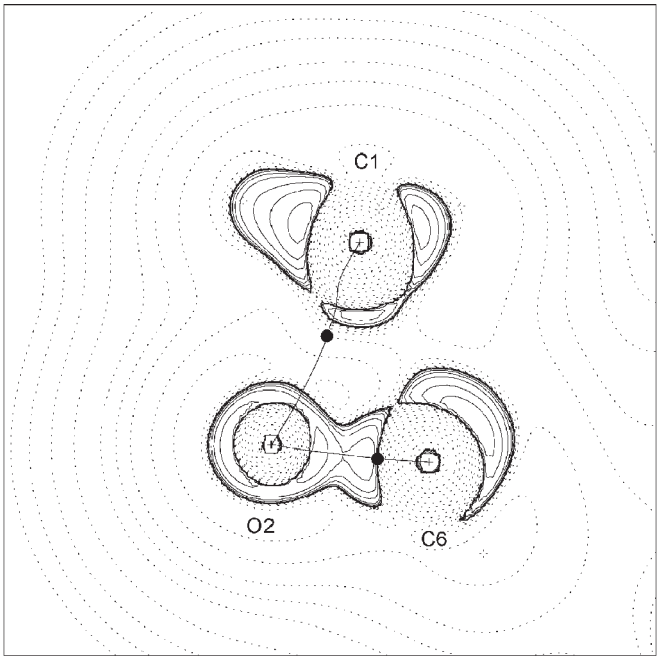
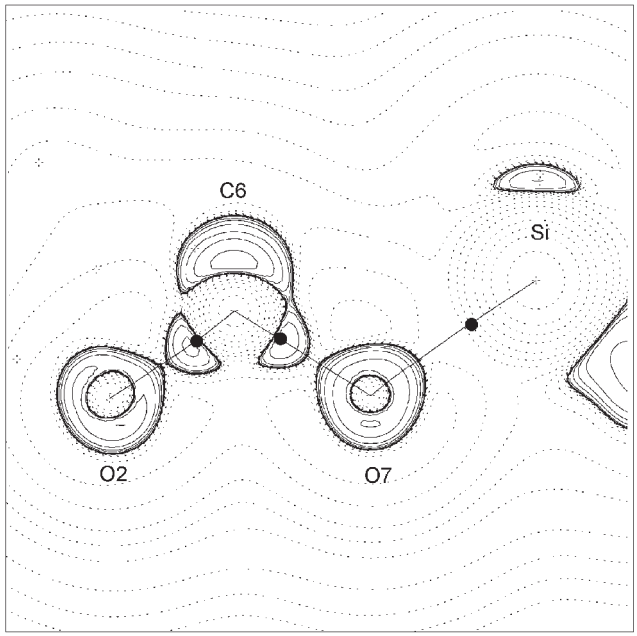
Fig. 6. Contour maps showing two views of the Laplacian of the electron density for $\mathbf{TS_{AF}}$ in the C1-O2-C6 and O2-C6-O7 planes generated from the MP2/6–311+G(2d,p) wavefunction. Solid contour lines correspond to $\nabla^2\rho < 0$ and broken lines are for $\nabla^2\rho > 0$. The dots along the bond paths denote the bond critical points.



$\mathbf{TS_{AF}}$



$\mathbf{TS_{AF}}$

the methyl group from oxygen to the carbene carbon, one would expect the σ_{C1-O2} orbital to be a major contributor to the HOMO and a large coefficient for the LUMO on C6. But it is apparent from the FMO plots in Fig. 2 that these conditions are not met, and hence, this latter mechanism may be ruled unfavorable. Furthermore, since the C1–O2 bond is locked in the symmetry plane of the carbene as indicated by the high isomerization barriers via $\mathbf{TS_{AB}}$ (Table 1), alignment of the σ_{C1-O2} orbital with the vacant out-of-plane carbene *p*-orbital would not occur readily.

The transition-state geometries computed for 1,2-methyl migration from oxygen to the carbene centre are shown in Fig. 5, along with the corresponding products, *anti*-silyl acetate **F** and *syn*-silyl acetate **G** (the transition states are labeled $\mathbf{TS_{AF}}$ and $\mathbf{TS_{CG}}$, respectively). In contrast to 1,2-silyl migration, the geometric features of these transition states are more consistent with an anion-like shift of the methyl group from oxygen to the carbene carbon. Compared with ground-state carbene conformers (Fig. 1), the breaking C1–O2 bond becomes elongated, the developing O2–C6 double bond shortens, and the C1-O2-C6 angle shrinks considerably in the two transition states. Most importantly, the methyl group is out-of-plane in the two transition states suggesting that the C1–O2 bond rotates for better alignment with the vacant carbene *p*-orbital.

As done earlier for 1,2-silyl migration, NBO and AIM analyses were used to monitor changes in electronic structure during 1,2-methyl migration. NBO-computed atomic charges seem to suggest that there is generally modest positive charge build-up at the C1 and O2 atoms, while there is positive charge depletion on C6 (Table 7). These observations are somewhat indicative of an anion-like shift of the methyl group from oxygen to the carbene *p*-orbital, accompanied by simultaneous formation of the O2–C6 double bond. In fact, the analysis indicates that formation of both the O2–C6 double bond and the new C1–C6 single bond is essentially complete in the two transition states.

AIM analyses at the B3LYP and MP2 levels of theory indicate that there is a tremendous decrease in $\rho(r_c)$ along the C1–O2 bond path, whereas $\rho(r_c)$ increases slightly along the O2–C6 bond path in going from **A** and **C** (Table 3) to $\mathbf{TS_{AF}}$ and $\mathbf{TS_{CG}}$, respectively (Table 8). There is also significant positive charge development at the C1 atom and sizeable positive charge depletion at the O2 atom, while the charge development at the C6 atom appears to be negligible. There is some deviation, however, from these general trends at the HF level. Nevertheless, the observations at the B3LYP and MP2 levels may be indicative of an anion-like shift of the methyl group from oxygen to the carbene carbon, in concert with the formation of the O2–C6 double bond. Surprisingly, AIM analysis seems to indicate that the C1–C6 bond is not yet fully developed in the transition state, in contrast to the prediction of NBO analysis.

To gain further insight into the electronic structure changes in going from **A** and **C** to $\mathbf{TS_{AF}}$ and $\mathbf{TS_{CG}}$, respectively, we have also compared contour plots of the Laplacian of the electron density $\nabla^2\rho$. Two views of such plots for $\mathbf{TS_{AF}}$ are shown in Fig. 6. The first contour plot is in the C1-O2-C6 plane and the second is in the O2-C6-O7 plane. In the first plot, there appears to be a slight build-up of charge concentration on C1, roughly along the dissociating C1–O2 bond path. This may be associated with an anion-like shift of the methyl group C1 from oxygen to the carbene carbon C6. Furthermore, both plots clearly show that the charge concentration corresponding to the carbene lone pair in **A** (Fig. 4) remains unchanged in $\mathbf{TS_{AF}}$, which is contrary to what was seen earlier for 1,2-silyl migration. This latter ob-

© 2002 NRC Canada

servation rules out the possibility of a mechanism involving nucleophilic attack by the carbene lone pair C6 at the methyl carbon C1.

Finally, the relative Gibbs free energy barriers computed for 1,2-methyl migration (via $\mathbf{TS_{AF}}$ and $\mathbf{TS_{CG}}$) are considerably higher than those computed for 1,2-silyl migration (via $\mathbf{TS_{AD}}$ and $\mathbf{TS_{BE}}$), as can be seen from Table 1. They are more than 40 kcal mol^{-1} higher at the HF level of theory, while they are more than 30 kcal mol^{-1} higher at the B3LYP and MP2 levels of theory. The very high barriers for 1,2-methyl migration are most likely due to the fact that the methyl group must rotate out-of-plane before migration can occur, and this means that the O2–C6 bond that, as discussed earlier, has strong double-bond character, must be broken in the process. This explains why 1,2-methyl migration from oxygen to the carbene centre is energetically unfavorable, a finding that is consistent with the predictions of FMO theory. In contrast, 1,2-silyl migration occurs in the valence plane of the carbene, the C6–O7 double-bond character can be maintained during the process, and the resulting barrier to migration is fairly low. This may explain why only 1,2-silyl migration is observed experimentally (17).

Conclusion

Ab initio molecular orbital theory and hybrid density functional theory calculations were carried out to investigate the mechanisms of intramolecular 1,2-migrations from oxygen to the carbene carbon in methoxysiloxycarbene as a model system for methoxytriphenylsiloxycarbenes. FMO theory, NBO analysis, and AIM theory were also used to shed light on the mechanistic details of 1,2 migrations in these carbenes. Our combined analyses clearly indicate that the mechanism for 1,2-silyl migration from oxygen to the carbene carbon in methoxysiloxycarbene involves nucleophilic attack by the carbene lone pair at silicon. In contrast, 1,2-methyl migration from oxygen to the carbene carbon appears to involve an anion-like shift of the methyl group from oxygen to the carbene *p*-orbital. In addition, the computed relative Gibbs free energy barriers are relatively low for 1,2-silyl migration, but significantly high for 1,2-methyl migration because the latter mechanism involves breaking a bond with considerable double-bond character. These findings are consistent with the fact that thermally generated methoxytriphenylsiloxycarbene rearranges to form the product via 1,2-triphenylsilyl migration not via 1,2-methyl migration (17).

Acknowledgments

This work was funded by research grants from the Natural Science and Engineering Research Council (NSERC) of Canada, the Fonds pour la Formation des Chercheurs et l'Aide à la Recherche (FCAR, Québec), and the Faculty Research and Development Program (FRDP) of Concordia University. Calculations were performed at the Centre for Research in Molecular Modeling (CERMM), which was established with the financial support of the Concordia University Faculty of Arts & Science, the Ministère de l'Éducation du Québec (MEQ), and the Canada Foundation for Innovation (CFI). The authors would like to thank Heidi Muchall for helpful discussions.

Biocapteurs ampérométriques à cholinestérases pour la détermination des pesticides organophosphorés

Graziella Turdean, Ionel Catalin Popescu et Liviu Oniciu

Résumé : Le but de cette étude est une présentation comparative des différents types de biocapteurs ampérométriques à cholinestérase pour la détermination des pesticides organophosphorés basée sur l'information bibliographique des 20 dernières années. L'étude contient la présentation de la structure et les propriétés des cholinestérases, les principales réactions impliquées dans le fonctionnement du biocapteur ampérométrique, leurs applications et les facteurs influençant le procès de la détection ou (et) de l'inhibition. Les valeurs de la limite de détection obtenues à l'aide des biocapteurs mono- ou bi-enzymatiques sont relativement plus élevées par rapport à celles obtenues par les méthodes immunologiques ou par chromatographie en phase gazeuse et liquide, qui demeurent les méthodes de référence. Comme il a été montré aussi pour d'autres biocapteurs ampérométriques, l'application du traitement cinétique de Michaelis–Menten, utilisé pour les réactions catalysées par l'enzyme libre, peut être extrapolée pour examiner la réponse des biocapteurs ampérométriques à l'enzyme immobilisée. Le compromis positif entre les avantages et les inconvénients, ainsi que les conditions expérimentales « douces », font du biocapteur ampérométrique monoenzymatique, un outil analytique intéressant pour la détection des pesticides organophosphorés.

Mots clés : biocapteurs ampérométriques, acetylcholinestérase, pesticides organophosphorés, cinétique, inhibition.

Abstract: The purpose of this study is a comparative presentation of the different types of the amperometric biosensors based on cholinesterases for the determination of organophosphorous pesticides using the bibliographical information of the last 20 years. The study contains the presentation of the structure and properties of the cholinesterases, the main reactions implied in the functioning of the amperometric biosensors, their applications and factors influencing the detection or (and) the inhibition process. The detection limit of the mono- or bi-enzymatic amperometric biosensors are relatively higher than those corresponding with the immunobiosensors or with gas and liquid chromatography, which are still considered as the reference methods. As shown, for many other amperometric biosensors, the Michaelis–Menten's kinetic treatment used for reactions catalyzed by free enzymes can be extended to describe the response of amperometric biosensors based on immobilized cholinesterases. The positive compromise between advantages and drawbacks, as well as the "soft" experimental conditions, point to the amperometric monoenzymatic bioelectrode, as an attractive analytical tool for the detection of organophosphorous pesticides.

Key words: amperometric biosensor, acetylcholinesterase, organophosphorous pesticides, kinetic, inhibition.

Introduction

Pendant les dernières années, l'utilisation des pesticides (insecticides, herbicides, fongicides) en quantités de plus en plus importantes — afin de surmonter les nécessités de nourriture réclamées par l'explosion démographique — a entraîné l'augmentation de la pollution de l'environnement, notamment avec des insecticides organophosphorés. Ces substances toxiques possèdent un effet nocif contre les insectes et les mammifères, mais aussi présentent un danger important pour l'être humain, puisqu'elles agissent au niveau du système nerveux.

Dû à leur persistance dans le sol et dans l'eau de la nappe phréatique, les normes nationales et internationales imposent des concentrations maximales admissibles des pesticides de plus en plus faibles. Les méthodes analytiques acceptées pour leur dosage utilisent des techniques très complexes pour l'identification et la détermination. Parmi ces techniques, les plus utilisées sont la chromatographie en phase liquide et en phase gazeuse, souvent couplées à la spectrométrie de masse, techniques très performantes mais aussi laborieuses, coûteuses et qui nécessitent un personnel hautement qualifié.

Étant très spécifique, le mécanisme d'inhibition des cholinestérases induit par les pesticides organophosphorés a conduit au développement de nombreuses techniques d'analyse rapide. Ainsi, une solution moderne aux méthodes déjà classiques est offerte par les méthodes électroanalytiques, qui utilisent des outils simples, capables de délivrer une information rapide dans différents domaines d'application :

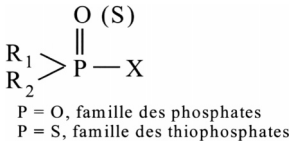
Fig. 1. Formule générale des pesticides organophosphorés.



agro-alimentaire (1), biomédical (2, 3) et environnement (4). Parmi ceux-ci, les biocapteurs électrochimiques sont de plus en plus utilisés. Ils consistent dans le couplage d'un récepteur de nature biologique à un transducteur électrochimique. Grâce à l'excellente spécificité des enzymes et à la très bonne sensibilité des transducteurs ampérométriques, la plupart des recherches récentes a été orientée vers la réalisation de biocapteurs ampérométriques enzymatiques. Ceux-ci mettent en valeur, à la fois, la grande variété des éléments de reconnaissance biologiques et les avantages de la technique ampérométrique, comme par exemple : la haute sensibilité et la bonne sélectivité pour l'espèce électroactive; le domaine de linéarité étendu; la fabrication facile d'un appareillage peu coûteux; l'utilisation des matériaux d'électrodes compatibles dans différents milieux.

Depuis la construction du premier biocapteur ampérométrique pour glucose (5) et malgré une activité de recherche intense, les applications des biocapteurs introduites dans la vie courante sont encore rares. L'obstacle majeur au développement et à la commercialisation de ces outils est l'instabilité de l'enzyme immobilisée. À la fois, l'existence de certaines substances susceptibles d'interférer au niveau du transducteur, souvent présentes dans les échantillons à analyser, constitue encore un problème à résoudre.

Les pesticides organophosphorés

Définition

Conformément aux normes du Food and Agricultural Organization (FAO) (6) un pesticide est défini comme « toute substance ou mélange de substances : (*i*) utilisée pour la prévention, la destruction ou le contrôle de tout animal, espèces de plantes, qui cause préjudice pendant, ou interfère avec, la production, le traitement, le stockage, le transport ou la commercialisation des aliments, des produits agricoles, du bois ou des produits en bois, du fourrage pour animaux; (*ii*) administrée aux animaux pour le contrôle des insectes; comme régulateur de croissance des plantes, défoliant, ou agent conservant les fruits pour prévenir leur chute prématurée; (*iii*) appliquée à la récolte (soit avant, soit après) en vue de protéger les produits de la détérioration pendant le stockage et le transport » (6).

Structure

Le grand développement des pesticides organophosphorés a commencé en 1944, quand Schrader a synthétisé le parathion. Les pesticides organophosphorés, dont la formule générale est présentée dans la figure 1, sont des esters, des amines ou des dérivés thiols de l'acide phosphorique ou phosphonique. Les groupements R_1 et R_2 peuvent être des alkyls ou des aryles et X est un groupe hydrolysable aliphatique, aromatique ou hétérocyclique. En général, ils sont des composés solubles dans l'eau. En milieu alcalin, ils sont rapidement hydrolysés et oxydés en acide (thio)phosphorique ou (thio)phosphonique (mono- ou di-substitué).

Modalités d'action des pesticides

L'action des pesticides organophosphorés sur les insectes et les mammifères se situe au niveau du système nerveux. Ces substances toxiques inhibent l'acétylcholinestérase (AChE), entraînant une accumulation d'acétylcholine dans les tissus nerveux. Au niveau des synapses cholinergiques, cette inhibition est due au blocage du site estérique de l'enzyme (phosphorylation ou carbamylation du OH de la sérine du site actif) (7–9) par les composés organophosphorés, qui agissent en compétition avec le substrat spécifique de l'enzyme (10). Cette fixation conduit à la formation de complexes intermédiaires de type phosphoryl- ou carbamyl-AChE, qui s'hydrolysent très lentement (11). L'accumulation de l'acétylcholine due à l'inhibition de l'AChE peut avoir des suites graves : maladies ou même la mort (12).

Sources de pollution par les pesticides

De grandes quantités de ces pesticides peuvent être apportées au milieu aquatique, soit directement (par dispersion), soit indirectement (par lavage des terrains agricoles), ou même accidentellement. La nature, la concentration, la solubilité dans l'eau et la capacité de dégradation des pesticides sont des facteurs qui influencent leur transport dans le milieu aquatique (13).

La contamination humaine par ces différentes substances toxiques se fait principalement par l'intermédiaire de l'eau, des plantes ou des animaux qui ont ingéré des plantes contaminées. Mais elle peut se faire également par ingestion, inhalation ou contact direct (14, 15).

Grâce à leur stabilité, les pesticides peuvent persister dans le sol pendant des mois ou des années. Une proportion importante de ces substances n'atteint pas leur cible et se dépose ou dérive dans différents écosystèmes. Une fraction se sublime dans l'air et fait l'objet d'un transport vers les zones océaniques les plus reculées. En milieu continental, on observe aussi une incorporation à la biomasse terrestre ou limnique.

Normes de qualité pour l'eau potable

Plusieurs normes réglementent l'utilisation et la commercialisation des pesticides. Les précautions concernant la protection des animaux (gibier, poisson) et du personnel, pendant la fabrication ou l'utilisation de ces pesticides, doivent être strictement respectées, certains de ces produits ayant un temps de demi-vie d'environ 3 mois.

Un des problèmes majeurs liés à l'utilisation de ces pesticides est la persistance des métabolites dans les eaux et dans les plantes, que l'on retrouve ultérieurement dans les aliments.

La législation concernant l'utilisation des pesticides est devenue de plus en plus stricte, recommandant des tests nombreux et sensibles. Ainsi la norme fixée pour la production de l'eau potable, par la Communauté Économique Européenne (CEE) (16), limite la teneur maximale en pesticides à 0,1 $\mu g\ L^{-1}$ pour chaque substance de ce groupe et à 0,5 $\mu g\ L^{-1}$ pour l'ensemble des pesticides et de leurs composés de dégradation, pendant que la U.S. Environmental

© 2002 CNRC Canada

Protection Agency établit des niveaux maximums pour chaque pesticide qui doit être mesuré (3).

Méthodes de détection des pesticides dans l'eau, l'air et le sol

Le développement des méthodes de « monitoring » est essentiellement centré sur trois niveaux : (*i*) outil rapide, très sensible et spécifique; (*ii*) technologie sophistiquée et durable ou solide; (*iii*) outil capable de combiner la sensibilité, la flexibilité et la solidité des techniques mentionnées (p. ex. biocapteur). Parmi les nombreuses méthodes de détection des pesticides organophosphorés rapportés dans la littérature — chromatographiques, spectophotométriques, électrochimiques, immunologiques et enzymatiques — nous n'allons détailler ici que les méthodes ampérométriques basées sur l'utilisation des cholinestérases.

Biocapteurs ampérométriques

Définition

Un biocapteur est un dispositif intégré, indépendant, capable de fournir des informations analytiques quantitatives ou demi-quantitatives, utilisant un élément de reconnaissance biologique (récepteur biologique) qui est en contact direct avec un transducteur (17–25). Cette définition est en conformité avec les normes émises par la Commission de l'IUPAC.

Caractéristiques de la détection ampérométrique

Suivant la définition déjà donnée, un biocapteur ampérométrique (BA) est constitué par deux unités opérationnelles de base : le récepteur et le transducteur. Dans le cas de BA, le transducteur est de type ampérométrique. Celui-ci est constitué notamment d'une électrode conventionnelle ou modifiée qui fournit à un potentiel contrôlé, comme signal de réponse, un courant électrique, entretenu par la réaction électrochimique d'une espèce chimique, résultante naturelle de la réaction biochimique ou d'un intermédiaire (médiateur redox), délibérément introduit dans la structure du BA (fig. 2).

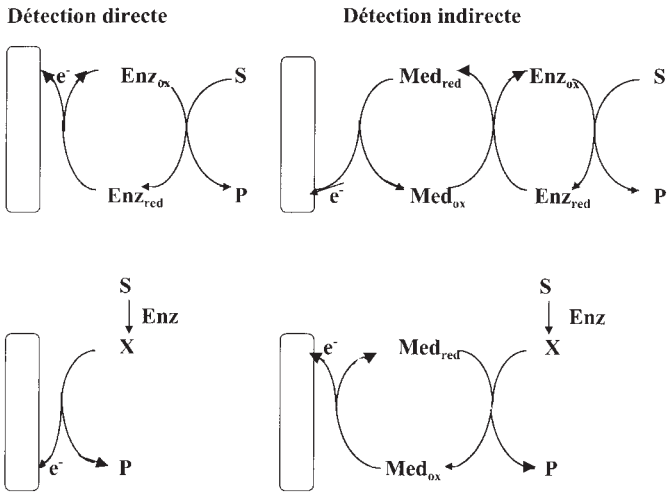
Le récepteur peut être de type catalytique (enzyme, organite, cellule, tissu) ou de type non catalytique (anticorps, antigène).

La quantité du substrat impliquée dans la réaction électrochimique, qui est à la base du fonctionnement du transducteur ampérométrique (TA), est donnée par la loi de Faraday. L'intensité (densité) du courant obtenu au niveau de l'interface électrochimique active dépend de la concentration de l'espèce électroactive, du type de transport de masse de l'espèce électroactive et de la valeur du potentiel de l'électrode (par l'intermédiaire d'une relation de type Butler–Volmer).

La construction, les performances et les possibilités d'utilisation des BA dépendent exclusivement de la nature du signal d'excitation et des conditions de transport de masse de l'espèce électroactive vers l'électrode. Selon la forme du signal d'excitation du TA, on peut avoir des mesures ampérométriques (à potentiel contrôlé) ou voltamétriques (balayage de potentiel d'électrode) (25, 26).

Les techniques ampérométriques nécessitant un appareillage simple sont, par conséquent, très utilisées pour la caractérisation des BA. D'autre part, elles ont l'avantage de

Fig. 2. Types de détection ampérométrique directe et indirecte. Enz_{ox}–Enz_{red}, l'enzyme; Med_{ox}–Med_{red}, le médiateur; S, le substrat, P, le produit; X, le reactant ou produit électroactif.



mesurer le courant à des valeurs fixes de potentiel d'électrode (généralement, dans la zone contrôlée par la diffusion), ce qui élimine la contribution du courant capacitif (limite de détection plus basse). Si la solution voisine du TA n'est pas agitée, le signal mesuré varie avec le temps (équation Cotrell), ce qui rend difficile les mesures. Différentes solutions ont été proposées : (*i*) utilisation des TA en régime hydrodynamique (électrode à disque tournant, électrode « wall-jet », etc.); (*ii*) insertion entre le BA et l'échantillon d'une barrière (membrane) qui limite l'augmentation en temps de l'épaisseur de la couche de diffusion; (*iii*) pulsation du potentiel d'électrode d'une valeur initiale correspondant à la zone d'inactivité électrochimique à une valeur finale située dans la zone d'activité électrochimique contrôlée par la diffusion; (*iv*) utilisation de microélectrodes (électrodes ayant une dimension caractéristique d'environ 1×10^{-6} m), avec leurs particularités remarcables (3), notamment : (*a*) le transport de l'espèce électroactive par diffusion sphérique, qui améliore l'accès de celle-ci vers la surface de l'électrode, et (*b*) le courant capacitif réduit, qui augmente le rapport signal/bruit.

Les techniques voltampérométriques (comme la voltampérométrie cyclique) ont d'excellentes capacités de diagnostic. Elles sont utilisées dans le processus d'élaboration et d'insertion du BA dans différentes techniques d'analyses. Les difficultés liées aux appareillages utilisés et à la contribution relativement importante du courant capacitif ($i_c \sim$ vitesse de balayage) limitent l'utilisation de ces techniques pour la détection ampérométrique.

Il est intéressant de remarquer que la sélectivité du BA, déterminée principalement par l'enzyme, peut être aussi modulée par le contrôle adéquat des étapes qui interviennent dans le fonctionnement du TA associé : le transfert de charge à l'interface du TA (contrôle électrochimique) et le transfert de matière vers l'électrode (contrôle hydrodynamique).

Techniques d'immobilisation de l'élément biologique

Les caractéristiques des capteurs à enzyme dépendent des propriétés de l'enzyme immobilisée (27). Dans le cas de l'immobilisation, l'enzyme soluble dans un milieu aqueux se

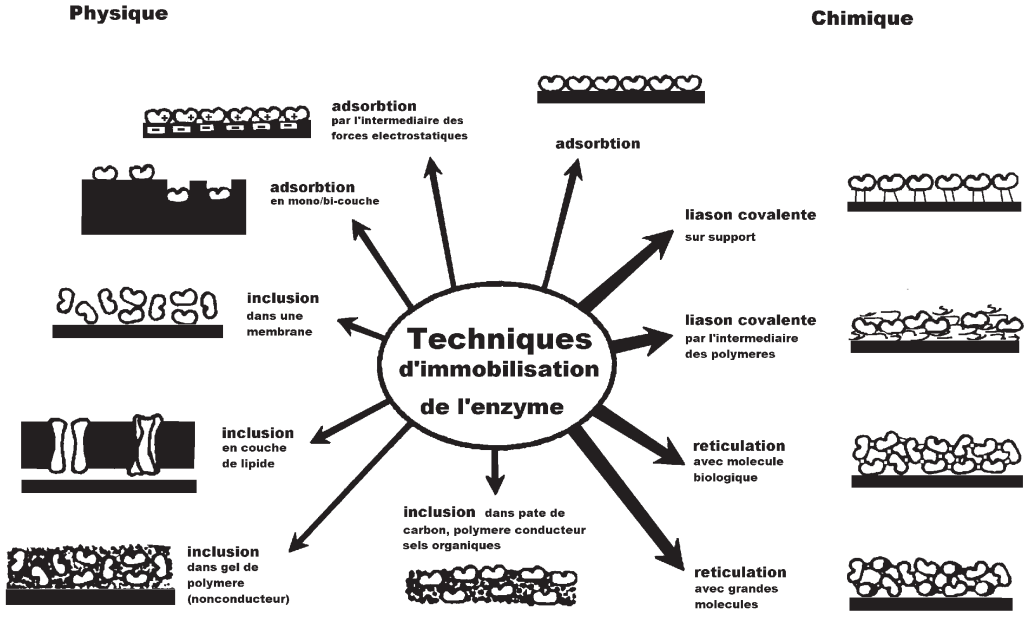
Tableau 1. Avantages et inconvénients de l'enzyme immobilisée (31–34).

Avantages	Inconvénients
Augmentation de la stabilité de l'enzyme vis-à-vis de la modification du pH ou de la température;	Augmentation de la complexité du système étudié;
Diminution du coût de l'analyse due à la réutilisation de l'enzyme;	Nécessité pour le substrat de diffuser vers l'enzyme et pour le co-substrat ou le produit de diffuser vers le transducteur;
Fonctionnement sur de longues périodes;	
Utilisation directe de l'enzyme dans le milieu réactionnel qu'il catalyse;	Modifications des propriétés de l'enzyme dues aux interactions support – site actif de l'enzyme et aux différences entre la phase aqueuse et le microenvironnement de l'enzyme
Séparation rapide du milieu réactionnel;	
Utilisation dans des solvants organiques ou à haute température, conditions dans lesquelles normalement l'enzyme perd son activité;	
Facilité de mise en oeuvre des réacteurs en continu; Limitation des interférences	

Fig. 3. Techniques d'immobilisation de l'enzyme.



fixe dans une matrice insoluble dans l'eau. Ainsi, on observe une décroissance artificielle de la mobilité de l'enzyme, associée à une transformation de la catalyse homogène en une catalyse hétérogène (28).

Les principales techniques d'immobilisation de l'enzyme sont présentées dans la figure 3.

Les méthodes d'immobilisation doivent garantir (28–30) : (*i*) le maintien de l'intégrité de la conformation tertiaire de l'enzyme, en particulier au niveau du site actif; (*ii*) l'accès du substrat au site actif de la biomolécule; (*iii*) le transport du substrat et du produit à travers la couche biologique immobilisée.

Après immobilisation, les propriétés de l'enzyme peuvent être modifiées par suite des effets conformationnels, des effets stériques et des effets de transfert de matière. Il est évident que les modifications observées sur les propriétés enzymatiques après immobilisation sont la résultante des différents facteurs cités, l'effet de chaque facteur isolé étant à déterminer.

Les avantages et les inconvénients de l'immobilisation de l'enzyme sont présentés dans le tableau 1.

Biocapteurs ampérométriques à cholinestérases

Les cholinestérases

Classification

Les cholinestérases sont divisées en acétylcholinestérase (E.C. 3.1.1.7.) (AChE) et en pseudocholinestérase (E.C. 3.1.1.8.) (p. ex. butyrylcholinestérase) (BuChE) (35–38).

© 2002 CNRC Canada

Historique

L'acétylcholinestérase a été découverte en 1938 par David Nachmanson. Il a isolé et purifié cette enzyme à partir des membranes excitables provenant des nerfs de différents mammifères, oiseaux, reptiles et insectes (39). La plupart des recherches, dirigées vers l'étude de sa structure, ont été réalisées avec de l'enzyme isolée et purifiée de la plaque électrique de l'anguille *Electrophorus electricus* (37, 40, 41).

Structure

L'enzyme est une protéine complexe qui possède un centre anionique, un centre estérique, une multitude de centres périphériques et de nombreux domaines hydrophobes (39). Le site actif de l'enzyme contient le centre anionique, qui fixe les groupements cationiques du substrat (p. ex. sels d'ammonium quaternaire) et le centre estérique (qui possède une sérine), dont le OH est acylé pendant la réaction d'hydrolyse (42, 43) (fig. 4).

Le centre anionique contient des charges négatives, qui proviennent du groupement COO^- des chaînes latérales des acides aminés aspartique ou glutamique. Ce centre anionique permet la fixation des charges positives (p. ex. choline) provenant du substrat (35).

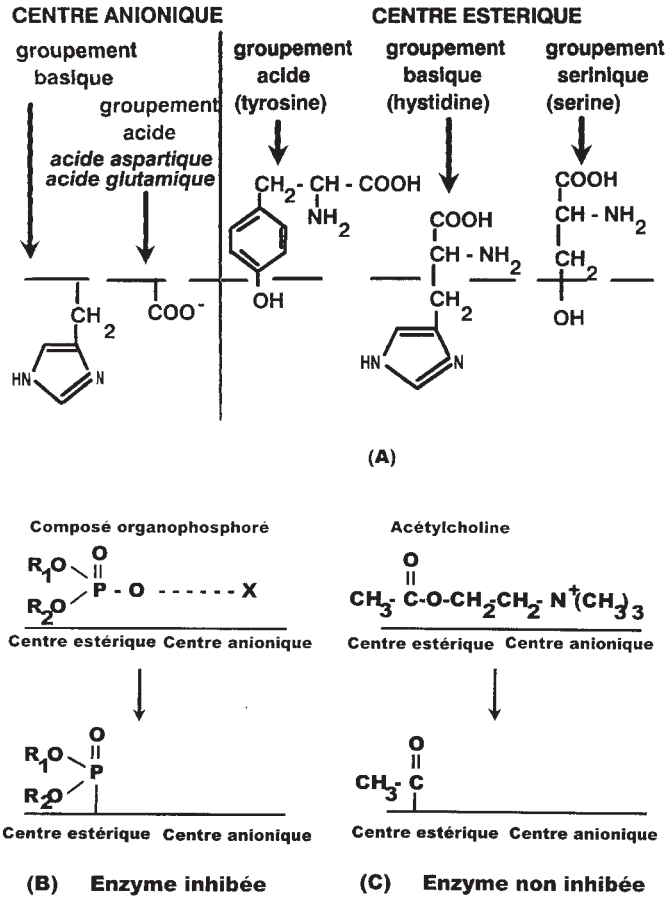
Les principales caractéristiques des cholinestérases sont présentées dans le tableau 2. D'autre part, il faut mentionner que de nombreuses études ont été élaborées sur le comportement des cholinestérases, dans des situations spécifiques, comme par exemple : le viellisement (37, 40, 42–49), l'inhibition des cholinestérases et l'inactivation thermique (50).

Techniques d'immobilisation des cholinestérases

Dans la plupart des applications, l'enzyme doit être immobilisée sous sa forme active (54). L'immobilisation diminue l'action des inhibiteurs irréversibles sur l'activité enzymatique (27). Dans le tableau 3 sont présentées les différentes modalités d'immobilisation de l'AChE et la BuChE (éventuellement couplées avec la choline oxydase, ChO) en fonction du type de détection utilisée. Le pH optimum d'immobilisation est situé entre 7,2 à 7,8 (54).

L'immobilisation de l'enzyme par « liaisons covalentes » met en jeu une réaction chimique, qui réalise une liaison irréversible entre la molécule d'enzyme et les groupements réactifs du support. À ce type de liaison s'ajoutent toujours des phénomènes d'électrosorption, qui consolident la liaison support–enzyme. La formation de la liaison covalente peut conduire à la modification de la structure tridimensionnelle de l'enzyme, altérant son activité enzymatique (28). Pour l'immobilisation de l'AChE par liaison covalente sur une surface de platine, on peut utiliser avec succès différentes méthodes de modification chimique du groupement OH présent sur la surface du support : (*i*) activation des groupements OH par le carbodiimide ou le chlorure de trésil, pour produire des groupements capables de réagir directement avec l'enzyme; (*ii*) modification basée sur la formation de pontages entre les groupements aminés d'un support et de l'enzyme par l'intermédiaire d'un ligand bi- ou multi-fonctionnel, ce qui permet d'écarter le biocatalyseur de son support solide et d'améliorer l'accessibilité du substrat au site actif de l'enzyme (29). De même, l'utilisation du glutaraldéhyde (GA), qui se lie sur les groupements aminés du silane, est également possible. D'autres réactifs hétérofonctionnels (ester

Fig. 4. La structure de l'acétylcholinestérase (A) et comparaison entre la structure de l'enzyme inhibée (B) et de l'enzyme non inhibée (C) (133).



n-γ-maleimidobutyriloxisuccinamidique) sont utilisés et peuvent former des liaisons avec les fonctions thiols de silane (54).

Dans la technique de « co-réticulation », les molécules d'enzyme sont liées entre elles par pontages intermoléculaires, faisant intervenir des agents bi- ou multi-fonctionnels. On obtient ainsi des structures de très haut poids moléculaire. La co-réticulation avec GA fournit des films reproductibles, dans lesquels, la densité enzymatique, l'épaisseur et la nature de la protéine inactive peuvent être contrôlées (28).

Réactions utilisées dans le fonctionnement des biocapteurs ampérométriques à cholinestérases

Les deux principales étapes impliquées dans le fonctionnement des biocapteurs ampérométriques à cholinestérases sont : la réaction biochimique d'hydrolyse catalysée par l'enzyme et la détection électrochimique de l'espèce électroactive formée pendant la réaction biochimique. Les réactions possibles sont synthétisées dans le tableau 4.

Le mécanisme de l'hydrolyse — du plus simple substrat — l'acétylthiocholine (ASCh), catalysé par l'AChE, suit trois étapes (39) décrites dans les schémas suivants (fig. 5).

L'ASCh se fixe sur le site actif de l'enzyme par des liaisons électrostatiques, qui se forment entre la charge positive

de l'atome d'azote d'ASCh et la charge négative du site anionique de l'enzyme, formant un complexe enzyme–substrat (ES) (étape I). En même temps, la réaction d'acétylation de l'OH de la sérine du site estérique est catalysée par la présence du groupement imidazole basique de l'histidine et par le groupement acide AH (l'hydroxyl de tyrosine). Il y a alors formation de l'enzyme acétylée EA (étape I). La désacétylation (étapes II, III) est une réaction rapide, qui permet la libération de l'enzyme libre (E) en quelques millisecondes.

L'hydrolyse de l'ASCh catalysée par l'AChE, en considérant les deux étapes d'acétylation et de désacétylation, a un mécanisme identique à celui d'une réaction acide–base (39).

La détection électrochimique est réalisée par l'oxydation de la thiocholine – produit électroactif de la réaction biochimique – dans le cas du système monoenzymatique ou par l'oxydation–réduction (en fonction de transducteur) de l'eau oxygénée, dans le cas du système bienzymatique. L'oxydation peut avoir lieu directement sur l'électrode ou par l'intermédiaire des médiateurs redox. Ces différentes modalités de détection possibles seront détaillées et exemplifiées par la suite.

Application des biocapteurs ampérométriques à cholinestérases pour la détection des pesticides organophosphorés

L'utilisation des biocapteurs ampérométriques à cholinestérase est largement répandue pour la détection de la concentration globale en pesticides. Le principe de détection d'un biocapteur est fondé sur l'effet inhibiteur exercé par les pesticides sur l'enzyme immobilisée. La différence entre l'activité enzymatique initiale et celle enregistrée après une incubation dans un échantillon contaminé, fournit des informations d'un côté sur la présence des pesticides et de l'autre côté sur le potentiel toxique et la concentration de l'échantillon (80, 92–94).

Les différents types de biocapteurs ampérométriques utilisés pour la détection des pesticides présentés par la suite sont classifiés selon le type de cholinestérase immobilisée acétylcholinestérase (AChE) ou butyrylcholinestérase (BuChE) et selon le nombre d'enzymes immobilisées (mono-, bi- ou tri-enzymatique).

Système monoenzymatique

L'utilisation de la technique ampérométrique monocholinestérique (AChE ou BuChE) nécessite l'utilisation comme substrat de l'acétylthiocholine ou de la butyrylthiocholine. Dans ce cas, la détection électrochimique est réalisée par l'oxydation de la thiocholine, conformément aux réactions 1 (tableau 4) (12, 55–57, 62, 63, 76, 77, 81–86, 95) ou réactions 2 (tableau 4) (57, 80–82, 87, 88).

Les conditions expérimentales de détection des pesticides et les limites de détection correspondantes sont présentées dans le tableau 5.

Du fait que la surtension d'oxydation du substrat (thiocomposé) sur le platine est relativement grande, on préfère utiliser des électrodes en carbone non- ou (et) modifiées. D'autre part l'oxydation de la thiocholine est un procès irréversible et suivant les conditions expérimentales (présence ou absence de l'oxygène, présence ou absence d'un médiateur) (62–63, 77, 96–100) la valeur du potentiel appliqué à l'électrode se situe dans l'intervalle entre –0,2 et –0,85 V/Ag/AgCl. Le mécanisme d'oxydation de la thiocholine (RSH) est analogue à celui de l'oxydation de la cystéine. La détermination du nombre d'électrons impliqués dans ce processus confirme que deux ions de Co (I) s'oxydent en même temps par interaction avec la liaison disulfurée du produit d'oxydation (RSSR) (99, 100).

L'immobilisation de l'AChE est possible par liaison covalente sur graphite modifié avec *N*-cyclo-hexyl-*N′* (2-*N*-méthylmorpholino) éthylcarbodiimide-4-toluènesulphonate (62, 101) ou par inclusion dans un mélange biocomposite, préparé de poudre de graphite, d'une résine époxydique (Epo-Tek H77) et de l'enzyme (12, 102). Dans ces cas, la détection de l'ASChI a lieu à +0,8 V/ESC (97) et de l'ASChCl à +0,7 V/Ag/AgCl. (12, 102) La réalisation d'une électrode biocomposite, dont la construction est simple et rigide, correspond à un biocapteur à usage unique très adéquat pour l'usage dans le domaine médical (102).

Nota : Med, médiateur redox.

Afin d'augmenter la stabilité de la biomolécule en vue de son immobilisation, sans que l'immobilisation ait un effet d'inactivation de l'enzyme, ceci a été possible grâce à la modification chimique de l'enzyme à l'aide des polymères synthétiques (p. ex. copolymère acrylamide – acide acrylique) et un agent de condensation comme le réactif Woodward (*N*-éthyl-5-phényloxazolium-3-sulphonate) (103). Une augmentation de la concentration du réactif Woodward réduit le nombre des liaisons hélicoïdales polymère–protéine, tout en maintenant l'activité enzymatique de l'AChE immobilisée.

Le matériel le plus utilisé pour la construction de l'électrode est le platine (55). On peut utiliser aussi une électrode d'argent recouverte d'un film de mercure. Le thiol formé pendant l'hydrolyse de l'iodure de butyrylthiocholine (BuSChI), en présence de BuChE immobilisée par réticulation avec GA sur une membrane de nitrocellulose, forme avec le mercure un composé électroactif, qui se réduit à un potentiel de –0,55 V/ECS. On obtient une limite de détection de 3×10^{-11} M de chlorophos (40). Un autre matériel souvent utilisé est la pâte de carbone, qui permet l'oxydation de la thiocholine à +0,61 V/Ag/AgCl (voltampérométrie hydrodynamique) (57).

Système bienzymatique à enzymes immobilisées

Lorsque l'on utilise l'acétylcholine comme substrat, le système cholinestérique doit être couplé avec une autre enzyme : la choline oxydase (ChO). La détection électrochimique est obtenue par l'oxydation de H_2O_2 produite dans la réaction biochimique sur une anode de platine (68, 71, 73, 96) ou par la mesure de la consommation de l'O_2 impliqué dans la réaction biochimique en utilisant une électrode Clark, conformément aux réactions 3 (tableau 4) (58, 71, 73, 75). Les différentes conditions expérimentales proposés pour la réalisation des biocapteur bienzymatique sont présentées dans le tableau 5.

L'inconvénient de la méthode bienzymatique est que l'étape d'oxydation de la choline peut être fortement influencée par les fluctuations de la teneur en O_2 dans le voisinage de l'électrode. Dans le cas où serait utilisée la détection ampérométrique d'H_2O_2, le fait que celle-ci a lieu à un potentiel relativement élevé, où certains composés peuvent être facilement oxydés, rend la méthode sensible aux interférences (104, 105).

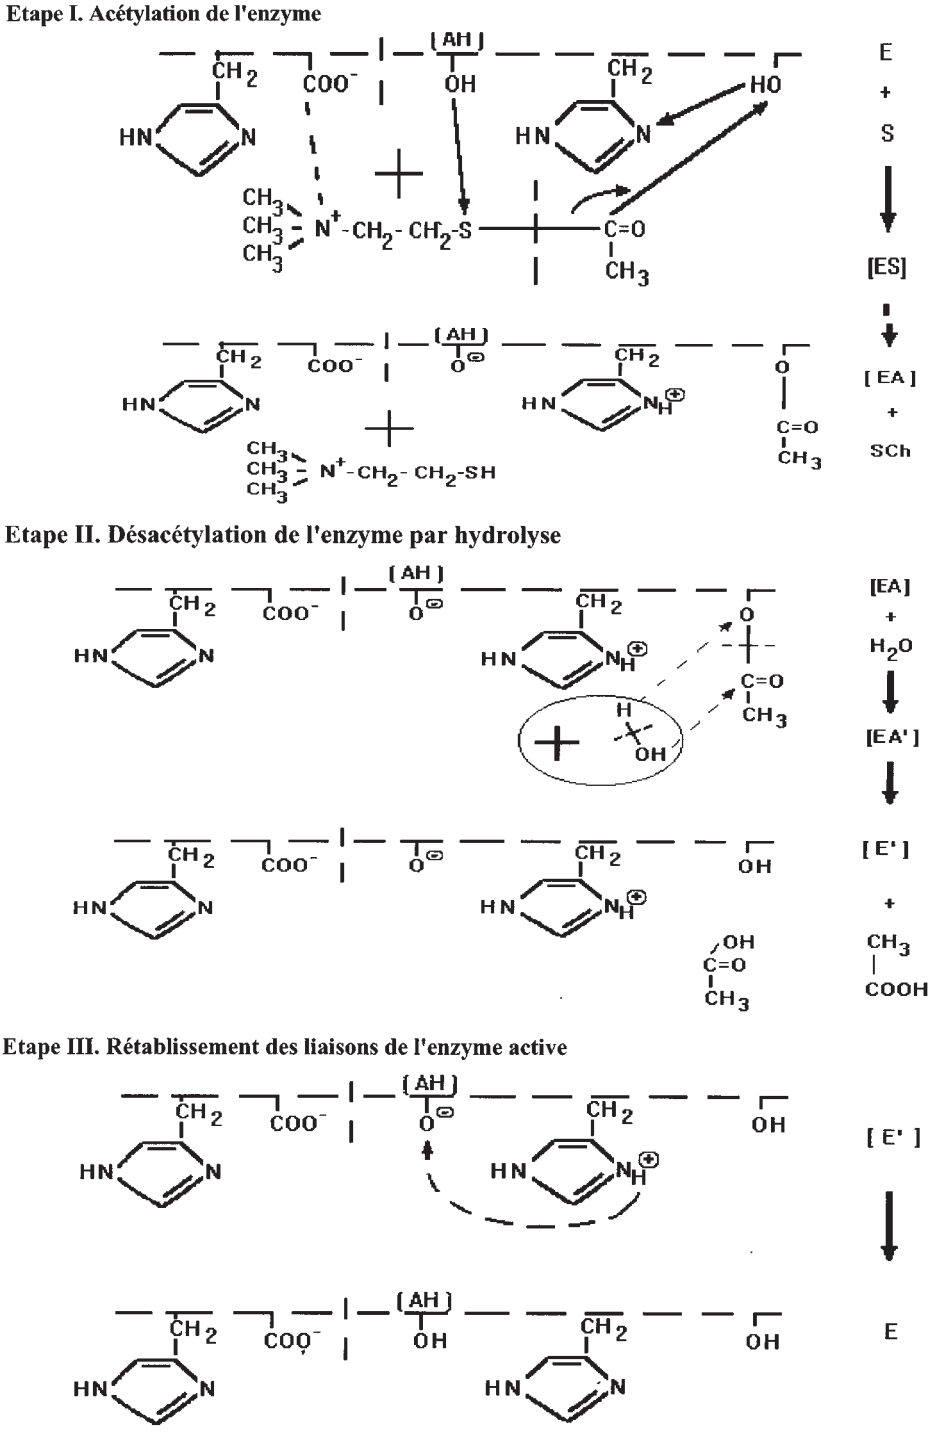
Le plus simple modèle de biocapteur bienzymatique consiste à associer une anode de platine et une cathode de Ag/AgCl (électrode Clark) et à les recouvrir ensuite d'une matrice enzymatique à base d'une membrane d'acétate de cellulose protégée par une membrane Immobilon™. La membrane d'acétate de cellulose protège l'anode de platine contre les éventuels interférents électrochimiques chargés négativement (p. ex. : phénols), très répandus dans l'eau (91).

Les études par voltampérométrie cyclique, avec une électrode d'or recouverte d'une membrane AChE + ChO, soulignent l'importance du transport de masse à l'intérieur de la matrice bienzymatique (tableau 4, équation [3]). L'hydrolyse, au niveau de la couche enzymatique, de l'acétylcholine (ACh) libre en choline (Ch), en présence d'AChE immobilisée, est réalisée avec un bon rendement. La concentration du produit (Ch) dans la matrice enzymatique est proportionnelle avec la concentration de l'ACh en phase aqueuse. Il est possible qu'il existe une lente libération de la Ch du réseau enzymatique, mais la choline oxydase fixe ce produit d'hydrolyse (Ch) avec une sensibilité qui dépend de la concentration d'ACh libre (ou de Ch dans la couche enzymatique) (106).

La voltampérométrie cyclique d'un médiateur (l'hexacyanoferrate (III)) sur une électrode de carbone vitreux avec l'AChE immobilisée indique un comportement irréversible du médiateur, contrairement au cas où l'électrode serait couverte de choline oxydase (ChO) quand le comportement du médiateur est réversible. Une relation non linéaire entre le

© 2002 CNRC Canada

Fig. 5. Mécanisme d'hydrolyse de l'acétylcholine catalysée par l'acétycholinésterase.



courant de pic (i_p) et la racine carrée de la vitesse de balayage des potentiels ($v^{1/2}$) est observée pour chaque électrode modifiée de ChO, AChE et AChE + ChO, indiquant un transfert de masse lent, dû à la complexité du film. Ainsi, les courbes i_p vs. $v^{1/2}$ révèlent, dans le cas des faibles vitesses de balayage des potentiels, un contrôle diffusif, suivi d'une limitation du courant dû au transfert des électrons observée aux grandes vitesses de balayage du potentiel. Ce phénomène de non linéarité est beaucoup plus prononcé quand l'électrode est modifiée avec un film bienzymatique (AChE + ChO). De même la différence de potentiel entre le pic anodique et le pic cathodique ($\varepsilon_a - \varepsilon_c$) augmente, si la complexité du film augmente (105).

Sur le même principe (réaction 3, tableau 4) a été imaginé un bioréacteur qui contient un complexe AChE–chitine immobilisée sur une colonne à l'aide du glutharaldéhyde (GA). La choline formée dans le réacteur passe dans un récipient contenant un biocapteur à ChO immobilisée sur une membrane de nylon (Pall Immunodyne Affinity) à l'aide de la polyazetidine. Avec ce système (en tampon phosphate, pH 7,5

à 37°C) on obtient des limites de détection de 1 ppb de malathion et 10 ppb de paraoxon (107).

Le principe de fonctionnement d'un biocapteur avec BuChE + ChO immobilisées est décrit par les réactions 4 (tableau 4) (4, 75).

L'oxydation de l'H_2O_2 dans une solution de tampon glycine 0,1 M, pH 8 à 25°C permet d'obtenir un seuil de détection de 6 μg L^{-1} pour le malathion et de 2 μg L^{-1} pour le paraoxon. Les interférents du paraoxon sont : Pb^{2+}, Hg^{2+}, Cd^{2+}, F^-, PO_4^{3-}, $[Fe(CN)_6]^{3-}$, salicilate, arséniate, acétate, nicotine, nicotinate, nicotinamide, tyrosine, alanine, hexaméthylène tétramine, hydroxyéthylamine (4). La même électrode peut être utilisée en milieu organique — chloroforme–hexan (50 %, v/v) — pour la détection de 4,5 μg L^{-1} paraoxon (75).

Système bienzymatique avec l'acétylcholinestérase en solution et la choline oxydase immobilisée

Le principe de fonctionnement de ce type de biocapteur est présenté dans la réaction 6 (tableau 4) (58, 84). Dans ce cas il faut remarquer, d'une part, qu'on observe une adsorption de l'AChE sur la membrane du biocapteur, ce qui modifie la précision des mesures de l'activité de l'enzyme inhibée. D'autre part, en raison de l'hydrolyse spontanée du paraoxon à pH > 8, dans le cas de l'AChE libre ou immobilisée la stabilité du pesticide impose que l'incubation soit faite à pH 7, de façon à assurer une sensibilité maximale du biocapteur bi-enzymatique. Dans ces conditions, avec une électrode de platine polarisée à +0,6 V/Ag/AgCl (détection de l'oxydation de H_2O_2), on obtient une limite de détection de 2,6 ppb de paraoxon (58).

Système trienzymatique

La possibilité de la réalisation d'un biocapteur trienzymatique a été investiguée en utilisant la séquence des réactions 8 (tableau 4) (72, 73, 78, 79).

Les trois enzymes, l'AChE, la ChO et la peroxydase (HRP), ont été immobilisées en présence d'un polymère redox PVP-Os(bpy)$_2$Cl (chlorure de poly(4-vinylpyridine-Os-2,2′-bypyridine) et d'un agent réticulant, le polyéthylène glycol (PEG), sur une électrode en carbone vitreux (72). D'autres manières d'immobilisation utilisent la réticulation du mélange des trois enzymes avec glutharaldéhyde (GA) sur « screen-printed electrode » (79) ou à l'aide des liaisons

électrostatiques (« self-assembled ») par l'intermédiaire du dialdehyde glutharique sur une électrode en or (78), qui permet la détection de 1 ppb trichlorfon. Pendant l'utilisation du système trienzymatique il est important de contrôler l'hydrolyse spontanée du substrat l'ACh en Ch, qui a lieu quelques minutes après la préparation de la solution d'ACh. La réponse du biocapteur n'est pas satisfaisante, car la choline formée diffuse lentement vers la ChO et, de plus, l'AChE est inhibée par la suite de l'immobilisation dans le polymère redox qui contient de la pyridine, connue comme ayant une action inhibitrice (72).

Influence des conditions expérimentales sur le fonctionnement du biocapteurs ampérométriques à cholinestérases pour la détection des inhibiteurs

Tenant compte de la particularité de la détermination des pesticides à l'aide des biocapteurs enzymatiques, l'influence des conditions expérimentales sur leur fonctionnement doit être examinée séparément sur la réaction enzymatique (enzyme–substrat) et sur celle d'inhibition (enzyme–substrat–inhibiteur).

Influence des conditions expérimentales sur la réaction enzymatique

Nature du milieu tampon

Différents types de solutions tampon (phosphate, glycine, citrate ou acide 4-(2-hydroxyethyl)-piperazine-1-éthane sulfonique (HEPES)) ont été utilisés pour la détection des pesticides. On peut remarquer que certaines de ces solutions tampon contiennent des additifs (comme NaCl, $MgCl_2$, KCl, gélatine) ayant le rôle d'augmenter la stabilité de l'AchE (11, 12, 28, 40, 56, 59, 63, 74, 79, 108).

pH

La dépendance de la réponse du biocapteur du pH du milieu réactionnel repose sur son influence sur l'activité enzymatique de l'AChE (71, 108). Les paramètres cinétiques intrinsèques de l'enzyme immobilisée ne sont pas les mêmes que pour l'enzyme libre, à cause des contraintes conformationnelles, diffusionnelles ou stériques (65). Ainsi, une valeur de pH optimal pour l'activité de l'AChE de 8 a été observée en travaillant dans une solution de tampon phosphate pour l'enzyme immobilisée, alors que pour l'enzyme libre, dans les mêmes conditions, le pH optimal est 9. Le changement du pH optimum pour l'activité enzymatique provoqué par l'immobilisation de l'enzyme est un phénomène connu, fréquemment observé (109). Dans la littérature sont rapportées aussi d'autres valeurs du pH optimal : 7,2 à 8 (phosphate, borate) (62, 63, 76, 77, 8) (phosphate) (56, 109), (HEPES 2,5 mM) (108, 110) et 8,5 (glycine) (71).

Une relation entre la concentration du tampon et le courant généré par le BA a été observée. Généralement, le courant mesuré par le capteur diminue avec l'augmentation de la concentration du tampon. Néanmoins, à une valeur très faible de celle-ci, le courant de fond est très stable. Une solution tampon HEPES, ayant une force ionique de 2,5 mM, maintient une ligne de base stable, avec un minimum de dérive (108, 110).

L'utilisation de certains matériaux pour la réalisation des électrodes composites impose parfois le pH de travail. Par exemple, aux valeurs du pH plus élevées que 7, on a constaté une faible dégradation de l'électrode du graphite–epoxi(Epo-Tek H77)–AChE (12).

Température

La réponse du biocapteur est caractérisée par des valeurs maximales si la température du substrat est de 30°C (67) ou 40°C (110). Néanmoins, généralement les mesures sont effectuées dans l'intervalle de température entre 20 et 30°C, car à partir de 50°C l'enzyme est rapidement dénaturée. Pour améliorer la précision des mesures, la température de travail doit être maintenue à une valeur constante, pour éviter toute fluctuation de la réponse du biocapteur qui pourrait être interprétée comme une inhibition (76).

Nature de la matrice

Les caractéristiques de la matrice utilisée comme support pour l'immobilisation de l'enzyme ont un impact important

© 2002 CNRC Canada

sur les performances du biocapteur : le domaine de réponse linéaire, la sensibilité, le temps de réponse, la stabilité opérationnelle et au stockage pendant la conservation (111).

Dans le cas de l'utilisation d'un système de détection bienzymatique et d'un transducteur de type Clark en milieu biologique, il est recommandé de protéger la matrice enzymatique par une membrane de type Nafion, dont le rôle est d'empêcher l'interférence de l'acide ascorbique — électroactif au potentiel de travail de l'électrode — avec le signal de la choline ou de l'acétylcholine (112). D'autres membranes qui améliorent les propriétés mécaniques de la matrice enzymatique peuvent être l'acétate de cellulose (69) ou le nitrate de cellulose (113). Il faut souligner que la membrane de protection agit comme une barrière de diffusion de l'H_2O_2, produite dans la couche enzymatique, vers l'électrode, en réduisant de 40 % l'amplitude du signal (69). Ainsi, la membrane, en limitant la diffusion du substrat, de l'inhibiteur et de l'H_2O_2, diminue aussi le pourcentage d'inhibition, en réduisant à la fois la concentration d'inhibiteur décelable.

Concentration optimale de l'enzyme immobilisée

Le degré d'inhibition est une expression dépendante de la concentration d'enzyme immobilisée. Quand cette concentration est suffisamment élevée, le biocapteur n'est plus influencé par la présence des inhibiteurs en faible concentration. Ceci s'explique par l'évolution de la concentration du substrat ou du produit dans la couche enzymatique qui est fonction de la quantité d'enzyme immobilisée. Pour une faible concentration d'enzyme immobilisée, la concentration du substrat décroisse lentement dans la couche d'enzyme jusqu'à une valeur stationnaire [S_e], qui se trouve à la surface de l'électrode. Quand la concentration d'enzyme immobilisée est élevée, la consommation du substrat a lieu très vite, dans une région de la couche enzymatique dénommée « de réaction », pendant que la région « morte » est limitée par une « interface », dont la position dépend de la concentration d'enzyme immobilisée (114).

Le signal fourni par le biocapteur dépend de la quantité d'enzyme immobilisée suivant une fonction hyperbolique : (*i*) dans la zone de faible concentration d'enzyme immobilisée, le système est contrôlé par la cinétique enzymatique, le signal étant fortement dépendant de la quantité d'enzyme et de la présence des inhibiteurs ou activateurs; (*ii*) dans la zone de grande concentration d'enzyme immobilisée (palier), le système est contrôlé par la diffusion du substrat, l'enzyme étant en excès vis-à-vis des possibilités d'accès du substrat et, par conséquent, peu dépendant de la présence des inhibiteurs.

Pour une concentration donnée de pesticide, le degré d'inhibition augmente avec la diminution de la quantité de l'enzyme fixée. Ainsi, il est important de fixer de faibles quantités d'enzyme, pour pouvoir déceler des concentrations faibles de pesticides (71).

Influence des solvants organiques

Le remplacement de l'eau par des solvants organiques a parfois comme résultat le changement de la sélectivité de l'inhibiteur enzymatique (p. ex. les inhibiteurs forts de l'enzyme dans l'eau deviennent faibles en milieu organique et vice versa) (115, 116).

La corrélation entre l'activité enzymatique et le degré d'inhibition dû à certains inhibiteurs de type pesticides ou métaux a été étudiée jusqu'à présent essentiellement en milieu aqueux. Le remplacement de l'eau par d'autres solvants non aqueux et l'étude de l'inhibition de l'activité enzymatique dans ces milieux sont justifiés par le fait que certains inhibiteurs ne sont pas solubles ou peu solubles dans l'eau (116, 117).

L'utilisation des biocapteurs enzymatiques pour la détection de l'inhibition de l'activité enzymatique représente un grand intérêt pour l'évaluation et le suivi de la pollution de l'environnement (118). Il est connu que l'AChE, la tyrosinase et la peroxydase, libres ou immobilisées, peuvent être utilisées pour la détection des pesticides (119). Les résidus des pesticides, présents dans l'eau ou dans les aliments en concentrations réduites, peuvent être concentrés facilement en solvants organiques et, après, déterminés à l'aide des biocapteurs (45, 120).

Les études réalisées en milieu non aqueux avec l'AChE immobilisée ont permis de classer les solvants en trois groupes (45) : (*i*) solvants organiques fortement hydrophobes, non miscibles à l'eau, qui n'influencent pas l'activité enzymatique; (*ii*) solvants organiques hydrophobes, partiellement miscibles à l'eau, qui influencent partiellement l'activité enzymatique, la présence de l'eau dans la solution maintient une partie de l'activité enzymatique; (*iii*) solvants organiques hydrophiles (alcools), totalement miscibles à l'eau, qui inactivent totalement l'enzyme par la destruction de la monocouche d'eau nécessaire à son fonctionnement.

En même temps l'activité de l'AChE immobilisée peut être classifiée selon le paramètre de hydrophobicité (log *P*) du solvant, où *P* représente le coefficient de répartition du solvant entre 1-octanol et l'eau (30, 45) : (*i*) non décelable en solvants hydrophiles avec $\log P < 0$; (*ii*) variable en solvants avec $0 < \log P < 2$; (*iii*) forte en solvants hydrophobes avec $\log P > 2$.

Pour les inhibiteurs irréversibles, l'influence des solvants organiques sur l'effet inhibiteur est considérée moins forte que pour les inhibiteurs réversibles (30).

Facteurs influençant l'inhibition de l'enzyme

L'activité de l'enzyme immobilisée utilisée pour la détection des inhibiteurs peut être altérée par la présence des inhibiteurs irréversibles, lorsque leur concentration est élevée ou en cas d'utilisation dans des conditions « dures » (température élevée, pH acide), qui conduisent à la dénaturation de la protéine. Les principaux facteurs qui influencent l'inhibition de l'AChE sont présentés ci-dessous :

Concentration du substrat

L'action des inhibiteurs sur les cholinestérases immobilisées dépend non seulement de la nature de l'enzyme et de l'inhibiteur, mais aussi de la concentration du substrat (27). En comparant la cinétique de réaction en présence du substrat et en présence de l'inhibiteur, il resulte que dans la présence simultanée du substrat et de l'inhibiteur, le processus d'inhibition est une compétition entre le substrat et l'inhibiteur qui se rattachent au même site actif de la cholinestérase. Pour la détection des pesticides à l'aide des biocapteurs on peut utiliser soit l'inhibition en présence du substrat, soit mesurer l'activité enzymatique restante après

© 2002 CNRC Canada

l'incubation du biocapteur en présence de l'inhibiteur (10). La seconde méthode est plus souvent utilisée, car elle élimine la compétition substrat–inhibiteur pour l'enzyme immobilisée.

Temps d'incubation

Le temps d'incubation est déterminé par le degré d'inhibition de l'enzyme. À une concentration donnée de pesticide, le degré d'inhibition augmente jusqu'à une valeur limite avec l'augmentation du temps d'incubation (10, 71). Les systèmes d'analyse en flux (FIA) présentent l'avantage d'être reproductibles et éliminent la nécessité d'atteindre un signal stationnaire (56, 57, 110).

pH

La littérature mentionne que l'inhibition de l'AChE par les composés organophosphorés est maximale au pH physiologique, pH 7,4 pour systèmes bienzymatiques (optimum pour ChO) (114) ou pH entre 8 et 9 pour systèmes monoenzymatiques (30).

Température

Des températures élevées d'incubation entraînent la dénaturation de l'enzyme et l'hydrolyse spontanée du pesticide analysé (71). La température optimale d'incubation est généralement de 30°C, pour un temps d'incubation qui ne doit pas dépasser 30 min.

Nature du pesticide

L'AChE immobilisée est plus rapidement inhibée par les pesticides organophosphorés (paraoxon), que par les pesticides de type carbamates (carbaryl) (10). L'AChE immobilisée à l'aide du glutaraldéhyde (GA) et de l'albumine de sérum bovin (BSA) sur la surface d'une électrode à pH est inactivée irréversiblement en présence des pesticides organophosphorés (dichlorvos) (121, 122).

Régénération

En présence des pesticides organophosphorés, on constate que l'inhibition de l'activité des cholinestérases est irréversible. Mais, dans certaines conditions, l'activité enzymatique peut être totalement récupérée après un certain temps de lavage de l'électrode avec des solutions tamponnées ou, le plus souvent, après une incubation dans des réactifs nucléophiles (9).

La phosphorylation de l'oxime permet la régénération de l'enzyme inhibée et le rétablissement de l'activité enzymatique conformément les équations [9] :

$$[9] \qquad \text{EInh} + \text{R–H} \xrightarrow{K_r} \text{EInh–R–H} \xrightarrow{k_r} \text{E–H} + \text{RInh}$$

Le pourcentage de régénération se calcule en utilisant l'équation [10] (123) :

$$[10] \qquad \%\ \text{réactivation} = \frac{a_{EIA} - a_{EI}}{a_E - a_{EI}} \times 100$$

où : a_E = activité de l'enzyme native; a_{EI} = activité de l'enzyme inhibée; a_{EIA} = activité de l'enzyme réactivée avec régénérateur.

Le degré de régénération spontanée de l'AChE dépend du pH, de la température et de la structure chimique du radical fixé sur l'atome de phosphore.

Lorsque l'activité de l'AChE présente dans une membrane a été fortement inhibée, la régénération de l'activité enzymatique n'est plus totale. Ceci peut être dû au fait que le complexe oxime phosphorylé, formé à l'intérieur de la membrane, diffuse difficilement (124). La faible régénération est due à un processus d'hydrolyse d'un groupement alkyl d'une liaison O–P, lié à la génération simultanée d'une charge négative de l'oxygène du groupement O–P, qui empêche la régénération avec des réactifs nucléophiles (125). La constante de régénération de premier ordre ($k_{r,obs}$) est donnée par l'équation [11] :

$$[11] \qquad \ln\,(A_o - A_r) = -(k_{r,obs}t) + \ln\,(A_o - A_i)$$

où : A_o = activité avant inhibition; A_i = activité après inhibition; A_r = activité après régénération.

Dans la plupart des cas, la régénération de l'AChE se réalise avec la iodure de *N*-méthyl-2-pyridaldoxime (2-PAM) (8, 9, 37, 56, 59, 108, 109, 124–128), conformément à l'équation [12] (129).

Le mécanisme de régénération de l'AChE consiste dans l'attaque nucléophile de l'oxygène du 2-PAM sur l'atome de phosphore, attaque favorisée par l'alcalinité du reste d'histidine (fig. 7).

D'autres oximes peuvent servir à la régénération des cholinestérases : bromure de 1,1′,triméthylène-bis(4-formylpyridinium) dioxime; 4-PAM, 3-PAM (121); mononitrosoacetone (MINA) (110, 130); obidoxime (111, 125); hydroxylamine (9) imidazopyridinium 4-oxime (8) 1-benzyl 2-carbaldoxime pyridinium (8); bromure de 1,1′,triméthylène-bis-(4-hydroxi iminométhyl)pyridinium (TMB-4) (27, 57, 127, 130, 131); isonitrosoacétofenone (NAP) (127); diacétylmonoxime (DAM) (131); chlorure de (1–1,2-diméthyl-2-nitropropyloximéthyl)-2-(hydroxi imométhyl)-3-méthyl imidazolium (ICD467) (126); chlorure de (1,1,méthylène bis(4-(hydroxi iminométhyl)pyridinium) (MMB-4) (126); chlorure de (1-(((4-(aminocarbonyl)pyridinio)métoxi)méthyl)-2-((hydroxi imino)méthyl)pyridinium) (HI-6) (126); chlorure de (oxi-bis-(4-hydroxi iminoéthyl pyridinium-1-méthyl) (toxigonin) (60), sulphosuccinimidyl-6-(biotinamide)hexanoate de sodium (73).

L'efficacité de la régénération dépend de la structure du groupement organophosphoré lié à l'enzyme (8) et, donc, du type d'inhibition (124, 130). Les difficultés de régénération de l'activité enzymatique imposent de réétalonner les biocapteurs après l'inhibition et la régénération (109).

Aspects cinétiques des réactions enzymatiques

Étant donné que le fonctionnement du biocapteur ampérométrique à cholinestérase est basé sur une réaction catalysée par l'enzyme (réactions dans le tableau 4), il faut brièvement examiner les modalités connues pour aborder cette réaction, du point de vue cinétique, dans le cas de l'enzyme immobilisée.

Cinétique enzymatique en phase hétérogène

De nombreux chercheurs ont essayé de modeler la réaction enzymatique quand l'enzyme est immobilisée. La ciné-

[12]

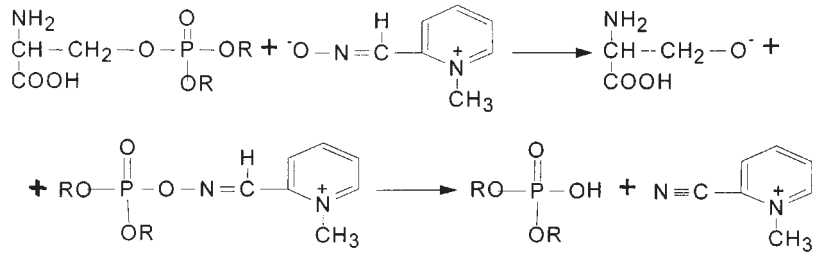

Fig. 7. Mécanisme de régénération de l'AChE inhibée le 2-PAM.

tique des réactions à enzyme immobilisée est complètement différente de celle à enzyme immobilisée parce que (30) : (*i*) l'immobilisation modifie la conformation de l'enzyme; (*ii*) l'interaction enzyme–substrat a lieu dans un milieu différent de celui de l'enzyme en solution; (*iii*) il existe une répartition du substrat entre la matrice contenant l'enzyme immobilisée et la solution; (*iv*) la réaction enzymatique peut être contrôlée par la diffusion.

Pour les enzymes immobilisées, en appliquant le traitement de Michaelis–Menten utilisé pour l'enzyme en solution, on peut déterminer une constante K_M apparente ($K_{M,app}$), qui n'est plus une caractéristique intrinsèque de l'enzyme, mais de la protéine immobilisée et de son environnement (donc du processus électroenzymatique). Cette constante cinétique dépend des phénomènes de diffusion, qui peuvent induire souvent des non linéarités sur les linéarisations utilisées pour calculer sa valeur.

Le processus global régissant le fonctionnement du capteur tient compte de la cinétique enzymatique, des phénomènes de diffusion à l'intérieur du matériau support de l'enzyme et aussi des étapes de transfert de charge avec l'électrode. Ces deux dernières ne sont pas déterminantes de vitesse (c'est-à-dire qu'elles n'interviennent pas dans la cinétique), si le potentiel de détection de l'espèce électroactive est correctement choisi et l'accès du substrat dans la matrice enzymatique est facile. Dans ce cas, la cinétique réactionnelle sera limitée par le processus biochimique. Ainsi, la cinétique peut être régie par la réaction enzymatique, si l'apport en substrat est suffisamment important. L'utilisation d'une convection forcée a été envisagée à l'aide d'une électrode tournante ou d'une agitation magnétique.

La réponse en courant du biocapteur constitue, en fait, une mesure de la vitesse du processus global (que l'on pourrait qualifier d'électroenzymatique), qui se déroule à l'électrode modifiée par le biomatériau. Du fait de la similitude des courbes *v* vs. [S] et *I* vs. [S], obtenues en phase homogène et avec une électrode à enzyme, il est possible d'utiliser le modèle de Michaelis–Menten pour modéliser le fonctionnement de l'électrode à enzyme (catalyse hétérogène). Ce procédé permet d'extraire des mesures expérimentales la constante Michaelis apparente ($K_{M,app}$) et le courant maximum ($I_{max,app}$). Bien que peu rigoureuses (puisqu'elles sont fortement dépendantes des conditions expérimentales), ces grandeurs sont très utiles pour caractériser globalement le comportement du biomatériel immobilisé.

Cinétique de la réaction d'inhibition de l'enzyme

Les inhibiteurs sont des substances capables d'interagir avec l'enzyme et, par conséquent, de réduire la vitesse de la réaction catalysée par l'enzyme. Il existe deux types d'inhibition de l'enzyme : réversible et irréversible. Dans l'inhibition réversible il existe un équilibre entre l'enzyme et l'inhibiteur. L'inhibition irréversible augmente avec le temps de contact enzyme–inhibiteur. Une inhibition totalement irréversible s'obtient quand la concentration de l'inhibiteur irréversible dépasse celle de l'enzyme.

Le mécanisme d'inhibition de l'AChE induit par les organophosphorés est analogue au mécanisme d'hydrolyse du substrat (l'équation 13) (132) et suit deux étapes (conformément les équations 14) :

[13] $$E + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} ES \xrightarrow{k_2} E + P$$

[14] $$E\text{–}OH + InhX \underset{k_{-1}}{\overset{k_{+1}}{\rightleftharpoons}} E\text{–}OH\text{–}InhX \quad (E) + (P) \quad (EInH) \xrightarrow{k_2} E\text{–}OH\text{–}Inh + X \quad (EP)$$

où : k_1 et k_{-1} sont les constantes de vitesse en sens direct et inverse de la formation de l'intermédiaire (ES); k_2 constante de vitesse de la formation du produit (P). (*i*) La formation réversible, avec la constante k_{+1}, du complexe de Michaelis enzyme–inhibiteur (EInh) très stable; l'attaque de l'inhibiteur (InhX) ayant lieu au niveau du groupement OH de la sérine du site actif de l'enzyme. La stabilité du complexe EInh dépend de la nature du radical X (133); (*ii*) la phosphorylation de l'enzyme, avec la constante k_2, (la liaison de l'inhibiteur par l'intermédiaire de son atome de

© 2002 CNRC Canada

phosphore au site actif de l'enzyme) avec le déplacement du groupement X (15, 113, 134).

La cinétique de détection des pesticides organophosphorés s'étudie par l'incubation de l'enzyme (AChE) libre ou immobilisée en présence de l'inhibiteur suivie par la mesure de l'activité restante (9, 10, 96). Cette approche est basée sur l'équation d'Aldrige [15] (8, 10, 30, 59, 91, 96) :

$$[15] \qquad \ln \frac{I}{I_O} = k_a [\mathrm{Inh}] t$$

où : I_o = signal avant inhibition; I = signal après inhibition (10, 71, 96, 110, 135); k_a = constante bimoléculaire, calculée à l'aide de la relation $k_a = k_2/K_d$ (96, 135), K_d = constante de dissociation du complexe EInh, calculée comme $K_d = k_{-1}/k_{+1}$; [Inh] = concentration d'inhibiteur; t = temps d'incubation.

Conclusions

Étant donnée l'ample utilisation dans le domaine agricole des pesticides organophosphorés, très toxiques, les normes de qualité de l'environnement sont devenues de plus en plus sévères et impératives à appliquer. Dans ce contexte, les propriétés analytiques de biocapteurs doivent être similaires avec les méthodes analytiques utilisées couramment. Les caractéristiques spécifiques des détecteurs demandés pour le contrôle de l'environnement sont : (*i*) spécificité pour un seul substrat (utile dans l'analyse qualitative); (*ii*) mesure de l'effet toxique global pour les systèmes d'alarme; (*iii*) spécificité de groupe pour l'identification rapide d'une classe de substances (utile dans les mesures sélectives).

Le principe de détection des pesticides à l'aide d'un biocapteur ampérométrique est fondé sur leur effet inhibiteur exercé par ceux-ci sur différentes cholinestérases. La différence entre l'activité enzymatique initiale et celle enregistrée après une incubation dans un échantillon contaminé, fournit des informations, d'un côté, sur la présence des pesticides et, de l'autre côté, sur le potentiel toxique de l'échantillon.

La fragilité et la complexité de l'outil biologique le rendent difficile à maîtriser complètement et en même temps constituent le frein le plus important au développement des biocapteurs. Les techniques d'immobilisation, les caractéristiques du transducteur, la technologie associée à la conception du prototype sont les autres facteurs d'ordre scientifique influençant le développement des biocapteurs. Du point de vue commercial, la difficulté réside dans la définition des besoins et la taille encore réduite du marché de l'instrumentation pour l'environnement — fortement conditionnés par la réglementation — malgré que l'effort financier, soit de la recherche, soit des industries, est important.

Différents types d'application ont été classifiés selon le type de cholinestérase et du système enzymatique utilisé. Les meilleures limites de détection citées pour le paraoxon (le plus étudié organophosphoré) sont : 0,3 à 1 μg L^{-1} (AChE) (56) et 1,5 μg L^{-1} (BuChE) (96) ou 0,14 μg L^{-1} = ppb (AChE + ChO) (58) et 2 μg L^{-1} (BuChE + ChO) (4). Le niveau de concentration détecté par le biocapteur se situe au niveau d'alarme, donc il peut être utilisé dans les échantillons d'eau de rivière ou estuaire, quelques jours après l'application des pesticides (136). Ces valeurs sont relativement grandes en comparaison avec celles rapportées pour la technique immunologique (4 ng parathion) (137), ou bien pour la chromatographie en phase gazeuse (0,1 μg L^{-1} metsulfuron-methyl) (138) ou liquide (0,08 μg L^{-1} paraoxon) (139), qui reste comme méthode de référence. La comparaison entre les résultats obtenus à l'aide des biocapteurs et par d'autres méthodes démontre que le biocapteur à cholinestérase peut être employé pour développer une méthode de mesure en continu, applicable dans l'eau de rivière (140). Malgré certains avantages, le biocapteur n'est pas implementé totalement dans le monitoring de l'environnement parce qu'il doit accomplir encore des nécessités demandés pour les techniques robustes comme (*i*) la reproductibilité de longue et courte durée; (*ii*) l'absence des réponses interférentes et (*iii*) la solidité suffisante pendant l'utilisation dans différents matrices de l'environnement.

Bien que ce domaine de recherche ait été étudié depuis un peu plus d'une vingtaine d'années, la recherche active de collaborations pluridisciplinaires (biochimie, toxicologie, écotoxicologie, chimie, électrochimie, physique, électronique et informatique) est laborieuse, et plusieurs programmes nationaux des Ministères de la Recherche ou programmes internationaux coordonnés par la Communauté européenne sont en déroulement présentement.

L'intérêt scientifique pour l'étude et le développement de l'instrumentation analytique est matérialisé par la publication des livres (voir références bibliographiques), d'une revue spécialisée (Biosensors & Bioelectronics) et par l'organisation périodique des congrès spécialement dédiés à ce sujet (p. ex. : BIOSENSORS'98 – Berlin, le 5ème; ou Biosensors'2000 – San Diego le 6ème).

Effect of protein binding on charge transfer in DNA: A simple model based on the superexchange mechanism

Abdelali Filali-Mouhim, Mustapha Benrahmoune, and Jean-Paul Jay-Gerin

Abstract: The effect of protein binding on the electronic coupling between distant redox centers in DNA is investigated in DNA–protein complex systems using the superexchange formalism. The systems (bridges) studied are described by a tight-binding electronic Hamiltonian in which site orbitals interact with one another through an exponentially decaying function of distance. Based on the "continuous-medium approximation," previously developed for large homogeneous three-dimensional systems (J.-M. Lopez-Castillo et al. J. Phys. Chem. **99**, 6864 (1995)), the intervening bridge is defined by a unique dimensionless parameter Γ/E that controls the distance dependence of the electronic coupling. Here, E is the energy separation between the orbitals of the bridging medium and the redox sites (tunneling energy), and Γ is the electronic bandwidth of the bridge taken as a continuous medium. It was found that, for a given value of $(\Gamma/E)_{DNA}$ far from the DNA's resonance conditions and for $(\Gamma/E)_{protein}$ values near the protein's resonance conditions, the electronic coupling is independent of the donor–acceptor distance when the acceptor lies within the "recognition region" of DNA. Moreover, when the redox centers are located on both sides of this region, the electronic coupling is many orders of magnitude larger than it should be, far from the protein's resonance conditions.

Key words: DNA, DNA–protein complexes, long-range electron and hole transfers, electronic coupling, superexchange mechanism, energetic control, continuous-medium approximation.

Résumé : Nous avons étudié, dans le cadre du mécanisme de superéchange, l'effet de la présence d'une protéine sur le couplage électronique entre sites rédox distants dans des complexes ADN–protéines. Les systèmes étudiés sont décrits par un Hamiltonien électronique modèle, basé sur l'approximation des liaisons fortes, dans lequel les divers sites possèdent tous la même énergie et interagissent entre eux selon une fonction exponentielle de la distance. En s'appuyant sur la théorie de l' « approximation du milieu continu », développée précédemment pour le cas de larges systèmes homogènes tridimensionnels (J.-M. Lopez-Castillo et al. J. Phys. Chem. **99**, 6864 (1995)), le milieu intermédiaire entre le donneur et l'accepteur est défini par un paramètre unique, sans dimension, Γ/E, qui contrôle la dépendance en distance du couplage électronique. E est ici l'énergie séparant les orbitales de ce milieu de celles des sites rédox et Γ la largeur de bande électronique du milieu intermédiaire considéré comme milieu continu. Nous avons trouvé que, pour une valeur donnée du rapport $(\Gamma/E)_{ADN}$ loin des conditions de résonance de l'ADN et pour des valeurs de $(\Gamma/E)_{protéine}$ proches des conditions de résonance de la protéine, le couplage électronique est indépendant de la distance donneur-accepteur lorsque l'accepteur est situé dans la région de l'ADN dite de « reconnaissance ». De plus, lorsque les sites rédox sont situés de part et d'autre de cette région, le couplage électronique est de plusieurs ordres de grandeur supérieur à ce qu'il devrait être loin des conditions de résonance de la protéine.

Mots clés : ADN, complexes ADN–protéines, transferts d'électron et de trou à longue distance, couplage électronique, mécanisme de superéchange, contrôle énergétique, approximation du milieu continu.

Introduction

DNA–protein interactions are ubiquitous in nature. Nearly all of the main cellular functions where DNA is involved are carried out in conjunction with proteins. This variety of interactions can be divided into three major categories: regulatory, enzymatic, and structural (1, 2). Regulatory interactions are associated with DNA replication (DNA synthesis) and gene expression, while enzymatic interactions include transcription (RNA synthesis), replication, and DNA repair. Structural interactions involve small, globular proteins, called histones, which play a key role in packaging nuclear DNA into chromosomes. (The entire DNA–histone complex is known as chromatin.) Protein binding to a DNA molecule

can be stabilized by electrostatic, hydrogen bonding, and (or) hydrophobic interactions, and usually occurs in a sequence-specific DNA region, termed "recognition region," which is selectively recognized by the protein through a discrete DNA-binding domain within its polypeptide chain (1–3).

Charge transfer (CT) through DNA and from proteins to DNA seems to play a crucial role in some of the above biological functions involving DNA–protein complexes (4). In particular, CT is the elementary step that triggers a repair mechanism following oxidative damage to the DNA (4–6). Most studies have hitherto focused on CT processes in a DNA environment alone (for reviews, see ref. 7), but recently CT in DNA–protein assemblies has been examined experimentally in the DNA–methyltransferase *Hha*I (M.*Hha*I) complex (8), where the wild-type enzyme bound to DNA significantly disrupts the base-pair stack and profoundly reduces the ability of DNA to mediate CT. In contrast, by use of a tryptophan mutant of native M.*Hha*I, which leaves the overall structure of the DNA without significant distortions, long-range oxidation damage to DNA is restored, demonstrating that bound proteins can modulate charge migration through the DNA (8). It was also reported that CT could be observed from histones to DNA in γ-irradiated chromatin at 77 K (9), as well as from DNA-bound tripeptides (Lys-Trp-Lys and Lys-Tyr-Lys) to DNA (10). At the theoretical level, recent studies (11) have provided evidence that electron transfer between the catalytic cofactor $FADH^-$ in DNA photolyase (an enzyme that catalyzes photorepair of thymine dimers in UV-damaged DNA by an electron-transfer reaction) and a thymine dimer bound in its active site is not direct, but indirect, with the adenine moiety acting as an intermediate. So far, however, complete three-dimensional structures of DNA–protein complexes have never been incorporated into computations, and many open questions still remain as to how DNA-binding proteins modulate CT reactions through DNA.

It is now clear that the DNA double helix, with its bridge system of four bases stacked upon each other, can act as a promoting medium for efficient one-dimensional CT over long distances (up to ~40–200 Å from the point of origin) (6, 7). Particularly in the last decade, the question of how excess electrons or holes migrate through DNA has attracted considerable interest and generated a great deal of controversy (12–14). During the past three years, however, aided by theoretical breakthroughs and more sophisticated experimental techniques, significant progress has been made toward elucidation of the mechanistic origin of CT processes in DNA (for recent reviews, see refs. 15 and 16). Among the various models that have been advanced, two principal mechanisms of CT in DNA are now considered to explain the wealth of existing experimental data (5–7, 13, 15–33). These are:

(*i*) A coherent, unistep charge tunneling between the localized donor and acceptor sites involving intervening bases as superexchange mediators (superexchange mechanism) (20–22, 34–38). This mechanism is characterized by the absence of any population physically residing on the DNA bridge during the CT process. The dependence of the CT rate constant on the donor–acceptor distance (R_{DA}) is of the form (39)

$$[1] \qquad k_{CT} \propto \exp(-\beta_{eff} R_{DA})$$

where the effective distance–decay coefficient β_{eff} is a characteristic of the bridge ($\beta_{eff} \approx 0.6$–1.8 $Å^{-1}$ for DNA bridges) (35). This single-step superexchange mechanism exhibits a strong dependence on distance, allowing only for short-range transfer.

(*ii*) An incoherent, multistep charge hopping between the bases of the bridge, with the charge wavefunction fully localized on each subsequent base (charge-hopping mechanism) (24, 25, 36, 37, 40–44). Here, the charge transfers by discrete jumps among the intervening bases (usually guanine (G) bases and multiple G units, in the case of hole transfer) in a random walk fashion until it reaches a trap site. The distance dependence of the CT rate constant is described by Ohm's law:

$$[2] \qquad k_{CT} \propto 1/N^{\eta}$$

where N is the number of DNA bases participating in the charge transport (or the number of hopping steps) and the exponent η has a value between 1 and 2 (36). This multistep charge-hopping mechanism depends only weakly on distance, allowing for long-range charge transport. A "transition" from superexchange to charge hopping when increasing the bridge length is found to occur at a "critical" bridge size N_x, which is determined by the energetics of the bridge, the donor–bridge energy gap, and the temperature (37).[2,3]

In comparison to DNA, CT reactions in proteins have been studied extensively at both the experimental and theoretical levels (see, for example, refs. 39, 51, and 52). It is now well established that native and "engineered" proteins can mediate long-range CT over lengths of several tens of angströms (up to ~10–30 Å) between distant redox centers (51, 52). The electronic coupling between these redox centers is a key parameter that controls CT rates in the molecules. Most theoretical approaches used to analyze experimental data were based on the superexchange mechanism (39).

[2] It is interesting to recall here the provocative data by Barton and co-workers (17, 45) in the early 1990s, suggesting a "molecular wire" mechanism in DNA, in which the charge can travel almost coherently through an electronic "π-way" of well-stacked DNA bases, according to a band-like motion (41, 46–48). This possibility that a DNA molecule might act as a conduction-band pathway for conducting electrical charge was first advanced by Eley and Spivey (49) nearly 40 years ago. The question of whether DNA behaves like a wire or like an insulator stimulated much debate (see, for example, ref. 12). Recent studies (12, 15, 20, 28), however, have highlighted that "DNA is by no means a wire," and that the mechanism underlying CT in DNA now appears to be a "sort of hybrid of two well-known CT processes," namely, superexchange and diffusive charge hopping, as mentioned above.

[3] While it now seems that charge carriers are indeed able to shuttle along a single DNA molecule over distances of at least a few tens of angströms, the situation of the electronic transport across long DNA ensembles (>400 Å) is much less clear. Various contradictory findings have been reported, ranging from well-insulating behavior to the support of superconducting currents through DNA (15, 50).

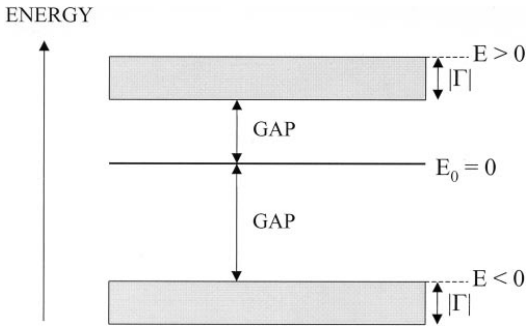
Fig. 1. Schematic representation of the conduction and valence energy bands (shaded areas) of the bridging medium in the framework of the CMA for $V_0 < 0$. In this case, $\Gamma < 0$ and the broadening of the electronic bands takes place on one side only (downwards in this case) of the initial orbital site energy E. $|\Gamma|$ is the electronic bandwidth and E_0 is the energy of redox sites taken as the zero of energy ($E_0 = 0$).



The present endeavor is devoted to the study of the effect of protein binding on the distance dependence of the electronic coupling between donor and acceptor in DNA using the superexchange formalism.[4] For this purpose, instead of focusing on a specific experimental system, here we investigate two DNA–protein model systems, whose energetic parameters are allowed to vary at will. The systematic variation of these parameters will provide us with information on how protein binding influences DNA-mediated CT characteristics.

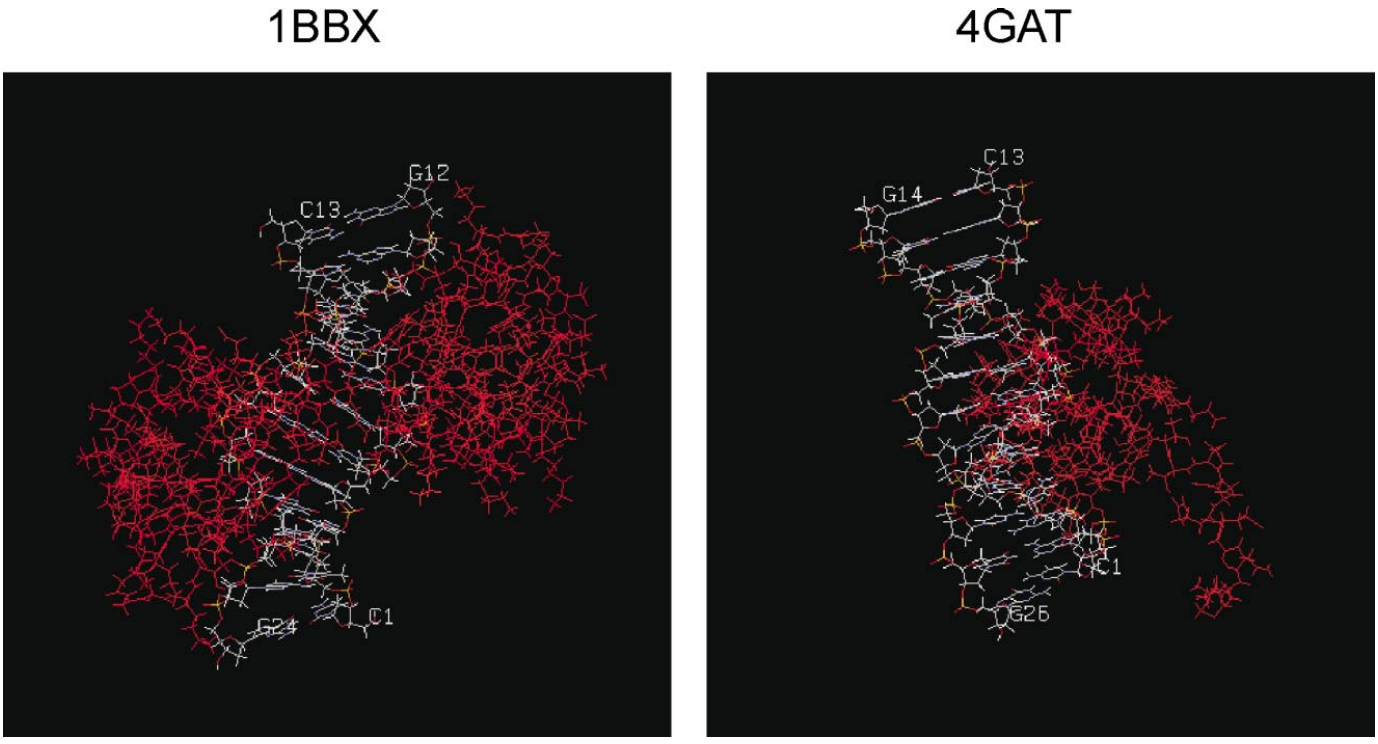
Model

Formally, in the weak coupling or non-adiabatic limit, the CT reaction rate constant (k) is given by a generalized version of Fermi's Golden Rule (53):

$$[3] \qquad k = \frac{2\pi}{\hbar}\left|T_{DA}\right|^2 (FC)$$

where $\hbar$ is Planck's constant divided by 2π, T_{DA} is the bridge-mediated effective electronic coupling between the donor (D) and acceptor (A) site wavefunctions, and FC is the Franck–Condon factor, a measure of the nuclear motion coupled to the CT process. T_{DA} is given by the sum of the direct through-space interaction (V_{DA}) between the two redox sites and of the superexchange coupling (V_S) that con-

Fig. 2. Molecular structures of 1BBX and 4GAT from the Protein Data Bank (http://www.rcsb.org/pdb). The following DNA sequences are for (*i*) 1BBX: 5′-($C_1T_2A_3G_4C_5G_6C_7G_8C_9T_{10}A_{11}G_{12}$)-3′ and 5′-($C_{13}T_{14}A_{15}G_{16}C_{17}G_{18}C_{19}G_{20}C_{21}T_{22}A_{23}G_{24}$)-3′; (*ii*) 4GAT: 5′-($C_1A_2G_3C_4G_5A_6T_7A_8G_9A_{10}G_{11}A_{12}C_{13}$)-3′ and 5′-($G_{14}T_{15}C_{16}T_{17}C_{18}T_{19}A_{20}T_{21}C_{22}G_{23}C_{24}T_{25}G_{26}$)-3′. The DNA bases are individually indexed from 1 to 24 (1BBX) and from 1 to 26 (4GAT) sequentially from one 5′ end to the 3′ end of the opposite strand. 1BBX has 758 and 2077 atoms for the DNA and protein subsystems, respectively. 4GAT has 823 and 1032 atoms for the DNA and protein subsystems, respectively.



[4] As indicated above, most recent advances are leading to a growing consensus that, at ambient temperature, both superexchange and hopping mechanisms for CT are active in DNA, although in most systems their relative contribution is not known (30). At low temperatures (77 K or below), however, superexchange becomes free from competing phonon-like thermally activated hopping and will thus prevail as the principal mode of CT processes (see, for example, refs. 30, 31, and 36).

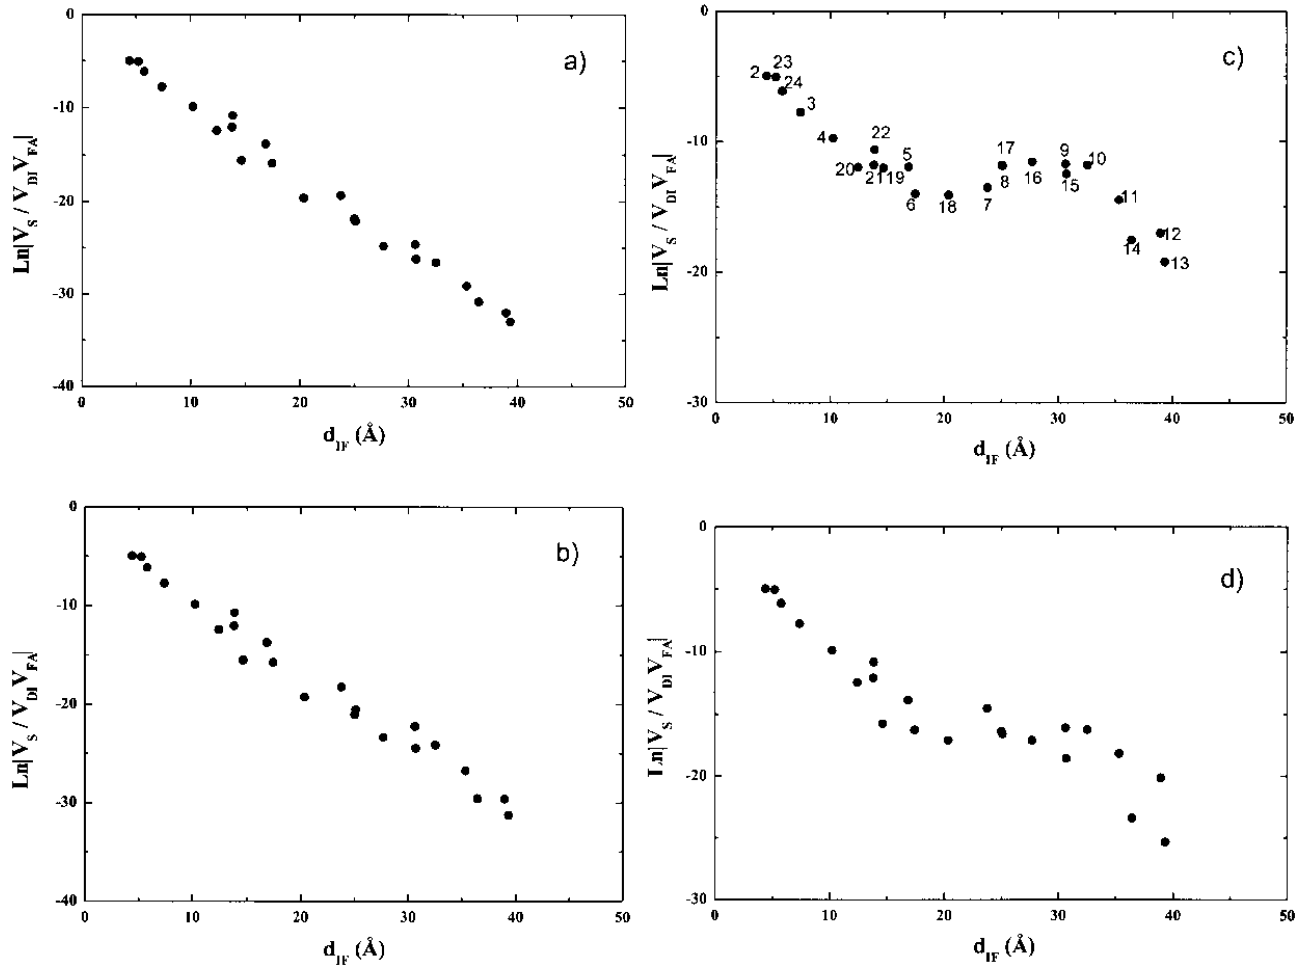
Fig. 3. Typical variations of $V_S/V_{DI}V_{FA}$ as a function of d_{IF} in the case of 1BBX for a fixed value of $(\Gamma/E)_{DNA} = -0.6$ (E_{DNA} = 3.58 eV) and various $(\Gamma/E)_{protein}$ values: (*a*) −0.2 ($E_{protein}$ = 7.65 eV); (*b*) −0.4 ($E_{protein}$ = 3.82 eV); (*c*) −0.6 ($E_{protein}$ = 2.55 eV); and (*d*) −0.8 ($E_{protein}$ = 1.91 eV). Here, the initial I site is located on atom C6 of the base 1 and we consider each of the other bases' C6 atoms as a possible final F site. The numbers in Fig. 3*c* refer to the bases' indexes of the 1BBX system, whose sequence is given in Fig. 2.



tains the information about the electronic properties (orbital energies and their couplings) of the DNA bridge (39, 53). The direct term V_{DA} is assumed to be negligible for long-range charge transfers and the superexchange term V_S is given by (39, 53–55)

$$[4] \qquad V_S = V_A^T \, G(E_0) V_D$$

where $G(E_0)$ is the Green function (56) for the bridge Hamiltonian, E_0 is the tunneling energy of the transferring charge between the degenerate redox-site orbitals (that is, the D and A orbitals have the same energy), and V_D and V_A are the vectors of interaction of the donor and acceptor with the intervening medium, respectively.[5] If we assume that the D and A sites are each coupled to a single site, respectively, at the entrance (called "initial" site, noted *I*) and at the exit (called "final" site, noted *F*) of the bridge, then V_S can be expressed as

$$[5] \qquad V_S = V_{DI} V_{FA} G_{IF}(E_0)$$

where the matrix element $G_{IF}(E_0)$ is related to the bridge Hamiltonian *H* by

$$[6] \qquad G_{IF}(E_0) = \langle I \,|(E_0 J - H)^{-1}|F\rangle$$

and *J* is the identity matrix.

The present model system is described by the tight-binding Hamiltonian

$$[7] \qquad H = \sum_{i=1}^{N} E \left|i\right\rangle\!\left\langle i\right| + \sum_{i \neq j} V(\boldsymbol{r}_i, \boldsymbol{r}_j) \left|i\right\rangle\!\left\langle j\right|$$

in which bridging sites have only one single *s*-type orbital of the same energy *E* (relative to E_0, taken as the origin of energy) and interact with one another via a pure "through-space" (TS) coupling law (35, 52)

$$[8] \qquad V(\boldsymbol{r}_i, \boldsymbol{r}_j) = V_0 \, e^{-\beta \left| \boldsymbol{r}_i - \boldsymbol{r}_j \right|}$$

where β represents the decay factor of the interaction, $\boldsymbol{r}_i$ and $\boldsymbol{r}_j$ are the coordinates of the interacting sites *i* and *j*, respec-

[5] V_A^T denotes the transpose of V_A.

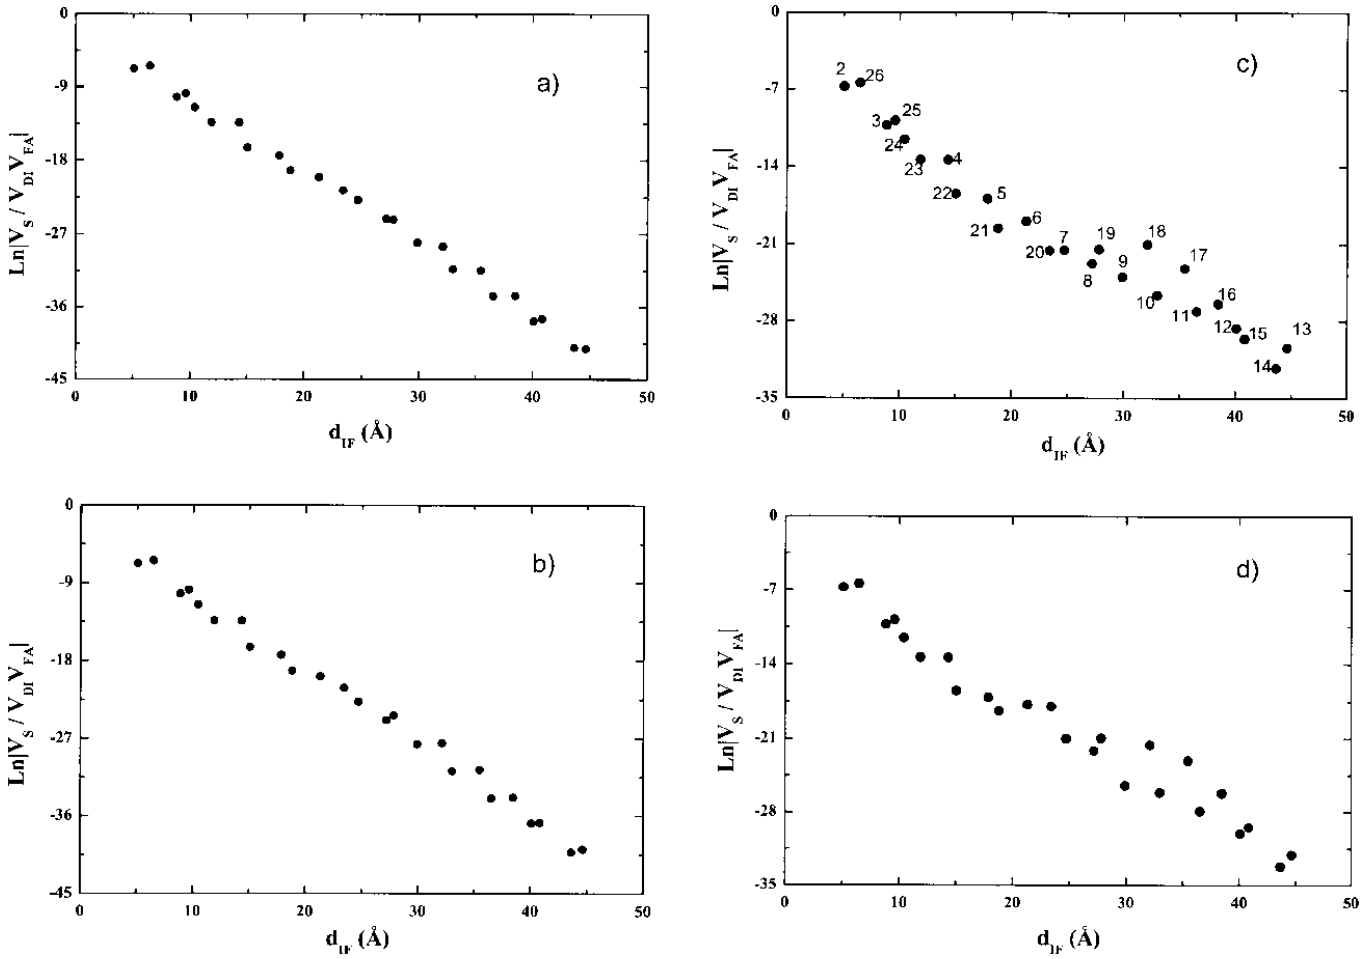
Fig. 4. Typical variations of $V_S/V_{DI}V_{FA}$ as a function of d_{IF} in the case of 4GAT for a fixed value of $(\Gamma/E)_{DNA} = -0.6$ and various $(\Gamma/E)_{protein}$ values: (*a*) −0.2; (*b*) −0.4; (*c*) −0.6; and (*d*) −0.8. Here, the initial I site is located on atom C6 of the base 1 and we consider each of the other bases' C6 atoms as a possible final F site. The numbers in Fig. 4*c* refer to the bases' indexes of the 4GAT system whose sequence is given in Fig. 2.



tively, and V_0 is an intersite coupling prefactor.[6] Using what we call the "continuous-medium approximation" (CMA) (54), we have shown in previous studies that this coupling law defines a unique dimensionless parameter Γ/E that controls the distance dependence of V_S in large three-dimensional disordered homogeneous media (54, 57, 58) as well as in proteins (52) and DNA (35). Here, $|\Gamma| = 8\pi\rho|V_0|\beta^{-3}$ is the electronic bandwidth of an associated continuous medium having the same orbital-site density (ρ) as the actual medium. $|\Gamma|$ is an approximate value of the exact half-bandwidth of the discrete medium (54). Noteworthily, for the case of DNA alone in the narrow-band limit ($|\Gamma/E| << 1$), we have shown that the CMA predicts β_{eff} values (~1.6–1.8 Å^{-1}) (35) that are in good order of magnitude agreement with those calculated by Priyadarshy et al. (34) using the same tunneling energies (E = 4–5 eV) and more realistic electronic Hamiltonian modelings of DNA.

A peculiar behavior of our CT model is that the bridging medium is represented by a single *s*-type band, so that the position of the donor–acceptor level with respect to that band determines which mediation mechanism (electron or hole type) prevails (54). This situation is different from that generally encountered in bridged systems such as proteins and DNA, where two bands are simultaneously taken into consideration: the so-called valence and conduction bands. In the latter case, the position of the donor–acceptor level within the existing gap allows the distinction between an electron- or hole-type dominant superexchange mechanism (54, 57, 59). Our CT model would then be suitable when a single band dominates the donor–acceptor electronic coupling.

For the present work, we assume that each of the DNA–protein complexes studied is characterized by two control parameters: $(\Gamma/E)_{DNA}$ and $(\Gamma/E)_{protein}$ for the DNA and the protein, respectively. Of course, this is an approximation when

[6] This *s*-orbital model is a rather simplified modeling of the electronic bridge Hamiltonian. However, this simplification may not be so crude, since the *p*-orbitals of the DNA bases in van der Waals contact along the helix weakly overlap (their interaction is only about 1/3 as large as the π-interaction between *p*-orbitals on neighboring atoms within the bases in the perpendicular plane; see, for example, refs. 12–14, 17, and 34). Based on this simplification, our model offers several important advantages: (*i*) under certain energetic conditions, it is an analytically solvable model; (*ii*) it incorporates in a simple manner the full three-dimensional atomic structure of the DNA–protein bridged system; and (*iii*) calculations based on it are much less consuming in computer time than those required by more refined quantum-chemical modelings.

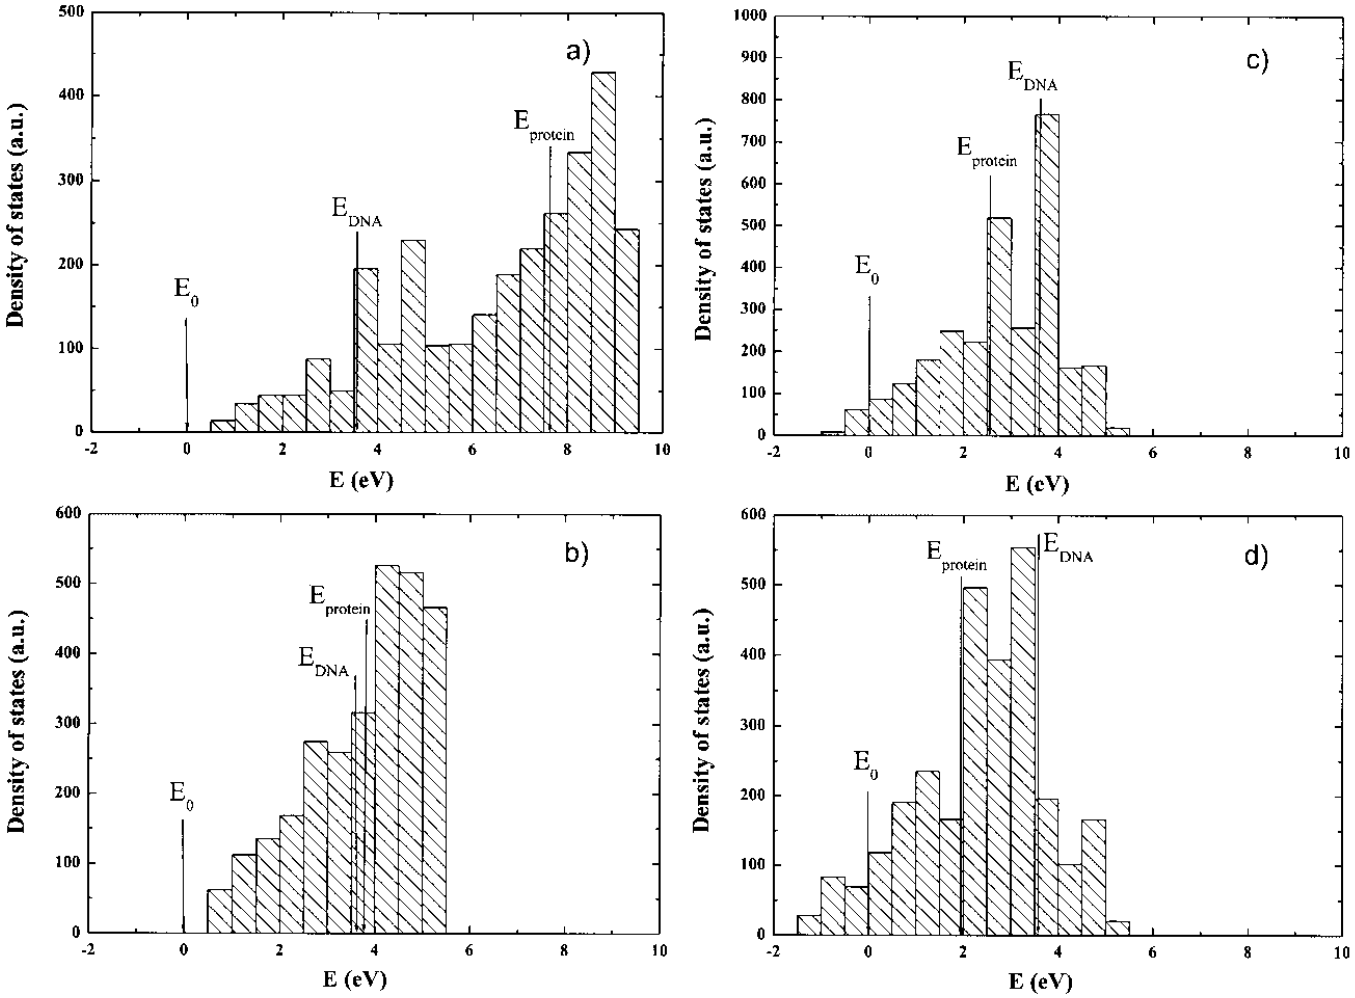
Fig. 5. Density of states (number of states per unit energy range, in arbitrary units) of the 1BBX DNA–protein complex as a function of energy. Initial orbital energies are the same as in Figs. 3*a–d* and are indicated here by vertical arrows: E_{DNA} = 3.58 eV; $E_{protein}$ = 7.65 eV (*a*); 3.82 eV (*b*); 2.55 eV (*c*); and 1.91 eV (*d*) (E_0 = 0).



the two electronic bands of the DNA and the protein overlap. Γ is calculated by adopting the parameter values V_0 = –6 eV, β = 1.7 Å^{-1}, and ρ = 0.07 and 0.05 Å^{-3} for the DNA and the protein, respectively. The chosen numerical values of V_0 and β are generally used in the modeling of electronic Hamiltonians for biological charge transfer systems (35, 39, 52, 54, 60), and ρ is taken from our previous studies (35, 52). Under these conditions (Γ < 0), the cases Γ/*E* < 0 and Γ/*E* > 0 correspond to the transfer of electrons (*E* > 0) through unoccupied orbitals and of holes (*E* < 0) through occupied orbitals, respectively. This terminology should, in fact, be reversed for V_0 > 0. A schematic representation of the continuous-medium electronic bands of the bridge is given in Fig. 1. Once Γ is determined, the control parameter is systematically varied, *E* is then deduced, and the Green's function matrix element (G_{IF}) in eq. [5] is computed numerically. From a qualitative point of view, our results are independent of the numerical values given to V_0, β, and ρ because of the universal character of Γ/*E* (35, 52, 54). The coupling prefactors V_{DI} and V_{FA} in eq. [5] are arbitrarily taken since they do not influence the distance decay rate of the electronic coupling.

The atomic coordinates of the two DNA–protein model systems considered in the present study (including hydrogen atoms) (Fig. 2) were obtained from the Protein Data Bank (files: 1BBX.pdb and 4GAT.pdb). Figure 2 shows that 1BBX's protein is a dimeric protein, which is bound to both strands of the DNA double helix, whereas 4GAT's protein is a monomeric protein, which is bound to only one DNA strand. For each system, we assume that the initial I site is located on the C6 atom of the first base and consider each of the other C6 atoms of the DNA bases as possible final F sites. (The phenomena observed are qualitatively independent of the nature and location of initial and final sites, which are arbitrarily chosen.)

Results and discussion

Figures 3*a–d* and 4*a–d* show, for 1BBX and 4GAT, respectively, typical numerical calculations of $V_S/V_{DI}V_{FA}$ as a function of d_{IF} (the distance between the I and F sites) for $(\Gamma/E)_{DNA}$ fixed at –0.6 (E_{DNA} = 3.58 eV) and $(\Gamma/E)_{protein}$ values equal to –0.2, –0.4, –0.6, and –0.8 ($E_{protein}$ = 7.65, 3.82, 2.55, and 1.91 eV, respectively). In most cases, we observe an exponential decay of the electronic coupling with distance (Figs. 3*a*, 3*b* and 4*a*, 4*b*). When $|\Gamma/E|_{protein}$ becomes large enough, however, the coupling decays exponentially as d_{IF} in-

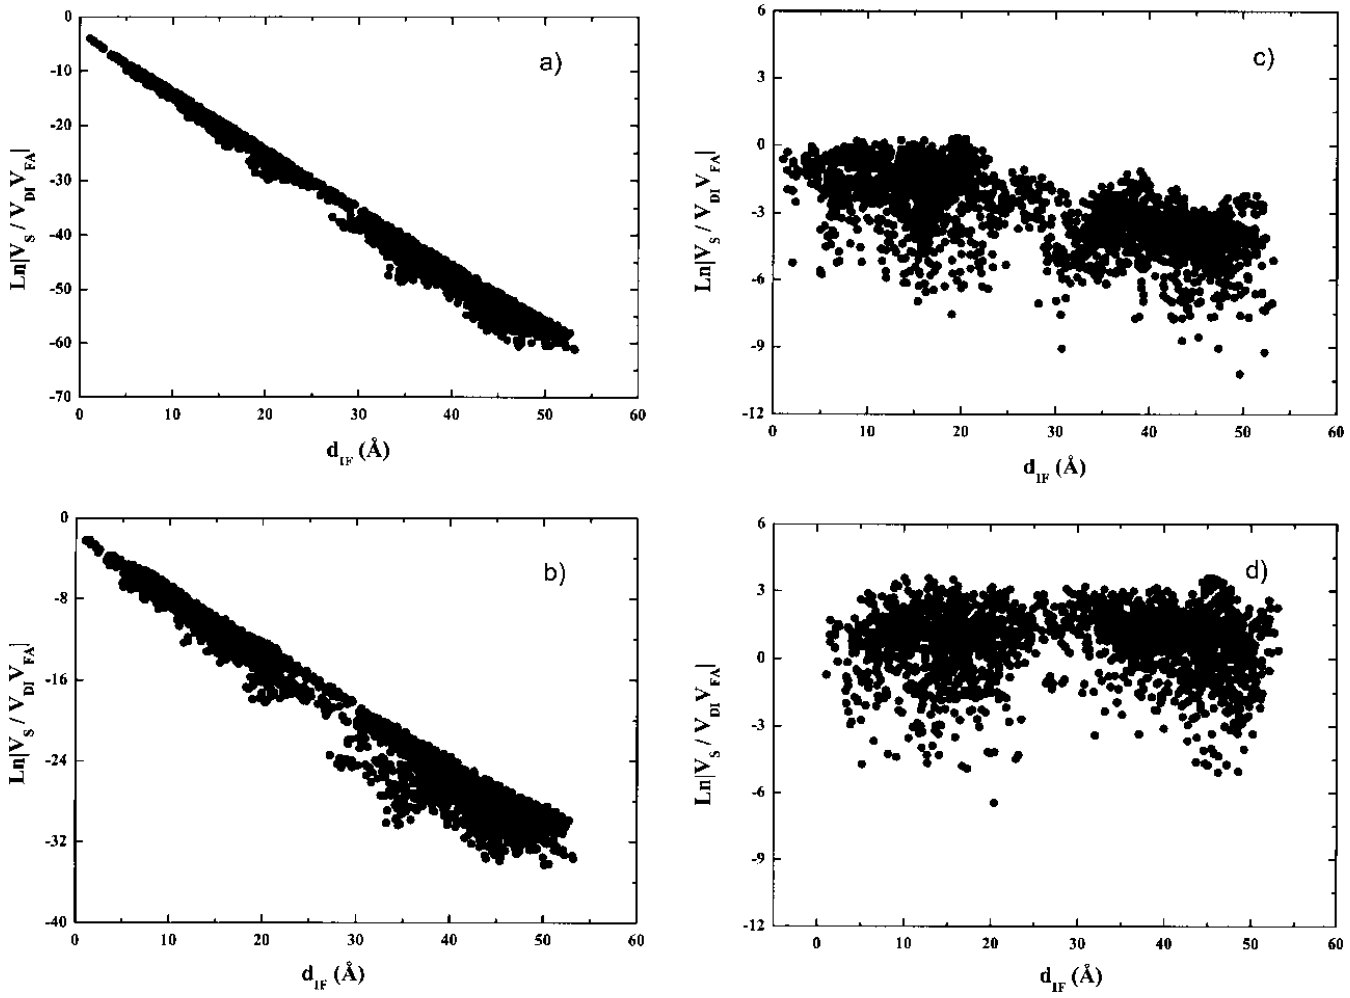
Fig. 6. Typical variations of $V_S/V_{DI}V_{FA}$ as a function of d_{IF} in the case of the 1BBX's protein, for various values of $(\Gamma/E)_{protein}$: (*a*) −0.2; (*b*) −0.4; (*c*) −0.6; and (*d*) −0.8. Note that the initial I site is located on the atom C_α (ALA1) and each of the other protein's atoms is considered as a possible final F site.



creases, except when the final F site is located within the "recognition region" of the DNA, which lies from bases 5 to 10, bases 15 to 20 for 1BBX (Figs. 2, 3*c*, and 3*d*), and bases 18 to 21 for 4GAT (Figs. 2, 4*c*, and 4*d*). Under those latter conditions, V_S is found to be independent of d_{IF}, similar to a metallic-type CT behavior. Interestingly, we observe that when the F site is located on the other side of this region (with respect to the initial I site), the electronic coupling is many orders of magnitude larger than it should be, far from the protein's resonance conditions. In this situation, the effect of the binding protein on the DNA–protein complex-mediated CT is apparent by only a slight modification of the effective-electronic coupling-decay coefficient β_{eff}, as we have observed (results not shown) by comparing β_{eff} in the DNA alone and in the DNA–protein complexes. We note that these results are independent of the location of the final F site, since the same phenomenon is observed when considering each of the other atoms as a possible location of this site.

Our results can be better understood if we focus on the energy levels of the DNA–protein system. In the case of 1BBX, for example, Figs. 5*a–d* show that the broadening of the electronic energy band mostly takes place on one side below the initial orbital-site energies, as predicted by the CMA. The phenomenon depicted in Figs. 3*c* and 3*d* is then due to the penetration of the donor–acceptor site energy ($E_0 = 0$) into the electronic conduction band of the system (Figs. 5*c* and 5*d*). This originates from effects that occur close to 1BBX's protein resonance conditions.[7] This point is clearly illustrated in Fig. 6, where the electronic coupling through the 1BBX's protein alone is plotted as a function of distance for $(\Gamma/E)_{protein}$ values equal to −0.2, −0.4, −0.6, and −0.8. Here, the initial I site is located on the atom C_α (ALA1), and we consider each of the other protein's atoms as a possible final F site. (Note that the phenomena observed are qualitatively independent of the nature and location of the initial site.) We observed an increase of the dispersion as $|\Gamma/E|_{protein}$ increases (Figs. 6*c* and 6*d*), which is a consequence of the approaching protein's resonance conditions as we have shown in previous studies (52), demonstrating that structural and geometrical effects become important near

[7] Recall that resonance is achieved whenever some energy level of the intervening bridge turns out to coincide with that of the donor–acceptor sites.

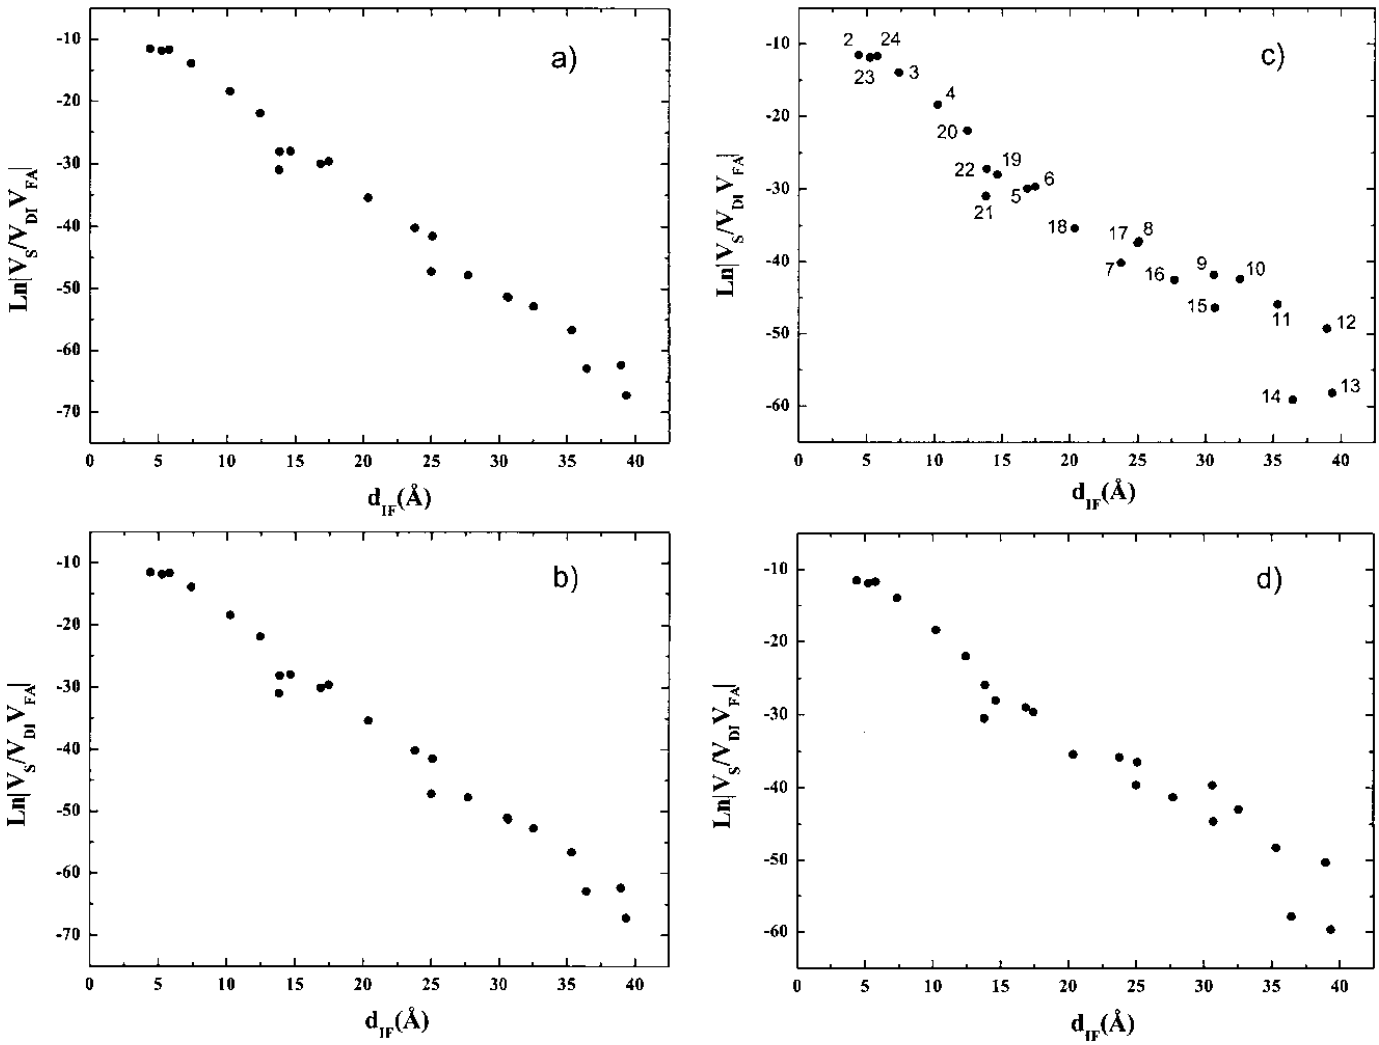
Fig. 7. Typical variations of $V_S/V_{DI}V_{FA}$ as a function of d_{IF} in the case of 1BBX for a fixed value of $(\Gamma/E)_{DNA} = 0.6$ ($E_{DNA} = -3.58$ eV) and various $(\Gamma/E)_{protein}$ values: (*a*) 0.6 ($E_{protein} = -2.55$ eV); (*b*) 0.8 ($E_{protein} = -1.91$ eV); (*c*) 2 ($E_{protein} = -0.76$ eV); and (*d*) 4 ($E_{protein} = -0.38$ eV). Here, the initial I site is located on the atom C6 of the base 1 and we consider each of the other bases' C6 atoms as a possible final F site. The numbers in Fig. 7*c* refer to the bases' indexes of the 1BBX system, whose sequence is given in Fig. 2.



resonance. This result clearly shows that in the DNA–protein bridged system, and for a given $(\Gamma/E)_{DNA}$, the CT pathways involving sites within the protein become important when $|\Gamma/E|_{protein}$ becomes large. The charge particle can thus easily "explore" regions of the protein far from the more direct pathways within DNA, connecting the initial and final sites. These latter conclusions are not valid near DNA's resonance conditions (that is, for $|\Gamma/E|_{DNA} \sim 1$), in which case the charge pathways in the protein are no longer dominant compared with those in DNA, and consequently the phenomena described in Figs. 3 and 4 are not observed.

In the case where $(\Gamma/E)_{protein}$ and $(\Gamma/E)_{DNA}$ are positive, the influence of the protein is observed for large $(\Gamma/E)_{protein}$ values (>1). Figures 7*a–d* show, in the case of 1BBX, typical numerical calculations of $V_S/V_{DI}V_{FA}$ as a function of d_{IF} for $(\Gamma/E)_{DNA}$ fixed at 0.6 ($E_{DNA} = -3.58$ eV) and $(\Gamma/E)_{protein}$ values equal to 0.6, 0.8, 2, and 4 ($E_{protein} = -2.55$, -1.91, -0.76, and -0.38 eV, respectively). The exponential decay of the electronic coupling with distance is still observed for $(\Gamma/E)_{protein}$ equal to 0.6 (Fig. 7*a*) and 0.8 (Fig. 7*b*), whereas no such decay was observed for $(\Gamma/E)_{protein}$ equal to -0.6 (Fig. 3*c*) and -0.8 (Fig. 3*d*). Effects similar to those shown in Figs. 3*c*, 3*d* and 4*c*, 4*d* are also observed for $(\Gamma/E)_{protein} > 1$, but they are not as pronounced when compared, for example, with what is observed in Fig. 3*c*. Moreover, the order of magnitude of the electronic coupling remains much lower in this case than in the case of negative control parameters. As before, these results can be understood from the electronic-band structure formalism: the DNA–protein system is brought to resonance conditions later in the case of $\Gamma/E > 0$ than in the case of $\Gamma/E < 0$, as can be seen from a comparison of the densities of states corresponding to negative (Fig. 5) and positive (Fig. 8) control parameters. This behavior can qualitatively be explained within the CMA (54): the broadening of the energy levels takes place exclusively on only one side (see Fig. 1) of the initial orbital-site energy, making the energy gap

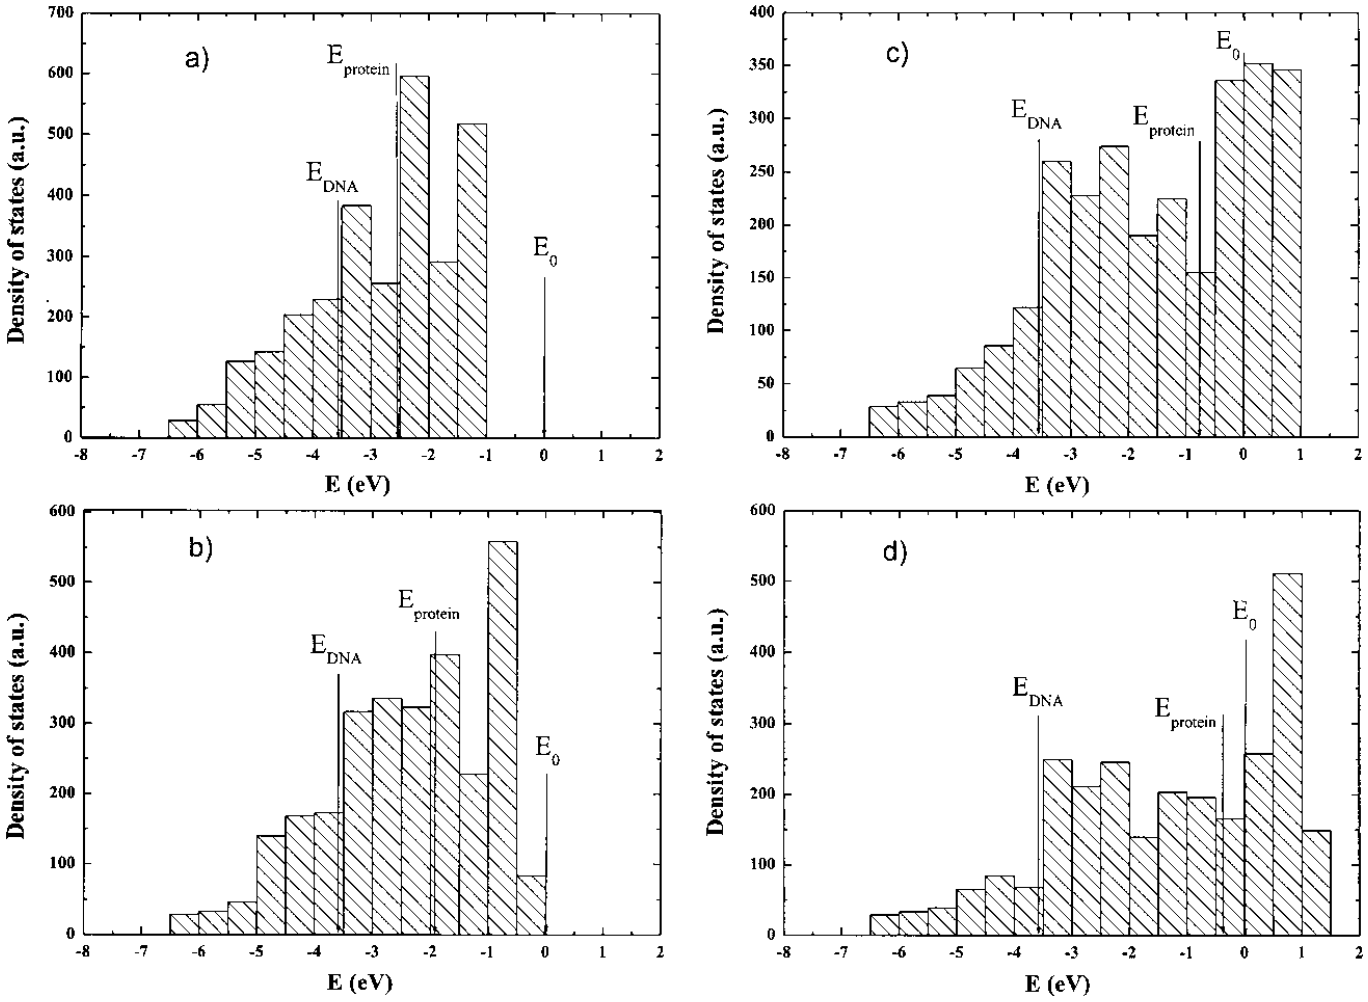
Fig. 8. Density of states (number of states per unit energy range, in arbitrary units) of the 1BBX DNA–protein complex as a function of energy. Initial orbital energies are the same as in Figs. 7*a–d* and are indicated here by vertical arrows: E_{DNA} = –3.58 eV; $E_{protein}$ = –2.55 eV (*a*); –1.91 eV (*b*); –0.76 eV (*c*); and –0.38 eV (*d*) (E_0 = 0).



larger for $\Gamma/E > 0$ than for $\Gamma/E < 0$, which explains why superexchange is easier in the latter case. A detailed discussion concerning the sign effects of the control parameters on the electronic coupling is given elsewhere (54).

The importance of the DNA–protein complex's three-dimensional structure is qualitatively captured by the present pure "through-space" coupling model. The effect of the electronic band generated by these TS interactions is expected to remain important under certain energetic conditions even if we consider the presence of other types of bonds, as it has been previously shown in the case of a folded random-chain system where "through-space" and "through-bond" interactions were simultaneously taken into account (61). In particular, the peculiar effect of protein binding on CT in DNA may be expected under relatively large values of the energetic gap between the redox centers and the bridging medium (i.e., $|E_{DNA}| > 3–4$ eV). Nevertheless, our results do not consider any dynamic effect caused by the flexibility and motions of the bridge, which depend on the actual base-pair sequence as well as the water content surrounding the molecule (41, 43, 44, 62–64). These factors could modulate the energetic gap and thus have an effect on the CT reaction rate. To provide an improved quantitative description of the present CT model, further calculations should account for thermal fluctuations of the medium in which CT occurs, combined with a more realistic quantum-chemical modeling of the electronic bridge Hamiltonian (11, 34, 65).

Despite its obvious simplicity, the CT model used here provides information about mechanistic issues that are rather difficult to probe experimentally or that generally require important computing resources. Our results show that in certain cases long-range CT reactions through DNA can be modulated by the presence of binding proteins, in accordance with experiment. These findings could hold important implications with respect to CT in chromosomal DNA, certain functions of DNA in biological systems, and also DNA damage–protection in vivo. In particular, they indicate that, under certain energetic conditions, the presence of a protein could promote CT over very long molecular distances. Experimental investigation is needed to further test such results.

Hydrogénation électrocatalytique sur des catalyseurs composites de nickel et hydroxyde d'aluminium en cellule dynamique

Patrick Dubé, Louis Brossard et Hugues Ménard

Résumé : L'hydrogénation électrocatalytique (HEC) du cyclohexanone en cyclohexanol a été étudié en milieu aqueux en mettant à profit des électrocatalyseurs à base de poudres composites. Les poudres sont constituées de nanoagrégats de nickel obtenus par déposition physique sous vide, sur des particules de $Al(OH)_3$, AlO(OH) et de γ-Al_2O_3. L'HEC a été réalisée dans une cellule de type dynamique. Le rendement en HEC dépend étroitement de la nature des particules non métalliques laquelle nature influence de façon déterminante l'adsorption–désorption des composés organiques impliqués dans la réaction.

Mots clés : électrocatalyse, oxyde d'aluminium, hydroxyde d'aluminium, hydrogénation, cellule dynamique.

Abstract: The electrocatalytic hydrogenation (ECH) of cyclohexanone into cyclohexanol has been studied in aqueous media with electrocatalysts on composites powders. These powders are formed of nanoaggregates of nickel obtained through a physical deposition under vacuum on particles of $Al(OH)_3$, AlO(OH), and γ-Al_2O_3. The ECH reaction was done in a dynamic cell. Its yield is closely dependent on the nature of the non-metallic particles whose nature greatly influences the adsorption–desorption of the organic compounds involved in the reaction.

Key words: electrocatalysis, aluminum oxide, aluminum hydroxide, hydrogenation, dynamic cell.

[Traduit par la Rédaction]

Introduction

L'hydrogénation électrocatalytique est une technique qui consiste à hydrogéner une molécule organique en utilisant l'hydrogène atomique, adsorbé sur une électrode (1), produit par électrolyse de l'eau. Dans une large mesure, la cinétique de l'hydrogénation électrocatalytique (HEC) est tributaire des matériaux d'électrodes utilisés. Ainsi, les premières électrodes, massives, ont fait place à des électrodes à grandes surfaces spécifiques en utilisant des matériaux ou des alliages métalliques de plus en plus complexes. Les matériaux électrocatalytiques les plus employés sont de la famille du nickel de Raney; ils ont une grande surface active, sont peu coûteux, le dégagement d'hydrogène y est facile et ils ont une bonne stabilité (2). Dès les années 1980, le nickel de Raney a permis d'hydrogéner une grande gamme de molécules organiques (3). Par ailleurs, le nickel de Raney subit une activation au préalable par la lixiviation de l'aluminium en milieu basique, et les phases résiduelles formées ont été déterminées (4, 5), ce qui a permis de confirmer la présence d'hydroxyde d'aluminium ($Al(OH)_3$), d'hydroxyde-oxyde d'aluminium (AlO(OH)) et d'alumine hydratée ($Al_2O_3 \cdot 3H_2O$) résiduel après lixiviation.

Par ailleurs, l'hydrogénation catalytique et l'HEC comprennent une étape d'adsorption de la molécule à hydrogéner (6, 7). Pour le nickel de Raney, des auteurs (8–10) indiquent que l'adsorption de la molécule à hydrogéner est aidée par la présence d'aluminium résiduelle et de ses oxydes, alors que d'autres (11) sont d'avis que l'adsorption de la molécule à hydrogéner a lieu sur les oxydes d'aluminium. Pour appuyer ces hypothèses, des études sur les propriétés d'adsorption de l'hydroxyde d'aluminium et de ses dérivés thermiques (AlO(OH) et Al_2O_3) démontrent que les molécules organiques avec un noyau aromatique comme les hydrocarbures aromatiques polycycliques (HAP) (12), peuvent être adsorbés plus ou moins facilement selon la nature du composé d'aluminium. La coexistence de sites d'adsorption non métalliques, très actifs, et de sites métalliques peu actifs pour l'adsorption des molécules organiques est potentiellement bénéfique pour l'HEC lorsque l'étape la plus lente de la réaction est l'adsorption de la molécule à hydrogéner ou la désorption de la molécule après hydrogénation (13). Le présent article s'intéresse à l'hydrogénation électrocatalytique du cyclohexanone en cyclohexanol en milieu aqueux sur des électrocatalyseurs composites (EC). Les EC sont constitués de très petits agglomérats de nickel déposés sur des particu-

les de $Al(OH)_3$, AlO(OH) ou γ-Al_2O_3. Cette étude s'insère dans le contexte plus global de l'hydrogénation du phénol en cyclohexanol où la formation du cyclohexanone comme intermédiaire est observé.

Réactions d'HEC

L'HEC est un processus qui diffère légèrement de l'hydrogénation catalytique et dont les étapes sont représentées par les équations [1] à [5*b*] (fig. 1). Dans le cas de l'HEC réalisé avec une électrode en matériaux composites, où il y a coexistence de sites métalliques peu adsorbants et de sites non métalliques fortement adsorbants pour les molécules organiques, l'hydrogène atomique est produit in situ par électrolyse de l'eau sur les sites métalliques, eq. [1]. L'adsorption de la molécule à hydrogéner a lieu préférentiellement sur les sites non métalliques (substrat), eq. [2] et l'hydrogène atomique, H(M), réagit avec la molécule organique adsorbée, eq. [3]. La seconde étape de ce processus est plus rapide que la première due à la présence d'un radical (14). La dernière étape est la désorption de la molécule organique hydrogénée pour libérer le site d'adsorption non métallique, eq. [4].

La quantité d'hydrogène adsorbé non utilisée pour l'HEC proprement dite va être perdue sous forme d'hydrogène gazeux, soit par désorption chimique (Tafel), eq. [5*a*] ou électrochimique (Heyrovski), eq. [5*b*].

Détails expérimentaux

Cellule électrochimique

Les essais ont été effectués dans une cellule dynamique en verre (fig. 2) déjà décrite en détail (15, 16). Cette cellule permet la circulation de la solution et de l'électrocatalyseur, ce dernier sous forme de particules qui entrent en contact avec le disque de carbone vitreux réticulé (CVR) poreux (Electrosynthesis Co.). Le CVR agit comme conducteur électrique et permet ainsi la formation d'hydrogène adsorbé sur les particules, M(H), eq. [1]. La contre-électrode est isolée du compartiment cathodique par une membrane de Nafion 117 (DuPont). L'électrolyte du compartiment cathodique (60 mL) est une solution tampon 1 M de phosphate de potassium à pH 7 (KH_2PO_4–NaOH). Un courant de 5 mA est imposé à l'électrode de CVR après avoir ajouté 200 mg de matériaux électrocatalytiques et 0,25 mmol de cyclohexanone à l'électrolyte. L'extraction des molécules organiques se fait dans l'acétate d'éthyle et l'analyse par chromatographie gazeuse se fait avec un standard externe. L'erreur sur ces mesures est estimée à 5 %.

Fabrication des électrocatalyseurs

Les trois poudres de départ utilisées étaient des hydroxydes d'aluminium (Anachemia et Alcan International) ayant des surfaces spécifiques mesurées par BET, de 0,23; 10 et 35 $m^2\ g^{-1}$. Les produits de calcination, le AlO(OH) et le Al_2O_3, ont été obtenus en chauffant la poudre d'hydroxyde d'aluminium ayant une surface BET de 0,23 $m^2\ g^{-1}$, pendant 24 h dans un four à la température appropriée, la poudre était en contact avec l'air ambiant. Le nickel métallique fut ensuite déposé sur les particules de poudre par déposition physique sous vide (*physical vapour deposition*, PVD) (17). Le dépôt obtenu est constitué d'agglomérats de nickel de quelques nanomètres de diamètre visible sur les bords des particules en microscopie électronique à transmission (fig. 3), ce dépôt se retrouve exclusivement à la surface des poudres et le nickel pénètre peu dans les pores (observé en MEB avec un mapping du nickel sur des images non montrées).

Caractérisation des catalyseurs

Les particules d'hydroxyde d'aluminium non chauffé de diverses surfaces spécifiques BET présentent une gamme de taille allant de 5 à 25 μm ainsi qu'une morphologie différente telle que montrée par les images de MEB (fig. 4–6). De plus, la taille des particules est mesurée à l'aide d'un analyseur de taille de type Analysette 22 Compact (Fritsch) en solution aqueuse.

Après calcination des poudres d'hydroxyde d'aluminium de 0,23 $m^2\ g^{-1}$, la surface spécifique est largement tributaire de la température de calcination (18). Cet effet est expliqué par la formation de pores lors de la déshydratation avant

250°C et par la restructuration cristalline après 250°C. La perte en eau permet de modifier la structure chimique de la poudre sans un effet marquant sur la taille des particules (tableau 1).

Résultats et discussion

Adsorption du phénanthrène sur l'hydroxyde d'aluminium

C'est à partir des isothermes d'adsorption du phénanthrène sur l'hydroxyde d'aluminium thermiquement modifié (8) (HATM) que la quantité de phénanthrène adsorbée est donnée en fonction de la masse d'HATM et de la surface spécifique d'HATM pour une concentration (C_e) en phénanthrène de 1,6 mmol L^{-1} (fig. 7). Pour une même masse de

poudre, les résutats confirment que plus la surface spécifique est grande, plus l'adsorption est importante. D'autre part, cette figure illustre aussi que la nature des sites d'adsorption a une influence déterminante sur l'adsorption (en considérant une même aire de surface d'adsorption). Ainsi, la surface ayant des groupements hydroxydes (100°C et 150°C) a une adsorption plus importante que celle sur des surfaces de type oxydes (250°C à 700°C). Ces observations laissent croire que la nature des sites actifs d'adsorption est susceptible d'avoir une influence significative sur les rendements en HEC des composés organiques dans la mesure où l'étape limitante de la réaction est l'étape d'adsorption ou de désorption de la molécule organique à hydrogéner ou la désorption de la molécule après HEC.

Influence de la taille des particules et de la surface spécifique sur l'HEC

La quantité de cyclohexanol formé par HEC augmente en fonction du diamètre de l'électrocatalyseur composite d'hydroxyde d'aluminium et de nickel. Pour une quantité de 200 d'électrocatalyseur le meilleur rendement correspond à une surface spécifique BET de 10 m^2 g^{-1} (fig. 8). On suppose que les sites privilégiés pour l'HEC sont les interfaces métal-hydroxyde – oxyde d'aluminium où les sites métalliques contiennent H_{ads} et les sites non métalliques contiennent la molécule organique adsorbée. L'aire de la surface catalytique réelle semble dépendre de la technique de déposition des agrégats métalliques des catalyseurs employée. Ainsi, le rendement en HEC est susceptible de dépendre de l'importance de l'interface métal – hydroxyde – oxyde d'aluminium (IMHA) et non de la surface BET. On en déduit que la surface électrocatalytique est beaucoup plus petite que la surface BET.

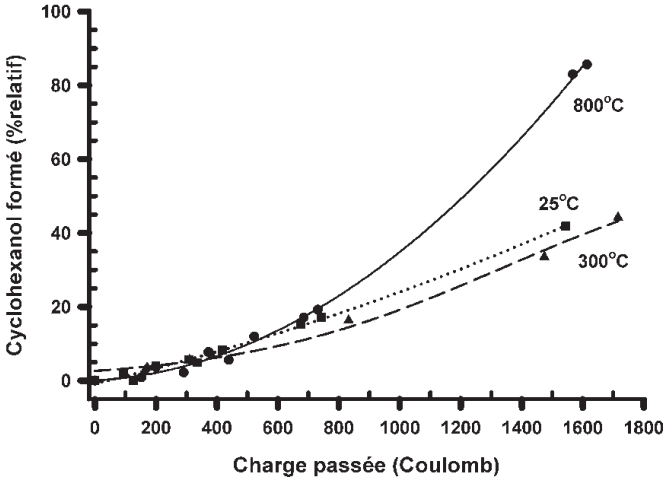
Le tableau 2 présente un résumé des rendements en HEC pour une charge de 1400 C avec les électrocatalyseurs utilisés. On y retrouve le diamètre moyen des particules (Analysette 22) et la surface géométrique des catalyseurs (BET). L'électrocatalyseur C a une plus grande activité en HEC que les électrocatalyseurs A et B. L'utilisation de poudre de nickel pur (200 mg), notée D, donne des rendements inférieurs aux catalyseurs composites A, B et C.

Influence de la nature des sites d'adsorption sur l'HEC

La figure 9 montre que l'activité des électrocatalyseurs fabriqués à partir d'hydroxyde d'aluminium calciné ou non, dépend de la nature des composés d'aluminium formés. Pour l'hydroxyde d'aluminium non chauffé, électrocatalyseur A′, selon la diffraction des rayons-X, la surface est constituée majoritairement de groupements hydroxyl (Gibbsite). Pour les particules calcinées à 300°C, électrocatalyseur E, la surface est partiellement recouverte d'oxyde et d'hydroxyl (Boehmite) et à 800°C, électrocatalyseur F, on retrouve une surface d'oxyde (Alumine gamma). En phase aqueuse, la Gibbsite et la Boehmite ont déjà des hydroxydes de surface, mais il est connu que l'alumine gamma s'hydrate partiellement en surface. Les propriétés acido-basique des matériaux peuvent donc dépendre du degré d'hydratation en solution et de la structure cristalline interne : en effet, selon Pascal (19), l'acidité de Lewis varie comme ceci, alumine < Gibbsite < Boehmite. De plus, les oxydes et hydroxydes d'aluminium

© 2002 CNRC Canada

Fig. 9. Hydrogénation électrocatalytique du cyclohexanone sur l'hydroxyde d'aluminium calciné avec nickel d'environ 0,2 % (p/p).



ont une forte capacité d'adsorption de l'eau et des molécules organiques polaires (20); cette tendance dépendant aussi du degré d'hydratation, il devient donc difficile de déterminer quel est l'effet prépondérant dans l'adsorption des molécules organiques. Toutes ces poudres après traitement thermique ont une taille moyenne similaire (tableau 1) ce qui facilite la comparaison, alors que les autres caractéristiques des électrocatalyseurs sont données au tableau 3. On observe pour une charge passée supérieure à 1400 C, un rendement en HEC bien meilleur dans le cas de l'électrocatalyseur F. L'électrocatalyseur F contient approximativement la même quantité de nickel que dans le cas des deux autres électrocatalyseurs. De plus, il ne semble pas y avoir de corrélation entre la surface BET de l'électrocatalyseur et son rendement en HEC. L'ensemble de ces observations indique le rôle clef joué par la nature du substrat non métallique sur l'adsorption ou la désorption des molécules organiques.

Conclusion

L'hydrogénation électrocatalytique du cyclohexanone a été réalisée en milieu aqueux à 25°C avec des électrodes composites de nickel déposé sur des substrats d'oxyde et d'hydroxyde d'aluminium. Les rendements en HEC dépendent étroitement de la nature du substrat d'aluminium utilisé; le substrat le plus favorable étant le γ-Al_2O_3. Ce qui met en évidence le rôle clef des étapes d'adsorption et de désorption des molécules organiques dans le procédé d'HEC.

Remerciements

Les auteurs remercient l'Alcan International limitée pour les échantillons d'hydroxyde d'aluminium fournis ainsi que le Conseil de recherches en sciences naturelles et en génie (CRSNG) et le fond de l'Université de Sherbrooke pour leur contribution financière.

Utilisation de vecteurs tournants pour l'optimisation de la formulation de mélanges de solvants

Serge Alex

Résumé : Cet article propose une stratégie simple qui permet d'optimiser la formulation de mélanges de solvants sans avoir recours à des modèles mathématiques et (ou) à des représentations graphiques sophistiqués. Les calculs peuvent être faits avec un chiffrier électronique (Excel, Lotus) et ne demandent pas de connaissance particulière, excepté quelques concepts de base en trigonométrie. Cette approche a été développée pour l'industrie du nettoyage et du dégraissage qui doit régulièrement reformuler des solutions de solvants à partir de composés purs. L'optimisation se fait en comparant soit visuellement soit par le calcul la somme des modules de vecteurs tournants normalisés, chacun d'eux représentant à la fois la composition chimique et un (ou plusieurs) des paramètres physico-chimiques à optimiser. Cette approche géométrique utilise une combinaison de coordonnées triangulaires et polaires permettant de ramener les nombreuses variables à représenter dans un espace à deux dimensions. La formulation d'une solution de solvants chlorés et bromés pour substituer des nettoyants purs sera utilisée afin d'illustrer les diverses étapes de calculs et l'intérêt de cette stratégie. La méthode présentée n'est pas restreinte à la problématique des solvants. Elle peut s'appliquer à tout problème de chimie impliquant des comparaisons de propriétés physico-chimiques de mélanges.

Mots clés : solvants, mélange, formulation, optimisation, dégraissage.

Abstract: A new strategy is proposed to optimize the design of solvent blends without using complex mathematical models and (or) graphical representations. All calculations are made with standard electronic programs, such as Excel, Lotus, etc. This approach was developed for the cleaning and degreasing industry, which has to find new recipes of solvent blends on a regular basis. The process relies on a visual analysis of the sum of normalized rotating vectors associated with the chemical composition and the physical properties of the individual components. This approach allows for representation of all parameters on a two-dimensional plot, including information about chemical composition, as well as the physical properties to be optimized. The research of a new mixture of halogenated solvents will be used as an example to illustrate the various steps of this technique. This method is not limited to solvent applications; it also applies to all problems that involve comparisons of physical and chemical properties of blends.

Key words: solvents, mixtures, components, optimization, cleaning.

Introduction

L'usage des solvants chlorés dans l'industrie entraîne de nombreux problèmes de pollution et d'atteinte à la santé (1–4). Ces dernières années des millions de dollars ont été dépensés pour trouver des produits pour les remplacer (5–7). Malgré cela, les alternatives ne sont pas toujours réalistes, car les produits de remplacement ont les défauts de leurs qualités, par exemple : (*i*) Les hydrocarbures et les cétones dégraissent bien et sont volatils, mais ils sont inflammables et pas toujours inoffensifs. (*ii*) Les formulations à base d'eau sont peu toxiques et peu inflammables, mais elles sont moins efficaces et laissent parfois une pellicule. (*iii*) Les dérivés à haut point d'ébullition telle que la *N*-méthylpyrrolidone dégraissent bien, sont peu toxiques, peu inflammables, mais s'évaporent mal. (*iv*) Enfin, nombre d'entre eux sont nocifs pour l'environnement global, car ils contribuent à la dégradation de la couche d'ozone, à l'augmentation de l'effet de serre, etc.

Aussi, une approche hybride est souvent choisie : les solvants chlorés sont conservés, car ils ne possèdent pas de point éclair, ne contribuent pas au réchauffement de la planète, n'attaquent pas la couche d'ozone, n'ont pas des temps de vie dans l'atmosphère très élevés et s'évaporent bien. Par contre pour réduire leur toxicité, ils sont souvent dilués avec une base compatible moins nocive. Cette astuce permet d'en limiter la toxicité, leur seul défaut, tout en conservant leur qualité exceptionnelle de solvant et leur coût peu élevé.

Par contre, trouver le mélange idéal oblige à essayer un nombre infini de combinaisons pour une application donnée si un plan d'expérience n'est pas choisi (8–10). Cette tâche est d'autant plus ardue qu'il faut optimiser des paramètres souvent antagonistes. Par exemple, dans l'industrie du nettoyage et du dégraissage, au moins quatre critères sont à concilier pour sélectionner une solution adéquate. Ce sont le taux d'évaporation, l'indice Kauri–Butanol ou tout autre indice de mesure de solubilité, la toxicité et le coût (1, 4, 5,

11). Les performances recherchées pour chacun d'eux sont : (*i*) Le taux d'évaporation : sa valeur doit être aussi élevée que possible pour limiter le temps de séchage. (*ii*) L'indice Kauri–Butanol (ou KB) : il faut un chiffre élevé pour assurer une bonne solubilisation des solutés. Certains formulateurs préfèrent utiliser les paramètres de Hansen (11) au lieu du KB, car ce dernier n'est pas applicable pour les composés oxygénés. Dans cette étude, le KB est particulièrement bien adapté et a donc été retenu, car expérimentalement il est facilement vérifiable. (*iii*) La toxicité : généralement, sauf exception, seule la toxicité des vapeurs de solvant est considérée. Ceci est justifié par le fait que le danger relié à l'ingestion et (ou) au contact cutané peut être facilement annulé par la pratique d'une hygiène appropriée ou par le port d'équipements individuels de protection. Aussi, le risque global ne dépend pas seulement de la toxicité intrinsèque de la substance, mais aussi de sa pression de vapeur qui renseigne sur la probabilité de la retrouver à l'état gazeux. Un produit est peu dangereux si sa nocivité et sa pression de vapeur sont faibles. (*iv*) Le coût : cette variable est importante pour les industriels, car à elle seule, elle peut déterminer le succès ou l'échec d'une formulation. Malgré, les programmes de plus en plus sophistiqués de recyclage de solvants avec pertes minimales, le prix des solvants demeure un élément déterminant dans le choix final.

Actuellement, il existe des programmes offerts par les fabriquants de solvants pour supporter la formulation tels que Arcocomp (Arco Chemical Company) qui optimise les paramètres de solubilité et le taux d'évaporation, Chemcomp (Dow Chemical Company) qui donne les profils d'évaporation, alors que Co-Act (Exxon Chemical Company) est surtout destiné à l'industrie des peintures et des polymères. Il est à noter que ce dernier renferme aussi une base de données qui contient les propriétés physico-chimiques de plus de 500 solvants (11). Shell Chemical et Eastman Chemical Company proposent aussi à leurs clients des programmes similaires. En dehors de ces produits spécialement conçus pour les formulateurs, il existe les méthodes d'optimisation classiques de recherche opérationnelle comme la méthode du Simplex, les arbres décisionnels de Taguchi ou encore les analyses en composantes principales, etc. (10, 12–14). Par contre, ces stratégies de calcul sont difficiles à appliquer dans ce cas de formulation, faute de modèle de base liant les critères de calculs ou de décision entre eux. Aussi, ce travail présente une approche qui a le mérite d'unifier et d'harmoniser les variables pour la sélection d'un bon solvant (c.-à-d. haut taux d'évaporation, indice Kauri–Butanol élevé, toxicité réduite et faible coût) malgré le manque de lien mathématique et physico-chimique entre les divers paramètres.

Un mélange pour le dégraissage de pièces métalliques de produits chlorés dilués par une base bromée moins toxique servira à illustrer cette technique d'optimisation. Les produits retenus pour le mélange sont le chlorure de méthylène (M), le trichloréthylène (T). Malgré leur toxicité discutable (et encore discutée), ils demeurent des produits très populaires (15). Le diluant est le 1-bromopropane (B) qui est considéré comme le produit de substitution idéal pour les dérivés chlorés et dont la nocivité est réduite.

Problématique

Une des difficultés première en formulation est de minimiser le nombre d'essais tout en étant sûr de couvrir toutes les possibilités de mélange offertes. De plus, il faut tenir compte de l'antagonisme des paramètres de sélection. Par exemple, si un solvant s'évapore bien, sa pression de vapeur est naturellement élevée, ce qui le rend potentiellement plus toxique comme il est plus probable de le retrouver sous forme vapeur. Pour le cas choisi, le tableau 1 résume les principales caractéristiques physico-chimiques des trois produits. Sans entrer dans les détails, le chlorure de méthylène

Nota : Les angles sont mesurés dans le sens horaire à partir de l'axe +y du cercle trigonométrique. M, chlorure de méthylène; T, trichloréthylène; B, 1-bromopropane.

*Cette composition est volontairement ajoutée pour avoir un vecteur commun dans chaque cadran.

(M) est le solvant le plus performant mais malheureusement le plus toxique, alors que le 1-bromopropane (B) est le moins efficace, le plus cher des trois, mais aussi le moins dangereux. Quant au trichloréthylène (T), il se situe entre les deux aussi bien en termes d'efficacité que de santé sécurité.

Stratégie d'étude

Pour optimiser les mélanges, un processus décisionnel graphique est proposé. Il se décompose en trois étapes, soit : (1) Choisir la concentration des solutions des trois solvants pour que l'ensemble couvre au mieux toutes les possibilités. (2) Choisir un mode de représentation graphique qui permette de rapidement visualiser chacun des quatre paramètres physico-chimiques pour chaque mélange. (3) Développer un outil décisionnel pour sélectionner les meilleurs mélanges en fonction des contraintes d'usage, de production et environnementales.

Étape 1 : Choix de l'ensemble de solutions

Une série de solutions contenant divers pourcentages en volume (noté ϕ_v) de chacun des solvants est sélectionnée pour couvrir le maximum de possibilités. Les choix sont résumés dans les trois premières colonnes du tableau 2, les valeurs sont choisies et distribuées par permutation. Le premier set (cadran 1) représente le choix de base, et les deux suivants sont obtenus par permutation des valeurs. Le nombre de solutions retenues est au total de 19, ce chiffre pourrait être augmenté si un résultat plus fin était recherché. Cette étape ne présente aucune difficulté.

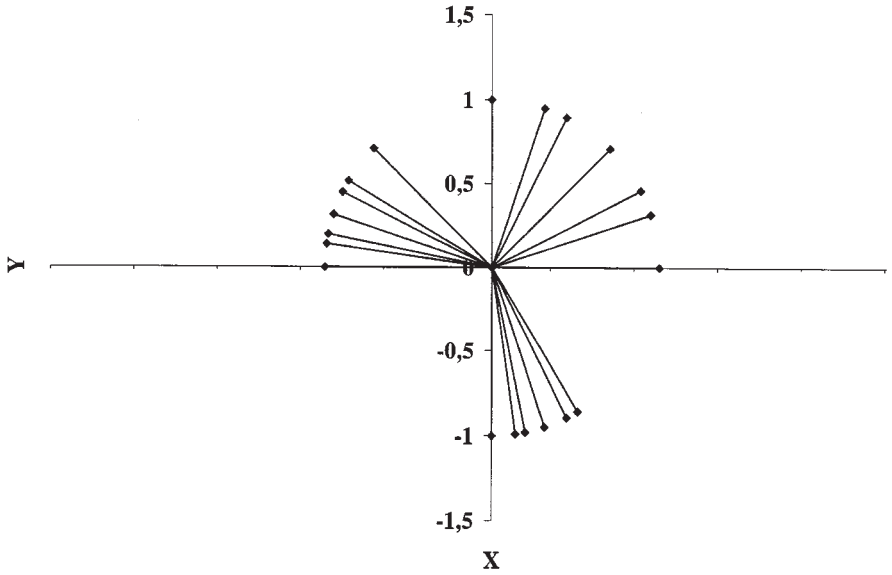
Étape 2 : Choix du mode de représentation

Les pourcentages volumiques de chaque substance doivent être représentés dans un espace à une ou deux dimensions pour être exploitables sur un graphique simple. De plus, une dimension doit rester libre pour représenter le (les) paramètre(s) à optimiser pour chaque constituant. Aussi, il faut impérativement réduire les trois pourcentages de la composition chimique en une coordonnée. La manière la plus simple d'y parvenir est de compresser ces variables en passant en coordonnées triangulaires pour supprimer une dimension, et finalement les reporter sur un graphique en coordonnées polaires pour libérer encore une autre dimension. Les colonnes 4 et 5 du tableau 2 illustrent cette opération. La procédure utilisée est détaillée dans les paragraphes suivants :

Dans le premier cadran : le pourcentage en volume ϕ_{v1} du chlorure de méthylène (M) est représenté en fonction de la somme de ceux du trichloréthylène (T) et du 1-bromopropane (B). Cette opération est appliquée pour les sept premières données de base. Puis, les coordonnées $\phi_{v1} = f(\phi_{v2} + \phi_{v3})$ sont reportées respectivement sur l'axe des y et des x du repère cartésien. En d'autres mots, l'axe des y

© 2002 CNRC Canada

Fig. 1. Représentation de Fresnel des solutions choisies.



supporte le pourcentage en M et celui des x la somme des pourcentages en T et B.

Dans le second cadran : cette série est associée à la première permutation, donc il faut changer le mode de représentation des coordonnées triangulaires par rapport au précédent pour éviter les chevauchements entre valeurs induits par la compression triangulaire. Dans ce cadran, la somme complémentaire (signe négatif) du pourcentage de chlorure de méthylène ϕ_{v1} ajouté à celui du trichloréthylène ϕ_{v2} est représentée en fonction du pourcentage de 1-bromopropane ϕ_{v3}. Le tracé de $\phi_{v3} = f(-(\phi_{v1} + \phi_{v2}))$ permet de lever la dégénérescence entre les divers pourcentages. Ainsi, l'axe des y supporte la valeur négative de la somme des pourcentages M + T. Quant à l'axe des x, il correspond aux pourcentages associés à B.

Dans le troisième cadran : pour la dernière permutation, le changement de représentation est encore obligatoire. Dans ce cas, le pourcentage de chlorure de méthylène ϕ_{v1} est représenté en fonction de la somme complémentaire (signe négatif) du pourcentage de trichloréthylène ϕ_{v2} ajouté à celui du 1-bromopropane ϕ_{v3}, soit $\phi_{v1} = f(-(\phi_{v2} + \phi_{v3}))$. Dans cet espace, l'axe des y correspond au pourcentage en M, alors que l'axe des x est l'opposé de la somme des pourcentages de T et B. Cela clôture le graphique avec la seconde permutation des sept derniers nombres.

Lorsque les valeurs (ϕ_{vi}, $\pm (\phi v_j + \phi_{vk})$) sont reportées dans la figure 1 en suivant la recette établie ci-dessus, un faisceau de vecteurs est alors obtenu. Chaque segment correspond à un mélange particulier et forme un angle θ caractéristique qui est facilement accessible par le calcul en utilisant la tangente. Celle-ci se dérive à partir des valeurs des coordonnées triangulaires (à savoir, $tg(\theta)$ est le rapport du coté opposé sur le coté adjacent, tous deux sont connus car ils correspondent aux pourcentages de base ou à ceux combinés). Ainsi, le rapport (ϕ_{vi}, $\pm (\phi_{vj} + \phi_{vk})$) donne accès à l'angle que forme les diverses solutions avec le repère, et θ devient associé à une composition chimique fixée et unique. Ceci forme une base de coordonnées polaires, où la longueur du segment (ou le module) demeure encore inutilisée et peut servir de support pour les paramètres à optimiser. La figure 1 représente le faisceau de directions induites, et ces dernières sont tracées via la projection orthogonale d'un vecteur de module unitaire ($r = 1$) sur les axes, soit :

[1] $y = r \cos \theta$

[2] $x = r \sin \theta$

La figure 1 est un ensemble de vecteurs tournants ou de Fresnel de module égal à 1. L'angle formé entre la direction et le repère, θ, évolue dans le sens horaire et a pour origine le couple ($x = 0$; $y = +1$), soit le point confondu avec l'axe vertical correspondant aux valeurs y positives.

Les variables de concentration ayant été réduites, il reste à faire subir le même traitement aux quatre paramètres qui sont : le prix, le taux d'évaporation, l'indice Kauri–Butanol et la toxicité. Chacun d'eux doit être calculé pour chaque solution de composition différente. Ensuite, la valeur est reportée sur la direction vectorielle correspondant à la composition choisie et devient le module du vecteur. Dans un premier temps, quatre graphes indépendants associés respectivement au prix, au taux d'évaporation, à l'indice Kauri–Butanol et à la toxicité sont construits, tous supportant 21 vecteurs ou compositions chimiques (incluant deux répétitions). L'obtention de ces graphiques pour chacun des critères s'effectue comme suit.

Représentation graphique du prix

Le prix pour chaque solution est calculé en pondérant les prix de revient des composantes individuelles soit :

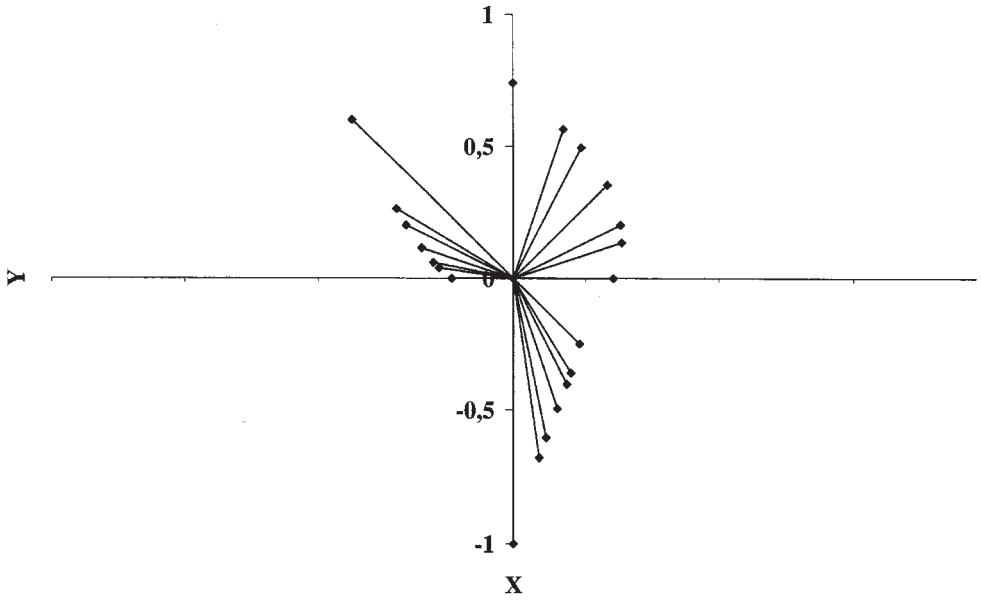
[3] $\mathbf{Pr}_j = \phi_{v1j}\mathrm{Pr}_1 + \phi_{v2j}\mathrm{Pr}_2 + \phi_{v3j}\mathrm{Pr}_3$

où $\mathbf{Pr}_j$ représente le prix résultant du j^e mélange. ϕ_{vij} et Pr_i sont respectivement le pourcentage volumique de la i^e composante du j^e mélange et le coût des solvants à l'état pur. Une fois l'ensemble $\mathbf{Pr}_j$ dérivé, les chiffres sont normalisés par rapport à **Prmin**, ce dernier étant le prix minimum, soit :

[4] $< \mathbf{Pr}_j > = \mathbf{Prmin}/\mathbf{Pr}_j$

© 2002 CNRC Canada

Fig. 2. Représentation des vecteurs tournants normalisés du paramètre prix.



Finalement, les entrées < $\mathbf{Pr}_j$ > sont reportées sous forme de segments de longueur normalisée sur la direction associée au mélange choisi. Cette opération est effectuée en utilisant une relation identique aux équations [1] et [2] (projections orthogonales) :

[5] $y = < \mathbf{Pr}_j > \cos \theta$

[6] $x = < \mathbf{Pr}_j > \sin \theta$

Le résultat est montré dans la figure 2, graphe qui illustre sous forme géométrique le paramètre prix. Plus la longueur du vecteur est proche de l'unité, moins cher sera le mélange. L'étape de normalisation est obligatoire pour pouvoir comparer le prix avec les autres critères (c.-à-d. : toxicité, taux d'évaporation, etc.) qui n'ont pas les mêmes unités et qui eux aussi devront être harmonisés. La normalisation aurait pu s'effectuer par rapport à la valeur maximale au lieu de celle minimale. Ici, le choix est fait afin que le vecteur le plus long corresponde aux meilleures conditions. Ainsi, un segment de module (mod.) unitaire est la meilleure note (ou score) possible. Avec cet exemple, le trichloréthylène est le premier choix en terme de prix, suivi de près par la solution 0,50:0,50 v/v de trichloréthylène et de chlorure de méthylène avec un score de 0,85 (ou mod. = 0,85). Cela signifie que ce mélange rencontre uniquement 85 % des meilleures performances disponibles à partir des trois substances de base choisies.

Représentation graphique du taux d'évaporation

Le taux d'évaporation τ est une mesure relative qui se calcule par rapport à une substance de référence à une température donnée. Généralement, l'acétate de butyle sert de standard et l'expérience se fait à 25°C. Ce taux se mesure en normalisant le temps requis pour évaporer 90 % de la masse du solvant étudié par rapport à celui nécessaire pour évaporer la même masse d'acétate de butyle. Pour les solvants halogénés, il peut aussi s'obtenir en mesurant la vitesse de disparition de deux liquides (le solvant étudié et la référence) sur un plan incliné (16). Les valeurs sont connues pour les substances pures et sont reportées dans le tableau 1. Le taux d'évaporation des solutions est dérivé en assumant qu'il existe une relation linéaire entre celui des produits purs et celui des mélanges. Cette hypothèse est justifiée par le fait qu'il n'existe pas d'interactions fortes entre les diverses composantes du mélange comme des liaisons de type hydrogène. Aussi, l'équation [7] conduit au taux d'évaporation τ.

[7] $\tau_j = \phi_{m1j}\ \tau_1 + \phi_{m2j}\ \tau_2 + \phi_{m3j}\ \tau_3$

où τ_j représente le taux d'évaporation du j^e mélange et ϕ_{mij} correspond au pourcentage massique du i^e composé dans le j^e mélange. Dans cette équation, les fractions volumiques doivent être remplacées par les fractions massiques pour tenir compte de la définition du taux d'évaporation (voir ci-dessus). τ_i est le taux d'évaporation de la i^e substance pure à 25°C déterminé par rapport à l'acétate de butyle (τ = 1,0 par définition).

Le pourcentage massique est calculé à partir des pourcentages volumiques ϕ_{vij}. La fraction volumique étant égale à $\phi_{vij} = V_i/V_t$ (où V_i est le volume de la i^e substance pure et V_t est le volume total de la solution), alors ϕ_{mij} est dérivé grâce à la formule $\phi_{vi}\rho_i/\Sigma_i\phi_{vi}\rho_i$, où ρ_i est la masse volumique des produits purs. Les valeurs des taux d'évaporation de chaque mélange sont ensuite normalisées en faisant l'opération suivante :

[8] $< \tau_j > = \tau_j/\tau\mathbf{max}$

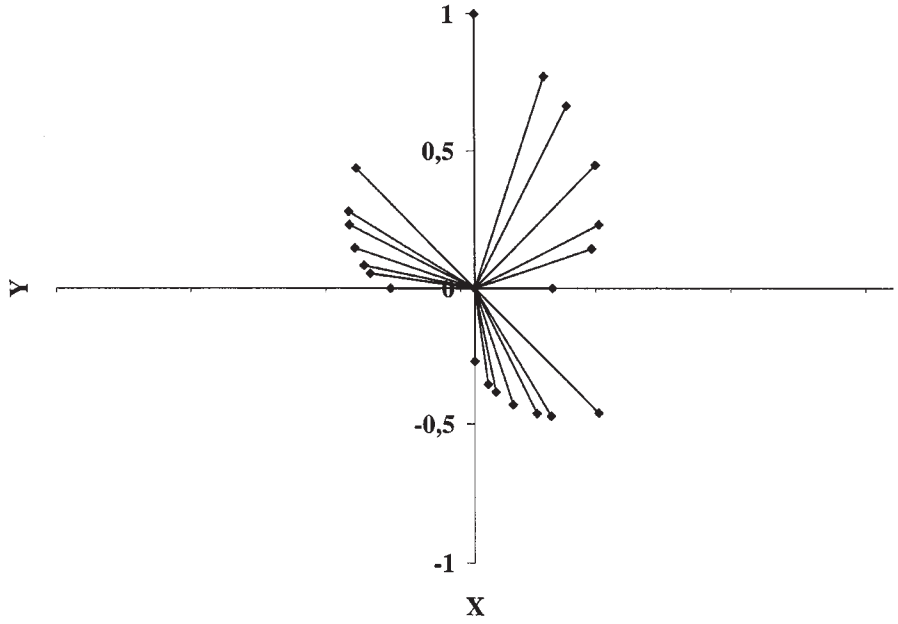
où τ_j est le taux d'évaporation du j^e mélange et $\tau\mathbf{max}$ est le taux d'évaporation le plus élevé. La figure 3 représente le faisceau de vecteurs correspondant en utilisant la relation habituelle :

[9] $y = < \tau_j > \cos \theta$

[10] $x = < \tau_j > \sin \theta$

© 2002 CNRC Canada

Fig. 3. Représentation des vecteurs tournants normalisés du taux d'évaporation.



Le vecteur le plus long correspond au taux d'évaporation le plus rapide, et donc, au mélange le plus performant par rapport à ce paramètre. La solution de chlorure de méthylène pure sort gagnante (mod. = 1 ou 100 %), suivie du mélange 0,750:0,125:0,125 v/v/v en M–T–B, milieu très riche en chlorure de méthylène et qui obtient un score de 81 % (mod. = 0,81).

Représentation graphique de l'indice Kauri–Butanol

L'indice de Kauri–Butanol (KB) permet de mesurer le pouvoir solvant des composés chimiques. Ce test simple consiste à ajouter le solvant à tester dans un volume imposé d'une solution de gomme de Kauri dans du butanol jusqu'à l'apparition d'un trouble (17). Le volume de solvant versé est corrigé par des étalonnages avec des substances tests (le toluène et un mélange heptane–toluène (75:25)) et l'indice KB est dérivé à partir de ces mesures et d'une formule standardisée (17). Pour le mélange, le KB peut être considéré comme une combinaison linéaire des indices de chaque composé pur pondérée par leurs pourcentages volumiques respectifs, les solutions étant idéales comme déjà mentionné. Certains auteurs utilisent les paramètres de Hansen (δ) au lieu de l'indice KB pour évaluer le pouvoir solvant, ceux-ci étant souvent mieux connus et documentés (11, 18), et surtout applicables à toutes les catégories de solvants. Eux aussi sont calculés en supposant que le coefficient résultant du mélange est une combinaison linéaire des δ pondérés par le pourcentage volumique de chaque composé pur (11). Dans cette étude, l'indice KB est particulièrement bien choisi, car il est alors plus facile et rapide de faire des vérifications expérimentales si nécessaire.

$$[11] \quad \mathbf{KB}_j = \phi_{v1j}KB_1 + \phi_{v2j}KB_2 + \phi_{v3j}KB_3$$

où $\mathbf{KB}_j$ représente l'indice résultant du j^e mélange. ϕ_{vij} et KB_i sont respectivement le pourcentage volumique du i^e composant du j^e mélange, et l'indice KBi, celui des substances pures. Comme précédemment, les indices sont normalisés en divisant chaque $\mathbf{KB}_j$ par le **KBmax**, ce dernier correspondant au mélange ayant le pouvoir nettoyant le plus grand :

$$[12] \quad < \mathbf{KB}_j > = \mathbf{KB}_j/\mathbf{KBmax}$$

Ensuite, l'ensemble $< \mathbf{KB}_j >$ est porté en graphique (voir fig. 4) sous forme harmonisée. Cette opération est effectuée en utilisant les projections orthogonales :

$$[13] \quad y = < \mathbf{KB}_j > \cos\theta$$

$$[14] \quad x = < \mathbf{KB}_j > \sin\theta$$

Le vecteur de longueur unitaire représente le meilleur solvant. On notera que leurs performances étant tellement voisines, les pointes des vecteurs sont presque toutes inscrites dans un même cercle (voir fig. 4). Les modules sont tous compris entre 1 et 0,90, ce qui démontre que leurs capacités nettoyantes sont similaires et ce paramètre influencera peu le choix final dans cet exemple.

Représentation graphique de la toxicité

Il n'existe pas de modèle établi pour définir la toxicité. De plus, malgré des années d'existence et d'utilisation, de nombreux désaccords existent dans la littérature concernant les dangers et risques reliés aux solvants chlorés et bromés (1, 15). Les tableaux 3A et 3B illustrent bien ce point (1). Aussi, la toxicité est illustrée en créant un indice qui combine la dose moyenne d'exposition (TWA ou « time-weighted average ») sur un temps *t* et la pression de vapeur saturante du composé, soit :

$$[15] \quad \mathbf{ITOX} = P_i/(\mathrm{TWA})_i$$

où P_i est la pression de vapeur saturante en mm Hg (1 mm Hg = 133,322 Pa) à 20°C (ou autres unités (19)) de la substance *i*. $(\mathrm{TWA})_i$ représente la dose limite admise pour la concentration des vapeurs sur une période de temps définie (elle s'exprime en ppm pour une période de temps fixée,

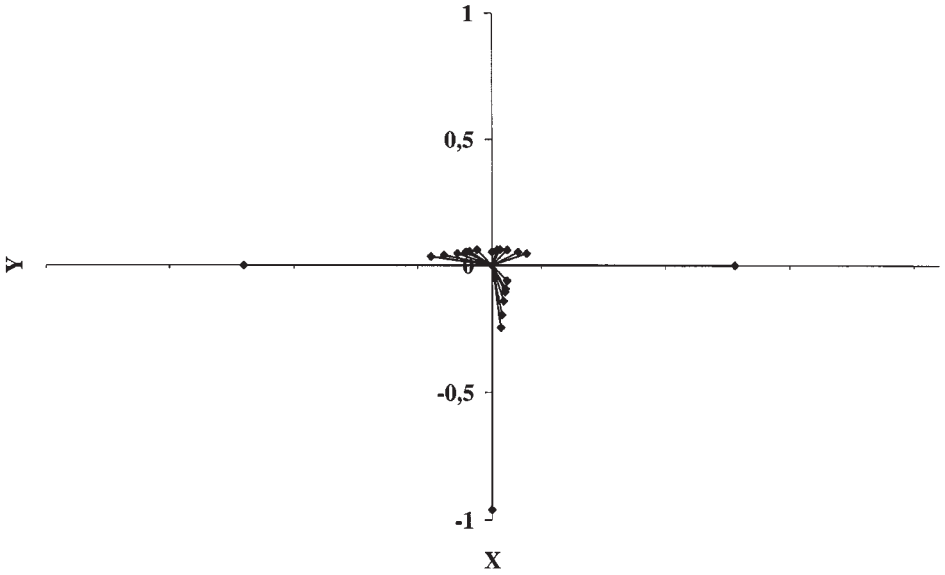
généralement prise sur 8 h (voir tableau 3B)). ITOX tient compte à la fois de la toxicité via la grandeur TWA et de la probabilité que les vapeurs existent en introduisant la notion de pression de vapeur. En effet, si un composé chimique est dangereux à cause de sa toxicité intrinsèque, il l'est réellement uniquement si sa volatilité est notable. Pour le mélange des trois substances, l'indice de toxicité ITOX se calcule de la façon suivante :

© 2002 CNRC Canada

Fig. 5. Représentation des vecteurs tournants pour l'indice ITOX (voir texte pour la définition de l'indice ITOX).



[16] $\mathbf{ITOX}_j = \Sigma_{i\,=\,1\ à\ 3}\ (\phi_{nij} P_i/(\mathrm{TWA})_i)$

où ϕ_{nij} est la fraction molaire de chacun des produits. Cette variable est dérivée de la fraction volumique calculée précédemment ($\phi_{nij} = \phi_{vi}\rho_i / M_{mi} / \Sigma_i \phi_{vi}\rho_i / M_{mi}$, où M_{mi} représente la masse molaire de la i^{e} espèce chimique exprimée en g mol^{-1}). Les termes P_i et $(\mathrm{TWA})_i$ ainsi que ϕ_{vi} et ρ_i ont déjà été définis plus haut. Dans ce modèle, la pression de vapeur au-dessus du liquide est supposée suivre la loi de Raoult (20), et donc la pression associée au mélange est directement reliée à la fraction molaire dans le liquide de chaque composé. Plus ITOX est élevé, plus le produit est dangereux. En effet si la pression est forte, ITOX croit avec ce terme. Simultanément, si TWA diminue, signe d'une grande toxicité, ITOX augmente alors, car le dénominateur chute. La figure 5 illustre les résultats obtenus. Une fois encore, les valeurs sont normalisées à l'unité par l'équation 17 pour pouvoir être comparées aux autres grandeurs.

[17] $< \mathbf{ITOX}_j > = \mathrm{ITOXmin}/\mathbf{ITOX}_j$

Les termes ont leur signification habituelle. Pour reporter les indices $< \mathbf{ITOX}_j >$ dans la figure 5, les équations habituelles sont nécessaires :

[18] $y = < \mathbf{ITOX}_j > \cos\theta$

[19] $x = < \mathbf{ITOX}_j > \sin\theta$

Plus le module du vecteur est grand, moins toxique sera le solvant. La forte volatilité et toxicité du chlorure de méthylène font que, dès qu'il est présent dans un mélange, celui-ci est grandement affecté. Aussi seules les compositions où il est absent obtiennent une note honorable. Notamment, il s'agit des solutions 0,00:0,00:1,00 v/v/v M–T–B (mod. = 1,00), 0,00:0,50:0,50 v/v/v M–T–B (mod. = 0,97) et 0,00:1,00:0,00 v/v/v M–T–B (mod. = 0,96). Les autres arrivent avec des scores nettement plus faibles, car le rapport *P*/TWA pour le chlorure de méthylène est environ 14 fois plus grand que celui des deux autres produits.

Optimisation des mélanges

Ce travail d'approche accomplit, les quatre paramètres importants sont supportés par des graphiques indépendants que l'on peut combiner par addition simple ou complexe pour réduire les variables. Ensuite, il existe plusieurs méthodes d'optimisation dépendant du mandat ou des contraintes imposées par l'usage ou le procédé. Avant de les présenter, le cas particulier où seul un paramètre est important permet de montrer que la représentation choisie fournit à la fois la meilleure solution et le degré de confiance.

Par exemple, si un formulateur doit impérativement optimiser la vitesse d'évaporation, seul ce critère est important, les autres facteurs étant secondaires. Dans ce cas, l'analyse peut consister non seulement à trouver le vecteur correspondant au taux d'évaporation le plus élevé, mais aussi à considérer des vecteurs moins performants mais acceptables. En effet, dépendant de l'usage recherché, des seuils d'acceptabilité représentant le pourcentage de performance du mélange acceptable par rapport à la situation idéale peuvent être imposés. Par exemple, si le formulateur recherche des mélanges avec des taux d'évaporation compris entre la perfection (mod. = 1) et ceux n'offrant que 80 % de la meilleure valeur : alors, cela signifie que tous vecteurs rencontrés dans la couronne incluse dans les rayons 1 et 0,8 seront des solutions. Ceci peut être résolu mathématiquement plutôt que graphiquement si on recherche l'économie d'une représentation graphique en se servant de l'équation du cercle :

[20] $x^2 + y^2 = R^2$

où R est le rayon du cercle et x et y sont les coordonnées cartésiennes. Alors, tous les mélanges dont les coordonnées (x,y) satisfont l'inéquation 19 :

[21] $1 \geq x^2 + y^2 \geq 0{,}64$

sont solutions. Les nombres 1 et 0,64 correspondent au carré des limites choisies (1 et 0,80). En effet, en regardant la fig. 3, rapidement on voit que seul le chlorure de méthylène pur (mod. = 1,00) et le mélange 0,750:0,125:0,125 v/v/v M–

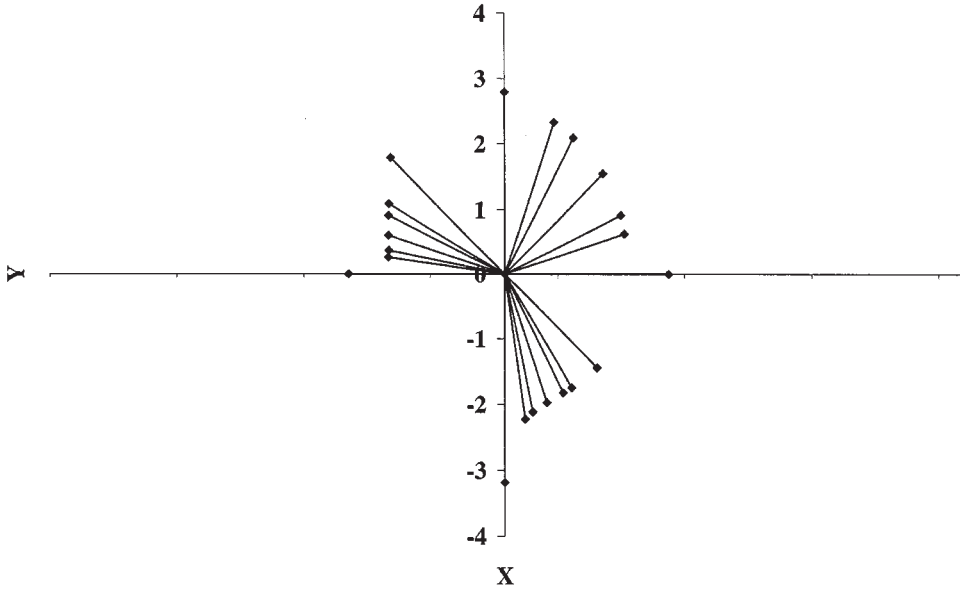
Fig. 6. Représentation de la somme simple des quatre paramètres.



T–B (mod. = 0,81) sont capables de respecter les bornes choisies. La normalisation offre donc un espace probabilisé.

Si l'ensemble des contraintes est considéré, l'approche simple utilisée ci-dessus n'est plus possible. Il faut alors trouver un mode de combinaison des paramètres pour comprimer les variables tout en tenant compte de la réalité chimique. Pour cela, il existe deux voies possibles soit la sommation des vecteurs (union) ou leur superposition (intersection) comme chacune des représentations des paramètres se comporte comme un ensemble dans le sens mathématique du terme.

Combinaison simple (ou union simple)

Lorsque la combinaison simple est retenue, chaque facteur possède un poids statistique équivalent et la somme vectorielle conduit au graphique de la figure 6 :

$$[22] \quad V_t(\theta) = V_1(\theta) + V_2(\theta) + V_3(\theta) + V_4(\theta) \text{ ou } \Sigma_{i = 1 \text{ à } 4}\, V_i(\theta)$$

où $V_i(\theta)$ est le vecteur représentant un des quatre critères (c.-à-d. prix, taux d'évaporation, etc.) pour une composition fixée par l'angle θ (revoir le tableau 1). $V_t(\theta)$ est la somme des quatre grandeurs, où tous les vecteurs ont un poids statistique égal. Aussi, le score maximal est forcément compris entre ±4. Normalement le (ou les) vecteur(s) ayant la plus grande valeur numérique en valeur absolue sera(ont) le(s) meilleur(s) candidat(s).

Ici, les trois premières solutions affublées du module (ou score) le plus élevé sont :

(1) celle constituée de 0,00:0,50:0,50 v/v/v M–T–B (mod. = 3,18),

(2) celle contenant uniquement le chlorure de méthylène (mod. = 2,79),

(3) celle fabriquée à partir de 0,50/0,50/0,00 v/v/v M/T/B (mod. = 2,66).

Les trois premiers choix conduiraient à ces candidats. Ainsi, aucune combinaison ternaire appartient à ce bloc, et les produits purs demeurent encore dans le peloton de tête. Ceci n'est pas surprenant, car ils sont reconnus pour leur grande performance. Le 1-bromopropane, qui est considéré comme la substance de substitution par excellence des solvants chlorés (21), n'arrive qu'au quatrième rang, étant lourdement pénalisé par son prix beaucoup plus élevé.

À ce stade, le choix définitif peut être soit le mélange ayant la meilleure note (0,00:0,50:0,50 v/v/v M–T–B), soit tous ceux compris dans un intervalle de probabilité de performance imposée comme vu plus haut. Toutefois, en ajoutant cette contrainte, le problème peut s'avérer sans solutions. Par exemple, si seuls les solvants rencontrant 90 % du score maximal (mod. = 4) pour chacun des paramètres sont acceptés, alors le problème n'a pas de solution, car le premier mélange a uniquement un module de 3,18 (valeur plus petite que 0,90 * 4 = 3,60).

Cette approche décisionnelle, avec des niveaux de paramètres identiques, n'est pas toujours réaliste. Il est donc possible d'aménager des variantes à ce schéma pour tenir compte de réalités particulières courantes.

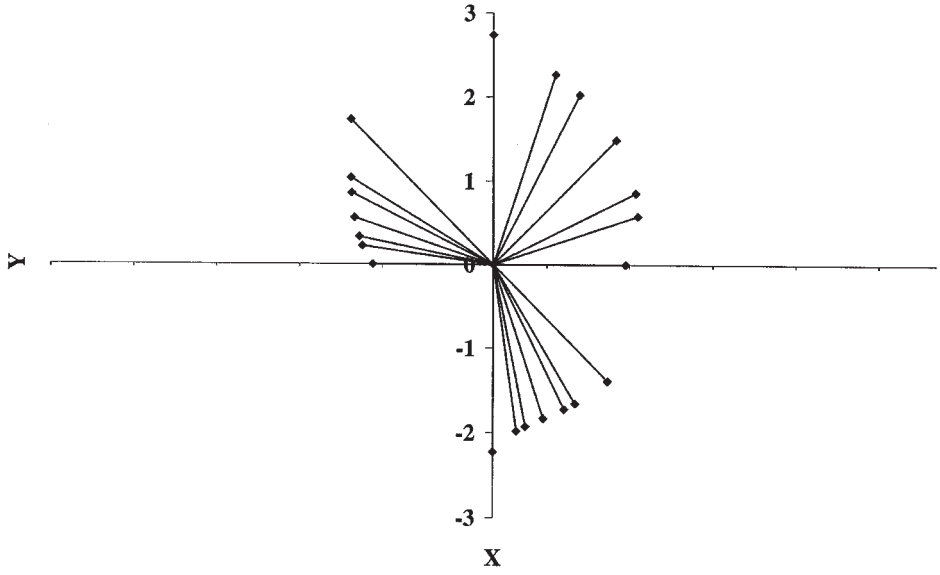
Variante 1 : cas de l'addition réduite

L'approche égalitaire n'est pas toujours représentative des situations rencontrées. En effet, l'optimisation de solutions nettoyantes dépend de facteurs propres à certains pays, à certaines coutumes de production ainsi que de la nature des lois et des procédés, etc. Par exemple en Allemagne, les solvants chlorés sont généralement confinés lors de leur usage, et le chargement et (ou) déchargement des machines se fait à l'aide de pompes et de circuits totalement isolés. Cette habitude de production supprime *de facto* l'aspect toxique du produit, car l'exposition des travailleurs aux vapeurs sont réduites, voire nulles. Aussi, il devient superflu de considérer la toxicité et seuls les trois autres facteurs méritent de la considération.

$$[23] \quad V_t(\theta) = V_1(\theta) + V_2(\theta) + V_3(\theta) \text{ ou } \Sigma_{i = 1 \text{ à } 3}\, V_i(\theta)$$

© 2002 CNRC Canada

Fig. 7. Représentation de la somme de trois paramètres (prix, taux d'évaporation et indice Kauri–Butanol).



Alors, $V_t(\theta)$ correspond à la somme des contributions qui proviennent du taux d'évaporation, de l'indice Kauri–Butanol et du prix. Cela conduit à une valeur maximale de ±3 pour le graphique et seuls les vecteurs qui ont l'amplitude la plus proche de ce chiffre sont les meilleurs candidats. La figure 7 illustre ce cas. Le module le plus grand revient alors au chlorure de méthylène seul, car, hormis sa toxicité, il est le plus performant pour les autres paramètres, excepté pour le prix où seul le trichloréthylène est de quelques dollars meilleur marché.

De la même façon, s'il existe des programmes efficaces de recyclage comme c'est devenu le cas, le facteur coût peut être minimisé, car une partie des matières premières fonctionne en circuit fermé. L'équation 21 prendrait encore une expression plus simple, car les vecteurs associés à la toxicité et au prix pourraient être négligés.

Variante 2 : cas de l'addition pondérée

Dans le paragraphe précédent, l'équation 21 répondait à des situations particulières mais claires et précises. Malheureusement, il existe des cas où il est plus difficile de totalement négliger un facteur, et la pondération doit se faire avec des valeurs différentes de zéro ou un (tout ou rien). Par exemple, l'opérateur peut modifier la combinaison des vecteurs en pondérant la somme vectorielle par des nombres entiers positifs a_{ij} entiers ou décimaux pour souligner ou minimiser l'importance d'un paramètre :

$$[24] \quad V_t(\theta)_j = a_{1j}V_1(\theta) + a_{2j}V_2(\theta) + a_{3j}V_3(\theta) + a_{4j}V_4(\theta) \text{ ou } \Sigma_{i = 1 \text{ à } 4}\, a_{ij}V_{ij}(\theta)$$

Les coefficients a_{ij} sont alors des nombres entiers ou décimaux dont le choix est dicté par l'usage et la pratique. La figure 8 donne un exemple particulier où les nombres a_{ij} ont tous été pris égaux à un, excepté celui associé à la toxicité qui est de 6. Alors, le meilleur solvant ne peut pas donner un résultat supérieur à ±9 (voir fig. 8). Les meilleurs scores sont obtenus par la solution de trichloréthylène seul (mod. = 7,98) et par le mélange 0,00:1,00:1,00 v/v/v M–T–B (mod. = 7,47), les autres options restant très loin derrière (mod. = 3,48 pour la plus proche) à cause de la présence de chlorure de méthylène qui est dangereux. Cette amplification de la toxicité pourrait correspondre à la situation d'un utilisateur qui travaille dans un atelier où il n'y a pas de confinement des solvants. Cette pondération amplifie le critère toxicité par rapport aux autres pour tenir compte de cette réalité.

Variante alternative : cas de l'intersection des vecteurs

Jusqu'à présent le tri des vecteurs s'est effectué en recherchant le module maximum directement issu de la sommation simple ou combinée de ces derniers. Il existe une alternative, déjà en partie introduite, qui consiste à imposer une (des) valeur(s) minimale(s) à chaque paramètre en fixant des seuils de probabilité comme vu précédemment à partir des attentes d'usage ou (et) de production. Pour illustrer ce formalisme, on suppose qu'un formulateur désire un mélange avec les caractéristiques imposées suivantes :

- un indice Kauri–Butanol compris entre 136 et 122,4 (mod. : 1–0,9)
- un prix compris entre 168 $ et 336 $ pour un volume de 10 L de produit (mod. : 1–0,5)
- un taux d'évaporation variant de 14,5 à 10,15 (mod. : 1–0,7)
- une toxicité qui ne soit pas supérieure à 2,5 fois celle du mélange le moins nocif (mod. 1–0,4).

Le tableau 4 résume la situation obtenue avec ces contraintes. Le nombre de vecteurs vérifiant les contraintes dans les limites fixées pour chacun des paramètres est donné dans la deuxième colonne. Enfin, lorsqu'on fait l'intersection des ensembles de solutions, seul le trichloréthylène pur peut remplir les quatre critères énumérés. En effet, il est le seul produit ayant un vecteur commun dans chaque ensemble car il respecte toujours les seuils fixés.

Choix de la variante décisionnelle

Au niveau décisionnel, les conditions d'utilisation du solvant fixent laquelle des approches doit être sélectionnée

© 2002 CNRC Canada

Fig. 8. Représentation des paramètres avec pondération (voir texte).

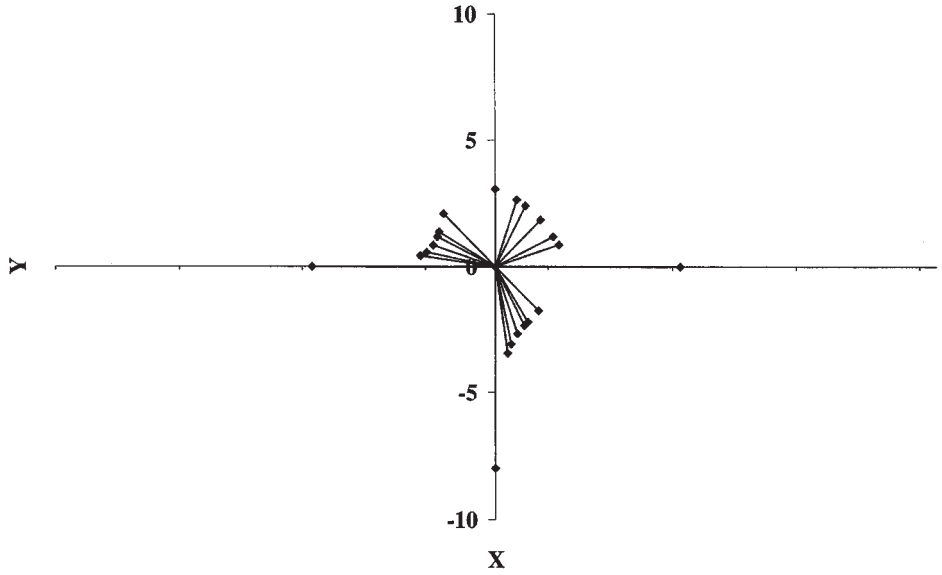


Tableau 4. Exemple de choix de mélange par intersection de vecteurs (voir texte).

Paramètre choisi et intervalle de tolérance	Nombre de mélanges respectant les critères	Paramètre de décision pour le choix des seuils
Indice KB Seuils : 1–0,9	19	Efficacité de nettoyage
Prix Seuils : 1–0,5	9	Budget
Taux d'évaporation Seuils : 1–0,7	3	Vitesse de lavage et temps de séchage
Indice ITOX Seuils : 1–0,4	2	Normes, lois et règlements
Intersection des quatre ensembles	1	Vecteur ayant rempli les quatre conditions (seul le trichloréthylène pur est acceptable)

entre (*i*) la « combinaison simple » (union d'un ensemble de vecteurs ayant le même poids statistique); (*ii*) l'« addition réduite » (union d'un nombre limité de vecteurs ayant le même poids statistique); (*iii*) l'« addition pondérée » (union de vecteurs pondérés) et (*iv*) l'« intersection des vecteurs » (sélection de vecteurs respectant des scores fixés).

(*i*) La combinaison simple a une tendance à favoriser les critères extrêmes. Notamment dans l'exemple traité, la toxicité du chlorure de méthylène et le coût élevé du bromopropane sont les facteurs qui ont le plus de poids sur le choix final. Cette approche est bien adaptée lorsque les contraintes d'usage ou de production du mélange sont inconnues ou floues, car aucun jugement ou prise de décision est nécessaire. Par contre, elle peut être trop discriminatoire pour les produits qui se démarquent.

(*ii*) L'addition réduite des paramètres, quand elle est possible, est la plus simple. Elle est une variante de la combinaison simple (certains coefficients sont nuls). Elle est particulièrement bien adaptée aux situations claires comme par exemple lorsque l'on rencontre des solvants confinés, des produits recyclés efficacement, etc. Dans ces cas de figures, il est facile de totalement ignorer un ou plusieurs paramètres avec certitude. Malheureusement, cela se limite aux cas simples comme mentionné dans le texte plus haut et peut être contestable, car il y a une part de subjectivité.

(*iii*) L'approche pondérée permet de favoriser une composante par rapport à une autre et elle atténue ou amplifie un ou plusieurs paramètres. Elle serait idéale, si le choix des coefficients de pondération ne serait pas parfois arbitraire lorsque les paramètres de choix ne sont pas connus ou calculables.

Ce défaut peut être compensé en sélectionnant un grand nombre de combinaisons de coefficients a_{ij} différents et ainsi créer une infinité de scénarios possibles. Alors, il est possible de construire une matrice V(*n*,*m*) de dimension égale au nombre de compositions *n* et de scénarios différents *m*, et elle devient à son tour le point de départ pour optimiser les mélanges en utilisant des méthodes classiques (Simplex, Analyse Factorielle, etc.).

(*iv*) Enfin, la méthode de superposition ou d'intersection des vecteurs n'est applicable que si les seuils de tolérance pour chaque paramètre sont connus ou faciles à fixer. Cette approche est très discriminatoire, mais conduit à des solutions fiables et indiscutables.

© 2002 CNRC Canada

Conclusion

La procédure de normalisation de vecteurs tournants offre un mode de représentation très souple et particulièrement bien adapté pour visualiser les propriétés physico-chimiques de mélanges ternaires et binaires. Peu importe, les variantes choisies comme outil de diagnostic, les résultats obtenus sont fiables et évitent de faire des mélanges inutiles. Par exemple, dans le cas traité, l'outil démontre que l'addition d'un solvant bromé à des solvants chlorés n'améliore rien à leurs performances, ce qui s'est avéré vrai sur le terrain, alors que cette pratique avait tenté de nombreux formulateurs.

Asymmetric total synthesis of (+)-*exo*-brevicomin based on enantioconvergent biocatalytic hydrolysis of an alkene-functionalized 2,3-disubstituted epoxide

Sandra F. Mayer, Harald Mang, Andreas Steinreiber, Robert Saf, and Kurt Faber

Abstract: A short total asymmetric synthesis of (+)-*exo*- and (–)-*endo*-brevicomin ((+)-*exo*-**3** and (–)-*endo*-**3**), which are components of the attracting pheromone system of several bark-beetle species belonging to the genera *Dendroctonus* and *Dryocoetes*, was accomplished via a chemoenzymatic protocol. The key step consisted of biocatalytic hydrolysis by bacterial epoxide hydrolases of *cis*-configured 2,3-disubstituted oxiranes bearing olefinic side chains. This reaction proceeded in an enantioconvergent fashion, by affording a single enantiomeric *vic*-diol from the *rac*-epoxide in up to 92% ee and 83% isolated yield.

Key words: bacterial epoxide hydrolase, 2,3-disubstituted oxirane, enantioconvergent hydrolysis, (+)-*exo*-brevicomin, (–)-*endo*-brevicomin.

Résumé : Faisant appel à un protocole chimioenzymatique, on a réalisé une courte synthèse asymétrique totale des (+)-*exo*- et (–)-*endo*-brévicomines [(+)-*exo*-**3** et (–)-*endo*-**3**], des composants du système de phéromone d'attraction de plusieurs espèces de scolytes des genres *Dendroctonus* et *Dryocoetes*. L'étape clé implique une hydrolyse biocatalytique à l'aide d'hydrolases bactériennes d'époxyde d'oxiranes 2,3-disubstitués, de configuration *cis*- et portant des chaînes latérales oléfiniques. Cette réaction s'est produite de façon énantioconvergente en ne fournissant, à partir de l'époxyde racémique, qu'un seul énantiomère de diol vicinal, avec un rendement isolé de 83% et un e.e. de 92%.

Mots clés : hydrolase bactérienne d'époxyde, oxirane 2,3-disubstitué, hydrolyse énantioconvergente, (+)-*exo*-brévicomine, (–)-*endo*-brévicomine.

[Traduit par la Rédaction]

Introduction

Bacterial epoxide hydrolases have been shown to be highly versatile biocatalysts for the preparation of nonracemic *vic*-diols. In particular, bulky 2,2-disubstituted epoxides were hydrolyzed with excellent selectivities (*E* values up to > 200) via kinetic resolution (1). In addition, we recently reported the asymmetric biohydrolysis of (±)-*cis*-2,3-dialkyl oxiranes, which led to the formation of the corresponding internal *vic*-diols in high enantiomeric purities. In the case of haloalkyl-substituted derivatives, enzyme-triggered cascade reactions were observed (2, 3). The remarkable feature of these biotransformations is the fact that — depending on the relative stereochemistry of the substrate — they did not follow a kinetic-resolution pathway but proceeded in an enantioconvergent fashion by furnishing a single enantiomeric *vic*-diol as the sole product in 100% theoretical yield. In view of their considerably improved economic balance, such "deracemization" processes have recently gained considerable attention (4).

To extend the preparative utility of this method, we investigated more synthetically useful substrates bearing various functional groups to allow for further synthetic transformations. Our previous experience indicated that bacterial epoxide hydrolases generally do not accept substrates with polar functional groups (such as OH, N_3) (5). We therefore turned our attention to 2,3-disubstituted oxiranes, *rac*-*cis*-**1** and *rac*-*trans*-**1**, bearing olefinic side chains, which would serve as functional groups for further (oxidative) transformations (Scheme 1) (6). For this reason we investigated a short synthesis of (+)-*exo*-brevicomin. In addition, (–)-*endo*-brevicomin was also synthesized in moderate optical purity.

(+)-*Exo*- and (–)-*endo*-brevicomin ((+)-*exo*-**3** and (–)-*endo*-**3**, respectively) are components of the attracting pheromone system of several bark-beetle species belonging to the genera *Dendroctonus* and *Dryocoetes* (7). In several species, *endo*-**3** is a minor component accompanying (+)-*exo*-**3**. The (–)-*endo* isomer has been reported to be an anti-aggregation pheromone for the southern pine beetle *Dendroctonus frontalis*.

Scheme 1. Retrosynthetic analysis.

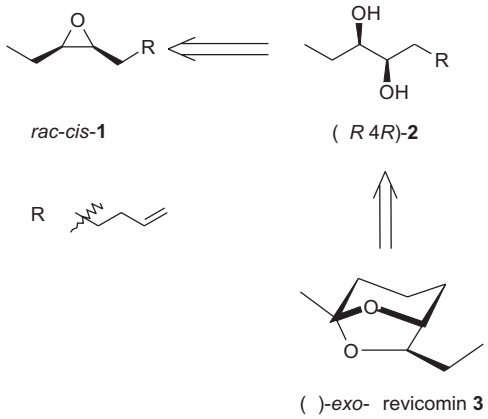

Fig. 1. Time-line of hydrolysis of *rac-cis*-**1** using *Mycobacterium paraffinicum* NCIMB 10420.

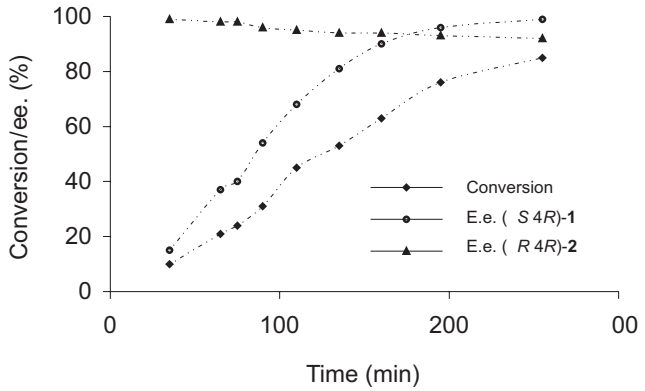

In contrast, (+)-*endo*-**3** increases aggregation (8). *Dentroctonus ponderosae* (Mountain Pine beetle) is known to produce (+)-*exo*-brevicomin with >98% ee, whereas the optical purities of the accompanying stereoisomer *endo*-**3** were reported in the range of 65–70% ee (9). Although a number of syntheses of brevicomin stereoisomers have been reported, few are satisfactory in terms of process simplicity (9). Herein, we wish to report a short chemoenzymatic synthesis of (+)-*exo*-brevicomin ((+)-*exo*-**3**) in 92% ee starting from diol (3*R*,*4R*)-**2**, obtained via biocatalytic hydrolysis of oxirane *rac-cis*-**1**. Because the latter process proceeded in an enantioconvergent fashion, the occurrence of an undesired stereoisomer was avoided, rendering this as a highly efficient synthetic sequence. In a related approach, (–)-*endo*-brevicomin ((–)-*endo*-**3**) was obtained in 72% ee starting from *rac-trans*-**1**.

Results and discussion

To provide insight into the factors governing the stereochemical course of the biohydrolysis that would facilitate the predictability of the reaction, 2,3-disubstituted alkene-functionalized oxiranes (*rac-cis*-**1** and *rac-trans*-**1**) were chosen as substrates. Oxiranes *rac-cis*-**1** and *rac-trans*-**1** were prepared from commercially available alcohols (*Z*)-**4** and (*E*)-**4** (Scheme 2). Conversion of the primary hydroxyl group of (*Z*)-**4** and (*E*)-**4** to the corresponding bromides was accomplished via the corresponding mesylates to furnish (*Z*)-**5** and (*E*)-**5**, respectively. The latter were transformed into the corresponding Grignard reagents and then were coupled to allyl bromide to give *cis*- and *trans*-configurated dienes, (*Z*)-**6** and (*E*)-**6**. Epoxidation of the electron-rich internal C=C bond using *m*-chloroperbenzoic acid proceeded regioselectively to furnish *rac-cis*-**1** and *rac-trans*-**1** in 37 and 44% yield, respectively, in three steps.

Substrates *rac-cis*-**1** and *rac-trans*-**1** were subjected to screening for biohydrolysis in Tris-buffer at pH 8.0 using various resting cells from *Actinomyces* spp. known to possess, in particular, strong secondary metabolic activity and strong epoxide hydrolase activity (5). The absence of any undesired spontaneous hydrolysis was verified under standard conditions in the absence of a biocatalyst within the anticipated reaction time of ~21 h. The only product formed during biohydrolysis was the desired diol, *threo*-**2** or *erythro*-**2**. The stereoselectivities (denoted as conversion (c) and enantiomeric purities of substrate (ee_S) and product (ee_P)) (10) obtained from the biohydrolysis of *rac-cis*-**1** and *rac-trans*-**1** are listed in Table 1.

Oxirane *rac-cis*-**1** was hydrolyzed with moderate to good selectivities by several bacterial strains with the predominant formation of diol (3*R*,4*R*)-**2** in up to 92% ee, except for *Rhodococcus equi* IFO 3730, which produced antipode (3*S*,4*S*)-**2** in moderate optical purity (Table 1, entry 7). Several data sets of c, ee_S, and ee_P clearly indicated that the transformation did not follow a kinetic-resolution pathway as indicated by a high ee_P at high conversion. This is most striking for entries 1–4 (Table 1).

The results obtained from *rac-trans*-**1** show a different pattern. Although this substrate was rapidly converted by several species of *Rhodococci* (Table 1, entries 1, 2, 5, and 7), the selectivities were significantly reduced in comparison with those of the corresponding *cis*-analogue *rac-cis*-**1**. The best result was with diol (3*R*,4*S*)-**2**, which was obtained in a moderate 72% ee (Table 1, entry 4).

An evaluation of the data obtained reveals the following general picture. (*i*) As can be deduced from the absolute configuration of the substrate and product, the enzymatic epoxide hydrolysis results in the inversion of configuration at the attacked oxirane carbon atom, and (*ii*) the biotransformation of *trans*-oxirane is faster, but hydrolysis of the *cis*-analogue is more enantioselective.

Any enantioconvergence of the reaction — indicated as a "deviation" from the classic kinetic-resolution protocol — can easily be detected if the ee of the product is beyond the benchmark of 50% conversion. This is most striking for *rac-cis*-**1** (ee of *threo*-**2** 92% at c 83%). The molecular reason for this phenomenon is that the hydrolysis of both enantiomers proceeds with opposite regioselectivity, i.e., the enzyme shows a predominant preference to attack an (*S*)-configurated oxirane carbon atom (2). For the *cis*-oxirane, *rac-cis*-**1** that consists of (3*R*,4*S*)- and (3*S*,4*R*)-enantiomers, an enantioconvergent hydrolysis is facilitated because each enantiomer has one "matching" (*S*)-center. This is not the case for the *trans*-isomer, *rac-trans*-**1**, which consists of(3*S*,4*S*)- and (3*R*,4*R*)-enantiomers, each possessing two "matching" or two "mismatching" centers.

The time line of a typical enantioconvergent transformation by *Mycobacterium paraffinicum* NCIMB 10420 is shown in Fig. 1. At the onset of the reaction, the faster-reacting (3*R*,4*S*)-

enantiomer of *rac-cis*-**1** is preferentially hydrolyzed from the racemate, via attack at the stereochemically preferred C-3 position, to furnish diol (3*R*,4*R*)-**2** in high ee until a conversion of about 50% is reached. Beyond this point, the transformation of the slower-reacting (3*S*,4*R*)-enantiomer takes place with high but opposite regioselectivity (via attack at C-2), thus yielding the same enantiomeric diol (3*R*,4*R*)-**2**. The relative reaction rate of the enantiomers was calculated from the progress curves of c, ee_S, and ee_P vs. time, and was found to be $E = 6.7$ (11). As a consequence, the ee of *threo*-**2** remained high throughout the course of the biotransformation and (3*R*,4*R*)-**2** was formed as the sole product.

With the end goal being the asymmetric synthesis of (+)-*exo*- and (–)-*endo*-brevicomin, *Mycobacterium paraffinicum* NCIMB 10420 was chosen for the preparative-scale biohydrolysis of *rac-cis*-**1**. This reaction gave (3*R*,4*R*)-**2** as the sole product in 83% yield and 92% ee in an enantioconvergent fashion (Scheme 3). In contrast, the biotransformation of *rac-trans*-**1** underwent kinetic resolution. The hydrolysis of *rac-trans*-**1** using *Rhodococcus ruber* DSM 44539, however,

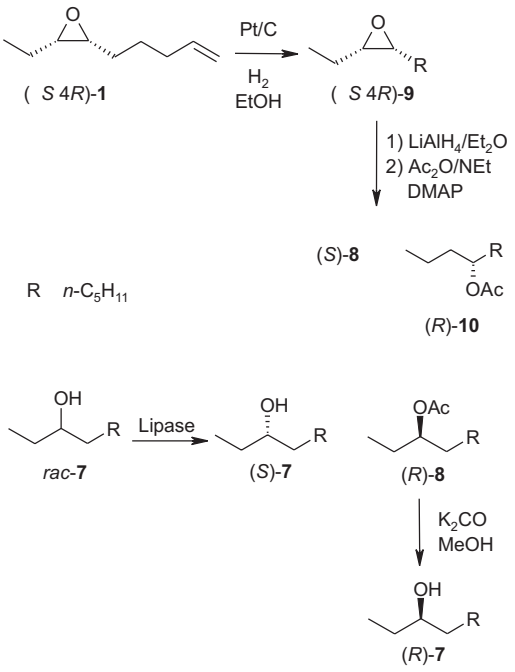
Scheme 4. Determination of absolute configuration of epoxide (3*S*,4*R*)-**1**.



yielded (3*R*,4*S*)-**2** in 58% yield and 72% ee (Scheme 3). Because the ee of the precursor to (–)-*endo*-brevicomin was within the suitable range of 65–70%, the material was used for further synthesis (9). Wacker oxidation of (3*R*,4*R*)-**2** or (3*R*,4*S*)-**2**, employing $PdCl_2$ as the catalyst and $CuCl_2$ as the reoxidant, gave (+)-*exo*- and (–)-*endo*-brevicomin in 92% ee (23% overall yield) and 72% ee (16% overall yield), respectively (Scheme 3).

The absolute configuration of diols (3*R*,4*R*)-**2** and (3*R*,4*S*)-**2**, and (+)-*exo*- and (–)-*endo*-brevicomin stereoisomers were confirmed by comparison of their optical rotation with known values (Table 2, vide infra). The absolute configuration of the remaining non-hydrolyzed epoxide (3*S*,4*R*)-**1** was elucidated via the following sequence (Scheme 4). Hydrogenation of the alkene-moiety of (3*S*,4*R*)-**1** (Pt/C and H_2) gave oxirane (3*S*,4*R*)-**9**. $LiAlH_4$ reduction of (3*S*,4*R*)-**9** afforded a mixture of the corresponding alcohols, alkan-3-ol and alkan-4-ol, which were converted into their acetates (*S*)-**8** and (*R*)-**10**, respectively (Ac_2O/NEt_3/DMAP cat.). The absolute configuration of (*S*)-**8** was determined via GLC analysis on a chiral stationary phase by co-injection with an independently synthesized sample of (*R*)-**8** (Scheme 4, vide infra).

Enantiopure acetate (*R*)-**8** was obtained by kinetic resolution of alcohol (±)-**7** using *Candida antarctica* lipase B. The absolute configuration of (*R*)-**8** was confirmed via deprotection of the acetate moiety (K_2CO_3/MeOH) to yield (*R*)-3-nonanol (*R*)-**7**. The absolute configuration (*R*)-**7** was confirmed by comparison of its known optical-rotation value (Table 2).

In conclusion, we have demonstrated that the biohydrolysis of *cis*-2,3-disubstituted oxiranes bearing olefinic side chains using bacterial epoxide hydrolases proceeded in a highly selective and enantioconvergent manner, which provided the corresponding *vic*-diols in high ee and in almost quantitative yield. Although the yields of the *trans*-analogues were sufficient, the selectivities were moderate. The optically enriched diols were transformed into pheromones in a straightforward manner.

Experimental

General

NMR spectra were recorded in $CDCl_3$ using a Bruker AMX 360 at 360 (^{1}H) and 90 (^{13}C) MHz and a Bruker DMX Avance 500 at 500 (^{1}H) and 125 (^{13}C) MHz. Chemical shifts are reported relative to TMS (δ 0.00) with $CHCl_3$ as internal

© 2002 NRC Canada

standard (δ 7.23 (^{1}H) and 76.90 (^{13}C)), coupling constants (*J*) are given in Hz.

TLC plates were run on silica gel Merck 60 (F_{254}) and compounds were visualized by spraying with Mo-reagent ($(NH_4)_6Mo_7O_{24}\cdot 4H_2O$ (100 g L^{-1}) and $Ce(SO_4)_2\cdot 4H_2O$ (4 g L^{-1}) in H_2SO_4 (10%)) (detection I) or by dipping into a $KMnO_4$ reagent (2.5 g L^{-1} $KMnO_4$ in H_2O) (detection II). Compounds were purified either by flash chromatography on silica gel Merck 60 (230–400 mesh) or, for volatile substances, by Kugelrohr distillation. Petroleum ether (p.e.) had a boiling range of 60–90°C. GC analyses were carried out on a Varian 3800 gas chromatograph equipped with FID and either an HP1301 or a HP1701 capillary column (both 30 m, 0.25 mm, 0.25 μm film, N_2). Enantiomeric purities were analyzed on a Varian 3800 gas chromatograph equipped with FID, using a CP-Chirasil-DEX CB column (column A, 25 m, 0.32 mm, 0.25 μm film) or an Astec Chiraldex G-PN (column B, 30 m, 0.25 mm). H_2 was used as a carrier gas. For programs and retention times vide infra.

High resolution mass spectra were recorded on a double focussing Kratos Profile Mass Spectrometer with electron impact ionization (EI, +70 eV). Optical rotation values were measured on a PerkinElmer polarimeter 341 at 589 nm (Na-line) in a 1-dm cuvette and are given in units of 10^{-1} deg cm^2 g^{-1}.

Solvents were dried and freshly distilled by common practice. For anhydrous reactions, flasks were dried at 150°C and flushed with dry argon just before use. Organic extracts were dried over Na_2SO_4, and then the solvent was evaporated under reduced pressure. *m*-Chloroperbenzoic acid (*m*-CPBA, Fluka, 70%) was used. Olefinic alcohols (*Z*)-**4** and (*E*)-**4** were purchased from Lancaster. For biotransformations, lyophilized bacterial cells were used. The bacteria were obtained from culture collections. SM strain numbers refer to the culture collection of the Institute of Biotechnology, Graz University of Technology. All strains were grown as previously described (12–15).

Syntheses of substrates and reference materials

General procedure for the synthesis of (Z)-5 and (E)-5

Compounds (*Z*)-**5** and (*E*)-**5** were obtained via mesylation of alcohols (*Z*)-**4** and (*E*)-**4**, followed by halide exchange using Method A.

Method A: Alcohol (50 mmol) was dissolved in CH_2Cl_2 (50 mL) and pyridine (100 mmol) was added. The stirred solution was cooled to 0°C and methanesulfonyl chloride (75 mmol) was added in small portions. The reaction mixture was allowed to warm to room temperature. After the reaction reached completion (16 h), water (70 mL) was added and the resulting two-phase system was stirred for 1 h to destroy excess methanesulfonyl chloride. Then the two layers were separated and the aqueous layer was extracted with CH_2Cl_2. The combined organic layers were washed with 5% aq HCl (50 mL) and sat. aq $NaHCO_3$ (50 mL). The organic phase was dried and concentrated. The crude mesylate (50 mmol) was dissolved in anhydrous acetone (50 mL) and LiBr (75 mmol) was added. The reaction mixture was allowed to stir at room temperature until completion (ca. 20 h). Then, 5% aq HCl (70 mL) was added, the two layers were separated and the aqueous phase was extracted with CH_2Cl_2. The combined organic layers were washed with sat. aq $NaHCO_3$ (70 mL) and the organic phase was dried and concentrated. Flash chromatography afforded the pure haloalkenes (*Z*)-**5** and (*E*)-**5**, details and spectroscopic data being given below.

*cis-1-Bromo-hex-3-ene ((Z)-**5**)*

Method A was employed using alcohol (*Z*)-**4** (10 g, 99.84 mmol) and LiBr for the halogenation. Flash chromatography (pentane–Et_2O, 10:1) gave *cis*-1-bromo-hex-3-ene (*Z*)-**5** as a colorless liquid (9.82 g, 61% over 2 steps). R_f (p.e.–EtOAc, 5:1) = 0.83 (detection II). ^{1}H NMR (500.13 MHz, $CDCl_3$) δ: 0.98 (t, *J* = 7.5, 3H), 2.04–2.10 (m, 2H), 2.60–2.65 (m, 2H), 3.38 (t, *J* = 7.2, 2H), 5.33–5.35 (m, 1H), 5.53–5.56 (m, 1H). ^{13}C NMR (125.77 MHz, $CDCl_3$) δ: 14.1, 20.6, 30.6, 32.5, 125.1, 134.7.

*trans-1-Bromo-hex-3-ene ((E)-**5**)*

Method A was employed using alcohol (*E*)-**4** (10 g, 99.84 mmol) and LiBr for the halogenation. Flash chromatography (pentane–Et_2O, 10:1) gave *trans*-1-bromo-hex-3-ene (*E*)-**5** as a colorless liquid (10.5 g, 65% over 2 steps). R_f (p.e.–EtOAc, 5:1) = 0.80 (detection II). ^{1}H NMR (500.13 MHz, $CDCl_3$) δ: 0.99 (t, *J* = 7.5, 3H), 2.01–2.06 (m, 2H), 2.53–2.57 (m, 2H), 3.37 (t, *J* = 7.2, 2H), 5.35–5.41 (m, 1H), 5.57–5.61 (m, 1H). ^{13}C NMR (125.77 MHz, $CDCl_3$) δ: 13.6, 25.5, 32.8, 36.0, 125.3, 135.4.

General procedure for the synthesis of (Z)-6 and (E)-6 (Method B)

Method B: To a stirred solution of allyl bromide (9.1 g, 75.5 mmol) in anhydrous Et_2O (20 mL) under an Ar atmosphere, a Grignard reagent, prepared from (*Z*)-**5** or (*E*)-**5** (50 mmol) in 15 mL of anhydrous Et_2O, was added at room temperature. The mixture was heated at reflux until the reaction was completed (16 h). Then 5% aq HCl (20 mL) was added and after 10 min the product was extracted with Et_2O. The combined organic extracts were dried and concentrated. The residue was purified by flash chromatography to give (*Z*)-**6** or (*E*)-**6**, details and spectroscopic data are given below.

*(Z)-Nona-1,6-diene ((Z)-**6**)*

Method B was employed using (*Z*)-**5** (8.2 g, 50.3 mmol). Flash chromatography (pentane) gave (*Z*)-**6** as a colorless liquid (5.4 g, 87%). R_f (p.e.) = 0.85 (detection II). ^{1}H NMR (360.13 MHz, $CDCl_3$) δ: 0.98 (t, *J* = 7.2, 3H), 1.37–1.51 (m, 2H), 1.99–2.11 (m, 6H), 4.95–5.05 (m, 2H), 5.33–5.43 (m, 2H), 5.79–5.87 (m, 1H). ^{13}C (90.6 MHz, $CDCl_3$) δ: 14.4, 20.6, 26.6, 29.1, 33.3, 114.5, 128.9, 132.0, 139.0.

*(E)-Nona-1,6-diene ((E)-**6**)*

Method B was employed using (*E*)-**5** (8.5 g, 52.1 mmol). Flash chromatography (pentane) gave (*E*)-**6** as a colorless liquid (5.9 g, 91%). R_f (p.e.) = 0.85 (detection II). ^{1}H NMR (360.13 MHz, $CDCl_3$) δ: 0.98 (t, *J* = 7.3, 3H), 1.41–1.50 (m, 2H), 1.98–2.09 (m, 6H), 4.94–5.04 (m, 2H), 5.40–5.47 (m, 2H), 5.78–5.83 (m, 1H). ^{13}C (90.56 MHz, $CDCl_3$) δ: 14.0, 25.7, 28.9, 32.0, 33.3, 114.4, 128.9, 132.4, 139.0.

General procedure for the synthesis of rac-cis-1 and rac-trans-1

Substrates *rac-cis*-**1** and *rac-trans*-**1** were prepared by epoxidation of alkenes (*Z*)-**6** and (*E*)-**6** using *m*-chloroperbenzoic acid (*m*-CPBA) following Method C.

© 2002 NRC Canada

Method C: To a vigorously stirred solution of the alkene (40 mmol) in anhydrous CH_2Cl_2 (400 mL) was added NaH_2PO_4 (ca. 2.6 equiv). After the mixture was stirred for 15 min at room temperature, it was cooled to 0°C and *m*-CPBA (1.05 equiv) was added slowly. The reaction was allowed to warm to room temperature and stirred for an additional 8 h. The white suspension was filtered and the resulting solution was treated with 10% aq $Na_2S_2O_5$ (100 mL) to destroy the excess of peracid. The resulting two-phase system was stirred for 30 min, the layers were separated and the organic phase was washed with sat. aq $NaHCO_3$ (50 mL). The organic phase was dried and evaporated. Kugelrohr distillation afforded pure oxiranes *rac-cis*-**1** and *rac-trans*-**1**. Details and spectroscopic data are given below.

*cis-3,4-Epoxynon-8-ene (rac-cis-**1**)*

Method C was employed using (*Z*)-**6** (5 g, 40.3 mmol). Kugelrohr distillation gave *rac-cis*-**1** as a colorless liquid (3.9 g, 69%). R_f (p.e.–EtOAc, 5:1) = 0.55 (detection I). bp_{20mbar} (Kugelrohr): 80–90°C. ^{1}H NMR (360.13 MHz, $CDCl_3$) δ: 1.01 (t, *J* = 7.0, 3H), 1.49–1.58 (m, 6H), 2.08–2.12 (m, 2H), 2.84–2.92 (m, 2H), 4.94–5.04 (m, 2H), 5.75–5.83 (m, 1H). ^{13}C NMR (90.56 MHz, $CDCl_3$) δ: 10.6, 21.2, 25.9, 27.2, 33.6, 57.1, 58.4, 114.9, 138.4. Anal. calcd. for $C_9H_{16}O$: C 77.05, 11.50; found: C 77.12, H 11.51.

*trans-3,4-Epoxynon-8-ene (rac-trans-**1**)*

Method C was employed using (*E*)-**6** (6 g, 48.4 mmol). Kugelrohr distillation gave *rac-trans*-**1** as a colorless liquid (5.1 g, 75%). R_f (p.e.–EtOAc, 5:1) = 0.65 (detection I). bp_{20mbar} (Kugelrohr): 85–95°C. ^{1}H NMR (360.13 MHz, $CDCl_3$) δ: 0.98 (t, *J* = 7.0, 3H), 1.48–1.58 (m, 6H), 2.09 (d, *J* = 5.9, 2H), 2.62–2.67 (m, 2H), 4.94–5.03 (m, 2H), 5.76–5.84 (m, 1H). ^{13}C NMR (90.56 MHz, $CDCl_3$) δ: 9.94, 25.2, 25.4, 31.5, 33.5, 58.4, 60.0, 114.8, 138.4. Anal. calcd. for $C_9H_{16}O$: C 77.05, 11.50; found: C 77.08, H 11.55.

General procedure for the synthesis of reference material for racemic diols rac-threo-2 and rac-erythro-2

The *rac*-diols *rac-threo*-**2** and *rac-erythro*-**2** were obtained by acid-catalysed hydrolysis of *rac-cis*-**1** and *rac-trans*-**1** following Method D.

Method D: Racemic diols *rac-threo*-**2** and *rac-erythro*-**2** were obtained by hydrolysis of the corresponding racemic oxiranes of *rac-cis*-**1** and *rac-trans*-**1** (1.1 mmol) in a mixture of water and THF (10 mL, 4:1) under acidic conditions (6 M H_2SO_4, 10 drops). After the reaction reached completion (2 h), the solution was extracted with EtOAc (2 × 10 mL). The combined organic layers were dried and concentrated. The residue was purified by flash chromatography. Details and spectroscopic data are given below.

*rac-threo-8-Nonene-3,4-diol (rac-threo-**2**)*

Method D was employed using oxirane *rac-cis*-**1** (0.3 g, 2.1 mmol). Flash chromatography (p.e.–EtOAc, 3:1) gave pure *rac-threo*-8-nonene-3,4-diol *rac-threo*-**2** (0.25 g, 74%). R_f (p.e.–EtOAc, 1:1) = 0.42 (detection I). Spectroscopic data were in full agreement with those previously reported (16). HRMS calcd. for $C_9H_{18}O_2$: 158.1307 [M^+]; found: 158.1314 [M^+].

*rac-erythro-8-Nonene-3,4-diol (rac-erythro-**2**)*

Method D was employed using oxirane *rac-trans*-**1** (0.3 g, 2.1 mmol). Flash chromatography (p.e.–EtOAc, 3:1) gave pure *erythro*-8-nonene-3,4-diol *rac-erythro*-**2** (0.21 g, 63%). R_f (p.e.–EtOAc, 1:1) = 0.45 (detection I). Spectroscopic data were in full agreement with those previously reported (16). HRMS calcd. for $C_9H_{18}O_2$: 158.1307 [M^+]; found: 158.1303 [M^+].

General procedure for preparative-scale biohydrolysis of rac-cis-1 and rac-trans-1

Racemic epoxides *rac-cis*-**1** (0.7 g, 5 mmol) and *rac-trans*-**1** (0.3 g, 2.14 mmol) were hydrolyzed using rehydrated lyophilized microbial cells (1 g *Mycobacterium paraffinicum* NCIMB 10420 for *rac-cis*-**1**, 0.4 g of *Rhodococcus ruber* DSM 44539 for *rac-trans*-**1**) in Tris-buffer (30 mL for *rac-cis*-**1**, 15 mL for *rac-trans*-**1**, 0.05 M, pH 8.0) on an orbit shaker (120 rpm) at 30°C. When the starting material was consumed (after 6 h for *rac-cis*-**1**, 4 h for *rac-trans*-**1**, as judged by TLC and GLC), the mixture was extracted continuously with CH_2Cl_2 for 24 h. The organic layers were dried and evaporated. The residue was flash chromatographed (p.e.–EtOAc, 3:1) to give (3*R*,4*R*)-**2** (0.66 g, 83%, ee 92%) or (3*R*,4*S*)-**2** (0.20 g, 58%, ee 72%). Spectroscopic data of these products matched those of material obtained by acidic hydrolysis of the corresponding *rac*-oxiranes. Elemental analysis of (3*R*,4*R*)-**2**: Anal. calcd. for $C_9H_{18}O_2$: C 68.30, H 11.45; found: C 68.35, H 11.46. Elemental analysis of (3*R*,4*S*)-**2**: Anal. calcd. for $C_9H_{18}O_2$: C 68.30, H 11.45; found: C 68.38, H 11.48.

General procedure for the synthesis of (+)-exo- and (–)-endo-brevicomin [(+)-exo- and (–)-endo-3, respectively] via Wacker-oxidation of diols (3R,4R)-2 and (3R,4S)-2, respectively, following Method E

Method E: Nonracemic diol (3*R*,4*R*)-**2** or (3*R*,4*S*)-**2** (3.2 mmol) was dissolved in anhydrous 1,2-dimethoxyethane (10 mL). The solution was stirred at room temperature. $PdCl_2$ (0.10 g, 0.57 mmol) and $CuCl_2$ (0.43 g, 3.2 mmol) were added and stirring was continued for 10 h. The brown solution was diluted with H_2O and Et_2O (10 mL each). After phase separation, the aqueous layer was extracted with Et_2O (2 × 10 mL). The combined organic phases were dried (Na_2SO_4) and concentrated. The residue was purified by flash chromatography. Details and spectroscopic data are given below.

*(+)-exo-Brevicomin ((+)-exo-**3**)*

Method E was employed using (3*R*,4*R*)-**2** (0.5 g, 3.2 mmol). Flash chromatography (pentane–Et_2O, 10:1) gave pure (+)-*exo*-**3** (0.37 g, 75%, ee 92%). R_f (p.e.–EtOAc, 5:1) = 0.54 (detection I). ^{1}H NMR (360.13 MHz, $CDCl_3$) δ: 0.92 (t, *J* = 7.4, 3H), 1.43 (s, 3H), 1.57–1.84 (m, 8H), 3.94 (t, *J* = 6.4, 1H), 4.15 (s, 1H,). ^{13}C NMR (90.56 MHz, $CDCl_3$) δ: 9.8, 17.2, 25.1, 28.0, 28.6, 35.0, 78.4, 81.2, 107.7. HRMS calcd. for $C_9H_{16}O_2$: 156.1150 [M^+]; found: 156.1145 [M^+].

*(–)-endo-Brevicomin ((–)-endo-**3**)*

Method E was employed using (3*R*,4*S*)-**2** (0.15 g, 0.95 mmol). Flash chromatography (pentane–Et_2O, 10:1) gave pure (–)-*endo*-**3** (0.09 g, 61%, ee 72%). R_f (p.e.–EtOAc, 5:1) = 0.57 (detection I). ^{1}H NMR (360.13 MHz, $CDCl_3$) δ: 0.96 (t,

© 2002 NRC Canada

J = 7.4, 3H), 1.40 (s, 3H), 1.53–1.92 (m, 8H), 3.93–3.97 (m, 1H), 4.14–4.18 (m, 1H). ^{13}C NMR (90.56 MHz, $CDCl_3$) δ: 11.0, 17.6, 22.0, 23.7, 25.1, 34.5, 76.6, 81.7, 107.0. HRMS calcd. for $C_9H_{16}O_2$: 156.1150 [M^+]; found: 156.1159 [M^+].

General procedure for the screening of biocatalysts for the hydrolysis of rac-cis-1 and rac-trans-1

Racemic epoxides *rac-cis*-**1** and *rac-trans*-**1** (5 μL) were hydrolyzed using rehydrated lyophilized cells (50 mg) in Tris-buffer (1 mL, 0.05 M, pH 8.0) by shaking the mixture at 30°C with 120 rpm. The reactions were monitored by TLC. After 21 h and 42 h, a 0.4 mL aliquot was extracted with EtOAc (2 × 0.4 mL). To facilitate phase separation, the cells were removed by centrifugation. The combined organic layers were dried and analyzed by GC on a chiral stationary phase.

Determination of enantiomeric purities (Table 3)

All chiral materials could be analyzed directly by GC on a chiral stationary phase (see Table 3) except 3-nonanol **7** and *rac-trans*-**1**. In the case of alcohol **7**, derivatization to the acetate **8** was optimal, which gave satisfactory enantioseparation. For epoxide *rac-trans*-**1** no enantioseparation using four different chiral columns (columns A or B; Astec Chiraldex B-TA capillary column (column C, 30 m, 0.25 mm); or Astec Chiraldex G-PH (column D, 30 m, 0.32 mm)) was possible.

Syntheses of chiral reference material and determination of absolute configuration

All chiral compounds were diastereomerically pure. The absolute configuration of oxirane *trans*-**1** was not investigated because no enantioseparation on GC (with 4 different chiral columns) was achieved.

Determination of absolute configuration of oxirane (3S,4R)-1

The remaining non hydrolyzed epoxide from the biotransformation of *rac-cis*-**1** using *Mycobacterium paraffinicum* NCIMB 10420 (Scheme 4) was separated from the formed product (3*R*,4*R*)-**2** by flash chromatography (pentane–Et_2O, 10:1). The alkene-functionality of oxirane (3*S*,4*R*)-**1** (0.027 g, 0.2 mmol, ee > 99%) was hydrogenated with Pt/C (0.02 g, Pt on activated carbon, (5% w/w)) in anhydrous EtOH (5 mL) under H_2 at atmospheric pressure (30 min). The catalyst was removed by filtration through a plug of Celite-545 and the solvent was evaporated. After flash chromatography (pentane–Et_2O, 10:1) *cis*-(3*S*,4*R*)-epoxynonane (3*S*,4*R*)-**9** (0.021 g, 74%, >99% ee) was isolated. R_f (p.e.–EtOAc, 5:1) = 0.65 (detection I). ^{1}H NMR (360.13 MHz, $CDCl_3$) δ: 0.91 (t, *J* = 7.4, 3H), 1.04 (t, *J* = 7.2, 3H), 1.33–1.70 (m, 10H), 2.86–2.93 (m, 2H). ^{13}C NMR data match those previously described (17). Without affecting the chiral centers in position 2 and 3 of the oxirane, (3*S*,4*R*)-**10** was converted into the acetates (*S*)-**8** and (*R*)-**10**, using $LiAlH_4$ (0.015 g, 0.4 mmol) in anhydrous Et_2O (5 mL) at room temperature. After the reaction was complete (1 h), the reaction was quenched by addition of sat. aq NH_4Cl (10 mL). The combined organic phases were dried and concentrated. The residue was dissolved in Ac_2O and NEt_3 (0.040 g, 0.4 mmol) and then DMAP (5 mg, cat.) was added. The mixture was heated at reflux for 4 h and quenched by addition of water and Et_2O. The organic phase was dried and evaporated. Without further purification, the resulting mixture of (*S*)-**8** and (*R*)-**10** used directly for determination of the absolute configuration via coinjection with an independently synthesized sample of (*R*)-**8** on GC using a chiral stationary phase. Analysis was focussed on acetate **8**, since enantiopure acetate **10** was not available.

(R)-3-Nonanol ((R)-7)

Since enantioseparation for alcohol (±)-**7** was impossible, the corresponding acetate (±)-**8** was used for analysis. A reference sample of (*R*)-**7** was synthesized as follows: Lipase from *Candida antarctica* B (150 mg) was dispersed in heptane (25 mL) and after addition of (±)-**7** (1.0 g, 6.94 mmol) and vinyl acetate (2.0 g, 23.2 mmol) the mixture was agitated (120 rpm) on an orbit shaker at room temperature, while the progress of the reaction was monitored by GC. After 48 h, the conversion had reached ~50% and after filtration of the biocatalyst, the solution was concentrated in vacuo. After flash chromatography (p.e.–EtOAc, 5:1) (*R*)-3-nonyl acetate (*R*)-**8** (0.41 g, 64%, >99% ee) was isolated. R_f (p.e.–EtOAc, 3:1) = 0.80 (detection I). ^{1}H NMR (360.13 MHz, $CDCl_3$) δ: 0.86–0.90 (m, 6H), 1.23–1.27 (m, 8H), 1.42–1.54 (m, 4H), 2.04 (s, 3H), 4.77–4.82 (m, 1H). ^{13}C NMR (90.56 MHz, $CDCl_3$) δ: 9.55, 14.1, 21.2, 22.6, 25.3, 27.0, 29.3, 31.8, 33.6, 75.6, 171.0. Next, (*R*)-**8** (0.20 g, 1.07 mmol) was dissolved in MeOH (10 mL) and K_2CO_3 (0.30 g, 2.15 mmol) was added. After 30 min the reaction reached completion. The reaction was quenched by addition of water (10 mL) and Et_2O (20 mL). The combined organic phases were dried and concentrated. After flash chromatography (p.e. –EtOAc, 5:1) (*R*)-3-nonanol ((*R*)-**7**) (0.11 g, 71%, >99% ee) was isolated. R_f (p.e.–EtOAc, 3:1) = 0.50 (detection I). Spectroscopic data were in full agreement with those previously reported (18). The absolute configuration of (*R*)-**7** was confirmed by comparison of its known optical rotation value (Table 2) (19). Thus, the absolute configuration of C-3 of **8** was proven to be *R*.

The absolute configuration of diols (3*R*,4*R*)-**2** and (3*R*,4*S*)-**2**, and (+)-*exo*- and (–)-*endo*-brevicomin was determined by comparison of optical rotation values (Table 2) (16, 20–22).

Acknowledgments

We wish to express our thanks to H. Sterk (University of Graz) for skilful assistance in NMR-spectroscopy and NOVO Co. (Denmark) for their generous donation of *Candida antarctica* lipase B. This research was performed within the Spezialforschungsbereich Biokatalyse (SFB-A4, project no. F-104) and was financed by the Fonds zur Förderung der wissenschaftlichen Forschung and the Austrian Ministry of Science.

Comparative study of the thermodynamic behaviour of the binary mixtures dimethyl carbonate + (benzene, *n*-heptane, cyclohexane, or toluene)

José M. Pardo, Diego González-Salgado, Clara A. Tovar, Claudio A. Cerdeiriña, Enrique Carballo, and Luís Romaní

Abstract: Isobaric molar heat capacities at 288.15, 298.15, and 308.15 K and densities and speeds of sound at 288.15, 293.15, 298.15, and 308.15 K were determined for the dimethyl carbonate + benzene system over the whole composition range and at atmospheric pressure. In addition, speeds of sound at the same temperatures for the dimethyl carbonate + *n*-heptane system are reported. These experimental data were used to obtain molar volumes, isobaric thermal expansivities, isentropic and isothermal compressibilities, and isochoric molar heat capacities. Excess quantities of the above-mentioned properties were calculated using the Benson and Kiyohara criterion. The thermodynamic behaviour of the dimethyl carbonate + (*n*-heptane, cyclohexane, benzene, or toluene) systems is comparatively analyzed.

Key words: binary mixtures, excess properties, dimethyl carbonate, benzene, hydrocarbon.

Résumé : Opérant à pression atmosphérique, on a déterminé les capacités calorifiques molaires isobares à 288,15, 298,15 et 308,15 K ainsi que les densités et les vitesses du son à 288,15, 295,15, 298,15 et 308,15 K du système carbonate de diméthyle + benzène sur l'ensemble des compositions. On rapporte aussi les vitesses du son à la même température pour le système carbonate de diméthyle + heptane. On a utilisé ces données expérimentales pour en tirer les volumes molaires, les expansivités thermales isobares, les compressibilités isoentropiques et isothermales ainsi que les capacités calorifiques molaires isochoriques. On a calculé les propriétés en excès des quantités mentionnées en faisant appel au critère de Benson et Kiyohara. Le comportement thermodynamique des systèmes carbonate de méthyle + (heptane, cyclohexane, benzène ou toluène) a été analysé de façon comparative.

Mots clés : mélanges binaires, propriétés en excès, carbonate de diméthyle, benzène, hydrocarbure.

Introduction

Oils based on organic carbonates are suitable substances to be used as lubricants for stationary air conditioners that operate with HFCs refrigerants (1, 2). For this reason, the knowledge of the thermodynamic properties of mixtures containing dialkyl carbonates has been of great importance in recent years. Previous work related to the description of the thermodynamic behaviour of the dialkyl carbonates + (*n*-alkane, cyclohexane, benzene, or toluene) mixtures mainly dealt with the composition dependence of excess molar volumes (V_m^E) (3–7), excess molar enthalpies (H_m^E) (8, 9), and excess molar Gibbs free energies (G_m^E) (5, 10, 11), usually at 298.15 K. The temperature and pressure dependence of these properties has not been extensively analyzed; only the volumetric properties for the dialkyl carbonate + toluene (12) systems (278.15–328.15 K) and for the dimethyl carbonate + *n*–octane (13) system (in a broad range of temperatures and pressures) are available. In this context, the determination of first- and second-order excess derivatives at several temperatures of mixtures containing dimethyl or diethyl carbonate with hydrocarbons has been the subject of our research (14, 15). We have reported the V_m^E and $C_{p,m}^E$ (excess isobaric molar heat capacities) values at several temperatures and the partial derivatives of the excess molar volume with respect to temperature ($[\partial V_m^E/\partial T]_p$) at 298.15 K for dimethyl and diethyl carbonates mixtures with a linear hydrocarbon (*n*-heptane) (14). Dialkyl carbonate + cyclic hydrocarbon (cyclohexane) mixtures were also studied, and values for V_m^E and $C_{p,m}^E$ at different temperatures as well as the excess isentropic (κ_S^E) and isothermal (κ_T^E) compressibilities, excess isobaric thermal expansivities (α_p^E), and excess isochoric molar heat capacities ($C_{v,m}^E$) at 298.15 K were obtained (15).

In this paper, a comparative study of the excess thermodynamic properties (V_m^E and $C_{p,m}^E$ at several temperatures, and κ_S^E, κ_T^E, α_p^E, and $C_{v,m}^E$ at 298.15 K) for the dimethyl carbonate + (benzene, *n*-heptane, cyclohexane, or toluene) systems was carried out. To this end, the densities (ρ), speeds of sound (u) at 288.15, 293.15, 298.15, and 308.15 K, and iso-

baric molar heat capacities ($C_{p,m}$) at 288.15, 298.15, and 308.15 K dimethyl carbonate + benzene system, were also determined. Experimental data were obtained over the entire composition range and at atmospheric pressure. Results were used to calculate molar volumes, isothermal, and isentropic compressibilities, isobaric thermal expansivities, and isochoric molar heat capacities. The excess properties of these magnitudes were obtained using the criteria of Benson and Kiyohara (16). To complete the thermodynamic description for the dimethyl carbonate + *n*-heptane system, we also include values for *u* at 288.15, 293.15, 298.15, and 308.15 K. The results are discussed in terms of the different interactions between a polar solvent (dimethyl carbonate) and the hydrocarbons.

Experimental

Materials

All the chemicals were supplied from Aldrich (>99% mol). Their purity was checked by gas chromatography analysis, and all were degassed and dried by passage through molecular sieves (4 Å, Fluka) prior to use.

Apparatus and procedures

The density (ρ) and the speed of sound (*u*) were obtained using a combined densimeter–sound analyzer Anton-Paar DSA-48 equipped with temperature regulation to within 0.005 K via the Peltier effect. This instrument is equipped with a cell to measure the density and another cell, serially connected to the previous one, to measure the speed of sound. Calibration was done by using pure water (Milli-Q) and *n*-heptane as density standards, and the former as the speed of sound standard. The densities of pure water at several temperatures were obtained from Riddick et al. (17) and those of *n*-heptane were reported in previous work (18); the latter were obtained using certified density standards supplied by Deutscher Kalibrierdienst-Physikalisch Technische Bundesanstalt. The speeds of sound of pure water were obtained from the work of Bilaniuk and Wong (19, 20). The instrument is precise to within ±3 × 10^{-5} g cm^{-3} for density and ±0.05 m s^{-1} for speed of sound.

Isobaric heat capacities per unit volume (C_pV^{-1}) were measured with a Setaram micro DSC II differential scanning calorimeter, using the stepwise method. Isobaric molar heat capacities ($C_{p,m}$) values are obtained from C_pV^{-1} and ρ data using the relation $C_{p,m} = (C_pV^{-1})(M\rho^{-1})$, where *M* is the molar mass. Vacuum and *n*-heptane were used as heat capacity standards; the $C_{p,m}$ values of the latter were taken from literature (21). More experimental details are available elsewhere (22). The precision in $C_{p,m}$ was estimated to be ±0.03 J mol^{-1} K^{-1}. Mixtures were prepared by weighing, using a Mettler AE-240 balance, with a precision of ±1 × 10^{-5} g.

Results and discussion

Results for the density (ρ, g cm^{-3}), speed of sound (*u*, m s^{-1}), and isobaric molar heat capacity ($C_{p,m}$, J mol^{-1} K^{-1}) are given in Tables 1–3. These data were fitted as a function of composition and temperature to the following expressions:

$$[1] \quad Y = \sum_{i=1}^{n} A_i x^{i-1}$$

$$[2] \quad A_i = \sum_{j=1}^{3} A_{ij} 10^{1-j} (T - T_0)^{j-1}$$

where *x* is the mol fraction of dimethyl carbonate, *T* is the absolute temperature (T_0 = 288.15 K), and *Y* can be ρ, *u*, or $C_{p,m}$. The fitting coefficients (A_{ij}) were obtained using the optimization method of Marquardt (23) and they are given in

Table 4, together with their respective standard deviations (s). The procedure to determine the number of parameters for each property has been described elsewhere (24).

The isentropic compressibility (κ_s) was calculated from ρ and u using the Laplace equation.

$$[3] \quad \kappa_s = 1/(\rho u^2)$$

The isobaric thermal expansivity (α_p) was obtained by analytical differentiation of the density-fitting equation. The procedure used to calculate α_p was previously validated (22) and allows the obtainment of data at an intermediate temperature of the working range (298.15 K in our case). The isothermal compressibility (κ_T) and the isochoric molar heat capacity ($C_{v,m}$) were obtained from the following equations:

$$[4] \quad \kappa_T = \kappa_S + \frac{T V_m \alpha_p^2}{C_{p,m}}$$

$$[5] \quad C_{v,m} = C_{p,m} \frac{\kappa_S}{\kappa_T}$$

Table 5 shows thermodynamic property data for the pure products compared with literature values. The density (ρ), speed of sound (u), isentropic compressibility (κ_S), and isobaric thermal expansivity (α_p) data of this work for dimethyl carbonate are similar to those found in literature. The scarcity of published data for heat capacities of organic carbonates does not permit a more comprehensive comparison, but it does, however, encourage new investigations to determine these thermodynamic properties at several temperatures. Good agreement between this work and literature values was also obtained for the ρ, u, and κ_S of benzene; a slight deviation was found for the α_p and κ_T. The value of u obtained for *n*-heptane is also close to the literature value and the deviation for the κ_T is less than 1%.

Excess properties were calculated by using the following expression:

$$[6] \quad Y^E = Y - Y^{id}$$

where Y^E is the excess quantity of the property Y, and Y^{id} its ideal value. Values for Y^{id} were calculated using the criterion of Benson and Kiyohara (16), and they are defined as follows:

$$[7] \quad V_m^{id} = xV_{m,1}^* + (1-x)V_{m,2}^*$$

$$[8] \quad C_{p,m}^{id} = xC_{p,m,1}^* + (1-x)C_{p,m,2}^*$$

$$[9] \quad \alpha_p^{id} = \phi\alpha_{p,1}^* + (1-\phi)\alpha_{p,2}^*$$

$$[10] \quad \kappa_T^{id} = \phi\kappa_{T,1}^* + (1-\phi)\kappa_{T,2}^*$$

$$[11] \quad \kappa_s^{id} = \kappa_T^{id} - \frac{TV_m^{id}(\alpha_p^{id})^2}{C_{p,m}^{id}}$$

$$[12] \quad C_{v,m}^{id} = C_{p,m}^{id} \frac{\kappa_s^{id}}{\kappa_T^{id}}$$

$$[13] \quad \phi = \frac{xV_{m,1}^*}{V_m^{id}}$$

where ϕ and x are the volume and mol fractions, respectively, of component 1 (dimethyl carbonate in this work) and superscript * denotes properties of the pure liquids.

The results using these criterion are shown in Figs. 1–4, where solid lines correspond to fitting polynomials of the Redlich–Kister-type equation.

$$[14] \quad Y = x(1-x)\sum_{i=1}^{n} A_i(2x-1)^{i-1}$$

The least-squares method was used to determine the polynomial coefficients (A_i), whose values for V_m^E, $C_{p,m}^E$, $C_{v,m}^E$, κ_S^E, κ_T^E, and α_p^E are given in Table 6, together with their respective standard deviations (s). The number of coefficients was determined in each case using an F-test.

The excess molar volumes (V_m^E) at 298.15 K of this work for the dimethyl carbonate + benzene system are in agreement with those of Rodriguez et al. (6) as can be seen in Fig. 1*a*. In addition, Fig. 1*a* shows the V_m^E values of this work at 288.15 K and 308.15 K. In all the cases, V_m^E values are positive and the fitted curves are parabolic and centred at equimolecular composition. Moreover, the V_m^E values slightly decrease with an increase of temperature. Figure 1*b* shows V_m^E at 298.15 K for the dimethyl carbonate + (benzene, *n*-heptane (14), cyclohexane (15), or toluene (12)) systems. In all cases, positive contributions (such as destruction of dipole–dipole interactions during the mixing process) overcome the negative contributions (e.g., free volume) resulting in positive V_m^E values. These values are higher for mixtures containing saturated hydrocarbons (*n*-heptane or cyclohexane), being especially important for the system containing cyclohexane, whose molecules behave as important order-destruction agents due to their globular forms (26–28). On the other hand, systems containing benzene or toluene, which have similar V_m^E values, display values that are significantly lower in relation to those of mixtures containing saturated hydrocarbons. Orye and Praustnitz (29) suggested the possibility of the formation of a charge-transfer complex between dimethyl carbonate and the unsaturated hydrocarbon (e.g., benzene or toluene). This interaction, which does not

exist in mixtures containing saturated hydrocarbons, appears to be the main factor responsible for these smaller V_m^E values. Evidence of complex formation can also be observed when the values of H_m^E (9) at equimolecular composition for these mixtures are compared. The net energetic balance is more positive for the mixtures containing *n*-heptane (1997 J mol^{-1}) or cyclohexane (1938 J mol^{-1}) than for the mixtures containing benzene (400 J mol^{-1}) or toluene (512 J mol^{-1}).

curves for the dimethyl carbonate + benzene system. As can be seen, $C_{p,m}^E$ values are negative, the fitted curves are parabolic, and $C_{p,m}^E$ values increase with an increase of temperature. Figure 2*b* compares the $C_{p,m}^E$ values at 298.15 K for the dimethyl carbonate + (benzene, *n*-heptane, or cyclohexane) systems. As can be seen, different composition dependence was found for the systems containing saturated hydrocarbons (W-shaped) with respect to that containing benzene. It is well-known that $C_{p,m}^E$ can be interpreted as a measure of the degree of non-randomness in the mixture. Saint-Victor and Patterson (30) showed in the framework of the Guggenheim quasi-chemical theory that non-randomness

contributes positively to $C^E_{p,m}$, whereas its absence (randomness) it results in negative $C^E_{p,m}$ values. W-shaped $C^E_{p,m}$ have been found for a variety of polar + *n*-alkane systems (31, 32) and they can be explained from the above-mentioned ideas. At the extremes of the composition range ($C^E_{p,m} < 0$), the order of the diluted component is fully destroyed because the mean separation among its molecules is longer than the typical distances, resulting in randomness. On the contrary, at intermediate compositions ($C^E_{p,m} > 0$), the shorter mean separation between like molecules allows for attractive interactions. In addition, the absence of specific interactions between unlike molecules makes interactions between like molecules (primarily dipole–dipole interactions in dimethyl carbonate) to be much more energetically favourable than those between unlike molecules, resulting in non-randomness in the mixture. This situation becomes more important as temperature is lowered and is, ultimately, responsible for phase separation. In the case of dimethyl carbonate + benzene ($C^E_{p,m} < 0$), the formation of charge-transfer complexes causes the situation to change with respect to that of mixtures with a saturated hydrocarbon. The interactions between unlike molecules are, therefore, not as energetically unfavourable, which results in a more random distribution of the molecules in the mixture.

The excess isobaric thermal expansivities (α^E_p) values for the dimethyl carbonate + (benzene, *n*-heptane, cyclohexane, or toluene) systems are shown in Fig. 3*a*. For the dimethyl carbonate + benzene system, the α^E_p values are small and negative, which is in agreement with the decrease of positive V^E_m values as the temperature increases. For the remaining systems, α^E_p values are positive, with lower values being found for the system containing toluene and higher values being found for the mixtures with cyclohexane or *n*-heptane. The small values found for mixtures containing aromatic hy-

© 2002 NRC Canada

drocarbons with respect to those containing saturated hydrocarbons can be explained by the presence of charge-transfer complexes in the former, which make the mixture more packed and, consequently, less expansible. Figure 3*b*, compares the excess isochoric molar heat capacities ($C^{E}_{v,m}$) for the dimethyl carbonate + (benzene, *n*-heptane, or cyclohexane) systems. Similar to $C^{E}_{p,m}$, $C^{E}_{v,m}$ exhibits a different behaviour for the systems containing benzene (values are close to zero).

The excess isentropic (κ^{E}_{S}) and isothermal (κ^{E}_{T}) compressibilities for the dimethyl carbonate + (benzene, *n*-heptane, or cyclohexane) mixtures are compared in Fig. 4. Similar to α^{E}_{p}, H^{E}_{m}, and V^{E}_{m}, the κ^{E}_{S} and κ^{E}_{T} values are much lower for the benzene system. Again, because the dimethyl carbonate + benzene system is a more closely packed mixture, it makes them less compressible. The maximum values of κ^{E}_{S} or κ^{E}_{T} for the system containing benzene are similar but slightly higher for κ^{E}_{S} (9.5 vs. 8.5 TPa^{-1}, respectively). For the other systems, the κ^{E}_{S} values are lower than the κ^{E}_{T} values and the maxima are drastically different (e.g., 62 vs. 96 TPa^{-1}, respectively, for dimethyl carbonate + cyclohexane mixture). As a rule, high V^{E}_{m} values imply high κ^{E}_{S} and κ^{E}_{T} values. It is reasonable that if the system is expanded during the mixing process it is easier to compress it (33, 34).

Table 7 shows a qualitative description of the thermodynamic behaviour of the above-discussed mixtures together with the cyclohexane + *n*-tetradecane system (35). As mentioned earlier, while the *n*-heptane and cyclohexane systems show the same thermodynamic behaviour, this behaviour is quite different from that of mixtures containing aromatic hydrocarbons. Interestingly, the dimethyl carbonate + benzene system exhibits the same pattern of behaviour as those of the cyclohexane + long chain *n*-alkane systems, even though the nature of the interactions are very different. In both cases, the V^{E}_{m} and H^{E}_{m} values are positive, the α^{E}_{p} values are negative, and the curves of the negative $C^{E}_{p,m}$ values vs. mol fraction are parabolic. Negative values and parabolic curves of $C^{E}_{p,m}$ values are related to a tendency towards randomness in the mixture. In the dimethyl carbonate + benzene system, the charge-transfer complexation between the carbonate molecule and the aromatic ring of benzene is ultimately responsible for this behaviour. For the cyclohexane + *n*-alkane mixtures, however, randomness is due mainly to the loss of orientational order in the pure *n*-alkane by virtue of the presence of cyclohexane molecules.

Conclusions

The charge-transfer complex formation between dimethyl carbonate molecules and the aromatic ring of benzene appears to be the main reason for the different thermodynamic behaviour of this system with respect to the dimethyl carbonate + saturated hydrocarbons systems. In this way, excess molar volumes (V^{E}_{p}) are lower for the former system resulting in a more packed mixture, which is thus more difficult to expand (lower α^{E}_{m}) and to compress (lower κ^{E}_{S} and κ^{E}_{T}). The excess molar enthalpies (H^{E}_{m}) are also lower due to the formation of these complexes in solution. Excess isobaric molar heat capacities ($C^{E}_{p,m}$) of mixtures containing benzene indicate a tendency towards randomness in the mixture; this behaviour contrasts with that of mixtures containing saturated hydrocarbons, which are random at the extremes of the composition range and non-random at intermediate compositions. In this sense, the thermodynamic behaviour of dimethyl carbonate + benzene system is very similar to that of cyclohexane + long chain *n*-alkane systems, which are also characterized by randomness in the mixture.

Multinuclear magnetic resonance studies of the aqueous products of the complexes *cis*- and *trans*-$Pt(Ypy)_2(NO_3)_2$ where Ypy = pyridine derivative

Fernande D. Rochon and Christian Tessier

Abstract: The hydrolyis or the aquation reactions of compounds of the types *cis*- and *trans*-$Pt(Ypy)_2(NO_3)_2$ (Ypy = pyridine derivative) were studied in D_2O and characterized by multinuclear (^{195}Pt, ^{13}C, and ^{1}H) NMR spectroscopy. In acidic pD, the product of the *cis* complexes is *cis*-$[Pt(Ypy)_2(D_2O)_2]^{2+}$, whereas in basic medium *cis*-$Pt(Ypy)_2(OD)_2$ is formed. The ^{195}Pt NMR resonances of the products containing ligands with an *ortho* substituent were observed at lower fields than the other complexes. The average coupling constant ($^3J(^{195}Pt–^1H)$ and $^3J(^{195}Pt–^{13}C)$) is 44 Hz for the diaqua species and 42 Hz for the dihydroxo compounds. At neutral pD, several hydrolyzed species were observed, except for the 2-picoline and 2,4-lutidine complexes, which contained only one compound, *cis*-$[Pt(Ypy)_2(D_2O)(OD)]^+$. The other hydrolyzed products for the ligands with no *ortho* substituent were identified as the dihydroxo-bridged dimer, the monohydroxo-bridged dimer, the trimer, and possibly the tetramer. The *trans* analogues have shown two signals in acidic pD corresponding to the diaqua monomer and the monohydroxo-bridged aqua dimer. Two species (the dihydroxo compound and the monohydroxo-bridged hydroxo dimer) were also observed in basic pD. In neutral medium, a third signal assigned to a longer chain hydroxo-bridged oligomer or polymer was detected.

Key words: platinum, pyridine derivative, nitrato, hydrolysis, NMR, aquation.

Résumé : Les réactions d'aquation et d'hydrolyse des complexes de types *cis*- et *trans*-$Pt(Ypy)_2(NO_3)_2$ (Ypy = dérivé de la pyridine) ont été étudiées dans D_2O et les produits ont été caractérisés par résonance magnétique multinucléaire (^{195}Pt, ^{13}C et ^{1}H). En milieu acide, le produit des complexes *cis* est *cis*-$[Pt(Ypy)_2(D_2O)_2]^{2+}$, tandis que *cis*-$Pt(Ypy)_2(OD)_2$ est formé en milieu basique. Les signaux en RMN du ^{195}Pt des complexes contenant des ligands substitués en position *ortho* ont été observés à plus bas champ que les autres. Les constantes de couplage moyennes $^3J(^{195}Pt–^1H)$ et $^3J(^{195}Pt–^{13}C)$ sont 44 Hz pour les espèces diaqua et 42 Hz pour les composés dihydroxo. À pD neutre, plusieurs espèces hydrolysées ont été observées, excepté pour les complexes contenant 2-picoline et 2,4-lutidine, qui ont montré une seule espèce, *cis*-$[Pt(Ypy)_2(D_2O)(OD)]^+$. Les autres produits hydrolysés pour les complexes contenant des ligands sans substituent *ortho* ont été identifiés comme le dimère à double ponts-hydroxo, le dimère à simple pont-hydroxo, le trimère et probablement le tétramère. Les composés analogues *trans* ont montré deux signaux à pD acide, correspondant au monomère diaqua et au dimère aqua à pont-hydroxo. Deux espèces (le composé dihydroxo et le dimère hydroxo à pont-hydroxo) ont aussi été observées en milieu basique. À pD neutre, un troisième signal attribué à un oligomère ou polymère à pont-hydroxo a été détecté.

Mots clés : platine, pyridine, nitrato, hydrolyse, RMN, aquation.

Introduction

The antitumor drug cisplatin (*cis*-$Pt(NH_3)_2Cl_2$) is one of the most widely used in chemotherapy. The complex remains unchanged in the plasma, because of the large chloride concentration (103 mM), but inside the cells, where the pH is neutral and the chloride ion concentration is much lower (4 mM), its mechanism of action involves aquation or hydrolysis reactions. In these conditions, *cis*-$Pt(NH_3)_2Cl_2$ produces different ionic species, especially the aqua-chloro complex *cis*-$[Pt(NH_3)_2(OH_2)Cl]Cl$. The latter can either bind to DNA (1), leading to the eventual destruction of the cell, or react with water to produce diaqua species. In neutral pH, it will exist mainly in the form of the monoaqua-monohydroxo complex *cis*-$[Pt(NH_3)_2(OH)(OH_2)]^+$ (2). This compound can also bind to DNA (1). It has also been shown in laboratories to produce different oligomeric species, which have been characterized by ^{195}Pt NMR (3–5) and by crystallographic methods (6–10).

Some of these compounds are toxic to humans and could be partially responsible for the toxicity of cisplatin. It is therefore important to study the hydrolysis reactions of a complex prior to its development as a drug.

Recently, our research group has undertaken a systematic study of complexes of the types *cis*- and *trans*-$Pt(Ypy)_2X_2$, where Ypy = pyridine derivative and X = Cl^-, I^-, and NO_3^-. Platinum complexes with pyridine derivatives are potent antitumor agents. The complex *trans*-$Pt(py)_2Cl_2$ (py = pyridine) is active towards Leukemia L1210 cells (11, 12), whereas *cis*-$Pt(NH_3)$(2-pic)Cl_2 (pic = picoline) is currently in clinical trials (13, 14). The compounds *cis*- and *trans*-$Pt(Ypy)_2X_2$, have been studied in our laboratories by various spectroscopic techniques and by crystallography (15, 16). We have characterized these well-known products to study their hydrolysis reactions. The solubility of the dichloro and the diiodo complexes in water is very low, but substitution of the halides by nitrato ligands leads to a greater aqueous solubility. We have now completed our spectroscopic aqueous solution study on the *cis*-dinitrato compounds and the results are reported below. We have also done a similar preliminary study on some *trans* compounds. These are more difficult to study, since the *trans*-dinitrato compounds are less soluble in water than their *cis* analogues. Only one study in the literature has been reported on a *trans* compound, i.e., *trans*-$Pt(NH_3)_2Cl_2$ (17).

Experimental

$K_2[PtCl_4]$ was purchased from Johnson–Matthey and was recrystallized in water before use. The pyridine derivatives were obtained from Aldrich, and silver nitrate was purchased from Analar. Deuterated chloroform was purchased from CDN Isotopes and methylene chloride-d_2 from MSD Isotopes.

The NMR spectra were measured on a Varian Gemini 300BB in D_2O. The fields were 300.075, 75.462, and 64.400 MHz for ^{1}H, ^{13}C, and ^{195}Pt, respectively. For the ^{195}Pt NMR spectra, $K_2[PtCl_4]$ (–1628 ppm in D_2O with KCl) was the external standard. The low-field ^{1}H NMR spectra were measured on a Varian EM-360L at 60 MHz. A V-2048 Signal Averager was used for the accumulations.

The pH values were measured on a Radiometer Copenhagen pH Meter, using a combined electrode Ag/AgCl (Fisher Scientific) at room temperature. For the pD values, the pH values were increased by 0.4 (18). The conductivity measurements were performed on a Radiometer Copenhagen model CDM2e instrument with a Radiometer No. CDC114 electrode.

The dinitrato complexes were prepared and characterized as reported in our recent publication (16).

The aquation or hydrolysis of the dinitrato complexes were studied in three different pH conditions. (*i*) The dinitrato compounds were dissolved in water or D_2O (pH ~2.0) and the ^{195}Pt, ^{1}H, and ^{13}C NMR spectra were directly measured. (*ii*) The pH of another fresh solution was adjusted to about 7 with NaOD and then the NMR spectra were immediately measured. (*iii*) The pH of a fresh solution of the dinitrato complex was adjusted to about 10.6 and then the NMR spectra were recorded. In a typical experiment, the dinitrato compound was dissolved in D_2O by heating in a hot-water bath. Immediately, the ^{195}Pt NMR spectrum was measured for about 1–3 h, the ^{1}H spectrum was then recorded for 30–60 min, and then the ^{13}C spectrum was measured overnight (~15 h). At neutral pH, where the number of species in solution is usually greater, the accumulation time was longer.

Results and discussion

The dinitrato complexes were prepared by the reaction of the diiodo complexes with a slight excess (10%) of silver nitrate in acetone (16).

$$[1] \quad Pt(Ypy)_2I_2 + 2AgNO_3 \rightarrow Pt(Ypy)_2(NO_3)_2 + 2\,AgI\downarrow$$

The reaction takes more than 24 h before observing a clear colorless solution of $Pt(Ypy)_2(NO_3)_2$ and a yellow silver iodide precipitate. Complexes with Ypy = py, 2-pic, 3-pic, 4-pic, 3,-5-lut, and 2,4-lut (lut = lutidine) were prepared and their aquation and hydrolysis reactions were studied at three different pH conditions: acidic, neutral, and basic.

cis-$[Pt(Ypy)_2(D_2O)_2]^{2+}$

When the *cis*-dinitrato compounds are dissolved in water or D_2O (~0.02 M), heating in a water bath is required for most samples, and the pH of the solution is acidic (pH = ~2.0 or pD = ~2.4).

$$[2] \quad cis\text{-}Pt(Ypy)_2(NO_3)_2 + 2D_2O \rightarrow cis\text{-}[Pt(Ypy)_2(D_2O)_2](NO_3)_2$$

The molar conductivity of the complexes were measured in water and varied between 233 and 264 S cm^2 mol^{-1}. These values correspond to the presence of three ions in solution and are close to those reported for *cis*-$[Pt(NH_3)_2(H_2O)_2](NO_3)_2$ (264 S cm^2 mol^{-1}) (19). These solutions (in D_2O) were characterized by multinuclear (^{195}Pt, ^{1}H, and ^{13}C) NMR spectroscopy.

The ^{195}Pt NMR spectra of these solutions show the presence of only one signal, corresponding to the diaqua species.

The chemical shifts of the complexes *cis*-$[Pt(2\text{-pic})_2(D_2O)_2]^{2+}$ and *cis*-$[Pt(2,4\text{-lut})_2(D_2O)_2]^{2+}$, which contain ligands with *ortho* substituents, are observed at lower fields (av. –1448 ppm) than the others (av. –1526 ppm), as shown in Table 1. Downfield chemical shifts of the complexes containing ligands with *ortho* substituents have already been observed for $[Pt(Ypy)Cl_3]^-$ (measured in D_2O) (20) and *cis*- and *trans*-$Pt(Ypy)_2(NO_3)_2$ (16). These downfield shifts have been assigned to the solvent effect, also called the *ortho* effect (21). For square-planar complexes, the solvent molecules can normally approach and weakly bind to the Pt atom on both sides of the coordination plane. For complexes containing pyridine with *ortho* substituents, the planar pyridine ligands are nearly perpendicular to the coordination plane (to reduce the steric hindrance with the *cis* ligands) and the *ortho* substituents are almost on top of the Pt atom. This conformation is particularly important in the *cis* geometry. The methyl groups located in the *ortho* positions thus prevent the approach of the solvent water molecules, resulting in a decrease of the electronic density around the Pt nucleus. Downfield ^{195}Pt NMR shifts were thus observed for $[Pt(2\text{-pic})Cl_3]^-$ (–1796 ppm) and $[Pt(2,6\text{-lut})Cl_3]^-$ (–1754 ppm) (measured in D_2O) compared with the $[Pt(Ypy)Cl_3]^-$ complexes with no *ortho* substituents (av. –1816 ppm) (20). Similar results were reported for *cis*- and *trans*-$Pt(2\text{-pic})_2(NO_3)_2$ complexes (16), which were measured in deuterated chloroform or dichloromethane, solvents which are not known to coordinate as easily to Pt as water. But the average environments around the Pt atom are different whether there is almost-free or limited rotation of the ligand around the Pt–N bond. These results are different from those observed for the complexes *cis*- and *trans*-$Pt(Ypy)_2I_2$, where Ypy = 2-pic and 2,4-lut (measured in $CDCl_3$) (15). The Pt signals of the latter complexes were reported at higher fields than the other analogues containing Ypy with no *ortho* substituent. Diaqua or dihydroxo complexes seem to behave like dinitrato complexes.

Several factors can be responsible for these different results. The solvent probably plays a very important role. Water, which can coordinate to platinum, may be responsible for the solvent effect discussed above. The charge on the complex might also be an important factor, but this is difficult to evaluate, since the ionic compounds are normally studied in D_2O, whereas the spectra of the neutral complexes are measured in organic solvents. Besides the presence of *ortho* substituents, the orientation of the pyridine ring is also influenced by the other ligands. Nitrato ligands are more bulky than monoatomic ligands, which might prevent the ap-

[a]n.o. = Not observed.

proach of the molecules of solvent to a much greater extent than the Cl^- or I^- ligands. The Pt–O bonds are shorter than Pt–I bonds, which would enhance the effect. Free rotation around the Pt–N bonds is much more limited in the complexes containing two 2-pic and 2,4-lut ligands than in the other compounds, especially in the *cis* geometry. The crystal structure determination of *cis*-$Pt(2\text{-pic})_2(NO_3)_2$ has shown that the two nitrato ligands are on opposite sides of the Pt plane and that the methyl groups of the 2-picoline ligands are in *anti* positions with respect to each other (16). This is the least sterically demanding conformation of the molecules. No rotamers were observed in solution. The NMR spectra of the 2-pic and 2,4-lut diaqua complexes (similar to the dinitrato complexes) could, therefore, correspond to one conformer, while almost-free rotations around the Pt–N and Pt–O bonds could be present in the other complexes.

To study the nature of the Pt–Ypy bond, attempts have been made in the literature (15, 16, 20, 21) to correlate the ^{195}Pt chemical shifts with the basicity of the pyridine ligands. Pyridine possesses empty π^* orbitals, which could accept electron density from the metal. In addition to the $\sigma(Ypy\rightarrow Pt)$ bond, $\pi(Pt\rightarrow Ypy)$ back-donating bonding could, therefore, be present. In the formation of the $\sigma(Ypy\rightarrow Pt)$ bond, electronic density is transferred from the pyridine ligands to the platinum nucleus, resulting in a shielding effect on the ^{195}Pt nucleus and a deshielding on the ligands (^1H and ^{13}C signals). The presence of $\pi(Pt\rightarrow Ypy)$ bonding would lead to the opposite effect. For complexes of the type $[Pt(Ypy)Cl_3]^-$, which were measured in D_2O, the correlation $\delta(^{195}Pt)$–pK_a was not observed because the solvent effect is a much greater factor, especially in water (20). For these ionic complexes, the $\delta(^{195}Pt)$ was related to the presence of substituents in *ortho* positions on the pyridine ligand. In the case of the compounds *cis*-$Pt(Ypy)(DMSO)Cl_2$, *cis*-$[Pt(Ypy)(DMSO)_2Cl]^+$, and *cis*-$[Pt(Ypy)_2(DMSO)Cl]^+$, a $\delta(^{195}Pt)$–pK_a correlation was reported, but only for complexes containing *para* substituents on Ypy (21). The latter DMSO complexes were measured in DMSO, a coordinating solvent. A weak relation between $\delta(^{195}Pt)$ and the basicity of the ligands was reported for complexes of the type $Pt(Ypy)_2X_2$ (X = Cl^- or I^- measured in $CDCl_3$) (15), but the dispersion around the straight line was fairly large. For the dinitrato complexes, the ^{195}Pt chemical shifts (in $CDCl_3$) seem to depend more on the position of the CH_3 substituents than on the basicity of the ligand (16). For the diaqua complexes, except for the 2-pic and 2,4-lut complexes, where the *ortho*-solvent effect is important, the ^{195}Pt chemical shifts seem to vary slightly with the basicity (22) of the protonated ligands

Other peak					–1080	–1056
Other peak						–1249

(Table 1), although the differences in chemical shifts are small and the errors fairly large (~5 ppm).

Our δ(Pt) values (–1440 to –1542 ppm) correlate well with the reported value for the *cis*-$Pt(NH_3)_2$ analogue (–1584 ppm (23)), and are at lower field than those reported for primary amine complexes (e.g., –1721 ppm for $EtNH_2$ (24)) and at much lower fields than those reported for ethylenediamine and its derivatives (–1867 to –1999 ppm) (25, 26). Complexes containing bidentate ligands are known to produce signals at much higher fields than those containing monodentate ligands.

The ^{1}H NMR chemical shifts of the diaqua complexes are listed in Table 2, as well as the $^3J(^{195}Pt–^1H)$ coupling constants and the Δδ values ($\delta_{complex} - \delta_{free\ ligand}$). The Δδ values are all positive, showing a net decrease of electron density on the ligands upon coordination. No relation could be found with the pK_a values of the protonated ligands, probably because the ligands are too different. $\Delta\delta_{av.}$ was also calculated using all the Δδ values except those of the methyl groups. This value is shown in square brackets in Table 2. If we exclude the 4-picoline complex, a linear relationship was found between $\Delta\delta_{av.}$ and the pK_a values (r^2 = 0.947), suggesting that the σ bond is very important in these complexes.

The $^3J(^{195}Pt–^1H)$ coupling constants vary between 40 and 47 Hz and agree well with the reported values for *cis*-$Pt(Ypy)_2Cl_2$ (40–44 Hz (15)), *cis*-$Pt(Ypy)_2I_2$ (40–43 Hz (15)), and *cis*-$Pt(Ypy)_2(NO_3)_2$ (40–47 Hz (16)). These are usually larger than those in the corresponding *trans* isomers (15, 16). For the 2-pic and 2,4-lut complexes, the $^4J(^{195}Pt–^1H)$ coupling constants with the *ortho* methyl group were measured as 13 and 11 Hz, respectively.

The ^{13}C NMR chemical shifts, the Δδ values ($\delta_{complex} - \delta_{free\ ligand}$), and the $^3J(^{195}Pt–^{13}C)$ coupling constants are listed in Table 3. The fact that Δδ is always positive indicates a net decrease of electron density on the bonded pyridine ligand compared with the free pyridine derivative. The σ(Ypy→Pt) bond seems to be much more important than the π(Pt→Ypy) back donation, if the latter is present. It is not possible to choose a valid probe in ^{13}C NMR to find a correlation between Δδ and the basicity of the protonated ligands, since local effects caused by the presence of the methyl substituents are too important. If we exclude the 4-pic complex, which seems to behave differently, the $\Delta\delta_{av.}$ for the ring C atoms (neglecting those which have a methyl substituent) is directly related to the pK_a of the protonated ligand (r^2 = 0.925). The calculated values of $\Delta\delta_{av.}$ are shown in Table 3. These results seem to confirm that the σ(Ypy→Pt) bond is very important in these complexes and that the π-backdonating component is more limited.

The $^3J(^{195}Pt–^{13}C)$ coupling constants vary between 42 and 46 Hz. These values compare well with the values reported for *cis*-$Pt(Ypy)_2Cl_2$ (41–45 Hz (15)), *cis*-$Pt(Ypy)_2I_2$ (40–45 Hz (15)), and *cis*-$Pt(Ypy)_2(NO_3)_2$ (41–48 Hz (16)). The $^2J(^{195}Pt–^{13}C)$ coupling constants were not observed, as reported for other similar compounds, probably because of inadequate orientation of the orbitals (16, 20).

cis-$Pt(Ypy)_2(OD)_2$

When the pH of the diaqua complex is raised with NaOD to about 10.6, the dihydroxo species are formed. The ^{195}Pt NMR spectra of these solutions show the presence of a single signal. The chemical shifts of the complexes *cis*-$Pt(2\text{-}pic)_2(OD)_2$ and *cis*-$Pt(2,4\text{-}lut)_2(OD)_2$, which contain ligands with *ortho* substituents, are observed at slightly lower fields (av. –1491 ppm) than the others (av. –1515 ppm), as shown in Table 1. The signals of the dihydroxo complexes are observed at slightly lower fields than the corresponding diaqua compounds (Δδ ($\delta_{dihydroxo}$-δ_{diaqua}) = 8 to 17 ppm), except for the ligands 2-pic and 2,4-lut. For these *ortho*-substituted ligands, the dihydroxo complexes were observed at higher fields than the diaqua compounds (Δδ = –38 and –47 ppm, respectively). In the literature, the reported values on similar complexes show that the dihydroxo complexes are observed at slightly lower fields than the corresponding diaqua species. For *cis*-$Pt(NH_3)_2(OD)_2$, the δ(Pt) is –1572 ppm (23) (Δδ = 12 ppm), whereas for *cis*-$Pt(C_2H_5NH_2)_2(OD)_2$, the δ(Pt) is –1695 ppm (24) (Δδ = 26 ppm). The results on the 2-pic and 2,4-lut complexes are clearly different from all the published values for dihydroxo and diaqua species. The explanation must come from the presence of the *ortho* substituent.

The shielding of a heavy atom like the ^{195}Pt nucleus has been expressed in the Ramsey equation, which contains some C terms representing the metallic coefficients of the platinum *d* orbitals. A more covalent bond will result in a decrease in the C terms and hence a shielding of the ^{195}Pt signals. D_2O is a more polarizable molecule than OD^-, leading to a more covalent Pt–OD_2 bond (in the diaqua system) compared with the Pt–OD bond in the dihydroxo complex. A greater covalency leads to a reduction of the C terms on the Pt atom and, therefore, an increase in the shielding in the Ramsey equation. The diaqua compounds should, therefore, be observed at higher fields than the dihydroxo complexes,

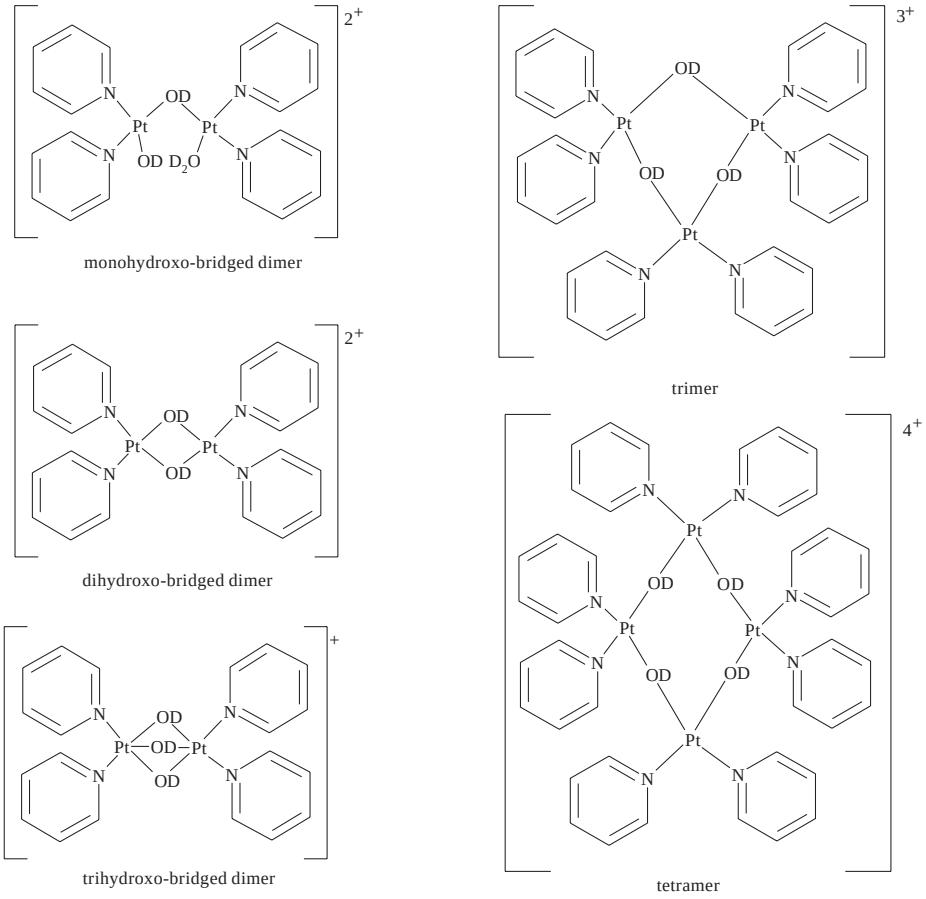
Fig. 1. Structures of the different *cis*-oligomeric species.



as observed in the literature and in our complexes, except for the ligands 2-pic and 2,4-lut. For the latter complexes, the *ortho* effect is probably a much greater factor. This behavior has not yet been reported in the literature. The solvent effect might also be quite different for an ionic complex like *cis*-$[Pt(Ypy)_2(D_2O)_2]^{2+}$ and for a neutral compound such as *cis*-$Pt(Ypy)_2(OD)_2$. The possibility that the *cis* compound containing 2-pic and 2,4-lut could isomerize to the *trans* complex in basic medium is not confirmed by the coupling constants observed in ^1H and ^{13}C NMR. These constants are usually smaller in the *trans* configuration (15, 16). Furthermore, the *trans* isomers with amines are usually observed at lower fields than the corresponding *cis* compounds.

The ^1H NMR spectra of the dihydroxo complexes are shown in Table 2. Similar to the diaqua species, a linear relationship was found between the $\Delta\delta_{av.}$ (in square brackets) and the pK_a values ($r^2 = 0.965$), except for the 4-picoline complex. The signals of the dihydroxo complexes are found at higher fields than the corresponding diaqua species, as seen by the smaller $\Delta\delta_{av.}$ values calculated for the dihydroxo compounds. The $^3J(^{195}Pt–^1H)$ coupling constants vary between 40 and 44 Hz and agree well with those observed for the diaqua complexes and those already reported and mentioned above (15, 16). For the 2-pic and 2,4-lut complexes, the $^4J(^{195}Pt–^1H)$ coupling constants with the *ortho*-methyl group are 11 Hz.

The ^{13}C NMR spectra of the dihydroxo complexes are shown in Table 3. The signals were observed at higher fields than those of the corresponding diaqua compounds (smaller $\Delta\delta_{av.}$ values for the dihydroxo compounds). Similar to the diaqua species, a linear relationship was found between the $\Delta\delta_{av.}$ (in square brackets) and the pK_a values ($r^2 = 0.952$), except for the 4-picoline complex. The $^3J(^{195}Pt–^{13}C)$ coupling constants vary between 42 and 45 Hz. They compared well with the values discussed above. The $^2J(^{195}Pt–^{13}C)$ coupling constants were not observed.

Hydrolysis of the *cis* complexes in neutral pH

The hydrolysis reactions were also studied in neutral medium. The dinitrato compounds were dissolved in D_2O (by heating in hot water) and the pH of the solution was raised with NaOD (1 M) to ca. 6.6 (pD = 7.0). The ^{195}Pt NMR spectra of these fresh solutions were immediately recorded. For most of the complexes, the spectra show several species in solution. These spectra were recorded using long accumulation times to reduce the background, but it was still quite significant. The presence of several peaks led to difficulties in the phase adjustment, and therefore, the determined proportion for each species is approximate, especially for the low-intensity signals.

The number of species seems to vary with the bulkiness of the ligand. For the most sterically hindered ligands, 2-pic and 2,4-lut, only one signal was observed, assigned to the

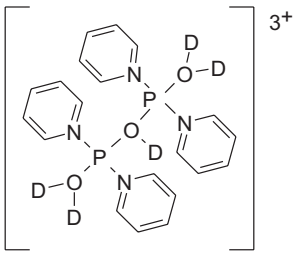
Fig. 2. Structure of the *trans*-diaqua dimer.



monoaqua–monohydroxo complex, *cis*-$[Pt(Ypy)_2(D_2O)(OD)]^+$, which is probably in equilibrium with some diaqua and dihydroxo species. For the 3,5-lut complex, two signals were observed at –1524 (80%) and –1426 (20%) ppm, while four peaks were found at –1507 (65%), –1454 (13%), –1421 (13%), and –1130 (9%) ppm for the for 4-pic compound. For the 3-pic complex, five signals were observed at –1520 (25%), –1463 (10%), –1436 (30%), –1386 (20%), and –1142 (15%) ppm. For the least sterically demanding ligand, pyridine, seven signals were observed at –1507 (25%), –1453 (30%), –1431 (10%), –1388 (10%), –1249 (5%), –1121 (5%), and –1056 (15%) ppm. These results are summarized in Table 4.

Our assignments for the different signals are based on published results for amine complexes, especially for the *cis*-$Pt(NH_3)_2$ system. The signals at highest field (–1496 ppm (av.) for the 2-pic and 2,4-lut complexes and at –1515 ppm (av.) for the other ligands) were assigned to the monoaquamohydroxo complex, *cis*-$[Pt(Ypy)_2(D_2O)(OD)]^+$. The next peak observed at an average value of –1457 ppm was assigned to the monohydroxo-bridged dimer *cis*-$[Pt(Ypy)_2(D_2O)(\mu\text{-}OD)Pt(Ypy)_2(OD)]^{2+}$ (see structure in Fig. 1), which is probably in equilibrium with its diaqua species *cis*-$[Pt(Ypy)_2(D_2O)(\mu\text{-}OD)Pt(Ypy)_2(D_2O)]^{3+}$ (or its dihydroxo analogue). This dimer was observed at 69 ppm (av.) from the *cis*-$[Pt(Ypy)_2(D_2O)_2]^{2+}$ species. A similar dimer has been reported (23) at –1547 ppm for *cis*-$[Pt(NH_3)_2(D_2O)(\mu\text{-}OD)Pt(NH_3)_2(D_2O)]^{3+}$, and at 47 ppm from the diaqua monomer *cis*-$[Pt(NH_3)_2(D_2O)_2]^{2+}$. The next signal observed at an average value of –1429 ppm (located at 97 ppm (av.) for the diaqua species) was attributed to the hydroxo-bridged cyclic trimer *cis*-$[Pt(Ypy)_2(\mu\text{-}OD)]_3^{3+}$ (Fig. 1). The corresponding trimer in the *cis*-$Pt(NH_3)_2$ system was observed at 74 ppm from the diaqua species (5). Crystal structures of the *cis*-$Pt(NH_3)_2$ trimer have been published (8, 9). The peak at –1387 ppm (139 ppm for the diaqua species), only observed with 3-pic and py, was assigned to the hydroxo-bridged cyclic tetramer, *cis*-$[Pt(Ypy)_2(\mu\text{-}OD)]_4^{4+}$. This species has not been reported in the literature for Pt–monodentate amine complexes, but it has been observed with ethylenediamine. The crystal structure of the Pt(en) tetramer has been published (27). The signal of the latter was reported at 202 ppm (26) from the diaqua species, but the $\Delta\delta$ are much larger in the Pt–bidentate systems. Another signal observed at much lower fields (av. –1131 ppm, at 395 ppm from the diaqua species) was assigned to the dihydroxo-bridged dimer *cis*-$[Pt(Ypy)_2(\mu\text{-}OD)]_2^{2+}$. In the *cis*-$Pt(NH_3)_2$ system, this dimer was observed at 423 ppm from the diaqua complex (3, 5). The crystal structures of several compounds of this type have been published (6, 7, 10). The chemical shifts for these species are found at much lower fields than the other compounds mentioned above because of the important strain of the four-membered ring. All of these structures are shown in Fig. 1. For pyridine, two other signals at –1249 and at –1056 ppm were observed (265 and 451 ppm from the diaqua compound). The origin of these resonances is not known. No such low field signal has been reported with monodentate amines. The only suggestion from the literature for a signal at such a low field was made for a trihydroxo-bridged dimer with bipyridine $[Pt(bipy)(\mu\text{-}OD)_3Pt(bipy)]^+$, as shown on Fig. 1. This signal was reported at 458 ppm from the dihydroxo species, but the authors could not confirm its structure. The color of this trihydroxo-bridged dimer (28) is red and our solution was colorless, but the red colour is probably associated with the presence of bipyridine. In a publication on the Pt(en) system (26), a signal was observed at very low field (636 ppm from $[Pt(en)(D_2O)_2]^{2+}$). The $\Delta\delta$ values are much larger for bidentate systems. The authors were unable to identify this peak, and we suggest that our signal observed at –1056 ppm for pyridine might have the same origin.

Table 5. $\delta(^{195}Pt)$ of the different aqueous products of the *trans* complexes.

Complex	Pyridine	3-Picoline
$[PtL_2(D_2O)_2]^{2+}$	–1425	–1430
$PtL_2(OD)_2$	–1478	–1473
$[PtL_2(D_2O)(OD)]^+$	–1474	–1471
$[PtL_2(D_2O)(\mu\text{-}OD)PtL_2(D_2O)]^{3+}$	–1319	–1308
$[PtL_2(OD)(\mu\text{-}OD)PtL_2(OD)]^+$	–1373	–1365
$[PtL_2(D_2O)(\mu\text{-}OD)PtL_2(OD)]^{2+}$	–1369	–1360
$[PtL_2(D_2O \text{ or } OD)(\mu\text{-}OD)]_n^+$	–1355	–1344

The ^{195}Pt NMR spectrum of the 3,5-lut complex dissolved in D_2O (neutral pH) was remeasured after one year. Three signals were observed, including a new species at –1456 ppm (15%), which was assigned to the presence of the monohydroxo-bridged dimer, that was not present in the fresh solution. The two other signals were observed at –1524 (*cis*-$[Pt(3,5\text{-}lut)_2(D_2O)(OD)]^+$, 75%), and –1426 ppm (*cis*-$[Pt(Ypy)_2(\mu\text{-}OD)]_3^{3+}$, 10%). The spectrum of the 3-pic complex was also measured after standing in D_2O for one year. Four species were observed at –1520 (20%), –1436 (35%), –1386 (15%), and a new peak at –1080 ppm (30%). The monohydroxo-bridged dimer and the cyclic dihydroxo-bridged dimer were no longer present. These results are listed in Table 4 along with their assignments.

The ^1H and ^{13}C NMR spectra of these solutions were measured, but could not be interpreted due to the great numbers of overlapping species. They are, therefore, not presented in this paper.

Study of the *trans* isomers

A similar study was attempted on the *trans* complexes. These compounds are much more difficult to dissolve than their *cis* analogues and heating in a water bath for a long time is required. Because of the aqueous insolubility of the other compounds, only the pyridine and the 3-picoline platinum complexes could be studied. In acidic media, two sig-

© 2002 NRC Canada

nals were observed at –1425 (~65%) and –1319 ppm for pyridine and at –1430 (~65%) and –1308 ppm for the 3-picoline compound. In basic media, one strong signal was observed at –1478 ppm for pyridine and at –1473 ppm for 3-picoline. There was also a second weaker signal (~10%) at slightly lower fields, –1373 and –1365 ppm, respectively. The most intense signals observed at higher fields probably correspond to the diaqua (acidic pD) and the dihydroxo species (basic pD), whereas the weaker signals have not been identified with certainty. These weaker signals are not, however, caused by a nitrato species (dinitrato, monoaqua-mononitrato, or monohydroxo-mononitrato), since the same two peaks (with identical intensities) were observed when the counter anions were changed to perchlorate, which are not known to coordinate to Pt in aqueous medium. The lower field peaks might be caused by the presence of the hydroxo-bridged dimers *trans*-$[Pt(D_2O)(Ypy)_2(\mu\text{-}OD)Pt(Ypy)_2(D_2O)]^{3+}$ (acidic pD) and *trans*-$[Pt(OD)(Ypy)_2(\mu\text{-}OD)Pt(Ypy)_2(OD)]^{+1}$ (basic pD) (Fig. 2). The study on the *trans*-$Pt(NH_3)_2$ system (17) shows only the presence of the diaqua species at low pH and the dihydroxo compound at high pH. At pH = 4 a second signal, assigned to the dimer $[\{trans\text{-}Pt(H_2O)(NH_3)_2\}_2(\mu\text{-}OH)]^{3+}$ was reported, while at pH = 9 the corresponding hydroxo compound $[\{trans\text{-}Pt(OH)(NH_3)_2\}_2(\mu\text{-}OH)]^{3+}$ was observed by Appleton et al. (17).

At neutral pD, our compounds showed the presence of three species at –1474 (65%), –1369 (30%), and –1355 (5%) ppm for the pyridine compound, and at –1471 (50%), –1360 (45%), and –1344 (5%) ppm for the 3-picoline complex. The higher-field signals correspond to the *trans*-$[Pt(Ypy)_2(D_2O)(OD)]^+$ compounds (in equilibrium with the diaqua and the dihydroxo species), the intermediate field signals correspond to the monohydroxo-bridged dimers (as discussed above), and the lower field signals probably correspond to the longer hydroxo-bridged oligomers or polymers, *trans*-$[Pt(Ypy)_2(D_2O \text{ or } OD)(\mu\text{-}OH)]_n^{n+}$, which could be cyclic or linear. For the $Pt(NH_3)_2$ system, Appleton et al. (17) have isolated a solid that formed after the solution was allowed to stand at pH = 5–6. The authors have formulated the solid as hydroxo-bridged polymeric cations, $[\{trans\text{-}Pt(\mu\text{-}OH)(NH_3)_2\}_n]^{n+}$ (the fourth ligand is probably H_2O or OH^-), which could be linear or cyclic. In our fresh solutions these polymers seem to be present in very small amounts (about 5%).

When the pyridine products in solution were remeasured after 7 months, the same three signals were observed, but the proportions of the three compounds were different: 20% for the monomer, 50% for the dimer, and 30% for the polymer.

Conclusion

When the complexes *cis*-$Pt(Ypy)_2(NO_3)_2$ were dissolved in D_2O, the diaqua complexes were observed in acidic media, while hydrolysis occurs in basic pH to produce the dihydroxo compounds. In ^{195}Pt NMR spectroscopy, the complexes containing the ligands 2-pic and 2,4-lut behave differently because of the *ortho* effect, which is probably a solvent effect. In acidic pH, monoaqua–mononitrato species were not detected, contrary to the results reported on the *cis*-$Pt(NH_3)_2$ system.

At neutral pH, several species can be observed. The δ(Pt) values of the different products are summarized in Table 5. The number of species depends on the bulkiness of the pyridine ligand. For the *ortho*-substituted ligands, only one complex is formed in solution, while for the least bulky ligand (pyridine), up to seven species were observed. The number and the structure of these species vary with time. The monoaqua–monohydroxo compound is the most important complex in fresh solutions. Different oligomeric ionic species are also formed, i.e., dihydroxo-bridged dimers, monohydroxo-bridged dimers, cyclic trimers, and probably cyclic tetramers. Two other unassigned signals were observed at lower fields. Attempts to crystallize these species were not successful.

The species in solution vary slightly with concentration and the time of heating to dissolve the dinitrato complexes. These complexes are not very soluble and must be heated in hot water before dissolving; it was difficult to reproduce the exact experimental conditions of sample preparation. Furthermore, there was, sometimes, a residue at the bottom of the NMR tube after the experiment was completed; therefore, there were some variations in the proportions of each species when the experiments were repeated.

The *trans* compounds are less soluble than the *cis* analogues and only the pyridine and 3-picoline complexes were studied. In acidic pH, the diaqua and the aqua monohydroxo-bridged dimer were observed, while at high pH, the dihydroxo monomer and the hydroxo monohydroxo-bridged dimer were identified. At neutral pH, a third signal assigned to a hydroxo-bridged cyclic or linear polymer was observed.

Size and temperature dependence of hydrocarbon solubility in concentrated aqueous solutions of urea and guanidine hydrochloride

Giuseppe Graziano

Abstract: At 25°C, methane and ethane are more soluble in water than in 7 M aqueous urea or 4.9 M aqueous guanidine hydrochloride (GuHCl); the reverse is true for larger hydrocarbons. In addition, the hydrocarbon solubility in 7 M aqueous urea or 4.9 M aqueous GuHCl increases compared with that in water on raising the temperature in the range of 5–45°C. These experimental data have not yet been rationalized. Using a well-founded theory of hydrophobic hydration, the present analysis indicates that the transfer of hydrocarbons from water to 7 M aqueous urea or to 4.9 M aqueous GuHCl is favored by the difference in the solute–solvent van der Waals interaction energy, and contrasted by the difference in the work of cavity creation. At room temperature, on increasing the hydrocarbon size, the first contribution rises in magnitude more rapidly than the second contribution, accounting for the threshold size occurrence. Moreover, the second contribution decreases in magnitude with an increase in temperature, becoming less unfavorable, while the first contribution is practically constant in the range of 5–45°C. The different temperature dependence of the work of cavity creation in such solvent systems is due to the fact that the density of 7 M aqueous urea and 4.9 M aqueous GuHCl decreases more rapidly than that of water when raising the temperature. The relationship between the density of a liquid and the work to create a cavity in it is discussed in detail.

Key words: work of cavity creation, solute–solvent van der Waals interaction energy, H-bond reorganization.

Résumé : À 25°C, le méthane et l'éthane sont plus solubles dans l'eau que dans des solutions aqueuses 7 M d'urée ou 4,9 M de chlorhydrate de guanidine, GuHCl; l'inverse est vrai pour les hydrocarbures à plus longues chaînes. De plus, dans l'intervalle de température allant de 5 à 45°C, une augmentation de la température provoque une augmentation de la solubilité des hydrocarbures dans des solutions aqueuses 7 M d'urée ou 4,9 M de GuHCl augmentent par rapport à celle dans l'eau. De telles données expérimentales n'ont pas été rationalisées jusqu'à maintenant. En se basant sur la théorie bien fondée de l'hydratation hydrophobe, l'analyse présentée ici indique que le transfert des hydrocarbures de l'eau vers des solutions aqueuses 7 M d'urée ou 4,9 M de GuHCl est favorisé par la différence d'énergie d'interaction de van des Waals soluté-solvant et que ceci est en opposition avec la différence dans le travail de création de la cavité. À la température ambiante, une augmentation de la taille de l'hydrocarbure, l'amplitude de la première contribution augmente plus rapidement que la seconde, ce qui explique l'existence du seuil de taille. De plus, l'amplitude de la deuxième contribution diminue avec la température, ce qui la rend moins favorable, alors que la première contribution est pratiquement constante dans l'intervalle de température de 5 à 45°C. Les différences dans la relation du travail de création d'une cavité avec la température, dans de tels systèmes de solvant, résulte du fait qu'une augmentation de la température s'accompagne d'une diminution plus rapide de la densité des solutions aqueuses 7 M d'urée ou 4,9 M de GuHCl que celle de l'eau. On discute en détail de la relation entre la densité d'un liquide et le travail de création d'une cavité.

Mots clés : travail de création d'une cavité, énergie d'interaction de van der Waals soluté-solvant, réorganisation des liaisons hydrogènes.

[Traduit par la Rédaction]

Introduction

About forty years ago, Wetlaufer et al. (1) determined the molar solubility of seven hydrocarbons (i.e., the first six compounds of the aliphatic series and toluene) in water, 7 M aqueous urea, and 4.9 M aqueous guanidine hydrochloride (GuHCl) over the temperature range 5–45°C. The Ben-Naim standard Gibbs energy change upon transfer from water to 7 M urea or to 4.9 M GuHCl is simply calculated from the relation (2)

$$[1] \qquad \Delta G^{\bullet} = RT \ln [C(H_2O)/C(\text{mix})]$$

where $C(H_2O)$ and C(mix) are the molar concentrations in water and in the mixed solvent system, respectively, and the filled circle denotes the Ben-Naim standard. The use of the Ben-Naim standard is strongly recommended because $\Delta G^{\bullet}$ is

Note: The hard-sphere diameter (12) and the *ASA* estimate (74) of each solute are also reported. For neopentane and toluene, the $\Delta G^{\bullet}$ values at 5°C were determined by extrapolation of the data at higher temperatures. Wetlaufer et al. (1) estimated an overall precision of ±2% for their molar solubility determinations; this should give rise to an uncertainty in the $\Delta G^{\bullet}$ values of about ±0.1 kJ mol^{-1} at 25°C. The hard-sphere diameter of toluene has been estimated from the *ASA* value.

directly obtained from the experimentally measured quantities, and it has a clear physical meaning (2, 3). In fact, $\Delta G^{\bullet}$ refers to the transfer of a solute molecule from a fixed position in liquid water to a fixed position in the mixed solvent. This is a rigorous statistical mechanical result that allows one to separate the contribution arising from the difference in translational degrees of freedom due to the different molar volume available to the solute molecule when the two phases have different densities (at 25°C the density is 0.99705 g cm^{-3} for water (4), 1.1044 g cm^{-3} for 7 M aqueous urea, and 1.1171 g cm^{-3} for 4.9 M aqueous GuHCl (5)). The corresponding thermodynamic quantities solely account for the difference in the solute–solvent coupling work for solutes that do not have conformational degrees of freedom. When the solute is flexible, the Ben-Naim standard also takes into account differences in the solute intramolecular energetics. From the temperature dependence of $\Delta G^{\bullet}$, it is possible to calculate the Ben-Naim standard enthalpy and entropy changes ($\Delta H^{\bullet}$ and $\Delta S^{\bullet}$, respectively) upon transfer at room temperature. The values of the thermodynamic functions for the transfer from water to 7 M urea and to 4.9 M GuHCl are presented in Tables 1 and 2, respectively, together with the hard-sphere diameters and accessible surface areas of the seven hydrocarbons.

For both transfer processes, the $\Delta G^{\bullet}$ values at 25°C are positive for methane and ethane, but negative for the other hydrocarbons, with the values increasing in magnitude when increasing the size of the solute molecule (see Tables 1 and 2). For the transfer, water→7 M urea, $\Delta G^{\bullet}$ (in kJ mol^{-1}) = 0.8 for methane, –0.1 for propane, –0.7 for neopentane, and –1.5 for toluene. For the transfer, water→4.9 M GuHCl, $\Delta G^{\bullet}$ (in kJ mol^{-1}) = 1.0 for methane, –0.1 for propane, –1.1 for neopentane, and –1.8 for toluene. Thus, there is a threshold size above which the presence of urea or GuHCl in water causes an enhancement of hydrocarbon solubility at room temperature; below this threshold size, the hydrocarbon solubility decreases. In contrast, all the $\Delta H^{\bullet}$ and $\Delta S^{\bullet}$ values at 25°C are positive, and do not show a clear trend as a function of the hydrocarbon size (see Tables 1 and 2). In addition, for both transfer processes, the $\Delta G^{\bullet}$ values become less positive (or more negative) with an increase in temperature. For the transfer, water→7 M urea, $\Delta G^{\bullet}$ (in kJ mol^{-1}) passes from 1.2 at 5°C to 0.6 at 45°C for methane, and from 0.3 at 5°C to –1.2 at 45°C for neopentane. For the transfer, water→4.9 M GuHCl, $\Delta G^{\bullet}$ (in kJ mol^{-1}) passes from 1.5 at 5°C to 0.8 at 45°C for methane, and from –0.3 at 5°C to –1.2 at 45°C for neopentane. This finding is not easy to rationalize because $\Delta G^{\bullet}$ becomes more positive with temperature for the transfer processes, gas→water and nonpolar liquid→water, of hydrocarbons (6). In fact, no reliable microscopic interpretation has been provided.

It should be noted that the values of $\Delta G^{\bullet}$ for the transfer of nonpolar amino acid side chains from water to 7 M urea and to 5 M GuHCl, determined by Nandi and Robinson (7)

Note: The hard-sphere diameter (12) and the *ASA* estimate (74) of each solute are also reported. For neopentane and toluene, the $\Delta G^{\bullet}$ values at 5°C were determined by extrapolation of the data at higher temperatures. Wetlaufer et al. (1) estimated an overall precision of ±2% for their molar solubility determinations; this should give rise to an uncertainty in the $\Delta G^{\bullet}$ values of about ±0.1 kJ mol^{-1} at 25°C. The hard-sphere diameter of toluene has been estimated from the *ASA* value.

from solubility measurements of several *N*-acetyl α-amino acid ethyl esters, are in semiquantitative agreement with those of Wetlaufer et al. (1). In fact, Nandi and Robinson (7) obtained, at 25°C, the following: (*i*) for the transfer, water→7 M urea, $\Delta G^{\bullet}$ (in kJ mol^{-1}) = 0.30 for Ala, 0.19 for Val, 0.15 for Leu, –0.06 for Nleu, and –0.66 for Phe; (*ii*) for the transfer, water→5 M GuHCl, $\Delta G^{\bullet}$ (in kJ mol^{-1}) = 0.48 for Ala, 0.27 for Val, –0.15 for Leu, –0.31 for Nleu, and –1.23 for Phe (7). Clearly, such values confirm the existence of a threshold size for the solubility enhancement due to urea or GuHCl. In addition, the data of Nandi and Robinson (7) show a temperature dependence resembling that obtained by Wetlaufer et al. (1) (see Tables IV and V in ref. 7). In contrast, from the solubility studies of α-amino acids by Tanford and co-workers (8), one determines, for nonpolar side-chains at 25°C, the following: (*i*) for the transfer, water→7 M urea, $\Delta G^{\bullet}$ (in kJ mol^{-1}) = 0.05 for Ala, –0.58 for Val, –1.06 for Leu, and –2.25 for Phe; (*ii*) for the transfer, water→4.9 M GuHCl, $\Delta G^{\bullet}$ (in kJ mol^{-1}) = –0.15 for Ala, –0.93 for Val, –1.70 for Leu, and –2.80 for Phe. Clearly, such values do not show the occurrence of a threshold size for the solubility enhancement. This is surely due to the presence of charges on the α-amino acid molecules that strengthen the interactions with urea and GuHCl, and limit the validity of the additivity principle.

On the other hand, Ben-Naim and Yaacobi (9), in accordance with the data of Wetlaufer et al., determined the following for the water→7 M urea transfer at 25°C: (*i*) for methane, $\Delta G^{\bullet}$ = 0.9 kJ mol^{-1}, $\Delta H^{\bullet}$ = 5.0 kJ mol^{-1}, and $\Delta S^{\bullet}$ = 13.8 J K^{-1}mol^{-1}; (*ii*) for ethane, $\Delta G^{\bullet}$ = 0.4 kJ mol^{-1}, $\Delta H^{\bullet}$ = 8.8 kJ mol^{-1}, and $\Delta S^{\bullet}$ = 28.0 J K^{-1}mol^{-1}. There was also agreement for the temperature dependence of the $\Delta G^{\bullet}$ values over the range of 10–30°C. Moreover, Breslow and Guo (10) found that $\Delta G^{\bullet}$ = –0.6 kJ mol^{-1} for the transfer of benzene from water to 5 M aqueous GuHCl at 20°C. Such experimental value agrees quantitatively with those determined by Wetlaufer et al. (1) for aliphatic hydrocarbons of similar size (i.e., isobutane and *n*-butane, see Table 2). The thermodynamic data of Tables 1 and 2, therefore, have to be considered reliable on a quantitative basis.

To the best of our knowledge, a complete rationalization of data of Wetlaufer et al. (1) has not yet been provided. No one has tried to perform this task with a convincing theoretical treatment. The analysis by Muller (11), limited to the water→7 M urea transfer, cannot be considered completely satisfactory. The model calculations of Muller did not reproduce the experimental data without the ad hoc introduction of eq. [11] in ref. 11, which has no physical justification. Recently, the author devised a simple but well-founded approach (12) that leads to a satisfactory rationalization for the occurrence of the threshold size at room temperature for the water→7 M urea transfer. In the present article, it will be shown that the same approach is able to account for all the nontrivial features of the data by Wetlaufer et al. (1), without the need of special assumptions.

Theory

The theoretical approach is described in detail in the accompanying paper[1]; this paper reports only the fundamental relationships to be used in this specific application. A liquid phase is a condensed state of matter and one should consider both the finite volume occupied by each molecule and the energetic interactions among molecules (i.e., both the repulsive and attractive parts of the intermolecular potential, as pioneered by van der Waals). On this basis, rigorous statistical mechanical approaches to solvation have been developed (13–15). The transfer of a solute molecule from a fixed position in water to a fixed position in the mixed-aqueous solvent system (both 7 M urea and 4.9 M GuHCl) can be dissected in the following subprocesses (12): (*i*) breaking solute–solvent attractive interactions in H_2O; (*ii*) closing the cavity therein; (*iii*) creating a cavity in the mixed solvent to accommodate the solute molecule; and (*iv*) turning on the solute–solvent attractive interactions in the mixed solvent. Accordingly, the Ben-Naim standard Gibbs energy change upon transfer is given by the following relation:

$$[2] \quad \Delta G^{\bullet} = [\Delta G_c(\text{mix}) - \Delta G_c(H_2O)] + [E_a(\text{mix}) - E_a(H_2O)] = \Delta\Delta G_c + \Delta E_a$$

where ΔG_c is the work of cavity creation and E_a is the average solute–solvent van der Waals interaction energy. These two terms represent the direct perturbation of each solvent system due to solute insertion. In response to the direct perturbation, a structural reorganization of solvent molecules occurs with associated enthalpy and entropy contributions (16). Since such structural reorganization is characterized by a rearrangement of H-bonds in H_2O, 7 M aqueous urea, and 4.9 M aqueous GuHCl, the corresponding enthalpy and entropy changes are indicated as ΔH^h and ΔS^h (note that in the accompanying paper[1] they are indicated as ΔH_r and ΔS_{nx} to be more general, given that there are no H-bonds in solvents such as benzene or *n*-hexane). The Ben-Naim standard enthalpy and entropy changes upon transfer are, therefore, given by

$$[3] \quad \Delta H^{\bullet} = [E_a(\text{mix}) - E_a(H_2O)] + [\Delta H^h(\text{mix}) - \Delta H^h(H_2O)] = \Delta E_a + \Delta\Delta H^h$$

$$[4] \quad \Delta S^{\bullet} = [\Delta S_x(\text{mix}) - \Delta S_x(H_2O)] + [\Delta S^h(\text{mix}) - \Delta S^h(H_2O)] = \Delta\Delta S_x + \Delta\Delta S^h$$

In the latter equation, ΔS_x is the entropy contribution due to the excluded volume effect associated with cavity creation in the solvent (16). It is exactly related to the work of cavity creation as follows:

$$[5] \quad \Delta S_x = -\Delta G_c/T$$

because ΔG_c, being a measure of the probability that a certain region of space in the solvent is devoid of solvent molecules, is purely of entropic origin (17).

According to eqs. [2]–[4], the Ben-Naim standard Gibbs energy change upon transfer is not affected by the reorganization of H-bonds in response to solute insertion. This is because the enthalpy–entropy compensation condition

$$[6] \quad \Delta H^h = T\Delta S^h$$

holds for the reorganization of H-bonds in such solvent systems. This is a very important topic which has been carefully analyzed and demonstrated by means of different theoretical approaches (18). For a general discussion on the occurrence of enthalpy–entropy compensation phenomena, see the review by Liu and Guo (19).

Ben-Naim was probably the first (20) to show that, for any reliable statistical mechanical definition of solvent structure, the standard solvation Gibbs energy change, being expressed as an ensemble average over the distribution function of pure solvent, depends upon the solvent structure, but does not derive any contribution from solvent structural changes induced by solute insertion (i.e., solvent structural changes correspond to a reorganization of H-bonds in the case of water and aqueous solutions). In addition, Ben-Naim pointed out that such solvent structural changes may dominate the standard solvation enthalpy and entropy changes, but in a compensating manner. From our point of view, the analysis devised by Lee (21) leads to a more clear physical interpretation. Lee demonstrated that enthalpy–entropy compensation is operative when the solute–solvent attractive interactions are weak in comparison to the solvent–solvent attractive interactions. This condition holds for hydrocarbons in both H_2O, 7 M aqueous urea, and 4.9 M aqueous GuHCl because van der Waals interactions are weak when compared with H-bonds.

Calculation procedure

The work of cavity creation is calculated using the theoretical equation provided by scaled particle theory (SPT) (22, 23) and reported in the accompanying paper[1].This theoretical equation is considered valid for calculating ΔG_c not only in pure liquids but also in the mixed-aqueous solvent systems (12). The author assumes that both 7 M aqueous urea and 4.9 M aqueous GuHCl can be treated as "uniform" solvents characterized by a single mean hard-sphere diameter and a single mean molar volume (12, 24). In this respect, Patterson wrote (25), "The simplest prescription is the one-fluid model where the mixture is taken to be equivalent to a single fluid with average molecular parameters. More complex two- and three-fluid models are available, but it is probable that they give no better results than the one-fluid." The reliability of the assumption was discussed in detail in previous work (12). It should be emphasized that, apart from the fundamental neutron-diffraction studies by Finney et al. (26) on aqueous urea solutions, further experimental measurements (27, 28) and computer simulations (29, 30) have confirmed that both GuHCl and urea, even at high molar concentrations, do not affect the H-bonding network of liquid water. This is simply due to the ability of guanidinium ions and urea molecules to form H-bonds in a pseudo-tetrahedral arrangement (31).

According to our assumption, the mean hard-sphere diameter of mixed-aqueous solvent systems is given by

Table 3. Experimental densities of water, 7 M urea, and 4.9 M GuHCl; apparent molar volume of urea in 7 M urea, and of GuHCl in 4.9 M GuHCl; mean molar volume of 7 M urea and 4.9 M GuHCl; volume-packing densities of water, 7 M urea, and 4.9 M GuHCl.

	T (°C)	ρ (g cm^{-3})	Φv (cm^3 mol^{-1})	v (cm^3 mol^{-1})	ξ
H_2O	5	0.99996		18.02	0.364
	25	0.99705		18.07	0.363
	45	0.99021		18.20	0.360
7 M urea	5	1.1138	44.0	22.0	0.427
	25	1.1044	45.0	22.3	0.421
	45	1.0921	45.9	22.6	0.416
4.9 M GuHCl	5	1.1267	70.1	24.2	0.427
	25	1.1171	71.4	24.5	0.422
	45	1.1074	72.2	24.7	0.418

Note: The data for water are from ref. 4; those for 7 M aqueous urea are from ref. 40; those for 4.9 M aqueous GuHCl are from ref. 39; M_w = 18.02 for H_2O, 60.06 for urea, and 95.53 for GuHCl.

$$[7] \qquad \sigma(\text{mix}) = x_1\sigma_1 + x_2\sigma_2$$

where the subscript 1 refers to water, the subscript 2 refers to urea or GuHCl, and x is molar fraction. The molar fraction of water in 7 M urea is 0.846 at 5°C, 0.844 at 25°C, and 0.842 at 45°C; the molar fraction of water in 4.9 M GuHCl is 0.882 at 5°C, 0.880 at 25°C, and 0.879 at 45°C. For water, σ_{H_2O} = 2.75 Å (32) is used, close to the location of the first peak in the oxygen–oxygen pair correlation function of liquid water (33). The values of σ_{urea} and σ_{GuHCl} have to be properly selected.

The latter can be determined by addressing the concept of equivalent hard sphere (34). Consider, for instance, that the pair-correlation function of *N*-acetyl-leucine-amide (NALA) molecules in aqueous solution, determined from neutron-scattering measurements, can be satisfactorily reconstructed by assuming that each NALA molecule is equivalent to a hard-sphere of 6.0 Å diameter (35).

The molar volume of GuHCl, calculated from the crystal density (36), is 70.55 cm^3 mol^{-1}, corresponding to 117.2 Å^3 per molecule. The partial molar volume of GuHCl in 4.9 M aqueous GuHCl at 25°C is 72.47 cm^3 mol^{-1}, corresponding to 120.3 Å^3 per molecule (37, 38). The apparent molar volume of GuHCl in 4.9 M aqueous GuHCl at 25°C is 71.40 cm^3 mol^{-1}, corresponding to 118.6 Å^3 per molecule (39). All these values closely correspond to the volume of a sphere of 6.2 Å diameter, and σ_{GuHCl} is therefore fixed at 6.2 Å. A similar procedure led to σ_{urea} = 5.0 Å (12). Inserting these values into eq. [7], one obtains σ (7 M urea) = 3.10 Å and σ (4.9 M GuHCl) = 3.20 Å in the whole range of 5–45°C.

In the same way, the mean molar volume of mixed-aqueous solvent systems is given by

$$[8] \qquad v(\text{mix}) = x_1v_1 + x_2v_2$$

where for water we use the experimental values of molar volume at the different temperatures (4); for urea we use the values of the apparent molar volume of urea in 7 M aqueous urea solutions determined by Stokes (40); and for GuHCl we use the values of the apparent molar volume of GuHCl in 4.9 M aqueous GuHCl solutions determined by Makhatadze and co-workers (39). These simple calculations show the following: (*i*) v (7 M urea) = 22.0, 22.3, and 22.6 cm^3 mol^{-1} at 5, 25, and 45°C, respectively; (*ii*) v (4.9 M GuHCl) = 24.2, 24.5, and 24.7 cm^3 mol^{-1} at 5, 25, and 45°C, respectively. Correspondingly, the mean volume-packing densities are (*i*) ξ(7 M urea) = 0.427, 0.421, and 0.416 at 5, 25, and 45°C, respectively; (*ii*) ξ(4.9 M GuHCl) = 0.427, 0.422, and 0.418 at 5, 25, and 45°C, respectively. All these data are presented in Table 3. The two "uniform" solvent systems, 7 M aqueous urea and 4.9 M aqueous GuHCl, therefore, have both a mean hard-sphere diameter and a mean volume-packing density larger than those of water.

The physical validity of our approach and the reliability of eqs. [7] and [8] are supported by the following findings: (*i*) the volume change associated with the mixing of urea or GuHCl and water is negligible (39, 40); and (*ii*) computer simulations show that both urea and GuHCl, even at high molar concentrations, do not significantly affect the structure of water (29–31), which is in line with the results of neutron diffraction, IR, and NMR studies (26–28, 41).

Size dependence of hydrocarbon solubility

The SPT estimates of ΔG_c in water, 7 M aqueous urea, and 4.9 M aqueous GuHCl are reported in Table 4. They are larger in both 7 M urea and 4.9 M GuHCl than in water. For instance, at 25°C, for methane, ΔG_c (in kJ mol^{-1}) = 21.1 in H_2O, 23.9 in 7 M urea, and 22.9 in 4.9 M GuHCl; for neopentane, ΔG_c (in kJ mol^{-1}) = 46.3 in H_2O, 52.4 in 7 M urea, and 49.9 in 4.9 M GuHCl; for toluene, ΔG_c (in kJ mol^{-1}) = 46.8 in H_2O, 53.1 in 7 M urea, and 50.5 in 4.9 M GuHCl. The magnitude of ΔG_c, with a fixed temperature and cavity radius, is determined by two geometrical features of the solvent (14, 42), i.e., ΔG_c raises (*i*) on decreasing the value of the hard-sphere diameter of its molecules for a given ξ; and (*ii*) on increasing its volume-packing density for a given σ. By adding urea or GuHCl to water to make a 7 M urea or a 4.9 M GuHCl solution, there is an increase in both the mean hard-sphere diameter of the solvent (3.10 Å for 7 M urea, 3.20 Å for 4.9 M GuHCl, and 2.75 Å for H_2O) and the mean volume-packing density (at 25°C, 0.421 for 7 M urea, 0.422 for 4.9 M GuHCl, and 0.363 for H_2O). Even though the two factors act in opposite directions, the second factor (mean volume-packing density) prevails,

Note: The $\Delta\Delta H^h$ estimates are obtained taking the difference $\Delta H^{\bullet} - \Delta E_a$; those of $\Delta\Delta S^h$ taking the difference $\Delta S^{\bullet} - \Delta\Delta S_x$, where the $\Delta\Delta S_x$ values are calculated using eq. [5].

so that ΔG_c in the two mixed-solvent systems is larger than in water.

This finding is correct from a physico-chemical point of view because (*i*) the addition of both urea and GuHCl to water causes an increase of the surface tension (10, 43); and (*ii*) there is a direct proportionality between the work of cavity creation in a solvent and its surface tension (44). In particular, following the proposal of Baldwin (45), we can consider that

$$[9] \qquad \Delta\Delta G_c = ASA\Delta\gamma$$

where *ASA* is the accessible surface area of the solute molecule and $\Delta\gamma$ is the increase in surface tension passing from pure water to 7 M urea or to 4.9 M GuHCl. Using the SPT estimates of $\Delta\Delta G_c$ at 25°C, shown in the second column of Table 5, and the *ASA* values listed in the first column of Table 1, estimates for $\Delta\gamma$ can be obtained. The average value of $\Delta\gamma$ is 21.5 J Å^{-2} mol^{-1} for 7 M urea and 12.9 J Å^{-2} mol^{-1} for 4.9 M GuHCl. The latter is close to the experimental value of 13.0 J Å^{-2} mol^{-1}, measured at 20°C by Breslow and Guo (10). The old data quoted by Timmermans (43), even though they do not allow a strictly quantitative comparison for 7 M urea because the surface tension was determined for less concentrated solutions, are in line with the above estimates. With respect to eq. [9], it should be noted that recent theoretical and computational approaches have demonstrated that the *ASA* significantly underestimates the macroscopic surface tension for molecular-sized solutes (46–48). A more appropriate procedure for aqueous solutions should use the van der Waals or molecular surface of the solutes. In any case,

computer simulations also indicate that ΔG_c should be larger in 7 M urea and 4.9 M GuHCl than in water (30).

Estimates of E_a at 25°C in water, 7 M urea, and 4.9 M GuHCl are determined with a "hybrid" procedure, using the relation $E_a = \Delta G^\bullet - \Delta G_c$, where $\Delta G^\bullet$ are the experimental data for the following solvation processes: gas→H_2O, gas→7 M urea, and gas→4.9 M GuHCl. The values of $\Delta G^\bullet$(gas→H_2O), $\Delta G^\bullet$(gas→7 M urea), and $\Delta G^\bullet$(gas→4.9 M GuHCl) come from the work of Wetlaufer et al. (1), using the relation $\Delta G^\bullet = RT \ln (C_g/C_l)$, where C_g and C_l are the molar concentrations in the gas and in the liquid, respectively (2). Note that, for the conditions adopted by Wetlaufer et al. (1), $C_g = 0.0409$ mol L^{-1} at 25°C for all hydrocarbons. The E_a estimates, determined with the hybrid procedure, are reported in Table 4, and show that E_a is larger, in absolute value, in both 7 M urea and 4.9 M GuHCl than in water. For instance, for methane, E_a (in kJ mol^{-1}) = –12.7 in H_2O, –14.7 in 7 M urea, and –13.5 in 4.9 M GuHCl; for neopentane, E_a (in kJ mol^{-1}) = –36.0 in H_2O, – 42.8 in 7 M urea, and –40.7 in 4.9 M GuHCl; for toluene, E_a (in kJ mol^{-1}) = –50.5 in H_2O, –58.3 in 7 M urea, and –56.0 in 4.9 M GuHCl.

To confirm this finding, the E_a values in water, at 25°C, calculated for aliphatic hydrocarbons by Jorgensen and co-workers (49), and that of toluene (obtained by adding to the estimate of Linse (50) for benzene the contributions of the methyl group), are listed in the last line of Table 4*a* (i.e., both Jorgensen and Linse performed calculations in TIP4P water). These values prove to be very close to those obtained with the hybrid procedure. In addition, the values of E_a in H_2O can be used to estimate E_a in the mixed-aqueous solvent systems by means of the following relation:

$$[10] \quad E_a(\text{mix}) = E_a(H_2O)\xi(\text{mix})/\xi(H_2O)$$

whose physical reliability is grounded in the general expression of the solute–solvent van der Waals interaction energy (23), which indicates that E_a is directly proportional to the solvent packing density (ξ). The values calculated by means of eq. [10] are listed in the last line of Table 4*b* for 7 M urea and Table 4*c* for 4.9 M GuHCl. These values qualitatively agree with those obtained using the hybrid procedure. The agreement is also quantitatively good for 7 M urea, but not for 4.9 M GuHCl. In such case, they are, on the average, too large by a magnitude of 2 kJ mol^{-1}. This is surely due to the fact that eq. [10], even though reliable and sound, cannot be quantitatively exact when there are charged species in solution, as in the case of GuHCl. The qualitative agreement, however, can be considered satisfactory, confirming that solute–solvent van der Waals interactions are stronger in both 7 M urea and 4.9 M GuHCl than in pure water. This point is supported by the fact that urea decreases the interfacial tension between alkanes and water (51) and by the results of computer simulations (30, 52). In addition, it is in accordance with the large polarizability of the urea molecule and guanidinium ion, due to the six π-electrons delocalized over the entire planar structure.

According to eq. [2], the $\Delta G^\bullet$ values for the transfer from water to the mixed solvent systems are governed by the balance between $\Delta\Delta G_c$ and ΔE_a. The first quantity is positive, whereas the second one is negative. Neither of these are large, but increase, in absolute value, with hydrocarbon size, and also remain close in magnitude (see the second and third columns of Table 5). In fact, the solubilities are similar (1), and the $\Delta G^\bullet$ values, regardless of the sign, are small and difficult to estimate by means of a purely theoretical approach. This is why we use the hybrid procedure to estimate E_a. It proves that ΔE_a increases in magnitude with hydrocarbon size more rapidly than $\Delta\Delta G_c$, in both 7 M urea and 4.9 M GuHCl, leading to the occurrence of a threshold size for the hydrocarbon solubility enhancement at 25°C.

This raises the question of why the increase in magnitude of ΔE_a is larger than that of $\Delta\Delta G_c$. A reliable explanation seems to be that for the transfer from H_2O to 7 M urea or to 4.9 M GuHCl, the increase of ΔG_c is simply a consequence of the change in the packing properties of the solvent system. The increase in magnitude of E_a reflects not only the change in the packing properties of the solvent system, but also direct-contact interactions between the solute molecule and urea molecules, or GuH^+ and Cl^- ions in the hydration shell (on this point see also *Appendix 1*). Molecular dynamics simulations (30) indicate that the number of urea molecules or GuH^+ and Cl^- ions located in the hydration shell of hydrocarbons increases with the size of the latter. This should be the molecular origin of the ΔE_a behavior.

We now analyze the Ben-Naim standard transfer enthalpy and entropy changes. The $\Delta\Delta S_x$ values are calculated using eq. [5], while those of $\Delta\Delta H^h$ and $\Delta\Delta S^h$ are obtained by calculating the differences $\Delta H^\bullet - \Delta E_a$ and $\Delta S^\bullet - \Delta\Delta S_x$, respectively. (Note that ΔH^h estimates could be directly calculated by means of computer simulations, but the associated uncertainty would be very large.) The obtained estimates of $\Delta\Delta H^h$, $\Delta\Delta S_x$, and $\Delta\Delta S^h$ are listed in the fourth, fifth, and sixth columns, respectively, of Table 5. They show that $\Delta H^\bullet$ and $\Delta S^\bullet$ are dominated by the contributions due to H-bond reorganization in both 7 M urea and 4.9 M GuHCl: $\Delta\Delta H^h > |\Delta E_a|$ and $\Delta\Delta S^h > |\Delta\Delta S_x|$. The reorganization of H-bonds upon solute insertion provides small positive values of ΔH^h and ΔS^h for the solvation of hydrocarbons in water (ref. 14; see also Table 5 of the accompanying paper[1]). The fact that $\Delta\Delta H^h$ and $\Delta\Delta S^h$ are positive for all hydrocarbons implies that ΔH^h and ΔS^h are positive and significantly larger in 7 M urea and 4.9 M GuHCl than in water. The H-bond reorganization upon solute insertion is, therefore, qualitatively similar in the three solvent systems, but it occurs to a far greater extent in the presence of urea or GuHCl. The geometric constraints imposed by the solute molecule on the surrounding solvent molecules should play the dominant role. When the latter are solely water molecules, the so-called straddling mechanism is able to minimize the waste of H-bonds (53); water molecules straddle the nonpolar solute by pointing in two or three tetrahedral directions tangential to the surface of the occupied volume. When there are also urea molecules or GuH^+ and Cl^- ions, the straddling mechanism is operative but cannot be as effective as in pure water because of geometric and energetic reasons. The planar structure of urea and GuH^+, and the presence of charges in the latter, affect the local configurations of water molecules.

These pictures of H-bond reorganization conflict with the iceberg or clathrate formation proposed by Frank and co-workers (54), Kauzmann (55), Nemethy and Scheraga (56), and others (57). They are, however, supported not only by theoretical approaches (13–16) and computer simulations

(58–60), but also by direct structural determinations from neutron scattering (61) and X-ray absorption spectroscopy measurements (62).

Temperature dependence of hydrocarbon solubility

We consider that the ΔE_a estimates are temperature independent in the range of 5–45°C, because the strength of the van der Waals interactions depends little on temperature when the solvent density does not markedly change (14, 63). This is the case for water, 7 M urea, and 4.9 M GuHCl, as indicated by the density values reported in Table 3. On the other hand, $\Delta\Delta G_c$ decreases with temperature (see the third column of Tables 6 and 7); this is the fundamental point. For instance, in the range of 5–45°C, $\Delta\Delta G_c$ (in kJ mol^{-1}) decreases (*i*) for methane, from 3.3 to 2.7 in 7 M urea, and from 2.1 to 1.7 in 4.9 M GuHCl; (*ii*) for isobutane, from 6.5 to 5.2 in 7 M urea, and from 4.1 to 3.0 in 4.9 M GuHCl; (*iii*) for neopentane, from 7.2 to 5.8 in 7 M urea, and from 4.5 to 3.3 in 4.9 M GuHCl. The calculated values of $\Delta\Delta G_c + \Delta E_a$ for both transfer processes are listed in the fourth column of Tables 6 and 7; they prove to be in satisfactory agreement with the experimental $\Delta G^{\bullet}$ data.

The temperature dependence of $\Delta G^{\bullet}$ is, therefore, due to the behavioral differences during cavity creation in water, 7 M urea, and 4.9 M GuHCl. The values reported in Table 4 indicate that ΔG_c increases with temperature in all three solvent systems, but the increase is larger in water than in 7 M urea and 4.9 M GuHCl. SPT indicates that ΔG_c depends on the hard-sphere diameter of solvent molecules and on the solvent-packing density. For all three solvent systems, the hard-sphere diameter is considered constant in the range of 5–45°C. Thus, the different temperature dependence of ΔG_c is because the solvent-packing density decreases a little more rapidly in 7 M urea and 4.9 M GuHCl than in water. In the range of 5–45°C, $\xi(H_2O)$ passes from 0.364 to 0.360, while ξ(7 M urea) passes from 0.427 to 0.416, and ξ(4.9 M GuHCl) passes from 0.427 to 0.418. In fact, in the temperature range considered, the densities of liquid water, 7 M aqueous urea, and 4.9 M GuHCl decrease by 1, 2, and 1.7%, respectively (see Table 3). In any case, a more fundamental discussion of ΔG_c is needed.

According to a general theorem of statistical mechanics (64), the work to create, in a solvent, a cavity suitable to host a given solute molecule is a measure of the probability that the requested region is devoid of solvent molecules (17). In other words, ΔG_c is related to the solvent density and can be directly computed from the density fluctuations of the pure solvent using computer simulations, i.e., by observing naturally occurring cavities in the pure liquid (65, 66). Specifically, ΔG_c is given by

$$[11] \quad \Delta G_c = -RT \ln P_0(\sigma) = -RT \ln [V_{avail}(\sigma)/V_{tot}]$$

where $P_0(\sigma)$ is the probability that a spherical region of diameter σ, centered at an arbitrary position, is not occupied by solvent molecules, and $P_0(\sigma)$ corresponds to the ratio of

the volume available to insert such a cavity ($V_{avail}(\sigma)$) over the total volume of the system (V_{tot}). (Remember that the location of the cavity has to be fixed, but arbitrarily in the liquid volume because the liquid density is uniform at equilibrium.) Equation [11] is easily transformed to

$$[12] \quad \Delta G_c = -RT \ln [V_{empty}/V_{tot}] - RT \ln [V_{avail}(\sigma)/V_{empty}]$$

where V_{empty} is the empty space of the system. It is worth noting that V_{avail} is a function of σ, whereas both V_{tot} and V_{empty} do not depend on the cavity size. Equation [12] is important because it clarifies the difference between V_{empty} and V_{avail}. Even though the empty space in a typical liquid is large (i.e., 50–60% of the total volume), the actual volume available for the insertion of a molecular-sized cavity is many orders of magnitude smaller because the non-overlap condition has to be satisfied (i.e., the excluded volume effect produced by the finite size of the impenetrable cores of molecules). In fact, if the empty volume is not partitioned to provide cavities whose size is at least equal to σ, such an empty volume proves to be not available, as if it were occupied by solvent molecules.

This means that the distribution of empty space in a liquid is a fundamental issue. In view of the pivotal role played by packing effects in liquids (67), it can be argued that the empty space is partitioned in smaller pieces in a liquid constituted by small molecules than in a liquid constituted by large molecules (14). In other words, the size of solvent molecules defines the length scale of the system. The results of computer simulations by Pratt and Pohorille (68) on a series of model liquids quantitatively confirmed these expectations. Clearly, $P_0(\sigma)$, being a probability, is always smaller than one, going asymptotically to zero on increasing the cavity size. Correspondingly, ΔG_c proves to be very sensitive to this near-zero $P_0(\sigma)$, i.e., it is strongly dependent upon the size of solvent molecules and the solvent packing density. This reasoning has a general validity because eqs. [11] and [12] are exact, and it also explains why ΔG_c is so sensitive to liquid-density changes (69). In conclusion, the magnitude of ΔG_c is solely determined by pure-solvent properties. The solute molecule plays no role, except for the definition of the cavity size needed to host it.

On the other hand, detailed computer simulations have pointed out that, when the solvent density and molecular size are fixed, ΔG_c does not depend upon the nature of the interactions acting among solvent molecules, i.e., H-bonds or van der Waals interactions (58, 70). Such intermolecular interactions, however, are responsible for the actual density of the pure liquid solvent and its temperature dependence. In fact, the density of liquid water changes very little over the range of 0–100°C (4) due to the strength of H-bonds with respect to thermal energy. On the other hand, the density of common organic solvents changes significantly with temperature (71) due to the weakness of van der Waals interactions. As a consequence, the intermolecular interactions affect ΔG_c indirectly by determining the density of the pure liquid at each temperature.

© 2002 NRC Canada

Equation [11] also provides a general explanation for the temperature dependence of ΔG_c. The latter is given by the product of two terms: (*i*) the R*T* term accounts for the thermal energy of the solvent molecules bombarding the cavity surface and increases linearly with temperature; and (*ii*) the logarithmic term depends on liquid density and decreases with temperature, since the density of all liquids diminishes on increasing temperature. The first term prevails for water and aqueous solutions; the second term prevails for common organic solvents (14, 15).

Finally, it is clear that ΔG_c depends upon the physical and structural features of solvent molecules, but it is absolutely not affected by the reorganization of solvent molecules upon solute insertion. All of the above reasoning clarifies why SPT works well: (*i*) it was exactly aimed to evaluate $P_0(\sigma)$, using geometric and statistical arguments, and provided a physically consistent expression for ΔG_c (22); and (*ii*) the experimental values of the solvent density and molecular sizes are used as input parameters in calculating ΔG_c (23).

We can now return to the different temperature dependencies of ΔG_c in water, 7 M aqueous urea, and 4.9 M aqueous GuHCl. The density of 7 M urea and 4.9 M GuHCl solutions decreases with temperature a little more rapidly than that of water because the geometric constraints due to the planarity of urea molecules and guanidinium ions cause a distortion of surrounding H-bonds on increasing the random thermal energy. This does not, however, imply that urea and GuHCl are water-structure breakers, because the differences in the temperature dependence of liquid density and hydrocarbon solubility are small between water, 7 M urea, and 4.9 M GuHCl. In this regard, it should be recognized that 7 M aqueous urea is 38% urea by weight (36) and 4.9 M aqueous GuHCl is 42% GuHCl by weight (39).

Discussion

It should be emphasized that a change in a thermodynamic function, being a macroscopic quantity, cannot provide any microscopic information. The overall process has to be dissected in subprocesses, each having a well-defined physical meaning and a rigorous statistical mechanical description, to try to obtain a molecular interpretation. This is the approach adopted in the present study. To further emphasize the situation, we point out that the values of $\Delta G^\bullet$, $\Delta H^\bullet$, and $\Delta S^\bullet$ collected in Tables 1 and 2 provide no information on their molecular origin. One could say that both transfer processes are contrasted by enthalpic effects because they are endothermic and are favored by entropic effects because they cause an entropy increase. But such a statement does not clarify anything and would be, to say the least, misleading. In contrast, the performed analysis, based on rigorous statistical mechanical theories of hydrophobic hydration (13–15), clarifies the molecular processes involved and how they give rise to the overall experimentally measured thermodynamic changes. The results obtained seem reliable and allow one to rationalize an important question.

In this respect, it is worth noting that a similar rationalization was provided by Roseman and Jencks (72), albeit in a qualitative fashion (i.e., no calculations were performed). They hypothesized that the increased solubility of large hydrocarbons is due to a more favorable sum of the work of cavity creation and van der Waals interaction energy in the presence of GuHCl and urea, compared with pure water. Furthermore, in the case of polar solutes, Roseman and Jencks (72) suggested that the contribution due to the formation of multiple H-bonds by GuHCl and urea, in addition to the first two always operative, renders even more negative the transfer-Gibbs energy change. In fact, Nandi and Robinson (7) determined $\Delta G^\bullet$ = –0.5 and –0.9 kJ mol^{-1}, respectively, for the transfer from water to 7 M urea and to 5 M GuHCl, at 25°C, of the CH_2CONH group (it contains one more hydrogen atom than the repeating unit of protein backbone). These numbers are significantly larger in magnitude than those obtained for aliphatic side chains (see Tables 1 and 2), suggesting that the interactions of urea and GuHCl with the peptide group are responsible for their denaturing action.

Clearly, the use of the SPT-valid equation to calculate ΔG_c in pure liquids for aqueous solutions of GuHCl and urea may be seriously questioned. This important topic has been discussed in detail in the work on alkane solubility in 7 M aqueous urea at room temperature (12). Here we add only the following points. The SPT equation is used solely to obtain estimates of ΔG_c, which is a measure of the excluded volume effect caused by solute insertion into the solvent. If we assumed, more correctly, that 7 M urea and 4.9 M GuHCl are mixtures, we could use the SPT-valid relation for mixtures to calculate ΔG_c (73). The results would be quantitatively, but not qualitatively, different. The work of cavity creation is always larger in 7 M urea and 4.9 M GuHCl than in water (data not shown). The simple approach is preferred when considering 7 M aqueous urea and 4.9 M aqueous GuHCl as uniform solvent systems to render a more clear analysis and interpretation of the calculations. Clearly, such an approach does not allow the calculation of the squeezing force exerted by whatever surrounding solvent molecules on the cavity surface (68), nor the single contributions from water, urea, and GuH^+ and Cl^- ions. To perform this type of analysis, computer simulations have to be carried out. We believe, however, that our procedure provides qualitatively correct ΔG_c estimates (for more on this point, see Appendix 2).

In conclusion, in the whole range of 5–45°C, the transfer of hydrocarbons from water to 7 M urea or to 4.9 M GuHCl is contrasted by the difference in the work of cavity creation (i.e., the $\Delta\Delta G_c$ term), but is favored by the difference in the solute–solvent van der Waals interaction energy (i.e., the ΔE_a term). The latter contribution increases in magnitude with hydrocarbon size more rapidly than the first one, accounting for the occurrence of a threshold size for the solubility enhancement at room temperature. The H-bond reorganization upon solute insertion is a compensating process in all three solvent systems and does not affect the transfer-Gibbs energy change. Moreover, on raising the temperature, the hydrocarbon solubility in 7 M urea or 4.9 M GuHCl increases compared with that in water because the $\Delta\Delta G_c$ term becomes less unfavorable, while the ΔE_a term is practically constant. The temperature dependence of $\Delta\Delta G_c$ reflects the fact that the density of 7 M urea and that of 4.9 M GuHCl decrease a little more rapidly than the density of liquid water.

The analysis performed appears to be in accordance with Occam's razor: the fewest possible assumptions should be made in explaining a thing because the simplest explanation is usually the correct one.

Appendix 1. Solvation thermodynamics in water–ethanol and water–*p*-dioxane mixtures

We would like to apply the same approach to the analysis of $\Delta G^{\bullet}$ data for the solvation of methane in water–ethanol and water–*p*-dioxane mixtures at 25°C. The experimental data, which come from the works of Yaacobi and Ben-Naim (75, 76), covers all the composition range from pure water to pure ethanol and from pure water to pure *p*-dioxane, and are reported in the fifth column of Tables 1A and 2A, respectively. We also point out that the solvation thermodynamics of ethane in such mixtures were determined and proved to be similar in all respects to those of methane (75, 76). For this reason the data for ethane are not analyzed here.

For each mixture, we have calculated the mean value of σ, v, and ξ using eqs. [7] and [8] and data for pure liquids (i.e., the molar volumes have been used in view of the qualitative purpose of this Appendix). Such estimates are listed in the second, third, and fourth columns of Tables 1A and 2A. The values of ΔG_c are calculated using the SPT relationship valid for pure liquids (eq. [22] of the accompanying paper[1]), with σ = 3.70 Å for methane. They are listed in column six of Tables 1A and 2A. The values of E_a are determined using the hybrid procedure, performing the difference $\Delta G^{\bullet} - \Delta G_c$, and they are listed in column seven of Tables 1A and 2A. It is evident that both ΔG_c and E_a show a non-monotonous trend as a function of the molar fraction of either ethanol (x_{EtOH}) or *p*-dioxane ($x_{dioxane}$) in the mixture. The trend of ΔG_c is a consequence of the combined dependence of the ΔG_c magnitude upon the values of σ and ξ of the solvent, as already discused in the text. The trend of E_a parallels that of the mean volume-packing density of the solvent. In water–ethanol mixtures, E_a (in kJ mol^{-1}) decreases, in absolute value, from –12.7 in pure water (ξ = 0.363), to –9.3 at x_{EtOH} = 0.20 (ξ = 0.348), and then increases to –14.0 in pure ethanol (ξ = 0.439). In water–*p*-dioxane mixtures, E_a (in kJ mol^{-1}) decreases, in absolute value, from –12.7 in pure water (ξ = 0.363), to –8.1 at $x_{dioxane}$ = 0.20 (ξ = 0.343), and then increases to –17.5 in pure p-dioxane (ξ = 0.538).

Even though this finding confirms the qualitative correctness of eq. [10], the latter does not work quantitatively well, as can be easily verified. This is due to the fact that E_a depends also upon the number of solvent molecules in contact with the solute surface, the so-called contact density. We suggest, therefore, that water molecules preferentially interact with ethanol and *p*-dioxane molecules to form H-bonds, and this causes a decrease in the number of solvent molecules in contact with the surface of the methane molecule. In other words, a preferential desolvation of the solute surface should happen, and it appears to occur to a greater extent when the molar fraction of both ethanol and *p*-dioxane is around 0.2. Clearly, this suggestion should be tested by means of detailed computer simulations, determining the pair correlation function between the solute and solvent molecules.

Appendix 2. Work of cavity creation in aqueous salt solutions

We would like to further test the reliability of using the SPT-valid relationship for pure liquids (eq. [22] of the accompanying paper[1]) to calculate ΔG_c in aqueous salt solutions. To this end, we take advantage of the results reported by Garde and co-workers (77). The authors calculated ΔG_c estimates in water and aqueous solutions of three tetramethylammonium salts: TMAF, TMACl, and TMABI (BI stands for big ion). At room temperature, using the test-particle-insertion method coupled with molecular dynamics simulations, Garde and co-workers found that, to create a cavity of 4.0 Å diameter, ΔG_c (in kJ mol^{-1}) = 24.9 in water, 28.7 in 3 M TMACl, 30.7 in 3 M TMAF, and 23.4 in 3 M TMABI (see Fig. 3 in ref. 77). ΔG_c is, therefore, larger in 3 M TMAF and 3 M TMACl than in water, but smaller in 3 M TMABI than in water. From the numbers reported in Tables 1 and 2 in ref. 77, we have determined, for the three salts, the values of the hard-sphere diameter, the apparent molar volume, and molar fraction in a 3 M aqueous solution. Specifically, (*i*) for TMAF, σ = 6.7 Å, Φ_v = 46.3 cm^3 mol^{-1} and x = 0.05; (*ii*) for TMACl, σ = 8.0 Å, Φ_v = 88.8 cm^3 mol^{-1} and x = 0.07; (*iii*) for TMABI, σ = 9.7 Å, Φ_v = 164.2 cm^3 mol^{-1} and x = 0.10. Then, using eqs. [7] and [8], we have calculated the mean values of σ, v, and ξ for the 3 M aqueous salt solutions; specifically, (*i*) for 3 M TMAF, σ = 2.95 Å, v = 19.5 cm^3 mol^{-1}, and ξ = 0.415; (*ii*) for 3 M TMACl, σ = 3.12 Å, v = 23.0 cm^3 mol^{-1}, and ξ = 0.416;

1.00	5.26	85.35	0.538	2.3	19.8	–17.5

(*iii*) for 3 M TMABI, σ = 3.45 Å, v = 32.6 cm^3 mol^{-1}, and ξ = 0.397. Correspondingly, to create a cavity of 4.0 Å diameter at 25°C, ΔG_c (in kJ mol^{-1}) = 23.9 in water, 26.1 in 3 M TMACl, 28.5 in 3 M TMAF, and 20.0 in 3 M TMABI. Such ΔG_c estimates are in line with the results of Garde and co-workers. The value in water is close to that from computer simulations, whereas those in salt solutions are underestimated by about 2.5 kJ mol^{-1}. This finding emphasizes that our approach, notwithstanding its simplicity, provides reliable ΔG_c numbers also in aqueous salt solutions.

Size dependence of the solubility of nonpolar compounds in different solvents

Giuseppe Graziano

Abstract: At 25°C, plots of the standard Gibbs energy change associated with the solvation of noble gases and aliphatic hydrocarbons vs. the size of the solutes prove to be approximately linear with a negative slope for common organic solvents but not for water. In the latter case, the plot has a characteristic V-shape. The slope is negative for noble gases, methane, and ethane, but is positive for larger alkanes. This means that the solubility of nonpolar solutes increases with solute size in every solvent except water. The solvation thermodynamics of noble gases and aliphatic hydrocarbons in five solvents (water, ethanol, benzene, *c*-hexane, and *n*-hexane) are analyzed in detail by a general theory, which is rederived to avoid risky misunderstandings. The calculations are performed in the same manner for all solvents, using simple formulas where the physical reliability is well established and the results are consistent. The work of cavity creation increases with solute size in every solvent, but to a far greater extent in water. Additionally, the work to turn on the solute–solvent attractive interactions increases in magnitude with solute size in every solvent, but to a lesser extent in water. By combining these two factors a satisfactory explanation for experimental data obtained emerges. The microscopic origins of the difference between water and common organic solvents are discussed.

Key words: solvation, excluded-volume effect, solute–solvent interactions, enthalpy–entropy compensation, molecular size.

Résumé : À 25°C, les courbes reliant le changement d'énergie de Gibbs standard associé à la solvatation de gaz rares et d'hydrocarbures aliphatiques avec la taille des solutés sont approximativement linéaires et la pente est légèrement négative pour les solvants organiques habituels, mais ce n'est pas le cas pour l'eau. Dans ce dernier cas, la courbe présente une forme en V caractéristique: la pente est négative pour les gaz rares, le méthane et l'éthane, mais elle est positive pour les hydrocarbures à plus longue chaîne. Ces observations signifient que la solubilité des solutés non polaires augmente avec la taille du soluté dans tous les solvants, excepté l'eau. Faisant appel à une théorie générale qui a été complètement redérivée pour éviter toute conception erronée, on a analysé en détail les données thermodynamiques pour la solvatation de gaz rares et d'hydrocarbures aliphatiques dans cinq solvants, soit l'eau, l'éthanol, le benzène, l'hexane et le *c*-hexane. Les calculs ont été réalisés de la même manière pour chacun des solvants, en utilisant des formules simples dont la fiabilité est bien établie et qui donnent des résultats cohérents. Le travail de création d'une cavité augmente avec la taille dans chaque solvant, mais cette augmentation est beaucoup plus grande dans l'eau. De plus, l'amplitude du travail nécessaire pour provoquer le développement d'interactions d'attraction soluté–solvant augmente avec la taille du soluté pour chaque solvant, mais elle augmente moins dans l'eau. En combinant ces deux tendances, il se dégage une explication satisfaisante des données expérimentales. On discute des origines microscopiques de la différence entre l'eau et les solvants organiques habituels.

Mots clés : solvatation, effet du volume exclu, interactions soluté–solvant, compensation enthalpie–entropie, taille moléculaire.

[Traduit par la Rédaction]

Introduction

The analysis of the experimental values of the standard Gibbs energy of solvation at 25°C of noble gases and aliphatic hydrocarbons in a variety of solvents pointed out an unexpected situation (1). When the $\Delta G^{\bullet}$ values in a given solvent were plotted against the solute diameter, approximate linear trends were obtained for every solvent studied except water. In the latter case, a straight line was found only for the hydration of noble gases, whereas a V-shape trend was obtained by combining the data for noble gases and aliphatic hydrocarbons (1). A complete explanation of this experimental finding is still lacking, even though a reasonable answer has recently been suggested (2).

It is worth noting that the change in the standard solvation Gibbs energy is defined, according to Ben-Naim (3), as $\Delta G^{\bullet} = RT \ln (C_g/C_l)$, where C_g and C_l are the molar concentrations of the solute in the gas and liquid phases at equilibrium. The $\Delta G^{\bullet}$ values provide a direct measure of the solubility of a solute in a given solvent.

The experimental values of the standard Gibbs energy of solvation at 25°C of noble gases and aliphatic hydrocarbons in five solvents (water, ethanol, benzene, *c*-hexane, and *n*-hexane) are listed in Table 1, and the corresponding standard enthalpy and entropy changes are reported in Tables 2 and 3, respectively (1, 2). Clearly, water as well as polar and nonpolar organic solvents are represented in our selection. Customary values of the hard-sphere diameters of both solvents and solutes are listed in the second column of Table 4 (4, 5). These values serve only to rank order of the relative size of the species considered, and do not imply that the molecules are really spheres.

Plots of $\Delta G^{\bullet}$ vs. σ are shown in Figs. 1–4 for the first four solvents. The plot for water has the characteristic V-shape, whereas the plots for ethanol, benzene, and *c*-hexane show approximately linear trends (*n*-hexane is not shown because it is qualitatively similar). The fundamental point is the sign of the slope of these plots — it is negative in all cases, except for large alkanes in water. This means that, at room temperature, on increasing the solute size, the solubility of both noble gases and alkanes increases in common organic solvents. It also increases for noble gases in water, but not for alkanes in water. This puzzling result is not simple to rationalize since the solvation mechanism of noble gases and aliphatic hydrocarbons in water cannot be different because all these solutes are nonpolar. A reliable explanation of the experimental data by means of a general theory of solvation, originally elaborated by Lee (6) and fruitfully applied by us to explain several aspects of hydrophobic hydration and solvation (7–9), will be provided. First, Lee's theory of solvation (6) will be described, followed by a detailed explanation of the procedures adopted to perform calculations. Finally,

Note: Additional data at 25°C used for SPT calculations are: v = 18.07 cm^3 mol^{-1} (ξ = 0.363) for water; v = 58.68 cm^3 mol^{-1} (ξ = 0.439) for ethanol; v = 89.41 cm^3 mol^{-1} (ξ = 0.513) for benzene; v = 108.75 cm^3 mol^{-1} (ξ = 0.517) for *c*-hexane; v = 131.62 cm^3 mol^{-1} (ξ = 0.497) for *n*-hexane.

the solvation process of noble gases and aliphatic hydrocarbons in the five selected solvents is analyzed and an explanation is suggested.

Theory of solvation

Solvation, as suggested by Ben-Naim (3), refers to the transfer of a solute molecule from a fixed position in the ideal gas phase to a fixed position in a solvent at constant temperature and pressure. The process can be regarded as the insertion of an external perturbing potential ($\Psi(\boldsymbol{X})$), where $\boldsymbol{X}$ is a vector representing a single configuration of the N molecules of the liquid solvent. On the basis of Widom's potential distribution theorem (10), the Ben-Naim standard Gibbs energy change is

$$[1] \qquad \Delta G^\bullet = -RT \ln \langle \exp[-\Psi(\boldsymbol{X})/RT] \rangle_p$$

where the subscript p means that the ensemble average is performed over the pure-solvent configurations, assuming an NPT ensemble. The average is taken using the probability density function of the pure solvent

$$[2] \qquad \rho_p(\boldsymbol{X}) = \frac{\exp[-H(\boldsymbol{X})/RT]}{\int \exp[-H(\boldsymbol{X})/RT]\, d\boldsymbol{X}}$$

where $H(\boldsymbol{X}) = U(\boldsymbol{X}) + PV(\boldsymbol{X})$ is the enthalpy function of a configuration, $U(\boldsymbol{X})$ and $V(\boldsymbol{X})$ are the corresponding internal energy and volume, and the denominator is the isobaric partition function of the system. The fluctuations in the system volume occurring in an NPT ensemble are, therefore, correctly accounted for. It is important to realize that, in performing the ensemble average in eq. [1], one has to consider the configurations of the system before the insertion of the potential, so that the Boltzmann weights in the average do not include $\Psi(\boldsymbol{X})$, which acts as a ghost (10).

Since a liquid is a condensed state of matter, the insertion of a solute molecule requires the exclusion of the solvent molecules from the region of space that will be occupied by the solute. On this basis, simple physical considerations suggest that the perturbing potential has to be factorized in the following manner (6):

$$[3] \qquad \exp\left[\frac{-\Psi(\boldsymbol{X})}{RT}\right] = \zeta(\boldsymbol{X}) \exp\left[\frac{-\psi_a(\boldsymbol{X})}{RT}\right]$$

where $\zeta(\boldsymbol{X})$ can assume only the values of one or zero, depending on whether there is a suitable cavity to host the solute molecule in the given solvent configuration, and $\psi_a(\boldsymbol{X})$ represents the attractive potential between the solute molecule and the surrounding solvent molecules. Insertion of eq. [3] into eq. [1] leads to

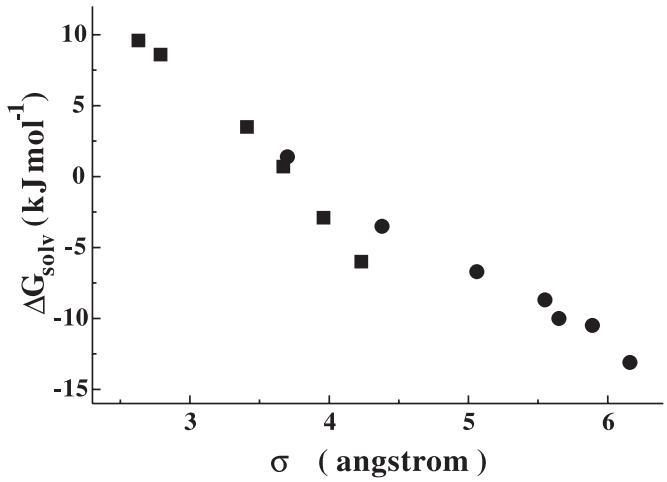

Fig. 4. Experimental Ben-Naim standard Gibbs energy changes associated with the solvation of noble gases (■) and aliphatic hydrocarbons (●) in *c*-hexane at 25°C as a function of the solute's size.

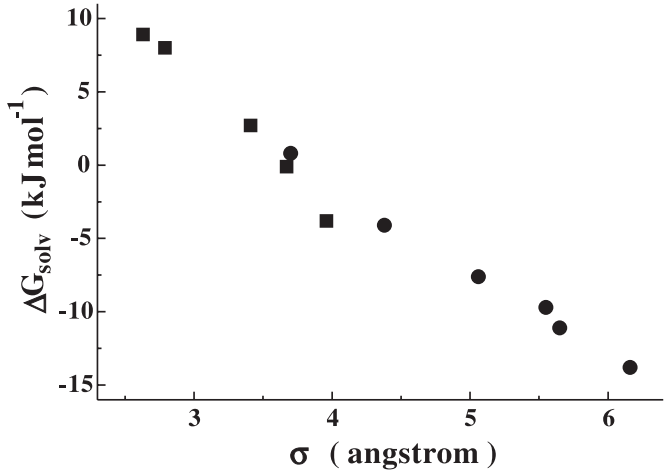

[4] $$\Delta G^{\bullet} = -RT \ln \langle \zeta(\boldsymbol{X}) \rangle_p - RT \ln \left\langle \exp\left[\frac{-\psi_a(\boldsymbol{X})}{RT}\right] \right\rangle_c$$

where the subscript c means that the ensemble average is performed over the solvent configurations possessing a suitable cavity to host the solute whose probability density function is

[5] $$\rho_c(\boldsymbol{X}) = \frac{\zeta(X)\ \exp[-H(\boldsymbol{X})/RT]}{\int \zeta(X)\ \exp[-H(\boldsymbol{X})/RT]d\boldsymbol{X}}$$

Clearly such configurations are only a small fraction of the total solvent configurations (i.e., those for which the function $\zeta(\boldsymbol{X})$ is equal to one). Equation [4] indicates that $\Delta G^{\bullet}$ is the sum of two terms: the work to create the cavity (ΔG_c) and the work to turn on the attractive solute–solvent potential (ΔG_a). The two subprocesses are analyzed in detail below.

Creation of the cavity

The work to create the cavity is given by the following:

[6] $$\Delta G_c = -RT \ln \langle \zeta(\boldsymbol{X}) \rangle_p$$

and corresponds to the work of selecting the configurations containing the cavity from the ensemble of pure-solvent configurations. This is an exact result of statistical mechanics because the ensemble average of $\zeta(\boldsymbol{X})$ corresponds to the probability of finding the desired cavity in the solvent (11, 12). Application of equilibrium thermodynamics leads to the following:

© 2002 NRC Canada

$$[7] \quad \Delta H_c = \langle H(\boldsymbol{X})\rangle_c - \langle H(\boldsymbol{X})\rangle_p$$

$$[8] \quad \Delta S_c = R \ln \langle \zeta(\boldsymbol{X})\rangle_p + (\Delta H_c/T) = \Delta S_x + (\Delta H_c/T)$$

The enthalpy change upon cavity creation is entirely due to solvent reorganization (12, 13), as is the entropy change upon cavity creation. The latter, however, consists of two parts: the first one, on the right-hand side of eq. [8], is due to the selection of the solvent configurations containing the cavity, and the second part is due to the reorganization of solvent molecules around the cavity. The latter contribution perfectly balances the change in enthalpy, so that ΔG_c is entirely entropic, and is due to the excluded-volume effect associated with the reduction in the size of the configuration space accessible to the solvent molecules (8, 14).

$$[9] \quad \Delta G_c = -T\Delta S_x$$

The excluded-volume effect is the entropic part of the perturbing potential.

Turning on the attractive potential

The work to turn on the attractive potential is defined as

$$[10] \quad \Delta G_a = -RT \ln \left\langle \exp\left[\frac{-\psi_a(\boldsymbol{X})}{RT}\right]\right\rangle_c$$

Application of the Gibbs–Helmholtz equation leads to

$$[11] \quad \Delta H_a = \langle \psi_a(\boldsymbol{X})\rangle_s + [\langle H(\boldsymbol{X})\rangle_s - \langle H(\boldsymbol{X})\rangle_c] = \langle \psi_a(\boldsymbol{X})\rangle_s + \Delta H_{ar}$$

where the subscript s means that the ensemble average is performed over the solution configurations whose probability density function is

$$[12] \quad \rho_s(\boldsymbol{X}) = \frac{\zeta(X)\, \exp\{-[\psi_a(\boldsymbol{X}) + H(\boldsymbol{X})]/RT\}}{\int \zeta(X)\, \exp\{-[\psi_a(\boldsymbol{X}) + H(\boldsymbol{X})]/RT\}\, d\boldsymbol{X}}$$

In other words, the solution configurations are the fraction of solvent configurations possessing the cavity occupied by the solute molecule that interacts with the surrounding solvent molecules. According to eq. [11], the enthalpy change consists of two parts: the average solute–solvent interaction energy, and the enthalpic contribution arising from the solvent reorganization upon turning on the attractive potential. The entropy change is

$$[13] \quad \Delta S_a = R \ln \left\langle \exp\left[\frac{-\psi_a(\boldsymbol{X})}{RT}\right]\right\rangle_c + [\langle \psi_a(\boldsymbol{X})\rangle_s/T] + (\Delta H_{ar}/T)$$

Using the inverse relationship demonstrated by Widom (10), eq. [13] becomes

$$[14] \quad \Delta S_a = -R \ln \left\langle \exp\left[\frac{-\psi_a(\boldsymbol{X})}{RT}\right]\right\rangle_s + [\langle \psi_a(\boldsymbol{X})\rangle_s/T] + (\Delta H_{ar}/T)$$

By setting $\kappa = \psi_a(\boldsymbol{X}) - \langle \psi_a(\boldsymbol{X})\rangle_s$, expanding the exponential function in power series, and keeping in mind that $\langle \kappa \rangle_s \equiv 0$, one obtains

$$[15] \quad -R \ln \left\langle \exp\left[\frac{-\psi_a(\boldsymbol{X})}{RT}\right]\right\rangle_s \approx -[\langle \psi_a(\boldsymbol{X})\rangle_s/T] - [\langle \kappa^2 \rangle_s/2RT^2]$$

When the attractive potential $\psi_a(\boldsymbol{X})$ is weak (15), the fluctuations in the value of $\langle \psi_a(\boldsymbol{X})\rangle_s$ are small, and the second term on the right-hand side of eq. [15] can be neglected. Thus

$$[16] \quad \Delta S_a \approx \frac{\Delta H_{ar}}{T}$$

and the solvent reorganization, associated with the process of turning on the attractive potential, is a compensating process. The condition of small fluctuations in the value of $\langle \psi_a(\boldsymbol{X})\rangle_s$ is verified for nonpolar compounds (16, 17), and the Gibbs energy change is simply given by the average solute–solvent interaction energy
