Building upon this research, we have recently turned our focus to the preparation of both linear and macrocyclic bis-(dinitrosyliron) complexes bridged by either one or two bis-(phosphine) ligands, respectively, in the anticipation that these dinuclear species may exhibit interesting and unusual properties related to the proximal nature of the two metal fragments (13). The pioneering work of Cowie and co-workers (14), Puddephatt and co-workers (15), and others demonstrates the reactivity advantages that can be brought about by connecting late metal fragments with bridging bis(phosphine) ligands such as DPPM (DPPM = bis(diphenylphosphino)methane). Moreover, Hong and co-workers have shown that dinuclear Group

10 complexes of the type cyclo[M(κ^2-DPPM)]$_2$(μ-DPPA)$_2$ (DPPA = bis(diphenylphosphino)acetylene) exhibit interesting photoluminescent behavior (16). Despite the well-established history of dinuclear bis(phosphine) complexes in the field of inorganic chemistry, bis(dinitrosyliron) derivatives of this class are still rare, and their reactivity properties remain essentially unexplored (17).

Herein we report the synthesis and structural characterization of bis(dinitrosyliron) complexes spanned by a structurally diverse series of bis(phosphine) ligands, including: (*a*) DPPM; (*b*) DPPH (DPPH = 1,6-bis(diphenylphosphino)hexane); (*c*) DPPA; and (*d*) DPPB (DPPB = 1,4-bis-(diphenylphosphino)benzene). Depending on the reaction conditions employed, either linear diiron constructs connected by one bis(phosphine) linker, (NO)$_2$FeP~PFe(NO)$_2$ (**A**), or macrocyclic species spanned by two bridging ligands, [(NO)$_2$Fe]$_2$(P~P)$_2$ (**B**), are obtained.

Results and discussion

The mononuclear complex, **3**, and the linear diiron species, **4–7**, were readily prepared from Fe(NO)$_2$(CO)$_2$ via addition of the desired bis(phosphine), as depicted in Scheme 2. For compounds **3–5**, these could then be converted into the corresponding cyclic compounds **8** (from either **3** or **4**) and **9** (from **5**) (Scheme 3). Compounds **3–9** are air sensitive and undergo complete decomposition after several hours. Decomposition also occurs (albeit more slowly) when these complexes are stored either in degassed solvents or as pure solids under dinitrogen at ambient temperature. Interestingly, Braunstein et al. have previously observed the formation of both **3** and **8** as side products in the process of preparing Pt–Fe clusters (18), while Atkinson et al., in examining the reaction between [Fe$_2$(μ-I)$_2$(NO)$_4$] and DPPM, were able to isolate compound **8** as the corresponding tetrahydrofuran-solvated complex (19). However, in both cases no X-ray crystallographic structural data were provided.

The conversion of Fe(NO)$_2$(CO)$_2$ into compounds **3–7** and subsequently into **8** or **9** is readily monitored by use of infrared spectroscopy; selected FT-IR data are listed in Table 1. The decrease in stretching frequencies observed for the car-

bonyl and the two nitrosyl ligands in **3–7** relative to Fe(NO)$_2$(CO)$_2$ is characteristic of phosphine-substituted dinitrosyliron complexes (9). In turn, the nitrosyl stretching frequencies observed for both **8** and **9** appear at an even lower wavenumber. The macrocyclic DPPM-supported complex, **8**, exhibits four distinct IR absorptions (1733, 1721, 1687, and 1668 cm^{-1}) in the solid and in solution (spectra obtained from samples dissolved in CH$_2$Cl$_2$ match previously reported values (19)), possibly arising from the interaction of the Fe(NO)$_2$ centers, as has been observed in other cyclic systems (19, 20). This phenomenon appears to depend on ring size, as the related ten-membered ring compound, **9**, displays only two nitrosyl stretching signals (1723 and 1679 cm^{-1}) in both the solid and liquid states. Based on the observed IR frequencies, the nitrosyl groups are best described as linear, donating NO$^+$ fragments (vide infra) (21, 22). The formation of **3–9** was also followed by use of NMR spectroscopy, and each of the dinuclear compounds (**4–9**) exhibit a single ^{31}P NMR resonance in the range of 33–57 ppm, consistent with a disubstituted bis(phosphine) complex.
In an attempt to evaluate how altering the characteristics of the bridging bis(phosphine) ligand impacts the structural topology of these linear and macrocyclic bis(dinitrosyliron) complexes, an X-ray crystallographic study of compounds **4**, **5**, **8**, and **9** was conducted. Crystallographic collection and refinement parameters and selected metrical parameters ap-

pear in Tables 2 and 3, respectively. Thermal ellipsoid plots of the refined molecular structures of the DPPM compounds, **4** and **8**, and the DPPA compounds, **5** and **9**, appear in Figs. 1 to 4, respectively.

The iron centers in all four of the crystallographically characterized compounds possess distorted tetrahedral geometries, a structural feature that is common to dinitrosyliron complexes (12, 22). The iron—iron distances in both the linear (**4**, ~5.2 Å; **5**, ~7.6 Å) and macrocyclic (**8**, ~4.4 Å; **9**, ~7.0 Å) compounds are all significantly longer than the

related distances found in other structurally characterized bis(dinitrosyliron) species described as possessing a metal—metal bond (23). The crystallographically determined structures of the linear species, **4** and **5**, can be compared with that of [Fe(NO)$_2$Cl]$_2$(μ-DPPE) (DPPE = 1,2-bis(diphenylphosphino)ethane), where DPPE stands as a single bridge joining the two metal centers (17).

Despite the range in N-Fe-N angles (115.6(4)° to 126.5(4)°), all eight of the Fe(NO)$_2$ units in compounds **4**, **5**, **8**, and **9** exhibit "attracto" conformations (N-Fe-N > O-Fe-

*Nitrosyl oxygen atoms.

O) (24–26). The observation of contracted Fe—N distances (~1.64 to ~1.73 Å) and lengthened N—O bonds (~1.16 to ~1.20 Å) in these complexes indicates significant iron–nitrosyl multiple bond character, arising owing to appreciable back-donation from the iron fragment into the π*-orbital on the nitrosyl ligand (22). By comparison, Ray et al. reported crystallographic data for a series of trigonal bipyramidal iron nitrosyl complexes, in which the Fe—N(O) and N—O distances are in the range of ~1.73–1.75 Å and ~1.12–1.15 Å, respectively (27). These X-ray structural data, in addition to the observation of nearly linear Fe-N-O linkages, corroborate the IR spectroscopic results and suggest that the NO units in **4**, **5**, **8**, and **9** function as three-electron donors.

Compounds **5** and **9** represent the first examples of crystallographically characterized species containing the Fe-(NO)₂(μ-DPPA) fragment, and as such are worthy of further commentary. The "*anti*" orientation of the Fe(NO)₂ groups, coupled with the presence of a crystallographic inversion center, results in an interesting solid-state molecular geometry for the linear bis(dinitrosyliron) species, **5**, in which ten of the non-hydrogen atoms (O(1), N(2), Fe(1), P(1), C(1), C(1A), P(1A), Fe(1A), N(2A), and O(1A)) are essentially coplanar (mean deviation from the plane ~0.32 Å). The non-linear nature of the P-C≡C fragment in **5** (P(1)-C(1)-C(1A) 172.9(8)°) parallels other crystallographically characterized compounds of the type L_nM-DPPA-ML_n (28–34) and presumably arises because of steric congestion in the vicinity of the triple bond. Interestingly, such steric demands do not result in a lengthening of the alkyne bonds in either **5** (1.21(1) Å) or **9** (C(1)-C(2) 1.198(4) Å; C(3)-C(4) 1.20(1) Å), which remain essentially unchanged relative to free DPPA (35).

The overall molecular structure of the macrocyclic DPPA compound, **9**, can be described as a severely twisted ten-membered ring, a geometry that is similar to Mo₂(μ-DPPA)₂(CO)₈ (36), but different from the nearly planar structure found for PdPtCl₄(μ-DPPA)₂ (37). The puckering of the ring framework in **9** gives rise to a "bow-tie" orientation of the alkyne units, in which these fragments are twisted by approximately 49° with respect to one another (Fig. 5). As was observed for **5**, the two P-C≡C-P units in **9** exhibit concave bowing; however, one P-C≡C-P fragment is only slightly bent (P(3)-C(3)-C(4) 173.9(9)°; P(4)-C(4)-C(3) 175.5(9)°), while the other exhibits more pronounced asymmetric bending (P(1)-C(1)-C(2) 170.8(9)°; P(2)-C(2)-C(1) 165.8(9)°). Upon viewing the structure of **9** down the Fe–Fe vector, it is evident that the DPPA ligands can be loosely classified as "staggered" (P(1)-C(1)-C(2)-P(2)) and "eclipsed" (P(3)-C(3)-C(4)-P(4)), with the former experiencing greater strain and subsequently more pronounced deviation from linearity than the latter. It is interesting to note that although Mo₂(μ-DPPA)₂(CO)₈ possesses similarly "staggered" and "eclipsed" DPPA ligands (36), a correlation between the degree of nonlinearity of the DPPA ligands and their relative orientation does not exist in this Mo-based system.

Experimental

General

All manipulations were carried out in an atmosphere of dry dinitrogen using freshly distilled and degassed solvents. Unless otherwise stated, all chemicals, including bis(diphenylphosphino)methane (DPPM, Aldrich), 1,6-bis-(diphenylphosphino)hexane (DPPH, Aldrich), bis(diphenylphosphino)acetylene (DPPA, Strem Chemicals), and 1,4-bis(diphenylphosphino)benzene (DPPB, Organometallics Inc.) were used as supplied. Fe(NO)₂(CO)₂ was prepared following a published procedure (38). The ¹H, ¹³C, and ³¹P NMR spectral data were acquired using either a Bruker AC-200 or AC-300 spectrometer in deuterated chloroform, unless otherwise stated. All ¹³C and ³¹P NMR spectra were recorded in proton-decoupled mode with phosphorus chem-

Fig. 1. The X-ray structure of **4**, showing the atomic numbering scheme. Anisotropic thermal displacement ellipsoids are shown at the 30% probability level.

Fig. 3. The X-ray structure of **5**, showing the atomic numbering scheme. Anisotropic thermal displacement ellipsoids are shown at the 30% probability level.

ical shifts externally referenced relative to 85% H_3PO_4 in D_2O. Melting and decomposition points were measured using differential scanning calorimetry performed on a DSC 2910 instrument (TA instruments). IR spectra were recorded on a Bio-Rad FTS-40 single-beam spectrometer using KBr pellets, unless otherwise stated. Mass spectra were recorded on a Micromass Quattro LC instrument using positive electrospray ionization (ESI+). Despite repeated attempts, satisfactory elemental analysis data for the compounds reported herein could not be obtained.

X-Ray crystallography

Crystallographic data for **4**, **5**, **8**, and **9·CH₂Cl₂** were collected from suitable samples mounted on glass fibers. The instrument used for the collection of diffraction data was a Siemens P4 diffractometer equipped with a Siemens SMART 1K CCD Area Detector (using the program SMART) and a rotating anode using graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). Data processing was carried out by use of the program SAINT, while the program SADABS was utilized for the scaling of diffraction data, the application of a decay correction, and an empirical absorption correction based on redundant reflections. Structures were solved by using the direct methods procedure in the Siemens SHELXTL program library and refined by full-matrix least squares methods on F^2. All non-hydrogen atoms, with the exception of the disordered atoms in **9·CH₂Cl₂**, were refined using anisotropic thermal parameters. Hydrogen atoms were added as fixed contributors at calculated positions, with isotropic thermal parameters based on the bonded carbon atom. Compound **5** crystallizes in the space group $P\bar{1}$ with half a molecule per asymmetric unit; the other half of the molecule may be generated by a crystallographic inversion center, resulting in the observation of only one molecule per unit cell ($Z = 1$). Combustion analysis, previously obtained by others (39), for compound **8** (similarly prepared in tetrahydrofuran) suggested the presence of one solvated tetrahydrofuran per molecule of **8** in the crystalline lattice. However, despite the fact that the data readily allow for a complete anisotropic refinement of the target molecule, attempts to resolve atomic positions for the disordered solvate were unsuccessful, leading to rather high values for the residual electron density and the refinement statistics. In the case of **9·CH₂Cl₂**, the final refined structure involved a disordered model in which the phenyl rings containing C(20)–C(25) and C(50)–C(55) could exist in either of two orientations resulting from rotation about the P—C(*ipso*) bond. Based on the observed thermal displacement

Fig. 4. The X-ray structure of **9·CH₂Cl₂**, with thermal displacement ellipsoids shown at the 30% probability level. For clarity, hydrogen atoms and the dichloromethane solvate have been omitted, and only the most highly populated components of the disordered phenyl rings are shown.

Fig. 5. Views of the crystallographically determined structure of **9·CH₂Cl₂**: (*a*) highlighting the "bow-tie" orientation of the alkyne units and (*b*) down the Fe(1)–Fe(2) vector (selected atoms omitted for clarity).
ellipsoids, it was assumed that only these carbon atoms were significantly affected by this disorder process. The occupancies for each of the two orientations were each allowed to be refined as a free variable (final ratio of approximately 55:45 for both of the phenyl units). Moreover, during the refinement of **9·CH₂Cl₂**, a disordered molecule of dichloromethane was located in the asymmetric unit. Given the magnitude, location, and number of electron density difference peaks observed in the region of the solvate, the final refined structure was based on a disordered model that involved two possible orientations generated by rotation about a fixed and non-disordered (fully occupied) central methylene carbon. The occupancies for each of the two orientations were each allowed to be refined as a free variable (final ratio of approximately 90:10). Hydrogen atoms for each unique component of the disordered phenyl and dichloromethane units were added at calculated positions with occupancy factors equal to the occupancy factor of the associated carbon atom. The hydrogen atoms were refined using a riding model with isotropic displacement parameters equal to 1.2 times the equivalent isotropic displacement parameter of the attached carbon (40–43).[3]

General preparation of compounds 3–7

Method (*a*): To an Erlenmeyer flask containing Fe(NO)₂-(CO)₂ was added a suspension of the phosphine ligand in pentane at room temperature. After stirring the solution for 18 h, the precipitate generated was filtered and washed with pentane. Method (*b*): To an Erlenmeyer flask containing the
phosphine ligand in THF was added Fe(NO)₂(CO)₂ at room temperature. After stirring the solution for 18 h, the solvent was removed under reduced pressure and the remaining solid washed with pentane.

General preparation of compounds 8 and 9

Method (*c*): A solution of the reactants was filtered into a sealable tube, degassed by use of freeze-pump-thaw procedures, flame-sealed under vacuum, and subsequently heated to 75°C.

These data can be obtained, free of charge, via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge, U.K.; fax +44 1223 336033; or deposit@ccdc.cam.ac.uk).

[Fe(κ^1-DPPM)(NO)$_2$(CO)] 3

Method (*a*): Fe(NO)$_2$(CO)$_2$ (0.1 mL, 0.9 mmol) and DPPM (170 mg, 0.44 mmol) in pentane (8 mL) produced **3** as bright orange-red powder (70 mg, 30%). Method (*b*): DPPM (170 mg, 0.44 mmol), Fe(NO)$_2$(CO)$_2$ (0.05 mL, 0.45 mmol), and THF (6 mL) produced **3** (160 mg, 69%), m.p. 119°C (with decomposition). IR (KBr) (cm^{-1}) ν: 2014 (CO), 1994 (CO), 1763 (NO), 1720 (shoulder) (NO), 1700 (NO). IR (THF-solution) (cm^{-1}) ν: 2005 (CO), 1761 (NO), 1718 (NO). ^{1}H NMR (200 MHz) δ: 3.21 (d, 2H, $^2J_{HP}$ = 8.7 Hz, CH$_2$), 7.27–7.49 (m, 20H, Ph). ^{13}C NMR (50 MHz) δ: 31.7 (m, CH$_2$), 127.9–137.6 (Ph), 221.3 (s, CO). ^{31}P NMR (121 MHz) δ: –25.0 (d, 1P, $^2J_{PP}$ = 105.6 Hz), 48.0 (d, 1P, $^2J_{PP}$ = 105.6 Hz, P-Fe).

[Fe$_2$(μ-DPPM)(NO)$_4$(CO)$_2$] 4

Method (*a*): Fe(NO)$_2$(CO)$_2$ (0.34 mL, 3.1 mmol) was added to a suspension of DPPM (120 mg, 0.31 mmol) in pentane (10 mL). During the course of the reaction the DPPM dissolved, and a dark red - brown powder precipitated, which was filtered and washed with pentane (190 mg, 92%). Method (*b*): DPPM (500 mg, 1.3 mmol), Fe(NO)$_2$-(CO)$_2$ (0.3 mL, 2.7 mmol), and THF (10 mL) produced **4** (690 mg, 79%), m.p. 144°C (with decomposition). IR (KBr) (cm^{-1}) ν: 2005 (CO), 1760 (NO), 1719 (shoulder) (NO), 1702 (NO). IR (THF-solution) (cm^{-1}) ν: 2004 (CO), 1764 (NO), 1718 (NO). ^{1}H NMR (300 MHz, CD$_2$Cl$_2$) δ: 3.76 (t, 2H, $^2J_{HP}$ = 9.7 Hz, CH$_2$), 7.41–7.44 (m, 20H, Ph). ^{13}C NMR (75 MHz) δ: 32.6 (t, $^1J_{CP}$ = 11.4 Hz, CH$_2$), 129.3 (t, J_{CP} = 5.2 Hz, C$_o$ or C$_m$), 131.1 (s, C$_p$), 132.6 (t, J_{CP} = 6.5 Hz, C$_m$ or C$_o$), 134.3 (t, J_{CP} = 22.2 Hz, C$_i$), 221.1 (s, CO). ^{31}P NMR (121 MHz) δ: 45.6 (s). Single crystals suitable for X-ray diffraction studies were grown from pentane by slow evaporation under an atmosphere of dinitrogen.

[Fe$_2$(μ-DPPA)(NO)$_4$(CO)$_2$] 5

Method (*b*): DPPA (300 mg, 0.76 mmol), Fe(NO)$_2$(CO)$_2$ (0.18 mL, 1.6 mmol), and THF (6 mL) yielded **5** (370 mg, 71%). IR (KBr) (cm^{-1}) ν: 2020 (CO), 2005 (CO), 1716 (NO), 1767 (NO). ^{1}H NMR (300 MHz) δ: 7.43–7.64 (m, 20H, Ph). ^{13}C NMR (50 MHz) δ: 129.1 (d, J_{CP} = 11.5 Hz, C$_o$ or C$_m$), 131.1 (s, C$_p$), 131.8 (d, J_{CP} = 14.4 Hz, C$_m$ or C$_o$), 132.0 (d, J_{CP} = 47.9 Hz, C$_i$), 218.7 (s, C≡O). ^{13}P NMR (121 MHz) δ: 33.1 (s). Single crystals suitable for X-ray diffraction studies were grown from pentane by slow evaporation under an atmosphere of dinitrogen.

[Fe$_2$(μ-DPPH)(NO)$_4$(CO)$_2$] 6

Method (*b*): DPPH (500 mg, 1.2 mmol), Fe(NO)$_2$(CO)$_2$ (0.3 mL, 2.8 mmol), and THF (15 mL) produced **6** (500 mg, 56%). IR (KBr) (cm^{-1}) ν: 1999 (CO), 1755 (NO), 1701 (NO). ^{1}H NMR (200 MHz) δ: 1.0–1.4 (m, 8H, PCH$_2$(C*H*$_2$)$_4$-CH$_2$P), 2.29 (m, 4H, PC*H*$_2$(CH$_2$)$_4$C*H*$_2$P), 7.40–7.42 (m, 20H, Ph). ^{13}C NMR (50 MHz) δ: 24.1 (s, 2 × *C*H$_2$), 30.0 (d, $^1J_{CP}$ = 8.4 Hz, 2 × P*C*H$_2$), 30.5 (s, 2 × *C*H$_2$), 128.7 (d, J_{CP} = 9.5 Hz, C$_o$ or C$_m$), 130.0 (s, C$_p$), 131.8 (d, J_{CP} = 11.8 Hz, C$_m$ or C$_o$), 134.0 (d, J_{CP} = 39.6 Hz, C$_i$), 222.0 (s, CO). ^{31}P NMR (121 MHz) δ: 49.2 (s).

[Fe$_2$(μ-DPPB)(NO)$_4$(CO)$_2$] 7

Method (*b*): DPPB (500 mg, 1.1 mmol), Fe(NO)$_2$(CO)$_2$ (0.27 mL, 2.5 mmol), and THF (25 mL) yielded **7** (760 mg, 94%); m.p. 301°C (with decomposition). IR (KBr pellet) (cm^{-1}) ν: 2009 (CO), 1999 (CO), 1760 (NO), 1707 (NO). ^{1}H NMR (200 MHz) δ: 7.34–7.42 (m, Ph). ^{13}C NMR (50 MHz) δ: 129.0 (d, J_{CP} = 10.8 Hz, C$_o$ or C$_m$ and o-C$_6$H$_4$), 130.8 (s, C$_p$), 132.3 (d, J_{CP} = 24.6 Hz, i-C$_6$H$_4$), 133.2 (d, J_{CP} = 13.6 Hz, C$_m$ or C$_o$), 136.9 (d, J_{CP} = 38.2 Hz, C$_i$), 221.0 (s, CO). ^{31}P NMR (121 MHz) δ: 57.1 (s).

[Fe$_2$(μ-DPPM)$_2$(NO)$_4$] 8

Method (*c*): After stirring DPPM (72 mg, 0.19 mmol) and **4** (125 mg, 0.19 mmol) in THF (6 mL) for 18 h, the solution gradually turned black. After 24 h a red crystalline product (**8**) was isolated by filtration (45 mg, 24%); these crystals were used for X-ray diffraction studies. Alternative route using method (*c*): **3** (150 mg, 0.28 mmol) in THF (5 mL) (35 mg, 13%); m.p. 167°C. IR (KBr) (cm^{-1}) ν: 1733 (NO), 1721 (NO), 1687 (NO), 1668 (NO); the spectrum run in CH$_2$Cl$_2$ matches previously reported values (19). ^{1}H NMR (200 MHz) δ: 3.7 (t, $^2J_{HP}$ = 6.5 Hz, 2 × CH$_2$), 7.5–7.3 (m, Ph, 40H). ^{31}P NMR (121 MHz) δ: 43.5 (s). MS-MS (90:10 CH$_2$Cl$_2$/MeOH, *m/z*, (%)): 1000 ([M]$^+$, 100), 970 ([M – NO]$^+$, 2), 500 ([M/2]$^+$, 45).

[Fe$_2$(μ-DPPA)$_2$(NO)$_4$] 9

Method (*c*): After stirring **5** (100 mg, 1.5 mmol) and DPPA (58 mg, 1.5 mmol) in THF (5 mL) for 18 h, the solution gradually turned black. After 72 h the tube was opened, the solvent removed under reduced pressure, and the remaining brown solid (**9**) washed with pentane (90 mg, 64%). Single crystals suitable for X-ray analysis were grown from CH$_2$Cl$_2$ by slow evaporation of the solvent under an atmosphere of dinitrogen. IR (KBr) (cm^{-1}) ν: 1723 (NO), 1679 (NO). ^{1}H NMR (200 MHz) δ: 7.51–7.09 (m, Ph, 40H). ^{31}P NMR (121 MHz) δ: 38.6 (s).

Summary

The results described herein demonstrate that both linear and macrocyclic organometallic complexes containing a pair of dinitrosyliron fragments spanned by either one or two bis(phosphine) ligands can be selectively prepared from Fe(NO)$_2$(CO)$_2$. The X-ray crystallographic characterization of four members of this series reveals that the choice of bridging bis(phosphine) ligand used in these syntheses has a profound influence on the molecular structure of the resulting diiron framework. This preliminary synthetic and structural investigation provides the groundwork for exploring the chemical, physical, and reactivity properties of this class of molecules. These studies are underway and will be the focus of future reports.

Dimethylplatinum(IV) chemistry: Stannyl, hydride, hydroxide, and aqua complexes

Ernest M. Prokopchuk and Richard J. Puddephatt

Abstract: The dimethylplatinum(II) complex [PtMe$_2$(Me$_3$TACN)] (Me$_3$TACN = 1,4,7-trimethyl-1,4,7-triazacyclononane) reacts easily with Me$_3$SnCl, Me$_2$SnCl$_2$, or HX (X = CF$_3$CO$_2$, CF$_3$SO$_3$, BF$_4$) to give the thermally stable cationic dimethylplatinum(IV) complexes [Pt(SnMe$_3$)Me$_2$(Me$_3$TACN)]$^+$, [Pt(SnMe$_2$Cl)Me$_2$(Me$_3$TACN)]$^+$, or [PtHMe$_2$(Me$_3$TACN)]$^+$. The complexes [PtMe$_2$(Me$_3$TACN)] and [PtHMe$_2$(Me$_3$TACN)]$^+$ are oxidized by moist air to give the hydroxo complex [PtMe$_2$(OH)(Me$_3$TACN)]$^+$, which can then be protonated reversibly to form the aqua complex [PtMe$_2$(OH$_2$)(Me$_3$TACN)]$^{2+}$. The structures of the hydroxo complex [PtMe$_2$(OH)(Me$_3$TACN)]$^+$, as both the BF$_4^-$ or CF$_3$SO$_3^-$ salt, and of the mixed hydroxo, aqua complex [PtMe$_2$(OH)(Me$_3$TACN)][PtMe$_2$(OH$_2$)(Me$_3$TACN)][BF$_4$]$_3$ have been determined and the complexes are shown to display interesting hydrogen bonding.

Key words: platinum, oxidation, organometallic, tin, hydride.

Résumé : Le complexe de diméthylplatine(II) [PtMe$_2$(Me$_3$TACN)] (Me$_3$TACN = 1,4,7-triméthyl-1,4,7-triazacyclo-nonane) réagit facilement avec le Me$_3$SnCl, le Me$_2$SnCl$_2$ ou HX (X = CF$_3$CO$_2$, CF$_3$SO$_3$, BF$_4$) pour conduire à la formation des complexes cationiques thermiquement stables du diméthylplatine(IV) [Pt(Sn(Me$_3$)Me$_2$(Me$_3$TACN)]$^+$, [Pt(Sn(Me$_2$Cl)Me$_2$(Me$_3$TACN)]$^+$ ou [PtHMe$_2$)Me$_2$(Me$_3$TACN)]$^+$. Les complexes [PtMe$_2$(Me$_3$TACN)] et [PtHMe$_2$)Me$_2$-(Me$_3$TACN)]$^+$ sont oxydés à l'air humide et fournissent le complexe hydroxo [PtMe$_2$(OH)(Me$_3$TACN)]$^+$ qui peut ensuite être protoné d'une façon réversible pour former le complexe aqua [PtMe$_2$(OH$_2$)(Me$_3$TACN)]$^{2+}$. On a déterminé les structures des complexes hydroxo [PtMe$_2$(OH)(Me$_3$TACN)]$^+$ sous les formes de sels de BF$_4^-$ ou de CF$_3$SO$_3^-$ et du complexe mixte hydroxo, aqua [PtMe$_2$(OH)(Me$_3$TACN)][PtMe$_2$(OH$_2$)(Me$_3$TACN)][BF$_4$]$_3$ et on a pu montrer que les complexes présentent des liaisons hydrogènes intéressantes.

Mots clés : platine, oxydation, organométallique, étain, hydrure.

[Traduit par la Rédaction]

Introduction

Aryl and alkyl(hydrido)platinum(IV) complexes are believed to be the intermediates in arene and alkane activation by electrophilic organoplatinum(II) complexes (1–6), and their chemistry has been the subject of much research (7–22). Octahedral methyl(hydrido)platinum(IV) complexes are stabilized by the presence of a strongly coordinating ligands that do not allow formation of the five-coordinate intermediate from which the reductive elimination of methane occurs (12, 13, 15, 18*d*). Facially coordinating tridentate ligands are ideal for stabilizing methyl(hydrido)platinum(IV) complexes and some stable examples **A, B** are shown in Chart 1 (12–15). In particular, the simple cyclic ligand 1,4,7-triazacyclononane (TACN) gave the stable cationic dimethyl(hydrido)platinum(IV) complex [PtHMe$_2$(TACN)]$^+$ (**A**) which was slowly oxidized by air to give the hydroxo complex [PtMe$_2$(OH)-

(TACN)]$^+$ (14). The oxidation of methylplatinum(II) complexes or hydrido(methyl)platinum(IV) complexes is of interest because it would be a key step in potential catalytic oxidation of methane to methanol, and there have been several studies of such reactions (14, 19–22). The dimethyl-(peroxo)platinum(IV) complex ([PtMe$_2$(OOH)(Tp*)], Tp* = hydridotris(3,5-dimethylpyrazolyl)borate) is isolated from the reaction of [PtHMe$_2$(Tp*)] (**B**) with oxygen and decomposes only slowly to the hydroxo complex [PtMe$_2$-(OH)(Tp*)] (19). The reaction of [PtMe$_2$(tmeda)] (tmeda = tetramethylethylenediamine) with dioxygen in methanol gives a mixture of [PtMe$_2$(OH)(OMe)(tmeda)] and [PtMe$_2$-(OOH)(OMe)(tmeda)] (20), and several complexes ([PtMe$_2$(OH)(OMe)(NN)]) have been obtained with NN = diimine (20–22).

The work described in this paper involves dimethylplatinum complexes of the ligand 1,4,7-trimethyl-1,4,7-triazacyclononane (Me$_3$TACN), and extends earlier studies using the ligand TACN (14). The ligands are similar but also different in several respects. The NH groups in TACN can cause complications by undergoing H,D-exchange with deuteriated reagents and solvents, while the methyl substituents in Me$_3$TACN are bulkier and more electron-releasing than the hydrogen atoms in TACN thus leading to significantly different steric and electronic effects. In addition to this comparative study, the ability of the ligand Me$_3$TACN to stabilize stannylplatinum(IV) complexes has been investigated. As background, it is noted that the oxidative addition

Chart 1.
of organotin halides to complexes [PtMe$_2$(NN)] (NN = diimine) to give **C** (Chart 1) are easily reversible (23, 24) whereas the reactions with complexes of the type [PtMe$_2$(HBpz$_3$)]$^-$ to give **D** (Chart 1) are irreversible (25).

Results

Preparation of [PtMe$_2$(Me$_3$TACN)]

The synthesis is shown in Scheme 1. The reaction of [Pt$_2$Me$_4$(µ-SMe$_2$)$_2$] with 2 equiv of the ligand Me$_3$TACN in deuterated acetone slowly gave the desired product [PtMe$_2$(Me$_3$TACN)] (**1**). The reaction did not go to completion but gave an equilibrium with some [PtMe$_2$(SMe$_2$)$_2$]. NMR analysis indicated that a typical reaction over 1 day gave about 90% **1** and 10% [PtMe$_2$(SMe$_2$)$_2$] and unreacted ligand. For this reason, complex **1** was normally prepared and used in situ, without isolation. Since **1** is much more reactive towards electrophilic reagents than [PtMe$_2$(SMe$_2$)$_2$], the removal of **1** from the equilibrium mixture led to an equilibrium shift and the subsequent products with Me$_3$TACN ligands were formed in good yield and were not contaminated by dimethylsulfide complex impurities.

Complex **1** was readily identified by its methylplatinum resonance at δ = 0.18, ^2J(PtH) = 90 Hz, in the ^{1}H NMR spectrum, and δ = –22.50, ^1J(PtC) = 869 Hz, in the ^{13}C NMR spectrum. At room temperature, the CH$_2$ and CH$_3$N resonances in the ^{1}H NMR spectrum appeared as broad peaks because of fluxionality involving exchange between free and coordinated N-donors of the ligand. At –50°C, the CH$_2$ resonances appeared as complex, overlapping multiplets in the region δ = 4.61–2.58, while the CH$_3$N resonances were resolved at δ = 2.62, ^3J(PtH) = 22 Hz, and δ = 2.26 in a 2:1 ratio, corresponding to the two coordinated MeN groups and one free MeN group, respectively.

Reactions of complex 1 with organotin halides

The new reactions are shown in Scheme 2. The reactions with Me$_3$SnCl and Me$_2$SnCl$_2$ gave the ionic platinum(IV) complexes [PtMe$_2$(SnMe$_3$)(Me$_3$TACN)]Cl (**2**) and [PtMe$_2$-(SnMe$_2$Cl)(Me$_3$TACN)]Cl (**3**), respectively. Both complexes **2** and **3** are colourless, air-stable solids that were readily characterized by their NMR spectra. For example, complex

Scheme 1.
Scheme 2.
2 gave methylplatinum and methyltin resonances in the ^{1}H NMR at δ = 0.47 (s, 6H, ^2J(PtH) = 59 Hz) and 0.16 (s, 9H, ^2J(SnH) = 45 Hz, ^3J(PtH) = 6 Hz) and in the ^{13}C NMR at δ = –10.11 (^1J(PtC) = 609 Hz, ^2J(SnC) = 36 Hz) and –8.65 (^2J(PtC) = 54 Hz), respectively. The observation of long-range couplings J(SnPtMe) and J(PtSnMe) clearly shows that there is a tin–platinum bond in **2**. There were two MeN resonances in the ^{1}H NMR at δ = 2.87 (^3J(PtH) = 23 Hz, PtNMe *trans* Me) and 2.49 (^3J(PtH) = 14 Hz, PtNMe *trans* Sn) and in the ^{13}C NMR at δ = 52.61 (^2J(PtC) = 15 Hz, PtNMe *trans* to Me) and 45.16 (^2J(PtC) = 10 Hz, PtNMe *trans* to Sn). In both cases the trend in coupling constants reflects the higher *trans*-influence of the stannyl compared to the methyl group. Complex **3** gave similar NMR spectral features as described for complex **2** and details are in the experimental section.

In solution in dichloromethane, there was no evidence for dissociation of the stannyl group and sealed solutions of **2** or **3** were stable for several months, though they did decompose slowly in the presence of air. The complexes thus have comparable properties as the corresponding tripyrazolylborate complexes, and have much higher thermal stability than the complexes with diimine ligands (23–25).

Protonation of complex 1 to give a dimethyl(hydrido)-platinum(IV) complex cation

Complex **1** reacted with acids HX (X = BF$_4$, CF$_3$CO$_2$, CF$_3$SO$_3$) in THF solution to form the corresponding dimethyl-

(hydrido)platinum(IV) complexes [PtHMe$_2$(Me$_3$TACN)]X (**4a–4c**) (Scheme 2). The tetrafluoroborate complex **4a** (X = BF$_4$) precipitated as it was formed, while the other complexes **4b** (X = CF$_3$CO$_2$) and **4c** (X = CF$_3$SO$_3$) were precipitated as colourless solids on addition of pentane. As expected (14), these hydridoplatinum(IV)complexes have high thermal stability, and solid samples or solutions in acetone were stable for at least 2 months at room temperature in the absence of air. Thermogravimetric analysis under nitrogen atmosphere showed that complex **4a**, in the solid state, does not begin to decompose until over 190°C.

The hydride resonance for the cation **4** was observed at δ = –20.99 with ^1J(PtH) = 1406 Hz, and the methylplatinum resonance was present at δ = 0.62 with ^2J(PtH) = 66 Hz, both in the range found for platinum(IV) complexes with hydride and methyl groups *trans* to nitrogen (9–15). The methylamine resonances were at δ = 3.02 (^3J(PtH) = 22 Hz) and 2.63 (^3J(PtH) = 17 Hz), in the expected 2:1 ratio for the methylamine groups *trans* to the methyl and hydride, respectively. It is clear that the ligand is rigidly bound to the platinum centre, that there is no easy ligand exchange, and that hydride has a higher *trans*-influence than methyl in the complex cation **4**.

For a solution of **4a** in acetone-d_6, slow exchange of the hydride ligand by deuteride occurred as monitored by ^{1}H NMR. As the exchange occurred, the hydride resonance of **4** decreased in intensity and a slight isotope effect on the chemical shift led to a new methylplatinum resonance at δ = 0.625, ^2J(PtH) = 66 Hz. However, there was no deuterium incorporation into the methylplatinum groups of **4**, indicating that there is no reversible formation of a methane complex (7, 10, 14–17). The complexes **4** were stable in the presence of excess acid HX, and no deuterium incorporation into the methylplatinum groups was observed with deuterio acids DX. All of these results indicate that the strong *fac*-tridentate coordination of the ligand Me$_3$TACN does not allow easy formation of a five-coordinate intermediate from complex **4** that could lead to either reversible or irreversible reductive elimination of methane. Hence, the hydrido complex cation **4** has good thermal stability and does not give H–D exchange into the methylplatinum groups. It is also noteworthy that the cation **4** is stable in the presence of free acid, while the neutral complex [PtHMe$_2$(Tp*)] (**B**) (Chart 1), which has similar thermal stability to **4** in the solid state (12), is decomposed in the presence of acid. This decomposition involves protonation of one Pt—N bond with partial ligand dissociation, thus allowing reductive elimination of methane (12). The analogous reaction is not observed with the cationic complex **4**, presumably because it is less basic and the Pt—N bonds are not susceptible to electrophilic attack.

Reactions of the complexes 1 and 4 with air

Exposure of a solution of the dimethylplatinum(II) complex **1** to the atmosphere led to rapid oxidation, with formation of the cationic dimethyl(hydroxo)platinum(IV) complex **5** (Scheme 3) as the hydroxide salt. The reaction was complete within minutes at room temperature. The cationic complex **4** reacted more slowly, but reaction was complete within 1 day at room temperature to give the same complex cation **5**, with little dependence on the anion. In the presence of excess acid, the product of air oxidation was the

dicationic aqua complex **6**. In either case, the rate of reaction of **4** with air was not significantly different if carried out in the presence or absence of light and no long-lived intermediates were detected in reactions monitored by ^{1}H NMR. Using pure **4a**, the reaction accelerated with time, but rate data were difficult to reproduce. The product complexes **5** and **6** were easily interconverted by adjusting the solution pH.

Characterization of the hydroxo and aqua complexes 5 and 6

Complexes **5** and **6** had distinct ^{1}H NMR spectra that were essentially independent of the nature of the anion. Thus, the methylplatinum resonance for **5** and **6** was at δ = 1.00 (^2J(PtH) = 68 Hz) and 1.48 (^2J(PtH) = 65 Hz), respectively, and proton exchange between **5** and **6** was slow enough that separate resonances of the two complexes were observed when both were present. The CH$_3$N resonances for **5** appeared in a 2:1 ratio at δ = 2.80 (^3J(PtH) = 12 Hz, *trans* to Me) and 2.86 ppm (^3J(PtH) = 32 Hz, *trans* to OH).

The complex cation [PtMe$_2$(OH)(Me$_3$TACN)]$^+$ (**5**) was structurally characterized as both the tetrafluoroborate and triflate salt, **5a** and **5c**, respectively. Selected bond distances and angles are listed in Table 1. There were two independent but similar molecules of **5c** as shown in Fig. 1. In each case, there is a *fac*-tridentate Me$_3$TACN ligand, two methyl groups, and a hydroxo ligand at the platinum(IV) centre of the cation. The Pt—N distances *trans* to the hydroxo ligand are shorter than those *trans* to methyl (Table 1), reflecting the difference in the *trans*-influence of these ligands. In both molecules, there is hydrogen bonding between the triflate anion and the hydroxo ligand with O(1)···O(5) = 3.18(1) Å and O(2)···O(7A) = 2.99(1) Å.

The structure of the cation [PtMe$_2$(OH)(Me$_3$TACN)]$^+$ in the tetrafluoroborate salt **5a** is very similar to that in **5c** but a more complex form of hydrogen bonding is present (Table 1, Fig. 2). There is a molecule of water of crystallization that is also involved in hydrogen bonding. The hydroxo ligand acts as a hydrogen bond donor to the BF$_4^-$ anion with O(1)···F(1A) = 2.91(1) Å, while the water molecule acts as a

Fig. 1. A view of the structure of complex [PtMe$_2$(OH)(Me$_3$-TACN)]$^+$CF$_3$SO$_3^-$ (**5c**) showing the two independent cations, each hydrogen-bonded to a triflate anion. Hydrogen atoms, except for those involved in the H-bonding, are omitted for clarity.

Fig. 2. A view of the structure of [PtMe$_2$(OH)(Me$_3$TACN)]-$^+$BF$_4^-$·H$_2$O (**5a**) showing part of an infinite helical chain formed by H-bonding. Hydrogen atoms are omitted for clarity.
hydrogen bond donor to both the hydroxo group and the BF$_4^-$ anion with O(10)···O(1) = 2.69(1) Å and O(10)···F(4) = 3.11(1) Å. The O···H···O hydrogen bonding is strong, and we note that the data could be interpreted as involving an aqua complex of platinum(IV) that is hydrogen bonded to a hydroxide ion, though this is considered a less accurate formulation. The same argument has been applied for hydrogen bonding in the complex [PtMe$_2$(OH)(Bpz$_4$)]·H$_2$O in which there is hydrogen bonding between the hydroxo ligand and water of crystallization (13). The Pt—O distance is slightly longer in **5a** than in either molecule of **5c** (Table 1), probably as a result of the stronger hydrogen bonding in **5a**. The hydrogen bonding in **5a** leads to the formation of helical chains with repeating units ···(OH···FBF···HOH)$_n$···, as shown in Fig. 2.

It was not possible to grow single crystals of the aqua complex [PtMe$_2$(OH$_2$)(Me$_3$TACN)]$^{2+}$ (**6**) but crystallization

from a solution of the tetrafluoroborate salt containing both **5a** and **6a** gave a complex formulated as the mixed hydroxo–aqua salt [PtMe$_2$(OH)(Me$_3$TACN)][PtMe$_2$-(OH$_2$)(Me$_3$TACN)][BF$_4$]$_3$ (**7**) in which there is strong hydrogen bonding involving both cations and one anion (Fig. 3). The hydrogen atoms for the hydroxo and aqua ligands were located and refined isotropically and their locations are shown in Fig. 3. The platinum centres have distorted octahedral geometry, with stereochemistry and bond parameters similar to those in the hydroxo complexes **5a** and **5c** (compare Tables 1 and 2). There is very strong hydrogen bonding between the hydroxo and aqua ligands of the two cations with O(1)···O(2) = 2.421(7) Å and weaker hydrogen bonding between the hydroxo ligand and tetrafluoroborate anion with O(1)···F(8A) = 2.806(6) Å (Fig. 3). The assignment of Pt(1)

as the hydroxo complex and Pt(2) as the aqua complex is based only on the difference in the OH distances for the OH···O hydrogen bonded unit (O(2)H(88) = 1.10(9) Å, O(1)H(88) = 1.34(9) Å, O(2)H(88)O(1) = 164(7)°, Fig. 3) and, since the location of hydrogen atoms in the presence of heavy atoms like platinum is always uncertain and the difference in OH distances is less than 3σ of the distances, the opposite assignment cannot be ruled out. Indeed, analysis of the minor differences in Pt—O distances and Pt—N distances *trans* to O suggests the other assignment. In the limit of very strong hydrogen bonding the combined aqua and hydroxide ligands could be considered as symmetrical $[H_3O_2]^-$ bridging between two platinum(IV) centres.

Discussion

The ligand Me$_3$TACN is shown to give particularly stable organoplatinum(IV) complexes, even compared to the similar ligand TACN (14). This is attributed to the greater tendency of the bowl-shaped Me$_3$TACN ligand to act as a facial tridentate ligand than TACN (23, 24), and to the greater electron-releasing properties of the methyl substituents in Me$_3$TACN than the hydrogen substituents in TACN. For bidentate TACN in a square-planar platinum(II) complex, the free nitrogen atom can be accommodated with the nitrogen lone pair away from platinum, but steric effects in bidentate Me$_3$TACN lead to a strong preference for the bowl conformation with the free nitrogen directed towards the platinum atom (26, 27), and the oxidation to platinum(IV) with synchronous formation of *fac*-tridentate Me$_3$TACN is very favorable. Hence, the cationic platinum(IV) complexes [PtMe$_2$-(SnMe$_3$)(Me$_3$TACN)]$^+$, [PtMe$_2$(SnMe$_2$Cl)(Me$_3$TACN)]$^+$, and [PtHMe$_2$(Me$_3$TACN)]$^+$ are all thermally stable complexes. Similarly, the complex [PtMe$_2$(Me$_3$TACN)] (**1**) is more easily oxidized by molecular oxygen than the TACN analog, almost certainly by the same mechanism, as shown in Scheme 4 (14). A related mechanism has been suggested recently for the reaction of [PtMe$_2$(tmeda)] with oxygen in methanol to give [PtMe$_2$(OOH)(OMe)(tmeda)] and [PtMe$_2$-(OH)(OMe)(tmeda)], and in this case the hydroperoxo complex could be isolated from reactions carried out at high dilution (20). No hydroperoxide was detected in the reac-

tions of Scheme 4, so it presumably reacts faster than it is formed under all conditions studied.

The complex cation [PtHMe$_2$(Me$_3$TACN)]$^+$ (**4**) is also somewhat more easily oxidized by O$_2$ than its TACN analog, but the mechanism of reaction is not clear. In neutral solution, oxidation of **4** is complete in 1 day whereas the oxidation of the TACN analog is only about one-third complete in this time (14). It has been shown that oxygen insertion into the Pt—H bond of [PtHMe$_2$(Tp*)] gives [PtMe$_2$(OOH)(Tp*)] by a radical chain mechanism, and that subsequent decomposition gives [PtMe$_2$(OH)(Tp*)] (19). This reaction is greatly accelerated by light whereas the rate of reaction of **4** with O$_2$ was not significantly affected by light, and no hydroperoxide intermediate was detected. An alternate mechanism might involve deprotonation of **4** to give **1**, followed by oxidation as described above (Scheme 5). This is consistent with the observation that oxidation of **4** is faster in neutral than in acid solution. It is also consistent with the observation of increased rate with time since the hydroxo, peroxo, and hydroperoxo complexes **5**, **8**, and **9** (Scheme 5) will all be more basic than **4**. Scheme 5 shows only the proposed deprotonation of **4** by the most basic peroxo complex **8**, but the overall effect should be that the relative concentration of **1b**:**4** should increase as reaction proceeds and so the

Scheme 4.

Scheme 5.
rate should increase. However, one might expect complete inhibition of oxidation under acid conditions if this were the sole mechanism, and this was not observed. It is possible that more than one mechanism might operate under different conditions, with a radical mechanism (19) operating when the catalysis by **1** cannot occur. The hydroxo and aqua complexes form interesting supramolecular structures through hydrogen bonding, as seen in Figs. 1–3. Finally, it is noted that the formation of hydroxo(methyl)platinum(IV) complexes is important for modelling potential intermediates in the formation of methanol from methane and air (2, 10), and that the characterization of the hydroxo and aqua complexes **5a**, **5c**, and **7** adds substantially to the understanding of these potential intermediates (13, 20).

Experimental

NMR spectra were obtained by using a Varian Inova 400 MHz spectrometer. The complex [Pt$_2$Me$_4$(μ-SMe$_2$)$_2$] was prepared according to the literature method (28). Solvents were dried and distilled immediately before use. Except when noted, reactions were carried out under nitrogen atmosphere by using either Schlenk or drybox techniques.

[PtMe$_2$(Me$_3$TACN)] (1)

To a solution of [Pt$_2$Me$_4$(μ-SMe$_2$)$_2$] (20.0 mg, 0.0348 mmol) in acetone-d_6 (0.5 mL) was added Me$_3$TACN (14 μL, 0.0696 mmol). After 20 h, the solution contained the product **1** (ca. 90%) and [PtMe$_2$(SMe$_2$)$_2$] (ca. 10%). For **1**: ^{1}H NMR (acetone-d_6, 20°C) δ: 2.83 (br, 6H, CH$_2$), 2.56 (br, 9H, NCH$_3$), 0.18 (s, 6H, ^2J(PtH) = 90 Hz, PtMe). ^{13}C NMR δ: 57.32 (s, CH$_2$), 46.28 (s, NMe), –22.50 (s, ^1J(PtC) = 869 Hz, PtMe). ^{1}H NMR (–50°C) δ: 4.61 (m, 2H, CH$_2$), 3.39 (m, 4H, CH$_2$), 2.70–2.58 (m, 6H, CH$_2$), 2.62 (s, 6H, ^3J(PtH) = 21 Hz, Pt–NMe), 2.26 (s, 3H, NMe), 0.17 (s, 6H, ^2J(PtH) = 90 Hz, Pt–Me).

For most synthetic reactions, a solution of [Pt$_2$Me$_4$(μ-SMe$_2$)$_2$] (75.0 mg, 0.131 mmol) and Me$_3$TACN (52 μL, 0.262 mmol) in THF (10 mL) was stirred for 20 h to give a solution of **1**. This solution was used in situ in reactions of **1**.
[PtMe$_2$(SnMe$_3$)(Me$_3$TACN)]Cl (2)

A mixture of **1** (0.39 mmol) and Me$_3$SnCl (0.39 mmol) in THF (5 mL) was stirred for 1 h. A white precipitate of the product formed. Pentane (30 mL) was added, the solvent was removed by cannula, and the product was dried under vacuum. Yield: 68%. ^{1}H NMR (CD$_2$Cl$_2$) δ: 3.83 (m, 2H, CH$_2$), 3.67 (m, 4H, CH$_2$), 3.01 (m, 2H, CH$_2$), 2.82 (m, 4H, CH$_2$), 2.87 (s, 6H, ^3J(PtH) = 23 Hz, PtNMe *trans* Me), 2.49 (s, 3H, ^3J(PtH) = 14 Hz, PtNMe *trans* Sn), 0.47 (s, 6H, ^2J(PtH) = 59 Hz, PtMe), 0.16 (s, 9H, ^2J(SnH) = 45 Hz, ^3J(PtH) = 6 Hz, SnMe). ^{13}C NMR δ: 61.56 (s, CH$_2$), 61.28 (s, CH$_2$), 58.22 (s, CH$_2$), 52.61 (s, ^2J(PtC) = 15 Hz, PtNMe *trans* to Me), 45.16 (s, ^2J(PtC) = 10 Hz, PtNMe *trans* to Sn), –8.65 (s, ^2J(PtC) = 54 Hz, SnMe), –10.11 (s, ^1J(PtC) = 609 Hz, ^2J(SnC) = 36 Hz, PtMe). Anal. calcd. for C$_{14}$H$_{36}$ClN$_3$PtSn (%): C 28.23, H 6.09, N 7.05; found: C 27.80, H 6.44, N 7.05.

[PtMe$_2$(SnMe$_2$Cl)(Me$_3$TACN)]Cl (3)

A mixture of **1** (0.38 mmol) and Me$_2$SnCl$_2$ (0.38 mmol) in THF (10 mL) was stirred for 5 h. A white precipitate of the product formed. Pentane (20 mL) was added, the solvent was removed by cannula, and the product was dried under vacuum. Yield: 67%. ^{1}H NMR (CD$_2$Cl$_2$) δ: 3.79 (m, 6H, CH$_2$), 3.45 (m, 2H, CH$_2$), 2.89 (m, 4H, CH$_2$), 3.04 (s, 6H, ^3J(PtH) = 23 Hz, PtNMe *trans* Me), 2.58 (s, 3H, ^3J(PtH) = 19 Hz, PtNMe *trans* Sn), 0.64 (s, 6H, ^2J(SnH) = 47 Hz, SnMe), 0.53 (s, 6H, ^2J(PtH) = 55 Hz, PtMe).^{13}C NMR δ: 61.90 (s, CH$_2$), 61.70 (s, CH$_2$), 59.53 (s, CH$_2$), 52.87 (s, ^2J(PtC) = 15 Hz, PtNMe *trans* to Me), 45.85 (s, ^2J(PtC) = 9 Hz, PtNMe *trans* to Sn), –1.57 (s, ^1J(SnC) = 315 Hz, ^2J(PtC) = 83 Hz, SnMe), –9.27 (s, ^1J(PtC) = 565 Hz, ^2J(SnC) = 49 Hz, PtMe). [PtHMe₂(Me₃TACN)]BF₄ (4a)

To a solution of **1** (0.43 mmol) in THF (10 mL) was added HBF₄ (54% in ether, 60 μL, 0.435 mmol) to give a colourless solution that was stirred for 2 h. Pentane (30 mL) was added, to give a white precipitate. The solvent was removed by cannula and the product was dried under vacuum. Yield: 170 mg, 82%. Decomposition at 193°C. The NMR parameters are as described for the triflate salt. Anal. calcd. for $C_{11}H_{28}BF_4N_3Pt$: C 27.28, H 5.83, N 8.68; found: C 27.09, H 5.98, N 8.63.

[PtMe₂(OH)(Me₃TACN)]CF₃SO₃ (5c)

A solution of [PtHMe₂(Me₃TACN)]CF₃SO₃ (0.045 mmol) in acetone-d_6 (0.5 mL) was exposed to the atmosphere for 24 h, resulting in 97% conversion to **5c**, as monitored by NMR. ¹H NMR (acetone-d_6) δ: 3.48 (m, 2H, CH₂), 3.36 (m, 4H, CH₂), 3.26 (m, 2H, CH₂), 3.19 (m, 4H, CH₂), 2.86 (s, 3H, ³J(PtH) = 32 Hz, NMe *trans* OH), 2.80 (s, 6H, ³J(PtH) = 12 Hz, NMe *trans* Me), 1.00 (s, 6H, ²J(PtH) = 68 Hz, PtMe). ¹³C NMR δ: 64.12 (s, ²J(PtC) = 10 Hz, CH₂), 58.79 (s, CH₂) 57.21 (s, CH₂) 50.82 (s, Pt-NMe *trans* OH), 46.12 (s, Pt-NMe *trans* Me), –1.01 (s, ¹J(PtC) = 665 Hz).

[PtMe₂(OH)(Me₃TACN)]BF₄ (5a)

To a solution of **1** (0.576 mmol) in THF (5 mL) was added H[BF₄] (54% in ether, 79.5 μL, 0.577 mmol) to precipitate **4a**. The mixture was stirred for 30 min, then the nitrogen atmosphere was replaced with air. After 20 h, the solvent was evaporated to give the product **5a** as a white solid that was crystallized from acetone. Yield: 139 mg, 48%. NMR data were identical with those of the triflate analogue. The product analyzed as 0.8[PtMe₂(OH)(Me₃TACN)]BF₄; 0.2[PtMe₂-(OH₂)(Me₃TACN)][BF₄]₂. Anal. calcd. for $C_{11}H_{28.2}B_{1.2}F_{4.8}N_3OPt$ (%): C 25.51, H 5.49, N 8.12; found: C 25.50, H 5.25, N 7.82.

[PtMe₂(OH₂)(Me₃TACN)][CF₃SO₃]₂ (6c)

To a solution of [PtMe₂(Me₃TACN)] (0.07 mmol) in acetone-d_6 (0.5 mL) was added triflic acid (0.14 mmol) to give a solution containing **6c**. ¹H NMR (acetone-d_6) δ: 4.30 (br, 2H, OH₂), 3.8–3.3 (m, br, CH₂), 3.03 (br s, 6H, NMe *trans* to Me), 2.95 (br s, 3H, NMe *trans* to OH₂), 1.48 [s, 6H, ²J(PtH) = 65 Hz, PtMe). On attempted isolation, partial deprotonation to **5c** occurred as determined by NMR analysis.

Structure determinations

Crystals of **5a**, **5c**, and **7** were grown from saturated THF (**5c**), acetone (**5a**), and methanol (**7**) solutions, and were mounted on glass fibres. Data were collected at –73°C by using a Nonius Kappa-CCD diffractometer with COLLECT

software (Nonius B.V., 1998). The unit cell parameters were calculated and refined from the full data set. Crystal cell refinement and data reduction were carried out using DENZO (Nonius B.V., 1998). The data were scaled using SCALEPACK (Nonius B.V., 1998). The crystal data and refinement parameters are listed in Table 3.

The SHELXTL V5.1 suite of programs was used to solve the structures by Patterson methods, followed by successive difference Fouriers. All of the non-hydrogen atoms in all three structures were refined with anisotropic thermal parameters. The hydrogen atom positions were calculated geometrically and were included as riding on their respective carbon atoms, except for H81, H82, and H88 on the hydroxo and aqua ligands in the structure of **7**, which were refined with isotropic thermal parameters. The water molecule in **5a** was modelled as an anisotropic oxygen (no hydrogen atoms added).

Photogeneration of a diene template for surface Diels–Alder reactions: Photoenolization of an *ortho*-methyl-benzophenone-modified Au cluster

Arnold J. Kell, Christopher C. Montcalm, and Mark S. Workentin

Abstract: A series of monolayer-protected clusters (MPCs) modified with a photoreactive [4-(11-mercaptoundecyl)-phenyl](2-methylphenyl)methanone (**1**) moiety have been prepared where **1** is co-absorbed to the MPC surface with dodecanethiol, octadecanethiol, or 11-mercaptoundecanoic acid methyl ester. Upon irradiation the MPC-anchored **1** reacts efficiently through its triplet excited states, yielding 1,4-biradicals that collapse to synthetically useful, long-lived photodienol intermediates, which can be efficiently trapped in Diels–Alder type chemistry by dienophiles — namely, dimethyl acetylenedicarboxylate (DMAD). In all cases the Diels–Alder trapping of the dienol occurred efficiently resulting in >60% conversion to the Diels–Alder adduct. This indicates that the local environment surrounding **1** did not influence its ability to react via the Diels–Alder reaction; however, the reaction could not be taken to completion. The inability to react completely is attributed to **1** binding to distinct sites on the MPC core; there are edge, vertice, and terrace sites. Selective population of these specific sites and the subsequent irradiations show that MPCs with **1** anchored predominantly at edge and vertice sites results in an extent of reaction of 85 ± 3%, whereas selectively populating the terrace sites results in an extent of reaction of 36 ± 2%. These results suggest that **1** anchored to edge and vertice sites is more reactive to the Diels–Alder reaction than that involving terrace sites.

Key words: monolayer protected cluster, site selective reactivity, Diels–Alder, photochemistry.

Resume : On a préparé une série d'agrégats protégés en monocouches (« MPC »), modifiés par une portion photoréactive de [4-(11-mercaptoundécyl)phényl](2-méthylphéyl)méthanone (**1**) cooabsorbée sur la surface des « MPC » avec du dodécanethiol, de l'octadécanethiol ou du 11-mercaptoundécanoate de méthyle. Par irradiation, le composé **1** attaché au « MPC » réagit de façon efficace, par le biais de ses états excités, pour donner des 1,4-biradicaux qui se décomposent en intermédiaires photodiénoliques utiles d'un point de vue synthétique et qui peuvent être piégés d'une façon efficace par des diénophiles tel l'acétylènedicarboxylate de diméthyle (ADCM), dans des réactions de type Diels–Alder. Dans tous les cas, le piégeage de type Diels–Alder du diénol se fait d'une façon efficace conduisant à plus de 60 % de conversion en adduit de Diels–Alder. Ce résultat indique que l'environnement local autour du composé **1** n'influence pas sa facilité à réagir par le biais de la réaction de Diels–Alder; toutefois, il n'a pas été possible d'obtenir une réaction complète. On attribue cette inhabilité du composé **1** à réagir complètement à la nature des sites auxquels il est attaché sur les « MPC » qui comportent des sites en bordures, aux sommets et sur des terrasses. Une population sélective de chacun de ces sites spécifiques suivie d'irradiations montrent que le degré de réaction s'élève à 85 ± 3 % lorsque le composé **1** s'est fixé sur des sites en bordures ou aux sommets des « MPC » mais qu'il n'est que de 36 ± 2 % lorsque le composé **1** s'est fixé sur des sites des terrasses des « MPC ». Ces résultats suggèrent que le composé **1** fixé sur des sites en bordure ou aux sommets sont plus réactifs vis-à-vis de la réaction de Diels–Alder que ceux des terrasses.

Mots clés : agrégat protégé en monocouche, réactivité sélective d'un site, Diels–Alder, photochimie.

[Traduit par la Rédaction]

Introduction

The irradiation of *ortho*-alkylated benzophenones generates synthetically useful *ortho*-quinodimethane enol intermediates (1, 2). This reaction, first described by Yang and Rivas (3), involves an intramolecular γ-hydrogen atom ab-straction from the *ortho*-alkyl substituent by the n,π* excited state of the carbonyl group, which generates a 1,4-biradical that subsequently collapses to the respective *E* and *Z*-dienols (Scheme 1). The lifetime of the *Z*-dienol is very short (0.03–1 μs) whereas that of the *E*-dienol is significantly longer (3 s). The *Z*-dienol has a short lifetime because its orienta-

Scheme 1. The generation of the photodienol and its subsequent Diels–Alder reaction.
tion allows reketonization and re-aromatization to occur easily through a 1,5-hydrogen shift; the reketonization process for the *E*-dienol requires acid or base catalysis. The long-lived *E*-dienol provides an intermediate that can be efficiently trapped by Diels–Alder dienophiles to yield, exclusively, the endo products, with excellent regioselectivity (1, 2). In this report we extend this photoinitiated Diels–Alder reaction to monolayer-protected gold clusters or MPCs. While there are a variety of reported photoinduced reactions on planar metal surfaces (4–15), there are surprisingly few reports of photochemical reactions (16, 17) or photophysical properties (18–20) of organic molecules anchored to MPCs even though these substrates are emerging as important new materials (21, 22). In recent studies we reported the intramolecular Norrish–Yang Type II photoreaction of an aryl ketone in this type of MPC environment (23, 24); those studies illustrated, among other things, that unimolecular carbonyl photoreactions can be efficient in MPCs and can lead to surface modifications. Here we report the photodienolization of an *ortho*-methyl-benzophenone-modified gold MPC and the subsequent trapping of the dienol by a model dienophile (Scheme 1). To the best of our knowledge, this study represents the first example of a bimolecular photochemical reaction on an MPC. Mrksich and co-workers recently reported elegant studies of an electrochemically generated quinone-immobilized dienophile on planar gold using Diels–Alder chemistry and showed that the reaction can be used for selective modification with proteins (25–28).

Little has been done to elucidate the dynamics (29) and reactivity associated with substrates anchored to MPC surfaces, considering that the MPC core is well known to be inhomogeneous (21, 30): there are edge, vertice, and terrace sites on each MPC. These distinct sites may display different reactivity; we have found evidence for this in our earlier studies (23). It is of interest to observe how efficiently a photo-induced bimolecular reaction, such as the Diels–Alder trapping of the *E*-dienol, can occur on the MPC surface and what factors associated with the MPC environment influence

its reactivity. The Diels–Alder reaction between the photodienol and a dienophile is a versatile probe of the MPC environment. This reaction allows for the study of (*i*) the ability of the ketone to be excited to the dienol in the MPC environment, (*ii*) the ability to trap the dienol, and (*iii*) the effects that co-absorbed substrates on the MPC surface have on the ability of the photodienol to react with a dienophile (will the photodienol in the monolayer environment be too sterically hindered to allow the subsequent Diels–Alder reaction?). Additionally, because the MPC core contains a number of distinct sites, selectively populating the different sites with **1** will help elucidate where these bimolecular reactions occur most efficiently on the MPC surface.

To address our interests in MPC reactivity we have prepared a series of MPCs designed to probe a variety of properties within the MPC environment (Fig. 1). A [4-(11-mercaptoundecyl)phenyl](2-methylphenyl)methanone (**1**) (Scheme 2) substrate was "place-exchanged" onto the surface of previously prepared dodecanethiolate (C_{12}MPC), octadecanethiolate (C_{18}MPC), and 11-mercaptoundecanoic acid methyl ester (MeO_2CC_{10}MPC) MPCs. The corresponding MPCs, defined as **1**-C_{12}MPC, **1**-C_{18}MPC, and **1**-MeO_2CC_{10}MPC, respectively, where, for example, **1**-C_{12}MPC represents the place-exchange of **1** onto an original C_{12}MPC, were then irradiated in the presence of a dienophile, namely dimethyl acetylenedicarboxylate (DMAD). The majority of this report makes use of DMAD as the dienophile, but the reaction was also shown to occur efficiently with other dienophiles such as dimethyl fumarate (DMFr) and dimethyl maleate (DMM). The dienophiles were selected because they were symmetric, making product identification more straightforward, and because the solution photochemistry involving *ortho*-methyl benzophenone with these dienophiles is well known to occur efficiently and regioselectively (i.e., where possible, only the endo product is generated) (3, 31–33).

The base MPCs were chosen so that a variety of effects associated with the Diels–Alder reaction between the photodienol and a dienophile could be studied. If we assume that

Scheme 2. The probe molecule incorporated into the MPC.

1
the methylene chains of both **1** and the dilutant chain (or the substrate on the original MPC, namely C_{12}, C_{18}, or MeO_2CC_{10}) pack similarly, then the mixed **1**-C_{12}MPC will allow for the photochemical generation of the dienol directly at the interface. In the case of **1**-C_{18}MPC, the resulting photodienol is expected to be embedded within the monolayer. This is of interest because embedding the dienol may hinder its ability to react with a dienophile. Both of these mixed MPCs bear nonpolar terminal methyl groups on the dilutant chain. Because the terminal groups on MPCs are known to influence some of their physical properties (21) — MPCs containing terminal carboxylic acid groups are soluble in methanol and water, whereas MPCs containing terminal methyl groups are soluble only in nonpolar solvents such as chloroform, dichloromethane, benzene, and hexanes — we were also interested in employing a dilutant chain containing a terminal ester. The terminal ester would serve to change the local polarity at the interface and may allow the polar dienophile to be incorporated into the interface (because both are polar), possibly allowing the Diels–Alder reaction to occur more efficiently. We were also interested in determining if the reactivity of **1** is influenced by its location on the MPC surface. As mentioned earlier, MPCs have distinct sites. Selective population of the different sites of the MPC surface with **1** will allow for the determination of differences in the efficiency of the Diels–Alder reaction when it occurs at edge and vertice sites, as compared with terrace sites. The extent of this bimolecular reaction within the MPC environment will be a valuable tool, employed in determining how steric and environmental effects introduced by the monolayer affect the ability of the dienophile to react with the surface-bound dienol.

Results and discussion

The **1**-MPCs were prepared from a [4-(11-mercaptoundecyl)phenyl](2-methylphenyl)methanone (**1**) precursor (Scheme 2). The synthesis of **1** started from (11-bromoundecyl)benzene, prepared by the addition of phenyl lithium to a large excess of 1,11-dibromoundecane. A Friedel–Crafts acylation reaction between (11-bromoundecyl)benzene generated in the mixture and *o*-toluoyl chloride in the presence of $AlCl_3$ generated 4-(11-bromoundecyl)phenyl(2-methylphenyl)methanone. The bromide was then converted to thiol through the reaction of potassium thioacetate and the hydrolysis of the resulting thioester with ethanolic K_2CO_3. The resulting thiol (**1**) was purified via column chromatography using 3:1 dichloromethane:hexanes as eluant and characterized by ^{1}H NMR, ^{13}C NMR, and IR spectroscopy and mass

spectrometry. Details of the synthetic transformations are provided in the experimental section.

Generally MPCs are prepared by the reduction of hydrogen tetrachloroaurate in the presence of a thiol (34, 35). This protocol is incompatible with **1** because the presence of a reducing agent will convert the carbonyl functionality to an alcohol. So, to prepare the desired **1**-MPC, we employ the place-exchange reaction (36, 37) developed by Murray and co-workers starting from well-defined base MPCs (35). The place-exchange reaction is an equilibrium-based reaction involving the replacement of free thiol from solution onto the MPC surface (36, 37). It is accomplished by stirring an excess of a thiol that is to be exchanged onto the MPC surface in the presence of an already prepared base MPC for 4–5 days. As mentioned earlier, the MPC core consists of different sites. It has been suggested that the place-exchange reaction populates the edge and vertice sites quickly (within 1 h) and population of the terrace occurs over a much longer timescale (36). This means that depending on the timescale of the place-exchange reaction, **1** can populate predominantly the edge and vertice sites (1 h), or all sites (the terrace, edge, and vertice sites) can be populated over much longer exchange times (4–5 days). This is an important property of the place-exchange reaction that was exploited and will be addressed later. The base MPCs were prepared according to procedures outlined by Murray and co-workers, as they are known to produce relatively monodisperse MPCs with a core diameter of 2.0 nm and general stoichiometry of $Au_{314}(X)_{108}$, where there are 314 gold atoms comprising the MPC core and X is the thiolate surrounding the MPC core (35).

Proton NMR spectroscopy was used to determine the purity and the extent of exchange (stoichiometry) of the resulting mixed MPCs (**1**-C_{12}MPC, **1**-C_{18}MPC, and **1**-MeO_2CC_{10}MPC, respectively). The purity of the MPC is judged by the amount of free thiol or disulfide remaining in solution after work-up and isolation of the MPC. Any free thiol or disulfide would appear as sharp resonances in the ^{1}H NMR spectrum. Figures 2*a* and 3*a* are typical ^{1}H NMR spectra, recorded in benzene-d_6, of the **1**-C_{12}MPC and **1**-MeO_2CC_{10}MPC, respectively, isolated after place-exchange; of particular note is the absence of sharp resonances assignable to free thiol (or disulphide in solution). The ^{1}H NMR spectrum of **1**-C_{18}MPC is not shown, but is similar to these (see supplemental information).[2] All of the spectra exhibit distinctive broad resonances (38, 39) at the chemical shifts measured for pure **1** in benzene-d_6 solution, confirming that the place-exchange has occurred. These resonances include those of the aromatic protons on the phenyl rings *ortho* to the carbonyl at 7.85 (2H) and 7.22 (1H) ppm, the protons on the methyl function *ortho* to the carbonyl at 2.29 ppm, and the CH_2 protons of the alkyl spacer α to the benzophenone function at 2.57 ppm (Figs. 2*a* and 3*a*). The remaining methylene protons of the alkyl chain for **1** appear between 1.15 and 1.90 ppm along with those of the dilutant chain, either C_{12}, C_{18}, or MeO_2CC_{10}. The resonance signal at 0.9 ppm in Fig. 2*a* is due to the terminal methyl protons of the remaining dodecanethiolate present on the MPC after the place-

Fig. 1. Cartoon depictions of the various MPCs studied, showing that the photodienol will be (*a*) at the interface, (*b*) embedded within the monolayer, or (*c*) near a more polar co-absorbed substrate.

a   *b*   *c*
Fig. 2. The irradiation of Au$_{314}$(C$_{12}$S)$_{50}$(**1**)$_{58}$ in benzene-d_6 (*) before irradiation (*a*) and after an irradiation period of 80 h in the presence of a 3-times molar excess of DMAD (*b*). The filled arrows indicate the decrease in intensity for the resonances associated with Au$_{314}$(C$_{12}$S)$_{50}$(**1**)$_{58}$ while the hollow arrows indicate an increase in the resonances associated with the product, namely Au$_{314}$(C$_{12}$S)$_{50}$(**1**)$_{26}$(**1**-DMAD)$_{32}$. Note: the DMAD has been washed away before the final ^{1}H NMR spectra was acquired. The ^{1}H NMR spectrum of an authentic sample of the model compound (2-DMAD) in benzene-d_6 is shown in (*c*) (actual molecule pictured).

Fig. 3. The irradiation of Au$_{314}$(MeO$_2$CC$_{10}$S)$_{59}$(**1**)$_{49}$ in benzene-d_6 (*) before irradiation (*a*) and after an irradiation period of ~96 h in the presence of a 3-times molar excess of DMAD (*b*). The filled arrows indicate the decrease in intensity for the resonances associated with Au$_{314}$(MeO$_2$CC$_{10}$S)$_{59}$(**1**)$_{49}$ while the hollow arrows indicate an increase in the resonances associated with the product, namely Au$_{314}$(MeO$_2$CC$_{10}$S)$_{59}$(**1**)$_{15}$(**1**-DMAD)$_{34}$.

exchange reaction (or in the case of **1**-C$_{18}$MPC, the resonance at 0.9 ppm is due to the terminal methyl group of octadecanethiolate). As expected, the resonances associated with the protons α, β, and γ to the thiolate moiety are not observed: because the substrates are anchored to the MPC surface they are unable to rotate freely, and the signal broadens into the baseline. There is some overlap of the broad resonances attributed to the terminal methyl group of the dilutant chain and those of the methylene groups of both **1** and the dilutant chain in the **1**-C$_{12}$ and **1**-C$_{18}$MPCs. This necessitates the use of an I$_2$ decomposition reaction that quantitatively liberates any thiolate bound to the MPC surface as disulfide and reduces the MPC core to elemental gold, allowing accurate integration to determine their stoichiometries (40). As mentioned above, the MPCs employed in the study have a general stoichiometry of Au$_{314}$(X)$_{108}$, where X is either C$_{12}$S, C$_{18}$S, or MeO$_2$CC$_{10}$S. The total number of substrates bound to the MPC surface is expected to remain constant after place-exchange, so the stoichiometry is based on the **1**:X ratio. The stoichiometries of the MPCs were Au$_{314}$-

(C$_{12}$S)$_{50}$(**1**)$_{58}$ and Au$_{314}$(C$_{18}$S)$_{74}$(**1**)$_{34}$ for the **1**-C$_{12}$MPC and the **1**-C$_{18}$MPC, respectively. These stoichiometries were determined in deuteriochloroform solution by comparison of the integrations for the resonance signal at 7.72 ppm attributed to the aromatic protons α to the carbonyl in **1** and the resonance signal at 0.86 ppm attributed to the terminal methyl group of either C$_{12}$ or C$_{18}$ after I$_2$ decomposition of the appropriate MPC.

In Fig. 3*a*, the resonance signal at 3.35 ppm and the shoulder at 2.28 ppm are due to the terminal methyl protons of the ester and the methylene protons α to the ester, respectively, on the MeO$_2$CC$_{10}$ moiety. The stoichiometry of the mixed **1**-MeO$_2$CC$_{10}$MPC was determined directly from the ^{1}H NMR spectrum of the MPC in benzene-d_6 by taking the ratio of the integrations for the resonance at 3.35 ppm (from MeO$_2$CC$_{10}$) and 7.85 ppm (from **1**) and was found to be Au$_{314}$(MeCO$_2$C$_{10}$S)$_{59}$(**1**)$_{49}$. This was possible because there was no overlap in these resonance signals, allowing accurate integration directly from the MPC.

Irradiations were carried out in argon- or N$_2$-purged benzene-d_6 solutions in Pyrex NMR tubes using a Rayonet photochemical reactor fitted with 350 nm bulbs and a merry-go-round apparatus. Generally, the solutions contained ~15–20 mg of **1**-C$_{12}$MPC, **1**-C$_{18}$MPC, or **1**-MeO$_2$CC$_{10}$MPC dis-

solved in 0.5 mL benzene-d_6 (~0.008–0.012 M with respect to **1**), with a three-times molar excess of the dienophile, namely dimethyl acetylenedicarboxylate (DMAD). Irradiation under these conditions produced MPCs consistent with the trapping of the photodienol (Scheme 1). The reaction can be monitored directly by NMR spectroscopy; this is illustrated in Figs. 2 and 3 for **1**-C_{12}MPC and **1**-MeO_2CC_{10}MPC, respectively, where the MPCs were irradiated in the presence of DMAD as the dienophile. The ^1H NMR and IR spectra of the MPCs irradiated in the presence of DMAD can be compared with those of an authentic sample of the Diels–Alder products made from irradiation of [4-(dodecyl)phenyl](2-methylphenyl)methanone (**2**), with DMAD as dienophile (Scheme 3). The irradiation product of **2** with DMAD was characterized via ^1H NMR, ^{13}C NMR, and IR spectroscopy, as well as mass spectrometry. The ^1H NMR spectrum of **2**-DMAD is shown in Fig. 2*c*. The key spectral changes that occur upon irradiation of **1**-C_{12}MPC, **1**-C_{18}MPC, and **1**-MeO_2CC_{10}MPC with DMAD are consistent with the formation of the Diels–Alder product. These include the appearance of two overlapping, broad aromatic peaks at 7.6 and 7.5 ppm and another aromatic resonance signal at 6.87 ppm, as well as broad peaks at 4.15 (the hydroxyl H), 3.62 (the methylene H's), and 3.35 ppm (the methyl ester H's), concomitant with a decrease in the intensity of broad aromatic peaks at 7.85, 7.22, and 7.05, along with the broad resonance at 2.39 ppm (the *ortho* methyl group of **1**) (Figs. 2 and 3). The ^1H NMR spectra comparing **1**-C_{12}MPC, **1**-DMADC_{12}MPC, and the model compound **2**-DMAD are shown in Figs. 2*a–c*, respectively. The IR spectra of the irradiated MPCs are consistent with the product as well, evidenced by the growth of peaks between 1715–1730 cm^{-1} (consistent with an ester functionality) and between 3434–3468 cm^{-1} (consistent with a hydroxyl moiety). Product formation was generally complete after 48–60 h with no sign of further reaction on extended irradiation. The success of these trapping experiments allows us to formulate some ideas about the reactivity and steric constraints of substrates confined to the MPC surface.

We begin our analysis of the Diels–Alder trapping of the photodienol by comparing the extents of reaction for the cases where the photodienol is directly at the interface (**1**-C_{12}MPC), when it is embedded within the monolayer (**1**-C_{18}MPC), and when the local polarity of the interface is varied (**1**-MeO_2CC_{10}MPC). The reaction proceeds efficiently, generating only one product on extensive irradiation on all of the MPCs studied. Irradiation of $Au_{314}(C_{12}S)_{50}(1)_{58}$, $Au_{314}(C_{18}S)_{74}(1)_{34}$, and $Au_{314}(MeO_2CC_{10}S)_{59}(1)_{49}$ produces MPCs with final stoichiometries of $Au_{314}(C_{12}S)_{50}(1)_{26}(1$-DMAD$)_{32}$ (64 ± 2% conversion to the Diels–Alder adduct), $Au_{314}(C_{18}S)_{74}(1)_{13}(1$-DMAD$)_{21}$ (60 ± 2%), and Au_{314}-$(MeO_2CC_{10}S)_{59}(1)_{15}(1$-DMAD$)_{34}$ (69%), respectively. The irradiations were carried out at least twice for $Au_{314}(C_{12}S)_{50}$-$(1)_{58}$ and $Au_{314}(C_{18}S)_{74}(1)_{34}$, whereas $Au_{314}(MeO_2CC_{10}S)_{59}$-$(1)_{49}$ was irradiated only once in parallel with $Au_{314}(C_{12}S)_{50}$-$(1)_{58}$ (Table 1).

These conversions are essentially identical, suggesting that the ability of the reaction to proceed is not affected by the length or the polarity of the dilutant chain co-absorbed to

Scheme 3. The photochemical generation of **2**-DMAD from **2**, which serves as the model for this reaction on the MPC surface.
the MPC with **1**. The extent of reaction was also not affected by the relative concentration of DMAD: the concentration was varied from 1 to 10 times the molar excess of **1**. Though the physical environment of the MPC was different in each of these MPCs studied, the reaction only proceeds to ~65% conversion in all cases. Assuming that the substrates bound to the MPC are distributed over the entire MPC surface because the place-exchange reaction employed was carried out over 5 days, the extent of reaction may be related to the number of **1** bound at the edge and vertice positions of the MPC as compared with the number bound to the terrace. That is, there may be a site-dependent reactivity associated with the substrates bound to the MPC surfaces.

As mentioned above, in the MPCs studied **1** should be positioned in each of the three distinct sites (i.e., on the edge, vertice, or terrace) (Fig. 4). It is assumed that every **1** bound to the MPC is capable of forming the photodienol. If this is the case, there must be certain sites on the MPC surface where the photodienol can be more efficiently trapped as the Diels–Alder adduct and others where the reaction is less efficient. It is intriguing to propose that there is a correlation between the position of substrates on the MPC core and the extent of reaction. To investigate this, the place-exchange reaction was exploited to selectively populate either the edge and vertice sites or the terrace sites with **1**.

Selective population of the edge and vertice sites occurs if short (~1 h) place-exchange reactions are carried out (36). Using this strategy, C_{12}MPC was stirred in the presence of **1** in toluene for 1 h under a nitrogen atmosphere, generating **1**(edge)-C_{12}MPC, where **1**(edge) implies that the **1** is positioned predominantly at the edge and vertice sites of a C_{12}MPC, as suggested by Murray and co-workers.[3] The MPC was purified and I_2 decomposition was utilized to determine the stoichiometry of this MPC, which was $Au_{314}(C_{12}S)_{71}(1)_{37}$. The MPC was then weighed out (~15 mg), dissolved in benzene-d_6, and irradiated in the presence of DMAD (three-times excess) until there were no further change in the ^1H NMR spectrum (Fig. 5). The spectral changes were similar to those explained for the above MPCs. Upon purification to remove the excess DMAD, the stoichiometry of the irradiated MPC was found to be $Au_{314}(C_{12}S)_{71}(1)_5(1$-DMAD$)_{32}$, which translates to an 85 ± 3% conversion to Diels–Alder adduct based on two irradiations. This is a significant increase in the conversion of **1** to the Diels–Alder adduct, suggesting that **1** positioned at the edge and vertice more readily undergo the reaction. However, this result does not indicate if **1** bound to the terrace is less reactive towards the Diels–Alder reaction. This can only be determined by preparing an MPC where **1** has been selectively positioned on the terrace.

---

[3] This is known to populate some of the terrace as well; see ref. 36.

Table 1. Stoichiometries of the original MPCs and the extents of reaction for their irradiations in the presence of DMAD.

MPC[a]	Stoichiometry (before irradiation)	Stoichiometry (after irradiation in presence of DMAD)[b]	Conversion (%)[c]
1-C_{12}MPC	$Au_{314}(C_{12}S)_{50}(\mathbf{1})_{58}$[d]	$Au_{314}(C_{12}S)_{50}(\mathbf{1})_{26}(\mathbf{1}\text{-DMAD})_{32}$	64 ± 2
1-C_{18}MPC	$Au_{314}(C_{18}S)_{74}(\mathbf{1})_{34}$[d]	$Au_{314}(C_{18}S)_{74}(\mathbf{1})_{13}(\mathbf{1}\text{-DMAD})_{21}$	60 ± 2
1-$C_{10}CO_2$MeMPC	$Au_{314}(MeO_2CC_{10}S)_{59}(\mathbf{1})_{49}$[e]	$Au_{314}(MeO_2CC_{10}S)_{59}(\mathbf{1})_{15}(\mathbf{1}\text{-DMAD})_{34}$	69
1(edge)-C_{12}MPC	$Au_{314}(C_{12}S)_{71}(\mathbf{1})_{37}$[d]	$Au_{314}(C_{12}S)_{71}(\mathbf{1})_{5}(\mathbf{1}\text{-DMAD})_{32}$	85 ± 3
1(terrace)-C_{12}MPC	$Au_{314}(C_{12}S)_{90}(\mathbf{1})_{18}$[d]	$Au_{314}(C_{12}S)_{90}(\mathbf{1})_{11}(\mathbf{1}\text{-DMAD})_{7}$	36 ± 2

Fig. 4. A cartoon representation of the MPC core and the assignments of the edge, vertice, and terrace sites.

Fig. 5. The irradiation of $Au_{314}(C_{12}S)_{71}(\mathbf{1})_{37}$ (where **1** is positioned predominantly at the edge and vertice sites on the MPC surface) in benzene-d_6 (*) before irradiation (*a*) and after an irradiation period fo 96 h in the presence of a 3-times molar excess of DMAD (*b*). The filled arrows indicate the decrease in intensity for the resonances associated with $Au_{314}(C_{12}S)_{71}(\mathbf{1})_{37}$ while the hollow arrows indicate an increase in the resonances associated with the product, namely $Au_{314}(C_{12}S)_{71}(\mathbf{1})_{5}(\mathbf{1}\text{-DMAD})_{32}$. Note: the DMAD was washed away before the ^{1}H NMR spectrum was acquired for (*b*).

Selectively populating the terrace with **1** is not as straightforward as populating the edge and vertice sites. The procedure involves initial preparation **1**-C_{12}MPC in a place-exchange reaction carried out over 5 days. This should populate the terrace, edge, and vertice sites with **1**. The resulting MPC (with a stoichiometry of $Au_{314}(C_{12}S)_{50}(\mathbf{1})_{58}$) is then subjected to a subsequent place-exchange reaction in the presence of an excess of dodecanethiol (C_{12}SH) for 1 h, which should populate predominantly the edge and vertice sites with dodecanethiol and displace any **1** positioned there. Conveniently, any **1** on the terrace should be trapped, allowing for the study of the reaction between its photodienol and DMAD. The stoichiometry of the resulting MPC was determined as for the other MPCs and found to be $Au_{314}(C_{12}S)_{90}(\mathbf{1})_{18}$ and will be referred to as **1**(terrace)-C_{12}MPC, where **1**(terrace) implies that **1** is predominantly at the terrace and the dilutant chain is C_{12}S. Upon irradiation of **1**(terrace)-C_{12}MPC in the presence of a three-times molar excess of DMAD, similar spectral changes were observed as for the previous MPCs, and the final stoichiometry of the MPC was $Au_{314}(C_{12}S)_{90}(\mathbf{1})_{11}(\mathbf{1}\text{-DMAD})_{7}$, which translates to a 36 ± 2% conversion to the Diels–Alder adduct based on two irradiations (Fig. 6). This conversion is much lower than that for the MPCs containing **1** at the edge and vertice positions, suggesting that the reactivity on the MPC surface is position dependent.

It is reasonable to assume that the edge and vertice sites, which may provide more room for a bimolecular reaction to occur based on the highly faceted shape of the MPC core (Fig. 4), are the positions on the MPC surface where the Diels–Alder reaction is occurring more efficiently. The idea of the edge and vertice sites anchoring substrates with less

order has been reported recently through an investigation that described how intracluster hydrogen bonding decreases the rate of cyanide-induced MPC decomposition (41), presumably because the highly faceted gold core prohibits effective intracluster chain interactions directly at the edge and vertice sites in the absence of substrates capable of hydrogen bonding. Our own work also suggests that mobility constraints imposed by aryl ketones anchored to terrace sites on MPCs prevent the unimolecular Norrish–Yang Type II reaction from occurring, whereas the reaction occurs more readily at the edge and vertice sites (23, 24). Also of note is a study involving the S_N2 reaction of amines and MPC-bound terminal bromides (40). The authors found the S_N2 reaction proceeds quite efficiently (at least 80% completion) regardless of the bulkiness of the amine. Though the product conversions for this simple reaction are higher than we report, the authors employed MPCs smaller (~140 gold atoms in the MPC core) than those we used. The smaller MPC

Fig. 6. The irradiation of $Au_{314}(C_{12}S)_{90}(\mathbf{1})_{18}$ (where **1** is positioned predominantly at terrace sites on the MPC surface) in benzene-d_6 (*) before irradiation (*a*) and after an irradiation period fo 96 h in the presence of a 3-times molar excess of DMAD (*b*). The filled arrows indicate the decrease in intensity for the resonances associated with $Au_{314}(C_{12}S)_{90}(\mathbf{1})_{18}$ while the hollow arrows indicate an increase in the resonances associated with the product, namely $Au_{314}(C_{12}S)_{71}(\mathbf{1})_{11}(\mathbf{1}\text{-DMAD})_7$. Note: the DMAD was washed away before the ^1H NMR spectrum was acquired for (*b*).
cores may result in more disordered monolayers. There have also been studies carried out on 2-D self-assembled monolayers (SAMs) suggesting that if edge sites are produced within the monolayer, the substrates at the edge sites are much more mobile and floppy, as evidenced by their ability to "trap" embedded groups (42, 43).

If the conversion were related to the number of edge and vertice sites on an MPC one may assume that it would be directly related to the percentage of edge and vertice sites on the MPC itself. Our results indicate that the conversion to Diels–Alder adduct is ~65%. A rough calculation[4] indicates that, assuming equal distribution over all sites on the MPC, 41% of **1** should reside at the edge and vertice sites. If the substrates at the edge and vertice sites and one atom row adjacent to the edge and vertice sites were able to undergo the reaction, this would account for 86% of the sites on the MPC surface. Because the conversion lies somewhere between these numbers, we offer the following explanation: there is the possibility that there is not an equal distribution of **1** over the entire surface of the MPC and slightly more **1** is concentrated at the edge and vertice sites. If this were true, it could explain why the conversion to Diels–Alder adduct is higher than the percentage of edge and vertice sites on the MPC surface. It is also possible that some of the **1** directly adjacent to the edge and vertice is capable of reacting, which would increase the conversion as well. We prefer the former explanation, based on the mechanism of place-exchange. At the beginning of the place-exchange reaction there is much more **1** than dodecanethiol in solution. The

edge and vertice sites are populated with **1** quickly, resulting in the displacement of dodecanethiol into solution. Consequently, both dodecanethiol and **1** will be in solution, but excess **1** is employed in the place-exchange reaction, so there will always be a higher concentration of **1** in solution. Because population of the MPC during the place-exchange reaction is dependent on the concentration of thiol in solution, and because the edge and vertice sites are populated most easily, they may be populated to a greater extent with **1**. This could account for the conversion of the $Au_{314}(C_{12}S)_{50}(\mathbf{1})_{58}$, $Au_{314}(C_{18}S)_{74}(\mathbf{1})_{34}$, and $Au_{314}(MeO_2CC_{10})_{59}(\mathbf{1})_{49}$ to $Au_{314}(C_{12}S)_{50}(\mathbf{1})_{26}(DMAD\text{-}\mathbf{1})_{32}$ (64 ± 2% conversion to Diels–Alder adduct), $Au_{314}(C_{18}S)_{74}(\mathbf{1})_{13}(DMAD\text{-}\mathbf{1})_{21}$ (62 ± 2%), and $Au_{314}(MeO_2CC_{10})_{59}(\mathbf{1})_{15}(\mathbf{1}\text{-DMAD})_{34}$ (69%), respectively, being slightly higher than expected.

Also of note are the results of irradiations of **1**-C_{12} and **1**-C_{18} MPCs in the presence of DMFr and DMM. The spectral changes observed in the ^1H NMR spectra are consistent with the generation of the Diels–Alder adducts, with the final stoichiometry of the photolysed MPCs being $Au_{314}(C_{12}S)_{50}(\mathbf{1})_{21}(\mathbf{1}\text{-DMFr})_{37}$ (64% conversion), $Au_{314}(C_{18}S)_{74}(\mathbf{1})_{13}(\mathbf{1}\text{-DMFr})_{21}$ (63% conversion), $Au_{314}(C_{12}S)_{50}(\mathbf{1})_{22}(\mathbf{1}\text{-DMM})_{36}$ (61% conversion), and $Au_{314}(C_{18}S)_{74}(\mathbf{1})_{15}(\mathbf{1}\text{-DMM})_{19}$ (58% conversion), respectively. The average conversion for these reactions is 62 ± 4%, which is, within experimental error, what we would expect based on the results of the analogous reaction with DMAD. These reactions show a variety of dienophiles can be employed in this reaction, and we are working on exploiting this aspect of the chemistry. The spectral data for the DMFr- and DMM-modified MPCs are provided in the supplemental information.

Experimental

Commercial solvents and reagents used

The compounds dodecanethiol, octadecanethiol, hydrogen tetrachloroaurate(III), tetraoctylammonium bromide, sodium borohydride, 1,11-dibromoundecane, 1.8 M phenyl lithium in cyclohexane-ether, *o*-toluoyl chloride, potassium thioacetate, dimethyl acetylenedicarboxylate, dimethyl maleate, and dimethyl fumarate were all purchased from Aldrich and used as received. Potassium carbonate (Caledon), aluminum chloride (BHD), benzene-d_6 (Cambridge Isotope Laboratories), and iodine (BDH) were also used as received. Acetone, dichloromethane, benzene, toluene, methanol, diethyl ether, and hexanes were purchased from either Caledon or EM Science and used as received. Tetrahydrofuran was dried by distillation from sodium/benzophenone. Ethanol (both anhydrous and 95%) was purchased from Commercial Alcohols Inc. Silica gel was purchased from EM Science.

General instrumentation

^1H NMR spectra were recorded on a Varian Mercury 400 (400.087 MHz) spectrometer in either deuteriochloroform or benzene-d_6 solutions and are reported in parts per million (ppm) with respect to chloroform or benzene peaks at 7.26 ppm or 7.15 ppm, respectively. ^{13}C NMR spectra were

---

[4] Our calculation assumes equal distribution of the substrate over the entire surface and involves dividing the number of atoms directly at edge and vertice sites and by the total number of surface atoms (41%) or dividing the number of atoms at the edge and vertice sites and those directly adjacent to the edge and vertice sites by the total number of surface atoms (86%).

recorded on a Varian Mercury 400 (100.602 MHz) spectrometer in either deuteriochloroform or benzene-d_6 solution and are reported in parts per million with respect to chloroform or benzene peaks at 77.0 or 128.02 ppm. UV–vis absorption spectra were recorded on a Cary 100Bio spectrometer in spectrometry-grade benzene. Mass spectra and exact masses were recorded on a MAT 8200 Finnigan high resolution mass spectrometer; the latter employed a mass of 12.0000 for carbon. IR spectra were recorded on a Bomem MB-Series or a Bruker Vector 33 spectrometer using a dropcasting technique on NaCl plates and are reported in wavenumbers (cm^{-1}).

Steady-state photolysis experiments

Steady-state irradiation experiments were carried out in septa-sealed Pyrex NMR tubes using benzene-d_6 as solvent or 5 mL Pyrex photolysis cells using reagent-grade benzene as solvent. The light source was a Rayonet photochemical reactor fitted with bulbs that emitted UV light in the 300–400 nm range, with a maximum at 350 nm and a merry-go-round apparatus to ensure an equal amount of radiation was received. In a typical procedure, ~15–20 mg of MPC was weighed out and placed under vacuum to ensure all solvent was removed. The MPC was then dissolved in ~0.5 mL benzene-d_6, degassed for 15 min with either argon or nitrogen gas, and sealed with a rubber septum and Parafilm. An ^{1}H NMR spectrum was recorded prior to the addition of dienophile and at intermittent reaction times until the reaction was complete. The temperature of the solutions was typically 38 ± 2°C.

[4-(11-Mercaptoundecyl)phenyl](2-methylphenyl)methanone (1)

To a solution of 1,11-dibromoundecane (5.2 g, 16.5 mmol) in dry THF (25 mL) was added phenyl lithium (3.7 mL of a 1.8 M solution, 6.7 mmol) dropwise, generating 11-phenyl-1-bromoundecane in situ. After aqueous workup and drying, the 11-phenylbromoundecane – 1,11-dibromoundecane mixture was redissolved with 25 mL dichloromethane and cooled in a salted ice bath. When the flask was cooled, o-toluoyl chloride (1.12 g, 7.26 mmol) and aluminum chloride (1.01 g, 7.59 mmol) were added, and the mixture was stirred for 4 h, maintaining a temperature of 0°C. Upon aqueous workup and drying with MgSO$_4$, the resulting [4-(11-bromoundecyl)phenyl](2-methylphenyl)methanone was purified via gradient column chromatography on silica gel, beginning with 10:1 hexanes:dichloromethane to elute the unreacted dibromoundecane and ending with 2:1 hexanes:dichloromethane which eluted [4-(11-bromoundecyl)phenyl](2-methylphenyl)methanone (0.90 g) as a clear colorless oil. The bromide was converted to the thioacetate through a reaction with potassium thioacetate in acetone, quantitatively generating [4-(11-acetylsulfanylundecyl)phenyl](2-methylphenyl)methanone. The thioacetate (0.72 g, 1.7 mmol) was then transferred to a 100-mL round-bottom flask fitted with a reflux condenser, dissolved in absolute ethanol, and the solution degassed with argon for 15 min after which time the solution was charged with potassium carbonate (0.24 g, 2.07 mmol) and heated to reflux for 3 h. The ethanol was removed via rotary evaporation, and the resulting liquid was redissolved in dichloromethane and washed with saturated

ammonium chloride (30 mL), washed with 3 × 30 mL of distilled water, and dried over MgSO$_4$ for 20 min. Concentration yielded a yellowish oil that was purified by column chromatography using silica gel and 3:1 dichloromethane:hexanes as eluant; a colorless oil (0.5 g, 1.30 mmol) was produced in 76% yield. UV–vis (benzene) (nm) (ε (M^{-1}cm^{-1})): 339 (9.790 × 10), 277 (7.832 × 10^3). IR (cm^{-1}) (dropcast on NaCl): 2925, 2853, 1661, 1604, 1267. ^{1}H NMR (400 MHz, CDCl$_3$) (ppm) δ: 7.73 (d, J = 7.8 Hz, 2H), 7.38 (m, H), 7.28 (m, 5H), 2.67 (t, J = 7.8 Hz, 2H), 2.52 (quartet, J = 7.0 Hz, 2H), 2.33 (s, 3H), 1.61 (m, 4H), 1.44–1.19 (m, 15H (includes SH proton)). ^{13}C NMR (400 MHz, CDCl$_3$) (ppm) δ: 198.36, 148.99, 138.90, 136.45, 135.24, 130.82, 130.29, 129.94, 128.51, 128.28, 125.08, 36.06, 34.05, 31.16, 29.51, 29.48, 29.45, 29.40, 29.25, 29.02, 28.34, 24.63, 19.91. EI-MS m/z (%): 382 (20), 364 (6), 223 (8), 195 (100), 119 (23), 84 (20), 49 (33). Exact mass calcd.: 382.2330; found: 382.2329.

[4-(11-Dodecyl)phenyl](2-methylphenyl)methanone (2)

To a flame-dried, 10-mL round-bottom flask fitted with an argon inlet and condenser was added aluminum chloride (1.8 g, 13.5 mmol), dichloromethane (7 mL), and phenyldodecane (2.5 g, 10.0 mmol), and the mixture was cooled in a salted ice bath. A solution containing o-toluoyl chloride (1.7 g, 11.0 mmol) in 2 mL of dichloromethane was then added to the mixture over 1 min. This mixture was left stirring for 3 h while warming to room temperature. The reaction was then quenched by pouring the entire contents of the flask into a beaker containing 40 mL of distilled water cooled in an ice bath. The organic layer was diluted with 20 mL dichloromethane, washed with 4 × 50 mL of distilled water, and dried over MgSO$_4$ for 30 min. Concentration of the dried organic phase yielded a yellow oil, which was purified by column chromatography using silica gel and 1:1 hexanes:dichloromethane as eluant, generating a clear, colorless liquid (1.83 g, 5.02 mmol) in 50% yield. IR (cm^{-1}) (dropcast on NaCl): 2926, 2853, 1662, 1605, 1264. ^{1}H NMR (400 MHz, CDCl$_3$) (ppm) δ: 7.72 (d, J = 7.8 Hz, 2H), 7.37 (t, H), 7.30–7.21 (m, 5H), 2.65 (t, J = 2H), 2.31 (s, 3H), 1.62 (quintet, 2H), 1.37–1.21 (m, 18H), 0.86 (t, 3H). ^{1}H NMR (400 MHz, C$_6$D$_6$) (ppm) δ: 7.84 (d, 2H J = 8.6 Hz), 7.20 (t, J = 7.8 Hz, H), 7.07 (m, H), 7.01–6.89 (m, 4H), 2.40 (t, J = 7.8 Hz, 2H), 2.28 (s, 3H), 1.45 (broad quintet, 2H), 1.36–1.16 (m, 18H), 0.91 (t, J = 7.0 Hz, 3H). ^{13}C NMR (400 MHz, CDCl$_3$) (ppm) δ: 198.36, 149.04, 138.95, 136.48, 135.26, 130.85, 130.30, 129.95, 128.49, 128.25, 125.09, 36.04, 31.90, 31.11, 29.64, 29.61, 29.54, 29.45, 29.33, 29.28, 22.67, 14.11. EI-MS m/z (%): 364 (3.5), 195 (100), 119 (9), 91 (8). Exact mass calcd.: 364.2766; found: 364.2765.

Dodecanethiolate MPC (C$_{12}$MPC)

Following the procedures of Brust et al. (34) and Murray and co-workers (35): to a 250-mL round-bottom flask was added hydrogen tetrachloroaurate(III) trihydrate (0.30 g, 0.768 mmol) dissolved in 28 mL distilled water (resulting in a bright yellow solution) and tetraoctylammonium bromide (2.01 g, 0.369 mmol) dissolved in 70 mL toluene (a clear and colorless solution). The contents were rapidly stirred for 30 min at room temperature to facilitate the phase transfer of

the hydrogen tetrachloroaurate(III) trihydrate into the toluene layer, which resulted in the organic layer turning a dark orange color and the aqueous layer becoming clear and colorless. After phase transfer, the aqueous layer was removed and dodecanethiol (0.15 g, 0.18 mL, 0.762 mmol) was added via a volumetric pipet to the solution, which was allowed to stir at room temperature while a fresh solution of sodium borohydride (0.33 g, 8.68 mmol) in 18 mL water was prepared. The aqueous sodium borohydride was added to the toluene solution over ~5 s and the mixture was allowed to stir at room temperature overnight (~18 h). The organic layer was washed with 3 × 20 mL distilled water, dried with MgSO$_4$, and concentrated. The concentrated MPC was then suspended in 200 mL of 95% ethanol and placed in the freezer overnight, during which time the C$_{12}$MPC precipitated from solution. The ethanol was then decanted and the MPC was dissolved in benzene and concentrated, resulting in the formation of a film in the round-bottom flask. This film was washed repeatedly with 10 × 15 mL of 95% ethanol warmed to 40°C. The MPC was pure, according to the ^{1}H NMR spectrum, which showed no signs of dodecanethiol, dodecyldisulfide, or tetraoctylammonium bromide.

Octadecanethiolate MPC (C$_{18}$MPC)

The octadecanethiolate MPC was synthesized as described above for the dodecanethiolate MPC. The procedure involved 0.20 g (0.51 mmol) hydrogen tetrachloroaurate, 1.32 g (2.41 mmol) tetraoctylammonium bromide, 0.20 g (5.59 mmol) sodium borohydride, and 0.146 g (0.51 mmol) octadecanethiol.

11-Mercaptoundecanoic acid methyl ester MPC (MeO$_2$-CC$_{10}$MPC)

The MPC was synthesized as described above for the dodecanethiolate MPC. The procedure involved 0.30 g (0.76 mmol) hydrogen tetrachloroaurate, 2.04 g (3.42 mmol) tetraoctylammonium bromide, 0.32 g (8.36 mmol) sodium borohydride, and 0.177 g (0.76 mmol) 11-mercaptoundecanoic acid methyl ester. The MPC was purified by washing with hexanes.

[4-(11-Mercaptoundecyl)phenyl](2-methylphenyl)methanone – dodecanethiolate MPC (1-C$_{12}$MPC)

Following the procedure outlined by Murray and co-workers (36, 37), C$_{12}$MPC (0.11 g, 0.136 mmol of dodecanethiol) was dissolved in 34 mL toluene in a 100-mL round-bottom flask fitted with an argon inlet. Excess [4-(11-mercaptoundecyl)phenyl](2-methylphenyl)methanone (0.0629 g, 0.163 mmol) was then added to the flask and the mixture was stirred for 4–5 days under argon. After 4–5 days the solution was concentrated and the mixed MPC was washed with warm (35–40°C) 95% ethanol to remove excess [4-(11-mercaptoundecyl)phenyl](2-methylphenyl)-methanone and dodecanethiol. The ^{1}H NMR (400 MHz, C$_6$D$_6$) spectra indicated that the [4-(11-mercaptoundecyl)-phenyl](2-methylphenyl)methanone was incorporated onto the MPC, and iodine-induced decomposition indicated that the MPC had a composition of Au$_{314}$(C$_{12}$S)$_{50}$(**1**)$_{58}$. Population of the edge and vertice sites with **1** was accomplished using the same conditions but with a decreased time period over which the exchange reaction took place (1 h) (36). The resulting MPC

had a stoichiometry of Au$_{314}$(C$_{12}$S)$_{71}$(**1**)$_{37}$. Population of the terrace with **1** was accomplished by stirring the Au$_{314}$-(C$_{12}$S)$_{50}$(**1**)$_{58}$ (0.050 g) (prepared via the 5 day place-exchange reaction described above) dissolved in 10 mL toluene with an excess of dodecanethiol (0.10 g) under a nitrogen atmosphere for 1 h. The resulting MPC had a stoichiometry of Au$_{314}$(C$_{12}$S)$_{90}$(**1**)$_{18}$.

[4-(11-Mercaptoundecyl)phenyl](2-methylphenyl)methanone – octadecanethiolate MPC (1-C$_{18}$MPC)

Following the procedure outlined above for Au$_{314}$(SC$_{12}$)$_{50}$-(**1**)$_{58}$, C$_{18}$MPC (0.05 g, 0.044 mmol octadecanethiolate) was dissolved in 15 mL toluene in a 100-mL round-bottom flask fitted with an argon inlet, to which [4-(11-mercaptoundecyl)phenyl](2-methylphenyl)-methanone (0.0226 g, 0.059 mmol) dissolved in ~3 mL toluene was added. After stirring for 4 days, the toluene was removed by rotary evaporation, and the mixed MPC was washed with a warmed (35–40°C) 6:1 ethanol:toluene solution to remove excess [4-(11-mercaptoundecyl)phenyl](2-methylphenyl)methanone and octadecanethiol. The resulting MPC had a composition of Au$_{314}$(C$_{18}$S)$_{74}$(**1**)$_{34}$, as determined via iodine decomposition.

[4-(11-Mercaptoundecyl)phenyl](2-methylphenyl)methanone – 11-mercaptoundecanoic acid methyl ester MPC (1-MeO$_2$CC$_{10}$MPC)

Following the procedure outlined above for Au$_{314}$(SC$_{12}$)$_{50}$-(**1**)$_{58}$, MeO$_2$CC$_{10}$MPC (0.15 g, 0.16 mmol 11-mercaptoundecanoic acid methyl ester) was dissolved in 40 mL toluene in a 100-mL round-bottom flask fitted with an argon inlet, to which [4-(11-mercaptoundecyl)phenyl](2-methylphenyl)methanone (0.073 g, 0.19 mmol) was added. After stirring for 4 days, the toluene was removed by rotary evaporation, and the mixed MPC was washed with ethanol to remove excess [4-(11-mercaptoundecyl)phenyl](2-methylphenyl)methanone and 11-mercaptoundecanoic acid methyl ester. The resulting MPC had a composition of Au$_{314}$-(MeO$_2$CC$_{10}$S)$_{59}$(**1**)$_{49}$, as determined by direct integration of the aromatic resonances at 7.85 ppm (resonances from protons α to carbonyl) and 3.42 ppm (resonances from protons of the terminal ester) in benzene-d_6 solution.

MPC decomposition procedure

As reported by Murray and co-workers (40), approximately 10 mg of mixed MPC was placed in a 10-mL round-bottom flask and dissolved in 2 mL dichloromethane. A small crystal of iodine (~1 mg) was added, and the solution was stirred until the originally brown, opaque solution became clear and a light purple colour with a black precipitate (20 min). The dichloromethane was rotary evaporated, and 0.5 mL deuteriochloroform was added to redissolve the resulting mixed disulfide. This was placed in an NMR tube by first passing it through a pipette equipped with a Kimwipe filter to remove the precipitate. The sample was then analyzed by ^{1}H NMR spectroscopy, where the integrations for the appropriate resonance signals were compared.

Generation of 2-methyl-4′-(dodecyl)benzophenone Diels–Alder adducts

In a typical procedure, [4-(11-dodecyl)phenyl](2-methylphenyl)methanone (**2**) (0.1 g, 0.41 mmol) was dissolved in

5 mL of benzene, transferred to a 5 mL Pyrex photolysis cell sealed with a septum, and the solution was degassed with argon for 20 min. The dienophile (namely dimethyl acetylene-dicarboxylate, dimethyl fumarate, or dimethyl maleate) (0.41 mmol) was then added to the degassed solution via syringe, and the mixture was irradiated for 12 h. The product was purified via column chromatography, employing 1% methanol in dichloromethane as eluant.

2-DMAD Diels–Alder adduct

IR (cm^{-1}) (dropcast on NaCl): 3474, 2924, 2853, 1732. ^{1}H NMR (400 MHz, C$_6$D$_6$) (ppm) δ: 7.55 (d, J = 8.6 Hz, 1H), 7.49 (d, J = 8.6 Hz, 2H), 6.9–7.05 (m, 4H), 6.82 (d, J = 7.8 Hz, 1H), 4.26 (s, 1H), 2.61 (s, 2H), 3.34 (s, 3H), 3.28 (s, 3H), 2.95 (t, J = 5.5 Hz, 2H), 2.46 (t, J = 7.0 Hz, 2H), 1.38–1.60 (m, 4H), 1.0–1.3 (br, 14H) 0.85 (t, J = 7.0 Hz, 3H). ^{13}C NMR (400 MHz, C$_6$D$_6$) (ppm) δ: 168.06, 166.66, 143.40, 142.09, 141.84, 140.41, 130.78, 128.51, 127.50, 127.36, 126.13, 74.67, 52.17, 36.12, 32.59, 32.01, 31.20, 30.39, 30.36, 30.28, 30.19, 30.09, 30.00, 23.40, 14.69. EI-MS m/z (%): 554 (45), 552 (42), 303 (6), 223 (8), 195 (100), 119 (23), 84 (20), 49 (33). Exact mass calcd.: 506.3032; found: 506.3028.

Conclusions

The Diels–Alder reaction of the photodienol generated from **1** in the MPC environment is shown to proceed efficiently, with similar extents of reaction regardless of the local environment surrounding the reactive group. In addition, this reaction exhibited evidence suggesting site-dependant reactivity. It appears as though there are properties inherent to substrates bound at specific sites on the MPC core that render them more or less reactive toward the Diels–Alder reaction. This is evidenced by the general trend observed with respect to the reactivity of **1** on the MPC surface: in the comparison of the reactivity of the multi-site-populated MPC — where all of the sites on the MPC are populated (**1**-C$_{12}$MPC) — placing **1** predominantly at terrace sites (**1**(terrace)-C$_{12}$MPC) results in significantly lower conversions, while placing **1** predominantly at edge and vertice sites (**1**(edge)-C$_{12}$MPC) results in significantly higher conversions. In fact, quantitatively speaking, the same amount of **1** reacts efficiently when the entire MPC is populated (**1**-C$_{12}$MPC) as when the majority of **1** is at the edge and vertice sites (**1**(edge)-C$_{12}$MPC); the number of **1** converted to **1**-DMAD is 32 in each case. Qualitatively, we attribute a more hindered environment within the terrace of the MPC as the main cause of the lowered extent of conversion. The most accessible sites — those at the edge and vertice — on the MPCs can undergo this rather complex bimolecular reaction more efficiently. Those within the terrace (where the monolayer is very well packed and more accurately mimics that of a 2-D SAM) are more hindered and less likely to undergo the rather complex bimolecular reaction. It is difficult to predict if the decreased ability for the terrace-bound dienol to react is due to steric constraints that do not allow the dienophile to reach the photodienol or if the dienophile is able to reach the dienol but cannot achieve the geometry required for the reaction to occur. The inability for these bimolecular reactions to reach completion is similar to what

we have found for unimolecular reactions carried out on identical MPC cores (23, 24). However, the reasons for the lowered extents of reaction are not expected to be the same. Mobility constraints play a definitive role in the efficiency of unimolecular reactions carried out on MPCs, but in this investigation, which involves bimolecular reactivity, sterics and the ability to adopt specific orientations play key roles in the efficiency of the reaction.

It is intriguing to propose that there are differences in reactivity and dynamics associated with the distinct sites on the MPC surface. We are currently investigating the effect that increasing and decreasing the size of the MPC core has on the extent of reaction, because the size of the terrace can be easily manipulated by increasing or decreasing the size of the metal core. This study will provide more insight on the physical properties inherent to substrates when they are anchored to specific sites on these highly faceted gold cores.

Potentiometric titration of metal ions in methanol

Graham Gibson, Alexei A. Neverov, and R.S. Brown

Abstract: The potentiometric titrations of nine lanthanide^{III} triflates, Zn^{II} and Cu^{II} triflate, and the Ni^{II}, Co^{II}, Mg^{II}, and Ti^{IV} perchlorates were obtained in methanol to determine the titration constants (defined as the $_s^s$pH at which the $[OCH_3^-]/[M^{x+}]_t$ ratios are 0.5 and 1.5) as well as the apparent $_s^s pK_a$ values for deprotonation of the metal-bound solvent molecules. The titrations were performed under various conditions with and without added salts as electrolytes, and the variations in the titration constants are discussed. In selected cases (La^{3+}, Zn^{2+}) the titration profiles were analyzed using a complex fitting program to obtain information about the species present in solution.

Key words: potentiometric titration, methanol, $_s^s$pH, metal ion, lanthanides, apparent $_s^s pK_a$.

Résumé : Opérant en solution méthanolique, on a effectué des titrages potentiométriques de neufs triflates de lanthanides^{III}, des triflates de Zn^{II} et de Cu^{II} et des perchlorates de Ni^{II}, de Co^{II}, de Mg^{II} et de Ti^{IV} afin de déterminer les constantes de titrage (définies comme le $_s^s$pH auquel les rapports $[OCH_3^-]/[M^{x+}]_t$ sont égaux à 0,5 et 1,5) ainsi que les valeurs apparentes de $_s^s pK_a$ pour la déprotonation des molécules de solvant fixées au métal. On a effectué les titrages sous diverses conditions, avec et sans addition de sels comme électrolytes, et on discute des variations dans les constantes de titrage. Dans des cas choisis (La^{3+}, Zn^{2+}) on a analysé les profils de titrage à l'aide d'un programme complexe d'ajustement des données afin d'en tirer de l'information sur les espèces présentes en solution.

Mots clés : titrage potentiométrique, méthanol, $_s^s$pH, ion métallique, lanthanides, $_s^s pK_a$ apparent.

[Traduit par la Rédaction]

Introduction

Recently we reported mechanistic aspects of di- and trivalent metal ion catalysis of the methanolysis of activated amides like acetylimidazole (1*a*) and β-lactams (1*b*), phosphate diesters (1*c*, 1*g*), and carbon-based esters (1*d*, 1*f*). Certain metal ions, notably La^{3+} and Eu^{3+}, give impressive rate enhancements for methanolysis of the substrates, in some cases several million- (1*d*, 1*f*) and billion-fold (1*c*, 1*g*). These studies revealed a number of interesting aspects about the M^{x+}/methanol system that proves of practical and fundamental interest in developing other useful catalytic systems for alcoholysis reactions. Among organic solvents, methanol is closest to water in terms of structure and solvation, but its lower dielectric constant of 31.5 vs. 78.5 at 25°C (2) allows a much greater organic substrate solubility than does water and promotes ion-pairing (ion association) of the M^{x+} and negatively charged substrates. Furthermore, unlike the situation in water where precipitation of M^{x+}(OH$^-$)$_n$ is a problem above the pK_a of the metal-coordinated waters (3), we have observed a greater solubility of most metal ions in MeOH throughout the entire pH region where ionization of M^{x+}(HOMe)$_y$ occurs.

While there are several advantages to the M^{x+}/methanol system, it became evident to us that detailed kinetic and mechanistic analyses required reliable methods for determining and controlling "pH" in methanol as well as determining equilibrium constants and "pK_a" values for the various ionizations of M^{x+}(HOMe)$_y$. Potentiometric titration methods are relatively simple and effective ways to obtain metal-ion complex stability constants and acid dissociation constants and, under favourable conditions, the speciation of complex mixtures in solution can be estimated with fair confidence (4). Potentiometric titrations have traditionally been done in aqueous solvents (5) and extensive tabulated data are available (6) but titrations in nonaqueous solvents have seen less use, particularly in the cases with metal ions (7*a*, 7*b*). A major reason for using nonaqueous solvents has been to determine acidity constants for compounds that could not be reliably measured in the relatively narrow range offered by amphiprotic water, or to better resolve ionizations (8). Since there was no simple way to reliably convert potentiometric readings to absolute pH in nonaqueous solvents referenced to that solvent (denoted $_s^s$pH),[2] nonaqueous solvents were generally inconvenient to use (8*c*) and apply, particularly in studies of reaction mechanism. Some years ago, deLigny and Rehbach (9*a*) empirically determined a method for measuring the $_s^s$pH in methanol by adding a correction constant of 2.34 (on the molality scale) to a measured electrode reading. More recently Bosch and co-workers (10) have reported

G. Gibson, A.A. Neverov, and R.S. Brown.[1] Department of Chemistry, Queen's University, Kingston, ON K7L 3N6, Canada.

[2]$_x^x$pH notation is based on the recommendations of the IUPAC, Compendium of analytical nomenclature, definitive rules 1997. 3rd ed. Blackwell, Oxford, U.K. 1998.

a method for determining $_s^s pH$ on the molarity scale which for our purposes is relatively simple: if a glass electrode is calibrated using standard aqueous buffers but the potentiometric measurements are taken in a nonaqueous solvent, the values are termed $_w^s pH$. Subsequently, one computes $_s^s pH = _w^s pH - \delta$, where δ is a correction factor of –2.24 on the molarity scale for measurements made as above in methanol (10). Although dependent on the junction potential of the electrode, there was found to be little difference between readings taken with different electrodes. Rived et al. (10c) have presented an extensive tabulation of $_s^s pK_a$ values in methanol for many organic acids and bases that can be used as buffers to control $_s^s pH$, and where previously unknown $_s^s pK_a$ values for materials are needed, these can be determined by titration according to the methods presented.

The titration of metal ions, however, is not as straightforward and forms the subject of the present report concerning the potentiometric titration of five common divalent metal ions (Zn^{II}, Co^{II}, Mg^{II}, Cu^{II}, Ni^{II}) and nine Ln^{III} ions, as well as Ti^{IV} in MeOH. We have analyzed the potentiometric data in two ways depending upon the level of information required concerning the $_s^s pH$-dependent species formed in solution. In addition we have determined qualitatively the effect on titrations of some added counterions often used as anionic components of buffers used for pH control in kinetic experiments and as supporting electrolytes.

Experimental

Materials

Methanol (anhydrous) was obtained in a SureSeal™ bottle (Aldrich) and used as received. Sodium methoxide was received in a SureSeal™ bottle as a 0.5 M solution in methanol which was diluted to make stock solutions ($4 \times 10^{-3} - 2 \times 10^{-2}$ M). Stock Na^+OMe^- solutions were stored under argon atmosphere and used within 5 days. All Ln^{III} metal ions were purchased as trifluoromethanesulfonate (OTf^-) salts from Aldrich. Stock solutions were prepared in methanol (1×10^{-2} or 5×10^{-2} M) and used within 2 days. $Ti(OMe)_4$ was purchased from Aldrich and a 2×10^{-3} M stock solution was prepared in methanol and converted to the perchlorate salt in situ by the addition of 4 equiv of perchloric acid. $Zn(OTf)_2$, $Cu(OTf)_2$, $Co(ClO_4)_2 \cdot 6H_2O$, and $Ni(ClO_4)_2 \cdot 6H_2O$ were obtained from Aldrich while $Mg(ClO_4)_2$ was obtained from Alfa Aesar; all were used as received. Tetrabutylammonium salts were used as purchased from Sigma–Aldrich (except the chloride, from Fluka) to prepare stock solutions in methanol ($5 \times 10^{-3} - 2 \times 10^{-2}$ M).

Potentiometric titrations

Titrations were performed using a Radiometer Vit90 Autotitrator equipped with an ABU91 Autoburette. The electrodes were Radiometer combination glass electrodes with a double junction design (model pHC2201 had a sleeve junction, and pHC2501 a porous ceramic pin, the latter type being recommended in reference (8a) and found to be most reliable in our studies). The lower reservoir of the pH electrode in contact with the test solution was filled with a 1 M solution of $LiClO_4$ in methanol. The temperature was kept at 25.0°C using a water bath and all titrations were conducted under Ar in a jacketed titration cell.

The metal ion concentration ranged from 1×10^{-4} to 4×10^{-3} M, and ionic strength was controlled with 0.01 M $Bu_4 NClO_4$ unless otherwise noted. Sodium methoxide titrant was standardized by titrating an aliquot of Fisher certified aq HCl, with the endpoint taken to be pH 7.0. Electrode calibration was accomplished by the so-called "practical method" (11), immersing it in standardized aqueous buffers at pH 4.0 and 10.0 followed by rinsing the electrode in anhydrous methanol. Subsequent acidity measurements in methanol gave experimental $_w^s pH$ readings very close to the actual hydrogen ion concentration, usually ~ 0.03 units higher (11) which was sufficient for our purposes. To the $_w^s pH$ readings was added the constant 2.24 to give the $_s^s pH$ as described by Bosch and co-workers (10). Titration data were analyzed by standard computer treatments provided within the program PKAS (4) and, in two selected cases, Hyperquad 2000 (version 2.1 NT) (12) as well, with the autoprotolysis constant of pure methanol taken to be $1 \times 10^{-16.77}$ at 25°C (10).

Since the stated water content of the Aldrich anhydrous methanol is <0.002%, the maximum water content for the metal ion solutions containing 2×10^{-3} M $Ni(ClO_4)_2 \cdot 6H_2O$ and $Co(ClO_4)_2 \cdot 6H_2O$ was $\sim 1.2 \times 10^{-2}$ M or 0.05%. For metal salts that were not used as hydrates, the water content of the methanol solution would be <0.01%. The inclusion of such a small amount of water did not significantly alter the characteristics of the solution relative to pure methanol, and therefore the correction factor of +2.24 was sufficiently precise for our purposes (9).

Results and discussion

Speciation of La^{3+}

Our initial titration studies focused on La^{3+} because it was the first ion we studied as a catalyst of the methanolysis of acetylimidazole (1a) and esters (1d) where the kinetic studies pointed to a catalytically active $(La^{3+}(^-OMe))_2$ dimer, formulated as **1**. Previously reported studies also support lanthanide hydroxy-bridged dimer formation in aqueous solution, both in the presence of special ligands (5b, 5d–5g, 5m) and in bare solvent (3, 5h, 5n, 7b), an example being the $La_2(OH)_5^+$ dimer **2** proposed to be important in the hydrolysis of an RNA model (5h). It is also known that lanthanide ions form polymeric species over extended periods in water, a process termed "ageing" (5e, 5f, 7b).
Shown in Fig. 1 are duplicate titration profiles of 2×10^{-3} M $La(OTf)_3$ in methanol with no added counterions, similar to the titration conditions in our first investigations of the La^{3+}-catalyzed methanolysis of esters (1d) and acetyl imidazole (1a).

Visual inspection of the curve indicates a consumption of ~2.5 equiv of methoxide per metal ion by $_s^s pH$ 11, comprising two regions having, what we will term for the moment, apparent titration values of ~7.8 (consuming 1 equiv of methoxide) and 10 (consuming ~1.5 equiv of methoxide).

Fig. 1. Two overlaid potentiometric titration profiles for 2×10^{-3} M La(OTf)$_3$ in methanol (no added electrolyte, $T = 25.0°$C).

Fig. 2. Potentiometric titration profiles for [La(OTf)$_3$] = 1×10^{-3} M (□), 2×10^{-3} M (△), and 4×10^{-3} M (○) in methanol in the presence of 0.01 M NBu$_4$ClO$_4$.
Notable is the fact that the titration curve is somewhat steeper in terms of $\delta[\text{OCH}_3^-]/\delta[_s^s\text{pH}]$ than expected for a simple ionization. This behaviour is consistent with the intervention of cooperative processes such as the formation of dimers or higher order aggregates (3, 13), or a change in the metal coordination number (14, 15) accompanying coordination of the methoxide. Indeed, as shown in Fig. 2 for (1–4) $\times$ 10^{-3} M [La(OTf)$_3$] conducted in the presence of 0.01 M Bu$_4$NClO$_4$ (to hold the ionic strength approximately constant), the shapes of the three titration curves change and move to lower apparent titration values with increasing [La(OTf)$_3$].

There are several standard methods for obtaining equilibrium constants from titrimetric data, one of the most sophisticated and current being the Hyperquad 2000 computer program (12) which allows one to calculate stability constants for suggested multispecies equilibrium situations. Through its use we have been able to obtain a satisfactory fit of the potentiometric data in Fig. 1 to a proposed multi-equilibrium process involving several sequential associations of OCH$_3^-$ to La^{3+} to form La$_2$(OCH$_3$)$_n$ dimers where n (the number of associated methoxides) varies from 1–5. The best fit stability constants are given in Table 1, and illustrated in Fig. 3 is a speciation diagram calculated on the basis of those constants which shows the distribution of species as a function of $_s^s\text{pH}$. According to this treatment, the two dominant species have even numbers of attached methoxides, e.g., La$_2$(OMe)$_2$ between $_s^s\text{pH}$ 8 and 10 (maximum concentration of ~80% at $_s^s\text{pH}$ 8.9), and La$_2$(OMe)$_4$ between $_s^s\text{pH}$ 10 and 12 (maximum concentration of ~80% at $_s^s\text{pH}$ 11). Species with odd numbers of methoxides (La$_2$(OCH$_3$)$_1$ and La$_2$-(OCH$_3$)$_3$) are also present to a lesser extent (maximum concentrations of ~25% in each reached at respective $_s^s\text{pH}$ values of 7.5 and 10). It is of note that the analogous Ln$_2$-(OH)$_2$ (suggested structure **3** in the La^{3+} cases) and Ln$_2$(OH)$_4$ species, complexed to two molecules of bis-tris propane (BTP), are observed to be the dominant forms in
aqueous solution (5f). In that case it was suggested that the BTP stabilizes the dinuclear core and prevents the formation of complexes with higher nuclearity and, eventually, the metal hydroxide precipitation. Apparently methanol solvent serves a similar role in stabilizing the dinuclear core, at least in the case of La^{3+}.
Knowledge of the species distribution, when combined with kinetic behaviour as a function of $_s^s\text{pH}$ and [M^{x+}], allows an insight into a complex multiequilibrium system where the different components may have different catalytic activity. Such an approach has been applied by Martell and co-workers (5d) and Gómez-Tagle and Yatsimirsky (5f) to Ln^{3+}-catalyzed hydrolysis of phosphate diesters in water. Previously we determined the kinetic constants for the La^{3+}-catalyzed methanolysis of the simple carbon-based ester p-nitrophenyl acetate (1d) as a function of both [La^{3+}]$_t$ and $_s^s\text{pH}$. The second-order rate constants for the La^{3+}-catalyzed reaction are superimposed on the speciation plot in Fig. 3, and coincide nicely with the bell-shaped concentration profile for La$_2$(OMe)$_2$ lending further support to our original

Table 1. Stability constants (log $_s^s K$ for the formation of $La_2(OMe)_n$ species in methanol (25.0°C).

^{a}Derived from fits of the potentiometric titration data using the program Hyperquad (12).

^{b}Defined as $-\log {}_s^s K_a$ for $La_2(OMe)_n(HOMe)_x \rightleftharpoons La_2(OMe)_{n+1}(HOMe)_y + H^+$, calculated from the data in column 2 as $16.77 - ({}_s^s pK^n - {}_s^s pK^{n-1})$ where 16.77 is the $-\log$ (auto protolysis constant) for pure methanol.

^{c}Averages of duplicate titrations of three $[La(OTf)_3]$ (1, 2, 4×10^{-3} M) in the presence of 0.01 M Bu_4NClO_4. Errors are calculated as the standard deviations of the mean of all six titrations.

^{d}Averages of duplicate titrations of $La(OTf)_3$ (2×10^{-3} M) with no added electrolyte. Errors calculated as the standard deviation of the mean.

Fig. 3. Speciation diagram for 1.0×10^{-3} M La^{3+} in methanol as a function of $_s^s pH$. Data superimposed on the figure as (●) are second-order rate constants for La^{3+}-catalyzed methanolysis of p-nitrophenyl acetate (1d).
suggestions of its intermediacy based exclusively on treatment of the kinetic data.[3]

Analogous Hyperquad fits of the Fig. 2 titration data for the three $[La^{3+}]$ determined in the presence of 0.01 M Bu_4-$NClO_4$ provide the average stability constants reported in Table 1 which can also be used to find the sequential microscopic acid dissociation constants of the La^{3+}-coordinated methanols ($_s^s pK_{a_2}$ to $_s^s pK_{a_5}$). It is of note that the constants determined in the presence of added Bu_4NClO_4 are some-

what different than those determined in its absence indicating that the overall equilibria depend upon the conditions and particularly on the presence of counterions which we show later can associate with the La^{3+}. In fact this introduces some limitations to the interpretation of the equilibrium constants. These must be considered conditional since they are derived from titrations determined under various conditions where the concentrations of $La(OTf)_3$ and supporting electrolyte, the activities, and the degree of ion pairing of the various species are not constant. It is important to realize that the low concentration or absence of supporting electrolyte is a technical necessity since high concentrations of anions can seriously impair the catalytic ability of the metal ion, and our goal is to achieve titration conditions that approximate as closely as possible the kinetic conditions.

We have not undertaken additional Hyperquad (12) treatment of these data to account for the various La^{3+}/ClO_4^- or La^{3+}/OTf^- equilibria because the inclusion of such will inevitably lead to mathematically acceptable results, but in the end this becomes a fitting exercise and does not provide useful chemical insight. Indeed it is possible to treat any of the potentiometric titration data for the lanthanides to various schemes involving complex equilibria similar to those used for La^{3+}, adding or removing various proposed components to obtain satisfactory fits. However, unless one has additional information for the presence or absence of specific species in any given case, the whole process has inherent uncertainties because alternative schemes can produce fits of similar quality implicating species for which there is no confirmatory evidence.

Simplification of analysis

Owing to the above limitations, we sought to analyze the titration data by simpler methods that identify ionization events associated with the consumption of CH_3O^- by the metal ions.

---

[3] Our previous work (1a) indicated that $La_2(OCH_3)_2$ and some higher order species ($La_2(OCH_3)_n$ where n is uncertain but >2) were involved in the catalysis. Fitting of the k_2 kinetic data shown in Fig. 3 as a linear combination of rate constants for the various $La_2(OCH_3)_n$ species provides a rate constant of (91.8 ± 8.8) $M^{-1}s^{-1}$ for the $La_2(OCH_3)_2$ and (38.0 ± 5.6) $M^{-1}s^{-1}$ for the $La_2(OCH_3)_4$ species with no involvement of $La_2(OCH_3)_3$.

Following Simms (16), we define the titration constants $\substack{s\\s}G'_1$, $\substack{s\\s}G'_2$, $\substack{s\\s}G'_3$, … etc., which are obtained as half neutralization points determined as if the solution contained monovalent, noninteracting acids. In our case, for the hypothetical metal ion methanolysis process shown in eqs. [1–3], the $\substack{s\\s}pG'_1$, $\substack{s\\s}pG'_2$, and $\substack{s\\s}pG'_3$ values are simply interpreted as the solution $\substack{s\\s}pH$ at which the $[OCH_3^-]/[M^{x+}]_t$ is 0.5, 1.5, and 2.5.

[1] $M^{x+}(HOCH_3)_x \rightleftharpoons M^{x+}(OCH_3^-)(HOCH_3)_y + H^+$

[2] $M^{x+}(OCH_3^-)(HOCH_3)_y$
$$\rightleftharpoons M^{x+}(OCH_3^-)_2(HOCH_3)_z + H^+$$

[3] $M^{x+}(OCH_3^-)_2(HOCH_3)_z$
$$\rightleftharpoons M^{x+}(OCH_3^-)_3(HOCH_3)_q + H^+$$
The $\substack{s\\s}G'_n$ values are not the individual $\substack{s\\s}K'_n$ values (defined as the dissociation constants of the polyvalent acid, not corrected for activities) pertaining to the three stepwise hypothetical ionizations in eqs. [1–3], but are related to them through the application of eqs. [4–6]:

[4] $\substack{s\\s}K'_1 = \substack{s\\s}G'_1 + \substack{s\\s}G'_2 + \substack{s\\s}G'_3$

[5] $\substack{s\\s}K'_1\substack{s\\s}K'_2 = \substack{s\\s}G'_1\substack{s\\s}G'_2 + \substack{s\\s}G'_1\substack{s\\s}G'_3 + \substack{s\\s}G'_2\substack{s\\s}G'_3$

[6] $\substack{s\\s}K'_1\substack{s\\s}K'_2\substack{s\\s}K'_3 = \substack{s\\s}G'_1\substack{s\\s}G'_2\substack{s\\s}G'_3$

This method identifies the half neutralization points, but it cannot accommodate the overall appearance of a titration curve that is too steep to be explained by sequential unconnected ionizations. This is because the method does not allow for situations where there is a cooperativity (e.g., $pK'_2 - pK'_1 < 0.6$), such as is observed where there is dimerization of the metal ions accompanying the ionizations.

Baes, Jr. and Mesmer (3a) describe the application of potentiometric titration to quantifying hydrolysis of cations in water according to the simplified process in eq. [7].

[7] $xM^{z+} + yH_2O \rightleftharpoons M_x(OH)_y^{(xz-y)+} + yH^+$
The ligand number ($\bar{n}$) is defined by the mol ratio of bound OH^- to the metal ions in solution and is given as:

[8] $\bar{n} = \sum y[M_x(OH)_y^{(xz-y)+}]/m_M$

where m_M is the total metal ion concentration including nonbound forms or:

[9] $m_M = \sum x[M_x(OH)_y^{(xz-y)+}]$

In principle it is possible to determine the ligand number $\bar{n}$ as a function of both the pH and metal ion concentration and thereby determine the formula of each hydroxide complex in eq. [7]. This should also be applicable to titrations performed in methanol, although such an exact treatment is unreliable at present because of the ion pairing and lack of ionic strength control. Nevertheless, it is possible to provide some valuable conditional constants which pertain to the average number of CH_3O^-/M^{x+}. From the forms of eqs. [8] and [9], it can be seen that when $\bar{n} = 0.5, 1.5,$ or 2.5, the observed $\substack{s\\s}pH$ would correspond to the Simms' titration constants or half-neutralization

points, $\substack{s\\s}pG'_1$, $\substack{s\\s}pG'_2$, and $\substack{s\\s}pG'_3$. The $\substack{s\\s}pG'_1$, $\substack{s\\s}pG'_2$ values for various Ln^{3+} ions are listed in Table 2.

Since the half neutralization constants do not define the overall shape of the titration profile we applied the program PKAS (4) to determine the apparent $\substack{s\\s}pK_a$ values pertaining to the overall titration curves. Simple fitting of the titration data to a di- or tribasic acid model failed, in most of the cases, to reproduce the steeper-than-normal shape of the titration profiles for the Ln^{3+} species. However, satisfactory fits can be obtained under the assumption that the Ln^{3+} ions exist predominantly as dimers having 1, 2, 3,…,-n associated ionizations as depicted in eqs. [10–13] (an assumption that is probably valid in the case of La^{3+} itself as determined by the Hyperquad fits described above). The so-determined apparent $\substack{s\\s}pK_{a_1}$ to $\substack{s\\s}pK_{a_4}$ values listed in columns 4–7 of Table 2 incorporate all microscopic equilibrium constants (such as those for dimerization, and association with counterions) that may affect the consumption of CH_3O^- by Ln^{3+}.

[10] $Ln^{3+}_2(HOCH_3)_xLn^{3+}_2 \rightleftharpoons$
$$Ln^{3+}_2(OCH_3^-)(HOCH_3)_m + H^+$$

[11] $Ln^{3+}_2(OCH_3^-)(HOCH_3)_m$
$$\rightleftharpoons Ln^{3+}_2(OCH_3^-)_2(HOCH_3)_p + H^+$$

[12] $Ln^{3+}_2(OCH_3^-)_2(HOCH_3)_p$
$$\rightleftharpoons Ln^{3+}_2(OCH_3^-)_3(HOCH_3)_q + H^+$$

[13] $Ln^{3+}_2(OCH_3^-)_n(HOCH_3)_r$
$$\rightleftharpoons Ln^{3+}_2(OCH_3^-)_{n+1}(HOCH_3)_s + H^+$$
The average of the best fit apparent $(\substack{s\\s}pK_{a_1} + \substack{s\\s}pK_{a_2})$ and $(\substack{s\\s}pK_{a_3} + \substack{s\\s}pK_{a_4})$ values is within experimental error of the two titration constants $(\substack{s\\s}pG'_1$ and $\substack{s\\s}pG'_2)$ for these events. In addition, the fits of this model to the experimental titration curves were much better than obtained with a simple dibasic acid model. Cases where cooperative interactions are at play are readily identified by the visual steepness of the curve. This situation invariably leads to a fit having computed apparent $\substack{s\\s}pK_{a_2} - \substack{s\\s}pK_{a_1} < 0.6$ suggesting that the second ionization of the dimer is easier than the first, perhaps because of bridging the ensuing methoxide between the two metal ions as in **1** and **2**.

Some trends among the lanthanide ions

Across the lanthanide series the titration curves all show consumption of between 2 and 2.5 equiv methoxide per metal ion comprising two distinct events, a first consuming 1 equiv OMe^-/Ln^{3+} followed by a second event consuming 1 to 1.5 equiv OMe^-/Ln^{3+} at higher $\substack{s\\s}pH$. Among the trends across the series, one of the most interesting is the shape of the titration profile, three examples belonging to Pr^{3+}, Eu^{3+}, and Yb^{3+} being given in Fig. 4. The difference between the $\substack{s\\s}pG'_1$ and $\substack{s\\s}pG'_2$ values of the two ionization events decreases with atomic number, with La^{3+}, Pr^{3+}, and Nd^{3+} having curves with clearly distinct steps, Sm^{3+} and Eu^{3+} to a lesser extent, and Gd^{3+} and all elements right of it in the series having a small difference between $\substack{s\\s}pG'_1$ and $\substack{s\\s}pG'_2$. This effect may be related to the so-called "gadolinium break", which refers to trends in complex formation constants across

Fig. 5. Relationship of $_s^s pG_1'$ for ionization of Ln^{3+}-bound methanol (Table 2) as a function of Ln^{3+} ionic radius (17).
the series and has been explained in part by a possible change in coordination number from 9 to 8 around gadolinium (3, 5k, 7a, 7b).

For the various lanthanide ions tested here, the $_s^s pG_1'$ values range from 5.3 (Yb^{3+}) to 7.8 (La^{3+}) and, in general, the methanols associated with the lighter lanthanides (like La^{3+}) are less acidic than the heavier lanthanides. Shown in Fig. 5 is
a plot of $_s^s pG_1'$ values vs. Ln^{3+} ionic radii (17) which follows the expected Lewis acidity trends where electrostatic association between OCH_3^- and the metal ion is stronger for the heavier cations because of their smaller ionic radii, stabilizing the species $(Ln^{3+})_{1,2}(OCH_3^-)_{1,2}$ (3a). This argument suggests more extensive oligomerization for the heavier Ln^{3+} ions, which is consistent with the general reduction of the $_s^s pG_2'$ across the row and smaller differences between $_s^s pG_1'$ and $_s^s pG_2'$ for the heavier ions. The plot in Fig. 5 shows breaks in the middle that may also result from the gadolinium break.

Table 3. Observed titration constants ($^s_spG'_1$, $^s_spG'_2$) and best fit $^s_spK_a$ values for dissociation of $M^{2+}(HOCH_3)_m$ in methanol ($T = 25.0°C$).

Other metal ions

We have applied the above titration analysis to other metal ions, notably Ti^{IV}, Zn^{II}, Co^{II}, Cu^{II}, Mg^{II}, and Ni^{II}, and the various titration constants (except for Cu^{II} discussed later) are given in Table 3. The titration profile for Ti^{4+} (not shown) shows exactly 3 equiv OMe^-/Ti^{4+} consumed before ^s_spH 4 followed by a fourth equivalent having an apparent $^s_spK_a$ of 5.8. This result indicates that the Ti^{4+} ion is most likely mononuclear throughout the titration, and is very acidic in methanol largely because of its tetravalent nature and small ionic radius which makes it a better Lewis acid than any of the Ln^{3+} ions. The formation of $Ti(OH)_2^{2+}$ even in a 1.5 M aq $HClO_4$ solution provides further evidence of the extreme acidity of ROH attached to this metal ion (3a).

The titration curves for the divalent transition metal ions Zn^{2+}, Co^{2+}, and Ni^{2+} are remarkably similar, as shown in Fig. 6. Each consumes 2 equiv OMe^-/M^{2+} in one step, and shows cooperativity where $^s_spK_{a_2} < {^s_spK_{a_1}}$. In the case of Zn^{2+}, we have determined through Hyperquad fitting of the potentiometric data that only the inclusion of $Zn^{2+}(OCH_3^-)$ and $Zn^{2+}(OCH_3^-)_2$ is required to explain the data, and that the microscopic $^s_spK_{a_1}$ and $^s_spK_{a_2}$ values are 10.66 and 8.94, close to the values determined by the PKAS fitting. Thus, the likely source of the cooperativity stems not from dimerization as was the case with the La^{3+} ions, but from a change in the M^{2+}-coordination number following the first association of methoxide to form $M^{2+}(OCH_3^-)$. It has been shown that for the similar process of $ZnCl_2$ formation in methanol, a change in coordination number from 6 or 5 to 4 following the association of the first Cl^- results in a cooperativity such that the second association of Cl^- proceeds more easily than the first (15). All three metal ions are only weakly acidic, with acid strength increasing in the order Co < Ni < Zn as ionic size decreases, a trend that is expected on the basis of Lewis acidity. The titration profile for Cu^{2+} is also shown on Fig. 6, and is quite different from those of the other transition metal ions in that it shows two separate titration steps, the first having a $^s_spG'_1$ of 6.5 consuming exactly 1 equiv of OCH_3^-/Cu^{2+}. However, the second titration step with an apparent $^s_spG'_2$ of 8.1 is extremely steep indicative of an oligomerization process, which, when fit with the PKAS program has computed $^s_spK_{a_3}$ and $^s_spK_{a_4}$ values of 11.4 and 4.5, respectively. Ultimately, when the titra-

tion mixture containing $Cu(OCH_3)_2$ is allowed to stand for some time, a heavy precipitate is formed consistent with the proposed oligomerization to form $(Cu(OCH_3)_2)_n$.

Qualitative salt effects

As has been observed in aqueous systems (4, 5d, 7a), certain anions can associate with M^{x+} in solution and the low dielectric constant of methanol (31.5 at 25°C (2)) solvent will increase ion pairing or association (18, 19). Bunzli and co-workers (20) showed that counterions normally considered "inert", such as triflate and perchlorate, coordinate to lanthanide ions in methanol as do Br^-, Cl^-, and NO_3^-. Gómez-Tagle and Yatsimirsky (5f) have noted that counterions, specifically perchlorate, inhibited the activity of their dimeric lanthanide catalyst **3** in H_2O. We have earlier observed that the M^{x+}-catalyzed methanolysis of acetyl imidazole and β-lactams is inhibited by the presence of certain counterions such as Cl^- (1a, 1b, 21). Thus, all our subsequent studies of the Ln^{3+} catalysis were undertaken in media containing as low concentrations of weakly coordinating counterions such as triflate and perchlorate as possible and, to better approximate our kinetic conditions, initial titrations were performed without added salts to limit ion pairing.

The addition of added salts does have profound effects on the titration profiles as exemplified by the profiles shown in Fig. 7 for 1×10^{-3} M $La(OTf)_3$ in the presence of 0.04 M Bu_4NX salts. Since the cationic portion is constant and incapable of direct binding to the metal, the effects noticed are largely due to the chemical nature of the anion. Of the anions investigated, nitrate perturbs the titration profiles most, moving the $^s_spG'_1$ value upward by about 3.6 units. Even though nitrate is not considered to be a strong binding ligand to most metal ions, it does have a special propensity to bind to lanthanides forming a mixture of inner and outer sphere complexes in aqueous solution, depending on concentration (22). It has also been noted that in a nonaqueous solvent, inner sphere complexes are formed which serve as a basis for the extraction of Ln^{III} (23) In our study in methanol its association constant with La^{3+} can be estimated to be at least 1×10^5 M^{-1} under the assumption of competitive binding of a single nitrate, probably indicative of a bidentate binding as has been observed in several crystal structures of Ln–nitrate

Fig. 6. Potentiometric titration of 2×10^{-3} M Zn(OTf)$_2$ (○), (Ni(ClO$_4$)$_2$ (△), Co(ClO$_4$)$_2$ (□), and Cu(OTf)$_2$ (◇) in methanol (no added electrolyte).

Fig. 7. Potentiometric titration curves of 1×10^{-3} M La(OTf)$_3$ in the presence of 0.04 M Bu$_4$NX salts. (*a*) (□) X = NO$_3^-$, (△) X = OTf, (▽) no added electrolyte; (*b*) (■) X = Cl$^-$, (▲) X = Br$^-$, (○) X = I$^-$, (▽) no added electrolyte.
species (24). For the halide series, the perturbation on $_s^s pG_1'$ follows the order Cl$^-$ > Br$^-$ > I$^-$. This trend is not surprising as the notoriously hard cation La^{3+}, which binds via predominantly electrostatic interactions, is expected to bind more weakly to the softer halides (I$^-$ and Br$^-$) that have significant covalent character in their bonds (5*i*, 7*a*).

While we have tried to minimize the salt effects by using weakly nucleophilic anions such as ClO$_4^-$ and CF$_3$SO$_3^-$(OTf$^-$), these too raise the $_s^s pG_1'$ to a certain extent. To investigate further the extent of perturbation of the $_s^s pG_1'$ we titrated 1×10^{-3} M La(OTf)$_3$ solutions containing 1, 2, and 4×10^{-2} M Bu$_4$NOTf (titration curves not shown). Both the $_s^s pG_1'$ ($_s^s pG_2'$) values increase, from 8.0 (10.3) in the absence of added salt to 8.3 (10.3), 8.4 (10.4), and 8.6 (10.5) at the three concentrations employed. This upward shift likely results from an ion association of the triflate with the La^{3+} which reduces its affinity for OCH$_3^-$, possibly by decreasing the Lewis acidity of the metal ion or by acting as a competitive inhibitor of methoxide binding in the various metal containing species. Perchlorate ion behaves similarly as judged by comparison of the titration $_s^s pG_1'$ and $_s^s pG_2'$ values given in Table 2, rows 2 and 3.

The divalent transition metal ions, already found to be less acidic than any of the trivalent metal ions studied, are also much less affected by association with added counterions. The titration profiles of 2×10^{-3} M Zn(OTf)$_2$ without and with 0.01 M added Bu$_4$NClO$_4$ (not shown) were essentially superimposable indicating a lack of ion association in this case.

Conclusions

The objective of this study was to find a convenient method to obtain titration constants for various metal ions in methanol solution, including the lanthanides and certain transition metal ions. The titration constants are crucial elements for determin-

ing the $_s^s pH$ values at which species with a known [OCH$_3^-$]/M^{x+} ratio exist. As such they are essential for interpreting our findings that La^{3+}, Eu^{3+}, and Zn^{2+} are remarkably active in catalyzing certain methanolysis reactions (1, 21). We have undertaken three different approaches for analyzing the titration data. We have applied the simplified method of Simms for determining certain titration constants, defined as half neutralization constants or $_s^s pG_1'$, conveniently interpreted as the solution $_s^s pH$ where the average OCH$_3^-$/M^{x+} ratio is 0.5 and 1.5. This allows one to define approximately the $_s^s pH$ regions where one can form the maximum concentrations of
certain species that may have kinetic activity. However, this approach does not reveal the intricate details of the acid–base equilibria involved and the constants are complicated composites of various equilibria including ion-pairing between the M^{x+} and solution counterions and metal dimerizations and (or) oligomerizations which can affect the ionizations of $(M^{x+})_n(HOCH_3)_m$ forms. Through subsequent application of a computer program (PKAS), the shape of the titration profile can be modeled, and apparent $^s_spK_a$ values can be derived. While these are also complicated functions of the various equilibria in solution, one can identify quickly situations where metal ion association exists because the titration profiles are much steeper than expected for a simple ionization.

When necessary, additional detailed information concerning the speciation of the M^{x+}/OCH_3^- forms can be obtained through fits of the potentiometric titration curves to multiequilibrium models using the computer program Hyperquad which gives the microsopic stability constants for the various species in solution. This type of fit is best undertaken for metal ions shown to be catalytically active, and where additional information concerning the likely speciation in solution is available. Through an extensive fitting of the La^{3+} titration data and comparison with our previous kinetic results for the catalyzed methanolysis of *p*-nitrophenyl acetate, we have confirmed that the active form of the catalyst is a previously proposed $La_2(OCH_3)_2$ dimer, giving further credence to the applicability of the titration and (or) kinetic treatment. Moreover, this method reveals a much more complex situation where another dimeric form $(La_2(OCH_3)_4)$ is present and reactive. As such, the advantage of this approach when applied to metal ion catalysis of methanolyses, is the ability to analyze complex kinetic behaviour attributable to a multiequilibrium system which may be difficult, if not impossible, to analyze by standard kinetic approaches. Further work from these laboratories will be aimed at extending the titration and kinetic methodology to other reactions, metal ions, and alcohol solvents.

New potential dendritic cores: Selective chemistry of dipentaerythritol

Hussein Al-Mughaid, T. Bruce Grindley, Katherine N. Robertson, and T. Stanley Cameron

Abstract: Methods were developed to convert dipentaerythritol efficiently into di-*O*-benzylidene, di-*O*-cyclohexylidene, di-*O*-1-ethylpropylidene, and di-*O*-methylene diacetals. The known di-*O*-benzylidene acetal, considered to be a single isomer, was shown to be close to a statistical mixture of the *cis,cis-*, *cis,trans-*, and *trans,trans*-isomers. Structures were established by a combination of NMR spectroscopy and X-ray crystallography. Reaction of the di-*O*-benzylidene acetals with benzyl chloride and potassium hydroxide surprisingly gave good to excellent yields of the monobenzyl ethers. An explanation for this observation was advanced. The dibenzyl derivatives of the di-*O*-benzylidene acetals were formed by reaction of their dianions with benzyl bromide in DMF. Selective reduction of the di-*O*-benzylidene acetals with triethyl-silane and boron trifluoride etherate gave 2′,6′-di-*O*-benzyldipentaerythritol. A crown ether was formed in modest yield (12%) by reaction of the dianion of the di-*O*-methylene acetal with α,α′-dibromo-*m*-xylene in DMF.

Key words: dipentaerythritol, pentaerythritol, acetals, dendrimer, selective benzylation, crown ether.

Résumé : On a mis au point des méthodes qui permettent de transformer efficacement le dipentaérythritol en diacétals di-*O*-benzylidène, di-*O*-cyclohexylidène, di-*O*-1-éthypropylidène et di-*O*-méthylène. On a démontré que l'acétal connu di-*O*-benzylidène, qui était considéré comme un seul isomère, est en fait un mélange pratiquement statistique des trois isomères *cis,cis-*, *cis,trans-* et *trans,trans-*. On a déterminé les structures par une combinaison de spectroscopie RMN et de diffraction des rayons X. La réaction des acétals du di-*O*-benzylidène avec le chlorure de benzyle en présence d'hydroxyde de potassium conduit d'une façon surprenante à des rendements allant de bons à excellents des éthers monobenzyliques. On propose une explication pour cette observation. Les dérivés dibenzyliques des acétals du di-*O*-benzylidène se forment par réaction de leurs dianions avec le bromure de benzyle dans le DMF. Une réduction sélective des acétals du di-*O*-benzylidène par le triéthylsilane et l'éthérate de trifluorure de bore conduit au 2′,6′-di-*O*-benzyldipentaérythritol. La réaction du dianion de l'acétal du di-*O*-benzylidène avec le α,α′-dibromo-*m*-xylène, dans le DMF, conduit à la formation d'un éther couronne avec un rendement modeste (12%).

Mots clés : dipentaérythritol; pentaérythritol; acétals; dendrimère; benzylation sélective; éther couronne.

[Traduit par la Rédaction]

Introduction

Dendrimers have become the subject of intense interest in the last few years (1–7). One of the molecules that has attracted the most attention as either the central core or a branching point of clusters and dendrimers is pentaerythritol (**1**) (8–19). In contrast, dipentaerthritol (**2**), an inexpensive commercially available compound with many of the favorable characteristics of pentaerythritol, has been almost totally neglected. Moreover, little is known about the regioselective substitution of **2**, whereas pentaerythritol has been extensively investigated and there are now methods available to selectively prepare a wide range of derivatives (20–29).

Dipentaerythritol has C_2v symmetry making its six primary hydroxyl groups identical. As a result, it has considerable potential as a core or a branching point for the formation of clusters and dendrimers. It is also a promising headgroup for gemini surfactants (30). In order for this potential to be achieved, the fundamental chemistry of this compound must be established. In this paper, we report studies of the selective formation of acetals of **2** and examine some further chemistry of these acetals.

Fig. 2. ORTEP diagram for *trans,trans*-2′,2′′:6′,6′′-di-*O*-benzylidene-2′,2′′,6′,6′′-tetra(hydroxymethyl)-4-oxa-1,7-heptanediol (**5**).
There are two previous reports of acetals of dipent-aerythritol (**2**). In 1950, Bograchov (31) reported that **2** reacted with benzaldehyde in benzene to form a di-*O*-benzylidene acetal with a sharp mp (166°C) in 60% yield, but did not discuss the possibility of stereoisomerism. He also reported di-*p*-methoxybenzylidene and di-*p*-nitrobenzylidene acetals. Later, Cabasso et al. (32) performed a trans-acetalization reaction of dipentaerythritol with diethyl 2,2-diethoxyethylphosphonate and obtained a bis-*O*-(2,2-diethyl phosphonoethylidene) diacetal in 90% yield, again without discussion of stereoisomerism. For all acetals derived from dipentaerythritol, 1,3-dioxane derivatives are produced that have single substituents at C-2 of the 1,3-dioxane ring and two different substituents at C-5. In these compounds, the 1,3-dioxane C-5 substituents are similar, both being CH_2OR groups, and the A-values of substituents at C-5 in 1,3-dioxane rings are small (33). Therefore, under the equilibrium conditions used above, mixtures of stereoisomers should have been produced and the results herein are in accord with this expectation.

Results and discussion

Acetal formation

Bograchov's procedure for the preparation of the di-*O*-benzylidene acetal of dipentaerythritol (**2**) in benzene did not specify reaction time or the precise amount of the catalytic *p*-toluenesulfonic acid used (31). Under conditions sim-

ilar to those used by Bograchov, a reaction time of 10 h at reflux in benzene with removal of water was found to give the best yield of the dibenzylidene acetals of 85%. Longer reaction times gave faster moving compounds (see later) on TLC; shorter reaction times resulted in lower consumption of dipentaerythritol. The use of toluene as the solvent under azeotropic conditions gave lower yields of the di-*O*-benzylidene acetals as will also be discussed later. The product was found to be a mixture of the three possible stereoisomers, the *cis,cis*-, *cis,trans*-, and *trans,trans*-isomers (Scheme 1). One isomer (**3**, mp 164–166°C) had a smaller R_f value on TLC on silica gel and it was separated by flash column chromatography. The other two isomers (**4** (mp 123–125°C), **5** (mp 170–173°C)) had very similar R_f values but were obtained individually by acetylation, separation of the diacetates (**4a** and **5a**) by chromatography, and deacetylation. Based on their melting points, the compound isolated by Bograchov was the *cis,cis*-isomer.

In the 1,3-dioxane rings of the acetals and their derivatives discussed in this publication, there are two very similar groups at C-5 of the 1,3-dioxane rings, CH_2OCH_2C groups and CH_2OH groups, or derived CH_2OR groups. The selection of which groups are used to determine *cis* or *trans* for all benzylidene acetals described here is based on the Cahn–Prelog–Ingold priorities (34) for the parent acetal, that is, at C-5 in each 1,3-dioxane ring, the arrangement of the CH_2OCH_2C group with respect to the phenyl group is used to name the configuration present. This has the advantage

4a R = Ac
Compound **4** was assigned the C_s symmetric *cis,trans*-structure from the observation of two sets of signals in the NMR spectra of it and its diacetate (**4a**), arising from the two diasterotopic halves of the molecules (see Tables 1 and 2). The structures of the two C_2v symmetric isomers (**3** and **5**) were obtained from their X-ray structures and from that of the di-*O*-benzoyl derivative of **3**, **3b**. ORTEP diagrams of the structures of **3b** and **5** are shown in Figs. 1 and 2 and the crystal data is given in Table 3. The X-ray structure of the *cis,cis*-structure **3** contains interesting hydrogen-bonding features that are discussed in detail elsewhere.[2] The crystal structures of it and of its di-*O*-benzoyl derivative (**3b**) (see Fig. 1) establish that **3** has the *cis,cis*-configuration and that of **5** confirms its assignment as the *trans,trans*-isomer.

The ^{1}H NMR chemical shifts of the exocyclic CH$_2$ groups do not fit the normal pattern (35) in which the signals of equatorial groups on six-membered rings are more deshielded than those of axial groups (see Tables 1 and 2). In the spectrum of the *cis,cis* isomer **3**, the methylene protons in the equatorial CH$_2$OH group appear at 3.44 ppm, while those in the axial CH$_2$OC group appear at 3.97 ppm; in the spectrum of the *trans,trans* isomer **5**, the methylene protons in the equatorial CH$_2$OC group appear at 3.21 ppm, while those in the axial CH$_2$OH group appear at 3.98 ppm. Weber had previously assigned signals for analogous pentaerythritol signals in the same way (25) and it is well-known that axial substituents at C-5 of 1,3-dioxane derivatives are more deshielded than equatorial substituents (36–38).

The ^{13}C NMR chemical signals of the CH$_2$OH groups are particularly useful for assignments, appearing in an other-

wise unoccupied region. Those of equatorially oriented carbons in *cis* rings appear at 64 to 65 ppm while the axial ones in *trans* rings appear at 62.0 to 62.5 ppm. In contrast to the observations made about for the ^{1}H NMR spectra above, this trend is opposite to what has been observed for 2-substituted-5-methyl-1,3-dioxanes; axial methyl carbons are more deshielded than those of their equatorial counterparts (37–39).

The individual proportions of the isomers in the 85% total yield of di-*O*-benzylidene isomers were obtained by taking the isolated yields of the diacetates of **4** and **5** and extrapo-

Scheme 4.

Scheme 5.
lating back to the original mixture. These were 34:41:24% for **3**:**4**:**5**, respectively, fairly close to a statistical distribution. As expected from the similarity of the substituents at the two C-5 positions of each 1,3-dioxane ring, the differences in stability between the *cis*- and *trans*-isomers are very small.

Murguía et al. (40) recently introduced the use of DMF–benzene mixtures as solvents for the formation of acetals from diols and polyols that are very insoluble in benzene or toluene, particularly from pentaerythritol. Azeotropic removal of water from this solvent mixture can be performed exactly as with pure benzene. Application of this procedure to the formation of benzylidene acetals of **2** gave about the same yield of di-*O*-benzylidene acetals as obtained under the conditions described above, that is, using benzene alone as a solvent. The stereoisomeric distribution, measured from the intensities of the ^{13}C NMR peaks for the C-2′,2″,6′,6″ carbons (70 to 71 ppm), was also very close to statistical.

Use of toluene or DMF–toluene mixtures for this reaction under conditions for the azeotropic removal of water was less satisfactory in that lower yields of the di-*O*-benzylidene acetals were obtained. Under these conditions, the product mixture always contained products that moved faster than the di-*O*-benzylidene acetals on TLC. The compound giving the most intense fast-moving spot was isolated and identified as di-*O*-benzylidenepentaerythritol (23, 41). This product probably arises from a fragmentation reaction, for which one possibility is shown in Scheme 2. Intermediates resulting from dehydration of compounds resulting from the aldol condensation of formaldehyde and acetaldehyde are thought to lead to the by-product dipentaerythritol during the preparation of pentaerythritol (42). A fragmentation reaction, such as that observed here, is expected to be aided by a large positive entropy of reaction and thus to be strongly favored by increased reaction temperature. It appears that the approximately 30°C increase in reaction temperature on changing the solvent from benzene to toluene is sufficient to make fragmentation a significant process.

In the report (32) of the transacetalization reaction of **2** with diethyl 2,2-diethoxyethylphosphonate, 10.2 g of **2** were stirred with 2.02 equiv of the acetal and 20 mL of concentrated hydrochloric acid at room temperature for 8 days. The product, a syrup, was obtained in 90% yield after neutralization and extraction. These were equilibrium conditions. As for the benzylidene acetals, there is no reason to believe that the *cis*- and *trans*-isomers would have significantly different stabilities. Therefore, this product should be a mixture of the three possible stereoisomers. The ^{1}H NMR and ^{13}C NMR spectra of the product were recorded at either 60 MHz or 100 MHz and at 25.2 MHz, respectively (32). In the ^{1}H NMR spectra (32), the methylene units in the CH$_2$OH groups were reported to appear as doublets (J = 7.5 Hz) with no identified coupling partner (the OH peak was a singlet).
Similarly, the methylene units in the CCH$_2$OCH$_2$C group were reported (32) to appear as a doublet (J = 6.0 Hz) with no identified coupling partner. Since neither of these two groups gave rise to doublets in individual isomers, this is clear evidence that a mixture was present. We conclude that the expected mixture was present in this literature product, even though the reported (32) spectral data cannot be interpreted fully. It should be noted that the spectra of the initial di-*O*-benzylidene acetal mixture are difficult to interpret, even on higher field spectrometers.

Reaction of dipentaerythritol with cyclohexanone in the presence of a 0.1 mol equiv (based on cyclohexanone) of *p*-toluenesulfonic acid monohydrate in benzene–DMF (40:60, v/v) for 6 h at reflux (the conditions of Murguía et al. (40)) afforded the diacetal **6** in 98% yield (Scheme 3). The amount of *p*-toluenesulfonic acid used is important; the reaction proceeded very slowly in the presence of <1 mol% but occurred rapidly when >2 mol% was added, again based on the ketone. Under the same conditions, 3-pentanone gave the corresponding diacetal **7** in 60% yield. The di-*O*-methylene acetal (**8**) derivative of dipentaerythritol was formed in 41% yield by stirring with 37% aqueous formaldehyde and concentrated hydrochloric acid at 85°C for 14 h.

It is interesting to note that the chemical shift differences between the two sets of signals for H′2, H2″, H6′, and H6″ were very small in the ^{1}H NMR spectra of **6**–**8** in chloroform-*d* (0 (0.034 in pyridine-d_5), 0, and 0.025 ppm, respectively) but were much larger in those of **3**–**5** (0.42, 0.41 and 0.32 (*trans*-ring), and 0.37 ppm, respectively). These differences reflect the conformational properties of the two sets of compounds. In the benzylidene acetals, the 2-phenyl group in each 1,3-dioxane ring fixes the chair conformer giving rise to distinct equatorial and axial orientations for the two protons on C-2′, C-2″, C-6′, and C-6″. In contrast, the 1,3-dioxane rings of **6**–**8** were present in both chair conformers in approximately equal amounts, also reflected in the small chemical shift difference between the acetal protons of the di-*O*-methylene acetal **8** (0.046 ppm).

Formation of benzyl ethers

Benzylation of diol **3** by stirring with potassium hydroxide in benzyl chloride as the solvent for 2 h at 105°C surprisingly afforded the monobenzyl ether (**9**) in 83% yield (Scheme 4). This high selectivity was reproduced a number of times in reactions performed at temperatures ranging from room temperature up to 105°C. Selective formation of a monoether from a diol in good yield is highly unusual and is only possible if the rate of the first substitution is substantially faster than that of the second. Neither allowing the reaction to proceed longer nor raising the reaction temperature produced the di-*O*-benzyl derivative. However, this latter compound (**10**) could be made by reaction with sodium hy-

Scheme 6.
Scheme 7.
Scheme 8.
dride and benzyl bromide in *N,N*-dimethylformamide (see Scheme 5).

The normal outcome of attempts to form monosubstituted products from two identical isolated reactive sites are mixtures of unsubstituted, monosubstituted, and disubstituted products because the site remaining after the first substitution has about the same reactivity as those in the original compound (43–47). Selective monobenzylation of these diols can arise in two ways: the reactivity of one diol hydroxyl group under these conditions may be greater than that of an isolated alcohol or the introduction of the first benzyl may have decreased the reactivity of the unreacted hydroxyl. The latter possibility could occur if the monobenzyl derivative existed mainly in conformations where the remaining hydroxymethyl group was shielded by the benzyl group. This possibility was investigated by measuring 1D-NOEs in chloroform. There were no substantial NOEs between the methylene hydrogens of the hydroxymethyl group and either the methylene hydrogens or the phenyl hydrogens of the benzyl group. We thus concluded that acceleration of the initial benzylation must be the cause of this effect.

To confirm this hypothesis, a competition reaction was performed in the presence of two equivalents of an unhindered primary alcohol (1-octanol) (equivalent number of hydroxyl groups) at room temperature for about the same time as nor-

mally taken for reaction completion with **3**. Surprisingly, these conditions yielded, after work-up, an approximately 2:1:1 mixture of the mono-*O*-benzyl derivative, the di-*O*-benzyl derivative, and 1-octanol benzyl ether with no indication of the presence of 1-octanol. The benzylation of the monobenzyl ether was much faster in the presence of 1-octanol than in its absence. This observation indicates that complexation of the potassium cation to at least two hydroxyl groups is key to the selectivity of this reaction. A tentative hypothesis is that complexation of the second hydroxyl to a potassium cation makes both hydroxyl protons sufficiently acidic that one can be removed easily, generating a more potent nucleophile (see Scheme 6). In the absence of 1-octanol, when one oxygen atom becomes hindered by formation of the monobenzyl ether, the remaining hydroxyl becomes too insufficiently acidic to be competitive as a nucleophile.

Bessodes and Boukarim (47) have obtained selective monobenzylation of 1,*n*-diols with benzyl bromide in tetrahydrofuran containing a catalytic amount of crown ether, using as base potassium hydroxide or sodium hydroxide, but not lithium hydroxide. They attributed the selectivity to a surface effect under their heterogeneous reaction conditions because the ineffective base (lithium hydroxide) was the only one to dissolve in the reaction medium. The selectivity obtained here was obtained under fairly similar conditions to those of these authors. However, the current selectivity cannot be attributed to surface reactions because selectivity was obtained under both homogeneous (higher temperatures) and heterogeneous conditions. Bouzide and Sauvé (46) obtained selective monobenzylation of symmetrical diols using silver oxide and benzyl bromide in dichloromethane and other nonpolar solvents. They attributed the selectivity to ease of

Scheme 9.

Experimental section
initial deprotonation from an intermediate similar to that proposed here.

Treatment of the *trans,trans*-isomer (**5**) under the same conditions also gave a mono-*O*-benzyl derivative (**11**) (69%). However, the *cis,trans*-isomer (**4**) can form two different monobenzyl ethers. Both isomers were formed; substitution on the equatorial hydroxymethyl group in the *cis*-ring to give compound **12** (54% yield) was preferred to substitution on the axial hydroxymethyl group in the *trans*-ring to give compound **13** (16% yield) (see Scheme 7).

Other reactions

Benzylidene acetals can be reduced to hydroxy benzyl ethers with a variety of reducing agents, most commonly $LiAlH_4$–$AlCl_3$ (48, 49), $NaCNBH_3$–HCl (50), and Et_3SiH–TFA (51). Recently, Debenham and Toone (52) have reported a facile procedure for the regioselective reductive cleavage of the benzylidene group to the corresponding benzyl ether with Et_3SiH–$BF_3 \cdot Et_2O$. Reduction of **4** under these latter conditions in dichloromethane for 12 h resulted in the clean formation of the dibenzyl ether of dipentaerythritol (**14**) in 64% yield. Application of the same procedure to the chromatographically purified mixture of di-*O*-benzylidene acetals (**3**–**5**) also gave **14** in similar yield (68%) (see Scheme 8).

Reaction of the di-*O*-methylene acetal with sodium hydride in DMF followed by α,α'-dibromo-*m*-xylene yielded a crown ether (**15**) in modest yield (12%) (Scheme 9). The observation of small chemical shift differences between the two sets of protons on C2′, C2″, C6′, and C6″ (0.034 ppm) and also between the two acetal protons (0.024 ppm) indicates that the chair conformers of the 1,3-dioxane rings in this crown ether are still inverting rapidly on the NMR time scale.

We have now developed efficient methods for the formation of di-*O*-cyclohexylidene and di-*O*-benzylidene and other acetals of dipentaerythritol. We have established that all diacetals of dipentaerythritol derived from aldehydes, as exemplified by the di-*O*-benzylidene acetals, will be present as mixtures of the *cis,cis*-, *cis,trans*-, and *trans,trans*-isomers and have developed a method to separate and identify them. We have demonstrated that these latter acetals can be converted either into monobenzyl ethers or dibenzyl ethers efficiently and have demonstrated other chemistry of these diacetals. The ability to form selectively substituted dipentaerythritol derivatives has allowed us to make both novel clusters with carbohydrate end groups (glycoclusters) and novel gemini surfactants which will be reported in subsequent publications.

General methods

Melting points were determined with a Fisher-Johns melting point apparatus and are uncorrected. ^{1}H and ^{13}C NMR spectra were recorded at 300 K in 5 mm NMR tubes on Bruker AC-250 MHz or AMX-400 MHz NMR spectrometers operating at 250.13 or 400.13 and 62.9 or 100.08 MHz, respectively, on solutions in chloroform-*d*, unless otherwise indicated. Chemical shifts are given in parts per million (ppm) (±0.01 ppm) relative to that of tetramethylsilane (TMS) (0.00 ppm) in the case of ^{1}H NMR spectra, and to the central line of chloroform-*d* (δ 77.23) for the ^{13}C NMR spectra. All assignments were confirmed by COSY, HETCOR, HMQC, or HMBC experiments. The exact masses of compounds **3**, **3a**, **4**, **4a**, **5**, **5a**, **8**, and **15** were measured on a CEC 21-110B mass spectrometer using electron ionization (70 eV). The exact masses of compounds **6**, **7**, **9**, and **14** were measured by positive ion mode electrospray ionization on a Micromass ZabSpec Hybrid Sector-TOF mass spectrometer. The liquid carrier (methanol) was infused into the electrospray source by means of a Harvard syringe pump at a flow rate of 10 µL min^{-1}. The masses of **10**, **11**, and **13** were measured on a Micromass MALDI-TOF mass spectrometer calibrated with a Sigma ProteoMass Peptide MALDI-MS calibration kit. Pyridine was dried by refluxing over calcium hydride followed by distillation. Dichloromethane was refluxed over calcium hydride for 1 h, then distilled over 3 Å molecular sieve. Chloroform was dried with magnesium sulfate, then distilled and stored over 4 Å molecular sieve. Cyclohexanone and 3-pentanone were distilled prior to use. *N,N*-Dimethylformamide was stored over activated 4 Å molecular sieve for 72 h. It was distilled under reduced pressure over freshly activated 4 Å molecular sieve. Benzyl chloride was dried with magnesium sulfate, refluxed over calcium hydride, and then fractionally distilled under reduced pressure, collecting the the middle fraction. It was stored over calcium hydride. Benzylidene acetals were visualized by quenching of fluorescence or by spraying the plate with a solution (53) of 0.2% *p*-methoxyphenol in ethanol – 2 N H_2SO_4 (1:1, v/v) and heating on a hot plate until colour developed. The di-*O*-methylene acetal was located by spraying (54) with an acidic solution of anisaldehyde in ethanol (ethanol (9 mL), anisaldehyde (0.5 mL), and concentrated sulfuric acid (0.5 mL)) and heating on a hot plate until colour developed. Other compounds were visualized by UV where applicable and (or) were located by spraying with a solution of 2% ceric sulfate in 1 M sulfuric acid followed by heating on a hot plate until colour developed. Compounds

were purified on silica gel (TLC standard grade, 230–400 mesh) by flash chromatography using specified eluents. Analyses were performed by the Canadian Microanalytical Service, Delta, B.C.

X-ray structure determinations

Crystals of **3b** (1.50 × 0.10 × 0.10 mm) and **5** (0.70 × 0.25 × 0.10 mm) were mounted on glass fibres. All measurements were made at room temperature on a Rigaku AFC5R diffractometer equipped with a 12 kW rotating anode generator and using graphite-monochromated Cu-Kα radiation. For each structure, cell constants and an orientation matrix for data collection were obtained from a least-squares refinement using the setting angles of a minimum of 24 reflections. During the data collections the intensities of three representative reflections were measured after every 150 reflections. Over this time the standards decreased by 3.9% for compound **5** so a polynomial decay correction was applied. An empirical absorption correction was also applied in each case; this resulted in transmission factors ranging from 0.665 to 1.000 (**3b**) or 0.660 to 1.000 (**5**). In both determinations, the data were corrected for Lorentz and polarization effects and a correction for secondary extinction was applied. The structures were solved by direct methods (55) and expanded using Fourier techniques. Full-matrix least-squares refinement on F^2 data was carried out using the program SHELXL97 (56). The non-hydrogen atoms were refined anisotropically. In general, the hydrogen atoms were included in geometrically calculated positions but were not refined. The only exception was H(O1) of compound **5**. The position of H(O1) was located in the Fourier difference map and was refined isotropically. Crystal data are summarized in Table 3.[3,4]

cis,cis-, _cis,trans_-, and _trans,trans_-2′,2′′:6′,6′′-Di-_O_-benzylidene-2′,2′′,6′,6′′-tetra(hydroxymethyl)-4-oxa-1,7-heptanediol (3, 4, and 5, respectively)

A suspension of dipentaerythritol (**2**) (12.71 g, 0.05 mol), benzaldehyde (11.2 mL, 0.11 mol, 2.2 equiv), and _p_-toluenesulfonic acid monohydrate (0.1 g) in benzene (270 mL) was refluxed for 2 h then allowed to cool to room temperature. Additional benzene (250 mL) and _p_-toluenesulfonic acid monohydrate (0.4 g) were then added and the mixture was refluxed for 8 h using a Dean–Stark apparatus. After being cooled to room temperature, the homogeneous reaction mixture was stirred with calcium carbonate (5 g) and filtered. The filtrate was dried over MgSO₄ and concentrated to an oily residue (18.28 g), which solidified upon standing. Part of the above residue (3.85 g) was separated by flash column chromatography using ethyl acetate – hexanes (1:1) as the eluent. A mixture (1.77 g) of isomers **4** and **5** eluted first (R_f = 0.32) (eluent ethyl acetate – hexanes, 2:1). The second component was isomer **3** (R_f = 0.15) (eluent ethyl acetate – hexanes, 2:1) as an amorphous solid (1.32 g, 34%), which was then recrystallized from 1-propanol to afford pure colorless needles, mp 164–166°C, lit. value (31) 166°C. For ¹H and ¹³C NMR data, see Table 1. EI-HR-MS calcd. for C₂₄H₃₀O₇: 430.1991; found: 430.1985.

The first eluting fraction (1.77 g) from the previous column was dissolved in pyridine (128 mL). The stirred solution was cooled to 0°C and acetic anhydride (128 mL) was added dropwise. After being allowed to warm to room tem-

perature, the solution was stirred for 12 h, then poured into ice water (500 mL). The resulting mixture was extracted with dichloromethane (4 × 50 mL). The combined extracts were dried over MgSO₄ and concentrated to an oily residue. The residue was separated by flash column chromatography on silica gel (ethyl acetate – hexanes, 1:5).

First to elute was 1,7-di-_O_-acetyl-_cis,trans_-2′,2′′:6′,6′′-di-_O_-benzylidene-2′,2′′,6′,6′′-tetra(hydroxymethyl)-4-oxa-1,7-heptanediol (**4a**), an amorphous solid (2.2 g). R_f 0.74 (ethylacetate – hexanes, 1:1), mp 108 to 109°C. For ¹H and ¹³C NMR data, see Table 2. EI-HR-MS calcd. for C₂₈H₃₄O₉: 514.2202; found: 514.2210.

The second component was 1,7-di-_O_-acetyl-_trans,trans_-2′,2′′:6′,6′′-di-_O_-benzylidene-2′,2′′,6′,6′′-tetra(hydroxymethyl)-4-oxa-1,7-heptanediol (**5a**), an amorphous solid (1.35 g) that crystallized from acetone–methanol as microcrystalline needles. R_f 0.66 (ethyl acetate – hexanes, 1:1), mp 139 to 140°C. For ¹H and ¹³C NMR data, see Table 2. EI-HR-MS calcd. for C₂₈H₃₄O₉: 514.2202; found: 514.2211.

A solution of **4a** (2.2 g, 0.004 mol) in dry chloroform (100 mL) was cooled to 0°C and 1 M sodium ethoxide (2 mL) was added dropwise. The mixture was then stirred until TLC indicated the disappearance of the starting material (3 h). The chloroform solution was washed with water (6 × 30 mL), dried over MgSO₄, and concentrated to afford the de-_O_-acetylated _cis,trans_-isomer **4** (1.53 g, 83%), which was recrystallized from 1-propanol; mp 126 to 127°C. For ¹H and ¹³C NMR data, see Table 1. EI-HR-MS calcd. for C₂₄H₃₀O₇: 430.1991; found: 430.1987.

1,7-Di-_O_-acetyl-_trans,trans_-2′,2′′:6′,6′′-di-_O_-benzylidene-2′,2′′,6′,6′′-tetra(hydroxymethyl)-4-oxa-1,7-heptandiol (**5a**) (1.35 g, 0.0026 mol) was de-_O_-acetylated as above, to give the _trans,trans_-isomer **5** as an amorphous solid (0.77 g, 82%), which was then recrystallized from 1-propanol to afford thin colorless plates; mp 170–173°C. For ¹H and ¹³C NMR data, see Table 1. EI-HR-MS calcd. for C₂₄H₃₀O₇: 430.1991; found, 430.1978. For X-ray data, see Table 3.[3,4]

1,7-Di-_O_-acetyl-_cis,cis_-2′,2′′:6′,6′′-di-_O_-benzylidene-2′,2′′,6′,6′′-tetra(hydroxymethyl)-4-oxa-1,7-heptanediol (3a)

Compound **3** (50 mg) was acetylated as for the **4**, **5** mixture above. Colorless crystals (55 mg, 92%) were obtained that were recrystallized from acetone–methanol; mp 104 to 105°C. For ¹H and ¹³C NMR data, see Table 2. EI-HR-MS calcd. for C₂₈H₃₄O₉ (M⁺): 514.2202; found: 514.2176. Calcd. for C₂₈H₃₃O₉: 513.2124; found: 513.2117.

Alternative method of preparation of _cis,cis_-, _cis,trans_-, and _trans,trans_-2′,2′′:6′,6′′-di-_O_-benzylidene-2′,2′′,6′,6′′-tetra(hydroxymethyl)-4-oxa-1,7-heptanediol (3, 4, and 5, respectively)

A suspension of dipentaerythritol (**2**) (1.0 g, 3.9 mmol), benzaldehyde (0.90 mL, 8.8 mmol, 2.2 equiv), and _p_-toluenesulfonic acid monohydrate (0.45 g, 2.6 mmol) in dry benzene (60 mL) and _N,N_-dimethylformamide (90 mL) was refluxed for 5 h with azeotropic removal of water. After being cooled to room temperature, the homogeneous reaction mixture was stirred with calcium carbonate (2 g) and filtered. The filtrate was dried over MgSO₄ and concentrated to an oily residue, which was purified by flash column chroma-

tography on silica gel (ethyl acetate – hexane, 1:2) to give a mixture of compounds **3**, **4**, and **5** (1.46 g, 85%).

Preparation of *cis,cis*-, *cis,trans*-, and *trans,trans*- 2′,2′′:6′,6′′-di-*O*-benzylidene-2′,2′′,6′,6′′-tetra(hydroxy-methyl)-4-oxa-1,7-heptanediol (3, 4, and 5, respectively) in toluene

A suspension of dipentaerythritol (5 g, 19.7 mmol), benz-aldehyde (4.4 mL, 43.3 mol, 2.2 equiv), and *p*-toluene-sulfonic acid monohydrate (0.5 g) in toluene (650 mL) was refluxed for 8 h using a Dean–Stark apparatus. After cooling to room temperature, the unreacted material (1.55 g) was fil-tered off. The filtrate was stirred with calcium carbonate (2 g) and filtered, dried over $MgSO_4$ and concentrated to dryness. The oily residue was separated by flash column chromatography using ethyl acetate – hexanes (1:1) as the eluent. First to elute was di-*O*-benzylidenepentaerythritol (0.19 g, 3.3%), mp 155–158°C, lit. value (57) 160°C. ^{1}H NMR spectrum was identical to that of Clark (41). The sec-ond component was a mixture (2.81 g) of isomers **4** and **5**. The third component was isomer **3** (0.94 g).

1,7-Di-*O*-benzoyl-*cis,cis*-2′,2′′:6′,6′′-di-*O*-benzylidene-2′,2′′,6′,6′′-tetra(hydroxymethyl)-4-oxa-1,7-heptanediol (3b)

Benzoyl chloride (0.1 mL) was added dropwise to a stirred solution of the *cis,cis*-isomer (**3**, 100 mg, 0.230 mmol) in dry pyridine (3 mL) and stirring was contin-ued for 1 h. The reaction mixture was poured into ice water (20 mL) and the resulting mixture was extracted with di-chloromethane (3 × 15 mL). The combined extracts were dried ($MgSO_4$) and concentrated to a solid residue (178 mg, 70%) which was then recrystallized from ethanol to afford fine colorless needles, mp 165–167°C. ^{1}H NMR δ: 7.97–8.02 (m, 4 × PhH, 20H), 5.45 (s, 2 × PhC*H*), 4.24 (s, 2 × CC*H*$_2$OCO), 4.23, 3.93 (AB q, 8H, *J* = 11.9 Hz, H2′, H2′′, or H6′, H6′′), 4.00 (CC*H*$_2$OC*H*$_2$C). ^{13}C NMR δ: 166.25 (2 × Ph*C*O), 128.45–138.11 (4 × Ph*C*), 102.07 (2 × acetal *C*), 70.13 (C*C*H$_2$OC*H*$_2$C), 69.89 (C2′, C2′′, C6′, C6′′), 64.40 (C*C*H$_2$OCO). For X-ray data, see Table 3.[3,4]

2′,2′′:6′,6′′-Di-*O*-cyclohexylidene-2′,2′′,6′,6′′-tetra(hydroxy-methyl)-4-oxa-1,7-heptanediol (6)

Dipentaerythritol (2.60 g, 0.010 mol), freshly distilled cyclohexanone (0.025 mol, 2.5 equiv), and *p*-toluenesulfonic acid (0.45 g, 2.6 mmol) were stirred in a refluxing mixture of dry benzene and dry dimethylformamide (130 mL, 4:6 (v/v)) for 6 h with removal of water. After being cooled to room temperature, the homogeneous reaction mixture was stirred with calcium carbonate (2 g) and filtered. The filtrate was dried over $MgSO_4$ and concentrated to give the title compound (4.02 g, 98%) as a pure colorless solid that was recrystallized from ethyl acetate, mp 116–118°C. ^{1}H NMR δ: 3.70 (s, 2 × H2′, H2′′, H6′, H6′′, 8H), 3.64 (s, C*H*$_2$OH, 4H), 3.49 (CC*H*$_2$OC*H*$_2$C, 4H), 1.42–1.74 (complex m, 2 × cyh H, 20H). ^{1}H NMR (pyridine-d_5, 400.13 MHz) δ: 4.05 (AB quartet, 2 × H2′, H2′′,H6′, and H6′′, Δν = 0.0336 ppm, *J* = 11.6 Hz, 8H), 4.03 (s, C*H*$_2$OH, 4H), 3.73 (CC*H*$_2$OC*H*$_2$C, 4H), 1.35–1.90 (complex m, 2 × cyh H, 20H). ^{13}C NMR δ: 98.66 (2 × acetal *C*), 72.55 (C*C*H$_2$OC*H*$_2$C), 63.86 (2 × C*H*$_2$OH), 62.21 (C2′, C2′′, C6′, C6′′), 39.63 (2 × C2), 32.72,

32.51 (2 × cyh C2, C6), 25.73 (2 × cyh C4), 22.63 (2 × cyh C3, C5). ES-HR-MS calcd. for $C_{22}H_{38}O_7$+Na: 437.2515; found: 437.2511.

2′,2′′:6′,6′′-Di-*O*-(1-ethylpropylidene)-2′,2′′,6′,6′′-tetra(hy-droxymethyl)-4-oxa-1,7-heptanediol (7)

Dipentaerythritol (2.60 g, 0.010 mol) was reacted with freshly distilled 3-pentanone (2.15 g, 2.6 mL, 0.025 mol) as above, to give the title compound (60%) as a colorless solid, mp 123–126°C. ^{1}H NMR δ: 3.67 (s, 2 × H2′, H2′′, H6′, H6′′, 8H), 3.63 (s, C*H*$_2$OH, 4H), 3.49 (CC*H*$_2$OC*H*$_2$C, 4H), 1.71 (q, 4 × CH$_3$C*H*$_2$-, 8H, *J* = 7.32 Hz), 0.88 (t, 4 × C*H*$_3$CH$_2$-, 12H, *J* = 4.88 Hz). ^{13}C NMR δ: 101.71 (2 × *C* (CH$_2$CH$_3$)$_2$, 72.32 (C*C*H$_2$OC*H*$_2$C), 63.60 (2 × *C*H$_2$OH), 62.36 (C2′, C2′′, C6′, C6′′), 39.25 (2 × C quat), 25.80, 25.53 (4 × CH$_3$*C*H$_2$-), 7.62 (4 × *C*H$_3$CH$_2$-). H-ES-MS calcd. for $C_{20}H_{38}O_7$ + Na: 413.2515; found: 413.2517.

2′,2′′:6′,6′′-Di-*O*-methylene-2,2,6,6-tetrahydroxymethyl-4-oxa-1,7-heptanediol (8)

2,2,6,6-Tetrahydroxymethyl-4-oxa-1,7-heptanediol **2** (26.0 g) was stirred with 37% aqueous formaldehyde (26 mL) and concentrated hydrochloric acid (26 mL) at 85°C for 14 h, then cooled to room temperature. Sodium hydroxide pellets were added slowly until the solution was basic (12.5 g) and the cooled solution was filtered. The filtrate was extracted with dichloromethane (3 × 50 mL) and the combined ex-tracts were washed with water (10 mL), dried ($MgSO_4$), and concentrated to a syrupy residue (25.76 g). The residue was taken up in chloroform (50 mL). When hexanes (75 mL) were added, a colorless amorphous precipitate (7.3 g after air drying) was obtained and concentration followed by rep-etition yielded more precipitate (2.0 g). The residue (14.0 g) was separated by flash column chromatography on silica gel using ethyl acetate – hexanes (3:1) as the eluant and a fur-ther 2.26 g were obtained. Total yield 11.56 g, 40.6%. R_f 0.34 (ethyl acetate – hexanes, 4:1). Recrystallization from chloroform—hexanes yielded lustrous colorless plates, mp 95 to 96°C. ^{1}H NMR (400.13 MHz) δ: 3.08 (br t, 2 H, *J* = 5.8 Hz, OH), 3.51 (s, 4 H, H-3,5), 3.64 (d, 4H, H-1,7), 3.72 (AB q, 8H, J_{AB} = 11.25 Hz, $\Delta\delta_{AB}$ = 0.025, CH$_2$s on C-2′,2′′,6′,6′′), 4.80 (AB q, 4H, J_{AB} = 6.08 Hz, $\Delta\delta_{AB}$ = 0.036, acetal CH$_2$). ^{13}C NMR (62.9 MHz) δ: 39.89 (C-2,6), 62.54 (C-1,7), 69.74 (C-2′,2′′,6′,6′′), 71.14 (C-3,5), 94.27 (acetal *C*). HR-EI-MS calcd. for $C_{12}H_{21}O_7$ (M − 1): 277.1287; found: 277.1270.

cis,cis-2′,2′′:6′,6′′-Di-*O*-benzylidene-7-benzyloxy-2′,2′′,6′,6′′-tetra(hydroxymethyl)-4-oxa-1-heptanol (9)

Powdered potassium hydroxide (0.3 g, 5 mmol) was dis-solved in a stirred solution of dry benzyl chloride (11.0 g, 10.0 mL, 86.9 mmol) over 20 min as the temperature was raised to 105°C. *cis,cis*-Diol **4** (100 mg, 0.23 mmol) was added and the solution was stirred for 2 h at 105°C. The re-action mixture was allowed to cool to room temperature and chloroform (25 mL) and water (25 mL) were added. The or-ganic layer was washed with water (2 × 25 mL) and dried ($MgSO_4$) and concentrated to a colorless syrup, that was pu-rified by column chromatography on silica gel using ethyl acetate – hexanes (1:1) as the eluant. Yield: 100 mg, 83%. ^{1}H NMR δ: 7.23–7.77 (m, 3 × PhH, 15H), 5.41 (2 × PhC*H*),

4.45 (s, PhC*H*$_2$O, 2H), 4.14, 3.73 (AB q, 4H, *J* = 12.5 Hz, H2′, H2′′ or H6′, H6′′), 4.11, 3.85 (AB q, 4H, *J* = 12.5 Hz, H6′, H6′′ or H2′, H2′′), 3.97, 3.92 (s, CC*H*$_2$OC*H*$_2$C, 4H), 3.45 (s, C*H*$_2$OH, 2H), 3.27 (s, CC*H*$_2$OC*H*$_2$Ph, 2H). ^{13}C NMR δ: 126.14–138.20 (3 × Ph*C*), 101.94, 102.08 (2 × Ph*C*), 73.64 (Ph*C*H$_2$), 72.80, 70.67 (C*C*H$_2$O*C*H$_2$C), 70.53, 70.35 (*C*2′, *C*2′′, *C*6′, *C*6′′), 70.43 (C*C*H$_2$O*C*H$_2$Ph), 65.44 (*C*H$_2$OH), 39.06, 39.12 (2 × *C* quat). HR-ES-MS calcd. for C$_{31}$H$_{36}$O$_7$ + Na: 543.2359; found: 543.2360.

1,7-Di-*O*-benzyl-*cis*,*cis*-2′,2′′:6′,6′′-di-*O*-benzylidene-2′,2′′,6′,6′′-tetra(hydroxymethyl)-4-oxa-1,7-heptanediol (10)

After a solution of *cis*,*cis*-diol **3** (100 mg, 0.23 mmol) in DMF (20 mL) was cooled to 0°C, a 60% oil suspension of sodium hydride (50 mg, 1.2 mmol) was added and the mixture was allowed to stir for 30 min. Benzyl bromide (0.2 mL) was added and the mixture was allowed to warm to room temperature, then stirred for a further 3 h. Methanol (1 mL) was added. After 15 min the mixture was concentrated under reduced pressure, then partitioned between ethyl acetate (25 mL) and water (25 mL); the aqueous layer was extracted with ethyl acetate (25 mL), and the combined ethyl acetate layers were dried over MgSO$_4$ and concentrated. The residue was purified by column chromatography on silica gel (ethyl acetate – hexane (1:5), R_f = 0.37) to give the title compound (**10**) as a colorless oil (77 mg, 54%). ^{1}H NMR δ: 7.30–7.50 (m, 4 × Ph*H*, 20H), 5.42 (2 × PhC*H*, 2H) 4.43 (s, 2 × PhC*H*$_2$O, 4H), 4.11, 3.90 (AB q, 8H, *J* = 11.6 Hz, H2′, H2′′, H6′, H6′′), 3.87 (s, CC*H*$_2$OC*H*$_2$C, 4H), 3.29 (s, CC*H*$_2$OC*H*$_2$Ph,4H). ^{13}C NMR δ: 126.36–138.59 (4 × Ph*C*), 101.99 (acetal *C*), 73.71 (*C*H$_2$Ph), 70.57 (C*C*H$_2$O*C*H$_2$C), 70.32 (*C*2′, *C*2′′, *C*6′, *C*6′′) 70.32 (*C*H$_2$O*C*H$_2$Ph), 39.38 (*C* quat.). MALDI-TOF HR-MS calcd. for C$_{38}$H$_{42}$O$_7$ + Na: 633.283; found: 633.274.

trans,*trans*-2′,2′′:6′,6′′-Di-*O*-benzylidene-7-benzyloxy-2′,2′′,6′,6′′-tetra(hydroxymethyl)-4-oxa-1-heptanol (11)

Powdered potassium hydroxide (0.3 g, 5 mmol) dissolved partially in a stirred solution of dry benzyl chloride (11.0 g, 10.0 mL, 86.9 mmol) over 20 min as the temperature was raised to 58°C. *trans*,*trans*-Diol **6** (100 mg, 0.23 mmol) was added and the mixture was stirred for 5 h at 58°C. The reaction mixture was allowed to cool to room temperature and chloroform (25 mL) and water (25 mL) were added. The organic layer was washed with water (2 × 25 mL) and dried (MgSO$_4$) and concentrated. The residue was purified by column chromatography on silica gel (ethyl acetate – hexane (1:1), R_f = 0.72) to give the title compound (**11**). Yield: 83 mg, 69%. Recrystallization from diethyl ether – hexanes afforded an amorphous solid, mp 100 to 101°C. ^{1}H NMR δ: 7.26–7.60 (m, 3 × Ph*H*, 15H), 5.41, 5.40 (2 × PhC*H*), 4.58 (s, PhC*H*$_2$O, 2H), 4.13, 3.82 (AB q, 4H, *J* = 11.6 Hz, H2′, H2′′ or H6′, H6′′), 4.07, 3.76 (AB q, 4H, *J* = 11.9 Hz, H6′, H6′′ or H2′, H2′′), 3.97 (d, C*H*$_2$OH, *J* = 4.9 Hz, 2H), 3.81 (s, CC*H*$_2$OC*H*$_2$Ph, 2H), 3.26, 3.21 (2s, CC*H*$_2$OC*H*$_2$C, 4H), 1.27 (t, 1H, OH). ^{13}C NMR δ: 126.25–138.59 (3 × Ph*C*), 102.08 (2 × Ph*C*), 73.70 (Ph*C*H$_2$), 72.85, 72.11 (C*C*H$_2$O*C*H$_2$C), 70.22, 70.00 (*C*2′, *C*2′′, *C*6′, *C*6′′), 69.03 (C*C*H$_2$O*C*H$_2$Ph), 62.81 (*C*H$_2$OH), 39.37, 39.23 (2 × *C* quat). MALDI-TOF HR-MS calcd. for C$_{31}$H$_{36}$O$_7$ + Na: 543.236; found: 543.217.

trans,*cis*-2′,2′′:6′,6′′-Di-*O*-benzylidene-7-benzyloxy-2′,2′′,6′,6′′-tetra(hydroxymethyl)-4-oxa-1-heptanol (12) and *cis*,*trans*-2′,2′′:6′,6′′-di-*O*-benzylidene-2′,2′′,6′,6′′-tetra(hydroxymethyl)-4-oxa-1-heptanol (13)

Powdered potassium hydroxide (0.3 g, 5 mmol) was partially dissolved in a stirred solution of dry benzyl chloride (11.0 g, 10.0 mL, 86.9 mmol) over 20 min as the temperature was raised to 80°C. *cis*,*trans*-Diol **4** (100 mg, 0.23 mmol) was added and the mixture was stirred for 3 h at 80°C. The reaction mixture was allowed to cool to room temperature and chloroform (25 mL) and water (25 mL) were added. The organic layer was washed with water (2 × 25 mL) then dried (MgSO$_4$) and concentrated. The oily residue was separated by flash column chromatography on silica gel (ethyl acetate – hexanes, 1:2). First to elute was compound **12**, an amorphous solid. Yield: 63 mg, 52%. R_f = 0.4 (ethyl acetate – hexanes, 1:2). It was recrystallized from 1-propanol; mp 124 to 125°C. ^{1}H NMR δ: 7.32–7.48 (m, 3 × Ph*H*, 15H), 5.44, 5.41 (2 × PhC*H*), 4.50 (s, PhC*H*$_2$O, 2H), 4.14, 3.78 (AB q, 4H, *J* = 12.21 Hz, H2′, H2′′ or H6′, H6′′), 4.12, 3.87 (AB q, 4H, *J* = 11.6 Hz, H6′, H6′′ or H2′, H2′′), 4.01 (d, C*H*$_2$OH, 2H, *J* = 6.1 Hz), 3.80 (s, 2H, CC*H*$_2$OC*H*$_2$C from the *cis*-ring), 3.35, 3.27 (2s, 4 H, CC*H*$_2$OC*H*$_2$Ph from the *cis*-ring, CC*H*$_2$OC*H*$_2$C from the *trans*-ring), 2.15 (t, 1 H, OH). ^{13}C NMR δ: 126.08–138.06 (3 × Ph*C*), 102.10, 102.07 (2 × Ph*C*), 73.76 (Ph*C*H$_2$), 73.20, 70.66 (C*C*H$_2$O*C*H$_2$C), 70.22, 70.18 (*C*2′, *C*2′′, *C*6′, *C*6′′), 70.44 (C*C*H$_2$O*C*H$_2$Ph), 63.33 (*C*H$_2$OH), 39.16, 39.33 (2 × *C* quat). Anal. calcd. for C$_{31}$H$_{36}$O$_7$: C 71.52, H 6.97; found: C 71.64, H 7.08.

The second component was also an amorphous solid (**13**, 19 mg, 16%). R_f = 0.25 (ethyl acetate – hexanes, 1:2), mp 90–92°C. ^{1}H NMR δ: 7.25–7.39 (m, 3 × Ph*H*, 15H), 5.43, 5.40 (2 × PhC*H*), 4.58 (s, PhC*H*$_2$O, 2H), 4.16, 3.77 (AB q, 4H, *J* = 11.9 Hz, H2′, H2′′ or H6′, H6′′), 4.14, 3.82 (AB q, 4H, *J* = 11.9 Hz, H6′, H6′′ or H2′, H2′′), 3.86, 3.84 (2s, 4H, C*H*$_2$OC*H*$_2$Ph in the *trans*-ring, CC*H*$_2$OC*H*$_2$C in the *cis*-ring), 3.47 (d, 2H, *J* = 5.8 Hz, C*H*$_2$OH), 3.41 (s, CC*H*$_2$OC*H*$_2$C in the *trans*-ring), 2.33 (t, 1H, OH). ^{13}C NMR δ: 126.06–138.36 (3 × Ph*C*), 102.24, 102.13 (2 × Ph*C*), 73.77 (Ph*C*H$_2$), 73.06, 72.43 (C*C*H$_2$O*C*H$_2$C), 70.60, 70.37 (*C*2′, *C*2′′, *C*6′, *C*6′′), 69.37 (C*C*H$_2$O*C*H$_2$Ph), 65.49 (*C*H$_2$OH), 39.24, 39.14 (2 × *C* quat). HR-ES-MS calcd. for C$_{31}$H$_{36}$O$_7$ + Na: 543.236; found: 543.259.

2,6-Bis(benzyloxymethyl)-4-oxa-1,7-heptanediol (14)

(*a*) From compound **4**. To a stirred solution of the *cis*,*trans*-diol **4** (0.16 g, 0.37 mmol, dried under vacuum for 12 h) in dry dichloromethane (5 mL) at 0°C was added triethylsilane (2.13 mL, 4.5 mmol, 36 equiv) and freshly distilled boron trifluoride etherate (0.56 mL, 1.5 mmol, 12 equiv). After being allowed to warm to room temperature, the solution was stirred for 12 h. The mixture was then diluted with dichloromethane (30 mL), washed with a saturated sodium hydrogen carbonate solution (40 mL), dried (MgSO$_4$), and concentrated. The residue was purified by flash column chromatography (ethyl acetate – hexanes (2:1), R_f = 0.21) to afford the title compound (**14**) as a colorless solid. Yield: 0.10 g, 64%, mp 95–97°C. ^{1}H NMR δ: 7.26–7.33 (m, 2 × Ph*H*, 10H), 4.46 (s, 2 × PhC*H*$_2$O, 4H), 3.61 (s, 4 × C*H*$_2$OH, 8H), 3.46 (s, 2 × CC*H*$_2$OC*H*$_2$Ph, 4H), 3.40 (s, CC*H*$_2$OC*H*$_2$C, 4H). ^{13}C NMR δ: 127.68–137.93 (2 × Ph*C*),

73.82 (2 × PhCH_2O), 71.96 (CCH_2OCH_2C), 71.75 (2 × CCH_2OCH_2Ph), 64.23 (4 × CH_2OH), 45.42 (2 × C quat). HR-ES-MS calcd. for $C_{24}H_{34}O_7$ + Na: 457.2202; found: 457.2202.

(*b*) From the mixture of compounds **3–5**. Application of the procedure from part (*a*) to the mixture of diols **3–5** (50 mg, 0.12 mmol) gave the same product (**14**) (36 mg, 68%).

Reaction of 2′,2′′:6′,6′′-di-*O*-methylene-2,2,6,6-tetrahydroxymethyl-4-oxa-1,7-heptanediol (8) with 1,3-di(bromomethyl)benzene

To a solution of sodium hydride (60% oil dispersion, 320 mg, 8 mmol) in dry DMF (50 mL) magnetically stirred in a three-necked round-bottomed flask under nitrogen was added dropwise, simultaneously, solutions of compound **8** (1.113 g, 4 mmol) in DMF (20 mL) and 1,3-di(bromomethyl)benzene (1.056 g, 4 mmol) in DMF (15 mL) from pressure-equalized dropping funnels. After two-thirds of the addition had been made, more 60% sodium hydride (400 mg, 10 mmol) was added before the dropwise addition was complete. The mixture was stirred 3 days, then concentrated. The residue was taken up in dichloromethane (30 mL) and the solution was washed with water (3 × 10 mL), dried (MgSO$_4$), and concentrated. Crystals of the title compound (**15**) were deposited which were recrystallized from choroform–hexanes. Yield: 180 mg, 12%. R_f = 0.81 (ethyl acetate — hexanes, 3:1), mp 197–199°C. ^{1}H NMR (400.13 MHz) δ: 3.30 (s, 4H, H-1,7), 3.53 (s, 4 H, H-3,5), 3.69 (AB q, 8 H, J_{AB} = 11.31 Hz, $\Delta\delta_{AB}$ = 0.0344, CH_2s on C-2′,2′′,6′,6′′), 4.64 (s, 4H, Bn H), 4.80 (AB q, 4H, J_{AB} = 6.08 Hz, $\Delta\delta_{AB}$ = 0.027, acetal CH_2), 7.03 (dd, 2H, J_{ortho} = 7.48 Hz, J_{meta} = 1.45 Hz, Ph H-4,6), 7.251 (t, 1H, Ph H-5), 7.512 (br s, Ph H-2). ^{13}C NMR (62.9 MHz) δ: 39.29 (C-2,5), 66.91 (C-1,7), 69.27 (Bn CH_2), 70.40 (C-2′,2′′,6′,6′′), 71.96 (C-3,5), 94.49 (acetal C), 123.11 (Ph C-2), 126.13 (Ph C-4,6), 128.17 (Ph C-5), 139.24 (Ph C-1,3). HR-EI-MS calcd. for $C_{20}H_{28}O_7$ (M^+): 380.1835; found: 380.1817.

Competition experiment

Powdered potassium hydroxide (0.15 g, 2.5 mmol) was suspended in dry benzyl chloride (5.5 g, 5 mL, 43.5 mmol) and this mixture was stirred at room temperature for 15 min. *cis*,*cis*-Diol **5** (50 mg, 0.12 mmol) was added followed by 1-octanol (0.23 mmol, 2 equiv, 0.036 mL) and the mixture was stirred for 2.5 h at room temperature. The solution was concentrated and the residue was examined by NMR.

An unusual abnormal Wolff rearrangement[1]

Howard E. Zimmerman and Pengfei Wang

Abstract: An unusual example of the abnormal Wolff rearrangement was studied. The bicyclic structure of the reactant and intermediates precluded some mechanistic possibilities of this unusual abnormal Wolff rearrangement. The study involved the photochemical rearrangement of diazodehydronorbornone bearing phenyl and 2-pyridyl groups at C-7. A number of examples of interesting stereoselectivity were encountered. The mechanism was investigated by use of ab initio QST type computations, which located a unique transition structure species accounting for the reaction mechanism.

Key words: abnormal-Wolff, carbene, rearrangement, QM computations, reaction mechanism.

Résumé : On a étudié un exemple inhabituel d'un réarrangement anormal de Wolff. La structure bicyclique du réactif et des intermédiaires ne permettaient pas certaines possibilités mécanistiques de cet exemple inhabituel d'un réarrangement anormal de Wolff. L'étude implique le réarrangement photochimique d'une diazodéhydronorbornone portant des groupes phényle et 2-pyridyle au niveau du C-7. On a rencontré un certain nombre d'exemples de stéréosélectivité intéressante. On a étudié le mécanisme sur la base de calculs théoriques ab initio de type QST qui ont permis de localiser la structure d'une espèce définie de transition permettant d'expliquer le mécanisme réactionnel.

Mots clés : réaction anormale de Wolff, carbène, réarrangement, calculs de type QM, mécanisme réactionnel.

Introduction and background

The Wolff rearrangement has been a valuable synthetic tool. Interestingly, in the special case of β,γ-unsaturation in the reactant diazoketone, there is a dramatic alteration of the reactivity (1). Remarkably, this rather interesting reactivity went unnoticed until the simultaneous efforts of our research group (2), that of Smith (3), and Lokensgard (4). The extensive studies by Smith established the generality and synthetic utility of the reaction.

Our own research was initiated with the idea of providing housone reaction intermediates involved in the photochemical rearrangement of 4,4-diphenylcyclopentenone (2*a*) which had been found to afford an unexpected unsaturated ketene. Indeed, it was found that at low temperature housones were formed (2) but fragmented on warming to afford ketenes of structure **5**. From room temperature irradiations only the ketene **5** was observed and isolated as methyl ester **6**. The mechanisms considered are shown in Scheme 1.

An independent generation of the intermediates was sought in the reaction of the stilbenyl diazoketone **7** which was observed to afford the same housone **4**, ketene **5**, and methyl ester **6** (Scheme 2). Parallel results were observed in the study of Smith (3) who obtained a large number of examples of the diazoketone reaction.

Recently, in connection with our studies of intramolecular proton transfer, we found closely related results in the Wolff rearrangement of dehydronorbornyl diazoketones. However, as a consequence of the bicyclic nature of the system, a number of mechanistic aspects, originally proposed, needed modification for this system.

Results

Synthesis of the diazoketones

The synthesis of the two diazoketones (**12-syn** and **12-anti**) of interest is outlined in Scheme 3. The reactant norbornenones, **10-syn** and **10-anti** derived from our earlier studies (5), and provided convenient starting points. In the case of the syn ketone **10-syn**, the initially formed lithium enolate was obtained as a solid and could be used directly rather than isolating the formylated ketone. Both diazoketone diastereomers (**12-syn** and **12-anti**) were obtained as yellow crystalline solids.

Results

The abnormal Wolff rearrangement

In contrast to the ordinary Wolff rearrangement of the saturated 7,7-diaryldiazonorbornyl ketones (5), the dehydronorbornyl counterparts **12-syn** and **12-anti** reacted to give

Scheme 1. Original reaction mechanisms considered.

Scheme 2. Reaction mechanism variations.
Scheme 3. Synthesis of the diastereomeric dehydronorbornyl diazocompounds.
unanticipated photoproducts. The reaction course of the *syn*-phenyl diastereomer (**12-anti**) is outlined in Scheme 4. In

addition to the expected normal Wolff rearrangement products (**14-anti-exo** and **14-anti-endo**) there were three rather

Scheme 4. Reaction of the *anti*-pyridyl diazoketone.

	29%	5%	10%	18%	16%
interesting but unexpected photoproducts — **15-anti-endo**, **15-anti-exo**, and **16-anti**.

The photolysis of **12-syn** led, in addition to the anticipated Wolff rearrangement products **14-syn-exo** and **14-syn-endo**, to two abnormal Wolff products (**15-syn-endo** and **16-syn**) (Scheme 5). These structures derived from proton NMR and NOE experiments. Further, the structures of **14-anti-exo**, **15-anti-exo** (see Table 1 for crystal data and structure refinement), and **16-anti** (see Table 2 for crystal data and structure refinement) were established by X-ray analysis. Details are given in the *Experimental section*. Also, the independent synthesis of **15-syn-exo**, which was not a photoproduct, but which was helpful in the structure determination of **15-syn-endo**, is outlined in Scheme 6. Also, Scheme 6 outlines the epimerization of **15-syn-endo** to **15-syn-exo**. This conversion favors the thermodynamically more stable diastereomer.

Discussion

Stereochemistry of the ethyl diazoacetate addition to the pyridyl cyclopentadiene; the unusual syn–endo addition to the pyridyl phenyl cyclopentadiene

Before proceeding to discussion of the abnormal Wolff mechanisms, we need to consider the unusual reaction depicted in Scheme 6. Thus, two facets of the cyclopropanation, utilized in the synthesis, are of interest and one is unique. In this highly stereoselective reaction, the preferential exo configuration of the product is anticipated on the basis of lesser steric repulsions than in an endo addition. In contrast, the kinetic preferences for the totally stereoselective syn addition to afford **15-syn-exo** is not so easily rationalized. However, copper-catalyzed addition of ethyl diazoacetate to alkene π bonds has been suggested (6) to proceed with the carbethoxy carbene sp^2-hybrid bonding as a ligand to copper while the electrophilic carbene *p*-orbital attacks the alkene π bond. In the present instance, analogous coordination of cupric ion to the pyridyl nitrogen and the carbene sp^2 orbital forces the carbene to bond syn (i.e., cis to the pyridyl group). Also LDA epimerization under thermodynamic conditions of **15-syn-endo**, available from the Wolff rearrangement as described above, led to **15-syn-exo**. However, the mixture of the two diastereomers favored the exo diastereomer.

The normal Wolff rearrangement and the stereochemistry of kinetic protonation

The stereochemistry of the normal Wolff rearrangement of the syn phenyl diazoketone **12-anti**, affords the rearrange-

ment products **14-anti-exo** and **14-anti-endo** (note Scheme 4). The observed 6:1 preference for formation of the exo product stereoisomer clearly arises from less hindered protonation of the intermediate enol **18-anti** as anticipated from the ubiquitous phenomenon originally reported by one of us (7a) and described in a long list of our publications (5, 7) (Scheme 7).

Interestingly, in the case of the **12-syn** diazoketone, although the Wolff rearrangement product from this diastereomer also gave the same preference for less hindered protonation, the stereoselectivity had dropped to 2:1. This is outlined in Scheme 8. The diminished stereoselectivity may be attributed to the intervention of some intramolecular hydrogen transfer from methanol hydrogen bonded to the pyridyl group. This was the dominant process in our study of the dihydro analog of the present system (5).

The abnormal Wolff rearrangement

In comparing our present results with those we and others carried out much earlier (2–4), we recognize that the housone (note species **4** of Scheme 2) of the earlier studies cannot be involved in the bicyclic system currently under study. Secondly, in contrast to species **3** (Scheme 2 again) there can be no delocalization in a diradical counterpart of **3** of the earlier study because of Bredt's rule limitations. Such a diradical would have an unstable structure discussed below as **26**. Yet housone intermediates were observed in the acyclic studies and thus must be taken as possible but not necessary for the abnormal Wolff rearrangement.

Turning now to the abnormal Wolff rearrangement products let us consider the anti-pyridyl reactivity first. Here, in the formation of **15-anti-endo** and **15-anti-exo**, we note that a species of generalized structure such as **20-anti** in Scheme 9 is likely to be involved. Thus, we know that, in proceeding to the ketene **21-anti**, bond 1—2 is severed and a new bond (4—6) is formed as well as π bond 3—4 being weakened. Also, the formation of methoxy product **16** involves formation of that same bond, 4—6, and pickup of methanol at C-3.

To provide some further light on this proposal, we proceeded with some computational efforts. Gaussian98 RHF/6-31G* optimization of the S0 carbene **19** and ketene **21** established these as energy minima. We next proceeded to QST2 and QST3 computations on the truncated system as outlined in Scheme 10. With singlet carbene **23** as reactant and ketene **25** as product species, with or without interposition of a species of geometry close to that depicted as a truncated **20-anti**, a transition structure of geometry **24** was obtained. This species was close in structure to that of **26**

except that bond 1—2 was elongated while the distance between atoms 4 and 6 approached normal single bond length.

Interestingly, structure **26** proved not to be an energy minimum and stable. Rather, geometry optimization with RHF/6-31G* of this starting species led to the carbene **23**. A further point of interest was the behavior of species **23** when a proton, placed in the vicinity (ca. 5 Å) of C-6, was included in the optimization. This reactant (i.e., **23**) then picked up the proton to afford cation **27** which proved to be an energy minimum. When a methanol molecule was introduced close to C-3, methoxyketone **28** resulted.

Thus, the truncated QST system behaved quite parallel to the experimental sequence suggested in Scheme 9. However,

there is an additional possibility in the case of formation of **15-syn-endo**, this deriving from species **27**. This alternative does not involve ketonization and is outlined in Scheme 11.

Finally, we need to consider the stereochemical outcome of several of the reactions in leading to photoproducts. In the case of **14-anti-exo** and **14-anti-endo** being formed in a ratio of ca. 6:1, compared with **14-syn-exo** and **14-syn-endo** in a ratio of 2:1 (note Schemes 4 and 5) the preference for the exo isomers is understood as a consequence of less hindered protonation of the enolic precursors. The lower diastereoselectivity in the syn-pyridyl seems possibly to arise

15-endo   **15-exo**
from the 2-pyridyl group delivering hydrogen-bonded methanol to a minor extent.

The preferential formation of **15-anti-exo** relative to **15-anti-endo** (Scheme 4) in a ca. 2:1 ratio, does not seem a consequence of less hindered protonation of their enolic precursor. Rather, there is some evidence (8) that methanol may π bond to the face of a phenyl group, thus delivering protons to the enolic precursor.

Conclusion

This study revealed an unanticipated but remarkable difference between the ordinary Wolff rearrangement of the satu-

rated norbornyl system previously studied and the dehydro counterpart. As this research proceeded, a number of stereochemical and mechanistic aspects were uncovered. One of the most interesting derived from the QST computations.

Experimental section

3-Diazo-7-*syn*-phenyl-7-*anti*-pyridin-2-yl-bicyclo[2.2.1]-hept-5-en-2-one (12-anti)

To diisopropylamine (0.78 mL, 5.2 mmol) dissolved in 2.5 mL of freshly distilled THF under nitrogen at –78°C was added 3.80 mL of *n*-BuLi (1.37 M) and stirred for 35 min at

Scheme 10. Computational mechanisms.
–78°C. **10-anti** dissolved in 25 mL of freshly distilled THF at room temperature was cooled to –78°C, LDA was added, and the mixture was stirred for 2 h. HCOOMe (2.4 mL, 14 mmol) was then added and the mixture was stirred overnight with the temperature gradually rising to ambient and then stirred for one more day. The suspension was filtered, and the solid was dissolved in 20 mL of 10% KOH, washed with 20 mL dichloromethane. The aqueous solution was adjusted to pH ca. 8 by addition of dilute HCl, and then extracted with dichloromethane. The combined organic layers were dried over Na_2SO_4 and concentrated to yield 1.0 g (79%) of **13-anti** as a light yellow solid: mp 178 to 179°C. ^{1}H NMR (CDCl_3) δ: 9.43 (d, J = 0.6 Hz, 1H), 8.47 (d, J = 5.0 Hz, 1H), 7.51 (td, J = 7.5, 2.0 Hz, 1H), 7.40 (d, J = 8.0 Hz, 2H), 7.28 (t, J = 7.5 Hz, 2H), 7.18 (m, 2H), 7.02 (ddd, J = 7.5, 5.0, 1.0 Hz, 1H), 6.84 (dd, J = 5.5, 3.0 Hz, 1H), 5.84 (m, 1H), 4.37 (m, 1H), 4.33 (m, 1H), 3.15 (m, 1H). ^{13}C NMR (CDCl_3) δ: 202.1, 196.4, 160.9, 149.0, 142.7, 140.4, 136.2, 129.2, 127.5, 126.8, 125.9, 122.0, 121.3, 74.9, 62.5, 61.2, 47.7.

The formyl ketone **13-anti** (1.0 g, 3.46 mmol) was stirred with tosyl azide (0.68 g, 3.46 mmol) in 23 mL of dichloromethane in an ice bath and triethylamine (1.0 mL, 6.92 mmol) was added. The reaction mixture was stirred overnight in the dark and allowed to warm up to ambient temperature. The mixture was concentrated in vacuo; the yellow residue was subjected to chromatography on neutral alumina (pH ca. 7.5). Elution with dichloromethane yielded 0.744 g (75%) of **12-anti** as yellow crystals: R_f 0.57 (dichloromethane–ether, 9:1), mp 155°C (decomposed). UV (CDCl_3): 260 nm (ε = 17 027), 322 nm (ε = 1622), 432 nm (ε = 22). IR (CDCl_3) (cm^{-1}): 2076 (strong), 1693 (strong). ^{1}H NMR (CDCl_3) δ: 8.45 (d, J = 5.0 Hz, 1H), 7.55–7.00 (m, 8H), 6.90 (dd, J = 5.0, 3.0 Hz, 1H), 6.30 (m, 1H), 5.00 (s, 1H), 4.25 (t, J = 3.0 Hz, 1H). ^{13}C NMR (CDCl_3) δ: 200.5, 161.3, 148.9, 143.2, 141.0, 136.3, 132.9, 128.9, 127.1, 127.0, 121.6, 121.2, 81.8, 63.8, 51.9. HR-MS-ESI m/z ([M + MeOH + Na]$^+$) calcd. for $C_{19}H_{17}N_3O_2Na$: 342.1218; found: 342.1199.

3-Diazo-7-*anti*-phenyl-7-*syn*-pyridin-2-yl-bicyclo[2.2.1]-hept-5-en-2-one (12-syn)

To diisopropylamine (2.2 mmol, 0.33 mL) dissolved in 1.0 mL of freshly distilled THF at –78°C was added *n*-BuLi (2.2 mmol, 1.6 M). The reaction mixture was stirred at –78°C for 1 h. The syn ketone **10-syn** (1.9 mmol, 0.5 g) in 14 mL of freshly distilled THF was stirred at room temperature until a clear solution was obtained, then the solution was cooled to –78°C, and LDA was added. The reaction mixture became brown, and was stirred at –78°C for 2.5 h. Methyl formate (1.0 mL, 6.0 mmol) was then added, and the resulting mixture was stirred at –78°C for 2 h and allowed to warm to room temperature during stirring overnight. The resulting brown suspension was filtered and washed with ether to give **11-syn** (0.51 g) as a gray solid. To the crude **11-syn** (372 mg) dissolved in 8.0 mL of dichloromethane and cooled in an ice bath, was added tosyl azide (248 mg, 1.26 mmol); the reaction mixture was stirred overnight in the dark and allowed to warm to room temperature. The mixture was then concentrated in vacuo and the residue was subjected to chromatography on neutral alumina (pH ca. 7.5). Elution with dichloromethane yielded 170 mg of **12-syn** as nice yellow crystals: R_f 0.57 (dichloromethane–ether, 9:1). IR (CDCl_3) (cm^{-1}): 2082 (strong), 1679 (strong). ^{1}H NMR (CDCl_3) δ: 8.53 (d, J = 5.0 Hz, 1H), 7.55 (td, J = 8.0, 2.0 Hz, 1H), 7.32–7.10 (m, 7H), 6.82 (dd, J = 5.0, 2.5 Hz, 1H), 6.35 (ddd, J = 5.0, 3.0, 1.0 Hz, 1H), 4.94 (m, 1H), 4.22 (m, 1H). ^{13}C NMR (CDCl_3) δ: 200.2, 161.2, 149. 6, 141.6, 140.7, 136.6, 128.4, 127.4, 126.5, 121.7, 82.0, 64.1, 51.8. HR-MS-ESI m/z ([M + Na]$^+$) calcd. for $C_{18}H_{13}N_3ONa$: 310.0956; found: 310.0959.

Irradiation of *anti*-pyridyl diazoketone (12-anti)

anti-Pyridyl diazoketone (**12-anti**) (644 mg, 2.23 mmol) in 200 mL of MeOH was irradiated with a 400 W medium pressure mercury lamp for 70 min through 0.50 cm of 0.20 M CuSO_4 as a filter solution. Methanol was then removed, and the brown residue was subjected to chromatography on silica gel. Elution with dichloromethane–ether (9:1) gave 116 mg (18%) of **15-anti-exo**, 66 mg (10%) of **15-anti-endo**. The next three fractions were combined and chromatographed on a second silica gel column, eluted with hexane–dichloromethane–ether (2:2:1) to yield **16-anti** (16%), **14-anti-exo** (29%), and **14-anti-endo** (5%). The combined yield was 78%.

Data for **15-anti-exo**: R_f 0.6 (dichloromethane–ether, 9:1). IR (CDCl_3) (cm^{-1}): 1722.9. ^{1}H NMR (CDCl_3) δ: 8.60 (ddd, J = 5.0, 2.0, 1.0 Hz), 7.55 (t, J = 8.0 Hz, 1H), 7.30–7.10 (m, 7H), 6.15 (m, 2H), 3.20 (m, 1H), 2.66 (dtd, J = 6.5, 2.5, 0.7 Hz, 1H), 1.29 (dd, J = 3.5, 2.5 Hz, 1H). ^{13}C NMR (CDCl_3) δ: 172.6, 165.3, 149.1, 144.7, 136.4, 136.1, 132.4, 128.4, 127.7, 126.3, 121.8, 121.3, 65.9, 51.7, 34.7, 34.3, 31.2. HR-MS-EI m/z ([MH]$^+$) calcd. for $C_{19}H_{18}NO_2$: 292.1337; found: 292.1340. The structure was proved by X-ray analysis.[3]

Data for **14-anti-exo**: IR (CDCl$_3$) (cm^{-1}): 1723.0. ^{1}H NMR (CDCl$_3$) δ: 8.40 (d, J = 5.0 Hz, 1H), 7.58 (d, J = 7.5 Hz, 2H), 7.42 (td, J = 8.0, 2.0 Hz, 1H), 7.24 (t, J = 7.5 Hz, 2H), 7.12 (m, 1H), 6.95 (d, J = 7.5 Hz, 1H), 6.88 (ddd, J = 7.5, 5.0, 1.0 Hz, 1H), 6.72 (t, J = 2.0 Hz, 2H), 3.98 (t, J = 2.0 Hz, 2H), 3.35 (s, 1H), 3.07 (s, 3H). ^{13}C NMR (CDCl$_3$) δ: 170.8, 166.2, 148.6, 142.0, 141.6, 135.8, 128.5, 127.6, 126.7, 121.5, 120.1, 92.2, 74.7, 51.4, 50.7. HR-MS-EI m/z ([MH]$^+$) calcd. for C$_{19}$H$_{18}$NO$_2$: 292.1337; found: 292.1341. The structure was further proved by preliminary X-ray analysis.

Data for **14-anti-endo**: IR (CDCl$_3$) (cm^{-1}): 1733.1. ^{1}H NMR (CDCl$_3$) δ: 8.43 (ddd, J = 5.0, 2.0, 1.0 Hz, 1H), 7.60–7.45 (m, 3H), 7.35–7.20 (m, 4H), 6.91 (ddd, J = 7.5, 5.0, 1.0 Hz, 1H), 6.55 (t, J = 2.0 Hz, 2H), 3.81 (q, J = 2.0 Hz, 2H), 3.75 (t, J = 2.0 Hz, 1H), 3.60 (s, 3H). ^{13}C NMR (CDCl$_3$) δ: 172.9, 164.3, 148.7, 142.9, 138.4, 128.5, 127.0, 126.6, 122.2, 120.5, 88.0, 71.5, 51.4, 51.3. HR-MS-EI m/z ([MH]$^+$) calcd. for C$_{19}$H$_{18}$NO$_2$: 292.1337; found: 292.1332.

Photolysis of *syn*-pyridyl diazoketone (12-syn)

syn-Pyridyl diazoketone (**12-syn**) (59 mg, 0.20 mmol) dissolved in 40 mL of MeOH was irradiated for 255 min using the CuSO$_4$ filter solution (vide supra). Methanol was then removed, and the residue was subjected to column chromatography on silica gel. Elution with dichloromethane–hexane–ether (2:2:1) yielded **14-syn-endo** (11%), **15-syn-endo** (43%), **14-syn-exo** (23%), and **16-syn** (8%), with a combined yield of 85%.

Data for **14-syn-endo**: IR (CDCl$_3$) (cm^{-1}): 1735.3. ^{1}H NMR (CDCl$_3$) δ: 8.55 (ddd, J = 4.5, 1.8, 1.0 Hz, 1H), 7.58 (td, J = 7.5, 1.8 Hz, 1H), 7.41 (d, J = 7.5 Hz, 1H), 7.20~7.05 (m, 6H), 6.57 (t, J = 2.0 Hz, 2H), 3.86 (q, J = 2.5 Hz, 2H), 3.59 (s, 3H), 3.58 (t, J = 2.5 Hz, 1H). ^{13}C NMR (CDCl$_3$) δ: 172.7, 163.6, 149.3, 143.8, 138.3, 136.4, 128.0, 127.8, 125.8, 121.5, 121.3, 88.0, 72.1, 51.7, 51.4, 29.7. HR-MS-EI m/z ([MH]$^+$) calcd. for C$_{19}$H$_{18}$NO$_2$: 292.1337; found: 292.1325.

Data for **15-syn-endo**: IR (CDCl$_3$) (cm^{-1}): 1738.1. ^{1}H NMR (CDCl$_3$) δ: 8.58 (ddd, J = 5.0, 2.0, 1.0 Hz, 1H), 7.61 (td, J = 7.5, 2.0 Hz, 1H), 7.35 (dt, J = 8.0, 1.0 Hz, 1H), 7.30~7.10 (m, 6H), 6.40 (d, J = 5.5 Hz, 1H), 6.05 (dd, J = 5.5, 2.0 Hz, 1H), 3.16 (s, 3H), 2.68–2.58 (m, 2H), 2.11 (t, J = 8.0 Hz, 1H). ^{13}C NMR (CDCl$_3$) δ: 169.7, 163.5, 148.7, 147.2, 137.8, 135.9, 128.4, 127.6, 126.8, 126.4, 122.9, 121.0, 64.3, 50.9, 34.6, 31.2, 29.7, 28.0. HR-MS-EI m/z ([MH]$^+$) calcd. for C$_{19}$H$_{18}$NO$_2$: 292.1337; found: 292.1324.

Data for **14-syn-exo**: IR (CDCl$_3$) (cm^{-1}): 1732.0. ^{1}H NMR (CDCl$_3$) δ: 8.52 (ddd, J = 5.0, 2.0, 1.0 Hz, 1H), 7.53 (td, J = 7.5, 2.0 Hz, 1H), 7.46 (dt, J = 8.0, 1.0 Hz, 1H), 7.20~7.00 (m, 6H), 6.75 (t, J = 2.0 Hz, 2H), 4.05 (t, J = 2.0 Hz, 2H), 3.40 (s, 1H), 3.16 (s, 3H). ^{13}C NMR (CDCl$_3$) δ: 170.6, 162.7, 148.6, 146.4, 141.9, 135.6, 128.5, 128.4, 127.9, 127.3, 126.8, 126.6, 125.4, 123.4, 121.3, 92.1, 75.2, 51.8, 50.9, 29.8. HR-MS-EI m/z ([MH]$^+$) calcd. for C$_{19}$H$_{18}$NO$_2$: 292.1337; found: 292.1324.

Data for **16-syn**: ^{1}H NMR (CDCl$_3$) δ: 8.51 (ddd, J = 5.0, 2.0, 1.0 Hz, 1H), 7.57 (td, J = 7.5, 2.0 Hz, 1H), 7.46–7.20 (m, 6H), 7.07 (ddd, J = 7.5, 5.0, 1.0 Hz, 1H), 3.82 (t, J = 2.0 Hz, 1H), 3.32 (s, 3H), 3.23 (td, J = 5.0, 1.0 Hz, 1H), 3.05 (s, 1H), 2.58 (tdd, J = 5.0, 2.0, 1.0 Hz, 1H), 1.74 (t, J = 5.0, 1H).

Synthesis of 4-*anti*-phenyl-4-*syn*-pyridin-2-yl-bicyclo-[3.1.0]hex-2-ene-6-carboxylic acid methyl ester (15-syn-exo)

5-Phenyl-5-pyridylcyclopenadiene (238 mg, 1.09 mmol) and methyl diazo acetate (250 mg, 2.50 mmol) and 12 mg of anhyd CuSO4 was refluxed in 1 mL of benzene for 75 min. The reaction mixture was concentrated and the residue was subjected to column chromatography, eluted with hexane–ether (3:1) to give **15-syn-exo** (15%) as the only adduct: R_f 0.17. IR (CDCl$_3$) (cm^{-1}): 1723.8. ^{1}H NMR (CDCl$_3$) δ: 8.56 (ddd, J = 4.5, 2.0, 1.0 Hz, 1H), 7.67 (td, J = 7.5, 2.0 Hz, 1H), 7.40 (dt, J = 8.0, 1.0 Hz, 1H), 7.32~7.12 (m, 6H), 6.23 (dd, J = 5.5, 1.0 Hz, 1H), 6.09 (dd, J = 5.5, 2.0 Hz, 1H), 3.65 (s, 3H), 2.80 (m, 1H), 2.71 (dt, J = 6.0, 2.5 Hz, 1H), 1.27 (dd, J = 3.5, 2.5 Hz, 1H). ^{13}C NMR (CDCl$_3$) δ: 172.4, 164.2, 149.1, 146.3, 137.7, 136.6, 130.9, 128.4, 126.8, 126.5, 122.8, 121.4, 65.9, 51.7, 36.0, 34.7, 31.6, 29.7. HR-MS-ESI m/z ([MH]$^+$) calcd. for C$_{19}$H$_{18}$NO$_2$: 292.1337; found: 292.1328.

An ab initio and AIM study on the decomposition of phosphite ozonides

Jeff L. Langeland and Nick H. Werstiuk

Abstract: DFT calculations at the Becke3PW91/6–31+G(d) level of theory provided optimized geometries, transition states, and wave functions suitable for the study of the reactivity and molecular structure with Atoms-in-molecules (AIM) of phosphite ozonide complexes. These calculations also provided activation energies for the extrusion of singlet oxygen from the ozonides, which occurs in a concerted manner. The molecular species investigated were trimethyl phosphite ozonide (**1**), triphenyl phosphite ozonide (**2**), trifluoromethyl phosphite ozonide (**3**), trifluoroethyl phosphite ozonide (**4**), 4-ethyl-1-phospha-2,6,7-trioxabicyclo[2.2.2]octane ozonide (**5**), 1-phospha-2,6,7-trioxabicyclo[2.2.2]octane ozonide (**6**), 1-phospha-2,8,9-trioxadamantane ozonide (**7**), and propylene phenyl phosphite ozonide (**8**). Single-point calculations at the Becke3PW91/6–311++G(d,p) level on the geometries obtained from the lower level theory yielded activation energies of 15.1 and 16.4 kcal mol^{-1} for the nonconstrained complexes **1** and **2**, respectively. These values differed from the electronegative trifluoro derivatives **3** and **4**, which had much higher barriers of 23.5 and 20.8 kcal mol^{-1}, respectively. The activation energies of the bicyclic complexes **5**–**7** were significantly higher than **1** and **2** and comparable to **3** and **4**, ranging from 23 to 26 kcal mol^{-1}. An intermediate barrier of 20.5 kcal mol^{-1} was computed for **8**. AIMPAC studies showed no direct correlation between the AIM atomic charges on the phosphorus or oxygen atoms of the ozonide ring with the ease of decomposition of **1**–**8** to singlet oxygen and the corresponding phosphate.

Key words: phosphite ozonide complexes, decomposition, DFT methods, AIM, activation energy.

Résumé : Des calculs de types « DFT » effectués au niveau Becke3PW91/6–31+G(d) de la théorie ont permis d'obtenir des géométries optimisées, des états de transition et des fonctions d'onde convenables pour l'étude de la réactivité et la structure moléculaire de complexes d'ozonides de phosphite par la méthode des atomes dans les molécules (« AIM »). Ces calculs ont aussi permis d'obtenir les énergies d'activation pour l'extrusion d'un atome d'oxygène singulet à partir des ozonides qui se fait d'une manière concertée. Les espèces moléculaires étudiées sont les ozonides du phosphite de triméthyle (**1**), du phosphite de triphényle (**2**), du phosphite de trifluorométhyle (**3**), du phosphite de trifluoroéthyle (**4**), du 4-éthyl-1-phospha-2,6,7-trioxabicyclo[2.2.2]octane (**5**), du 1-phospha-2,6,7-trioxabicyclo[2.2.2]octane (**6**), du 1-phospha-2,8,9-trioxaadamantane (**7**) et du phosphite de propylène et de phényle (**8**). Des calculs ponctuels au niveau Becke3PW91/6–311++G(d,p) effectués sur les géométries obtenues au niveau inférieur de la théorie ont permis d'évaluer à 15,1 et 16,4 kcal mol^{-1} les énergies d'activation respectives pour les complexes sans contraintes **1** et **2**. Ces valeurs diffèrent de celles des dérivés trifluoro électronégatifs, **3** et **4**, pour lesquels les valeurs étaient beaucoup plus élevées, soit 23,5 et 20,8 kcal mol^{-1} respectivement. Les énergies d'activation pour les complexes bicycliques **5**–**7** sont beaucoup plus élevées que celles des composés **1** et **2** ainsi que celles des composés comparables **3** et **4**; elles s'étalent de 23 à 26 kcal mol^{-1}. Pour le composé **8**, on a calculé que sa valeur est intermédiaire à 20,5 kcal mol^{-1}. Des études de type « AIMPAC » ont montré qu'il n'existe aucune corrélation directe entre les charges atomiques « AIM » des atomes de phosphore ou d'oxygène de l'ozonide et la facilité avec laquelle les composés **1**–**8** se décomposent en oxygène singulet et en phosphate correspondant.

Mots clés : complexes d'ozonides de phosphite, décomposition, méthodes « DFT », « AIM », énergie d'activation.

duced from the reaction is thermally unstable and yields the corresponding phosphate and, as later discovered (2), singlet oxygen, as shown in Scheme 1.

This reaction was important because the ozonide complex can react with certain alkenes through a direct bimolecular reaction (3–5) or by first releasing $^1O_2$ that can react with the alkene (6–8). The direct attack shows different regioselectivity — with the reaction appearing to occur in a stepwise fashion — as opposed to the concerted attack of singlet oxygen (3, 9). The product distribution depends on the mode of attack with allylic hydroperoxides, cyclic peroxides, and 1,2-dioxetanes being formed (8). Various structures were proposed for the ozonide complex, including several pentacoordinated monomeric and dimeric species (1, 10). From

Scheme 1.

$$(R_3O)_3P \ + \ O_3 \ \xrightarrow[\text{CH}_2\text{Cl}_2]{-78^\circ\text{C}} \ (R_3O)_3P\underset{O}{\overset{O}{\diamond}}O \ \xrightarrow{\Delta} \ (R_3O)_3P{=}O \ + \ {}^1O_2$$

the ^{31}P NMR chemical shift at δ = –63 ppm (1) relative to H$_3$PO$_4$ and from freezing point depression experiments on triphenyl phosphite ozonide (**2**) in CHCl$_3$, Bartlett and Chu (11) suggested that the ozonide is monomeric with a penta-coordinated phosphorus atom. Recently, Dimitrov and Seppelt (12) confirmed this hypothesis by obtaining a crystal structure of 4-ethyl-1-phospha-2,6,7-trioxabicyclo[2.2.2]oc-tane ozonide (**5**).

There have been several kinetic studies involving the rates of decomposition of various POCs (6, 8, 10, 13). For bicyclic POCs **5** and **7**, Stephenson and McClure (13) observed that the rate of decomposition varied slightly with substituent. Amazingly, Ramos et al. (6) observed that there was signifi-cant variation in the rate of oxygen evolution from bridge-head-substituted derivatives of bicyclic ozonide **6** (for example with the substituent -CH$_2$OCO-C$_6$H$_5$ vs -CH$_2$O-SO$_2$-p-CH$_3$C$_6$H$_4$), even though the change in the R group was five atoms away from the phosphorus atom. For ozonides **1**–**4** that have rotational freedom about the P—OR bond, the rate constants varied by more than two orders of magnitude in some cases (13). A reactive intermediate dis-played as **I** was first suggested by Stephenson and McClure (13) (R = Ph) for the decomposition of **2**, to account for the differences in rate constants for unrestrained ozonide com-plexes **1**–**4** vs. the restrained POCs **5**–**8**.

These authors did not speculate as to the electronic distribu-tion of this species. It was suggested that the intermediate has apical oxygen atoms and equatorial phenoxy groups de-rived from pseudorotation, which occurs after the cleavage of an O—O bond. There has been conflicting evidence that **I** is a viable species. Mendenhall et al. (10) suggested that the mode of decay would be through a bimolecular reaction if an intermediate such as **I** existed. Bartlett and Chu (11) gave some evidence that **I** was not likely because they found no significant changes in rate constants between hindered and non-hindered POCs with reactive olefins. However, Bartlett and Lonzetta (14) rationalized that **I** (R = CH$_3$) was plausi-ble, as the methoxy groups would preferentially occupy the equatorial positions (rather than the phenoxy groups of **2** (R = Ph)).

Our interest in using POCs as a source of singlet oxygen ($^1O_2$) for study by photoelectron spectroscopy and the varia-tion in the mechanistic proposals presented to date led us to a computational study of these molecules and their decom-position to phosphate and $^1O_2$. To our knowledge there have been no computational studies on this unusual family of molecules at any level of theory. We undertook a DFT and Atoms-in-molecules (AIM) (15) study to investigate and clarify the mechanism of extrusion of $^1O_2$ and to obtain in-formation on the molecular structure of selected POCs and transition states, as well as the role of structure in determining the activation energy. A brief investigation of the molecular orbitals was also undertaken to examine the consequence of substituent effects and to draw conclusions as to why these ozonides are thermally unstable. The results are presented in this paper.

Methods

Optimized equilibrium geometries of the POCs — dis-played in Fig. 1 — and transition states (TSs) were obtained at the Becke3PW91/6–31+G(d) level, which includes the three-parameter Becke-Perdew-Wang, (Becke3PW91) ex-change-correlation potential (16), using either Gaussian 94 or Gaussian 98 (17). The transition states were found by stretching one of the O—O bonds in the optimized geometry of a POC from 1.44 to 1.75 Å. These geometries were then optimized with a restraint on that bond distance at the PM3 level, which was followed by removal of the restraints and a TS search. Final TS structures were obtained at the Becke3PW91/6–31+G(d) level by performing an opt=TS calculation, by reading in the force constants from the PM3 level. Selected geometrical parameters of **5** and **5-TS** are collected in Table 1. The Z-matrices of the other optimized geometries and transition states are included as Supplemen-tary information.^{2} Frequency calculations, to characterize the optimized geometries or TSs as well as the zero point ener-gies (ZPE), were performed for all structures. Single-point calculations were carried out at the Becke3PW91/6–311++G(d,p) on the lower-level optimized geometries. The Becke3PW91 functional was used because it has been shown to estimate energies of ionization potentials, proton affini-ties, and other chemical properties within acceptable values compared with G2 theory but without the computational cost (18). Diffuse functions were included with the expectation that a better description of phosphorus-containing ozonides and their transition states would be realized. The activation energies (E_a), calculated from eq. [1], are collected in Ta-ble 2.

[1] $E_a = \{ \ [\ (TS)_{Energy} + (TS)_{ZPE}] - [\ (POC)_{Energy}$

$\qquad\qquad\qquad\qquad\qquad\qquad + (POC)_{ZPE}] \ \} + RT$

Bond critical points and molecular graphs were obtained with AIM2000 (19). Integrations over atomic basins to obtain electron populations — the L values (15) were less than 10^{-2} — and net atomic charges (included as Supplementary information)[2] were carried out with PROAIM or PROMEGA of the AIMPAC (20) suite of programs. The hydrogens of **2** and **4** were not integrated.

Results and discussion

Selected geometrical parameters of **5** and **5-TS** are collected in Table 1. The results for **5** agree well with crystal-structure data obtained recently (12). The geometrical parameters of the other POCs are very similar to those found for **5** (see the Z-matrices of the Supplementary information).[2] The ozonide ring conformation was virtually identical in all optimized geometries.

The ozonide ring torsional angle varied only slightly, from a low of 11.0° for **1** to a high of 13.6° for **8**. All other bond distances were essentially the same in the POCs with other bond and torsional angles varying only as a function of substituent. For example, in comparing the bicyclic structures of **5** and **6**, the equilibrium geometries were almost identical. This was expected because of the rigidity of these molecules, their overall similarity, and the lack of rotational freedom in the P–OR groups.

In all cases, it was found that the $^1O_2$ is preferentially extruded between two P—OR bonds, as opposed to directly over one of the oxygens. For example, in the case of **5**, singlet oxygen arises from O_3 and O_4 and is extruded between and slightly above atoms O_7 and O_8, thus forming a new P_1=O_5 double bond (see Fig. 3 for numbering). This preferential mode for dissociation can easily be rationalized since the O_5-P_1-O_3 group of atoms rotates slightly downward and bonds P_1—O_3 and O_4—O_5 stretch, giving rise to the new P_1=O_5 double bond and $^1O_2$. Since this process is concerted, a large amount of structural organization would be required if the singlet oxygen would be extruded over atom O_6. The transition states also showed little variation in the conformation of the ozonide ring. The torsional angle of the ozonide ring for **1** was computed at 16° while the values for all the other POCs ranged between 22–25°. For the non-ozonide portion of the molecule, the transition states of **5**–**7** showed little variation from their equilibrium geometries. For the

bicyclic structure **5**, very little structural rearrangement is permitted along the reaction coordinate from ozonide to products. Points A, B, and C in Fig. 2 corresponded to selected geometries along the Intrinsic reaction coordinate (IRC). This calculation was performed to ensure that **5-TS** connected the ozonide to the products. Because all of the calculated transition states appeared to exhibit little variation from one another, only one IRC was calculated. Fig. 3 displays the geometries A, B, and C of the **5-TS** IRC, showing both the ozonide (negative reaction coordinate) and the phosphate plus singlet oxygen (positive reaction coordinate) being formed. The increase in the O_5-P_1-O_3 angle and the twisting of the ozonide dihedral angle, as well as P_1—O_3 and O_4—O_5 bond distances, clearly indicate that the TS (point B of Fig. 2) is on the reaction coordinate.

The intermediate of the type **I** proposed by Stephenson and McClure (13) was not found in our study (when we studied **I** with R = Me) for computational efficiency. However, the E_a for the formation of such an intermediate would be expected to be quite large. The calculated TSs exhibited very little structural displacement of the P–OR groups. A great deal of internal re-organization involving both steric and electronic factors would be required if an ozonide such as trimethyl phosphite ozonide (**1**) was transformed to a structure that resembles the previously described intermediate. An "optimized" structure was found for **I** but the O–O ligand migrated more than 6 Å away from the phosphorus atom. Therefore, **I** with R = Me is not a stationary point on the potential energy surface.

One imaginary frequency between $400i$ to $600i$ cm^{-1} was calculated for all POC transition states. With the aid of the molecular visualization package MOLEKEL (21), these negative frequencies were animated. The exaggerated animation showed that, starting with a P_1-O_3-O_4-O_5 ozonide torsional angle of approximately 22° in the TS, the evolving $^1O_2$ would twist to an almost 90° torsional angle (see the side view of Fig. 3 for a partial sequence) when these atoms were at the furthest point away from the reaction centre. The exaggerated animated imaginary frequencies clearly exhibited the correct normal mode for the dissociation to singlet oxygen and phosphate as well as the return to starting material.

Fig. 2. IRC for 5 from the TS (**B**), to the ozonide A, and to the product side C. The energies of the ozonide and phosphate and singlet oxygen relative to the TS (point B) are –23.5 and –44.6 kcal mol^{-1}, respectively.

Fig. 3. Front and side view of geometries **A**, **B**, and **C** along the reaction coordinate for the decomposition of 4-ethyl-1-phospha-2,6,7-trioxabicyclo[2.2.2]octane ozonide (**5**). The side view is a 90° rotation and tilted forward slightly to show the twisting of the extruding singlet oxygen. For clarity, the ethyl substituent and hydrogens have been omitted. Atom O_6 lies behind the carbon atom in the side view.

Stephenson and McClure (13) also suggested that a pre-equilibrium of an ozonide before decomposition could occur to give a structure similar to **X**. They rationalized **X** from thermochemical analysis that Benson and Shaw (22) performed, which indicated a maximum oxygen—oxygen bond strength of only 2 kcal mol^{-1} — compared with the relatively high E_as for **1**–**8**. However, the analysis by Benson and Shaw (22) was based on the assumptions that: (*a*) the O—O bond would be similar to that of other trioxides; (*b*) the ring strain was similar to that in 4-membered rings containing sulphur, and (*c*) the solvation enthalpy of $^1O_2$ in solvent was small. We are unaware of any recent calculations or experimental evidence of these ozonides to prove otherwise. However, low temperature ^{31}P NMR (11) revealed only one sharp peak δ = –63 ppm (relative to H_3PO_4), suggesting no equilibrium to **X**.

X
Also, recent calculations (23) on polyoxides of the type $H(O)_nH$ ($n > 2$) suggest that the bond dissociation energy for $n = 3$ was 33 kcal mol^{-1} and the minimum barrier for any $n > 2$ would be 6.4 kcal mol^{-1}. Mendenhall et al. (10) discounted both a diradical and zwitterionic intermediate of type **X** based on the lack of observation of bimolecular self-reactions. A TS or intermediate structure resembling **X** at the uBecke3PW91/6–31+G(d) level was not found in our study. At the semiempirical level (PM3), a TS was found for the above, but when the transition state search was performed at the ab initio level by reading in the force constants from the PM3 calculation, the TS that we described above was obtained. The "intermediate" for **X**, found at the PM3

level by restraining the O_3—O_4 and P_1—O_5 bonds, also converted to a structure resembling the TSs that we described above when calculated at the uBecke3PW91/6–31+G(d) level of theory. The P_1—O_5 bond would significantly stretch (approximately 0.5 Å) and the ozonide ring torsion would twist (approximately 10°). If the O_3—O_4 bond was not stretched far enough (less than 0.2 Å from equilibrium distance) then the **X** intermediate would return to the ozonide at the uBecke3PW91/6–31+G(d) level of theory. Therefore,

we were unable to locate a stable structure that resembled **X** (R = Me) either as a TS or an intermediate.

The computed activation energies are collected in Table 2. Several identifiable patterns are in the data. The greater the size and the more electronegative the R substituent of the POC, the higher is the barrier for extrusion of $^1O_2$. Generally, the single-point calculations at the Becke3PW91/6–311++G(d,p) level gave E_as (eq. [1]) of 2.0 to 4.5 kcal mol^{-1} less than the value obtained at the Becke3PW91/6–31+G(d) level. The unconstrained POCs **1**–**4** showed a substantial variation in their E_as. Trimethyl phosphite ozonide (**1**) had the lowest calculated activation energy of the POCs at 15.1 kcal mol^{-1}. An experimental E_a is not known, as the lifetime, even at –88°C, is extremely short (14). The calculated E_a for **2**, 16.5 kcal mol^{-1}, was in good agreement with the experimental value (2) of 14.4 kcal mol^{-1}. Steric factors might play a small role in determining the E_a of **2** vs. **1** in that the methoxy ligands pose less steric hindrance than the phenoxy groups of **2**. There was only a small increase in activation energy for **2**, as the singlet oxygen tends to extrude above the P–OR ligands and was not substantially affected by the phenoxy groups of **2** relative to the methoxy groups of **1**.

For trifluoromethyl phosphite ozonide (**3**) and trifluoroethyl phosphite ozonide (**4**) the calculated activation energies were approximately 10 and 5 kcal mol^{-1} higher than that of the trimethyl analogue. The equilibrium geometries of **1**, **3**, and **4** had similar geometry of the P–OR groups and would be best described as trigonal pyramidal (as well as the other POCs studied). The transition states of **1**, **3**, and **4** also showed this same type of geometry. However, there was a variation in the torsional angle within the ozonide ring (15.9, 25.2, and 26.2°, respectively), and the P–OR conformations differed somewhat. The substituent effect of the electronegative fluorine groups that caused the large separation of E_a values between **1** and **3** will be explained qualitatively though the AIM molecular graphs in the next section. Ozonide **4** was similar in conformation to **3**. The phosphorus and oxygen atoms in the P–OR ligands are buffered through an additional methylene group. This buffering relative to **3** appears to be a major factor as to why the E_a of **4** was only 20.4 kcal mol^{-1}, approximately 3 kcal mol^{-1} less than the E_a for **3**.

For the bicyclic POCs **5**–**7** the calculated activation energies were in the range of 23–26 kcal mol^{-1}, much higher than those found experimentally. The experimental values for the E_a of **5** were found to be only 8.5 kcal mol^{-1} with acetone as the solvent (10) and 4.4 kcal mol^{-1} calculated from rate constants obtained in CH$_2$Cl$_2$ at two different temperatures (13). These results do not compare well with the computed value of 26.0 kcal mol^{-1} (Becke3PW91/6–31+G(d)) or 23.5 kcal mol^{-1} obtained at the Becke3PW91/6–311++G(d,p) level. However, the experimental (13) first-order rate constant was found to be 9.75×10^{-5} s^{-1} for **5** compared with 740×10^{-5} s^{-1} for **2** in dichloromethane at –5°C. This suggests that **2** would have a lower activation barrier than **5**. For this reason we suggest that the experimental E_a of **5** should have been higher than that observed. We therefore arrive at the same conclusion that Schaap et al. (8) reached, in that "additional experiments on the thermal stability of **5** seem to be required". In comparing **5** and **6** there was no

substitution effect noted, as the computed E_a for **5** was only 0.2 kcal mol^{-1} higher than the value for **5**. This was expected, since the change was small and the substitution was five atoms away from the reaction centre. As noted earlier, Ramos et al. (6) saw a variation of one order of magnitude in rate constants for derivatives of **6** in some cases. They argued that the remote-substituent effect was perhaps a spatial, steric, or electronic effect, which affects the stability of the POCs. Others (13) observed an average rate constant of $k = 1.4 \pm 0.4 \times 10^{-4}$ s^{-1} for a total of eight constrained POCs, which varied dramatically in their structure. At the semiempirical level (PM3) we found no stable conformation for some of the ozonides studied by Ramos et al. (6) that would suggest a spatial or electronic effect to account for the variation they saw in the rate constants. The calculated value for **7** was more than 6 kcal mol^{-1} higher than the experimental value (8) of 19.1 ± 1.2 kcal mol^{-1}. The experimental value was derived from rate constants obtained at five different temperatures with a small error, so it would appear to be correct. However, the precautions necessary for the reproducibility experiments using CH$_2$Cl$_2$ as the solvent has also been voiced (10). Ozonide **8** showed an approximate 5 kcal mol^{-1} decrease in E_a compared with POCs **5**–**7**. The explanation offered here is that there is at least some flexibility within **8**. This seems reasonable since the flexibility and E_a of **8** is generally in between that of **1**–**4** and **5**–**7**. The ease of rotation about the P—OR bond along with electronegative substituents seems to be the determining factors in the E_as of the complexes studied. A referee suggested that the binding energy of ozone to the phosphate should have been investigated for completeness of this study. However, we feel that this would have no bearing on the interpretation of the results. Justification for this arises from the fact that the ozonides are prepared at –78°C and decompose quantitatively to phosphate and singlet oxygen (6, 10) above this temperature. We therefore conclude that there is no competing reaction or equilibrium that involves the dissociation of the POCs to phosphite and ozone; no ozonolysis products of alkenes have been found in the reactions.

AIM analysis

We carried out AIM analyses with the wave functions obtained at the Becke3PW91/6–31+G(d) level. Bond critical points and bond paths were obtained for all POCs. With the exception of **1**-, **2**-, **3**-, and **4-TS**, as well as propylene phenyl phosphate derived from **8**, the POCs showed no anomalies. However, what was truly interesting about these TSs were the hydrogen and fluorine bond paths from the P–OR groups (R = CH$_3$, Ph, CF$_3$, or CH$_2$CF$_3$) to the lower oxygen (atom O$_3$) of the extruding singlet oxygen (Fig. 4). Since atom O$_3$ was found to have a negative charge of –0.74e in the optimized geometry and –0.34e in the TS (discussed later), the two hydrogen atoms appear to show a favourable interaction with sufficient electron density, which may stabilize the TS somewhat. At the unexpected bond critical points **1** and **2** for the **1-TS** in Fig. 4, the electron densities, $\rho(\mathbf{r})$, were 0.016 and 0.018 au, respectively. Similar values were found for the critical points in the **2**-, **3**-, and **4-TS**s. For points **3**–**7** in Fig. 4, the $\rho(\mathbf{r})$ values were 0.010, 0.012, 0.013, 0.025, and 0.016 au, respectively. These electron density values were much less than for the other bond critical points within

Fig. 4. Molecular graphs with selected bond critical points of the transition states for POCs **1**, **2**, **3**, and **4**. The lines that connect the atoms are bond paths, and the points between atoms are the bond critical points. For clarity, the phenyl rings of **2-TS** have been truncated.
the molecule. For comparison, the density values for some other bond critical points in **1-TS** were; P_1—O_3 = 0.046, P_1—O_5 = 0.195, P_1—O_{6-8} = 0.184–0.187, O_3—O_4 = 0.377, O_4—O_5 = 0.172, O_6—C_{11} = 0.232, and C_{11}—R (R = H) = 0.280–0.285 au. There have been several recent reports on molecules that show similar, unusual molecular graphs. Koch and Popelier (24) studied four van der Waals complexes, including formaldehyde–chloroform and benzene–formaldehyde systems. They suggested that the intermolecular interaction energy would be less than 0.5 kJ mol^{-1} for the complexes. Others (25) suggested a much higher intramolecular stabilization energy occurs in ribonucleosides. These ribonucleosides exhibited several CH···O interactions, which accounted for approximately 5–18 kcal mol^{-1} in stability vs. the conformations in which these interactions were not present. Our intent was not to describe a full quantitative analysis of these interactions, as there are eight hydrogen-bonding criteria within the AIM formalism (24, 26, 27). However, we would like to suggest that, since **1-** and **2-TS** exhibit such a molecular graph, the lower activation energy compared with POCs **5–7** might result from the stabilization of the transition state through these weak hydrogen-bonding interactions. This type of stabilization could result in a lowering of the E_a. Similar interactions, which had activation barriers moderately higher than **1** or **2**, were also noted for the **3-** and **4-TSs**. The bond paths in **3-TS** connect two fluorine atoms in one of the P-OCF$_3$ groups to atom O_3 in the extruding singlet oxygen (Fig. 4). It is possible that the extrusion of singlet oxygen is hindered through electrostatic repulsion by the fluorine atoms (typically bearing a negative charge of –0.67 to –0.69e) with atom O_3, which also carries a net negative charge (approximately –0.33 to –0.34e). This is contrasted to the slight positive charge (typically

0.05 to 0.06e) found on the hydrogen atoms of **1** and **2**. Because the hydrogen atoms are somewhat electron deficient, interactions with the partially negatively charged O_3 atom would tend to lower the energy of the TSs. We would suggest that the E_a for **3** would be slightly lower than calculated if the repulsive interactions between the fluorine atoms and the oxygen atom of the extruding singlet oxygen were not present. Similarly, we would suggest that the activation energies of the POCs **1** and **2** would be slightly higher if these weak hydrogen interactions with atom O_3 were not present. It is difficult to account for the elevated E_a of **4** relative to **1**, as there are two similar bond paths (points 6 and 7 in Fig. 4) with relatively high ρ values compared with the previous points, as discussed in the case of **1-TS**. It would be expected that these weak interactions would stabilize the **4-TS** and lower the E_a, as described for **1-TS**. The electronegative fluorine groups may play a role in determining the E_a of **4** relative to **1**, although no unusual bond critical points between the fluorines and the extruding singlet oxygen were observed. Still, the E_a for **4** was almost 4 kcal mol^{-1} less than that for **3**, which suggests that the electronegative fluorine groups, combined with CH···O interactions, give the intermediate E_a of **4** relative to **1** or **3**. However, at this time, it is difficult to quantify a precise explanation as to why the activation energy of **4** had this intermediate value. Since POCs **5–8** did not exhibit any of the above-mentioned anomalous molecular graphs, there is no stabilization or destabilization of the TSs that leads to the calculated activation energies, which are very similar (especially for **5–7**, where the E_as differed by less than 2 kcal mol^{-1}).

The AIMPAC results for the atomic charges for the atoms within the POCs, TSs, and selected phosphates are collected in Table 3. On the whole, there was little variation in the net

Table 3. AIM net charges of selected atoms of phosphite ozonides and transition states.

[a]**1-P**, **3-P**, **5-P**, and **8-P** are the corresponding phosphates derived from **1**, **3**, **5**, and **8**.

atomic charges for individual atoms from the optimized geometries to the TSs and then to the phosphates of the POCs studied.

The equilibrium geometries exhibited a highly electron-deficient phosphorus atom, with the charges varying from 3.48e for **5** to 3.63e for **3**. In going to the TS, the phosphorus atom essentially retains its net charge, as do the remaining atoms in the molecule with the exception of atoms O_3 and O_5. Atom O_3 exhibits a nominal one-half decrease in negative charge while atom O_5 tends to double its negative charge. From the TS to the phosphate, essentially only atoms O_5 and O_3 are affected. For example, from **1-TS** to the phosphate (**1-P**) and singlet oxygen we see that atom O_5 increases its negative charge from –0.94 to –1.47e while atom O_3 changes from –0.48e to zero in singlet oxygen. All other atoms show almost complete retention of atomic populations from ozonide to TS to phosphate.

It was suggested (12) that the more electropositive the phosphorus atom in the cyclic and bicyclic systems, the stronger the O—O bond in the ozonide portion of the molecule, thus resulting in an elevated E_a. However, in the case of POC **1**, the phosphorus atom had a positive charge of +3.61e, which was marginally higher than the values found for the bicyclic structures but slightly lower than **3**. For **1** and **2**, the charges on the phosphorus atom had an intermediate value compared with the other POCs **3–8**. Ozonides **1** and **2** are the most reactive of the series (2, 12) and have significantly lower calculated E_as relative to **3**. But, since the atomic charges on the phosphorus atom for **1** and **2** were intermediate in their values, there does not seem to be a direct correlation between atomic charges on the phosphorus atom and activation parameters. This argument is substantiated by noting that the atomic charges on the phosphorus atom were very similar in the starting materials, TSs, and phosphates for all of the POCs, as seen from Table 3. The electron-withdrawing fluorine groups, as in **3** and **4**, for the most part

did not affect the net atomic charge on the phosphorus. The substituted trifluoromethyl carbon atoms (C_9–C_{11}) in **3** had substantial positive charges of approximately +2.4e in the optimized geometry, TS, and phosphate. However, the neighbouring oxygens to the trifluoromethyl substituent in **3** had no change to their net charges compared with the other POCs. The bicyclic ozonides (**5–7**) and **8** had virtually identical atomic charges in the ozonides and TSs (Table 3). However, the E_a of **8** was approximately 5 kcal mol^{-1} less than **5–7**. Therefore, from the above results, we draw the conclusion that there is no direct correlation with net atomic charges of individual atoms in the POCs with an increase or decrease in activation energy.

Because these complexes decompose at low temperatures, the frontier MOs of the ozonide ring were investigated. It was found that a large degree of antibonding character existed in the ozonide ring. For POCs **1**, **3**, and **5** the molecular orbitals were investigated to see why the ozonides might be unstable and why there was "twisting" of the evolving singlet oxygen in all the transition states. The HOMOs of these POCs and their TSs immediately shed light on the above two questions. Figure 5 illustrates the HOMO of ozonides **1**, **3**, and **5** and their associated TSs. The large antibonding character of the p-orbitals of the oxygen atoms in the ozonide ring, along with minor contributions from the p-orbitals of the bicyclic ring oxygens, is evident. Of note is the bonding interaction seen between atoms O_3 and O_5. Also, the HOMO showed no bonding interactions between the phosphorus and the oxygen atoms in the ozonide ring. Thus, this result would suggest that the O_5—O_4 bonds would break first, followed by the simultaneous cleavage of the P_1—O_3 bond, with formation of singlet oxygen and the phosphate.

With the antibonding character associated with their occupied MOs, it is easy to rationalize why these molecules readily decompose. Upon heating, POC **5** would go to the

Fig. 5. Highest occupied molecular orbitals of POCs **1**, **3**, and **5** (*a*, *c*, *e*) and the corresponding transition states (*b*, *d*, *f*).

(*a*) **1**-HOMO (*b*) **1-TS**-HOMO

(*c*) **3**-HOMO (*d*) **3-TS**-HOMO

(*e*) **5**-HOMO (*f*) **5-TS**-HOMO
TS, as depicted above. The twisting of the $^1O_2$ occurs to create more bonding character between O_3 and O_4, within the HOMO of the TS (Fig. 5, points (*e*) and (*f*)). The MOs of **1** and **3** were also investigated and were somewhat similar to those found for **5**. Qualitatively, there did not appear to be any significant deviation to rationalize the 10 kcal mol^{-1} difference in the E_as for **1** and **3**. The illustration for the **5-TS** HOMO at points 1 and 2 in Fig. 5*f* appears to exhibit more bonding interaction of the oxygen and phosphorus atoms than does **1**. A similar interaction, as for the **5-TS** HOMO, is noted for the **3-TS** HOMO, only more substantial (Fig. 5*d*). However, the internuclear distances of P_1-O_3 and P_1-O_4 in **1-TS** were greater than those of **5-TS** and even greater than in **3-TS**. Therefore, conclusions as to the relative lowering of the activation barrier through these weak additional bonding interactions are difficult to quantify.

As a final note, the decomposition of the POC TSs described above exhibited similar characteristics to an oxaphosphetane transition state (OP-TS) from a Wittig reaction decomposing to the phosphine oxide and alkene products. The mechanism for the Wittig decomposition remains somewhat controversial, especially when considering the non-

stabilized and stabilized ylides (28, 29). However, recent calculations (30) at the Becke3PW91/6–31G(d) show the OP-TS has a dihedral angle of approximately 7–29° (*trans* route) for the four atoms that make up the ring in the TS. The puckering of the OP-TS is similar to the TSs that we calculated, and the varying angles may be attributed to the substituents on the aldehyde examined by Vedejs and Marth (29). These calculations also showed imaginary frequencies that ranged between 300*i* to 400*i* cm^{-1}, similar to the ones we described.

Conclusions

Plausible optimized geometries and transition states for the POCs investigated gave the calculated activation energies. The computed E_as for the extrusion of singlet oxygen from the ozonides were within reasonable agreement with experimental results, with the exception of 4-ethyl-1-phospha-2,6,7-trioxabicyclo[2.2.2]octane ozonide. The activation energies ranged from a low of 15.1 kcal mol^{-1} for trimethyl phosphite ozonide to a high of 25.6 kcal mol^{-1} for 1-phospha-2,8,9-trioxadamantane ozonide from single point calculations at the Becke3PW91/6–31++G(d,p) level of theory. A nice correlation was found: the more hindered and electronegative the P–OR groups, the higher the activation barriers. The AIM results indicated that there is no correlation between the atomic charges on the atoms near the reaction centre and the reactivity of the POCs. We have discounted structures **I** and **X**, which were proposed to be likely intermediates or TSs, as no suitable geometries were found in our study. Weak electrostatic interactions — both attractive and repulsive — that either lower or raise the E_a may occur in POCs in which the TSs are stabilized or destabilized by such interactions. Qualitative arguments were presented from a frontier molecular orbital description to account for the thermal instability of these ozonides.

An ab initio molecular orbital study of the geometry of the dicationic Wallach rearrangement intermediate[1]

Robin A. Cox, David Y.K. Fung, Imre G. Csizmadia, and Erwin Buncel

Abstract: Ab initio calculations have been performed on several different structures for the dicationic intermediate proposed for the Wallach rearrangement of aromatic azoxy compounds to hydroxy-substituted azo systems in strongly acidic media. For the unsubstituted parent compound azoxybenzene, these calculations reveal that the preferred structure for the intermediate is planar, as previously assumed, but bent rather than linear as we have formulated it. The presence of two methyl groups at the *para* positions of both aromatic rings does not change this situation, but six methyl groups at all *para* and *ortho* ring positions lead to a different preferred structure — still bent but with the two aromatic rings now at 90° to one another rather than being coplanar — undoubtedly due to steric interference between the *ortho* methyl groups. In all the cases examined the two positive charges reside primarily in the aromatic rings rather than on the nitrogens, which are sp^2 hybridized and still have their lone pairs. The overall structures can best be regarded as two six-electron π systems joined together, with little communication between the two rings. For the most part the calculations are in good agreement with experimental observations. Recent calculations on other possible reaction intermediates by other groups are also discussed.

Key words: Ab initio calculations, Wallach rearrangement, azoxyarenes, reaction intermediate, acid catalysis, intermediate structure, reaction mechanism.

Résumé : On a effectué de calculs théoriques sur plusieurs structures différentes d'intermédiaires dicationiques proposés pour le réarrangement de Wallach, en milieu fortement acide, de composés azoxy aromatiques en systèmes azo portant des substituants hydroxy. Pour le composé azoxybenzène parent, ne comportant pas de substituant, ces calculs mettent en évidence que la structure privilégiée de l'intermédiaire est planaire comme on le croyait antérieurement, mais qu'elle est repliée et non pas linéaire comme on l'avait formulé. La présence de deux groupes méthyles dans les positions *para* des deux noyaux aromatiques ne modifie pas cette situation, mais si le composé azo comporte six groupes méthyles, un dans chacune des positions *ortho* et *para*, la structure privilégiée est différente tout en demeurant repliée; les deux noyaux aromatiques sont toutefois maintenant à 90° l'un par rapport à l'autre plutôt que d'être coplanaires et cette situation est probablement causée par l'interférence entre les groupes méthyles en *ortho*. Dans tous les cas examinés, les deux charges positives se retrouvent principalement sur les noyaux aromatiques plutôt que sur les atomes d'azote dont les hybridations sont sp^2 alors qu'ils portent toujours leurs paires d'électrons non pairés. La meilleure façon de visualiser les structures globales est de les considérer comme deux systèmes à six électrons π reliés sans grande communication entre les deux noyaux. Dans l'ensemble, les calculs sont en bon accord avec les observations expérimentales. On discute aussi d'autres calculs récents relatifs à d'autres intermédiaires réactionnels possibles par d'autres groupes.

Mots clés : calculs ab initio, réarrangement de Wallach, azoxyarènes, intermédiaire réactionnel, catalyse acide, structure de l'intermédiaire, mécanisme réactionnel.

Scheme 1.

Introduction

The Wallach rearrangement, originally discovered by Wallach and Belli in 1880 (1), is the rearrangement of aromatic azoxy compounds in strong aqueous acidic media to azo compounds having an hydroxy group elsewhere in the molecule (normally in a *para* position), as shown below for the parent compound azoxybenzene **1** rearranging to *p*-hydroxyazobenzene **2**.
The reaction mechanism for the rearrangement of **1** and of related aromatic azoxy compounds has been the subject of a considerable amount of work by various research groups; we have carried out a number of careful kinetic and other studies of this process over several decades (2–7). Despite comments in advanced-level textbooks about the mechanism being "not completely settled" (8), the mechanism that we proposed originally (2) has essentially stood the test of time.

This mechanism has been given in several review articles (9–13); for **1** itself in concentrated sulfuric and other acids it is given in Scheme 1. In brief, pre-equilibrium protonation of **1** gives a species that is stable in the strong acid reaction media (2); this is then attacked by a second molecule of acid in the rate-determining step, only the strongest acids in the medium being capable of reacting in this general-acid-catalysis process (4). The result is a dicationic intermediate, which we have been writing as having the structure **3** (and which could be called 1,2-diaza-1,2-diphenylethyne). Subsequent fast processes give the observed reaction product **2** on workup, as shown; if **4** is the first-formed product it is

known to hydrolyze rapidly to **2** as the reaction mixture is diluted (14).

In general, aromatic azoxy compounds appear to react via the mechanism in Scheme 1 if the acidity of the medium is high (**1** and some azoxypyridines (7)). However, at lower acidities the more reactive compounds (several azoxynaphthalenes (6) and hexamethylazoxybenzene (5)) can react via a quinonoid intermediate mechanism as well (10); this will be discussed below.
While compiling information for a recent review (10) we became aware of an apparent discrepancy in the products formed from different alkyl-substituted compounds. Hexamethylazoxybenzene **5** gives the hydroxymethyl product **6** (5), whereas the 4,4′-dialkyl compounds **7** give at least some of the rearranged products **8** and **9** (15). Admittedly the reaction conditions in these two cases were quite different. The reaction of **5** was carried out under highly dilute kinetic conditions of some 10^{-4} M where intermolecular reactions are quite unlikely; products equivalent to **8** and **9** were

searched for but not found, **6** being the only product observed (16). The reaction of **7** took place under synthesis conditions at much higher concentrations (>1 M), and much byproduct formation was observed, some of it clearly by intermolecular processes (15). Nevertheless the discrepancy seems to be real, and we thought that it might be due to the dicationic intermediate having different geometries in the two cases — the *ortho* methyl groups perhaps causing steric interference in the case of **5** — thus driving the reaction in a different direction.
There are no recent theoretical calculations on these dicationic intermediates. Many years ago we performed simple Hückel MO calculations on the two possible structures for **3** given above (17); the calculations showed that both geometries were possible but were unable to distinguish between them in terms of energy. More recent semi-empirical AM1 calculations on several possible Wallach rearrangement intermediates (18) did not include these, which is surprising since **3** has actually been observed by NMR at –78°C in SbF_5–HF–SO_2 (19). While this observation does not necessarily mean that **3** really is an intermediate in concentrated aqueous sulfuric acid and related reaction media, it does make it more probable than other unobserved intermediates. Consequently we decided to perform some up-to-date ab initio calculations on possible structures for the dicationic intermediates in the reactions of **1**, **7** (with R = Me for **7**), and **5**; these are given as **10**, **11**, and **12** below, with the four different structures calculated for each one being designated as *a*, *b*, *c*, and *d*.

Calculations

Gaussian 94/98 (20) was used to perform Hartree–Fock (HF) calculations using the standard 3–21G and 6–31G* basis sets on the structures of interest, as has been done before for cationic intermediates (21) and other species (22–23). Recently it has been shown that HF/3–21G calculations give results comparable with those obtained using the higher-order MP2/6–311++G** level of theory (24), and thus it was not deemed necessary to use this theory level on these quite large species. Frequency calculations were performed on optimized structures to determine whether the geometry of the structures found were local minima ($\lambda = 0$) or saddle points ($\lambda = 1, 2, \ldots 3N - 6$, where N is the number of atoms in the molecule) of their potential energy surfaces. (The index λ represents the number of negative values of the Hessian matrix (corresponding to the number of imaginary frequencies) for a given critical point.) Surface points generated by scan calculations were plotted using Axum 5.0C and Microsoft Excel 97; these plots are not provided as they add little information to that given in the tables and structures in this paper. The results of the calculations are summarized for the various structures in Tables 1 and 2, and calculated Mulliken charges on the relevant atoms of those structures found to be minima are given in Table 3.

Results

The results of our calculations can be summarized in the structure diagrams given below; in all the left-hand structures the two phenyl rings are coplanar, and in all the right-hand ones they are perpendicular to one another. Both levels of theory used gave the same results.
In each case the most stable (lowest energy) structure found for that species is boxed. Not all of the structures were found to be energy minima; see Tables 1 and 2. Energy differences between the structures (for each of the three species **10**, **11**, and **12**) calculated at the two levels of theory are given in the Tables. Calculated Mulliken charges on relevant atoms of those structures found to be minima at the RHF/6–31G* level are given in Table 3.

Discussion
The global minimum structures, **10***a*, **11***a*, and **12***d*, are all bent, not linear; the C–N–N bond angles are near 120° (115°

Table 1. Computed energies, bond angles, and torsional angles of the Wallach rearrangement dicationic intermediate at the RHF/3–21G level of theory.

for **10**a and **11**a and 131° for **12**d). The conclusion must be that the positive charges in the molecules reside primarily on the rings and not on the nitrogens, which, with these bond angles, must be sp^2 hybridized with the lone pairs still present, as shown above (**10**a was also found to be the most stable structure according to simple Hückel MO calculations (17)).

Communication between the two aromatic rings seems not to be important. Compound **12**d is the global minimum structure for **12** despite having a torsional angle between the two rings of close to 90° (actually 105°), undoubtedly caused by *ortho* methyl steric interference, whereas **10**a and **11**a are flat (0°). There is precedence for this, insofar as the azine $R_2C=N–N=CR_2$ species studied by Rademacher and co-workers have also been shown to consist of two essentially planar halves (25).
Scheme 2.
Scheme 3.
Thus the intermediates can probably best be regarded as two six-electron π systems joined together, as indicated for the partial structure above, with the torsional angle between them being of little consequence. Rademacher finds that in his cases the nitrogen lone pairs are in conjugation with the opposite part of the molecule (25); there is some evidence for that here (in Table 3 the charge densities at the 4 and 4′ carbons in **10***a* are actually very slightly negative), but his systems did not involve aromatic electron sextets as ours do, and lone-pair delocalization would add very little extra stabilization in our case. Zuman and Ludvík state that "the delocalization is either minimal or absent" in both cyclic and acyclic compounds containing the C=N–N=C grouping, according to electrochemically determined reduction potentials (26).

With methyl groups present, the calculated charge density on the rings is higher than it is in their absence (Table 3), and this is consistent with the experimental observation that alkylated azoxybenzenes react faster than does azoxybenzene itself (5). Much of this charge is delocalized onto the hydrogens of the methyl groups (by hyperconjugation), see Table 3, which become acidic as a consequence, explaining why **6** is formed from **5** by base attack on the methyl hydrogens (5) rather than the rearranged phenols equivalent to

8 and **9** that would result from nucleophilic attack on carbon, as in Scheme 1 above for **1**. It also makes it likely that the formation of **8** and **9** from **7** is a secondary reaction of some sort under the high concentration reaction conditions used (15); this reaction needs to be re-examined under reaction conditions corresponding to those used for **5** (5). We hope to be able to undertake a study of this type in the future.

Consistent with the higher charge density on the methyl hydrogens found for **5** is the fact that **5** also undergoes a quinonoid-intermediate mechanism at low acidity, see Scheme 2 (5); the regular dication mechanism takes over from this at acidities higher than 80% H_2SO_4. Even one positive charge in the molecule is sufficient to make the methyl hydrogens acidic enough to react.

Recent semi-empirical AM1 calculations concerning the Wallach rearrangement involved many other postulated reaction intermediates (18). Though the authors state that α–β interconversions of aromatic azoxy compounds in acid (from either direction) are low-energy processes taking place via species like **13** (various states of protonation of **13** being possible), this is at variance with the experimental facts, i.e., that these interconversions are not significant under controlled Wallach rearrangement reaction conditions (13). Only

Scheme 4.
one such reaction has been properly investigated, the β–α isomerization of the 4-NO_2 compound (27), and that requires protonation of the NO_2 group first, certainly not a low-energy process (13).
Another conclusion of these AM1 studies (18) was that "the quasiplanarity of the azoxybenzene ring is destroyed during the reaction". According to the present work this is clearly not the case for the intermediates formed from azoxybenzene **1** itself or from **7** — the torsional angles between the rings found here being 0° — although the rings do not have to be coplanar; we find **12d** with a torsional angle of 105° to be the stable form for the intermediate formed from **5**.
The major conclusion to which Özen et al. came (18) was that the reaction mechanism for **1** involved quinonoid intermediate **14**, a mechanism originally proposed by Duffey and Hendley (28). This is also certainly at variance with the experimental facts, since isotopic substitution studies have clearly shown that the two nitrogens become equivalent during the reaction (12, 13). Interestingly, we know that some reactive azoxybenzenes can indeed use this mechanism, e.g., **5** as in Scheme 2 above and the azoxynaphthalene **15** as shown in Scheme 3 (6), but not azoxybenzene itself! Apart from the isotopic substitution results the kinetics are also at variance with this mechanism, since the correct mechanism clearly requires the involvement of two acid molecules, not one (4).

Thus we have shown that the mechanism of the Wallach rearrangement in strong acid media clearly involves dicationic intermediates such as **10a**. Insofar as this has a bent structure rather than the linear one **3** as given in Scheme 1, the overall mechanistic scheme requires slight modification, as shown in Scheme 4. (For clarity, only one of the possible resonance forms is given for several structures in Scheme 4.) Note that the azo–azoxy function remains in the same bent format throughout in this mechanism, which is satisfying in terms of the principle of least nuclear motion. This principle states that those reactions are favoured that require the least amount of relative atom displacement in going from reactant to product (29).

Acrylonitrile (AN)–Cu$_9$(100) interfaces: Electron distribution and nature of bonded interactions

Petar M. Mitrasinovic

Abstract: There is a fundamental interest in the investigation of the interfacial interactions and charge migration processes between organic molecules and metallic surfaces from a theoretical standpoint. Quantum mechanical (QM) concepts of bonding are contrasted, and the vital importance of using combined QM methods to explore the nature of the interfacial interactions is established. At the one-electron level, the charge distribution and nature of bonded interactions at the AN–Cu$_9$(100) (neutral and charged (–1)) interfaces are investigated by both the Becke (B) – Vosko (V) – Wilk (W) – Nusair (N)/DZVP density functional theory (DFT) method and the MP2/6–31+G* strategy within the conceptual framework provided by natural bond orbital (NBO) – natural atomic orbital (NAO) population analysis and Atoms-In-Molecules (AIM) theory. By this approach, the interfacial interactions are given physical definitions free of any assumptions and are visualized by using the topological features of the total electron density. A natural link between the electron density on the one side and the shapes (not energies) of the highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) on the other side is clarified. The question of whether the spatial extents of the HOMO and LUMO resemble the corresponding spatial maps of the negative (charge locally concentrated) and positive (charge locally depleted) Laplacian of the total electron density in [AN–Cu$_9$(100)]$^{-1}$ is addressed.

Key words: AN–Cu$_9$(100) interfaces, NBO–NAO population, electron distribution, AIM, bonded interactions.

Résumé : D'un point de vue théorique, il existe un intérêt fondamental pour les recherches sur les interactions interfaciales et les processus de migration de charge entre des molécules organiques et les surfaces métalliques. On met en relief les concepts de la mécanique quantique (MQ) de liaison et on démontre l'importance vitale d'utiliser des méthodes de MQ pour explorer la nature des interactions interfaciales. Au niveau d'un électron, on a étudié la distribution de la charge et la nature des interactions de liaison aux interfaces AN–Cu$_9$(100) (neutres ou portant une charge de (–1)) par la théorie de la densité fonctionnelle (TDF) de Becke (B) – Vosko (V) – Wilk (W) – Nusair (N)/DZVP ainsi qu'en faisant appel à la stratégie MP2/6–31+G* dans le cadre conceptuel fournit par l'analyse des populations d'orbitale liante naturelle (OLN) et d'orbitale atomique naturelle (OAN) ainsi que la théorie des atomes dans la molécule (ADM). Par cette approche, on donne des définitions physiques des interactions interfaciales qui sont exemptes de toute hypothèse et qui sont visualisées en faisant appel à des caractéristiques topologiques de la densité totale d'électron. On a clarifié un lien naturel entre d'une part la densité électronique et d'autre part les formes (non pas les énergies) de l'orbitale moléculaire haute occupée (OH) et de la basse vacance (BV). On a essayé de déterminer si, dans [AN–Cu$_9$-(100)]$^{-1}$, les distributions spatiales des orbitales moléculaires OH et BV ressemblent aux cartes spatiales correspondantes des laplaciens négatifs (charge ponctuellement concentrée) et positifs (charge ponctuellement appauvrie) de la densité électronique totale.

Mots clés : interfaces AN–Cu$_9$(100), population OLN–OAN, distribution électronique, ADM, interactions liées.

[Traduit par la Rédaction]

Introduction

The semiconductor industry is facing difficulties with respect to its ultimate goal: to maintain a stable growth of the density of packing on a single chip. The permanent trend for reducing the size of conventional MOS (metal–oxide–semiconductor) components, followed by the significant rise in the costs needed for producing integrated circuits of a larger scale, reflects the difficulties in the best possible sense (1). In this context, the potential of molecular electronics to become an alternative to the semiconductor industry is growing rapidly. Many experimental and theoretical studies have been addressing the question of identifying the functional abilities of single molecules or molecular self-assemblies to behave as wires, diodes, transistors, and rectifiers. An experiment performed by Reed et al. (2) has shown that phenyl-

P.M. Mitrasinovic.[1] Laboratory for Chemistry of Novel Materials, Center for Research on Molecular Electronics and Photonics, The University of Mons-Hainaut, B-7000 Mons, Belgium, Europe.

ene-based derivatives are capable of behaving as a conducting wire when inserted into a metallic break junction. There are indications that some molecules such as nanotubes (3) and DNA (4) conduct a current when inserted between two metal electrodes. An ancient idea — dating back to Aviram and Ratner (5) — that organic moieties linked by a saturated spacer between two metallic electrodes can act as a rectifier has recently been verified experimentally (6, 7). Mujica et al. (8) have noticed that molecular rectification is rare because the interplay between different transport regimes (for a specific interface) such as tunneling, hopping, and diffusion is temperature dependent. The authors (8) have also indicated that the current of the charge-carrying particles in the coherent tunneling regime depends strongly on the following factors: (*i*) the nature of the molecular bridge and the contacts; (*ii*) the strength of the surface–molecule interaction; (*iii*) the position of the Fermi energy; and (*iv*) the profile of the electrochemical potential across the interface. The density of states within the HOMO–LUMO gap (HLG) makes the precise position of the Fermi energy level sensitive to a small amount of charge transfer. Thus, the Fermi energy level should be viewed as a fitting parameter inside a reasonable range. Several theoretical investigations (9–14) devoted to the understanding of the conducting mechanisms through molecular wires have shown that the electronic structure of the molecule and the geometry of the metal–organic interfaces, as well as the nature of the chemical interactions, are crucial. By modifying original contacts between a conjugated molecule and a metallic surface by the addition of the sulfur and gold atoms to a terminal carbon of the molecule, Seminario et al. (15) have shown that the character of the organic–metal interactions is local. The authors of ref. 1 have stated on p. 10 077: "…there is still a fundamental interest from a theoretical standpoint to address separately, at least in the case of long molecular wires, the charge injection mechanism (i.e., the interfacial interactions between molecules and metallic surfaces 32, 33) and the charge migration process…" (1). The present study opens the question of the nature of bonded interaction at organic–metal interfaces from a more rigorous (in a physical sense) point of view.

There have been theoretical attempts to rationalize the experimental results that characterize the organic–metal interfaces. Although useful, there are well-known problems associated with such attempts, which have been quite extensively reviewed (16). The partitioning schemes of the molecular interaction energy used are arbitrary, and the definitions of additive contributions to the energy are obscure. The divisions of the molecular interaction energy into classically interpretable segments do not distinguish different aspects of electron behavior. The charge transfer and electrostatic components do not have the usual physical meanings considered in the Mulliken and Morokuma analyses, respectively (17(*a*)). The descriptions of bonded interactions have also been sought in orbitals that are not invariant (17(*b*)). This study readily makes the distinctions.

Seminario et al. (18, p. 3017) have noticed that most previous work dedicated to the understanding of conduction mechanism has been based on "…the orbital energetics without considering the spatial extent of the conduction channels…" (18). To predict the electronic transport of a charged molecule when some unoccupied orbitals of the neutral molecule become occupied following application of an external voltage, the spatial profile of the LUMO and the HLG have been observed, because the HLG may be viewed as a measure of the hardness of the electron density (18–20). It has been proposed that a prerequisite for a satisfactory charge transmission through a molecular junction is the delocalization of the LUMO without referring to the total electron density (21). This study is a fundamental reformulation of this qualitative approach for a deeper reason that the success of frontier molecular orbital theory to rationalize the interfacial charge migration process may depend on if the spatial maps of the HOMO and LUMO resemble those determined by negative and positive values of the Laplacian of the total electron density, which determines the reactivity.[2]

Becke and Edgecombe (22) have noted that physically meaningful descriptions of electron behavior must be sought in the density matrix (or related functions) and not in the orbitals. Wave functions (or more generally density matrices) are therefore indispensable for the interpretation of electron behavior. At the one-electron level, the density matrix may be diagonalized by using the natural orbitals (NOs) (23, 24). By writing the NOs as linear combinations of the atomic orbitals, an invariant description of electron behavior can be related to a localized picture of the atomic orbitals involved in bonding. On one hand, NBO analysis (25, 26) is often in good agreement with such descriptions (27). On the other hand, Bader et al. (28) recognized an alternative orbital-independent description of electron localization based on the electron density. A bond path, as defined by Bader in his AIM theory (29, 30), is a universal indicator of bonded interactions (31). In this study, the behavior of the electrons in the AN–Cu$_9$(100) complexes in terms of the charge distribution and nature of bonded interactions is described by use of the NBO–NAO–AIM strategy.

The plan of this paper is as follows. The theoretical background is given in the following section. The primary intention of this part is to emphasize the importance of using combined theoretical methods in investigating the organic—metal bonded interactions. By using NBO–NAO (23) population analysis and AIM (29, 30) theory, the electron distribution and nature of bonded interactions between AN and Cu$_9$(100) are explored in the "Electron distribution" and "Nature of bonded interaction" sections, respectively. The initial parts of nucleophilic reactions in the complexes are quantitatively expressed by use of the Fukui function f_+ (32). In the "[AN–Cu$_9$(100)]$^{-1}$: Laplacian of total electron density and spatial extents of HOMO and LUMO" section, the spatial extents of the HOMO and LUMO are contrasted to those of the negative and positive Laplacian in [AN–Cu$_9$(100)]$^{-1}$, respectively. Finally, the present qualitative approach is contrasted to those used in various contributions to this topic.

Background

It is difficult to explore the nature of bonded interactions at organic–metal interfaces without the concept of bonding

---

[2] P.M. Mitrasinovic. Unpublished data.

and the association of atoms in molecules. Bonds are implicit in the very notion of association. An appropriate question to be raised, which is not entirely metaphysical, is whether the bonds hold the atoms together or whether the bonds are the outcome of other processes. In the context of this question, the key quantum mechanical concepts of bonding are contrasted below, indicating the importance of the use of NBO analysis and AIM theory to characterize bonded interactions.

Quantum mechanical descriptions of bonding can be classified into three groups. The first is based on the partition of the molecular interaction energy (33–39). The strength of the arbitrary partitioning schemes to divide the molecular interaction energy into classically interpretable segments is less pronounced than their weakness to ignore different aspects of electron behavior. The determination of electron behavior is crucial. The second interprets bonding by using density matrices (22, 27, 40). Ruedenberg (40) sought to extract physically meaningful descriptions of bonding, but Fulton (27) fully succeeded in his attempt of this kind at the one-electron level. Due to computational costs, the one-electron density matrices of good quality for organic–metal complexes are unattainable at the present time. The intention of this study is, still, to investigate the interfacial interactions by use of theoretical techniques capable of producing qualitative interpretations, which are comparable to those rooted in the density matrices. NBO analysis fulfils the requirement (25, 26). The third description of bonding takes advantage of the characteristics of the electron density within the molecule to interpret bonding (28–31). Note that the electronic charge density distribution determines the three-dimensional arrangements of the negative charge of an atom or a molecule, the sizes and shapes of molecules, and the electric moments. In other words, the electron density, as a physically measurable quantity, determines all chemical and physical properties of atoms and molecules. The actual distribution of charge within the molecule allows us to classify ionic and covalent bonding patterns, but they are given physical definitions free of any assumptions. AIM theory (28–31) is of particular interest for characterizing the organic—metal -bonded interactions.

The original definition of natural orbitals was given by using the density matrix from a full configuration interaction (CI) wave function (24). The wave function is the best one constructed for a given basis set. The idea contained in the NAO and NBO analyses is that the one-electron density matrix can be used for defining the shape of the atomic orbitals in the molecules and for deriving chemical bonds from electron density between atoms (23). The first-order density matrix can be diagonalized by the eigenvectors called NOs and the eigenvalues called Occupation Numbers. The summation of all contributions from orbitals on a specific atom gives the atomic charge. The NAOs usually contribute more than 99% to the electron density, giving a compact expression of the wave function in terms of atomic orbitals. Since the NAOs are defined from the one-electron density matrix, the electron occupation is between 0 and 2, and the NAOs converge to defined values as the size of the basis set is increased. NAO and NBO analyses may be run for correlated wave functions. On the basis of computational considerations, the NAO procedure is an attractive choice for analysis purposes,

involving only matrix diagonalization of small subsets of the density matrix.

The charge density distribution in the donor and acceptor molecules and in intermolecular regions can be used to characterize weak bonds within AIM theory (28–31). A line of the highest electron density linking any bonded pair of atoms is called a bond path. The existence of a bond path is a necessary and sufficient condition for the existence of a bond. The point of a line of the highest electron density where the gradient, $\vec{\nabla}\rho(r)$, of the density $\rho(r)$ is equal to zero is the bond critical point (CP). The properties of the density at this point give quantitative information about the characteristics of that bond. A bond path between a pair of nonchemically bonded atoms is termed an interaction line. The Laplacian of the electron density ($\nabla^2\rho(r)$) indicates where the electron density is locally concentrated ($\nabla^2\rho(r) < 0$) and depleted ($\nabla^2\rho(r) > 0$) and, therefore, contains a large amount of chemical information. Note also that the electronic charge operator is simply the negative of the number operator (–1 for an electron) in the quantum mechanical sense. The problem is in the definition of an atom in a molecule. The most rigorous division of a molecular volume into atomic subspaces is given by Bader and co-workers (28–31).

In general, a reaction is followed by a change in the electron density that may be quantified by the Fukui function (32).

$$[1] \qquad f(r) = \frac{\partial \rho(r)}{\partial N}$$

The Fukui function indicates the change in the electron density at a given position when the number of electrons N is changed. A finite difference of the function associated with the addition of an electron is

$$[2] \qquad f_+(r) = \rho_{N+1}(r) - \rho_N(r).$$

The function is expected to be the initial part of a nucleophilic reaction, and the reaction will probably occur where the function is large (41). The function may be written in terms of orbital contributions as

$$[3] \qquad f_+(r) = \phi^2_{LUMO}(r) + \sum_{i=1}^{N} \frac{\partial \phi_i^2(r)}{\partial n_i}$$

The last terms become zero in the frozen molecular orbital approximation, and the Fukui function contains only the contribution from LUMO (32).

Electron distribution

In this section, analysis of the charge distribution and charge-transfer processes at the AN–Cu$_9$(100) interfaces is performed using the NBO–NAO partitioning scheme. The natural charges obtained in this way were shown to be sufficiently reliable and stable to computational parameters (23). A two-layer Cu$_9$(100) cluster was used to simulate the actual surface. The following are recommendations in the literature: that the geometry of AN is not affected by the size of the clusters (9 atoms) and that the use of smaller clusters (<9 atoms) will affect the binding energy (42). Also, the use of larger clusters would mimic the density of states of the actual surface (43). The chosen cluster size may be viewed

Fig. 1. Optimized geometries: (*a*) AN; (*b*) AN–Cu$_9$(100); (*c*) [AN–Cu$_9$(100)]$^{-1}$.
both as a compromise among the recommendations and as representative of the problems being addressed. A static electric field of –0.015 atomic units (au) was chosen to simulate the driving voltage between the electrode and the molecule. The results reported below are based on calculations done at the B-VWN/DZVP(DFT) (44–46) and MP2/6–31+G* levels of approximation. The optimized geometries (Fig. 1) were generated using the program DMol (17, 47, 48). The interatomic distances of the Cu$_9$(100) clusters were frozen at the bulk values (17). The natural population analysis was carried out by use of the Gaussian 98 suite of programs (49).

B-VWN/DZVP(DFT)

The NBO analysis shows the high percentage (>99%) contribution of the NAOs to the molecular charge distribution, i.e., 99.58% of 20 in the AN valence, 99.48% of 119 in the AN–Cu$_9$(100) valence, and 99.52% of 120 in the [AN–Cu$_9$(100)]$^{-1}$ valence. AN is set as a standard against which the changes in the charge distribution caused by the formation of the bonds can be measured. The identified sites between which the bonding occurs are C(1)—Cu(8) and N(7)—Cu(15) in AN–Cu$_9$(100), as well as C(1)—Cu(8) in [AN–Cu$_9$(100)]$^{-1}$. The NECs of these atomic sites, given in Table 1, contain only those valence NAOs that have been substantially modified in terms of the electron distribution by incorporating the isolated AN into the AN–Cu$_9$(100) complexes. In comparison to the standard, the natural charges indicate that the C(1) and N(7) sites become more negative by –0.41 and –0.27 in AN–Cu$_9$(100) and that the C(1) site gains a negative charge of –0.40 in [AN–Cu$_9$(100)]$^{-1}$. The Cu(8) and Cu(15) atoms have the overall natural charges of +0.15 and +0.32 in AN–Cu$_9$(100), while the Cu(8) site is essentially neutral (slightly negative, –0.08) in [AN–Cu$_9$(100)]$^{-1}$. The C(1)—Cu(8) and N(7)—Cu(15) bonds in AN–Cu$_9$(100) should be looked upon as being ionic (charge separated) as far as the natural charges are concerned. The changes in the electron distribution are most pronounced in the second shells of C(1) and N(7) and in the 3d and 4s NAOs of Cu(8) and Cu(15) in AN–Cu$_9$(100), as given in Table 1. By adding an electron to the neutral complex AN–Cu$_9$(100), the C(1) site does not experience any substantial change while Cu(8) gains a negative charge of –0.23, of which –0.21 is assigned to the 4s. After applying an electric field to the neutral complex AN– Cu$_9$(100), the N(7) atom in [AN–Cu$_9$(100)]$^{-1}$ becomes more positive, by +0.14, than N(7) in AN–Cu$_9$(100), of which +0.16 is assigned to the 2p NAO and –0.02 to the 2s and has an overall natural charge of –0.45. The Cu(15) atom in [AN–

Table 1. B-VWN/DZVP(DFT): natural charges and electron configurations (NECs) at interaction sites.

Molecule	Atom (site)	Natural charge	Configuration
AN	C(1)	–0.29	2s(1.04)2p(3.24)
	N(7)	–0.32	2s(1.62)2p(3.67)
AN–Cu$_9$(100)	C(1)	–0.70	2s(1.12)2p(3.53)
	Cu(8)	+0.15	4s(0.84)3d(9.88)
	N(7)	–0.59	2s(1.59)2p(3.96)
	Cu(15)	+0.32	4s(0.81)3d(9.83)
[AN–Cu$_9$(100)]$^{-1}$	C(1)	–0.69	2s(1.13)2p(3.52)
	Cu(8)	–0.08	4s(1.05)3d(9.90)

Cu$_9$(100)]$^{-1}$ becomes more negative by –0.46 than the Cu(15) atom in AN–Cu$_9$(100), of which –0.12 is distributed into the 3d NAO and –0.34 into the 4s and has an overall natural charge of –0.14.

It is also possible to determine the molecule(AN)–cluster(Cu$_9$) charge separation by simply summing the appropriate natural charges of atoms. The molecule–cluster natural charge separation is AN(–0.79)–Cu$_9$(+0.79) in the neutral complex. In some respects the C(1)—Cu(8) and N(7)—Cu(15) bonds in AN–Cu$_9$(100) can be considered as charge separated, as far as the molecule–cluster natural charge separation is concerned. The molecule–cluster natural charge separation in [AN–Cu$_9$(100)]$^{-1}$ is AN(–0.67)–Cu$_9$(–0.33). Thus, the AN molecule as a whole becomes more positive by +0.12 while the Cu$_9$ cluster as a whole becomes more negative by –1.12, after applying an external voltage to the neutral complex AN–Cu$_9$(100).

Additional information about the nature of bonded interactions is provided by Tables 2 and 3, containing the spin-separated NAOs at the interaction sites. The letters "a" and "b" used in the analysis mean "alpha (spin up)" and "beta (spin down)", respectively. Since the valence electrons tend to be chemically active, the total occupancies of the spin-separated NAOs at the interaction sites in AN–Cu$_9$(100) involved in the bonding are 2.33a and 2.31b at C(1), 2.77a and 2.74b at N(7), 5.4a and 5.34b at Cu(8), and 5.3a and 5.34b at Cu(15). The occupancies of the σ-bonding and antibonding C(1)—Cu(8) NOs of the alpha spin are 0.79 (72.4% at C(1)) and 0.28 (27.6% at C(1)) in AN–Cu$_9$(100). The occupancies of the σ-bonding and antibonding N(7)—Cu(15) NOs of the alpha spin are 0.77 (81.5% at N(7)) and 0.28 (18.5% at N(7)) in AN–Cu$_9$(100). Table 3 shows that the valence occupancies of the spin-separated NAOs are 2.36a and 2.27b at C(1), as well as 5.59a and 5.38b at Cu(8), in

[AN–Cu$_9$(100)]$^{-1}$. The occupancies of the σ-bonding and antibonding C(1)—Cu(8) NOs of the "up" spin are 0.96 (57.6% at C(1)) and 0.32 (42.4% at C(1)) in [AN–Cu$_9$(100)]$^{-1}$.

MP2/6–31+G*

The NBO analysis shows the high percentage (>99%) contribution of the NAOs to the molecular charge distribution, that is, 99.40% of 20 in the AN valence, 99.28% of 119 in the AN–Cu$_9$(100) valence, and 99.56% of 120 in the [AN–Cu$_9$]$^{-1}$ valence. The summary of NO population analysis is given in Table 4. By incorporating the isolated AN into the AN–Cu$_9$(100) complex, the natural charges indicate that the C(1) and N(7) sites become more negative by –0.41, of which –0.25 is distributed into 2p and –0.11 into 2s at C(1) and –0.46 into 2p and +0.06 into 2s at N(7). The Cu(8) and

Cu(15) atoms have the natural charges of –0.05 and +0.49 in AN–Cu$_9$(100), respectively. As far as the natural charges are concerned, the N(7)—Cu(15) bond is charge separated (ionic), while the C(1)—Cu(8) bond is not, in AN–Cu$_9$(100). By adding an electron to the neutral complex, the C(1) site becomes slightly more negative by –0.05 while the Cu(8) site gains a negative natural charge of –0.56, of which –0.55 is assigned to 4s. In comparison to the neutral complex, the change of the Cu(8) natural charge of –0.56 is substantial. The overall natural charges of the C(1) and Cu(8) sites in [AN–Cu$_9$(100)]$^{-1}$ are –0.78 and –0.61, respectively.

By summing the appropriate natural charges of atoms, the molecule–cluster natural charge separation is AN(–0.94)–Cu$_9$(+0.94) in the neutral complex. In some respects the C(1)—Cu(8) and N(7)—Cu(15) bonds in AN–Cu$_9$(100) can be considered as charge separated, as far as the molecule–

	N(7)	–0.28	2s(1.62)2p(3.63)	–0.14	–0.14	–0.22
AN–Cu$_9$(100)	C(1)	–0.73	2s(1.11)2p(3.55)	–0.57	–0.16	–0.40
	Cu(8)	–0.05	4s(1.02)3d(9.40)4p(0.44)	–0.09	+0.04	–0.28
	N(7)	–0.69	2s(1.56)2p(4.09)	+0.25	–0.94	–0.45
	Cu(15)	+0.49	4s(0.71)3d(9.53)4p(0.15)	+0.18	+0.31	+0.25
$[AN–Cu_9(100)]^{-1}$	C(1)	–0.78	2s(1.13)2p(3.59)	+0.49	–1.27	–0.04
	Cu(8)	–0.61	4s(1.57)3d(9.35)4p(0.48)	–0.71	+0.10	–0.71

[a]The given NAOs have been substantially modified in terms of the charge distribution by incorporating AN into AN–Cu$_9$(100).
[b]The Mulliken charges are only to be used to demonstrate the arbitrary and unpredictable behavior of this partitioning scheme.

cluster natural charge separation is concerned. The molecule–cluster natural charge separation in $[AN–Cu_9(100)]^{-1}$ is AN(–0.36)–Cu$_9$(–0.64). Therefore, the AN molecule as a whole becomes more positive by +0.58 while the Cu$_9$ cluster as a whole becomes more negative by –1.58 after applying an external voltage to the neutral complex AN–Cu$_9$(100).

Additional information about the nature of bonded interactions is provided by Tables 5–7, containing the valence NAOs at the interaction sites in AN and the spin separated valence NAOs at the interaction sites in AN–Cu$_9$(100) and $[AN–Cu_9(100)]^{-1}$, respectively. The total occupancies involved in the bonding in AN are 4.30 at C(1) and 5.26 at N(7). The total occupancies involved in the bonding in AN–Cu$_9$(100) are 2.53a and 2.13b at C(1), 2.22a and 3.42b at N(7), 5.27a and 5.15b at Cu(8), and 5.18a and 5.06b at Cu(15). By bonding AN to Cu$_9$(100), the site C(1) gains a bonding NAO occupancy of 0.38a and loses that of 0.02b, while the site N(7) loses a bonding NAO occupancy of 0.41 having the "up" spin and gains that of 0.79 having the "down" spin. The occupancies of the σ-bonding and anti-

bonding C(1)—Cu(8) NOs of the alpha spin are 0.73 (66.83% at C(1)) and 0.26 (33.17% at C(1)) in AN–Cu$_9$(100), respectively. The occupancies of the σ-bonding and antibonding N(7)—Cu(15) NOs of the alpha spin are 0.62 (65.31% at N(7)) and 0.22 (34.69% at N(7)) in AN–Cu$_9$(100), respectively. Table 7 also shows that the valence occupancies of the spin-separated NAOs are 1.48a and 3.24b at C(1) and 5.7a and 5.05b at Cu(8) in $[AN–Cu_9(100)]^{-1}$. By adding an electron to the neutral complex, the C(1) site loses an alpha-bonding occupancy of 1.05 and gains a beta one of 1.11, while the Cu(8) site gains an alpha-valence occupancy of 0.43 and loses a beta one of 0.1. The occupancies of the σ-bonding and antibonding C(1)—Cu(8) NOs of spin "up" are 0.6 (36.12% at C(1)) and 0.2 (63.88% at C(1)) in $[AN–Cu_9(100)]^{-1}$.

The AN molecule retains its planarity in AN–Cu$_9$(100) while it becomes distorted after applying an external voltage, as given in Fig. 1. The C(1)—C(2), C(3)—N(7), and C(2)—C(3) geometric bond lengths (GBLs) in AN are 2.52 au, 2.21 au, and 2.66 au, respectively. The C(1)—C(2) and

[a]a = alpha (spin up); b = beta (spin down); Val = valence.

C(3)—N(7) GBLs in both AN–Cu$_9$(100) and [AN–Cu$_9$(100)]$^{-1}$ are 2.7 au and 2.27 au, while those of the C(2)—C(3) bonds are 2.57 au and 2.59 au, respectively. The elongation of the C(1)—C(2) and C(3)—N(7) bonds and the shortening of the C(2)—C(3) bonds with reference to AN confirm electron transfer from Cu$_9$ to AN. The calculated value of the ionization potential (IP) of 4.43 electron volts (eV) for Cu$_9$ confirms recent measurements of 4.2 eV, which is comparable with the IPs of Na (5.14 eV) and K (4.34 eV) (50). A similar electron transfer in NO population has been reported for an AN molecule with an Na atom, as well as for an acrolein molecule with an Na atom (51, 52).

Nature of bonded interactions

In this section, the nature of the AN–Cu$_9$(100) interfacial interactions is investigated by use of AIM theory at the B-VWN/DZVP(DFT) and MP2/6–31+G* levels of theory. The calculations pertaining to the topological features of the electron density were performed by use of the program EXTREM (53). The figures were created by use of the program MOLDEN (54).

B-VWN/DZVP(DFT)

The Bader (AIM) (29, 30) analysis shows the existence of the C(1)—Cu(8) and N(7)—Cu(15) through-space interactions in AN–Cu$_9$(100), as well as that between the C(1) and the Cu(8) in [AN–Cu$_9$(100)]$^{-1}$; that is, bond paths — lines of the highest electron density linking the pairs of the atoms — exist. The total bond path lengths (TBPLs) are in agreement with the geometric bond lengths. For example, the TBPLs of the C(1)—Cu(8) and the N(7)—Cu(15) in AN–Cu$_9$(100) are 3.9223 au and 3.5795 au, while the corresponding GBLs are 3.9204 au and 3.5779 au, respectively. Also, the TBPL of the C(1)—Cu(8) bond in [AN–Cu$_9$(100)]$^{-1}$ is 4.1189 au while the C(1)—Cu(8) GBL is 4.1172 au. The bond critical point is

determined by the condition that the gradient of the electron density is equal to zero, and the properties of the density at this point provide quantitative characteristics of a bond. The bond CPs have a small electron density of 0.0829 ea_0^{-3} between C(1) and Cu(8) and of 0.1093 ea_0^{-3} between N(7) and Cu(15) in AN–Cu$_9$(100), as well as of 0.0669 ea_0^{-3} between C(1) and Cu(8) in [AN–Cu$_9$(100)]$^{-1}$. The positions of the bond CPs are clear as pronounced minima of the electron density in the regions between the corresponding nuclei in Fig. 2. The Laplacian (the second derivative of the density) of the bond CPs has values of +0.1189 (C(1)—Cu(8)) and +0.3184 (N(7)—Cu(15)) in AN–Cu$_9$(100) and of +0.1095 (C(1)—Cu(8)) in [AN–Cu$_9$(100)]$^{-1}$, characteristic of a donor–acceptor bond.

Applying an external voltage to the neutral complex caused a change in the number of electrons, from 289 in AN–Cu$_9$(100) to 290 in [AN–Cu$_9$(100)]$^{-1}$. The Fukui function f_+ has values of –0.43 at C(1), +0.39 at Cu(8), –0.02 at N(7), and +30.18 at Cu(15), respectively. The changes of the electron density at C(1), Cu(8), and N(7) are not substantial, and therefore, a nucleophilic reaction may not be expected to occur in the vicinity of the interaction sites. Such a reaction may be possible in the vicinity of Cu(15).

MP2/6–31+G*

The Bader analysis shows that the total bond path lengths are in agreement with the geometric bond lengths (i.e., AN–Cu$_9$(100): C(1)—Cu(8) TBPL = 3.9265 au, GBL = 3.9205; N(7)—Cu(15) TBPL = 3.5809 au, GBL = 3.5779 au; [AN–Cu$_9$(100)]$^{-1}$: C(1)—Cu(8) TBPL = 4.1214 au, GBL = 4.1172). The bond CPs have a small total electron density of 0.0805 ea_0^{-3} between C(1) and Cu(8) and of 0.1076 ea_0^{-3} between N(7) and Cu(15) in AN–Cu$_9$(100), as well as of 0.0657 ea_0^{-3} between C(1) and Cu(8) in [AN–Cu$_9$(100)]$^{-1}$. The values of the spin electron densities at the bond CPs are

Fig. 2. Electron density. B-VWN/DZVP(DFT). (*a*) AN–Cu$_9$(100); (*b*) [AN–Cu$_9$(100)]$^{-1}$.

N(7)   C(1)   Cu(8)   Cu(15)   N(7)   C(1)   Cu(8)
0.0414 ea_0^{-3} (C(1)—Cu(8)) and 0.0554 ea_0^{-3} (N(7)—Cu(15)) in AN–Cu$_9$(100), as well as 0.0338 ea_0^{-3} (C(1)—Cu(8)) in [AN–Cu$_9$(100)]$^{-1}$. The Laplacian of the bond CPs has values of +0.0892 (C(1)—Cu(8)) and +0.3704 (N(7)—Cu(15)) in AN–Cu$_9$(100) and of +0.0867 (C(1)—Cu(8)) in [AN–Cu$_9$(100)]$^{-1}$, characteristic of a donor–acceptor bond.

The Fukui function f_+ has values of –0.49 at C(1), +133.2 at Cu(8), +2.84 at N(7), and +172.17 at Cu(15), respectively. The changes of the electron density of the Cu(8) and Cu(15) sites are substantial, indicating that a nucleophilic reaction may be expected to occur in the vicinity of the interaction sites.

[AN–Cu$_9$(100)]$^{-1}$: Laplacian of total electron density and spatial extents of HOMO and LUMO

In this section, the Laplacian of the electron density is analyzed and contrasted to the spatial extents of the HOMO and LUMO in [AN–Cu$_9$(100)]$^{-1}$.

The Laplacian itself contains features such as bonds and lone pairs, which are not observable in the density itself. The cut of the Laplacian of the electron density is given in Figs. 3 and 4. From left to right, the nuclei in the plane of the cut are N(7), C(1), and Cu(8). The electron density is locally concentrated in spatial regions determined by a negative Laplacian and locally depleted in those regions determined by a positive Laplacian. Having a slightly positive value of the Laplacian, the position of the bond critical point is nicely visible in the region between C(1) and Cu(8).

In most previous work, the HLG has been observed as a crucial parameter for understanding conductance mechanisms through molecular junctions. The ability of a molecule to rearrange its electron density under the presence of an external electron underlies such observations. If the ability is not that pronounced, the molecular admittance to the incoming electron is less recognizable and, therefore, a molecule is more stable. As the first consequence, by employing the electronegativity equalization theorem and a relative alignment of the Fermi energy level with respect to the HLG (20, 55–59), the barrier to electron transfer is proportional to the HLG to the first approximation. As the second consequence, the size of the HLG may be regarded as a measure of the hardness of the electron density. The relative alignment of

N(7)   C(1)   Cu(8)
Fig. 4. [AN–Cu$_9$(100)]$^{-1}$ — Laplacian of electron density. MP2/6–31+G*.

N(7)   C(1)   Cu(8)
the Fermi energy level is strongly dependent upon the density of states within the HLG and is sensitive to a small amount of charge transfer. Thus, the physical essence is contained in the electron density distribution.

Electron transfer, from Cu_9 to AN, leads to substantial change in the molecular structure according to the nature of the LUMO in AN. Electrons occupy some unoccupied orbitals of the neutral complex after the action of an external voltage. An area with locally concentrated electron density is susceptible to attack by an electrophile while an area with locally depleted electron density is susceptible to attack by a nucleophile. In general, it has been found that a map of negative values of the Laplacian of the total electron density resembles a spatial extent of the HOMO while that of positive values of the Laplacian resembles a spatial extent of the LUMO (60). The spatial extent of the LUMO or, more conceivably, the extent of its electron delocalization may be employed to describe electronic molecular transport of a charged molecule qualitatively if and only if (according to this study) a spatial extent of the LUMO resembles a map of positive values of the Laplacian of the total electron density. What do the spatial extents of the HOMO and LUMO in $[AN–Cu_9(100)]^{-1}$ indicate?

B-VWN/DZVP(DFT)

The cut of the HOMO in $[AN–Cu_9(100)]^{-1}$ is given in Fig. 5. The plane of the cut is the same as that of the Laplacian in Fig. 3. Note the contour map of the negative Laplacian (Fig. 3). The contours encompass C(1) and N(7), showing roughly circular curvatures, but those around C(1) are not fully closed. Note the contour lines of the HOMO residing in the same regions in Fig. 5. In its immediate vicinity, C(1) is encompassed by the negative contours. The contours are also shifted behind C(1) where the corresponding lines of the Laplacian are not fully closed. In the vicinity of N(7), the negative contours encircle N(7) towards C(1) but not fully behind the N(7) nucleus, in Fig. 5. Regardless of the qualitative differences, the area determined by negative values of the Laplacian spreads roughly in the same spatial regions as that of the HOMO.

The cut of the LUMO in $[AN–Cu_9(100)]^{-1}$ is given in Fig. 6. The plane of the cut is the same as that of the Laplacian in Fig. 3. Focus on the region between C(1) and Cu(8). The contour lines of the LUMO in this region are negative, spreading both toward the left and the right with respect to the C(1)—Cu(8) bond line. In contrast to it, the contour lines of the Laplacian in the same region are positive. It is clear that the spatial extent of the LUMO does not resemble that of the positive Laplacian.

MP2/6–31+G*

The cut of the HOMO in $[AN–Cu_9(100)]^{-1}$ is given in Fig. 7. The plane of the cut is the same as that of the Laplacian given in Fig. 4. The negative contours of the HOMO show a circular curvature in the immediate vicinity of C(1), which spreads right under the C(1)—Cu(8) internuclear axis. In contrast to the Laplacian, there are some positive contours of the HOMO in the immediate vicinity of C(1), which are still edged by the negative ones right above the C(1)—Cu(8) interaction line. The N(7) site is also surrounded by two concentric spatial profiles of the negative

Fig. 6. $[AN–Cu_9(100)]^{-1}$ — LUMO. B-VWN/DZVP(DFT).

N(7)   C(1)   Cu(8)
contours, of which the outer one is substantially extended both toward the left and the right with respect to N(7). Regardless of the qualitative differences, the area determined by negative values of the Laplacian spreads roughly in the same spatial regions as that of the HOMO.

The cut of the LUMO in $[AN–Cu_9(100)]^{-1}$ is given in Fig. 8. The plane of the cut is the same as that of the Laplacian in Fig. 4. Focus on region between C(1) and Cu(8). It is clear that the map of the LUMO resembles that determined by positive values of the Laplacian conspicuously.

The fundamental question related to the essential origin of the electron distribution in the AN–Cu_9 systems is not yet resolved.

Discussion

Most results related to the characterizations of the interfacial interactions are strongly dependent on the molecular geometries used. The first aspect is that considerable effects of the increase of the cluster size and the choice of metal surface on the molecular properties are well known. The second aspect is that methods chosen to generate the optimized geometries need to be computationally efficient with respect to the number of atoms involved in such calculations. The third aspect is that a satisfactory basis set is required, providing that the structure is qualitatively correct. In contrast to the Cu$_9$ cluster, the problems associated with the clusters having the open-shell characters are well known. The strong dependence of degenerate open-shell atomic energies on the occupancy of the atomic orbitals within DFT is associated with the different densities of the degenerate atomic orbitals. The degenerate atomic orbitals can be populated in different ways. It is difficult to reproduce the exact degeneracy of these states within the average thermo chemical accuracy (2 kcal mol^{-1}) by using approximate exchange-correlation functionals that depend on density gradient (61). There are recommendations that the local spin-density (LSD) approximation, in combination with some improved optimization algorithms (62, 63), is capable of generating reliable adsorption structures of adsorbates (64, 65).

The questions that have been previously addressed regarding the nature of the organic—metal-bonded interactions can be summarized as follows (17, 66–68). Where is the energetically preferable adsorption site for a molecule on different metal surfaces? How are the structures for a molecule at different adsorption sites on different metal surfaces? What are the different contributions to the bond between interaction sites? What are the differences for the adsorption of a molecule to different metal surfaces? The extraction of orbitals important in the bonding to the metal surfaces has been the key objective, but simplified structures have been needed for the construction of the orbitals. The simplified structures

sometimes had all atoms except those in the top layer removed (66). There are two reasons for these implications. First, the energetic requirements are based on the arbitrary partition of the molecular interaction energy. Second, the descriptions of bonded interactions are sought in orbitals. The physics underlying these results is not clear for two primary reasons. In a pure physical sense, the general trend contradictory to the investigations is to have the clusters of larger sizes involved in calculations to mimic the density of states of the actual surface. If the analysis of tracing bond paths between the atoms in the AN–Cu$_9$ systems is carried out in a greater detail, it is possible to intuitively predict the directions of "hypothetical" bond paths linking the atoms of the organic molecule to those of a "hypothetical" cluster possessing a size that is larger or smaller than the actual one. In other words, the existence of possible bond paths is physically independent of increasing or decreasing the cluster size. This is the essence of the understanding that the bond path is a universal indicator of bonded interactions, as noted by Bader in 1990 when his AIM theory was released (29).

The question raised at the very end of the previous section is fundamentally profound. Possible DFT analyses of the density of states and band structures would probably indicate that the origin of the electron distribution in this system is more complicated than that based solely on classical interpretations. The first quantitative measurement of the 2D band structure at a self-assembling interface between a thiolate and a silver surface by use of two-photon photoemission may be an appropriate guidance for some future work (69). Experimental and theoretical investigations converging to the same answer are worth being pursued.

Summary

The electron distribution around the nuclei and the nature of bonded interactions at the AN–Cu$_9$ interfaces need to be investigated by combining different quantum mechanical methods. The QM methods include ab initio electron corre-

lation effects and lead toward the invariant descriptions of the interfacial interactions.

The success of frontier molecular orbital theory to rationalize the organic–metal charge migration process may depend on whether the spatial extents of the HOMO and LUMO support the corresponding topological features of the total electron density, which determines the reactivity.

The essential origin of the electron transfer in the AN–Cu_9 system is not yet described.

The message of this study is best described by C.A. Coulson, "In a profound sense the description of the bonds in a molecule is simply the description of the distribution of electrons around the nuclei", as quoted from p. 2 of ref. 34.

Photo aldol reactions with 5-methoxyoxazoles: Highly regio- and diastereoselective synthesis of α-amino β-hydroxy carboxylic acid derivatives

Axel G. Griesbeck and Samir Bondock

Abstract: A versatile route to derivatives of α-amino β-hydroxy carboxylic acids, either with tertiary (from a corresponding glycine equivalent) or a quaternary α-carbon center is described. The key reaction is the cycloaddition of electronically excited carbonyl compounds (aromatic and aliphatic aldehydes, respectively) to oxazoles. To make the products hydrolytically more labile, a methoxy substituent at position C-5 was introduced leading to the formation of cycloadducts with an orthoester substructure. The photocycloaddition, either with triplet excited (aromatic) carbonyls or with singlet excited (aliphatic) carbonyls, led to the formation of mixtures of *endo*- and *exo*-diastereoisomers with moderate to very high *exo*-selectivities. The 4-unsubstituted 5-methoxyoxazole **1** (glycine equivalent) gave the [2 + 2]-adducts **3a**–**3f** with aldehydes **2a**–**2f** in high yields and excellent diastereoselectivities. Hydrolysis of these compounds resulted in the α-amino β-hydroxy esters **4a**–**4f** with preferred *erythro* (*S**,*S**) configuration. As an extension of this process, 4-alkylated 5-methoxyoxazoles **5a**–**5f** were applied as alkene components and the corresponding cycloadducts with benzaldehyde **6a**–**6f** were obtained. Again, the *exo*-diastereoisomers were formed as the major products in diastereoselectivities from 73:27 (*exo:endo*) up to >95:5. Hydrolysis of these adducts resulted in the formation of α-amino β-hydroxy esters **7a**–**7f** with *like* (*S**,*S**) configuration of the major diastereoisomers.

Key words: photo aldol reaction, oxazoles, oxetanes, photocycloaddition, amino acids, hydroxy acids.

Résumé : On décrit une voie versatile pour obtenir des acides α-amino-β-hydroxycarboxyliques portant des centres α-carbonés tertiaire (à partir de la glycine équivalente correspondante) ou quaternaire. La réaction clé est une cycloaddition de composés carbonylés électroniquement excités (aldéhydes aromatiques et aliphatiques respectivement) à des oxazoles. Afin de que les produits soient plus facilement hydrolysables, on a introduit un substituant méthoxyle en position C-5 afin d'obtenir des cycloadduits comportant une structure orthoester. La photocycloaddition, avec des carbonyles (aromatiques) excités à l'état triplet ou avec des carbonyles (aliphatiques) excités à l'état singulet, conduit à la formation de mélanges de diastéréomères *endo*- et *exo*- dans lesquels la sélectivité en faveur de l'*exo*- est de modérée à très élevée. La réaction du 5-méthoxyoxazole non substitué en position 4 (**1**) (équivalent de la glycine) avec les aldéhydes **2a**–**2f** donne les adduits [2 + 2] **3a**–**3f** avec des rendements élevés et d'excellentes diastéréosélectivités. L'hydrolyse de ces composés conduit aux α-amino-β-hydroxyesters **4a**–**4f** avec la configuration *érythro* (*S**,*S**) préférée. Comme extension de ce procédé, on a utilisé les 5-méthoxyoxazoles alkylées en position 4 (**5a**–**5f**) comme composants alcéniques et, par réaction avec les benzaldéhyde, on a obtenu les cycloadduits correspondants **6a**–**6f**. Une fois de plus, les diastéréoisomères se forment comme produits majeurs, avec des diastéréosélectivités allant de 73:27 (*exo:endo*) jusqu'à >95:5. L'hydrolyse de ces produits conduit à la formation des α-amino-β-hydroxyesters **7a**–**7f** dans lesquels les diastéomères de configuration apparentée à (*S**,*S**) sont prépondérants.

Mots clés : réaction photoaldolique, oxazoles, oxétanes, photocycloaddition, acides aminés, hydroxyacides.

[Traduit par la Rédaction]

Introduction

The photochemical aldol addition route has been developed by Schreiber (1) as a powerful photochemical tool for the synthesis of β-hydroxy carbonyl compounds. This concept is surprising because electronic excitation leads, in most cases, to an *umpolung* effect, i.e., the regioselectivity of the carbonyl addition to enolate analogues is expected to be reversed. This is in fact the case for monoalkenes such as 2,3-dihydrofuran (2). The Paternò–Büchi reaction of furan and furan derivatives, however, with electronically excited aliphatic as well as aromatic aldehydes proceeds highly regioselective to give the 2,7-dioxabicyclo[3.2.0]hept-3-enes with the substituent at C-6 preferentially in the *exo*-position.

A.G. Griesbeck[1] **and S. Bondock.** University of Cologne, Institute of Organic Chemistry, Greinstr. 4, D-50939 Köln, Germany.

In these cases, the heteroaromatic dienes operate as vinylogue enolate equivalents. The *exo–endo* selectivity is unusually high (e.g., 212:1 for the benzaldehyde–furan case) for a *two-step triplet* photocycloaddition (2). Aliphatic aldehydes react with slightly lower *exo*-selectivity and a weak spin-selectivity effect (3) was determined; singlets favor the formation of the *exo*-diastereoisomer less pronounced than the corresponding triplets (4).[2] These photocycloadditions have been extensively used for synthetic applications especially because of the extraordinarily high degree of diastereocontrol (5–12). Several other five-membered aromatic heterocycles were used as alkene components in the Paternò–Büchi photocycloaddition (13–19) and recently the oxazole-based route to α-amino β-hydroxy ketones was added by us (20). As substrate, the commercially available 2,4,5-trimethyloxazole was used and excellent (*exo*-)diastereoselectivities were observed for the photocycloaddition with aldehydes. An attractive family of target compounds, which might be available by this route, consists of derivatives of α-amino β-hydroxy carboxylic acids (21–26), either with tertiary (from a corresponding glycine equivalent) or quaternary α-carbon centers (Fig. 1).

Results and discussion

To investigate this concept, we first applied the 4-unsubstituted 5-methoxyoxazole **1** (27) as a diene and as the glycine equivalent in the photocycloaddition with aldehydes **2a**–**2f**. In all cases only one regioisomeric bicyclic oxetane (**3a**–**3f**) was detected in the crude photolysis mixture and, in most cases, only one diastereoisomer (Scheme 1). From the comparison with the results from the trimethyloxazole experiment (20) and NMR comparison with the hydrolysis products, the *exo*-configuration of the cycloadducts could be determined. Especially, the strong ring-current-induced upfield shift for the phenylated product **3a** is indicative of the *exo*-configuration of the aryl substituent; for **3a**: ^{1}H NMR (H-1) δ: 4.58 ppm; for **3d**: ^{1}H NMR (H-1) δ: 5.04 ppm. The ring-current effects detected for the phenylated compound **3a** were analogous in size to effects detected in β-lactams which resulted from the Yang cyclization of amino-acid-derived chiral butyrophenone derivatives (28). The primary photoproducts (**3a**–**3f**) were hydrolytically unstable and underwent twofold ring opening to give the β-hydroxy amino acid esters **4a**–**4f** (Table 1). In most cases, the diastereoisomeric ratio (d.r.) of the ring-opened products matched the d.r. of the oxetane precursors.

The relative configuration of the methyl esters of phenylserine (**4a**) (29) and β-hydroxyleucine (**4e**) (30) were already elucidated in the literature and by comparison with our data, the *erythro* (*S**,*S**) configuration for the major diastereoisomers of **4a**–**4f** was established, e.g., for the β-hydroxyleucine derivative **4e**: ^{13}C NMR for the β-carbon δ: 77.2 ppm for *R**,*S** (29); 69.8 ppm for the major diastereoisomer (*S**,*S**) obtained via the photo aldol route.

Subsequently, we investigated a series of 5-methoxy oxazoles (**5a**–**5f**) as substrates with an additional substituent at C-4. These substrates were easily available from the amino acids alanine, α-amino butyric acid, valine, norvaline,

Fig. 1. The aldol and photo aldol route to β-hydroxy carbonyl compounds.
leucine, and isoleucine (31–33). The photocycloadditions of **5a**–**5f** with benzaldehyde were performed using equimolar amounts of the substrates in benzene. The primary photoadducts (**6a**–**6f**) were formed with excellent diastereoselectivities except for additions to oxazole substrates with bulky substituents R[2]. Again, the strong ring-current-induced upfield shifts for the phenylated products were indicative of the *exo*-configuration of the aryl substituent. Because of the less-pronounced diastereoselectivities of the benzaldehyde additions in these cases, both *endo-* and *exo*-isomers could be compared. The isopropyl-substituted oxazole **5d** gave in 80% yield a mixture of diastereoisomers (regioisomeric purity >98% in all cases) (**6d**). The ^{1}H NMR chemical shifts of the methyl groups for *i*-Pr in *exo*-**6d** were 0.52 and 0.73 ppm, and in *endo*-**6d** were 0.93 and 0.98 ppm, again analogous to effects detected for photochemically synthesized β-lactams (28).

Upon chromatography, most of the products were hydrolyzed to give the (*S**,*S**) α-acylamino β-hydroxy carboxylic acid esters **7a**–**7f** (Scheme 2, Table 2). The relative configuration of the oxetanes (**6**) was confirmed by NMR spectroscopy and spectral comparison with representative literature-known products (*anti*-**7**) (34–37).

Whereas the high *exo*-selectivity of the photocycloaddition of electronically excited aldehydes to the C4-unsubstituted oxazole **1** is analogous to the furan case, the high diastereoselectivity for the trisubstituted oxazoles **5a**–**5f** deserves a comment. In the triplet photocycloaddition to cycloalkenes (38), ring alkylation leads to a *decrease* in selectivity and, in some cases, to selectivity inversion because of interference with the spin-orbit-coupling geometries (39). This is obviously not the case for the oxazoles **5a**–**5f** which indicates that the secondary orbital interaction model originally applied for the benzaldehyde–furan reaction is operating (2). Figure 2 shows the triplet 1,4-biradical conformers **A**–**C** with reactive spin-orbit-coupling geometries (40). If most of the spin inversion process is directed through the channel **C**, high *exo*-selectivity is expected. The *endo*-contribution from **A** becomes only relevant for bulky groups R[2] (as for **5d**–**5f**).

An alternative interpretation, proposed by Abe, for the high *exo*-selectivities observed in triplet photocycloadditions

---

of aldehydes to heterocyclic dienes was recently proposed by Abe.[3] It is also based on the comparison of the intermediate 1,4-triplet biradical conformers as depicted in Fig. 2, however, with emphasis on the additional anomeric stabilization in structure **C** and **B** that is not present in **A** (no lone pair at oxygen antiperiplanar to the ring oxygen). This small difference in energy is sufficient to explain the high *exo*-selectivities and the cleavage competition as expressed in the quantum yields (3).

Conclusions

In summary, an efficient stereoselective photochemical protocol for the synthesis of α-amino β-hydroxy carboxylic acid derivatives was developed. The major advantage of these light-induced reactions in comparison with classical thermal aldol processes is the high diastereocontrol in the (triplet as well as singlet) photocycloaddition. As a plausible explanation for the high *exo*-selectivity, secondary orbital effects are postulated at the stage of the ISC (intersystem crossing)-active triplet-1,4-biradical conformers. The adducts of the Paternò–Büchi reactions were hydrolytically unstable and ring-opened to give α-*N*-acylamino β-hydroxy carboxylic acid methyl esters. As major diastereoisomers, the *erythro*-products with tertiary α-carbon centers and the *like* (*S**,*S**) products with quaternary α-carbon centers were formed.

Experimental

General remarks

All reactions were carried out in oven-dried glassware (100°C). All solvents were dried before use. Ether was distilled from sodium–benzophenone, chloroform, and dichloromethane from calcium hydride. Aldehydes were purchased from Aldrich and were distilled before use. Mixtures of ethyl acetate and *n*-hexane were used as eluents. TLC: commercially precoated polygram© SIL-G/UV 254 plates (Macherey–Nagel). Spots were detected with UV light in an iodine chamber. ^{1}H NMR: Bruker AC 300 (300 MHz). ^{13}C NMR: Bruker AC 300 (75.5 MHz), carbon multiplicities were determined by DEPT. UV–vis: Hitachi U-3200. Mass spectroscopy (EI or CI): Finnigan Incos 500; m/z (rel. %). HR-MS (FAB): Finnigan MAT H-SQ 30. Preparative TLC: silica gel (2–25 µm) on TLC plates (Fluka) (layer thickness 0.25 mm, medium pour diameter 60 Å, 20 × 20 on glass plates). All melting points were determined with a Büchi melting point apparatus (type Nr. 535) and are uncorrected. Combustion analyses: Elementar Vario EL. Rayonet® chamber photoreactors RPR-208 (8 × 3000 Å lamps, ca. 800 W, λ = 300 ± 10 nm) were used for irradiation.

Synthesis of 5-methoxyoxazoles

General procedure

N-Acetyl-L-amino acid methyl ester (0.1 mol) was dissolved in 20 mL of chloroform in a 250 mL flask; 20.8 g (0.1 mol) of phosphorous pentachloride were added and the flask was fitted with a calcium chloride tube. The solution was gently warmed by means of a water bath (ca. 60°C) with stirring until the HCl gas evolution ceased and the solution became an intense yellow. Then, the flask was cooled by an ice–salt bath and 50 mL of absolute ether were added. To the cooled mixture, 20% aq KOH was added dropwise with vigorous stirring until neutralization. The mixture was stirred at room temperature for 30 min. The organic layer was subsequently separated and the aqueous layer was extracted with 2 × 200 mL of ether. The combined organic extracts were washed with water and brine and dried over anhyd MgSO$_4$. After removal of the solvents under vacuum, the remaining oil was distilled by a Büchi Kugelrohr apparatus to give the product.

Photolyses of 5-methoxyoxazoles with aldehydes

General procedure

A mixture of the 5-methoxyoxazole (5 mmol) and the aldehyde (5 mmol) was dissolved in 50 mL benzene, the solution transferred to a vacuum jacket quartz tube, and degassed with a steady stream of N$_2$ gas. The reaction mixture was irradiated at 10°C in a Rayonet photoreactor (RPR-208, λ = 300 ± 10 nm) for 24 h. The solvent was evaporated (40°C, 20 torr (1 torr = 133.322 Pa)) and the residue was purified by preparative thick layer chromatography (EA = ethyl acetate, H = hexane).

exo-5-*Methoxy-3-methyl-7-phenyl-4,6-dioxa-2-aza-bicyclo[3.2.0]heptene-2-ene* (exo-3a)

A solution of benzaldehyde (0.53 g, 5 mmol) and 2-methyl-5-methoxyoxazole (0.57 g, 5 mmol) in 50 mL of benzene was irradiated for 24 h according to the general procedure. The crude product was purified by preparative thick layer chromatography (EA:H = 1:4) to give 0.55 g (65%) of the oxetane as a colorless oil. R_f = 0.43 (EA:H = 1:4). IR (film) (cm^{-1}): 2987 (C-H), 1635 (C=N), 1600 (Ph), 1440 (CH), 1012 (C-O). ^{1}H NMR (300 MHz, CDCl$_3$) δ: 2.11 (s, 3H, CH$_3$), 3.79 (s, 3H, OCH$_3$), 4.58 (d, *J* = 7.7 Hz, 1H, 1-H), 5.68 (d, *J* = 7.7 Hz, 1H, 7-H), 7.26–7.31 (m, 5H, H$_{arom}$). ^{13}C NMR (75.5 MHz, CDCl$_3$) δ: 15.9 (q), 52.8 (q), 76.2 (d, C-1), 83.0 (d, C-7), 122.9 (s, C-5), 125.4 (d), 126.2 (d), 128.1 (d), 134.3 (s), 167.7 (s, C-3). HR-MS calcd. (C$_{12}$H$_{13}$NO$_3$): 219.0892; found: 219.0886.

exo-5-*Methoxy-1,3-dimethyl-7-phenyl-4,6-dioxa-2-aza-bicyclo[3.2.0]heptene-2-ene* (exo-6a)

A solution of benzaldehyde (0.53 g, 5 mmol) and 2,4-dimethyl-5-methoxyoxazole (0.64 g, 5 mmol) in 50 mL benzene was irradiated for 24 h according to the above general procedure. The crude product was purified by preparative thick layer chromatography (EA:H = 1:4) to give 0.59 g (72%) of the oxetane as a colorless oil. R_f = 0.51 (EA:H = 1:4). IR (film) (cm^{-1}): 2987, 2894 (C-H), 1615 (C=N), 1605 (Ph), 1445 (CH), 1008 (C-O). ^{1}H NMR (300 MHz, CDCl$_3$) δ: 0.79 (s, 3H, CH$_3$), 1.99 (s, 3H, CH$_3$), 3.52 (s, 3H, OCH$_3$), 5.19 (s, 1H, 7-H), 7.21–7.25 (m, 5H, H$_{arom}$). ^{13}C NMR (75.5 MHz, CDCl$_3$) δ: 13.4 (q), 14.8 (q), 51.2 (q), 75.8 (s, C-1), 89.3 (d, C-7), 124.9 (s, C-5), 125.7 (d), 128.2 (d), 129.1 (d), 136.3 (s), 164.9 (s, C-3). HR-MS calcd. (C$_{13}$H$_{15}$NO$_3$): 233.0762; found: 233.0758.

Synthesis of *erythro* (2S*,3S*)-α-acetamido-β-hydroxy esters

General procedure

To a solution of bicyclic oxetanes (2 mmol) in 20 mL methylene chloride, 0.5 mL of concd HCl was added. The mixture was stirred in an open flask at room temperature for 2 h and the reaction was controlled by TLC. The reaction mixture was quenched by being poured into water and extracted with methylene chloride (3 × 20 mL). The organic layer was washed with 5% NaHCO$_3$ and brine and dried over anhyd MgSO$_4$. The solvent was removed in vacuo and the residual oil was purified by preparative thick layer chromatography.

Methyl (2S*,3S*) 2-(N-acetylamino)-3-hydroxy-3-phenyl-propionate (erythro-4a)

According to the above general procedure, bicyclic oxetane **3a** (0.44 g, 2 mmol) was cleaved hydrolytically in 3 h. Preparative chromatography yielded 0.33 g (70%) of the product as a colorless oil. $R_f = 0.34$ (EA:H = 1:4). IR (film) (cm^{-1}): 3500 (OH), 3370 (NH), 2983, 2894 (C-H), 1725 (COO), 1675 (CON), 1605 (Ph), 1445 (CH), 1018 (C-O). ^{1}H NMR (300 MHz, CDCl$_3$) δ: 2.07 (s, 3H, CH$_3$CO), 3.97 (s, 3H, OCH$_3$), 4.45 (d, $J = 9.7$ Hz, 1H, CHN), 5.85 (d, $J = 9.7$ Hz, 1H, CHOH), 6.37 (bs, 1H, NH), 7.28–7.35 (m, 5H, H$_{arom}$). ^{13}C NMR (75.5 MHz, CDCl$_3$) δ: 23.7 (q), 52.4 (q), 75.4 (d, C-2), 81.6 (d, C-3), 126.2 (s, C-5), 128.9 (d), 129.6 (d), 134.3 (s), 169.3 (s, CON), 170.3 (s, COO). Anal. calcd. (C$_{12}$H$_{15}$NO$_4$): C 60.75, H 6.37, N 5.90; found: C 60.65, H 6.42, N 5.85.

Methyl (2S*,3S*) 2-(N-acetylamino)-3-hydroxy-3-phenyl-propionate (erythro-7a)

According to the above general procedure, bicyclic oxetane **6a** (0.47 g, 2 mmol) was cleaved hydrolytically in 4 h. Preparative chromatography yielded 0.32 g (65%) of the product as a colorless oil. $R_f = 0.33$ (EA:H = 1:4). MS (EI, 70 eV) m/z (%): 249 (M$^+$ – H$_2$, 4), 236 (M$^+$ – Me, 8), 202 (8), 192 (M$^+$ – CO$_2$Me, 15), 191 (78), 160 (10), 131 (100), 105 (50), 91 (20), 77 (30), 51 (10). IR (film) (cm^{-1}): 3500 (OH), 3320 (NH), 2988 (C-H), 1720 (COO), 1680 (CON), 1580 (Ph), 1440 (CH), 1025 (C-O). ^{1}H NMR (300 MHz, CDCl$_3$) δ: 1.23 (s, 3H, CH$_3$), 2.12 (s, 3H, CH$_3$CO), 3.79 (s, 3H, OCH$_3$), 4.06 (s, 1H, CHOH), 7.28–7.35 (m, 5H, H$_{arom}$). ^{13}C NMR (75.5 MHz, CDCl$_3$) δ: 13.5 (q), 21.4 (q), 21.4 (q), 23.4 (q), 47.7 (s, C-2), 49.1 (d, C-3), 52.9 (q), 127.6 (s, C-5), 128.4 (d), 129.6 (d), 133.5 (s), 169.9 (s, CON), 179.4 (s, COO). HR-MS calcd. (C$_{13}$H$_{17}$NO$_4$): 251.1254; found: 251.1249.

TiO$_2$-photocatalyzed reactions of some benzylic donors

Laura Cermenati, Maurizio Fagnoni, and Angelo Albini

Abstract: TiO$_2$-photocatalyzed oxidation of toluene (**1a**), benzyltrimethylsilane (**1b**), and 4-methoxybenzyltrimethylsilane (**1c**) has been carried out in acetonitrile under oxygen, under nitrogen, and in the presence of electrophilic alkenes under various conditions (using Ag$_2$SO$_4$ as electron acceptor, adding 2.5% H$_2$O, changing solvent to CH$_2$Cl$_2$). Benzyl radicals, formed via electron transfer and fragmentation, are trapped. A good material balance is often obtained. The overall efficiency of the process depends on the donor E_{ox}, on the rate of fragmentation of the radical cation, and on the acceptor present (Ag$^+$ is an efficient oxidant, an electrophilic alkene a poor one, O$_2$ is intermediate). With ring-unsubstituted benzyl derivatives **1a** and **1b**, oxidative fragmentation occurs mainly close to the catalyst surface. The benzyl radicals form at a high local concentration and give benzaldehyde under O$_2$, bibenzyl under N$_2$ and dibenzylated derivatives by attack on the alkenes (acrylonitrile, fumaronitrile, maleic acid). In this case, using CH$_2$Cl$_2$–O$_2$ enhances the yield of benzaldehyde. With methoxylated **1c**, however, the radical cation migrates into the solution before fragmentation and, therefore, the free benzyl radical is formed. This radical in part is oxidized to the cation, giving a considerable amount of benzylacetamide (or of the alcohol with water), and in part is trapped by the alkenes. The last reaction is less efficient in this case and yields monobenzyl derivatives.

Key words: photocatalysis, oxidation, alkylation.

Résumé : On a effectué l'oxydation photocatalysée du toluène (**1a**), du benzyltriméthylsilane (**1b**) et du 4-méthoxy-benzyltriméthylsilane (**1c**) par le TiO$_2$ dans l'acétonitrile, sous atmosphère d'azote ou d'oxygène, et en présence d'alcènes électrophiles et sous diverses conditions (faisant appel au Ag$_2$SO$_4$ comme accepteur d'électron, avec addition de 2,5% d'eau et en changeant le solvant pour le CH$_2$Cl$_2$). On a piégé les radicaux benzyles qui se forment par transfert d'électron et fragmentation. On a souvent obtenu une bonne balance pour les produits ayant réagi. L'efficacité globale du processus dépend du E_{ox} du donneur, de la vitesse de fragmentation du cation radical et de la présence d'un accepteur (Ag$^+$ est un oxydant efficace, un alcène électrophile est mauvais alors que O$_2$ est intermédiaire). Avec les dérivés **1a** et **1b** comportant un noyau benzyle non substitué, la fragmentation oxydante se produit relativement près de la surface du catalyseur. Les radicaux benzyles se forment à une concentration locale élevée et conduisent à la formation de benzaldéhyde en présence de O$_2$, en bibenzyle sous N$_2$ et en dérivés dibenzylés par attaque sur les alcènes (acrylonitrile, fumaronitrile, acide maléique). Dans ce cas, l'utilisation de CH$_2$Cl$_2$–O$_2$ conduit à une augmentation du rendement en benzaldéhyde. Toutefois, avec le dérivé méthoxy **1c**, le cation radical migre en solution avant la fragmentation et on observe la formation d'un radical libre. Ce radical est partiellement oxydé en cation conduisant à la formation de benzaldéhyde et à une quantité considérable de benzylacétamide (ou d'alcool avec l'eau); il est aussi piégé par les alcènes. La dernière réaction est moins efficace dans ce cas et elle conduit aux dérivés monobenzyliques.

Mots clés : photocatalyse, oxydation, alkylation.

[Traduit par la Rédaction]

Introduction

Titanium dioxide is extensively used for the photoinduced mineralization of organic contaminants in polluted water (1). Under these conditions, photoinduced charge separation is followed by hole and electron transfer to water and oxygen, respectively, and the reaction of the organic molecule mainly involves hydrogen abstraction by the thus formed hydroxyl radicals; the organic radicals then react with oxygen or the superoxide anion. The alternative possibility that the organic substrate is directly oxidized at the semiconductor surface is of interest in two respects. First, because it has been shown that, at least with reasonable donors, this mechanism participates in the TiO$_2$ photocatalytic oxidation in water (2) and second, because, particularly in nonaqueous solvents, such a path may lead to the controlled oxidation of the substrate, rather than to the complete oxidation to CO$_2$ that is the target when photocatalysis is used for the recovery of polluted

water. With reference to the second aspect, a number of positive results have been obtained. As an example, TiO_2-photocatalyzed oxygenation of cyclohexane neat or mixed with organic solvents gives useful yields of products from the intermediate oxidation, e.g., of cyclohexanone (3, 4). Substituting a different electron acceptor for oxygen, e.g., the silver cation, adds flexibility (5). In this case different radical reactions, e.g., radical dimerization, occur in nitrogen-flushed solution while controlled oxygenation takes place in the presence of oxygen. Furthermore, the acceptor can be an organic molecule, e.g., an electrophilic alkene, which functions also as a radical trap and is alkylated (6). More generally, photocatalysis in organic solvents may have some synthetic interest (7), as opposed to the destructive mineralization occurring in water.

Both controlled oxygenation and alkylation reactions have been carried out successfully with benzylic derivatives. This is not surprising because the pioneering work by Arnold has shown that these compounds are both susceptible to photo-induced single electron oxidation and prone to fragmentation at the radical cation stage (8). In particular, benzylic oxygenation and benzylic coupling in acetonitrile and in aqueous media by TiO_2–Ag^+ have been described by Baciocchi and Sebastiani and co-workers (5, 9) in several reports. We were curious to compare such a reaction with the TiO_2-photocatalyzed alkylation of alkenes (6, 10) through a systematic examination. We surmised that this comparison may give information about the mode of reaction, in particular with regard to the formation of the radicals either as solvated species or close to the semiconductor surface, a difference that is important for synthetic applications.

Therefore, we chose a small group of benzyl derivatives and compared the effect of some key experimental parameters as well as the effect of trapping by electrophilic alkenes. As described in the following, this examination indeed revealed new facets and demonstrated the versatility of the system.

Results and discussion

Photocatalysis of benzylic derivatives

Three benzylic derivatives were examined under standard conditions (0.02 M solutions in, 3.5 mg mL^{-1} Degussa TiO_2, 3 h irradiation) in tightly stoppered vessels, after flushing either with oxygen or with nitrogen. Scheme 1 shows the products formed and Table 1 reports the % conversion of starting material and the % yield (calculated on the converted substrate) of products formed.

The effects of adding silver sulfate and of a small percentage of water on the reaction in acetonitrile as well as of changing the solvent to dichloromethane are compared. For each condition, the results with the three substrates are listed in sequence. No significant reaction took place over this time when TiO_2 was omitted.

Toluene (**1a**) reacted sluggishly in oxygen-flushed acetonitrile and gave only traces of benzaldehyde **2a**. Both conversion and yield of the aldehyde increased in the presence of 2.5% water, and further some benzyl alcohol (**3a**) and phenylpropionitrile (**6a**) were formed. Adding 0.01 M Ag_2SO_4 or having both this salt and water present at the

same time did not increase the rate of conversion, but enhanced the yield of the aldehyde (35–45%), accompanied, in the latter case, by some benzyl alcohol. Carrying out the photoreaction in oxygen-flushed dichloromethane rather than in MeCN caused more extensive oxidation leading to the aldehyde (59% at a 42% conversion of **1a**), but also to a large amount of benzoic acid (**4a**, 29%).

No appreciable reaction took place in nitrogen-flushed acetonitrile (not reported), but it did in the presence of silver sulfate, where the main product was bibenzyl (**5a**, 65% for a 16% conversion) accompanied by minor amounts of aldehyde **2a** and nitrile **6a**, as well as traces of **3a** and of benzylacetamide (**7a**). No significant reaction occurred in the presence of 2.5% water in MeCN nor upon irradiation in nitrogen-flushed CH_2Cl_2 (not reported; the other substrates examined likewise did no react under these conditions).

Compared with **1a**, benzyltrimethylsilane (**1b**) was more easily photooxidized in MeCN–O_2 (25% conversion, 66% aldehyde, compare entries 2 and 1). Adding water had little effect (except for the formation of a small amount of propionitrile), while adding Ag_2SO_4 did not increase the rate of oxidation but improved selectivity for the formation of benzaldehyde (92%, entry 8). In dichloromethane the reaction was faster than in MeCN, with a similar product distribution.

Again, no reaction took place under nitrogen in MeCN, MeCN – 2.5% H_2O or CH_2Cl_2. However, **1b** was quite reactive in deoxygenated MeCN in the presence of Ag^+. The conversion was larger than under oxygen (64 rather than 25%, entry 17) and bibenzyl was the main product (70%). Also formed were small amounts of alcohol, aldehyde, and propionitrile, as well as compounds resulting, as indicated by mass spectrometry, from the benzylation of bibenzyl and the starting benzylsilane. The experiment with both water and Ag^+ gave somewhat less of bibenzyl and more of benzyl alcohol.

With 4-methoxybenzylsilane (**1c**) the rate of photooxidation in MeCN further increased (85% conversion) and the aldehyde (**2c**, 77%) was accompanied by a significant amount of the alcohol (**3c**, 6%), which increased in the presence of water (12%, entry 6). The presence of the silver salt made the reaction more selective for the aldehyde (83%, entry 9). This time, in dichloromethane the oxidation was slower than in MeCN (55% rather than 85%, entry 15) and led to both aldehyde and alcohol. Compound **1c** was reactive under nitrogen, though somewhat slower than under oxygen, provided, as with the previous donors, that Ag^+ was present; the main product was the bibenzyl derivative (**5c**, 55%), but 4-methoxybenzylacetamide (**7c**, 25%) was also important (entry 18). In the presence of both water and Ag^+, 4-methoxybenzyl alcohol (**3c**) was the main product (36%, entry 21). The solution became acidic during the irradiation and was neutralized with triethylamine before work-up. If this precaution was omitted, further benzylation reactions via the benzylic cation formed from the alcohol led to the formation of small amount of diphenylmethanes, a fact that has been previously noted (9a), but is an artifact due to the acidity developed (compare to 11). Small amounts (0.5 to 1%) of 4-methoxytoluene were detected in all the photocatalytic experiments with **1c**. The photooxidation of **1c** was tested at a somewhat large scale (0.78 g) in an immersion well appara-

tus and it gave 90% conversion (of which 91% was the aldehyde) after 8 h irradiation.

These results clearly support the role of radical cations formed by hole transfer at the surface of the semiconductor in the photooxidation of benzylic substrates (see Scheme 2), adding to previous evidence by Baciocchi and Sebastiani and co-workers (5, 9), showing that Ag⁺ can be a substitute for oxygen in the role of electron acceptor. Favorable conditions for the process are that the reagent is reasonably easily oxidized and bears a good electrofugal group that makes fragmentation of the radical cation competitive with back electron transfer to the semiconductor. Thus, a moderate donor such as toluene (E_{ox} 2.2 V vs. SCE) with a poor leaving group is slowly oxidized; in MeCN, cleavage of a proton from the toluene radical cation (**1a**⁺) is more than 100 times slower than cleavage of a trimethylsilyl cation from **1b**⁺ (12). Introduction of a silyl group in α and of a methoxy group on the ring both make the reagents better donors such as **1b** (E_{ox} 1.78 V) and **1c** (E_{ox} 1.31V) (13) and offer a good

electrofugal cation Me₃Si⁺ from the radical cation. These compounds react much faster than **1a** and give consistently a good material balance. Fragmentation is no longer the rate-limiting step. With these highly reactive radical cations, it can be appreciated that Ag⁺ is a superior oxidant to O₂ (with **1b**, an increase in the rate of reaction by a factor of 2.5 in MeCN/Ag⁺ in comparison with the experiments under oxygen).

Fragmentation leads to benzyl radicals (Scheme 2). In nitrogen-flushed solution, these mainly dimerize to bibenzyls **5a**, **5c**. A minor process is hydrogen abstraction from the solvent, which generates ·CH₂CN radicals revealed by the presence of arylpropionitriles **6a**, **6c** and is consistent with the formation of a small amount of methylanisole from **1c**. The ratio of nitrile (**6**) – bibenzyl (**5**) is larger with toluene (0.2) than with silane **1b** (<0.02 in neat MeCN, though it grows to 0.1 with 2.5% H₂O), consistently with the fast desilylation and thus the higher local concentration of radicals in the latter case.

Scheme 2.
Scheme 3.
Also with **1c** only traces of nitrile are formed, but there another reaction competes. This is oxidation of the benzyl radical to the cation (Scheme 2). This process is revealed both by addition to acetonitrile, resulting after reaction with adventitious water, in the formation of amide **7c**, and, in the presence of 2.5% water, in the formation of alcohol **3c**. As previously proposed (9), the radical is oxidized by silver cations (0.4 V in MeCN) (14). Accordingly, from **1c** the yield of amide is 25%, and with the better nucleophile H_2O the sum of the alcohol + amide is 42%, because oxidation of the 4-methoxybenzyl radical, with E_{ox} 0.23 V (15), is fast. In contrast, no amide is formed from **1b** and only traces from **1a**, since oxidation of the unsubstituted benzyl radical (E_{ox} 0.73 V) (15) is slow.

In the presence of oxygen, benzyl radicals are trapped by oxygen or the superoxide anion formed in the initial electron transfer (Scheme 2). Decomposition of the hydroperoxides or of the peroxyl radicals leads to the aldehydes (Ag^+ when present makes the decomposition faster). In the case of **1c**, the presence of the hydroperoxide was revealed by an enhancement of the yield of alcohol **3c** (by a factor of 2) upon treatment of the irradiated solution by triphenylphosphine. When this process is efficient, secondary oxidation to benzoic acids is less important. Thus the aldehyde:acid ratio grows when the SET path is favored by the electron donating characteristics of the reagent (the ratio is 4 with **1b**, 25 with **1c**) or by the use of a better acceptor, such as Ag^+, which allows better transient charge separation at the semiconductor surface (the ratio is ca. 30 for both **1b** and **1c**). Water is oxidized competitively with the aromatic substrate in the case of poorly reacting toluene and the increased yield

of aldehyde and the formation of some propionitrile (entry 4) are indicative of the participation of OH· radicals. However, competitive oxidation of water does not occur in the case of silanes **1b** and **1c**. With these compounds, the result is not affected by the presence of 2.5% water, except for the formation of more alcohol with the latter one, another indication of the increased role of the benzyl cation in this case.

Using dichloromethane in the place of acetonitrile obliterates the difference in the rate of oxidation in the series **1a**–**1c**, enhancing the rate of the first two substrates and slightly lowering the rate for the last one. This remarkable effect can again be rationalized on the basis of the electron transfer mechanism for the fragmentation. A less polar solvent increases absorption of the substrate on the surface, thus facilitating oxidation. Furthermore, superoxide anion is expected to be a stronger base in less polar CH_2Cl_2 than in MeCN (compare to 16), and assists deprotonation of the radical cation (and apparently also desilylation, since some alcohol is formed from the silanes), adding to the action of basic centres on TiO_2. This offers an alternative mechanism of reaction (path *b* in Scheme 3) for substrates for which fragmentation of the *free* radical cation is unimportant (see below).

Photocatalysis of benzylic derivatives in the presence of electrophilic alkenes

Previous work had shown that TiO_2 photocatalysis in the presence of electrophilic alkenes leads to efficient alkylation (6, 10). In that case, the alkene functions both as electron ac-

ceptor and as radical trap, and we were curious to compare the present system with Ag$^+$ as the oxidant.

As shown in Table 2 and Scheme 4, with TiO$_2$–Ag$^+$ the percentage conversion of donors **1a**–**1c** was similar to that observed in the absence of the alkene, but even a poor trap such as acrylonitrile (**8x**, 0.1 M) led to the formation of a certain amount of adduct. As an example, from **1b** 15% of the bibenzylated propionitrile **10ax** was formed at the expense of bibenzyl (dropping from 70% to 39%, entry 3). A lower amount of **10ax** (5%) was formed from **1b** with a lower trap concentration (0.02 M **8x**, entry 1) as well as from a poorer radical precursor such as toluene and 0.1 M **8x** (entry 2). However, a better trap such as fumaronitrile (**8y**) was effective at the 0.02 M concentration with both **1a** and **1b**, making the yield of bibenzylated **10ay** (28–33%, mixture of the two diastereoisomers) comparable to that of bibenzyl (30–43%, entries 4, 5). Bibenzylation was obtained in a similar yield (34%) also from **1b** and maleic acid (**8z**, entry 7).

The result was different with the methoxybenzylsilane **1c**. In this case, the yield of bibenzyl was much reduced when the alkenes **8** were present (while the yield of amide **7c**, if anything, slightly increased), but trapping by the alkene was inefficient, giving a small amount of the mono derivatives **9cy**, **9cz**, and with **8y** only traces of bisadduct **10cy** (entries 6, 8).

As compared with our previous data on the benzylation reaction in the absence of the silver salt (6), a large difference in rate and product distribution is now observed. In the absence of Ag$^+$, the reaction of **1b** with e.g., **8z** required 20 h for a 15% conversion and gave 7% bibenzyl, 80% monoadduct, and 5% bisadduct, rather than 60% conversion in 3 h and 34, 2, and 34%, respectively, of the products in the present experiment. In the presence of the alkene alone, the conversion of **1b** reached 35% after 60 h and that of **1c** 100% after 30 h; it was 10–50 times slower than in the presence of Ag$^+$ and the monoadducts were by far the major products (50–80%). No useful result was obtained from **1a**.

The difference is due to the double role of 1,2-electron-withdrawing substituted alkenes such as **8y** and **8z**. These act both as electron acceptors (**8y**, E_{red} −1.63 V vs. Ag/Ag$^+$) (17) and as radical traps. In the absence of other acceptors, the alkene radical anions build up and either directly trap the radicals or reduce the radical adducts, thus leading to the monobenzylated alkenes (path a, a', Scheme 4).

With the silver cation the two functions are separated, the inorganic cation being the main oxidant and the alkene functioning as radical trap because Ag$^+$ is a better acceptor. Under these conditions photoinduced fragmentation of the donors is much faster with **1b** and **1c**, and even with **1a** some reaction occurs, while none was observed in the absence of Ag$^+$. Furthermore, the radical anion **8**$^-$ does not

build up in this case, and the relatively stable (α-cyano or carboxyl) adduct radicals have no easy path for reduction. Thus, these couple with a benzyl radical to give the bisadduct (path *b*, Scheme 4, see below). This path requires a high concentration of benzyl radicals, a situation that applies in the vicinity of the photocatalyst surface with donors **1a**, **1b**. The nonstabilized radical cations of these substrates do not migrate and fragment (with different efficiency) close to the surface (path *a* in Scheme 3), generating a high local concentration of the radicals.

On the contrary, migration of the longer lived stabilized radical cation from **1c** precedes fragmentation; thus, the free benzyl radical is formed from the solvated radical cation (path *c* in Scheme 3). The solvated radical is in part oxidized by Ag^+ (soluble in MeCN), and thus, is not available for trapping. A part is trapped, as revealed by the strong decrease of bibenzyl in the presence of alkenes, but the radical adduct has little opportunity both for coupling with benzyl radicals (because of the low concentration in solution) and for reduction (since no reducing $8^{.-}$ builds up). Presumably higher molecular weight products are formed and the yield of isolated products (monoadducts **9** and traces of bisadducts **10**) is far from balancing the amount of radicals trapped.

Thus, trapping by alkenes gives an indication about the mode of α-cleavage, in solution or close to the surface. On the other hand, the photoinduced reaction becomes mush faster with Ag^+, but the yield of the useful process, alkylation of the electron-withrawing substituted alkene is decreased by the competing oxidation of the radical, and from the synthetic point of view the reaction in the absence of silver salts (6) is preferable.

Conclusions

The TiO_2 photocatalytic oxidation of benzylic donors gives products resulting from the trapping of benzyl radicals (benzaldehydes, bibenzyl or alkylated derivatives), sometimes with satisfactory material balance. The efficiency of the electron transfer oxidation of these substrates depends on the oxidation potential of the donor, on the presence of an electrofugal group in the α position, and on the presence of a good electron acceptor that allows exploitation of the transient charge separation on the semiconductor surface. Among these, Ag^+ is more efficient than O_2, and both of these are much better than an electrophilic alkene. On the other hand, the presence of a strong oxidant such as silver sulfate causes partial further oxidation of the radical to the cation and limits the benzylation of electrophilic alkenes since it hinders a required step, reduction of the adduct radical.

Comparing photocatalysis for the substrates **1a**–**1c** suggests that the reaction occurs via two main mechanisms. The stabilized radical cation $1c^{.+}$ is solvated and fragments in solution (path *c*, Scheme 3). The free radical formed can be trapped. Further oxidation of the radical to the cation also has an important role. The shorter lived, less stable analogues $1a^{.+}$, $1b^{.+}$ do not migrate and mainly fragment close to the surface of the catalyst (path *a*), e.g., yielding bibenzyl or bibenzylation of added electrophilic alkenes. Deprotonation of $1a^{.+}$ is slow, so that with 2.5% water the

cosolvent is competitively oxidized. This process is faster in CH_2Cl_2, probably via a $O_2^{.-}$ assisted reaction (path *b*).

Experimental

Reagents

Degussa P25 titanium dioxide was dried in a oven at 110°C for 24 h and acetonitrile was distilled over calcium hydride and stored over molecular sieves. The chemicals were commercially available or prepared through conventional procedures for the case of **1c**.

Irradiations

Irradiations were carried out on magnetically stirred solutions contained in 4.5 cm diameter serum-capped Pyrex cylindrical reactors. Suspensions (40 mL) containing the benzylic derivatives (0.02 M), the appropriate additives (see Tables 1 and 2) and 140 mg TiO_2 were used. These were sonnicated for 1 min and then stirred and flushed with either oxygen or purified nitrogen (through needles) in the dark for 20 min. The tubes were put in the centre of four 15 W phosphor-coated lamps (centre of emission, 360 nm) and irradiated for 3 h while maintaining slow gas flow and stirring. The suspension was then filtered over a 0.2 µm porosity filter under vacuum and either directly analyzed or rotary evaporated and taken up to a fixed volume.

The products were identified by comparison of their GC–MS spectra with authentic samples (compounds **9cy**, **9az**, **9cz** and diastereoisomeric **10ax**, **10ay**, **10cy**, **10az** were previously reported) (6) and quantified by GC on the basis of calibration curves using dodecane or cyclododecane as the internal standard. Gas chromatography analyses were carried out by using an HP 5890 apparatus with a 0.3 mm × 30 m capillary column with a flame ionization detector. Gas chromatography – mass spectrometry determination was performed using an HP 5970B instrument operating at a ionizing voltage of 70 eV, connected to an HP 5890 instrument equipped with the same column as above.

A larger scale irradiation was carried out with **1c** (0.78 g, 0.02 M) in a suspension of TiO_2 (0.7 g) in MeCN (200 mL) in an immersion well apparatus fitted with a Pyrex-filtered, water-cooled medium pressure mercury arc (150 W). The suspension was magnetically stirred and flushed with argon during irradiation (8*h*).

Application of time-resolved linear dichroism spectroscopy: Intensity borrowing in charge transfer complex absorption spectra

Dustin Levy and Bradley R. Arnold

Abstract: Time-resolved linear dichroism spectroscopy has been used to study the influence of solvent on the charge transfer complex formed between hexamethylbenzene and 1,2,4,5-tetracyanobenzene. It was shown that cyano-substituted solvents induce a 1500 cm^{-1} increase in the charge transfer transition energies relative to those observed in chlorinated solvents. Furthermore, the angle between the charge transfer absorption transition moments and the photochemically produced radical anion absorption transition moment, after relaxation, has been measured for this complex in several solvents. A simple model was used to correlate the angles measured using time-resolved linear dichroism spectroscopy with the extent of localized excitation mixed into the charge transfer transitions. These measurements reveal that different charge transfer transitions borrow intensity from the localized excitation to different extents. By using different excitation wavelengths, the partitioning of the borrowed intensity among the charge transfer transitions of this complex could be evaluated for the first time.

Key words: 1,2,4,5-tetracyanobenzene, hexamethylbenzene, donor–acceptor complex, photoinduced electron transfer, photoselection.

Résumé : On a fait appel à la spectroscopie de dichroïsme linéaire résolu en fonction du temps pour étudier l'influence du solvant sur le complexe de transfert de charge qui se forme entre l'hexaméthylbenzène et le 1,2,4,5-tétracyanobenzène. On a trouvé que, les solvants portant des groupes cyano induisent une augmentation de 1500 cm^{-1} dans les énergies de transition du transfert de charge par comparaison avec celles observées par les solvants chlorés. De plus, on a mesuré dans plusieurs solvants l'angle entre les moments de la transition d'absorption de transfert de charge et le moment de transition d'absorption de l'anion radical produit photochimiquement, après relaxation. On a utilisé un modèle simple pour établir une corrélation entre les angles mesurés en faisant appel à la spectroscopie de dichroïsme linéaire résolu en fonction du temps et le degré d'excitation localisée qui se mêle aux transitions de transfert de charge. Ces mesures révèlent que les diverses transitions de transfert de charge emprunte à des degrés différents de l'intensité de l'excitation localisée. En utilisant des longueurs d'onde d'excitation différentes, on a pu évaluer pour la première fois le niveau d'intensité emprunté par les diverses transitions de transfert de charge de ce complexe.

Mots clés : 1,2,4,5-tétracyanobenzène, hexaméthylbenzène, complexe donneur–accepteur, transfert d'électron photoinduit, photosélection.

Introduction

An important class of intermolecular interactions leads to the formation of charge transfer (CT) complexes. These complexes are characterized by the appearance of a weak electronic absorption that is not present in the spectrum of the isolated reaction partners. The CT complex ground state wave function is usually depicted as a mixture of the wave functions for nonbonded interactions and of the ion-pair state (1–5). Several recent spectroscopic studies have sug-

gested that this two-state model is severely oversimplified and that the contribution of localized excited states must also be considered (6–13). Our studies of the CT complexes formed between 1,2,4,5-tetracyanobenzene (TCNB) as acceptor and methylated benzene donors have shown conclusively that the two-state model is not uniformly applicable to all CT complexes (6, 7, 14). Significant intensity borrowing from the localized excitation band (LE) of the acceptor was proven in the case of several TCNB complexes (14) and has been proposed for many other types of CT complexes (15, 16).

A clarification is required on this point. It has been customary to call the transition that appears when an acceptor and donor are combined a CT transition. For many CT complexes the transition of interest will not be purely CT in nature and in some cases may not even be dominated by a CT contribution. For the sake of simplicity and continuity with the established literature it should be understood that the term CT transition, as used herein, simply identifies the new transition and is not making a statement about its character.

[1]Corresponding (e-mail: barnold@umbc.edu).

Presently, a distinction between the pure CT transition moment and the observed CT transition moment, which may include a contribution from LE states, will be made clear.

Little is known about the nature of the CT excited states or how the LE contribution influences the processes that lead to photoinduced charge separation and the formation of contact radical ion-pairs (CRIP). The effects of mixing LE and CT states on the CT emission spectrum and rate constants for return electron transfer have been studied (17). It was shown that a small contribution from the LE dominates the photophysical behavior of the resultant CRIP–exciplex. We believe that the rapid relaxation observed for several CT complexes (6–13) is also a result of the mixing of LE intensity into the CT transition. It is therefore desirable to examine ways in which the extent of LE mixing may be influenced and how LE mixing affects the photophysics of these complexes.

The decrease in the integrated absorption intensities (oscillator strengths) of the localized bands within CT complex absorption spectra has been used as a measure of the degree of intensity borrowing (14). These measurements require the CT absorption spectra to be free from the contributions of unbound acceptor and donor, which in turn requires knowledge of the association constant for complex formation. The difficulties in determining the association constants for weakly bound complexes are now well known (15, 16, 18, 19). Such analysis assumes the LE band shape remains constant within the complex when compared to the free chromophore, (14) which is not true in all solvents. Furthermore, these measurements do not allow the partitioning of the borrowed oscillator strengths among the multiple CT transitions to be determined.

Time-resolved linear dichroism (TRLD) has been used to study CT complexes in detail (6, 7). The angle between the CT absorption transition moment and the photochemically produced radical anion absorption transition moment, after relaxation, has been measured for several complexes. A simple theoretical model was developed which correlated the extent of localized excitation mixed into the CT transitions with the results of TRLD measurements. One shortcoming of the initial study (7) was that the partitioning of the LE intensity among the multiple CT bands could not be determined because of the severely overlapping CT transitions. The following report examines the influence of different solvent environments on CT absorption spectra where the borrowing of LE intensity and the partitioning of this intensity among the possible CT transitions are determined.

Experimental

Methods

The ps pump-probe apparatus used in these time-resolved linear dichroism experiments has been described in detail elsewhere (20). A Continuum PY61C Nd:YAG laser was used to produce 1064-nm pulses of ca. 35 ps in duration. The 1064-nm fundamental was doubled and subsequently tripled to produce 355-nm pulses for sample excitation. Focusing the 355-nm light into a 10-cm solution cell and isolating the stimulated Raman emission at 404 nm (H_2O) or 446 nm (cyclohexane) allowed different excitation wavelengths to be used. Continuum was generated by focusing

12 mJ of the residual 1064-nm light into a 10-cm quartz cell containing a 1:1 mixture of D_2O–H_2O. The resultant continuum pulse was spatially filtered, collimated, passed through a polarizer, and split into two beams, one of which was used as a reference beam while the other passed through the sample. The sample and reference beams were coupled into separate legs of a bifurcated fiber-optic bundle and dispersed using a 0.3 m spectrograph. Transient absorption spectra were obtained using a dual diode array and single wavelength kinetic measurements were performed using matched PMT detectors. An IBM compatible computer allowed automated control of the experiment through serial and general-purpose interface bus (GPIB) interfaces in addition to data storage and analysis.

Solutions of TCNB and hexamethylbenzene (HMB) (both approximately 1×10^{-2} M) were placed in a quartz cuvette with the appropriate solvent. Ground-state absorption spectra were recorded using a Beckman DU 640 UV–vis spectrometer. During data collection, the samples were stirred using a magnetic stirrer and 200 pulse pairs were averaged to obtain a ΔOD measurement at each delay setting. The resultant traces were fit using a simplex computer program to find the nonlinear least-squares minimum of the error between a model function and the observed data.

Materials

TCNB was purchased from Aldrich Chemical Co. and purified by passing it through silica gel twice with methylene chloride as the eluting solvent, followed by recrystallization from chloroform. HMB was purchased from Aldrich and purified by passing it through alumina with 1,2-dichloroethane as the eluting solvent followed by recrystallization from ethanol. Chloroform (CLF), methylene chloride (MCL), and 1,2-dichloroethane (DCLE) were purchased from VWR as HPLC grade and were used as received. Acetonitrile (ACN) was obtained as HPLC grade from Aldrich and was used without further purification. Butyronitrile (BCN), pentanenitrile (PCN), and octanenitrile (OCN) (all from Aldrich) were purified by fractional distillation and passed twice through activated alumina prior to use.

Results

Absorption spectra

The ground-state absorption spectra of mixtures of HMB and TCNB in CLF or OCN as solvent are shown in Fig. 1. The observed spectra demonstrate the characteristics of CT complex formation when two new absorption bands are observed upon mixing the individual acceptor and donor. The positions of the first absorption maximum observed in several solvents are included in Table 1.

Time-resolved spectroscopy

Excitation of the TCNB–HMB complex in CLF solvent with 355-nm light results in the observation of a new species that absorbs at 468 nm. This new species has been assigned previously to the TCNB radical anion produced within the laser pulse. The production and decay of the radical anion are recorded in the trace shown in Fig. 2. The excitation was linearly polarized along the laboratory Z-axis and the probe beam was linearly polarized at 54.7° with respect to the lab-

Fig. 1. Normalized absorption spectra of the HMB–TCNB CT complex in chloroform (top panel) and octanenitrile (bottom panel). Both spectra can be described using two CT bands (solid lines) and a LE band (dashed line). The resulting predicted spectrum coincides with the experimental spectrum (dark line) in all cases. The excitation wavelengths used to excite these complexes, 22 420 cm^{-1} (446 nm), 24 750 cm^{-1} (404 nm), and 28 170 cm^{-1} (355 nm) are included on the diagram (vertical dashed lines).
oratory Z-axis. In this configuration the observed trace is due to the formation and decay of the ion pair convoluted with the instrument response function and does not contain dichroic information. The currently accepted model for the dynamics of photochemically produced ion-pairs gives the ion-pair decay as a two-exponential function with a constant offset and requires five adjustable parameters. In an effort to reduce the number of adjustable parameters, the magic angle trace was analyzed as a single-exponential decay. A rapid relaxation process has been reported for this complex with a lifetime of 5 ps in ACN (10). This process is too rapid to be resolved by our apparatus and need not be included in the kinetic scheme. Least-squares analysis yielded the following parameters: $A_{MA} = 0.125$ (OD), $k_{MA} = 1.40 \times 10^9$ s^{-1} with an instrument response of 35 ps assuming a Gaussian profile. The fitted line is included in Fig. 2 and the parameters obtained are collected in Table 1.

Two additional decay traces were recorded as shown in Fig. 3. In the first trace (open squares) the probe beam was linearly polarized along the laboratory Z-axis (i.e., parallel to the excitation) and in the second (filled squares) the probe beam was polarized within the laboratory XY-plane (i.e., perpendicular to the excitation). Except for the polarization of the probe beam, all three traces (Figs. 2 and 3) were collected under identical conditions. The shapes of the traces shown in Fig. 3 are due to a composite of the ion-pair decay and the randomizing rotations of the ion-pairs in solution superimposed on the instrument response profile of the laser system. The set of dichroic traces were fit assuming a single exponential anisotropy time constant, along with two anisotropy preexponential factors, one for each trace. The param-

eters obtained from the magic angle traces are used to describe the production and decay of the ion-pair and were used as fixed parameters in the fitting of the dichroism data. For the traces shown in Fig. 3, the dichroism decay rate constant obtained was $k_{OR} = 3.37 \times 10^{10}$ s^{-1} and the pre-exponential factors were $A_{(\parallel)} = -0.038$ (OD units) for the parallel trace and $A_{(\perp)} = 0.0107$ (OD units) for the perpendicular trace.

Similar sets of traces were obtained for the 355-nm excitation of HMB–TCNB CT complexes in MCL, DCLE, OCN, PCN, BCN, and ACN. The analysis of these data followed the procedure as described above and led to the fit parameters collected in Table 1.

The effect of excitation wavelength was also studied where Raman shifting of 355-nm light was used to allow excitation at 404 nm (water) or 446 nm (cyclohexane). The magic angle trace for the 446-nm excitation of the HMB–TCNB complex in OCN solvent is shown in Fig. 4 and the set dichroic traces is shown in Fig. 5. Additional traces for HMB–TCNB in DCLE and BCN excited using these wavelengths were also measured. The fit parameters resulting from the analysis of these data are also collected in Table 1.

Discussion

Multiple absorption bands are frequently observed within CT spectra and examination of Fig. 1 shows this to be true for the HMB–TCNB complex. These bands arise when multiple states participate in CT interactions. HMB has a doubly degenerate ground state and the weak interactions associated with complex formation are unlikely to split these states significantly. On the other hand, TCNB has two low lying excited states that are separated by 5800 cm^{-1} (14). Both of these excited states can participate in CT interactions and two CT absorption bands are expected for the HMB–TCNB complex as indicated in the diagram in Fig. 6. Each band should have approximately the same oscillator strength with the second absorption band 5800 cm^{-1} higher in energy than the first. For convenience these transitions will be designated CT1 for the low-energy transition and CT2 for the high-energy transition to distinguish between them and to reflect the possibility that they may include a significant contribution from the LE.

Examination of the ground-state spectra in Fig. 1 reveals that the absorption bands are relatively broad and significant overlap of the transitions occurs. Band shape analysis was performed on the CT spectra to help identify band maxima and to allow the band overlap at the excitation wavelengths to be assessed. In this analysis two Gaussian band profiles were assumed with a set width of 2820 cm^{-1} and a constant energy difference of 5800 cm^{-1}. These values are consistent with those found for complexes between TCNB and several methyl-substituted benzene donors (14). Fig. 1 shows the HMB–TCNB CT spectra in CLF and OCN, including the predicted absorption bands. The predicted spectrum, obtained as the sum of the two CT bands along with the LE, is included in Fig. 1 and it coincides with the experimental spectrum at all wavelengths in all solvents. Excellent agreement between the experimental and expected spectra was achieved for all solvents, which justifies the use of the parameters assumed.

The solid line indicates the best fit of the observed trace using a single exponential decay convoluted with a 35 ps instrument response.

Fig. 3. Top panel: ps pump-probe transient absorption decay trace of the HMB–TCNB CT complex in chloroform excited at 355 nm and observed using 468-nm light polarized parallel (open squares) and perpendicular (filled squares) to the excitation. The solid lines indicate the best fit of the dichroic traces assuming a single-exponential anisotropy decay in addition to the parameters obtained by fitting the magic angle trace (see text (Fig. 2)). Bottom panel: plot of the orientation factor as a function of time calculated using the above dichroic traces. The solid line indicates the fit of the orientation factor based on the parameters obtained from the fit of the individual traces above. The dashed line indicates the isotropic K_i value of 0.333.

Continuum models are generally used to describe the influence of solvent on absorption spectra (15, 21, 22). One such model predicts a linear relationship between the frequency of maximum absorbance ($\bar{\nu}_{MAX}$) and the solvent parameter f, given by eq. [1] where D and n are the solvent dielectric constant and refractive index, respectively (22).

[1] $$f = \left(\frac{D-1}{D+2} - \frac{n^2-1}{n^2+2} \right)$$

A plot of ($\bar{\nu}_{MAX}$) for CT1 of the HMB–TCNB complex vs. f is shown in Fig. 7. Clearly, the chlorinated and cyano-substituted solvents fall into distinct groups where the transition energies are lower in chlorinated solvents by 1500 cm^{-1} relative to cyano-substituted solvents. Similar observations have been reported previously for chloranil (15, 23), 1,3,5-trinitrobenzene (15, 23, 24), and tetracyanoethylene (15, 25) complexes with various donors when the CT absorption maxima were compared in hydrocarbons, alcohols, and halogenated solvents. Specific solvent–solute interactions have been invoked to account for the large differences in transi-

tion energy with changing solvent, although the exact nature of the interaction is not well understood. Germane to the present discussion is that solvent can be used to significantly alter the energies of the CT transitions and the LE transitions are not affected appreciably. These solvent effects will facilitate a test of the hypothesis that the magnitude of intensity borrowing will be sensitive to the energy difference between the CT and LE excited states.

Descriptions of TRLD and the methods of analysis of dichroic data have been published (6, 7). Recall that the anisotropic nature of light absorption can be used to produce partially oriented samples of excited states by a process

Fig. 4. Picosecond pump-probe transient absorption decay trace of the HMB–TCNB CT complex in octanenitrile excited at 446 nm and observed with 468-nm light polarized at the magic angle (open squares). The solid line indicates the best fit of the observed trace using a single-exponential decay convoluted with a 45 ps instrument response.
Fig. 5. Fig. 6. Molecular orbital depiction of the CT1, CT2, and LE transitions associated with the HMB–TCNB complex.
known as photoselection (26–30). Two sets of axes systems are required in the following discussion. The first is the laboratory frame of reference in which three mutually perpendicular axes are depicted using the upper case letters X, Y, and Z. The second is the molecular frame in which mutually perpendicular axes will be depicted using the lower case letters x, y, and z. The configuration of the TRLD apparatus allows the excitation beam to be linearly polarized with the electric vectors of the photons directed along the laboratory Z-axis. When the sample absorbs these photons and the excited states produced are subsequently probed with a second beam of linearly polarized light, the measured absorbance obtained when the electric vector of the probe beam is paral-

lel (OD_Z) compared to the absorbance perpendicular (OD_Y) to the laboratory Z-axis may be different. The ratio of the parallel and perpendicular absorbance at wavelength λ, at any time, is defined as the dichroic ratio ($d_\lambda = OD_{Z(\lambda)}/OD_{Y(\lambda)}$). It is particularly convenient to describe the observed orientation in terms of orientation factors as opposed to other, perhaps better known, order parameters (29, 30). The orientation factor of the probe transition (K_i) is obtained directly from the dichroic ratio ($K_i = d_\lambda/(d_\lambda+2)$). The magnitude of K_i reflects both the degree of alignment of the sample within the laboratory frame and the angle between the ground-state absorption transition moment vector (TMV) and the probe TMV within the molecular frame. The alignment of the sample is described by the magnitude of the principal orientation factors (K_X, K_Y, K_Z) which can be predicted using photoselection theory (29, 30).

Photoselection of linear absorbers results in uniaxial orientation of excited states with the principal orientation factors: $K_Z = 0.60$ and $K_X = K_Y = 0.20$ (29, 30). In this case the unique axis of the sample, the average orientation of the ground state CT TMV within the molecular frame and the direction of the electric vector of the excitation beam will all coincide with the laboratory Z-axis. The measured value of K_i is then related to the average angle between the ground state CT TMV (and the laboratory Z-axis) and the TCNB radical anion transition moment vector after relaxation to the CRIP. Equation [2] allows the absolute value of this angle to be calculated and the values obtained are collected in Table 2.

[d]Measured angle between the ground state CT transition moment(s) and the relaxed CRIP transition moment.

$$[2] \qquad \left|\phi_i\right| = \tan^{-1}\sqrt{\frac{\left(K_Z - K_i\right)}{\left(K_i - K_Y\right)}}$$

A vector addition scheme has been described (6, 7) and is reproduced in Fig. 8, in which the pure CT transition moment (M_{CT}^2) and the contribution of the LE transition moment ($f_{LE}M_{LE}^2$) are added, resulting in the observed transition moment (M_{CTi}^2).

To see how these angles relate within the molecular frame, knowledge of the transition moment vector directions is required. According to calculations the LE TMV is directed along the long in-plane axis of TCNB. The pure CT TMV will be directed between the centers of charge density of the donor and acceptor. For centrosymmetric molecules like HMB and TCNB the centers of charge density will coincide with the centers of mass. The angle $\theta = 100 \pm 4°$, was estimated from crystallographic data and calculated structures of the CT complex (6, 7). The last TMV direction

Fig. 8. Diagram depicting the vector addition of the pure CT TMV (M_{CT}) with a contribution for the LE TMV ($f_{LE}^{0.5}M_{LE}$) to obtain the observed CT TMV (M_{CTi}). The angle θ is the angle between the pure CT TMV and the long in-plane axis of TCNB. The angle ϕ' is the angle between the observed CT TMV and the TCNB radical anion TMV which coincides with the long in-plane axis of TCNB.
needed is that of the TCNB radical anion absorption at 468 nm, which, according to calculations, also coincides with the long in-plane axis of TCNB, as shown in Fig. 8. Finally, the angle ϕ', also depicted in Fig. 8, will be the angle obtained using TRLD spectroscopy assuming that relaxation of the complex does not lead to an observable rotation. Numerical evaluation of ϕ' is possible using eq. [3].

$$[3] \qquad \sin(\phi') = \frac{M_{CT}\sin(180 - \theta - \phi')}{f_{LE}^{0.5}M_{LE}}$$

Inspection of eq. [3] reveals that the magnitude of ϕ' will depend on the ground-state geometry of the CT complex, the magnitude of LE intensity borrowed within the specific CT transition under consideration, and the geometry of the CRIP.

Consider the limiting case when intensity borrowing is negligible. The predicted angle is $\phi' = 80°$. A measured value of $|\phi| = 70°$ was reported for HMB–TCNB complexes in DCLE where intensity borrowing was known to be negligible. It was proposed that the difference between the predicted and measured angles was due to rotation of the complex as a result of a small geometry change between the ground state and the relaxed CRIP (6, 7). Assuming this to be true, the model predicts the angles before relaxation occurs but the measured angles are those observed after relaxation to the CRIP. A topochemical increment to the observed orientation must be assessed to account for the relaxation. Based on the measured rotation of several methylbenzene complexes with TCNB an average value of 7° is expected (7). Therefore, the measured angles can be compared with the predicted angles only after the topochemical increment of 7° has been added ($\phi' = |\phi| + 7°$).

Three excitation wavelengths were used in the current study (355, 404, and 446 nm). The relevant excitation energies are shown pictorially in Fig. 1 where it is observed that different fractions of CT1 and CT2 are excited using these different wavelengths. In all solvents, 446 nm excites only

CT1 and the measured angles are consistently $|\phi| = 70°$. The magnitude of the angle is comparable with the limiting case in which CT1 is pure CT in nature. The consistency of the measured angle in all solvents studied suggests that solvent does not change the ground-state geometry.

A dramatic difference between the solvent groups is observed when 355-nm light is used to excite the samples. At this wavelength CT2 is responsible for all of the absorption in chlorinated solvents and the measured angle remains $|\phi| = 70°$. Thus, it can be concluded that in chlorinated solvents CT2 is a pure CT transition. In cyano-substituted solvents 355-nm light excites both CT1 (35%) and CT2 (65%) based on the band shape analysis. In these solvents the measured angle falls to $|\phi| = 63°$. Figure 9 shows that the orientation factors for 355- and 446-nm excitation of the HMB–TCNB complex in OCN are indeed measurably different. Based on the ratios of CT1 and CT2 excited at 355 nm and assuming CT1 is pure CT, as the results of 446-nm excitation suggest, the measured angle if CT2 were excited alone would be closer to $|\phi| = 59°$.

Having already ruled out differences in ground-state geometry in these solvents, LE intensity borrowing in the CT2 transitions is the most probable explanation for the variation in the observed angles. The energy difference between the LE and CT2 transitions is less than 200 cm^{-1} in cyano-substituted solvents as compared to 1700 cm^{-1} in chlorinated solvents. The energy differences between the CT1 and LE transitions are even greater, being about 6000 and 8000 cm^{-1} in cyano-substituted and chlorinated solvents, respectively. It appears that the solvent interaction lowers the energy gap between the LE and CT transitions sufficiently to allow the two states to mix and intensity borrowing to occur.

Assuming the observed deviation in the angle is indeed the result of LE intensity borrowing, it is possible to calculate the fraction of LE that must be incorporated into CT2 in the cyano-substituted solvents to produce the observed angle. Given the measured angle of $|\phi| = 59°$, and taking into account the topochemical increment of 7°, the percentage of LE oscillator strength incorporated into CT2 can be calculated based on the geometric constraints given by the model depicted in Fig. 8. In cyano-substituted solvents the observed higher energy CT transition, CT2, is 10–20% LE in character.

Conclusions

Time-resolved linear dichroism spectroscopy has been used to study the influence of solvent on intensity borrowing in the charge transfer complex formed between hexamethylbenzene and 1,2,4,5-tetracyanobenzene. For the HMB–TCNB CT complex two CT transitions are observed. It was shown that cyano-substituted solvents induce a 1500 cm^{-1} increase in the charge transfer transition energies relative to those observed in chlorinated solvents. Furthermore, the angle between the charge transfer absorption transition moments and the photochemically produced TCNB radical anion absorption transition moment, after relaxation, has been measured for this complex in several solvents. A simple model was used to correlate the angles measured using time-resolved linear dichroism spectroscopy with the extent of localized excitation mixed into the charge transfer transi-

Fig. 9. Plot of orientation factor (K_i) as a function of time for the HMB–TCNB CT complex in octanenitrile observed at 468 nm after 355-nm excitation (filled squares) and 446-nm excitation (open squares). The solid lines indicate the best fit of the orientation factor assuming a single-exponential anisotropy decay. The dashed line indicates the isotropic K_i value of 0.333.
tion excited. These measurements reveal that the different CT transitions borrow LE intensity to different extents. It was shown that both CT transitions of the HMB–TCNB complex in chlorinated solvents are pure CT in nature. In cyano-substituted solvents, the lower energy CT transitions are pure CT in nature but the higher energy transition must include a significant contribution, as much as 20%, due to LE oscillator strength.

Substituent effects in oxime radical cations. 1. Photosensitized reactions of acetophenone oximes

H.J. Peter de Lijser, Jason S. Kim, Suzanne M. McGrorty, and Erin M. Ulloa

Abstract: A variety of *ortho-*, *meta-*, and *para-*substituted (-H, -F, -Cl, -CF₃, -CN (*meta* and *para* only), -CH₃, -OCH₃, and -NO₂) acetophenone oximes were synthesized and studied using laser flash photolysis (LFP) and steady-state photolysis experiments in acetonitrile with chloranil as the photosensitizer. In addition, semi-empirical (AM1) calculations were performed on the neutral species, the radical cations, and the corresponding iminoxyl radicals. The data was analyzed in terms of the electrochemical peak potentials of the oximes, the quenching rates of triplet chloranil (LFP), the calculated ionization potentials, and the measured conversions of the oximes in the steady-state photolysis experiments. Photolysis of the oximes in the presence of chloranil results in the formation of the chloranil radical anion, which reacts rapidly with the oxime radical cation to form the semiquinone radical and an iminoxyl radical. Evidence for the formation of the chloranil radical anion and the semiquinone radical was obtained from LFP studies. The measured quenching rates from the LFP studies represent the rates of electron transfer from the oximes to triplet chloranil. This data was correlated to various radical and polar substituent constants. The Hammett studies suggest that steric, polar, and radical effects are important for *ortho-*substituted acetophenone oximes, polar effects are important for *para-*substituted oximes, and radical stabilization is more important than polar effects for the *meta-*substituted substrates. The calculated ionization potentials of the oximes show an excellent correlation with the measured quenching rates supporting the electron transfer pathway. On the basis of calculated charge densities, we conclude that the measured substituent effects are transition state effects rather than ground state effects. At this point all of the available data suggests that the conversion of the oximes is controlled by two energetically opposing reactions, namely oxidation of the neutral oxime, which is favorable for oximes with electron-donating substituents, and deprotonation of the oxime radical cation, which is favorable for oximes with electron-withdrawing substituents. The overall result is a reaction with little selectivity as far as substituent effects are concerned.

Key words: oxime, radical cation, iminoxyl radical, electron transfer, substituent effect.

Résumé : On a synthétisé une grande variété d'oximes d'acétophénones substituées en *ortho-*, *méta-* et *para-* (-H, -F, Cl, -CF₃, -CN (uniquement en *méta-* et *para-*), -CH₃, -OCH₃ et -NO₂) qu'on a étudiées par des expériences de photolyse éclair au laser (PEL) et de photolyse à l'état stationnaire dans l'acétonitrile, en utilisant le chloranile comme photosensibilisateur. De plus, on a effectué des calculs semiempiriques (AM1) sur les espèces neutres, les cations radicaux et les radicaux iminoxyles correspondants. On a analysé les données en fonction des potentiels électrochimiques maximaux des oximes, les vitesses de désactivation du chloranile triplet (PEL), des potentiels d'ionisation calculés et des conversions mesurées des oximes dans les expériences de photolyse à l'état stationnaire. La photolyse des oximes en présence de chloranile conduit à la formation de l'anion radical du chloranile qui réagit rapidement avec le cation radical de l'oxime pour conduire à la formation du radical de la semiquinone et à un radical iminoxyle. On a obtenu des indications relatives à la formation de l'anion radical du chloranile et du radical de la semiquinone à partir des études de PEL. Les vitesses mesurées de désactivation obtenues à partir des études de PEL correspondent aux vitesses de transfert d'électron des oximes vers le chloranile triplet. On a pu établir une corrélation entre ces données et diverses constantes de radicaux et de substituants polaires. Les études de Hammett suggèrent que les effets stériques, polaires et radicalaires sont importants pour les oximes des acétophénones substituées en *ortho-*, que les effets polaires sont importants pour les oximes des acétophénones substituées en *para-* et que la stabilisation radicalaire est plus importante que les effets polaires pour les substrats substitués en *méta-*. Les potentiels d'oxydation calculés des oximes présentent une excellente corrélation avec les vitesses de désactivation mesurées ce qui supporte une voie de transfert électronique. Sur la base des densités de charge calculées, on en conclut que les effets de substituants mesurés sont des effets liés aux états de transition plutôt que des effets liés aux états fondamentaux. À ce point, toutes les données disponibles

suggèrent que la conversion des oximes est contrôlée par deux réactions énergétiquement opposées, soit l'oxydation de l'oxime neutre qui est favorable aux oximes portant des substituants électrodonneurs ou la déprotonation du cation radical de l'oxime qui est favorable aux oximes portant des substituants électroattracteurs. Le résultat global est une réaction qui, du point de vue des effets de substituants, ne présente pas beaucoup de sélectivité.

Mots clés : oxime, cation radical, radical iminoxyle, transfert d'électron, effet de substituant.

[Traduit par la Rédaction]

Introduction

Oximes and oxime ethers have found use as protection groups for carbonyl compounds (1). The regeneration of carbonyl compounds form oximes can be achieved using a variety of methods, including oxidative, reductive, and photochemical techniques (2, 3). Of specific interest to us are the photochemical techniques (3) as well as other studies focusing on the photochemical behavior of these compounds (4). Haley and Yates (3) studied the photohydrolysis of oximes and concluded that the reactive excited state was the lowest singlet state since triplet sensitization did not result in the formation of any products, with the exception of *syn–anti* isomerization. The latter observation is consistent with Padwa and Albert's (4*j*) work on the triplet-sensitized photolysis of oxime ethers. It is interesting to note, however, that the measured quantum yields in the aqueous photohydrolysis reactions were typically low and certain substituted substrates did not react at all. We recently reported on our studies involving the photosensitized regeneration of carbonyl compounds from oximes (5). Photolysis of oximes in the presence of the triplet sensitizer chloranil resulted in formation of the corresponding carbonyl compounds in reasonable to good yields. The data is most consistent with an electron transfer mechanism and we have proposed that the oxime radical cation reacts rapidly with the sensitizer (chloranil) radical anion to form the iminoxyl radical and the hydrochloranil (semiquinone) radical (Scheme 1).

An important issue that has not yet been addressed is whether the formation of the iminoxyl radicals from oximes via an electron transfer pathway is a two-step process or a concerted proton-coupled electron transfer (PCET) process (6). Both oxime radical cations and iminoxyl radicals are important intermediates in chemical and biochemical processes (7), however, despite the large amount of data available on the structure of these species (7, 8), little is known about their reactivity. A complete understanding of the mechanistic aspects of these reactions and the intermediates involved is therefore desirable.

The electronic structure of iminoxyl radicals has been proposed as that shown in Scheme 2*a* (8*c*, 8*f*).

According to this description, which is based on ESR measurements, no spin density is available on carbon. Several other mechanistic interpretations involving iminoxyl radicals have suggested the possibility of a resonance structure as shown in Scheme 2*b* (9*a*, 9*c*).

Although the formation of carbonyl compounds from oxime radical cations (Scheme 3) can be most easily explained on the basis of the resonance structure shown in

Scheme 1.
Scheme 2*b*, more detailed studies are necessary to support this hypothesis.

Structure–reactivity studies have been of great value for the exploration of mechanistic problems and the involvement of reactive intermediates (10). A number of linear free energy relationships (LFERs) for dealing with different intermediates (cations, anions, radicals) in both ground state and excited state reactions have been developed over the past decades (11). It is well established that when studying aromatic substrates, only the *meta*- and *para*-substituted compounds are considered. In general, steric effects and hydrogen bonding prohibit the true electronic nature of *ortho*-substituent effects and, therefore, are most often not considered when discussing substituent effects. A variety of specific scales for dealing with *ortho*-substituents have been developed (12). For example, Trible and Traynham (12*c*) reported a method for measuring electronic effects of *ortho*-substituents by means of NMR in DMSO solution using *ortho*-substituted phenols. This scale is known as the σ_o^- or $\Delta\delta_o$ scale. A value for *o*-NO$_2$ was not available as it did show significant hydrogen bonding even in DMSO solution, however, a value of 1.20 was reported earlier by Dietrich et al. (13). Separation of steric and electronic effects has been an active field of study, initiated by Taft (14) who proposed E_s and $E_s°$ values. Charton (15) indicated that the Taft E_s values are a linear function of the van der Waals radii and independent of electronic effects, whereas the $E_s°$ values are a function of electronic effects only without any significant contribution of steric effects. A new steric parameter (E_s^e) which was corrected for electronic effects, was introduced by Unger and Hansch (16).

Although reasonable correlations are obtained for most ionic reactions by using the traditional polar substituent constants such as σ_m, σ_p (referred to here as σ_{pol}), and σ^+, those involving radicals are often much poorer. To deal more effectively with this problem, a variety of new scales that specifically deal with free radicals (e.g., $\sigma_\alpha\cdot$ (17*a*–17*d*), σ_{rad} (17*e*, 17*f*), $\sigma_J\cdot$ (17*g*–17*j*), and $\sigma_{JJ}\cdot$ (17*l*)) were developed. Typically, dual parameter correlations are done for free radical reactions, which then reveal the relative importance of the substituent effect on the radical species (17).

The use of LFER studies in radical ion reactions is much more limited and no specific scales have been developed.

Scheme 2.
Scheme 3.
For reactions involving a radical cation species, the observed rates are most often correlated with the Brown–Okamoto σ^+ parameter (18), owing to the fact that stabilization of the positive charge is typically more important then that of the radical. The effect depends on the type of reaction studied, and both small and large effects have been reported (19). For example, Nave and Trahanovsky (19a) found a ρ-value of –2.0 for the one-electron oxidative cleavage of 2-aryl-1-phenylethanols using cerium(IV), whereas Fox and Chen (19e) found a relatively small reaction constant (ρ^+ = –0.56) for the TiO_2-photocatalyzed oxidative cleavage of olefins. Clearly, the use of a structure–reactivity study is expected to aid in the development of an understanding of complicated mechanistic problems.

Here, we report on a detailed Hammett study involving a series of *ortho*-, *meta*-, and *para*-substituted acetophenone oximes to examine the effects of substituents on the reactivity of the oxime radical cations and iminoxyl radicals. To obtain as much detailed information as possible, we have included all but one (4-*tert*-butyl) of the groups necessary for a complete assessment of the reactivity for both radical and ionic reactions, as suggested by Exner (20) and Dust and Arnold (17a), respectively.

Results and discussion

Laser flash photolysis studies of oximes

Formation of iminoxyl radicals from oximes via photosensitized reactions can potentially result from three pathways: (*i*) electron transfer followed by proton transfer; (*ii*) proton-coupled electron transfer; or (*iii*) hydrogen atom transfer. If the intermediate radical cation – radical anion pair has a long enough lifetime, it should be possible to distinguish among pathways (*i*) and (*ii*) or (*iii*) using spectroscopic methods. A nanosecond laser flash photolysis experiment would most likely not be able to differentiate between pathways (*ii*) and (*iii*). The intermediates of interest, triplet chloranil, chloranil radical anion, and semiquinone radical, were each generated separately and their spectra were recorded. The chloranil radical anion was obtained by photolysis of a chloranil–biphenyl mixture (in acetonitrile) and the semiquinone radical was obtained from photolysis of a chloranil–toluene mixture. The spectrum of triplet chloranil shows a maximum of 508 nm and a shoulder at 480 nm. The

chloranil radical anion shows a sharp absorption around 445 nm, whereas the semiquinone radical is observed at 433 nm. These spectra are consistent with those reported in the literature (21). Attempts to observe the oxime radical cation directly via photoionization (308 nm) were unsuccessful and a direct kinetic analysis (observing the rate of disappearance of the oxime radical cation) was therefore not possible.

Photolysis of an argon-purged solution containing acetophenone oxime and chloranil resulted in the formation of the chloranil triplet, which was rapidly quenched by acetophenone oxime (Fig. 1). At approximately 400 ns after the pulse, two new species were formed. We assigned these two signals to the chloranil radical anion (445 nm) and the semiquinone radical (433 nm). At longer times, the strong signal of the semiquinone radical was obvious, however, the shoulder at 445 nm indicated the presence of the chloranil radical anion. Similar spectra were obtained for a variety of other oximes, suggesting that the mode of action for the initial steps is always the same. On the basis of these results, we concluded that the initial steps involved in the chloranil-sensitized photolysis of oximes are electron transfer from the oxime to triplet chloranil to form a triplet radical ion pair, followed by deprotonation to form the iminoxyl radical and the semiquinone radical. Because of the presence of the chloranil radical anion in these spectra, we believe that neither hydrogen atom transfer nor proton-coupled electron transfer are important pathways in these reactions.

Photosensitized reactions of *ortho*-, *meta*-, and *para*-substituted acetophenone oximes

The results of the photosensitized reactions of the *ortho*-, *meta*-, and *para*-substituted acetophenone oximes are listed in Table 1. Accurate peak potentials (E_p) could not be obtained for the o-CF_3, o-Cl, and o-CH_3 derivatives. Reasonable numbers (based on electronic properties) were obtained for o-F, o-OCH_3, and o-NO_2 acetophenone oximes. A possible reason for the large positive numbers for the o-CF_3, o-Cl, and o-CH_3 derivatives is a steric effect. These three groups are unable to orient themselves in such a manner that the oxime moiety can become coplanar with the aromatic ring upon ionization. This was confirmed by semiempirical (AM1) calculations (22). The calculated dihedral angles for these three radical ions are 33.7° (CF_3), 28.9° (Cl), and 33.5° (CH_3). This is significantly larger than acetophenone oxime (7.9°) or the o-F derivative (17.3°). The exception is o-NO_2 acetophenone oxime for which the calculated dihedral angle is 70.3°. Further analysis of the structure revealed that the NO_2 group is coplanar with the aromatic ring and lined up such that one of the oxygens of the nitro group is directed towards the carbon of the oxime moiety (distance is 2.5 Å) providing some stabilization. This particular orientation results in the presence of large charge and spin densities on the oxime carbon.

The calculated ΔG_{ET} values (using the Weller equation (23)) for several of the substituted oximes are positive (endothermic) suggesting that electron transfer is not favorable. However, the results from nanosecond laser flash photolysis experiments do not agree with that conclusion. Quenching of the excited triplet state of chloranil (monitored at 510 nm) is fast ($4 \times 10^7 - 1 \times 10^{10}$ M^{-1} s^{-1}) for all *ortho*-substituted

Fig. 1. Time-resolved (ns) spectra resulting from the quenching of triplet chloranil by acetophenone oxime in argon-purged acetonitrile solution showing the spectral bands of triplet chloranil (λ_{max} = 508 nm), chloranil radical anion (shoulder at λ_{max} = 445 nm), and the semiquinone radical (λ_{max} = 433 nm). Delay times are 380, 390, 400, 425, 450, 475, and 500 ns (increasing curves).
acetophenone oximes (Table 1). A typical decay trace and quenching plot are shown in Fig. 2. The discrepancy between the ΔG_{ET} and quenching rates (k_q) can (in part) be clarified by the results of the product studies. Previously, it was suggested that the photochemistry (photohydrolysis) of oximes occurs via their singlet states as triplet sensitization did not result in the formation of products (3). Results obtained by us[2] and others (3, 4j), suggest that triplet sensitization (energy transfer) results in *syn–anti* isomerization in oximes, whereas electron transfer results in the formation of carbonyl compounds and other products[3] (5). Similar to our previous studies on the photosensitized electron transfer reactions of oximes, the major product formed in these reactions is the corresponding carbonyl compound (5). However, it is important to note that photolysis of the *o*-NO$_2$, *o*-CH$_3$, and *o*-Cl oximes also resulted in large amounts of *syn–anti* isomerization, suggesting that both electron transfer and energy transfer pathways are important in these reactions. The fact that two of these oximes had peak potentials more positive than 2.5 V and all three oxime radical cations had large dihedral angles is consistent with the idea that in order for electron transfer to take place favorably, the substituent must be able to become coplanar with the aromatic ring upon ionization.

Analysis of the laser flash photolysis (LFP) data reveals that it is consistent with substituent effects as predicted on the basis of electronic properties, i.e., oximes with electron-withdrawing groups such as -NO$_2$ and -CF$_3$ are expected to

react slower than oximes with electron-donating groups such as -OCH$_3$. To explore the behavior of these substituted oximes further, the energy required for ionization of the neutral oxime ($\Delta\Delta H_f$) was calculated for each oxime. The results are listed in Table 1 and a plot of the calculated ionization potentials against the measured k_q values (Fig. 3) reveals that there is an excellent correlation (r^2 = 0.85). It must be noted that some of the measured rates are close to the diffusion-controlled limit, however, there is no sign of these rates leveling off. One could argue that the value of *p*-OCH$_3$ is probably the closest to that limit, however, when that point is omitted the slope of the line does not change significantly, nor does the r^2 value change much. This correlation supports the idea that the diffusion-controlled limit is not reached and we are confident that the measured rate constants reflect the influence of the substituent on the initial electron transfer process. Comparison of the *ortho*- and *para*-values of $\Delta\Delta H_f$ (Table 1) is also consistent with a steric effect. The $\Delta\Delta H_f$ values for the *ortho*-substituted oximes are consistently higher than those of the *para*-substituted oximes (with the exception of the nitro-substituted oximes).

Analysis of the data for the *meta*-substituted oximes in Table 1 indicates that no correlation exists between the measured peak potentials and the quenching rates (k_q). The exact reason for this is unclear and at this point we will not discuss these observations. There is an excellent correlation between the measured k_q values and the calculated $\Delta\Delta H_f$ values. The initial (electron transfer) reaction is fast for all the *meta*-substituted oximes and the differences are clearly due to electronic effects. An energy transfer pathway is ruled out as no *syn–anti* isomerization was observed for any of these oximes. Interesting electronic effects were observed for the *m*-OCH$_3$ derivative. Analysis of the spin and charge distributions from the AM1 calculations reveals that there is an unusually large (positive) spin density and negative charge on the carbon of the oxime moiety. In addition, the dihedral angle (–33.2°) is larger than for all the other substituents, which suggests that the large peak potential (measured) is possibly due to the fact that coplanarity cannot be achieved (as was observed for certain *ortho*-substrates). The calculated C=N bond length is much shorter than in any of the other oximes, the N—O bond length is much longer, and the O—H bond length is shorter than in the other oxime radical cations. Also, the calculated charge density on the hydroxyl proton is smaller than usual and is only slightly larger than that of the hydroxyl proton in the neutral oxime. These results suggest that oxidation does not occur on the oxime moiety but rather somewhere else in the molecule. Several other conformers were examined as well, all of which displayed the same characteristics, suggesting that electronic effects rather than conformational effects cause this phenomenon.

The data obtained for the *para*-substituted oximes clearly shows that the major trends are different from those of the *ortho*- and *meta*-substituted oximes and actually reflect the true (polar) nature of the substituents much better. This is not unexpected; many radical ion reactions correlate well

Table 1. Reactivity data for *ortho*-substituted acetophenone oximes.

^{a}Peak potential measured by cyclic voltammetry.
^{b}Rate of triplet chloranil quenching.
^{c}Conversion determined by calibrated GC-FID after 20 min of photolysis except for *ortho*-substituted oximes which were subjected to 2 h photolysis.
^{d}Calculated using semiempirical (AM1) methods; the number is the difference between the calculated heats of formation of the radical cation and the neutral species.

Fig. 2. Decay of the chloranil triplet signal (at 510 nm) in the presence of acetophenone oxime (1.6×10^{-4} M). (Inset) Determination of the rate constant for quenching triplet chloranil by acetophenone oxime.

Fig. 3. Correlation between the measured quenching rates (LFP) of triplet chloranil and the calculated (AM1) ionization potentials ($\Delta\Delta H_f$) of the acetophenone oximes.
with the σ^+ parameter (18), suggesting a strong polar effect in these reactions. A reasonable correlation ($r^2 = 0.84$) is observed between the measured E_p and k_q values. Electron-donating substituents activate the molecule (i.e., less positive peak potentials are obtained relative to the unsubstituted compound) and electron-withdrawing substituents deactivate the molecule; the overall range ($\Delta\Delta G_{ET}$) spans more than 21 kcal mol^{-1}. On the basis of the measured peak potentials, calculated ΔG_{ET} values, the measured k_q values, and the

calculated $\Delta\Delta H_f$ values, we conclude that quenching of triplet chloranil proceeds predominantly via an electron transfer process to form the oxime radical cation. However, as indicated above, a competitive energy transfer pathway for the o-NO$_2$, o-CH$_3$, and o-Cl derivatives cannot be ruled out.

At this point we believe that the measured k_q values most accurately represent the substituent effect on the initial electron transfer process. As such, we have used this particular set of data to determine the influence of steric (E_s^e), polar (σ_o^-, σ_{mb}, σ_{pol}), and radical (σ_α, σ_{rad}, $\sigma_{JJ}\cdot$) effects on this initial process. Since no *ortho*-substituent constants are available for these scales, we have opted to use the data available for the *para*-substituents. The substituent constants used in this study are listed in Table 2.

Correlation of the quenching rates with the σ_o^- substituent constants for *ortho*-substituents reveals a reasonable correlation ($\rho = -1.76$, $r^2 = 0.81$; Table 3) and suggests that there is a significant polar *electronic* contribution from the *ortho*-substituents. Correlation of the data with the steric parameter E_s^e shows that steric effects are important ($\rho = +1.00$, $r^2 = 0.81$), however, a dual parameter fit using both E_s^e and σ_o^- does not improve the correlation. To determine if there was a radical stabilization effect in these reactions, the data was correlated with both σ_o^- and the (*para*) radical substituent coefficients σ_{rad}, $\sigma_{JJ}\cdot$, and $\sigma_\alpha\cdot$, however, the correlations were significantly worse when including σ_{rad} or $\sigma_{JJ}\cdot$ and only a small improvement was observed when using σ_o^- and σ_α ($\rho\cdot/\rho_o = 3.3$, $r^2 = 0.81$) suggesting that radical effects are potentially important for *ortho*-substituents. Care has to be taken to interpret this data, as no *ortho*-substituent constants are available. The fact that better correlations are observed when using the $\sigma_\alpha\cdot$ constants rather than the σ_{rad} or $\sigma_{JJ}\cdot$ constants is most likely due to the fact that the $\sigma_\alpha\cdot$ constants are derived from benzylic substrates and take into account the deviation of the half-empty orbital from the plane of the aromatic ring and the resulting decreasing spin delocalization. If this is correct, it would suggest that a resonance structure such as shown in Scheme 2*b* has a significant contribution.

Correlation of the log of the relative rate (log (k_X/k_H) for the *meta*-substituted oximes with a variety of substituent constants reveals that both polar and radical stabilizing effects are important, however, the magnitude of the radical stabilization constant is much larger (Table 3). These analyses indicate that both polar substituent constants (σ_{pol} and σ_{mb}) give similar results, whereas the results from the radical substituent constants are significantly different. The best results are obtained when using Creary's radical (σ_{rad}) substituent constants. A dual parameter correlation using σ_{pol} and σ_{rad} gives a value of 4.2 for the ratio ρ_{rad}/ρ_{pol}. Similarly, a value of 6.2 is obtained when using σ_{mb} and σ_{rad}. All of these data clearly indicate that radical effects are important in stabilizing the transition states of the electron transfer reactions of *meta*-substituted acetophenone oximes. This is consistent with the observation by Jiang and Ji (17*l*) who noted a *meta*-(radical) substituent effect in the thermal cycloaddition reactions of α,β,β-trifluorostyrenes, which was independent of a polar effect.

Correlation of the quenching rates (k_q) for the *para*-substituted oximes with the familiar polar and radical substituent constants shows that good results are obtained when using polar substituent constants (Table 3). The slope is typically

small, which is not unusual for radical ion reactions, and supports the formation of a positively charged species in the transition state. Poor correlations are observed when using the radical substituent constants. Clearly, radical stabilizing effects are not of significant importance for these derivatives. Dual parameter correlations do not significantly improve these results, however, there is some variation in the ρ_{rad}/ρ_{pol} ratios. Using σ^+ and σ_{rad} gives $\rho_{rad}/\rho_{pol} = 1.0$, whereas using σ^+ and σ_α gives $\rho_{rad}/\rho_{pol} = 3.7$.

When analyzing kinetic data of this kind it is common practice to combine the results of the *meta*- and *para*-substituents. When doing so for the data presented here (Table 4), the results emphasize the observed trends for the individual series; however, overall the correlations are worse than for the individual series. This is most likely due to the fact that different stabilizing effects are important for each series of compounds. Poor correlations are observed when using k_q and the radical substituent constants and good correlations when using polar substituent constants or a dual parameter correlation. However, as stated above, a much better insight into these reactions is obtained when using individual series rather than a mixed set.

It has been suggested that substituent effects are often ground state effects rather than an effect on the transition state of the reaction under investigation, especially when considering phenols and similar species (24). To see if this is also true for these oximes, we have calculated the spin and charge distributions in the ground state (neutral) and in the radical cation species. The calculations show that both sets of compounds are affected by the substituents. In general, the radical ion species is more susceptible to these effects, however, large effects are also seen in the calculated charge densities for the neutral ground state species with -NO$_2$ and -OCH$_3$ substituents. The calculated charge densities on the carbon of the oxime moiety of the radical ion seem to accurately reflect the substituent effects. For the *ortho*-substituted substrates, a plot of the charge density against the σ_o^- values gives an excellent correlation ($r^2 = 0.90$), whereas a plot of charge density of the neutral compound against the same σ_o^- values gives a poor correlation (Fig. 4*a*). The slopes of the two lines (0.13 vs. 0.01) are significantly different and we conclude that for the *ortho*-substrates ground state effects are less important than the effect of the substituent in the transition state of the electron transfer reaction. The calculations for the *meta*-substituted oximes show the familiar pattern of larger (more positive) charge densities on the carbon of the oxime moiety when electron-withdrawing groups are present, as can be seen from the correlation (slope = 0.08) between these calculated charge densities and the polar σ values (σ_{pol}), which is acceptable when the m-OCH$_3$ point is omitted (Fig. 4*b*). A better correlation is observed when using the ground state charge densities of the same carbon and plotting them against σ_{pol} ($r^2 = 0.91$), however, the slope (0.008) is smaller by a factor of 10. This clearly demonstrates that polar effects are more important for the radical ions of the *meta*-substituted oximes but not as much for the neutral ground state molecules. A reasonable correlation ($r^2 = 0.80$) also exists between the calculated spin densities at the carbon of the oxime moiety and the σ_{rad} constants (ignoring the m-OCH$_3$ point). The slope in this case (–0.84) is much larger than that observed for the charge density,

$\sigma_{mb} + \sigma_{\alpha\cdot}$				–0.61	+2.98	0.76

suggesting that radical effects are more important than polar effects for the *meta*-substituted acetophenone oximes. These results are in good agreement with the Hammett correlations discussed above. Similar results are obtained for the *para*-substituted oximes. The calculated charge densities follow the trends as expected for typical electron-donating and electron-withdrawing groups. Correlation of the calculated charge densities with the polar parameters σ_{pol} and σ_{mb} revealed that there is a reasonable relationship between these in the ground state ($r^2 = 0.92$ and 0.91, respectively) as well

as for the radical ions ($r^2 = 0.70$ and 0.79, respectively), however, the slopes are significantly different (Fig. 4*c*). Good correlations are also found when using the σ^+ constants. These results suggest that both ground state effects and stabilization of the transition state of the electron transfer pathways are important. Similar to the results for the *ortho*- and *meta*-substituted oximes, the ground state effects are less important than the transition state effects. This observation is consistent with O—H bond dissociation energy (BDE) data for a series of substituted benzaldehyde oximes as calculated by Bordwell and Ji (9*a*). The BDE values show little variation with different substituents (e.g., *p*-OCH_3 (87.8 kcal mol^{-1}), *p*-CN (87.8 kcal mol^{-1}, *p*-CF_3 (87.9 kcal mol^{-1})), which would be expected for compounds for which ground state effects are not important. Although it is not obvious from any of these correlations, the *p*-OCH_3 substituted oxime shows a somewhat abnormal behavior, similar to that observed for the *m*-OCH_3 derivative. The C=N bond length is significantly shorter than for most other *para*-substituted oxime radical cations and the calculated N—O bond length is much longer. These results are not as drastic as those observed for the *meta*-derivative, however, it seems to suggest that oxidation elsewhere in the molecule is competitive with oxidation of the oxime moiety. These results are supported by a plot of the log of the relative charge or spin densities against the different substituent constants. In all cases, the point for the *p*-OCH_3 derivative substantially deviates from the best-fit line.

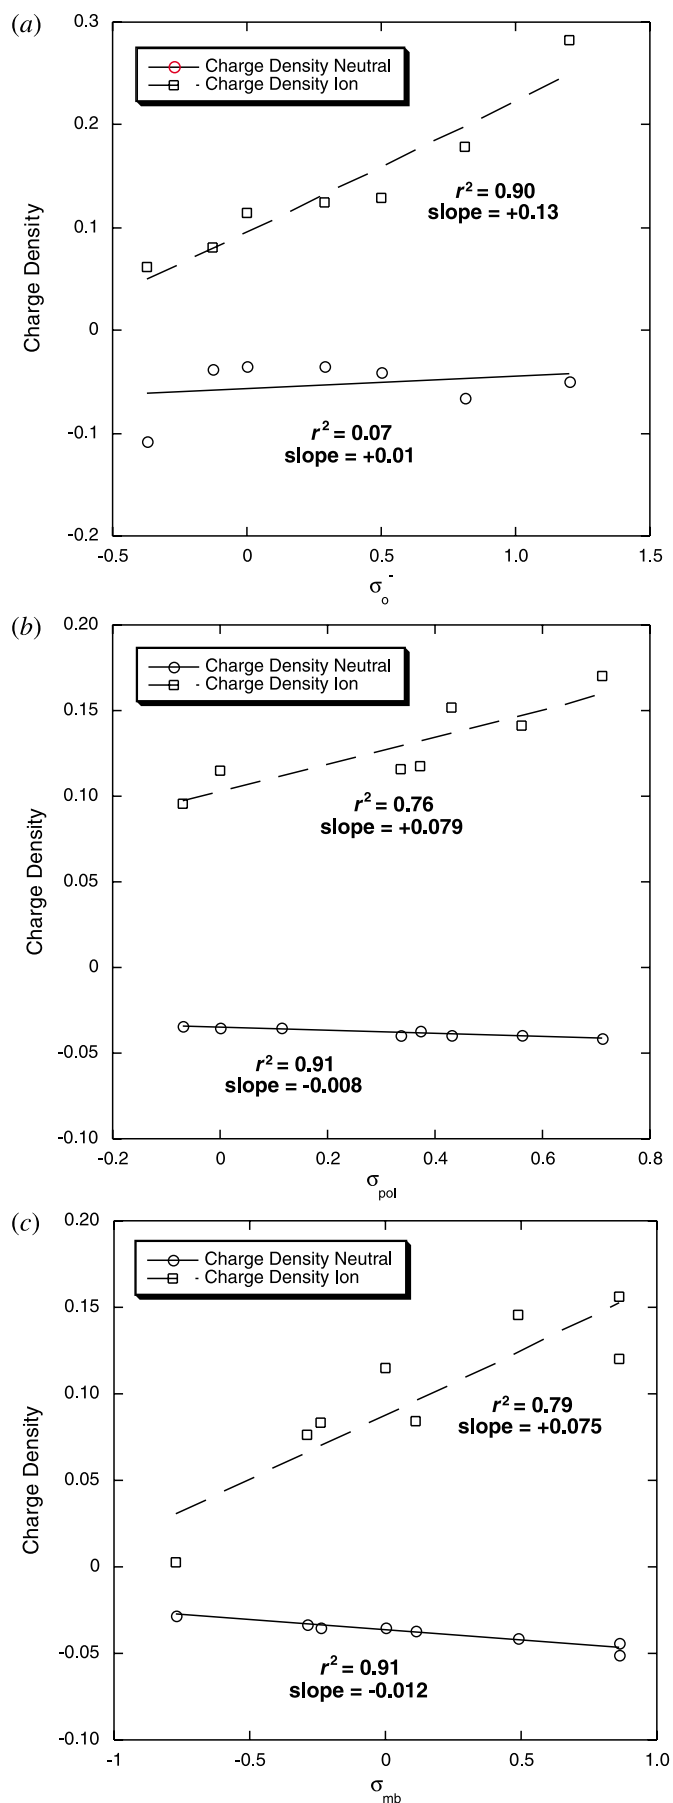
In contrast to these observations are the results from the calculations on the iminoxyl radicals. The calculated spin densities on the carbon of the oxime moiety are all quite similar and do not reflect any significant substituent effects. A large amount of (negative) spin density is present on the carbon and large amounts of positive spin density are present on both the nitrogen and the oxygen. Similar results were obtained for the *meta*- and *para*-substituted iminoxyl radicals. The fact that all of the calculated parameters for the *m*-OCH_3 derivative are similar to those of the other *meta*-substituted oximes, confirms that the unusual behavior noted before is due to electronic effects in the radical cation. Deprotonation of the *meta*-methoxyacetophenone oxime radical

Fig. 4. Correlation between (*a*) the *ortho*-substituent constant σ_o^- and the calculated (AM1) charge density on the iminoxyl carbon of the *ortho*-substituted acetophenone oximes; (*b*) the polar (*meta*) substituent constant σ_{pol} and the calculated charge density on the iminoxyl carbon of the *meta*-substituted acetophenone oximes; (*c*) the polar (*para*) substituent constant σ_{mb} and the calculated charge density on the iminoxyl carbon of the *para*-substituted acetophenone oximes.

cation leads to an iminoxyl radical with electronic properties similar to those of other iminoxyl radicals. These results indicate that: (*i*) substituent effects are not important for iminoxyl radicals; and (*ii*) a complete electronic structure of iminoxyl radicals must include both configurations as shown in Scheme 2.

Steady-state photolysis of *meta*- and *para*-substituted acetophenone oximes

Steady-state photolysis of the oximes was carried out in a Rayonet photochemical reactor. In a typical experiment, the oxime (0.015 M) and chloranil (0.005 M) were irradiated using black lights ($\lambda_{max} = 350$ nm) for 20 min to keep the conversion low. The progress of the reaction was followed by gas chromatography with flame ionization detection (GC-FID) and the conversion of the oximes was determined by calibrated GC-FID. Analysis of the data in Table 1 indicates that even at these short irradiation times significant conversion occurs. No obvious relationship among conversion and any other parameter (k_q, E_p, $\Delta\Delta H_f$, etc.) was found and correlation of the log of the relative conversion with the usual substituent parameters failed as well. These results can be explained on the basis of the proposed mechanism and additional data available in the literature. Several pieces of information are available. First, the measured quenching rates for the reactions of the substituted oximes with triplet chloranil are believed to represent the initial electron transfer reaction between these two species and the variation in the measured rate constants is due to substituent effects. As expected on the basis of electronic properties of these substituents, the presence of electron-donating groups increases the quenching rate and the presence of electron-withdrawing groups slows it down. Second, calculations have shown that (*i*) the ionization potentials correlate well with the measured rate constants (supporting the electron transfer pathway), (*ii*) the effects are not due to ground state effects, and (*iii*) the substituents have no significant effect on the spin distribution of the iminoxyl radicals. Third, Bordwell and Ji (9*a*) calculated the pK_a values of a variety of oximes, including several substituted benzaldehyde oximes and acetophenone oxime itself. For example, the calculated pK_a values of the oxidized *p*-CH$_3$, *p*-OCH$_3$, and *p*-NO$_2$ benzaldehyde oximes are –11, 0.7, and –22, respectively. Benzaldehyde oxime radical cation and acetophenone oxime radical cation both have a pK_a value of –13. These results demonstrate that electron-donating groups (-CH$_3$, -OCH$_3$) decrease the acidity, whereas electron-withdrawing groups (-NO$_2$) increase the acidity of the radical ions. Combining all this data and applying it to the working mechanism of the first steps of these reactions (electron transfer followed by deprotonation of the oxime radical cation) can explain the observed conversions. Compounds with electron-donating groups are more easily oxidized and ex-

hibit fast quenching rates, however, the resulting radical ions must overcome larger barriers for the deprotonation step. The opposite is true for oximes with electron-withdrawing substituents, which have slower quenching rates but will undergo a faster deprotonation step because the resulting radical cations are more acidic. Clearly, this is a simplified picture and many more factors are likely to be important in the overall reactions of these substrates. For example, this explanation does not yet include the follow up steps, which are likely to be important. Oxidation of the iminoxyl radical (Scheme 3) would result in the formation of a carbocation species, which would be expected to show a large substituent effect. We continue to investigate the scope and limitations of the photosensitized electron transfer reactions of oximes as well as the structure and reactivity of iminoxyl radicals.


Conclusions

This study has shown that quenching of the excited photosensitizer (chloranil) by substituted acetophenone oximes is typically fast except in those cases where there is a significant steric effect. This steric effect is only observed with the substituent in the *ortho*-position reactions and can also be noticed from the measured peak potentials. It is believed that bulky *ortho*-substituents such as -CH$_3$, -CF$_3$, -NO$_2$, and -Cl prevent the oxime moiety and aromatic ring from becoming coplanar so that conjugation is minimized. Under these conditions, energy transfer can be competitive with electron transfer as shown by significant *syn–anti* isomerization. The measured quenching rates correlate well with the calculated (AM1) ionization potentials for the radical ions, suggesting that the quenching represents an electron transfer pathway. Correlation of the quenching rates with Hammett substituent constants revealed that for the *ortho*-substituted oximes, steric (E_s^e), polar electronic (σ^-), and radical ($\sigma_\alpha \cdot$) effects are important. For *meta*-substituted oximes, both polar and radical effects dominate the quenching rates, however, the large magnitude of the radical reaction constants suggests that radical effects dominate. As expected, polar effects dominate the *para*-substituted oximes. It seems clear that to predict the influence of a substituent on the photosensitized electron transfer reactions of acetophenone oximes, the best results will be obtained by analysis of the quenching rates and when studying individual series of compounds. On the basis of the correlation between calculated (AM1) charge densities on the carbon of the oxime moiety and polar substituent constants it is concluded that ground state effects are relatively unimportant and the observed substituent effects represent transition state effects. Also of importance is the observation that the quenching rates do not correlate with the measured conversions of the oximes. This is explained in terms of two important but energetically opposing steps: oxidation and deprotonation. Whether this process consists of two individual steps (oxidation followed by deprotonation) or a single proton-coupled electron transfer step is unclear, although the LFP studies currently favor the former pathway. The latter pathway is certainly a possibility in the electrochemical experiments because of the timescale in these reactions. In the photochemical experiments it would be possible if the energetics are favorable, and on the basis of the results obtained so far, we predict that it would be more likely to occur in the case of oximes with electron-withdrawing substituents as their acidity (upon one-electron oxidation) is much larger and the deprotonation step is expected to be much faster. Future experiments will have to clarify this issue.[4]

Experimental

Materials

All chemicals other than the oximes were commercially available. Acetonitrile (Fisher) was HPLC grade and used as received. All oximes were prepared via standard procedures (25) from the corresponding ketones (Aldrich or Lancaster Synthesis, Inc.). A typical procedure consisted of combining equal amounts (~1 g) of hydroxylamine hydrochloride and the appropriate acetophenone with 5 mL of water and 3 mL of 3 M NaOH. Ethanol (95%) was used to create a clear solution, which was then refluxed for 60 min. The reaction solution was allowed to cool, and the product was extracted with diethyl ether. The solvent was evaporated and the crude product collected and purified by recrystallization or column chromatography. The purity was checked by GC-FID (> 98% peak area), GC–MS, ^{1}H NMR, FT-IR, and melting point determination.

Steady-state photolysis experiments and sample analysis

Appropriate amounts of the *ortho*-substituted acetophenone oxime (0.025 M) and chloranil (0.025 M) were weighed out and dissolved in 5 mL of acetonitrile. The studies on the *meta*- and *para*-substituted oximes utilized 0.015 M oxime and 0.005 M chloranil. The solution was placed in a Pyrex tube and photolyzed in a Rayonet RPR-100 photochemical reactor, equipped with 16 RPR-3500A (black light phosphor) bulbs ($\lambda = 350$ nm) for up to 3 h. The progress of the reactions was followed by GC-FID and the products were identified by GC–MS. Conversion of the starting material and product yields were determined by calibrated GC-FID. Sample analyses were performed on a Hewlett-Packard 5890 series II gas chromatograph coupled to a Hewlett-Packard 5971 series mass selective detector (MSD) and on a Perkin-Elmer (PE) Autosystem equipped with a flame ionization detector (FID). The HP GC–MS was equipped with an HP-5 capillary column (30 m × 0.25 mm i.d., film thickness 0.25 mm). The PE GC-FID was equipped with a Chrompack CP-Sil–5-Cb capillary column (30 m × 0.32 mm i.d, film thickness 0.25 mm).

Cyclic voltammetric measurements

Cyclic voltammetry at a sweep rate of 100 mV s^{-1} was used to obtain the oxidation potential of the oximes. All electrochemical experiments were performed using a BAS CV-50 voltammetric analyzer and a BAS C3 electrochemis-

Chemistry of photogenerated α-hydroxy-*p*-nitrobenzyl carbanions in aqueous solution: protonation vs. disproportionation

James Morrison, Peter Wan, John E.T. Corrie, and V. Ranjit N. Munasinghe

Abstract: The photochemistry of *p*-nitrobenzyl derivatives **6–10** has been studied in aqueous solution as a function of pH, using product analysis, UV–vis spectrophotometry, and laser flash photolysis (LFP). The compounds were chosen with the aim of further exploring the propensity of these systems to give rise to α-hydroxy-*p*-nitrobenzyl carbanions on photolysis, and to study their mechanisms of subsequent reaction. α-Hydroxy-substituted carbanions are anions that cannot be readily formed using thermal routes but which are believed to have some interesting chemistry. Three methods were employed for photogenerating these carbanions: (*i*) decarboxylation; (*ii*) retro-Aldol reaction; and (*iii*) carbon acid deprotonation. All three methods proved to be successful using the *p*-nitrobenzyl chromophore. Photogenerated α-hydroxy-*p*-nitrobenzyl carbanions react via disproportionation, giving rise to oxidized and reduced products; simple protonation of the anion was undetectable.

Key words: photodecarboxylation, nitrobenzyl carbanions, photoredox, nitroaromatic compounds, excited-state carbon acids.

Résumé : Opérant en solutions aqueuses en fonction du pH et faisant appel à l'analyse des produits, à la spectrophotométrie UV–vis et à la photolyse éclair au laser, on a étudié la photochimie des dérivés *p*-nitrobenzyles (**6–10**). On a choisi les composés dans le but de pouvoir explorer plus à fond la propension de ces systèmes de donner naissance à des carbanions α-hydroxy-*p*-nitrophényles par photolyse et d'étudier les mécanismes de leur réaction subséquente. Les carbanions portant un substituant α-hydroxy sont des anions qui ne peuvent pas se former facilement par les voies thermiques, mais que l'on soupçonne d'avoir des propriétés chimiques intéressantes. On a utilisé trois méthodes pour la photogénération de ces carbanions: (*i*) la décarboxylation; (*ii*) la réaction rétroaldolique et (*iii*) la déprotonation d'un acide carbonique. Ces trois méthodes ont été couronnées de succès avec le chromophore *p*-nitrobenzyle. Les carbanions α-hydroxy-*p*-nitrobenzyles photogénérés réagissent par une réaction de métathèse qui conduit à la formation de produits oxydés et de produits réduits; on n'a pas pu mettre en évidence de protonation simple de l'anion.

Mots clés : photodécarboxylation, carbanions nitrobenzyles, photorédox, composés nitroaromatiques, état excité d'acides carbonés.

[Traduit par la Rédaction]

Introduction

Carbanions are synthetically useful and fundamentally important reactive intermediates in organic chemistry (1). The reactivity of carbanions as either nucleophiles, bases, or as electron donors is well-known and substituents strongly influence their stability and reactivity. This is exemplified by the enormous range of carbon acid pK_a values (1) and these data are useful in predicting the conditions necessary to generate a carbanion and its subsequent reactivity. Substituent effects on the negatively charged intermediate may be manifested through resonance, inductive effects, or by providing a new reaction pathway. α-Hydroxy carbanions **1**, in which

an hydroxy group (an oxygen acid) is directly attached to the carbanion, are an interesting type of carbanion whose formation and stability has been the subject of theoretical interest (2, 3). However, for obvious reasons, the breadth of experimental knowledge of these carbanions is quite limited. Nonetheless, α-hydroxy carbanions have been proposed as intermediates in photochemical (4–6) and enzymatically catalyzed (7, 8) reactions.

To study "free" carbanions in solution it is advantageous to generate appreciable amounts of these intermediates quickly. A well-known route is via photochemical reaction (9), preferably one that is fast and efficient. The simplest conceivable photochemical route to a carbanion is via a heterolytic C—C or C—H bond cleavage, for example via photodecarboxylation or photodeprotonation, respectively. Nitrobenzyl compounds, with their electron-withdrawing nitro group, are particularly adept at inducing these photocleavage reactions, generally via the triplet excited state (10, 11). While it is well-known that *o*-nitrobenzyl systems are highly photoreactive (generally via initial transfer of the benzylic hydrogen to the nitro group), the *m*- and *p*-isomers also display a range of photochemical reactivity not often reported for the *o*-isomer (10, 11). Both *m*- and *p*-nitrobenzyl compounds are known to undergo a variety of photofragmentation reactions, such as photodecarboxylation (12), photodeprotonation (4), and photoretro-aldol reaction (13), all of which have been proposed to generate *m*- and *p*-nitrobenzyl carbanions as intermediates. However, prior to our studies, only the parent *p*-nitrobenzyl carbanion was observed by transient methods (vide infra).

Margerum and Petrussis (12) were the first to investigate the chemistry of photogenerated *p*-nitrobenzyl carbanion (**2**), which they prepared by photodecarboxylation of *p*-nitrophenylacetic acid (**3**) (Scheme 1). The observed chemistry of photogenerated **2**, to give *p*-nitrotoluene (simple protonation) and *p*,*p*′-dinitrobibenzyl (**4**) (disproportionation product), may be described as "conventional" *p*-nitrobenzyl carbanion chemistry since thermally generated **2** (formed by deprotonation of *p*-nitrotoluene in *tert*-butyl alcohol – KOH) has also been observed to give **4** (14–16). Carbanion **2** is strongly stabilized by the *p*-nitrophenyl ring and is thus readily observable by UV–vis spectrophotometry as well as by μs and faster laser flash photolysis (LFP) (λ_{max} 358 nm; τ = 53 s at pH 13) (12). The complex decay kinetics of carbanion **2** (mixed first- and second-order) were studied in some detail by Craig et al. (17, 18), who explained the data as arising via two competing pathways of reaction: (*i*) a simple protonation pathway to give *p*-nitrotoluene; and (*ii*) a bimolecular coupling pathway (of two molecules of **2**), followed by loss of two electrons (the final fate of which was not determined) to form **4**. Wan and Muralidharan (13) discovered a second method for generating carbanion **2**, by base-catalyzed photoretro-aldol reaction of **5**, with subsequent chemistry identical to that reported above.

The chemistry of α-hydroxy-nitrobenzyl carbanions is not as well understood. Wan and Yates (4) first proposed water and hydroxide-mediated photodeprotonation of the benzylic proton of *m*- and *p*-nitrobenzyl alcohols, to give the corresponding α-hydroxy nitrobenzyl carbanions (eq. [1]). In retrospect, the proposal of C—H bond deprotonation in the excited (triplet) state as a primary step was unusual, as there was no precedent for such a pathway at the time. In addition, reprotonation of these carbanions apparently does not occur, as shown by the absence of deuterium exchange, but instead redox chemistry was observed (4). *p*-Nitrobenzyl alcohol was found to give a simple intramolecular redox product in base (*p*-nitrosobenzaldehyde), whereas *m*-nitrobenzyl alcohol gave a mixture of *m*-nitrobenzaldehyde (60–70%) and *m*-azoxybenzaldehyde (40–30%) (in neutral, acid, and basic

Scheme 1.
solutions), via an apparent disproportionation of the photogenerated carbanion. Disproportionation chemistry has also been observed for photogenerated α-hydroxy-*p*-(*p*-nitrophenyl)benzyl carbanion in neutral solution (6). The observation of disproportionation and redox pathways is perhaps not unexpected considering that even the parent *p*-nitrobenzyl carbanion (**2**) displays this kind of reactivity. Moreover, theoretical calculations (3) have shown that simple anions (in the gas phase) such as $^-CH_2OH$ and $^-CH_2NH_2$ are unstable with respect to their radicals. This suggests that carbanions of this kind have an intrinsic propensity for disproportionation chemistry (for example, via initial electron transfer). Some of the products described above (4, 6) are consistent with this pathway.
The aim of this work is to study in more detail the chemistry of a variety of photogenerated α-hydroxy-*p*-nitrobenzyl carbanions (**1**, R′ = *p*-nitrophenyl) and related species, using product studies and LFP. For this purpose *p*-nitromandelic acid (**6**) and its *O*-acetyl derivative **7** are obvious initial substrates since it is anticipated that these compounds will undergo efficient photodecarboxylation, to give the corresponding α-hydroxy and α-acetoxy-*p*-nitrobenzyl carbanions. *p*-Nitrophenylethylene glycol (**8**) would be expected to undergo base-catalyzed photoretro-aldol reaction to give the parent α-hydroxy-*p*-nitrobenzyl carbanion in basic medium. Finally, *p*-nitrobenzhydrol (**9**), and the corresponding methyl

Scheme 2. Synthesis of **6** and **7**. Reagents and conditions: (*a*) SOCl$_2$; (*b*) Br$_2$; (*c*) Hg(OAc)$_2$, HOAc; (*d*) Cl$_3$C(NH)O-*t*-Bu, CH$_2$Cl$_2$;
(*e*) CsCO$_3$, MeOH; (*f*) TFA.
ether **10** are expected to give α-hydroxy (or methoxy) *p*-nitrobenzyl carbanions via photodeprotonation.

Results and discussion

Materials

p-Nitromandelic acid (**6**) is only sporadically reported in the literature and its synthesis, unlike that of the corresponding *o*-nitro isomer (**19**), is surprisingly difficult. In our hands the complex procedure described by Carrara et al. (20), based on formation of *p*-nitromandelonitrile and subsequent acidic hydrolysis, was not reproducible. We, therefore, adopted the route shown in Scheme 2 which yielded first the *O*-acetyl derivative **7**. Because of concerns about the stability of **6** under basic conditions and possible difficulties of isolation, we chose to prepare it via the *tert*-butyl ester **12**. Subsequent mild base treatment (CsCO$_3$ in methanol) gave the alcohol **13**, from which **6** was obtained by TFA-mediated cleavage of the *tert*-butyl group.

Glycol **8** was available from a previous study (21). *p*-Nitrobenzhydrol (**9**) and its methyl ether derivative **10** were made by standard methods (see *Experimental*).

Product studies

UV–vis spectrophotometry was used as a quick and informative tool to monitor the photochemistry of substrates **6**–**10** under various conditions and preparative photolyses were used to identify products formed. Photolysis of *p*-nitromandelic acid (**6**) as its carboxylate salt (~100% H$_2$O, pH 7, Ar purged, Rayonet photoreactor, 300 nm) in a UV cuvette resulted in formation of new (permanent) absorption bands at 289 and 308 nm (Fig. 1). No transient species was observed on this time scale. Strikingly different spectral changes that imply different photochemistry were observed upon photolysis of the *O*-acetyl derivative **7** (Fig. 2). A strong absorption band at 369 nm that was observed immediately after brief irradiation (Ar purged) decayed via complex kinetics over the course of several minutes (Fig. 3; the decay cannot be satisfactorily fitted to either first- or second-order kinetics; it is assumed to be a mixture of these components). The overall decay was slower in D$_2$O, consistent with a component of the processes involving proton (deuteron) transfer from solvent. The 369 nm absorption band was not observed using this technique upon photolysis of **7** in oxygen-saturated solution (τ < 10 s). These observations are very similar to those reported for the 358 nm absorption band of the parent *p*-nitrobenzyl carbanion (**2**) (12, 17, 18).

Therefore, the 369 nm transient is assigned to α-acetoxy-*p*-nitrobenzyl carbanion (**14**).

Preparative photolysis of **6** and **7** (1 × 10^{-3} M, 1:1 H$_2$O–CH$_3$CN, Rayonet photoreactor, 300 nm) confirmed the observations from UV–vis spectrophotometry that indicated different reaction pathways for these compounds. Low conversion runs (<30%) of **6** at pH 7 (Ar purged) followed by product isolation gave *p*-nitrobenzaldehyde (**15**) and *p*,*p*′-azoxybisbenzaldehyde (**16**) (Scheme 3). The relative yields of **15** and **16** (60–70% and 40–30%, respectively) were independent of conversion (up to ~40%), consistent with both being primary photoproducts. These are the expected disproportionation products of an α-hydroxy-*p*-nitrobenzyl carbanion intermediate, analogous to the reported products of the photochemistry of *m*-nitrobenzyl alcohol (4) and *p*-(*p*-nitrophenyl)benzyl alcohol (6). At high conversion (>50%) insoluble orange precipitates and some soluble (but unidentified) secondary photoproducts were observed. Photolysis of **6** in oxygen-saturated solution gave mostly **15** (>90%) and some minor unidentified products. At pH 13 (Ar purged), low conversion (~15%) runs gave **15** and **16** (60–70% and 40–30%, respectively, as at pH 7). Photolysis at pH 3 gave the intramolecular redox product *p*-nitrosobenzaldehyde (**17**) in addition to **15** and **16** (relative yields 28:50:22). The formation of **17** in acidic solution is reminiscent of the intramolecular photoredox chemistry reported for *p*-nitrobiphenyl systems (6). We were not able to enhance the relative yield of **17** since the photodecarboxylation quantum yield becomes negligible in solutions below pH 3, because ionization of the carboxylic acid is suppressed. For example, irradiation of **6** at pH 1 resulted in quantitative recovery of substrate. These observations are consistent with a mechanism in which **17** must arise via initial decarboxylation of the ionized form of **6**. The requirement of an acidic solution for formation of **17** will be discussed later.

Preparative photolysis of **7** (pH 7, Ar purged) gave the product of simple decarboxylation, i.e., *p*-nitrobenzyl acetate (**18**) and the expected disproportionation product, α,α′-bisacetoxy-*p*,*p*′-dinitrobibenzyl (**19**) (eq. [2]). The relative yield of **18** to **19** was ~ 1:1 in H$_2$O–CH$_3$CN but this ratio was dramatically altered in 1:1 D$_2$O–CH$_3$CN (~5% α-deuterated **18** and ~95% **19**). Thus, when the protonation pathway (**14** → **18**) is retarded in D$_2$O by a primary solvent isotope effect, the disproportionation pathway that gives **19** becomes dominant. Photolysis of **7** in oxygen-saturated solution gave **15** (60%) and *p*-nitrobenzoic acid (40%); neither **18** nor **19** was observed. This indicates that interception of

Fig. 1. UV–vis traces observed on photolysis of **6** in ~100% H_2O (6.6×10^{-5} M, 0.01 M pH 7 phosphate buffer, Ar purged). Each trace represents 15 s irradiation at 300 nm (4 lamps). Arrows indicate changes in absorbance.
Fig. 2. UV–vis traces observed before (dashed line) and immediately following 15 s photolysis (300 nm, 16 lamps) of **7** in ~100% H_2O (solid lines) (6.7×10^{-5} M, 0.01 M pH 7 phosphate buffer, Ar purged). Each trace of the dark reaction is separated by 30 s. Arrows indicate changes in absorbance during the dark reaction.
14 by dissolved oxygen is much more efficient than either protonation or disproportionation.
p-Nitrophenylethylene glycol (**8**) was found to be photoreactive only in basic solution. UV–vis traces of the reaction (~100% H_2O, pH 13, Ar purged) allowed observation of a

Fig. 3. Decay in absorbance of **14** photogenerated from **7** in ~100% H_2O (complete within 5 min) or ~100% D_2O (complete within 15 min) measured at 369 nm immediately following 15 s photolysis (6.7×10^{-5} M, 300 nm, 16 lamps, pH(D) 7, Ar purged). Neither trace could be fitted satisfactorily to a first- or second-order kinetic equation.
strong transient absorption band at λ_{max} 403 nm that decayed within 1 h (Fig. 4) with complex kinetics (Fig. 4, inset). The initial decay appears to obey first-order kinetics; however, after approximately 20 min the decay becomes (reproducibly) more complex, suggestive of contributions from competing reactions. This transient was observed only in basic solution (Fig. 5); no spectral changes were observed in neutral or acidic solution (below pH 11), even on prolonged irradiation. The transient was also not observed in oxygen-saturated basic solution.
Preparative photolysis of **8** (1×10^{-3} M, pH 13, Ar) gave **15** and **16** (60–70% and 40–30%, respectively), as observed for **6** in neutral or basic solution. In keeping with the cuvette results above, no reaction was observed at pH 7. Base catalysis of the reaction of **8** is in line with observations made for **5** (13), although the latter is not known to give an observable 403 nm transient. In a previous study of **8** in our laboratory (21), a long-lived radical anion species was photogenerated and assigned from its ESR spectrum as *p*-nitrobenzaldehyde radical anion (**20**). Its lifetime in the ESR spectrum was similar to that observed for the transient 403 nm absorption band. Radical anion **20** has previously been reported to have an absorption maximum of ~400 nm (22) and the present data are in good agreement with this.

Irradiation of *p*-nitrobenzhydrol (**9**) at pH 13 (~100% H_2O, Ar purged, 300 nm) in a UV cuvette resulted in initial spectral changes that were consistent with formation of **21**. However, other components were evidently present, as the initial spectrum was not stable over time and underwent complex changes over the course of 10–30 min in the absence of light, indicating that relatively slow dark processes were occurring. No spectral changes were observed at pH 7, consistent with base catalysis of photoreaction. Preparative

Scheme 3.
Fig. 4. UV–vis traces observed before (dashed line) and immediately following 30 s photolysis (300 nm, 16 lamps) of **8** in ~100% pH 13 H_2O (7.4×10^{-5} M, Ar purged). Each trace is separated by 5 min (solid lines). Arrows indicate changes in absorbance during the dark reaction. Inset: observed decay of the 403 nm absorption band.

omatic signals). This is in agreement with previous studies of *m*- and *p*-nitrobenzyl alcohols (4), in which the corresponding photogenerated carbanions were also found not to undergo deuterium incorporation at the benzylic position. *p*-Nitrobenzhydryl methyl ether (**10**) might be expected to display "conventional" *p*-nitrobenzyl carbanion chemistry upon photodeprotonation, which would lead to deuterium incorporation. However, prolonged irradiation of **10** (pD 13, 10 h) resulted in complete recovery of substrate, with no evidence of deuterium exchange.

photolysis of **9** (1×10^{-3} M, 1:1 H_2O–CH_3CN, pH 13) gave two isolable disproportionation products, *p*-nitrobenzophenone (**21**) and *p,p'*-azoxybisbenzophenone (**22**) (60–70 and 40–30% relative yield, respectively), and a third minor (<10%, relative to **21**) product that has not been fully characterized but is believed to be derived from further reduction of **22** (see *Experimental*) (eq. [3]). Observation of base-catalyzed products from **9**, which is reminiscent of the photochemistry of *m*- and *p*-nitrobenzyl alcohol (4), suggests that the reaction pathway involves initial deprotonation from the benzylic position of **9**. However, attempts to trap the α-hydroxybenzyl carbanion intermediate from **9** with D_2O (at pD 13) were unsuccessful. Thus, extended photolysis of **9** in 1:1 D_2O–CH_3CN (pD 13) to >80% conversion followed by recovery of unreacted substrate showed complete absence of deuterium incorporation at the methine positon (as monitored by ^{1}H NMR integration of this signal relative to the ar-

The quantum yield for reaction of **6** was estimated using *p*-nitrophenylacetic acid (**3**) ($\Phi = 0.6$) (12, 17) as secondary actinometer. Comparative photolysis of **3** and **6** to low conversion (<20%) gave a quantum yield for the reaction of **6** in 100% H_2O (pH 6) of 0.4 ± 0.1. Quantum yields for reaction of **7** (pH 7), **8** (pH 14), and **9** (pH 13) were also estimated using product analysis and were 0.4, 0.5, and 0.02, respectively.

Fig. 5. Initial change in 403 nm absorbance (ΔOD = OD immediately after irradiation minus OD before irradiation) upon irradiation of **8** in ~100% H$_2$O, pH 1–14 (300 nm, 16 lamps, 15 s photolysis time, 7.4×10^{-5} M, Ar purged).
Fig. 6. LFP traces for **7** (4.7×10^{-5} M) with 1×10^{-4} M IrCl$_6^{2-}$ in ~100% H$_2$O (pH 7, N$_2$ purged, λ_{ex} 308 nm). Diamonds represent the spectrum sampled 1.8 μs after the laser pulse, which includes carbanion **14** at 369 nm. Squares and triangles (sampled at 9.2 and 34 μs) represent the decay of the 369 nm band simultaneous with the bleaching of the IrCl$_6^{2-}$ absorption bands at 430 and 490 nm to the final spectrum (at 130 μs) represented by circles. Top inset: decay of carbanion **14** ($k_{obs} = 6.2 \times 10^4$ s^{-1}, monitored at 360 nm). Bottom inset: bleaching of IrCl$_6^{2-}$ ($k_{obs} = 6.2 \times 10^4$ s^{-1}, monitored at 490 nm).
Laser flash photolysis

p-Nitrobenzyl carbanion **2** (which absorbs strongly at λ_{max} 358 nm) has been extensively studied by transient methods (12, 17). Its lifetime is sensitive to pH but not to oxygen and is shortened in the presence of IrCl$_6^{2-}$ that acts as a one-electron acceptor (23–25). When the π system is further extended with another phenyl ring, as is the case for *p*-(*p'*-nitrophenyl)benzyl carbanion (**23**), the absorption maximum is at much longer wavelength (λ_{max} 470 nm) (6). Further

Fig. 7. LFP traces for **6** in ~100% H$_2$O, pH 6.0 (4.6×10^{-5} M, 0.01 M phosphate buffer, N$_2$ purged, λ_{ex} 266 nm). Diamonds represent the spectrum sampled 700 ns after the laser pulse, which includes α-hydroxy carbanion **25** at 360 nm. Squares and triangles represent the decay of the spectrum at 2.6 and 6.9 μs after the laser pulse, respectively. Final spectrum after the decay (sampled at 36 μs) of **25** to the product at 340 nm is represented by circles. Top inset: decay of carbanion **25** ($k_{obs} = 2.6 \times 10^5$ s^{-1}, monitored at 360 nm). Bottom inset: growth of product ($k_{obs} = 3.1 \times 10^5$ s^{-1}, monitored at 290 nm).
Fig. 8. LFP traces for **8** in ~100% H$_2$O, pH 13.0 (5.7×10^{-5} M, N$_2$ purged, λ_{ex} 266 nm) which includes α-hydroxy carbanion **25** at 360 nm. Squares and triangles represent decay of the spectrum at 900 μs and 2.8 ms, respectively. After the decay of **25** was complete, the spectrum of radical anion **20** was observed; represented by circles, sampled at 14 ms after the laser pulse. Inset: Decay of **25** ($k_{obs} = 6.7 \times 10^{-2}$ s^{-1}, monitored at 360 nm) is simultaneous with the growth of radical anion **20** ($k_{obs} = 4.2 \times 10^{-2}$ s^{-1}, monitored at 410 nm).
substitution of the carbanion with an α-hydroxy group does not shift the absorption maximum, as α-hydroxy-*p*-(*p'*-nitro-

Fig. 9. LFP traces observed for **9** in ~100% H_2O, pH 13.0 (5.3×10^{-5} M, N_2 purged, λ_{ex} 266 nm). Diamonds represent the spectrum sampled 1.7 μs after the laser pulse, which includes carbanion **27** at 460 nm. Squares and triangles represent decay of the spectrum, sampled at 8.6 and 28 μs, respectively. Circles represent spectrum after the decay of **27** at 77 μs. Inset: decay of **27** ($k_{obs} = 5.2 \times 10^4$ s^{-1}, observed at 460 nm).
Fig. 10. Plot of the initial change in absorbance (ΔOD_{init}) at 460 nm upon LFP of **9** at pH 10–14 (5.3×10^{-5} M, ~100% H_2O, N_2 purged, λ_{ex} 266 nm). Each point represents the average initial ΔOD observed for 10 shots, assigned to carbanion **27** formed by photodeprotonation of **9**.
phenyl)benzyl carbanion (**24**) was also observed at 470 nm (6). Thus, it was anticipated that the *p*-nitrobenzyl carbanions generated from **6–8** should also have absorption maxima near 360 nm. This indeed was found to be the case for carbanion **14** formed from **7** (λ_{max} 369 nm, vide supra), which was sufficiently long-lived to allow detection by conventional UV–vis spectrophotometry. LFP of **7** (266 nm, pH 7, ~100% H_2O, N_2 purged) also gave **14** (λ_{max} 369 nm) which did not decay within the 150 ms (longest possible) time window of our LFP system, consistent with it being a very long-lived species (vide supra). However, LFP of **7** in the presence of $IrCl_6^{2-}$ (308 nm, N_2 purged) showed an accelerated decay of the 369 nm transient that was simultaneous with bleaching of $IrCl_6^{2-}$ bands at 430 and 490 nm (Fig. 6).

Fig. 11. LFP traces observed for **6** in ~100% H_2O, pH 13.0 (4.6×10^{-5} M, N_2 purged, λ_{ex} 266 nm). Diamonds represent the spectrum sampled 5.1 μs after the laser pulse, which includes carbanion **28** (420 nm) formed by photodeprotonation of **6**, and carbanion **25** (360 nm) formed by photodecarboxylation of **6**. Squares and triangles represent partial decay of the spectrum (decay of **28** and not **25**), sampled at 26 and 69 μs, respectively. Circles represent the spectrum after **28** has completely decayed, leaving **25** and possible products from **28**. Top inset: decay of **28** ($k_{obs} = 2.1 \times 10^4$ s^{-1}, monitored at 420 nm). Bottom inset: growth of product from **28** ($k_{obs} = 2.2 \times 10^4$ s^{-1}, monitored at 350 nm).
Fig. 12. Plot of the initial change in absorbance (ΔOD_{init}) at 420 nm upon LFP of **6** at pH 3–13 (4.6×10^{-5} M, ~100% H_2O, N_2 purged, λ_{ex} 266 nm). Each point represents the average initial ΔOD observed for 10 shots. Above pH 7 ΔOD_{init} is mostly attributed to carbanion **28** formed by direct carbon acid deprotonation. At pH 7 and below ΔOD_{init} is mostly attributed to **25** formed by photodecarboxylation which has weak absorption at 420 nm (assignment based on lifetimes).
LFP of **6** (266 nm) at pH 6 gave a transient at ~360 nm with a similar absorption profile as that of carbanion **14** (Fig. 7). It decayed via first-order kinetics (τ = 3.8 μs, 0.01 M phosphate buffer, pH 6) to a weaker but permanent absorption in the range 300–340 nm, assignable as a mixture

of **15** and **16**. Assignment of the 360 nm transient to **25** is based on its similarity to **14**. Additionally, LFP of **6** in the presence of IrCl$_6^{2-}$ showed an accelerated decay of the 360 nm band in synchrony with bleaching of the IrCl$_6^{2-}$ bands at 430 and 490 nm.

LFP of **8** at pH 13 also gave carbanion **25** ($\tau = 1.5$ ms) as a transient (Fig. 8). No transients were observed at pH 7 consistent with its lack of photochemical reactivity in neutral solution (vide supra). Decay of **25** (at pH 13) was concomitant with the growth of a band at 400 nm, which did not decay within 150 ms (Fig. 8, inset). The long-lived 400 nm transient (not observed in the presence of oxygen) is assigned to radical anion **20**, which was also observed by UV–vis spectrophotometry (Fig. 4). Closer examination of the kinetic trace at 410 nm (Fig. 8, inset) also showed evidence of a shorter-lived species ($\tau = 63$ μs) absorbing in this region, the identity of which is not known with certainty but which we have tentatively assigned to carbanion **26**, arising via benzylic deprotonation of **8**.

LFP of **9** at pH 13 gave a broad absorption band at 460 nm (Fig. 9) that decayed by first-order kinetics to baseline (Fig. 9, inset). The intensity of the 460 nm absorption was strongest at pH 14 and was progressively weaker at lower pH values; at pH 10 no signal was observable (Fig. 10). This apparent base catalysis of transient formation supports its assignment as carbanion **27**. Its absorption maximum is red-shifted by 100 nm compared to carbanion **25** (λ_{ex} 360 nm) which is compatible with the extended conjugation available from the additional phenyl ring.

The LFP spectrum of **6** at pH 13 was dominated by a band at 420 nm (Fig. 11), which decayed ($\tau = 47$ μs) to a long-lived ($\tau > 150$ ms) 360 nm band. The ΔOD of the 420 nm band as a function of pH is shown in Fig. 12, which has an apparent titration plot, suggesting that the 420 nm transient is carbanion **28** (with an excited stated pK_a of ~8 for the benzylic proton of **6**). This seems reasonable considering the analogous photodeprotonation observed for **9** at high pH.

Mechanisms of reaction

Our study of the photochemistry of *p*-nitrobenzyl derivatives **6**–**10**, by a combination of product studies, UV–vis spectrophotometry, and LFP, has provided additional insights into their mechanisms of reaction. It seems clear that the aqueous photochemistry for all of **6**–**9** involves *p*-nitrobenzyl carbanions. Indeed, several α-hydroxy-*p*-nitrobenzyl carbanions, generated by C—H bond deprotonation or by decarboxylation (or deformylation), were observed for the first time. With the present data, an overall mechanistic picture of the photochemistry of these compounds is now available.

Photodecarboxylation of **6** (assumed to be via T$_1$) occurs with appreciable quantum efficiency at pH 3–13 to generate **25** (Scheme 4). The lack of photoreactivity of **6** and absence of an LFP signal attributable to **25** at pH values 1 and 2 indicate that photodecarboxylation only occurs via the carboxylate form of **6**. The necessary steps to generate products **15** and **16** from **25** most likely involve overall loss of an electron and a proton (sequentially or via one-step loss of a hydrogen atom), to generate radical anion **20** (λ_{max} 403 nm, vide supra), which is known to be long-lived at high pH but undetectable at lower pH (21). Radical ion **20** has been

shown to lead to reduction product **16** (21), while scavenging of the electron of **20** by residual oxygen or on work-up would lead to **15**. The formation of **17** at pH 3 suggests an alternate pathway involving an overall intramolecular redox reaction for **25**. This new pathway is observed at a pH that coincides with significant protonation of the nitro group of **25**, to give **29** (similar *aci*-nitrobenzyl compounds have pK_a ~ 3, (6, 17, 26)). Net dehydration of **29** gives **17**.

At pH values > 8, photoionization of the benzylic proton of **6** (to give **28**) apparently competes with photodecarboxylation, as shown in LFP studies, although to what extent is not entirely clear with the data available. We have not isolated any product at high pH that might be expected to arise via **28**, but only compounds **15** and **16** as seen at pH values in the range ~4–7. The possibility of facile reprotonation of **28** to give back **6** (in the ground-state reaction) is a distinct possibility. However, we have not attempted any deuterium incorporation experiments at these high pHs because of the obvious complication of thermal background exchange in basic D$_2$O. Thus, further understanding of the competing benzylic C-H deprotonation of **6** requires additional studies.

The proposed reaction pathway for **8** (pH > 12) (Scheme 5) is simpler. LFP observations at pH 13 indicate that generation of **25** from **8** occurs much more cleanly, with no significant photoionization at the benzylic position. Carbanion **25** (from **8**) gives radical anion **20** (via overall loss of an electron and a proton), as shown by growth of the radical anion absorption band (λ_{max} 403 nm) concomitantly with decay of the absorption band of **25** (λ_{max} 360 nm) (Fig. 8). The subsequent decay of **20** appears to be more complex, after a phase with initial first-order kinetics (Fig. 4, inset), and is suggestive of multistep pathways for subsequent formation of **16**.

The α-acetoxy carbanion **14** generated via photodecarboxylation of **7** behaves as a conventional *p*-nitrobenzyl carbanion (mimicking **2**, Scheme 1). The two observed products, **18** and **19**, arise via protonation and coupling pathways (giving a dianion, which subsequently loses two electrons to give **19**) (18). Given that the observed lifetime of **14** is very long compared to that of **25**, both its protonation and coupling processes must be slow. In contrast, the lifetime of **25** at pH 6 is more than 7 orders of magnitude shorter (μs vs. min). Clearly the disproportionation pathway available to **25** is sufficiently fast that protonation or coupling cannot compete. Comparison of the pseudo-first-order rate constants for reaction of these carbanions with IrCl$_6^{2-}$ (**25** reacts only about 2 times faster than **14**) suggests that the oxidation potentials of **14** and **25** are roughly equivalent. Thus, the key structural feature that allows the efficient disproportionation pathway observed for **25** is the α-hydroxyl proton. This is consistent with gas-phase theoretical calculations (3) that have shown anions such as $^-$CH$_2$OH and $^-$CH$_2$NH$_2$ to be unstable with respect to their radicals.

The reaction pathway of **9** is similar in essence to those of **6** and **8**. It differs in that the carbanion **27** is formed by direct C—H bond heterolysis, and is the only *p*-nitrobenzyl carbanion that could form in this case. To our knowledge, only one other example of LFP observation of a carbanion generated by photoionization has been reported (6). The subsequent product-forming steps from **27** are believed to be similar to those proposed for **6** and **8**; i.e., the carbanion for-

Scheme 4.
Scheme 5.
mally loses a hydrogen atom to form the corresponding radical anion, which subsequently disproportionates to products **21** and **22**. The complete absence of photochemistry from **10** indicates the sensitive nature of excited-state deprotonation with respect to substituents. Further work will be needed to understand the factors that influence the operation of these substituent effects, which may be quite subtle.

Experimental

General

^{1}H NMR spectra were obtained on Bruker AC300 or JEOL FX90Q instruments in CDCl$_3$ unless otherwise specified. Low-resolution mass spectra were obtained on a Finnigan 3300 (CI) and HR-MS were obtained on a Kratos Concept H (EI) instrument. UV–vis spectra were recorded on a Varian Cary 5 instrument. Acetonitrile (HPLC grade) and distilled water were used for product studies and LFP experiments. Reagent grade CH$_2$Cl$_2$ was redistilled before use for work-up protocols. The following buffers (0.01 M) were used for some product studies and LFP static and flow cell experiments: potassium phosphate – phosphoric acid (pH 3), acetate – acetic acid (pH 4 and 5), potassium phosphate (pH 6–8), sodium carbonate – sodium bicarbonate (pH 9–11). Aqueous H$_2$SO$_4$ and NaOH were used for solutions at other pH values.

Materials

p-Nitrobenzaldehyde (**15**) and *p*-nitrobenzophenone (**21**) (Aldrich) were recrystallized (ethanol–H$_2$O) prior to use. Sodium hexachloroiridate(IV) hexahydrate 99.9+% (Strem) was used without further purification. Product **18** was prepared by substitution of *p*-nitrobenzyl bromide with sodium acetate. An authentic sample of product **22** was prepared by reduction of **21** with paraformaldehyde–KOH, as described elsewhere (27).

O-*Acetyl* **p**-*nitromandelic acid* (7)

A stirred suspension of 4-nitrophenylacetic acid (15.3 g, 84.5 mmol) in thionyl chloride (6.66 mL, 91.3 mmol) was refluxed for 1 h. The solution was allowed to cool and bromine (14.9 g, 93 mmol) was added in one portion. The mixture was heated at 70°C for 5.5 h and stirred overnight at room temperature. Ice water was added and the mixture was extracted with Et$_2$O. The organic phase was washed with brine, dried and evaporated to a brown oil (22 g) that was dissolved in a mixture of THF (230 mL) and water (100 mL) and stirred for 6 h at room temperature. The solution was concentrated under reduced pressure to remove most of the THF and water (50 mL) was added. The mixture was extracted with Et$_2$O and the ethereal extract was washed with brine, dried and evaporated to give a solid (18.5 g) that contained the starting nitrophenylacetic acid and the product **11** (typical ratio ~ 1:4). After two crystallizations from

benzene–hexanes, the contamination by starting material was reduced to 8% and this material (11.7 g) was used without further processing. Within the mixture, **11** had ^{1}H NMR δ: 8.22 (d, J = 8.8 Hz, 2H, Ar-H), 7.73 (d, J = 8.8 Hz, 2H, Ar-H), 5.40 (s, 1H, CHBr).

A mixture of the impure bromo compound **11** (11.49 g, 41.65 mmol) and mercury(II) acetate (28.2 g, 88.4 mmol) in glacial acetic acid (88 mL) was refluxed for 0.5 h. The solution was cooled, diluted with water, and extracted with Et$_2$O. The ether phase was washed with water and brine, dried and evaporated under reduced pressure. The residue was crystallized from water to give the acetate **7** (7.5 g, 37%), mp 153 to 154°C (lit. mp (28) 157–159°C). ^{1}H NMR δ: 8.25 (d, J = 8.8 Hz, 2H, Ar-H), 7.69 (d, J = 8.8 Hz, 2H, Ar-H), 6.04 (s, 1H, CHOAc), 2.23 (s, 3H, Me).

p-*Nitromandelic acid (6)*

tert-Butyl 2,2,2-trichloroacetimidate (4.0 g, 18.3 mmol) in CH$_2$Cl$_2$ (32 mL) was added in one portion to a solution of **7** (2.73 g, 11.4 mmol) in CH$_2$Cl$_2$ (69 mL) and the solution was stirred overnight at room temperature. The mixture was diluted with CH$_2$Cl$_2$, washed with saturated NaHCO$_3$, water, and brine, dried and evaporated. The residue was dissolved in Et$_2$O (~10 mL) and most of the trichloroacetamide was precipitated by the addition of hexanes (~40 mL). The filtrate was evaporated and purified by flash chromatography (EtOAc–hexanes, 3:17) to give *tert*-butyl acetoxy-(4-nitrophenyl)acetate (**12**) as a yellow solid, (2.56 g, 76%). A sample crystallized from hexanes had mp 80 to 81°C (lit. mp (28) 82°C). ^{1}H NMR δ: 8.24 (d, J = 8.8 Hz, 2H, Ar-H), 7.66 (d, J = 8.8 Hz, 2H, Ar-H), 5.91 (s, 1H, CHOAc), 2.23 (s, 3H, Me), 1.41 (s, 9H, CMe$_3$).

A solution of **12** (2.53 g, 8.6 mmol) in methanol (25 mL) was treated with cesium carbonate (0.14 g, 0.43 mmol) in methanol (5 mL) and stirred for 0.5 h at room temperature. The solution was diluted with EtOAc, washed with satd. NaHCO$_3$ and brine, dried and evaporated under reduced pressure. The residue was purified by flash chromatography (EtOAc–hexanes, 3:17) to give *tert*-butyl hydroxy-(4-nitrophenyl)acetate (**13**) (1.51 g, 70%), mp 91.5–93°C (hexanes). ^{1}H NMR δ: 8.21 (d, J = 8.8 Hz, 2H, Ar-H), 7.63 (d, J = 8.8 Hz, 2H, Ar-H), 5.16 (d, $J_{H,OH}$ = 4.5 Hz, 1H, CHOH), 3.72 (d, $J_{H,OH}$ = 4.5 Hz, 1H, OH), 1.42 (s, 9H, CMe$_3$). Anal. calcd. for C$_{12}$H$_{15}$NO$_5$: C 56.91, H 5.97, N 5.53; found: C 56.75, H 5.97, N 5.38.

The *tert*-butyl ester **13** (1.8 g, 7.1 mmol) was stirred with trifluoroacetic acid (36 mL) for 1 h at room temperature, then evaporated under reduced pressure to a brown gum which solidified on trituration with Et$_2$O. The solid was crystallized twice from toluene to give **6** as yellow needles (0.7 g, 48%), mp 128.5–130°C (lit. mp (29) 126 to 127°C). ^{1}H NMR (CD$_3$OD) δ: 8.25 (d, J = 8.8 Hz, 2H, Ar-H), 7.69 (d, J = 8.8 Hz, 2H, Ar-H), 5.26 (s, 1H, CHOH).

p-*Nitrobenzhydrol (9)*

Reduction of *p*-nitrobenzophenone (**21**) (Aldrich) with NaBH$_4$ gave a white solid, which upon recrystallization from ethanol–H$_2$O gave white crystals of *p*-nitrobenzhydrol (**9**), mp 69 to 70°C. IR (KBr disc, cm^{-1}): 1190 (m), 1340 (s), 1450 (m), 1510 (s), 1600 (m), 3300–3500 (s). ^{1}H NMR (300 MHz) δ: 2.37 (s, 1H, exchanges with D$_2$O, OH), 5.90 (s, 1H, methine), 7.33 (m, 5H, arom.), 7.56 (d, J = 8.8 Hz,

2H, arom.), 8.17 (d, J = 8.8 Hz, 2H). HR-MS (EI) calcd. for C$_{13}$H$_{11}$NO$_3$: 229.0739; found: 229.0739.

p-*Nitrobenzhydryl methyl ether (10)*

A solution of **9** (300 mg) in methanol (50 mL) (in the presence of 10% concd H$_2$SO$_4$) was refluxed for 24 h. Addition of ether and washing with H$_2$O resulted in extraction of a light yellow oil which by ^{1}H NMR was found to contain 5% **9** and 95% **10**. Preparative TLC (CH$_2$Cl$_2$ and silica gel) allowed isolation of a colourless oil (R_f 0.9) *p*-nitrobenzhydryl methyl ether (**10**). IR (neat, cm^{-1}): 1090 (s), 1190 (m), 1350 (s), 1450 (m), 1520 (s), 1600 (m). ^{1}H NMR (300 MHz) δ: 3.38 (s, 3H, methyl), 5.29 (s, 1H, methine), 7.30 (m, 5H, arom.), 7.51 (d, J = 8.8 Hz, 2H, arom), 8.16 (d, J = 8.8 Hz, 2H, arom.). HR-MS (EI) calcd. for C$_{14}$H$_{13}$NO$_3$: 243.0896; found: 243.0893.

α,α′-*Bisacetoxy-*p,p′*-dinitrobibenzyl (19)*

Esterification of the corresponding diol (0.5 g), which was available from a previous study (21), in refluxing (10 h) glacial acetic acid (in the presence of 10% concd H$_2$SO$_4$) gave 89% yield of an approximate 1:1 mixture of *cis-* and *trans-*α, α′-bisacetoxy-*p,p′*-dinitrobibenzyl (**19**). Recrystallization from ethyl acetate – hexanes enriched one of the diastereomers, thus allowing distinction between the ^{1}H NMR signals of the two diastereomers. IR (mixture of diastereomers, KBr disc, cm^{-1}): 1220 (s), 1350 (s), 1460 (w), 1530 (s), 1610 (m), 1750 (s). ^{1}H NMR (300 MHz) diastereomer A (40%) δ: 2.07 (s, 6H, COCH$_3$), 6.14 (s, 2H, methine), 7.34 (d, J = 8.8 Hz, 4H, arom.), 8.16 (d, J = 8.8 Hz, 4H, arom.). ^{1}H NMR (300 MHz) diastereomer B (60%) δ: 2.10 (s, 6H, COCH$_3$), 6.11 (s, 2H, methine), 7.33 (d, J = 8.8 Hz, 4H, arom.), 8.13 (d, J = 8.8 Hz, 4H, arom.). MS (mixture of diastereomers, + LSI-MS) 389 m/e (M$^+$ + 1).

Product studies

UV–vis photolyses were carried out for 3 mL of the appropriate solution in Suprasil quartz cuvettes. Immediately before photolysis, each sample was Ar or O$_2$ purged for 5 min, then quickly sealed with a Teflon stopper. During the photolysis the cuvette sat on top of an inverted 1 L beaker inside the Rayonet reactor (300 nm, 4–16 lamps) and was cooled with an internal fan. Irradiations did not exceed 10 min (total photolysis time); no heating of the samples was observed.

Preparative photolyses were carried out with the substrate (20–100 mg) dissolved in the appropriate solvent (100 mL) in a quartz tube. The solution was irradiated at 300 nm (Rayonet reactor, 4–16 lamps) with continuous cooling (by a cold finger) and purging by a stream of Ar for approximately 15 min before and continuously during irradiation (via a long stainless steel needle). Photolysis times ranged from 1 min to 20 h, depending on the conversion desired, the efficiency of the reaction, and the amount of substrate used. After photolysis, aqueous samples were acidified to pH 1 to 2 and extracted with CH$_2$Cl$_2$. Typical experiments are described below.

Photolysis of p-*nitromandelic acid (6) in 1:1 H$_2$O–CH$_3$CN (pH 7)*

A solution of **6** (20 mg) in 1:1 H$_2$O–CH$_3$CN (100 mL, pH adjusted to 7 with NaOH, Ar purged) was photolyzed for

2 min (300 nm, 16 lamps). After work-up, ^{1}H NMR of the photolysate allowed observation of two aldehyde products (60% **15**, 40% **16**) and **6** (36% total conversion). Preparative TLC (CH$_2$Cl$_2$ and silica gel) allowed isolation of the two products, one of which was identified as **15** (R_f 0.5) by comparison with an authentic sample; the other (R_f 0.3) identified as *p,p′*-azoxybisbenzaldehyde (**16**), mp 192°C. IR (KBr disc, cm^{-1}): 1200 (m), 1320 (m), 1460 (m), 1600 (m), 1700 (s). ^{1}H NMR δ: 8.01 (d, *J* = 8.1 Hz, 2H, arom.), 8.05 (d, *J* = 8.1 Hz, 2H, arom.), 8.26 (d, *J* = 8.1 Hz, 2H, arom.), 8.49 (d, *J* = 8.1 Hz, 2H, arom.), 10.05 (s, 1 H, CHO), 10.14 (s, 1 H, CHO). HR-MS (EI) calcd. for C$_{14}$H$_{10}$N$_2$O$_3$: 254.0692; found: 254.0689.

Photolysis of *p-nitromandelic acid (6) in 1:1 H$_2$O–CH$_3$CN (pH 3)*

A solution of **6** (20 mg) in 1:1 H$_2$O–CH$_3$CN (100 mL, pH 3, 0.01 M phosphate buffer, Ar purged) was photolyzed for 5 min (300 nm, 16 lamps). Following work-up, ^{1}H NMR allowed observation of the aldehyde peaks of **15** and **16**, as well as an aldehyde signal which had not been present in the pH 7 product studies. Based on integration the relative yields of these products were 50% (**15**), 22% (**16**) and 28% of the new aldehyde product, and the total conversion from substrate was 61%. This procedure was repeated until approximately 90 mg of photolysate had been collected. An initial attempt to separate the new product via preparative TLC (CH$_2$Cl$_2$ and silica gel) resulted in recovery of **15** and the new product in one band (R_f 0.6). A second attempt (1:9 ethyl acetate:hexanes and silica gel) succeeded in separating **15** (R_f 0.2) from the new light yellow product (R_f 0.3), identified as *p*-nitrosobenzaldehyde (**17**) (based on identical ^{1}H NMR with that reported in the literature (30)). IR (KBr disc, cm^{-1}): 1200 (m), 1260 (s), 1390 (m), 1460 (w), 1595 (m), 1690 (s). ^{1}H NMR δ: 8.03 (d, *J* = 8.8 Hz, 2H, arom.), 8.17 (d, *J* = 8.1 Hz, 2H, arom.), 10.20 (s, 1H, CHO). HR-MS (EI) calcd. for C$_7$H$_5$NO$_2$: 135.0321; found: 135.0323.

Photolysis of O-acetyl *p-nitromandelic acid (7) in 1:1 H$_2$O–CH$_3$CN (pH 7)*

A solution of **7** (20 mg) in 1:1 H$_2$O–CH$_3$CN (100 mL, pH adjusted to 7, Ar purged) was photolyzed for 20 min (300 nm, 4 lamps). Following work-up, ^{1}H NMR of the photolysate revealed 23% conversion to **18** and **19** (47 and 53%, respectively), each of which were identified by addition of an authentic sample (vide supra) which enhanced the ^{1}H NMR signals.

Photolysis of *p-nitrophenylethylene glycol (8) in 1:1 H$_2$O–CH$_3$CN (pH 13)*

A solution of **8** (100 mg) in 1:1 H$_2$O–CH$_3$CN (100 mL, pH 13, Ar purged) was photolyzed for 30 min (300 nm, 16 lamps). Following work-up ^{1}H NMR of the photolysate revealed 69% conversion to **15** and **16** (60 and 40%, respectively), identified as above (vide supra).

Photolysis of *p-nitrobenzhydrol (9) in 1:1 H$_2$O–CH$_3$CN (pH 13)*

A solution of **9** (20 mg) in 1:1 H$_2$O–CH$_3$CN (100 mL, pH 13, Ar purged) was photolysed for 60 min (300 nm, 16 lamps). After photolysis the solution turned a deep red color

that did not dissipate for up to several hours. Upon acidification to pH 2 with aq HCl, the color turned to yellow (between pH 10 and 11), with formation of a yellow precipitate. Extraction of the whole mixture with CH$_2$Cl$_2$ gave a ^{1}H NMR that showed ~15% conversion of **9** to **21** and **22** (70 and 30%, respectively), and a third, unidentified product. In a separate experiment, the precipitate formed during acidification was isolated by suction filtration and found to contain **22** and the unidentified product (in a ~1:1 mixture), while the filtrate contained **9** and **21**. Preparative TLC (CH$_2$Cl$_2$ and silica gel) failed to separate **22** from the unidentified product. Based on analysis of the ^{1}H NMR pattern of the unidentified product (as a mixture with **22**), we have tentatively identified it as a secondary photoproduct of **22**, i.e., a hydroxyazobenzene derived from **22**, consistent with the known photo-Wallach rearrangement of aromatic azoxy compounds (31).

Quantum yields

The quantum yield of **6** was measured by preparative photolysis and ^{1}H NMR using **3** as secondary actinometer (Φ = 0.6) (12). Photolysis of **3** (20 mg, pH 7, 100 mL 100% 0.01 M phosphate buffer, 300 nm, 4 lamps, 2 min, Ar purged) followed by assessment of the conversion to product (10–15%) allowed calculation of the number of photons emitted by the apparatus. In a following photolysis of **6** (100% pH 6 0.01 M phosphate buffer) using identical conditions, assessment of conversion (5–10%) allowed calculation of the quantum yield for the reaction. These photolyses were repeated four times, and the average quantum yield was calculated.

Laser flash photolysis (LFP)

LFP data was acquired using either a Nd:YAG laser (Spectra-Physics Quanta-Ray GCR-11, λ$_{ex}$ 266 nm; this laser was used for most LFP experiments) or a Lumonics excimer laser (EX-510, λ$_{ex}$ 308 nm; this laser was used for experiments using IrCl$_6^{2-}$) with pulse widths ~20 ns and power attenuated to ~20 mJ/pulse. Signals were digitized with a Tektronix TDS 520 recorder. Solutions with OD = 0.3 at λ$_{ex}$ were used to ensure even penetration of the laser light. Quartz flow cells were used for all studies except for the measurement of ΔOD$_{init}$ at various pH values (Figs. 10 and 12), where quartz static cells were used. Samples in flow cells were continuously purged with a stream of N$_2$ or O$_2$ for 15 min before and during the experiment. Samples in static cells were purged with N$_2$ or O$_2$ for 5 min and subsequently sealed prior to the experiment. The contents of static cells were mixed between each laser shot to avoid depletion of the solution in the irradiated volume.

Intramolecular reactions of dialkoxycarbenes with a carbonyl group

Małgorzata Dawid and John Warkentin

Abstract: Thermolysis of 5,5-dimethyl-2-methoxy-2-(2-oxocyclohexylmethoxy)-Δ^3–1,3,4-oxadiazoline (**3a**) in benzene at 110°C generated a carbonyl ylide intermediate that gave, in a minor side reaction, a product of 1,3-dipolar cyclo-addition to the carbonyl group. The major fate of the ylide was fragmentation to acetone and a dialkoxycarbene, MeO-(RCH$_2$O)C:, where R = 2-oxocyclohexyl. The carbene, in turn, underwent overall [2 + 1] cycloaddition to the carbonyl group, presumably to afford diastereomeric dialkoxyoxiranes that could not be isolated. A product of methanolysis of the presumed oxiranes was isolated by GC and its structure was determined by means of X-ray diffraction. Methanol is believed to result from reaction of an intermediate or product with adventitious water. Deliberate hydrolysis of the product of methanolysis gave a hydroxy lactone, the structure of which was also secured by means of single crystal X-ray diffraction. Those structures indicated the likely structures of the oxirane precursors. A second, and major, product from the carbene was a bicyclic ketone. Similar products were obtained from intramolecular reactions of a carbene tethered to cyclopentanone through a two-carbon or a one-carbon tether. Some compounds that are apparently "dimers" of the oxiranes were also isolated and identified by means of X-ray diffraction. These dimers are thought to originate from the reaction of a ring-opened oxirane (a dipole or a cation from electrophilic opening of the oxirane) with a mol-ecule of the oxirane rather than from bimolecular reaction between two oxirane molecules. The oxiranes open by cleav-age of the (RO)$_2$C—O bond rather than the oxirane C—C bond, the normally observed sense of thermal ring opening. The properties of the carbenes and the presumed oxiranes serve to point out the options available to such intermediates and suggest that some new, synthetically useful reactions may become possible.

Key words: bicyclic ketone, dialkoxycarbene, dialkoxyoxirane, hydroxylactone, "oxirane dimers".

Résumé : La thermolyse de la 5,5-diméthyl-2-méthoxy-2-(2-oxocyclohexylméthoxy)-Δ^3-1,3,4-oxadiazoline (**3a**), dans le benzène, à 110 °C, génère la formation d'un ylure de carbonyle comme intermédiaire qui réagit, dans une réaction la-térale mineure, pour former un produit de cycloaddition 1,3-dipolaire sur le groupe carbonyle. La réaction principale de l'ylure est une fragmentation en acétone et en dialkoxycarbène, MeO(RCH$_2$O)C:, dans lequel R = 2-oxocyclohexyle. Par la suite, le carbène subit une réaction globale de cycloaddition [2 + 1] sur le groupe carbonyle qui fournit proba-blement les dialkoxyoxiranes diastéréomères qui n'ont pas été isolés. Faisant appel à la CG, on a toutefois pu en isoler un produit de méthanolyse et on a déterminé sa structure par diffraction des rayons X. On croit que le méthanol est issu de la réaction d'un intermédiaire ou d'un produit avec de l'eau présente de façon fortuite. L'hydrolyse délibérée du produit de méthanolyse conduit à une hydroxylactone dont la structure a été déterminée par diffraction des rayons X sur un cristal unique. Ces structures suggèrent celles des oxiranes qui leur ont donné naissance. Un deuxième et le plus important produit provenant du carbène est une cétone bicyclique. Des produits semblables ont été obtenus par le biais de réactions intramoléculaires d'un carbène auquel on a attaché une cyclopentanone par le biais de rallonges à un ou deux atomes de carbones. On a aussi isolé des composés qui sont apparemment des dimères d'oxiranes et on les a identifiés par le biais de la diffraction des rayons X. On croit que ces dimères trouvent leur origine dans la réaction d'un oxirane à cycle ouvert (un dipôle ou un cation résultant de l'ouverture électrophile de l'oxirane) avec une molé-cule d'oxirane plutôt par une réaction bimoléculaire entre deux molécules d'oxirane. Les oxiranes s'ouvrent par rupture de la liaison (RO)$_2$C—O plutôt que par ouverture de la liaison C—C de l'oxirane, le sens d'ouverture normalement ob-servé dans l'ouverture thermale du cycle. Les propriétés des carbènes et des oxiranes suggérés permettent de préciser les diverses options ouvertes à ces intermédiaires et de suggérer que de nouvelles réactions utiles en synthèse puissent se développer.

Mots clés : cétone bicyclique, dialkoxycarbène, dialkoxyoxirane, hydroxylactone, dimères d'oxirane.

Introduction

The nucleophilicity of dialkoxycarbenes was first reported by Hoffmann's group, and other examples followed (1). Relative nucleophilicities of various carbenes have been quantified by Moss et al. (2). The nucleophilic characteristics of dialkoxycarbenes are evident from their sluggish reactions with simple alkenes, such as cyclohexene (1*b*, 3) and their greater reactivity toward Michael acceptors such as isocyanates and diphenylketene (1*d*), for example. Donor-atom-substituted carbenes are also capable of bimolecular nucleophilic displacements. Nucleophilic substitution at unsaturated carbon occurs between an imidazolylidene and 2,3,4,5,6-pentafluoropyridine (4) and in reactions of dimethoxycarbene (DMC) with hexachlorocyclopentadiene (5), 1-fluoro-2,4-dinitrobenzene, and hexafluorobenzene (6), for example, although the yields can be very low (6).

A common reaction of nucleophiles with carbonyl compounds is addition, to change the geometry at the carbonyl carbon from planar to tetrahedral. Diaminocarbenes were known to attack at the carbonyl carbon atom of aldehydes (7), and DMC appears to add to the carbonyl group of hexafluoroacetone (Scheme 1) (8), fluorenone (9), and cyclohexanone (10). Recently it was shown that DMC reacts to effect insertion into the bond between the carbonyl carbon and the α-oxygen atom of anhydrides (11) and a lactone (12). Similar apparent insertion into the bond between a carbonyl carbon and the α-carbon of strained cyclic ketones was reported (12) (Scheme 2). Such reactions could be concerted or they could involve tetrahedral intermediates with dipolar or diradical characteristics. Either of those intermediates could rearrange by ring enlargement or cyclize to isolable dialkoxyoxiranes, as in the case of addition of dimethoxycarbene to cyclohexanone (Scheme 3) (10). Dimethoxycarbene also reacts with thiocarbonyl compounds to form dimethoxythiiranes (13). Although imidazolylidenes are known to form stable dipolar intermediates by forming a single bond to carbon disulfide (14), carbon dioxide (15), or sulfur trioxide (16), attack of a less-nucleophilic dialkoxycarbene at a carbonyl or thiocarbonyl group could be concerted, leading directly to a dialkoxyoxirane or a dialkoxythiirane.

The nucleophilic reactivity of dialkoxycarbenes was suggested by the previously demonstrated reactions of vinylogous dialkoxycarbenes with ketones (17–19). It is not surprising that vinylogous dialkoxycarbenes are better nucleophiles than saturated analogues because the former carbenes are presumably more polarizable and can disperse positive charge better in a stepwise or nonsynchronous concerted reaction. The stepwise pathway for vinylogous dialkoxycarbenes is illustrated in Scheme 4.

It was of interest to us to explore further the possible intramolecular reactions of non-vinylogous dialkoxycarbenes with a tethered carbonyl group. Previously only one case of such a process had been reported and that was for reaction with the carbonyl group of a tethered cyclobutanone (12). We now report reactions of a dialkoxycarbene with the carbonyl group of a cyclohexanone tethered at the α-position with a one-carbon tether to the carbene, as well as reactions of dialkoxycarbenes tethered analogously to cyclopentanone with a one- or two-carbon tether.

Methods, results, and discussion

The oxadiazoline precursors (**3**) of dialkoxycarbenes were prepared from 2-hydroxyalkyl cyclanones (**2**) and 2-acetoxy-2-methoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (**1**) by the exchange method (19), as illustrated in Scheme 5. The exchange had to be done carefully to minimize dehydration of **2a** or destruction of **3** subsequent to their formation. Protection of the carbonyl group of **2a** with 1,2-ethane dithiol and subsequent exchange followed by deprotection was achieved but that route did not offer any improvement of the yield of **3a**. Compounds **3** were isolated by chromatography on silica.

After purification of **3a** by chromatography, a benzene solution was heated for 24 h at 110°C in a sealed glass tube. Products isolated by chromatography on silica included **4** (7%) and 1-methoxy-8-oxa-9-oxobicyclo[4.2.1]nonane (**5**, 31%), as shown in Scheme 6. Acetal **6** (16%), which had two methoxy signals in the ^{1}H NMR spectrum and the correct mass for **6**–OMe, was isolated by means of GC. Despite many attempts the material could not be crystallized. Structure **6** was inferred from the structure of the single product of hydrolysis of the material (below). In addition, diastereomers **7a** and **7b**, both crystalline solids, were isolated by means of radial chromatography on silica. Compound **7a** was identified completely by means of single crystal X-ray diffraction and **7b** was assigned on the basis of its NMR spectra, which closely resembled those of **7a**.

The products can be accounted for as follows. Oxadiazoline **3a** loses N$_2$ in the first step to generate carbonyl ylide **8** (Scheme 7). Intramolecular cycloaddition of the ylide to the carbonyl group leads to **4**, the stereochemistry of which was assigned on the basis of the structure of the product of acid-catalyzed hydrolysis of **4**, hydroxy lactone **9**. The structure of **9** was secured by means of single crystal X-ray diffraction.

A major fate of the carbonyl ylide must be the well-precedented loss of acetone (1*k*) to afford carbene intermediate **10**, which attacks the carbonyl group of the cyclohexanone to generate intermediate **11** or, possibly, the oxiranes **12** (Scheme 7). The intermediacy of diastereomers **12** is speculative because many attempts to isolate a sample by gas chromatography gave material that contained **6** and, possibly, the diastereomers **12**. Deliberate hydrolysis of such samples led to hydroxy lactone **9** only. The structure of **9** means that both the ylide **8** (precursor of **4**) and the carbene **10** (precursor of **11**) react from that conformation in which the side chain is axial, as shown in Scheme 7.

Although the rearrangement of **10** to **5** amounts to an insertion (overall) of the carbene into a C—CO bond of the carbonyl group, the reaction is not necessarily concerted. Reactions of cyclic ketones with diazomethane, leading to products of ring expansion, are believed to be stepwise (20). Those reactions are reasonable models for ring expansion of cyclic ketones by reaction with dialkoxycarbenes. It was shown previously that migration of the more-substituted carbon is preferred when α-alkylcyclobutanones react with dimethoxycarbene to afford corresponding dimethoxycyclopentanones (12). In the case of postulated intermediate **11**, in which migration of the more-substituted carbon would lead to a four-membered ring (Scheme 7), the less-substituted α-carbon migrated to expand the ring from six-

Scheme 4.

to seven-membered. A simple model that aids in visualization of the transition state charge separation is the enolate alkylation model (12) shown in Scheme 8. It should perhaps be emphasized that such structures, with enolate and cation character, are simply models for actual transition states or intermediates.

An additional product from thermolysis of **3a** was the complex compound **13**, consisting essentially of 3 equiv of the proposed oxirane intermediate. Its structure was determined by means of single crystal X-ray diffraction. Scheme 9 is a rationalization for its formation from reaction of the ring-opened oxirane with the oxirane. It should be emphasized that the mechanism, involving intermediates **11** and **13**, is speculative. Instead of the dipolar species **11**, one could invoke a cationic intermediate formed by protonation (by adventitious water) and subsequent ring-opening of an oxirane **12**. That cation could then act as an electrophile to
open a second molecule of oxirane. The connectivity of **14** does require that the oxirane intermediates *do not open to carbonyl ylides*; the usual sense of thermal ring opening of oxiranes. Presumably there were other compounds, analogous to **14**, that we were unable to isolate.

Heating of a solution of **3b** in benzene afforded similar products. A major product (33%) was 1-methoxy-2-oxa-8-oxobicyclo[3.3.1]nonane (**17**). Again there was indirect evidence for isomeric oxirane intermediates, probably **15** and **16** (Scheme 10), although they were too unstable to be isolated. Preparative gas chromatography gave fractions that changed during the collection process, probably because of hydrolysis. Two stable compounds (**18** and **19**) were also isolated by means of GC and identified by means of single crystal X-ray diffraction. Compound **18** is probably formed by the methanolysis of **15** and **16**. The source of methanol is again assumed to be hydrolysis of an intermediate by adventitious water.

The hexahydropyranyl ring of **19** is fused *trans* to the 1,4-dioxanyl ring and the ring juncture of the hexahydropyranyl and cyclopentyl rings is *cis*. It is analogous to compound **11** that was obtained from **3a**, and it appears, at first sight, to be a head-to-tail dimer of the dipolar intermediate that would result from stepwise addition of the nucleophilic carbene center to the carbonyl group (Scheme 10). Such a dimerization is unlikely, of course, because reactive intermediates are not expected to accumulate to concentrations that

Scheme 5.

(**a**: m=1, n=2; **b**: m=2, n=1; **c**: m=1, n=1)
Scheme 6.
could lead to bimolecular reactions between them. We are therefore led to propose, again, that there is a bimolecular reaction between a dipolar species, in equilibrium with the oxirane precursor and the oxirane. Alternatively, a cationic species, from electrophile-catalyzed ring opening of the oxirane, reacts with the oxirane to generate **19**. Isomers of **19** might be expected, given that isomeric oxiranes such as **15** and **16** could result from the carbene. The GC trace showed compounds with retention times similar to that of **19**, and we assume that isomers of **19** were generated and that they account for some of material imbalance.

Thermolysis of **3c** gave products analogous to those from **3a** and **3b** (Scheme 11). Compound **22** (2%) can be attributed to dipolar cycloaddition of the ylide from **3c** to the carbonyl group, and the carbene from **3c** afforded **23** and **24**, because we were able to isolate a product (**25**) of apparent methanolysis of **24**. Lactone **26** was also obtained as was bicyclic ketone **28** (28%), possibly from rearrangement of a dipolar intermediate **23**. In the case of **3c**, two dimers (**29** and **30**) of the putative oxirane intermediate could be obtained in crystalline form suitable for single crystal X-ray diffraction. Compound **27** is apparently the product of hydrolysis of a product like **29**. In diastereomer **29** the 1,4-dioxanyl ring is in the chair conformation, and it is fused *cis* to the tetrahydrofuranyl rings. In diastereomer **30** the 1,4-dioxanyl ring is in a boat conformation, and both tetrahydrofuranyl rings are again fused *cis* to it. As in cases of **3a** and

3b, there were other products with GC retention times similar to those of **29** and **30**. Those products were probably also dimers, isomers of **29** and **30**.

In order to trap a possible intermediate, thermolysis of **3a** was carried out in the presence of dimethyl acetylenedicarboxylate (DMAD). The yield of **5** was reduced by a factor greater than two, and there were formed, instead, two products isolated in essentially equal amounts, ca. 3% each, with greater GC retention times. It was possible to isolate those compounds, by means of semipreparative GC followed by MPLC, and to determine that they were diastereomers **32** and **33** (Scheme 12). Structure **32** was secured by means of single crystal X-ray diffraction while **33** was inferred from its NMR spectrum, which was very similar to that of **32**. It is clear from the connectivity that DMAD *had not intercepted a carbonyl ylide* such as **30**, which is the intermediate that is normally obtained from thermal, conrotatory ring opening of an oxirane, but something like dipole **31** or the cation from protonation of **31**. The cation mechanism appears to fit best because a cationic intermediate would not be likely to attack the triple bond but it could coordinate instead to carbonyl oxygen.

In summary dialkoxycarbenes, tethered *alpha* to the carbonyl group of cyclohexanone or cyclopentanone, react intramolecularly with the carbonyl group to generate an intermediate with a new five- or six-membered ring. Dialkoxy-oxirane intermediates could not be isolated but they were

Scheme 7.
Scheme 8.
inferred from products of their ring opening by methanol or water. Some novel oxirane dimers were isolated, as well as, in each case, a bicyclic ketone.

Experimental

Preparation of oxadiazoline 3a

A solution of 2-acetoxy-2-methoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (**1**) in CH_2Cl_2, containing about 30% of an acy-

clic isomer (19), was treated with hydroxy ketone **2a** (21) and trifluoroacetic acid in dichloromethane. After washing with dilute base, the organic layer was dried and the solvent was evaporated. Chromatography of the residue (silica gel, hexane:ethyl acetate:Et_3N (85:15:0.5)) gave oxadiazoline **3a** (67% of pure product) as a colourless oil. IR (neat, KBr) (cm^{-1}): 2989, 2944, 2865, 1711, 1452, 1211, 1167, 1136, 914. ^1H NMR (300 MHz, $CDCl_3$, 1:1 mixture of two diastereoisomers) δ: 4.14 (dd, J = 9.9, 5.1 Hz, 1H, OCH_a),

Scheme 9.

7(diasteriomers) → 13 → 14 (ca 2%)

Scheme 10.

4.04 (dd, J = 9.9, 5.1 Hz, 1H, OCH$_a$), 3.71 (dd, J = 9.9, 7.7 Hz, 1H, OCH$_b$), 3.59 (dd, J = 9.9, 7.7 Hz, 1H, OCH$_b$), 3.45 (s, 6H), 2.65 (m, 2H), 2.34 (m, 6H), 2.03 (m, 2H), 1.90 (m, 2H), 1.67 (m, 4H), 1.54 (s, 12H), 1.44 (m, 2H). ^{13}C NMR (75 MHz, CDCl$_3$) δ: 210.7, 137.1, 119.3, 63.9, 52.0, 50.4, 42.2, 31.4, 24.7, 24.2, 24.1. EI-MS m/z (%): molecular ion not observed, 225 ([M – OMe$^+$], 3), 170 (7), 129 (15), 111 (59), 94 (47), 73 (60), 55 (100). CI-MS (NH$_3$) m/z: 274 ([M + NH$_4^+$], 28).

Thermolysis of 3a in benzene

A solution of **3a** (0.51 g, 2 mmol) in benzene (20 mL) in a sealed tube was heated at 110°C for 18 h. Evaporation of the solvent left a residue that was chromatographed on silica (hexane:ethyl acetate, 90:10) to afford bicyclic ketone **5** (31%), hydroxy orthoester **6** (16%), **4** (7%), and compounds **7** (<5%).

Semipreparative gas chromatography (OV-17, 5%, helium at 50 mL min^{-1}; temperature program, 80°C for 5 min, increased at 4°C min^{-1} to 250°C; retention time 26–29 min) gave **6**, which is probably a product of oxirane methanolysis,

as a semicrystalline material. A crystal suitable for X-ray crystallography could not be obtained. Exposure of the sample to the atmosphere led to its slow hydrolysis to **9**.

Product 4

Yield: 7%, colourless oil. ^{1}H NMR (300 MHz, CDCl$_3$) δ: 4.12 (dd, J = 8.3, 4.7 Hz, 1H), 3.57 (d, J = 8.3 Hz, 1H), 3.35 (s 3H), 2.20 (m, 1H), 2.03 (m, 1H), 1.44 (s, 6H), 1.4–1.85 (m, 7H). ^{13}C NMR (75 MHz, CDCl$_3$) δ: 126.5, 108.8, 87.6, 71.0, 51.4, 44.6, 32.1, 29.3, 28.1, 28.0, 23.5, 23.0. EI-MS m/z (%): 229 ([M + 1]$^+$, 4), 213 (55), 154 (45), 153 (48), 111 (41), 93 (100), 81 (66), 55 (84), 43(80). Compound **4** in CDCl$_3$ was converted rapidly to lactone **9** during storage.

1-Methoxy-8-oxa-9-oxobicyclo[4.2.1]nonane (5)

Yield: 31%, colourless oil. IR (neat) (cm^{-1}): 2938, 2866, 1767, 1456, 1189, 1158, 1075, 998. ^{1}H NMR (200 MHz, CDCl$_3$) δ: 4.34 (dd, J = 8.8, 5.2 Hz, 1H), 4.07 (d, J = 8.8 Hz, 1H), 3.28 (s, 3H), 2.67 (m, 1H), 1.15–1.90 (m, 8H). ^{13}C NMR (50 MHz, CDCl$_3$) δ: 216.0, 104.9, 70.3, 51.1, 45.6, 33.0, 31.2, 23.7, 22.6. EI-MS m/z (%): 171 ([M + 1]$^+$, 15),

Scheme 11.
Scheme 12.
142 (42), 110 (68), 83 (55), 74 (100), 53 (92), 41 (100). CI-MS (NH$_3$) m/z: 188 ([M + NH$_4$]$^+$, 100).

Product 6

Semicrystalline. ^{1}H NMR (500 MHz, CDCl$_3$) δ: 3.80 (dd, J = 14.4, J = 2.5 Hz, 2H), 3.39 (s, 3H), 3.35 (s, 3H), 2.43 (d, J = 1.4, 1H), 2.37 (m, 1H), 1.44–1.90 (m, 6H). EI-MS m/z (%): 171 ([M – OMe]$^+$, 100), 147 (18), 112 (73), 97 (56), 83 (23), 69 (14). Compound **6** was rapidly converted to lactone **9** during storage.

Product 7a

Colourless crystals, mp 118°C. ^{1}H NMR (200 MHz, C$_6$D$_6$) δ: 4.02 (t, J = 7.8 Hz, 2H), 3.50 (dd, J = 7.8, 4.1 Hz, 2H), 3.45 (s, 6H), 2.68 (m, 2H), 2.13 (m, 2H), 1.94 (m, 2H), 1.69–1.55 (m, 6H) 1.40–1.26 (m, 6H). ^{13}C NMR (50 MHz, C$_6$D$_6$) δ: 116.7, 79.6, 68.9, 48.7, 42.5, 29.9, 25.2, 22.3, 22.2.

EI-MS m/z (%): 341 ([M + 1]$^+$, 100), 340 ([M]$^+$, 78), 339 (46), 154 (100), 153 (22), 139 (19), 109 (21), 95 (29), 79 (30). The connectivity and stereochemistry of **7a** were established by means of single crystal X-ray diffraction.

Product 7b

Colourless crystals, mp 148°C. ^{1}H NMR (200 MHz, C$_6$D$_6$) δ: 4.21 (t, J = 7.7 Hz, 2H), 3.45 (s, 6H), 3.21 (dd, J = 7.7, 3.3 Hz, 2H), 2.25 (m, 2H), 1.44–1.98 (m, 16H). ^{13}C NMR (50 MHz, C$_6$D$_6$) δ: 117.6, 80.0, 70.1, 48.1, 43.4, 31.6, 28.6, 23.5, 23.3.

Hydroxy lactone 9

Yield: 16% (formed during chromatography), colourless crystals, mp 129°C. IR (neat, KBr) (cm^{-1}): 3420 (br), 2972, 2879, 1769, 1439, 1372, 1211, 1161, 1011, 970. ^{1}H NMR (200 MHz, CDCl$_3$) δ: 4.40 (dd, J = 8.6, 7.0 Hz, 1H), 4.05

(dd, J = 8.6, 7.5 Hz, 1H), 2.68 (br s 1H), 2.50 (m 1H), 1.32–1.93 (m, 8H). ^{13}C NMR (50 MHz, CDCl$_3$) δ: 179.1, 73.2, 69.2, 41.0, 31.6, 23.6, 21.8, 21.0. EI-MS m/z (%): molecular ion not observed, 154 (13), 112 (42), 97 (57), 83 (78), 55 (100). CI-MS (NH$_3$) m/z: 174 ([M + NH$_4$]$^+$, 100). The connectivity and stereochemistry of **9** were established by means of single crystal X-ray diffraction.

Synthesis of 3b

A solution in CH$_2$Cl$_2$ of 2-acetoxy-2-methoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (**1**), containing about 40% of an acyclic isomer (19), was treated with hydroxy ketone **2b** and trifluoroacetic acid in dichloromethane. After washing with dilute base, the organic layer was dried and the solvent was evaporated. Chromatography of the residue gave pure oxadiazoline **3b** (57%) as a colorless oil. IR (neat) (cm^{-1}): 2961, 2885, 1744, 1449, 1212, 1136, 1125, 1108, 921. ^1H NMR (300 MHz, CDCl$_3$, 1:1 mixture of two diastereomers) δ: 3.70–3.85 (m, 4H, -OCH$_2$), 3.43 (s, 3H, -OCH$_3$), 3.42 (s, 3H, -OCH$_3$), 2.43–1.50 (m, 18H), 1.53 (s, 12H). ^{13}C NMR (75 MHz, CDCl$_3$) δ: 220.7, 137.1, 119.2, 63.1, 52.0, 46.4, 38.0, 29.8, 29.6, 24.3, 24.2, 20.9. EI-MS m/z (%): molecular ion not observed, 181, 153 (100), 129, 112, 111, 83 (100). CI-MS (NH$_3$) m/z: 274 ([M + NH$_4$]$^+$).

Thermolysis of 3b

A solution of **3b** (0.51 g, 2 mmol) in benzene (20 mL) in a sealed tube was heated at 110°C for 20 h. Evaporation of the solvent left a residue that was chromatographed on silica (hexane:ethyl acetate, 90:10) to afford bicyclic ketone **17** (33%), hydroxyorthoester **18** (~10% after thermolysis), and dimer **19** (ca. 4%).

Product 17

Yield: 33%, colourless oil. IR (neat) (cm^{-1}): 2946, 2861, 1740, 1464, 1452, 1164, 1064, 1044. ^1H NMR (300 MHz, CDCl$_3$) δ: 4.09 (dd, J = 11.8, 6.1 Hz, 1H), 3.60 (d, J = 12.2, J = 4.4, Hz, 1H), 3.39 (s 3H), 2.86 (m, 1H), 1.51–2.26 (m, 8H). ^{13}C NMR (75 MHz, CDCl$_3$) δ: 212.8, 102.5, 65.0, 50.4, 45.4, 40.5, 35.9, 32.0, 17.9. HR-MS m/z calcd. for C$_9$H$_{14}$O$_3$: 170.0943; found: 170.0969.

Product 18

Only a few colourless crystals could be obtained for X-ray diffraction. The compound hydrolysed spontaneously to the corresponding hydroxylactone.

Product 19

Colourless crystals, yield ca. 3%. ^1H NMR (200 MHz, CDCl$_3$) δ: 3.77 (m, 4H), 3.28 (s, 6H, -OCH$_3$), 2.73 (m, 2H), 2.18–1.32 (m, 16H). ^{13}C NMR (75 MHz, CDCl$_3$) δ: 108.9, 84.9, 61.4, 47.9, 42.6, 33.5, 27.8, 27.2, 20.9. The structure and stereochemistry were confirmed by means of single crystal X-ray diffraction.

Synthesis of 3c

A solution in CH$_2$Cl$_2$ of 2-acetoxy-2-methoxy-5,5-dimethyl-Δ^3-1,3,4-oxadiazoline (**1**), containing about 40% of an acyclic isomer (19), was treated with hydroxy ketone **2c** and trifluoroacetic acid in dichloromethane. After washing with dilute base, the organic layer was dried and the solvent

was evaporated. Chromatography of the residue gave pure oxadiazoline **3c** (60%) as a colorless oil. IR (neat) (cm^{-1}): 2959, 2888, 1742, 1458, 1211, 1140, 1104, 917. ^1H NMR (300 MHz, CDCl$_3$, mixture of two diastereoisomers) δ: 3.81–4.02 (overlapping multiplets, 4H), 3.43 (s, 3H), 3.42 (s, 3H), 1.60–2.42 (m, 14H), 1.54 (s, 6H), 1.53 (s, 3H), 1.52 (s, 3H). ^{13}C NMR (75 MHz, CDCl$_3$) δ: 218.5, 136.9, 119.5, 63.6, 63.5, 52.0, 48.8, 38.7, 27.0, 24,3, 24.1, 20.9. EI-MS m/z (%): molecular ion not observed, 211 ([M – OMe]$^+$, 9), 173 (38), 139 (11), 129 (10), 97 (100), 84 (26), 69 (100). CI-MS (NH$_3$) m/z: 260 ([M + NH$_4$]$^+$, 58).

Thermolysis of 3c

A solution of **3c** (0.51 g, 2 mmol) in benzene (20 mL) in a sealed tube was heated at 110°C for 20 h. Evaporation of the solvent left a residue that was chromatographed on silica (hexane:ethyl acetate, 90:10) to afford bicyclic ketone **28** (28%), **25** (10% isolated, unstable compound, hydrolysing, in part, to hydroxylactone **26** during the separation procedure), product **22** (2% isolated, undergoes hydrolyses to α-hydroxylactone **26**), hydroxylactone **26**, product **27**, some of which could have hydrolysed to **26** during TLC separation (5% isolated), and dimers **29** and **30** (about 3% each).

Product 22

Colourless oil. ^1H NMR (200 MHz, C$_6$D$_6$) δ: 4.09 (dd, J = 9.0 Hz, J = 6.4 Hz, 1H), 3.62 (s, 3H), 3.47 (dd, J = 9.0, J = 2.9 Hz, 1H), 2.57 (m, 1H), 2.32 (m, 1H), 2.0–1.55 (m, 4H), 1.54 (s, 3H), 1.50 (s, 3H), 1.27 (m, 1H). ^{13}C NMR (50 MHz, C$_6$D$_6$) δ: 124.8, 109.4, 98.1, 70.9, 51.1, 50.1, 34.2, 31.3, 28.1, 27.7, 25.5. Product **22** hydrolysed easily to **26**.

Product 25

Colourless oil. IR (neat) (cm^{-1}): 3510 (br), 2954, 2881, 1449, 1365, 1168, 1135, 1113, 1045, 982. ^1H NMR (500 MHz, CDCl$_3$) δ: 3.92 (t, J = 10.1 Hz, 1H), 3.37 (dd, J = 10.2, J = 5.6 Hz, 1H), 3.34 (s, 3H), 3.31 (s, 3H), 2.88 (br. s, 1H), 2.34 (m, 1H), 1.98–2.10 (m, 2H), 1.72–1.80 (m, 3H), 1.45 (m, 1H). ^{13}C NMR (125 MHz, CDCl$_3$) δ: 118.2, 90.6, 69.6, 51.5, 50.7, 47.9, 35.1, 32.6, 26.1. EI-MS m/z (%): 189 ([M + 1]$^+$, 5), 157 ([M – OMe]$^+$, 100), 98 (10), 75 (8).

Product 26

Colourless oil. IR (neat) (cm^{-1}): 3425 (br), 2962, 2876, 1765, 1446, 1383, 1211, 1156, 1008, 978. ^1H NMR (200 MHz, C$_6$D$_6$) δ: 3.74 (t, J = 9.3 Hz, 1H), 3.04 (dd, J = 9.4, J = 5.8 Hz, 1H), 2.91 (br s, 1H), 2.29 (m, 1H), 2.00–0.85 (m, 6H). ^{13}C NMR (50 MHz, C$_6$D$_6$) δ: 179.5, 83.6, 71.1, 46.4, 39.0, 31.3, 24.8. EI-MS m/z (%): 143 ([M + 1]$^+$, 41), 112 (10), 98 (94), 97 (100), 83 (19). CI-MS (NH$_3$) m/z: 160 ([M + NH$_4$]$^+$, 100).

Product 27

Colourless oil. IR (neat) (cm^{-1}): 3051, 2954, 2875, 1754, 1642, 1441, 1364, 1202, 1074, 1018, 929. ^1H NMR (200 MHz, C$_6$D$_6$) δ: 5.69 (m, 1H), 4.97 (m, 2H), 4.04 (dd, J = 9.1, J = 6.2 Hz, 1H), 3.69 (s, 3H), 3.43 (dd, J = 9.1, J = 1.6 Hz, 1H), 3.37 (s, 3H), 2.47 (m, 1H), 1.50–2.25 (m, 12H). ^{13}C NMR (125 MHz, C$_6$D$_6$) δ: 171.1, 138.4, 127.1, 115.2, 106.8, 98.7, 71.7, 51.7, 50.1, 36.0, 33.8, 32.7, 31.6, 25.9, 22.1. EI-MS m/z (%): 264 (9), 254 (100), 253 ([M – CO-

(OCH$_3$)]$^+$, 45). HR-MS m/z calcd. for C$_{16}$H$_{24}$O$_6$: 312.1573; found: 312.1555. Compound **27** hydrolysed readily to **26**.

Product 28

Colourless oil. IR (neat) (cm^{-1}): 2947, 2888, 1774, 1449, 1330, 1178, 1094, 959, 721. ^{1}H NMR (200 MHz, CDCl$_3$) δ: 4.28 (dd, J = 8.4 Hz, J = 4.5 Hz, 1H), 4.21 (t, J = 8.4 Hz, 1H), 3.36 (s, 3H), 2.60 (m, 1H), 1.60–2.15 (m, 6H). ^{13}C NMR (125 MHz, CDCl$_3$) δ: 211.9, 102.5, 67.8, 52.0, 45.3, 40.8, 34.6, 18.6. EI-MS m/z (%): 157 ([M + 1]$^+$, 5), 128 (58), 113 (10), 97 (32), 84 (20), 74 (100). CI-MS (NH$_3$) m/z: 174 ([M + NH$_4$]$^+$, 100).

Product 29

^{1}H NMR (200 MHz, C$_6$D$_6$) δ: 4.22 (t, J = 8.6 Hz, 2H), 3.38 (s, 6H), 3.32 (dd, J = 8.6, J = 5.3 Hz, 2H), 2.87 (m, 2H), 2.27 (m, 2H), 1.45–2.05 (m, 10H). ^{13}C NMR (50 MHz, C$_6$D$_6$) δ: 115.2, 92.1, 69.6, 49.2, 47.3, 36.4, 31.5, 25.4. EI-MS m/z (%): 312 ([M]$^+$, 2), 281 ([M – OCH$_3$]$^+$, 9), 141 (81), 140 (100), 139 (63), 112 (62), 111 (42), 79 (27). The structure and stereochemistry were secured by means of single crystal X-ray diffraction. The structure of **30**, an isomer of **29**, was also determined by means of single crystal X-ray diffraction.

Thermolysis of 3a in the presence of dimethyl acetylene-dicarboxylate (DMAD)

A solution of **3a** (0.26 g, 1 mmol) and DMAD (1.3 mmol) in benzene (10 mL) in a sealed tube was heated at 110°C for 20 h. Evaporation of the solvent left a residue that was chromatographed on silica (hexane:ethyl acetate, 90:10) to afford a mixture of diastereomers **32** and **33**. The diastereomers were separated with a Merck (LOBAR, MPLC) silica column, eluent EtOAc–hexane, 10:90).

Product 32

Colourless oil, yield: 3%. IR (neat) (cm^{-1}): 2950, 2860, 2248, 1724, 1439, 1254, 1062, 909. ^{1}H NMR (300 MHz, CDCl$_3$) δ: 4.28 (dd, J = 8.5, J = 4.6 Hz, 1H), 3.77 (s, 3H), 2.69 (d, J = 8.5 Hz, 1H), 3.34 (s, 3H), 3.55 (s, 3H), 3.47 (s, 3H), 2.3 (br. m, 1H), 2.12 (m, 1H), 1.30–1.85 (m, 8H). ^{13}C NMR (75 MHz, CDCl$_3$) δ: 153.2, 126.8, 111.5, 90.2, 80.9, 72.8, 71.8, 52.9, 51.8, 51.4, 43.4, 29.8, 27.8, 23.1, 22.6. EI-MS m/z (%): molecular ion not observed, 281 ([M – CO]$^+$, 32), 229 (13), 140 (35), 111 (100), 93 (64).

Product 33

Colourless crystals, yield: 3%, mp 68°C. ^{1}H NMR (300 MHz, CDCl$_3$) δ: 4.19 (dd, J = 8.6, J = 4.3 Hz, 1H), 3.77 (s, 3H), 3.61 (d, J = 8.7 Hz, 1H), 3.56 (s, 3H), 3.40 (s, 3H), 2.25 (br m, 1H), 2.14 (m, 1H), 1.30–1.90 (m, 8H). ^{13}C NMR (75 MHz, CDCl$_3$) δ: 153.0, 127.0, 112.0, 88.8, 79.5, 72.8, 71.3, 52.9, 52.0, 51.5, 43.8, 30.6, 27.7, 23.1, 22.7. The structure of **33** (Scheme 12) was determined by means of single crystal X-ray diffraction.

Generation of 6-methylene-2,4-cyclohexadienylideneketene by flash photolysis of benzocyclobutenone in aqueous solution and study of the reactions of this ketene in that medium

Y. Chiang, A.J. Kresge, and H.-Q. Zhan

Abstract: Flash photolysis of benzocyclobutenone in aqueous solution produced a transient species with a microsecond lifetime whose rates of decay were measured in perchloric acid, sodium hydroxide, and buffer solutions over the acidity range $[H^+]$ $1 \times 10^{-13} - 10^0$ M. This produced a rate profile, isotope effects, and buffer behaviour typical of ketene reactions, and that, together with product identification, served to identify this transient as 6-methylene-2,4-cyclohexadienylideneketene, formed by electrocyclic opening of the four-membered ring of benzocyclobutenone. Comparison of rates of reaction of this ketene with those of its saturated analog, pentamethyleneketene, produced some expected as well as some unexpected results.

Key words: cyclobutenone chemistry, electrocyclic ring opening, ketene hydration, rate profile, solvent isotope effects.

Résumé : La photolyse éclair de la benzocyclobuténone en solution aqueuse produit une entité transitoire de temps de vie de la microseconde dont on a mesuré les vitesses de décroissance dans l'acide perchlorique, l'hydroxyde de sodium et des solutions tampons dont l'acidité $[H^+]$ s'étale de 1×10^{-13} à 10^0. Sur la base de ces données, on a établi que le profil de vitesse de réaction, les effets isotopiques et le comportement vis-à-vis des tampons sont typiques des réactions des cétènes et, en les combinant à l'identification du produit, on a pu établir que cette entité transitoire est le 6-méthylènecyclohexa-2,4-diénylidènecétène qui se forme par une ouverture électrocyclique du cycle à quatre chaînons de la benzocyclobuténone. Une comparaison des vitesses de réaction de ce cétène avec celles de son analogue saturé, pentaméthylènecétène, a conduit à des résultats dont quelques-uns étaient attendus alors que d'autres étaient inattendus.

Mots clés : chimie de la cyclobuténone, ouverture électrocyclique de cycle, hydratation d'un cétène, profil de vitesse de réaction, effets isotopiques de solvant.

[Traduit par la Rédaction]

Introduction

Three decades ago, Don Arnold, studying the photochemistry of benzocyclobutenone (**1**) (1) corroborated an earlier observation (2) that irradiation of this ketone in methanol solution produced methyl 2-methylbenzoate (**3**). He then postulated that this reaction occured through electrocyclic opening of the four-membered ring to give 6-methylene-2,4-cyclohexadienylideneketene (**2**) followed by the well-known addition of alcohols to ketenes to form the ester product (eq. [1]).

[1]
Support for this hypothesis was provided by subsequent observations (3) that irradiation of benzocyclobutenone in low-temperature hydrocarbon matrices converts it into an unstable but observable substance with UV and IR spectral properties expected of 6-methylene-2,4-cyclohexadienylideneketene. Additional evidence for this structural assignment came from a room-temperature flash photolytic study of benzocyclobutenone in ether solution that showed generation and decay of a transient species whose pattern of reactivity with added reagents agreed with expectation for this ketene (4).

We now add to these previous investigations a flash photolytic study of benzocyclobutenone in aqueous solution. This has allowed comparison of rates of hydration of 6-methylene-2,4-cyclohexadienylideneketene with those of other ketenes, and that has revealed some interesting features concerning the reactivity of this substance.

Experimental section

Materials

Benzocyclobutenone, a gift from Dr. P. Schiess, was made by flash vacuum pyrolysis of 2-methylbenzoyl chloride (5). 2-Methylbenzamide was prepared by treating 2-methylbenzoyl chloride (6) with concentrated aqueous ammonia (7). All other materials were the best available commercial grades.

Kinetics

Rate measurements were made using a nanosecond, eximer laser flash photolysis system operating at λ_{exc} = 248 nm that has already been described (8), and reactions were followed by monitoring absorbance decay at λ = 400 nm. Initial substrate (benzocyclobutenone) concentrations were ca. 1×10^{-5} M, and the temperature of all reacting solutions was controlled at 25.0 ± 0.05°C. The rate data so obtained conformed to the first-order rate law well, and observed first-order rate constants were obtained by least-squares fitting of a single exponential function.

Product analyses

Product compositions were determined by HPLC using a Varian Vista 5500 instrument with a NovoPak C_{18} reverse-phase column and methanol–water (50:50, v/v) as the eluent. Reaction solutions containing substrate at similar concentrations as used for the kinetic measurements (ca. 1×10^{-5} M) were subjected to a single pulse from a microsecond flash photolysis system (9), and products were identified by comparing retention times and UV spectra with those of authentic samples.

Results and discussion

Reaction identification

Flash photolysis of benzocyclobutenone in aqueous solution produced a transient species with strong absorbance at λ = 400 nm. This is the wavelength at which 6-methylene-2,4-cyclohexadienyleneketene showed a strong absorption band when generated in low-temperature matrices (3) or in ether solution at room temperature (4), which indicates that this ketene is generated by irradiation of this precursor in an aqueous solvent just as in these other media. Additional support for this conclusion comes from the fact that 2-methylbenzoic acid (4) was found to be the only product formed by flash photolysis of benzocyclobutenone in unbuffered water and in 0.001 M aqueous perchloric acid solution (eq. [2]) consistent with the known proclivity of ketenes to react with water giving carboxylic acid products (10a).

[2]
In aqueous ammonium ion – ammonia buffers, 2-methylbenzamide (5) was formed as well (eq. [3]) which again is consistent with the known reaction of ketenes with ammonia and amines to give amide products (10b, 11).

[3]

Rate profile

Rates of decay of 6-methylene-2,4-cyclohexadienylideneketene were measured in aqueous perchloric acid and sodium hydroxide solutions and in acetic acid, biphosphate ion, tris-(hydroxymethyl)methylammonium ion, and ammonium ion buffers. The ionic strength of these solutions was maintained at 0.10 M through the addition of sodium perchlorate as required, except in the case of perchloric acid solutions at concentrations greater than 0.1 M, where the ionic strength was equal to the acid concentration. These data are summarized in Tables S1-S3.[2]

The measurements in buffers were made using series of solutions of varying buffer concentration but constant buffer ratio and therefore, because the ionic strength was constant, constant hydronium ion concentration. In each solution series, observed first-order rate constants proved to be linear functions of buffer concentration, and the data were therefore analyzed by least-squares fitting of the buffer dilution expression shown as eq. [4]. The zero-buffer-

[4] $k_{obs} = k_{intcpt} + k_{buff}[\text{buffer}]$

concentration intercepts obtained in this way (k_{intcpt}), together with the rate constants obtained in perchloric acid and sodium hydroxide solutions, are displayed as the rate profile shown in Fig. 1. Hydronium ion concentrations of the buffer solutions needed for this purpose were obtained by calculation using acidity constants of the buffer acids from the literature and activity coefficients recommended by Bates (12).

This rate profile shows a long uncatalyzed portion extending from $[H^+] = 1 \times 10^{-1}$ to $[H^+] = 1 \times 10^{-11}$, with weak hydroxide ion catalysis and even weaker hydronium ion catalysis. Such behavior is typical of ketene hydrations, where the hydroxide ion reaction is only moderately faster than uncatalyzed hydration and acid catalysis is often not observed.[3] This profile therefore provides further evidence that the transient species observed is a ketene.

As is often the case for acid-catalyzed reactions in concentrated acid solutions, rates of hydration of 6-methylene-2,4-cyclohexadienyleneketene in perchloric acid solutions more concentrated than 0.1 M increased more steeply than in direct linear proportion to acid concentration. The data were therefore treated by the Cox–Yates method using the X_o excess acidity function (14). The analysis was done by least-squares fitting of eq. [5], where H^+

[5] $k_{obs} = k_{uc} + k_{H^+}[H^+]10^{mX_o}$

---

[2] Tables of rate data (Tables S1–S4) have been deposited and may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa ON, K1A OS2, Canada (http://www.nrc.ca/cisti/irm/unpub_e.shtml for information on ordering electronically).
[3] See, for example, ref. (13).

Fig. 1. Rate profile for the hydration of 6-methylene-2,4-cyclohexadienylideneketene in aqueous solution at 25°C.

Fig. 2. Correlation of rates of uncatalyzed (k_{uc}) and hydroxide-ion-catalyzed (k_{HO^-}) ketene hydration; 6-methylene-2,4-cyclohexadienylideneketene (●), other ketenes (○).
represents the hydronium ion, with [H$^+$] and X_o as independent variables, and k_{uc}, k_{H^+}, and m as parameters to be determined by the fit. This gave k_{uc} = (1.35 ± 0.01) × 10^5 s^{-1}, k_{H^+} = (1.45 ± 0.03) × 10^5 M^{-1} s^{-1}, and m = 1.20 ± 0.03. This value of m was then used to calculate the quantity [H$^+$]10^{mX_o}, which was used as the abscissa for the rate profile of Fig. 1. Because X_o becomes equal to zero at hydronium ion concentrations less than 0.1 M, and 10^{mX_o} consequently becomes equal to unity, [H$^+$]10^{mX_o} differs from [H$^+$] only at [H$^+$] > 0.1.

With this definition of the abscissa, the rate law that applies to the rate profile of Fig. 1 is the expression shown in eq. [6]. Least-squares fitting of this expression gave k_{H^+} = (1.44 ± 0.01) × 10^5 M^{-1} s^{-1}, k_{uc} = (1.35 ± 0.01) × 10^5 s^{-1}, and k_{HO^-} = (9.26 ± 0.06) × 10^6 M^{-1} s^{-1}. It is

[6] $k_{obs} = k_{H^+}[H^+]10^{mX_o} + k_{uc} + k_{HO^-}[HO^-]$

gratifying that the values of k_{H^+} and k_{uc} obtained in this way are in excellent agreement with those produced by the Cox–Yates analysis of the perchloric acid data.

It has been observed that substituent effects on the rates of uncatalyzed ketene hydration (k_{uc}) are remarkably similar to those on the rates of hydroxide-ion catalyzed hydration (k_{HO^-}) and this similarlity has been used to support a common nucleophilic reaction mechanism for both processes (10a). It has also led to the good correlaton of rate constants for these two reactions illustrated in Fig. 2 (15). This figure also shows that the presently determined data fit this correlation well, thus substantiating identification of the presently observed transient species as 6-methylene-2,4-cyclohexadienylideneketene.

Isotope effects

Rates of hydration of 6-methylene-2,4-cyclohexadienylideneketene were also measured in moderately concentrated solutions of HCl in H$_2$O and DCl in D$_2$O. These data are summarized in Table S4[2] and are displayed in Fig. 3.

Once again, observed rate constants increased more steeply than in direct proportion to acid concentration, and the Cox–Yates method (14) using the X_o scale for HCl (16) was used to analyze the data. The X_o scale has not been determined for DCl in D$_2$O solution, but other acidity func-
Fig. 3. Reaction of 6-methylene-2,4-cyclohexadienylideneketene in aq HCl–H$_2$O (O) and DCl–D$_2$O (Δ) solutions at 25°C.
tions are known to be the same for D$_2$O as for H$_2$O solutions of hydrochloric (17) and perchloric (18) acids when the comparison is made at the same molar acid concentration. It seems reasonable to assume that the same would be true for the X_o scale, and values of X_o for HCl in H$_2$O were therefore used for the D$_2$O solutions.

Least-squares analysis using eq. [5] gave k_{uc} = (1.37 ± 0.02) × 10^5 s^{-1}, k_{H^+} = (1.39 ± 0.09) × 10^5 M^{-1} s^{-1}, and m = (1.64 ± 0.17) for the H$_2$O solutions and k_{uc} = (9.35 ± 0.01) × 10^4 s^{-1}, k_{D^+} = (4.66 ± 0.02) × 10^5 M^{-1} s^{-1}, and m = (1.40 ± 0.10) for the D$_2$O solutions. These values of k_{uc} and k_{H^+} agree well with those determined for H$_2$O solutions of HClO$_4$ (vide supra). The difference between the HCl and HClO$_4$ values of m, on the other hand, is somewhat greater than their combined standard deviations, suggesting that medium effects are not quite the same in concd HCl as in concd HClO$_4$ solutions.

These data provide the isotope effects k_{H^+}/k_{D^+} = 2.98 ± 0.25 and $(k_{uc})_{H_2O}/(k_{uc})_{D_2O}$ = 1.46 ± 0.03. Acid-catalyzed hydration of ketenes is known to occur by rate-determining protonation of the β-carbon atom of the ketene, followed by rapid reaction of the acylium ion thus formed with water

(10c, 19). In the present case, protonation is more likely to occur on the *exo*-carbon atom of the methylene group, because that will regenerate a benzene ring and benefit from a gain of benzene resonance energy (eq. [7]). In any event, there will be a hydron in flight in

[7]
the rate-determining step of this reaction and the isotope effect will consequently have a primary component. It will, however, have an inverse secondary component as well, produced by tightening of the hydrogen–oxygen bonds of the transition state moiety on its way to becoming a water molecule. The isotope effect observed ($k_{H^+}/k_{D^+} = 2.98$) is in fact a typical value for such a process (20).

Uncatalyzed hydration of ketenes, on the other hand, occurs through nucleophilic attack of a water molecule on the carbon atom of the ketene carbonyl group, generating an enol intermediate, which then ketonizes in a fast subsequent step (10a, 15) (eq. [8]). Formation of the

[8]
enol could occur either through a zwitterion, or the zwitterion could be avoided by simultaneous proton shuffling. In either case, the solvent isotope effect would be small because there would be no primary component; in zwitterion formation because no hydron transfer takes place, and in simultaneous proton shuffling because the hydron transfer here is between oxygen atoms with the hydron lying in a stable potential well at the transition state and consequently not being in flight (21). The isotope effect observed ($k_H/k_D = 1.46$) is a typical value for such a process (15).

Reaction in buffers

The rate measurements in acetic acid and ammonium ion buffers were each made at four different buffer ratios, which allowed separation of the buffer-dependent rate constants of eq. [4] (k_{buff}) into their buffer base (k_B) and buffer acid (k_{HA}) components. This was done through the use of eq. [9], in which f_A is the fraction of buffer present in the acid form.

[9] $\quad k_{buff} = k_B + (k_{HA} - k_B)f_A$

Least-squares fitting of this equation gave $k_B = (1.23 \pm 0.07) \times 10^6$ M^{-1} s^{-1} and $k_{HA} = -(8.84 \pm 5.26) \times 10^4$ M^{-1} s^{-1} for the acetic acid buffers, and $k_B = (1.72 \pm 0.11) \times 10^6$ M^{-1} s^{-1} and $k_{HA} = (1.76 \pm 8.99) \times 10^4$ M^{-1} s^{-1} for the ammonium ion buffers. In both cases, therefore, the buffer-dependent reaction was wholly of the basic type.

A similar analysis could not be carried out for the biphosphate and tris-(hydroxymethyl)methylammonium ion buffers because measurements here were made at only one buffer ratio. It seems fair to assume, however, that the buffer-dependent reaction here was also wholly of the basic type, inasmuch as the acid and base strengths of the components of these buffers lie between those (acetic acid and ammonium ion) for which analysis using eq. [9] showed only a

Substrate	k_{HO^-} (M^{-1} s^{-1})	k_{uc} (s^{-1})	k_{H^+} (M^{-1} s^{-1})
	9.26×10^6	1.35×10^5	1.44×10^5
	6.24×10^3	2.30×10^1	2.78×10^3

[a]Aqueous solution, 25°C; data for pentamethyleneketene from ref. (15).

base reaction. Using this reasonable assumption, the buffer-dependent rate constants for the biphosphate and tris-(hydroxymethyl)methylammonium buffers (k_{buff}) were transformed into buffer base rate constants. The results, together with the buffer base rate constants obtained from acetic acid and ammonium ion buffers, are listed in Table 1.

Inspection of Table 1 shows that the reactivity of the buffer bases does not increase regularly with buffer base strength, as it would if the buffer bases were acting as proton transfer agents. Tris-(hydroxymethyl)methylamine, for example, is a stronger base than either acetate or hydrogen phosphate ions, and yet its rate of reaction is only a quarter of that of the ions. The reactivity order shown by Table 1, on the other hand, is what might be expected if the buffer bases were reacting as nucleophiles: tris-(hydroxymethly)methylamine, with its large bulk, should be a poorer nucleophile than the other smaller bases of this table. Bases, of course, react with ketenes as nucleophiles and not as proton transfer agents (11), and the data in Table 1, therefore, provide still more evidence that the substance produced by photolysis of benzocyclobutenone is 6-methylene-2,4-cyclohexadienylideneketene.

Reactivity

Rates of hydration of the presently studied ketene are considerably faster than those of other ketenes whose reactions do not convert a cyclohexadienyl structure into an aromatic benzene ring. The data assembled in Table 2 provide a comparison with pentamethyleneketene (15), a substrate also possessing a six-membered carbocyclic ring. It may be seen that the present ketene is the much more reactive substance, by a factor of 1500, corresponding to a free energy of activation difference of $\delta G^{\neq} = 4.3$ kcal mol^{-1}, for the hydroxide-ion-catalyzed process and by a factor of 5900 or $\delta \Delta G^{\neq} = 5.1$ kcal mol^{-1} for the uncatalyzed reaction. The greater difference for the slower uncatalyzed hydration is of course

understandable as operation of the reactivity–selectivity principle.

The hydronium-ion-catalyzed reaction of 6-methylene-2,4-cyclohexadienylideneketene is also faster than that of pentamethyleneketene, but now the difference, a factor of 52 or $\delta\Delta G^{\neq} = 2.3$ kcal mol^{-1}, is much less than those for the hydroxide ion and uncatalyzed processes. This is surprising, because the hydronium ion catalysis of 6-methylene-2,3-cyclohexadienylideneketene hydration presumably takes place by rate-determining proton transfer to the *exo*-carbon atom of the methylene group, as shown in eq. [7]. This immediately converts a cyclohexadienyl structure into an aromatic ring and profits from a gain in benzene resonance energy. The hydroxide-ion-catalyzed and uncatalyzed reactions, on the other hand, occur by nucleophilic attack on the ketene's carbonyl carbon atom (10*a*, 15), as illustrated for the uncatalyzed process in eq. [8]. Because this nucleophilic attack occurs in the ketene molecular plane (4), it puts negative charge into an orbital that is orthogonal to the cyclohexadienyl π system. Delocalization of this charge into the π system therefore does not occur, and this suggests that aromatization of the cyclohexadienyl ring in the reaction's rate-determining transition state does not take place; the reaction therefore does not benefit from a gain in benzene resonance energy.

These arguments lead to the expectation that hydronium-ion-catalyzed hydration of 6-methylene-2,4-cyclohexadienylideneketene should be faster than that of pentamethyleneketene by an amount greater than those for the hydroxide-ion-catalyzed and uncatalyzed reactions, contrary to the data presented in Table 2. The reason for this unexpected difference is not clear.

Compounds of chromium(VI): The pyridine – chromic anhydride complex, benzimidazolinium dichromate, and three 2-alkyl-1*H*-benzimida-zolinium dichromates

T. Stanley Cameron, Jason A.C. Clyburne, Pramod K. Dubey, J. Stuart Grossert, K. Ramaiah, J. Ramanatham, and Sergei V. Sereda

Abstract: Pyridine, when allowed to react with chromic anhydride under strictly anhydrous conditions, gives the known, very air-sensitive, crystalline 2:1 Lewis acid–base complex **1**. The crystal structure has now been successfully determined. When benzimidazole and three 2-alkyl-1*H*-benzimidazoles were treated with chromium trioxide in aqueous acetic acid, crystalline dichromate salts (**2–5**) were readily formed. These salts consist of dichromate anions linked to the cations by hydrogen bonds of the type N—H···O. The chromium atoms have distorted tetrahedral environments, with the Cr—O distances being typical for dichromate anions. In the cases of the 2-methyl and 2-ethyl salts, the anions are disordered about a centre of inversion. The hydrogen bonding arrangements are discussed and the structures are compared with other oxygenated chromium(VI) species. The dichromate salts are useful selective oxidants for a range of primary and secondary alcohols; examples of these reactions are reported.

Key words: chromium(VI), pyridine – chromium trioxide complex, benzimidazolinium dichromate salts, controlled oxidation of alcohols.

Résumé : La réaction de la pyridine avec de l'anhydride chromique dans des conditions strictement anhydres fournit le complexe acide–base de Lewis 2:1 (**1**), un composé cristallin bien connu et très sensible à l'air. On en a maintenant déterminé la structure cristalline. Le traitement du benzimidazole et de trois 2-alkyl-1*H*-benzimidazoles par le trioxyde de chrome en solution acétique aqueuse conduit à la formation facile de dichromates cristallins (**2–5**). Ces sels sont constitués d'anions dichromates liés à des cations par des liaisons hydrogènes du type N—H···O. Les atomes de chrome se trouvent dans des environnements tétraédriques déformés dans lesquels les distances Cr—O sont typiques pour des anions de dichromate. Dans les cas des sels comportant des substituants 2-méthyle ou 2-éthyle, les anions sont désordonnés autour d'un centre d'inversion. On discute des arrangements des liaisons hydrogènes et on compare les structures avec celles d'autres espèces oxygénées du chrome(VI). Les dichromates sont utiles comme oxydants sélectifs pour tout un éventail d'alcools primaires et secondaires; on rapporte des exemples de telles réactions.

Mots clés : chrome(VI), complexe pyridine – trioxyde de chrome, dichromate de benzimidazolinium, oxydation contrôlée d'alcools.

Introduction

Benzimidazoles constitute an important group of heterocyclic compounds which possess a wide spectrum of biological activity. There have been few reports of 2-substituted benzimidazoles containing sulphur and recent work towards this goal (1, 2) has involved an attempted oxidization at the benzylic position of 2-ethyl-1*H*-benzimidazole to form 2-acetyl-1*H*-benzimidazole, using chromium trioxide in aqueous acetic acid. Instead of a ketone, the substance isolated was a yellow-orange crystalline material containing chromium. Similar materials were formed from three other benzimidazoles. A review of the literature describing nitrogen heterocycles forming complexes and salts with oxygenated

chromium(VI) species revealed that a considerable range of substances has been described, many of which were intended as selective oxidants for organic substrates (3–5). It was apparent that many of these reagents had not been thoroughly characterized, such as by X-ray diffraction techniques. Also, many papers are not cross-referenced to each other. The parent pyridine–chromic anhydride complex $[(C_5H_5N)_2.CrO_3]$ (**1**) was first described by Sisler et al. (6) over 50 years ago. It was suggested that an X-ray crystal structure of the compound would be forthcoming, but to our knowledge the structure has never been published. The complex was reported by Collins et al. (7) as being labile towards aqueous hydrolysis, yielding a species suggested to be dipyridinium dichromate $([(C_5H_5NH)_2Cr_2O_7])$. Other dichromate salts which have been reported include pyridinium (8), quinolinium (9), and 2- and 4-benzylpyridinium (10) and a complex between benzotriazole and chromic anhydride was claimed to be a versatile oxidant (11).

A limited number of nitrogen heterocyclic dichromate salts have been characterized by X-ray crystal diffraction techniques. These include bis(1H$^+$-pyrazinium N^4-oxide) dichromate (12), bis(2-amino-5-nitropyridinium) dichromate (13), ethylenediaminium dichromate (14), and a series of bipyridyl dichromate salts (15). A significant paper by Pressprich et al. (16) reported on the crystal structure of

dipyrazinium trichromate $([(C_4H_4N_2H)_2Cr_3O_{10}])$ and reviewed the bonding in a range of chromate anions. The present work extends this series, correlates work on these species with that on chromic anhydride complexes, introduces another oxidizing agent which showed selectivity for the conversion of primary alcohols into aldehydes, and provides a compact collection of the literature in this area.

reducible species. The complex **1** was prepared using a modification of the original method (6). Pyridine (30 mL, dried by distillation from CaH$_2$), was distilled in a vacuum line (17) on to CrO$_3$ (0.27 g). After 20 min, a yellow precipitate formed in the stirred mixture which was then allowed to stand overnight. Filtration in a nitrogen atmosphere gave a crop of bright red, extremely air-sensitive needles (0.31 g). The IR spectrum (Nujol, Nicolet FT-IR) had ν_{max} 1602, 1246, 1207, 1074, 926 (broad, very strong), 763, 697, 638, 333, 323 cm^{-1} and was similar to a published spectrum (18). The extreme air sensitivity of the complex could account for the fact that its crystal structure has not yet been published — indeed it is the most air-sensitive compound encountered by one of us (TSC) in over 35 years of X-ray crystallography.

Preparation of the benzimidazole–dichromate salts (2–5)

A solution of chromic anhydride or potassium chromate (10 mmol) in aq acetic acid (5% v/v, 10 mL) was added to a solution of the required benzimidazole (10 mmol, commercially unavailable compounds were prepared by the method of Phillips (19)) in aq AcOH (5% v/v, 10 mL) and the mix-

ture was stirred for 15 min. The separated product was filtered, washed (water), and recrystallized twice from dilute aqueous acetic acid to give yellow-orange crystals, with physical data as follows: bis(1*H*-benzimidazolinium) dichromate (**2**) prisms, mp 150–152°; bis(2-methyl-1*H*-benzimidazolinium) dichromate (**3**) plates, mp 148–150°; bis(2-ethyl-1*H*-benzimidazolinium) dichromate (**4**) needles, mp 155–157°; and bis(2-propyl-1*H*-benzimidazolinium) dichromate (**5**) plates, mp 140–143°. IR (KBr) of **4** (cm^{-1}): 2870, 2745, 2630, 1620, 1559, 1455, 1410, 954, 921, 770, 616. ^{1}H NMR (d_6-DMSO) of **4** δ: 1.4, 3.0, 6.0, 7.3, 7.6 (all broad, s, approx. ratio = 3:2:4:2:2). EI-MS of **4** gave the same mass spectrum as 2-ethyl-1*H*-benzimidazole. Classical analyses on **2–5** indicated a 1:1 heterocycle:Cr stoichiometric ratio.

X-ray data collection and structure refinement

An X-ray structural study of **1–5** was performed with a Rigaku AFC5R diffractometer, using a 12 kW rotating anode and graphite-monochromated Mo-K$_\alpha$ radiation. The crystal of **1** was sealed into a glass capillary while the others were mounted on glass fibers. Data were collected at 296 ±

C6-N2-Cr1	117.6(6)

^{a}Other C—C bond distances were in the range of 1.364(3)–1.367(3) Å.

Structures were solved by direct methods (SIR92 for **1**, **3**, **4** (20), SHELXS97 for **2**, **5** (21)), expanded using Fourier techniques (DIRDIF-94) (22), and refined by full-matrix least-squares techniques in a fully anisotropic approximation for **2**–**4** and a partial anisotropic approximation for **1** and **5**. It should be noted that the crystal of **5** was a very weak scatterer. Structures for **1**–**4** were refined on F^2 using

Fig. 2. The structure of bis(1*H*-benzimidazolinium) dichromate (**2**) showing 50% probability thermal ellipsoids, together with the hydrogen bonding network in the crystal.
SHELXL97 (21) whereas that for **5** was refined on *F* using teXsan (23). Extinction parameters were refined for all structures and the Flack parameter was refined for **1.** Hydrogen atoms were not located in Fourier difference maps; they were set geometrically and included in the final refinement with fixed positional and thermal parameters. Corrections for Lorentz and polarization effects were applied. An absorption correction (ψ scan) was applied to **3** and **5** and a decay correction was applied to **5** (decay –38.4%). Neutral atom scattering factors were from Cromer and Waber (24), anomalous dispersion effects were included in F_{calc} (25), the values for the values for $\Delta f'$ and $\Delta f''$ were those of Creagh and McAuley (26), and the values for the mass attenuation coefficients are those of Creagh and Hubbell (27).

Controlled oxidation of alcohols using 4

A solution of the alcohol (2.5 mM) in glacial acetic acid was added in portions to a stirred suspension of **4** (1.25 g, 2.5 mM) in glacial acetic acid at room temperature. After 30 min the colour had changed from orange-yellow to green and the reaction was worked up by pouring into water, followed by a regular extraction procedure with diethyl ether. The residual benzimidazole could be recovered from the aqueous layer by adjusting the pH. A selection of results is presented in Table 4.

Results and discussion

The preparation of compound **1** proved to be challenging owing to its great air sensitivity. However, nicely crystalline material was obtained, which resulted in the well-defined crystal structure depicted in Fig. 1, with selected geometrical parameters for **1** being given in Table 5. The chromium atom is bonded to five ligands in an almost perfect trigonal bipyramid. It should be noted that this structure can be refined in either of the space groups *C*2 or *C*2/*c*. In *C*2/*c* the Cr—O(3) bond should be coincident with a twofold axis, but this results in the anisotropic thermal parameters of O(3) being unreasonably distorted with the ratio 4.3:1 of the displacement parameters across and along the Cr—O(3) bond. The mean *abs*(E^2 – 1) value for all general reflections *hkl* was 0.809, where the values predicted for centric and acentric cells are 0.968 and 0.736, respectively. Nevertheless, with the structure being so nearly centrosymmetric, the distinction between *Cc* and *C*2/*c* will be a matter of opinion. The structure was therefore refined in *C*2, the refinement proceeding routinely, without recourse to disorder.

The mean chromium—oxygen bond length at 1.626 Å is slightly longer than the mean nonbridging chromium—oxygen bond length of 1.599(5) Å in the parent $(CrO_3)_\infty$ (28) and is intermediate between the single (1.736(2) Å) and double

(1.578(2) Å) bonds in the chromate ester (CrO$_2$(OCPh$_3$)$_2$) (29). The mean of the two chromium—nitrogen bonds at 2.150 Å can be compared with typical lengths of 2.158–2.178 Å for the nitrogen—chromium(VI) bond (30). More specifically, comparison can be made with the lengths of the chromium—nitrogen bonds in oxodiperoxopyridinechromium(VI) ([CrO$_5$·C$_5$H$_5$N]) at 2.047(13) Å (31, 32) and in the complex with chromyl chloride of a secondary amine chlorodioxo-(2,2,6,6,-tetramethylpiperidine)chromium(VI) ([CrO$_2$Cl(NC$_9$H$_{18}$)]) at 1.81(1) Å (33). The latter compound is not actually a complex, but has a formal N—Cr bond. It is also instructive to make comparisons with some other Lewis acid–base complexes involving pyridine. Three examples, with the N—X bond distance in brackets, are pyridine–boron trichloride (1.592(3) Å) and pyridine–boron trifluoride (1.604(5) Å) (34), examples of strongly bound complexes to a small electrophilic atom, with the third example, pyridine 1-sulphonate (1.829 Å) (35), being a strongly bound larger electrophile.

Another noteworthy feature of **1** is that the planes of the two pyridine rings are twisted at an angle of ca. 60° with respect to each other, as would be expected if electron-pair repulsions are to be minimized. These data are overall in accord with the bonding between the pyridine rings and the chromic anhydride being a classic example of a Lewis acid–base complex. A trigonal pyramidal structure for **1** was originally proposed by Sisler et al. (36). The IR spectrum of **1** is not especially informative, although the strong band at 926 cm^{-1} likely results from Cr—O stretching vibrations (31). Confirmation that the pyridine–chromic anhydride complex is monomeric is consistent with its solubility prop-

erties in organic solvents (37), with dissolution in dichloromethane avoiding the pyrophoric nature of the complex dissolved in pyridine. This complex has been used for many years as a selective oxidant for organic alcohols, although many procedures and stoichiometric ratios have been published, especially for the selective oxidation of primary alcohols to aldehydes (37).

The isolation of the dichromate salts **2**–**5** offered the opportunity to explore their chemistry and to supplement the limited literature on the structural features of heterocyclic chromate salts. A picture of compound **2** (50% probability thermal ellipsoids) is given in Fig. 2 while selected geometrical parameters are given in Table 6.

In compounds **3** and **4**, the chromate anions are disordered about $\bar{1}$, with oxygen atom O(2) occupying two positions and the two CrO$_3$ groups being staggered with respect to each other. The geometry of chromate anions, associated with heterocyclic cations, of general form [R$^+$]$_2$[Cr$_n$O$_{3n+1}$]$^{2-}$, continues to attract attention (12, 16, 38, 39). A smooth correlation of terminal and bridging Cr—O distances with increasing degree of polymerization has been noted (16). The lengths of the bridging Cr—O bonds in **2** are 1.794(2) and 1.795(2) Å, but are 1.78(1) and 1.80(1) Å in **5** for a mean of 1.79 Å; the terminal bonds of both **2** and **5** are clustered around a mean value of 1.60 Å. These may be compared with the literature values of 1.780(7) and 1.615(18) Å, respectively (16). The nonbridging bond angles are close to tetrahedral at 105.98(13)–112.0(2)° in **2** and 106.7(7)–112.3(8)° in **5**, whereas the bridging bond angles are 129.25(14), 130.4(3), 134.0(4), and 123.2(6)° for the four salts, respectively. Again, these are comparable to literature values, namely, 127.0(4)° (12), 122.7(1)° (13), 124.7(8)° (14), and 135.3(5)° (15). These numbers show that there is considerable flexibility in the bonding about the bridging oxygen atom. The ability of dichromate anions to build an acentric polar framework has been studied by Pecaut and Masse (13) in connection with attempts to design efficient organic–inorganic nonlinear optical crystals. Compounds **2**–**5** have nonpolar space groups, with symmetrical molecular arrangements. The dimensions of the dichromate anions in **3** and **4** are similar to those of **2** and **5** but the structures of **3** and **4** are disordered.

Hydrogen bonds, of the type N—H···O, play a crucial role in determining the molecular packing in these systems. Interestingly, the hydrogen bonding networks in the four structures are different, as outlined in Table 7. These values are in general agreement with published values for such hydrogen bonds (40–42). In **2**, each dichromate anion is linked to five benzimidazolinium cations through three strong hydrogen bonds and a pair of bifurcated hydrogen bonds (Fig. 2). Five of the seven oxygen atoms are involved in the hydrogen bonding, but oxygen atoms O(1) (and by symmetry, O(5)) are not. These two oxygen atoms, therefore, have larger thermal parameters than the other four terminal oxygen atoms. These facts are mirrored in the chromium—oxygen bond lengths (Table 6). The molecular structure thus takes on the form of an infinite molecular chain along *a*, which is joined together by the fifth hydrogen bond (N(1)—H(9)···O(4)) in a molecular layer in plane (010). In contrast to this, structure **3** has two hydrogen bonds which create a molecular sheet in plane (201), while in **4** there is a bimolecular chain along

	N4—H15⋯O7	0.95	2.03	2.95(3)	163.4

(001) and in **5** there is simply a three-dimensional network. When the alkyl side chain is a methyl or ethyl group, a larger cavity than for **2** is created for the dichromate anion and the hydrogen bonding occurs only to two of the terminal oxygen atoms. Since there is no hydrogen bond to the bridging oxygen atom, the anion can become disordered. When the alkyl side chain is a propyl group, the cavity for the anion is again smaller with hydrogen bonding to both terminal and bridging oxygen atoms. The anion is now no longer disordered. In some cases (structures **2** and **3**) the cations are unfavourably stacked with nearly parallel directions of their dipoles, the interplane distances being in the range 3.45 to 3.60 Å. Thus, hydrogen bonding plays an important role in these structures, compensating for the repulsions between the adjacent cations.

Finally, these dichromate salts appear to have some useful chemical properties. We have found that the selective oxidation process described in this work, using equimolar amounts of **4** and the alcohol in glacial acetic acid, is simple to carry out and does not require rigorously anhydrous conditions. Work up is straightforward and the reaction is efficient in terms of reagent use since the benzimidazole can be recovered. Studies were carried out using the other benzimidazolinium salts, **2**, **3**, and **5** as oxidants, but **4** gave somewhat superior results. Compounds **3–5**, but not **2**, gradually and irreversibly darkened on standing in the air, presumably because of a slow surface oxidation of the heterocyclic side chain. However, the process did not appear to yield any synthetically useful quantities of oxidized heterocycles.

Conclusions

Crystals of the strong oxidant $CrO_3 \cdot Pyr_2$ were prepared and characterized by X-ray crystallography more than 50 years after the compound was first prepared. A series of benzimidazolinium dichromate salts was prepared and characterized, their crystal structures were studied and their utility as selective oxidants for alcohols was explored.

Alkali metal ion controlled product selectivity during photorearrangements of 1-naphthyl phenyl acylates and dibenzyl ketones within zeolites

M. Warrier, Lakshmi S. Kaanumalle, and V. Ramamurthy

Abstract: Photochemical behaviors of 1-naphthyl phenyl acylates and dibenzyl ketones included in zeolites have been compared. 1-Naphthyl phenyl acylates while in solution produce eight photoproducts; within NaY it gives a single product. The selectivity is attributed to the restriction brought on the mobility of the primary radical pair by the alkali metal ions present in zeolites. Photochemistry of dibenzyl ketones within NaY reveals that the intersystem crossing in caged radical pairs could be influenced by the heavy alkali metal ions. Structures of complexes among Li^+ ion and the guest 1-naphthyl phenyl acetates and dibenzyl ketone computed at the B3LYP level have been useful to understand the origin of the observed product selectivity within zeolites.

Key words: photo-Fries reaction, zeolites, cation–π interaction, spin-orbit coupling, heavy atom effect.

Résumé : On a comparé les comportements photochimiques des phénylacylates de 1-naphtyle et des dibenzylcétones inclus dans des zéolites. Les phénylacylates de 1-naphtyle en solution conduisent à huit photoproduits alors qu'il ne s'en forme qu'un lorsqu'ils sont inclus dans NaY. On attribue la sélectivité à la restriction imposée à la paire de radicaux primaires par les ions des métaux alcalins présents dans les zéolites. La photochimie des dibenzylcétones dans NaY révèle que le passage entre systèmes dans une paire de radicaux en cage peut être influencé par les ions des métaux alcalins lourds. Les structures des complexes entre l'ion Li^+ et les molécules de phénylacétates de 1-naphtyle et de dibenzylcétones qui ont été calculées au niveau B3LYP se sont avérées utiles pour comprendre l'origine de la sélectivité des produits qui a été observée pour les réactions dans les zéolites.

Mots clés : réaction de photo-Fries, zéolites, interaction cation–π, couplage spin-orbite, effet d'atome lourd.

Introduction

Photo-Fries rearrangement of phenylacetate and photo-Claisen rearrangement of allylphenyl ether yield *ortho*-hydroxy and *para*-hydroxy isomers as products (Scheme 1) (1). In solution, independent of the polarity of the medium, one obtains a mixture. On the other hand, within alkali metal ion exchanged X and Y zeolites, *ortho*-hydroxy isomers are obtained as the major products from phenylacetate and allyl-phenyl ether (2). Selectivity obtained within zeolites was very high even during the photo-Fries rearrangement of 1-naphthyl acetate and 1-naphthyl benzoate (Scheme 1) (3). The results with 1-naphthyl esters suggested that zeolites could favor the formation of a single product (2-acetyl-1-naphthol and 2-benzoyl-1-naphthol) by discriminating among three possible photoproducts, all of which may be formed with equal probability in isotropic media.

Both photo-Fries and photo-Claisen rearrangements proceed via a similar mechanism (1). Promotion to the excited singlet state results in fragmentation of the ester and the ether. Cage escape, recombination, and hydrogen migration

result in both the *ortho-* and the *para*-isomers (Scheme 2). However, the factors that control the outcome of the products vary with the nature of the medium. In solution, it is the electron densities at various aromatic carbons in the aryloxy radical which control the regioselectivity. We suggested that the selectivity within zeolites resulted from the restriction imposed on the mobility of the aryloxy and the acetyl fragments by the cations present in zeolites (2). Vasenkov and Frei (4) provided support for the existence of Na^+-acetyl radical interaction within solvent-free NaY through time-resolved FT-IR spectroscopy. They also confirmed that only 2-acetyl-1-naphthol is formed upon photolysis of 1-naphthyl acetate within solvent-free NaY. The acetyl radicals generated by photolysis of 1-naphthyl acetate (reacting from excited singlet state) within NaY decay following a single exponential law with a lifetime of 71 ± 15 μs. The acetyl radical generated from pinacolone (reacting from triplet state) has a much longer lifetime (315 ± 30 μs). The difference in lifetime between singlet and triplet radical pairs suggested that the reactivity of the reactive radical generated from the excited singlet and triplet states of the precursors

would behave differently. Further, the long lifetime (μs) of the acetyl radical suggested that the ortho and (or) para selectivity in photo-Fries reaction would depend on the nature of the "spin" of the primary radical pair. To test these possibilities and to further explore the selectivity in photo-Fries reactions in naphthyl systems we have exmined the photobehavior of three 1-naphthyl phenylacyl esters **1a–1c** and three dibenzyl ketones **2a–2c** (Scheme 3) (5). The study mainly consisted of photoproducts analysis. To gain an insight into the alkali ion binding to the reactants within zeolites density functional theory (DFT) calculations were performed. Results of these studies are presented in this report.

Results

Photolysis of 1-naphthyl phenylacyl esters 1a–1c

Photolysis of 1-naphthyl phenylacyl esters **1a–1c** in hexane resulted in a mixture of products (Scheme 4), yields of which are presented in Table 1. The product distributions obtained in this study is identical to the ones reported by Gu and Weiss (6) recently. Photolysis of **1a–1c** within different cation-exchanged zeolites, however, showed formation of mainly the *ortho-* rearrangement product (2-phenylacyl-1-naphthol (**3**)) accompanied by minor amounts of 1-naphthol (**8**) (Table 2). Percentage conversion for the same length of

irradiation and for the same loading level of **1a–1c** within zeolites decreased from light alkali metal ion-exchanged zeolites (e.g., LiY) to heavy alkali metal ion-exchanged zeolites (e.g., TlY) (Table 2). Based on our earlier studies (7), facile intersystem crossing leading the reactive excited singlet esters into their unreactive triplet state was suspected for the decrease in reactivity within heavy alkali metal ion-exchanged zeolites. To ascertain this possibility, emission spectra of **1a–1c** in different alkali metal ion-exchanged zeolites at 77 K were recorded. As seen in Fig. 1 for 1-naphthyl phenylacetate, the emission was mainly fluorescence in LiY and NaY and mainly phosphorescence in CsY and TlY. Similar emission behavior was obtained in the case of **1b** and **1c**.

Photolysis of dibenzyl ketones 2a–2c

Photolysis of dibenzyl ketones **2a–2c** in hexane yielded only the decarbonylation products 1,2-diphenyl ethane, 2,3-diphenyl butane, 2,3-diphenyl 2,3-dimethylbutane, respectively (Scheme 4, Table 3). These results are consistent with the original reports by Engel (8a), Robbins and Eastman (8b), and Turro and co-workers (8c, 8d). The same products obtained in hexane were formed upon photolysis of **2a** and **2b** in light-atom-exchanged zeolites (e.g., LiY and NaY) (Table 3). Photolysis of **2a** and **2b** in heavy-atom-exchanged zeolites such as CsY and TlY resulted in rearrangement products, 2-methyl-phenyl benzyl ketone and 4-methyl-phenyl benzyl ketone, and 2-ethyl-phenyl α-methyl benzyl ketone and 4-ethyl-phenyl α-methyl benzyl ketone in addi-

tion to 1,2-diphenylethane and 2,3-diphenylbutane, respectively (Scheme 4) (9). The relative yields of the rearrangement products (2-alkyl and 4-alkyl-phenyl benzyl ketone) with respect to the decarbonylated products were dependent on the rates of decarbonylation of the phenyl acyl radical which in turn depended on the stability of the benzylic radicals formed. For example, in the case of dibenzyl ketone (**2a**), which forms, after decarbonylation, a primary benzyl radical, yield of the rearrangement products was as high as 79% in TlY zeolite (Table 3). In the case of

[b]In addition to **11c**, cumene and α-methylstyrene are formed as minor products. The yield on this column represents all three.

α,α,α′,α′-tetramethyl dibenzyl ketone (**2c**), where a stable substituted tertiary benzyl radical is formed, the yield of the rearrangement products was <1% in TlY (Table 3).

Alkali metal ion interaction with 1-naphthyl phenylacyl esters and dibenzyl ketones probed through computations

To gain a better insight on the role of cations (present within zeolite supercages) on the observed photobehavior of naphthyl esters and dibenzyl ketones within zeolites, density functional theory (DFT) calculations on Li[+] binding to 1-naphthyl phenyl acetate and dibenzyl ketone were carried out (10). The polarized 6-31G* basis set was used for C, H, O, and Li. In view of the complexities involved in the reactions inside the zeolite cage, the goals of the computational work were necessarily limited to a few specific aspects. First, the magnitude of the interaction energies among Li[+] and 1-naphthyl phenyl acetate and dibenzyl ketone were quantified. This provided a measure of the potential role of different cations in altering the reactivity of 1-naphthyl phenyl acetate and dibenzyl ketone. In addition to the energy, the structures of lithium ion – 1-naphthyl phenyl acetate and lithium ion – dibenzyl ketone complexes were analyzed. Interaction energies of Li[+] were determined based on gas-phase optimized geometries of metal ion complexes with 1-naphthyl phenyl acetate and dibenzyl ketone.

The computed geometries of 1-naphthyl phenyl acetate and dibenzyl ketone are shown in Figs. 2 and 3. In both the cases, two low energy conformers were identified and these were used for complexation with lithium ion. Intuitively, binding of Li[+] is expected to be higher with the substrate when it interacts simultaneously with either two aryl rings or an aryl ring and a carbonyl chromophore. Thus, we have chosen initial guess geometry with the Li[+] positioned between the two functional groups. During the calculation the cations were free to move to find the most stable position. Calculations did not include any structural moiety from the zeolite. In the case of 1-naphthyl phenyl acetate, three geometry-optimized structures obtained upon metal ion complexation along with their interaction energies are shown in Fig. 2. Interaction energies of Li[+] to 1-naphthyl phenyl acetate were almost similar in all three structures. Two geometry-optimized structures for the lithium ion complex with dibenzyl ketone were obtained (Fig. 3). Since within a zeolite, the cations are bound to oxygen counter ions, the metal ions are likely to interact less effectively with 1-naphthyl phenyl acetate and dibenzyl ketone than the com-

puted values. Nevertheless, the interaction between the alkali metal ion and the substrates is expected to be significant within zeolites.

Discussion

Details of the photo-Fries reaction of 1-naphthyl phenylacyl esters in solution and polymer medium have recently been discussed by Gu, Weiss, and co-workers (5). Product distributions obtained upon photolysis of esters **1a**–**1c** in hexane could be understood based on the mechanism provided in Scheme 5. Homolytic cleavage of the esters occurs from their excited singlet state to yield singlet geminate radical pair **A**. It is followed by in-cage recombination (giving rearranged products **3** and **4**) or cage escape. Decarbonylation of phenylacyl radical within the cage results in the radical pair **B** and outside the cage leads to naphthoxy and benzyl free radicals. Reactions of these two radicals either within or outside the cage result in products **5**–**8**, and product **9** is the result of coupling between two alkyl radicals outside the cage. In this study we make use of the photo-Fries reaction of 1-naphthyl phenylacyl esters to establish that zeolites are capable of influencing the product distributions in a reaction that gives as many as eight products. Further, the reaction allows us to probe the characteristics of zeolite cages, knowledge of which could be further used to control photoreactions. All our conclusions are based on photoproduct distributions and attempts to monitor the rates of reactions through time-resolved diffuse reflectance laser techniques were not successful. The following aspects of the mechanism presented in Scheme 5 are noteworthy. The relative ratio of products **3** to **4**, and **5** to **6** provide information about the rotational mobility of reactive fragments present in cages **A** and **B** (Scheme 5). The relative yields of products **8** and **9** give an indication about the translational mobility of radical fragments. The relative selectivity observed in the photo-Fries products **3** and **4** and the decarbonylated products **5** and **6** provides valuable information concerning restrictions imposed by the zeolite on different time scales.

When 1-naphthyl phenylacyl esters **1a**-**1c** were irradiated in hexane, eight photoproducts (shown in Scheme 4) were formed and the relative yields remained the same independent of the conversion in the range 5–40% (Table 1). Upon photolysis of 1-naphthyl phenylacyl esters **1a**–**1c** within LiY, NaY, and KY zeolites led essentially to a single product **3** (Table 2). The selectivity was dramatic, going from eight products in hexane solution to a single product (2-phenylacyl 1-naphthol (**3**)) in zeolites. For this to happen,

the two primary radicals in **A** formed upon photofragmentation must be coupling before the decarbonylation of phenylacyl radical. Thus, two questions need to be addressed: (*a*) Why is the *ortho*-isomer (2-phenylacyl 1-naphthol **3**) alone formed?; and (*b*) Why do the primary phenylacyl (and related) radicals not decarbonylate within zeolites, or why is the coupling of radical in cage **A** faster than decarbonylation?

Scheme 5.
If one accepts that the two reactive fragments, naphthoxy and phenylacyl radicals, would be held close to each other by the intrazeolite cations, preference for ortho coupling to yield **3a**–**3c** over the para coupling to yield **4a**–**4c** is understandable. This suggestion is based on the optimized structures for the Li^+ – 1-naphthyl phenyl acetate complex shown in Fig. 2. Photofragmentation of the Li^+ – 1-naphthyl phenyl acetate complex present in these structural forms would lead to naphthoxy and phenylacyl radicals being held close to each other by the alkali metal ion. Lack of separation enforced by the zeolite wall and the alkali metal ion would place the two radicals, having opposite electronic spins (favorable for bond formation), close to one another. Due to restricted mobility enforced by the alkali metal ion, the attack of the acyl fragment would occur at the nearest available position on the aromatic ring, namely the 2-position of the naphthoxy ring.

The lack of formation of products **5**–**9** implies that the primary radical pair **A** do not proceed to the radical pair **B**. This suggests that the recombination of the naphthoxy and phenylacyl radicals within a zeolite must be rapid compared with cage diffusion and decarbonylation of the phenylacyl radical. The rates of decarbonylation of phenylacyl and 1-methyl 2-phenylacyl and 1,1′-dimethyl 2-phenylacyl radicals have been estimated to be 4.8×10^6 s^{-1}, 4.0×10^7 s^{-1}, and 1.5×10^8 s^{-1}, respectively (11). It is important to note that even in **1c** where the intermediate 1,1′-dimethyl 2-phenylacyl radical decarbonylates ~30 times faster than phenylacyl radical, no decarbonylation products were obtained within zeolites and the only product obtained was 2-phenylacyl 1-naphthol **3c**. Given this, the rate of diffusion of the radical pair **A** out of the cage must be smaller than the maximum rate of decarbonylation observed in the case of 1,1′-dimethyl

2-phenylacyl radical (1.5×10^8 s^{-1}). In the absence of data relating to the rate of decarbonylation within zeolites, we can only speculate that the lack of products due to decarbonylation and radical pair **B** is most likely due to the fact that the rate of recombination in the case of cage pair **A** is faster than the rates of decarbonylation and cage escape. Intuitively then, if the recombination step can be slowed the decarbonylation could become competitive. This led us to explore the photochemistry of dibenzyl ketones, where the same phenylacyl radical would be produced as part of a triplet radical pair. Results of these are discussed below.

At this point, a discussion on the lack of reactivity of the naphthyl esters within heavy alkali metal ion exchanged zeolites is appropriate. An important observation within CsY and TlY was that no photoproducts from **1a**–**1c** were observed in these zeolites. Enhanced intersystem crossing efficiency in heavy cation exchanged zeolites and the fact that these esters are unreactive in their triplet states explain the lack of reactivity within CsY and TlY. Evidence for intersystem crossing can be found in the emission spectra for the ester **1a** in different cation exchanged zeolites shown in Fig. 1. Fluorescence predominates in light atom zeolites like LiY and NaY. Within KY and RbY, phosphorescence increases at the expense of fluorescence. In TlY there is only phosphorescence, suggesting complete population of the triplet state. Consistent with this, naphthyl esters **1a**–**1c** were unreactive within TlY.

Upon excitation, dibenzyl ketones similar to 1-naphthyl phenylacyl esters, yield products via two stages of radical pair formation, α-cleavage to yield primary caged radical pair **A** and decarbonylation to give the secondary free radicals (or radical pair **B**) (Scheme 6) (12). An important difference among 1-naphthyl esters and dibenzyl ketones is that

Scheme 6.
the former reacts from S_1 to give the singlet radical pair and the latter from T_1 to give the triplet radical pair. The radical pair **A** resulting from dibenzyl ketones following intersystem crossing can undergo coupling to yield the rearrangement products 4-methylphenyl benzyl ketone and 2-methylphenyl benzyl ketone or decarbonylate (following or prior to intersystem crossing) to yield the caged radical pair **B** or diffuse apart to give two free radicals. Since intersystem crossing is required for the formation of rearrangement products, relative yields of 4-methyl-phenyl benzyl ketone and 2-methylphenyl benzyl ketone with respect to decarbonylated products (diphenylethanes) provides information concerning the extent of restriction imposed by zeolite cages on longer time scales (compared with 1-naphthyl phenylacyl esters chemistry) on the radical pair **A**. Further, the dibenzyl ketone systems allow us to probe the influence of heavy cations on the intersystem crossing process in radical pairs.

Decarbonylation to give diphenylethanes is the only reaction upon irradiation of dibenzyl ketones **2a**–**2c** in hexane solution (Scheme 4) (12). Decarbonylation accounted for >90% of the products when the dibenzyl ketones **2a**–**2c** included in zeolites LiY, NaY, and KY were photolyzed. This behavior was distinctly different from that of the naphthyl esters **1a**–**1c** which did not decarbonylate within the same zeolites. We had indicated above that if we could slow the rate of recombination of the geminate radical pair it might be possible to observe decarbonylation of phenylacyl radicals within zeolites. Results with the dibenzyl ketones suggest that we have achieved this goal. Because of the triplet character of the radical pair, even close proximity and lack of mobility are unable to favor the recombination of the radical pair over the decarbonylation process. The fact that the "spin" prevents the recombination of the radical pair is evident from the dependence of the product distribution on the alkali metal ion present in zeolites. Higher yields of rearrangement products (4-methylphenyl benzyl ketone and 2-methylphenyl benzyl ketone) from dibenzyl ketone were obtained within heavy alkali metal ion exchanged zeolites (Ta-

ble 3). Similar dependence of product distribution on the alkali metal ion was observed in the case of α,α′-dimethyl-dibenzyl ketone **2b**. Significantly, the ketone **2c** gave only 2,3-diphenyl-2,3-dimethyl butane, α-methyl styrene, and cumene in all zeolites.

Turro and Zhang (13) rationalized the variations in the yield of the rearrangement products from **2a** within MX zeolites on the basis of "cation size effect". Within X zeolites the yield of the rearranged products 4-methylphenyl benzyl ketone and 2-methylphenyl benzyl ketone were dependent on the size of the cation; larger the size, higher the yield. They proposed that smaller free volume within a cage would restrict the mobility of enclosed radicals and thus prolong the lifetime of the triplet radical pair. Long lifetime would favor intersystem crossing and recombination to yield the rearranged products. Thus, cations with larger sizes are predicted to yield more rearrangement products. This feature is unlikely to play a role in Y zeolites, which contain fewer cations. The supercage of X zeolites contains four type II and ~3.5 type III cations whereas Y zeolites contain four type II cations and no type III cations. Absence of type III cations makes more room for the guest molecules. Also, if cage free volume was a major factor, cation size would influence product distributions accordingly. Ionic radii of different cations are shown in Table 4. Product distributions in KY and TlY provide an ideal case to compare and discuss size effects on product formations during the photolysis of **2a**. Both cations K+ and Tl+ are of the same size but differ in their spin orbit coupling parameters by 2 orders of magnitude (Table 4). Rearrangement products are produced in much larger yields in TlY than in KY. This suggests that size is not the most important parameter in deciding selectivity within Y zeolites.

A comparison of the results observed with dibenzyl ketones and 1-naphthyl phenylacyl esters provides an insight into how a zeolite may be influencing the reactivity of intermediates generated within its cages. First, let us compare the behavior of dibenzyl ketone **2a** and 1-naphthyl phenylacyl ester **1a**. Both systems upon photolysis generate phenylacyl

radical. In NaY while **1a** quantitatively rearranged to **3**, **2a** gave only 10% of the rearranged products **12** and **13** (Scheme 4). Clearly, in the later case, the phenylacyl radical decarbonylates before it has a chance to recombine to form the rearranged products. This difference, we believe, is the result of the spin state of the geminate radical pair. When a mechanism to spin interconversion is provided as with TlY, the yields of the rearranged products from **2a** increased to ~79%, suggesting that the spin barrier is the main reason for the lack of rearrangement in **2a**. An insight into the process is gained by comparing the behaviors of naphthyl ester **1c** and dibenzyl ketone **2c**. While the former gives the rearranged product **3** quantitatively, the latter gives only the corresponding decarbonylated product **11c**. In this case due to the presence of α-methyl groups, the decarbonylation occurs 30 times faster than in unsubstituted phenyl acyl radical (compare the rates of decarbonylation of phenylacyl and 1,1′-dimethyl 2-phenylacyl radicals: 4.8×10^6 s^{-1} and 1.5×10^8 s^{-1}) (11). Since we would have detected 1% of the rearranged product by GC, we believe that the rate of Tl$^+$ induced ISC in the geminate pair (**A**^{3} to **A**^{1}, Scheme 6) must be $<1 \times 10^6$ s^{-1}. Thus, a comparison of the results observed with dibenzyl ketones and naphthyl esters suggest that lack of products due to decarbonylation in the case of naphthyl esters **1a**–**1c** is due to the fact that the primary radical pair **A** is formed in the singlet state. Based on the computed structures for lithium ion – dibenzyl ketone complexes (Fig. 3), one would expect that the radical pairs resulting from fragmentation of dibenzyl ketone would be held close to each other within a zeolite cage. The structures of the complexes being similar in dibenzyl ketone and 1-naphthyl phenyl acetate one would expect the primary radical pair to be positioned in a similar manner from the two systems within a zeolite cage facilitating the formation of the rearranged products. The lack of rearranged products in the dibenzyl ketone system within LiY and NaY suggests that restricting the mobility of the radical pair near one another alone is not sufficient. Coupling between the two radicals can occur only when they have the singlet spin. In dibenzyl ketone systems where the radical pair is produced in the triplet state the limiting factor for coupling is the spin. When the mechanism for spin interconversion becomes available as within heavy cation exchanged zeolites the rearranged products are formed. Thus, the cations serve two roles: they restrict the mobility of the radical pair and provide a mechanism for spin interconversion.

Summary

Photochemistry of a series of 1-naphthyl phenylacyl esters and dibenzyl ketones were investigated in different cation exchanged zeolites. Naphthyl esters which give eight products in isotropic solution give essentially a single product within light alkali metal ion exchanged zeolites. Consistent with the known triplet reactivity of these molecules, within heavy alkali metal ion exchanged zeolites no photoproducts were obtained. Most importantly, within light alkali metal ion exchanged zeolites these molecules do not undergo decarbonylation. The reaction stops at the stage of the primary radical pair and observed products are formed from this radical pair. Alkali metal ion binding to the reactant ester in a cooperative fashion to two parts of the reactant molecule is suggested to favor recombination of the primary radicals (**A**) at the nearest possible site, namely the 2-position of the naphthoxy ring. Such effects fail to stop decarbonylation when the primary radical pair is formed in the triplet state. A comparison of the photobehavior of dibenzyl ketones with that of naphthyl esters reveals this facet of the mechanism. Results presented here suggest that it is possible to steer the course of a photoreaction and direct the formation of a specific photoproduct by using zeolites as reaction media.

Experimental

NaY zeolite was obtained from Zeolyst International, the Netherlands. Monovalent cation exchanged (Li$^+$, K$^+$, Rb$^+$, Cs$^+$, and Tl$^+$) zeolites were prepared by stirring 10 g of NaY with 100 mL of a 10% solution (in water) of the corresponding metal nitrate for 12 h with continuous refluxing. The zeolite was filtered and washed thoroughly with distilled water. This procedure was repeated three times. The zeolite was then heated in an oven at 120°C for about 6 h to obtain the cation exchanged zeolite used for photolysis. The exchange levels were estimated by ICP analysis and they were in the range 60–85%.

1-Naphthyl phenylacyl esters **1a** and **1b** were gifts from W. Gu and R.G. Weiss of Georgetown University. 1-Naphthyl phenylacyl ester **1c** was synthesized as per Scheme 7 (14).

Step *a*

Lithium diisopropyl amide (0.02 mol) in dry THF (100 mL) was stirred under nitrogen at –78°C. To this 2 g (0.015 mol) of 2-phenyl propionaldehyde in dry THF was added dropwise with continuous stirring. To the resulting orange dispersion 2.7 g (0.02 mol) of methyl iodide was added dropwise. The mixture was stirred for 12 h and then poured over an ice water mixture and extracted with three 20 mL portions of diethyl ether. The ether layer was dried with anhyd MgSO$_4$, filtered, and evaporated to give a crude mixture of the product aldehyde (**14**). Pure **14** was obtained by purification using column chromatography (silica gel and hexane); yield: 35%. MS data: 148 (M$^+$, 6.5), 119 (97.8), 103 (14.1), 91 (100), 77 (28.3), 65 (8.7), 51 (27.2), 41 (54.3).

Scheme 7.

14 **15** **1c**
Step *b*

Silver oxide was prepared by adding a solution of 5.1 g (0.03 mol) of AgNO$_3$ in 10 mL of water to a solution of 2.4 g (0.06 mol) of NaOH in 10 mL of water. Continuous shaking during the addition ensured complete reaction and resulted in a brown semisolid mixture. This mixture was cooled with an ice bath and 2 g (0.014 mol) of the aldehyde **14** was added slowly with continuous stirring. The oxidation reaction was allowed to proceed for 2 h. The black silver suspension was removed by suction filtration and was washed with warm water. The combined filtrate was allowed to cool and the washings were acidified with concentrated hydrochloric acid precipitating about 1.8 g of the corresponding acid (**15**); yield: 70%. MS data: 164 (M$^+$, 23.5), 119 (100), 103 (12.2), 91 (73.5), 77 (20.4), 65 (6.1), 51 (17.3), 41 (30.6).

Step *c*

The acid, **15** (2 g) (0.012 mol), 1.76 g (0.012 mol) of 1-naphthol, 2.5 g (0.012 mol) of DCC, and 0.15 g (0.0012 mol) of DMAP were mixed together in 50 mL of dry methylene chloride. The mixture was stirred under nitrogen for 12 h. The resulting suspension was then filtered to remove the white residue. The filtrate was washed with water and aqueous acetic acid (5%). The resulting methylene chloride solution was then dried with anhyd MgSO$_4$ giving a crude mixture of the product ester **1c**. The mixture was purified by column chromatography, eluting with petroleum ether, then with 5% methylene chloride in petroleum ether, and finally with 1% ethyl acetate in petroleum ether. Yield: 23%. The resulting ester was a thick viscous colourless liquid. ^{1}H NMR (CDCl$_3$, 400 MHz) δ: 1.89 (s, H), 7.18 (1H, d), 7.35–7.55 (7H, m), 7.6 (2H, d), 7.73 (2H, d), 7.85 (2H, d). ^{13}C NMR (CDCl$_3$, 100 MHz) δ: 26.4, 47, 118, 121, 125.5, 126 (Ar-C), 126.5, 127, 127.3, 128, 128.8, 134.8, 144, 146.8, 175.2. MS data *m/e* (relative intensity): 290 (M$^+$, 14.7), 144 (75), 119 (100), 115 (41.2), 103 (10.3), 91 (51.5), 77 (13.2), 63 (10.3), 41 (32.4).

Dibenzyl ketone (**2a**) was used as obtained from Aldrich. Dibenzyl ketones **2b** and **2c** were synthesized following the procedure described below.

Synthesis of α,α′-dimethyl dibenzyl ketone (2b) (15)

Dibenzyl ketone (**2a**) (1 g, 0.005 dissolved in 15 mL of dry THF was added dropwise to the cooled solution (–10°C) of pottassium hydride (0.4 g, 0.01 mol) in 15 mL dry THF. The resulting light yellow suspension was allowed to stir for 30 min and then 0.62 mL (0.01 mol) of methyl iodide was added dropwise. The white suspension formed was allowed to stir for 12 h, acidified with dil. HCl and extracted with diethyl ether. The ether layer was dried with anhyd MgSO$_4$ and evaporated to give a crude product mixture. Pure **2b** was

obtained by column chromatography eluting with 2% ethyl acetate in petroleum ether. The product was a colorless oil; yield 31%. ^{1}H NMR (CDCl$_3$, 400 MHz) δ: 1.35, 1.45 (d, 3H), 3.9, 4 (q, 1H), 7–7.5 (10 H, m). ^{13}C NMR (CDCl$_3$, 100 MHz) δ: 18.5, 19, 51, 51.7, 140.2, 141, 141.8, 143.2, 210.3, 211.3. MS data *m/e* (relative intensity): 238 (M$^+$, 4.4), 133 (10.3), 128 (2.9), 105 (100), 89 (1.5), 77 (17.6), 63 (1.5), 51 (5.9), 39 (2.9).

Synthesis of α,α,α′,α′-tetramethyl dibenzyl ketone (2c) (15)

Dibenzyl ketone (**2a**) (1 g, 0.005 mol) dissolved in 15 mL of dry THF was added dropwise to the cooled solution (–10°C) of potassium hydride (0.8 g, 0.02 mol) in 15 mL dry THF. The resulting light yellow suspension was allowed to stir for 30 min and then 1.24 mL (0.02 mol) of methyl iodide was added to the solution dropwise. The white suspension formed was allowed to stir for 12 h at room temperature, acidified with dil. HCl, and extracted with diethyl ether. The ether layer was dried with anhyd MgSO$_4$ and evaporated to give a crude product mixture. Pure **2c** was obtained by column chromatography, eluting on a silica gel column with 2% ethyl acetate in petroleum ether. The product was a white solid; yield 81%. ^{1}H NMR (CDCl$_3$, 400 MHz) δ: 1.3 (s, 12 H), 7.18–7.3 (10H, m, Ar-H). ^{13}C NMR (CDCl$_3$, 100 MHz) δ: 28 (-CH$_3$), 53.2 (-C(CH$_3$)$_2$), 125.8 (Ar-C), 126.5 (Ar-C), 128.5 (Ar-C), 144.5 (Ar-C), 213.4 (C=O). MS data *m/e* (relative intensity): 266 (M$^+$, 0.9), 147 (6.8), 119 (100), 103 (4.5), 91 (45.5), 77 (9), 51 (4.5), 41 (18).

Identification of photoproducts

Photoproducts from **1a** and **1b** have been identified previously by W. Gu and R.G. Weiss of Georgetown University. The spectra of the photoproducts **3a**–**10a** and **3b**–**10b** agreed with the reported data. Authentic samples provided by Gu and Weiss were used to identify the GC peaks. Irradiation of **1c** in hexane gave 1-naphthol, **9c**, and **3c** as the major products. An authentic sample obtained from Aldrich was used to identify 1-naphthol. The spectral data for **9c** and **3c** are shown below: For **9c**: ^{1}H NMR (CDCl$_3$, 400 MHz) δ: 1.34 (s), 7.06–7.5 (10 H, m). ^{13}C NMR (CDCl$_3$, 100 MHz) δ: 25.2, 43.6, 125.5, 126.8, 128.6, 146.8. MS data *m/e* (relative intensity): 238 (M$^+$, 0.5), 128 (0.5), 119 (100), 91 (50), 77 (9.2), 65 (2.6), 51 (3.9), 41 (17). The other photoproducts from ester **1c** were assigned by comparing their GC retention times with similar products from the photolysis of esters **1a** and **1b**.

Photoproducts upon photolysis of dibenzylketones namely diphenylethane (**11**), cumene (**17**), and α-methyl styrene (**18**) were compared to the original samples obtained from Aldrich. Products **14** and **19** were prepared by preparative photolysis of **2b** and **2c**, respectively, in hexane. Spectral data for **14**: ^{13}C NMR (CDCl$_3$, 400 MHz) δ: 18.5, 19, 46.5,

47.5, 126.2, 127.9, 128.5, 146. MSl data m/e (relative intensity): 210 (4.4), 106 (8.9), 105 (100), 91 (3.3), 77 (15.6), 65 (2.2), 51 (5.6), 39 (3.3). For **19**: ^{1}H NMR (CDCl$_3$, 400 MHz) δ: 1.34 (s), 7.06–7.5 (10 H, m). ^{13}C NMR (CDCl$_3$, 100 MHz) δ: 25.2, 43.6, 125.5, 126.8, 128.6, 146.8. MS data m/e (relative intensity): 238 (0.5), 128 (0.5), 119 (100), 91 (50), 77 (9.2), 65 (2.6), 51 (3.9), 41 (17).

Synthesis of 2-methyl phenyl benzyl ketone (12) and 4-methyl phenyl benzyl ketone (13)

In a small round-bottomed flask, 0.5 g (0.003 mol) of the corresponding acid chloride (2-methyl benzoyl chloride or 4-methyl benzoyl chloride) was added to 15 mL dry THF. This mixture was kept stirring at –10°C under a nitrogen atmosphere. A benzyl magnesium chloride (0.0025 mol) suspension in THF was added dropwise to the above solution. The light yellow solution was allowed to stir for 12 h at room temperature (25°C) followed by addition of satd NH$_4$Cl solution in water and extraction with three 20 mL portions of diethyl ether. The ether layers were combined, dried with anhyd MgSO$_4$, and evaporated to give a crude product mixture. Pure **12** or **13** was then obtained by column chromatography, eluting on a silica gel column with 2% ethyl acetate in petroleum ether. For **12**: ^{1}H NMR (CDCl$_3$, 400 MHz) δ: 2.45 (s), 4.23 (s), 7.2–7.4 (8H, m), 7.74 (1H, d). ^{13}C NMR (CDCl$_3$, 100 MHz) δ: 21.3, 48.5, 125.5, 126.8, 128.5, 130, 132, 133, 134.5, 136.6, 137.6, 138.8, 201.5. MS data m/e (relative intensity): 210 (2.7), 165 (1.1), 119 (100), 91 (69.4), 65 (48.6), 51 (8.3), 39 (25). For **13**: ^{1}H NMR (CDCl$_3$, 400 MHz) δ: 2.42 (s), 4.28 (s), 7.22–7.38 (7H, m), 7.94 (2H, d). ^{13}C NMR (CDCl$_3$, 100 MHz) δ: 21.7, 45.4, 127.6, 129.4, 129.6, 130.1, 130.2, 135, 135.6, 144.9, 198.5. MS data m/e (relative intensity): 210 (2.7), 165 (1.4), 119 (100), 91 (48.6), 65 (37.8), 51 (6.8), 39 (17.6).

Synthesis of 2-ethyl phenyl α-methyl benzyl ketone (15) and 4-ethyl phenyl α-methyl benzyl ketone (16)

Ethyl benzene (10 g) (0.09 mol) and 14.5 g (0.094 mol) of phenyl acetyl chloride were placed in a small round-bottomed flask. Into a conical flask, 12.5 g (0.09 mol) of AlCl$_3$ was weighed out and this solid was added with frequent shaking to the contents of the round-bottomed flask. The mixture turned dark green with evolution of HCl gas during the addition. After addition was complete, a reflux condenser was attached and the round-bottomed flask was heated on a water bath for 3 h. The contents of the flask were poured into a mixture of crushed ice and concd HCl with continuous stirring. The resultant water layer was extracted with five 25 mL portions of diethyl ether. The ether layers were combined, dried with anhyd MgSO$_4$, and evaporated to give a crude product mixture. The non-methylated precursors to **15** and **16** could be isolated by column chromatography, eluting on a silica gel column with a 5% ethyl acetate in petroleum ether mixture. They were then methylated using the procedure used for the ketones **2b** and **2c** described earlier. Purification by silica gel chromatography, eluting with 2% ethyl acetate in petroleum ether afforded pure **15** and **16**. Spectral data for **15**: white colored solid. ^{1}H NMR (CDCl$_3$, 400 MHz) δ: 1.25 (t), 1.6 (d), 2.7 (q), 4.7 (q), 7.23–7.45 (8H, m), 7.76 (1H, d). ^{13}C NMR: (CDCl$_3$, 100 MHz) δ: 16, 20, 29, 48, 127, 128.2, 128.5, 129, 130.2,

134.5, 142, 149.8, 200. MS data m/e (relative intensity): 238 (1.9), 165 (1.3), 133 (100), 119 (3.7), 105 (22.2), 91 (5.6), 77 (18.2), 51 (5.6), 39 (3.7). For **16**: light orange colored solid. ^{1}H NMR (CDCl$_3$, 400 MHz) δ: 1.25 (t, 3H), 1.6 (d, 3H), 2.7 (q, 2H), 4.7 (q, 1H), 7.2–7.4 (7H, m), 7.95 (2H, d). ^{13}C NMR (CDCl$_3$, 100 MHz) δ: 16, 20, 29, 48, 127, 128.2, 128.5, 129, 130.2, 134.5, 142, 149.8, 200. MS data m/e (relative intensity): 238 (1.6), 165 (1.6), 133 (100), 105 (21.8), 89 (4.7), 77 (15.6), 51 (6.3), 39 (3.1).

Photolysis

Known amounts of substrate (3 mg) and activated (450°C, air oven) zeolite (300 mg) were stirred together in hexane for at least 6 h, filtered, and washed with excess hexane. GC analysis of the hexane layer made sure that all substrate was loaded into the zeolite. The loading level was kept about 1 molecule per 12 supercages for the esters **1a–1c** and 1 molecule in 7 supercages for the ketones **2a–2c**. The "loaded" zeolite sample was transferred to fresh hexane solvent (10 mL) and photolyzed (Pyrex tubes, 450 W medium pressure mercury lamp) as a hexane slurry. A continuous nitrogen purge was maintained through the slurry during the irradiation of ketones **2a–2c**. For the esters **1a–1c**, 30% conversion was achieved upon 2 h of photolysis in zeolites LiY, NaY, and KY. The reaction proceeded very slowly in zeolites RbY and CsY and was almost completely absent in TlY. A 30% conversion was achieved after 2 h of irradiation for ketone **2a**, 1 h of irradiation for ketone **2b**, and 30 min of irradiation for ketone **2c**. GC analysis of the hexane layer of the irradiated slurry confirmed that all the products and the reactant remained within the zeolite. After irradiation, the samples were extracted with a 5% water in THF solution and analyzed on a GC (Hewlett-Packard 5890 (FID detector), column SPB-5 (30 m, 0.32 mm i.d., 1.0 mm film thickness)). The conditions used for the GC run for esters **1a–1c** were: initial temperature (100°C), initial time (1 min), rate (5°C per min), final temperature (250°C), final time (10 min). The GC conditions used for ketone **2a** were: initial temperature (100°C), initial time (1 min), rate (2°C per min), final temperature (160°C), final time (10 min), rate A (10°C per min), final temperature A (250°C), final time A (1 min). GC conditions used for ketones **2b** and **2c** were: initial temperature (100°C), initial time (1 min), rate (5°C per min), final temperature (250°C), final time (10 min). In general, mass balance as followed by using a calibration compound on a GC was found to be ~85%. The calibration compound used for the esters **1a–1c** was 1-naphthyl acetate and for the ketones **2a–2c** was phenyl phenyl acetate.

Absorption spectra

Absorption spectra were recorded using a Shimadzu 2101 PC UV–vis spectrophotometer with a diffuse reflectance accessory attachment. The dried zeolite samples were packed into a 2 mm quartz cuvette (in a dry box) and sealed with teflon tape. Conversion of the reflectance spectra to the absorption spectra was carried out using a Kubelka–Munk program supplied with the instrument.

Emission spectra

Emission spectra were recorded for the three naphthyl esters **1a–1c**. The spectra were recorded on a Edinburgh FS-

900 CDT spectrofluorimeter. Solid zeolite samples were taken in quartz ESR tubes placed in a quartz cylindrical Dewar, and the emissions collected at right angles were recorded. The ester samples were excited at 290 nm. The fluorescence λ_{max} was 340 nm and the phosphorescence λ_{max} was 525 nm. Lifetime measurements were carried out on an Edinburgh FL-900 CDT single photon counter using a hydrogen filled ns flashlamp (40 KHz) as the light source. The samples were excited at 290 nm, and the emitted photons were collected at the peak maximum of the fluorescence bands of the adsorbed substrates. The lamp profile was collected with ludox as the scattering medium. The observed decays were fitted using the distribution or the exponential analysis program supplied with the instrument. The lifetimes were fitted to an exponential fit. The suitability of the fit was ascertained by a χ^2 value close to unity. The decays within the zeolites were usually biexponential.

Computations

Geometry optimizations were carried out using the restricted hybrid Hartree–Fock density functional theory (RB3LYP) with Becke three parameter exchange functional in conjunction with correlation functional by Lee, Yang, and Parr (LYP). The 6-31G(d) basis set was used for C, H, O, Li. Stationary points have been characterized as true minima by frequency calculations. All of the calculations were carried out using the Gaussian 98 series of programs (10).

A generally applicable synthetic approach for heteroleptic thiolate complexes of bismuth

Lisa Agocs, Glen G. Briand, Neil Burford, Melanie D. Eelman, Nadia Aumeerally, Deanna MacKay, Katherine N. Robertson, and T. Stanley Cameron

Abstract: As part of a systematic development of bismuth coordination chemistry, we are exploiting the thermodynamic and hydrolytic stability of Bi—S bonds. A series of heteroleptic thiolate bismuth complexes have been isolated and characterized. The generally applicable synthetic methodology involves the use of hetero-bifunctional ligands containing a thiolate moiety as an anchor to facilitate coordinate interaction of weak donors (carbonyls, amines, hydroxyls) with bismuth. The bifunctional nature of the ligands is manifested in chelating roles. Important comparisons with established thiolate complexes of bismuth are discussed.

Key words: bismuth, thiolate, heteroleptic, crystallography.

Résumé : Dans le cadre d'un développement systématique de la chimie de coordination du bismuth, on essaye d'exploiter la stabilité thermodynamique et hydrolytique des liaisons Bi—S. On a isolé et caractérisé une série de complexes hétéroleptiques de thiolate de bismuth. La méthode de synthèse généralement applicable implique l'utilization de ligands hétéro-bifonctionnels comportant une portion thiolate agissant comme ancre pour faciliter l'interaction du coordinat des donneurs faibles (carbonyles, amines, hydroxyles) avec le bismuth. La nature bifonctionnelle des ligands se manifeste dans les rôles d'agents chélatant. On discute d'importantes comparaisons avec des complexes bien établis de thiolate de bismuth.

Mots clés : bismuth, thiolate, hétéroleptique, cristallographie.

[Traduit par la Rédaction]

Introduction

Bismuth compounds have been used to treat a variety of medical disorders for over 200 years (1). Most obvious is the widespread gastrointestinal application of the commercially available preparations Pepto-Bismol® and De-Nol®, which contain *"bismuth subsalicylate"* (BSS) and *"colloidal bismuth subcitrate"* (CBS), respectively. However, the mechanisms of bioactivity are not understood and chemical characterization of these compounds remains incomplete. Indeed, the chemical database for bismuth is still superficially developed.

The high thermal and hydrolytic stability of the sulfur–bismuth bond are responsible for the fact that sulfur compounds represent the most extensive series of bismuth complexes for which there is a reliable set of data (2). We have recently developed a series (3, 4) of bismuth thiolates. Their antimicrobial behaviour (5) and ulcer healing capabilities (6) suggest a structure–bioactivity relationship for the bismuth environment. In this context, it is interesting to see that BSS and bismuth nitrate react readily with thiol-based biomolecules to give predictable complexes (7), leading us to specu-

late that the biochemical fate of bismuth pharmaceuticals begins with thiolation.

It is now necessary to devise universally applicable synthetic procedures that enable rational development of the thiolate coordination chemistry for bismuth in the presence of other donors. To this end, we have examined complexes with hetero-bifunctional ligands bearing a thiolate functionality that serves as an anchor to promote or assist interaction of weaker tethered donors with bismuth. This has enabled us to control the reaction stoichiometry, giving access to series of complexes bearing one (**1**), two (**2**), and three (**3**) thiolate ligands (4, 8). Molecular drawings **1**–**11** illustrate connectivity only, as drawings of these complexes aimed at describing bonding features (e.g., Lewis) are not meaningful or are misleading.

We now report the first systematic preparation and comprehensive characterization of heteroleptic thiolate complexes of bismuth. Facile synthesis and isolation of the chlorodithiolate complexes **4** and **5** (9) highlights their suitability as precursors to dithiolate–aminothiolates **6a** (R = Me) and **7a**, dithiolate–hydroxythiolates **6b** and **7b**, and the dithiolate–esterthiolate **8**. Compound **1b** is also versatile and

a: E = NR$_2$
b: E = OH
has allowed for the isolation of an oxothiolate–aminothiolate **9a** (R = H). The compounds are rare, resilient examples of amino-, alkoxo-, and ester-complexes of bismuth.

a: E = NR$_2$
b: E = OH
Experimental

General

Bismuth chloride, 2-mercaptoethanol, 2-aminoethanethiol hydrochloride, *N,N*-dimethylaminoethanethiol hydrochloride, *N,N*-diethylaminoethanethiol hydrochloride, methyl thiosalicylate, and 1,2-ethanedithiol were used as received from Aldrich. Potassium hydroxide was used as received from BDH. All reactions were performed at room temperature under an atmosphere of nitrogen. All isolated products are air stable. Melting points were recorded on an Electrothermal melting point apparatus. IR spectra were recorded as Nujol mulls on CsI plates using a Nicolet 510P spectrometer or a Bruker Vector 22 spectrometer. Raman spectra were obtained for powdered and crystalline samples on a Bruker RFS 100 spectrometer. Vibrational spectra are presented as

wavenumber (cm^{-1}) maxima with ranked intensities for each absorption given in parentheses (the most intense peak is given a ranking of 1). Chemical analyses were performed by Canadian Microanalytical Service Ltd., Delta, British Columbia.

Synthetic procedures

Compounds **6**–**8** were prepared according to a general procedure involving the dropwise addition of an ethanolic solution (50 mL) of thiol and KOH to a stirred slurry of **4** or **5** in ethanol (50 mL). The resulting reaction mixtures were allowed to stir overnight at room temperature. The precipitates were suction filtered using a Buchner funnel and washed with two 10 mL aliquots of water. Reagents are presented in Table 1 along with yields, elemental analyses, melting points, and vibrational spectroscopic data for each compound.

Compound **6b** was also obtained by the dropwise addition of 1,2-ethanedithiol to an aqueous solution of bis(2-hydroxyethanethiolato)bismuth(III) chloride (**2b**) (3) (100 mL). The reaction was stirred overnight at room temperature and suction filtered.

Compound **9a** was prepared by addition of a solution of KOH and 2-mercaptoethanol in ethanol (50 mL) to a slurry of bismuth chloride in ethanol (50 mL). The resulting yellow reaction mixture was stirred for 3 h at which point an ethanolic solution (50 mL) containing KOH and 2-aminoethanethiol chloride was added dropwise. This reaction mixture was allowed to stir overnight at room temperature. The reaction mixture was suction filtered.

Compounds **6a**–**9a** were crystallized from filtrates reduced in volume on a rotary evaporator and cooled in the refrigerator (4°C) for 1 day to give yellow needles (**6a**) or left to evaporate slowly over a period of 4 days to give yellow needles (**7a**, **8**) or green-gold plates (**9a**). Compound **6b** was isolated as an analytically pure powder and was recrystallized as green-gold cubic crystals from hot DMF.

X-ray crystallography

Data were collected on a Rigaku AFC5R diffractometer with graphite-monochromated Cu-Kα radiation (λ = 1.54178 Å) and a 12 kW rotating anode generator. The structures were solved by direct methods (SHELXS86 (**6a**), SIR92 (**6b**, **7a**, and **9a**)) or Patterson methods (SIR92 (**8**)). They were refined by full-matrix least-squares on *F* using 1435 (**6a**) and 468 (**9a**) reflections with *I* > 3.00σ(*I*) or on *F*^{2} using 1298 (**6b**), 1970 (**7a**), and 1397 (**8**) unique reflections (SHELXL97) (10). Unit cell parameters were obtained from the setting angles of high angle centred reflections. The choice of space groups was based on systematically absent reflections and was confirmed by the successful solution and refinement of the structures.

All data were collected using the ω–2θ scan technique. The intensities of three representative reflections were measured after every 150 reflections. No decay corrections were applied. Data were corrected for Lorentz and polarization effects, and an empirical absorption correction was applied for each structure. Secondary extinction was refined for **6**–**8**. All of the heavy atoms were refined anisotropically for each structure except **9a**, where only Bi and S atoms were made anisotropic (the remainder being refined isotropically). Hy-

Atomic coordinates, bond

lengths and angles, and thermal parameters have been deposited.[2]

Results and discussion

Facile hydrolysis of many bismuth element bonds typically results in essentially quantitative precipitation of bismuthyl (BiO$^+$) salts, and this has impeded studies aimed at

rational and systematic development of bismuth chemistry. Some complexes involving weakly donating functionalities have been isolated in the absence of moisture, but many conventional types of ligands have yet to be observed coordinated to bismuth. As a result, numerous complexes of bismuth represent unique examples for a particular ligand,

Fig. 1. Crystallographic views of (*a*) **6a**, (*b*) **6b**, (*c*) **7a**, (*d*) **8**, (*e*) **9a**. Thermal ellipsoids are drawn to 50% probability. Hydrogen atoms have been omitted for clarity.
rather than a series of related compounds and general synthetic procedures have not been established to allow for assessment of physical and chemical properties.

A wide range of bismuth thiolate complexes are known due to the high thermal and hydrolytic stability of the sulfur–bismuth bond (2), however, most complexes involve multithiolation. Hetero-bifunctional ligands containing a thiolate moiety and an auxiliary donor have proven effective for developing complexes of bismuth with new donors. Moreover, the chelate interaction of the weaker donor mediates the thiophilicity of the bismuth centre and it is possible to isolate kinetically stable, partially thiolated complexes, so that all three stoichiometric combinations (**1**, **2**, **3**) have been prepared for aminoethanethiolate (**4**) and esterthiolate (**8**, **11**) complexes.

We have now exploited the features of bifunctional thiolate ligands to develop synthetic procedures for heteroleptic bismuth complexes. The starting materials **4** (12) and **5** (9) that are readily obtained via precipitation, react slowly at room temperature with potassium thiolate solutions in a slurry with little or no change in the visual appearance of the reaction mixture. Nevertheless, the precipitates are characterized as analytically pure metathesis products formed in

reasonable yield. Some yields are relatively low, however, conditions to optimize them have not yet been assessed.

Compounds **6–9a** have been crystallographically and spectroscopically characterized. Molecular structures are shown in Fig. 1 and selected bond lengths are compared with those of compounds **1–5** in Table 3. The spirocyclic environments observed for bismuth in **6a**, **6b**, **7a**, and **9a** confirm auxiliary coordination of the hydroxyl (**6b**), amino (**6a**, **7a**, and **9a**) and alkoxide (**9a**) functional groups to the bismuth centre in each respective example. The structures are consistent with the homoleptic thiolate series **1–3** (3, 4, 13), except for compound **8** in that the ester functionality is terminal (Bi-O, 3.55(2) Å; cf. Bi-O 2.56–2.86 Å (8, 11)), showing no evidence of interaction with bismuth. This is an unexpected structural feature, when one compares the structure of tris(thiosalicylato)bismuth **11**, which exhibits a definitively hexacoordinate site for bismuth and typical Bi—O coordinate bond distances (Bi—O 2.72(2)–3.08(2) Å) (14). Although the cross-ring S2—Bi distance is relatively long (3.0688 (4) Å) in **8**, we speculate that this interaction lowers the Lewis acidity of the bismuth center to render the carbonyl donation ineffective.

The structural features of compounds **6–9a** represent a useful contribution to the developing database for the chelate–thiolate coordination chemistry of bismuth, as documented in Table 3. Mono-, bis-, and tris-thiolate complexes of bismuth exhibit a narrow range of Bi—S bond distances. The geometry at bismuth varies considerably throughout the series of complexes including a variety of coordination numbers. Nevertheless, most complexes are observed to have Bi—S bond lengths within a narrow range (2.5 to 2.6 Å), so that the thiolate interaction is essentially independent of the number of thiolate ligands, the presence of auxiliary intramolecular coordination to bismuth, or the number of intermolecular interactions at bismuth. The unusually long Bi—S bonds in **1c**, **2b**, and **2c** are likely due to strong intermolecular interactions in the solid state that provide for a dimeric arrangement for **1c** and a polymeric (ribbon-like) structure for **2b** and **2c** (3, 8). The fourth Bi-S contact in **7a** and **8** represent the intramolecular cross-ring thioether donation, which is predictably weaker than those of the thiolates. The relatively weak interactions of the amines are likely made possible by the chelate arrangement. The Bi—N distances are comparable to those of the thiolates despite the smaller size of nitrogen. These observations are consistent with the realization that amine complexes of bismuth are extremely rare and the most reliable comparative data comes from complexes of pyridine derivatives (2), which are in the range of the Bi—N distances listed in Table 3. The relative Bi—O distances are in agreement with the relative Lewis basicity of the oxygen donor in that interactions of hydroxyl (**2b**, **6b**, **9b**, **10**) and carbonyl (**1c**, **2c**, **3c**, **8**, **11**) ligands are longer than interactions with alkoxide (**9a**, **9b**, **10**) functionalities.

Conclusion

The use of thiolates in bifunctional ligands offers a synthetically versatile approach to bismuth complexes involving weak Lewis donors and provides for a general systematic and comprehensive development of bismuth chemistry.

Variation of the ease of α-sulfonyl carbanion formation with the orientation of different β-substituents: Experimental evidence for the generality of negative hyperconjugation as an important substituent effect

James F. King, Manqing Li, Allan Zijun Cheng, Vinod Dave, and Nicholas C. Payne

Abstract: Following up on our previous observation that the rate of formation of a β-alkoxy-substituted α-sulfonyl carbanion depends on the stereochemistry of the alkoxy group, we have found similar behaviour when the β-substituent is R_2N, RS, or R_3N^+. With each substituent, the variation of k_N (defined by $k_N = (k_{exch})_X /(k_{exch})_{model}$) is consistent with an equation of the form $\log k_N = a + b \cos^2 \theta$, where θ is the H-C-C-X torsion angle. We propose that the a term describes the polar (field plus inductive) effect and the b term the negative hyperconjugative effect of the substituent; we show how the variations in a and b may be readily accommodated within this framework. Some features of the trialkylammonio group previously postulated in the literature are discussed in the light of our results.

Key words: negative hyperconjugation, substituent effects, stereoelectronic factors, sulfonyl carbanions, anomeric effect.

Résumé : Suite à notre observation antérieure à l'effet que la vitesse de formation d'un carbanion α-sulfonyle portant un substituant β-alkoxyle dépend de la stéréochimie du groupe alkoxyle, on a observé un comportement semblable avec les substituants β sont R_2N, RS ou R_3N^+. Avec chacun de ces substituants, la variation de la valeur k_N (où $k_N =$ $(k_{éch})_X/(k_{éch})_{modèle}$) peut être calculée par une équation de la forme $k_N = a + b \cos^2 \theta$ dans laquelle θ correspond à l'angle de torsion H-C-C-X. On suggère que le terme a correspond à l'effet polaire (champ plus inductif) et alors que le terme b serait associé à l'effet d'hyperconjugaison négative du substituant et on montre comment les variations dans les termes a et b peuvent facilement être accomodés dans ce cadre. À la lumière de nos résultats, on discute de certaines caractéristiques du groupe trialkylammonio postulées antérieurement dans la littérature.

Mots clés : hyperconjugaison négative, effets de substituants, facteurs stéréoélectroniques, carbanions sulfonyles, effet anomère.

[Traduit par la Rédaction]

Introduction

We have recently reported (1) on an extended investigation, which showed that the ease of deprotonation of a sulfone to form the α-sulfonyl carbanion can be influenced strongly not only by the presence of a β-alkoxy substituent but also by its geometry. Specifically, we investigated a series of β-alkoxy sulfones of the general formula **A** (X = RO)

J.F. King,[1] M. Li, A.Z. Cheng, V. Dave, and N.C. Payne.[2] Department of Chemistry, The University of Western Ontario, London, ON N6A 5B7, Canada.

[1]Corresponding author concerning the organic chemistry (e-mail: scijfk@uwo.ca).

[2]Corresponding author concerning the X-ray crystallography (e-mail: noggin@uwo.ca).

(Scheme 1), and observed a dependence of the ease of carbanion formation (**A → B**) on θ, the H_α-C_α-C_β-X torsion angle. More precisely, if we define $(k_{exch})_X$ as the second-order rate constant for the H-D exchange of the β-substituted substrate (**A**), $(k_{exch})_{model}$ as the rate constant for H-D exchange in an appropriate model (e.g., **A** with X = H or CH_3), and $k_N = (k_{exch})_X/(k_{exch})_{model}$, then we observed the relation summarized by eq. [1]

[1] $\log k_N = a + b \cos^2 \theta$

where $a = 1.70$ and $b = 2.62$.

This result was interpreted in terms of a (more or less) angle-independent combination of field and inductive effects responsible for the a term taken with torsion angle dependent negative hyperconjugation, leading to the $b \cos^2 \theta$ component. This term is maximal at $\theta = 0°$ and $\theta = 180°$ and in reactions of molecules with these torsion angles is responsible for the *major* part of the electronic effect of the β-alkoxy group on the ease of formation of a β-alkoxy α-sulfonyl carbanion. The negative hyperconjugation was identified as π-type donation of the incipient carbanionic electrons into the

Scheme 1.

antibonding orbital, σ^*_{CO}. Such hyperconjugation would be expected to be smallest at $\theta = 90°$ with values increasing from 90° to maxima at 0° and 180°.

Related negative hyperconjugative interactions have been treated theoretically (2–5). Especially relevant to the present study is the paper by Schleyer and Kos (5) who calculated ΔE for the conversion of two conformations of $ROCH_2CH_2^-$: (*i*) that with the *p*-orbital on the carbon atom coplanar with the C—O bond (in our terminology, $\theta = 180°$); and (*ii*) that with the *p*-orbital at 90° to the C—O bond ($\theta = 90°$). They estimated that the perpendicular conformation was less stable than the coplanar by 13.2 kcal mol^{-1} and assigned the energy difference to negative hyperconjugation. For the reaction $CH_3CH_2^- + ROCH_2CH_3 - CH_3CH_3 + ROCH_2CH_2^-$ with the carbanion in the coplanar conformation they estimated $\Delta E = -23.5$ kcal mol^{-1}. Note that the stabilization assigned to hyperconjugation (13.2 kcal mol^{-1}) is somewhat greater than that of the polar effect (11.3 kcal mol^{-1}), i.e., our conclusions based on the experiment are in full accord with those of Schleyer and Kos (5), derived from ab initio MO calculations.

It was reasonable to expect that other substituents, especially those that are highly electronegative or have a low-lying antibonding C–X orbital (σ^*_{CX}), would show the same behaviour as β-alkoxy substituents, though this expectation could not be taken for granted. We therefore set out to examine a further set of β-substituted sulfones with two aims in mind: (*i*) to provide experimental evidence for the generality of the effect shown by the alkoxy group; and (*ii*) in the event that this proved to be the case, to obtain a set of *a* and *b* parameters (see eq. [1]) for each substituent to determine if our hypotheses about the contributions of negative hyperconjugation and field and inductive effects would withstand the light of the additional information.

Results and discussion

Materials and methods

In our previous study (1) the β-alkoxysulfones **1a**, **2a**, and **3a** (Scheme 2) had proved both convenient and well behaved. Accordingly, we set out to explore the effect of other substituents by examining the analogues **1b–1e**, **2b–2e**, and **3b–3e**. The low solubility of **1e** rendered kinetic studies impossible in our hands and, in view of the satisfactory results previously obtained with the heterodecalins **4a** and **4d** turned instead to the disulfone **4c**.

The monocyclic substrates (**1** and **2**) varied from commercially available (**1b**), previously known (**1d**), to readily prepared by straightforward routes from known precursors, as

Scheme 2.
described in the *Experimental* section. Conjugate addition of dimethylamine to the unsaturated sulfone (**5**), for example, proved a convenient route to **2b** and thence to **2c**. Analogous conjugate addition of dimethylamine and methanethiol to **6** led to the bicyclic substrates, **3b** and **3d**, respectively, and these in turn were converted easily into **3c** and **3e**. The present study requires a firm assignment of the stereochemistry of each substrate, and we postulate the following picture.

The conjugate addition is believed to take place by attack of the nucleophile on the less-hindered *exo* face of the sulfone (**6**) in the arrangement shown in **7** with formation of the sulfonyl carbanion with the phenylsulfonyl group *endo* (Scheme 3); the usual stereospecific protonation of the carbanion (**8**) leads directly to **3**. Evidence for this pathway was obtained by treating **6** with sodium methoxide in methanol to obtain **3a**, which had been previously obtained by another route (1). The structure and stereochemistry of **3a** had been firmly established by its mode of synthesis and by single crystal X-ray structure determination. The generality of the stereochemistry of this addition was then secured by X-ray structure determination of **3c**.[3]

The H-D exchange rates were determined by following the disappearance of the ^{1}H NMR signal of the α-sulfonyl hydrogen with time, as described earlier (1). A 1:1 mixture of D_2O and dioxane-d_8 was the most frequently used solvent medium, though solubility reasons or the availability of rate data for the model compounds sometimes led to other media. The second-order rate constants for the substrates (**1b–1d**, **2b–2e**, **3b–3d**, and **4c**) together with those of the corresponding model compounds (**1f**, **2f**, and **3f**) are given in Table 1. Missing from the table is compound **3e** for which a combination of low solubility, signal overlap, and apparent reaction complexity has frustrated our efforts to obtain rate

7   **8**
constants to date. For two of the substrates in Table 1, namely the quaternary ammonium salts **2c** and **3c**, the reaction showed no sign of any initial H-D exchange but, rather, gave the unsaturated sulfones, **5** and **6**, respectively. This, of course, is simply a Hofmann elimination and is the expected result whenever one generates a carbanion vicinal to a quaternary ammonium centre. Since this reaction consumes a molecule of base for each reaction it was necessary to modify the experimental procedure to include the use of a buffer system. The reaction gave the same second-order rate constant with buffer concentrations differing by 400-fold, pointing to specific base catalysis. One simple mechanism is that the initially-formed carbanion undergoes rapid unimolecular extrusion of the tertiary amine, i.e., that the process is an irreversible E1cB reaction. The reversible E1cB is excluded by lack of H-D exchange in the starting material, but the possibility remains for a *cis*-E2 reaction of **3c** and a similar reaction from a twist form in **2c**. To check this point we have plotted the log k_N values for **2a**–**2e** (the ~60° series) vs. **1a**–**1e** (the ~180° series). The ~180° set and all but **2c** in the ~60° series showed only H-D exchange and can be expected to show a reasonably linear correlation in such a plot. In the event we obtained a fair straight line with no sign of positive deviation of the point for **2e**. The same features were also found in a similar plot of **3a**–**3d** (the ~0° set) vs. **1a**–**1d**. These observations are in accord with the simple picture that all of the reactions with rate constants listed in Table 1 involve rate-determining carbanion formation.

Kinetic results

The log k_N values for the dialkylamino, trialkylammonio, and thioalkyl substituents in Table 1 are presented in Fig. 1, along with the line for the alkoxy substituents obtained earlier (1). The two points for the alkylsulfonyl groups are not plotted, but it is evident that they fall close to the corresponding points for the trialkylammonio function. From the curves in Fig. 1 it is evident that the torsion angle dependence originally observed with the alkoxy group is also found with the other substituents, i.e., the phenomenon is general. The parameters for eq. [1] obtained by a nonlinear least-squares fit of the data to eq. [1], along with the parameters for eq. [1] that fit the two alkylsulfonyl points, are presented in Table 2. Shown also are σ^*_0 (which is identical to σ^*_{180}) and σ^*_{90} values, as defined by the equations in the footnotes to Table 2 (cf. ref. (1)). We note specifically that σ^*_{90} (because $\cos^2 90 = 0$) is given simply by $\sigma^*_{90} = a/4.9$ and discussions of the trends in σ^*_{90} and a values are equivalent.

First we note that the a parameters (and the σ^*_{90} values) follow the order $RS < R_2N < RO < RSO_2 < R_3N^+$, precisely the order of the electronegativities of the heteroatoms (modified where appropriate by formal or actual charges). We note

Fig. 1. Plot of log k_N vs. the H-C_α-C_β-X torsion angle (θ) for β-substituted sulfones **1b**, **2b**, **3b** (circles), **1c**, **2c**, **3c** (squares), and **1d**, **2d**, **3d** (triangles). The points are experimental (Table 1), and each line derived from a nonlinear least-squares fit to eq. [1]; the a and b parameters are listed in Table 2. The solid line is for X = RO and is taken from ref. (1).
explicitly that this is not the order of the usual Taft σ^* or σ_I values, parameters which have long been regarded as describing the polar effect alone, although the fact that $\sigma^*_{CH_2X}$ for X = MeS is greater than that for X = Me_2N (see Table 2) has long been a difficult point to reconcile with a simple polar (field and (or) inductive) effect. The picture presented in the current paper, that the polar effect is augmented by hyperconjugation, is, by contrast, highly satisfactory; when the hyperconjugation is not present (i.e., when θ ≈ 90°) then the σ^*_{90} values follow the expected polar-effect order as noted above.

It is also of interest to note that even the upper range of the σ^* values from the literature is less than the σ^*_{180} (= σ^*_0) value. Though individual σ^* determinations may well be subject to factors unique to the system, it seems likely that one reason why σ^*_{180} is greater than σ^* as commonly measured is that in many instances the substrate being examined does not consist of a conformationally homogeneous material with all molecules having the H-C_α-C_β-X angle (or its analogue) at 180° (or 0°). A mixture of two (or more) conformations would show Winstein–Holness kinetics, which would reflect the population of the less reactive (or unreactive) conformer and the substituent constant (σ*) would be correspondingly reduced. As a simple illustration we point to structure **A** in which the torsion angle (θ) is at the favourable angle of 180°. At the same time, simple conformational considerations point to a strong nonbonding interaction between the X and R groups that can be alleviated, for example, by rotating around the C_α—C_β bond to place the X group antiplanar to the C_α—S bond. In an unconstrained system this conformation can be expected

[a]Equation [1]: $\log k_N = a + b \cos^2\theta$ where θ is the H-C$_\alpha$-C$_\beta$-X torsion angle.
[b]$\sigma^*_{90} = \sigma^*_\theta$ for $\theta = 90°$ and $\sigma^*_0 = \sigma^*_{180} = \sigma^*_\theta$ for $\theta = 0°$ or $180°$; $\sigma^*_\theta = (a + b \cos^2\theta)/4.9$, see ref. (1).
[c]Values for $(\sigma_I)_X$ taken from ref. (6), transformed using the relation $\sigma^*_{CH_2X} = (\sigma_I)_X/0.45$.
[d]Values for a and b and derived values of σ^*_θ for RSO$_2$ were calculated from the two points in Table 1 assuming eq. [1] applies.

to be (*i*) an important conformer, and (*ii*) less reactive than the original conformer shown as **A**, and a value of σ^* obtained with such a conformational mixture would be smaller than σ^*_{180}.

The second parameter in eq. [1], namely *b*, describes the sensitivity of the rate constant to change in the torsion angle (θ). According to our interpretation the parameter *b* measures the extent of the hyperconjugation in each system, and the question immediately arises, does the extent of the hyperconjugation as measured by *b* concur with theory? The hyperconjugation that we are invoking involves π-type donation of the electrons of the incipient carbanion into a σ^*_{C-X} orbital. For simplicity we shall restrict further discussion to the stabilization of the (full) carbanion derived from the H-C$_\alpha$-C$_\beta$-X torsion angle of 180° as indicated by **9** (Scheme 4). The general orbital interaction diagram, patterned on those given by Rauk (7*a*), is shown in Fig. 2.[4] To the extent that the hyperconjugative overlap shown in **9** occurs, the energy of the carbanion is lowered; the lowering is shown in Fig. 2 as $\Delta\epsilon_{CX}$. The value of $\Delta\epsilon_{CX}$ is given approximately by eq. [2], where h^2_{AB} is the interaction matrix element and ϵ_A and ϵ_B are the energies of the interacting orbitals (7*b*).

$$[2] \qquad \Delta\epsilon_{CX} \approx \frac{h^2_{AB}}{\epsilon_A - \epsilon_B}$$

For the hyperconjugative interaction itself, the h^2_{AB} term, which involves in the present cases π-type interaction of two carbon atoms (C$_\alpha$ and C$_\beta$), is not expected to change much from one molecule to another, and the variation in $\epsilon_A - \epsilon_B$ is the chief source of the change in the energy of hyperconjugation and, hence, in the magnitude of parameter *b*.

We should recall that the magnitude of *b* reflects a variation in $\log k_N$ and that k_N is defined as $(k_{exch})_X/(k_{exch})_{model}$, where, for simplicity in the comparison of the orbital interactions, we take X = C as the model system. The energies of hyperconjugation in the model (carbon) and substituted system are given by eq. [2], specifically the respective approximations $\Delta\epsilon_{CC} \approx h^2_{AB}/(\epsilon_{\sigma^*_{CC}} - \epsilon_C)$ and $\Delta\epsilon_{CX} \approx h^2_{AB}/(\epsilon_{\sigma^*_{CX}} - \epsilon_C)$. As it happens (and as will be shown below), all of the values for the energy levels for the antibonding C-X orbitals ($\epsilon_{\sigma^*_{CX}}$) of the substituents in this study are lower in energy than that for the antibonding C-C orbital ($\epsilon_{\sigma^*_{CC}}$) and hence for each of the examples in this paper $\Delta\epsilon_{CX}$ is greater than $\Delta\epsilon_{CC}$, i.e., the hyperconjugative interactions from these X substituents

Scheme 4.

9
Fig. 2. Orbital interaction diagram for hyperconjugative stabilization of an electron pair in a *p*-orbital on carbon by π-type interaction with an adjacent antibonding C-X orbital (σ^*_{C-X}) as illustrated in **9**.
are all stabilizing relative to the carbon model. That the energy levels of the σ^*_{CX} orbitals are lower than that of σ^*_{CC} arises in most of the present cases because the heteroatom of the substituent is more electronegative than carbon. Taking oxygen as the example, we see from the familiar orbital interaction diagrams in Fig. 3 that the lower energy of σ^*_{CO} vs. σ^*_{CC} arises because of the lower energy of the oxygen atomic orbital relative to carbon (taken with eq. [2] and the analogous expression required for the homopolar C—C bond). When X = R$_2$N, one may readily determine by interpolation that the energy difference between σ^*_{CC} and σ^*_{CN} is rather less than that with oxygen. Addition of the full positive charge on nitrogen, as in R$_3$N$^+$, sharply lowers the energy of the nitrogen atomic orbital, which substantially lowers the energy of σ^*_{CX} when X = R$_3$N$^+$, leading to a very large value of the parameter *b* for this substituent.

The effect of the RS group depends less on electronegativity differences than on the smaller overlap in a σ-bond between carbon and sulfur as compared with carbon and

---

[4]It may be helpful at this stage to note explicitly that the symbol σ^* in this paper (unavoidably) refers to two different things: (*i*) the Taft substituent constant; and (*ii*) an antibonding σ orbital.

Fig. 3. Orbital interaction diagram showing σ-bond formation leading to σ*$_{CO}$ having lower energy than σ*$_{CC}$.
carbon (or oxygen). This feature is reflected in eq. [2] by the h$^2_{AB}$ term that is smaller with the C—S bond than C—C or C—O; this leads to a smaller value of Δε$_U$ (and Δε$_L$) for the C-S array than that for the C-O system shown in Fig. 3. This in turn results in a lower value for the energy of σ*$_{CS}$ than for σ*$_{CC}$ or σ*$_{CO}$ and hence, by the argument given above using eq. [2], to a greater hyperconjugative stabilization with RS than with RO, i.e., to a larger *b* parameter for RS than RO. The still larger value for RSO$_2$ is a simple reflection of the effect of the formal positive charge on the sulfur atom. The qualitative orbital interaction picture therefore predicts the following sequences for *b*: (*i*) R$_2$N < RO < R$_3$N$^+$; and (*ii*) RO < RS < RSO$_2$. These patterns are, of course, observed, and, in our view, this agreement of theory and experiment provides a strong case for the basic hypothesis that negative hyperconjugation is at the root of the torsion angle dependence of the heteroatom substituents observed in our investigation.

The trialkylammonio group: a perfectly normal substituent?

The role of the field effect

On occasion, trialkylammonio groups, and indeed quaternary ammonio functions in general, have been implicated in controversy concerning their role as substituents. The present study has yielded some relevant information and a few comments seem in order. It is necessary to recall that unlike most substituents on the standard roster, the trialkylammonio group is monopolar and its interaction with a developing charge at a reacting centre via the field effect (i.e., through space) is not the same as that of a dipolar substituent such as the alkoxy group. This becomes apparent when one looks at the results of a brief study in which we compared the field effect of the methoxy and trimethylammonio groups using the classic treatment of Bjerrum (8) and Eucken (9) and Kirkwood and Westheimer (10, 11). Specifically, we looked at the variation in energy as a function of the H-C-C-X torsion angle of the species X–C$_\beta$–C$_\alpha$$^{\delta-}$···H bearing a partial charge on C$_\alpha$ obtained by partial deprotonation of the C$_\alpha$-hydrogen. The study is presented in detail elsewhere (12), but we will mention three points here: (*i*) the variation of the

energy of the interaction of the charges with change in torsion angle yields a curve (superficially rather like a simple cosine curve, i.e., +cos θ) with the principal changes in energy around θ = 90 ± 50°; (*ii*) more strikingly, the curves for the dipolar and monopolar groups are reversed, i.e., the largest stabilizing effect of the Me$_3$N$^+$ group is found at θ ≈ 0° (at which point the interaction between the positive nitrogen and the incipient negative charge is maximal), whereas the stabilization due to the (dipolar) alkoxy substituent is greatest when θ ≈ 180° (at which point the destabilization due to the interaction of the incipient negative charge and the δ$^-$ on the alkoxy oxygen atom is minimal). (Note that the interaction of the incipient negative charge with the *positive* end of the dipole, i.e., C$_\beta$, is unaffected by change in the torsion angle (θ)); (*iii*) the magnitude of the energy of interaction with the monopolar trimethylammonio group is distinctly larger (typically by a factor of about five times) than that with the dipolar (alkoxy) group. If the Bjerrum–Eucken–Kirkwood–Westheimer picture is correct in principle, the simple observation that the trialkylammonio group shows qualitatively the same behaviour as the dipolar substituents establishes beyond reasonable doubt that the field effect cannot be the major contributor to the effect of a β-substituent on the ease of formation of an α-sulfonyl carbanion. This, of course, adds further weight to the conclusion drawn previously that the principal interaction is negative hyperconjugation. The question remains, how much influence, if any, does the field effect have in this system?

One way of looking at the matter takes one along the following lines of thought. Our observation of a reasonable fit of our log *k* values to a simple *a* + *b* cos^2 θ relationship could be merely a fortuitous simplification, i.e., the reality may be more complex than first appearance would suggest. One might imagine, for example, that with more (and more accurate) k_N values the "true" log k_N vs. θ relationship requires another term, –*c* cos θ, such that the resulting curve for the negative hyperconjugation energy would look more like the familiar Karplus curve describing NMR coupling constants vs. torsion angle; the key change with the negative cos θ term is that the value of log k_N at 0° becomes distinctly smaller than that at 180°. Lambert's curves for the stabilization of incipient carbocations by the Me$_3$Si group show such

an appearance with the effect at 0° much weaker than that at 180° (13). Such a difference between 0 and 180° is usually ascribed to poorer π-type overlap in the 0° array vs. that at 180°. Is it possible that the field effect of the trialkylammonio group is just the correct magnitude to cancel any effect of a cos θ term? Such a picture is not inconceivable, but if the field effect were of real importance with R_3N^+, at least some sign would be expected to show up with a dipolar group. With the latter any field effect term would have the *same* sign as the cos θ component, and one would expect to see a clear sign of a lower value for log k_N at 0 vs. 180°. Careful inspection of the curves for the RO, RS, and R_2N groups shows little, if any, sign of such a result, suggesting that the combined influence of the field effect and any cos θ term cannot be large. In summary, the results from the present study are most simply accounted for by a primary negative hyperconjugation energy with, as a first approximation, a $\cos^2 θ$ dependence on the torsion angle (θ). In addition, there is also an inductive effect totally independent of θ and a field effect sufficiently small that the expected variation with θ is not clearly evident to us; the possibility of a more substantial field effect is not rigorously excluded.

Any reverse anomeric effect?

Perrin (14) has defined the reverse anomeric effect as "the tendency for cationic substituents on a tetrahydropyran ring to take the equatorial position". This notion had its roots in a 1965 report by Lemieux and Morgan (15) who noted that the ^1H NMR spectra of glycosylpyridinium ions pointed to an equatorial orientation for the ammonio group and not the usual axial conformation expected from the normal anomeric effect. They suggested that the putative effect might arise from field-effect interactions of the free electron pairs on the anomeric oxygen with the monopolar quaternary ammonio group. The considerable array of experiments, up to about 1995, designed to assess this proposal has been nicely summarized by Perrin (14). A relatively recent report by Kirby et al. (16) points to "a preference — though not a strong preference — for the conformation … favoured by the normal anomeric effect". Perrin et al. (17), in a recent report on the effect of protonation in *N*-glycopyranosyl imidazoles, found a small preference for the axial orientation of the protonated imidazolyl group relative to the unprotonated group. They concluded that "there is no firm evidence for [the reverse anomeric] effect" and that "previous evidence for this effect is not reliable" (17).

The present study is in qualitative accord with these recent investigations of the reverse anomeric effect in that we see a substantial negative hyperconjugative stabilization with all electron-withdrawing groups whether dipolar or monopolar. We must note, however, that there is a very sizable difference in magnitude of the hyperconjugative effect in our carbanionic system and in the glycoside ammonium salts. The *N*-methylation of the amines (e.g., **1b** → **1c**) is accompanied by a change in hyperconjugative stabilization of the incipient carbanion of about 5.9 kcal mol^{-1} (i.e., $2.303RT(6.29 - 1.95)/1000$). The changes in the *A* value accompanying protonation of the nitrogen reported by Perrin are all less than 0.3 kcal mol^{-1}. This difference between the carbanionic and carbohydrate systems is expected on the basis of eq. [2]. The energy of the electrons of the (incipient)

negative charge on carbon is much higher than that of the free electron pair on the tetrahydropyran oxygen atom, with the result that the denominator in eq. [2] ($\epsilon_A - \epsilon_B$) is relatively small in the carbanionic species and much higher in the carbohydrates.

The supposed inability of the trialkylammonio group to stabilize by delocalization

It has long been recognized that "the $(CH_3)_3N^+$ group cannot enter into conjugation in a conventional manner" (18), and the conclusion that has commonly been drawn is that the trialkylammonio group exerts its electronic effect exclusively by the polar (i.e., field plus inductive) effect. Our present results point to negative hyperconjugation of a β-trialkylammonio group in α-sulfonyl carbanion formation, and hence, any study that explicitly depends on the assumption that the trialkylammonio group functions only via the field and inductive effects probably requires reexamination.

Swain and co-workers (19, 20) based an important analysis of substituent effects on the possibility of assigning unique field and resonance parameters to every substituent. One of its cornerstones is that the large substituent effect of the trimethylammonio group has no resonance component and is entirely a polar effect. Bordwell et al. (21) have also invoked the same basic picture to assign the respective polar and resonance effects to electron-withdrawing groups. These pictures are, at the very least, incomplete in that they both ignore the possibility of hyperconjugation. In light of our work, it is tempting to suggest that our σ^*_{90} parameter would be the place to start in assigning the simple polar (field plus inductive) effect of any group.

Experimental

The experimental procedures are as described earlier (1), except that some of the rates in the **3** series were measured with a Varian Mercury 400 MHz instrument. Mass spectra: (*a*) electron impact (EI) and chemical ionization (CI) spectra were recorded using a direct-exposure probe at 70 eV with the source temperature at 150–175°C and isobutane as the gas for the CI measurements; (*b*) fast atom bombardment (FAB) were recorded using a glycerol – oxalic acid matrix at room temperature with xenon at 8 kV. New compounds were purified until ^1H and ^{13}C NMR spectra showed only signals appropriate to the assigned structure. Camag DF-5 silica gel was used for chromatography. *N*-Methylthiomorpholine 1,1-dioxide (**1b**) was obtained from Lancaster Synthesis Ltd.

4,4-Dimethyltetrahydro-1,4-thiazinium iodide 1,1-dioxide (1c)

A solution of **1b** (50 mg, 0.34 mmol) and MeI (238 mg, 1.68 mmol) in MeOH (1 mL) was allowed to stand overnight at room temperature. Ether (5 mL) was added and the precipitate filtered off and washed with ether giving **1c** as a white solid, mp 315°C (with decomposition (decomp.)) (80 mg, 82% yield). ^1H NMR (D$_2$O) δ: 3.2, (s, 6H), 3.5–3.7 (m, 4H), 3.8–4.0 (m, 4H). HR-MS calcd. for $C_6H_{14}NO_2S$: 164.0745; found (FAB) *m/z*: 164.0739.

3-(Dimethylamino)tetrahydrothiapyran 1,1-dioxide (2b)

$4H$-2,3-Dihydrothiapyran-1,1-dioxide (5) (22) (50 mg, 0.38 mmol) and dimethylamine (1 mL) were sealed in an NMR tube. After 2 days at room temperature, the tube was cooled in an ice bath and opened carefully and warmed to room temperature to let the excess Me_2NH evaporate. The residue was dissolved in CH_2Cl_2 and washed with 10% hydrochloric acid, 5% sodium chloride, and satd. NaCl and dried over $MgSO_4$. Removal of the solvent gave 2b as a white solid, mp 84–86°C, in almost quantitative yield. ^1H NMR (CDCl$_3$) δ: 1.25–1.50 (m, 2H), 1.80–2.02 (m, 2H), 2.23 (s, 6H), 2.70–2.85 (m, 2H), 2.90–3.05 (m, 2H), 3.10–3.20 (m, 1H). ^{13}C NMR (CDCl$_3$) δ: 20.9, 27.3, 40.5, 51.1, 52.2, 60.4. HR-MS calcd. for $C_7H_{15}NO_2S$: 177.0822; found (EI) m/z: 177.0821.

3-(Trimethylammonio)tetrahydrothiapyran 1,1-dioxide iodide (2c)

A solution of 2b (20 mg, 0.11 mmol) and MeI (100 mg, 0.70 mmol) in MeOH (2 mL) treated as in the preparation of 1c gave 2c as a white solid, mp 315°C (with decomp.) (31 mg, 86% yield). ^1H NMR (CDCl$_3$) δ: 1.50–1.85 (m, 2H), 2.15–2.40 (m, 2H), 2.90 (s, 9H), 2.85–3.20 (m, 2H), 3.36–3.52 (m, 1H), 3.66–3.80 (m, 2H). HR-MS calcd. for $C_8H_{18}NO_2S$: 192.1058; found (FAB) m/z: 192.1058.

endo-2-(Phenylsulfonyl)-3-exo-(dimethylamino)norbornane (3b)

The reaction of (6) (23) (100 mg, mmol) in CDCl$_3$ (0.5 mL) containing excess Me_2NH in a sealed NMR tube was monitored by ^1H NMR. After 24 h the volatile material was evaporated under reduced pressure and the residue chromatographed on a 20 g silica gel plate (benzene–ether, 1:1) giving 3b (100 mg, 83%) as a colourless solid, mp 105–107°C. IR (Nujol) ν_{max}: 1307 (s), 1292 (s), 1158 (s). ^1H NMR (CDCl$_3$) δ: 1.14 (m, 3H), 1.50–1.64 (m, 2H), 2.13 (s, 6H), 2.17–2.20 (br s, 2H), 2.44 (d, 1H, J = 5 Hz), 2.75 (d, 1H, J = 4 Hz), 3.22–3.24 (m, 1H), 7.42–7.59 (m, 3H), 7.79–7.87 (m, 2H). ^{13}C NMR (CDCl$_3$) δ: 23.2, 26.2, 37.1, 39.5, 39.9, 43.0, 69.5, 70.3, 127.8, 128.8, 133.1, 140.2. HR-MS calcd. for $C_{15}H_{21}NO_2S$: 279.1293; found (EI) m/z: 279.1297.

Trimethyl-exo-3-[endo-2-(phenylsulfonyl)norbornyl]ammonium iodide (3c)

A diethyl ether solution (5 mL) of 3b (200 mg, 0.71 mmol) and excess MeI was refluxed for 24 h. The volatile material was evaporated and the residue rinsed several times with ether leaving 3d as a colourless solid, mp 209–211°C (250 mg, 85%). IR (Nujol): 1387 (s), 1312 (s), 1158 (s). ^1H NMR (D$_2$O) δ: 1.10–1.40 (m, 3H), 1.50–1.90 (m, 3H), 2.10 (br s, 1H), 2.86 (d, 1H, J = 4 Hz), 3.07 (s, 9H), 3.87 (d, 1H, J = 6 Hz), 4.33 (br s, 1H), 7.54–7.63 (m, 2H), 7.66–7.75 (m, 1H), 7.85–7.91 (m, 2H). ^{13}C NMR (CDCl$_3$) δ: 24.5, 29.7, 39.7, 43.1, 44.3, 55.6, 70.5, 80.0, 130.6, 132.5, 137.8, 139.5. HR-MS calcd. for $C_{16}H_{24}NO_2S$: 294.1528; found (FAB) m/z: 294.1529.

1,4-Dithiane 1,1-dioxide (1d)

Literature preparation (24), mp 202–204°C. ^1H NMR (CDCl$_3$) δ: 3.05–3.20 (m, 4H), 3.20–3.30 (m, 4H). ^{13}C NMR (CDCl$_3$) δ: 27.7, 54.1.

3-(Methylthio)tetrahydrothiapyran 1,1-dioxide (2d)

A solution of 3-bromotetrahydrothiapyran 1,1-dioxide (25) (350 mg, 1.64 mmol) and NaSMe (173 mg, 2.46 mmol) in 2-butanol (30 mL) was refluxed for 1 h under N$_2$. Work up and recrystallization from EtOAc–hexane gave 2d as white needles (210 mg, 71%), mp 94 to 95°C. ^1H NMR (CDCl$_3$) δ: 1.3–1.5 (m, 1H), 2.0–2.5 (m, 3H), 2.14 (s, 3H), 2.5–3.2 (m, 4H), 3.2–3.5 (m, 1H). ^{13}C NMR (CDCl$_3$) δ: 13.5, 23.1 30.8, 41.1, 50.8, 56.8. HR-MS calcd. for $C_6H_{12}O_2S$: 180.0279; found (EI) m/z: 180.0276.

3-(Methylsulfonyl)tetrahydrothiapyran 1,1-dioxide (2e)

A mixture of 2d (230 mg, 1.28 mmol), glacial HOAc (~1 mL), and 30% H$_2$O$_2$ (~2 mL) was heated at 100°C for 15 min. The mixture was cooled, water (30 mL) was added, and the mixture extracted with CH$_2$Cl$_2$ (5 × 40 mL). The combined extracts were then washed with 5% aq NaOH (2 × 30 mL) and satd. NaCl (2 × 60 mL). Evaporation of the solvent and recrystallization from EtOH gave 2e as white crystals (57 mg, 21%), mp 210.5–212°C. ^1H NMR (CDCl$_3$) δ: 1.20–1.30 (m, 1H), 2.05–2.50 (m, 3H), 2.94 (s, 3H), 3.05–3.25 (m, 2H), 3.40–3.60 (m, 2H), 4.0–4.2 (m, 1H). ^{13}C NMR (CDCl$_3$) δ: 22.0, 23.5, 38.6, 49.8, 50.8, 59.1. HR-MS calcd. for $C_6H_{13}O_4S$ ([M + 1]): 213.0255; found (CI) m/z: 213.0261.

endo-2-(Phenylsulfonyl)-exo-3-(methylthio)norbornane (3d)

endo-2-Chloro-exo-3-(phenylsulfonyl)norbornane (23) (230 mg, 0.85 mmol) and sodium methoxide (92 mg, 1.3 mmol) in dry MeOH (5 mL) were refluxed for 5 h. The MeOH was evaporated and the residue taken up in CH$_2$Cl$_2$. The solution was washed with water and evaporated. Chromatography on a silica gel plate (20 g, 20 × 20 cm) developing with benzene–ether (3:1) gave 3d (190 mg, 79%) as a colourless solid, mp 119–121°C. IR (Nujol) (cm^{-1}) ν_{max}: 1387 (s), 1158 (s). ^1H NMR (CDCl$_3$) δ: 1.34–1.49 (m, 3H), 1.64–1.82 (m, 2H), 2.04 (s, 3H), 2.26–2.37 (m, 1H), 2.39 (d, 1H, J = 5 Hz), 2.55 (br s, 1H), 3.10–3.22 (m, 2H), 7.20–7.58 (m, 2H), 7.59–7.66 (m, 1H), 7.87–7.97 (m, 2H). ^{13}C NMR (CDCl$_3$) 16.0, 23.3, 27.6, 37.8, 40.3, 43.8, 49.8, 73.5, 128.01, 128.06, 133.4, 140.1. HR-MS calcd. for $C_{14}H_{18}O_2S_2$: 282.0748; found (EI) m/z: 282.0742.

endo-2-(Phenylsulfonyl)-exo-3-(methylsulfonyl)norbornane (3e)

A solution of 3d (130 mg, 0.46 mmol) in MeOH (8 mL) at 0°C was added with stirring to a solution of OXONE® (847 mg, 1.4 mmol) in H$_2$O (5 mL) at 0°C, and the mixture allowed to come to room temperature. After 4.5 h the mixture was extracted with excess CH$_2$Cl$_2$, the organic layer dried, and the solvent evaporated. The residue was chromatographed on a 20 g silica gel plate (benzene–ether, 3:1) giving the sulfone (3e) as a colourless solid (123 mg, 85%), mp 190 to 191°C. IR (Nujol) ν_{max}: 1297 (s), 1148 (s). ^1H NMR (CDCl$_3$) δ: 1.25–1.60 (m, 3H), 1.70–1.90 (m, 2H), 2.27 (br s, 2H), 3.04 (s, 3H), 3.04–3.15 (br s, 1H), 3.50 (d, 1H, J = 4 Hz), 3.89 (br s, 1H), 7.56–7.68 (m, 2H) 7.65–7.73 (m, 1H), 7.85–7.97 (m, 2H). ^{13}C NMR (CDCl$_3$) δ: 22.5, 28.0, 38.1, 39.8, 40.6, 41.1, 64.7, 67.3, 128.3, 134.1, 136.2,

138.2. HR-MS calcd. for $C_{14}H_{19}O_4S_2$ ([M + 1]): 315.0725; found (CI) m/z: 315.0730.

1,4-Dithia-*trans*-decalin 1,1,4,4-tetroxide (4c)

Literature preparation (26), mp 289–291°C (sealed capillary), lit. (26) mp value 288°C. ^{1}H NMR (CDCl$_3$) δ: 1.25–1.45 (m, 2H), 1.55–1.75 (m, 2H) 1.88–2.05 (m, 2H), 2.24–2.38 (m, 2H), 3.29–3.42 (m, 2H), 3.40–3.53 (m, 2H), 3.68–3.88 (m, 2H). ^{13}C NMR (CDCl$_3$) δ: 20.2, 23.3, 49.0, 61.6.

Influence of alkali metal cations on the photoheterolysis of 9-cyclopropyl-9-fluorenol and the reactivity of the 9-cyclopropyl-9-fluorenyl cation in non-acidic zeolites

Melanie A. O'Neill and Frances L. Cozens

Abstract: Alkali metal cation regulation of carbocation formation and reactivity in non-acidic zeolites is probed using the photoheterolysis reaction of 9-cyclopropyl-9-fluorenol. Nanosecond time-resolved diffuse reflectance is employed to directly observe the 9-cyclopropyl-9-fluorenyl cation as a transient species within the non-acidic zeolites. The efficiency of carbocation formation via photoheterolysis and the dynamics of other reaction pathways available to photoexcited 9-cyclopropyl-9-fluorenol are found to be strongly dependent on the zeolite alkali metal counterion. In particular, the yield of carbocation decreases with increasing counterion size in a manner consistent with the zeolite assisting the excited state C—O bond cleavage via Lewis acid catalysis involving the metal cation. Zeolite encapsulation is also found to modulate the ability of water and methanol to assist photoheterolysis. For instance, the influence of coadsorbed water on the photoheterolysis reaction within zeolites is found to be highly sensitive to the alkali metal cation. The rate constant for intrazeolite decay of the 9-cyclopropyl-9-fluorenyl cation increases significantly as the alkali metal cation size increases and as the Si–Al ratio decreases. These reactivity trends suggest that the intrazeolite decay of the 9-cyclopropyl-9-fluorenyl cation involves nucleophilic addition at the active site [Si-O-Al]$^-$ bridges of the zeolite framework. In addition, the reactivity of the 9-cyclopropyl-9-fluorenyl cation within alkali metal zeolites can be regulated by the co-inclusion of reagents such as methanol, water, and 1,1,1,3,3,3-hexafluoro-2-propanol.

Key words: cation-exchanged zeolites, 9-cyclopropyl-9-fluorenyl cation, laser photolysis, reactivity.

Résumé : La formation de carbocation contrôlée par les cations de métaux alcalins, et la réactivité dans les zéolites non acides sont mises en évidence en utilisant la réaction de photohétérolyse du 9-cyclopropyl-9-fluoroénol. On a employé le pouvoir réflecteur diffus résolu dans des temps de l'ordre de la nanoseconde, pour observer directement le cation 9-cyclopropyl-9-fluorényle comme une espèce intermédiaire dans les zéolites non acides. On a trouvé que l'efficacité de la formation du carbocation via la photohétérolyse ainsi que la dynamique d'autres chemins réactionnels disponibles pour exciter photochimiquement le 9-cyclopropyl-9-fluorénol dépendent fortement du contre-ion métal alcalin zéolite. En particulier, le rendement de carbocation décroît avec l'augmentation de la taille du contre-ion d'une manière qui suggère une influence de la zéolite sur l'état excité résultant du clivage de la liaison C—O via une catalyse acide de Lewis impliquant le cation métallique. On a également trouvé que l'encapsulation de la zéolite module la capacité de l'eau et du méthanol à assister la photohétérolyse. Par exemple, on a trouvé que l'influence de l'eau coadsorbée sur la réaction de photohétérolyse dans la zéolite dépend fortement du cation de métal alcalin. La constante de vitesse pour la décroissance de la zéolite encapsulée dans le cation 9-cyclopropyl-9-fluorényle augmente de façon significative lorsque la taille du cation de métal alcalin augmente et lorsque le ratio Si–Al diminue. Ces réactivités suggèrent que la décroissance de la zéolite encapsulée dans le cation 9-cyclopropyl-9-fluorényle implique une addition nucléophile au niveau des ponts [Si-O-Al]$^-$ du site actif du squelette de la zéolite. De plus la réactivité du cation 9-cyclopropyl-9-fluorényle à l'intérieur des zéolites de métal alcalin peut être contrôlée par la coinclusion de réactifs tels le méthanol, l'eau et le 1,1,1,3,3,3-hexafluoro-2-propanol.

Mots clés : zéolites à échange de cation, cation 9-cyclopropyl-9-fluorényle, photolyse au laser, réactivité.

Introduction

Zeolites (1–3) continue to demonstrate their potential as unique and versatile host materials for a variety of chemical transformations (4–10). The efficient catalytic activity of zeolites and the important role of cationic intermediates in these reactions have been the impetus for much research aimed at understanding the chemistry of carbocations (11–18) and radical cations (8, 16, 19–25) within the cavities and channels of zeolites. However, to date, most studies of

carbocations within zeolite hosts have focused on proton-exchanged Brønsted zeolites, or zeolites with divalent metal ions such as Ca^{2+} that possess strong acidic properties upon thermal activation (26–29). In the highly acidic environment of acid zeolites a wide number of carbocations can be readily generated and, more importantly, are thermodynamically and kinetically stabilized to the extent that they can be readily examined by steady-state techniques such as solid-state NMR (12, 15, 30–34), UV–vis diffuse reflectance (9, 35–39), and UV–vis absorption spectroscopy (40, 41). This research has contributed to the emerging picture of Brønsted zeolites not as superacid solid materials as once envisioned, but as strong acids whose ability to stabilize and influence the reactivity of cationic species is closely linked to the dynamic role of the zeolite framework in carbocation chemistry (12). Thus, although several types of relatively stabilized carbocations such as triarylmethyl (38), xanthylium (11, 36), indanyl (30), and cyclopentenyl cations (33) can be detected as stable ions in acidic zeolites, more reactive species such as phenethyl cations (30) do not persist within these environments.

In addition to strong Brønsted and Lewis acid sites, stabilization of positively charged intermediates in acidic zeolites has been attributed to the high electrostatic fields associated with the intrazeolite environment and the tight confinement provided by the zeolite micropore, which protects the ion from nucleophilic attack (9, 42, 43). Consequently, non-protic zeolites have also been shown to be useful media for the photochemical generation and stabilization of radical cations (8, 19, 23, 24), and more recently have been shown to be unique hosts for the study of reactive carbocations (17, 18). Further insights into carbocation-mediated reactions can be obtained from studies investigating the behavior of carbocations within non-protic, alkali metal cation-exchanged zeolites. For example, using alkali metal cation zeolites, the influence of the counterion on the generation and kinetic stability of the carbocation can be readily explored. In this way it is possible to examine the effect of properties such as electrostatic field strength and exchangeable counterion size on the chemistry of carbocations within the cavities of alkali metal cation zeolites. While the negatively charged framework in proton-exchanged zeolites is generally presumed to act as a large, relatively non-nucleophilic counterion, the possibility that localized sites of electron density in these zeolite frameworks, namely the [Si-O-Al]⁻ bridges, may be reactive towards carbocation intermediates can also be explored.

9-Fluorenol derivatives are attractive probe molecules for investigating within non-acidic zeolites carbocation formation and reactivity, both of which have been studied extensively in solution (44–49). In solution the absorption spectra and absolute reactivity of a wide range of 9-substituted-9-fluorenyl cations have been well characterized as a function of substituent and solvent conditions (50–53). In addition, the formation of 9-fluorenyl cations by photoheterolysis of 9-fluorenols is an interesting probe reaction, particularly since considerable experimental evidence suggests that photoheterolysis of the C—O bond of 9-fluorenols is assisted by proton sources (44–46, 49). Therefore, generation of 9-fluorenyl cations in non-protic zeolites addresses questions concerning the existence and nature of acidic sites

within these frameworks and their potential to catalyze heterolysis reactions. Since 9-fluorenols are known to undergo both heterolysis and ionization upon photoexcitation in solution (48), the competition between carbocation and radical cation formation can be directly examined as a function of the local zeolite environment. This can afford new insights into the dynamics of carbocation formation within non-acidic zeolites.

Herein we report on the dynamics of photoexcited 9-cyclopropyl-9-fluorenol (cPrFOH) and on the reactivity of the photogenerated 9-cyclopropyl-9-fluorenyl cation in alkali metal cation zeolites. The presence of the cyclopropyl substituent at the 9-position affords a significant degree of stability to the 9-fluorenyl cation without introducing unwanted steric bulk or structural changes associated with a 9-aryl substituent (50). In the present work the photogeneration and reactivity of the 9-cyclopropyl-9-fluorenyl cation is used to investigate the internal environment within non-protic Y and X zeolites in terms of their ability to mediate photoheterolysis and to influence the reactivity of cationic intermediates. Particular emphasis is placed on the rather dramatic role the alkali metal cation plays in defining both the reactivity of photoexcited cPrFOH towards photoheterolysis and the lifetime of the corresponding 9-cyclopropyl-9-fluorenyl cation. In addition, the presence of protic co-reagents, such as methanol, water and 1,1,1,3,3,3-hexafluoro-2-propanol (HFIP), on the efficiency of both photoheterolysis and the reactivity of the carbocation was investigated.

Results

Laser photolysis of 9-cyclopropyl-9-fluorenol in dry NaY

The transient diffuse reflectance spectrum obtained upon 308 nm laser irradiation of cPrFOH in evacuated (1×10^{-4} torr, 1 torr = 133.322 Pa) dry NaY has three distinct absorption bands at 380, 445, and 640 nm and a well-defined shoulder at 330 nm (Fig. 1a). The absorption bands located at 380 and 445 nm, together with the shoulder at 330 nm bear a close resemblance to the known absorption spectrum of the 9-cyclopropyl-9-fluorenyl cation previously generated photochemically in 2,2,2-trifluoroethanol (TFE) (50). The similarities between the diffuse reflectance spectrum in NaY and the known absorption spectrum of the 9-cyclopropyl-9-fluorenyl cation strongly suggest that this carbocation contributes significantly to the absorption bands observed at 330, 380, and 445 nm in NaY. In addition, the transient species observed at 380 and 445 nm is unreactive towards oxygen, but decays more rapidly in the presence of nucleophiles such as water and methanol (vide infra), consistent with its identification as a cationic intermediate. Furthermore, the absorption at these wavelengths decays (Fig. 1 inset) with a first-order rate constant of 3.8×10^5 s⁻¹ (Table 1) that lies in the range expected for the 9-cyclopropyl-9-fluorenyl cation based on the reactivity of other 9-fluorenyl cations (18) within NaY. These observations are all consistent with the presence of the 9-cyclopropyl-9-fluorenyl cation generated by photoheterolysis of cPrFOH within the cavities of NaY (Scheme 1, path (a)).

A significant long-lived absorption remains at 380 nm after the decay of the 9-cyclopropyl-9-fluorenyl cation is

Table 1. Decay rate constants for the 9-cyclopropyl-9-fluorenyl cation in dry and hydrated alkali metal cation Y zeolites, ratio of carbocation decay rate constant observed under hydrated and dry conditions, and increase in carbocation yield upon hydration.

Zeolite	k_{dry} (10^5 s^{-1})	k_{hyd} (10^5 s^{-1})	k_{hyd}/k_{dry}	Increase in carbocation yield upon hydration (%)
LiY	0.64 ± 0.01	2.5 ± 0.1	3.9	3

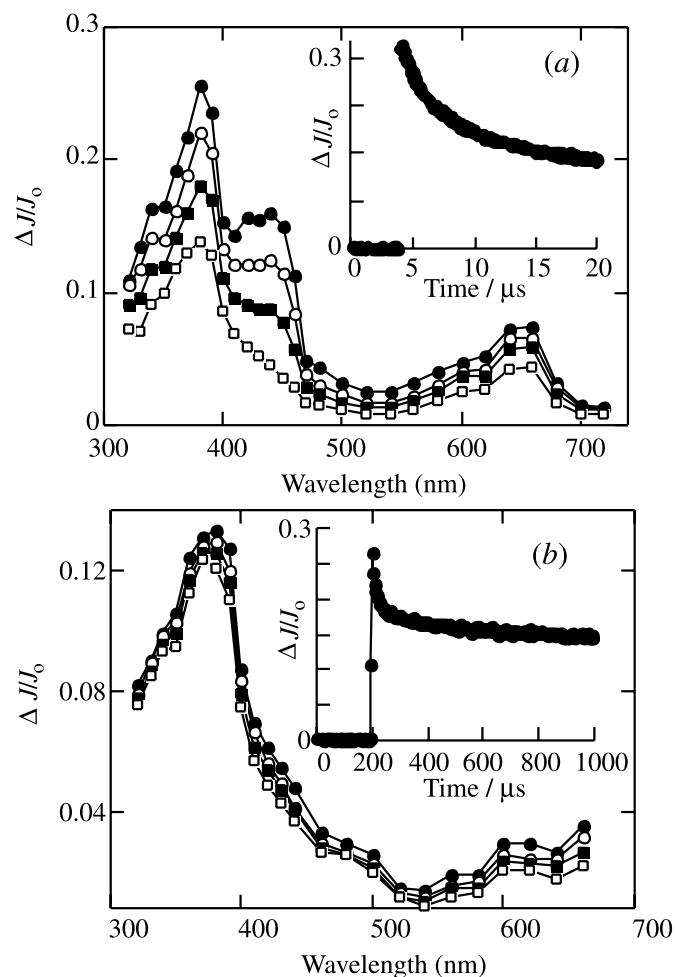
Fig. 1. (*a*) Transient diffuse reflectance spectra generated 700 ns (●), 2.40 μs (○), 7.00 μs (■), and 34.0 μs (□) after 308 nm laser irradiation of cPrFOH in evacuated NaY. Inset shows the decay trace monitored at 445 nm over a short time scale. (*b*) Transient diffuse reflectance spectra generated 16.8 μs (●), 294 μs (○), 440 μs (■), and 684 μs (□) after 308 nm laser irradiation of cPrFOH in evacuated NaY. Inset shows the decay trace monitored at 380 nm over a long time scale.


(47) and is identified as the triene isomer generated by photoinduced rearrangement of cPrFOH within NaY (Scheme 1, path (b)). Evidence to support the identification of the long-lived 380 nm band to the rearranged triene isomer is the lack of dependence on the addition of oxygen to the zeolite sample and the long lifetime where virtually no decay is observed at time scales as long as 1 ms after the laser pulse (54). Both observations are consistent with the expected behavior for the rearranged triene isomer.

The transient diffuse reflectance spectrum shown in Fig. 1a also has long wavelength absorption with a maximum at 640 nm and a shoulder near 600 nm. This absorption band is not associated with either the 9-cyclopropyl-9-fluorenyl cation or the triene isomer, but is highly characteristic of fluorene-type radical cations (46, 48, 55). The detection of the cPrFOH radical cation following laser photolysis of cPrFOH in NaY is anticipated based on the observation that other 9-alkyl-9-fluorenols undergo photoionization in alkali metal zeolites to generate the corresponding radical cation (18). Thus, the absorption band at 640 nm is attributed to the cPrFOH radical cation produced by photoionization of cPrFOH within NaY (Scheme 1, path (c)).

The cPrFOH radical cation decays over a broad range of time scales from a few μs to several hundreds of μs and thus exhibits notable fast and slow components. Although the decay kinetics of the radical cation are somewhat complex, the decay of the fast component at 640 nm can be represented by a first-order process described by the rate constants given in Table 2. As fluorene-type radical cations are known to have a second absorption band at 380 nm (46, 48), part of the fast decaying absorption in this region following laser photolysis of cPrFOH within NaY must also contain a contribution from the cPrFOH radical cation. The 380 nm band is therefore very complex, with three species contributing to the absorption at that wavelength. As a result, detailed examination of the reactivity of the 9-cyclopropyl-9-fluorenyl cation focussed on the 445 nm region where only the carbocation has significant absorption.

Laser photolysis of 9-cyclopropyl-9-fluorenol in dry alkali metal cation MY zeolites

Laser photolysis of cPrFOH incorporated within other alkali metal cation (LiY, KY, RbY, and CsY) zeolites was carried out to examine the effect of the zeolite environment on the generation and reactivity of the 9-cyclopropyl-9-fluorenyl cation. The transient diffuse reflectance spectra obtained upon 308 nm excitation of cPrFOH in the MY zeolites under dry vacuum conditions (1×10^{-4} torr, 1 torr =

complete (Fig. 1b). This suggests the presence of an additional species upon laser photolysis of cPrFOH in NaY. The spectral appearance of this species is closely similar to that previously observed upon laser irradiation of other 9-fluorenols in alkali metal cation zeolites (18) and in solution

RbY	8.5 ± 0.5
CsY	5.6 ± 0.2

133.322 Pa) are shown in Fig. 2. Each spectrum clearly exhibits distinct features, especially with regard to the 9-cyclopropyl-9-fluorenyl cation probed at 445 nm, which shows a dramatic dependence on the zeolite counterion both in terms of yield and absolute reactivity (Fig. 2 insets). For instance, as the size of the alkali metal counterion increases upon going from Li$^+$ to Rb$^+$, the observed rate constant for the disappearance of the 9-cyclopropyl-9-fluorenyl cation increases significantly from $k = 6.4 \times 10^4$ s^{-1} in LiY to $k = 1.04 \times 10^6$ s^{-1} in RbY (Table 1). In addition, the intensity of the absorption at 445 nm, which is proportional to the yield of carbocation formation, decreases significantly along the zeolite series and is not detected at all in CsY. Thus, the

Fig. 3. Variation in the yield of the 9-cyclopropyl-9-fluorenyl cation (◆), cPrFOH radical cation (○), and rearranged triene isomer (□) as a function of alkali metal cation radius following laser photolysis of cPrFOH in evacuated LiY, NaY, KY, RbY, and CsY zeolites.
alkali metal counterion exerts two distinct effects: it modulates both the efficiency of the photoheterolysis reaction and carbocation formation (Fig. 3) and the reactivity of the resulting 9-cyclopropyl-9-fluorenyl cation.

In addition to carbocation formation via heterolysis, the efficiencies of ionization and rearrangement are also strongly influenced by the nature of the zeolite counterion (Fig. 3). The yield of the triene isomer was evaluated from the absorption at 380 nm after the other transients with absorption at that wavelength had completely decayed. The yield of the triene isomer initially increases with increasing alkali cation size to a maximum in KY where subsequent increases in counterion size result in an overall decrease in the yield of the triene isomer. Correspondingly, the yield of radical cation, as determined from the intensity of absorption observed at 640 nm immediately following the laser pulse, decreases slightly upon going from Li^+ to K^+ and then increases in the larger alkali metal cation zeolites and is the major transient formed in CsY.

The transient diffuse reflectance spectrum generated upon laser photolysis of cPrFOH within the cavities of dry, evacuated NaX is characterized by three absorption maxima at 380, 445, and 640 nm, and closely resembles the spectra observed in the alkali metal cation Y zeolites, in particular KY. The first-order decay rate constant for the carbocation at 445 nm in NaX of $k = 7.9 \times 10^5$ s^{-1} is twice as large as in NaY where $k = 3.8 \times 10^5$ s^{-1} (Table 1). At longer times scales after the carbocation has completely decayed (>20 μs), and most of the radical cation has disappeared (>200 μs), an intense absorption band at 380 nm due to the triene isomer is observed and exhibits no decay in NaX over times as long as 1 ms.

Co-adsorption of water and methanol in NaY

Water has been shown to strongly influence the photoheterolysis of 9-fluorenol derivatives in solution and tends to increase the efficiency of photoheterolysis relative

to non-protic solvents such as acetonitrile (45, 49). The effect of such reagents on the microenvironment of the zeolite cavity can be examined by investigating how co-adsorbates influence both the photochemistry of cPrFOH and reactivity of the 9-cyclopropyl-9-fluorenyl cation.

The transient diffuse reflectance spectra obtained upon laser photolysis of cPrFOH in NaY containing 6% water and 6% methanol[2] along with the corresponding decay traces at 445 nm are shown in Fig. 4. The first-order rate constants $k = 7.2 \times 10^5$ s^{-1} and $k = 9.9 \times 10^5$ s^{-1} obtained for the decay of the carbocation at 445 nm in NaY containing 6% water and 6% methanol, respectively, are considerably faster than that observed under dry conditions ($k = 3.8 \times 10^5$ s^{-1}). In addition, upon coincorporation of these protic reagents, the transient spectra more closely resemble that observed upon photolysis of the same precursor in neat TFE where carbocation formation is the dominant reaction pathway. In particular, the long-lived absorption at 380 nm because of the rearranged triene isomer and long wavelength absorption because of the cPrFOH radical cation are attenuated in the zeolite hosts containing a proton source. The attenuation of these absorption bands suggests that photoheterolysis of the C—O bond is now the dominant reaction pathway and that water and methanol co-adsorbed within the zeolite framework strongly influences the behaviour of photoexcited cPrFOH. The spectra show that the influence of methanol is not as dramatic as the influence of water on the relative yield of carbocation with respect to the other processes that are available to photoexcited cPrFOH within the zeolite environment. As such, the transient spectrum observed in NaY containing methanol continues to possess visible absorption because of the triene isomer at 380 nm and cPrFOH radical cation at 640 nm.

The rate constant for the decay of the 9-cyclopropyl-9-fluorenyl cation at 445 nm increases as a function of the concentration of methanol and water (Fig. 5a). The increase in the rate constant upon the addition of methanol or water to the zeolite cavity is in agreement with a mechanism involving nucleophilic attack of the carbocation via co-incorporated methanol or water (eq. [1]). The greater dependence on methanol concentration as compared to water is consistent with the greater nucleophilicity of methanol as compared to water towards reactive carbocations within zeolites (17, 18).

[1]
When the change in diffuse reflectance ($\Delta J/J_o$) is monitored at 445 nm following photolysis of cPrFOH in NaY as a function of water or methanol content, a steady increase in the yield of carbocation with increasing adsorbate concentration is revealed (Fig. 5b). This clearly demonstrates that C—O bond heterolysis of excited cPrFOH in NaY is progressively enhanced by co-adsorption of increasingly higher concentrations of either water or methanol. Notably, the increase in photoheterolysis within NaY is more substantial

using water as a protic additive as compared to methanol. This is consistent with the higher efficiency of water as a reagent to promote photoheterolysis of 9-fluorenols in solution.

Co-adsorption of 1,1,1,3,3,3-hexafluoro-2-propanol in NaY

We previously reported that the inclusion of small amounts of HFIP within alkali metal cation zeolites enhances the yield and the lifetime of the 9-methyl-9-fluorenyl and 9-fluorenyl cations (18). Similarly, the inclusion of small amounts of HFIP within NaY influences both the yield and the lifetime of the 9-cyclopropyl-9-fluorenyl cation generated by laser photolysis of cPrFOH in NaY. Thus, the inclusion of progressively larger concentrations of HFIP leads

to a progressive increase in the yield of the 9-cyclopropyl-9-fluorenyl cation (Fig. 5*b*). The magnitude by which HFIP enhances photoheterolysis is less than that achieved using water as a co-adsorbate, but is similar to the enhancement obtained via the addition of methanol to the zeolite sample. In addition, the rate constants for decay of the 9-cyclopropyl-9-fluorenyl cation exhibit a progressive decrease with increasing concentrations of HFIP (Fig. 5*a*). This contrasts with the influence of methanol or water and is consistent with the known kinetic stabilizing effect of HFIP on the reactivity of reactive carbocations in solution (56, 57).

Co-adsorption of water in MY zeolites

The transient diffuse reflectance spectrum obtained upon 308 nm laser photolysis of cPrFOH in hydrated LiY (Fig. 6*a*) closely resembles the absorption spectrum of the 9-cyclopropyl-9-fluorenyl cation in TFE. Weak absorption due

Fig. 6. Transient diffuse reflectance spectra generated at 200 ns (●), 1.76 μs (○), 7.40 μs (■), and 14.0 μs (□) after 308 nm laser irradiation of cPrFOH in hydrated (*a*) LiY and (*b*) KY; transient diffuse reflectance spectra generated at 50 ns (●), 180 ns (○), 380 ns (■), and 3.46 μs (□) after 308 nm laser irradiation of cPrFOH in hydrated (*c*) RbY and (*d*) CsY.
to the cPrFOH radical cation at 640 nm persists under hydrated conditions, but little long-lived absorption at 380 nm due to the rearranged triene isomer is evident. Increased carbocation generation is also apparent from the transient diffuse reflectance spectra obtained in hydrated KY and hydrated RbY (Figs. 6*b* and 6*c* and Table 1) where the transient spectra show a significantly enhanced yield of the 9-cyclopropyl-9-fluorenyl cation upon the absorption of water into the zeolite. In each case the addition of water into the MY framework caused an increase in the observed rate constant for the decay of the 9-cyclopropyl-9-fluorenyl cation compared to dry conditions (Table 1). Notably, the relative reactivity of the carbocation in hydrated alkali metal cation zeolites is the same as observed in the absence of water. Thus, the 9-cyclopropyl-9-fluorenyl cation is longest lived in hydrated LiY and becomes progressively shorter lived as the counterion size increases. In addition, the long-lived absorption because of the triene isomer continues to contribute to the absorption at 380 nm in hydrated KY, and particularly in hydrated RbY where the isomer is still a very dominate species. Interestingly, the transient diffuse reflectance spectrum observed in hydrated CsY is very similar to that in dry CsY. The spectrum does not contain any significant contribution from the 9-cyclopropyl-9-fluorenyl cation but instead strongly resembles that of the cPrFOH radical cation in combination with the triene isomer (Fig. 6*d*). Thus, heterolytic cleavage of the hydroxy group does not seem to be a facile process for photoexcited cPrFOH in CsY under either dry or hydrated conditions. The

rate constants for the decay of the cPrFOH radical cation in dry MY zeolites are given in Table 2.

Discussion

Influence of alkali metal cations on the 9-cyclopropyl-9-fluorenyl cation formation

Photoexcitation of cPrFOH encapsulated within dry alkali metal cation zeolites leads to the formation of the 9-cyclopropyl-9-fluorenyl cation via photoheterolysis of the C—O bond (48, 50). As the photohydroxylation reaction of 9-fluorenols is thought to occur predominately from the singlet excited state in the presence of a proton source (45, 46), which is needed to assist in the cleavage of the hydroxyl group, it is of interest to ascertain the mechanism of interaction between the intrazeolite environment and the leaving hydroxide ion. One possible explanation is that the zeolite framework actually aids the photodehydroxylation reaction where the metal cation assists the excited state C—O bond cleavage via Lewis-acid-type catalysis (Scheme 2). In this case, interaction of the alkali metal cation stabilizes the hydroxide ion as the C—O bond cleaves in the excited state. A weak interaction between the alcohol functionality of cPrFOH and the zeolite alkali metal cation is expected even in the ground state, based on similar interactions between alkali metal cations and methanol within zeolites (58–63). Once an interaction is established in the ground state, cPrFOH will likely be oriented appropriately for Lewis-acid-assisted

Scheme 2.
heterolysis upon photoexcitation. The ground state interaction should be highly dependent on the cation size. For instance the calculated binding energies of methanol at the bare alkali metal cations are 150 kJ mol^{-1} for Li$^+$ and 61 kJ mol^{-1} for Cs$^+$ (63). The binding energies of methanol within the alkali-metal-exchanged zeolites have been estimated to be about half as large as those associated with the bare cations, which correlates with the lower positive charge of the cations at zeolite clusters (63).

The notion that the zeolite counterion facilitates the cleavage of the hydroxyl group from photoexcited cPrFOH is supported by the distinct variation in photoheterolysis efficiency as a function of zeolite counterion (Fig. 3). For instance, the overall yield (absolute and relative) of the 9-cyclopropyl-9-fluorenyl cation decreases dramatically as the Y zeolite counterion is varied from Li$^+$ to Cs$^+$. In fact, although carbocation formation is the dominant reaction pathway of photoexcited cPrFOH in LiY, no carbocation is detected in CsY. The large variation in the yield of carbocation as a function of alkali metal cation size is most consistent with a reduction in the efficiency of the photoheterolysis reaction as the counterion size increases from Li$^+$ to Cs$^+$. This is the anticipated trend in efficiency for a heterolysis reaction involving Lewis acid catalysis within the zeolite cavities (Scheme 2) since the Lewis acidity of the counterion, and of the zeolite interior, decreases significantly within increasing alkali metal cation size (64, 65).

Influence of protic reagents on the 9-cyclopropyl-9-fluorenyl cation formation

In alkali metal cation zeolites both the absolute yield of carbocation formation and the yield relative to competing processes such as ionization and rearrangement increase upon inclusion of protic reagents such as water, methanol, and HFIP, within the zeolite. The concentration of reagent needed to observe this effect is relatively small, often only a few molecules per zeolite cavity. Under these conditions, the surrounding environment experienced by the photoexcited 9-fluorenol is not comparable to a solvent cage of these reagents, as would be the case, for instance, at much higher concentrations, or in a slurry of zeolite and cosolvent. Instead, the intrazeolite environment is akin to that observed under dry conditions with the exception that additional guest molecules, the protic reagent, are present within the zeolite cavities. Therefore, the ability of these protic guest molecules to enhance photoheterolysis is likely a consequence of the combined influences of both the zeolite matrix and the proton source, with the protic reagent actively participating in the C—OH bond cleavage of the excited state 9-fluorenol. The protic reagent incorporated within the zeolite cavity can interact with the oxygen of the excited 9-fluorenol and stabilize the incipient charge on the developing hydroxide ion

Scheme 3.
(Scheme 3). Direct assistance of the photodehydroxylation of 9-methyl-9-fluorenol and 9-fluorenol by zeolite-encapsulated HFIP has been previously demonstrated from studies of isotope effects using HFIP-OD (18).

The experimental results obtained within hydrated alkali metal cation zeolites support the notion that Lewis acid catalysis is an important interaction for carbocation generation. The dependence of carbocation yield on the alkali metal cation size is maintained even under hydrated conditions, where the carbocation yield is the highest in hydrated LiY and decreases dramatically with cation size such that no carbocation is observed in hydrated CsY. Thus, even under conditions where small amounts of water are included within the zeolite cavities, the distinct influence of the zeolite microenvironment continues to control the efficiency of carbocation formation. This is noteworthy considering the powerful ability of water to regulate the efficiency of photoheterolysis of 9-fluorenol derivatives in homogeneous aqueous acetonitrile solutions. These observations provide further evidence that the zeolite framework and, particularly the alkali metal counterions, plays a direct and defining role in intrazeolite photoheterolysis, and that carbocation formation is likely a consequence of Lewis-acid-type interactions between the excited state 9-fluorenol and the framework alkali metal cation.

In this regard, it is interesting to consider the magnitude by which hydration influences the efficiency of photoheterolysis within different zeolite environments. In LiY, where heterolysis is the favored reaction pathway of photoexcited cPrFOH in the absence of a proton source, the inclusion of water does little to further enhance the excited-state bond cleavage. Conversely, in RbY, where the absolute and relative yield of photoheterolysis is very low compared to other reaction pathways, the inclusion of water dramatically increases the yield of the photoheterolysis reaction. However, in this case the spectrum still has significant contributions from the triene isomer and the cPrFOH radical cation. Thus, in the strongest Lewis acid zeolite (LiY), Li$^+$-assisted photoheterolysis dominates the chemistry of photoexcited cPrFOH and the co-adsorbed water participates little in the heterolysis reaction. Conversely, in RbY, Rb$^+$-assisted heterolysis is a relatively minor pathway for photoexcited cPrFOH, and water has a much greater opportunity to participate in photoheterolysis. In CsY, the ability of the zeolite to facilitate photoheterolysis of cPrFOH, even under hydrated conditions, is too small to compete with the other photochemical processes taking place within CsY, particularly

photoionization to the cPrFOH radical cation. These observations suggest that the zeolite framework continues to directly influence the heterolysis reaction and that the ability of water to modulate heterolysis is determined by combined effects of the co-adsorbed water and the specific zeolite environment (66, 67).

The enhanced photoheterolytic generation of the 9-cyclopropyl-9-fluorenyl cation observed in alkali metal cation zeolites upon inclusion of protic reagents is more significant for water than for methanol. This trend in relative efficiencies is not surprising considering that water is superior in its ability to facilitate photoheterolysis of 9-fluorenols in homogeneous solution (44–46). However, the observation that inclusion of small amounts of methanol increases the efficiency of intrazeolite photoheterolysis is contrary to results observed in homogeneous solution where carbocation formation is extremely inefficient in neat methanol. For instance, from product studies and time-resolved experiments, it has been shown that the 9-methyl-9-fluorenyl cation is not generated to a significant extent upon excitation of 9-methyl-9-fluorenol (MeFOH) in neat methanol, but is readily formed in methanol–water mixtures, with the efficiency of photoheterolysis increasing at higher water content (44–46). As described above the current observation that the addition of small amounts of methanol can help induce photoheterolysis of 9-fluorenols within zeolite cavities is likely due to an association of the included protic reagent with the zeolite framework (Scheme 3). A binding of this nature should increase the acidity of the alcohol and thereby elevate the ability of the proton to assist C—O bond cleavage.

Absolute reactivity of the 9-cyclopropyl-9-fluorenyl cation in alkali metal cation zeolites

A fundamental impetus for studying reactive carbocations in non-acidic zeolites is to develop an understanding of the mechanisms by which non-protic zeolites interact with positive ion species and to assess their potential as hosts for these reactive intermediates. Recent studies of reactive carbocations within non-acidic zeolites in our laboratory have shown that the environment within these zeolites can support the generation and stabilization of reactive carbocations as transient species. The detection in the μs time regime of the 9-cyclopropyl-9-fluorenyl cation in alkali metal zeolites further supports these ideas. The significant lifetime of carbocations in alkali metal cation zeolites is not due to a thermodynamic effect, like that present in acid zeolites where the highly acidic environment shifts an otherwise unfavorable equilibrium to the side of the carbocation. Similarly, it is not due to a situation in which the strength of the nucleophilic sites of the zeolite framework is reduced by protonation. The ability to observe reactive carbocations on the ns to μs time scale in alkali metal cation zeolites is instead attributed to the unique intrazeolite environment, specifically the confined environment, polar, anionic matrix, and large electrostatic fields within the zeolite cages.

The carbocation lifetime depends dramatically on the nature of the zeolite environment, specifically on the identity of the alkali metal counterion and the Si–Al ratio. As shown in Table 1, the lifetime of the 9-cyclopropyl-9-fluorenyl cation decreases systematically as the alkali counterion is varied from Li$^+$ to Rb$^+$. This trend is consistent with an increase

in the nucleophilicity of the zeolite framework as the alkali cation size is increased. Several recent studies have demonstrated that one effect of cation exchange in Y zeolites is modification of the electron donating ability, or Lewis basicity of the [Si-O-Al]$^-$ active sites within the framework (23, 65, 68–71). This effect can be rationalized by a progressive decrease in interaction strength between the zeolite counterion and the electron-rich framework oxygen sites as the counterion becomes larger and more charge diffuse. Similarly, the tight interaction of a small, charge dense cation such as Li$^+$ with [Si-O-Al]$^-$ framework sites will render these sites considerably less nucleophilic than similar framework sites interacting more loosely with a large, charge diffuse cation such as Rb$^+$. Decreased cation–framework interactions are thus manifested as increased framework nucleophilicity, and correspondingly enhanced rate constants for nucleophilic addition to encapsulated carbocations as the counterion size is increased (eq. [2]). In fact, the variation in lifetime of the 9-cyclopropyl-9-fluorenyl cation with zeolite structure parallels that previously observed for the *p*-methoxycumyl cation where intrazeolite decay via nucleophilic addition of the framework has been established (17).
The 9-cyclopropyl-9-fluorenyl cation decays significantly faster, by almost an order of magnitude, in NaX (Si/Al = 1.2) than in NaY (Si/Al = 2.4). This observation is also consistent with a decay mechanism involving addition of nucleophilic framework sites. Considerable research has shown that the Lewis basicity of zeolites increases as the Si–Al ratio decreases (65, 68, 69, 72, 73). An increase in Lewis base strength results in an increase in the nucleophilicity of each site thereby enhancing the reactivity of these sites towards carbocation addition. The increased reactivity of the 9-cyclopropyl-9-fluorenyl cation in NaX as compared to NaY correlates nicely with this expectation. It must also be recognized that NaX possesses a significantly larger number of [Si-O-Al]$^-$ bridges than NaY.

Infrared (74–76) and NMR (12, 77–81) investigations of alkoxy intermediates indicate that framework-bound carbocations covalently attach to [Si-O-Al]$^-$ sites. In addition, theoretical investigations indicate that the oxygen atoms within [Si-O-Al]$^-$ bridges bind carbocations more tightly than oxygen atoms within [Si-O-Si] bridges (82, 83). Such observations indicate that the [Si-O-Al]$^-$ bridges are the dominant nucleophilic sites within the zeolite lattice. As a result, the smaller Si–Al ratio of NaX as compared to NaY renders the number of potential nucleophilic sites available for attack on encapsulated carbocations to be higher in NaX. Thus, in addition to the enhanced nucleophilicity associated with individual sites, the increased concentration of such sites also contributes to the higher reactivity of the carbocation in NaX relative to NaY. Thus, the notion that the decay of the 9-cyclopropyl-9-fluorenyl cation observed in alkali metal cation zeolites proceeds via direct nucleophilic

addition of the zeolite to yield a framework-bound alkoxy intermediate is consistent with the current view of carbocation behaviour in acid zeolites.

Further evidence that nucleophilic addition of the zeolite framework is responsible for the disappearance of 9-cyclopropyl-9-fluorenyl cation within alkali metal cation zeolites can be obtained by correlating the lifetime of the carbocation with the nucleophilicity of the zeolite framework. As previously described (17), it is possible to discuss the nucleophilicity of the zeolite in terms of the electron density associated with the active nucleophilic sites, the zeolite lattice oxygen atoms bound to aluminum. One method for obtaining the average electron density at these sites is to calculate the partial negative charge on the framework oxygen atom using Sanderson electronegativity principles (84–86). While calculation of the average charge on a zeolite framework atom is an oversimplification that masks the heterogeneous nature of the zeolite environment, it has proved successful in rationalizing a number of physicochemical characteristics (87, 88), including Brønsted acidity and catalytic efficiency (89), Lewis and Brønsted basicity (65, 70, 72, 73), and redox properties (23). For the purpose of the current work, Sanderson electronegativity principles provide a means to correlate the observed variation in carbocation lifetime with a measure of zeolite nucleophilicity (17). The Sanderson electronegativity and partial charge on the framework oxygen atoms of the alkali metal Y zeolites used in this study are given in Table 3. A plot of the log of the lifetime of the 9-cyclopropyl-9-fluorenyl cation in alkali metal cation Y zeolites vs. the charge on the framework oxygen yields a linear relationship (Fig. 7). The correlation between the lifetime of the carbocation and the charge on the framework oxygen is consistent with a mechanism of carbocation decay involving addition of the zeolite framework. Furthermore, it is significant to note that the slope of the correlation is virtually identical to that obtained for the *p*-methoxycumyl cation (17) (Fig. 7). The close match in lifetime variation as a function of the zeolite microenvironment strongly supports the notion that both carbocations decay via the same mechanism within alkali metal cation zeolites.

Beyond lending support to a decay mechanism characterized by nucleophilic addition, the observed variation in lifetime of the 9-cyclopropyl-9-fluorenyl cation with framework oxygen charge provides good evidence that this carbocation is not generated by photoheterolysis within CsY. As shown in Fig. 7, the correlation between the carbocation lifetime and the oxygen charge leads to an estimated lifetime for the 9-cyclopropyl-9-fluorenyl cation in CsY of 280 ns, which is within the time resolution of the ns diffuse reflectance system. Thus, the inability to detect the 9-cyclopropyl-9-fluorenyl cation in CsY is presumably not due to rapid decay of this carbocation within the laser pulse, but instead it is more likely due to inefficient photoheterolysis of cPrFOH within CsY.

Reactivity trends of carbocations in MY zeolites

The 9-cyclopropyl-9-fluorenyl cation is significantly less reactive within alkali metal cation zeolites than the 9-alkyl-9-fluorenyl and unsubstituted 9-fluorenyl cations previously investigated (18). This parallels the relative reactivity of these carbocations in solution, where the lifetime of the 9-

Table 3. Unit cell composition, equalized electronegativity ($S_{zeolite}$), and partial charge on the framework oxygen atoms (δ_O) of alkali metal zeolites.

Fig. 7. Variation in the log of the lifetime of the 9-cyclopropyl-9-fluorenyl cation (●) and the 4-methoxycumyl cation (○) as a function of the charge on the framework oxygen atom. The extrapolated lifetime for the 9-cyclopropyl-9-fluorenyl cation in CsY is included and indicated with (■). Data for the 4-methoxycumyl cation (○) were taken from ref. (17).
cyclopropyl-9-fluorenyl cation is several orders of magnitude larger than the lifetimes of 9-alkyl-9-fluorenyl and the 9-fluorenyl cation (50, 51). This difference is attributed to the strong stabilization of the carbocation center provided by the cyclopropyl substituent (90), where the order of 9-fluorenyl cation reactivity is due to the ability of the substituent to stabilize the carbocation center. However, an interesting observation can be made by considering the reactivity range exhibited by 9-fluorenyl cations in zeolites as compared to solution (Table 4). In particular, it is observed that the unstable 9-fluorenyl cation is significantly longer lived within the zeolites LiY and NaY as compared to water, or even the weakly nucleophilic solvent TFE. Conversely, the more stabilized 9-cyclopropyl-9-fluorenyl cation is actually one to two orders of magnitude more reactive in these alkali metal cation zeolites than in TFE, and exhibits somewhat similar lifetimes in NaY and water. The net result is that the environment within the zeolite cavities exerts a dramatic *leveling effect*, whereby the relative reactivity of carbocations is significantly less sensitive to the relative thermodynamic stability than observed in solution. This further suggests that the zeolite plays a significant role in

Table 4. Lifetimes of 9-R-9-fluorenyl cations in LiY, NaY, TFE, and water, and the reactivity range exhibited by these cations in each environment.

R	Lifetime (ns)			
	LiY	NaY	Water	TFE
H	345	145	<0.02[a]	1.1[b]
Methyl	540	290	0.275[a]	120[c]
Cyclopropyl	15 600	2600	150[d]	140 000[e]
Reactivity range:	45	18	>7500	120 000

carbocation-mediated reactions and is more than merely an inert, non-nucleophilic reaction vessel.

Summary

In dry LiY, NaY, KY, and RbY zeolites cPrFOH undergoes photoheterolysis to yield the 9-cyclopropyl-9-fluorenyl cation as a transient intermediate. Both the photoheterolysis reaction and the reactivity of the resultant 9-cyclopropyl-9-fluorenyl cation are strongly dependent on the nature of the intrazeolite environment. The dramatic influence of the alkali metal cation on photoheterolysis efficiency demonstrates the importance of the zeolite environment to the efficiency of heterolysis and suggests that the zeolite assists the excited state C—O bond cleavage via Lewis acid catalysis involving the metal cation. In addition, carbocation formation within these zeolites is enhanced by coincluded protic reagents in a manner that is consistent with direct participation of these reagents in the C—O bond cleavage. The observations that methanol can effectively increase the efficiency of photoheterolysis in zeolites, but not in solution, and that water is inefficient at effecting heterolysis in CsY but very efficient at inducing heterolysis in solution, suggest that the zeolite plays a defining role in the photoheterolysis even in cases where the cleavage is directly assisted by a co-adsorbed reagent. This is attributed to the interplay between the zeolite, the protic reagent and the 9-fluorenol substrate, and the influences of such interactions on heterolysis and other reaction pathways available to photoexcited 9-fluorenols in zeolites.

Trends in the absolute reactivity of the 9-cyclopropyl-9-fluorenyl cation as a function of the nature of the charge balancing cation and the Si–Al ratio suggest that intrazeolite decay of the carbocation involves nucleophilic addition of lattice oxygen atoms in [Si-O-Al]$^-$ bridges. Consequently, the lifetime of the 9-cyclopropyl-9-fluorenyl cation can be correlated to the charge on the framework oxygen atom as has previously been reported for the 4-methoxycumyl cation. Due to the distinct influences of zeolite encapsulation on photoheterolysis efficiency and carbocation reactivity, it is possible to control the yield and lifetime of the 9-cyclopropyl-9-fluorenyl cation by simple zeolite modifications such as alkali metal exchange.

Our current understanding, based on the study of reactive carbocations in non-acidic zeolites, is that the application of zeolitic systems to controlling and catalyzing positive-ion-mediated processes may not be derived from the ability of these materials to enhance carbocation lifetimes over what can be achieved in certain solvents. Instead, the use of zeolites in carbocation chemistry may more aptly be directed towards modifying carbocation reactivity and the efficiency of carbocation formation relative to competitive processes in ways which are distinct from those observed in homogeneous environments.

Experimental

Materials

9-Cyclopropyl-9-fluorenol was synthesized by Grignard addition of the cyclopropyl bromide to fluorenone, purified by recrystallization three times from 95% ethanol, and fully characterized using ^{1}H and ^{13}C NMR spectroscopy. Spectroscopic grade solvents were used in zeolite sample preparation and laser experiments and were commercially available from BDH or Aldrich and used without additional purification. NaY, Si/Al = 2.4, and NaX, Si/Al = 1.2, were purchased from Aldrich and used as received. The exchanged zeolites were prepared as previously described (17). The percent exchange is typically 47% for LiY, 97% for KY, 44% for RbY, and 47% for CsY. It is known that for the larger cations such as Rb$^+$ and Cs$^+$, only the accessible Na$^+$ which occupy type II and type III sites can be readily exchanged (2). Thus, the maximum cation exchange is ~70%. Values of ~50% exchange indicate that a small percentage of type II cations are not completely exchanged. The low percent exchange for the LiY sample is because hydrated Li$^+$ also does not readily exchange the type III cations.

Zeolite samples

9-Cyclopropyl-9-fluorenol was incorporated into alkali metal zeolites using hexane as a carrier solvent to achieve a loading level of approximately one molecule in every 10 supercages. A general procedure for sample preparation is as follows. Zeolites (typically 300–400 mg) are activated for at least 12 h at 450°C to remove the co-adsorbed water. The dehydrated zeolite is removed from the oven and placed in approximately 20 mL of anhydrous hexane in a sample tube and sealed with a septum. A small quantity (typically <250 μL) of a relatively concentrated (typically 1×10^{-1} to 1×10^{-2} M) dichloromethane solution of cPrFOH is then added to the zeolite–hexane slurry, the mixture is stirred for 1 to 2 h, and then the carrier solvent is separated from the zeolite solid by centrifuge. An additional 20 mL aliquot of hexane is then added to the material and the mixture is again stirred for approximately 30 min to remove surface adsorbates, centrifuged, and the zeolite sample is separated from the supernatant liquid. To remove the remaining hexane the zeolite–substrate complex is placed in a desiccator that is evacuated with a vacuum pump (1×10^{-3} torr, 1 torr = 133.322 Pa) for 8–12 h. The sealed desiccator containing the zeolite powder is placed in a glove bag under an inert atmosphere of dry nitrogen to transfer the dried zeolite composite

---

[3]F.L. Cozens and M.A. O'Neill. Unpublished results.

to a 3×7 mm^2 quartz laser cell. This is attached to a vacuum line equipped with a diffusion pump (1×10^{-4} torr, 1 torr = 133.322 Pa) for an additional 12 h to remove any oxygen and any residual hexane, which may be present.

During the incorporation procedure, the utmost care is taken to keep the zeolite sample dry. In particular, all manipulations of dried composites are carried out in an atmosphere of dry nitrogen. UV analysis of the combined decants indicated that 100% of the organic precursor was incorporated within NaY. The initial amount of cPrFOH was adjusted to account for the reduced % incorporation in the larger alkali cation zeolites, such that the final concentration was approximately one molecule in every 10 supercages for all zeolites examined.

Hydration of 9-cyclopropyl-9-fluorenol–zeolite composites was carried out by exposing a known quantity of the vacuum dried 9-cyclopropyl-9-fluorenol–zeolite composite to the atmosphere. The sample was spread into a thin layer in a petri dish to allow efficient hydration, and the changes in sample mass because of water uptake were monitored. The uptake of water by the zeolite was dependent on the charge balancing cation and Si–Al ratio. Typical values of water uptake (expressed as weight percent) by the 9-cyclopropyl-9-fluorenol–zeolite composites are ca. 12%, 10%, 6%, 3% and 2% for the alkali metal zeolites LiY through CsY respectively, and ca. 5% for NaX.

The coadsorbed alcohols, methanol and HFIP, were introduced after substrate incorporation and evacuation. In this case the laser cells containing the zeolite composites were preweighed before putting the samples into the cells in the glove bag. In this manner the mass of the zeolite samples within the cells could be accurately determined. The typical zeolite mass used in studies with coadsorbed reagents was ca. 100 to 200 mg. To inject the coadsorbate, the laser cells were sealed with a rubber septum. A small quantity of the neat alcohol (typically 1 µL) was then injected into the top of the cell using a syringe. Care was taken to ensure that the zeolite powder did not come into direct contact with the alcohol. The sample was then gently heated with hot air to vaporize the alcohol, during which time the cell was rotated to ensure an even distribution of reagent throughout the sample. The sample was then allowed to cool and thoroughly mixed before laser experiments were conducted.

Nanosecond laser flash photolysis

A computer-controlled ns laser flash photolysis system was employed in this study and has been previously described (17). The excitation source was a pulsed Lambda-Physik excimer laser containing a Xe–HCl–He gas mixture (308 nm, ≤100 mJ/pulse, <10 ns pulse). Diffuse reflectance experiments involve measuring the fraction of reflected light absorbed by the transient, denoted as the reflectance change ($\Delta J/J_o$), where J_o is the reflectance intensity before laser excitation and ΔJ is the change in reflectance intensity after excitation due to absorption by photogenerated transients. The diffuse reflected light is focused through a grating monochromator into a photomultiplier system before being captured with a Tektronix 620A digitizing oscilloscope and transferred via a GPIB interface to a Power Macintosh 7100 computer which controls the laser system using a program written with LabView^{TM} 3.0 software. The resulting appara-

tus couples relatively short laser pulse widths with a rapid and efficient detection system so that reactive intermediates with lifetimes = 20 ns can be studied in opaque samples.

Intramolecular sensitization within steroids: Excited-state interaction of C-17 α and β carbon–bromine bonds with a C-6 carbonyl group

Wen-Shan Li, Lokman Torun, and Harry Morrison

Abstract: The synthesis, photochemistry, and photophysics of 17α-bromo-3α-(triphenylsilyloxy)-5α-androstan-6-one (**1**) and 17β-bromo-3β-(triphenylsilyloxy)-5α-androstan-6-one (**2**) have been studied in aqueous tetrahydrofuran. The 17α-bromo isomer gives evidence (reduced ϕ_f, τ_1, and ϕ_{isc} for the ketone) for interaction between the ketone and C–Br moieties in the excited singlet state. Some photodehalogenation is also observed upon excitation of the ketone chromophore. This interaction seems to be absent or minimal for the 17β-bromo isomer.

Key words: photodehalogenation, bromosteroid, ketosteroid, intramolecular singlet–singlet energy transfer (ISSET).

Résumé : On a réalisé la synthèse et on a étudié la photochimie et la photophysique de la 17α-bromo-3α-(triphénylsilyloxy)-5α-androstan-6-one (**1**) et de la 17β-bromo-3β-(triphénylsilyloxy)-5α-androstan-6-one (**2**) dans le tétrahydrofurane. Avec l'isomère 17α-bromo, on a observé des résultats (valeurs réduites de ϕ_f, τ_1 et ϕ_{isc} pour la cétone) suggèrent l'existence d'une interaction entre les portions cétone et C–Br dans l'état singulet excité. On a aussi observé la présence de photodéshalogénation lors de l'excitation du chromophore de la cétone. Cette interaction semble être absente ou minimale dans l'isomère 17β-bromo.

Mots clés : photodéshalogénation, bromostéroïde, cétostéroïde, transfert d'énergie singulet–singulet intramoléculaire (TESSI).

Introduction

For many years chemists have evinced interest in the use of rigid, well-defined hydrocarbon skeletons to study the photophysical and photochemical consequences of excited-state intramolecular energy transfer between distal functional groups. The most extensively studied frameworks have involved norbornylogous (1) and steroidal (2) backbones. The use of steroids to study intramolecular singlet–singlet and triplet–triplet energy transfer dates back to the 1960s (3). Though most efforts in the field have emphasized photophysics, we have had a particular interest in the capability of the steroid skeleton to facilitate the photochemical activation of a reactive, non-light absorbing, functional group (2). Both through-space and through-bond interactions can effect such a result. Given the interchromophore distances involved, chemistry resulting from triplet–triplet intramolecular energy transfer involving rings A and D of the steroid skeleton most convincingly makes the case for coupling through the hydrocarbon framework (4, 5).

In general, our program has explored the chemistry of unsaturated (e.g., ketone and olefin) acceptor groups resulting from the transfer of energy from an absorbing ("antenna") chromophore. However, in a preliminary communication, we recently presented evidence that a σ-bonded (e.g., C-Br) functionality attached to the steroid framework could be activated by interaction with a ketone antenna (2). Specifically, photonic excitation (directly or indirectly) of a 6-keto (i.e., ring B) functionality can effect the photochemical cleavage of an α C-17 (ring D) C—Br bond in the androstane **1**. We now present the details of this chemistry and extend the earlier study to include the β C-17 analogs (**2**). (Note that TPS and TBDMS in **2** are triphenylsilyl and *tert*-butyldimethylsilyl, respectively).

The somewhat surprising outcome of our most recent observations is that the interaction between the C-6 ketone and the C-17 C—Br bond appears to be specific to the 17α isomer.

Results and discussion

Preparation of steroid substrates

17α-Bromo-3α-(triphenylsilyloxy)-5α-androstan-6-one (1; 3α-TPSO–6ketone–17α-Br)

This substrate was prepared as outlined in Scheme 1, starting with 17β-hydroxy-5α-androstane-3,6-dione that had itself been prepared from 17β-hydroxyandrost-4-en-3-one (6).

The assignment of structure to **1** was confirmed by X-ray analysis which clearly established the α orientations of both the 3-TPSO and 17-Br functionalities (2).

17β-Bromo-3β-(triphenylsilyloxy)-5α-androstan-6-one (2a; 3β-TPSO–6ketone–17β-Br)

The title compound was prepared in six steps from commercially available 5-androsten-3β-ol-17-one (dehydroisoandrosterone) as outlined in Scheme 2. The selective reduction of the vinylbromide in ring D in the presence of the cycloalkene in ring B is noteworthy. The conversion to the cycloalkyl bromide is virtually quantitative. An expanded discussion of this reaction as a synthetic tool will be presented elsewhere. As with compound **1**, X-ray analysis (Fig. 1) was employed to confirm the β bromide stereochemistry at C-17 as well as the β configuration of the 3-TPSO group. The latter was a matter of convenience in the availability of starting material. The stereochemistry in ring A is of no consequence to the photophysics discussed in this paper. The axial and pseudo-axial configurations of the methine protons at C-3 and C-17, respectively, were also evident in the chemical shifts of their resonances at 3.6–3.8 δ, characteristically upfield of the resonances for their equatorial and pseudo-equatorial counterparts in **1** that appear at 4.2–4.3 δ (7).

Two analogs of **2a** were also prepared. One was 17β-bromo-3β-(*tert*-butyldimethylsilyloxy)-5α-androstan-6-one (**2b**),

using a route totally analogous to that used for **2a**. The other was 17β-bromo-3β-methoxy-5α-androstan-6-one (**2c**), wherein the 3-ol was methylated prior to the reduction of ring D and hydroboration–oxidation in ring B.

Photochemistry of compounds 1 and 2a–2c

The photolysis of **1** was studied using both 266 and 308 nm laser light. A mixture of THF and water was employed to facilitate solubility and ammonium hydroxide was present to neutralize released HBr. A summary of our observations, reproduced from our communication (2), is presented in eq. [1].

[1]

	ϕ_{-1}	ϕ_4	ϕ_5
266 nm	0.094	0.031	0.021
308 nm	0.086	0.025	0.017

	ϕ_{6+7}	ϕ_8
	0.029	0.0066
	0.036	0.0067
Scheme 2.
The assignment of **4** and **5** as the 6α and 6β alcohols, respectively, rests on the (axial) 6H resonance (3.14–3.28 δ) in **4** being located well upfield of the (equatorial) 6H resonance (3.54–3.60 δ) in **5** (7). The debromination characteristic of **8** was readily evident in the mass spectrum and in the disappearance of the downfield C-17 methine proton and C-17 carbon resonances characteristic of **1**. Compounds **4**, **5**, and **8** were independently synthesized, the alcohols by sodium borohydride reduction of **1**, and **8** by reduction of 5α-androstan-3,6-dione with K-Selectride followed by silylation. Compounds **6** and **7** were inseparable and handled as a mixture. The mass spectrum confirms the net addition of THF to **1** and the proton NMR is consistent with the assignment. These products are expected consequences of hydrogen abstraction from THF by the 6-keto group followed by

bond formation by the radical pair. We cannot distinguish among the possible diastereomers that could result from such a mechanism.

Among the products shown in eq. [1], the most interesting is the debrominated steroid (**8**). To confirm that cleavage of the C-17 C—Br bond is occurring by intramolecular sensitization, we photolysed the 3α-OH–17α-Br steroid, both alone and in conjunction with **1**, using both 266 and 300 nm irradiation. No debromination was observed in any of these cases. Nor could debromination of this steroid be sensitized by the 3α-OH–6ketone (**9**) or by acetone (as solvent) using 300 nm irradiation.

Quantum efficiencies are included in eq. [1]. Note that the data for 266 vs. 308 nm irradiation are essentially identical within experimental error. The former deposits energy in the

9
aryl chromophore while the latter selectively excites the carbonyl group. The lack of any significant dependence on the initial site of excitation is reasonable, since we have earlier demonstrated that singlet–singlet energy transfer from an α-arylsilyloxy group at C-3 to a ketone at C-6 is 90% efficient (8). (The efficiency drops to 77% when the arylsilyloxy group is β at C-3 (8)). These efficiencies are readily calculated from eq. [2] (or an analogous equation utilizing singlet lifetimes) (8). Inserting the TPSO fluorescence quantum efficiency for **1** of 9.5×10^{-4}, and using either that for **10** (1.0×10^{-2}) or **11** (9.3×10^{-3}) as the reference ("*r*"), likewise provides an efficiency of singlet energy transfer from C-3 to C-6 ($\phi^1_{\text{intra}3 \rightarrow 6}$) of 90%.

10 **11**
[2] $\qquad \phi^1_{\text{intra}3 \rightarrow 6} = [\phi_{f(r)} - \phi_{f(1)}]/\phi_{f(r)}$

The highly efficient transfer of singlet energy to C-6 from the TPSO group, and the ability of the ketone, when directly excited, to initiate cleavage of the C-17 C—Br bond, argue for activation of the C—Br bond as involving the 6-keto group as the sensitizing chromophore. We return to this

point, and address the question of the excited-state multiplicity of the ketone as sensitizer, later in the discussion.

The photochemistry of the β 17-Br series was studied in a manner identical to that outlined above for **1**. We began with the 3β-TPSO derivative (**2a**) but quickly found that the photolysis mixture was less readily resolved by the usual analytical techniques than had been the case with **1**. Recognizing that the aryl chromophore at C-3 was, in fact, superfluous for sensitization at C-17, we turned to the two analogs (**2b** and **2c**), which retained the requisite 6-keto functionality and proved more amenable to study by GLC. The photolysis of **2b** is outlined in eq. [3]. Note that only direct photolysis of the ketone with 311 nm light was employed since the TBDMSO functionality is transparent to 266 nm light.

The products proved to be analogous to those reported in eq. [1], with the exception that *no dehalogenated steroid could be detected*. The alcohols (**12** and **13**) were formed in a ca 1:1 ratio and together constituted 73% of the product mixture by area count. They were each identified by GC–MS spectrometry as a 6-ol but the spectral data in hand did not permit a specific assignment of stereochemistry to a specific peak. Three other peaks, totaling 27% of the product, were also resolvable by GLC. Each gave molecular ions by GC–MS corresponding to a THF adduct and are assigned as such, but again the data in hand did not allow one to differentiate among the possible diastereoisomers and they are grouped in eq. [3] as **14**.

Compound **2c** was likewise photolyzed with 311 nm light (see eq. [4]). Again, no dehalogenated steroid was detectable. In this case only a single peak, constituting 41% of the product area count, could be attributed to a 6 hydroxy product (**15**); the GC–MS spectrum did not allow us to distinguish between the two possible diastereomers. Four peaks at longer retention times, which together constituted 53% of the product, each gave mass spectra consistent with a THF adduct. They are grouped in eq. [4] as the mixture of isomers (**16**). Finally, a sixth peak (**17**, 6%) was detected with a retention time intermediate between the alcohols and the

THF adducts that has not been identified. Its mass spectrum indicates that it still retains bromine.

In summary, much of the photochemistry of the two C-17 stereoisomers derives from reactions at C-6 that one would anticipate as resulting from initial hydrogen abstraction from the THF by the ketone exited state. Only in **1** do we see any indication of activation at C-17. Mechanistic and photophysical studies were conducted to further clarify the nature and extent of this interaction.

Mechanistic and photophysical studies

Our first concern was to establish the multiplicity of the ketone excited state(s) responsible for the chemistry depicted in eq. [1]. This was done using *cis*-piperylene (1.2 mM) as a potential triplet quencher for the 300 nm photolysis of 6 mM **1**. The contrasting effects on the products were striking; 50–70% of the alcohol and THF adduct (**4–7**) formation was quenched whereas there was no effect on the formation of the C-17 cleavage product (**8**). That the hydrogen abstraction chemistry should derive from the ketone triplet state is to be expected. What was not so obvious is that the C-17 cleavage chemistry would involve the ketone excited singlet state.

Nevertheless, this conclusion is supported by singlet lifetime data obtained for a pair of 3α-OH 6-keto steroids in which the C-6 ketone is the only emitting chromophore, i.e., compounds **3** (with Br at C-17) and **9** (no Br at C-17). Values of 2.5 ± 0.2 and 3.6 ± 0.1 ns were measured for these two compounds, respectively. We attribute the ca 31% reduction in ketone singlet lifetime in **3** to interaction between

the carbonyl singlet excited state and the C-Br functionality. The reduction in singlet lifetime should also be manifested in the relative quantum efficiencies for intersystem crossing at C-6 (ϕ_{isc}) in these two steroids. Knowing that the reduction products at C-6 derive from the triplet state, and assuming that the ketone ϕ_{isc} would be ca 1.0 in the model (**9**), the relative conversions to C-6 reduction products (at identical photon flux) should provide the ϕ_{isc} for C-6 in **3**. In the event, we observed a 37% diminution (by GLC) of alcohols and THF adducts from photolysis of the halogen-containing steroid (**3**) relative to that observed with the model (**9**), thus leading us to estimate that ϕ_{isc} for **3** is 0.63. The ratio of 1.6 for the relative ϕ_{isc}s for **9**:**3** compares well with the ratio of 1.4 for their respective singlet lifetimes. The two sets of data, taken together, lead to the conclusion that there is an additional mode of singlet decay present in **3** that causes a reduction in this compound's singlet lifetime and ϕ_{isc}.

Perhaps most notable in this series of studies is that the measured singlet lifetime for the C-6 ketone in the 17β C-Br steroid (**2c**) is 3.2 ± 0.2 ns. It is debatable as to whether the 11% reduction relative to **9** is statistically significant, but it seems clear that the α C-17 C-Br functionality in **3** has a much great effect on the C-6 ketone singlet state than does a β C—Br bond in the same location. This conclusion is supported by a comparison of the photoreactivity of **2c** relative to the non-brominated model (**9**) as was done for the ϕ_{isc} study for **3** described above. We found that the relative photoreactivities of compounds **2c** vs. **9** was 1.06, essentially identical within experimental error. It is also interest-

ing to note that the C-6 ketone triplet seems to be ineffective in sensitizing cleavage of the C-17 C—Br bond, despite the fact that its estimated (using cyclohexanone) energy of ca 78 kcal mol^{-1} (9) should be well in excess of the estimated (using isopropyl bromide) bond energy for the C—Br bond of ca 68 kcal mol^{-1} (10). Additional studies in a solvent less capable of intercepting the carbonyl triplet state are necessary to confirm that triplet energy remains totally localized at the ketone. The challenge, of course, will be to do this while simultaneously efficiently trapping the C-17 radical generated by C-Br homolysis.

Further consideration of the interaction between the C-6 carbonyl group and the C-17 C—Br bond in 1

Given that the singlet lifetime of the C-6 ketone has been shortened from 3.6 to 2.5 ns by the presence of an α C-17 C—Br bond (see above), if one assumes that this shortening is entirely due to new decay involving an interaction between the two moieties, one calculates a rate constant for this decay mode of 1.2×10^8 s^{-1}. An analogous calculation using the 37% reduction in ϕ_{isc} yields a rate of singlet decay because of interaction of 1.5×10^8 s^{-1}. We have already estimated that ca 37% of the ketone singlets are diverted from intersystem crossing by this interaction. Only 0.0066 (the quantum by efficiency for formation of **8** (eq. [1])) is accounted for by product formation resulting from C-Br cleavage. Clearly, a very small fraction (ca 2%) of the diverted singlets surface as product, either because cleavage of the interacting C—Br bond is minimal or because there is efficient cleavage but also efficient radical-pair recombination.

As to the specific nature of the ketone–C-Br interaction, we suggest that this may occur through TBI coupling of the ketone n,π* singlet state with the C-Br n,σ* state, by analogy with the proposed explanation for the sensitized photoactivation of a β C—Cl bond in chloronorbornenes (11) and chlorobenzobicyclics (12). The strong stereoelectronic dependence of the interaction is not surprising, there being ample precedent in systems having fewer σ bonds between the two moieties (13). However, the apparent preference for interaction with the α, pseudo-axial C—Br bond at C-17 was unexpected, since the "all trans" rule is generally accepted as leading to enhanced coupling of σ-bonded equatorial vs. axial substituents with the steroid framework (14). Nevertheless, though we have likewise observed a greater rate of intramolecular triplet–triplet energy transfer (intraTTET) from an equatorial (DPSO) donor at C-3 to an olefin at C-17, relative to its axial C-3 counterpart (4), the inverse was observed when the donor was σ-bonded to C-17. In that event, intraTTET from C-17 to C-3 was found to be almost 10-fold faster from the α-DPSO group (15). Thus, the evaluation of additional steroidal ketobromides, both by experiment and by theory, is needed to determine whether the stereoelectronics associated with the C-6–C-17 interaction studied here is prototypical or peculiar to the specific placement of the C—Br bond at C-17 in ring D.

Experimental

General

A considerable amount of the experimental details is available in the doctoral dissertation of L. Torun (16) or as supplemental material for the preliminary communication (2). Thus, only the most salient features are presented below or as supplemental material.[2]

^{13}C NMR spectra were obtained in CDCl$_3$ with a Varian spectrometer operating at 50 MHz with chemical shifts relative to the residual chloroform peak at 77 ppm unless otherwise noted. ^{1}H NMR spectra were obtained in CDCl$_3$ with a Varian spectrometer operating at 200 MHz with chemical shifts relative to the residual chloroform peak at 7.24 ppm. In the case of two synthetic intermediates, the proton count in the steroid aliphatic region read ca 5–10% high relative to the downfield protons; this is indicated in the listing of the proton spectra. Mass spectrometry utilized a Finnigan 4000 mass spectrometer operating at a source temperature of 250°C. Electron impact (EI) mass spectra and chemical ionization (CI) mass spectra were recorded at an ionization energy of 70 eV, with the latter utilizing isobutane at a pressure of 0.30 torr (1 torr = 133.322 Pa). Elemental analysis was done by HR-MS using either FAB or EI ionization on samples analytically pure by GLC. Ultraviolet absorption spectra were recorded using 1-cm quartz cells on a dual beam Cary model 100 UV–vis spectrophotometer interfaced to a computer using Cary software. Steady-state fluorescence spectra were obtained with 1 cm square fluorescence cells on a SLM Aminco SPF-500 spectrophotometer using a 250 W xenon arc lamp operating in the A/B mode. Fluorescence quantum efficiencies were obtained using toluene as the reference. The fluorescence lifetime measurements were obtained using a PTI model 100 spectrophotometer at room temperature. All the fluorescence samples were purged with argon for 20 min prior to analysis. For the X-ray structural analysis, crystals of 17α-bromo-3α-(triphenylsilyloxy)-5α-androstan-6-one (**1**) were prepared by recrystallization of column-purified material from hexane–CH$_2$Cl$_2$. A colorless plate with dimensions of $0.41 \times 0.35 \times 0.22$ mm was placed on a glass fiber in a random orientation. X-ray data were collected with MO Kα radiation (λ = 0.71073 Å) on a Nonius Kappa CCD computer-controlled diffractometer equipped with a graphite crystal, incident beam monochromator. Cell constants and an orientation matrix for data collection were obtained from least-squares refinement, using the setting angle of 17 224 reflections in the range $4 < \theta < 27°$. Data were collected at a temperature of $173 \pm 1°$C to a maximum of 2θ of 55.8°. Melting points were determined with a Fisher-Johns melting point apparatus and are uncorrected. Laser irradiations were conducted at 266 nm using a Continuum NY-61 Nd:YAG laser equipped with a frequency quadrupler (10 Hz, ca 3.0 mJ/pulse). Samples (3 mL, 10.0 mM) were degassed with argon for at least 25 min prior to irradiation

---

and kept closed with septa. They were photolyzed in square vycor photolysis cells with continuous stirring using a 2 mm stirring bar. The power of the laser was measured with an OPHIR power meter, model AN/2. Data were corrected for scatter and reflectance of light from the cell walls. For 311 nm irradiations, a reactor was equipped with 8×311 nm Phillips TL01 (20 W) lamps and a merry-go-round turntable apparatus that positioned 8 cylindrical quartz tubes (10 mm i.d.) approximately 2 cm from the lamps. The 300 nm irradiation employed a Rayonet Reactor (New England Ultraviolet Co.) equipped with lamps having maximal output at 300 nm. All solutions were deoxygenated with a stream of argon prior to photolysis. Uranyl oxalate actinometry was used for the quantum efficiency determinations. 4-Androsten-3,17-dione, 3β-hydroxy-5α-androstan-17-one, 17β-hydroxy-5α-androtan-3-one, 3β-hydroxy-5-androsten-17-one, 5-androsten-3β-ol-17-one (dehydroisoandrosterone), and testosterone were purchased from Sigma.

17-Bromo-3β-hydroxy-androsta-5,16-diene (VI)

3β-Hydroxy-5-androsten-17-hydrazone (V) (2.0 g, 6.57 mmol), prepared from commercially available 3β-hydroxy-5-androsten-17-one (IV), was dissolved in pyridine (30 mL) and the solution cooled in an ice bath. NBS (2.0 g, 16.85 mmol) dissolved in 15 mL of pyridine was added dropwise to the solution over 5 min. After stirring the yellow-colored solution at ice bath temperature for 5 min, the solution was poured into 50 mL of ice water and the mixture extracted with ether. The combined ether layers were washed with 10% HCl (3×20 mL), NaHCO$_3$ solution (3×20 mL), and water (2×20 mL) and dried over Na$_2$SO$_4$. The crude product was chromatographed on silica gel with 2% EtOAc in hexane to give a white solid product in 48–65% yield; mp: 163 to 164°C. ^{1}H NMR (CDCl$_3$, 200 MHz) δ: 5.90–5.80 (dd, 1H), 5.4–5.3 (m, 1H), 3.6–3.4 (m, 1H), 2.4–0.85 (m, ca 24 H). ^{13}C NMR (CDCl$_3$, 50 MHz) δ: 141.2, 135.6, 129.0, 121.1, 71.6, 55.5, 50.4, 48.5, 42.2, 37.1, 36.7, 34.5, 31.8, 31.5, 31.3, 30.7, 20.6, 19.3, 15.0. CI (m/z): (M + H)$^+$: 351/353 (base peak). EI: 350/352 (M)$^+$; 91 (base peak).

17β-Bromo-5-androsten-3β-ol (VII)

Hydrazine monohydrate (3.0 mL) was added to a flask containing 17-bromo-3β-hydroxy-androsta-5,16-diene (VI) (0.7 g, 1.99 mmol) dissolved in 30 mL of methanol. To this solution was added K$_3$Fe(CN)$_6$ (1.2 g, 3.64 mmol) and a catalytic amount of Cu(OAc)$_2$ (~10 mg). The resulting solution was stirred at room temperature with continuous monitoring by GC. Hydrazine monohydrate (3.0 mL each time) was added as needed to eliminate all starting material in the solution. A total of 9 to 10 mL was added over 3 days. The milky white solution was filtered and MeOH was removed in vacuo. The resulting aqueous residue was partitioned between dichloromethane and water and extracted with dichloromethane. The solvent was dried over Na$_2$SO$_4$, concentrated, and purified by column chromatography on silica gel using 15% EtOAc in hexane to afford a white solid in 85–92% yield; mp: 145–147°C. ^{1}H NMR (CDCl$_3$, 200 MHz) δ: 5.4–5.2 (d, 1H), 3.85–3.65 (t, 1H), 3.65–3.40 (m, 1H), 2.40–0.75 (m, 26H). ^{13}C NMR (CDCl$_3$, 50 MHz) δ: 140.88, 121.10, 71.59, 61.94, 51.34, 50.01, 43.82, 37.21,

36.54, 36.19, 32.82, 32.44, 31.50, 24.53, 20.63, 19.38, 13.96. EI (m/z): 352/354 (M)$^+$.

17β-Bromo-3β-(triphenylsilyloxy)-5-androsten (VIII)

17β-Bromo-5-androsten-3β-ol (VII) (52 mg, 0.14 mmol) was added to a round-bottomed flask containing DMF (2.0 mL). To this solution was added triphenylsilyl chloride (0.65 mg, 0.22 mmol), imidazole (20 mg, 0.28 mmol), and a catalytic amount of 4(dimethylamino)pyridine, and the solution was stirred under argon for 12 h. Water (10 mL) was added and the solution was extracted with ether. The organic extracts were washed with water. After drying and concentrating, the crude product was chromatographed on a Chromatotron plate prepared with silica gel using hexane to obtain 0.27 g (80%) as an oily product. ^{1}H NMR (CDCl$_3$, 200 MHz) δ: 7.65–7.58 (m, 6H), 7.48–7.32 (m 9H), 5.25–5.10 (bs, 1H), 3.85–3.65 (m, 2H), 2.60–0.80 (m, ca 25H). ^{13}C NMR (CDCl$_3$, 50 MHz) δ: 141.24, 135.40, 134.94, 134.89, 130.10, 129.97, 127.90, 127.76, 73.31, 62.03, 51.34, 49.96, 43.82, 42.30, 37.16, 36.56, 36.19, 32.80, 32.45, 31.77, 31.53, 24.53, 20.59, 19.40, 13.97. EI (m/z): 610/612 (M$^+$), 259 (Ph$_3$Si)$^+$ base peak. HR-MS (EI) calcd. for C$_{37}$H$_{43}$BrOSi: 610.2267; found: 610.2250.

17β-Bromo-3β-triphenylsilyloxy-5α-androstan-6α-ol (IX)

The general procedure used for hydroboration was to add the silylated bromoandrostene (ca 0.5 to 0.6 mmol) to a flask containing 10 mL of dry THF, cool to ice bath temperature, and then add a borane solution (1 M) in THF (0.8 mL) under argon. After stirring in an ice bath for 1 h, and then at room temperature for 12 h, the excess borane was destroyed with water. A 2 N solution of NaOH (1.5 mL) and 30% H$_2$O$_2$ (1.5 mL) was added and the resulting mixture stirred at 50°C for 1 h. After cooling to room temperature, the crude product was extracted with ether (3×15 mL). The combined organic layers were washed with water and dried over Na$_2$SO$_4$, and concentrated under reduced pressure. The residue was chromatographed on a column using CH$_2$Cl$_2$:hexanes (1:2) to obtain the products as white solids in >90% yield. For 17β-bromo-3β-triphenylsilyloxy-5α-androstan-6α-ol: ^{1}H NMR (CDCl$_3$, 200 MHz) δ: 7.72–7.6 (m, 6H), 7.50–7.30 (m, 9H), 3.85–3.65 (t, 2H), 3.45–3.3 (m, 1H), 2.40–0.50 (m, 27 H). ^{13}C NMR (CDCl$_3$, 50 MHz) δ: 135.38, 134.85, 129.85, 127.74, 72.88, 69.14, 61.83, 53.60, 51.81, 50.79, 44.04, 40.90, 37.22, 36.18, 35.06, 32.39, 32.10, 31.34, 24.30, 20.58, 14.09, 13.38. CI (m/z): 353/355 (M – Ph$_3$SiO)$^+$. HR-MS (FAB) calcd. for C$_{37}$H$_{45}$BrO$_2$Si: 628.2372; found: 628.2352.

17β-Bromo-3β-(triphenylsilyloxy)-5α-androstan-6-one (2a)

17β-Bromo-3β-triphenylsilyloxy-5α-androstan-6α-ol (IX) (0.24 g, 0.38 mmol) was dissolved in 5 mL of dichloromethane and added to a stirred suspension of pyridinium chlorochromate (0.123 g, 0.58 mmol) and sodium acetate (0.031 g, 0.44 mmol). The solution was stirred at room temperature for 3 h, filtered, concentrated, and chromatographed on a silica gel column using hexane to afford 0.16 g (85% yield) of an oily product that solidified over several days; mp 186–190°C. ^{1}H NMR (CDCl$_3$, 200 MHz) δ: 7.70–7.55 (m, 6 H), 7.50–7.30 (m, 9H), 3.80–3.60 (m, 2H), 2.40–2.17 (m, 2H), 2.15–1.50 (m, 12H), 1.50–0.96 (m, 6H), 0.89 (s,

3H), 0.84 (s, 3H). ^{13}C NMR (CDCL$_3$, 50 MHz) δ: 210.14, 135.40, 129.92, 127.79, 72.21 61.17, 56.75, 53.77, 51.45, 48.25, 44.44, 40.73, 38.58, 36.88, 35.96, 32.28, 30.97, 28.91, 24.25, 20.99, 14.11, 13.15. CI (*m/z*): 627/629 (M$^+$), 351/353 (base peak). HR-MS (FAB) calcd. for C$_{37}$H$_{43}$BrO$_2$Si: 627.2294; found: 627.22267.

17β-Bromo-3β-(tert-butyldimethylsilyloxy)-5α-androstan-6-one (2b)

The methods used for this preparation were analogous to those described above for **2a**. It was obtained as a white crystalline material, mp 172 to 173°C. ^{1}H NMR (CDCl$_3$, 200 MHz) δ: 3.83–3.67 (t, 1H), 3.59–3.40 (m, 1H), 2.40–0.95 (m, 20H), 0.85 (s, 9H), 0.80 (s, 3H), 0.74 (s, 3H), 0.01 (s, 6H). ^{13}C NMR (CDCl$_3$, 50 MHz) δ: 210.31, 71.26, 61.21, 56.95, 53.91, 51.48, 46.27, 44.46, 40.78, 38.58, 36.83, 36.01, 32.30, 31.24, 30.18, 25.84, 24.27, 21.04, 18.18, 14.13, 13.18, –4.63, –4.71. HR-MS (CI) calcd. for C$_{25}$H$_{43}$BrO$_2$Si (M + H)$^+$: 483.2294; found: 483.2309.

17β-Bromo-3β-methoxy-5α-androstan-6-one (2c)

The methods used for this preparation were analogous to those described above for **2a**. ^{1}H NMR (CDCl$_3$, 200 MHz) δ: 3.85–3.65 (t, 1H), 3.32 (s, 3H), 3.20–2.90 (m, 1H), 2.40–1.50 (m, 11 H), 1.50–0.95 (m, 7 H), 0.81 (s, 3H), 0.74 (s, 3H). ^{13}C NMR (CDCl$_3$, 50 MHz) δ: 210.05, 78.92, 61.14, 56.62, 55.60, 53.80, 51.39, 46.18, 44.41, 40.98, 38.50, 36.57, 35.92, 32.25, 27.44, 25.80, 24.22, 21.00, 14.10, 13.06. CI (*m/z*): 383/385 (M + H)$^+$. EI: 382/384 (M$^+$), 353/355 (base peak). HR-MS calcd. for C$_{20}$H$_{29}$BrO$_2$: 382.1507; found: 382.1507.

Photolyses

The details for the preparative photolysis of compound **1** have been presented (2). For the study of 17β-bromo-3β-(*tert*-butyldimethylsilyloxy)-5α-androstan-6-one (**2b**), 5.0 mM solutions in THF:H$_2$O (9:1) containing ca 5 mM of NH$_4$OH were degassed with argon for 20 min and irradiated in quartz tubes with 311 nm light for 5 h. The reactions were analyzed by GLC using a 30 m DB-5 column at 280°C under isocratic conditions. The starting material, with a retention time of 11.9 min, was the major component of the reaction mixtures and constituted 65% of the total area counts. Five photoproducts were also observed in the chromatograms. Two major photoproducts appeared with retention times of 11.1 and 11.2 min in a 12.1:13.6 relative ratio. There were three other peaks with retention times of 20.5, 21.5, and 21.9, with relative ratios of 6.0:1.51:1.5. The five products were characterized by GC–MS analyses. The two major photoproducts had very similar EI and CI mass spectra, with a (M + H)$^+$ molecular ion evident in the CI mass spectrum at *m/z* 485/487. Loss of water was evident at 467/469. There were three additional photoproducts with retention times of 20.5, 21.5, and 21.9 min. One (20.5 min) exhibited a small molecular ion peak in the CI spectrum at *m/z* = 555/557 corresponding to the addition of THF to **2b**. The spectrum also contained a fragment ion peak at *m/z* = 537/539 as the base peak, corresponding to the loss of water. The other two products had very similar EI and CI mass spectra but lacked the small molecular ion peak.

Photolysis of 17β-bromo-3β-methoxy-5α-androstan-6-one (**2c**) was conducted in a similar manner. Five photoproducts were detectable by GLC in addition to unreacted starting material (6.3 min) that made up 69% of the total GLC area count. The first photoproduct had a retention time at 6.2 min and constituted 10% of the total area count. The EI mass spectrum showed a molecular ion peak at *m/z* = 384/386 corresponding to reduction of the ketone. Fragment ions were observable at 366/368 (M – H$_2$O)$^+$ and 353/355 (base peak; M – OCH$_3$)$^+$. The other four photoproducts had relatively long GLC retention times (11.9, 12.2, 12.4, and 12.7 min), were formed in a ratio of 4.5:4.9:1.7:1.6, respectively, and had a combined area count constituting 13% of the total area. All four products had identical EI mass spectra and very similar CI mass spectra. The former contained the THF fragment ion (*m/z* = 71) as the base peak, and included fragment ion peaks at *m/z* = 383/385 (M – THF)$^+$ and *m/z* = 351/353 (M – THF – CH$_3$OH)$^+$. The base peak in the CI spectra appeared at *m/z* = 437/439 [(M + H) – H$_2$O)$^+$. A sixth photoproduct (9.0 min) constituted 1.3% of the total area count. Its CI mass spectrum exhibited a fragment ion at *m/z* = 368/370 as the base peak.

Intramolecular photosensitization of the pinene–ocimene rearrangement

Kevin McMahon and Peter J. Wagner

Abstract: Bonding of nopol to the para position of acetophenone produces 5,5-dimethyl-2-(2-(*p*-acetylphenoxy)ethyl)bicyclo[3.1.1]hept-2-ene **1**, which contains two chromophores: a *para*-alkoxyacetophenone and an α-pinene, connected by a single methylene group. UV irradiation of **1** in both benzene and methanol produces none of the intramolecular [2 + 2] cycloaddition that most *para*-(3-buten-1-oxy)acetophenones undergo. Instead, the pinene unit rearranges to a triene skeleton identical to that of ocimene, a known photoproduct of pinene. At modest conversion the diene portion of the triene is cis but gradually is converted to a 52:48 trans:cis ratio. It is concluded that intramolecular triplet energy transfer from the excited ketone chromophore forms the 1,2-biradical triplet state of the pinene moiety, which then undergoes cyclobutylcarbinyl ring opening to a 1,4-biradical that cleaves to the 1,3,6-triene structure of ocimene. This mechanism is suggested to be responsible for the earlier reported intermolecularly sensitized rearrangement of α-pinene to the ocimene isomers.

Key words: intramolecular energy transfer, triplet pinene, cyclobutylcarbinyl ring opening, photosensitization.

Résumé : La fixation du nopol en position para de l'acétophénone produit le 5,5-diméthyl-2-(2-(*p*-acétylphénoxy)éthyl)bicyclo[3.1.1]hept-2-ène **1** qui contient deux chromophores : la *para*-alkoxyacétophénone et l'α-pinène, reliés par un seul groupe méthylène. L'irradiation UV du composé **1** dans le benzène et dans le méthanol ne donne aucun des produits de cycloaddition intramoléculaire [2 + 2] que les *para*-(3-butén-1-oxy)acétophénones donnent généralement. L'unité pinène se réarrange de préférence en un triène dont le squelette est identique à celui de l'ocimène, un photoproduit connu du pinène. A un taux modéré de transformation la portion diène du triène est cis, mais elle se transforme graduellement pour donner un rapport trans : cis de 52 : 48. On en conclut que le transfert d'énergie intramoléculaire du triplet à partir du chromophore cétone excitée forme l'état triplet 1,2-biradical de l'unité pinène qui, par ouverture subséquente du cycle du cyclobutycarbinyle, donne un 1,4-biradical qui s'ouvre à son tour pour donner la structure 1,3,6-triène de l'ocimène. On suggère que ce mécanisme est responsable du réarrangement intermoléculaire sensibilisé de l'α-pinène en isomères de l'ocimène rapporté antérieurement.

Mots clés : transfert d'énergie intramoléculaire, pinène triplet, ouverture du cycle du cyclobutylcarbinyle, photosensibilisation.

[Traduit par la Rédaction]

Introduction

Many years ago two papers were published reporting the acetophenone-photosensitized isomerization of α-pinene to *cis*- and *trans*-ocimene (Scheme 1) (1, 2). Both authors suggested triplet energy transfer from the ketone as the initiator of pinene's rearrangement; but given the incomplete understanding of excited-state reactivity in those years, neither could provide a compelling mechanism describing how triplet pinene rearranges. Frank suggested the possibility of thermal rearrangement following intersystem crossing of the triplet pinene to a vibrationally excited ground state, a then relatively popular notion already subject to suspicion. Kropp merely noted that rearrangement must be facile since other-

wise, as in norbornene, the biradical triplet would have abstracted hydrogen atoms from the solvent. Both authors noted that the initially formed *cis*-ocimene undergoes sensitized cis → trans isomerization, gradually forming a nearly 1:1 equilibrium.

This paper describes our discovery of an intramolecular version of the photosensitized pinene rearrangement and a simple mechanism for the rearrangement based on the 1,2-biradical nature of triplet alkenes (3). To test whether intramolecular [2 + 2] cycloaddition of remote double bonds to triplet benzenes (4) works with cyclic alkenes, nopol was attached para to acetophenone to form **1**. Irradiation of **1** caused rearrangement of the dimethylbicyclo[3.1.1]heptene ring to a mixture of the *cis*- and *trans*-isomers of 3-(2-(*p*-

Scheme 1. Photosensitized rearrangement of α-pinene.

α-Pinene   *cis*-Ocimene   *trans*-Ocimene
acetylphenoxy)ethyl)-7-methylocta-1,3,6-triene, the same transformation that α-pinene itself undergoes (Scheme 2).

Results

Compound **1** was prepared via S_N2 reaction of the tosylate of nopol with potassium *p*-acetylphenoxide in DMF as described in the *Experimental section*.
1 was irradiated in the same way that other *p*-alkenoxy-acetophenones had been (4). Preliminary experiments were run in deaerated NMR tubes containing benzene-d_6 or methanol-d_4 solutions 0.02 M in both **1** and methyl benzoate (as an internal standard). Similar results were obtained in both solvents. NMR spectra at various conversions revealed no significant changes in the alkoxyacetophenone portion of the molecule, and the UV spectrum of the product mixture was dominated by an intense peak at 270 nm characteristic of *p*-alkoxyphenyl ketone chromophores. However, changes in the NMR spectrum for the pinene portion of the molecule were consistent with the formation of an ocimene-like triene. Only tiny traces of peaks ascribable to other unidentified products were noted, but it was obvious that no significant amount of cycloaddition of the pinene double bond to the benzene ring occurred. As with the early studies on pinene itself, the *cis*-ocimene unit was the only product at low conversions but it gradually equilibrated to a 48:52 cis–trans ratio in 73% combined yield at 84% conversion of starting **1**. The products of larger scale reactions were purified by preparative TLC. That the pinene portion of **1** was no longer present was indicated by the lack of significant optical activity in the product solutions at high conversion.

The conversion of the pinene moiety to a triene was demonstrated by the addition of four vinyl proton peaks (6.8 or 6.3 and 5.30–5.06 ppm) to the single vinyl proton peak at 5.34 ppm as well as the increase in ^{13}C vinyl peaks (110–122 ppm) from two to six. The chemical shifts and coupling constants of the nonaromatic protons correspond very closely to those reported for ocimene (2), including the dif-

Scheme 2. Photoinduced rearrangement of compound **1**.
ference between the cis and trans isomers, most notably the 0.5 ppm difference between the H_2 peaks (see *Experimental*.)

Discussion

This experiment has revealed that triplet energy transfer from the excited acylbenzene chromophore to a tethered alkene can occur at the expense of possible cycloaddition. That such energy transfer could occur was not unexpected, given the early bimolecular examples, although no such total quenching of cycloaddition occurs for acetophenone with a *para* 3-methyl-3-penten-1-oxy tether (5), which also has a trialkyl-substituted double bond. Caldwell and co-workers' (6) measurement of the triplet energies of various olefins indicate an E_T of 77 kcal/mol for 2-methyl-2-butene, but only 75 kcal/mol for 1-methylcyclohexene, a better model for α-pinene. Both E_Ts are higher than that of *p*-acetylanisole (~71 kcal/mol (7)), so any energy transfer is quite endothermic. The apparent lack of much if any energy transfer to the trisubstituted acyclic double bond undoubtedly reflects its higher endothermicity. We should note that the lowest triplet of *p*-alkoxy alkanophenones is π,π*, whereas acetophenone itself has a n,π* lowest triplet. However, there appear to be only slight differences between n,π* and π,π* ketones in rate constants for intramolecular energy transfer (8).

It must be noted that we cannot distinguish quantitatively between intermolecular and intramolecular energy transfer in the case of **1**, although its low concentration should have minimized any intermolecular interactions. The 4 kcal endothermicity of energy transfer to pinene would be expected to slow down a bimolecular process to a rate constant ~1×10^7 M^{-1} s^{-1} (9). Intramolecular reactions usually enjoy rate enhancement, but it has been shown that compounds with a three-atom chain between triplet donor and acceptor have an effective molarity near 1, with very similar first- and second-order rate constants (10). That being the case, energy transfer to the pinene moiety should be only about 10% as fast as the ~1×10^8 s^{-1} rate constant for [2 + 2] cyclo-addition by acylbenzenes with simple acyclic alkenoxy tethers (4). The lack of cycloaddition in **1** then probably involves some form of steric hindrance to proximity between the pinene unit and the benzene ring, either at the charge transfer stage or at the C—C bonding stage.

Ab initio computations at the 3-21G and 6-31G*/UHF levels affirm the 1,2-biradical character of triplet α-pinene, with the two *p*-like SOMOs at a roughly 45° angle and the one on the carbon next to the bridgehead nearly parallel to

the bridgehead—Me₂C bond. This alignment should provide for efficient cleavage of the four-membered ring to yield a 1,4-biradical that can then cleave to two double bonds. Scheme 3 depicts this chain of events for **1**. We suspect that this same biradical double cleavage occurs in pinene itself. The ring-opening of cyclobutylcarbinyl radicals to 4-penten-1-yl radicals was not widely recognized and studied until the early 1980s, although Scheme 4 shows an early example of this same ring opening in the benzoyl-peroxide-initiated addition of carbon tetrachloride to β-pinene (11). The rate constant for cyclobutylmethyl ring opening has been measured as 4×10^3 s^{-1} in Australia (12) and 1.5×10^4 s^{-1} in Canada (13). A comparable rate constant for opening of the four-membered ring in triplet α-pinene would seem unable to compete with measured triplet decay rates in the 1×10^7 s^{-1} range for alkenes (6). However, in this case radical ring-opening involves loss of both electronic excitation and bicyclic ring strain, as well as formation of a tertiary radical site and thus, may be sufficiently exothermic to be quite rapid. Whatever the exact kinetics, the likelihood that the rearrangement begins with a known radical reaction further confirms the biradical nature of triplet alkenes (3, 6).

Another possibility is that charge transfer interaction between the bicycloheptene double bond and the triplet phenone produces enough radical-cation character in the pinene to allow ring opening with spread of the radical-cation character between tertiary and allylic sites. Further bond cleavage could then generate a diene radical-cation that collapses to an ocimene structure after back electron transfer. This possibility deserves further study.

Experimental

Preparation of reactant

Nopol tosylate

(1R)-(–)-Nopol (Aldrich, 20.00 g, 0.11 mol) in pyridine (32 mL) was cooled to 0°C. Tosyl chloride (13.65 g, 0.0716 mol) was added portion-wise under argon over 1 h. The mixture was stirred mechanically for a further 5 h at low temperature. Then H₂SO₄ (2 N, 100 mL) was added to the mixture. The resulting solution was extracted using ether (3 × 100 mL). The combined organic extracts were washed with 2 N NaOH, NaHCO₃, and NaCl. After drying over MgSO₄, the ether was removed by distillation at reduced pressure. The crude product was purified by dry column flash chromatography (silica gel, CH₂Cl₂), to give a colorless oil (13.33 g, 0.045 mol, 63%). [α]$^{25°C}$ (CHCl₃, c = 0.0273): –23.81 (589 nm), –24.94 (578 nm), –28.46 (546 nm), –48.02 (436 nm), –75.46 (365 nm). ¹H NMR (CDCl₃, 300 MHz) δ: 7.76 (d, 2H, 8.40 Hz, Tos), 7.32 (d, 2H, 7.80 Hz, Tos), 5.22 (br s, 1H, =CH), 4.01 (t, 2H, 6.90 Hz, O-CH₂), 2.43 (s, 3H, Tos), 2.32–2.24 (m, 3H), 2.17–2.15 (m, 2H), 2.04–2.01 (m, 1H), 1.91 (td, 1H, 6.00,

Scheme 3. Mechanism for triplet pinene rearrangement.
Scheme 4. Radical cyclobutylcarbinyl ring opening in pinene.
6.00, 1.50 Hz), 1.21 (s, 3H, Me), 1.05 (d, 1H, 8.40 Hz), 0.74 (s, 3H, Me). ¹³C NMR (CDCl₃, 75.5 MHz) δ: 144.63, 142.61, 133.28, 129.77, 127.85, 119.67, 68.57, 45.53, 40.56, 37.99, 36.08, 31.50, 31.27, 26.16, 21.62, 21.04

5,5-Dimethyl-2-(2-(p-acetylphenoxy)ethyl)bicyclo[3.1.1]hept-2-ene (1)
Nopol tosylate (2.00 g, 0.00675 mol), *p*-hydroxyacetophenone (1.38 g, 0.0101 mol), and K₂CO₃ (2.80 g, 0.0202 mol) were added to DMF (50 mL) and heated to 60°C under argon for 15 h. The mixture was then cooled to room temperature and water (50 mL) was added. The solution was extracted with ether (3 × 30 mL). The combined organic layer was washed with 2 N NaOH (2 × 30 mL) and aq NaCl (2 × 30 mL), and then dried over MgSO₄. After removal of the ether at reduced pressure, the desired product was obtained without further purification as a colorless oil (1.35 g, 0.0047 mol, 71%). [α]$^{25°C}$ (CHCl₃, c = 0.0273): –27.56 (589 nm), –28.66 (578 nm), –32.56 (546 nm), –54.77 (436 nm), –84.82 (365 nm). UV (CH₃OH) λ$_{max}$: 275 (14 789), 216 (11 668), 204 (11 965). MS *m/z*: 284 (<1%), 241 (18), 137 (25), 121 (15), 105 (100), 93 (21), 91 (29), 79 (23), 77 (22), 43 (44). ¹H NMR (CDCl₃, 300 MHz) δ: 7.90 (d, 2H, 9.00 Hz, H₁₁), 6.88 (d, 2H, 9.00 Hz, H₁₀), 5.34 (br s, 1H, H₃), 4.01 (t, 2H, 7.05 Hz, H₉), 2.53 (s, 3H, COMe), 2.44 (tdd, 2H, 7.05, 1.2, 1.2 Hz, H₈), 2.36 (ddd, 1H, 8.70, 5.62, 5.62 Hz, H₅), 2.23 (br d, 2H, 8.40 Hz, H₇), 2.08 (br d, 2H, 5.40 Hz, H₄), 1.26 (s, 3H, 6-Me), 1.16 (d, 1H, 8.40 Hz, H₁), 0.80 (s, 3H, 6-Me). ¹³C NMR (CDCl₃, 75.5 MHz) δ: 196.74, 162.90, 144.17, 130.56, 130.18, 118.90, 114.15, 66.56,

45.89, 40.73, 38.08, 36.33, 31.64, 31.37, 26.28 21.17. HR-MS calcd. for $C_{19}H_{24}O_2$: 284.1770; found: 284.1776.

Irradiation procedures

Samples of **1** were irradiated in both benzene and methanol solutions. Solutions of **1** (0.0047 g, 1.65×10^{-5} mol) and methyl benzoate (0.0020 g, 1.47×10^{-5} mol) in deuterated solvent (0.75 mL) were placed in an NMR tube. These were irradiated at room temperature in a Rayonet reactor with 300 nm lights. After 1 h and 84% conversion of starting ketone, NMR analysis indicated that the pinene portion of **1** had been converted to two ocimene structures in a 48:52 (cis–trans) ratio in 73% combined yield. This ratio was based on the relative intensities of the 6.77 and 6.34 ppm proton peaks. In the early stages of the reaction, only the cis-isomer was observed. Further irradiation led to equilibration of the two isomers. No optical rotation was observed for the product mixture. Larger scale reactions were purified by PTLC (silica gel, CHCl₃).

cis   **trans**
The isomer mixture obtained at full conversion was analyzed by ¹³C NMR, UV, and MS. Italicized data represent the NMR peaks for the aryl ketone portion of the molecules, which remain nearly identical to their analogs in the reactant. The mass spectrum indicated that the products are isomers of the reactant **1**, while an intense 270 nm UV peak indicated that the alkoxyacetophenone portion of the molecule survived irradiation unscathed.

3-(2-(p-Acetylphenoxy)ethyl)-7-methyl-cis-octa-1,3,6-triene and 3-(2-(p-acetylphenoxy)ethyl)-7-methyl-trans-octa-1,3,6-triene

UV (CH₃OH) λ_max: 270. MS *m/z*: 284 (6), 241 (7), 137 (20), 133 (48), 121 (53), 105 (100), 79 (62), 77 (56), 69 (27), 55 (27), 43 (73). ¹³C NMR (CDCl₃, 75.5 MHz, DEPT) δ: *196.62, 162.83, 162.77,* 139.86 (CH), *134.60 (CH), 133.38, 132.53, 132.40 (CH), 131.77, 131.69 (CH), 130.50 (CH), 130.49 (CH), 130.21, 130.16,* 121.97 (CH), 121.71 (CH), 114.16 (CH), 114.07 (CH), 113.64 (CH₂), 110.81 (CH₂), 67.34 (CH₂), 66.61 (CH₂), 32.90 (CH₂), 27.43 (CH₂), 26.57 (CH₂), *26.24 (CH₃),* 26.11 (CH₂), *25.61 (CH₃),* 17.75 (CH₃), 17.72 (CH₃).

¹H NMR spectra of the individually isolated isomers were measured to compare chemical shifts and coupling constants to those reported for ocimene (2). Italicized data again represent NMR peaks for the aryl ketone portion of the molecules, which remain nearly identical to their analogs in the reactant.

3-(2-(p-Acetylphenoxy)ethyl)-7-methyl-cis-octa-1,3,6-triene

Stereoselective O$_2$-induced photoisomerization of all-*trans*-1,6-diphenyl-1,3,5-hexatriene

Jack Saltiel, Govindarajan Krishnamoorthy, Zhennian Huang, Dong-Hoon Ko, and Shujun Wang

Abstract: Irradiation of all-*trans*-1,6-diphenyl-1,3,5-hexatriene (*ttt*-DPH) in degassed acetonitrile (AN) gives *ctt*- and *tct*-DPH, relatively inefficiently, mainly via isomerization in the singlet excited state. The triplet contribution to the photoisomerization is small due to a very low intersystem crossing yield (ϕ_{is} = 0.01). Central bond isomerization is quenched in the presence of air by a factor of 1.4, consistent with the expected quenching of the lowest singlet and triplet excited states by oxygen. However, the presence of air enhances terminal bond photoisomerization by nearly twofold. Triplet-sensitized *ttt*-DPH photoisomerization favors *tct*-DPH formation and is quenched by oxygen. It follows that the interaction of singlet-excited *ttt*-DPH with O$_2$ suppresses isomerization to *tct*-DPH but opens a new isomerization pathway to *ctt*-DPH. The presence of dimethylfuran, a singlet O$_2$ trap, has no effect on the photoisomerization, eliminating the possible involvement of singlet O$_2$ in this new reaction. *ttt*-DPH radical cations are ruled out as intermediates because the presence of fumaronitrile, which leads to their formation, suppresses both central and terminal bond photoisomerizations. In contrast to acetonitrile, *ctt*-DPH formation is quenched by oxygen in methylcyclohexane, suggesting the requirement of a polar environment. Strikingly different deuterium isotope effects distinguish the direct and O$_2$-induced photoisomerization pathways. A comparative study of *ttt*-DPH-d_0 with *ttt*-DPH-d_2 and *ttt*-DPH-d_4, involving deuteration of one and both terminal double bonds, reveals an inverse kinetic isotope effect (k_H^{ox}/k_D^{ox} = 0.92) for the O$_2$-induced reaction. An attractive mechanism for the new oxygen-induced photoisomerization involves charge transfer from the S$_1$ state of *ttt*-DPH to oxygen followed by collapse of the exciplex to either a zwitterionic or a biradicaloid species through bonding at one of the benzylic positions. Rotation about the new single bond in this intermediate followed by reversion to DPH and O$_2$ gives the observed result.

Key words: diphenylhexatrienes, trans-cis photoisomerization, oxygen sensitization.

Résumé : L'irradiation du 1,6-diphénylhexa-1,3,5-triène complètement *trans* (*ttt*-DPH), dans de l'acétonitrile dégazé (AN) conduit d'une façon relativement inefficace à la formation des *ctt*- et *tct*-DPH, principalement par le biais d'une isomérisation dans l'état excité singulet. La contribution triplet à la photoisomérisation est faible en raison du très faible rendement du passage intersystème (ϕ_{is} = 0,01). L'isomérisation de la liaison centrale est piégée en présence d'air par un facteur de 1,4 qui est en accord le piégeage par l'oxygène des états excités singulet et triplet les plus bas. Toutefois, la présence d'air augmente la photoisomérisation de la liaison terminale par un facteur égal pratiquement à deux. La photoisomérisation du *ttt*-DPH sensibilisée au niveau triplet favorise la formation de *tct*-DPH et elle est piégée par l'oxygène. Il en découle que l'interaction de l'oxygène avec le *ttt*-DPH excité à l'état singulet supprime l'isomérisation en *tct*-DPH mais qu'elle conduit à une nouvelle voie d'isomérisation conduisant au *ctt*-DPH. La présence de diméthylfurane, un piège pour O$_2$ à l'état singulet, n'a pas d'effet sur la photoisomérisation ce qui élimine la possibilité d'implication du O$_2$ à l'état singulet dans cette nouvelle réaction. On a éliminé la possibilité d'une implication des cations radicaux *ttt*-DPH comme intermédiaires sur la base du fait que la présence de fumaronitrile qui conduit à leur formation supprime les photoisomérisations des liaisons tant terminale que centrale. Par opposition à ce qui est observé avec l'acétonitrile, la formation de *ctt*-DPH est piégée par l'oxygène dans le méthylcyclohexane ce qui suggère la nécessité d'un environnement polaire. Des effets isotopiques du deutérium très différents distinguent les voies de photoisomérisations directe et induite par O$_2$. Une étude comparative des *ttt*-DPH-d_0, *ttt*-DPH-d_2 et *ttt*-DPH-d_4 impliquant la deutération d'une et des deux doubles liaisons terminales permet de mettre en évidence un effet isotopique cinétique inverse, k_H^{ox}/k_D^{ox} = 0,92, pour la réaction induite par O$_2$. Un mécanisme intéressant pour la nouvelle photoisomérisation induite par l'oxygène implique un transfert de charge de l'état S$_1$ du *ttt*-DPH vers l'oxygène, suivi d'une décomposition de l'exciplex en espèces soit zwitterionique ou biradicaloïde par le biais de la formation d'une liaison à l'une des positions benzyliques. Une rotation autour de la nouvelle liaison simple de cette intermédiaire, suivie d'une

[Traduit par la Rédaction]

Introduction

all-*trans*-1,6-Diphenyl-1,3,5-hexatriene (*ttt*-DPH) has been used as a model for the long polyenes related to the retinols and vitamin A. It is the first member of the α,ω-diphenylpolyene vinylogous family whose all-s-trans conformer exhibits fluorescence both from the initially excited $1\ ^1B_u$ state and from a lower energy singlet excited state that, following Hudson and Kohler, is identified as the forbidden doubly excited $2\ ^1A_g$ state (1–3). The lowest singlet excited states of all longer diphenylpolyenes (1–3) and of all conjugated polyenes starting with 1,3-butadiene (4–7), have also been identified as $2\ ^1A_g$ states. In degassed solutions the trans → cis photoisomerization of *ttt*-DPH following direct excitation occurs inefficiently by a combination of singlet and triplet pathways (8). In the triplet state, the ground state isomers of DPH exist as a mixture of freely equilibrating conformers in which ttt, tct, and ctt geometries dominate (9). In the absence of oxygen, triplet excitation transfer events between relatively long-lived DPH triplets and DPH ground states of different geometry are links in quantum chain processes that enhance the contribution of triplets to the photoisomerization, compensating somewhat for the low intersystem crossing yields. The quenching of the triplets by oxygen significantly decreases their lifetime and prevents their participation in quantum chain events (9).

Changing the solvent from methylcyclohexane (MCH) to acetonitrile (AN) increases the rates of photoisomerization in the singlet excited state manifold, the increase being especially pronounced (20-fold) at the terminal double bonds (8, 10), thereby decreasing the singlet excited state lifetime and the contribution of the competing decay channels of fluorescence (ϕ_f = 0.65 and 0.27 at 20°C in MCH (11) and AN (10), respectively) and intersystem crossing (ϕ_{is} = 0.029 and 0.010 at 20°C in MCH (12) and AN (13, 14), respectively). Photoisomerization in the ttt → ctt direction in AN is almost entirely a singlet excited state process (98%) that is attenuated by a factor of 1.36 on deuteration of the olefinic hydrogens of the terminal double bond (10).

We report here the effect of oxygen on the photoisomerization of *ttt*-DPH and its 1,2-dideuterio and 1,2,5,6-tetradeuterio derivatives upon direct excitation in AN. In contrast to the central bond whose photoisomerization is attenuated, consistent with oxygen quenching of singlet and triplet excited states, oxygen enhances photoisomerization at the terminal double bonds. The mechanism of this new photoisomerization pathway is addressed in this paper.

Experimental section

Materials

Sources and purification procedures for all-*trans*-1,6-diphenyl-1,3,5-hexatriene (100.0%, HPLC), benzophenone, *trans*-stilbene, anthracene, and acetonitrile have been described (8, 10). Acetonitrile was used as received or purified

using a known procedure (15). Lithium perchlorate (Spectrum, anhydrous ACS reagent) was used as received. The syntheses of 1,2-dideuterio- (*ttt*-DPH-d_2, 99.9%, HPLC) and 1,2,5,6-tetradeuterio-all-*trans*-1,6-diphenyl-1,3,5-hexatriene (*ttt*-DPH-d_4, 98.0%, HPLC, 1.7% *tcc*-DPH-d_4, major contaminant) have been described (10). Prior to use in this study, *ttt*-DPH-d_4 was recrystallized three times to a final purity of 99.4% with 0.5% *tcc*-DPH-d_4, the major contaminant.

ttc-DPH-d_0

ttc-DPH-d_2

ctt-DPH-d_2
Irradiation procedure

Irradiations were carried out in a Moses merry-go-round (16) apparatus immersed in a thermostated water bath. A heating coil connected to a thermoregulator (Polyscience Corporation) was used to control the temperature to 20 ± 0.1°C. The benzophenone-sensitized photoisomerization of *trans*-stilbene was used for actinometry ($\phi_{t\rightarrow c}$ = 0.55) (17, 18). A Hanovia medium pressure Hg lamp (200 W, Ace Glass, Inc.) and Corning CS 7-37 and 0-52 filters were used for excitation at 366 nm. Aliquots of actinometer solutions (3.0 mL) were pipetted into Pyrex ampoules (13 mm o.d.), degassed, and flame-sealed at a constriction. Air-saturated DPH solutions (1.0×10^{-3} M in AN, 3 mL aliquots) were

irradiated in 13 mm o.d. Pyrex ampoules lightly stoppered with Teflon-tape-covered rubber stoppers. In some instances, the ampoules were provided with fritted disks at the bottom for bubbling air or oxygen throughout the irradiation. Sample preparation, degassing, and analysis were performed in almost complete darkness (red light).

Analytical procedures

Actinometer solutions were analyzed by GLC and DPH solutions by HPLC (λ_{mon} = 350 nm) as previously described (8, 9), except that on replacing AN with hexanes prior to HPLC analyses, a stream of argon was used to evaporate the solvent and care was exercised to avoid taking samples to dryness (10). This procedure minimizes ctt-DPH losses.

Fluorescence measurements

Fluorescence *spectra* were measured with a Hitachi/PerkinElmer MPF-2A fluorescence spectrophotometer as previously described (19), or with a Hitachi F4500 fluorimeter. Fluorescence spectra were recorded for both air-saturated and Ar-bubbled solutions of DPH in AN in standard 1 cm^2 quartz cells. Temperature was maintained at 20.0 ± 0.1°C using a Neslab-RTE 4DD constant temperature circulation bath, and was monitored continuously during each scan with an Omega Engineering Model 199 RTD digital thermometer in a reference cell placed in the same constant temperature cell holder. Fluorescence *lifetimes* were measured with a phase modulation Fluorolog-τ2 lifetime spectrofluorometer (SPEX) equipped with a 450 W Xe arc source, a Hamamatsu R928P photomultiplier tube, and a Lasermetrics BNC1072FW Pockel cell (KD_2PO_4). The Fluorolog-τ2 modulates the frequency of the excitation light from 0.5 to 300 MHz. A glycogen solution (τ = 0 ns, scattered light) was used as reference. Temperature was maintained at 20.0 ± 0.1°C and was monitored continuously during each scan as described above. Air-saturated ttt-DPH solutions (2.0×10^{-6} M) were employed. Software (DMF 3000F Spectroscopy) provided by the manufacturer was used to analyze the data. Determinations of the quality of the lifetimes were based on examination of the statistics of the fit (a plot of the residual deviations vs. frequency) and reduced χ^2 values that were all close to unity.

Results

Photochemical observations

Photostationary states were approached from the ttt-DPH-d_n (n = 2 and 4) side. Degassed DPH samples (1.0×10^{-3} M) in air-saturated AN were irradiated for different time intervals at 20.0°C until HPLC analysis revealed no further change in the isomer composition. Photostationary state fractions are shown in Table 1. Overall conversions for quantum yield measurements were kept below 8% and were corrected for back reaction as has been described (10). Quantum yields are also shown in Table 1. The effect of additives was studied for ttt-DPH-d_0. The presence of up to 0.40 M LiClO$_4$ had no effect on ctt/tct conversion ratios for both air-saturated and degassed AN solutions. The presence of 0.188 M 2,5-dimethylfuran (DMF) had no significant effect on photoisomerization quantum yields of 1.38×10^{-3} M ttt-DPH-d_0 in air-saturated AN. Similarly, addition of up to

[a]Values in parentheses are corresponding values under degassed conditions from ref. (10); estimated uncertainties in absolute quantum yields are ±5%.

1.2×10^{-3} M diethylamine (DEA) to 1.00×10^{-3} M ttt-DPH-d_0 in degassed or air-saturated AN solutions did not alter the photoisomerization quantum yields.

Fluorescence measurements

The fluorescence of 1.0×10^{-3} M ttt-DPH-d_0 in degassed and air-saturated AN was found to be independent of [DEA] up to 1.5×10^{-3} M. Fluorescence lifetimes at different temperatures for air-saturated solutions are compared in Table 2 with those for degassed solutions (10). Excellent fits to the single exponential decay model were obtained ($\chi^2 \leq 1.2$) and the lifetimes were independent of excitation and monitoring wavelengths, within experimental uncertainty. Reproducibility in independent measurements was better than ±0.1 ns.

Discussion

Background

The ground state of molecular oxygen is generally a very effective quencher of electronically excited molecules (20). Rate constants for oxygen quenching of singlet excited states of aromatic hydrocarbons in hydrocarbon solvents are often close to the diffusion-controlled limit. Corresponding values for triplet state quenching are usually an order of magnitude smaller owing to restrictions by spin statistical factors (20–22). These quenching events are commonly associated with formation of the lowest singlet state of the oxygen molecule $O_2^*(^1\Delta_g)$, sometimes through the intermediacy of the higher energy state $O_2^*(^1\Sigma_g^+)$. In the case of singlet excited states of aromatic hydrocarbons, induced intersystem crossing has been shown to accompany oxygen quenching in hydrocarbon media (23), a pathway to triplets that is diminished by polar solvents such as acetonitrile (23–25). The importance of a charge transfer (CT) quenching pathway by oxygen was first established by Kikuchi et al. (26) who showed that, for anthracenecarbonitriles and acridinium salts, fluorescence quenching rate constants in acetonitrile decrease as the free energy for full electron transfer (ΔG_S^{CT}) increases from negative to positive values. A comprehensive systematic study of the contribution of CT in the quenching of aromatic hydrocarbon singlet and triplet states by oxygen in AN was described by Abdel-Shafi and Wilkinson (27). With the exception of tetracene that undergoes significant chemical degradation, the net rate constants for the triplet quenching

[b]From ref. (10).

pathway involving CT were shown to correlate well with ΔG_T^{CT}, indicating a transition state with 13.5% CT character (27). Net rate constants for the analogous process involving excited singlet states were as high as 1.6×10^{10} M^{-1} s^{-1} but could not be determined over a sufficiently large ΔG_S^{CT} range to establish a meaningful logarithmic dependence on this quantity (27). Except in the case of 2,6-dimethoxynaphthalene (DMN) for which the quenching event is accompanied by a small yield of $^2DMN^{\cdot+}$ (3×10^{-3}) (25), attempts to detect the radical cations of the donors and $^2O_2^{\cdot-}$ have failed, despite the exothermicity of full electron transfer in AN for most of the excited singlet donors studied (25, 27).

Energy transfer from the triplet state of *ttt*-DPH to O_2 in air-saturated solutions yields $O_2^*(^1\Delta_g)$ with unit efficiency (28). Quenching of the singlet state of *ttt*-DPH leads to $O_2^*(^1\Delta_g)$ less efficiently and the efficiency decreases with increasing solvent polarity (0.5 and 0.3 in cyclohexane and methanol, respectively) (29). Competing with $O_2^*(^1\Delta_g)$ formation is O_2-induced intersystem crossing leading to as much as a 10-fold increase in ϕ_{is} (0.015 to 0.15 for degassed vs. air-saturated methanol (12)).

Two-photon laser excitation of *ttt*-DPH gives the radical cation (^2ttt-DPH$^{\cdot+}$) in a variety of solvents (30, 31). In AN the lifetime of the radical cation (7.3 μs) is insensitive to the presence of air (31, 32). The radical cation is also observed on quenching of ^1ttt-DPH* by electron acceptors in polar solvents including AN (12, 13). It isomerizes to a new transient, assigned as a product of trans → cis photoisomerization, which reverts thermally to ^2ttt-DPH$^{\cdot+}$, and reacts efficiently with electron donors to give back the starting *ttt*-DPH (31).

Oxygen effects on *ttt*-DPH photoisomerization

We reported earlier that the fluorescence quantum yields and lifetimes of *ttt*-DPH-d_n (n = 0, 2, and 4) in AN are nearly independent of deuterium substitution at the terminal double bonds (10). It was not surprising, therefore, that oxygen in air-saturated AN solutions at 20°C attenuates fluorescence quantum yields and lifetimes of the three *ttt*-DPH-d_n (n = 0, 2, and 4) by the same 1.31 ± 0.01 factor, within experimental uncertainty (10). The 1.3_4 ratio of the lifetimes at 20°C in Table 2 is in reasonable agreement with the quantum yield measurements and the effect is similar at different temperatures. Use of $1.9 \pm 0.2 \times 10^{-3}$ for the oxygen concentration in air-saturated AN (33) gives $k_{qox} = (3.5 \pm 0.4) \times 10^{10}$ M^{-1} s^{-1} for the quenching of the excited singlet states of

ttt-DPH-d_n (n = 0, 2, and 4) by molecular oxygen, a value close to the diffusion-controlled limit.

The range of attenuations of $\phi_{ttt \to tct}$ values by oxygen is slightly larger (1.36 to 1.40) than the attenuations of fluorescence quantum yields and lifetimes, because in addition to quenching the singlet excited state, oxygen dramatically shortens the lifetime of DPH triplets, effectively eliminating quantum chain contributions to the photoisomerization (9b). Oxygen interferes with the photoisomerization of the central bond of *ttt*-DPH-d_n (n = 0, 2, and 4) only in so far as it deactivates *ttt*-DPH-d_n excited singlet (primarily) and triplet states. Photoisomerization quantum yields in the presence of FN in degassed and air-saturated AN solutions are consistent with an O_2 induced sixfold (compared with factors of 7 and 10 reported for cyclohexane and methanol, respectively, (12, 29)) enhancement of ϕ_{is} (34). In this case, however, this is a minor perturbation because it only raises ϕ_{is} from 0.01 to 0.06.

The results in Table 1 reveal a strikingly different O_2 effect on terminal bond photoisomerization. Instead of the expected ~1.3-fold attenuation, ϕ_{ctt} values are enhanced by factors of 2 to 2.5, progressively increasing with terminal bond deuteration. Correspondingly, the presence of air strongly shifts photostationary state (PSS) compositions to larger *ctt*-DPH contributions at the expense of *ttt*-DPH. Oxygen enhanced *trans* to *cis* 1,2-diarylethene photoisomerization quantum yields have previously been observed, but were generally attributed to O_2 induced intersystem crossing (35–38). For instance, in the case of *trans*-4,4′-diphenylstilbene, quenching of the highly fluorescent singlet excited state by ~1×10^{-2} M O_2 in methylcyclohexane increases $\phi_{t \to c}$ 18-fold from 0.0025 to 0.045. However, because DPH triplets in AN favor decay to *tct*-DPH over decay to *ctt*-DPH by at least a factor of 5 (9a), O_2-catalyzed intersystem crossing would be expected to increase ϕ_{tct} more than ϕ_{ctt}. Instead, we observe enhancement of the latter and quenching of the former. We conclude that the differential O_2 effects on central and terminal bond photoisomerization rule out the O_2-induced intersystem crossing pathway in *ttt*-DPH.

In the *Background section*, we reviewed evidence for the formation of radical cations (^2ttt-DPH$^{\cdot+}$) in AN solutions. We recently evaluated and ruled out their possible involvement in the photoisomerization of *ttt*-DPH following direct excitation in degassed AN (8). Briefly, fluorescence and photoisomerization quantum yields, measured as a function of fumaronitrile (FN) concentration, show that ^2ttt-DPH$^{\cdot+}$ radical cations formed from the $^1(ttt$-DPH–FN)* exciplex (13) undergo no photoisomerization (8). It is not surprising, therefore, that we find that addition of up to 0.015 M diethylamine (DEA) has no effect on the photoisomerization quantum yields and, in particular, on the ϕ_{ctt}:ϕ_{tct} ratio in either degassed or air-saturated AN. At the high concentrations employed, DEA, a known, effective quencher of ^2ttt-DPH$^{\cdot+}$ radical cations, $k_q = 1.05 \times 10^9$ M^{-1} s^{-1} (31a), should have intercepted them all, in view of their long lifetime (7.3 μs) (31). In the unlikely event that electron transfer from ^1ttt-DPH* to O_2 contributes to the formation of ^2ttt-DPH$^{\cdot+}$ radical cations, they are not involved in *trans* → *cis* photoisomerization.

The possibility that O_2 opens a thermal free radical isomerization process can be ruled out because the observed

formation of more cis double bonds moves the system up hill thermodynamically (9b). We are left with addition followed by elimination starting from ^1ttt-DPH*–O_2 interaction, as a viable Schenck-type mechanism (39) for the O_2-induced photoisomerization (Scheme 1). Although the adduct (adducts for ttt-DPH-d_2) in Scheme 1 is shown as a zwitterionic species because this process is much more pronounced in AN than in MCH,[2] the possibility that the adduct is biradicaloid cannot be ruled out. Bond formation at the benzylic positions should be favored because it leads to the more delocalized carbon-centered cation or radical intermediate. Rotation about the new single bond followed by loss of O_2 would explain enhanced ctt-DPH formation. In principle, the intermediate could form either from the interaction of ^1ttt-DPH* with ground state O_2 ($^3\Sigma_g$) or by the addition of singlet $^1O_2*$ ($^1\Delta_g$) to ground state ttt-DPH. However, if $^1O_2*$ were responsible for enhanced values under direct excitation conditions, then O_2 would enhance ϕ_{ctt} values even more under triplet-sensitized conditions because the efficiency of $^1O_2*$ formation is higher when ^3ttt-DPH* is quenched by $^3O_2$ (28, 29). It follows that the involvement of $^1O_2*$ can be ruled out because we have found no photoisomerization enhancement of any kind under triplet-sensitized conditions in air-saturated AN (9). As a further precaution, we now report that addition of 0.188 M 2,5-dimethylfuran (DMF), a very efficient $^1O_2*$ scavenger (28, 41), has no effect on the ϕ_{ctt}: ϕ_{tct} ratio in air-saturated AN.

Deuterium isotope effect

The small increasing trend in ϕ_{tct} values under both degassed and air-saturated conditions with increasing deuterium substitution is consistent with the effect of deuterium on the lifetime of ^1ttt-DPH* (10). Terminal bond deuterium substitution does not affect rate constants for central bond isomerization. In contrast, ϕ_{ctt} values decrease strongly in degassed solutions and show a less-pronounced decrease in the presence of air. The torsional relaxation rate constants for dihydro- and dideuterio-terminal bonds in ^1ttt-DPH* are subject to a normal deuterium isotope effect ($k_H/k_D = 1.36$)

(10). Analysis of ϕ_{ctt} values in the presence of air is accomplished by dissecting them into contributions from the normal pathway, involving the fraction of ^1ttt-DPH* not intercepted by oxygen $(1 - f_{ox})$, and the new pathway, involving the fraction of ^1ttt-DPH* that is intercepted by oxygen (f_{ox}) and follows the pathway in Scheme1. Since nearly all terminal bond isomerization in degassed solution is a singlet excited state reaction, we expect that, in the presence of air, the normal pathway will experience the same attenuation as fluorescence. Substitution of $k_{qox} = 3.5 \times 10^{10}$ M^{-1} s^{-1} for the quenching of the excited singlet states of ttt-DPH-d_n ($n = 0$, 2, and 4), $[O_2] = 1.9 \times 10^{-3}$ M, and the singlet excited state lifetimes ($\tau_f{}^0$) (10) in eq. [1] gives the $(1 - f_{ox})$ values listed in

[1] $(1 - f_{ox}) = k_{qox}\tau_f{}^0[O_2]/(1 + k_{qox}\tau_f{}^0[O_2])$

Table 3. Quantum yields for terminal bond isomerization by the normal singlet excited state pathway ($\phi_{ctt+ttc}{}^S$) obtained by multiplying the values under degassed conditions (given in parentheses in Table 1) by the $(1 - f_{ox})$ attenuation factors, were subtracted from observed quantum yields in the presence of air to obtain $\phi_{ctt+ttc}{}^{ox}$, the quantum yields for the O_2-induced pathway (Table 3). Assuming that Scheme 1 applies, the ratio of the rate constant for bond formation at a benzylic position bearing hydrogen ($k_H{}^{ox}$), to the analogous rate constant for a benzylic position bearing deuterium ($k_D{}^{ox}$) is given by

[2] $k_H{}^{ox}/k_D{}^{ox} = (\alpha_D/\alpha_H)(\phi_{ctt}{}^{d0}/\phi_{ctt}{}^{d4})(\tau_{d4}{}^{ox}/\tau_{d0}{}^{ox})$

where the αs are decay fractions to ctt-DPH for the deuterated and undeuterated DPH–O_2 adducts, the quantum yields are the values for the O_2-induced pathway from Table 3, and the fluorescence lifetimes are in the presence of air. Taking $\alpha_D = \alpha_H$ and substituting for the other quantities in eq. [2] using the data for ttt-DPH-d_0 and ttt-DPH-d_4 gives $k_H{}^{ox}/k_D{}^{ox} = 0.94$. This requires that formation of the DPH–O_2 exciplex be somewhat reversible, as no intermolecular deuterium isotope effect would be expected if exciplex formation were irreversible and product determining. A similar treatment using the data for ttt-DPH-d_0 and ttt-DPH-d_2 gives $k_H{}^{ox}/k_D{}^{ox} = 0.90$. The inverse secondary deuterium isotope effect is consistent with the expected sp^2 to sp^3 rehybridization in the transition states leading to the adducts (42, 43).

Significant fractions of ^1ttt-DPH*–O_2 quenching interactions must follow the adduct pathway to isomerization. These fractions (f_{ad}) can be estimated from $f_{ox}/(\alpha\phi_{ctt+ttc}{}^{ox})$ by assuming equal partitioning of the adducts to cis and trans double bonds ($\alpha = 0.5$). The resulting values are rela-

---

[2]In MCH, the presence of air attenuates tct- and ctt-DPH formation by factors of 0.35 and 0.58, respectively (34, 40).

tively insensitive to deuterium substitution falling in a narrow 0.62 to 0.66 range (Table 3).

Trapping the exciplex

Initial indications that the O_2-induced photoisomerization pathway is quenched when $Li^+ClO_4^-$ is included in AN (34), were not confirmed when great care was taken to avoid *ctt*-DPH loss in sample preparation for HPLC analysis. Because no changes in $\phi_{ctt}:\phi_{tct}$ ratios were observed even when a saturated $Li^+ClO_4^-$ solution (~0.4 M) was used in air-saturated AN, we can conclude that Li^+ fails to intercept an ion pair in this case. This approach has been shown to succeed in several instances (44). Apparently, in our case, either charge transfer is not complete in the exciplex, or the exciplex is too short-lived. An interesting anomaly is our preliminary observation that on attempting to increase the contribution of the O_2-induced photoisomerization pathway by increasing the O_2 concentration (bubbling O_2 during the irradiation) we were surprised to find lower $\phi_{ctt}:\phi_{tct}$ ratios than in the presence of air. If the mechanism in Scheme 1 is correct, this result suggests that, at the higher concentration, oxygen quenches the *ttt*-DPH–O_2 exciplex. While oxygen quenching of singlet exciplexes is well-known (45), quenching of an oxciplex is unprecedented and remains to be established.

The effect of central bond torsional mobility on the Rydberg state ring opening of alkylcyclobutenes

Bruce H.O. Cook and William J. Leigh

Abstract: The stereochemistry of the π,R(3s) excited state ring opening of a series of bicyclic alkylcyclobutenes has been studied in hydrocarbon solution with 228 nm excitation. In these compounds, the C=C bond is shared between the cyclobutene ring and a five-, six-, or seven-membered ancillary ring, which has the effect of restricting the torsional mobility about the central C—C bond in the isomeric diene products. It has previously been shown that monocyclic alkylcyclobutenes undergo stereospecific *conrotatory* ring opening upon excitation at the long wavelength edge of the π,R(3s) absorption band (228 nm), and nonstereospecific ring opening upon irradiation at shorter wavelengths (within the π,π* absorption band). Different behaviour is observed for the bicyclic systems studied in the present work. The bicyclo[3.2.0]hept-1-ene, bicyclo[4.2.0]oct-1-ene, and one of the bicyclo[5.2.0]non-1-ene derivatives yield nearly the same mixtures of *E,E*- and *E,Z*-diene isomers upon irradiation at 214 and 228 nm, with the product mixtures being heavily weighted in favor of the isomer(s) corresponding to disrotatory ring opening. The results may indicate that the stereochemical characteristics of the Rydberg-derived ring opening of alkylcyclobutenes depends on the ability of the molecule to twist about the "central" bond (i.e., the C=C bond in the cyclobutene) as ring opening proceeds. It is proposed that restricting the torsional mobility about the central bond activates internal conversion from the π,R(3s) to the π,π* potential energy surface, from which predominant disrotatory ring opening ensues.

Key words: cyclobutene, Rydberg, ring opening, photopericyclic, electrocyclic.

Résumé : Opérant en solution dans des hydrocarbures et avec une excitation à 228 nm, on a étudié la stéréochimie de l'ouverture de cycle dans l'état excité π,R(3s) d'une série d'alkylcyclobutènes bicycliques. Dans ces composés, la liaison C=C est partagée entre le cycle du cyclobutène et un cycle ancillaire à cinq-, six- ou sept-chaînons qui a pour effet de restreindre la mobilité torsionnelle autour de la liaison C—C centrale des produits diéniques isomères. Il a été démontré antérieurement que les alkylcyclobutènes monocycliques subissent une ouverture de cycle *conrotatoire* stéréospécifique lors de leur excitation dans la portion de grande longueur d'onde de la bande d'absorption π,R(3s) (228 nm) et une ouverture de cycle non stéréospécifique par irradiation à des longueurs d'onde plus faibles (dans la bande d'absorption π,π*). Dans le présent travail, on observe un comportement différent pour les systèmes bicycliques. Lors de leur irradiation à 214 ou à 228 nm, le bicyclo[3.2.0]hept-1-ène, le bicyclo[4.2.0]oct-1-ène et un des dérivés du bicyclo[5.2.0]non-1-ène conduisent pratiquement tous aux même mélanges *E,E*- et *E,Z*- de diènes isomères; les mélanges contiennent principalement les isomères résultant d'une ouverture disrotatoire du cycle. Les résultats suggèrent que les caractéristiques stéréochimiques de l'ouverture de cycle d'alkylcyclobutènes se produisant dans la région de Rydberg dépend de la facilité de la molécule à se retourner autour de la liaison centrale (c'est-à-dire la liaison C=C du cyclobutène) lorsque l'ouverture de cycle se produit. On suggère qu'une restriction de la mobilité torsionnelle autour de la liaison centrale active la conversion interne de π,R(3s) à la surface d'énergie potentielle π,π* à partir de laquelle il résulte une ouverture de cycle disrotatoire.

Mots clés : cyclobutène, Rydberg, ouverture de cycle, photopéricyclique, électrocyclique.

Introduction

The direct irradiation of simple alkylcyclobutenes in the gas phase or solution results in electrocyclic ring opening and stereospecific [2 + 2]-cycloreversion to yield the corresponding alkyne and alkene (1–4). It has been known for several years that contrary to early indications (5), the ring opening reaction proceeds *non*stereospecifically (6, 7), in apparent violation of simple orbital symmetry selection rules for photoelectrocyclic reactions (8) as well as the results of

high level ab initio calculations (9, 10), all of which predict that the process should proceed with preferred *disrotatory* stereochemistry when initiated by population of the lowest π,π^* excited singlet state of the molecule. Assuming that orbital symmetry selection rules are, in fact, obeyed in the π,π^* reaction, there are at least three possible explanations for this behaviour (6): (*i*) ring opening proceeds *adiabatically*, yielding the photochemically allowed (disrotatory) diene isomer(s) in the lowest π,π^* excited singlet state, from which the forbidden (thermally allowed, conrotatory) isomer(s) are formed via *E,Z*-isomerization; (*ii*) the conrotatory isomers are formed via reaction from upper vibrational levels of the ground state of the cyclobutene, populated by internal conversion in competition with disrotatory π,π^* state ring opening; and (*iii*) the conrotatory isomers are formed via competing reaction of the radical-cation-like $\pi,R(3s)$ Rydberg excited singlet state, which is known to be of similar energy to the π,π^* (valence) singlet state in alkylcyclobutenes (4, 11, 12), just as it is in other aliphatic alkenes (13–15).[2]

Much of our work in this area over the past 15 years has been directed at attempting to distinguish between these possibilities, through studies of the effects of substituents, excitation wavelength, and various structural constraints on the stereochemistry of the reaction (4, 6, 12, 16–23). By the mid-1990s, we had concluded: (*i*) that the $\pi,R(3s)$ state is responsible for the [2 + 2]-cycloreversion reaction but is not involved in ring opening (12, 24); and (*ii*) that the adiabatic, π,π^* state ring opening mechanism most adequately accounts for the nonstereospecificity of the reaction (19, 21, 22).

The first conclusion was based on an analysis of the photochemistry of a series of 7-substituted bicyclo[4.2.0]oct-7-ene derivatives (**1**), in which the energy of the $\pi,R(3s)$ state varies systematically as a function of the non-conjugating substituent attached to the cyclobutenyl C=C bond (12). The quantum yield of ring opening products is highest in the case of the 7-trifluoromethyl derivative **1c**, in which the $\pi,R(3s)$ state is significantly higher in energy than the π,π^* singlet state, and the yields of ring opening relative to cycloreversion products increase with increasing excitation wavelength between 193 and 214 nm (the opposite is true for **1a**, **1b**). Furthermore, the degree of nonstereoselectivity associated with ring opening is roughly constant throughout the series of compounds, and does not vary with excitation wavelength. It was thus concluded that the π,π^* state alone is responsible for ring opening, and hence, that the nonstereospecificity of the reaction somehow originates in the specific manner in which ring opening proceeds on the potential energy surface of this electronic state. However, it is difficult to rule out the possibility that the trifluoromethyl substituent in **1c** might also affect excited state dynamics in addition to altering the relative energies of the $\pi,R(3s)$ and π,π^* states, and perhaps cause a fundamental

change in the reactivity of the π,π^* state compared to that in the parent compound. Indeed, recent ultrafast time-resolved experiments (25, 26), as well as detailed theoretical calculations (27–29), strongly suggest that such possibilities *cannot* be ignored in other cycloalkenes such as cyclohexene and norbornene. Thus, there may be other viable explanations for the observed trends in the photoreactivity of **1a**–**1c** that go well beyond simple arguments based on the effects of the substituents on the relative energies of the $\pi,R(3s)$ and π,π^* excited states in these molecules. One possibility is that in **1a** and **1b**, ring opening proceeds from both the $\pi,R(3s)$ and π,π^* states, each with a high degree of stereoselectivity (conrotatory from the Rydberg state and disrotatory from the π,π^* state); in **1c**, ring opening proceeds only from the π,π^* state, but with a lower degree of disrotatory stereoselectivity owing to a fundamental change in excited-state dynamics caused by the strongly polarizing trifluoromethyl substituent. Such alternatives are difficult to rule out solely on the basis of simple product studies.

b. R = Me
c. R = CF$_3$

1
The second conclusion was based on an examination of the photochemistry of the series of constrained cyclobutenes **2** and **4**, comparing the relative yields of isomeric dienes obtained upon 214-nm photolysis of these compounds to values predicted from the quantum yields for direct *E,Z*-photoisomerization of the corresponding isomeric dienes (19, 21, 22). For example, 214 nm irradiation of *cis*-2,2,6,7-tetramethylbicyclo[3.2.0]hept-1-ene (*cis*-**2**) in hydrocarbon solution yields a mixture of three diene isomers, *E,E*-, *E,Z*-, and *Z,E*-**3** (eq. [1]); the two *E,Z*-isomers are formed in a ratio that is *identical* (within experimental error) to that obtained from direct (254 nm) irradiation of the photochemically allowed (*E,E*) diene isomer (21). Reasonable (but not perfect) agreement was also observed between the isomeric diene ratios obtained from 214-nm photolysis of the symmetrically substituted bicyclic cyclobutenes **4**, and values calculated from the quantum yields for *E,Z*-photoisomerization of their isomeric dienes **5** (19, 22). This series of compounds bears the important feature that the dienes **3** and **5a**–**5d** are constrained to exist in the *s*-cis conformation, similar to that which would (presumably) be formed directly in the electrocyclic ring opening reaction. This allows one to independently determine the excited state torsional decay characteristics of the product in the conformation in which it is initially formed from ring opening of the corresponding cyclobutene derivative. Acyclic dienes generally prefer the *s*-trans conformation, so such analyses are more problematic with monocyclic cyclobutenes.

---

[2] There is a long-standing debate, which to our knowledge has never been resolved, as to the identity of the excited state responsible for the weak long-wavelength absorptions in the condensed phase UV absorption spectra of tetraalkyl-substituted alkenes — whether they are the Rydberg absorptions, substantially reduced in intensity and blue-shifted relative to their character in the gas phase spectrum, or those corresponding to a very weak transition to a low-lying valence state such as the π,σ^* state (13). We favour the Rydberg state assignment because of the similarities between the photochemistry of alkenes in hydroxylic solvents and the chemistry of the corresponding radical cations under similar conditions (14, 15). The photochemistry of 1,2-dimethylcyclobutene in methanol exhibits similar features as that of other alkenes in hydroxylic media (4).

Thus, the mechanism that emerged from these studies is one in which the π,π* excited singlet state of the cyclobutene undergoes purely disrotatory ring opening, but with internal conversion to the ground state potential energy surface occurring *after* the diene is fully formed rather than at a geometry intermediate between reactant and product (19, 21, 22); a mixture of diene isomers is formed not because the reaction itself is nonstereospecific, but because the product is formed in an excited singlet state whose main avenue for relaxation to the ground state is cis,trans-isomerization.

This mechanism is fully compatible with orbital symmetry selection rules, as well as with high level theoretical studies that indicate that within the first ~50 fs after excitation to the π,π* (1^1B_2) state, ring opening is initiated with the disrotatory stereochemistry that is predicted by orbital symmetry (9, 10). Mathies and co-workers (30, 31) had previously reached the same conclusion on the basis of an analysis of the resonance Raman spectrum of cyclobutene. However, the vibrational assignments on which their analysis was based have been refuted (32), and it appears that a different experimental approach will be required to define the stereochemistry of the process on this timescale (10, 32). To date, however, neither theory nor ultrafast spectroscopic methods have been able to address the question of why, if π,π* state ring opening proceeds with a high degree of stereochemical integrity in its very early stages, mixtures of both dis- and conrotatory dienes are *ultimately* formed upon irradiation of stereo-labelled cyclobutene derivatives in solution.

More recent results from our laboratory strongly suggest that the adiabatic ring opening mechanism, with only the π,π* state being involved in the reaction, may be incorrect, or at least not general (4). If the π,R(3*s*) excited state of cyclobutene is really not involved in ring opening, as was concluded on the basis of the photochemistry of **1a**–**1c** (12),

then it would be predicted that photolysis of cyclobutene derivatives with especially low Rydberg state energies, under conditions where the Rydberg state is selectively and exclusively excited, should lead *only* to cycloreversion. This premise was tested with the monocyclic, 1,2-disubstituted cyclobutene derivatives **6** and **7**, whose gas phase UV absorption spectra indicate to have spectroscopic π,R(3*s*) excited singlet states of substantially lower energies than the valence (π,π*) state (4). Indeed, photolysis of the three compounds at the long-wavelength edge of their Rydberg absorptions (228 nm) leads mainly to [2 + 2]-cycloreversion in both the gas phase and solution, consistent with the previous assignment of this reaction mode to the π,R(3*s*) Rydberg state. Surprisingly however, all three derivatives also undergo ring opening upon excitation under these conditions, and furthermore, the stereochemically labelled derivatives *cis*- and *trans*-**7** appear to do so with clean, *conrotatory* stereochemistry — the stereochemistry associated with the *ground state* ring opening reaction. In a subsequent paper, we showed that high yields of ring opening products are obtained upon 228 nm photolysis of other 1,2-dialkylcyclobutenes (**8** and **9**) as well, and by comparing the quantum yields for product formation to values calculated on the basis of RRKM theory, demonstrated that the process is most likely a discrete reaction of the Rydberg excited state, rather than being the result of internal conversion to upper vibrational levels of the ground state of the cyclobutene, from which thermal ring opening would ensue (23).

6   **7**   **8**   **9**
These latest discoveries require that we reconsider the possibility that the overall nonstereospecificity observed with shorter wavelength excitation, where the valence and Rydberg absorptions overlap, is in fact due to competing *stereospecific* reactions from the π,π* and π,R(3*s*) excited states. As a first step in this reanalysis, we have chosen to have a closer look at the possible role of the Rydberg state in the ring opening of some of the compounds that led us in the first place to conclude that the π,π* state reacts adiabatically (22). We thus report the results of a study of the photolysis of the cis- and trans-isomers of the bicyclic cyclobutene derivatives **4b**–**4d** at 228 nm, where the π,R(3*s*) Rydberg absorptions are well-isolated from the higher energy π,π* absorption band and can be excited selectively.

Results

The UV absorption spectra of *cis*-7,8-dimethylbicyclo[4.2.0]oct-1-ene (*cis*-**4c**) in the gas phase (1 atm = 101.325 kPa, SF$_6$ buffer) and in hexane solution are shown in Fig. 1. The spectra and the differences between them are very similar to those reported earlier for *cis*-1,2,3,4-tetramethylcyclobutene (*cis*-**7**) (4); they clearly show both that the π,R(3*s*) excited state is significantly lower in energy than the valence (π,π*) state in this compound, and that it should be populated selectively upon photolysis with

Fig. 2. Plots of DIS:CON diene isomer ratios vs. % conversion of **4**, for the photolysis of (*a*) *cis*- and (*b*) *trans*-6,7-dimethylbicyclo[3.2.0]hept-1(5)-ene (*cis*- and *trans*-**4b**) in deoxygenated hexane solution at 214 nm (●, ———) and 228 nm (○, – – –).

monochromatic 228-nm light, at the long-wavelength edge of the absorption spectrum. As expected, the fine structure associated with the gas phase Rydberg absorptions in *cis*-**4c** is washed out in the solution phase spectrum, leaving behind a weak, featureless absorption that tails out to >230 nm. Similar features are observed in the spectra of *trans*-**4c** and the cis- and trans-isomers of **4b** and **4d** in hexane solution under similar conditions (22).

Photolyses of *cis*- and *trans*-**4b**–**4d** were carried out using the light from 16 W Zn (214 nm) and Cd (228 nm) resonance lamps, on argon-saturated solutions containing 0.06 M substrate and 0.001 M of *n*-octane as an internal GC standard. The solutions were analyzed by capillary gas chromatography between ca. 0.2 and 2–5% conversion of substrate (except in the case of *trans*-**4b** with 214 nm light, which was analyzed between 3.5 and 9% conversion). The photolyses produced mixtures of *E,E*- and *E,Z*-**5b**–**5d** as the only detectable products under the analytical conditions employed in this work (eqs. [2] and [3]), except in the case of *trans*-**4d**, which also afforded small amounts of *Z,Z*-**5d**. Relative product yields were determined from the intercepts of plots

of relative product concentrations (e.g., [*E,E*]/[*E,Z*]-**5** in the case of the cis-isomers, and the inverse for the trans-isomers) vs. % conversion of starting material, which are shown in Figs. 2–4 for the 214 and 228 nm photolyses of *cis*- and *trans*-**4b**–**4d**. Plotting the data in this way magnifies the effects of secondary photolysis on the primary isomeric diene yields (as well as the errors associated with the measurement of relatively small GC peak areas); the plots for all six of the compounds studied in this work generally had nonzero slopes, indicative of significant secondary photolysis effects throughout the course of the experiments in each case. Thus, the intercepts represent the best estimates of the true primary isomeric diene yields in the photolyses. Table 1 summarizes the results of these experiments, where the isomeric diene ratios are expressed as the relative yields of disrotatory:conrotatory isomers as defined above. It should be noted that while error bars were not specifically calcu-

lated for each of the data points shown in the plots of Figs. 2–4, they will naturally be largest at low conversions and decrease in size with increasing conversion. This is of particular concern for the results of photolysis of *trans*-**4b** at 214 nm, which was carried out with a more dilute sample (and to higher conversion of starting material) than the other experiments. Thus, the *E,Z/E,E*-ratio reported for this experiment in Table 1 should be considered a lower limit, with the true value of *E,Z*-**5b**/*E,E*-**5b** being a maximum of about 4.0 (as previously reported (22)). Also included in the table are the analogous product ratios obtained with 193 nm excitation, from previous work (22). The 214 nm product ratios obtained in the present work are in satisfactory agreement with those reported previously (22).

Table 1 also contains the photostationary state (pss) compositions for direct irradiation of **5b**–**5d** with 228 nm light,

which were determined under the same conditions as those employed above for photolysis of the cyclobutenes. These ratios were determined by exhaustive photolysis of samples of *E,E*- and *E,Z*-**5**, which led to the formation of complex mixtures of *cis*- and *trans*-**4** and other isomeric products, but common mixtures of *E,E*-, *E,Z*-, and *Z,Z*-**5**. Comparison of the diene photostationary state ratios to the isomeric diene ratios from photolysis of the cyclobutenes verifies that the latter more or less accurately represent the true primary product ratios from photolysis of *cis*- and *trans*-**4b** and **4c**. The situation is less clear for *cis*- and *trans*-**4d**, in particular that of the cis-isomer, where the relative yields of *E,E*-, *E,Z*-, and *Z,Z*-**5d** are very similar to the diene pss ratio at 228 nm. The extinction coefficient at 228 nm is significantly lower for this compound than for the others studied in this work

Table 1. Isomeric diene ratios from direct irradiation of bicyclic cyclobutenes *cis-* and *trans-***4b-d** as deoxygenated solutions in hexane at 25°C, expressed as the ratios of disrotatory:conrotatory isomers.

Wavelength (nm)	cis-**4b** (*EE/EZ*)	trans-**4b** (*EZ/EE*)	cis-**4c** (*EE/EZ*)	trans-**4c** (*EZ/EE*)	cis-**4d** (*EE/EZ*)	trans-**4d** (*EZ/EE+ZZ*) [*EE:EZ:ZZ*]
193[a]	2.5 ± 0.4	9.1 ± 1.2	3.4 ± 0.4	5.6 ± 0.7	9.1 ± 0.9	3.6 ± 0.4
214	1.8 ± 0.6	2.7 ± 1.4[b]	3.0 ± 0.5	4.6 ± 0.3	6.9 ± 1.0	1.8 ± 0.4 [1.0:3.7:1.0]
228	2.47 ± 0.07	1.64 ± 0.11	2.5 ± 0.8	2.8 ± 0.4	0.54 ± 0.12	1.4 ± 0.2 [1.0:4.5:2.3]
pss[c]	5.0:4.1:1.0		2.3:2.0:1.0		2.1:4.1:1.0	

Note: The ratios reported correspond to *E,E/E,Z-***5** ratios from the *cis-*isomers and *E,Z/E,E-***5** ratios from the *trans-*isomers. The *Z,Z-*isomers were not detected at conversions less than ~2% in any of the photolyses except that of *trans-***4d**, which contained small amounts of all three diene isomers at *t* = 0. The DIS:CON ratios for the latter compound are thus expressed as *E,Z/(E,E + Z,Z)*. The values listed for the 214 and 228 nm photolyses, which were carried out on 0.06 M solutions in all cases but one, are the intercepts from the plots of product ratio vs. %conversion shown in Figs. 2–4. Those for 193 nm photolyses are reproduced from ref. 22, and were determined using 0.02 M solutions of **4**.

[a]From ref. 22.

[c]Photostationary state compositions from photolysis of the corresponding dienes (**5**) at 228 nm, expressed as *EE:EZ:ZZ*.

(22), and thus, we cannot rule out the possibility that secondary photolysis effects distort the true product ratios in this case.

Discussion

The solution phase absorption spectra of monocyclic 1,2-dialkylcyclobutenes such as *cis-* and *trans-***7** consist of a dominant π,π* absorption band with maximum below 195 nm, and a weak tail absorption that extends out to ~230 nm (4, 16). In the corresponding gas phase spectra, the latter is intensified considerably and takes on distinctive fine structure, characteristic of olefinic π,R(3*s*) absorptions (13). The gas and solution phase spectra of *cis-***4c** show similar characteristics to those of **7** in this regard (22). Interestingly, the solution phase UV spectra of *cis-* and *trans-***4b** show enhanced (though weak) absorption in the 220–240 nm range compared with the other compounds in the series, and are virtually identical to one another. The solution phase spectra of *cis-* and *trans-***4c** and **4d**, on the other hand, show the similarities and differences characteristic of monocyclic 1,2-dialkylcyclobutenes of corresponding stereochemistry at C-3 and C-4 (4, 16, 22). It can thus be concluded that the relative energies of the (spectroscopic) valence and Rydberg excited states are unaffected by the structural constraints imposed by the ancillary cycloalkyl ring in these compounds.

Direct irradiation of *cis-***7** with 228 nm light in hydrocarbon solution or in the gas phase at 1 atm (1 atm = 101.325 kPa) results in stereospecific conrotatory ring opening, affording the isomeric diene *E,Z-***10** in ca. 40% overall yield, along with *Z*-2-butene (*Z-***11**) and 2-butyne (**12**) in ca. 60% yield (eq. [4]) (4). Direct irradiation of the trans-isomer under the same conditions, on the other hand, yielded a mixture of all three diene isomers (25% total), *E-***11**, and **12** (ca. 75%), with the yield of *E,Z-***10** relative to those of the *E,E-* and *Z,Z-*isomers increasing continuously over the 0.15–0.4% conversion range. However, control experiments showed the relative isomeric diene yields to be distorted by secondary photolysis effects, and demonstrated that the yields of *E,Z-***10** observed under these conditions are consistent with the *actual* formation of a ca. 1:1 mixture of *E,E-* and *Z,Z-***10**. We thus concluded that ring opening of *trans-***7** at 228 nm very likely exhibits similar conrotatory selectivity to that of the

cis-isomer, producing a nearly equal mixture of the *E,E-* and *Z,Z-*dienes.

The product distributions obtained upon irradiation at this wavelength, where the π,R(3*s*) states of the cyclobutenes are selectively populated, are much different than those obtained with shorter wavelength (193–214 nm) excitation, where both conrotatory and disrotatory diene isomers are formed in similar amounts. Since both excited states are populated in the 193–214 nm wavelength range, it was concluded that the π,π* state must be responsible for ring opening to yield the disrotatory diene isomer(s), and that reaction competes effectively with internal conversion to the lower energy Rydberg state. At short excitation wavelengths, the conrotatory isomers may arise because the π,π* process occurs adiabatically, as we previously concluded (22), or because the π,R(3*s*) excited state is also populated (by direct excitation and (or) by internal conversion from the π,π* state), or both.

[4]
The present work shows that in contrast, the mixtures of diene isomers formed upon ring opening of the fused

bicyclic cyclobutenes *cis*- and *trans*-**4b** and **4c** at 228 nm are only modestly different from those obtained with shorter wavelength excitation, where in each case there is a very distinct preference for the formation of the disrotatory diene isomers. In all cases but *cis*-**4b**, there appears to be a consistent wavelength dependence in the product ratios, with the yield of conrotatory product(s) increasing modestly as the excitation wavelength increases. As we found previously in our studies of the photochemistry of **7** at this wavelength (and as the data of Figs. 2–4 clearly show), secondary photolysis effects are generally very difficult to control, and thus, the product ratios reported cannot be considered to be quantitatively accurate. Nevertheless, the trends are clear; the corresponding disrotatory diene isomers are the major products of irradiation of both isomers of **4b** and **4c** at 228 nm, just as they are at shorter irradiation wavelengths.

Assuming that the Rydberg state is indeed *exclusively* excited in these compounds upon absorption of a 228 nm photon, the fact that similar distributions of diene isomers are observed for **4b** and **4c** as with shorter excitation wavelengths (where the π,π^* state is also directly populated) suggests either that ring opening within the Rydberg state exhibits similar characteristics to π,π^* state ring opening in these compounds or that (conrotatory) Rydberg state ring opening is less efficient than in monocyclic derivatives, allowing internal conversion to the π,π^* state (at a non-Franck–Condon geometry), from which ring opening occurs with predominant disrotatory stereochemistry, to compete more effectively.

One interpretation of the results for **4b** and **4c** is that Rydberg state ring opening, in addition to proceeding with preferred conrotatory stereochemistry, also involves twisting about the "central" C=C bond as ring opening proceeds; accordingly, incorporating the cyclobutenyl C=C bond in a second ancillary ring would be expected to result in a structurally induced barrier to Rydberg state ring opening. Scheme 1 shows a hypothetical reaction coordinate diagram for dis- and conrotatory ring opening on the π,π^* and $\pi,R(3s)$ excited state surfaces, which incorporates these ideas and illustrates their possible ramifications on the stereochemical characteristics of the reaction. Disrotatory (π,π^* state) ring opening is assumed to proceed, at least initially, with little deviation of the 4-carbon system from planarity, since short wavelength (≤214 nm) irradiation of **4a**–**4d** proceeds with high efficiency, with no real variation in quantum yield throughout the series (22); the π,π^* surface falls in energy along this reaction coordinate, as predicted both by simple orbital symmetry considerations (8) and recent ab initio calculations (9, 10). If the $\pi,R(3s)$ surface rises in energy along the disrotatory reaction coordinate, the result will be a thermally activated crossing of the two surfaces at some intermediate geometry (A). The conrotatory reaction coordinate is represented as projecting perpendicularly to the disrotatory one, as it involves both conrotatory twisting about C1—C4 and C2—C3 and torsion about the central C1—C2 bond, leading eventually to *s-trans*-diene. In monocyclic cyclobutenes, the $\pi,R(3s)$ surface is proposed to fall in energy along this reaction coordinate, while the π,π^* surface increases in energy owing to orbital symmetry effects, thus resulting in preferred conrotatory ring opening upon selective population of the Rydberg state. In **4b**–**4d** on the other hand,

motions along the conrotatory (+ central bond torsion) reaction coordinate in the $\pi,R(3s)$ state encounter the structurally induced barrier, possibly allowing the excited molecule to traverse the (presumably somewhat smaller) barrier to the π,π^* surface along the disrotatory reaction coordinate, from which ring opening proceeds with the characteristics of that excited state. It might further be expected that the structurally induced barrier to Rydberg state conrotatory ring opening should decrease as the size and flexibility of the ancillary ring increases, and thus, allow reaction via this pathway to be more competitive with internal conversion to the π,π^* state, where ring opening proceeds with preferred disrotatory stereochemistry. Unfortunately, the data for *cis*- and *trans*-**4d** are not sufficiently reliable to address this possibility in a conclusive way; certainly, there is no evidence for it in the wavelength dependence associated with the ring openings of *cis*- and *trans*-**4b** and **4c**.

It is relevant to point out the analogy between cyclobutene Rydberg state ring opening and the ring opening of cyclobutene radical cations (CB$^{\cdot+}$), to the extent that the latter species constitutes a reasonable model for the "semiionized" olefinic $\pi,R(3s)$ Rydberg state (14, 15). The reaction has been extensively studied in recent years (33–42), and is known to proceed with the preferred conrotatory stereochemistry (36) that theory predicts (39, 43–47). Calculations indicate that the reaction proceeds via two competing conrotatory pathways: a nonsynchronous concerted pathway leading to *s-cis*-1,3-butadiene (*s-cis*-BD$^{\cdot+}$) radical cation, and one involving rotation about the ionized double bond leading to *s-trans*-BD$^{\cdot+}$ via a transition state exhibiting structural characteristics of the cyclopropylcarbinyl radical cation (43, 45–47). Interestingly, photolysis of CB$^{\cdot+}$ in a low-temperature matrix has been reported to yield *s-trans*-BD$^{\cdot+}$ exclusively (39).

This explanation is obviously highly speculative, and undoubtedly not the only one possible. Nevertheless, it contains a number of features that might be tested experimentally. For example, the idea that ring opening on the $\pi,R(3s)$ potential energy surface can be impeded by the introduction of a structurally induced barrier might be tested through studies of the temperature dependence of the reaction stereochemistry in these and monocyclic cyclobutenes as a function of excitation wavelength. Ultrafast time-resolved studies, along the lines of those recently reported for other aliphatic alkenes (25, 26), would also offer potentially invaluable information on the mechanism. Finally, it still remains to be established to what extent the $\pi,R(3s)$ state contributes to the ring opening of alkylcyclobutenes at shorter excitation wavelengths (185–214 nm), where the π,π^* excited singlet state is also populated. Further work in this area is clearly necessary.

Summary and conclusions

Alkylcyclobutenes have two low-lying excited singlet states of similar energy, the π,π^* (valence) and $\pi,R(3s)$ (Rydberg) state, and both lead to electrocyclic ring opening to the isomeric 1,3-dienes. The Rydberg state is markedly lower in energy than the π,π^* state in 1,2-dialkylcyclobutenes, a characteristic that allows the photochemistry associated with this excited state to be studied under conditions of selective excitation.

Scheme 1.
In such compounds, excitation at the short wavelengths necessary for population of the π,π* state results in non-stereospecific ring opening, and the yields of formally allowed (disrotatory) diene isomers relative to the formally forbidden (conrotatory) ones vary with excitation wavelength and the stereochemistry and other structural characteristics of the substrate. On the other hand, selective excitation at the long-wavelength edge of the absorption band, where the π,R(3s) Rydberg state absorptions appear in the gas phase spectrum, results in reaction characteristics that vary much more dramatically with substrate structure; monocyclic derivatives open with clean conrotatory stereospecificity, while bicyclic derivatives, in which the cyclobutenyl C=C bond is shared with a second ancillary ring, appear to exhibit predominant disrotatory stereoselectivities, similar to what is observed upon shorter wavelength (π,π*) excitation. These results are interpreted as suggesting that the Rydberg state process involves both conrotatory motions about the cyclobutenyl C1—C4 and C2—C3 bonds *and* twisting about the C=C bond as the reaction is initiated on the excited-state surface. Impeding the latter motions through appropriate structural constraints has the effect of directing the molecule over a barrier and onto the π,π* state surface, in which ring opening with predominant disrotatory stereochemistry ensues. The wavelength dependent stereoselectivities that have been observed with most of the compounds that have now been studied suggest that internal conversion from the π,π* state to the lower-lying Rydberg state is slow relative to ring opening, or at best competitive with it.

The true degree of disrotatory stereoselectivity that is associated with the π,π* state reaction unfortunately remains poorly defined, though it is clear that in some cases at least, it is very high. At least two viable mechanisms remain which could explain the non-stereospecificity observed upon excitation of alkylcyclobutenes in the region of the π,π* absorption: adiabatic ring opening within the π,π* state, and the competing involvement of the Rydberg state, populated either by direct absorption or (incomplete) internal conver-

sion from the π,π* state. Further study of the reaction will be necessary to conclusively distinguish between these possibilities.

Experimental

The cyclobutenes studied in this work were prepared and purified as previously reported (22), while photoproducts were identified by GC coinjection with authentic samples or after isolation from semipreparative scale photolyses of the corresponding cyclobutene derivative. The cyclobutenes were purified to >99% purity by semipreparative gas chromatography (20% TCEP on 80/100 Chromosorb PNAW, $0.25'' \times 6''$, stainless steel, Chromatographic Specialties, Inc.), followed where necessary by passage through a 1:5 (silver nitrate:silica gel) microcolumn using pentane as the eluant. Only the sample of *trans*-**4d** remained contaminated with isomeric dienes after this treatment, but the amounts were small (ca. 1% in total by GC), and were accounted for in the analyses of the 214 and 228 nm photolyses of this compound. Hexanes (BDH Omnisolv) and *n*-octane (Aldrich) were used as received from the suppliers. UV absorption spectra were recorded using a Cary 50 UV–vis spectrophotometer in 1 cm Suprasil cells. Analytical gas chromatographic separations were carried out using a Hewlett-Packard 5890 gas chromatograph equipped with a flame ionization detector and a 0.22 mm × 15 m DB-1 fused silica microbore capillary column (Chromatographic Specialties, Inc.). FID response factors were determined for all compounds by construction of standard working curves from mixtures of stock solutions of the pure compounds.

Samples for photolysis contained the cyclobutene (ca. 0.06 M) and *n*-octane (0.001 M) in hexane solution. Aliquots (ca. 0.3 mL) were placed in 5 mm quartz tubes containing a micro stirring bar, sealed with rubber septa, and deoxygenated with a stream of dry argon. Photolyses were carried out using 16 W Philips 93106E zinc or 16 W Philips 93107E cadmium resonance lamps for irradiation at 214 or 228 nm, respectively, with constant agitation of the solutions with a magnetic stirrer. Aliquots were removed from the cells by microlitre syringe at suitable photolysis intervals and analysed by GC. Product formation was monitored as a function of photolysis time in all cases.

The conformational behaviour of methylenecyclohexanes revisited

Heidi M. Muchall, Petrina R.N. Kamya, and Jean Lessard

Abstract: Conformational analyses on 2-substituted (methoxy, vinyloxy, and acetoxy) methylenecyclohexanes have been performed computationally with HF, B3LYP, PBE0, and MP2 and the 6-31G(d) basis set. The global minimum for the methoxy substituent is an axial conformer. For the vinyloxy substituent, except with PBE0, an axial conformer is determined as the global minimum. The acetoxy substituent prefers the equatorial orientation. This sequence is in keeping with the operation of an "unsaturation effect" in addition to an anomeric effect. For a full conformational analysis, torsional potentials for the substituents have been generated, which show further low-energy minima, which affect the equilibrium composition. In general, axial conformers dominate the equilibria. To reproduce the experimentally observed predominance of equatorial conformers for vinyloxy and acetoxy substituents, PBE0 has to be employed. CSGT isotropic shielding tensors at the B3LYP/6-311+G(d,p)//B3LYP/6-31G(d) level have been employed for comparison with experimentally observed ^{13}C chemical shifts.

Key words: conformational analysis, methylenecyclohexanes, anomeric effect, unsaturation effect.

Résumé : On a réalisé une analyse conformationnelle de méthylènecyclohexanes portant des substituants (méthoxy, vinyloxy et acétoxy) en position 2 en faisant appel à des méthodes de calcul théorique à l'aide de HF, B3LYP, PBE0, MP2 et l'ensembles de bases 6-31G(d). Le minimum global pour le substituant méthoxy est le conformère axial. Pour le substituant vinyloxy, tous les ensembles à l'exception du PBE0 attribuent le minimum global au conformère axial alors que le substituant acétoxy occupe préférentiellement l'orientation équatoriale. Cette séquence est en accord avec l'opération de l'effet d'insaturation en plus de l'effet anomère. Pour une analyse conformationnelle complète, on a généré les potentiels de torsion des substituants qui mettent en évidence d'autres minima de basse énergie qui affectent la composition de l'équilibre. En général, les conformères axiaux prédominent à l'équilibre. Afin de reproduire la prédominance des conformères équatoriaux observée expérimentalement pour les substituants vinyloxy et acétoxy, il faut utiliser l'ensemble PBE0. Pour pouvoir faire une comparaison avec les valeurs observées expérimentalement pour les déplacements chimiques ^{13}C, on a utilisé des tenseurs de blindage isotrope CSGT au niveau B3LYP/6-311+G(d,p)//B3LYP/6-31G(d).

Mots clés : analyse conformationnelle, méthylènecyclohexanes, effet anomère, effet d'insaturation.

[Traduit par la Rédaction]

Introduction

2-Substituted oxanes exhibit an anomeric effect, i.e., a substituent –OR prefers the axial (*gauche*) rather than the equatorial (*anti*) position. The commonly accepted reason for this is a stabilizing n_O-σ^*_{C-O} interaction in the axial orientation, but electrostatic (dipole–dipole) interactions destabilizing the equatorial orientation are most probably involved as well (1, 2). If the heteroatom of the oxane ring is replaced by a double bond, such as in 3-methoxycyclohexene and 2-methoxy-methylenecyclohexane (**1**), the methoxy group also prefers the pseudoaxial or axial orientation, and this preference has been explained by a stabilizing π-σ^*_{C-O} interaction, electrostatic (dipole–quadrupole) interactions being considered less impor-

tant than the orbital interaction (3). The axial preference is larger for an acetoxy group than for a methoxy group in 2-substituted oxanes (4–6) and in 3-substituted cyclohexenes (5, 6), as expected from larger n_O-σ^*_{C-O} or π-σ^*_{C-O} interactions of the axial conformer in the case of the acetoxy group, which is more electron withdrawing and thus a better electron acceptor (i.e., σ^*_{C-O} is lower in energy) than the methoxy group (1, 7).

In 1979, dynamic ^{13}C NMR studies of 2-substituted methylenecyclohexanes, such as and including **1**–**3**, revealed an unexpected conformational behaviour (5). From low-temperature experiments (3% solutions in $CHFCl_2$–CD_2Cl_2 (4:1 v/v) at –110°C), the chemical shifts of C^4 of the axial (ax) and equatorial (eq) species were determined. The assignment of the observed chemical shifts as belonging to the

axial or equatorial conformer was based on the γ-effect, in that a ^{13}C nucleus in the γ-position from the substituent is shielded by 4.5 ppm in the axial relative to the equatorial conformer. From the individual chemical shifts and the observed averaged C^4 chemical shift δ_m at 0°C, the proportion x of the equatorial conformer was calculated as $\delta_m = x\delta_{eq} + (1 - x)\delta_{ax}$. With a δ_m of 22.6 ppm for **1**, 23.3 ppm for **2**, and 23.9 ppm for **3**, it was concluded that the equatorial orientation is preferred for unsaturated substituents: **1** 41% eq, **2** 61% eq, and **3** 80% eq. At –110°C, by integration of the signals, the proportion of the equatorial conformer was determined to be 33% for **1** and more than 95% for **3** (6). This unexpected substituent behaviour was termed the "unsaturation effect" (5, 6).
As was pointed out in a contribution by Forsyth and Sebag (8), even though chemists are nowadays able to accurately calculate ^{13}C chemical shifts of organic compounds by ab initio methods, this is still not being done routinely. Accurate geometries are needed for calculated chemical shifts to be useful, and for a conformationally flexible system this means establishing the important conformers and evaluating their contribution to an equilibrium. To our knowledge, there are no computational studies as to the conformational behaviour of 2-substituted methylenecyclohexanes. Here we present a computational study of the conformational behaviour of the three representative species, **1**, **2**, and **3**, that illustrates the importance of a full conformational analysis that takes the rotamers of the substituent into account.

Computational details

The Gaussian 98 program package was employed in all calculations (9). All minimum-energy conformations were initially optimized at HF/6-31G(d) and followed with optimizations at B3LYP/6-31G(d) (10, 11). Optimizations were also performed with the "parameter free" density functional PBE0 (12, 13) (Gaussian keyword PBE1PBE) and for **3** also with MP2(full). If not stated otherwise, representative geometry parameters in the text are given for B3LYP/6-31G(d), but the optimized species from all levels are virtually superposable. Frequency calculations were performed at HF/6-31G(d) and PBE0/6-31G(d) for zero-point vibrational (ZPV) energies, which are reported unscaled. Torsional analyses (relaxed scans) were performed at HF/6-31G(d) and in one case (for ϕ_1 in **3**, see below) also at B3LYP/6-31G(d) (partial optimizations in the gas phase) and PBE0/6-31G(d) (partial optimizations in dichloromethane). In our torsional analyses, minima with a relative energy of more than

Fig. 1. Low-energy conformers (**a** axial, **e** equatorial) of 2-methoxymethylenecyclohexane (**1**). Relative energies (B3LYP/6-31G(d)) are given in kcal/mol.
2.5 kcal/mol were not studied further, as the corresponding conformers do not contribute significantly to an overall equilibrium.

For an evaluation of a solvent influence, HF/6-31G(d)//HF/6-31G(d) and PBE0/6-31G(d)//PBE0/6-31G(d) calculations were carried out with dichloromethane (dielectric constant 9.08) and the self-consistent isodensity polarized continuum model (SCI-PCM) at an isodensity value of 0.0004. Isotropic shielding tensors were calculated with B3LYP/6–311+G(d,p)//B3LYP/6-31G(d) using the CSGT (continuous set of gauge transformations) method (14). To obtain chemical shifts, the values were corrected for the calculated absolute shielding for carbon in tetramethylsilane (181.98; the experimental value is 188.1 (15)) at this level of theory.

Results

Conformations

2-Methoxymethylenecyclohexane (1)

To locate all relevant minima on the potential energy surface, the H-C-O-C torsion angle φ was twisted through 360° in both the axial and equatorial forms in 30° steps. Four low-energy conformations of **1** were identified. These were fully optimized at HF/6-31G(d), B3LYP/6-31G(d), and PBE0/6-31G(d). The B3LYP-optimized conformers are given in Fig. 1; all energies are listed in Table 1.

As expected from a possible, stabilizing π-σ*$_{C-O}$ interaction and in analogy to the anomeric effect, the global minimum is an axial species, **1-a1** (φ –50°). A low-energy barrier (φ 0°) connects rotamers **1-a1** and **1-a2** (φ +43°). Similarly, a low-energy barrier connects **1-e1** (φ –34°) and **1-e2** (φ +37°). All model chemistries agree on one order of stability for the four conformers, and the relative energies indicate that all four are populated significantly at 0°C. We have calculated the equilibrium populations at 273 K at all levels of theory employed (Table 1). As can be seen from Table 1, the relative energies and the resulting equilibrium composition are virtually identical for the gas-phase calculations. The population of the axial conformers is about 80%; that of the equatorial conformers is about 20%. As expected, the use of free energies does not show a significant change from these values (data not given). In contrast, the inclusion of solvent

[b]Total energy from an optimization that includes solvent at this level is –385.934210 hartrees.

Fig. 2. Low-energy conformers (**a** axial, **e** equatorial) of 2-vinyloxymethylenecyclohexane (**2**). Relative energies (B3LYP/6-31G(d)) are given in kcal/mol.

2-a1 ±0   **2-a2** +0.07   **2-a3** +0.42   **2-a4** +1.03

2-e1 +0.18   **2-e2** +0.28   **2-e3** +0.38   **2-e4** +0.65
does not change the order of stability of the four conformers but decreases all energy differences. This causes an almost doubling of the equatorial population in the equilibrium, and the sum of the axial conformers decreases to about 70%. In the dynamic ^{13}C NMR experiments of **1**, the equilibrium composition at 0°C was estimated to be 59% axial in CHFCl$_2$-CD$_2$Cl$_2$ (5, 6) and 65% axial in the less polar CF$_2$Br$_2$-CD$_2$Cl$_2$ (6), which is in reasonable agreement with our calculated data.

2-Vinyloxymethylenecyclohexane (2)

Energy profiles were obtained for two torsion angles, H-C-O-C (ϕ_1) and C-O-C-C (ϕ_2). From the information in these profiles, eight low-energy conformations were identi-

fied and optimized at HF/6-31G(d), B3LYP/6-31G(d), and PBE0/6-31G(d). The B3LYP-optimized conformers are given in Fig. 2, energies are listed in Table 2.

Torsion angles ϕ_1 in all eight conformers are in the range of either +50° or –50°, which are similar values to those found in **1**. While the conformer with ϕ_1 near 180° is a high-energy minimum, **2** does not exhibit a significant preference (0° over 180°) for ϕ_2. All model chemistries, except for the uncorrected (ZPV energies not included) PBE0/6-31G(d) and the solvent calculations at this level, agree on an axial species, **2-a1**, as the global minimum. This is in contrast to the interpretation from the NMR experiments and in line with a stabilizing π*-σ$_{C-O}$ interaction. For the two PBE0 calculations, **2-e1** is the global minimum. The other seven con-

Note: Relative energies (kcal/mol) in parentheses, equilibrium populations at 273 K.

formers lie within 1.5 kcal/mol for all methods, but the model chemistries do not agree on the order of stability. In particular, gas-phase HF/6-31G(d) calculations give a relatively large energy difference between **2-a1** and **2-e3**, the most stable of the equatorial conformers (Table 2), which results in an equilibrium concentration of the axial conformers of over 60%. Relative energies from B3LYP and from HF solvent calculations lead to a sum of the axial conformers that is significantly smaller at about 50%. The sum of axial conformers only drops below 50% with PBE0, in accord with experiment. All model chemistries reproduce the experimentally observed increase in equatorial conformer concentration from **1** and therefore the "unsaturation effect". At the PBE0 level this trend is reproduced particularly well, with the experimental equilibrium composition of **2** at 0°C of 39% axial and 61% equatorial (5).

2-Acetoxymethylenecyclohexane (3)

Energy profiles were obtained for two torsion angles, H-C-O-C (ϕ_1) and C-O-C-O (ϕ_2). From the information in these profiles, four low-energy conformations were identified and optimized with HF/6-31G(d) and MP2(full)/6-31G(d). With B3LYP/6-31G(d) and PBE0/6-31G(d), only three conformers, **3-e1**, **3-a1**, and **3-a2** were identified. The

Fig. 3. Low-energy conformers (**a** axial, **e** equatorial) of 2-acetoxymethylenecyclohexane (**3**). Relative energies (B3LYP/6-31G(d)) are given in kcal/mol. Compound **3-e2** was obtained with PBE0/6-31G(d) (geometry optimization in CH$_2$Cl$_2$, SCI-PCM).
B3LYP-optimized conformers are given in Fig. 3, energies are listed in Table 3.

For **3**, the model chemistries agree on neither the order nor the number of the conformers. In agreement with the interpretation of the NMR studies (5, 6), in the gas phase, HF, B3LYP, and PBE0 give an equatorial species, **3-e1**, as the global minimum. With MP2, **3-a1** is most stable. Yet while there are four low-energy conformers at the HF and MP2 levels, there are only three with B3LYP and PBE0. With HF and MP2, in addition to the three conformers shown in Fig. 3, the fourth conformer **3-e2** has a torsion angle ϕ_1 of –18° (with ϕ_2 at 0°), in analogy to **1-e1**, **2-e1**, and **2-e3**; for B3LYP and PBE0 (gas-phase geometries), the potential energy surface does not possess a stationary point in that region. This is evident from the torsional analysis of ϕ_1 using B3LYP/6-31G(d) and starting with the optimized **3-e1** (diamonds in Fig. 4). The equilibrium composition varies widely with the model chemistry chosen. At MP2 and furthest from experiment, the composition shows about 80% axial conformers. With HF and B3LYP this value drops to just above 50%. The experimentally observed equatorial predominance (5, 6) is only reproduced with PBE0. But even there, the equatorial conformer (gas-phase geometry) is only present with just over 50%, instead of the estimated 80% at 0°C from experimental data.

In an attempt to identify the source of this discrepancy between experiment and theory for **3**, which is absent for both **1** and **2**, we obtained the torsional profile for **3** with an equatorial substituent using PBE0/6-31G(d), performing geometry optimizations in the solvent, and covering the region of ϕ_1 in which the "missing" conformer **3-e2** should be. The result is given in Fig. 4 (squares). Obviously, while the relative energy is increasing monotonously from the optimized **3-e1** at 30° for the gas phase species (diamonds), there is an additional minimum with the inclusion of solvent. A subsequent

geometry optimization at PBE0/6-31G(d) in this region confirmed that the fourth conformer **3-e2** is recovered when the solvent is considered in the geometry optimization (Table 3). This conformer is given in Fig. 3 in brackets.

Unfortunately, we were not able to optimize **3-a1** or **3-a2** with the inclusion of solvent (at any level), which would be needed to determine the equilibrium composition.[2] At this point, an assumption seems feasible. Checks on selected species (**1-a1**, **1-e1**, and **3-e1**) at the HF level have revealed that it matters little in which manner the solvent is considered in the calculations. Regardless of whether the geometry is optimized in the solvent cavity (the total energies for the three species are given in Tables 1 and 3) or whether the energy is just evaluated for the gas-phase geometry in the solvent cavity, the magnitude of the stabilization due to the solvent is about the same. If we thus assume that the solvent-optimized conformers **3-a1** and **3-a2** are also both 0.45 kcal/mol less stable than **3-e1** (Table 3), then the equilibrium exhibits 67% equatorial species, which finally is in much better agreement with the experimental value.

Chemical shifts

γ-Effect

We tested our choice level of theory for NMR calculations by checking for the reproducibility of the γ-effect (16) in methylcyclohexane (**4**). With B3LYP/6-31G(d), **4-a** is 2.15 kcal/mol higher in energy than **4-e**, in good agreement with the experimental A value of 1.74 kcal/mol (17). The calculated relative energy leads to an equilibrium composition at 273 K of 98% **4-e** : 2% **4-a** or 97% **4-e** : 3% **4-a** at room temperature. The experimental and calculated chemical shifts for the ring carbon atoms of **4-e**, **4-a**, and cyclohexane are given in Fig. 5.

As expected, with our choice of model chemistry, the experimental chemical shifts are reproduced well. For cyclohexane, there is a difference between calculated and experimental chemical shifts $\Delta\delta$ of 5.5 ppm. A difference of this magnitude is also found for **4**. The averaged calculated values for the equilibria at 0 and 25°C are C^1 40.5 ($\Delta\delta$ = 7.5 ppm), C^2 39.9 ($\Delta\delta$ = 4.3 ppm), C^3 32.0 ($\Delta\delta$ = 5.4 ppm), and C^4 31.6 ppm ($\Delta\delta$ = 5.0 ppm).

As can be seen from Fig. 5, the γ-effect is reproduced qualitatively: C^3 in **4-a** is shielded by 6.0 ppm in comparison to **4-e**.

Methylenecyclohexanes

The calculated chemical shifts for C^4 of all conformers of **1**–**3** are given in Table 4. The chemical shift for **3-e2** was estimated as follows: chemical shifts were determined for **3-e1** and **3-e2** at B3LYP/6-311+G(d,p)//HF/6-31G(d); for **3-e1**, the difference from the B3LYP/6-311+G(d,p)//B3LYP/6-31G(d) value was determined and the chemical shift for **3-e2** was adjusted accordingly. Within an axial or equatorial series, the C^4 chemical shift varies little with the choice of substituent at C^2, while it is systematically larger for those

rotamers with a negative ϕ (or ϕ_1) than for rotamers with a positive value for this torsion angle. This also holds for our estimated value of **3-e2**. We have estimated the γ-effect from separately weighted averages of axial and equatorial conformers. In this way, the γ-effect ($\delta_{eq} - \delta_{ax}$) for **1** is about 5 ppm, for **2** about 4.5 ppm, and for **3** about 4 ppm, the actual values depending little on the specific energy differences used in the weighting. This reduction in the γ-effect results from a progressively more shielded averaged chemical shift for the equatorial species (for example, 30.80 ppm in **1**, 30.35 ppm in **2**, 29.73 ppm in **3**, from the PBE0 solvent

^{a}Difference to **1**.
^{b}Difference to **2**.

calculations) and an essentially stable chemical shift for the axial species (25.86 ppm in **1**, 25.76 ppm in **2**, 25.92 ppm in **3**).

The weighted averages δ_m for an equilibrium consisting of all axial and equatorial species at 0°C and the experimental chemical shifts at this temperature are listed in Table 5. The difference $\Delta\delta_m$ that results from a change of substituent at C^2 is also given. Replacing methoxy at C^2 with vinyloxy leads to an experimentally observed $\Delta\delta_m$ of 0.7 ppm, and this is reproduced well with all model chemistries. If we also consider that the difference between experimental and calculated values δ for cyclohexane and methylcyclohexane is about 5.5 ppm, the chemical shifts determined using relative energies from PBE0 solvent calculations give the best agree-

ment with experiment for both **1** and **2**. The experimentally observed deshielding of 0.6 ppm as vinyloxy is exchanged for acetoxy, on the other hand, is not reproduced by any of the model chemistries listed (Table 5). Instead, the calculated δ_m for **2** and **3** is about the same (or even slightly smaller) at all levels, as can be seen from the $\Delta\delta_m$ in Table 5. This of course is in accord with the calculated equilibrium composition for **2** and **3**, which is also similar and lies, for the equatorial conformers, at about 60% at the DFT level.

As discussed above, for **3**, the observed equatorial preference is only reproduced with PBE0, and the equilibrium is estimated to contain about 67% equatorial conformers when the solvent-optimized conformers are considered. The estimated δ_m of 28.68 ppm reflects the fact that even this equilibrium is not rich enough in equatorial conformers.

Conclusions

The unexpected increase in equatorial conformer upon introducing unsaturation in the 2-substituent of methylenecyclohexanes that was observed experimentally (**1** 41% eq, **2** 61% eq, and **3** 80% eq in $CHFCl_2$-CD_2Cl_2 at 0°C) and was termed the "unsaturation effect" was qualitatively reproduced. For **1** (methoxy substituent), the equilibrium was well described already at the HF level when relative energies from single-point solvent calculations were employed. For **2** (vinyloxy substituent), to reproduce the observed equatorial preference, PBE0 had to be employed, and again single-point solvent calculations gave the best results. Agreement with the large equatorial preference in the equilibrium of **3** (acetoxy substituent) was only obtained with relative energies from solvent-optimized conformers at the PBE0 level, even though the equilibrium composition could only be estimated because of the lack of data for the axial conformers. ^{13}C chemical shifts for C^4 (in γ-position to the substituent), which were calculated as weighted averages from all equilibrium species, confirmed the progressively increased deshielding in the methoxy–vinyloxy–acetoxy series that was observed experimentally.

In this study, we have shown that the experimentally observed "unsaturation effect" can indeed be reproduced computationally. We will now focus on studies towards an explanation of this effect.

Cyclization of 5-hexenyl radicals from nitroxyl radical additions to 4-pentenylketenes and from the acyloin reaction

Huda Henry-Riyad and Thomas T. Tidwell

Abstract: Photochemical Wolff rearrangements were used to form 5-substituted-4-pentenylketenes **1a**–**1d** (RCH=CHCH$_2$X-CH$_2$CH=C=O: **1a** R = H, X = CH$_2$; **1b** R = Ph, X = CH$_2$; **1c** R = c-Pr, X = CH$_2$; **1d** R = H, X = O), which were observed by IR at 2121, 2120, 2119, and 2126 cm^{-1}, respectively, as relatively long-lived species at room temperature in hydrocarbon solvents. These reacted with the nitroxyl radical tetramethylpiperidinyloxyl (TEMPO, TO·) forming carboxy-substituted 5-hexenyl radicals **3**, which were trapped by a second nitroxyl radical forming 1,2 diaddition products **4a**–**4d**. On thermolysis, **4a**–**4d** underwent reversible reformation of the radicals **3**, which underwent cyclization forming cyclopentanecarboxylic acid derivatives **6** or **11** as the major products. However, in the case of **1b**, the cyclopentane derivative was formed reversibly and on prolonged reaction times the only product isolated was PhCH=CH-(CH$_2$)$_4$CO$_2$H (**8b**) from hydrogen transfer to C$_\beta$ and cleavage of the TEMPO group. Cyclopropylcarbinyl radical ring opening in the cyclized radical **5c** from **1c** led to the 2-(4-N-tetramethylpiperidinyloxybut-1-enyl)cyclopentane derivative **11** as the major product. In a test for 5-hexenyl radical ring closure in the radical anion intermediate of the acyloin condensation, the ester CH$_2$=CH(CH$_2$)$_3$CO$_2$Et (**12a**) gave the acyloin **13a** (76%) as the only observed product, while PhCH=CH(CH$_2$)$_3$CO$_2$CH$_3$ (**12b**) with Na in toluene gave 21% of the acyloin product **13b** and 42% of 2-benzylcyclopentanol (**15**) from cyclization of the intermediate radical anion.

Key words: ketenes, free radical cyclization, TEMPO, acyloin condensation.

Résumé : On a utilisé les réarrangements photochimiques de Wolff pour produire des 4-penténylcétènes substitués en position **5 1a**–**1d** (RCH=CHCH$_2$XCH$_2$CH=C=O : **1a** R = H, X = CH$_2$; **1b** R = Ph, X = CH$_2$; **1c** R = c-Pr, X = CH$_2$; **1d** R = H, X = O). On a observé ces produits en IR à 2121, 2120, 2119 et 2126 cm^{-1} respectivement, comme étant relativement des espèces à longue durée de vie dans des solvants hydrocarbonés à la température ambiante. Ces produits substitués réagissent avec le radical nitroxyle tétraméthylpipéridinoxyle (TEMPO, TO·) en formant des radicaux 5-hexényles portant un substituant carboxy **3**, qui sont piégés par un deuxième radical nitroxyle pour donner des produits de diaddition 1,2 **4a**–**4d.** Par thermolyse, ces produits **4a**–**4d** redonnent de façon réversible le radical **3** qui par cyclisation forme les dérivés de l'acide cyclopentanecarboxylique **6** ou **11** comme produits majoritaires. Toutefois dans le cas du composé **1b** le dérivé cyclopentane se forme de façon réversible, et en prolongeant les temps de réaction le seul produit obtenu est le : PhCH=CH(CH$_2$)$_4$CO$_2$H (**8b**) résultant du transfert d'hydrogène sur C$_\beta$ et du clivage du groupe TEMPO. L'ouverture du cycle du radical cyclopropylcarbinyle dans le radical cyclisé **5c** obtenu à partir du composé **1c** conduit au dérivé 2-(4-tétraméthylpipéridinyloxybut-1-ényl)cyclopentane **11** comme produit majoritaire. Dans un essai de cyclisation du radical 5-hexényle de l'anion radicalaire intermédiaire de la condensation acyloïne, l'ester CH$_2$=CH(CH$_2$)$_3$CO$_2$Et (**12a**) donne l'acyloïne **13a** (76%) comme seul produit observé, tandis que le composé PhCH=CH(CH$_2$)$_3$CO$_2$CH$_3$ (**12b**) avec le Na dans le toluène donne 21% de l' acyloïne **13b** et 42% de 2-benzylcyclopentanol (**15**) à partir de la cyclisation de l'anion radicalaire intermédiaire.

Mots clés : cétènes, radical libre, cyclisation, TEMPO, condensation acyloïne.

[Traduit par la Rédaction]

Introduction

As part of our studies of the reactions of ketenes with aminoxyl radicals (1), we have examined the reactivity of 4-pentenylketenes **1a**, **1b** with TEMPO (TO·) (1a). For **1a** (R = H, X = CH$_2$) and **1b** (R = Ph, X = CH$_2$) generated from diazo ketones **2** (eq. [1]) these reactions were found to proceed by radical attack at the carbonyl carbon forming enolic radicals **3** which then were trapped by a second TEMPO giving the 1,2-diaddition products **4** (eqs. [2] and [3]). Cyclization of the intermediate 5-hexenyl radicals **3** forming cyclopentylmethyl radicals **5** and capture as cyclopentanes **6** was

H. Henry-Riyad and T.T. Tidwell.[1] Department of Chemistry, University of Toronto, Toronto, ON M5S 3H6, Canada.

[1]Corresponding author (e-mail: ttidwell@chem.utoronto.ca).

evidently too slow to compete with capture of **3** by TEMPO at these concentrations. However, on thermolysis of **4a** in *tert*-butyl alcohol according to the protocol of Studer (2*a*) cyclization forming **6a** was successful, indicating that upon equilibration of **3a** and **4a** cyclization to **5a** was followed by capture by TEMPO forming **6a** as a *cis–trans* mixture (eq. [3]).

[1] (scheme)

2a,b

2a (R = H, X = CH₂)   **1a** (R = H, X = CH₂)
2b (R = Ph, X = CH₂)   **1b** (R = Ph, X = CH₂)

[2] **1a,b** $\xrightarrow{TO\bullet}$ (scheme) **3a,b**

[3] **3a,b** $\xrightarrow{TO\bullet}$ (scheme) **4a,b**   TO•

[4] **4a** $\underset{110°C}{\overset{t\text{-BuOH},\ -TO\bullet}{\rightleftharpoons}}$ **3a** ⇌ **5a** $\xrightarrow{TO\bullet}$ **6a** (70%)
However, when the 1,2-bis(TEMPO) addition product **4b** from 5-phenyl-4-pentenylketene (**1b**) was heated as in eq. [4], the corresponding cyclization product **6b** was not observed, and other reactions appeared to be taking place (1*a*). Further investigations have now been carried out to elucidate the behavior of **4b**, and the reactivity of 5-cyclopropyl-4-pentenylketene **1c** as well as the 2-oxa-4-pentenylketene analogue **1d** have been studied, and the results are reported here.

The reactions of ketenes with TEMPO and the reactions of these substrates are of interest because of current studies of the reactions of TEMPO with free radicals and the chemistry of the adducts (2, 3), especially in living free radical polymerization (4). Free radical rearrangements are also of wide applicability in organic synthesis (5, 6). In other recent studies designed to examine the formation and reaction of TEMPO esters, we have reported the thermal reactivity of Ph₃CCO₂T (**1j**) and the addition of TEMPO to the unreactive ketenes CH₂=C=O and PhMe₂SiCH=C=O (**1k**).

Results

The thermolysis reaction of the bis(TEMPO) adduct **4a** (1*a*) from **1a** in *tert*-butyl alcohol by the protocol of Studer (2*a*) was reexamined, and, in addition to the cyclized TEMPO ester **6a** (70%), tetramethylpiperidine (TH, 8%) was also identified (eq. [5]). The presence of carboxylic acid absorption in the IR was also detected in the crude product, but the acid was not isolated.

Heating the bis(TEMPO) adduct **4b** (1*a*) of 5-phenyl-4-pentenylketene **1b** at 130°C for 18 h in *tert*-butyl alcohol

[5] (scheme) **4a** $\xrightarrow[130\ °C]{t\text{-BuOH},\ -TO\bullet}$ **6a** (70%) + TH (8%)
gave no detectable cyclized product, but instead the carboxylic acid **8b** was isolated (54%), along with TH (14%). Experiments at shorter time intervals revealed that **8b** was not the first formed product, but the cyclized ester **6b** (mixture of stereoisomers) was present early in the reaction, as well as the cyclized acid **7b** (eq. [6]).

[6] (scheme) **4b** $\xrightarrow[130°C]{t\text{-BuOH}}$ **8b** + **6b** + **7b** + TH

Time (h)	**8b**	**6b**	**7b**	TH
2.5	–	32%	10%	
5	–	22%	12%	
10	34%	–	7%	
18	54%	–	–	14%
As a test of the source of carboxylic acids and TH in these reactions, the thermolysis of the ester **9** of phenylacetic acid and 2,2,6,6-tetramethylpiperidinol under Studer's conditions was examined. This reaction was found to give phenylacetic acid (35%) and TH (30%) after 7 days at 130°C (eq. [7]).

The cyclopropyl group serves as a useful clock for investi-

[7] PhCH₂CO₂T $\xrightarrow[130°C]{t\text{-BuOH}}$ PhCH₂CO₂H + TH
    9   35%   30%
gating the presence of free radicals and so the new 5-cyclopropyl-substituted 4-pentenyl diazomethyl ketone **2c** was prepared as shown (eqs. [8] and [9]). Photolysis of **2c** gave the ketene **1c** as identified by the IR absorption at 2119 cm⁻¹ (eq. [10]), and addition of TEMPO to the pre-formed ketene gave the 1,2-diaddition product **4c** in 71% yield (eq. [11]). Thermolysis of **4c** resulted in the formation of the cyclized ester **11** (mixture of stereoisomers) in 65% yield, along with TH in 15% yield (eq. [11]).

[8] Ph₃P(scheme)CO₂H + (scheme)$\xrightarrow{}$ **10**

[9] **10** $\xrightarrow[(2)\ CH_2N_2]{(1)\ (COCl)_2}$ **2c**

[10] **2c** $\xrightarrow{h\nu}$ **1c**, IR 2119 cm⁻¹
The incorporation of hetero atoms in 5-hexenyl radical chains is a method to enhance their propensity for cyclization to cyclopentylmethyl radicals (4), and so the ketene precursor 2-oxa-4-pentenyl diazomethyl ketone **2d** was prepared from 3-oxa-5-hexenoic acid (**7h**) by conversion to the acyl chloride and reaction with diazomethane. Photolysis of **2d** in pentane at room temperature gave the ketene **1d**, as identified by its ketenyl IR absorption at 2126 cm^{-1} (eq. [12]), and upon reaction with TEMPO this gave the product **4d** of 1,2-addition of two molecules of TEMPO to the ketenyl moiety (eq. [13]). Thermolysis of **4d** in *tert*-butanol at 130°C gave the cyclized product **6d** (*cis–trans* mixture) in 67% yield (eq. [13]).
The acyloin condensation (8) is a reaction proposed to involve radical anion intermediates formed by electron transfer from sodium to esters, but we are unaware of examples of radical cyclization under these conditions. As a further test of the cyclization of 5-hexenyl radicals, the acyloin condensations of ethyl 5-hexenoate (**12a**) (**7j**) and methyl 6-phenyl-5-hexenoate (**12b**) (**7b, 7i**) were investigated. Reaction of **12a** with sodium in toluene gave the acyloin **13a** in 76% yield as the only isolated product (eq. [14]), and for further characterization this was oxidized to the diketone **14a** (45%). Similar reaction of **12b** gave the cyclized product *cis*-2-benzylcyclopentane **15** (42%) along with the acyloin **13b** (21%) (eq. [15]). Oxidation of **13b** formed the corresponding α-diketone **14b** (52%). The stereochemistry of **15** was assigned by comparison with the reported spectra (**7j**).
Discussion

As already reported (**1a**), the formation of the cyclized product **6a** (eq. [4]) is in accord with the mechanism in which the initially formed product **4a** of 1,2-diaddition of TEMPO reforms the radical **3a** upon heating, and this undergoes cyclization leading to **6a**, which is stable to ring opening. The formation of carboxylic acids and TH as observed from **4a–4c** and from PhCH$_2$CO$_2$T (**9**) under these conditions is however unusual, and this reaction is under further investigation.

2-Oxa-4-pentenylketene (**1d**) reacted similarly to **1a** with TEMPO (eq. [12]), and formed the cyclized product **6d** upon thermolysis in an analogous manner (eq. [13]). However, no improved efficiency of cyclization was observed compared to the carbon analogue **1a**.

The initial 1,2-diaddition of TEMPO to 5-phenyl-pentenylketene **1b** (eqs. [2] and [3]) was also reported previously (**1a**). Upon heating this is also found to form the cyclized product **6b** at short reaction time, analogously to the previously observed formation of **6a** (eq. [4]). However, **6b** is reactive under these conditions, and is gradually converted to **8b**, evidently by reforming the intermediate radical **5b** which reopens to **3b**, which abstracts hydrogen and also undergoes loss of the TEMPO group as found for PhCH$_2$CO$_2$T (eqs. [16] and [17]).
The formation of **11** (eq. [11]) in the reaction of TEMPO with 5-cyclopropyl-4-pentenylketene (**1c**) indicates that radical **3c** is formed by TEMPO dissociation from **4c**, and then undergoes cyclization to **5c** (eq. [18]). Ring opening of **5c** gives **16** which is captured by TEMPO forming **11** (eq. [19]).

[19] **5c**   ⟶
The possibility of 5-hexenyl radical cyclization during the acyloin condensation does not appear to have been previously examined, but acyloin reactions of linoleic and oleic esters gave the normal acyloin products, and did not undergo the potential radical cyclization which would form 10-membered rings (8a). In this study, ethyl 5-hexenoate (**12a**), which could form a five-membered ring by radical cyclization, gave the normal acyloin product (eq. [14]). However, when the double bond is activated with a phenyl substituent cyclization does occur with the formation of **15** from **12b** (eq. [15]). Evidently the intermediate radical anion **17** from single electron transfer to **12b** (eq. [20]) undergoes competitive acyloin condensation, forming **13b**, and cyclization leading to **15** via **18** (eq. [21]). Related radical cyclizations of radical anions from ketones are known (5b). The scope and mechanism of this interesting reaction are under further study.

[20]

[21]
In summary, radical cyclization of the 5-hexenyl radicals **3** resulting from TEMPO addition to 4-pentenylketenes **1** does not compete with the addition of a second TEMPO forming the 1,2-diaddition products **4**. However, upon heating under the conditions of Studer (2a) the products **4** reversibly reform **3**, which cyclize to cyclopentylmethyl radicals **5** which are captured by TEMPO for **1a** and **1d**, and for **1b** are in equilibrium with **3b**, which eventually reacts by hydrogen abstraction. The cyclopropyl derivative **5c** undergoes cyclopropylcarbinyl radical ring opening forming **11** after addition of TEMPO. Degradation of TEMPO esters to carboxylic acids and TH is noted, and is under further study. 5-Hexenyl radical cyclization is observed in the radical ion intermediate of the acyloin condensation when the double bond is activated with a phenyl substituent.

Experimental

Chromatography was carried out on silica gel. Solutions for reactions of TEMPO products were degassed and kept under argon or nitrogen. Gas chromatography (GC) was carried out with a flame ionization detector and a Simplicity 5 column (poly-5% diphenylsiloxane – 95% dimethylsiloxane). The disubstituted alkenes studied were *cis–trans* isomers that were not separated but the NMR spectra were assigned from the mixtures.

Lithium hexamethyldisilazide was prepared, by addition to a solution of 1,1,1,3,3,3-hexamethyldisilazane (1.04 equiv) in

1 to 2 mL THF cooled in an ice water bath, of a hexane solution of *n*-butyllithium (1.0 equiv) via syringe, followed by stirring the mixture at room temperature for 15–30 min prior to use (7d).

(4-Carboxybutyl)triphenylphosphonium bromide (**7c**, **7f**, **7g**) was prepared by addition of Ph_3P (5.06 g, 19.3 mmol) to a solution of 5-bromovaleric acid (3 g, 16.6 mmol) in acetonitrile (7.5 mL). The resulting mixture was stirred at 80°C under reflux for 24 h, concentrated, and the residue was washed with benzene, hexane, and ether and dried giving (4-carboxybutyl)triphenylphosphonium bromide (6.75 g, 92%) as a white solid. ^1H NMR (400 MHz, $CDCl_3$) δ: 1.70 (m, 2, $CH_2CH_2CH_2$), 1.91 (m, 2, $CHCH_2CH_2$), 2.90 (t, 2, CH_2CO, $J = 6.9$ Hz), 3.68 (m, 1, Ph_3PCH), 7.73–7.78 (m, 15, Ar).

Thermolysis of 4a

The bis-TEMPO adduct **4a** (20 mg, 0.047 mmol) in degassed *t*-BuOH (4 mL) was heated 24 h in a sealed ampoule at 130°C, and GC analysis indicated the presence of 2,2,6,6-tetramethylpiperidine (8 ± 1%). The solvent was removed under reduced pressure and chromatography ($CHCl_3$–MeOH, 9:1) gave a product containing carboxylic acid based on the IR spectrum ($CDCl_3$) 3516, 1745, 1700 cm^{-1}. Base extraction and rechromatography ($CHCl_3$–MeOH, 9:1) afforded **6a** (14 mg, 70%, *E*:*Z* (45:55)) (1a). The carboxylic acid product was not recovered from the aqueous layer.

Thermolysis of *N*-2,2,6,6-tetramethylpiperidinyl 2-(*N*-2,2,6,6-tetramethyl piperidinyloxy)-7-phenyl-5-heptenoate (4b)

The bis-TEMPO adduct **4b** (20 mg, 0.040 mmol) under nitrogen in degassed *t*-BuOH (4 mL) was sealed in an ampoule and heated 18 h at 132–135°C in a refluxing xylene bath. Gas chromatography showed the presence of TH (14 ± 2%). The solvent was removed under reduced pressure and chromatography ($CHCl_3$–MeOH, 9:1) gave the known (7b) uncyclized acid **8b** $PhCH=CH(CH_2)_4CO_2H$ (54%). IR ($CDCl_3$) (cm^{-1}): 1703, 3518. ^1H NMR (400 MHz, $CDCl_3$) δ: 1.54–1.83 (m, 4, $CH_2CH_2CO_2H$), 2.23 (m, 2, $CHCH_2CH_2$), 2.42 (m, 2, $CH_2CH_2CO_2H$), 5.66 (m, 1, *cis*-PhCH=C*H*), 6.18 (m, 1, *trans*-PhCH=C*H*), 6.37 (m, 1, PhC*H*=CH),), 7.33 (m, 5, Ar). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 24.5, 28.9, 32.8, 33.9, 126.2, 127.1, 128.7, 128.8, 128.9, 129.6, 130.4, 130.5, 131.3, 132.5, 137.6, 137.9, 178.8 (*CO*). EI-MS (*m/z*): 204 (M$^+$), 186, 157, 144, 130, 117, 104, 91, 77, 65. HR-EI-MS (*m/z*) calcd. for $C_{13}H_{16}O_2$: 204.1143; found: 204.1150.

Heating of **4b** with shorter reaction times gave *N*-2,2,6,6-tetramethyl-piperidinyl 2-(phenyl-*N*-2,2,6,6-tetramethylpiperidinyloxymethyl)cyclo pentanecarboxylate (**6b**) which was purified by chromatography (CH_2Cl_2). ^1H NMR (500 MHz, $CDCl_3$) δ: 2.66–2.85 (m, 44), 3.25–3.28 (m, 1, C*H*CO_2T), 4.76 (d, 1, C*H*PhOT, $J = 6.8$ Hz), 7.22–7.39 (m, 5, Ar). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 17.2, 17.3, 20.5, 20.6, 23.4, 24.8, 28.7, 29.1, 29.7, 31.1, 31.9, 32.1, 32.2, 32.3, 32.7, 39.0, 39.1, 39.2, 39.25, 45.7, 47.3, 59.8, 60.1, 87.7 *C*H(OT)Ph, 126.0, 127.2, 127.5, 128.5, 128.9, 131.0, 137.7, 140.9, 175.5 (*CO*). EI-MS (*m/z*): 499 (M$^+$), 326, 187, 157, 140, 117, 91, 69, 55. HR-EI-MS (*m/z*) calcd. for $C_{31}H_{51}N_2O_3$: 499.3907; found: 499.3900. IR ($CDCl_3$) (cm^{-1}): 1751. Further chromatography (EtOAc–MeOH, 3:7) gave 2-(phenyl-*N*-2,2,6,6-tetramethylpiperidinyloxymethyl)cyclo-

pentane carboxylic acid (**7b**). IR (CDCl$_3$) (cm^{-1}): 3513, 1701. ^{1}H NMR (500 MHz, CDCl$_3$) δ: 1.06–2.38 (m, 24), 2.78–2.80 (m, 1, C*H*CHOTPh), 2.98–3.02 (m, 1, C*H*CO$_2$H), 4.80 (d, 1, C*H*OTPh) *J* = 8.9 Hz), 7.23–7.36 (m, 5, Ar). ^{13}C NMR (125 MHz, CDCl$_3$) δ: 17.4, 21.5, 22.9, 25.4, 30.3, 31.8, 38.5, 40.0, 46.9, 47.7, 53.7, 61.2, 88.8 (*C*HOTPh), 126.5, 127.6, 128.0, 128.6, 129.1, 130.1, 130.4, 139.7, 178.9 (*C*O). EI-MS (*m/z*): 360 (M$^+$), 293, 239, 203, 185, 157, 142, 125, 91, 69, 55. HR-EI-MS (*m/z*) calcd. for C$_{22}$H$_{34}$NO$_3$: 360.2534; found: 360.2539.

6-Cyclopropyl-5-hexenoic acid (10)

4-Carboxy-*n*-butyltriphenylphosphonium bromide (5 g, 11.3 mmol) in THF (15 mL) was treated with lithium hexamethyldisilazide (23.7 mmol) in THF (4 mL) at 25°C with stirring. After 15 min, cyclopropanecarboxaldehyde (0.79 g, 11.3 mmol) in THF (5 mL) was added at 25°C, rapidly decolorizing the red-orange mixture. After 15 min, water (25 mL) and ether (25 mL) were added. The organic phase was rinsed with 20 mL of water. The combined aqueous solution was washed with EtOAc (25 mL), acidified with 10% HCl, and extracted with EtOAc. The united EtOAc extracts were rinsed with H$_2$O, dried with Na$_2$SO$_4$, and concentrated. Kugelrohr distillation gave **10** (1.12 g, 64%) (*E/Z* isomers, 1:1). ^{1}H NMR (400 MHz, CDCl$_3$) δ: 0.30–0.32 (m, 2), 0.63–0.67 (m, 2, *E*-isomer), 0.69–0.73 (m, 2, *Z*-isomer), 1.49–1.58 (m, 1), 1.65–2.41 (m, 6), 4.80 (dd, 1, *J* = 10.6, 9.8 Hz, *c*-PrHC*H*=CH, Z-isomer), 5.02 (dd, 1, *J* = 15.2, 8.2 Hz, *c*-PrHC*H*=CH, E-isomer), 5.30 (dt, 1, *J* = 10.6, 6.2 Hz, CH=C*H*CH$_2$, Z-isomer), 5.45 (dt, 1, *J* = 15.2, 6.4 Hz, CH=C*H*CH$_2$, E-isomer).

6-Cyclopropyl-5-hexenoyl chloride

Oxalyl chloride (1.05 g, 8 mmol) was added dropwise to a stirred solution of 6-cyclopropyl-5-hexenoic acid (**10**, 0.76 g, 4 mmol) in CCl$_4$ (10 mL) and stirred for 2 h. The solvent was removed in vaccuo to give 6-cyclopropyl-5-hexenoyl chloride as a dark brown oil (1.20 g, 92%) containing *E/Z* (50:50), used subsequently without further purification. ^{1}H NMR (400 MHz, CDCl$_3$) δ: 0.31–0.32 (m, 2), 0.71–0.73 (m, 2, *E*-isomer), 0.74–0.79 (m, 2, *Z*-isomer), 1.52–1.6 (m, 1), 1.90 (distorted q, 2, CH$_2$C*H*$_2$CH$_2$), 2.32 (dt, 2, CHC*H*$_2$CH$_2$), 3.05 (t, 2, *J* = 7.2 Hz, C*H*$_2$COCl), 4.84 (dd, 1, *J* = 10.5, 8.4 Hz, *c*-PrHC*H*, Z-isomer), 5.20 (dd, 1, *J* = 13.2, 7.7 Hz, *c*-PrHC*H*=CH, E-isomer), 5.35 (dt, 1, *J* = 9.4, 7.5 Hz, CH=C*H*CH$_2$, Z-isomer), 5.50 (dt, 1, *J* = 11.4, 8.5 Hz, CH=C*H*CH$_2$, E-isomer).

1-Diazo-7-cyclopropyl-6-hepten-2-one (2c)

6-Cyclopropyl-5-hexenoyl chloride (1.20 g, 7.0 mmol) in ether (5 mL) was added dropwise over a period of 0.5 h to a stirring cooled solution of 0.018 mol of diazomethane (3 equiv) in ether (60 mL) which the solution was stirred at 0°C for 2 h. Excess diazomethane was removed by evacuating with a water aspirator through an empty Erlenmeyer flask and quenched in acetic acid, and the solution was concentrated. Chromatography (EtOAc–hexane, 3:7) gave **2c** (0.92 g, 5.2 mmol, 74%) as a yellow oil containing *E/Z* isomers (47:53). IR (pentane) (cm^{-1}): 2102, 1662. ^{1}H NMR (400 MHz, CDCl$_3$) δ: 0.29–0.32 (m, 2), 0.63–0.66 (m, 2, *E*-isomer), 0.69–0.74 (m, 2, *Z*-isomer), 1.32–1.34 (m, 1, *E*-iso-

mer), 1.48–1.53 (m, 1, *Z*-isomer), 1.73 (distorted q, 2, CH$_2$C*H*$_2$CH$_2$), 2.00–2.35 (m, 4), 4.80 (dd, 1, *J* = 10.6, 6.3 Hz, *c*-PrHC*H*=CH, Z-isomer), 4.98 (dd, 1, *J* = 12.3, 8.2 Hz, *c*-PrHC*H*=CH, E-isomer), 5.23 (s, 1, COCH*N*$_2$), 5.28 (dt, 1, *J* = 10.4, 9.9 Hz, CH=C*H*CH$_2$, Z-isomer), 5.45 (dt, 1, *J* = 13.2, 6.4 Hz, CH=C*H*CH$_2$, E-isomer). ^{13}C NMR (100 MHz, CDCl$_3$) δ: 7.2, 10.0, 13.9, 25.4, 27.2, 32.2, 126.9 (CH=*C*HCH$_2$), 135.3 (*c*-Pr*C*H=CH), 195.2 (*C*O). EI-MS *m/z*: 179 (MH$^+$), 149 (M$^+$ – N$_2$), 135, 121, 107, 91. HR-EI-MS *m/z* calcd. for C$_{10}$H$_{14}$N$_2$O: 179.1186; found: 179.1184.

5-Cyclopropyl-4-pentenylketene (1c) and reaction with TEMPO

1-Diazo-7-cyclopropyl-6-hepten-2-one (**2c**, 100 mg, 0.56 mmol) in pentane (75 mL) was photolyzed for 30 min with 250-nm light to give ketene **1c** (IR: 2119 cm^{-1}). TEMPO (183 mg, 1.18 mmol, 2.1 equiv) was added to the preformed ketene and the solution was left stirring at room temperature for 24 h. Chromatography with CH$_2$Cl$_2$ gave **4c** (191 mg, 0.40 mmol, 71%) *E/Z* isomers (50:50). IR (CDCl$_3$) (cm^{-1}): 1770. ^{1}H NMR (400 MHz, CDCl$_3$) δ: 0.28–0.31 (m, 2), 0.62–0.65 (m, 2, *E*-isomer), 0.68–0.72 (m, 2, *Z*-isomer), 1.08–2.20 (m, 43), 4.48 (distorted t, 1, CH$_2$C*H*OT), 4.75 (dd, 1, *J* = 10.2, 7.3 Hz, *c*-PrHC*H*=CH, Z-isomer), 4.92 (dd, 1, *J* = 9.4, 8.2 Hz, C*H*=CHCH$_2$, E-isomer), 5.31 (dt, 1, *c*-PrHCH=C*H*, Z-isomer), 5.45 (dt, 1, *J* = 13.9, 7.5 Hz, CH=C*H*CH$_2$, E-isomer). ^{13}C NMR (100 MHz, CDCl$_3$) δ: 6.6, 7.1, 9.8, 13.7, 17.2, 17.4, 20.8, 20.9, 24.7, 24.9, 27.8, 32.1, 32.3, 32.4, 32.6, 34.8, 39.5, 40.7, 60.2, 60.5, 83.7 (*C*HOT), 127.6, 127.7 (CH=*C*HCH$_2$), 134.6, 134.7 (*c*-Pr*C*H=CH), 171.9 (*C*O$_2$T). EI-MS *m/z*: 464 (MH$^+$), 448 (M$^+$ – CH$_3$), 322 (M$^+$ – T), 306, 278, 182, 156 (TO$^+$), 140 (T$^+$), 126, 83, 55. HR-EI-MS *m/z* calcd. for MH$^+$ C$_{28}$H$_{51}$N$_2$O$_3$: 463.3869; found: 463.3899.

Thermolysis of 4c

The bis-TEMPO adduct **4c** (50 mg, 0.108 mmol) in degassed *t*-BuOH (5 mL) was heated in a sealed ampoule at 130°C for 18 h. GC analysis indicated the presence of 2,2,6,6-tetramethylpiperidine (15 ± 2%). Concentration and chromatography (CHCl$_3$–MeOH, 9:1) afforded the cyclized ester **11** containing carboxylic acid. IR (CDCl$_3$) (cm^{-1}): 3512, 1740, 1702. Base extraction and chromatography (CH$_2$Cl$_2$–MeOH, 9:1) afforded ester **11** (32 mg, 0.069 mmol, 65%). IR (CDCl$_3$) (cm^{-1}): 1750. ^{1}H NMR (500 MHz, CDCl$_3$) δ: 1.08–2.00 (m, 42), 2.22 (dt, 2, C*H*$_2$CH$_2$OT), 2.51 (m, 1, *Z*-C*H*CO$_2$T), 2.79 (m, 1, *E*-CHCO$_2$T), 3.71–3.74 (t, 2, *J*= 6.71 Hz, C*H*$_2$OT), 5.43–5.48 (m, 1, *c*-PnC*H*=CH), 5.52–5.56 (m, 1, *c*-PnCH=C*H*). ^{13}C NMR (125 MHz, CDCl$_3$) δ: 17.4, 20.4, 20.8, 24.2, 24.8, 25.0. 30.0, 30.4, 31.5, 32.2, 33.3, 33.6, 39.8, 47.7, 50.4, 56.0, 76.5 (*C*H$_2$OT), 127.5 (CH=*C*HCH$_2$), 133.9 (*c*-Pn*C*H=CH), 180.6 (*C*O$_2$T). EI-MS *m/z*: 463 (MH$^+$), 447 (M$^+$ – CH$_3$), 306 (M$^+$ – OT), 278 (M$^+$ – CO$_2$T), 182, 156 (TO), 140 (T), 126, 109, 93, 83, 69, 55. HR-EI-MS *m/z* calcd. for C$_{28}$H$_{50}$N$_2$O$_3$: 462.3816; found: 462.3821.

Allyloxyacetyl chloride

Oxalyl chloride (3.99 g, 2.7 mL, 0.03 mol) was added dropwise to a stirred solution of allyloxyacetic acid (7 h, 1.75 g, 0.015 mol) in dichloromethane (20 mL) followed by

stirring at room temperature for 2 h. The solvent was removed in vacuo to give allyloxyacetyl chloride as a yellow oil (1.85 g, 0.0137 mol, 92%) used subsequently without further purification. ^{1}H NMR (400 MHz, CDCl$_3$) δ: 4.12–4.23 (m, 4, CH_2OCH_2COCl), 5.26–5.39 (m, 2, CH_2=CH), 5.85–5.98 (m, 1, CH$_2$=CH).

1-Diazo-4-oxa-6-hexen-2-one (2d)

Allyloxyacetyl chloride (1 g, 7 mmol) was dissolved in ether (5 mL) and added dropwise over 0.5 h to a stirring cooled solution of of diazomethane (0.018 mol, 2.5 equiv) in ether (100 mL), and the solution was stirred cold for 2 h. The excess diazomethane was removed by evacuating with a water aspirator pump and quenched into acetic acid. Concentration and chromatography (EtOAc–hexane, 1:3) gave 2d (0.71 g, 5.1 mmol, 69%) as a yellow oil. IR (pentane) (cm^{-1}): 2107, 1661. ^{1}H NMR (400 MHz, CDCl$_3$) δ: 3.95–4.04 (m, 4, CH_2OCH_2COCHN$_2$). 5.17–5.37 (m, 2, CH_2=CH), 5.73 (s, 1, COCHN$_2$), 5.79–5.92 (m, 1, CH$_2$=CH). ^{13}C NMR (100 MHz, CDCl$_3$) δ: 53.3, 57.3, 67.2, 76.4, 118.1 (CH=CHCH$_2$), 133.7 (CH=CH), 193.9 (CO). EI-MS m/z: 141 (MH$^+$), 84, 69, 55. HR-EI-MS m/z calcd. for MH$^+$ C$_6$H$_9$N$_2$O$_2$: 141.0657; found: 141.0664.

(2-Oxa-4-pentenyl)ketene (1d) and reaction with TEMPO

1-Diazo-3-allyloxy-2-propanone (2d, 250 mg, 1.8 mmol) in 75 mL of pentane was photolyzed for 60 min with 250-nm light to give the corresponding ketene (IR: 2126 cm^{-1}). TEMPO (585 mg, 3.8 mmol, 2.1 equiv) was added to the preformed ketene and the solution was stirred at room temperature for 6 h. Concentration and chromatography (CH$_2$Cl$_2$) gave the bis-adduct 4d (562 mg, 1.32 mmol, 73%). IR (CDCl$_3$) (cm^{-1}): 1773. ^{1}H NMR (400 MHz, CDCl$_3$) δ: 1.22–1.82 (m, 36), 3.94–4.05 (m, 2, OCH_2CHOT), 4.11 (d, 2, J = 4.2 Hz, CH$_2$=CHCH_2O), 4.68 (t, 1, J = 5.5 Hz, CHOT), 5.15–5.31 (m, 2, CH_2=CH), 5.83–5.94 (m, 1, CH$_2$=CH). ^{13}C NMR (100 MHz, CDCl$_3$) δ: 17.4, 17.5, 20.6, 20.8, 21.0, 21.1, 32.4, 34.0, 34.4, 39.6, 39.7, 40.8, 60.5, 60.7, 70.1, 72.8, 83.6 (CHOT), 117.7 (CH$_2$=CH), 135.0 (CH$_2$=CH), 170.5 (CO$_2$T). EI-MS m/z: 410 (MH$^+$ – CH$_3$), 308, 285 (M$^+$ – T), 268 (M$^+$ – TO), 240 (M$^+$ – CO$_2$T), 156 (TO$^+$), 140 (T), 126, 83, 69, 58. ES-MS m/z 425 (MH$^+$), 447 (MNa$^+$), 463 (MK$^+$).

The bis-TEMPO adduct 4d (100 mg, 0.23 mmol) in degassed t-BuOH (5 mL) was heated for 5 h at 135°C in a refluxing xylene bath. After concentration chromatography (CHCl$_3$–MeOH, 9:1) gave the cyclized product 6d (67 mg, 0.16 mmol, 67%). IR (CDCl$_3$) (cm^{-1}): 1756. ^{1}H NMR (500 MHz, CDCl$_3$) δ: 1.04–1.70 (m, 36), 2.74–2.97 (m, 2), 3.72–4.10 (m, 6, CH_2). ^{13}C NMR (125 MHz, CDCl$_3$) δ: 17.3, 17.5, 20.2, 20.3, 20.4, 20.9, 23.0, 30.0, 32.2, 32.4, 32.5, 33.4, 33.5, 39.3, 39.4, 39.9, 41.5, 43.2, 46.1, 59.9, 60.2, 60.3, 74.9 (CH$_2$OT), 172.9 (CO$_2$T). EI-MS m/z: 341, 311, 270, 216, 156, 142, 126, 83, 69. ES-MS m/z: 447 (MNa$^+$), 463 (MK$^+$).

6-Phenyl-5-hexenoic acid (7b)

4-Carboxybutyltriphenylphosphonium bromide (2.0 g, 4.5 mmol) in dry THF (6 mL), under nitrogen, was treated with lithium hexamethyldisilazide (1.8 mL, 9.48 mmol). Af-

ter 15 min, water and ether were added, the organic phase was rinsed with water (20 mL) and the combined aqueous solution was washed with EtOAc (25 mL), acidified with 10% HCl, and extracted with EtOAc. The united EtOAc extracts were rinsed with H$_2$O, dried with Na$_2$SO$_4$, and concentrated. Kugelrohr distillation gave 6-phenyl-5-hexenoic acid (0.68 g, 80%) containing $trans/cis$ isomers (87:13). ^{1}H NMR (400 MHz, CDCl$_3$) $trans$-isomer δ: 1.70–2.56 (m, 6), 6.15 (m, 1, PhCH=CH), 6.45 (m, 1, PhCH=CH), 7.20 (m, 5, Ar), 10.65 (br s, 1, CO$_2$$H$); cis-isomer δ: 1.70–2.56 (m, 6), 5.60 (m, 1, PhCH=CH), 6.45 (m, 1, PhCH=CH), 7.20 (m, 5, Ar), 10.65 (br s, 1, CO$_2$$H$).

6-Phenyl-5-hexenoyl chloride (7b)

Oxalyl chloride (1.05 g, 8 mmol) was added dropwise to a stirred solution of 6-phenyl-5-hexenoic acid (0.76 g, 4.0 mmol) in CCl$_4$ (10 mL) followed by stirring at room temperature for 2 h. The solvent was removed in vaccuo to give 6-phenyl-5-hexenoyl chloride as a yellow oil (0.81 g, 3.9 mmol, 97%) containing E/Z isomers (85:15), used subsequently without further purification. ^{1}H NMR (400 MHz, CDCl$_3$) δ: 1.89 (distorted q, 2, CH$_2$CH_2CH$_2$), 2.29 (dt, 2, CHCH_2CH$_2$), 2.95 (t, 2, J = 6.8 Hz, CH_2COCl), 6.16 (m, 1, PhCH=CH, Z-isomer), 5.61 (m, 1, PhCH=CH, E-isomer), 6.41 (m, 1, PhCH=CH, E and Z isomers), 7.31–7.36 (m, 5H, Ar).

Methyl 6-phenylhex-5-enoate (12b) (7i)

To a stirred mixture of methanol (0.2 mL, 4.9 mmol) and triethylamine (0.62 mL, 4.9 mmol) in CH$_2$Cl$_2$ (30 mL) at 0°C was added of 6-phenyl-5-hexenoyl chloride (1 g, 4.9 mmol). The reaction mixture was stirred for 20 min then 2 M HCl (10 mL) was added. The organic layer was washed with NaHCO$_3$ and brine, dried, and concentrated. Chromatography (CH$_2$Cl$_2$) yielded 12b, (0.90 g, 4.4 mmol, 90%) as a yellow oil (E/Z isomers, 93:7). ^{1}H NMR (400 MHz, CDCl$_3$) $trans$-12b δ: 1.82–1.88 (q, 2, CH$_2$CH_2CH$_2$), 2.25–2.32 (dt, 2, CHCH_2CH$_2$), 2.37–2.42 (t, 2, J = 4.9 Hz, 2, CH_2CO$_2$CH$_3$), 3.69 (s, 3, E-OCH$_3$), 3.94 (s, 3, Z-OCH$_3$), 6.22 (m, 1, PhCH=CH), 6.39 (m, 1, PhCH=CH), 7.31–7.36 (m, 5, Ar).

Acyloin reaction of 12a

Sodium metal (0.64 g, 28 mmol) and toluene (100 mL) were refluxed for 1 h with vigorous stirring, and ethyl hex-5-enoate (7j) (12a, 0.20 g, 20 mmol) in toluene (10 mL) was added dropwise over 20 min, and stirred a further 2 h. The solution was cooled and MeOH (15 mL) was added, the mixture was poured into water–EtOAc and acidified with 10% HCl, extracted with EtOAc, washed with water and NaHCO$_3$, dried, and concentrated. Chromatography (hexane–EtOAc, 7:3) gave 13a (7-hydroxydodeca-1,11-diene-6-one, 2.08 g, 76%). IR (CDCl$_3$) (cm^{-1}): 1707, 3519. ^{1}H NMR (400 MHz, CDCl$_3$) δ: 1.61–1.82 (m, 6, CH$_2$CH_2CH$_2$ and CHOHCH_2), 2.04–2.18 (m, 4 C=CHCH_2), 2.40 (t, 2, J = 7.4 Hz, CH$_2$CO), 4.96–5.09 (m, 4, CH_2=C), 5.75–5.85 (m, 2 CH$_2$=CH). ^{13}C NMR (100 MHz, CDCl$_3$) δ: 23.0, 23.9, 33.2, 33.5, 33.9, 38.9, 77.6 (CHOH), 115.1, 115.8, 137.7, 138.5, 180.1 (CO). EI-MS m/z: 196 (M$^+$), 182, 169, 167, 149, 125, 107, 99, 97, 81, 69, 55. HR-EI-MS m/z calcd. for C$_6$H$_9$O: 97.0656; found: 97.0653.

Oxidation of 13a

Pyridinium chlorochromate (1.6 g, 7 mmol) and **13a** (1.0 g, 5.1 mmol) in CH_2Cl_2 (20 mL) were heated at reflux for 1.5 h. The mixture was filtered through Celite, washed with ether, and the filtrate was concentrated. Chromatography (hexane–EtOAc, 7:3) gave dodeca-1,11-diene-6,7-dione (**14a**) as a yellow oil (0.44 g, 2.3 mmol, 45%). IR ($CDCl_3$) (cm^{-1}): 1711. ^1H NMR (400 MHz, $CDCl_3$) δ: 1.63–1.78 (m, 4, $CH_2CH_2CH_2$), 2.08–2.19 (m, 4, $CHCH_2$), 2.37 (t, 4, J = 7.2 Hz, CH_2CO), 4.98–5.12 (m, 4, $CH_2=CH$), 5.77–5.83 (m, 2, $CH_2=CH$). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 24,6, 34.5, 52.0, 115.8, 138.7, 200.0 (CO). EI-MS m/z: 195 (MH+), 167, 153, 149, 140, 125, 97, 81, 69, 55. HR-EI-MS m/z calcd. for $C_{12}H_{19}O_2$: 195.1380; found: 195.1385.

Acyloin reaction of 12b

Sodium metal (0.2 g, 8.6 mmol) and toluene (20 mL) were heated to reflux with vigorous stirring for 1 h. To this was added methyl 6-phenylhex-5-enoate (**12b**, 0.88 g, 4.3 mmol) in toluene (10 mL) dropwise over 20 min. Stirring was continued for a further 2 h. The solution was cooled and MeOH (2 mL) was added. The mixture was poured into water–EtOAc and acidified with 10% HCl, extracted with EtOAc, washed with water and $NaHCO_3$, dried, and concentrated. Chromatography (hexane–EtOAc, 7:3) afforded the cyclized product *cis*-**15** (7*j*) as a colourless oil (0.32 g, 1.8 mmol, 42%). IR ($CDCl_3$) (cm^{-1}): 3608. ^1H NMR (400 MHz, $CDCl_3$) δ: 1.25–2.14 (m, 8, 3CH_2, CHCH_2Ph, and OH), 2.52–2.57 (m, 1, CHHAr), 2.74–2.79 (m, 1, CHHAr), 3.90–3.93 (m, 1, CHOH), 7.28–7.37 (m, 4, Ar). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 21.7, 30.1, 34.4, 40.0, 50.1, 78.8 (CHOH), 126.2, 128.5, 128.6, 129.1, 141.3. EI-MS m/z:176 (M+), 158 (M+ – H_2O), 143, 129, 117, 104, 98, 85, 67, 57. HR-EI-MS m/z calcd. for $C_{12}H_{16}O$: 176.1199; found: 176.1201. 1,12-Diphenyl-7-hydroxy-dodeca-1,11-dien-6-one (**13b**) was obtained as a yellow oil (0.31 g, 21%) 78:22 double bonds of *E/Z* isomers. IR ($CDCl_3$) (cm^{-1}): 1705, 3522. ^1H NMR (400 MHz, $CDCl_3$) δ: 1.79–1.84 (m, 6, 2$CH_2CH_2CH_2$ and CHOHCH_2), 2.24–2.28 (m, 2, CH_2CH_2CO), 2.33–2.36 (m, 4, 2CHCH_2CH_2), 5.59–5.63 (m, Z-PhCH=CH), 6.17–6.23 (m, E-PhCH=CH), 6.38–6.44 (m, 2, 2PhCH=CH), 7.21–7.39 (m, 10, Ar). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 24.5, 27.4, 28.7, 32.4, 33.5, 37.5, 50.2, 79.4 (CHOH), 126.2, 127.3, 128.4, 128.6, 128.7, 128.9, 129.6, 130.4, 131.2, 133.9, 137.8, 179.6 (CO). EI-MS m/z:244 (M+ – PhCH=CH), 210, 190, 130, 117, 105, 91, 77. HR-EI-MS m/z calcd. for $C_{16}H_{22}O_2$: 244.1456; found: 244.1454.

Oxidation of 13b

Pyridinium chlorochromate (0.35 g, 1.6 mmol) and **13b** (0.32 g, 1 mmol) in dry CH_2Cl_2 (5 mL) were heated at reflux for 1.5 h. The black mixture was filtered through Celite, washed with ether, and the filtrate was concentrated. Chromatography (hexane–EtOAc, 7:3) gave 1,12-diphenyldodeca-1,11-diene-6,7-dione (**14b**) as a yellow oil (0.18 g, 52%), 81:19 *E/Z* double bonds. IR ($CDCl_3$) (cm^{-1}): 1711. ^1H NMR

(400 MHz, $CDCl_3$) δ: 1.81–1.94 (m, 4, $CH_2CH_2CH_2$), 2.37–2.41 (m, 4, CHCH_2CH_2), 2.43 (t, 4, CH_2CH_2CO), J = 7.6 Hz), 5.61–5.72 (m, Z-PhCH=CH), 6.18–6.28 (m, E-PhCH=CH), 6.40–6.58 (m, 2, PhCH=CH), 7.17–7.45 (m, 10, Ar). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 24.5, 29.9, 32.5, 126.2, 127.4, 128.2, 128.4, 128.7, 129.6, 130.5, 131.2, 197.0 (CO). EI-MS m/z: 243 (M+ – Ph-CH=CH), 215 (M+ – $C_{10}H_{11}$), 202 (M+ – $C_{11}H_{13}$), 190 (M+ – $C_{12}H_{13}$), 174 (M+ – $C_{12}H_{13}O$), 146 (M+ – $C_{13}H_{13}O_2$), 130, 117, 105, 91, 77. HR-EI-MS m/z calcd. for $C_{16}H_{19}O_2$: 243.1177; found: 243.1192.[2]

The photochemistry of *trans*-1,4,4,4-tetraphenyl-but-2-en-1-one: A highly efficient aryl migration (type B) enone photorearrangement

John R. Scheffer and Kodumuru Vishnumurthy

Abstract: Photolysis of *trans*-1,4,4,4-tetraphenylbut-2-en-1-one (**3**) in acetonitrile or benzene leads to *trans–cis* isomerization (**7**) along with rearrangement to *trans*-1-benzoyl-2,2,3-triphenylcyclopropane (**8**). Formation of the latter product represents a new example of the aryl migration (type B) enone photorearrangement reaction first reported by Zimmerman and co-workers for 4,4-diphenylcyclohex-2-en-1-one (**1**). The quantum yield in the case of enone **3** (0.4) is approximately 10 times greater than that for 4,4,-diphenylcyclohex-2-en-1-one, a result that is ascribed to steric acceleration of phenyl migration from the triphenylmethyl group plus greater resonance stabilization of the intermediate biradical.

Key words: photochemistry, mechanism, rearrangement, aryl migration, enone, di-π-methane.

Résumé : La photolyse de la *trans*-1,4,4,4-tétraphénylbut-2-én-1-one (**3**) dans l'acétonitrile ou le benzène conduit à une isomérisation *trans–cis* (**7**) ainsi qu'à un réarrangement en *trans*-1-benzoyl-2,3,3-triphénylcyclopropane (**8**). La formation de ce dernier produit représente un nouvel exemple de réaction de photoréarrangement d'énone avec migration d'aryle (type B) qui avait été observé pour la première fois par Zimmerman et ses collaborateurs pour la 4,4-diphénylcyclohex-2-én-1-one (**1**). Le rendement quantique dans le cas de l'énone **3** (0,4) est approximativement dix fois plus grand que celui observé avec la 4,4-diphénylcyclohex-2-én-1-one; on attribue cette différence à l'accélération stérique associée à la migration du phényle à partir du groupe triphénylméthyle ainsi qu'à la plus grande stabilisation par résonance du biradical intermédiaire.

Mots clés : photochimie, mécanisme, réarrangement, migration d'un groupe aryle, énone, di-π-méthane.

[Traduit par la Rédaction]

Introduction

Many of the principles of organic photochemistry with which we are familiar today rest on early studies of the light-induced behavior of enones and dienones (1). As an example, consider the case of 4,4-diphenylcyclohex-2-en-1-one (**1**) (eq. [1]), whose photochemistry was first reported by Zimmerman and Wilson (2) in 1964 and subsequently investigated in more detail by Zimmerman and Hancock (3) in 1968. In these studies, irradiation of ketone **1** in solution was shown to afford *trans*-5,6-diphenylbicyclo[3.1.0]hexan-2-one (**2**) in rather low quantum efficiency (Φ = 0.043) but excellent chemical yield; trace amounts of *cis*-5,6-diphenyl-bicyclo[3.1.0]hexan-2-one and 3,4-diphenylcyclohex-2-en-1-one were also formed. Formally a di-π-methane process involving the enone double bond and a double bond on one of the phenyl groups, the formation of photoproduct **2** takes place in the triplet state via a 1,2-phenyl shift accompanied

J.R. Scheffer[1] and K. Vishnumurthy. Department of Chemistry, University of British Columbia, 2036 Main Mall, Vancouver, BC V6T 1Z1, Canada.

[1]Corresponding author (e-mail: scheffer@chem.ubc.ca).

by cyclopropane ring closure. Subsequent studies by the Zimmerman group used the aryl migration cyclohexenone photorearrangement reaction to investigate the relative excited-state migratory aptitudes of aryl groups bearing electron-donating and electron-withdrawing substituents (4).

[1]

In seeking variations of the aryl migration enone photorearrangement for the purpose of investigating asymmetric induction in organic photochemical reactions, we chose *trans*-1,4,4,4-tetraphenylbut-2-en-1-one (**3**, eq. [1]) as a potential target molecule. This choice is attractive from several points of view. For one, we anticipated that modification of the benzoyl group to accept ionic chiral auxiliaries (5) would be relatively easy. A second, unrelated motivation was that preparation of analogs of enone **3** in which the

three terminal aryl groups are, for example, phenyl, *p*-methoxyphenyl, and *p*-cyanophenyl, offers the possibility of investigating the relative excited-state migratory aptitude of three aryl groups simultaneously, rather than only two at a time as in the case of cyclic enones. In the present article we outline the synthesis of the parent compound (**3**) and describe its basic photochemical behavior in solution.

Results

The synthesis of enone **3** was accomplished in straightforward fashion through the known intermediates **5** and **6** (6) (eq. [2]). The final step, selenium dioxide oxidation of ketone **6**, proceeded in 94% overall yield to afford the target enone **3** as a colorless crystalline solid, mp 133–136°C. The assignment of *trans* stereochemistry to enone **3** followed from its proton NMR spectrum, which showed the vinyl hydrogens as doublets at 8.00 and 6.67 ppm with a 15.6 Hz coupling constant between them. By way of contrast, the *cis* isomer of enone **3** (i.e., compound **7**, eq. [3]), which could be isolated in small amounts when **3** was irradiated for relatively short periods of time (vide infra), exhibited an NMR spectrum in which the vinyl doublets appeared at 6.79 and 6.32 ppm with a mutual coupling constant of 12 Hz.

The photochemistry of enone **3** was examined in both benzene and acetonitrile solution and the progress of the reaction monitored by gas chromatography. This showed the formation of two photoproducts, subsequently shown to be *cis*-enone **7** and *trans*-1-benzoyl-2,2,3-triphenylcyclopropane (**8**) (eq. [3]). Photolysis was stopped when GC analysis indicated the complete disappearance of enone **3**, at which point the **7**:**8** ratio was approximately 1:3; chromatography of this reaction mixture allowed small amounts of *cis*-enone **7** to be isolated and characterized. Continuing the photolysis until no further enone **7** could be detected by GC analysis (ca. 2 h) and subsequent silica gel column chromatograpy allowed cyclopropyl ketone **8** to be isolated in 96% yield. The structure and *trans* stereochemistry of photoproduct **8** were assigned on the basis of a comparison of its mp and spectroscopic properties with those reported in the literature for the

same compound prepared via the oxadi-π-methane photorearrangement of β,γ-unsaturated ketone **9** (eq. [3]) (7). The quantum yield for formation of photoproduct **8** from enone **3** in benzene, extrapolated to 0% conversion, was found to be 0.4 (valerophenone actinometry). Although sensitization–quenching studies were not carried out, given the high efficiency with which phenyl ketones form triplets it seems virtually certain that the photorearrangement of enone **3** is triplet-mediated.

[3]

Discussion

While cyclopropyl ketone **8** has the gross structure expected of a straightforward 1,2-phenyl migration photorearrangement of enone **3**, its stereochemistry differs from that of the major product **2** formed in the photolysis of 4,4-diphenylcyclohex-2-en-1-one. In the latter case, the migrating phenyl group ends up *cis* to the carbonyl group, whereas in ketone **8** there is a *trans* relationship between these two moieties. Both results are consistent with the concerted mechanism proposed by Zimmerman and Hancock (3) in which phenyl migration is synchronous with cyclopropane ring formation. As depicted in eq. [4], this mechanism predicts that *cis*-enones (e.g., **1** and **7**) will form products in which the migrating group (Ar) and the C=O group are *cis* to one another (e.g., **2**), and that *trans*-enones (e.g., **3**) will lead to products having a *trans*-Ar – C=O relationship (e.g., **8**). There is a problem with this picture, however, in that independent photolysis of *cis*-enone **7** did not form the expected *cis*-Ar – C=O diastereomer; only photoproduct **8** was observed. This indicates that either the concerted photorearrangement of *cis*-enone **7** is slower than its isomerization to *trans*-enone **3** (no **3** could be detected, however), or that both enones rearrange by a non-concerted mechanism through a common, conformationally equilibrated intermediate such as **11** (eq. [4]) in which ring closure with clockwise rotation about the C-2—C-3 bond is favored, leading to photoproduct **8**.[2] Zimmerman and Hancock (3) also concluded that a non-concerted mechanism is capable of rationalizing the stereochemical course of the photorearrangement of cyclohexenone **1**. At the moment, therefore, a definitive choice between the concerted and non-

[2]

---

[2] Biradical **11** is expected to be more stable than its conformer **10** in which the benzoyl group interferes with a phenyl group on C-4. Clockwise rotation around C-2—C-3 during ring closure of biradical **11** is favored over counterclockwise rotation, since the latter pathway leads to increased nonbonded interactions between the benzoyl group and the phenyl group on C-3.

concerted pathway cannot be made, although it could be argued that the triplet nature of the photorearrangement favors the latter.

A final point of discussion concerns the 10-fold higher quantum yield for the photorearrangement of acyclic enone **3** compared with that of cyclic enone **1**. Although quantum yields are not always a reflection of rates of reaction, it is tempting to equate the higher quantum yield for the photorearrangement of enone **3** with relief of steric crowding in the triphenylmethyl group as well as greater resonance stabilization of the intermediate biradical **10**.

Work is continuing in our laboratory on developing methods for carrying out the aryl migration enone photorearrangement enantioselectively as well as synthesizing triarylmethane analogs of enone **3** for use in excited-state migratory aptitude studies.

Experimental

Instrumentation and general procedures

Commercial spectral grade solvents were used for photochemical experiments unless otherwise noted. Infrared spectra were recorded on a Perkin-Elmer 1710 Fourier transform spectrometer. Solid samples were ground in KBr (1–5%) and liquid samples were run neat as thin films. Melting points were determined on a Fisher-Johns hot stage apparatus and are uncorrected. ^{1}H NMR spectra were recorded in deuterated solvents as noted on a Varian AV-300 (300 MHz) instrument. ^{13}C NMR spectra were run on the same instrument at

75 MHz under broadband ^{1}H decoupling. Low- and high-resolution mass spectra were obtained from a Kratos MS 50 instrument using electron impact (EI) ionization at 70 eV or the chemical ionization (CI) method; intensities of the ions are given in parentheses. Ultraviolet spectra were recorded on a PerkinElmer Lambda-4B spectrophotometer in the solvent indicated. Gas chromatographic analyses were performed on a Hewlett-Packard HP 5890 instrument.

1,1,1,4-Tetraphenylbutane (5)

The known compound **5** (6) was synthesized by a modified procedure of Brook and Pierce (6) (8). Mercury (36.5 g, 182 mmol) was placed in a 100 mL two-necked round-bottomed flask equipped with a magnetic stirrer and a reflux condenser and the system thoroughly flushed with anhydrous nitrogen. Sodium (0.365 g, 15.9 mmol) was carefully added in several small pieces to the mercury under nitrogen with cooling by means of a water bath. A solution of 2.0 g (7.2 mmol) of triphenylmethyl chloride (Aldrich) in 50 mL of anhydrous ether was then added to the sodium amalgam under nitrogen with stirring, whereupon a blood red color developed over a period of approximately 1 h. Stirring was continued for an additional 2 h after which 1.78 g (8.9 mmol) of 3-phenyl-1-bromopropane (**4**) (Aldrich) was added. The red color disappeared immediately and the resulting solution was stirred at room temperature for 4 h. The reaction mixture was worked up by hydrolysis with 20 mL of distilled water followed by extraction with diethyl ether. The ether layers were combined, dried over anhydrous sodium sulphate, and concentrated in vacuo to afford a non-crystalline residue that was subjected to silica gel column chromatography using 2% ethyl acetate in petroleum ether as the eluting solvent. This afforded 1.70 g (53%) of compound **5** as a colorless solid. Recrystallization from ether:petroleum ether (2:1) gave colorless needles, mp 94 to 95°C (lit. (6) mp 92 to 93.5°C).

1,4,4,4-Tetraphenylbutan-1-one (6)

The known compound **6** (6) was prepared using an oxidation procedure of Muzart (9). To a solution of 0.89 g (2.5 mmol) of compound **5** in 4.2 mL of dichloromethane was added 0.074 g (0.74 mmol) of chromium trioxide (Aldrich) and 6.6 mL of a 70% aqueous solution of *tert*-butylperoxide (Aldrich) and the resulting mixture stirred for 36 h at room temperature. The biphasic reaction mixture was worked up by addition of 8 mL of saturated aqueous sodium thiosulphate solution until no longer oxidizing to starch-iodide paper and then extracted with dichloromethane (2 × 15 mL). The combined organic layers were washed with water and brine and then dried over anhydrous magnesium sulphate. Removal of the solvent in vacuo followed by radial chromatography over silica gel (2% ethyl acetate in petroleum ether) afforded 0.7 g (75%) of ketone **6** as a colorless solid. Recrystallization from ethyl acetate gave small prisms, mp 141–143°C (lit. (6) mp 139 to 140.5°C).

trans-1,4,4,4-Tetraphenylbut-2-en-1-one (3)

Following an oxidation procedure of Bernstein and Littell (10), a solution of 1.0 g (2.7 mmol) of ketone **6** and 1.2 g (10.8 mmol) of selenium dioxide (Aldrich) in 125 mL of *tert*-butanol and 5.6 mL of glacial acetic acid was refluxed

with stirring for 48 h. The reaction mixture was diluted with 25 mL of ethyl acetate, filtered, and the filtrate washed with water, 10% aqueous sodium hydroxide, water again, brine, and then dried over anhydrous sodium sulphate. Removal of the solvent in vacuo followed by GC analysis of the residue revealed the presence of both ketone **3** and ketone **6** in a 2:1 ratio. This mixture was subjected to a second oxidation identical to the first but on half the scale until GC analysis indicated the complete disappearance of starting material **6**. Workup as before afforded a crude reaction mixture that was subjected to radial chromatography over silica gel (5% ethyl acetate in petroleum ether) to afford 0.94 g (94%) of solid enone **3**. Recrystallization from ethyl acetate:hexane (3:1) gave colorless needles, mp 133–136°C. IR (KBr) (cm^{-1}): 3054, 1667, 1610, 1490, 1445, 1326, 1304, 1291, 1223, 1179, 1033, 1004, 757, 702, 590. ^{1}H NMR (CDCl$_3$, 300 MHz) δ: 8.0 (d, 1H, J = 15.6 Hz, vinyl), 7.79–7.76 (m, 2H), 7.51–7.46 (m, 1H), 7.4–7.35 (m, 2H), 7.30–7.19 (m, 9H), 7.09–7.06 (m, 6H), 6.67 (d, 1H, J = 15.6 Hz, vinyl). ^{13}C NMR (CDCl$_3$, 75 MHz) δ: 190.7, 154.4, 144.4, 137.9, 132.8, 130.1, 129.1, 128.6, 128.1, 126.9, 126.6, 125.5, 61.3. LR-MS (EI) m/z: 374 (M$^+$), 269, 191, 165, 105, 91, 77, 51. HR-MS (EI) m/z calcd. for C$_{28}$H$_{22}$O: 374.1671; found: 374.1672. Anal. calcd. for C$_{28}$H$_{22}$O: C 89.80, H 5.93; found: C 89.81, H 5.95.

Photolysis of enone 3

Enone **3** (0.1 g, 0.27 mmol) was dissolved in 30 mL of acetonitrile and the solution purged with nitrogen for 30 min. The solution was then irradiated for 2 h through Pyrex using the output of a Hanovia 450 W medium pressure mercury lamp. GC analysis of an aliquot revealed the complete consumption of starting material and the formation of a single photoproduct. Removal of the solvent in vacuo followed by radial chromatography over silica gel (2% ethyl acetate in petroleum ether) afforded 0.096 g (96%) of photoproduct **8** as a colorless solid. Recrystallization from a mixture of diethyl ether and petroleum ether afforded small prisms, mp 126–128°C (lit. (7) mp 125–127°C). The methine hydrogens of compound **8** exhibited a mutual 6 Hz coupling in the ^{1}H NMR, thus confirming their *trans* relationship (11). When 0.02 g of enone **3** in 15 mL of benzene was irradiated through Pyrex for 1 h, GC analysis indicated the presence of a mixture of *trans*-enone **3**, its *cis* isomer **7**, and cyclopropyl ketone **8** in a 3:10:20 ratio. Photolysis was continued for an additional 15 min until GC analysis showed the complete consumption of starting material **3**. Subsequent removal of solvent in vacuo followed by radial chromatography as before afforded 0.012 g of photoproduct **8** and 0.004 g of *cis*-enone **7**, mp 136–139°C (from ethyl acetate). IR (KBr): 3058, 2974, 1672, 1597, 1581, 1494, 1447, 1226, 1175, 1036, 991, 901, 842, 738, 702. ^{1}H NMR (C$_6$D$_6$, 300 MHz) δ: 7.59–7.56 (m, 2H), 7.32–7.29 (m, 6H), 7.12–6.91 (m, 12H), 6.79 (d, 1H, J = 12 Hz, vinyl), 6.32 (d, 1H, J = 12 Hz, vinyl). ^{13}C NMR (CDCl$_3$, 75 MHz) δ: 192.4, 147.4, 145.5, 136.7, 132.7, 130.4, 129.6, 128.6, 128.4, 128.1, 128.0, 127.7, 126.4, 61.7. LR-MS (EI) m/z: 374 (M$^+$), 269, 191, 165, 105, 91, 77, 51. HR-MS (EI) m/z calcd. for

C$_{28}$H$_{22}$O: 374.1671; found: 374.1669. Anal. calcd. for C$_{28}$H$_{22}$O: C 89.80, H 5.93; found: C 89.78, H 5.97.

Quantum yield determination

The quantum yield for formation of cyclopropyl ketone **8** in benzene was determined using valerophenone actinometry (Φ = 0.33) (12) according to the standard protocol used in our group (13). *n*-Tetradecane and *n*-nonadecane were used as internal standards for the solutions of actinometer and ketone **8**, respectively. Quantum yields were determined at varying conversions and plotted against conversion; the reported quantum yield of 0.4 represents the value extrapolated to 0% conversion.

The photochemistry of 1-(3,5-dimethoxyphenyl)-2-(4-methoxyphenyl)ethyl ethanoate in alcohol solvents: A search for carbocation rearrangements

J.C. Roberts and J.A. Pincock

Abstract: The photochemistry of the title compound **1** in methanol and 2,2,2-trifluoroethanol has been examined. In both solvents two ether products were obtained: one (**18**) resulting from trapping of the carbocation **2** (expected from photosolvolysis of **1**), and the other (**19**) from the carbocation **3** (expected after rearrangement by hydride migration of cation **2**). The substituted *trans*- and *cis*-stilbene derivatives **20** and **21** were also primary photoproducts. Analysis of product yields as a function of time revealed that the ether product **19** was formed by secondary photolysis of the stilbene derivatives, presumably by a pathway involving excited state protonation. Nanosecond laser flash photolysis results demonstrated that substituted *trans*-stilbene **20** was produced on the same time scale as the laser pulse.

Key words: ester photochemistry, stilbene photoadditions, carbocation rearrangements.

Résumé : On a étudié la photochimie du composé mentionné dans le titre **1** dans le méthanol et dans le 2,2,2-trifluoroéthanol. Dans les deux solvants on obtient deux éthers : L'un deux (**18**) résulte du piégeage du carbocation **2** (produit attendu de la photolyse du composé **1**), et l'autre (**19**) provient du carbocation **3** (produit attendu d'un réarrangement par migration d'un ion hydrure du cation **2**). Les dérivés *trans* et *cis* des stilbènes substitués **20** et **21** sont également des photoproduits primaires. L'analyse des produits obtenus en fonction du temps, révèle que l'éther **19** résulte d'une photolyse secondaire des dérivés du stilbène, vraisemblablement selon un chemin impliquant la protonation de l'état excité. Les résultats de la photolyse éclair au laser, avec des impulsions de l'ordre de la nanoseconde, démontrent que le *trans*-stilbène substitué **20** est produit dans la même échelle de temps que l'impulsion laser.

Mots clés : photochimie d'un ester, photoadditions du stilbène, réarrangements de carbocations.

[Traduit par la Rédaction]

Introduction

The photochemical generation of carbocations by cleavage of arylmethyl leaving group σ bonds (ArCR₂-LG) is currently of considerable interest (1). One focus has been on the mechanism for formation of the arylmethyl cation with the two possibilities being either (*i*) direct heterolytic cleavage to an ion pair from the excited singlet state, or (*ii*) excited state homolytic cleavage followed by rapid redox electron transfer converting the first formed radical pair to an ion pair (2). Product studies have been extensively used to probe these two possible pathways. Another focus has been the direct observation of arylmethyl cations by laser flash photolysis (LFP) techniques (3), which has provided information regarding the reactivity of these species, in particular

their rates of reaction with various nucleophiles and solvents.

The observation of products resulting from rearrangements of carbocations is a well-established phenomenon in ground state chemistry and appears in early chapters of all modern text books on introductory organic chemistry. The driving force for these rearrangements is formation of a more stable cation from a less stable one, with both 1,2-carbon and hydrogen migrations as well-known examples. We hoped to apply the above two photochemical techniques to observe a hydride shift by both product studies and directly by LFP. We chose the substrate **1** and the cations **2** and **3** as targets (eq. [1]).

The idea behind this choice is that the 3,5-dimethoxyphenyl chromophore efficiently promotes the photochemical

doi: 10.1139/V03-072

[1]
generation of carbocations via C—O bond cleavage (4, 5). For instance, the yield of ion-derived products from the photolysis of 3,5-dimethoxybenzyl acetate in methanol is 60% with a quantum yield of 0.37 (6). A rate constant for this excited state bond cleavage has not been determined because the lack of fluorescence precludes determination of the excited singlet state lifetime, but we estimate that the rate constant is greater than 1×10^9 s^{-1}. If it is formed, carbocation **2** is expected to rearrange rapidly to the more stable isomer **3** by a hydride shift. The difference in stability for the two cations can be demonstrated by the relative rates of solvolysis for 4-methoxybenzyl tosylate and 3,5-dimethoxybenzyl tosylate (1:1 $\times 10^5$ in 80% aqueous acetone at 25°C) (7). Finally, the 4-methoxybenzyl cation has a characteristic absorption band at 340 nm that has been used previously to study its reactivity by LFP (8). Therefore, if **3** is formed from **2**, the time evolution of its growth could be observable.

A similar approach has been reported recently by Lee-Ruff and co-workers (9). In the first example (9), photolysis of the vicinal diol **4** in acetonitrile, methanol, and 2,2,2-trifluoroethanol (TFE) gave the radical-derived product **5**, along with the pinacol rearrangement product **6** (Scheme 1). The proposed mechanism proceeds through the cations **7** and **8**. The efficient formation of **7** results from the previously reported high photochemical reactivity of 9-hydroxyfluorene derivatives to give fluorenyl cations which are not stabilized by aromatic delocalization because they have $4n$ π electrons (10). The cation **7** was observed by LFP, and its unimolecular rearrangement to **8** (not observed) was found to have a

rate constant of 5×10^5 s^{-1} in 1,1,1,3,3,3-hexafluoroisopropanol (HFIP). In a second example (11), the irradiation of the 9-fluorenol derivative **9** in methanol gave the ether **10** (28%) and the elimination product **11** (7%). However, the ether **12** (which would have been formed after a 1,2-hydride shift converting **13** to **14**) was not detected in the reaction mixture (Scheme 2). When **9** was submitted to strong acid conditions at −78°C, **13** was detected spectroscopically, but **14** was not observed until the solution was warmed to room temperature. Quenching of the cold or warmed solution with methanol gave **10** or **12**, respectively. The authors rationalized these observations by suggesting that cation **14** is not formed by a 1,2-hydride shift, but rather by a deprotonation–protonation sequence involving the by-product **11** (a process which is only possible in the strong acid experiments). This suggests that the activation barrier for rearrangement of **13** to **14** is high enough to prevent the process from competing with rapid quenching by methanol when **13** is generated photochemically.

Results

Synthesis of ester 1

Arylmethyl esters such as **1** are easily accessed by esterification of the corresponding alcohols, and therefore, alcohol **15** was identified as the direct precursor that was required for the preparation of **1**. For the synthesis of **15**, a Grignard reaction between 3,5-dimethoxy-bromobenzene **16** and 2-(4-methoxyphenyl)ethanal **17** was chosen. As shown in Scheme 3, the bromide **16** was synthesized by a Sandmeyer reaction (12) in a low yield (33%) that is consistent with literature precedent (13). The aldehyde **17** was prepared in 74% yield over three steps by Darzens' sequence from 4-methoxybenzaldehyde as reported by Macchia and co-workers (14). Grignard coupling of **16** with **17** gave **15** (96% yield), and esterification by the procedure of Steglich and Neises (15) gave the desired ester **1** (70% yield). Details of the procedures are in the *Experimental* section.

A methanolic solution of ester **1** had absorption maxima at 274 nm ($\varepsilon = 3600$ M^{-1} cm^{-1}) and 280 nm ($\varepsilon = 3300$ M^{-1} cm^{-1}). Excitation of **1** at 274 nm results in fluorescence with λ_{max} at 298 nm, and the 0,0 band is at 288 nm (415 kJ mol^{-1}). Since 3,5-dimethoxybenzyl acetate itself does not fluoresce, this observation is attributed to the 4-methoxyphenyl chromophore, which will absorb competitively with the more reactive portion of the molecule. To check for any interaction between the two chromophores, the absorption spectra of 4-methylanisole and 1-(3,5-dimethoxyphenyl)ethyl ethanoate were recorded and normalized. Summation of the normalized spectra resulted in a slightly higher absorption (8%) than was observed at the λ_{max} of **1** (274 nm). No increased absorption was observed at longer wavelengths. Therefore, the competitive absorption between the two chromophores may decrease the quantum yield of the reaction, but there does not appear to be any strong ground-state interaction between them.

Photolysis of ester 1 in methanol

Photolysis of a nitrogen-saturated solution of **1** in methanol using a Rayonet reactor and 254 nm lamps afforded a

Scheme 1. Formation of ketone **6** via the photochemical pinacol rearrangement of cation **7**.
Scheme 2. The photochemistry of fluorenol **9** in methanol.
mixture of seven products after irradiation for 1 h (Scheme 4). Figure 1 shows the normalized product yields as a function of time. Preliminary identification of the products was made on the basis of their mass spectra (GC–MS). Pure samples were obtained either by independent syntheses or by isolation following photochemical reactions (vide infra). The reaction was also monitored by gas chromatography with a flame ionization detector (GC-FID). The GC-FID response was calibrated using each of the pure samples, allowing the accurate calculation of product yields (Table 1). Further details on the methods used to obtain accurate val-

ues for the product yields can be found in the *Experimental* section.

As shown in Fig. 1 and Table 1, almost 90% of **1** is consumed after 1 h of irradiation, and by this time there is very little change in the relative percentages of the products over time. For the purposes of the current project, the methyl ethers **18a** and **19a** (R = CH$_3$) are of the greatest interest, since they are the products that would be formed from nucleophilic attack of the solvent on carbocations **2** and **3**. Although the yield of **19a** is difficult to measure at low conversions, the ratio of **18a** to **19a** appeared to decrease with

Scheme 3. The synthesis of 1-(3,5-dimethoxyphenyl)-2-(4-methoxyphenyl)ethyl ethanoate **1**.
Scheme 4. Products detected following the photolysis of ester **1** in methanol and TFE.
time until a steady state ratio of 21:1 was reached; after only 10 min, however, **18a**:**19a** = 33:1.

The substituted stilbenes **20** and **21** are clearly primary photoproducts, but at low conversions the *trans* isomer is formed in higher yield than the *cis* (*trans*:*cis* = 2:1 at 2% conversion). The two isomers then photoequilibrate to a ratio of 1:1 at high conversion of **1**. The substituted phenanthrene **22** is produced by secondary photochemistry — a photochemically allowed conrotatory electrocyclic reaction of the *cis*-stilbene **21**, followed by oxidation of the dihydrophenanthrene intermediate. This reaction has been well-established for the photochemistry of other electron-rich

stilbene derivatives (16). Finally, products **23** and **24** are radical-derived by-products of the reaction.

As noted above, the identification of most products was made by comparison with authentic samples. Ether **18a** was synthesized by reaction of alcohol **15** with sodium hydride and iodomethane. To produce **19a** in a similar alkylation method, the required alcohol **25** was synthesized by Grignard coupling of 4-bromoanisole and 2-(3,5-dimethoxy-phenyl)ethanal **26** (the aldehyde, in turn, was prepared by the Darzens' sequence from 3,5-dimethoxy-benzaldehyde). The substituted *trans*-stilbene **20** was produced by dehydration of **15** with *p*-toluenesulfonic acid in benzene. Photo-

Table 1. Product yields after photolysis of ester **1** for 1 h in methanol and TFE.

Solvent	% Conversion[a]	**18**[b]	**19**[b]	**20**	**21**	**22**	**23**	**24**
Methanol (R = CH$_3$)	89	42	2	18	19	4	5	10
TFE (R = CH$_2$CF$_3$)	82	30	27	13	13	5	4	7

[a]Product yields are normalized to 100% because mass balances were essentially quantitiative; see the *Experimental* section for complete analysis details.

[b]For R = CH$_3$, products are designated **18a** and **19a**. For R = CH$_2$CF$_3$, products are designated **18b** and **19b**.

chemical *cis–trans* isomerization of **20** in acetonitrile provided access to the substituted *cis*-stilbene **21** in a steady-state ratio of *trans*:*cis* = 1:2 (Pyrex filter, 280 nm cut-off). Finally, irradiation of **20** in an aerated solution of methanol gave the substituted phenanthrene **22** after purification by column chromatography. Complete synthetic procedures for all of these compounds are included in the *Experimental* section.

An issue of some concern was whether or not **18a** could react by secondary photochemistry, and thereby revert to carbocation **2**. To this end, a nitrogen-saturated solution of **18a** in methanol was irradiated. Although the ether was consumed (25% conversion after 1 h, 47% after 5 h), only the reduction product **23** was detected. This is clearly a result of radical, not cation, intermediates. Column chromatography of the reaction mixture after a high-conversion photolysis of **18a** provided a convenient method for isolating larger amounts of pure **23** than were obtained following photolysis of **1** in methanol.

Photolysis of ester 1 in TFE

With hopes of prolonging the lifetime of cation **2**, and thereby allowing more time for the rearrangement to **3**, the

photochemistry of **1** in TFE was examined under the same conditions as the experiments in methanol. Figure 2 shows the normalized product yields as a function of time. As indicated in Scheme 4 and Table 1, the same photoproducts were formed, keeping in mind that the addition of TFE to cations **2** and **3** leads to the ethers **18b** and **19b** (i.e., with R = CH$_2$CF$_3$). The synthesis of both trifluoroethyl ethers was accomplished from alcohols **15** and **25** using a modification of the Mitsonobu reaction developed by Falck and co-workers (17). Attempts to alkylate either **15** or **25** using NaH–DMSO and 2-bromo-1,1,1-trifluoroethane gave no detectable amounts of the desired ethers. Just as in the case of the ether **18a** (R = CH$_3$), **18b** (R = CH$_2$CF$_3$) was also checked for its photochemical reactivity (this time in TFE). Consumption of the ether was observed (29% conversion after 1 h), and compound **23** was again the only product detected. None of the isomeric ether **19b** was detected, confirming that **18b** is not sufficiently reactive to give carbocation intermediates.

Although the % conversion of **1** over 1 h is essentially the same in methanol and TFE (89 vs. 82%) the product yields do show some significant differences. As discussed earlier for the reaction in methanol (R = CH$_3$), the ratio of the ether

Fig. 2. Product yields as a function of time for the photolysis of ester **1** in TFE (Note: compounds **23** and **24** have been removed for improved clarity).
product derived from cation **2** (**18a**) to the product derived from cation **3** (**19a**) is 21:1 after 1 h. The analogous ratio for **18b**:**19b** (the reaction in TFE, R = CH$_2$CF$_3$) is 30:27 (approximately 1:1), supporting the possibility that the less nucleophilic solvent (TFE) perhaps allows more time for the 1,2-hydride shift to occur. However, examination of Fig. 2 reveals that the ratio of **18b**:**19b** is not constant. In fact, the changes in the relative amounts of the ether products during the photolysis of **1** are much more pronounced in TFE (**18b**:**19b** = 16:1 after 2 min; 1:1 after 1 h) than in methanol (**18a**:**19a** = 33:1 after 10 min, 21:1 after 1 h).

With the intention of observing the growth of cation **3** directly, a solution of **1** in TFE was subjected to LFP at 266 nm. As shown in the representative spectrum (Fig. 3), an intense absorption band was observed from 280 (the lowest wavelength used) to 350 nm, with a maximum of approximately 300 nm. Importantly, the signal did not decay over any time window investigated with the laser system (10 ns to 50 µs). The same signal was observed in solutions that were purged with either oxygen or nitrogen. To explore the idea that the signal might be due to a transient species that decays over a much longer time period, a solution of **1** in TFE was submitted to 50 laser pulses, and monitored using a conventional UV–vis spectrometer. The signal did not decay after 30 min, indicating that this signal is not due to a reactive intermediate, but rather to a strongly absorbing photoproduct. Comparison of the laser spectrum with the UV absorption spectra of the isolated products **18**–**23** suggests that *trans*-stilbene **20** (λ_{max} = 303 nm, ε_{max} = 29 000 M^{-1} cm^{-1}) is the compound responsible for the absorption (Fig. 4).

Also shown in Fig. 4 is the absorption spectrum of **1**. At the maximum light output of the lamp used for the photolysis experiments (λ = 254 nm), the extinction coeffi-

cient of **20** (ε_{254} = 3030 M^{-1} cm^{-1}) is more than three times larger than that of **1** (ε_{254} = 800 M^{-1} cm^{-1}). Furthermore, **20** absorbs much more strongly than **1** at longer wavelengths. This means that when the photolysis of **1** has proceeded to the point that [**1**] < 3[**20**], the majority of the light will be absorbed by **20**. The results from the photolysis of **1** in the two solvents suggest that this condition would be met between 10 and 15 min after starting the photolysis.

At this point, an important issue must be addressed. Because the formation of **20** during LFP of the ester **1** makes the direct observation of cations **2** and **3** virtually impossible, the use of product yields in assessing the importance of rearrangement becomes critical. If the excited state of **20** is sufficiently reactive to photochemical addition of the alcohol solvent to give the ethers **18** and **19**, then any conclusions about cation rearrangements will be incorrect. To address this point, the photochemistry of **20** in methanol and TFE was examined.

Photolysis of substituted *trans*-stilbene 20 in methanol and TFE

The formation of **20** during the photolysis of **1** corresponds to the loss of acetic acid from the parent ester. For this reason, 1 equiv of acetic acid was added to the solution of **20** in either solvent before irradiation, so as to reproduce the reaction conditions as accurately as possible. No product formation was observed after stirring the solutions of **20** in methanol or TFE with added acetic acid for 48 h in the dark, thus, ensuring that **20** does not react by ground-state chemistry during the time frame of the photolysis experiment.

Photolysis of **20** in the two solvents gave a mixture of four products (Scheme 5). All of the products have already been observed during the photolysis of **1**, and so calibrated

Scheme 5. Products detected following the photolysis of substituted *trans*-stilbene **20** in methanol and TFE.

Fig. 4. Comparison of the absorption spectra of ester **1** and substituted *trans*-stilbene **20** (both 3.45×10^{-5} M in methanol).
product yields were calculated (Table 2). The normalized product yields as a function of time are shown in Figs. 5 (methanol) and 6 (TFE). In striking contrast to the ester **1**, which exhibits very similar reactivity in either methanol or TFE, **20** reacts much faster in TFE than in methanol. After 1 h, the % conversion of **20** in methanol is 48%, whereas the % conversion is 80% after the same time in TFE. In both solvents, the substituted stilbene isomers approach the steady state composition of 1:1 and then disappear simultaneously, although this process occurs much more rapidly in TFE. Another important observation is that the ether products observed require the formation of both carbocations **2** and **3** by photochemical protonation of **20**. Furthermore, in contrast to the results for **1**, the ethers produced from nucleophilic attack on the rearranged carbocation **3** (i.e., **19a** and **19b**) are formed in greater yield than their isomeric counterparts (**18a** and **18b**). In fact, **18a** was not detected even after 5 h of irradiation. These results strongly suggest that cation **3** is formed rapidly upon photolysis of **20** in methanol and TFE.

Discussion and conclusions

The general mechanism that has been developed for ester photochemistry seems to hold for ester **1**. Both ion- and radical-derived products are formed. The results from the photolysis of **1** in methanol and TFE initially suggested that the desired 1,2-hydride shift occurred as was predicted

(eq. [1]). This was based on the idea that TFE, being a less nucleophilic solvent, would promote the formation of carbocation **3** from carbocation **2**. The difference in the final product ratios (**18**:**19**) seemed to support this idea. However, closer inspection of the data revealed that this ratio is not constant over the course of the experiment. For the reaction in methanol, **18a**:**19a** = 33:1 after 10 min, and 20:1 after 60 min. The change is even more drastic for the photolysis in TFE: after 2 min **18b**:**19b** = 16:1, but after 1 h the ratio is **18b**:**19b** = 1:1. The change in the relative amounts of the products that result from nucleophilic attack on carbocations **2** and **3** indicates that a secondary photochemical reaction occurs during the steady-state photolysis of **1**. One possible explanation is that the ethers **18** decay over the course of the photolysis experiments involving **1**. Although these ethers were shown to be photochemically active in the control experiments, they appear to react too slowly to account for the observed change in the **18**:**19** ratio. Furthermore, the presence of several strongly absorbing compounds in the same reaction mixture will make absorption by the ethers **18** even less likely. Indeed, the only experiment in which decay of either **18a** or **18b** was detected was during the photolysis of **20** in TFE (Fig. 4). The yield of **18b** does decrease over the final 2 h of the experiment (4 to 2%), but only after most of the substituted stilbenes have been converted to products.

A much more satisfying explanation of the observed change in the **18**:**19** ratio is that secondary photochemistry provides an alternative pathway for the formation of the

Table 2. Product yields after photolysis of substituted *trans*-stilbene **20** in methanol and TFE.

Solvent	Time (h)	% Conversion[a]	**18**[b]	**19**[b]	**21**	**22**
Methanol (R = CH_3)	1	48	0	4	88	8
Methanol (R = CH_3)	5	63	0	10	64	26
TFE (R = CH_2CF_3)	1	80	4	60	27	9
TFE (R = CH_2CF_3)	4	95	2	87	3	8

[a]Product yields are normalized to 100% because mass balances were essentially quantitiative; see the *Experimental* section for complete analysis details.

Fig. 5. Product yields as a function of time for the photolysis of substituted *trans*-stilbene **20** in methanol.
products derived from the cation **3**, specifically the ethers **19**. As shown in the control experiments involving **18a** and **18b**, there is no pathway for converting **18** to **19**. Rather, the secondary photochemical reaction is addition of the solvent to the excited state of the substituted *trans*-stilbene **20**. As clearly shown by the steady-state photolysis results, cation-derived products (i.e., **18** and **19**) can be formed in reasonable efficiency from **20** under the same reaction conditions used for the photolysis of ester **1**. Furthermore, this reaction favours the ethers **19** over **18**, which is the reverse of the regiochemistry observed for the photolysis of **1**. The LFP experiments demonstrate that **20** is formed rapidly upon irradiation of **1**, and will be available to absorb competitively with **1** very early in the photolysis experiments involving the ester. Therefore, as the substituted *trans*-stilbene **20** accumulates during the photolysis of **1**, the photochemistry of **20** will become more important, and **19** (formed primarily from **20**) will eventually be formed more rapidly than **18** (formed primarily from **1**). Indeed, even if the formation of **20** did not make the observation of benzylic carbocations by LFP impossible (by obscuring the wavelengths of interest), the observation of a signal corresponding to cation **3** would not be conclusive evidence for the rearrangement of interest.

Unfortunately, the rapid formation of **20** upon photolysis of **1** makes the ester a poor substrate for the investigation of cation rearrangements. Our results are similar to those of Lee-Ruff and co-workers (11) (Scheme 2), where the desired cation rearrangement is too unfavourable to compete with rapid quenching by the alcohol solvent (either by nucleophilic attack or by deprotonation). However, the photochemistry of **1** is further complicated by the fact that the by-products themselves react by secondary photochemistry, making reliable assessment of the rearrangement extremely difficult.

There are several other points that need to be addressed for a thorough understanding of the photochemistry of **1** and its photoproducts. Firstly, although deprotonation of cation **2** or **3** appears to be the most likely pathway for formation of **20**, more study is needed to rule out other mechanisms. Work is in progress to examine the possibility that substituted stilbenes **20** and **21** are produced by either a radical pathway or by concerted photochemical elimination of acetic acid from **1**. In addition, the 1,2,2-trimethyl derivative of **1** is currently being synthesized. This substrate may allow the observation of a rearrangement without the complications present for **1** because rearrangement and nucleophilic trap-

Fig. 6. Product yields as a function of time for the photolysis of substituted *trans*-stilbene **20** in TFE.
ping may be the only reactions available for the initial carbocation.

Secondly, the photochemical addition of alcohols to substituted stilbenes needs to be investigated in much greater detail. At first, the reaction appears to be analogous to the photohydration of substituted styrenes that has been studied extensively by McEwen and Yates (18), who demonstrated that excitation of 3-methoxystyrene in water gave the Markovnikov addition product faster than 4-methoxystyrene (another example of the photochemical meta effect). Additional support for the presence of a carbocation intermediate in such photochemical additions was provided by McClelland and co-workers (19), who found that laser flash photolysis of 4-methoxystyrene in TFE produced a transient absorption signal at 340 nm that was attributed to the corresponding cation. However, the presence of a second aromatic ring in the single chromophore of the substituted stilbenes makes the assessment of substituent effects much more complicated than for substituted styrenes (with regards to both the rate of the reaction and the regiochemistry of the addition).

A survey of the literature indicates that the photochemical addition of methanol to a variety of substituted stilbenes was first observed by Laarhoven and co-workers (20). In contrast to the results for substituted styrenes, the yield of stilbene–solvent adduct was found to be independent of acid concentration. This suggested that protonation of the singlet excited state is not the rate-limiting step in the photochemical addition of methanol to substituted stilbenes. With the aid of experiments conducted in deuterated methanol, the authors concluded that the addition of methanol to stilbenoid systems occurs via two competing mechanisms: (*i*) direct addition across the central bond; and (*ii*) rearrangement of the excited state via a 1,2-hydride shift to give a carbene inter-

mediate, which then inserts directly to the methanol O—H(D) bond. However, the influence of electron-rich substituents in the meta position was never addressed (the only compound examined with meta substitutents was the symmetric 3,3′-dimethylstilbene). In more recent work, Lewis et al. (21, 22) have made several detailed studies of the effect of electron-donating substituents (mostly amino) on the fluorescence behaviour of substituted stilbenes and related compounds. These results indicate that stilbenes with electron-donating meta-substituents have longer singlet lifetimes and higher fluorescence quantum yields than the para-substituted analogues. Furthermore, the authors attribute this observation to a higher barrier for bond torsion in the meta-substituted cases. Addition of methanol was only observed in one case (21) (eq. [2]). However, methanol was not employed as a solvent for many of the photophysical studies that were of interest to the authors, so the reaction may in fact be more general.

[2]
From the results of the current study, just how the photochemistry of **20** fits with the examples in the literature is not yet clear. The rapid addition of the solvent (TFE in particular) appears to be because of the two meta substituents (the 3,5-dimethoxyphenyl ring), while the preferred regiochemistry is governed by the para substituent (4-methoxyphenyl ring). We had originally believed that the increased reactivity of **20** in TFE compared to methanol could be attributed to the greater effective acidity of the former solvent, which might lead to more rapid protonation of the excited state. However, the study by Laarhoven and co-workers (20) seems to indicate that the mechanism of solvent addition may be even more complicated. Clearly, a larger set of stilbene derivatives is required to confidently assess the factors controlling the reaction. This work is currently in progress.

Experimental

General procedures

Melting points were determined on a Fisher–Johns apparatus and are uncorrected. ^{1}H and ^{13}C NMR spectra were recorded in deuterated chloroform on a Bruker AC 250F instrument, and chemical shifts are reported as parts per million (ppm) relative to tetramethylsilane internal standard. The coupling constants of the ABX systems observed in several compounds were analysed by matching the line positions with those of simulated spectra. Gas chromatography was performed on a Perkin-Elmer Autosystem XL instrument (controlled by a computer with TurboMass and TurboChrom software) with one Turbomass detector and one FID (both columns: Supelco 30 m/0.25 mm MDN-5S 5% phenyl methylsiloxane, film thickness 0.50 μm). For GC–MS, the injection volume was 1 μL; mass spectral data are reported in units of mass over charge (m/z) with intensities relative to the base peak (in brackets). For GC-FID, an injection volume of 2.5 μL was used. The same temperature program was used for both detectors: 60°C for 1 min, ramp at 20°C/min to 240°C, hold at 240°C for 20 min. Ultraviolet spectra were recorded on a Varian–Cary Bio 100 spectrometer.

Methanol, water, ethyl acetate, and hexanes were all distilled prior to use. Dichloromethane, benzene, dimethylsulfoxide (DMSO), TFE, pentane, and the deuterated solvents were all reagent grade, while acetonitrile was HPLC grade (these solvents were used without extra purification). Tetrahydrofuran (THF) was distilled from sodium–benzophenone, and then a second time from lithium aluminium hydride before being kept under nitrogen. All starting materials were supplied by Aldrich Chemicals, with the exception of 3,5-dimethoxyaniline and 3,5-dimethoxybenzaldehyde (Avocado Chemicals). Thin layer chromatography was performed using plates from Eastman-Kodak. Preparative chromatography was performed using 60–250 mesh silica gel from Silicycle.

Synthetic procedures

3,5-Dimethoxybromobenzene (16)

This compound was prepared from the diazonium ion made from 3,5-dimethoxyaniline using the procedure described (12) for the synthesis of *o*-bromochlorobenzene,

yield 33%: mp 64–65°C, lit. (13) mp 64–66°C. ^{1}H NMR δ: 6.66 (d, 2H, J = 2.4 Hz), 6.37 (t, 3H, J = 2.4 Hz), 3.76 (s, 6H). ^{13}C NMR δ: 161.2, 123.0, 109.8, 99.8, 55.5. GC–MS m/z: 218 (82.6), 216 (100.0), 108 (69.7), 79 (41.6), 77 (56.2), 63 (48.9), 51 (26.3).

2-(4-Methoxyphenyl)ethanal (17)

This compound was prepared from 4-methoxybenzaldehyde by glycidic ester condensation as described (14), yield of 74% over three steps: ^{1}H NMR δ: 9.66 (d, 1H, J = 2.4 Hz), 7.09 (d, 2H, J = 8.5 Hz), 6.88 (d, 2H, J = 8.5 Hz), 3.75 (s, 3H), 3.57 (d, 2H, J = 2.4 Hz). ^{13}C NMR δ: 199.8, 159.0, 130.8, 123.9, 144.4, 55.2, 49.6. GC–MS m/z: 121 (100), 91 (20.5), 78 (23.9), 77 (31.2), 51 (12.2).

1-(3,5-Dimethoxyphenyl-2-(4-methoxyphenyl)ethan-1-ol (15)

For this reaction, all glassware was dried in an oven and purged with nitrogen gas prior to use. Liquid transfers were performed using a cannula needle under positive pressure. A solution of 3,5-dimethoxybromobenzene **16** (4.00 g, 18.4 mmol) in THF (20 mL) was prepared, and then transferred to a dropping funnel atop a three-necked 100 mL round-bottomed flask containing magnesium turnings (2.68 g, 110 mmol) in THF (5 mL). Approximately 10% of the aryl halide solution was run into the flask, along with a small crystal of iodine. After 15 min of stirring, the yellow colour of the iodine disappeared, and the mixture began to reflux. The remaining solution in the dropping funnel was added to the magnesium over 15 min, and the mixture was refluxed for 30 min after the addition was complete. After cooling to room temperature, the resulting orange solution was transferred under nitrogen to a clean three-necked flask.

A solution of 2-(4-methoxyphenyl)ethanal **17** (2.76 g, 18.4 mmol, distilled under vacuum prior to use) in THF (20 mL) was prepared. The solution was then added dropwise to the solution containing the Grignard reagent, and the resulting mixture was refluxed for 30 min after the addition was complete. After cooling to room temperature, the yellow solution was poured into a separatory funnel containing saturated ammonium chloride solution (100 mL) and dichloromethane (50 mL). The layers were separated, and the aqueous portion was extracted with dichloromethane (2 × 50 mL). The combined organic extracts were washed with distilled water and saturated sodium chloride solution (2 × 75 mL each). After drying over anhydrous magnesium sulfate and filtering, the solvent was removed under reduced pressure to give 5.10 g of the product alcohol (96%). Further reactions were performed using the crude material, although characterization was performed using a sample recrystallized from ethyl acetate – hexanes, mp: 97–99 °C. ^{1}H NMR δ: 7.09 (d, 2H, J = 8.6 Hz), 6.83 (d, 2H, J = 8.6 Hz), 6.49 (d, 2H, 2.4 Hz), 6.36 (t, 1H, J = 2.4 Hz), 4.76 (m, 1H, J_1 = 8.5 Hz, J_2 = 4.9 Hz, J_3 = 2.4 Hz), 3.77 (s, 9H), 2.95 (m, 1H, J_1 = 13.7 Hz, J_2 = 4.9 Hz), 2.89 (m, 1H, J_1 = 13.7 Hz, J_2 = 8.5 Hz), 2.07 (d, 1H, J = 2.4 Hz). ^{13}C NMR δ: 160.8, 158.4, 146.5, 130.5, 130.0, 113.9, 103.8, 99.6, 75.4, 55.4, 55.3, 45.1. GC–MS m/z: 271 (5.6), 270 (35.8), 167 (13.1), 139 (35.8), 122 (100.0), 121 (49.9), 77 (16.0). HR-MS calcd.: 288.1361; found: 288.1357 ± 0.0008.

1-(3,5-Dimethoxyphenyl)-2-(4-methoxyphenyl)ethyl ethanoate (1)

This compound was prepared using the method of Steglich and Neises (15). A solution of *N,N*-dimethyl-4-aminopyridine (63 mg, 0.52 mmol) and acetic acid (312 mg, 5.2 mmol) in dichloromethane (25 mL) was prepared, and then added to a solution of 1-(3,5-dimethoxyphenyl)-2-(4-methoxyphenyl)ethan-1-ol **15** (1.5 g, 5.2 mmol) in dichloromethane (30 mL). After the resulting solution was cooled in an ice bath, 1,3-dicyclohexylcarbodiimide (1.17 g, 5.67 mmol) was added in one portion. The resulting mixture was stirred at 0°C for 5 min, and then allowed to stir at room temperature for 3 h. The urea precipitate was filtered off, the solvent was removed under reduced pressure, and the residue was taken up in dichloromethane (50 mL) and filtered again. The clear solution was then washed with 0.5 M hydrochloric acid and distilled water (2×25 mL each). The organic material was then dried with anhydrous magnesium sulfate, filtered, and the solvent removed under reduced pressure to give a clear oil. The oil was adsorbed onto silica for column chromatography. Using 5% ethyl acetate – hexanes as the eluant provided 1.5 g of a solid product, which was recrystallized from the solvent mixture to give 1.2 g of colourless crystals (70%), mp: 68–69°C. ^{1}H NMR δ: 7.03 (d, 2H, J = 8.6 Hz), 6.78 (d, 2H, J = 8.6 Hz), 6.40 (d, 2H, J = 2.4 Hz), 6.37 (t, 1H, J = 2.4 Hz), 5.81 (m, 1H, J_1 = 7.9 Hz, J_2 = 6.1 Hz), 3.77 (s, 3H), 3.75 (s, 6H), 3.08 (m, 1H, J_1 = 14.0 Hz, J_2 = 7.9 Hz), 2.97 (m, 1H, J_1 = 14.0 Hz, J_2 = 6.1 Hz), 2.02 (s, 3H). ^{13}C NMR δ: 170.1, 160.7, 158.3, 142.6, 130.5, 129.1, 113.6, 104.6, 99.7, 76.7, 55.3, 55.2, 42.1, 21.2. GC–MS *m/z*: 270 (41.5), 167 (49.1), 139 (20.3), 121 (100), 77 (14.9). HR-MS calcd.: 330.1467; found: 330.1461 ± 0.0008.

1-(3,5-Dimethoxypheny)-2-(4-methoxyphenyl)-1-methoxyethane (18a)

A 60% sodium hydride – oil suspension (0.08 g of suspension, 0.002 mmol NaH) was washed with hexane to remove the oil. After decanting the washes, the residue was taken up in DMSO (2 mL) and added to a solution of 1-(3,5-dimethoxyphenyl)-2-(4-methoxyphenyl)ethan-1-ol **15** (0.288 g, 1.00 mmol) in DMSO (5 mL). The mixture was stirred at room temperature for 30 min, and then a solution of methyl iodide (0.284 g, 2.00 mmol) in DMSO (5 mL) was added dropwise. After stirring the solution for 3.5 h, distilled water (12 mL) was added slowly to quench the reaction. The organic layer was drawn off, and the aqueous portion was extracted with dichloromethane (3×10 mL). The combined organic material was washed with distilled water (3×25 mL), dried with anhydrous magnesium sulfate, and filtered. Removal of the solvent under reduced pressure gave 0.25 g of material, which was adsorbed onto silica for column chromatography. Elution using 2.5% ethyl acetate – hexanes gave the pure ether (0.098 g, 32%). Characterization was performed on a sample that was further purified by bulb-to-bulb distillation. ^{1}H NMR δ: 7.03 (d, 2H, J = 6.7 Hz), 6.78 (d, 2H, J = 6.7 Hz), 6.38 (m, 3H), 4.21 (dd, 1H, J_1 = 5.5 Hz, J_2 = 7.6 Hz), 3.77 (s, 3H), 3.75 (s, 6H), 3.20 (s, 3H), 3.01 (dd, 1H, J_1 = 7.6 Hz, J_2 = 13.7 Hz), 2.82 (dd, 1H, J_1 = 5.5 Hz, J_2 = 13.7 Hz). ^{13}C NMR δ: 160.8,

158.0, 144.4, 130.4, 113.5, 104.6, 99.6, 85.4, 56.9, 55.3, 55.2, 43.8. GC–MS *m/z*: 303 (0.8), 302 (4.4), 271 (1.5), 270 (6.3), 182 (10.4), 181 (100.0), 121 (12.1). HR-MS calcd.: 302.1518; found: 302.1522 ± 0.0008.

1-(3,5-Dimethoxypheny)-2-(4-methoxyphenyl)-1-(trifluoro-ethoxy)ethane (18b)

This compound was prepared using the method of Falck et al. (17). To a solution of 1-(3,5-dimethoxyphenyl)-2-(4-methoxyphenyl)ethan-1-ol **15** (0.300 g, 1.04 mmol) in benzene (20 mL) was added 1,1′-(azodicarbonyl)dipiperidine (0.525 g, 2.08 mmol). The flask was purged with nitrogen for 10 min, and tri(*n*-butyl)phosphine (0.421 g, 2.08 mmol) was added. After stirring the reaction mixture for another 15 min, TFE (1.04 g, 10.4 mmol) was added. The mixture was stirred at room temperature for 1 h, and the solvent was then removed under reduced pressure. The residue was taken up in dichloromethane, filtered, and the liquid then adsorbed onto silica gel for column chromatography. Elution with 5% ethyl acetate – hexanes gave the desired product (0.154 g, 40% yield). ^{1}H NMR δ: 7.03 (2H, d, J = 8.6 Hz), 6.78 (d, 2H, J = 8.6 Hz), 6.38 (s, 3H), 4.43 (dd, 1H, J_1 = 5.5 Hz, J_2 = 7.3 Hz), 3.77 (s, 3H), 3.75, (s, 6H), 3.64 (m, 2H), 3.09 (dd, 1H, J_1 = 14.0 Hz, J_2 = 7.3 Hz), 2.86 (dd, 1H, J_1 = 14.0 Hz, J_2 = 5.5 Hz). ^{13}C NMR δ: 161.0, 158.2, 142.6, 130.5, 129.7, 124.0 (q, J = 278.6 Hz), 113.5, 104.6, 100.1, 84.9, 66.0 (q, J = 34.3 Hz), 55.3, 55.2, 43.5. GC–MS (*m/z*): 371 (1.5), 370 (7.9), 270 (6.8), 250 (11.6), 249 (100.0), 166 (22.1), 121 (81.1). HR-MS calcd.: 370.1392; found: 370.1392 ± 0.0008.

2-(3,5-Dimethoxyphenyl)ethanal (26)

The sodium salt of 3-(3,5-dimethoxyphenyl)glycidic acid was prepared in two steps (62% yield) using the same procedures as described for the synthesis of 2-(4-methoxyphenyl)ethanal **17** (14). Decarboxylation of the sodium salt was accomplished using the method of Bullimore et al. (23), giving the desired aldehyde in 20% yield (12% over three steps). ^{1}H NMR δ: 9.69 (t, 1H, J = 2.4 Hz), 6.40 (t, 1H, J = 1.8 Hz), 6.35 (d, 2H, J = 1.8 Hz), 3.77 (s, 6H), 3.58 (d, 2H, J = 2.4 Hz). ^{13}C NMR δ: 199.2, 161.3, 134.0, 107.6, 99.3, 55.3, 50.7.

1-(4-Methoxyphenyl)-2-(3,5-dimethoxyphenyl)ethan-1-ol (25)

A solution of 4-bromoanisole (1.04 g, 5.55 mmol) in THF (10 mL) was prepared under nitrogen, and then transferred to a dropping funnel atop a three-necked 100 mL round-bottomed flask containing magnesium turnings (0.81 g, 33.3 mmol). Approximately 10% of the aryl halide solution was added to the magnesium along with an iodine crystal, and the reaction began within 10 min. The remaining aryl halide solution was added over 5 min, and the resulting mixture was heated to reflux for 30 min after the addition was complete. After cooling to room temperature, the resulting orange solution was transferred under nitrogen to a clean three-necked flask.

A solution of 2-(3,5-dimethoxyphenyl)ethanal **26** (1.00 g, 5.55 mmol) in THF (10 mL) was added dropwise to the Grignard reagent, and the resulting mixture was refluxed gently for 30 min. The mixture was then cooled, and added to a separatory funnel containing saturated ammonium chlo-

ride (50 mL) and dichloromethane (25 mL). The layers were separated, and the aqueous portion was extracted with dichloromethane (2 × 50 mL). The combined organic extracts were washed with water and saturated sodium chloride (2 × 25 mL each), and then dried with anhydrous magnesium sulfate. Removal of solvent under reduced pressure gave a crude oil, which was purified by column chromatography (10% ethyl acetate – hexanes, eluant) to give the desired product (1.00 g, 63% yield). ^{1}H NMR δ: 7.26 (d, 2H, J = 8.5 Hz), 6.87 (d, 2H, J = 8.5 Hz), 6.33 (s, 3H), 4.81 (dd, 1H, J_1 = 8.5 Hz, J_2 = 4.9 Hz), 3.78 (s, 3H), 3.73 (s, 6H), 2.92 (m, 2H, J_1 = 8.5 Hz, J_2 = 4.9 Hz, J_3 = 13.7 Hz), 2.12 (s, 1H). ^{13}C NMR δ: 160.7, 159.0, 140.6, 136.1, 127.2, 113.7, 107.4, 98.6, 74.7, 55.3, 55.2, 46.3.

2-(3,5-Dimethoxypheny)-1-(4-methoxyphenyl)-1-methoxyethane (19a)

A 60% sodium hydride – oil suspension (0.083 g of suspension, 2.08 mmol NaH) was washed with hexane to remove the oil. After decanting the washes, the residue was taken up in DMSO (5 mL) and added to a solution of 2-(3,5-dimethoxyphenyl)-1-(4-methoxyphenyl)ethan-1-ol 25 (0.300 g, 1.00 mmol) in DMSO (10 mL). The mixture was stirred at room temperature for 30 min, and then a solution of methyl iodide (0.295 g, 2.08 mmol) in DMSO (5 mL) was added dropwise. After stirring the solution for 5 h, distilled water (15 mL) was added slowly to quench the reaction. The organic layer was drawn off, and the aqueous portion was extracted with dichloromethane (3 × 20 mL). The combined organic material was washed with distilled water and saturated sodium chloride solution (2 × 20 mL each), dried with anhydrous magnesium sulfate, and filtered. Removal of the solvent under reduced pressure gave 0.34 g of material, which was adsorbed onto silica for column chromatography. Elution using 5% ethyl acetate – hexanes gave the pure ether (0.24 g, 32%). Characterization was performed on a sample that was further purified by bulb-to-bulb distillation. ^{1}H NMR δ: 7.15 (d, 2H, J = 8.5 Hz), 6.87 (d, 2H, J = 8.5 Hz), 6.29 (t, 1H, J = 1.8 Hz), 6.26 (d, 2H, J = 1.8 Hz), 4.27 (dd, 1H, J_1 = 6.2 Hz, J_2 = 7.4 Hz), 3.80 (s, 3H), 3.71 (s, 6H), 3.17 (s, 3H), 3.06 (dd, 1H, J_1 = 13.4 Hz, J_2 = 7.4 Hz), 2.80 (dd, 1H, J_1 = 13.4 Hz, J_2 = 6.2 Hz). ^{13}C NMR δ: 160.4, 159.1, 140.9, 133.6, 128.0, 113.7, 107.4, 98.3, 84.4, 56.5, 55.2 (two signals), 45.0. GC–MS (m/z): 302 (not observed), 286 (9.3), 270 (6.7), 165 (11.5), 151 (29.8), 122 (9.2), 121 (100.0). HR-MS calcd.: 302.1518; found: 302.1526 ± 0.0008.

2-(3,5-Dimethoxypheny)-1-(4-methoxyphenyl)-1-(trifluoroethoxy)ethane (19b)

This compound was prepared using the method of Falck et al. (17). To a solution of 2-(3,5-dimethoxyphenyl)-1-(4-methoxyphenyl)ethan-1-ol 25 (0.300 g, 1.04 mmol) in benzene (20 mL) was added 1,1′-(azodicarbonyl)dipiperidine (0.525 g, 2.08 mmol). The flask was purged with nitrogen for 10 min, and tri(n-butyl)phosphine (0.421 g, 2.08 mmol) was added. After stirring the reaction mixture for another 15 min, TFE (1.04 g, 10.4 mmol) was added. The mixture was stirred at room temperature for 1 h, and the solvent was then removed under reduced pressure. The residue was taken up in dichloromethane, filtered, and the liquid then adsorbed onto silica gel for column chromatography. Elution with 5% ethyl acetate – hexanes gave the desired product (0.210 g,

55% yield). ^{1}H NMR δ: 7.16 (d, 2H, J = 9.2 Hz), 6.30 (d, 2H, J = 9.2 Hz), 6.31 (t, 1H, J = 1.8 Hz), 6.29 (d, 2H, J = 1.8 Hz), 4.50 (dd, 1H, J_1 = 5.5 Hz, J_2 = 7.3 Hz), 3.80 (s, 3H), 3.72 (s, 6H), 3.62 (m, 2H), 3.14 (dd, 1H, J_1 = 14.0 Hz, J_2 = 7.3 Hz), 2.83 (dd, 1H, J_1 = 14.0 Hz, J_2 = 5.5 Hz). ^{13}C NMR δ: 160.5, 159.6, 140.1, 132.0, 128.1, 124.0 (q, J = 278.6 Hz), 114.0, 107.4, 98.8, 84.1, 65.8 (q, J = 34.3 Hz), 55.3, 55.2, 44.8. GC–MS (m/z): 370 (1.1), 271 (5.8), 270 (27.6), 220 (10.6), 219 (100.0), 135 (27.3). HR-MS calcd.: 370.1392; found: 370.1389 ± 0.0008.

trans-1-(3,5-Dimethoxyphenyl)-2-(4-methoxyphenyl)ethene (20)

A solution of 1-(3,5-dimethoxyphenyl)-2-(4-methoxyphenyl)ethan-1-ol 15 (4.00 g, 13.9 mmol) in benzene (600 mL) was prepared in a three-necked round-bottomed flask. A portion of p-toluenesulfonic acid (0.29 g, 1.5 mmol) was added, and the solution was heated to reflux with stirring. Water was removed from the mixture by way of a Dean–Stark trap. After 6 h, analysis by GC–MS indicated that 97% of the starting material had reacted, and the reaction mixture was allowed to cool to room temperature. The solution was then washed with distilled water, and saturated sodium chloride solution (2 × 200 mL each). A portion of benzene (100 mL) was used to reextract the aqueous washes. The combined organic material was then dried with anhydrous magnesium sulfate, filtered, and the solvent was removed under reduced pressure to give an orange oil. Isolation of the desired product was achieved using column chromatography with 20% ethyl acetate – hexanes (eluant). Recrystallization of the resulting product from pentane gave white crystals (1.27 g, 34% yield), mp 55–57°C, lit. (24) mp 53–54°C. ^{1}H NMR δ: 7.43 (d, 2H, J = 8.6 Hz), 7.05 (d, 1H, J = 16.5 Hz), 6.91 (d, 1H, J = 16.5 Hz), 6.90 (d, 2H, J = 8.6 Hz), 6.65 (d, 2H, J = 2.4 Hz), 6.38 (t, 1H, J = 2.4 Hz), 3.83 (s, 9H). ^{13}C NMR δ: 161.0, 159.4, 139.7, 129.9, 128.7, 127.8, 126.6, 114.1, 104.3, 99.6, 55.4, 55.3. GC–MS m/z: 271 (17.6), 270 (100.0), 269 (15.5), 239 (19.7), 224 (13.0), 196 (12.7), 195 (12.33), 165 (10.3), 153 (12.4), 152 (17.6), 141 (10.5). HR-MS calcd.: 270.1256; found: 270.1263 ± 0.0008.

cis-1-(3,5-Dimethoxyphenyl)-2-(4-methoxyphenyl)ethene (21)

A solution of trans-1-(3,5-dimethoxyphenyl)-2-(4-methoxyphenyl)ethene 20 (0.40 g, 1.5 mmol) in acetonitrile (340 mL) was prepared in a large photolysis reaction vessel, and purged with nitrogen for 30 min. A 450 W, medium-pressure Hanovia mercury lamp with a Pyrex filter (300 nm cut-off) was employed to irradiate the solution for 30 min. Analysis by GC-FID indicated that by this time the mixture had achieved a photostationary state consisting of a 2:1 ratio of the cis and trans isomers. The solvent was removed under reduced pressure, and the residue was prepared for column chromatography. Separation of the isomers was achieved using 2.5% ethyl acetate – hexanes (eluant), and the pure cis isomer was isolated as a clear oil (0.15 g, 38% yield). ^{1}H NMR δ: 7.19 (d, 2H, J = 8.5 Hz), 6.78 (d, 2H, J = 8.5 Hz), 6.52 (d, 1H, J = 12.2 Hz), 6.44 (d, 1H, J = 12.2 Hz), 6.43 (d, 2H, J = 2.4 Hz), 6.32 (t, 1H, J = 2.4 Hz), 3.78 (s, 3H), 3.67 (s, 6H). ^{13}C NMR δ: 160.6, 158.7, 139.5, 130.3, 130.2, 129.6, 128.7, 113.5, 106.6, 99.7, 55.2. GC–MS m/z: 271

(16.44), 270 (100.0), 269 (17.5), 239 (22.5), 224 (14.5), 165 (10.6), 153 (12.7), 152 (18.6), 141 (10.6), 127 (11.2), 115 (14.6). HR-MS calcd.: 270.1256; found: 270.1254 ± 0.0008.

2,4,6-Trimethoxyphenanthrene (22)

A solution of *trans*-1-(3,5-dimethoxyphenyl)-2-(4-methoxyphenyl)ethene **20** (0.30 mg, 1.1 mmol) in methanol (340 mL) was prepared in a large photolysis reaction vessel. To promote the formation of the desired product, no nitrogen was used. A 450 W, medium-pressure Hanovia mercury lamp with a Pyrex filter (280 nm cut-off) was employed to irradiate the solution for 7 h. The solvent was removed under reduced pressure, and the residue was adsorbed onto silica and placed at the top of a dry-flash column (2 cm diameter, 7.5 cm length). Elution with 2.5% ethyl acetate – hexanes gave 0.10 g of a white solid. Recrystallization from methanol gave the desired product as clear crystals (0.076 g, 25% yield), mp 111–113°C. ^{1}H NMR δ: 9.08 (d, 1H, J = 2.8 Hz), 7.76 (d, 1H, J = 8.8 Hz), 7.65 (d, 1H, J = 8.6 Hz), 7.49 (d, 1H, J = 8.8 Hz), 7.17 (dd, 1H, J_1 = 2.8 Hz, J_2 = 8.6 Hz), 6.88 (d, 1H, J = 2.7 Hz), 6.74 (d, 1H, J = 2.7 Hz), 4.10 (s, 3H), 3.99 (s, 3H), 3.95 (s, 3H). ^{13}C NMR δ: 161.9, 160.0, 158.2, 158.1, 136.0, 131.6, 129.4, 128.1, 124.5, 115.4, 114.7, 109.6, 101.3, 99.0, 55.8, 55.4, 55.3. GC–MS (*m/z*): 269 (18.1), 268 (100.0), 225 (16.4), 210 (22.7), 152 (15.6), 139 (18.2). HR-MS calcd.: 268.1099; found: 268.1112 ± 0.0008.

1-(3,5-Dimethoxypheny)-2-(4-methoxyphenyl)ethane (23)

A solution of 1-(3,5-dimethoxyphenyl)-2-(4-methoxyphenyl)-1-methoxyethane **18a** (0.0523 g, 0.173 mmol) in methanol (50 mL) was prepared and poured into a quartz reaction vessel. After purging with nitrogen gas for 30 min, the stirred solution was irradiated for 5 h at 25°C. The solvent was removed under reduced pressure, and the residue was purified by column chromatography (2.5% ethyl acetate– hexanes, eluant) to give the desired product (0.020 g, 42% yield). ^{1}H NMR δ: 7.10 (d, 2H, J = 8.5 Hz), 6.83 (d, 2H, J = 8.5 Hz), 6.33 (s, 3H), 3.79 (s, 3H), 3.77 (s, 6H), 2.84 (s, 2H). ^{13}C NMR δ: 160.7, 157.87, 144.3, 133.8, 129.4, 113.8, 106.5, 97.9, 55.3, 55.2, 38.5, 36.8. GC–MS (*m/z*): 273 (2.1), 272 (11.4), 151 (2.0), 122 (9.1), 121 (100.0).

2-(3,5-Dimethoxypheny)-1-(4-methoxyphenyl)propane (24)

This photoproduct was not synthesized or isolated; thus, the identification rests solely on the GC–MS spectrum (*m/z*): 287 (2.3), 286 (12.0), 165 (15.0), 122 (10.2), 121 (100.0). The molecular ion of *m/z* 286 and the major fragment ions of *m/z* 165 and *m/z* 122 (the two possible benzylic carbocations that may be formed by cleavage of the molecular ion) strongly support the assignment.

Photolysis procedures

In all four photolysis reactions, a similar procedure was used. The solid starting material (**1**: 100 mg, 0.30 mmol; **20**: 50 mg, 0.20 mmol) was placed in a 100 mL volumetric flask, and the flask was filled to the mark with the solvent of interest. After the substrate was fully dissolved, the solution was poured into a quartz reaction vessel and purged with nitrogen for 30 min. The solution was thermostated at 25°C with an immersion circulating water tube, and mixed with a magnetic stirrer. In the reactions involving **20**, an equimolar

amount of acetic acid (11 µL, 0.20 mmol) was added to the solution, and the solution was stirred overnight to check for the presence of ground-state reactions (none were found). The photolyses were performed using a Rayonet reactor with 10 low-pressure mercury lamps (254 nm emission). While the reaction was in progress, 1 mL samples were analyzed using the GC conditions outlined above.

The purified photoproducts were used to obtain calibrations for the GC-FID response of each compound as a function of concentration. These calibrations were then used to convert the peak areas from the reaction chromatograms to concentrations. The concentrations of the components were then converted to percentages based on the initial concentration of the starting material and the amount of material consumed during the reaction.

Laser flash photolysis of **1** was performed using a 2.28 × 10^{-4} M solution in TFE, which had an absorbance of 0.45 at 266 nm. A portion of this solution was excited using a Continuum Nd:Yag NY-61 laser (266 nm, <8 ns/pulse, ≤15 mJ/pulse). Several time domains (10 ns to 50 µs) were used, as well as three different conditions: air-saturated, nitrogen-saturated, and oxygen-saturated.

The photo-NOCAS reaction: Trapping an intermediate

Robert M. Borg, Danielle Franke, and Adrian Vella

Abstract: Irradiation of a mixture of 1,4-dicyanobenzene, phenanthrene, and 2,3-dimethyl-2-butene in acetonitrile–methanol solvent in the presence of acrylonitrile or methyl acrylate leads to a diversion from the usual photo-NOCAS product formation towards products that result from the formal addition of methanol and electrophilic alkenes to the butene.

Key words: photo-NOCAS, photoinduced electron transfer, photosubstitution, photoaddition, redox photosensitization, alkene, 2-methoxyalkyl radical.

Résumé : L'irradiation d'un mélange de 1,4-dicyanobenzène, de phénanthrène et de 2,3-diméthylbut-2-ène dans un mélange d'acétonitrile et de méthanol, en présence d'acrylonitrile ou d'acrylate de méthyle conduit à la formation d'un produit de photo-NOCAS qui diffère du produit usuel et qui résulte de l'addition formelle de méthanol et d'alcènes électrophiles au butène.

Mots clés : photo-NOCAS, transfert d'électron photoinduit, photosubstitution, photoaddition, photosensibilisation redox, alcène, radical 2-méthoxyalkyle.

[Traduit par la Rédaction]

Introduction

The photo-NOCAS reaction is a well-established one with numerous examples having appeared in the literature (1). The acronym stands for nucleophile-olefin combination aromatic substitution, and was proposed by Arnold (2) to represent a class of photosubstitution reactions that was first discovered in his laboratories almost 20 years ago (3). Such a reaction is depicted in Scheme 1. As the mechanistic scheme illustrates, irradiation of the redox photosensitizer phenanthrene (**1**) leads to electron transfer between the first excited singlet state of **1** and 1,4-dicyanobenzene (**2**). The ensuing radical cation of **1** then serves to generate the radical cation of 2,3-dimethyl-2-butene (**3**) by means of a secondary electron transfer step. Nucleophilic interception of the radical cation of **3** by methanol, followed by deprotonation and coupling of the resulting radical **4** with the radical anion of **2** and loss of cyanide ion, leads to the photo-NOCAS product **5** in high yield (3).

R.M. Borg,[1] D. Franke, and A. Vella. Department of Chemistry, University of Malta, Msida, Malta MSD 06.

[1]Corresponding author (e-mail: robert.m.borg@um.edu.mt).

[2]The reduction potential for the *tert*-butyl radical has been estimated to be around –2.5 V vs. Ag (4). In comparison, the reduction potential for **2** has been measured as –2.0 V vs. Ag (3).

[3]The reduction potential for the 1,1-diphenylethyl radical has been measured as –1.61 V vs. Ag (4).

The alkoxy-substituted radical **4** is a proposed key intermediate in the reaction, and does not undergo reductive back electron transfer (BET) upon encountering the radical anion of **2**, since it is well-known that tertiary alkyl radicals are more difficult to reduce than **2**.[2] This is in contrast with similar phenylated radicals, where BET *does* occur,[3] and is followed by protonation, leading to the overall *anti-Markovnikov* addition of methanol (and no NOCAS-type products), as illustrated for 1,1-diphenylethene (**6**) in Scheme 2 (5). For this reason, reports on the photosensitized (electron transfer) simple addition of nucleophiles to alkylated olefins are few, and in those cases involve strained alkenes (1*b*, 1*c*, 6).

It occurred to us that it might be possible to intercept radical intermediates such as **4** before coupling with the cyanoaromatic radical anion takes place. We now wish to describe the trapping of the alkoxy-substituted radical **4** by means of electron-poor olefins.

Results and discussion

A mixture of phenanthrene (**1**), 1,4-dicyanobenzene (**2**), 2,3-dimethyl-2-butene (**3**), and acrylonitrile (**8a**) dissolved in acetonitrile:methanol (3:1 by volume) was irradiated for 16 h by means of a 400 W medium pressure mercury lamp through Pyrex ($\lambda > 280$ nm). Monitoring of the reaction by gas chromatography (GC) revealed that formation of the usual photo-NOCAS product (**5**) had been suppressed, and that a major new peak at shorter retention time had appeared. Evaporation of solvent in vacuo, followed by hexane extraction of the photolysates, resulted in the isolation of a yellow liquid which was vacuum distilled to afford a colourless oil. Repetition of the above procedure in the presence of methyl acrylate (**8b**), instead of acrylonitrile, resulted in the

Scheme 1.

Scheme 2.

S = Biphenyl

Scheme 3.

isolation of another colourless oil. Dark control experiments established the photochemical nature of the process; furthermore, the products were not formed in the absence of **2**, and yields were lower and the reactions inefficient in the absence of phenanthrene (**1**).

The two major new photoproducts were identified as 5-cyano-2-methoxy-2,3,3-trimethylpentane (**9a**) and methyl 5-methoxy-4,4,5-trimethylhexanoate (**9b**), respectively, (Scheme 3), by spectroscopic techniques. Thus, for example, the 250 MHz ^{1}H NMR spectrum obtained for **9a** exhibits, besides three singlets for the methyl and methoxy groups, an AA′BB′ non-first-order system of two multiplets at δ1.76 and 2.39. This is typical of adjacent methylene groups where the geminal protons in each group are magnetically nonequivalent (7). The spectrum for **9b** is practically identical, except for an additional sharp singlet at δ 3.67. The presence of a cyano group is clearly indicated by the sharp absorption peak at 2244 cm^{-1} in the IR spectrum of **9a**, whilst **9b** gives an ester carbonyl stretch signal at 1740 cm^{-1}. Other spectro-

scopic data (given below) are also in accordance with the proposed structures.
When the above irradiations were attempted with 1,1-diphenylethene (**6**) as the electron-rich alkene, instead of 2,3-dimethyl-2-butene (**3**) (and with biphenyl as the redox photosensitizer), only the anti-Markovnikov adduct 2,2-diphenylethyl methyl ether ((**7**), Scheme 2) was formed (5), both in the absence and presence of either acrylonitrile (**8a**) or methyl acrylate (**8b**). No products analogous to **9a** and **9b** could be detected.

In accordance with the established mechanism (3) for the photo-NOCAS reaction (Scheme 1) we are suggesting that the introduction of electron-poor alkenes into the reaction mixture allows the interception of the alkoxy-substituted radical **4**.[4,5] This results in the formation of a cyano- (or carboxymethyl-) centered radical intermediate (**10**) whose reduction potential clearly is less negative than that of **4**.[6] Upon encounter with the dicyanobenzene radical anion, therefore, BET to **10** occurs in preference to addition as occurs with **4**. Protonation of the resulting anion leads to the final products (Scheme 4).

At first glance, it seems remarkable that the reactions being reported here proceeded as desired, in view of the complex nature of the reaction mixture. In fact, the material balance is not a good one. The electron-poor alkenes had to be replenished several times during the photolysis, as it was

[4] The alternative scenario, i.e., interception of the radical cation of **3** by **8a** or **8b**, followed by nucleophilic attack by methanol cannot be ruled out. However, since the bimolecular rate constant for attack by methanol on phenylated alkene radical cations has been estimated to be as high as 1×10^9 M^{-1} s^{-1} (8), then with methanol at solvent concentrations, nucleophilic capture should compete easily with other processes.

[5] Albini has described the similar trapping of radicals generated via photoinduced electron transfer (9).

[6] The reduction potential of the cyanomethyl radical has been estimated to be –0.97 V vs. Ag (1c).

Scheme 4.
observed that they were being consumed at a much faster rate than that for product formation. Inspection of the photolysates and distillation residues by ^{1}H NMR spectroscopy revealed the presence of complex aliphatic mixtures that could not be analysed by GC. Presumably, these might be polymers and (or) oligomers of acrylonitrile (**8a**) or methyl acrylate (**8b**). A reaction mixture in which radical ions are formed might involve the electrophilic alkenes at a stage other than that shown in Scheme 4. For example, upon excitation of phenanthrene (**1**) to the first excited singlet state, electron transfer might occur to **8a** or **8b** in competition with transfer to 1,4-dicyanobenzene (**2**). The radical anions of these alkenes might even be formed via electron transfer from the dicyanobenzene radical anion. Either of these processes seems unlikely. The reduction potentials of both **8a** ($E_{1/2}^{red}$ = –2.7 V, vs. Ag) (10) and **8b** ($E_{1/2}^{red}$ = –2.6 V, vs. Ag) (10) are substantially more negative than that for **2** ($E_{1/2}^{red}$ = –2.0 V, vs. Ag) (3). Use of these values in the Weller equation (11) gives theoretical free energy changes for electron transfer from the excited singlet of **1** to either **8a** or **8b** that are appreciably positive.[7] However, it has been reported (12) that acrylonitrile (**8a**) quenches the excited state of anthracene with a (albeit low) rate constant of ca. 1×10^7 M^{-1} s^{-1}, in an initiation step leading to polymerization. Conceivably, a similar pathway involving phenanthrene might lead to oligomers and (or) polymers in the current systems. This is reinforced by the observation that irradiation of **8a** or **8b** in the presence of phenanthrene in acetonitrile–methanol solution leads to the formation of a gummy residue whose ^{1}H NMR spectrum closely resembles that obtained in the above photolysis.

The negative results obtained with 1,1-diphenylethene might be interpreted as an indication that back electron transfer from the dicyanobenzene radical anion to the 1,1-diphenylethyl-2-methoxy radical intermediate (Scheme 2) is fast. This is probably both a consequence of the relatively

high reduction potential of **2** and the relative ease of reduction of this radical.[3] Attempts to lessen the rate of this BET step through the use of a cyanoaromatic with a lower reduction potential such as 9,10-dicyanoanthracene ($E_{1/2}^{red}$ = –1.2 V vs. Ag (13)) proved unsuccessful.

Experimental

Phenanthrene (BDH Chemicals Ltd.) and 1,4-dicyanobenzene (Aldrich Chemical Co. Ltd.) were recrystallized three times from 96% ethanol. Acrylonitrile (Aldrich) and methyl acrylate (BDH) were distilled before use. 2,3-Dimethyl-2-butene and 1,1-diphenylethene (both Aldrich) were used as received. Acetonitrile (Rathburn, HPLC grade) was purified by elution through an activated alumina column, followed by reflux and distillation over calcium hydride. Methanol (Aldrich, analytical grade) was used as received.

Irradiations were carried out in Pyrex tubes at 15°C ± 5° by means of a water-cooled 400 W medium pressure mercury lamp (Photochemical Reactors Ltd.). Typically, 0.3 g of **1**, 1.1 g of **2**, and 1 g of **3** were dissolved in 25 mL of a 3:1 mixture of acetonitrile:methanol containing either 1.4 g of **8a** or 2.2 g of **8b**. During irradiation of the mixture, the progress of the reaction was monitored by GC (BP1, 50 m × 0.22 mm). At ca. 4-h intervals, the rapidly decreasing concentration of the trapping alkene **8a** (or **8b**) was restored by the addition of 0.5 g aliquots. When product formation had ceased, the solvent was removed in vacuo, and the resulting mixture of oil and solid was extracted with hexane. Evaporation of the hexane extracts, followed by vacuum distillation of the resulting yellow oil, led to the isolation of the product as a colourless oil.

5-Cyano-2-methoxy-2,3,3-trimethylpentane (9a)
Yield: 1.27 g (63%),[8] bp 88–96°C (ca. 0.1 mmHg (1 mmHg = 133.322 Pa)). MS (EI) m/z (%): 169 (1), 154 (8), 138(2), 115 (2), 96 (2), 83 (4), 73 (100), 69 (3), 55 (9), 30 (8). HR-MS (FAB) calcd. for C$_{10}$H$_{20}$NO (i.e., M + 1): 170.15447; found: 170.15438.

Methyl 5-methoxy-4,4,5-trimethylhexanoate (9b)
Yield: 0.86 g (35%),[8] bp 84–106°C (ca. 0.1 mmHg (1 mmHg = 133.322 Pa)). IR (NaCl) cm^{-1} ν: 2975, 2952, 2826, 1740, 1476, 1392, 1375, 1366, 1248, 1195, 1147, 1123, 1073. ^{1}H NMR (250 MHz, CDCl$_3$–TMS) δ: 3.67 (s, 3H), 3.16 (s, 3H), 2.33 (m, 2H), 1.69 (m, 2H), 1.09 (s, 6H), 0.86 (s, 6H). ^{13}C NMR (62.9 MHz, CDCl$_3$–TMS) δ: 175.3, 79.2, 51.5, 49.1, 40.1, 32.3, 30.3, 21.8, 19.1. MS (EI) m/z (%): 202 (3), 187 (19), 178 (16), 171 (13), 123 (21), 115 (10), 95 (20), 83 (13), 74 (25), 73 (100), 69 (16), 51 (17), 30

---

[7] ΔG was estimated to be +41 and +31 kJ mol^{-1}, respectively, using the value of 346 kJ mol^{-1} for the first singlet of **1**, and an oxidation potential of +1.31 V vs. Ag (3).

[8] Due to its volatility, unconsumed residual 2,3-dimethyl-2-butene (**3**) (as revealed by GC) was not recovered during work-up. These are therefore minimum yields, based upon the theoretical total consumption of (**3**).

(17). HR-MS (FAB) calcd. for $C_{11}H_{22}NaO_3$ (i.e., M + Na): 225.14665; found: 225.14662.

Conclusion

It has been demonstrated that the photo-NOCAS reaction can be diverted from the final substitution step by interception with electron-poor alkenes. In spite of the poor material balance, the reactions described here not only provide further evidence for the proposed mechanism of the photo-NOCAS reaction, but lead to convenient yields of products that are not trivially synthesized by other routes.[9] Ongoing studies in our laboratories are focusing on other alkene–nucleophile systems so as to further define the scope and limitations of these reactions.

[9]Giese (14) has described the synthesis of similar compounds via the methoxymercuration reaction of alkenes, followed by reduction in the presence of methyl acrylate. However, his method fails with tetra-substituted alkenes.

C-H⋯H-C interactions in organoammonium tetraphenylborates: another look at dihydrogen bonds

Katherine N. Robertson, Osvald Knop, and T. Stanley Cameron

Abstract: The crystal structures of the tetraphenylborates of the dabcoH⁺, guanidinium (MeCN solvate), and biguanidinium cations are shown to contain a variety of C-H⋯H-C dihydrogen (DB) bonds of nominally zero polarity, as well as a variety of N-H⋯N, C-H⋯N, N-H⋯Ph, and C-H⋯Ph hydrogen (HB) bonds. These intermolecular bonds have been characterized topologically after multipole refinement of the structures. The coexistence of the DBs and HBs in each of the structures makes it possible to establish their relative strength hierarchy. It also illustrates the importance of the DBs in satisfying the tendency of these structures to maximize the total intermolecular bonding engagement. To compare the above DBs with other DBs, the results of an extensive set of MP2/6-31G(d,p) calculations (supplied by I. Alkorta) were analyzed for reference correlations between the bond-critical parameters. Thus, for an X-H⋯H-Y bond, the difference $\Delta\varepsilon(H)_m$ between the Mulliken charges on the H atoms in the uncomplexed X-H and H-Y components correlates quite well with the X-H⋯H-Y parameters and can be used for predicting the topological strength of an X-H⋯H-Y bond. The use of the difference $\Delta\varepsilon(H)_c$ *in the bond* does not appear to change the correlation significantly; closer correlations are observed when the amount of charge transferred on formation of the H⋯H bond is used instead of $\Delta\varepsilon(H)_m$ or $\Delta\varepsilon(H)_c$. Bonding interactions are obtained even between like or symmetry-related H atoms as a consequence of induced-dipole interactions, which accounts for the existence of the above intermolecular C-H⋯H-C bonds with $d(H⋯H) = 2.18–2.57$ Å, electron density at the bond-critical point of ~0.05–0.08 e/Å³, and a rough estimate of the H⋯H binding energy of ~1–5 kcal/mol. Examination of the bond-critical parameters of X-H⋯H-Y bonds also suggests a criterion of stability of these bonds with respect to the transition from non-shared (closed-shell) X-H⋯H-Y interaction to covalent (shared-shell) X⋯H-H⋯Y interaction. This transition appears to be discontinuous.

Key words: bond-critical parameters, bond topology, dihydrogen bonds, hydrogen bonds, organoammonium tetraphenylborates.

Résumé : On a démontré que les structures cristallines des tétraphénylborates des cations dabcoH⁺, guanidium (solvaté avec du MeCN) et biguanidinium comportent une variété de liaisons dihydrogènes (DB) C-H⋯H-C de polarité nominale nulle ainsi que des liaisons hydrogène (HB) de N-H⋯H, C-H⋯H, N-H⋯Ph et C-H⋯Ph. On a caractérisé ces liaisons intermoléculaires d'une façon topologique après un affinement multipolaire des structures. La coexistence de DB et de HB dans chacune de ces structures permet d'établir la hiérarchie de leurs forces relatives. Elle illustre aussi l'importance des DB pour satisfaire la tendance de ces structures à maximiser l'engagement de liaison intermoléculaire total. Dans le but de comparer les DB observées plus haut avec d'autres DB, on a analysé les résultats d'un grand nombre de calculs effectués au niveau MP2/6-31G(d,p) (fournis par I. Alkorta) pour trouver des corrélations de référence entre des paramètres critiques pour les liaisons. Ainsi, pour une liaison X-H⋯H-Y, il existe une bonne corrélation entre la différence $\Delta\varepsilon(H)_m$ entre les charges de Mulliken sur les atomes dans les composants X-H et H-Y non complexés et les paramètres X-H⋯H-Y et elle peut être utilisée pour faire des prédictions relatives à la force topologique d'une liaison X-H⋯H-Y. Il ne semble pas que la corrélation change de façon significative si on utilise la différence $\Delta\varepsilon(H)_c$ dans la liaison; de meilleures corrélations peuvent être obtenues par l'utilisation de la quantité de charge transférée lors de la formation de la liaison H⋯H au lieu des $\Delta\varepsilon(H)_m$ ou $\Delta\varepsilon(H)_c$. On obtient des interactions de liaison même avec des atomes H semblables ou apparentés par symétrie en raison des interactions entre dipôles induits qui expliquent l'existence des liaisons intermoléculaires C-H⋯H-C rapportées plus haut avec un $d(H⋯H) = 2,18–2,57$ Å, la densité électronique au point critique de liaison d'environ 0,05–0,08 e/Å³ et une évaluation approximative de l'énergie de liaison H⋯H d'environ 1,5 kcal/mol. L'examen des paramètres critiques de liaison des liaisons X-H⋯H-Y suggère aussi un critère de stabilité de ces liaisons par rapport à la transition d'interaction non partagée (couche fermée) X-H⋯H-Y à interaction covalente (couche partagée) X⋯H-H⋯Y. Cette transition semble discontinue.

Introduction

In this paper we describe and discuss features that are observed in the electron-density distributions of C-H⋯H-C groupings in the recently determined[2] crystal structures of three organoammonium tetraphenylborates, and which point to the existence of bonding interactions between the hydrogen atoms. Numerous examples of presumed X-H⋯H-Y bonding interactions (termed "dihydrogen bonds", DB, in ref. 2 and provisionally referred to as "bonds" in the following) have been reported previously (cf. refs. 3–9 for comprehensive reviews). These rely almost entirely on the evidence provided by unusually short H⋯H distances rather than on detailed topological criteria, or by ab initio energies of formation (cf. refs. 10–38 for mostly experimental results and refs. 39–67 for theoretical aspects). It has been largely (though not always, e.g., refs. 8 and 39) assumed that these interactions depend for their existence and strength on the "polarity" of the H⋯H group, i.e., on the observed or postulated non-negligible difference $|\Delta\varepsilon(H)|$ between the net (usually Mulliken) charges $\varepsilon(H)$ on the two H atoms. There is thus a "donor" H_d and an "acceptor" H_a atom in the pair. In the tetraphenylborates, the distinctive feature of the C-H⋯H-C bonds is the *smallness* of $|\Delta\varepsilon(H)|$. With one exception, the bonds are formed between C-H groups of phenyl rings on neighbouring BPh_4^- anions; the net charges on the H atoms are very small to begin with (68) and so their differences are even smaller. This contrasts with the previously reported examples of DBs, in most of which $|\Delta\varepsilon(H)|$ is appreciable (but see ref. 38). In the following we report details of our observations and discuss geometric and topological arguments for and against interpreting these interactions as *bonds*.

The interatomic distances d in this paper are in Å, the electron density $\rho_c = \rho(r_c)$ at the bond-critical point (BCP) is in e/Å^3, the Laplacian $\nabla_c^2 = \nabla^2\rho(r_c)$ is in e/Å^5, and the net (Mulliken) atom charge on H, $\varepsilon(H)$, is in e. Standard deviations σ_f of fit (for *f* degrees of freedom) are quoted also as a percent of the observed range of the dependent variable, thus $\sigma_{25} = 0.063 \sim 3.5\%$. The following shorthand notation is used: $d_H = d(H\cdots H)$, $\rho_H = \rho_c(H\cdots H)$, $\nabla_H^2 = \nabla_c^2(H\cdots H)$, etc. Where these quantities refer exclusively to the ab initio values in Table 1, they are designated as d_A, ρ_A, etc. In composite plots, where parameters from two or more data sets are included, a non-discriminatory common parameter label (e.g., ρ_c) stands for any of the set-specific labels, such as ρ_H, ρ_A, etc. The optimizations listed in Table 1 with A as the sole reference were carried out at the MP2/6-31G(d,p) level, without basis set superposition error (BSSE) corrections and were not checked by frequency calculations.

Evidence of H⋯H (set H) and other (set E) intermolecular bonding interactions

It is now widely accepted that, for a chemical bond between two atoms X and Y to exist, the electron-density dis-

tribution between X and Y has to satisfy certain requirements. These requirements have been formulated by Bader in his "Atoms in Molecules" (AIM) theory (69–72). They are, for the purposes of this investigation, concisely summarized in refs. 48 and 71. The principal topological requirement is the existence of a clearly characterized bond path BP between X and Y and of a (3,–1) BCP in this path. Association of the BP with an actual *bond* and the corresponding bond energy is easily demonstrated for classical chemical bonds but not so easily for very weak hydrogen bonds and a fortiori for DBs (5). The evidence for the existence of C-H⋯H-C bonds, presented in the following, is essentially geometric and topological in nature.

The three salts we have investigated are 1-azonia-4-azabicyclo[2.2.2]octane tetraphenylborate, (dabcoH$^+$)BPh$_4$ (DTB); guanidinium tetraphenylborate solvate, [C(NH$_2$)$_3$]BPh$_4$·MeCN (GTB); and biguanidinium tetraphenylborate, {[(H$_2$N)$_2$C-]$_2$-N}BPh$_4$ (BTB). Their crystal structures and topological features are described in detail separately,[2] as are particulars of the multipole refinements. Briefly, high-resolution X-ray diffraction data were collected at –120°C (or lower) using Mo Kα radiation. After data processing, a preliminary least-squares refinement with the conventional spherical model led to the determination of a scale factor, starting positions, and thermal parameters for the multipole refinement of each structure. The multipole refinements were performed using the XD software package (cited in ref. 2) and are described in detail elsewhere. Since neutron data were not available, hydrogen atom positions were constrained such that all X-H bond lengths corresponded to appropriate neutron values. The program XDGEOM of the XD package was used to search for the intermolecular (interion) contacts of 3 Å or less in each of the structures. The XDPROP program of the XD package was then used to search for critical points in the electron density distribution, generated from the final multipole model of each compound, for each of the located short contacts. Bond paths were also calculated using the XDPROP function of the XD package.

The structures were searched, among other things, for inter-ion and ion–solvent contacts (with H⋯Y distances shorter than 3 Å) between a hydrogen atom and any possible acceptor Y. The search included all inter-ion/solvent contacts but not intra-ion contacts. All eligible geometric contacts were then subjected to a topological investigation, which involved searching for BCPs and associated BPs between the atoms. Of the 43 geometrically close C-H⋯Y contacts investigated, all but one were found to have associated BCPs and BPs. Two new contacts were located in the topological search, for a total of 44 interactions of various types being studied. The interactions could be characterized in two ways:

(*i*) *Geometry.* Criteria have been developed to determine, with confidence, interaction type based solely on the geometry of the interaction.[2] For example, if in a C-H⋯Ph interac-

[d]A: these results were supplied, at the authors' request, by Dr. I. Alkorta by way of extension of ref. 42.[4] Remko's (47) MP2(Full)/6-31G(d) $d(H···H)$ values for linear **4**, **8**, **14**, and **17** are 1.889, 2.105, 2.116, and 2.271 Å, respectively (no imaginary frequencies).

[e]Optimized in MP2/6-31G(d,p); G_c(H–H) = 0.58466 au, K_c(H–H) = 0.58471 au.

tion the minimum H$_C$···C$_{ring}$ distance is longer than the corresponding H$_C$···H$_{ring}$ distance by 0.40 Å or more, then an H···H contact would be expected to occur.

(*ii*) *Bond path*. As described more completely elsewhere,[2] the H···H contacts always have BPs that begin at one H$_C$ atom and terminate at another H$_C$ atom, although they may follow either C-H bond for a portion of its distance.

Generally, there was good agreement between the two classification methods. For example, a total of 15 H···H con-

tacts were located by each method in the three structures: two in DTB, five in GTB, and eight in BTB (set **H**). They are reported in Table 2 (and in more detail in Table A), according to the C-H$_d$···H$_a$-C description that gives the best (largest) C-H···H angle. Only one H$_{anion}$···H$_{cation}$ contact was found (in DTB) and no H$_{ion}$···H$_{solvent}$ contact; the rest were of the H$_{anion}$···H$_{anion}$ type. Other types of contact identified in the structures included (N-)H···N, (N-)H···Ph, and (C-)H···Ph hydrogen bonds (set **E**, n = 27).[3] The bond-critical parameters of all the interactions studied are listed in Table B for

---

[3] In addition, nine (C-)H···N contacts were also found, and four of a type intermediate between H···H contacts and C-H···Ph bonds; these are not discussed here.

[a]Type of H atom on the phenyl ring.

[b]Internuclear H⋯H distance.

[c]In the multipole refinements the hydrogen atoms were placed at the appropriate neutron bond lengths; error estimates on distances and angles are not available. The standard error on the C-C bond lengths in the structures ranged from 0.001–0.005 Å and the standard error on the corresponding C-C-C bond angles ranged from 0.1–0.3°.

[d]Approximate $\Delta\varepsilon(H)_m$ from B3LYP/6-31G(d,p) optimization of BPh_4^- (68).

Fig. 1. C-H$_{cation}$⋯H$_{anion}$-C interaction in DTB (**d** in Table 2). Black dots indicate positions of the bond-critical points in the H⋯H contacts. Note that the Xn_atom label in the bond path diagrams refer to symmetry-generated atoms. Details for the generation of these atoms are given in the deposited material (Table A).

comparison.[4] All these contacts are fully described elsewhere;[2] here we give only a summary of the H⋯H parameters (Table 2) and a sample of interaction diagrams showing projections of the H⋯H BPs (Figs. 1–4).

The internuclear distances d_H in **H** are all shorter than 2.6 Å, the shortest being 2.18 Å (Table 2). The H⋯H contacts occur between all three types of phenyl hydrogens. The C-H⋯H angles vary from approximately 115° to 176°, without a detectable trend with d_H (cf. a similar observation for B-H⋯H and N-H⋯H angles, ref. 29). The observed H⋯H BPs always start at one H atom and end on another, but sometimes they are appreciably curved (Figs. 1–4).[5] In extreme cases the path starts out in the direction of the midpoint of a C-H bond, but just before its completion it veers sharply toward the H atom (cf. Fig. 4). The *length* of the BP then differs significantly from the *internuclear* H⋯H distance in Table 2. It is not simple to trace the actual length of a BP as the path curves in space, and its length projected on a plane containing the two H atoms provides only a minimum estimate of the actual length. Inspection of the complete BPs has shown that, on the average, the internuclear H⋯H distances underestimate the actual length by some 5–10%, i.e., ~0.22–0.25 Å. For a BP as curved as that in Fig. 4 there is also the question: how exactly should its length be measured? To the terminating H atom (BP longer) or to the point where the bond path first approaches the C-H bond (BP shorter)?

[4]Supplementary data may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada (http://www.nrc.ca/cisti/irm/unpub_e.shtml for information on ordering electronically). Tables deposited: A. Geometric and bond-critical parameters for the H⋯H interactions in the tetraphenylborates studied. B. Bond-critical parameters for all intermolecular interactions of 3 Å or less in the tetraphenylborates studied. Figures deposited: A to I. Bond path diagrams for all the experimental H⋯H interactions.

[5]*Intramolecular* C-H⋯H-C BPs with similar features have recently been observed in a variety of ab initio structures of benzenoid and other hydrocarbons by Matta et al. (38). For these, differences between the internuclear H⋯H distance and the actual BP length are reported to amount to as much as ~0.27 Å (i.e., ca. 13%; converted from au).

Fig. 2. C-H$_{anion}$···H$_{anion}$-C contacts to ring 1 in GTB (H23···H12, **e**; H13···H12, **k**; H14···H15, **h** in Table 2). The ring-critical points are not shown. Note one C-H···Ph HB is also formed.

Fig. 3. C-H$_{anion}$···H$_{anion}$-C contacts to ring 1 in BTB (H16···H15, **b**; H16···H16, **c**; H46···H13, **a**; H36···H14, **j** in Table 2). The ring-critical points are not shown.

Establishing a comparison norm (set A)

To position the DB parameters of Table 2 in the body of known DBs, it is desirable to establish some kind of reference norm. Experimental determinations of such parameters have been spotty (cf. ref. 28), and ab initio calculations are not always available at the same theory level, thus precluding systematic comparisons on equal footing. For our purposes a suitable norm is conveniently established with recourse to the ab initio calculations of Alkorta et al. (42), who studied, among other species, a number of linear X-H···H-Y complexes (Table 1). Additional calculations by Alkorta[6] have expanded the original MP2/6-31G(d,p) set to that presented in Table 1 and named set **A**.[7] Examination of **A** permits the following observations to be made:

(*a*) As would be expected, ρ_A increases monotonically with decreasing d_A (Fig. 5). This non-linear dependence can be represented by a power or an exponential function. A power regression yields

[1] $\rho_A = 0.717 d_A^{-3.113}$, $r^2 = 0.996$,

$$\sigma_{31} = 0.0240 \sim 1.3\%,$$

as against the exponential regression

[2] $\rho_A = 13.28 \exp(-2.727 d_A)$, $r^2 = 0.997$,

$$\sigma_{31} = 0.0204 \sim 1.1\%.$$

Although eq. [2] has a smaller σ, neither fit is entirely satisfactory, as, in modelling ρ_A, eq. [1] overestimates and eq. [2] underestimates ρ_A at large d_A, i.e., for weak DBs. The empirical hybrid function related to $\rho_A = 1/2$(eq. [1] + eq. [2]) but independently refined,

[3] $\rho_A = 0.313 d_A^{-3.001} + 8.038 \exp(-2.789 d_A)$

($r^2 = 0.999$, $\sigma_{29} = 0.0124 \sim 0.7\%$), gives a better result. It also closely accommodates the matching data point for the H$_2$ molecule (Table 1). Although eq. [3] provides an acceptable overall fit to d_A,ρ_A, a more detailed examination shows that the d_A,ρ_A set in fact has a structure that cannot be entirely ignored and that may be important.

(*b*) The ∇_A^2 vs. d_A plot (Fig. 6) is of the type observed for the (N-)H···N[8] and (F-)H···F (74) hydrogen bonds. The variation of ∇_A^2 with d_A over the considerable data range is approximated very well by the difference of two exponentials,

[4] $\nabla_A^2 = 57.52 \exp(-2.163 d_A)$

$$- 1779.4 \exp(-4.996 d_A),$$

$r^2 = 1.000$, $\sigma_{29} = 0.119 \sim 0.35\%$.[9] The regression line has a maximum of 1.253 at $d_A = 1.507$ and crosses the $\nabla_A^2 = 0$ line at $d_A = 1.212$. However, for $d_A > 1.3$Å (which would amply cover the present experimental range), the **A** set is more closely fitted by

---

[6] The authors are indebted to Dr. Ibon Alkorta for supplying, at their request, the MP2/6-31G(d,p) results for the complexes listed in Table 1 but not examined in ref. 42.

[7] MP2/6-31G(d,p) optimizations of CNH···HCN, HCCH···HCCF, HCCH···HCN, HCCH···HF, and H$_3$BH$^-$···$^+$HNF$_3$ were also attempted but failed to yield results suitable for inclusion in **A**.

[8] Ref. 73 and O. Knop, K.N. Rankin, and R.J. Boyd, to be published.

[9] This fit, while close, might perhaps be improved somewhat, arithmetically, by including a join function to bridge the low and the high d_A regions, analogous to (though conceptually different from) that employed in ref. 74 for fitting d_c,∇_c^2 of F-H···F *hydrogen* bonds.

Fig. 4. One of the C-H$_{anion}$···H$_{anion}$-C interactions in BTB (H44···H33, **l** in Table 2). The H···H bond path first heads toward the midpoint of the C33-H33 bond but then changes course and terminates at H33.

Fig. 5. Correlation of d_A and ρ_A (eq. [3]). Solid circles, LiH···HY; open circles, HBeH···HY; open squares, H$_3$BH$^-$···HY; open triangles, LiCCH···HY; solid triangles, H$_2$BH···HY; solid squares, H$_3$CH···HY; open diamond, H$_2$. Inset: location of the data points for sets **E** and **H** relative to the correlation lines A (thick), E (eq. [9], thin), and N (eq. [10], broken line). Solid circles, H···H (set **H**); open circles, (N-)H···N; open triangles, (N-)H···Ph; open squares, (C-)H···Ph; solid triangles B, C, P1, P2 (see text; footnote 10). Positions of group centroids are indicated by X.

[5] $\nabla_A^2 = -4.270 + 8.916d_A - 4.706(d_A)^2$
$+ 0.7461(d_A)^3$

($r^2 = 0.986$, $\sigma_{26} = 0.0329 \sim 3.9\%$). This partial regression appears to be better suited to the experimental range of d_c, ∇_c^2 values for H···H bonds. The statistical model function eq. [4] may be regarded as *formally* representing two opposing tendencies, which compensate each other at $\nabla_c^2 = 0$.

(*c*) An excellent cubic correlation over the entire ρ_A, ∇_A^2 data range is

[6] $\nabla_A^2 = 0.0743 + 9.859\rho_A - 23.61(\rho_A)^2$
$+ 4.450(\rho_A)^3$

($r^2 = 1.000$, $\sigma_{29} = 0.078 \sim 0.2\%$; Fig. 7), with a maximum of 1.139 at $\rho_A = 0.224$ and $\nabla_A^2 = 0$ at $\rho_A = 0.465$. The regression line constrained to pass through the origin is only slightly worse:

[7] $\nabla_A^2 = 10.58\rho_A - 24.57(\rho_A)^2 + 4.78(\rho_A)^3$

($r^2 = 1.000$, $\sigma_{29} = 0.092 \sim 0.3\%$; Fig. 7), with a ∇_A^2 maximum of 1.165 at $\rho_A = 0.231$ and $\nabla_A^2 = 0$ at $\rho_A = 0.474$. These regressions are compared with the corresponding regression for the (N-)H···N hydrogen bonds (set **N**, $n = 54$, MP2/6-31G(d,p);[8] Fig. 7),

[8] $\nabla_A^2 = 16.89\rho_N'' - 25.69(\rho_N'')^2$, $r^2 = 0.983$,
$\sigma_{51} = 0.531 \sim 3.8\%$.

Relative to the N curve, the A curves cross the $\nabla_A^2 = 0$ line sooner and fall off less sharply in the $\nabla_c^2 < 0$ region.

Each of the three heterocorrelations *a–c* thus finds its counterpart in the (N-)H···N (set **N**) and (F-)H···F (74) *hydrogen* bonds, so that, formally, there is no qualitative difference in the functional dependence between hydrogen and dihydrogen bonds.

Experiment vs. the ab initio norm

With the ab initio norm *a–c* established we can relate **A** to the experimental sets **H** and **E**, as well as to other experimental and ab initio results.[10]

The inset of Fig. 5 contains two kinds of comparison. First, it shows the experimental d_A, ρ_A data points of set **E**, i.e., for the topologically qualified (N-)H···N, (N-)H···Ph,

---

[10]There still is, in the literature, a scarcity of bond-critical parameter values for H···H bonds fully characterized by their BPs and BCPs, but the following (B, C, P1, and P2 in the plots; Figs. 5, 8, and 9) can be quoted for comparison. Point B refers to the (C-)H···H(-Mn) bond in CABNIC01 and CABNIC02 (28): $d_c = 2.12(1)$, $\rho_c = 0.066(5)$, $\nabla_c^2 = 0.79(3)$. Point C refers to the H9···H12 bond in the MP2/6-31G(d,p) optimized [Ir(H)$_3$(PH$_3$)$_2$(NHCHNH$_2$)] (60): $d_c = 1.818$, $\rho_c = 0.149$, $\nabla_c^2 = 1.060$. Point P1 refers to the (B1-)H3···H12(-N10) and point P2 to the (B9-)H15···H5(-N2) bond in the MP2/6-31G(d,p) optimized (H$_3$BNH$_3$)$_2$ dimer (48). For P1, $d_c = 1.726$, $\rho_c = 0.128$, $\nabla_c^2 = 1.118$; for P2, $d_c = 2.149$, $\rho_c = 0.065$, $\nabla_c^2 = 0.836$. The charges on the H atoms for P1 and P2 are AIM rather than Mulliken charges; they cannot be used with the latter in our correlations (personal communication from P.L.A. Popelier and refs. 76 and 77; cf. also ref. 52).

Fig. 6. Correlation of d_A and ∇_A^2 (eq. [4]). Inset: enlargement of the main plot for large d_A. The local cubic approximation eq. [5] is represented by the broken line. Symbols as in caption of Fig. 5.

Fig. 7. Correlation of ∇_c^2 and ρ_c for sets **A** (eq. [7]) and **N** (eq. [8], broken line). The N line terminates at the $\rho_S = 1.026$, $\nabla_S^2 = -10.22$ point for the symmetric hydrogen bond (75). Inset: enlargement for small ρ_A. Thin line, unconstrained regression eq. [6]; thick line, eq. [7]. Symbols as in caption of Fig. 5.

and (C-)H···Ph hydrogen bonds of Table B. Each group of contacts is cleanly separated from the other two and there is clear visual evidence that the (C-)H···Ph hydrogen bonds are weaker than the (N-)H···Ph bonds.[2] The 27 d_E,ρ_E data points can be fitted by a common exponential regression

[9] $\rho_E = 5.306 \exp(-1.639 d_E)$, $r^2 = 0.901$,

$$\sigma_{25} = 0.0114 \sim 6.9\%.$$

Second, the d_H,ρ_H points for the H···H contacts are compared with the ab initio norm (set **A**). They all fall above the A curve, but visually it is obvious that, as a group, they are closer to the A than to the E curve and, as measured by ρ_c, correspond to weaker interactions than do the hydrogen bonds of **E**. The experimental point B and the ab initio points C, P1, and P2 are consistent with the **H** set.[10] The regression line N for the ab initio set **N**,

[10] $\rho_N = 1.308 d_N^{-3.928} + 13.32 \exp(-2.580 d_N)$

($r^2 = 0.990$, $\sigma_{50} = 0.0334 \sim 3.3\%$) is below the E line, the difference arising partly from the underestimation of **N** in the MP2/6-31G(d,p) optimization.

The parallel comparison for d_H,∇_H^2 is shown in Fig. 8. The **H** points (Fig. 8*b*) are somewhat above line A (eq. [5]), but they and points B, C, P1, and P2 otherwise follow more or less the trend of line A. The disposition of the **E** points about their common regression line (Fig. 8*a*) again reveals a clean separation of the three classes of HBs, in the strength sequence (N-)H···N, (N-)H···Ph, (C-)H···Ph. The exponential regression shown for **E**,

[11] $\nabla_E^2 = 60.18 \exp(-1.733 d_E)$, $r^2 = 0.92$,

$$\sigma_{25} = 0.095 \sim 6.8\%,$$

coincides, over the data range, quite closely with the corresponding local cubic approximation eq. [5] (Fig. 6, inset). As in Fig. 5 (inset), the regression line for the **N** set in Fig. 8*a*,

[12] $\nabla_N^2 = 427.8 \exp(-2.671 d_N'')$

$$- 44515 \exp(-5.935 d_N'')$$

($r^2 = 0.985$, $\sigma_{50} = 0.515 \sim 3.7\%$), is below the E line.

For ρ_E,∇_E^2 (Fig. 9*a*) the separation of (N-)H···N, (N-)H···Ph, and (C-)H···Ph is also clean. The regression line E for this data set,

[13] $\nabla_E^2 = 8.91 \rho_E$, $r^2 = 0.90$, $\sigma_{25} = 0.110 \sim 8.0\%$,

is significantly below the ab initio curve N for the (N-)H···N bonds.[8] Unlike in Figs. 5 and 8, the **H** points in Fig. 9 are mixed up considerably with the points of **E**, mainly with those for the (C-)H···Ph bonds; points B, C, P1, and P2, not included in the regressions, appear to correspond to stronger H···H interactions. The lack of separation is consistent with the essentially similar character of the H···H and weak HBs.

At comparable d_c (Fig. 5, inset), ρ_c in set **H** is about half that in the (N-)H···Ph HBs. The ρ_H values that are observed at, say, ~0.05 e/Å³ in H···H bonds of ca. 2.4 Å length are comparable to the ρ_c values in (C-)H···Ph HBs of ca. 2.9 Å

Fig. 8. Location of the d_c, ∇_c^2 data points for sets **E** (*a*) and **H** (*b*) relative to the correlation lines A (eq. [4], thick), E (eq. [11], thin), and N (eq. [12], broken line). Symbols as in caption of Fig. 5 (inset).

Fig. 9. Location of the ρ_c, ∇_c^2 data points of sets **E** (*a*) and **H** (*b*) relative to the correlation lines A (eq. [7], thick), E (eq. [13], thin), and N (eq. [8], broken line). Symbols as in caption of Fig. 5 (inset).

length. The DBs are thus significantly weaker than the (N-)H···Ph or the (C-)H···Ph bonds in the three structures and weaker also than the H···H bonds in B, C, P1, and P2.[10] This is reflected more quantitatively in the positions of the centroids of the three groups of data points for sets **H** and **E** (Figs. 5 (inset), 8, and 9):[11]

	Type	n	$\bar{d}_c$	$\bar{\rho}_c$	$\bar{\nabla}_c^2$
Set **H**	(C-)H···H(-C)	15	2.37[11]	0.054[10]	0.51[12]
Set **E**	(N-)H···Ph	12	2.56[10]	0.079[17]	0.72[16]
	(C-)H···Ph	13	2.89[7]	0.048[7]	0.41[12]

[11]The corresponding centroids for the nine (C-)H···N hydrogen bonds (not discussed here;[3] Table B) are $\bar{d}_c$ = 2.82[12], $\bar{\rho}_c$ = 0.053[10], and $\bar{\nabla}_c^2$ = 0.54[9], respectively.

Fig. 10. (*a*) Correlation of d_A with $\Delta\varepsilon(H)_m$. Regression line Rl, eq. [14]. Solid diamonds, set **H**. (*b*) Correlation of d_A with $\Delta\varepsilon(H)_c$. Regression line R2: $d_A = 2.673 - 0.115 \exp[3.922\Delta\varepsilon(H)_c]$, $r^2 = 0.81$, $\sigma_{28} = 0.163 \sim 11\%$. Symbols as in caption of Fig. 5.

All three comparisons thus confirm the strength hierarchy[2] of the three types of HBs in **E** and testify to the non-negligible strength of the observed H···H interactions.

In Fig. 5 (inset) the **H** data points fall above their ab initio reference line A by roughly a similar amount as the **E** data points fall above the comprehensive ab initio reference line N for the (N-)H···N bonds[8] if N is taken as a common estimate of points of the **E** set. The discrepancy between the experimental points and the reference curve appears thus to arise mainly from inadequacies of the MP2/6-31G(d,p) model.

The lengths of the H···H contacts in **H** are not unusual among those reported from experiment for main-group X and Y. Ref. 9 suggests 1.7–2.2 Å for d(H···H) and 90–135° for X-H···H or H···H-Y as the overall range for DBs, with an upper limit of 2.65 Å in C-H···H-B bonds. More specifically, in adducts of $LiBH_4$ (27), $NaBH_4$ (25), and $NaCNBH_3$ (25), the range of (corrected) intermolecular distances is 1.62–2.28 Å. As for *intramolecular* H···H contacts, Matta et al. (38) find, in documented ab initio BPs in a variety of benzenoid and other hydrocarbons, d(H···H) < 2.12 Å between hydrogens on benzenoid carbons and d(H···H) > 2.17 Å and up to ~2.70 Å between hydrogens of Me groups (distances converted from au; van der Waals radius of H assumed to be ~2.39 Å). Similarly, the 16 bifurcated, highly bent B-H(···H-C)$_2$ intramolecular H···H bonds in TARNOP, TARNUV, TARPAD, TARPEH, and TARPIL (not characterized topologically) are reported (21) to have a range of 2.22(4)–2.94(5) Å and an unweighted grand mean of 2.51[18] Å compared with the intermolecular d_H(**H**) of 2.38[11] Å and a range of 2.18–2.57 Å (Table 2).

Do bond-critical parameters of DBs depend on $\Delta\varepsilon(H)$?

As pointed out in the Introduction, the Mulliken charges $\varepsilon(H)$ on the phenyl hydrogens of **H** are very small (68) and their differences $\Delta\varepsilon(H)$ are even smaller. Yet in spite of their almost negligible polarity the H···H contacts have topological characteristics that suggest kinship with authenticated DBs. To investigate to what extent $\Delta\varepsilon(H)$ is a determinative factor in the formation of an H···H bond, d_A, ρ_A, and ∇^2_A have been plotted against $\Delta\varepsilon(H)_m = |\varepsilon(H_d)_m - \varepsilon(H_a)_m|$, the difference between the Mulliken charges on the pertinent H atoms in the two species XH and HY prior to complexation (Figs. 10–12). In none of these plots are the data points cleanly separated into an LiH and an HBeH set (Table 1) or even more finely, but it is evident that the parameters correlate significantly with $\Delta\varepsilon(H)_m$.

As might be anticipated, the d_A values decrease with increasing $\Delta\varepsilon(H)_m$, and the decrease is steep (Fig. 10*a*). In spite of the considerable scatter the $\Delta\varepsilon(H)_m$,d_A pairs are quite well fitted by

[14] $d_A = 2.635 - 0.096 \exp[4.787\Delta\varepsilon(H)_m]$,

$$r^2 = 0.91, \sigma_{30} = 0.153 \sim 8.0\%.$$

With the outlier **26** removed, r^2 increases to 0.94, $\sigma_{29} = 0.125 \sim 6.5\%$, but the new regression line differs from that of eq. [14] only insignificantly.

The range of ρ_A is too large to display the features of a $\Delta\varepsilon(H)_m$,ρ_A plot in sufficient detail directly. However, a $\Delta\varepsilon(H)_m$,ln ρ_A plot (Fig. 11*a*) can be fitted reasonably well by

[15] $\ln \rho_A = -4.442 + 0.376 \exp[4.088\Delta\varepsilon(H)_m]$,

$$r^2 = 0.93, \sigma_{30} = 0.329 \sim 7.0\%.$$

The functional form of this regression reveals that even at $\Delta\varepsilon(H)_m = 0$ the ρ_A value is still about 0.018 e/Å^3 (compare this with Bader's (69) ρ_c in Ne···HF and Ar···HF, 0.067 and 0.052 e/Å^3, respectively).

The sign inversion of ∇^2_A within the observed $\Delta\varepsilon(H)_m$ range lends the ∇^2_A vs. $\Delta\varepsilon(H)_m$ plot (Fig. 12*a*) a particularly informative character. For $\Delta\varepsilon(H)_m$ up to ca. 0.52, ∇^2_A shows

Fig. 11. (*a*) Correlation of ln ρ_A with $\Delta\epsilon(H)_m$. Regression line Rl, eq. [15]. Solid diamonds, set **H**. (*b*) Correlation of ln ρ_A with $\Delta\epsilon(H)_c$. Regression line R2: ln $\rho_A = -4.827 + 0.686 \exp[2.648\Delta\epsilon(H)_c]$, $r^2 = 0.84$, $\sigma_{28} = 0.360 \sim 7.8\%$. Symbols as in caption of Fig. 5.

Fig. 12. (*a*) Correlation of ∇^2_A with $\Delta\epsilon(H)_m$. Regression line Rl, eq. [16]. (*b*) Correlation of ∇^2_A with $\Delta\epsilon(H)_c$. Regression line R2: $\nabla^2_A = 0.231 + 2.19[\Delta\epsilon(H)_c]^{2.00}$, $r^2 = 0.86$, $\sigma_{27} = 0.102 \sim 12\%$. (*c*) Correlation of ∇^2_A with $\Delta\epsilon(H)_m$, all data pairs shown. Regression line R3: $\nabla^2_A = 218 - 405\Delta\epsilon(H)_m$, $r^2 = 0.92$, $\sigma = 6.8\%$. Symbols as in caption of Fig. 5; solid diamonds, set **H**.

a steady non-linear increase with $\Delta\epsilon(H)_m$. This portion of the plot can be represented by

[16] $\nabla^2_A = 0.232 + 2.390[\Delta\epsilon(H)_m]^{1.790}$, $r^2 = 0.78$,

$$\sigma_{27} = 0.127 \sim 12\%,$$

i.e., $\Delta\epsilon(H)_m$ and ∇^2_A in this region are correlated, and the variation is monotonic. However, the ∇^2_A values for **1**, **2**, and

11 are negative, and at the same time the magnitudes of ∇^2_A of **1** and **2** are also dramatically large relative to $\nabla^2_A < 0.52$ (Fig. 12*c*). This indicates a change-over from an essentially electrostatic to a covalent bond character and suggests that the sign of ∇^2_c can be used as a diagnostic of the X-H···H-Y/X···H-H···Y instability (see below). This change of the interaction regime occurs at $\Delta\epsilon(H)_m \sim 0.54$. There is some uncertainty concerning **23**, which has a positive Laplacian and

a $\Delta\varepsilon(H)_m$ value larger than that of **11**. Possibly this has to do with the negative charge on the complex.

To compare the experimental parameters of **H** with those of the **A** set, estimates of $\varepsilon(H)$ for the phenyl hydrogens are required. These are obtained from the $\varepsilon(H)_m$ for the free BPh_4^- anion in its ground-state S_4 conformation (B3LYP/6-31G(d,p), ref. 68: 0.064[2] e for the *ortho*, 0.038[1] e for the *meta*, and 0.035 e for the *para* hydrogens). Thus $\Delta\varepsilon(H)_m = 0$ for like hydrogens, ~0.026 e for *ortho–meta*, ~0.029 e for *ortho–para*, and ~0.003 e for *meta–para* H···H contacts. These values, even for the *ortho* interactions, are 10–20 times smaller than the $\Delta\varepsilon(H)_m$ in Table 1. One would therefore expect BPs in the tetraphenylborates, if any, only for the *ortho* interactions, but in fact BPs are observed even *between like H atoms* (Table 2).

In Fig. 10*a* the centroid of **H** is at $d_H = 2.37[11]$ Å, $\Delta\varepsilon(H)_m = 0.016[13]$ e, i.e., only ca. 0.13 Å below the regression line and thus well within 1σ of the fit. The ∇^2_H values in **H** (Fig. 12*a*) stretch over a wider interval than might be expected but otherwise are consistent with the general location anticipated for (C-)H···H(-C) interactions. Only very small differences are observed between the *o*, *m*, and *p* types of the phenyl hydrogens. In **H** there is a small ρ_H at the BCP even at $\Delta\varepsilon(H)_m$ nominally zero (**c** and **f**) or close to zero (Table 2). These "residual" ρ_H values are commented upon in the Discussion.

Differences between $\Delta\varepsilon(H)_m$ and $\Delta\varepsilon(H)_c$

The use of $\Delta\varepsilon(H)_m$ in the correlation plots is anticipatory, i.e., it is expected that the correlation will depend on the difference of the $\varepsilon(H)_m$ charges in the respective "monomers", without consideration of the a priori unknown extent of the variation of $\varepsilon(H)$ on complexation. Figure 13 compares the differences $\Delta\varepsilon(H)_m$ and $\Delta\varepsilon(H)_c$, i.e., before and after the formation of the DB (Table 1). Constrained linear regression ($\varepsilon(H)_c$ values were not obtained for **1** and **2**, both of the $Li^+···H-H···NX_3$ type) yields

[17] $\Delta\varepsilon(H)_c = 1.136\Delta\varepsilon(H)_m$, $r^2 = 0.90$,

$$\sigma_{29} = 0.055 \sim 8.8\%.$$

With **26** not included,

[18] $\Delta\varepsilon(H)_c = 1.118\Delta\varepsilon(H)_m$, $r^2 = 0.96$,

$$\sigma_{28} = 0.036 \sim 5.8\%.$$

Thus the difference $\Delta\varepsilon(H)_c - \Delta\varepsilon(H)_m$ increases quasilinearly with $\Delta\varepsilon(H)_m$. Replotting Figs. 10*a*–12*a* in terms of $\Delta\varepsilon(H)_c$ does not produce major qualitative changes in the trends (Figs. 10*b*–12*b*), although the shifts in the positions of *individual* data points may be large (cf. **19**, **23**, **24**, **26**).

Fig. 13. Correlation of $\Delta\varepsilon(H)_m$ and $\Delta\varepsilon(H)_c$ (Table 1). Solid line, all $\Delta\varepsilon(H)_m,\Delta\varepsilon(H)_c$ pairs, regression line (eq. [17]) constrained to pass through the origin; dotted line, $\Delta\varepsilon(H)_c = \Delta\varepsilon(H)_m$. Symbols as in caption of Fig. 5.

Is there a bond-critical criterion of H···H/H_2 instability?

With decreasing $d(H···H)$ the two atoms will eventually come sufficiently close for the covalent component of the H···H interaction to dominate, and formation of a perturbed H_2 molecule, X···H-H···Y, will then become energetically favourable. As a consequence, loss of H_2 from the DB complex may occur in the course of its formation from XH and HY during the optimization process.[12] Thus, for example, MP2/6-31G(d,p) optimization of the linear complex $H_3BH^-···^+HNH_3$ ($\Delta\varepsilon(H)_m = 0.659$) has been described (5, 42) as dissociative,[13] with liberation of H_2, and an attempted similar optimization of $H_3BH^-···^+HNF_3$ ($\Delta\varepsilon(H)_m = 0.705$) resulted in the formation of BH_3, H_2, and NF_3 (I. Alkorta, personal communication).[14] At which point the instability begins to occur can, in our context, be investigated only in geometric/topological terms, as we have not examined the energy aspects of the problem. However, it is noted that the ∇^2_A values of the three species with very short H···H contacts, viz. **1**, **2**, **11** (and of course H_2), are all negative and thus indicative of covalent bonding interactions.

[12]Under experimental conditions, loss of H_2 from a DB complex already formed need not occur even at very short H···H distances (24, 25, 27, 30; also 44, 46, 50–53), although such loss has been reported in some cases (78–80).

[13]Interestingly, crystalline ammonium borohydride $NH_4^+BH_4^-$ has been reported to be stable below –20°C and to liberate H_2 at higher temperatures (81, 82).

[14]The position of the X-H···H-Y/X···H—H···Y equilibrium can be shifted by application of an external electric field (44). By choosing the strength and direction of the field (ab initio calculations) it was possible to displace the two H atoms along the bond and thus to manipulate the equilibrium in the LiH/HF, $H_3BH^-/^+HNH_3$, and $HBeH/^+HNH_3$ bond systems from a DB, via a coordinated H_2 molecule, to H_2 and vice versa. In set **A** the variation of the bond type is achieved by "chemical" manipulation of X and Y, without external fields. The results of ref. 44 emphasize the difference between DB stability in the ab initio calculation and in the crystal environment (cf. also ref. 65).[13]

Fig. 14. Variation of d_A with the relative position $\xi_A = d(H_d\cdots BCP)/d_A$ of the BCP in the $H_d\cdots H_a$ bond. Regression line Rl, eq. [20]; regression line R2, eq. [19]. Symbols as in caption of Fig. 5; open diamond, H_2.

Fig. 15. Variation, with $\xi_A = x_A/d_A$, of ρ_A in the $H\cdots H$ bonds. Regression line Rl: $\rho_A = 1.857 - 2130(\xi_A - 1/2)^{3.30}$ (exact fit). Regression line R2, eq. [21]. Symbols as in caption of Fig. 5; open diamond, H_2.

Plotting d_A against the relative position $\xi_A = d(H_d\cdots BCP)_A/d_A$ of the BCP in the $H\cdots H$ bond (Fig. 14), we see that, for $d_A > 1.1$ Å, d_A decreases steadily with increasing ξ_A:

[19] $d_A = 2.759 - 0.195 \exp[25.96(\xi_A - 1/2)]$,

$$r^2 = 0.89, \ \sigma_{27} = 0.354 \sim 28\%,$$

(regression R2, **11** not included); at the $\xi_A = 1/2$ limit, $d_A = 2.564$ Å. In contrast, the two data points with $d_A < 1$ Å, **1** and **2**, do not fall on an extension of line R2. They and the point for H_2 can be accommodated by R1:

[20] $d_A = 0.596/(1.324 - \xi_A)$, $r^2 = 0.77$,

$$\sigma_1 = 0.016 \sim 23\%,$$

i.e., by an entirely different regression function. The gap in d_A between the two groups of data points indicates that a change takes place somewhere between $d_A \sim 0.85$ and ~1.1 Å. This change involves the manner in which $d(H\cdots H)$ determines the relative position of the BCP and with it the character of the interaction. While this plot involves only geometric parameters, d_A and $\xi_A = x_A/d_A$, the existence of the gap is confirmed by the presence of parallel features in the ξ_A,ρ_A (Fig. 15) and ξ_A,∇_A^2 (Fig. 16) plots, both of which involve the non-geometric parameters ρ_A and ∇_A^2.

In Fig. 15 the electron density ρ_A at the BCP,

[21] $\rho_A = 0.0165 + 0.00278 \exp[59.66(\xi_A - 1/2)]$,

$$r^2 = 0.91, \ \sigma_{27} = 0.0186 \sim 7\%,$$

increases with ξ_A to ca. 0.2 e/Å^3 at $\xi_A \sim 0.573$, at which point it jumps suddenly (catastrophically?) to ~1.45 e/Å^3 with very little change in ξ_A but with a considerable contraction of d_A, from 1.385 Å in **23** to 0.805 Å in **2**. After this, ρ_A continues to increase but now *with decreasing* ξ_A. At the same time the Laplacian ∇_A^2 at the BCP of **1** and **2** changes sign, indicating the now strongly covalent nature of the $H\cdots H$ interaction. This contraction process ends at the H_2 molecule with $\xi_A = 1/2$. Corresponding features are observed in the ξ_A,∇_A^2 plot of Fig. 16 (cf. also Fig. 12).

The number of data points in the $\xi_A = 0.573$–0.575 interval unfortunately is too small for elucidating the features of the plot in this region in more detail, but it seems that **11**, with its small negative Laplacian of –0.25 e/Å^5, represents the incipient stage of the change in the $H\cdots H$ regime.

The regression value $\rho_A \sim 0.02$ e/Å^3 at $\xi_A = 1/2$ (eq. [21]) is within 1σ(eq. [21]), i.e., statistically $\rho_A(\xi_A = 1/2) = 0$ cannot be dismissed. However, the observed ρ_H values, all with ξ_A close to 1/2, are all larger than 0.04 e/Å^3 (Table 2), i.e., non-zero and thus compatible with the regression value of ρ_A from eq. [21].

Discussion

Unlike many of the crystal structures reported to contain DBs, the structures of the three organoammonium tetraphenylborates offer the advantage of containing, beside at least two distinct intermolecular $H\cdots H$ contacts shorter than 3 Å in each structure, a variety of weak N-H$\cdots$Y and C-H$\cdots$Y hydrogen bonds (Table B). Thus, coming from the

Fig. 16. Variation, with ξ_A, of ∇_A^2 at the BCP in the H⋯H bonds. Regression line R1: $\nabla_A^2 = -34.15 + 146283(\xi_A - 1/2)^{3.617}$ (exact fit). Regression line R2: $\nabla_A^2 = 0.2219 + 73.58(\xi_A - 1/2)^{1.708}$, $r^2 = 0.87$, $\sigma_{27} = 0.096 \sim 11\%$. Inset: expansion of the R2 plot. Symbols as in caption of Fig. 5; open diamond, H_2.

Fig. 17. Intermolecular bonding engagement of phenyl ring 1 in BTB (DBs and HBs up to 3 Å). (Bottom) Projection on the plane of ring 1: phenyl – ring 1 interactions. (Top) Projection roughly perpendicular to the plane of ring 1: cation – ring 1 interactions. X indicates either the centroid of a phenyl ring (X(1B), X(1C)) or of a ring bond (X(1D)).

same structure, the DBs and the corresponding HBs can be compared on equal footing in terms of bonding engagement and bond-critical parameters.

There are numerous short (i.e., less than the sum of the van der Waals radii) H⋯H contacts reported in the literature and presumed to be bonding even though their characterization is incomplete, being based on no more evidence than the d(H⋯H) distance instead of on complete topology. In the present case, each of the 15 observed intermolecular H⋯H contacts (set **H**) has a clearly characterized BP and a BCP, thus satisfying the most important of the criteria of the H⋯H bonding interaction (48, 71). The BPs are all somewhat curved (Figs. 1–4), which makes it difficult to establish their "true" lengths; the internuclear H⋯H distances d_H are therefore used instead in describing the contacts. The d_H and the associated ρ_H and ∇_H^2 values are listed in Table 2.

The simultaneous presence of intermolecular HBs and H⋯H contacts in the three structures demonstrates also the important principle of exhaustive (saturation) bonding in crystal structures containing such bonds. The schematic view of the bonding engagement of phenyl ring 1 in BTB (Fig. 17) serves as an instructive illustration of the importance of the total intermolecular interaction. Here *every phenyl hydrogen* is either a donor or an acceptor of a proton in a DB and (or) an HB bond, and the DBs, while weaker than the HBs, are not unimportant.[15] Another excellent ex-

ample of exhaustive intermolecular bonding is found in the dabcoH$^+$ cation in DTB, but it is difficult to present all the bonding interactions of the cation satisfactorily in a 2D projection.

Comparison norm for bond-critical parameters

To compare d_H, ρ_H, and ∇_H^2 with the corresponding parameters of other H⋯H and (X-)H⋯Y bonds, it was convenient to establish a comparison norm utilizing Alkorta's[6] extensive ab initio data listed in Table 1 (set **A**). As the d_A,ρ_A, d_A,∇_A^2, and ρ_A,∇_A^2 plots (Figs. 5–7) show, these parameters are strongly and smoothly pairwise correlated. The correlation curves give no indication of discontinuities or other features that would point to the existence of a qualitative differentiation in the nature of the H⋯H bonds in set **A** with respect to their length.

However, when the relative position $\xi_A = d(H_d \cdots BCP)/d_A = x_A/d_A$ of the BCP in the H⋯H bond is plotted against d_A (Fig. 14), the data points are seen to fall in two groups (separated by a gap at d_A between approximately 0.9 and 1.15 Å), and *two* correlation curves with quite different slopes are required to represent the complete data set when the subset with $d_A < 0.9$ Å is augmented by the d_A,ξ_A point for the H_2 molecule. The existence of the gap is confirmed in Fig. 15, where ρ_A, which is not a purely geometric param-

---

[15]Cf. also the NaBH$_4$·N(CH$_2$CH$_2$OH)$_3$ adduct, in which there is no conventional hydrogen bonding, but all the OH groups are engaged in H⋯H bonds to the anion (25).

eter, is plotted against ξ_A. The gap in this plot occurs between $d_A \sim 0.5$–1.4 e/Å^3 and at $\xi_A \sim 0.575$. The corresponding exclusionary, "taboo" domain is shown in Fig. 18, from which it is evident that the smoothness of the d_A,ρ_A correlation curve in Fig. 5 is only apparent (in spite of the excellent statistical figures of merit, eq. [3]) and that the failure to detect the gap in the d_A,ρ_A plot arises from the paucity or nonexistence of data points in the taboo domain. It is precisely in this domain that complications involving existence or stability of DB-containing species have been reported (24, 30, 46, 50, 51, 78, 80, 83). The data points of **H** all have d_A values above 2 Å, so the existence of the taboo domain does not interfere with our discussion of the experimental results.

The sudden jump in ρ_A from R1 to R2, at practically constant ξ_A at **23** and **2** but with considerable concomitant contraction of $d(H \cdots H)$ (Fig. 15), invites speculation about a possible connection with the unexpected observation (50) on the perpendicular H$_2$ ligand in the "elongated" dihydrogen complex, OsCl$_2(\eta^2$-H$_2)($NH$=CPh$_2)($P-$i$-Pr$_3)_2$ (**Os1**), modelled by OsCl$_2(\eta^2$-H$_2)($NH$=CH$_2)(PH_3)_2$ (**Os2**). While B3LYP optimization of **Os2** resulted in $d(H \cdots H) = 1.294$ Å, close to that obtained from the NMR $J(H,D)$ coupling in **Os1**, further examination revealed that the total energy of **Os2** was practically independent of $d(H \cdots H)$ between 0.90 and 1.60 Å. This means that in this complex the oxidative addition and its reverse, the reductive elimination of H$_2$, occur in the coordination sphere of the complex without any activation barrier, i.e., the two hydrogen atoms move freely in a wide region of the Os coordination sphere.

Do the H···H BPs represent *bonds*?

For an H···H contact characterized by a BP and a BCP to qualify as a dihydrogen *bond*, additional criteria must be satisfied. According to Popelier (48, 71; cf. also ref. 5), these additional criteria are the same as those that apply to *hydrogen* bonds. The H···H contacts in the ab initio set **A** appear to satisfy the first four (geometric/topological) criteria of the eight listed tentatively by Popelier (Table 10.2 of ref. 71), as well as the fifth, the shift of the electronic charge from H$_a$ to H$_d$ on formation of the bond from the fragments, i.e., $\varepsilon(H_d)_c < \varepsilon(H_d)_m$. Compliance with criteria 6–8 cannot be tested explicitly with the limited data at our disposal at present. However, the linear complexes **4**, **8**, **12**, and **14** (42) correspond to global minima on their respective MP2/6-31G(d,p) potential energy surfaces, which guarantees that these criteria also are satisfied. These stable, equilibrium-geometry complexes are used to construct and calibrate the various correlation curves described above. Because of the smooth continuity of most of the correlation curves it is reasonable to assume that when data points for other, less-well documented H···H complexes are accommodated by these curves, the H···H contacts in the latter *also* correspond to H···H *bonds*. This conjecture is particularly useful when dealing with H···H complexes for which only information from crystallography is available, which means practically all complexes with experimentally determined d_H, ρ_H, and ∇^2_H values. The conjecture is further

Fig. 18. The presumed exclusionary domain in the d_A,ρ_A plot (cf. Fig. 5). DB complexes with d_A,ρ_A points falling inside the broken-line rectangle are unstable (evolution of H$_2$) or nonexistent.

supported by the remarkable self-consistence of all the **A** and other data.

On this argument the H···H contacts in the organoammonium tetraphenylborates should be regarded as (C-)H···H(-C) *bonds*. Furthermore, by the same token, the (N-)H···N, (N-)H···Ph, and (C-)H···Ph contacts in the three salts (set **E**) also constitute hydrogen bonds, even though some of them are quite weak.

The DBs of set **H** are weak as H···H bonds go. Of particular interest is the almost negligible polarity of the H···H group. The H···H bonds between like phenyl hydrogens have $\Delta\varepsilon(H)_c$ values that should in principle be zero but for their crystallographic nonequivalence. The classical precedent for a non-covalent H···H bond between like atoms is the methane dimer (CH$_4)_2$. The dimer was not formed in SCF calculations, which would suggest that its C-H···H-C contact interactions are repulsive. However, a detailed post-HF investigation (ref. 39 and references therein) showed that it was bound in all six configurations examined: H$_3$CH···H$_2$CH$_2$ (C_s), H$_2$CH$_2$···H$_2$CH$_2$ (D_{2h} and D_{2d})[16], HCH$_3$···H$_3$CH (D_{3h} and D_{3d}), and H$_3$CH···HCH$_3$ (D_{3h}).[17] The attractive nature of the interactions is consistent with the results of CH$_4$-CH$_4$ scattering experiments (crossed molecular beams, cited in ref. 39). In fact, they are weak van der Waals interactions of induced dipole – induced dipole type. The H$_3$CH···HCH$_3$ (D_{3h}) configuration was the one associated with C···C distances longer than ca. 4.5 Å. The optimized

---

[16]The H$_2$CH$_2$···H$_2$CH$_2$ (D_{2d}) configuration 3b (Fig. 3 of ref. 39) is erroneously labelled as being of D_{2h} symmetry.
[17]The configuration of most interest to us, H$_3$CH···HCH$_3$ (D_{3d}), was not examined, but it may be assumed that, qualitatively, the general result obtained for H$_3$CH···HCH$_3$ (D_{3h}) would for our purposes serve also for the D_{3d} configuration.

H···H distance in the MP2/6-31G** calculation was 2.699 Å compared with the best (lowest energy) MP2/6-311G(2d,2p) calculation, 2.686 Å. The value found for $H_3CH···HCH_3$ (D_{3d}, **33**) is somewhat smaller, $d_A = 2.661$ Å, the difference, if it is of consequence, being probably attributable to the repulsion of the non-bonded, eclipsed hydrogens in the D_{3h} configuration. The "finite" ρ_A values of 0.016 e/Å³ at $\Delta\varepsilon(H)_c = 0$ in **33** and the experimental values $\rho_H = 0.04–0.08$ e/Å³ at $\Delta\varepsilon(H)_c \sim 0$ and $d(C···C) \sim 4.2–4.6$ Å for the DBs of the **H** set (Fig. 11) are therefore not surprising. On a conservative estimate, the H···H interactions at $d_A > 2$ Å, being a continuous mix of Coulombic and dipolar contributions, are qualitatively of the same type and are to be viewed as constituting dihydrogen *bonds*, regardless of the convergence to zero of $\Delta\varepsilon(H)_c$, the estimator of the "Coulombic" component of the interaction.

Involvement of $\Delta\varepsilon(H)$

Although the plots of Figs. 10–12 show appreciable "chemical" scatter, there is little doubt that correlations exist in all these cases (eqs. [14–16]; eqs. [17] and [18]; Fig. 13). At $\Delta\varepsilon(H) = 0$ the regression values of d_A, ρ_A, and $\bar{\nabla}_A^2$ are non-zero, in agreement with both observation (set **H**) and calculation (methane dimer, ref. 39).

By their nature, the $\Delta\varepsilon(H)$ should not be expected to give *close* correlations. Better results in this respect can be obtained using different charge measures (see below). However, $\Delta\varepsilon(H)_m$ has a rough predictive value, as the $\varepsilon(H)_m$ values in the XH and HY fragments may already be available, and the a priori likelihood of existence of an X-H···H-Y complex can be estimated without calculation.

It is not clear at present how $\Delta\varepsilon(H)_m$ relates, quantitatively, to the stability of an X-H···H-Y complex vis-à-vis the corresponding X···H-H···Y complex. Investigating this matter in some detail might well repay the extra effort.

Estimating the H···H binding energy

In a paper that came to our attention only quite recently (66) the authors investigate, among other things, relationships between the binding energy E_b and the bond-critical parameters of DB-containing complexes. From the results of their MP2/aug′-cc-pVTZ (MP* for short) calculations they find that, for several M-H···H′-Y (M = Li, Na) complexes, linear relationships exist between E_b and ρ_c* (Fig. 4, ref. 66; also ref. 32) and between E_b and the charge Δq* transferred from MH to the H···H bond (Fig. 3, ref. 66). These important findings offer a discussion of the H···H bonds in a way alternative to that based on $\Delta\varepsilon(H)$ and a possibility of estimating E_b for the complexes in Table 1 from the data at our disposal at present.

Since the complexes LiH···HCN, LiH···HCCH, LiH···HCCF, and LiH···HNC (this last-named is non-linear in MP*, H-N-Li = 149.4°) are common to both ref. 66 and set **A**, the following empirical correspondences can be established:

$$d_c^* = 0.619 + 1.856 \ln d_A, \quad r^2 = 1.000,$$

$$\sigma_2 = 0.003 \sim 0.6\%$$

Fig. 19. Correlation of ρ_A and Δq_A. All $\Delta q_A,\rho_A$ pairs, eq. [24]; with **5** and **26** not included, eq. [25].

$$\Delta q^* = 6.36\Delta q_A^{1.744}, \quad r^2 = 0.997, \quad \sigma_2 = 0.0017 \sim 3\%$$

$$\rho_c^* = -0.015 + 1.333\rho_A, \quad r^2 = 0.997,$$

$$\sigma_2 = 0.005 \sim 3\%.$$

From the linearity of ρ_c^*,E_b and $\Delta q^*,E_b$ it follows that $\Delta q^*,\rho_c^*$ also is linear. From the parameter values for complexes **1***–**8*** of ref. 66 one obtains

$$[22] \quad \rho_c^* = 0.066 + 1.867\Delta q^*, \quad r^2 = 0.996,$$

$$\sigma_6 = 0.007 \sim 2.5\%.$$

Furthermore,

$$[23] \quad E_b = -0.59 - 89.6\Delta q^* - 36.34\rho_c^*, \quad r^2 = 0.984,$$

$$\sigma_5 = 1.3 \sim 6\%$$

(ρ_c* in e/Å³, Δq* in e, E_b in kcal/mol), i.e., loci of equal E_b in the $\Delta q^*,\rho_c^*$ plot will form a system of parallel straight lines with negative slopes.

Treating the bond-critical parameters of set **A** in a similar manner, we have

$$[24] \quad \rho_A = 0.018 + 1.753\Delta q_A$$

(all $\Delta q_A,\rho_A$ pairs, $r^2 = 0.94$, $\sigma_{29} = 0.025 \sim 5.0\%$) and, with **5** and **26** not included,

$$[25] \quad \rho_A = 0.016 + 1.843\Delta q_A, \quad r^2 = 0.985,$$

$$\sigma_{27} = 0.012 \sim 2.4\%$$

(Fig. 19). The intercept 0.016(12) ~ 1.4σ_{27} is non-zero. Interestingly, when $\Delta q_A = 1$, then ρ_A is 1.857 e/Å³, which reproduces exactly the ρ_A value for H_2 (Table 1).

The rough estimate of E_b that can be obtained for the DBs of **H** by combining the above relations leads to values between ~1 and ~5 kcal/mol, i.e., of an order comparable to the recently quoted estimates (38) for intramolecular (C-)H⋯H(-C) bonds in benzenoid and other hydrocarbons.

Conclusions

A number of intermolecular (C-)H⋯H(-C) contacts with $d(\mathrm{H}\cdots\mathrm{H}) \leq 3$ Å in the crystal structures of the three organoammonium tetraphenylborates studied are characterized by well-defined bond paths and bond-critical points. These contacts exist primarily between phenyl hydrogens of neighbouring BPh_4^- anions. The Mulliken charges ε(H) on these H atoms are very small and their differences Δε(H) are estimated to range from nominally zero to ca. 0.03 e. To determine whether the H⋯H contacts (set **H**) correspond to actual (C-)H⋯H(-C) dihydrogen *bonds*, their topological bond-critical parameters ρ_c and $\overline{\nabla}_c^2$ have been compared with an ab initio norm constructed from Alkorta's MP2/6-3lG(d,p) values of the parameters for a variety of linear X-H⋯H-Y complexes. This detailed comparison leads to the conclusion that the observed H⋯H contacts indeed represent dihydrogen bonds. The simultaneous presence of a number of (N-)H⋯N, (N-)H⋯Ph, and (C-)H⋯Ph hydrogen bonds in the three crystal structures (set **E**) makes it possible to establish relative topological strengths of the (C-)H⋯H(-C) DBs and the hydrogen bonds. The sequence is (N-)H⋯N, (N-)H⋯Ph, (C-)H⋯Ph, with the dihydrogen bonds weaker than any of these hydrogen bonds (but see text).

Examination of the various bond-critical parameters in the Alkorta set (set **A**) reveals a remarkable self-consistence of the binary parameter correlations. Discontinuities in certain of the correlations demonstrate the existence of a transition from a mainly unshared-shell X-H⋯H-Y to a mainly shared-shell (covalent) X⋯H-H⋯Y regime, as a consequence of the "chemical" effect of the choice of the X,Y pair (and the charges on X and Y) on the H⋯H distance. In the limit this transition ends in liberating H_2 from the complex or in preventing a stable complex from forming in the first place.

Controlling parameters for radical cation fragmentation reactions: Origin of the intrinsic barrier

Deepak Shukla, Guanghua Liu, Joseph P. Dinnocenzo, and Samir Farid

Abstract: C—C bond cleavages of radical cations of 2-substituted benzothiazoline derivatives were investigated to determine the parameters controlling the fragmentation rate constants. In spite of the low oxidation potentials of the compounds, fragmentation rate constants greater than 1×10^6 s^{-1} could be achieved through weakening of the fragmenting bond by substituents that stabilize the radical fragment and exert steric crowding. A quantitative assessment of the relative roles of radical stabilization vs. steric effects to weaken the fragmenting C—C bond was achieved through DFT calculations. The calculated activation enthalpies matched reasonably well with the experimentally determined values. A thermokinetic analysis revealed that the fragmentations of benzothiazoline radical cations have relatively large intrinsic kinetic barriers, ascribed to the delocalized nature of the product radical and cation fragments. Interestingly, the same factors that lead to the large intrinsic barriers led, simultaneously, to large thermodynamic driving forces for the fragmentations, which should lead to lower activation barriers. These effects oppose each other kinetically and provide important insight into the design of fast radical ion fragmentation reactions.

Key words: benzothiazoline, radical cation, fragmentation, steric effects, DFT.

Résumé : Dans le but de déterminer les paramètres qui contrôlent la constante de vitesse de fragmentation, on a étudié la rupture de la liaison C—C des cations radicalaires des dérivés de la benzothiazoline substituée en position 2. En dépit du faible potentiel d'oxydation de ces composés, on peut obtenir des constantes de vitesse de fragmentation supérieures à 1×10^6 s^{-1} en affaiblissant la liaison qui subit la fragmentation à l'aide de substituants qui stabilisent le fragment radicalaire tout en exerçant un encombrement stérique. Faisant appel aux calculs DFT, on a évalué quantitativement le rôle relatif de la stabilisation du radical par rapport aux effets stériques dans l'affaiblissement de la liaison C—C qui se fragmente. Les enthalpies de liaisons calculées correspondent assez bien avec les valeurs expérimentales. Une analyse thermocinétique a révélé que les fragmentations des cations radicalaires de la benzothiazoline ont une large barrière cinétique intrinsèque relative, attribuable à une délocalisation du radical et des fragments de cations obtenus. Il est intéressant de noter que les mêmes facteurs qui conduisent à une large barrière intrinsèque, conduisent simultanément à de très grandes forces motrices thermodynamiques pour la fragmentation, ce qui devrait provoquer une diminution de la barrière d'activation. Cinétiquement, ces effets qui s'opposent l'un à l'autre fournissent une connaissance plus profonde du processus impliquant les réactions rapides de fragmentation de l'ion radical.

Mots clés : benzothiazoline, cation radical, fragmentation, effets stériques, DFT.

Introduction

One-electron oxidation can decrease bond dissociation energies of otherwise stable molecules to such an extent that fast fragmentation can occur readily. This effect is best understood in terms of a thermodynamic cycle, pioneered by Arnold and co-workers (1). According to the cycle, the higher the oxidation potential of the molecule, the lower the bond dissociation energy of the radical cation and, in general, the more likely that fast fragmentation of the corresponding radical cation would be achieved. Conversely, as the oxidation potential is lowered, the bond dissociation energy (BDE) of the radical cation increases and will eventually reach a point where the fragmentation will be too slow to be competitive with other reactions of the radical cation. Fragmentations of C—C bonds of several radical cations

have been investigated and it has been confirmed that the fragmentation rate constants indeed depend strongly on the oxidation potential of the substrate (2).

$$BDE(R'–R^{•+}) = BDE(R'–R) − E^{ox}(R'–R) + E^{ox}(R'•)$$

It is conceivable that compounds with low oxidation potentials could yield radical cations that rapidly fragment if the fragmenting bonds are weakened through proper substitution. There are, in principle, two ways to weaken such bonds: (1) by having substituents on the fragments (the radical and the cation) that stabilize these species; and (2) by steric crowding in the reactants. There are a number of reported examples where fragmentation of radical cations derived from low oxidation potential compounds have been achieved by such weakening of the fragmenting bonds (3).

Herein, we report a new class of low oxidation potential compounds — substituted benzothiazolines — that undergo rapid fragmentation when oxidized to their radical cations. Pulsed laser techniques were used to generate and characterize the benzothiazoline radical cations, as well as to measure their fragmentation kinetics. In addition, DFT calculations were performed to estimate the BDEs of the radical cations as well as their activation barriers for fragmentation. Finally, the relative contributions to bond weakening in the radical cations from stabilization of the fragments vs. steric crowding were determined.

Results and discussion

Structural features and synthesis

The initial aim of this work was to choose an electrophore with such a low oxidation potential that cleavage of a non-stabilized radical fragment upon one-electron oxidation would be very slow. Systematic structural changes to increase the stability of the radical fragment would then be tested with the aim of achieving fragmentation of the radical cation with a rate constant of 1×10^5 to 1×10^7 s^{-1}, a convenient range for transient kinetics. Substituted benzothiazoline (2,3-dihydrobenzothiazole) derivatives, BT–R (eq. [1]) appeared to be well-suited for this study. They have low oxidation potentials (e.g., 0.77 V vs. SCE for R = Me), the cation fragment (BT$^+$) is highly stabilized, and derivatives with varying R — the cleaving radical fragment — can be readily synthesized.

[1]

Compound **1** was used as a model nonfragmenting analogue to determine the absorption spectrum of the main chromophore of the radical cation.

Five other derivatives (**2**–**6**) with varying substitution of R to promote fragmentation, were synthesized to test the effect of increasing stabilization of the radical R· and of weakening of the bond on the fragmentation rate constant.

The benzothiazoline derivatives were prepared from 2-methylamino-benzenethiol according to reported procedures (eq. [2]) (4, 5) through direct condensation with the appropriate ketone (compounds **2** and **3**) or through reaction with an acid chloride to give a thiazolium salt, followed by the addition of CH$_3$MgBr (compounds **1** and **4**–**6**).

Experimental approach

Different approaches were considered to generate and study the fragmentation kinetics of the radical cations of the benzothiazoline derivatives (BT–R$^{.+}$), by flash photolysis. In one approach, an excited sensitizer reacts with a donor (acting as a cosensitizer, C) to form the radical cation of the latter (C$^{.+}$) in high quantum yield (6). Next, a secondary electron transfer from BT–R to C$^{.+}$ generates BT–R$^{.+}$. To avoid direct excitation of the reactant, it is desirable for the sensitizer to absorb at longer wavelength than the BT–R derivative. The absorption of BT–R derivatives below 350 nm renders sensitizers such as 1,4-dicyanonaphthalene and *N*-methylquinolinium of limited use. The dynamics of the radical cations BT–R$^{.+}$ are most conveniently studied at their absorption maxima, which, as shown below, are near 420 nm. Thus, sensitizers such as 9,10-dicyanoanthracene that have strong absorptions in this region are also of limited use.

Because of the lack of a suitable electron transfer sensitizer with absorption in the 370 ± 10 nm window that would meet the above requirements, we applied a different approach to generate the radical cations BT–R$^{.+}$. This approach is based on the chemistry of *N*-methoxyphenanthridinium (MeOP^{+}), which is reported to undergo photochemical N—O bond cleavage to yield phenanthridine radical cation (P$^{.+}$) and a methoxy radical (eq. [3]) (7). The radical cation of phenanthridine is a powerful oxidant (oxidation potential of phenanthridine is ~1.9 V vs. SCE) that can be used in a subsequent bimolecular reaction to generate the radical cation of an added donor (eq. [3]).

[3]

Steady state photolysis and reaction products

To correlate the decay of the radical cations to their fragmentations, it was important to first confirm that the products of these reactions are those expected according to eqs. [1] and [3]. The photoreactions of MeOP^{+} with the benzothiazolines **3–6** at equimolar concentrations in CD$_3$CN were followed by ^{1}H NMR and the products were identified by comparison with authentic samples (see *Experimental section* for details). The products were indeed those expected from the N-O fragmentation of MeOP^{+} (phenanthridine and methanol) and those of the C-C fragmentation of the radical cations BT–R$^{.+}$ (2,3-dimethylbenzothiazolium and products of the cleaved radical R·). In each case the main product of the radical R· was the dimer R–R (~70 to >90%). In some cases the deuterated product R–D (via deuterium abstraction from the solvent), and (or) the corresponding olefin (via loss of hydrogen atom) were formed (eq. [4]) (see *Experimental section*).

[4]

^{a} **4** and **5** yielded the corresponding R–D derivatives,
4 and **6** yielded the corresponding olefins:
α-methylstyrene and 1,1-diphenylethylene, respectively.

An unexpected, minor photolysis product of these reactions was adduct **7** (eq. [4]).[4] This compound was formed in all reactions of **3–6** in ~12–20% yield. The structure of this compound, which has not yet been isolated in pure form, was based on ^{1}H NMR spectral analysis. Importantly, the alternative assignment of the isomeric structure **8** to this compound was ruled out by independent synthesis of **8** via the base-catalyzed reaction of MeOP^{+} with dimethylbenzothiazolium (eq. [5]). Assignment of the NMR signals of compound **8** was based on several 2D NMR and NOE experiments, which establish the connectivity of the two moieties.

Photolysis of MeOP^{+} in the presence of the benzyl derivative (**2**) yielded, in addition to phenanthridine and methanol, 2-methyl-3-ethylbenzothiazolium, an expected fragmentation product of **2**$^{.+}$. However, none of the likely products of benzyl

---

^{4} The mechanism for formation of **7** has not been investigated. One possibility involves initial reaction of MeO· with BT–R by hydrogen atom abstraction from the N-Me group. The resulting α-amino radical might then add to MeOP^{+} at C-6 to give a *N*-alkoxy amine radical cation. Subsequent intramolecular electron transfer from the benzothiazoline moiety to the *N*-alkoxy amine radical cation followed by fragmentation of the resulting benzothiazoline radical cation would produce **7**. Further experiments are required to test this hypothesis.

Fig. 1. Absorption spectrum of phenanthridine radical cation (P$^{.+}$) obtained from photolysis of MeOP$^+$ in acetonitrile (closed circles) and that obtained in the presence of 1,4-dimethoxybenzene (DMB) (open circles), which matches the spectrum of an independently generated DMB$^{.+}$.[5]

Fig. 2. Absorption spectra of the radical cations of compounds **1** and **4**, obtained from photolysis (380 nm) of MeOP$^+$ in the presence of these electron donors in acetonitrile. The spectra were obtained after a delay time of >2 μs to avoid contributions owing to the secondary transient species produced from photolysis of MeOP$^+$ (see text).

[5]

radical, such as 1,2-diphenylethane or toluene were formed in this reaction. There is also no indication that either benzyl methyl ether (a coupling product between benzyl and methoxy radicals) or *N*-benzylacetamide (an addition product of benzyl cation to acetonitrie, followed by hydrolysis) is formed. In spite of the fact that not all fragmentation products have been identified in this case, the clear evidence for formation of the benzothiazolium salt suggests that fragmentation of **2**$^{.+}$ does take place. Additional support for this conclusion is provided by the fact that the activation enthalpy calculated for fragmentation of **2**$^{.+}$ agrees well with that measured experimentally for its disappearance (see *Density functional calculations*).

Characterization of the radical cations BT–R$^{.+}$

The following experiments were carried out to probe the applicability of MeOP$^+$ photochemistry (eq. [2]) to generate and study the reactivity of radical cations by flash photo-

lysis. Irradiation of MeOP$^+$ in acetonitrile gave a transient (λ_{max} at 670 nm), which was assigned to P$^{.+}$ based on the lack of quenching by dioxygen and on its efficient quenching by 1,4-dimethoxybenzene (DMB, E^{ox} = 1.3 V vs. SCE). In the presence of 0.1 M DMB, the 670 nm absorption is completely replaced by that shown in Fig. 1 (λ_{max} = 440 and 458 nm), which corresponds to the spectrum of DMB radical cation generated independently.[5] Using the benzothiazoline derivatives as donors (eq. [3]) this approach provided a convenient method to generate their radical cations and to study their fragmentation kinetics.

As expected, the phenanthridine radical cation (P$^{.+}$) is efficiently intercepted by the benzothiazoline derivatives ($k_q \approx$ 6 × 10^9 M^{-1} s^{-1}). Thus, 355 or 380 nm laser excitation of MeOP$^+$ in the presence of 5–10 mM of **1** in aerated or in argon-saturated acetonitrile led to a long-lived species (~200–250 μs) with an absorption maximum at ~410 nm (Fig. 2). Support for assigning this absorption to **1**$^{.+}$ was obtained from a number of experiments. Excitation of 1,4-dicyanonaphthalene at 343 nm in the presence of 0.3 M biphenyl as a cosensitizer in acetonitrile led to the formation of biphenyl radical cation, characterized by the strong absorption at 670 and 380 nm. Absorption due to the sensitizer radical anion was removed by purging the samples with dioxygen, where electron transfer leads to the formation of O$_2$$^{.-}$, which does not absorb in the visible region. Addition of **1** (0.5 to 1.5 mM) led to quenching of the biphenyl radical cation with a bimolecular rate constant of 1.8 × 10^{10} M^{-1} s^{-1} and concomitant appearance of an absorption identical to that

[5] An authentic spectrum of DMB$^{.+}$ was obtained in aerated acetonitrile by 355 nm excitation of DCA (OD$_{355}$ = 0.6) in the presence of 0.15 M biphenyl (as a cosensitizer) and 0.01 M DMB.

obtained in the above mentioned experiment with MeOP$^+$.[6] Similarly, 343 nm excitation of *N*-methylquinolinium with toluene (1.5 M) as a cosensitizer in dioxygen-purged 1,2-dichloroethane generated the toluene radical cation (λ_{max} = 450 nm), which was efficiently quenched by **1** (~2 mM). The transient spectrum recorded after complete quenching of the toluene radical cation was also very similar to that obtained in the other experiments mentioned above.

Assigning the ~410 nm absorbing transient to **1**$^{·+}$ was further confirmed through electron transfer interception by a lower-oxidation-potential compound. The transient obtained from the reaction of MeOP$^+$ with **1** in acetonitrile was readily quenched by tri-*p*-anisylamine (E^{ox} = 0.52 V vs. SCE) with the concomitant formation of the radical cation of the latter, characterized by its absorption maximum at 720 nm (6). Plots of the rate constants for the transient decays and for growth of the trianisylamine radical cation vs. amine concentration were linear. Slopes of the plots provided a quenching rate constant of 4.1×10^9 M^{-1} s^{-1}.

Shown also in Fig. 2 is the spectrum of **4**$^{·+}$ obtained using MeOP$^+$ as described above for **1**$^{·+}$. Clearly the absorption spectra of the radical cations are not the same in spite of the fact that the low-oxidation-potential electrophore (the benzothiazoline moiety) is the same. The weak absorption that appears as a shoulder at ~470 nm in the spectrum of the nonfragmenting **1**$^{·+}$ seems to be considerably enhanced in the spectrum of **4**$^{·+}$. The spectra of **2**$^{·+}$ (not shown) and of **5**$^{·+}$ (Fig. 3) are similar to that of **4**$^{·+}$.

Additional support for the spectral assignment of the benzothiazole radical cations was derived from the transient assigned to **5**$^{·+}$, whose decay was concomitant with formation of the 9-methylfluorenyl radical. Unlike the radicals resulting from the fragmentation of the other radical cations mentioned in this work, which lack absorptions in the visible region, the methylfluorenyl radical could be readily identified by its absorption (λ_{max} = 485 nm) (see Fig. 3) (8). This absorption matches that of an authentic sample, also shown in Fig. 3, generated from photolysis of the dimer (compound **9**) (eq. [6]). As expected, in aerated solution this absorption band is suppressed as a result of quenching by dioxygen.

[6]

9

Fig. 3. (Top) Transient spectra from photolysis (380 nm) of MeOP$^+$ in the presence of the methylfluorenyl derivative **5** (0.01 M) in acetonitrile at different delay times after the pulse. The spectrum after (*a*) 0.2 μs is essentially that of the radical cation **5**$^{·+}$, with increasing delay times ((*b*) and (*c*)) this spectrum is gradually replaced by that of methylfluorenyl radical. (Bottom) Spectrum after (*d*) 13 μs delay and spectrum of methylfluorenyl radical obtained from direct photolysis of the dimer (**9**) (*e*) at 308 nm in acetonitrile. The spectra from photolysis of MeOP$^+$ could not be measured below 400 nm because of absorption by MeOP$^+$.

Fragmentation rate constants and activation energies

The fragmentation rate constants of the radical cations BT–R$^{·+}$, obtained via 355 or 380 nm excitation of MeOP$^+$, were determined from the decay kinetics in acetonitrile. The use of MeOP$^+$ in these flash photolysis experiments allowed for a high enough concentration (10–15 mM) of the reactants to ensure fast interception of the phenanthridine radical cation. Under these conditions the growth rates of the radical cations are faster than their decay. For all samples the radical cation decays were somewhat complicated by the presence of a second transient species. The decay rate constant for this latter species was the same in all samples and had the same temperature dependency. The nature of this second transient has not been established, but it is likely to

---

[6] Compound **1** absorbs at the excitation wavelength and concentrations higher than 1.5 mM and could not be used in these experiments.

Table 1. Comparison of fragmentation rate constants (k_{fr} at 25°C) and activation enthalpies for substituted benzothiazoline radical cations 2^{+}–6^{+} and R-H bond dissociation energies.

Compound (R-)	k_{fr} (s^{-1})	$\Delta H^{\ddagger}$ (BT–R^{+})[a]	BDE (R-H)[b]
2 (PhCH$_2$-)	1	~16[c]	89.8

4 (PhCMe$_2$-)	1.9×10^5	9.6 ± 0.5	87.3
5 (9-MeFl-)	5.0×10^6	3.9 ± 0.7	79.7
6 (Ph$_2$CMe-)	6.1×10^6	4.4 ± 0.6	82.8

Note: All energies in kcal/mol.

[a]From nonlinear least-squares fit of the temperature-dependent rate data; reported errors are one standard deviation.

[b]Reference (9).

[c]This value was estimated from the room temperature fragmentation rate constant for 2^{+} assuming that the activation entropy was the same as for 3^{+}.

be due to a species resulting from MeOP$^+$ chemistry because of its independence on the added BT–R derivative. Thus, although this experimental approach suffered from the need to analyze the data as a sum of two exponentials, it offered the best option to obtain the desired kinetic data.

The fragmentation rate constants of 3^{+}–6^{+} were in the range that could be readily determined by laser flash photolysis. The rate constants of these reactions were also measured as a function of temperature (see Fig. 4). Listed in Table 1 are the fragmentation rate constants at 25°C and the activation enthalpies, which were derived from nonlinear least-squares fitting of the kinetic data in Fig. 4.

Unlike the fragmentations of 3^{+}–6^{+}, which could be readily investigated by flash photolysis, the radical cation 2^{+} had a lifetime of ~50–60 μs and, importantly, its decay showed only a slight temperature dependence. This behavior suggests that the decay may be largely due to other deactivation processes rather than being a measure of the fragmentation rate constant. Indeed, based on cyclic voltammetry, a rate constant of only 1 ± 0.2 s^{-1} was obtained for the fragmentation of 2^{+} (see *Experimental section*).

From the above mentioned data it is evident that the fragmentation rate constants for 2^{+}–6^{+} fall into three groups. Cleavage resulting in formation of the primary, benzyl radical (from 2^{+}) is particularly slow (~1 s^{-1}). The cleavages to form both the secondary, diphenylmethyl radical (from 3^{+}) and of the tertiary, cumyl radical (from 4^{+}) are in the range of ~1 × 10^5 s^{-1}. The cleavages to form the tertiary, methylfluorenyl, and diphenylethyl radicals (from 5^{+} and 6^{+}) are in the range of 5×10^6 s^{-1}. The increased substitution on the radical fragment clearly increases the fragmentation rate constant.

Although the activation energies for the fragmentation of 2^{+}–6^{+} roughly correlate with increasing stability of the radical fragment, further analysis reveals that other factors must also play a role in controlling the fragmentation barriers. The relative radical (R·) stabilities can be estimated from the R—H bond dissociation energies (BDE (R-H)) of the corresponding hydrocarbons, as shown in Table 1. The data show clear discontinuities in the correlation of BDE (R-H) and $\Delta H^{\ddagger}$. For example, $\Delta H^{\ddagger}$ for 3^{+} and 4^{+} are identical within experimental error yet, as judged by BDE (R-H), the radical formed from 4^{+} is less stabilized than from 3^{+} by 1.5 kcal/mol. Similarly, $\Delta H^{\ddagger}$ (5^{+}) is 0.5 kcal/mol lower than $\Delta H^{\ddagger}$ (6^{+}), however, based on radical stability one would ex-

Fig. 4. Plot of the logarithm of fragmentation rate constants divided by the absolute temperature (ln (k_{fr}/T)) for the radical cations of compounds **3–6** vs. the reciprocal of the absolute temperature ($1000/T$) in acetonitrile. The negative slopes of the linear plots obtained by least-squares fitting are: 4.82, 4.84, 2.00, and 2.15, respectively. The dashed line (negative slope of 2.98) corresponds to the decay rate constant of another intermediate from the photolysis of MeOP$^+$ detected in all cases (see text).
pect the radical formed from 5^{+} to be ca. 3 kcal/mol more stablized than that formed from 6^{+}. These data clearly reveal that radical stability is not the sole determinant of the relative energetic barriers for radical cation fragmentation; it seems likely that differential steric effects also play a crucial role. To gain insight into the relative contributions of these two factors, we decided to use density functional theory to calculate both the bond dissociation energies and the activation energies for C—C bond fragmentation of 2^{+}–6^{+}.

Density functional calculations

The thermodynamic and kinetic properties of the substituted benzothiazoline radical cations were modeled with density functional calculations. The B3LYP functional was chosen because it has been shown to be particularly well-suited to radical cation calculations (10). Computations were performed with the Gaussian 98 series of programs (11). All geometries were fully optimized using a 6-31G* basis set and all optimized species were determined to be either minima or saddle points by frequency calculations. The radical cation carbon–carbon BDEs for 2^{+}–6^{+} were determined as the differences between the energies of the benzothiazolium cation (BT$^+$) and the radical fragments (R·) and that of the most stable radical cation conformer, unless otherwise noted. The energy differences include electronic energies, zero point energy corrections, and thermal corrections (at 298.15 K). In several cases, BDEs from higher energy radical cation conformers were calculated to compare with the transition state energies for conformational interconversion.

Activation energies

The activation energies for fragmentation of $2^{\cdot+}$–$6^{\cdot+}$ were sought for comparison with the experimentally determined values. The relative energies of the conformational isomers of the radical cations were first computed to determine the lowest energy conformer for each compound. The energetic barriers for conformational interconversion were also computed. The results are graphically illustrated in Fig. 5.

The activation energies for fragmentation were computed from the lowest energy conformer for each radical cation. For the radical cations with the lowest activation energies for fragmentation, activation energies were also computed for the higher energy conformers. The results are shown in Fig. 5.

The highest computed barrier for fragmentation (14.4 kcal/mol) was found for $2^{\cdot+}$. This value is in line with the observed fragmentation rate constant for $2^{\cdot+}$ of ~1 s^{-1}, which corresponds to an activation barrier of ~16 kcal/mol, ~2 kcal/mol higher than the computed value. The computed barriers for $3^{\cdot+}$ (7.8 kcal/mol) and $4^{\cdot+}$ (7.0 kcal/mol) are substantially lower. Gratifyingly, the computed barriers for $3^{\cdot+}$ and $4^{\cdot+}$ are also consistent with those determined experimentally (9.5 and 9.6 kcal/mol). Again, as in the case of $2^{\cdot+}$, the measured barriers for $3^{\cdot+}$ and $4^{\cdot+}$ are higher than the computed values by ca. 2 to 3 kcal/mol.

As shown in Fig. 5, the computed activation energies for fragmentation of $3^{\cdot+}$ and $4^{\cdot+}$ begin to become comparable to the activation energies for conformational interconversion. This trend continues as one progresses toward the most reactive radical cations ($5^{\cdot+}$ and $6^{\cdot+}$). In these latter cases, the activation energies computed for fragmentations from the lowest energy conformers are both lower than for conformational interconversion, particularly for $6^{\cdot+}$. The computed activation energy for fragmentation of $6^{\cdot+}$ (4.7 kcal/mol) is in excellent agreement with the experimental value (4.4 kcal/mol) and is ca. 3 kcal/mol less than for $3^{\cdot+}$ and $4^{\cdot+}$, in reasonable agreement with the experimental results ($\Delta\Delta H^{\ddagger} \approx$ 5 kcal/mol).

Interestingly, the computed fragmentation barrier from the lowest energy conformer of $5^{\cdot+}$ (6.4 kcal/mol) is intermediate between those calculated for $4^{\cdot+}$ and $6^{\cdot+}$. This contrasts with the measured activation enthalpy for fragmentation of $5^{\cdot+}$ (3.9 kcal/mol), which is more similar to that of $6^{\cdot+}$ (4.4 kcal/mol) than to that of $4^{\cdot+}$ (9.6 kcal/mol). A possible origin of this apparent discrepancy was discovered when comparing the relative energies of the conformers for $2^{\cdot+}$–$6^{\cdot+}$ with those for the corresponding neutral molecules (2–6). Calculations revealed that the lowest energy conformers for radical cations $2^{\cdot+}$–$6^{\cdot+}$ also corresponded to the lowest energy conformers for the neutral molecules 2–6, except for

the $5^{\cdot+}/5$ pair.[7] The lowest energy conformer for $5^{\cdot+}$ is predicted to be n (see Fig. 5), whereas the lowest energy conformer of 5 is predicted to be c (E_{rel} (5_n) = 2.3; E_{rel} (5_s) = 1.4 kcal/mol). The relative energies of the calculated conformers for 5 suggest that over the temperature range used to measure the fragmentation kinetics of $5^{\cdot+}$ (–35 to +21°C), >90% of 5 should be present as 5_c. Making the reasonable assumption that one-electron oxidation of 5 does not result in simultaneous oxidation and conformational interconversion, one would expect 5 to be oxidized to initially form $5_c^{\cdot+}$, i.e., *not* the lowest energy conformer of the radical cation ($5_n^{\cdot+}$). Consequently, if the energy barrier for fragmentation from $5_c^{\cdot+}$ is less than the barrier for conformational interconversion to the lower energy $5_n^{\cdot+}$ conformer, then the experimental activation barrier for fragmentation of $5^{\cdot+}$ should be compared to the computed fragmentation barrier predicted from $5_c^{\cdot+}$ not from $5_n^{\cdot+}$.

Figure 5 shows that the computed activation enthalpy for fragmentation of $5_c^{\cdot+}$ (4.4 kcal/mol) is in good agreement with the experimental value (3.9 kcal/mol). Interestingly, the computations also show that the energy of the fragmentation transition state from $5_c^{\cdot+}$ is equal to that for conformational interconversion to $5_n^{\cdot+}$. Thus, the calculational results predict that a significant fraction of $5_c^{\cdot+}$ should partition to the $5_n^{\cdot+}$ conformer, which is predicted to have a significantly larger barrier to fragmentation (6.4 kcal/mol). As illustrated in Fig. 5, if $5_c^{\cdot+}$ partitions between fragmentation and conformational interconversion, one would expect the experimental decay of $5^{\cdot+}$ to show biexponential behavior, i.e., a fast component due to fragmentation from $5_c^{\cdot+}$ and a slow component due to fragmentation from $5_n^{\cdot+}$. Unfortunately, the presence of the unknown species resulting from MeOP$^+$ chemistry masked our ability to establish whether the fragmentation of $5^{\cdot+}$ was biexponential. Finally, it is worth noting that all of the calculated transition state energies refer to activation enthalpies, whereas the kinetics are obviously determined by the lowest activation free energies. It seems plausible that the activation entropies for the radical cation fragmentations might be significantly lower than $\Delta S^{\ddagger}$ for the conformational interconversions. If so, the activation free energy for fragmentation of $5_c^{\cdot+}$ might be lower than for conformational interconversion to $5_n^{\cdot+}$. This also would be consistent with our kinetic data.

Bond dissociation energies

Gas phase and solution phase bond dissociation energies were calculated for the benzothiazoline radical cations $2^{\cdot+}$–$6^{\cdot+}$. The gas phase bond dissociation energies (BDE (BT-R$^{\cdot+}$)$_g$), were determined using B3LYP/6-31G* calculations as the sum of the enthalpies of the benzothiazolium cation (BT$^+$)

[7] The origin of the reversal in conformer stability for 5 vs. $5^{\cdot+}$ can be traced to two factors: (*i*) a change in the geometry at nitrogen upon one-electron oxidation; and (*ii*) the conformational inflexibility of the fluorenyl ring. The calculations on neutral molecules 1–6 showed that the nitrogen atom is strongly pyramidalized. In contrast, the nitrogen is much less pyramidalized in the corresponding radical cations and is actually planar for $1^{\cdot+}$. The planarization of the nitrogen in radical cations causes the N-CH$_3$ group to move closer to the R groups at C-2, resulting in increased, destabilizing nonbonded interactions. For $5/5^{\cdot+}$, planarization of the nitrogen upon one-electron oxidation resulted in a severe steric interaction between the N-CH$_3$ group and syn-C-1 hydrogen on the fluorenyl ring for the $5_c^{\cdot+}$ conformer, which caused a significant bow in the ring. In 5 this interaction is greatly diminished by pyramidalization at nitrogen which moves the N-CH$_3$ group away from the fluorenyl ring. We attribute the interchange in the relative stabilities of the c and n conformers of 5 vs. $5^{\cdot+}$ to this structural reorganization. Interestingly, in the otherwise structurally similar pair $6/6^{\cdot+}$, a similar steric interaction between the N-CH$_3$ group and one of the hydrogens in the syn-phenyl group of $6_c^{\cdot+}$ is relieved by rotation of the phenyl group. A comparable structural relaxation for $5_c^{\cdot+}$ is not possible because rotation of the syn-phenyl ring is constrained by its linkage to the other phenyl group that makes up the fluorenyl ring.

Fig. 5. Results of density functional calculations showing the relative potential energies (kcal/mol) for the ground state conformers of $2^{\cdot+}$–$6^{\cdot+}$ and for the transition states that interconnect them. Also shown are activation enthalpies for fragmentation from selected radical cation conformers (vertical lines). Shown in bold are the ground and transition states for the proposed, reacting conformers.
The results are shown in Table 2, along with the experimental and calculated activation energies for radical cation fragmentation. The data show that there is a general correlation of $\Delta H^{\ddagger}$ with the radical cation BDEs.

Table 2 also lists estimates of the solution phase bond dissociation energies for $2^{\cdot+}$–$6^{\cdot+}$ (BDE $(BT\text{-}R^{\cdot+})_s$) which were obtained by using Arnold's thermodynamic cycle method (1), as shown below. For these estimates we have used the approximation that the oxidations of **2**–**6** are similar to the reversible oxidation potential measured of **1** (0.77 V vs. SCE in CH$_3$CN). The oxidation of the 2,3-dimethylbenzothiazolium radical was estimated from the (irreversible) reduction of the corresponding cation (~–1.3 V vs. SCE in CH$_3$CN). Finally, the bond dissociation energies of the neutral benzothiazolines **2**–**6** (BDE $(BT\text{-}R)_g$), were estimated by DFT calculations. The results shown in Table 2 reveal that the estimated solution phase, radical cation bond dissociation energies are ca. 7–9 kcal/mol lower than those calculated for the gas phase. The lower solution phase BDEs would be consistent with greater solvation of the benzothiazolium cation than that of the radical cations.
The relative BT-R bond dissociation energies for $2^{\cdot+}$–$6^{\cdot+}$ presumably reflect contributions from differences in both the stabilization of the radicals and the steric crowding present in the radical cations. We sought to estimate the comparative contributions of these factors to the relative BDEs. Relative radical stabilization energies of R· can be defined in a number of ways. One of the most general definitions has been pioneered by Rüchardt, who has compared the difference in stability between a pure hydrocarbon radical and its substituted analogue in which one or more alkyl groups are replaced by substituents (12). The advantage of this approach is that it provides radical stabilization increments for substituents that are transferable between different radicals because the intrinsic differences in stabilities for primary, secondary, and tertiary radicals are factored out. To assess the relative effects of radical stabilities on the BDEs for $2^{\cdot+}$–$6^{\cdot+}$, however, we *do* want to include the differences in stabilities between primary, secondary, and tertiary radicals. Therefore, we have adopted the more traditional approach to assessing radical stabilities by comparing the relative R-H BDEs to a reference compound. We are primarily interested in only the *relative* contributions to radical stability along the series, therefore, we have chosen the least stabilized radical in this series (PhCH$_2$·) as our reference. Thus, we define

and the radical fragments (R·) minus the enthalpy of the most stable radical cation conformer. For $5^{\cdot+}$, the enthalpy of the $5_c^{\cdot+}$ conformer was used for the reasons described above.

Table 2. Experimental ($\Delta H^{\ddagger}_{exp}$) and calculated ($\Delta H^{\ddagger}_{calcd}$) activation energies for fragmentation of $2^{\cdot+}$–$6^{\cdot+}$, gas phase C-R bond dissociation energies calculated for **2–6** (BDE (BT-R)$_g$), gas phase (BDE (BT-R$^{\cdot+}$)$_s$), and solution phase (BDE (BT-R$^{\cdot+}$)$_s$) bond dissociation energies calculated for $2^{\cdot+}$–$6^{\cdot+}$.

Compound (R-)	$\Delta H^{\ddagger}_{exp}$	$\Delta H^{\ddagger}_{calcd}{}^{a}$	BDE (BT-R)$_g{}^{a}$	BDE (BT-R$^{\cdot+}$)$_g{}^{a}$	BDE (BT-R$^{\cdot+}$)$_s{}^{b}$

^{b}{[BDE (BT-CH$_2$Ph$^+$)$_g$ – BDE (BT-R$^{\cdot+}$)$_g$] – [BDE (PhCH$_2$-H) – BDE (R-H)]}.
^{c}{[BDE (BT-CH$_2$Ph$^+$)$_s$ – BDE (BT-R$^{\cdot+}$)$_s$] – [BDE (PhCH$_2$-H) – BDE (R-H)]}.

relative radical stabilities for the present purpose as BDE (PhCH$_2$-H) – BDE (R-H).[8] For the relative steric contributions to the BDEs for $2^{\cdot+}$–$6^{\cdot+}$, we also use the benzyl substituted radical cation as a reference. Thus, the relative steric effects are estimated by subtracting the radical stabilization contribution from the difference in radical cation BDEs, i.e., {[BDE (BT-CH$_2$Ph$^+$) – BDE (BT-R$^{\cdot+}$)] – [BDE (PhCH$_2$-H) – BDE (R-H)]}. The results of this analysis are shown in Table 3. Note that the relative steric effects estimated from the gas phase and solution BDEs for $2^{\cdot+}$–$6^{\cdot+}$ are in good agreement.

The results in Table 3 show that, relative to $2^{\cdot+}$, the BDEs for $3^{\cdot+}$–$6^{\cdot+}$ roughly fall into two classes. For $5^{\cdot+}$, the relative contributions owing to radical stabilization and steric effects are nearly equal, 10 and 11 kcal/mol, respectively. For radical cations $3^{\cdot+}$, $4^{\cdot+}$, and $6^{\cdot+}$, the relative radical stabilization and steric contributions to bond weakening are 3–7 kcal/mol and 11–17 kcal/mol, respectively, i.e., the steric effects dominate.

Origin of the radical cation fragmentation barriers

Estimates of the BDEs for radical cations $3^{\cdot+}$–$6^{\cdot+}$ in Table 2 show that all are predicted to be exothermic in solution. Nonetheless, the radical cations have substantial activation barriers to fragmentation. It is of interest to compare this behavior to that observed for the fragmentations of substituted bibenzyl radical cations ($10^{\cdot+}$) reported by Maslak et al. (3a) and to the alkylated NADH radical cations ($11^{\cdot+}$) reported by Savéant and co-workers (13). These radical cation fragmentations were found to have very small in-

trinsic barriers for fragmentation (≤4 kcal/mol), showing that the internal and solvent reorganization energies for the reactions are quite small. In this respect the fragmentations of $3^{\cdot+}$–$6^{\cdot+}$ are clearly different. Based on the fact that $3^{\cdot+}$ and $4^{\cdot+}$ have substantial activation energies for fragmentation ($\Delta H^{\ddagger} \approx 10$ kcal/mol) despite the reactions being exothermic by 9 to 10 kcal/mol in solution, one can conclude that the intrinsic barriers for fragmentation of the substituted benzothiazline radicals studied here are >10 kcal/mol.
What is the origin of the difference in the intrinsic barriers for fragmentation of $10^{\cdot+}$ and $11^{\cdot+}$ vs. $2^{\cdot+}$–$6^{\cdot+}$? We propose that the difference is related to the relative internal reorganization energies of the fragmentations. It is perhaps easier to think about the problem by considering the origin of the barrier for the reverse reaction, i.e., cation + radical recombination. The barrier for the recombination reaction will be directly related to the extent of delocalization of the cation and radical fragments. The greater the degree of delocali-

^{8}Although it would have been desirable to use BDE (R-CH$_3$) rather than BDE (R-H) to estimate relative radical stabilities, the former values are not well determined for the systems studied here.

zation, the greater will be the degree of electronic, internal reorganization, and, therefore, the greater will be the reaction barrier. When comparing the cation and radical fragments produced from fragmentation of 10^{+} vs. 2^{+}–6^{+}, the primary difference is likely related to the extent of delocalization of the cation, i.e., the benzyl cation (in the case of 10^{+}) vs. the benzothiazolium cation (in the case of 2^{+}–6^{+}). The benzothiazolium cation is expected to have significantly less carbocation character at the recombination site than a benzyl cation, which would lead to a larger internal reorganization energy for the benzothiazolium cation + radical recombination. In addition, for benzothiazoline radical cations 3^{+}–6^{+}, the radicals produced by fragmentation are more delocalized than a simple benzyl radical, which will also lead to greater internal reorganization energies for recombination and, consequently, for fragmentation too. For the fragmentation of 11^{+} vs. 2^{+}–6^{+}, we presume that delocalization of the cation fragments for the two systems is somewhat similar. However, the relative extent of radical delocalization is clearly different. For 11^{+}, the radical fragment — $\cdot t$-Bu — is clearly much more localized than any of the radicals formed from fragmentation of 2^{+}–6^{+}. Thus, cation + radical recombination to form 11^{+} should have a lower internal reorganization energy than the recombinations to form 2^{+}–6^{+}.

The proposition that the cation + radical recombination reactions to form 2^{+}–6^{+} should have significant barriers is supported by the fact that even addition of a localized, primary radical to benzothiazolium cation **12** has a rate constant of only 1×10^6 M^{-1} s^{-1} at 25°C (14). It should be clear that addition of the delocalized radicals, such as those derived from fragmentation of 2^{+}–6^{+}, would have significantly lower rate constants. Consequently, the fragmentations of 2^{+}–6^{+} are expected to have significant intrinsic barriers.
Conclusions

There are three main conclusions from this work. First, we have demonstrated that benzothiazoline derivatives, which are among the lowest oxidation potential compounds yet investigated as candidates for radical cation fragmentation, can undergo rapid fragmentation upon one-electron oxidation if the fragmenting bond is sufficiently weakened by a combination of stabilizing the radical fragment and by steric crowding in the reactants. These two factors allow the rate constants for fragmentation of benzothiazoline radical cations to be tuned by over 6 orders of magnitude. Second, benzothiazoline radical cations were found to have considerably large intrinsic activation barriers (>10 kcal/mol) for fragmentation. The barriers were attributed to large reorganization energies of the product fragments, the benzothiazolium cation and the resonance-delocalized radicals. Consequently, the same factors that lead to the thermodynamic driving forces for the fragmentations — the stabilities of the benzothiazolium cation and the resonance-delocalized radicals — simultaneously result in large intrinsic barriers.

These factors lead to opposing kinetic effects. On the one hand, the natural exothermicities of the reactions should decrease the activation barriers for fragmentation according to the Bell–Evans–Polanyi principle. On the other hand, the large intrinsic barriers increase the activation energies. This analysis reveals a fundamental limitation of using delocalized cation and radical products in the design of fast radical cation fragmentation reactions. As shown in the present work, steric effects are the more attractive structural feature to utilize for designing fast radical ion fragmentations because they do not increase the intrinsic barrier. Third, for relatively fast radical ion fragmentations of sterically congested systems such as those described in this work, one should keep in mind that the energetic barriers for fragmentation can be lower than the barriers for conformational interconversion. In these cases, the possibility exists that the most stable radical ion conformer may not necessarily be the reactive conformer.

Experimental section

General method

^{1}H NMR spectra were recorded with either a General Electric/Nicolet QE-300 spectrometer or a Brüker Avance-400 spectrometer. ^{13}C NMR spectra were recorded with an Avance-400 spectrometer. Proton chemical shifts (δ) are reported in parts per million (ppm) downfield from tetramethylsilane or in ppm relative to the singlet at 7.24 ppm for the residual CHCl$_3$ in the chloroform-d or the multiplet at 1.93 ppm for the residual CHD$_2$CN in the acetonitrile-d_3. Reported proton–proton coupling constants assume first-order behavior. Splitting patterns are designated as singlet (s), doublet (d), triplet (t), quartet (q), multiplet (m), and broad (br). The meta- and para-couplings are ignored. Ortho-, meta-, and para-hydrogens of phenyl groups are designated o-, m-, and p-; for magnetically nonequivalent phenyl groups the signals of the second phenyl group are designated o'-, m'-, and p'-. The aromatic hydrogens of the benzothiazoline and benzothiazolium derivatives are numbered 4–7 from the α position to N. Carbon chemical shifts are reported in ppm relative to internal acetonitrile-d_3 (117.61 and 0.60 ppm) or chloroform-d (77.34 (t) ppm).

Acetonitrile was refluxed over CaH$_2$ for 24 h and distilled fresh prior to use under an atmosphere of nitrogen. Anhydrous diethyl ether and tetrahydrofuran were freshly distilled from benzophenone ketyl under nitrogen.

Electrochemical measurements

Cyclic voltammetric measurements were carried out on a glassy carbon disk electrode using a CHI660 electrochemical analyzer (CH Instruments, Inc.) in acetonitrile with tetrabutylammonium perchlorate as electrolyte. 2,3-Dimethylbenzothiazolium showed irreversible reduction with a peak potential of –1.30 V vs. SCE. A reversible oxidation potential was obtained for compound **1** (0.77 V vs. SCE, 3 mm electrode at 0.5 V/s). Compounds **3** and **6** showed irreversible oxidation with peak potentials at 0.63 and 0.65 V vs. SCE, respectively.

Using a 33 μm carbon electrode at a scan rate ≥25 V/s, compound **2** showed a quasi-reversible oxidation of 0.70 V vs. SCE. Scanning at slower rates (2.5–10 V/s) and with

varying delays, a rate constant of 1 ± 0.2 s^{-1} was obtained for the follow-up chemical reaction, presumably the fragmentation of $2^{\cdot+}$.

Laser flash photolysis

Nanosecond laser flash photolysis experiments were carried out using either 380 or 355 nm excitations. For 380 nm excitation, a Lambda Physik Lextra 50 excimer laser (XeCL, 308 nm; <180 mJ/pulse; 10 ns pulses) and a Lambda Physik LPD 3002 pumped-dye laser (Exciton-384 dye for 380 nm; <10 mJ/pulse; 7 ns pulses) were used. For 355 nm excitation, the frequency-tripled output from an OPOTEK Vibrant Q-switched Nd:YAG laser system (pulse width 4 ns, 2–8 mJ) was used. The excitation pulses were attenuated, when necessary, using neutral density filters.

Transient absorption was monitored at right angles to the excitation. A pulsed Oriel 150 W xenon lamp (Model 66007) was used as the monitoring beam. The analyzing beam was collected and focused on the entrance slit (2 nm) of an Instrument S. A. H-20 monochromator. A Hamamatsu R-446 photomultiplier tube (PMT) in a custom housing (Products for Research) was attached to the exit slit of the monochromator. A computer-controlled Stanford Research Systems high voltage power supply (model PS310) was used with the PMT. The signals from the PMT were digitized using a Tektronix TDS 620 oscilloscope and transferred to a PC, via a GPIB interface, for data storage and processing. A Quantum Composer pulse generator (Model 9318) provided TTL trigger pulses to control the timing for the laser, lamp, and oscilloscope.

Appropriate long pass filters were placed on either side of the sample to prevent photolysis by the analyzing light.

Spectral measurements

To acetonitrile solutions of *N*-methoxyphenanthridinium hexafluorphosphate (MeOP$^+$) with an OD of 0.5–0.77 at the excitation wavelength (380 or 355 nm) were added benzothiazolines **2–6** (5–15 mM). The samples were thoroughly purged with either dioxygen or argon (~10 min) before passing them through a 1×1 cm^2 quartz flow cell. The flow rate was adjusted so that fresh sample was available for each laser shot.

Kinetics measurements

The samples were purged with either dioxygen or nitrogen prior to, and during, laser irradiation. Typically, a solution of MeOP$^+$ in acetonitrile (OD at 380 nm = 0.6–0.8) was exposed to 380 nm laser excitation (0.5–0.6 mJ/pulse) in the presence of the benzothiazoline derivative (6 to 7 mM), and the decay of the radical cation was followed between 420–450 nm on the ns to µs time scale. For temperature dependence studies, fresh samples were equilibrated at each temperature for 15–20 min prior to the measurement. Each set of experiments was repeated at least three times.

Materials

2-Methylamino-benzenethiol was prepared according to a literature procedure by reductive ring opening of 2,3-dihydro-1,3-benzothiazole (Aldrich) using lithium aluminum hydride (15). Methyl iodide, trimethyloxonium tetrafluoroborate, acetophenone, 1-phenyl-2-butanone, 1,1-diphenyl-

acetone, cumene, α-methylstyrene, 1,1-diphenylethylene, and fluorene were all obtained from Aldrich Chemical Company and used without further purification. 1,1,2,2-Tetraphenylethane (16), 2,2,3,3-tetraphenylbutane (17), 2,3-dimethyl-2,3-diphenylbutane (18), and compound **9** (19) were prepared following previously reported methods. 2-Phenyl-2-methylpropionoyl chloride was prepared from the corresponding acid (20*a*) by reaction with PCl$_5$ using a procedure analogous to that described in ref. (20*b*). Products of the cleaved radicals were identified by comparison with ^{1}H NMR spectra of authentic samples.

2,3-Dimethylbenzothiazolium hexafluorophosphate

This material was prepared by modification of a literature procedure (4). To a stirred solution of acetyl chloride (5.0 g, 63.7 mmol) in benzene (dry, 200 mL), a solution of 2-methylamino-benzenethiol (8.84 g, 63.7 mmol) in benzene (20 mL) was added dropwise at room temperature. The reaction mixture was refluxed for 1 h. Solvent removal provided a pale yellow solid that was dissolved in water (200 mL) followed by addition of potassium hexafluorophosphate (7.0 g in 100 mL H$_2$O) to afford a white precipitate (19 g, 79%). ^{1}H NMR (CD$_3$CN) δ: 8.24 (d, J = 8 Hz, 1H), 8.05 (d, J = 9 Hz, 1H), 7.92 (t, J = 8 Hz, 1H), 7.82 (t, J = 8 Hz, 1H), 4.15 (s, 3H), 3.09 (s, 3H).

N-Methoxyphenanthridinum hexafluorophosphate

N-Methoxyphenanthridinum tetrafluorboate was prepared from the reaction of phenanthridine-*N*-oxide with trimethyloxonium tetrafluorborate in dichloromethane (7). A solution of the BF$_4$ salt (1 g) in ~15 mL water was added to an aqueous solution of potassium hexafluorophosphate (2 g in ~10 mL). The mixture was cooled and the precipitate was recrystallized from water as a crystalline pale yellow solid. ^{1}H NMR (CD$_3$CN) δ: 10.09 (s, 1H), 9.06 (d, 1H), 9.02 (d, 1H), 8.57 (t, 2H), 8.43 (t, 1H), 8.24–8.13 (m, 3H), 4.61 (s, 3H).
2,2,3-Trimethylbenzothiazoline (1)

This compound was prepared according to a literature procedure (5). To a stirred suspension of 2,3-dimethyl-benzothiazolium toluene-4-sulfonate (5.0 g, 14.32 mmol) in anhydrous diethyl ether (125 mL) at –40°C, methylmagnesium bromide (2.87 M solution in diethyl ether, 5.3 mL, 15 mmol) was added dropwise over 5 min under an atmosphere of N$_2$. The reaction mixture was refluxed for 2 h and then quenched with aqueous ammonium chloride solution (70 mL). The organic layer was separated and the aqueous layer was extracted with ether (3 × 50 mL). The organic extracts were combined, washed successively with water (2 × 100 mL) and with brine solution (2 × 100 mL), and dried

over anhydrous magnesium sulfate. Filtration and removal of the solvent yielded a red oil (2.2 g, 77%). The crude product was distilled under reduced pressure, bp 80°C at 10 mmHg (1 mmHg = 133.322 Pa) (lit. (5c) bp 75–80°C at 10 mmHg (1 mmHg = 133.322 Pa)) to yield a colorless oil (2.0 g, 76%). MS m/z: 179 (M$^+$, calculated for $C_{11}H_{15}NS$). ^{1}H NMR (CDCl$_3$) δ: 7.05 (d, J = 7.4 Hz, H-7), 6.99 (t, J = 7.6 and 7.8 Hz, H-5), 6.64 (t, J = 7.4 and 7.6 Hz), 6.31 (d, J = 7.8 Hz, H-4), 2.72 (s, NCH$_3$), 1.65 (s, C(CH$_3$)$_2$). ^{13}C NMR (CDCl$_3$) δ: 146.64, 124.17, 121.70, 117.55, 106.31, 61.03, 37.28, 28.58, 28.40.

2-Benzyl-2-ethyl-3-methyl-benzothiazoline (2)

A solution of 2-methylamino-benzenethiol (1.0 g, 7.2 mmol) and 1-phenyl-2-butanone in absolute ethanol (7 mL) was refluxed for 48 h under an atmosphere of N$_2$. The reaction mixture was cooled and kept at –40°C for 3 h. A precipitate came out of solution, which rapidly melted at room temperature to afford a yellow oil. The latter was distilled under reduced pressure (165–167°C at 0.04 mmHg (1mmHg = 133.322 Pa)) to obtain a very pale yellow oil (1.2 g, 63%). MS m/z: 269 (M$^+$, calculated for $C_{17}H_{19}NS$). ^{1}H NMR (CDCl$_3$) δ: 7.36–7.26 (m, 5H), 7.04 (d, J = 7.4 Hz, 1H), 7.00 (t, J = 7.6 and 7.8 Hz, 1H), 6.64 (t, J = 7.4 and 7.6 Hz, 1H), 6.30 (d, J = 7.8 Hz, 1 H), 3.28 (d, J = 13.4 Hz, 1H), 3.10 (d, J = 13.4 Hz, 1H), 2.86 (s, 3H), 2.10 (sextet, J = 14.9 and 7.2 Hz, 1H), 1.72 (sextet, J = 14.9 and 7.2 Hz, 1H), 1.05 (t, J = 7.2 Hz, 3H). ^{13}C NMR (CDCl$_3$) δ: 148.17, 136.36, 131.10, 127.74, 126.62, 125.17, 124.17, 121.09, 117.60, 105.48, 85.78, 45.46, 30.19, 29.04, 9.15. ^{13}C DEPT135 NMR (CDCl$_3$) δ: 131.10, 127.74, 125.17, 121.09, 117.60, 105.48, 45.46 (negative peak), 30.19 (negative peak), 29.04, 9.15.

2,3-Dimethyl-2-diphenylmethyl-benzothiazoline (3)

A solution of 2-methylamino-benzenethiol (2.0 g, 14.38 mmol) and 1,1-diphenylacetone (3.02 g, 14.38 mmol) in absolute ethanol (15 mL) was refluxed for 52 h under an atmosphere of N$_2$. Upon cooling to –40°C, a colorless solid (2.3 g, 48%) formed which was recrystallized twice from ethanol to yield colorless plates (2.0 g, 42%), mp 82°C. MS m/z: 331.0 (M$^+$, calculated for $C_{22}H_{21}NS$). ^{1}H NMR (CDCl$_3$) δ: 7.67 (o-H, 2H), 7.53 (o′-H, 2H), 7.33 (m′-H, 2H), 7.27 (p′-H, 1H), 7.20 (m-H, 2H), 7.14 (p-H, 1H), 6.99 (d, J = 7.4 Hz, 1H), 6.92 (t, J = 7.5 and 7.8 Hz, 1H), 6.59 (t, J = 7.4 and 7.5 Hz, 1H), 6.14 (d, J = 7.8 Hz, 1H), 4.51 (s, CHPh$_2$), 2.69 (s, N-CH$_3$), 1.75 (s, CH$_3$). ^{13}C NMR (CDCl$_3$) δ: 147.71, 140.69, 129.89, 128.23, 127.70, 127.03, 126.31, 125.25, 124.06, 121.00, 117.51, 105.99, 83.77, 59.53, 29.14, 27.81. ^{13}C DEPT45 NMR (CDCl$_3$) (only CH and CH$_3$ carbons) δ: 129.89, 129.83, 128.23, 127.70, 127.03, 126.31, 125.25, 121.00, 117.51, 105.99, 59.53, 29.14, 27.81.

2-Cumyl-2,3-dimethyl-benzothiazoline (4)

To a stirred solution of 2-phenyl-2-methylpropionyl chloride (4.8 g, 26.3 mmol) in benzene (dry, 80 mL), a solution of 2-methylamino-benzenethiol (3.7 g, 26.4 mmol) in benzene (20 mL) was added dropwise at room temperature. The reaction mixture was refluxed for 1.5 h. Solvent removal gave an oil that was dissolved in CH$_2$Cl$_2$ (100 mL). The resulting solution was added dropwise to rapidly stirred

diethyl ether (dry, 850 mL) to form a yellow precipitate. The precipitate was dissolved in water (400 mL) at 70–80°C and an aqueous solution of potassium hexafluorophosphate (4.8 g in 100 mL H$_2$O) was added. Upon cooling the solution, a pale yellow precipitate formed. Recrystallization from acetonitrile – diethyl ether (1:10) gave a colorless solid of the 2-cumyl-3-methyl-benzothiazolium salt (9.0 g, 83%). ^{1}H NMR (CD$_3$CN) δ: 8.35 (d, J = 8.0 Hz, H-7), 8.02 (d, J = 8.3 Hz, H-4), 7.94 (t, J = 7.3 and 8.3 Hz, H-5), 7.88 (t, J = 7.3 and 8.0 Hz, H-6), 7.5–7.42 (m, m- and p-H, 3H), 7.37–7.35 (m, o-H, 2H), 3.75 (s, NCH$_3$), 2.04 (s, C(CH$_3$)$_2$). ^{13}C NMR (CD$_3$CN) δ: 142.10, 130.10, 129.62, 128.25, 125.82, 123.79, 117.30, 116.75, 45.72, 37.92, 28.73. ^{13}C DEPT45 NMR (CD$_3$CN) δ: 130.10, 129.62, 128.91, 128.25, 125.82, 123.79, 116.75, 37.92, 28.73.

To a stirred suspension of 2-cumyl-3-methyl-benzothiazolium hexafluorophosphate (1.0 g, 2.42 mmol) in tetrahydrofuran (80 mL) under an atmosphere of N$_2$, methylmagnesium bromide (2.73 M solution in ether, 7.5 mL, 22 mmol) was added dropwise over 15 min at –70°C. The reaction was stirred at –70°C for an additional 30 min, followed by 4 h at room temperature, and then refluxed for 15 min. The reaction was quenched with aqueous ammonium chloride solution (50 mL, pH ~ 4) and extracted with diethyl ether (3 × 50 mL). The ether extracts were washed with brine solution (2 × 50 mL), dried over anhydrous magnesium sulfate, filtered, and the solvent removed to afford a pale yellow oil (0.54 g, ~79%). The crude material was recrystallized from aqueous methanol to yield a pale yellow solid, mp 70–71°C. MS m/z: 283 (M$^+$, calculated for $C_{18}H_{21}NS$). ^{1}H NMR (CDCl$_3$) δ: 7.56 (d, o-H, 2H), 7.34 (t, m-H, 2H), 7.27 (t, p-H, 1H), 6.99–6.95 (m, 2H), 6.62 (t, 1H), 6.31 (d, 1H), 2.54 (s, 3H), 1.78 (s, 3H), 1.62 (s, 3H), 1.54 (s, 3H). ^{13}C (CDCl$_3$) δ: 149.95, 144.51, 128.81, 127.23, 126.31, 125.66, 124.90, 119.81, 117.74, 107.0, 87.03, 49.99, 34.06, 24.76, 24.64, 23.49. ^{13}C DEPT135 (CDCl$_3$) (only CH and CH$_3$ carbons observed) δ: 128.81, 127.23, 126.31, 124.90, 119.81, 117.74, 106.99, 34.07, 24.76, 24.64, 23.49.

2-(1,1-Diphenylethyl)-2,3-dimethyl-benzothiazoline (5)

Reaction of 2,2-diphenylpropionyl chloride with 2-methylamino-benzenethiol, as described above for compound 4 (reflux time of 5 h), gave the corresponding benzothiazolium chloride in 70% yield as colorless cubes from acetonitrile – diethyl ether (1:10). ^{1}H NMR (CDCl$_3$) δ: 8.57 (d, 1H), 8.12 (d, 1H), 7.87 (t, 1H), 7.72 (t, 1H), 7.48–7.44 (m, 6H), 7.25–7.21 (m, 4H), 4.29 (s, 3H), 2.66 (s, 3H). ^{13}C NMR (CDCl$_3$) δ: 186.79, 144.05, 143.36, 141.55, 130.76, 129.17, 127.79, 123.25, 118.27, 53.64, 40.54, 27.68.

Similarly, compound 5 was prepared from the reaction of 2-(1,1-diphenylethyl)-3-methylbenzothiazolium chloride with MeMgBr as described above for compound 4. Compound 5 was obtained in 46% yield as colorless crystals from ethanol, mp 58–62°C. MS m/z: 345 (M$^+$, calculated for $C_{23}H_{23}NS$). ^{1}H NMR (CDCl$_3$) δ: 7.37–7.17 (m, 10H), 6.98 (d, J = 7.4 Hz, 1H), 6.97 (t, J = 7.5 and 7.8 Hz, 1H), 6.63 (t, J = 7.4 and 7.5 Hz, 1H), 6.31 (d, J = 7.8 Hz, 1H), 2.20 (br. s, 3H), 2.06 (s, 3H), 1.98 (s, 3H). ^{13}C NMR (CDCl$_3$) δ: 153.83, 149.34, 133.55, 130.81, 129.35, 127.39, 127.09, 126.51, 125.68, 125.05, 119.85, 107.62, 34.32, 27.58, 25.65.

2,3-Dimethyl-2-(9-methylfluoren-9-yl)-benzothiazoline (6)

9-Methylfluorene-9-carbonyl chloride (prepared in an analogous manner to 2-phenyl-2-methylpropionoyl chloride, see above) was reacted with 2-methylamino-benzenethiol, as described above under compound **4** (1 h reflux time), to give the corresponding benzothiazolium hexafluorophosphate salt as colorless crystals in 96% yield. ^{1}H NMR (CDCl$_3$) δ: 8.89 (d, $J \approx 8$ Hz, 1H), 8.30 (d, $J \approx 8$ Hz, 1H), 7.91 (d, $J \approx 7.6$ Hz, 2H), 7.79 (t, $J \approx 7$ and 8 Hz, 1H), 7.71 (t, $J \approx 7$ and 8 Hz, 1H), 7.54 (t, 2H), 7.41–7.36 (m, 4H), 3.30 (s, 3H), 2.22 (s, 3H). ^{13}C NMR (CDCl$_3$) δ: 181.55, 144.38, 143.32, 139.78, 130.70, 130.07, 129.51, 128.87, 128.73, 125.57, 123.88, 121.70, 117.01, 54.21, 36.37, 29.06.

The benzothiazolium salt was treated as described above for compound **4** to give compound **6** as a colorless viscous oil in 40% yield after flash chromatography (silica gel, 60% hexane – diethyl ether). MS m/z: 343 (M$^+$, calculated for C$_{23}$H$_{21}$NS). ^{1}H NMR (CDCl$_3$) δ: 7.89 (d, $J = 7.6$ Hz, 1H), 7.78 (d, $J = 7.7$ Hz, 1H), 7.74 (d, $J \approx 7.5$ Hz, 1H), 7.72 (d, $J \approx 7.5$, 1H), 7.41 (t, $J = 7.5$ Hz, 1H), 7.36 (t, $J = 7.5$ Hz, 1H), 7.30 (t, $J = 7.4$ Hz, 1H), 7.22 (t, $J = 7.5$ Hz, 1H), 7.01 (d, $J = 7.4$ Hz, H-4), 6.95 (t, $J = 7.4$ and 7.9 Hz, H-6), 6.66 (t, $J = 7.4, 7.4$ Hz, H-5), 6.32 (d, $J = 7.9$ Hz, H-7), 2.61 (s, 3H), 1.79 (s, 3H), 1.62 (s, 3H). ^{13}C NMR (CDCl$_3$) δ: 150.21, 148.91, 148.58, 141.215, 140.97, 127.68, 127.52, 126.85, 126.77, 126.45, 126.01, 125.02, 125.98, 119.84, 119.61, 119.17, 118.49, 108.36, 85.96, 61.87, 34.58, 23.35, 20.75.

General procedure for photolysis of benzothiazolines in acetontrile-d_3

An equimolar (~0.01 M) solution of the benzothiazoline and MeOP$^+$ in acetonitrile-d_3 was purged with nitrogen for 5–10 min and then irradiated for 5–10 min in a Rayonet reactor equipped with 400 nm lamps. The color of the reaction mixture changed from pale yellow to slightly darker yellow during the photolysis. After photolysis, a known amount of internal standard, viz., tetrachloroethane was added into the reaction mixture and ^{1}H NMR recorded. Products were identified by comparison with ^{1}H NMR spectra of authentic samples prepared independently. The yields of products were determined by ^{1}H NMR integration of diagnostic proton signals of products relative to the area of peak due to internal standard tetrachloroethane (δ 6.3, s, 2H).

Photolysis products of 3

2,3-Dimethybenzothiazolium (82%, 8.25 (d, $J = 8.2$ Hz, H-7), 8.09 (d, $J = 8.5$ Hz, H-4), 7.92 (t, $J = 7.2$ and 8.5 Hz, H-5), 7.83 (t, $J = 7.2$ and 8.2 Hz, H-6), 4.16 (s, 3H), 3.10 (s, 3H)), phenanthridine, 1,1,2,2,-tetraphenylethane (93%), adduct **7** (27%), CH$_3$OH(D) (54%).

Photolysis products of 4

2,3-Dimethybenzothiazolium (87%), phenanthridine (85%), 2,3-dimethyl-2,3-diphenylbutane (70%), α-methylstyrene (5%), cumene (18%), adduct **7** (13%), CH$_3$OH(D) (63%).

Photolysis products of 5

2,3-Dimethybenzothiazolium (88%), phenanthridine (83%), bis-(9-methyl-9-fluorenyl) (**9**) ((85%) δ: 7.49 (d, $J = 7.5$ Hz, 4H), 7.23 (t, average $J = 7.4$ Hz, 4H), 7.06 (t, average $J = 7.4$ Hz, 4H), 6.88 (very broad, 4H), 1.91 (s, 6H)), 9-methyl-fluorene (11%), adduct **7** (13%), CH$_3$OH(D) (66%).

Photolysis products of 6

2,3-Dimethybenzothiazolium (88%), phenanthridine (65%), 2,2,3,3-tetraphenylbutane (82%), 1,1-diphenylethylene (12%), adduct **7** (22%), CH$_3$OH(D) (63%).

Attempted isolation of adduct 7

An equimolar (0.01 M) solution of benzothiazoline **3** and MeOP$^+$ in acetonitrile (25 mL) was irradiated under nitrogen for 20 min in a Rayonet reactor equipped with 400 nm lamps. The solution was concentrated to ~2 mL and diluted with diethyl ether (~50 mL). A precipitate formed which was collected and identified by ^{1}H NMR as 2,3-dimethyl-benzothiazolium. Upon addition of hexane to the ethereal solution the mixture turned turbid and, upon standing, resulted in formation of an oil. The supernatant liquid was decanted and the oil was repeatedly washed with hot hexane to further remove phenanthridine and 1,1,2,2,-tetraphenyl-ethane. Analysis of the hexane-washed solid by ^{1}H NMR showed that it was a mixture of primarily 2,3-dimethybenzo-thiazolium salt and adduct **7**, along with traces of 1,1,2,2,-tetraphenylethane and phenanthridine.

Compound 7

^{1}H NMR (CD$_3$CN) δ: 8.18 (d, $J = 6.3$ Hz, 1H), 7.85–7.77 (m, 5H), 7.48 (t, $J = 7.7$ Hz, 1H), 7.37 (t, $J = 7.7$ Hz, 1H), 7.24 (d, $J \approx 8$ Hz, 1H), 7.21 (t, $J = 7.5$ Hz, 1H), 7.10 (t, $J = 7.4$ Hz, 1H), 7.89 (br d, 6.4, 1H), 5.30 (dd, $J = 4.8$ and 7.4 Hz, 1H), 4.96 (dd, $J = 4.8$ and 14.6, 1H), 4.75 (dd, $J = 7.4$ and 14.6 Hz, 1H), 3.80 (s, 3H), 2.53 (s, 3H).

Preparation of adduct 8

To an equimolar solution of *N*-methoxyphenanthridinium hexafluorophosphate (35.5 mg, 0.1 mmol) and 2,3-dimethyl-benzothiazolium hexafluorphosphate (30.9 mg, 0.1 mmol) in 4 mL CD$_3$CN, ~30 mg anhydrous sodium carbonate was added. The solution was stirred at room temperature and the reaction was monitored by ^{1}H NMR. After ~8 h, the conversion was nearly complete yielding almost exclusively compound **8**, which was identified by its NMR spectrum (CD$_3$CN). The chemical shifts of the ^{1}H NMR were assigned based on NOE, COSY, and TOCSY experiments using a 500 MHz spectrometer; those of strongly overlapping signals were further confirmed by comparison with simulated spectra. The NOE experiment indicated the proximity of H-6 (methine triplet at 5.299 ppm) to H-7 (aromatic hydrogen at 7.217 ppm) and of H-3′ (methyl singlet at 3.881 ppm) to H-4′ (aromatic hydrogen at 7.912 ppm).

Metallocene-catalyzed olefin polymerizations using triphenylcyclopropenium tetrakis(pentafluorophenyl)borate as the activator

Huiying Li and Douglas C. Neckers

Abstract: Triphenylcyclopropenium (TPCP) tetrakis(pentafluorophenyl)borate activates bis(cyclopentadienyl)dimethyl titanium resulting in a highly reactive initiating system for the polymerization of styrene. In contrast to triphenylmethyl tetrakis(pentafluorophenyl)borate which is quite active in the absence of the metallocene, TPCP borate shows no activity for styrene polymerization in the absence of bis(cyclopentadienyl)dimethyl titanium. TPCP is the most efficient activator in the carbonium ion – borate class. We propose, based on ^{1}H NMR evidence that reaction of Cp_2TiMe_2 and TPCP borate leads to the formation of the cationic Ti complex $[Cp_2TiMe]^+B(C_6F_5)_4^-$. Evidence for the latter is also provided by UV–vis spectroscopy in that we found a bathochromic shift of the Cp_2TiMe_2 LMCT absorption band from 361 to 482 nm in CH_2Cl_2 and 487 nm in toluene, respectively. Thermal decomposition of the cationic complex $[Cp_2TiMe]^+B(C_6F_5)_4^-$ leads to less activity. The systems are good catalysts for ethylene polymerization as well, but are less active when using propylene. A conventional Ziegler–Natta coordination polymerization mechanism accounts for ethylene and propylene polymerization while a carbocationic polymerization mechanism is proposed for styrene.

Key words: triphenylcyclopropenium tetrakis(pentafluorophenyl)borate, bis(cyclopentadienyl)dimethyl titanium, activator, olefin polymerization.

Résumé : Le tétrakis(pentafluorophényl)borate de triphénylcyclopropénium (TPCP) active le bis(cyclopentadiényl)diméthyltitane qui conduit à un système très réactif pour initier la polymérisation du styrène. Par opposition au tétrakis(pentafluorophényl)borate de triphénylméthyle qui est très actif en l'absence de métallocène, le borate de TPCP ne présente aucune activité vis-à-vis de la polymérisation du styrène en l'absence du bis(cyclopentadiényl)diméthyltitane. Le TPCP est l'activateur le plus efficace de la classe borate – ion carbonium. On suggère, sur la base de données de RMN du ^{1}H, que la réaction du Cp_2TiMe_2 et du borate de TPCP conduit à la formation du complexe cationique du Ti, $[Cp_2TiMe]^+B(C_6F_5)_4^-$. Ce résultat est également appuyé par des mesures effectuées par spectrométrie UV–vis qui démontrent un déplacement bathochrome de la bande d'absorption du LMCT du Cp_2TiMe_2 de 361 nm vers 482 nm pour le CH_2Cl_2 et vers 487 nm pour le toluène, respectivement. Une décomposition thermique du complexe cationique $[Cp_2TiMe]^+B(C_6F_5)_4^-$ conduit à une perte d'activité. Les systèmes sont aussi de bons catalyseurs pour la polymérisation de l'éthylène, mais ils sont moins réactifs pour le propylène. Un mécanisme de polymérisation conventionnel de Ziegler–Natta par coordination permet d'expliquer la polymérisation de l'éthylène et du propylène alors qu'on propose un mécanisme de polymérisation carbocationique pour le styrène.

Mots clés : tétrakis(pentafluorophényl)borate de triphénylcyclopropénium, bis(cyclopentadiényl)diméthyltitane, activateur, polymérisation d'oléfine.

Introduction

Metallocene coordination polymerization catalyst systems for olefins are an important research and development topic (1). Successful catalysts invariably consist of transition metal complexes called *catalyst precursors* and activators also called *co-catalysts*. The partners react forming an active species that is comprised of a cation–anion ion pair. The struc-

ture of the activator significantly influences catalytic activity, the character of the polymerization, and polymer properties.

The number of viable co-catalysts for metallocene polymerizations is rather limited (2). Methylaluminoxane (MAO) is an important industrial co-catalyst, but must be used in huge excess to achieve high activity. Triphenylmethyl carbenium ion ("trityl") if paired with $B(C_6F_5)_4^-$ (**1**) has been reported to be a highly efficient activator for group 4 dimethylmetallocenes (3) at low co-catalyst to catalyst ratios (1:1). A number of other borates have also been developed to improve properties such as solubility in organic solvents and thermal stability (4).

Fig. 1. Structure of the activator and the catalyst.

Cp = cyclopentadienyl

1
We have recently discovered that triarylcyclopropenium salts may be used as cationic initiators for both the thermal and photochemical polymerization of epoxides (5, 6). Triphenylcyclopropenium (TPCP) cation is a strong electrophile (7) and when TPCP salts paired with weakly nucleophilic anions tetrakis(pentafluorophenyl)gallate are dissolved in ketones with active α-hydrogens such as cyclohexanone we found that super acids (presumably H-Ga(C_6F_5)$_4$) form. Super acids also result from irradiation of TPCP$^+$Ga(C_6F_5)$_4^-$ in various solvents (8).

In view of this new discovery we wished to explore further the advantages of cyclopropenium salts in various polymerization reactions. We report herein results of olefin polymerization catalyzed by bis(cyclopentadienyl)dimethyl titanium (**3**) using TPCP borate (**2**) as the activator (Fig. 1).

Experimental section

Materials

All chemicals were used as received from Aldrich unless otherwise noted. Benzene and toluene were distilled over sodium under argon. CH_2Cl_2 was freshly distilled over CaH_2 under argon. α,α-Dichlorotoluene was purchased from Acros Organics and used as received. Bis(cyclopentadienyl)titanium dichloride was purchased from Strem Chemicals Inc. and used as received. Styrene was distilled over CaH_2 at 50°C under vacuum and kept over molecular sieves (4 Å) under argon in a refrigerator. Potassium tetrakis(pentafluorophenyl)borate was prepared as reported (9). Bis(cyclopentadienyl)dimethyltitanium (**3**) was prepared according to the literature (10) and kept in a freezer as a solution (~36%) in toluene.

Measurements

^{1}H and ^{19}F NMR spectra were recorded either with a Varian Gemini 200 NMR or a Varian Unity plus 400 NMR spectrometer. Chemical shifts are in ppm with TMS as the internal standard (^{1}H NMR) or CFCl$_3$ as the external standard (^{19}F NMR). Melting points were determined with a Thomas Hoover capillary melting point apparatus and were uncorrected. UV–vis spectra were recorded on a Shimadzu
UV-2401PC UV–vis recording spectrophotometer. Number- and weight-average molecular weights (M_n and M_w) and polydispersity ratios (M_w/M_n) were estimated by gel permeation chromatography (GPC) on a Shimudzu HPLC system equipped with a Plgel 5 μm MIXED-C 300 × 7.5 mm column (Polymer Laboratories), using THF as the eluent with a flow rate of 1.0 mL min^{-1} by polystyrene calibration, and a RID-10A refractive index (RI) detector.

Synthesis of TPCP tetrakis(pentafluorophenyl)borate (2)

To a suspension of TPCP chloride (11) (1.51 g, 5 mmol) in acetonitrile (25 mL) was added a solution of potassium tetrakis(pentafluorophenyl)borate (4.00 g, 5 mmol) in acetonitrile (15 mL) and the reaction mixture stirred at room temperature for 2 h. The solid thus formed was removed by filtration and the filtrate concentrated to give a brown viscous substance that was further purified using a silica gel column with CH_2Cl_2 as the eluent. After washing with pentane, the product was obtained as white crystals (62%), mp 209 to 210°C. ^{1}H NMR (CDCl$_3$) δ: 7.88 (dd, $^3J_{H-H}$ = 7.6, 7.8 Hz, 6H, 3,5-H on phenyl), 8.06 (t, $^3J_{H-H}$ = 7.8 Hz, 3H, 4-H on phenyl), 8.42 (d, $^3J_{H-H}$ = 7.6 Hz, 6H, 2,6-H on phenyl). ^{19}F NMR (CDCl$_3$) δ: –133.12 (s, 2, 6-F on C_6F_5), –163.40 (sm, 4-F on C_6F_5), –167.20 (s, 3,5-F on C_6F_5). Anal. calcd. for $C_{45}H_{15}F_{20}B$: C 57.11, H 1.60; found: C 57.02, H 1.66.

Polymerization of styrene

In a typical polymerization, **2** (0.03 mmol) was dissolved in solvent (2 mL) (TPCP tetrakis(pentafluorophenyl)borate dissolved in CH_2Cl_2 and is partially soluble in toluene) and the solution degassed (freeze–thaw) for three cycles. **3** (0.03 mmol, 36% in toluene) was also dissolved in styrene (2 mL) and the solution degassed as above. The catalyst solution in styrene was then transferred into the solution of **2** under dry argon at room temperature and the mixture stirred for 30 min. Subsequently, the polymerization mixture was quenched with MeOH (containing 1% HCl). The resulting polymer was purified twice from CH_2Cl_2–MeOH or until a white powder of the polymer was obtained. The polymer was dried under vacuum overnight. The activity of the catalyst system was calculated by the following:

Activity = weight of polymer (g)/(Ti (mol) monomer (mol) time (h))

Polymerization of styrene with preactivated initiating systems

In a typical polymerization run, **3** (36% in toluene) was mixed with CH_2Cl_2 (2 mL), and the solution degassed using freeze–thaw techniques for three cycles. This initiating solu-

tion in CH_2Cl_2 was then transferred into the polymerization tube (prevacuum evacuated) containing **2** under dry argon (the reactions are quite sensitive to spurious moisture) at room temperature and the mixture stirred (aged) for 10 min. The mixture turned from yellow to dark red. Styrene (predegassed) was next introduced into the system, and the polymerization mixture stirred at room temperature for 15–30 min. It was next quenched by MeOH (containing 1% HCl). The resulting polystyrene (PS) was purified twice from CH_2Cl_2–MeOH or until a white powder of the polymer was obtained, and the polymer then dried under vacuum overnight.

Polymerization of ethylene

In a typical polymerization run, a solution of **3** (1.5–3.0 mmol, 36% in toluene) in CH_2Cl_2 (2 mL) was degassed for three cycles and then transferred into a polymerization tube (25 mL, prevacuumed) containing **2** (1.5–3.0 mmol) under an ethylene atmosphere. The catalyst system was preactivated for 10 min at room temperature and then ethylene at 1 atm (1 atm = 101.325 kPa) was bubbled through the solution. Polyethylene (PE) precipitated from the solution immediately. After 5 min, the polymerization reaction was quenched with MeOH (containing 1% HCl, 5 mL). The polymer was collected by filtration. After washing with MeOH, the polymer was dried under vacuum overnight. The resulting polymer did not dissolve in THF or in 1,1,2,2-tetrachloroethane.

Polymerization of propylene

Polymerization of propylene resulted if a similar procedure to that used for ethylene polymerization was employed. Propylene was bubbled through the catalyst solution at 1 atm (1 atm = 101.325 kPa) for 30 min at room temperature. After quenching with MeOH (1% HCl), the resulting polypropylene (PP) (viscous oil) was collected by carefully decanting the solvent and subsequently dried under vacuum overnight.

^1H NMR studies

To complete the reaction of Cp_2TiMe_2 with TPCP salts, a mol ratio of 1.1:1.0 for TPCP:Ti was used in this experiment. In a typical experiment, CD_2Cl_2 was vacuum distilled over CaH_2, trapped at 78 K, and then degassed by freeze–thaw techniques for three cycles. The catalyst (0.03 mmol, 36% solution in toluene) was dissolved in the above CD_2Cl_2 and the solution transferred to a vacuum evacuated tube containing TPCPB (0.032 mmol) at –78°C. The solution was subsequently warmed to room temperature and held there for 5 min. During this period, the catalyst system turned from yellow to dark red. The dark red solution was next transferred into an NMR tube that had been degassed by passing dry argon through it for 30 min. The NMR tube was cooled to –78°C again and taken to the NMR. The sample temperature was equilibrated for 1 h at 0°C and the NMR data collected.

UV–vis studies

Absorption spectra of the catalyst systems were recorded under dry argon in a quartz cuvette (1.0 cm path length). In a typical experiment, a solution of **3** (4.2×10^{-4} M) in CH_2Cl_2 (containing traces of toluene) was degassed for three cycles. **2** was placed in a quartz cuvette and the cuvette degassed with bubbling dry argon for 20 min. Catalyst solution was introduced using a two-tipped needle and the vessel sealed under dry argon. UV–vis spectra of the resulting solutions were recorded at room temperature at various times.

Results and discussion

Synthesis of TPCP borate

Anion exchange of TPCP chloride with $KB(C_6F_5)_4^-$ afforded triphenylcyclopropenium tetrakis(pentafluorophenyl)borate **2** as a white solid, mp 209 to 210°C. **2** is stable under air at room temperature and soluble in CH_2Cl_2 but only slightly soluble in toluene.

Polymerization of styrene

Styrene polymerizations were carried out in toluene or CH_2Cl_2 at 23°C under dry argon (Table 1). Control experiments show neither **2** nor **3** had significant activity when used alone in CH_2Cl_2 or toluene. Following the prescribed period of preactivation, **2** was among the most active activators for styrene polymerization (entry 6) of the type carbonium ion – borate (12). The solvent had little effect on initiation activity (entries 1 and 2), but polystyrene obtained from toluene solution was of lower weight average molecular weight (M_w), presumably because of the limited solubility of **2** and the active species. The activity of a preactivated initiating system was much higher than that without preactivation. If the preactivation time was increased to 20 min (entry 4), the activity of the initiating system was reduced by about 50%. We presume this is due to the thermal decomposition of the catalytic cationic complex at room temperature.

The efficiency of **2** in the polymerization of styrene is compared to that of the trityl salt **1** in toluene. Titanocene **3** shows a high activity of 6.04×10^6 g (PS)/mol (Ti) × mol (styrene) × h in the presence of **1** (entry 11), however, from control experiments, **1** itself is a rather active initiator for the polymerization of styrene with the activity of 5.60×10^6 g (PS)/mol (Ti) × mol (styrene) × h (entry 12). This is not the case with **2**.

All polystyrene samples obtained in our reactions are soluble in 2-butanone indicating only atactic polystyrene (a-PS) is formed. This was confirmed by ^{13}C NMR spectroscopy (13).

Polymerization of ethylene and propylene

Polymerization was carried out at room temperature by bubbling of ethylene (1 atm, (1 atm = 101.325 kPa)) through a preactivated solution of **4** (1.5–3.0 mmol) formed by reaction of an equimolar concentration of **2** and **3** in CH_2Cl_2 (2 mL) (Table 1). PE immediately precipitated from the solution. After 5 min, quenching the reaction mixture with acidic methanol yielded lightly yellow polymers with T_m 127 ~ 130°C. The PE obtained was not soluble in organic solvents such as CH_2Cl_2, THF, and 1,1,2,2-tetrachloroethane.

Bubbling of propylene into the catalyst system for 30 min, followed by quenching of the polymerization mixture with acidic methanol, gave polypropylene as a viscous oil of relatively low molecular weight $(4.0–7.2) \times 10^3$ g mol^{-1}. Though the quantity of catalyst used had little affect on the yield of

[a]Polymerization conditions: Styrene polymerization: temperature = 23°C, styrene = 2 mL, solvent = 2 mL, [Styrene] = 4.4 M. Ethylene and propylene polymerization: temperature = 23°C, solvent = 2 mL, monomer pressure = 1 atm (1 atm = 101.325 kPa).
[b]Unit: g (PS)/(mol Ti $\times$ mol styrene $\times$ h); g (PE or PP)/(mol Ti $\times$ atm $\times$ h) (1 atm = 101.325 kPa).
[c]Toluene was used as the solvent.
[d]Preactivation time: 10 min.
[e]Preactivation time: 20 min.
[f]The polymers were not soluble in CH_2Cl_2, THF, and $CHCl_2CHCl_2$ for M_w measurement.
[g]Trityl tetrakis(pentafluorophenyl)borate was used as the activator.
[h]Only trityl tetrakis(pentafluorophenyl)borate was used.

PE and PP, the use of a large amount of catalyst (5.0 mmol) for propylene resulted in polymers that exhibited a bimodal molecular weight distribution pattern.

Formation of the cationic complex

The dimethyl Ti(IV) complex reacts with a stoichiometric amount of TPCPB at room temperature to yield the cationic titanium – monomethyl complex $[Cp_2TiMe]^+[B(C_6F_5)_4]^-$ (**4**) as a dark red solution. If the reaction is carried out at 0 or –23°C, it takes longer (>30 min) to form the red solution. On the basis of its NMR spectrum taken at 0°C, the cationic complex **4** exhibits resonances at δ 6.38 (s, 10H), 1.30 (s, 3H) attributed to the Cp and Ti-Me hydrogens, respectively. The spectrum of **4** differs from that of the parent Cp_2TiMe_2 (^1H NMR in CD_2Cl_2 at 25°C δ: 6.07 (s, 10H), –0.15 (s, 6H)) and the integrated ratio of Cp to methyl evolved to 10:3 in the activated complex as compared to a value for the parent compound of 10:6. Bochmann et al. (14) reported a similar complex was generated by reaction of the parent complex with dimethylanilinium tetraphenylborate and that it exhibits resonances at δ 6.28 (s, 10H), 1.26 (s, 3H). We presume that the resonance differences from the two cationic complexes are due to differences in ion pairing. There were also small resonances in the ranges of 0.20–2.00 and 6.40–6.70 which could not be assigned.

If the catalyst solution is warmed to 25°C and equilibrated for 30 min, the resonances at δ 6.38 and 1.30 decrease slightly, and the resonances at δ 0.22 and 6.56, 6.64, 6.72 grow presumably because of decomposition of the cationic complex. One of the deactivation processes of the metallocenium cation that may occur results from Cl^- abstraction from the solvent if the reaction is carried out in CH_2Cl_2 (15). During our NMR studies no by-products such as CH_3-CD_2Cl were observed.

UV–vis spectroscopy

There are a number of reports of spectroscopic studies of the reactions of zirconocene precursors with MAO (16) and $PhMe_2NH^+B(C_6F_5)_4^-$ (17) but few such reports with activated titanocene catalysts (18). In the zirconocene studies, the activated complex formed is easily distinguished by changes in the positions of the ligand-to-metal charge transfer (LMCT) bands in the optical spectra. Though UV–vis spectroscopy is not suitable for catalyst systems containing trityl cation owing to the overlap of absorption of the cation with the LMCT bands of the complexes formed in the activation process (Fig. 2), TPCP cation has no absorption beyond 320 nm. Thus, one may examine the LMCT bands formed from catalyst systems containing TPCP cation using UV–vis spectroscopy.

In the absence of **2**, **3** shows a LMCT band at 361 nm in both CH_2Cl_2 and toluene. The LMCT absorption band of **3** is shifted to 482 nm in CH_2Cl_2 in the presence of **2** and to 487 nm in toluene, respectively, corresponding to a decrease of electron density on the metal center (16a). This is consistent with the formation of cationic Ti(IV) complex observed by NMR spectroscopy. During styrene polymerization, we found that with preactivation, a deep approximately dark red solution of initiator was required in order for the system to exhibit the highest activity. Yellow solutions showed little or no activity as polymerization initiators. Therefore, the corresponding species, which absorbs at 482 nm, must be the actual active species.

In the case of the **2**, **3** couple, formation of the active species **4** was followed by observing the absorption changes in dichloromethane at 482 nm (Fig. 3). In the absence of monomer at fixed concentrations of reagents, the maximum concentration of **4** was observed after 17 min (Fig. 3a). The absorption then decayed presumably because of the thermal

Fig. 2. UV–vis spectra of catalyst Cp_2TiMe_2 (**3**) and a mixture of **2** and **3** in CH_2Cl_2. Concentration of catalyst and activator: [**3**] = 4.2×10^{-4} M, [**2**] = 4.8×10^{-4} M; spectrum of the mixture of **2** and **3** was taken after being mixed for 17 min.

Fig. 3. Variation of the absorption of **2** and **3** at 482 nm with time in CH_2Cl_2. [**3**] = 4.2×10^{-4}M, ratio of **2**:**3**:styrene in mol (*a*) in the absence of styrene; (*b*) in the presence of styrene; and (*c*) styrene added at 17 min.
decomposition of the active cationic complex. Consistent with results obtained in the polymerization of styrene in that if the initiation system was preactivated for times greater than 17 min (e.g., 20 min, entry 4, Table 1), one observes decreased activity. Consistent with the lower activity observed for the polymerization of styrene when the initiator is prepared in its presence, the growing in of the absorption at 482 nm was much slower in the presence of styrene than in its absence (Fig. 3*b*). This can be explained if styrene consumes the active species during its formation. A rapid decay of **4** also results from the addition of styrene to the initiation system (Fig. 3*c*). We presume this to be from the reaction of styrene at the Ti center resulting in a decreased concentration of the cationic complex **4** (Scheme 1).

The formation and decay of cationic complex **4** was studied by following the absorption changes at 482 nm. The formation and decay lifetimes of the active species were obtained by fitting the experimental data to a double exponential decay function using ORIGIN 6.1 software. The species grew in rapidly with τ_1 of 7.96 min and then decayed slowly with τ_2 of 28.9 min.

Mechanism of olefin polymerization

The mechanism we propose for olefin polymerization is that dimethyl Ti(IV) complex reacts with a stoichiometric amount of TPCPB at room temperature to yield the cationic titanium – monomethyl complex $[Cp_2TiMe]^+[B(C_6F_5)_4]^-$ (**4**). The system is active for nonfunctionalized olefins like ethylene, propylene, and styrene with polymerization of ethylene and styrene being much faster in CH_2Cl_2 at room temperature than the polymerization of propylene. That ethylene polymerization is faster than that of propylene is consistent with a coordination polymerization mechanism (Scheme 2).

It has recently been found that some well-characterized Ziegler–Natta catalysts can also initiate carbocationic poly-
Scheme 1. Electrophilic attack of **4** on styrene.
Scheme 2. Coordination polymerization pathway.
merization of olefins (19) and that styrene may undergo polymerization via both coordination and carbocationic mechanisms. Using $Cp*TiMe_3–B(C_6F_5)_3$ as the catalyst and if the polymerization is carried out at a low temperature, only atactic polystyrene was produced. If the polymerization temperature rises to above –10°C, highly syndiotactic polystyrene is obtained (20). At high temperature Ti(III) complex formed by reductive decomposition was confirmed to be the active catalyst for production of syndiotactic polystyrene (21). At lower temperatures, cationic Ti(IV) complex

Scheme 3. Cationic polymerization of styrene.
initiates a carbocationic process for the production of atactic polystyrene.

Our spectroscopic studies indicate that cation $[Cp_2TiMe]^+$ is more stable than $[Cp^*TiMe_2]^+$ but that it decomposes, though moderately, at room temperature on the polymerization time scale. The decay lifetime of the cationic complex is 28.9 min indicating that most of the cationic complex survived during the polymerization process. Each of the PS samples prepared using our initiating system is soluble in 2-butanone, suggesting no syndiotactic PS (s-PS) forms. Therefore, we assume that the cationic Ti(IV) complex is the actual active species in the system reacting as a carbocationic initiator with styrene and producing atactic polystyrene (Scheme 3). The relatively narrow polydispersities of the resulting PS samples (1.92–2.56) is further evidence for a carbocationic polymerization process.

In summary, TPCP borate efficiently reacts with bis(cyclopentadienyl) dimethyltitanium to form cationic Ti complex $[Cp_2TiMe]^+B(C_6F_5)_4^-$ (4). The formation of cationic Ti complex **4** was confirmed by NMR spectroscopy. The reaction was also studied using UV–vis spectroscopy and observed the bathochromic shift of the Cp_2TiMe_2 LMCT main absorption band from 361 to 482 nm in CH_2Cl_2. The kinetic profile showed the cationic species grew in rapidly and then decayed slowly. Though the cationic complex $[Cp_2TiMe]^+B(C_6F_5)_4^-$ was observed to be thermally unstable and its activity in the polymerization of styrene decreased with time, the system shows generally high polymerization activity for both ethylene and styrene. It is less active for the polymerization of propylene. The cationic Ti(IV) complex is proposed to be a conventional Ziegler–Natta coordinative catalyst for ethylene and propylene polymerization, while it acts as a carbocationic initiator for styrene polymerization.

Oxidation of cyclohexane using a novel RuO₂–zeolite nanocomposite catalyst

Bi-Zeng Zhan, Mary Anne White, James A. Pincock, Katherine N. Robertson, T. Stanley Cameron, and Tsun-Kong Sham

Abstract: We report the synthesis, using an organic-template-free hydrothermal crystallization method, and catalysis of a new type of nanocomposite material, 1.3 nm-sized RuO_2 particles confined in faujasite zeolite. The zeolite-confined RuO_2 composites were fully characterized with X-ray powder diffraction, Ru K-edge X-ray absorption, and high-resolution transmission electron microscopy. XRD and X-ray fluorescence analysis indicate that the framework is faujasite zeolite with a Si:Al ratio of 1.25. Ru K-edge X-ray absorption near-edge structures indicate that the ruthenium species in the zeolite is Ru(IV) with nearest-neighbor octahedral environments similar to hydrous RuO_2, i.e., distorted "RuO_6". The k^2-weighted extended X-ray absorption fine structure indicates that the Ru(IV) species anchored in the zeolite likely form amorphous RuO_2 with a 2D-chain structure, in which RuO_6 units are connected together by two shared oxygen atoms. TEM shows that the particle size of RuO_2 encapsulated inside the supercages of FAU is about 1.3 nm. The RuO_2–FAU composites display significant catalytic activity in the oxidation of cyclohexane with tBHP under mild (room temperature and 1 atm (1 atm ≡ 101.325 kPa)) conditions. The ketone and alcohol concentration can be as high as 0.26 mol L^{-1} in 5 h with 48% peroxide efficiency. The catalyst is stable and reusable. Possible oxidation mechanisms are also discussed.

Key words: nanocomposite, ruthenium oxide, catalysis, oxidation, zeolite.

Résumé : Faisant appel à une méthode de cristallisation hydrothermique sans gabarit organique on a effectué la synthèse d'un nouveau matériau nanocomposite, des particules de RuO_2 d'une taille de 1,3 nm confinées dans un zéolite de faujasite, et on a examiné ses propriétés comme catalyseur. Les composites de RuO_2 confinées dans le zéolite ont été caractérisés par diffraction des rayons X sur des poudres, absorption de rayons X par l'arête K du Ru et par microscopie électronique de transmission à haute résolution. L'analyse de la diffraction et de la fluorescence des rayons X indiquent que le squelette est le zéolite de faujasite avec un rapport de Si:Al de 1,25. Les structures près des rebords obtenues par absorption de rayons X par l'arête K du Ru indiquent que l'espèce ruthénium du zéolite est le Ru(IV) avec un environnement octaédrique pour les voisins immédiats, comme dans le cas du RuO_2 hydratée c'est-à-dire du « RuO_6 » déformé. La structure fine d'absorption étalée des rayons X indique que l'espèce Ru(IV) ancrée dans le zéolite forme vraisemblablement du RuO_2 amorphe avec une structure en chaîne bidimensionnelle dans laquelle les unités de RuO_6 sont reliées entre elles par deux atomes d'oxygène partagés. La méthode « TEM » montre que la taille des particules de RuO_2 encapsulées dans les supercages de FAU est d'environ 1,3 nm. Les composites RuO_2–FAU présentent une activité catalytique significative dans l'oxydation du cyclohexane par le tBHP dans des conditions douces (température ambiante et 1 atm (1 atm ≡ 101.325 kPa)). Les concentrations de cétone et d'alcool peuvent atteindre une valeur de 0,26 mol L^{-1} en 5 h, avec une efficacité de peroxyde de 48%. Le catalyseur est stable et peut être réutilisé. On discute aussi des mécanismes d'oxydation possibles.

Mots clés : nanocomposite, oxyde de ruthénium, catalyse, oxydation, zéolite.

Introduction

Oxidation of cyclohexane under mild conditions is one of the most interesting and challenging topics in oxidation chemistry (1–4). Considerable effort has been made to develop novel homogeneous and heterogeneous catalysts and catalytic processes for the oxidation of cyclohexane to cyclohexanol and cyclohexanone (1–9). To achieve satisfactory selectivity (>80%), yield usually must be sacrificed (~4% conversion) because of free-radical autoxidation processes (5). Incorporation of transition metal compounds into molecular sieves offers one of the most promising ap-

proaches to enhance the selectivity because the free radicals generated by autoxidation are constrained by the well-defined porous system. Various metals and metallo-complexes have been incorporated into zeolites, silicates, SAPO, ALPO, and mesoporous materials and used as catalysts for alkanes and alkenes oxidation (5–10). Among them, zeolite-confined metallophthalocyanines have displayed the attractive activity of cyclohexane oxidation with *t*BHP at room temperature (8, 9). However, there are several drawbacks in these systems, such as the complicated synthetic procedures and the use of expensive metallo-complexes. Development of an efficient and recyclable catalyst for alkane oxidation under mild conditions is still a significant challenge.

Ruthenium compounds have considerable potential for oxidation of alkanes and alkenes because of their rich redox properties (11 oxidation states, ranging from Ru^{-II} to Ru^{VIII}) (11–13). Recently, RuO_2, especially $RuO_2(110)$, has been receiving considerable attention for its extraordinarily high catalytic activity (14–18). The outstanding catalytic ability of the $RuO_2(110)$ surface is attributed to the existence of coordinatively unsaturated ruthenium atoms (14–16). Interestingly, a structure similar to $RuO_2(110)$ was found in amorphous hydrous RuO_2 (19). Nanomaterials can be novel catalysts because of the large surface area and the high density of active sites (20–21). Thus, it is expected that zeolite-confined hydrous nano-RuO_2 could exhibit favourable oxidation chemistry. Recently, we have reported the synthesis of faujasite zeolites (FAU) with controllable particle size and surface properties by using an organic-additive-free hydrothermal crystallization approach (22, 23). This organic-additive-free synthetic method makes it possible to synthesize zeolite-based host–guest materials in a simple one-step modification or build-the-bottle-around-the-ship approach (10), namely directly adding guest molecules into the fresh-prepared aluminosilicate gel before hydrothermal crystallization. Furthermore, FAU zeolites have a unique and well-defined pore system: ~1.3 nm supercages are tetrahedrally connected by 12-membered-ring channels with ~0.74 nm openings (24). Therefore, physically trapped nanoparticles or molecules with sizes between about 0.74 and 1.3 nm cannot diffuse out of the supercages unless the strict framework of the zeolite is destroyed (8–10). In this paper, we report the synthesis and catalysis of novel nanocomposite materials, viz. faujasite zeolites with confined RuO_2 nanoclusters (abbreviated as RuO_2–FAU) with a one-step modification of the hydrothermal synthetic method for FAU. The catalytic results indicate that these materials are very efficient and stable catalysts for cyclohexane oxidation at room temperature.

Results and discussion

All the synthesized zeolite-confined hydrous RuO_2 samples were characterized by X-ray powder diffraction as shown in Fig. 1. The XRD patterns of as-synthesized RuO_2–FAU samples match very well with simulated XRD results for faujasite zeolites (25). For our sample with the highest RuO_2 loading, RuO_2–FAU(1.63) (where the number in brackets refers to RuO_2 concentration in mmol g^{-1}; see the *Experimental* section for details), a few weak peaks appear

Fig. 1. XRD patterns for synthetic RuO_2–FAU composites and pure FAU. The numbers in parentheses are RuO_2 concentrations in the FAU zeolites in mmol g^{-1}.
at 2θ values of 12.6°, 18.6°, 21.8°, 28.2°, and 33.5°, indicating the presence of small amounts of NaP-1 zeolite impurity (25). In comparison with the XRD pattern of pure FAU zeolite, the 2θ values of the diffraction peaks of RuO_2–FAU composites are slightly higher, and they increase with increased RuO_2 loading. Figure 2 gives an example of the shift of the *hkl*(642) diffraction peak as a function of RuO_2 loading. This shift demonstrates encapsulation of RuO_2 inside the cages of FAU zeolite using our hydrothermal crystallization method. No new diffraction peaks belonging to RuO_2 compounds were found, indicating that the RuO_2 in the zeolite is amorphous.

The Ru K-edge X-ray absorption near-edge structures of all the RuO_2–FAU composites resemble those of hydrous RuO_2 (26). This indicates that the ruthenium species in the zeolite is Ru(IV) with nearest-neighbor octahedral environments similar to hydrous RuO_2, i.e., distorted "RuO_6" (19). It also shows that all the Ru(III) species are oxidized to Ru(IV) under the hydrothermal synthetic conditions. Furthermore, the k^2-weighted extended X-ray absorption fine structure of RuO_2–FAU composites is virtually the same as that of amorphous $RuO_2 \cdot 2.32H_2O$ (26) indicating that the Ru(IV) species anchored in the FAU zeolite likely form amorphous RuO_2 with a 2D-chain structure, in which RuO_6 units are connected together by two shared oxygen atoms (19). This is consistent with the XRD results. A schematic structure of a RuO_2 nanocluster in FAU zeolite is given in Scheme 1.

Figure 3 shows a typical high-resolution transmission electron microscopy (TEM) image taken at the RuO_2–FAU(0.78) sample. The dark spots, homogeneously distributed through the sample and not seen in the pure FAU, are reasonably attributed to the RuO_2 particles. Figure 3 clearly indicates that these particles are very uniform, in the size range 1.3 ± 0.2 nm. This is the same size as the supercages of FAU zeolite. Likely the RuO_2 nanoclusters are incorporated into the supercages of FAU zeolite during the hydro-

Fig. 2. XRD pattern showing the shift of the *hkl*(642) diffraction peak of FAU zeolites as a function of RuO_2 loading.

Scheme 1. The 2D-chain structure of RuO_2 in zeolite.
thermal crystallization process and the growth of RuO_2 clusters is strictly constrained by the rigid zeolitic framework. The encapsulation of nano-RuO_2 inside the zeolite is further confirmed by catalytic results (vide infra). It is estimated that, on average, every 1.3 nm RuO_2 cluster contains five Ru atoms, as deduced from the bond lengths.

All the synthetic RuO_2–FAU nanocomposites were employed as catalysts for cyclohexane oxidation at room temperature using *tert*-butyl hydroperoxide (*t*BHP) as the oxidant. The catalytic oxidation results are given in Table 1, along with the results of the FePcY-PDMS catalyst (8). Several control experiments were carried out to determine the catalytically active sites of RuO_2–FAU catalysts: no catalytic products were observed when unmodified FAU zeolite was used as the "catalyst" (entry 1, Table 1), showing that pure FAU does not have any catalytic activity at room temperature even in the presence of *t*BHP. No oxidation products were detected on mixing cyclohexane with RuO_2–FAU without *t*BHP. In the absence of cyclohexane, *t*BHP is decomposed to *tert*-butyl alcohol, O_2, and a very small amount of *tert*-butyl peroxide (*t*-BuOO*t*-Bu). Very high catalytic activity of cyclohexane oxidation was observed using RuO_2–FAU composites as catalysts. Furthermore, cyclohexane conversion was found to increase with increased RuO_2 nanocluster

loading in the FAU zeolites (entries 2, 3, and 5, Table 1). This clearly demonstrates that RuO_2 incorporated in the zeolitic framework provides the catalytically active sites for the alkane oxidation. The turnover number (TON) of RuO_2–FAU(0.15) is about 630, which is close to the best results (990) achieved with FePcY-PDMS as the catalyst (entry 6, Table 1), although our oxidation reaction was carried out in a simple batch reactor (8). Higher RuO_2 concentrations can increase catalytic activity, i.e., cyclohexane conversion, but give lower TONs because of the partial blockage of zeolitic channels by the RuO_2 nanoclusters. Comparing the cyclohexane conversion, TON value, and peroxide efficiency, we conclude that the optimum concentration of RuO_2 in RuO_2–FAU is ca. 0.78 mmol g^{-1}, e.g., about one RuO_2 nanocluster in every two to three supercages.

Cyclohexanol (*ol*) and cyclohexanone (*one*) are the predominant products (about 90 mol%). The *one*:*ol* ratio increases from 1.3 in RuO_2–FAU(0.15) to 3.3 in RuO_2–FAU(1.63) (entries 2 and 5, Table 1), showing that higher RuO_2 concentration can lead to further oxidation of the alcohol to the ketone. The high oxidation activity of RuO_2–FAU is also revealed from the low proportion (<8 mol%) of cyclohexyl hydroperoxide (CHHP) in the products. The only observed side product, *tert*-butyl cyclohexyl peroxide, is relatively minor (<5 mol%). No over-oxidation products, such as adipic acid, were found. Furthermore, no dicyclohexyl by-product was found in the oxidation mixture, which contrasts with the Ce/silicate catalysts (27). It appears that, because of the steric constraints imposed by the zeolitic channels and (or) cages, two cyclohexyl radicals cannot be created in one channel and (or) cage at the same time. This provides strong evidence that RuO_2 is indeed confined in the supercages of FAU zeolite. The shape-selectivity of RuO_2–FAU nanocomposites to both substrates and products is also observed in other catalysis experiments such as the oxidation of alcohols (26) and alkyl-aromatics.[2]

If we assume that 1 mol of ketone product is formed for every 2 mol of peroxide, the peroxide efficiency is about 48% for both RuO_2–FAU(0.78) and RuO_2–FAU(1.63) catalysts (entries 3 and 5, Table 1), which is higher than the observed 35% efficiency in FePcY-PDMS (8). The concen-

[e]Efficiency of *tert*-butyl hydroperoxide, i.e., the percentage of peroxide used for substrate oxidation.

[f]Catalytic results from a third run. After each run, the solid catalyst was separated by centrifugation and then fully washed with acetone and reused for a next run under the same conditions.

[g]Reaction was carried out with 0.32 g of FePcY-PDMS in a counter-current membrane reaction with 40 mmol of *t*BHP as a 7% solution in water, 300 mmol of cyclohexane.

tration of *one* + *ol* with RuO$_2$–FAU(1.63) reached 0.26 mol L^{-1} in 5 h at RT (entry 5). Furthermore, RuO$_2$ is physically occluded in the zeolite supercage, making the catalyst reusable. After reaction, a clear, colorless organic phase was separated by centrifugation. Leaching of RuO$_2$ in the filtrate is negligible: the concentration of Ru in the organic phase is less than 30 ppb (ICP analysis). Further stirring of the organic phase with *t*BHP did not change the product composition, showing that trace amounts of Ru did not cause any oxidation under the experimental conditions, e.g., RT and 1 atm (1 atm ≡ 101.325 kPa). About 90% of the reactivity, e.g., the conversion of both *ane* and *t*BHP, remained in the third run (entries 3 and 4, Table 1).

The high activity of RuO$_2$–FAU can be related to the oxidation mechanism. A competitive oxidation of C$_6$H$_{12}$–C$_6$D$_{12}$ over RuO$_2$–FAU(0.78) catalyst at RT showed an isotopic effect of k_H/k_D = 8.3 ± 0.2 (extrapolated to 0% conversion). This indicates the existence of an electrophilic oxo-species (e.g., eqs. [1] and [2]) (8, 28). The relative reactivity of primary, secondary, and tertiary C—H bonds provides further evidence for the presence of Ru-oxo species. In adamantane oxidation over RuO$_2$–FAU(0.78) zeolite, we found the tertiary C—H bonds to be 9.7 times more reactive than secondary C—H bonds (secondary:tertiary product ratio of 0.31; statistical factor of 3). This product ratio is significantly higher than 0.05 with Fenton chemistry and 0.14 for hydroxyl radicals (29), but remains in the range required for oxo-chemistry as observed in P-450 and its model systems (8, 30, 31). However, we cannot rule out a small contribution from a free-radical pathway (e.g., eqs. [3]–[7]), as we observe a small amount of CHHP, *t*BCP, and O$_2$ products in the cyclohexane oxidation. Quite likely, two competitive oxidation pathways are involved since there are different Ru(IV) environments in the RuO$_2$–FAU composite catalyst. Looking at the 2D-chain RuO$_2$ structure, two different coordination environments of Ru(IV) are found: in a five-Ru-atom RuO$_2$ nanocluster, the two end Ru atoms are completely different from those three Ru in the middle. Two types of oxygen, e.g., bridged and terminal, could also be involved in the oxidation process.

Ru-oxo oxidation mechanism

[1] t-BuOOH + Ru(IV) → t-BuOH + Ru(VI)=O

[2]   Ru(VI)=O + C$_6$H$_{12}$ → Ru(IV) + C$_6$H$_{11}$OH

Free-radical oxidation mechansim

[3] t-BuOOH + Ru(IV) → t-BuOO· + Ru(III) + H$^+$

[4]   2t-BuOO· → 2t-BuO· + O$_2$

[5] t-BuO· + C$_6$H$_{12}$ → t-BuOH + C$_6$H$_{11}$·

[6]   2t-BuO· → t-BuOOt-Bu

[7] t-BuO· + C$_6$H$_{11}$· → t-BuOOC$_6$H$_{11}$
Conclusions

We have synthesized a new type of nanocomposite material, nanosized RuO$_2$ in a faujasite zeolite, using an organic-template-free hydrothermal crystallization approach. The ruthenium encapsulated inside the supercages of FAU is amorphous hydrous RuO$_2$ with a particle size of 1.3 nm. It has a 2D-chain structure in which RuO$_6$ units are connected together by sharing two oxygen atoms (26). The RuO$_2$–FAU composites display significant catalytic activity in the oxidation of cyclohexane with *t*BHP under mild (room temperature and 1 atm (1 atm ≡ 101.325 kPa)) conditions. The ketone and alcohol concentration can be as high as 0.26 mol L^{-1} in 5 h with 48% peroxide efficiency. Furthermore, RuO$_2$ is physically trapped in the zeolite supercage, making the catalyst potentially reusable.

Experimental details

Chemical reagents included fumed silica (11 nm, Sigma), tetraethylorthosilicate (Aldrich), NaOH (Aldrich), NaAlO$_2$ (Allied Chemical), Al(OH)$_3$ (McArthur Chemical), RuCl$_3$·3H$_2$O (Aldrich), and RuO$_2$ (A.D. Mackay). All other organic and inorganic chemicals were reagent grade and were used without further purification.

Synthesis of pure faujasite zeolite

The pure faujasite zeolite was synthesized by hydrothermal crystallization in an oil bath with both controllable temperature and stirring rate. Unmodified faujasite zeolite was synthesized using hydrothermal crystallization methods reported previously (22, 23). Aluminosilicate gel was prepared by mixing freshly prepared aluminate and silicate solutions together in the molar ratio $5.5Na_2O:1.0Al_2O_3:4.0SiO_2:190H_2O$. The powdered products were recovered with centrifugation and washed with deionized (DI) water until pH < 8, and then dried at room temperature for 24 h for further characterization. X-ray fluorescence analysis showed that the Si:Al ratio for the 4-day crystallization sample was 1.25, within the range of 1.0 ~ 1.5 for faujasite-X zeolite.

Synthesis of RuO_2–FAU composites

The RuO_2–FAU nanocomposites were synthesized with one-step modification to the method for pure FAU, namely adding $RuCl_3·3H_2O$ into the freshly prepared aluminosilicate gel, before hydrothermal crystallization. A measured amount of $RuCl_3·3H_2O$ was added to an aluminosilicate gel containing 5.34 g NaOH, 2.42 g $NaAlO_2$, 3.43 g SiO_2, and 50.0 g H_2O. The gel was aged for 2 days and then crystallized at 90°C for 15 h with stirring. The resultant black powder was separated from solution by centrifugation and then washed thoroughly with DI water to remove any physically absorbed species. All the synthesized samples were dried at room temperature for further characterization and catalytic investigations. ICP–MS analysis indicated that three RuO_2–FAU samples with different RuO_2 loadings were synthesized: RuO_2–FAU(0.15), RuO_2–FAU(0.78), and RuO_2–FAU(1.63), where the numbers in the parentheses are RuO_2 concentrations in the FAU zeolites in mmol g^{-1}. These correspond, respectively, to one RuO_2 nanocluster in every ca. 10, 2.2, and 1.1 supercages of FAU (on average, every 1.3 nm RuO_2 nanocluster contains five Ru atoms, as deduced from the bond lengths).

Cyclohexane oxidation

The oxidation reactions were carried out in sealed vials containing a mixture of 0.1 g RuO_2–FAU catalyst, 10 mmol cyclohexane, 4 mmol tBHP, and 2 mL acetone as solvent. The reaction products were analyzed and quantified by GC after 5 h of room-temperature reaction, and identified by either GC–MS or GC with standard samples. All the reactions were run under aerobic conditions. All the GC analyses were performed on a Supelco MDN-55 column (30 m × 0.25 mm × 0.50 μm) with a Perkin-Elmer Auto System GC equipped with an FID. GC–MS for the product identification was conducted using a Perkin-Elmer Auto System XL GC with a Perkin-Elmer TurboMass mass spectrometer. Chlorobenzene was chosen as the internal standard for GC analyses. Cyclohexyl peroxide was converted to cyclohexanol for quantification. This was done by reacting the oxidation mixture with excess triphenyl phosphine at room temperature for 20 min, followed by GC analysis. The consumption of tert-butyl hydroperoxide was directly calculated from the GC results.

Control reactions

Pure FAU as catalyst: 0.1 g FAU was used as the "catalyst" instead of 0.1 g RuO_2–FAU composite. All other con-
ditions are the same as described above. Without tBHP: the mixture of 0.1 g RuO_2–FAU catalyst, 10 mmol cyclohexane, and 2 mL acetone was stirred for 5 h. Without cyclohexane: 0.1 g RuO_2–FAU catalyst, 4 mmol tBHP, and 2 mL acetone were mixed together and stirred for 5 h at room temperature. Reaction products were analyzed with GC.

Isotope effect

The reaction was conducted in sealed vials containing a mixture of 0.1 g RuO_2–FAU catalyst, 5 mmol C_6H_{12}, 5 mmol C_6D_{12}, 4 mmol tBHP, and 2 mL acetone as solvent. The reaction products taken at different reaction times were analyzed and quantified by GC.

Adamantane reaction

The reaction was conducted in sealed vials containing a mixture of 0.1 g RuO_2–FAU catalyst, 2 mmol adamantane, 4 mmol tBHP, and 2 mL acetone as solvent. The reaction products taken at different reaction times were analyzed and quantified by GC and identified by GC–MS.

Characterization

X-ray powder diffraction patterns were recorded on a Rigaku Miniflex System using Cu-Kα radiation, 30 kV, 15 mA with a scanning speed of 1° (2θ) min^{-1}, $T = 20°C$. Ru K-edge XAFS measurements were made at the Bending Magnet Beamline of the PNC (Pacific Northwest Consortium)-CAT (Collaborative Access Team) at the Advanced Photon Source (APS) at Argonne National Laboratory. APS is a 7 GeV, third-generation electron storage ring, operating typically at 100 mA injection current. All the measurements were conducted in fluorescence mode using a Xe-filled ion chamber with filter and solar slit arrangements. High-resolution TEM images were recorded with a FEI Tecnai-12 operated at 80 kV.

Intramolecular excimer fluorescence from folded ground state rotamers of *N,N′*dimethyl-*N,N′*-dipyrenylurea protophanes

Frederick D. Lewis and Todd L. Kurth

Abstract: The molecular structure, absorption, and fluorescence spectra of *N,N′*-dimethyl-*N,N′*-di-1-pyrenylurea and *N,N′*-dimethyl-*N,N′*-di-2-pyrenylurea have been investigated and compared to the properties of *N,N,N′*-trimethyl-*N′*-pyrenylurea model compounds. Di-1-pyrenylurea exists as a mixture of folded (*E,E*) syn- and anti-rotamers that interconvert via flipping of one of the pyrene rings to an unfolded (*E,Z*) rotamer geometry. The symmetric di-2-pyrenylurea exists as a single folded (*E,E*) conformation which is in equilibrium with a less-stable, unfolded (*E,Z*) rotamer. The absorption and fluorescence spectra of the dipyrenylureas at 77 K in a rigid glass are similar to those of monopyrenylurea model compounds. However, in fluid solution, the dipyrenylureas exhibit excimer fluorescence and very weak monomer fluorescence which have identical decay times. This behavior is attributed to fast rotational equilibrium between folded rotamers which exhibit excimer fluorescence and unfolded rotamers which exhibit monomer fluorescence. The behavior of the dipyrenylureas is compared with that of other systems that form intramolecular pyrene excimers and diarylureas.

Key words: excited state rotamers, dipyrenylureas, pyrene excimers, ureaphane.

Résumé : On a étudié la structure moléculaire et les spectres d'absorption et de fluorescence de la *N,N′*-dimethyl-*N,N′*-di-1-pyrénylurée et de la *N,N′*-diméthyl-*N,N′*,-di-2-pyrénylurée et on les a comparés aux propriétés correspondantes de composés modèles de la famille des *N,N,N′*-triméthyl-*N′*-pyrénylurée. La di-1-pyrénylurée existe sous la forme de mélange de rotamères syn- et anti- repliés (*E,E*) qui donnent lieu à une interconversion par le biais de l'inversion d'un des noyaux pyrène vers un rotamère de géométrie dépliée (*E,Z*). La di-2-pyrénylurée existe sous la forme d'une seule conformation repliée qui est en équilibre avec un rotamère déplié (*E,Z*) moins stable. Les spectres d'absorption et de fluorescence des dipyrénylurées à 77 K, dans un verre rigide, sont semblables à ceux des composés modèles de la famille des monopyrénylurées. Toutefois, en solution fluide, les dipyrénylurées présentent une fluorescence d'excimère et une très faible fluorescence de monomère qui ont des temps de dégénérescence identiques. On attribue ce comportement à un rapide équilibre rotationnel entre les rotamères repliés qui présentent de la fluorescence d'excimère et les rotamères dépliés qui présente de la fluorescence de monomère. On compare le comportement des dipyrénylurées avec celui des diarylurées et d'autres systèmes qui forment des excimères pyrènes intramoléculaires.

Mots clés : rotamères à l'état excité, dipyrénylurées, excimères de pyrène, uréephane.

[Traduit par la Rédaction]

Introduction

Pyrene excimer fluorescence is among the most widely used probes of molecular conformation and structure (1). The calculated optimum excimer geometry for two independent pyrene molecules is a slightly slipped sandwich structure (2). Molecules possessing two pyrene chromophores that can adopt sandwich structures display large monomer–excimer spectral shifts. Examples include the 1,3-dipyrenylpropanes (**1** and **2**) (3–6) and [*n.n*](2,7)pyrenophanes (*n* = 2, 3, or 4) (3–5) (7). Conversely, molecules in which only partial overlap of the two pyrenes is possible dis-

play either monomer fluorescence or excimer fluorescence with small monomer–excimer spectral shifts. Examples include 1,2-di(1-pyrenyl)ethane (**3**), which cannot adopt a parallel sandwich structure, and [2.2](1,3)pyrenophane (**6**) (8) and [2.2](1,8)pyrenophane (**7**) (9), which have extended and splayed ground state structures, respectively. A particularly instructive example of the effect of overlap on pyrene fluorescence is provided by the 1,8-dipyrenyl-naphthalenes (**8**–**10**) investigated by Staab and co-workers (10). Both the di-2-pyrenylnaphthalene (**10**) and the syn rotamer of the di-1-pyrenylnaphthalene (**8**) have extensive overlap between pyrenes and display excimer fluorescence, whereas the anti-

rotamer of the di-1-pyrenylnaphthalene (**9**) has minimal overlap and displays monomer fluorescence. Vögtle refers to systems in which two aryl groups are constrained to a face-to-face geometry by a single linker as "protophanes", to distinguish them from cyclophanes in which aryl groups are connected by two or more linkers (11). Structures of **1**–**10** are shown in Chart 1.

Several *N,N′*-dimethyl-*N,N′*-diarylureas adopt folded (*E,E*) structures, both in the solid state and in solution, in which the two aryl groups are face-to-face (e.g., Fig. 1) (12). Computational studies of the ground state conformational energy surface of *N,N′*-dimethyl-*N,N′*-di-1-naphthylurea indicate that the folded (*E,E*) rotamers are more stable than the (*E,Z*) isomers by 2 to 3 kcal/mol.[2] The tertiary diarylureas are unique among conformationally mobile, singly linked diaryl systems in their preferential formation of face-to-face conformers.

We have previously observed that several diarylureas display excimer fluorescence in solution and monomer fluorescence in rigid glasses at 77 K (13). Evidently, large amplitude geometric relaxation of the locally excited, Franck–Condon singlet state of the folded (*E,E*) rotamers is necessary for the formation of a fluorescent excimer. Reported here are the syntheses, calculated structures, and fluorescence spectra of *N,N′*-dimethyl-*N,N′*-di-1-pyrenylurea

(**11**) (Fig. 1), *N,N′*-dimethyl-*N,N′*-di-2-pyrenylurea (**12**) (Fig. 2), and their monoaryl analogs *N,N,N′*-trimethyl-*N′*-1-pyrenylurea (**11m**) and *N,N,N′*-trimethyl-*N′*-2-pyrenylurea (**12m**). The dipyrenylureas exhibit both monomer and excimer fluorescence, which are attributed to the major folded rotamer (excimer) and a minor extended rotamer (monomer), respectively, (e.g., Fig. 2*d*). The monomer–excimer spectral shifts are dependent upon the strength of the intramolecular pyrene–pyrene interaction in the relaxed excited state.

Results and discussion

Molecular structures

HF/6-31G** geometry optimizations (14) confirm that, as in the case of other tertiary diarylureas, conformers in which the Py-N-C=O geometry is E are of lower energy than their Z isomers (12, 13, 15). The *E,E*-di-1-pyrenylurea **11** is pre-

---

[2]Manuscript in preparation.

dicted to exist as a mixture of syn- and anti-rotamers, the former being more stable by ca. 1.0 kcal/mol (see Figs. 1*a* and 1*b*). The more symmetric *E,E*-di-2-pyrenylurea **12** exists in a single conformation (Fig. 2*a*–2*c*). For **11** and **12**, the calculated energy of the *E,E*-rotamer is lower than that of the *E,Z* by ca. 1.5–2.5 kcal/mol. The minimized structures shown in Figs. 1 and 2 illustrate that the tertiary dipyrenylureas have large angles between the pyrene planes. While the short axes of the pyrenyl planes are approximately parallel, the rotational (θ) and splay (ϕ) angles are roughly 50° and 60°, respectively, (see Figs. 2*a* and 2*c*). These geometries presumably result from alleviation of the repulsive aryl–aryl interactions, causing a slight perturbation of the loosely constrained urea linker. A slightly higher energy minimum (+0.72 kcal/mol), corresponding to inversion of the nitrogen centers and having more extensive pyrene–pyrene interaction, exists for *anti*-**11** (Fig. 1*c*). The barrier to urea nitrogen inversion is very low (16), thus, creating a broad potential energy minimum in which urea linker strain is balanced against the repulsive through space aryl–aryl interactions. Although symmetry prevents the observation of similar multiple conformations for *syn*-**11** and **12**, their potential energy surfaces are undoubtedly similar.

The ab initio optimized *E,E* geometries of **11** and **12** are consistent with crystal structures of several tertiary diarylureas that adopt folded geometries (12). Further evidence for protophane structures of **11** and **12** is provided by their [^1]H NMR spectra (Fig. 3). Comparison of the spectra of the mono- and dipyrenylureas show that the aryl protons of the latter lie up-field of the former, as expected for folded conformations with face-to-face aromatic groups (17). In the case of **11**, exchange broadening is observed in the room temperature [^1]H NMR spectrum, in accord with the restricted interconversion of the syn- and anti-*E,E*-rotamers. Having only a single *E,E* conformation, no such broadening is observed in the spectrum of **12**.

Absorption and fluorescence spectra

The long-wavelength portions of the absorption spectra of the mono- and dipyrenylureas in methyltetrahydrofuran (MTHF) are shown in Fig. 4. They all have long-wavelength maxima near that of pyrene (see Table 1) and weaker tails at longer wavelengths. The absorption spectra of **11** and **11m** appear to be broadened and display increased intensity at longer wavelengths when compared to the spectra of **12** and **12m**. This is as expected due to the greater electronic interaction of the pyrene frontier orbitals with substituents at the 1- vs. 2-position (18). ZINDO calculations (19) for the mono-arylureas also correctly predict a small red shift for the first maximum and a stronger long-wavelength tail in the spectrum of **11m** relative to that of **12m**. Vibrational structure similar to that of pyrene is observed in the tails of the absorption spectra of **11m** and **12m**. The band shifts and broadening in the UV spectra of **11** and **12** prevent the observation of such long-wavelength structure. We previously suggested that the broader spectrum of **11** vs. **11m** might be a consequence of weak exciton coupling between the two pyrenes (13). This may also be the case in the spectra of **12** with respect to **12m**.

The fluorescence excitation and emission spectra of the mono- and dipyrenylureas at 77 and 298 K in MTHF are

Fig. 3. Low-field [^1]H NMR spectra (298 K, CDCl₃) of the tertiary mono- (**11m** and **12m**) and dipyrenylureas (**11** and **12**).
Fig. 4. Absorption spectra in MTHF of the mono- (**11m** and **12m**) (dashed lines) and dipyrenylureas (**11** and **12**) (solid lines).
shown in Fig. 5. The excitation spectra are independent of the wavelength of emission monitored. The 298 K excitation spectra are similar in appearance to the absorption spectra (Fig. 4). The fluorescence maxima of the 1-pyrenylureas are at shorter wavelengths than those of the 2-pyrenylureas. The deceptive Stokes shifts in the spectra of **12m** and **12** are a consequence of the long-wavelength absorption bands having very low oscillator strength. Well-resolved vibronic structure is observed in the emission spectra of all four pyrenylureas at 77 K. The spectra of **11** and **12** are similar to those of their monoarylurea analogs **11m** and **12m**. No phosphorescence is observed for any of the pyrenylureas.

The fluorescence maxima, quantum yields, and decay times for pyrene and the pyrenylureas are reported in Table 1. The 77 K fluorescence decays of all the ureas are best fit by dual exponentials. The multiple exponential decays are most likely a consequence of an array of closely related conformations that are frozen in the solvent matrix, the behavior of which can be effectively fit with either distributed or the

Scheme 1.
multiple component kinetics. In the case of **11**, different decay times might be expected for the syn- and anti-rotamers,[3] whereas **12** is expected to exist predominantly as a single rotamer.

The 298 K fluorescence emission spectra of **11m** and **12m** are broadened and red-shifted when compared to their 77 K spectra. These changes reflect the occurrence of geometric relaxation prior to emission in fluid solution and may be attributed to increased molecular planarity in the singlet state. The calculated (HF/6-31G**) (14) dihedral angles between the pyrene and urea planes are 69° and 118° in the ground states of **11m** and **12m**, respectively. Upon excitation, planarization and thus, an increase in the pyrene—N bond order would result in more effective conjugation leading to a decrease in the HOMO–LUMO gap and a bathochromic shift in the fluorescence spectrum.

Large red shifts are observed for the fluorescence of **11** and **12** at 298 vs. 77 K, the red shift for **11** being larger than
that for **12**. These shifts are attributed to the formation of intramolecular pyrene excimers. The appearance of excimer fluorescence at 298 K but not 77 K indicates that geometric relaxation of the Franck–Condon singlet state occurs in fluid solution, presumably resulting in contraction of both the splay and rotational angles of the dipyrenylureas. Weak short-wavelength shoulders are observed in the 298 K fluorescence spectra of both **11** and **12**. The positions of these shoulders are similar to the maxima of the monoarylureas **11m** and **12m**, respectively (see Table 1). Deconvolution of the spectrum of **12** results in slightly shifted monomer and excimer maxima. The monomer and excimer emission have identical excitation spectra.

The decay times for both the excimer fluorescence and the weak monomer fluorescence from **11** and **12** at 298 K are the same, indicative of rapid equilibrium between the species responsible for excimer and monomer fluorescence. We attribute these emissions to the folded (*E,E*) and extended (*E,Z*) ground state rotamers, respectively. In the case of **11** both the syn- and anti-(*E,E*)-rotamers must be in equilibrium with the *E,Z* rotamer (Scheme 1). A similar kinetic scheme was proposed by Zachariasse et al. (4) to account for the observation of a single decay time for the extended and twofolded excited state rotamers of **1** in toluene at temperatures above 20°C. The very weak monomer emission observed for **11** and **12** is indicative of a low population of the extended (*E,Z*) rotamer in the excited state as well as in the ground state. The decay times for **11** and **12** are identical to those of the monopyrenylureas **11m** and **12m** (Table 1). This agreement may simply be fortuitous, as the *E,Z* rotamers of

---

[3] Variable low-temperature fluorescence decay analyses led to the resolution of lifetimes corresponding to those of the syn and anti rotamers of *N,N′*-dimethyl-*N,N′*-di-1-naphthylurea. Manuscript submitted.

11 and **12** possess two nonequivalent pyrenes, whereas **11m** and **12m** possess a single pyrene.

Equilibrium between excited state rotamers requires that the rate of equilibration be faster than the decay time of the shortest-lived conformer (ca. $3–5 \times 10^7$ s^{-1} for **11** and **12**). Assuming that the conversion of E,E to E,Z conformers is isoentropic, a barrier of 5 to 6 kcal/mol would result in a rate constant of $\sim 1 \times 10^9$ s^{-1}. The line broadening observed in the NMR spectrum of **11** is consistent with a ground state barrier of this magnitude. Rotational barriers of ca. 10–28 kcal/mol have been determined for protophane systems (20). Linker geometry and repulsive polar and steric interactions between the opposing aryl groups can lower this barrier.

Comparison with other intramolecular excimer-forming molecules

The excimer fluorescence maxima and monomer–excimer spectral shifts for **11** and **12** and those of several other dipyrenyl systems are summarized in Table 2. The 1,3-dipyrenyl-propanes **1** and **2** have nonfolded structures in the ground state, and they display monomer fluorescence at 77 K and excimer fluorescence at 298 K. They can readily adopt un-strained face-to-face sandwich excimer geometires and have large values of $\Delta\nu$, which are similar for the 1,1-, 2,2-, and 1,2-pyrenyl isomers (5). The $[n.n](2,7)$pyrenophanes **3–5** have parallel sandwich-like structures in the ground state and display excimer fluorescence both in a 1.3 K glass and at room temperature (7).[4] Their $\Delta\nu$ values decrease as the length of the alkyl tethers increases, presumably because of decreased electronic interaction between the two pyrenes. The $[2.2](1,3)$pyrenophane **6** has an extended ground state structure and displays pyrene monomer fluorescence in non-polar solvents, both at 77 and 298 K (8). In polar solvents, it displays overlapping monomer and excimer fluorescence. The observation of excimer fluorescence in polar solvents is attributed to a "harpooning" mechanism in which photo-induced charge transfer triggers folding. The value of $\Delta\nu$ in polar solvents is smaller that that for either **1** or **3**, suggesting that it does not adopt a fully overlapping structure. The $[2.2](1,8)$pyrenophane **7** has a splayed structure and displays a smaller value of $\Delta\nu$ than those for the other cyclophanes (9).

The crystal structures of the 1,8-di-1-pyrenylnaphthalenes display nearly parallel pyrene rings, with splay angles $<3°$ and rotational angles of $<15°$ (10). The two pyrene rings of **8** and **10** have slightly slipped sandwich geometries, where **9** has only partial pyrene–pyrene overlap. The barrier for thermal isomerization of **9** to **8** is 28 kcal/mol, much higher than the value obtained for the interconversion of $syn-$ and $anti-$ E,E-N,N'-dimethyl-N,N'-di-1-naphthylurea, ca. 12 kcal/mol (calculated via ^{1}H NMR exchange simulations).[2] The values of $\Delta\nu$ for **8–10** in a 1.3 K MTHF glass reflect their structural differences. The smallest value is observed for **9**, which has the least extensive overlap in the ground state, and **8**, with maximal overlap, has the greatest.

The calculated ground state structures of **11** and **12** have rather poor pyrene–pyrene overlap and a large splay angle, similar to that of **7**. Thus, it is not surprising that they do not

display excimer fluorescence in a 77 K glass. The formation of a fluorescent excimer at 298 K presumably requires a decrease in the average pyrene–pyrene separation, which would result in increased strain in the urea linkage. Thus, the difference in energy between folded E,E and extended E,Z conformations may actually be smaller in the excited state than in the ground state. The value of $\Delta\nu$ for **11**, which exists predominantly as the syn conformer, is similar to that for syn-1,8-di-1-pyrenylnaphthalene (**8**). The value of $\Delta\nu$ for **12** is similar to that for 1,8-di-2-pyrenylnaphthalene (**10**). Thus, we might expect that the relaxed pyrene excimer geometries of **11** and **12** are similar to those of **8** and **10**, respectively.

The behavior of the dipyrenylureas is qualitatively similar to that of several other diarylureas that we have studied. Tertiary di-2-naphthylurea and di-2-anthrylurea also display monomer fluorescence at 77 K and broadened, red-shifted emission in solution. The values of $\Delta\nu$ for these tertiary ureas are 2200 and 2900 cm^{-1}, respectively, significantly smaller than the values for **11** and **12**. As a consequence of these small spectral shifts, it is not possible to resolve monomer and excimer fluorescence. The fluorescence decays of the dinaphthyl- and dianthrylureas are also single exponentials, indicative of either emission from a single rotamer or rapid equilibration between rotamers.

Concluding remarks

The fluorescence properties of excimer-forming dipyrenyl systems are highly dependent upon the nature of the linker connecting the two pyrene chromophores. Systems such as the pyrenophanes **3–5** and the 1,8-dipyrenylnaphthalenes in which the two pyrenes are parallel and strongly overlapping display excimer fluorescence both in low temperature

---

^{4}F. Diederich. Personal communication, 2002.

glasses and in room temperature solutions. Systems with poor overlap and rigid linkers such as the pyrenophanes **6** and **7** and the 1,8-dipyrenylnaphthalene **9** display monomer fluorescence both in glasses and in solution. Systems with highly flexible linkers such as the 1,3-dipyrenylpropanes **1** and **2** display monomer fluorescence in rigid glasses and excimer fluorescence in solution.

The protophanes **11** and **12** possess a linker which restricts ground state conformational mobility, resulting in weak electronic interactions between poorly stacked pyrenes. As a consequence, **11** and **12** display monomer fluorescence in a rigid glass, unlike the 1,8-dipyrenylnaphthalenes **8** and **10** which display excimer emission at 1.3 K. In fluid solution the locally excited states of **11** and **12** can undergo geometric relaxation to form excimers with monomer–excimer spectral shifts similar to those of **8** and **10** (Table 2). The unique conformational properties of the tertiary diarylureas, as well as their ease of synthesis, make them well suited for the study of intramolecular excimer and exciplex behavior in "ureaphane" systems with two or more arene layers.

Experimental

General

^{1}H NMR spectra were measured on an Inova 500 spectrometer. UV–vis spectra were measured on a Hewlett-Packard 8452A diode array spectrometer using a 1 cm path length quartz cell. Total emission spectra were measured on a SPEX Fluoromax spectrometer. Low-temperature spectra were measured in a Suprasil quartz "EPR" tube (id = 3.3 mm) using a quartz liquid nitrogen cold finger dewar at 77 K. Total emission quantum yields were measured by comparing the integrated area under the total emission curve at an equal absorbance and the same excitation wavelength as an external standard (9-methylanthracene) (Φ_f = 0.35 at 298 K in cyclohexane) (21). Emission spectra are uncorrected and the estimated error for the quantum yields is ±10%. Fluorescence decays were measured using a Photon Technologies International (PTI) stroboscopic detection instrument with a hydrogen or nitrogen lamp using a scattering solution to profile the instrument response function. Nonlinear least-squares fitting of the decay curves employed the Levenburg–Marquardt algorithm as described by James et al. (22) and implemented by the PTI Timemaster software (23). Goodness-of-fit was determined by simultaneously judging the χ^2 (<1.2 in all cases), the residuals, the Durbin–Watson parameter (>1.5 in all cases), and the Runs Test (>–1.9 in all cases). Multiple wavelength detection and global analyses were applied in relevant cases. All solutions were either purged with nitrogen for 30 min or degassed under vacuum (<0.1 torr (1 torr = 133.322 Pa)) through five freeze–pump–thaw cycles.

Materials

All reagents are commercially available and were used as received. Anhydrous MTHF containing 200 ppm 2,6-di-*tert*-butyl-4-methylphenol (BHT, Aldrich) was distilled from potassium hydroxide under a nitrogen atmosphere immediately prior to use.

2-Aminopyrene

2-Aminopyrene was synthesized via the method of Streitwieser et al. (24). This method consists of a potassium metal reduction of liquid ammonia, forming a potassium amide solution, to which 1-bromopyrene is added. The resulting mixture of 1- and 2-aminopyrene is purified by HCl extraction. The isomers are then separated by crystallization and multiple column and preparative TLC. Our yields were less than those reported by Streitwieser (<10%). ^{1}H NMR (CDCl$_3$, 500 MHz) δ: 4.13 (s, 2H), 7.46 (s, 2H), 7.86 (t, ^3J = 8 Hz, 1H), 7.87 (d, J = 9 Hz, 2H), 7.98 (d, J = 9 Hz, 2H), 8.09 (d, J = 8Hz, 2H). MS m/z: 217 (M$^+$).

N,N′-Diarylureas

To a solution of amine (10 mmol) in dichloromethane (20 mL), was added 2.2 equiv of triethylamine, followed by 1.6 mmol of triphosgene. After the mixture had been stirred for 10 min, the solvent was removed using a rotary evaporator. The solid residue was washed with water and recrystallized from DMF–water (10:1). The resulting crystalline amide was washed with water and dried under vacuum. *N,N′*-Di-1-pyrenylurea was characterized and reported previously (13). Due to its insolubility, NMR data was not obtainable for *N,N′*-di-2-pyrenylurea.

N,N-Dimethyl-N′-2-pyrenylurea:
^{1} NMR (DMSO-d_6, 500 MHz) δ: 3.08 (s, 6H), 8.01 (t, J = 7.5 Hz, 2H), 8.09 (d, J = 9 Hz, 2H), 8.16 (d, J = 9 Hz, 2H), 8.27 (d, J = 7 Hz, 1H), 8.45 (s, 2H), 8.90 (s, 1H).

N,N′-Dimethyl-N,N′-diarylureas

To a solution of *N,N′*-diarylurea (10 mmol) in 20 mL DMF was added drop-wise 1.5 equiv of NaH in 10 mL DMF, followed by 1.5 equiv of MeI. The mixture was stirred at room temperature until the starting material was consumed (ca. 2 to 3 h), and was then mixed with water, and extracted with CH$_2$Cl$_2$. The organic layer was washed with water and dried with anhydrous potassium carbonate. After the solvent was removed, the residue was purified by column chromatography using mixed solvent (acetone and hexane). The *N,N′*-dimethyl-*N,N′*-di-1-pyrenylurea (**11**) was characterized and reported previously (13).

N,N′-Dimethyl-N,N′-di-2-pyrenylurea (**12**):
^{1}H NMR (CDCl$_3$, 500 MHz) δ: 3.46 (s, 6H), 7.26 (d, J = 9 Hz, 2H), 7.36 (s, 2H), 7.52 (d, J = 9 Hz, 2H), 7.90 (t, J = 7.7 Hz, 1H), 7.97 (d, J = 7.7 Hz, 2H).

N,N,N′-Trimethyl-N′-arylureas

To a solution of aminopyrene (0.66 g, 3 mmol) in dichloromethane (20 mL) was added 1.4 mL triethylamine (10 mmol), followed by 0.3 g triphosgene (1 mmol). After the mixture had been stirring for 30 min, a mixture of 0.6 g dimethylamine hydrochloride (7 mmol), 1.4 mL triethylamine (10 mmol), and 20 mL CH$_2$Cl$_2$ was added. The mixture was refluxed for 10 min, the solvent was then removed using a rotary evaporator. The solid residue was washed with water and recrystallized from acetone–hexane (1:1) to give the relevant *N,N*-dimethyl-*N′*-pyrenyl urea. The *N,N*-dimethyl-*N′*-1-pyrenylurea was characterized and reported previously (13).

N,N-*Dimethyl*-N′-*2-pyrenylurea:*

^{1}H NMR (DMSO-d_6, 500 MHz) δ: 3.08 (s, 6H), 8.01 (t, J = 7.5 Hz, 2H), 8.09 (d, J = 9 Hz, 2H), 8.16 (d, J = 9 Hz, 2H), 8.27 (d, J = 7 Hz, 1H), 8.45 (s, 2H), 8.90 (s, 1H). This was methylated with MeI–NaH as described above. The crude *N,N,N′*-trimethyl-*N′*-pyrenylureas were purified by column chromatography. *N,N,N′*-Trimethyl-*N′*-1-pyrenyl-urea (**11m**) was characterized and reported previously (13).

N,N,N′-*Trimethyl*-N′-*2-dipyrenylurea (**12m**):*

^{1}H NMR (CDCl$_3$, 500 MHz) δ: 2.71 (s, 6H), 3.46 (s, 3H), 7.85 (s, 2H), 7.97 (t, [3]J = 7.4 Hz, 1H), 7.971 (d, J = 9 Hz, 2H), 8.06 (d, J = 9 Hz, 2H), 8.16 (d, J = 9 Hz, 2H).

Aminosilanes as two-electron donors: A technological application of radical cation chemistry

Ian R. Gould, Stephen A. Godleski, Paul A. Zielinski, and Samir Farid

Abstract: Aminosilanes possess the appropriate structural features for use as two-electron sensitizers in silver halide photography. Here, we describe studies of the nucleophile-assisted cleavage reactions of the C—Si bonds in their radical cations. Water is identified as a useful nucleophile. It is found that the kinetics of these reactions are best described by taking into account a radical cation – water complex. The cleavage reactions are also controlled by steric effects at silicon and by the proximity of a carboxylate group that can modify the nucleophilicity of the water. Cleavage forms an α-amino radical that can donate a second electron to 9,10-dicyanoanthracene as a solution-phase electron acceptor.

Key words: silane, radical cation, two-electron sensitization, fragmentation, steric effects.

Résumé : Les aminosilanes possèdent les caractéristiques structurales appropriées qui permettent de les utiliser comme sensibilisateurs à deux électrons dans la photographie à l'halogénure d'argent. Nous décrivons les études portant sur les réactions de clivage, avec assistance nucléophile, de la liaison C—Si dans leurs cations radicalaires. L'eau est identifiée comme un nucléophile utile. On a trouvé que les cinétiques de ces réactions sont mieux décrites en tenant compte d'un complexe cation radicalaire – eau. Les réactions de clivage sont contrôlées également par les effets stériques du silicium, et par la proximité du groupe carboxylate qui peut modifier la nucléophilicité de l'eau. Le clivage conduit à un radical α-amino qui peut donner un second électron au 9,10-dicyanoanthracène en tant qu'accepteur d'électron dans la phase en solution.

Mots clés : silane, cation radicalaire, sensibilisation à deux électrons, fragmentation, effets stériques.

[Traduit par la Rédaction]

Introduction

Fragmentation reactions of radical cations yield interesting and useful catalytic species, such as radicals, protons, and electrophiles (1). Pioneering work on these reactions by Arnold and co-workers explored their scope and defined their thermodynamics (2), and qualitative and quantitative studies on a wide variety of radical cation fragmentation reactions have now been reported (1, 2). Recently, a technological application for radical cation fragmentation was discovered in silver halide photography (3, 4). The primary event in the photographic process is excitation of a sensitizing dye that results in one-electron injection from the excited dye into the silver halide (5). Trapping of the resultant oxidized dye by electron transfer from an organic amine forms the amine radical cation. Fragmentation of this radical cation forms an α-amino radical that is capable of injecting a

second electron into the silver halide, potentially doubling the efficiency of the photographic system (3, 4). This application of radical cation chemistry is termed two-electron sensitization (TES) of silver halide, and the amine precursor to the radical cation is a two-electron sensitizer (3, 4).

For proper operation, a two-electron sensitizer must meet several criteria. One of these is that the radical cation should fragment on the microsecond timescale, preferably with a rate constant, k_{fr}, that is controllable (3). The fragmentation reactions of the TES compounds described to date are decarboxylation reactions of amine carboxylates, as shown schematically in eq. [1]. The rate constants for fragmentation, k_{fr}, of several of these radical cations were reported (3).

[1]
They exhibit a strong dependence on the oxidation potential of the amine. A useful method of controlling the fragmentation rate constant that does not depend upon oxidation potential or, even better, that could compensate for the effect of oxidation potential, would provide a greater degree of control in the application of these compounds. The development of structures that provide such control is the subject of the present paper, which describes fragmentation reactions of aminosilane radical cations. These reactions are subject to control by steric factors and respond to the medium in a

different way than do the decarboxylation reactions. Fragmentation reactions of aminosilane radical cations have been described previously by Mariano and co-workers, and kinetic measurements of these reactions were reported (6). Here, we describe more detailed kinetic studies; we further explore the factors that control the rate constants for fragmentation of these radical cations; and we provide solution-phase evidence that aminosilanes can act as TES reagents. Fragmentation of the C—Si bond in silane radical cations is usually not a unimolecular reaction for many systems but occurs via a nucleophilic-assisted mechanism, as indicated in eq. [2], where $X–SiR_3^{\bullet+}$ represents a generic silane radical cation (6, 7). One consequence of this is that the bimolecular rate constants for the desilylation reactions have been found to be sensitive to steric effects, particularly with respect to substitution at silicon (7).

[2]
For example, the reactivity of triethyl derivatives (**1**, $R_3 = Et_3$) was observed to be almost an order of magnitude lower than the corresponding trimethyl analogues ($R_3 = Me_3$) (7). The reactivity of the derivative $R_3 = Me_2$-t-Bu was still lower, and the $R_3 = i$-Pr_3 compound was dramatically less reactive than the triethylsilane compound, $R_3 = Et_3$. Because the substituents on silicon have only a small influence on the oxidation potential of the compound, these donors offer an obvious way to change, k_{fr}, without changing the oxidation potential of the radical cation precursor.

In the TES scheme, the radical X• should be reducing enough to inject an electron into the conduction band of silver halide, i.e., it should have an oxidation potential that is equal to, or more negative than, ca. –0.9 V vs. SCE (3). From previous work on the carboxylate TES donors, a set of structural features to meet this requirement for X• have been identified (3). Specifically, a radical site that is α to nitrogen in a dialkylaniline (Structure **2**) is sufficiently reducing — even when the radical is primary — so long as the aniline is substituted with a strong electron-donating group, e.g., 4-methoxy. However, with weakly electron-donating groups or with electron-withdrawing groups in the 4 position, such a radical must have secondary substitution (Structure **3**) to be sufficiently reducing.

R' = OMe, etc.

2

R' = Me, CHO, etc.

3
To generate such radicals via desilylation reactions, trialkylsilicon groups should be placed at the α positions of dialkylanilines. In addition, to be useful for photographic purposes, such compounds require a water-solubilizing

substituent. Here, we describe a series of useful TES donors, based on desilylation chemistry, which satisfy these various requirements.

Results and discussion

Structural features and synthetic approach

The basic structure that has the important required features is shown in eq. [3].

[3]
Cleavage of the C—Si bond generates the desired α-amino radical. The β-propionate group serves as a water-solubilizing functionality. Decarboxylation, as in eq. [1], does not occur because this would generate a primary, unstabilized alkyl radical.

The synthetic route employed is outlined in Scheme 1. The *tert*-butyl ester of aniline β-propionate, prepared via Michael addition of *tert*-butyl acrylate to aniline, was reacted with the appropriate trialkylsilane triflates (see experimental section) to provide the *tert*-butyl ester silyl aniline derivatives **4E** and **5E**. The *tert*-butyl group was removed with trifluoroacetic acid, and the sodium carboxylate salt **4S** was obtained using sodium methoxide or sodium hydroxide. The 4-formyl *tert*-butyl ester derivatives **6E** and **7E** were obtained from **4E** and **5E** via a Vilsmeier reaction. Removal of the *tert*-butyl group as before gave the carboxylate **6S**. The structures of the compounds are summarized in Table 1.

Solution phase studies on the radical cations

Experimental approach

The rate constants for fragmentation of the radical cations were obtained using transient absorption spectroscopy, using 9,10-dicyanoanthracene (DCA) as the excited-state electron acceptor. The radical cations of the donor molecules, $X–SiR_3^{\bullet+}$, were formed by oxidation of the donor using a biphenyl radical cation ($C^{\bullet+}$) in a cosensitization scheme (Scheme 2) (8).

Fragmentation of $X–SiR_3^{\bullet+}$ leads to the formation of the radical, $X^{\bullet}$. If $X^{\bullet}$ is sufficiently reducing, it can donate an electron to another DCA molecule so that *two* reduced acceptors are formed for *one* absorbed photon in an exact solution phase analogue of the TES scheme (3). Formation of this second-reduced DCA can easily be observed in a time-resolved absorption experiment when k_{fr} is not so small that its formation is significantly slower than the processes that remove the $DCA^{\bullet-}$. Indeed, observation of two DCA reduction processes represents a convenient method for confirmation of fragmentation of the radical cations, because it provides evidence for formation of the $(X^{\bullet})$ radical cleavage product. In general, reduction of two DCA molecules is observed for all of the silane radical cations studied here, when k_{fr} is greater than ca. 10^6 s^{-1} (see for example, Fig. 1 below). As discussed further below, in some cases the $X^{\bullet}$ radicals could be directly observed. When evidence of radical forma-

$$DCA^* \qquad DCA^{\bullet-} \qquad DCA^{\bullet-} \qquad DCA^{\bullet-} \qquad 2\ DCA^{\bullet-}$$
tion was obtained in this way, the rate constant for fragmentation of the radical cation, k_{fr}, was simply equated to the observed rate constant for its pseudo-first-order decay.

The decay kinetics of the donor radical cation can be monitored in different ways, depending on the system under investigation. One problem is that there is no analyzing wavelength where only the radical cation absorbs, i.e., contributions from the DCA radical anion (DCA$^{\bullet-}$) to the overall absorption decay kinetics are always observed. The simplest way to deal with this is to saturate the solution with oxygen, which scavenges DCA$^{\bullet-}$ to form the nonabsorbing superoxide (O$_2^{\bullet-}$). Under these conditions, a fast-absorption decay is observed, owing to the reaction of DCA$^{\bullet-}$, with a pseudo-first-order rate constant, k_{O_2}, which is usually ca. 7×10^6 s^{-1} in aqueous acetonitrile. This is followed by a slower pseudo-first-order decay as a result of the reaction of the donor radical cation. This method is easily implemented when the X–SiR$_3^{\bullet+}$ fragmentation rate is much slower than the rate of reaction of the DCA$^{\bullet-}$ with oxygen. As k_{fr} increases to ca. 2–3×10^6 s^{-1}, it becomes necessary to analyze the observed absorption decay as a sum of two exponentials.

In principle, the fragmentation rate can also be determined from the rate of growth of the radical product, X$^{\bullet}$ (Scheme 2). The radical products derived from **4** and **5** cannot be readily observed in the visible region of the spectrum.

With the 4-formyl derivatives **6** and **7**, however, the radicals can be observed at long wavelengths (>730 nm). In this wavelength region, the radical cation and radical anion absorb only weakly, and grow-in of X$^{\bullet}$ can be observed as a result of fragmentation of the X–SiR$_3^{\bullet+}$. As discussed above, however, the radicals also react with the DCA sensitizer to form DCA$^{\bullet-}$, so that the exponential grow-in is followed by an exponential absorption decay with a pseudo-first-order rate, k_{DCA}, that depends upon the DCA concentration, (Scheme 2). One interesting feature of such a double exponential kinetic scheme is that the rates can become "reversed" (9). This is the case if the rate of decay of the radical caused by the reaction with DCA, k_{DCA}, is faster than the rate at which it is formed owing to the fragmentation reaction, k_{fr}. Under these conditions, the rate of *growth* of the absorption signal is equal to k_{DCA} (i.e., the process that *removes* the X$^{\bullet}$) and the rate of the *decay* of the absorption signal is equal to k_{fr} (i.e., the process that *forms* the X$^{\bullet}$) (9). The two processes can be distinguished, and the fragmentation rate correctly identified, by changing the concentration of DCA, which affects only the pseudo-first-order k_{DCA} and not k_{fr}.

Finally, under certain conditions, an estimate for k_{fr} can be obtained from analysis of the growth of the second DCA$^{\bullet-}$ signal because of the reaction of X$^{\bullet}$ with DCA. When k_{fr} and

[e]First-order rate constant for decay of the radical cation in acetonitrile.

k_{DCA} are of similar magnitude, a double exponential analysis of the data can be used to estimate both rate constants, as illustrated in Fig. 1, below.

In the present study, we have used all three techniques as k_{fr} varied as a function of the concentration of the nucleophile (usually water, see below). The absorbance as a function of time, in each case, is analyzed according to a specific type of double exponential analysis. Shown in Fig. 2 are representative transient absorption spectra observed upon excitation of a solution of DCA–biphenyl in the presence of the aminosilanes, in this case silane **4S**. According to Scheme 2, after oxidation of the silane by the biphenyl radical cation and before its fragmentation, equal concentrations of the silane radical cation and the DCA radical anion are present. From the previously determined extinction coefficient of the DCA radical anion (8), the extinction coefficient of the silane radical cations can thus be obtained by comparing the signal sizes due to the radical anion and radical cation. The optimum wavelength for observing the silane radical cations

is clearly around 530 nm (Fig. 2 and ref. 6), and wavelengths in this region were chosen for direct observation of these species.

Shown in Fig. 3 is a transient absorption decay at 530 nm for excitation of DCA–biphenyl in the presence of aminosilane **6E**. A fast-absorbance decay caused by reaction of DCA$^{\bullet-}$ with oxygen is observed, followed by a slower decay as a result of fragmentation of the silyl radical cation, **6E**$^{\bullet+}$. The total absorbance, A, is fitted to an equation of the form shown in eq. [4], where t is time and A_1 and A_2 represent the

[4] $\qquad A = A_1 e^{-k_1 t} + A_2 e^{-k_2 t} + A_3$

absorbances owing to DCA$^{\bullet-}$ and **6E**$^{\bullet+}$, respectively, and A_3 represents small amounts of residual absorbance at infinite time. In this case, k_1 corresponds to k_{O_2} and k_2 corresponds to k_{fr}.

Figure 4 shows the formation and decay of the radical, X$^{\bullet}$, formed from fragmentation of the radical cation of the 4-formyl-substituted silylaniline **7E**. The absorbance is fitted

Fig. 1. Optical density (in units of 10^{-3}, mOD) at 705 nm, as a function of time, t, observed upon excitation of DCA–biphenyl and **4S** in argon-purged acetonitrile containing 9.3 M water, showing two-electron reduction of DCA. The absorbance at this wavelength is mainly due to the radical anion DCA$^{\bullet-}$. The jump in optical density at zero time initial is owing to absorbance by **4S**$^{\bullet+}$ and DCA$^{\bullet-}$. The growth in absorbance is owing to reduction of a second DCA after fragmentation of the **4S**$^{\bullet+}$. The change in absorbance with time is described by *a consecutive a → b → c process in which c is monitored*. The smooth curve represents the best fit to the data according to $15.3 - 12.2 \exp(-6.1 \times 10^5 \, t) + 5.0 \exp(-1.5 \times 10^6 \, t)$. The slower component corresponds to the **4S**$^{\bullet+}$ reaction, k_{fr} under the present conditions, and the faster component to reduction of the second DCA.

Fig. 2. Transient absorption spectra of (open circles) the radical anion of 9,10-dicyanoanthracene (DCA$^{\bullet-}$) in acetonitrile solvent and (closed circles) the radical cation of a representative amino-silane **4S** (**4S**$^{\bullet+}$) in acetonitrile in the presence of 20% water, showing overlap of the spectra. The spectrum of **4S**$^{\bullet+}$ in aceto-nitrile in the presence of less water is somewhat broader. The figure indicates that the optimum wavelength for direct observation of the aminosilane radical cations is around 530 nm.

to an equation of the form shown in eq. [5], where A_1 represents the absorbance of X$^{\bullet}$ at the concentration of the X–SiR$_3$$^{\bullet+}$ precursor extrapolated to zero time and A_2 represents

$$[5] \qquad A = (A_1 \, k_1)/(k_2 - k_1) \, (e^{-k_1 t} - e^{-k_2 t}) + A_2$$

the residual absorbance at infinite time. In this case, the "normal" situation applies, i.e., k_1 corresponds to k_{fr}, and k_2 corresponds to k_{DCA}. Figure 1 shows the growth in absorption caused by the formation of the second DCA$^{\bullet-}$, as a result of reaction of X$^{\bullet}$ with DCA, for excitation of DCA–biphenyl with silane **4S**. The absorbance is fitted according to eq. [6], where A_1 represents the absorbance of the second DCA$^{\bullet-}$ at infinite time, A_2 represents the absorbance of the first DCA$^{\bullet-}$ that appears at essentially zero time, and k_1 corresponds to k_{fr} and k_2 to k_{DCA}.

$$[6] \qquad A = A_1[1 + (k_2 e^{-k_1 t} - k_1 e^{-k_2 t})/(k_2 - k_1)] + A_2$$

Fragmentation rate constants

Experiments were performed in acetonitrile at a varying concentrations of water because, in a photographic dispersion, water is the likely nucleophile to assist the fragmentation process. In all cases, the rate of fragmentation of the radical cations increased with increasing water concentration (6, 7). Typical data are shown in Fig. 5 for the radical cations of silanes **6E** and **4E**.

As observed previously (6), the dependence on added water as a nucleophile is somewhat nonlinear, with the reaction rate becoming less dependent at higher water concentrations. The kinetics of reactions involving high concentrations of hydroxylic quenchers, such as water, often exhibit nonlinear behavior that has been subject to a variety of explanations (6, 10). For example, with increasing water concentration, the character of the solvent gradually changes from polar aprotic to polar protic, which would be expected to decrease the nucleophilicity of the water (11). However, the radical cations are strong Lewis acids, and an alternate explanation of the behavior, in this case, may be due to reversible formation of a complex. Previously, Mariano and co-workers suggested a similar explanation for the nonlinear dependence of this reaction on water concentration, in terms of a covalent complex between the oxygen of the nucleophile and the silicon on the radical cation (6). Such a complex, whatever its structure, can be characterized by a second-order rate constant for formation, k_C, and a first-order rate constant for separation, k_{-C}, Scheme 3. The ratio of these rate constants, k_C/k_{-C}, defines an overall equilibrium constant, K_{eq}. Nucleophile-assisted fragmentation can occur within the complex, with a first-order rate constant, k_{Nu}, Scheme 3. In this scheme, k_0 is the pseudo-first-order decay rate constant of the radical cation in the absence of added nucleophile. Based on Scheme 3, the decay of the radical cation and the growth of the radical X$^{\bullet}$ are properly described by two exponential components. However, when k_{-C} is much larger than k_{Nu}, the time constant for one of these components is much larger than the other, and this fast component also has a small amplitude. Under these conditions, only the larger and slower component is actually observed. The time constant

Scheme 3.

$$X{-}SiR_3^{\bullet+} + H_2O \underset{k_{-C}}{\overset{k_C}{\rightleftharpoons}} X{-}SiR_3^{\bullet+}/H_2O \xrightarrow{k_{Nu}} X^\bullet + R_3Si{-}\overset{+}{O}H_2$$

$$\downarrow k_0$$

product

Fig. 3. Optical density (in units of 10^{-3}, mOD) at 530 nm, as a function of time, t, observed upon excitation of DCA–biphenyl and **6E** in oxygen-purged acetonitrile containing 1.1 M water. Both the radical anion of DCA (DCA$^{\bullet-}$) and the radical cation **6E**$^{\bullet+}$ contribute to the total absorbance, and the decay is thus a sum of *two independent pseudo-first-order exponentials*. The smooth curve represents the best fit to the data and is given by: $5.1 \exp(-8.1 \times 10^6\, t) + 32.3 \exp(-4.0 \times 10^6\, t) + 0.6$. The faster decay corresponds to reaction of DCA$^{\bullet-}$ with oxygen and the slower decay to reaction of **6E**$^{\bullet+}$ with water, i.e., k_{fr} under the present conditions.

Fig. 4. Optical density (in units of 10^{-3}, mOD) at 740 nm, as a function of time, t, observed upon excitation of DCA–biphenyl and **7E** in argon-purged acetonitrile containing 2.1 M water. The absorbance at this wavelength is mainly owing to the radical resulting from fragmentation of the radical cation, **7E**$^{\bullet+}$. The absorbance is described by *a consecutive a → b → c process in which the intermediate b is monitored*. The smooth curve represents the best fit to the data and is given by: $-21.05 \exp(-2.1 \times 10^6\, t) + 19.1 \exp(-3.4 \times 10^5\, t) + 3.9$.[4] The negative component corresponds to radical growth, k_{fr} under the present conditions, and the positive component to radical decay caused by reduction of DCA. The spike at early time is owing to the biphenyl (cosensitizer) radical cation (see text), which reacts very rapidly with **7E**.

for this component is given by eq. [7] and is equated to k_{fr}.[2] Using eq. [7], values for K_{eq} and k_{Nu} that reproduce the observed dependence of k_{fr} on water concentration can be obtained.[3]

[7] $\quad k_{fr} = 0.5 \{k_C [H_2O] + k_0 + k_{-C} + k_{Nu}\}$
$\qquad\qquad - 0.5 \{(k_C [H_2O] + k_0 - k_{-C} - k_{Nu})^2$
$\qquad\qquad\qquad + 4k_C [H_2O]k_{-C})\}^{0.5}$

The data are summarized in Table 1. The values for K_{eq} are roughly the same for all of the reactions studied here and are small, ca. 0.1 M^{-1}. In contrast to K_{eq}, however, k_{Nu} depends quite strongly upon the substituents on the radical cat-

ion (Table 1). Although Table 1 summarizes the best values for the parameters, we find that reasonable fits to the data can actually be obtained using both slightly higher and lower values for K_{eq} (by ca. 30%) than those given in Table 1, with corresponding changes in k_{Nu} in the opposite direction. Although there is some uncertainty associated with absolute values of K_{eq} and k_{Nu}, the product $K_{eq}k_{Nu}$ is determined quite accurately and represents a good measure of the relative reactivities of the different compounds, Table 1. $K_{eq}k_{Nu}$ has dimensions of M^{-1} s^{-1}, is equivalent to the initial slope of the observed rate constant vs. water concentration,

---

[2] Equation [7] gives the time constant of the slower observed component as a difference between two functions. The time constant of the faster component is given by the sum of the same two functions, which is too large (>10^8 s^{-1}) to be resolved under the experimental conditions.

[3] In principle, fitting of the dependence of k_{fr} on [H$_2$O] using eq. [7] allows determination of values for both k_C and k_{-C}. However, the k_{fr} calculated using eq. [7] are insensitive to the *absolute* values of k_C and k_{-C} when k_C is ~10^8 M^{-1} s^{-1} or larger.

[4] The form of this equation is not identical to that of eq. [5] due to a small absorption at this wavelength of DCA$^{\bullet-}$, the kinetics of which are superimposed and are described by eq. [6].

Fig. 5. Observed rate constants for pseudo-first-order decay of the radical cations $6E^{\bullet+}$ and $4E^{\bullet+}$, k_{fr}, as a function of water concentration, in acetonitrile at room temperature, illustrating the effect of the oxidation potential of the precursor. The curves are calculated as described in the text, with values for effective bimolecular rate constants, $K_{eq}k_{Nu}$, of 3.6×10^6 M^{-1} s^{-1} for $6E^{\bullet+}$ and 4.1×10^5 M^{-1} s^{-1} for $4E^{\bullet+}$.

Fig. 6. Observed rate constants for pseudo-first-order decay of the radical cations $6E^{\bullet+}$ and $7E^{\bullet+}$, k_{fr}, as a function of water concentration, in acetonitrile at room temperature, illustrating the effect of steric hindrance at silicon. The curves are calculated as described in the text, with values for effective bimolecular rate constants, $K_{eq}k_{Nu}$, of 3.6×10^6 M^{-1} s^{-1} for $6E^{\bullet+}$ and 5.4×10^5 M^{-1} s^{-1} for $7E^{\bullet+}$.

and represents the "effective" bimolecular rate constant. This value can thus be compared to the bimolecular rate constants reported for nucleophile-assisted fragmentation of silane radical cations reported elsewhere (6, 7). Importantly, the use of $K_{eq}k_{Nu}$ allows for the nonlinear dependence on water concentration to be properly accounted for.

The effect of a 4-formyl substituent is to significantly enhance the reactivity toward water as a nucleophile. This is expected based upon previous work on silane and other radical cations (1, 2, 6, 7) and is easily explained using the thermodynamic cycle approach to understanding radical cation reactivity, pioneered by Arnold and co-workers (12). Using such cycles, it can easily be shown that when all other factors are equal, the thermodynamics of a radical cation reaction should become more favorable with increasing oxidation potential of the precursor, leading to a faster reaction (12). In the present case, the electron-withdrawing formyl group increases the oxidation potential of the aminosilane and faster reaction results, as observed in the comparison between **6E** and **4E** in Fig. 5. The data of Table 1 (see also **6S** vs. **4S** and **7E** vs. **5E**) indicate that the effect of the 4-formyl substituent is to increase $K_{eq}k_{Nu}$ by approximately one order of magnitude, as compared with the corresponding unsubstituted compound. Comparable increases in rate constant for cleavage using methanol as the nucleophile were observed previously by Mariano and co-workers for similar silane radical cations with electron-withdrawing groups on nitrogen (6).

The aminosilanes are considerably easier to oxidize than the aryltrialkylsilanes studied previously (7), yet the reactivities of their radical cations towards water as a nucleophile are almost as high. This may be a consequence of the fact that the positive charge is likely to be more localized on the nitrogen in the aminosilane radical cations, i.e., close to the site of nucleophilic attack. In the anisyl silane, **8**, the positive charge may be located more on the oxygen, i.e., away from the site of nucleophilic attack.

8

In addition to oxidation potential, the silanes offer a means to control the rate of fragmentation via steric effects, as illustrated in Fig. 6, where the dependence on water concentration is shown for trimethylsilyl **6E** and triethylsilyl **7E**. The $K_{eq}k_{Nu}$ for the triethylsilanes are smaller than those of the trimethyl analogues by a factor of ca. 6 ± 1 for both the unsubstituted and the 4-formyl anilines (Table 1, see **5E** vs. **4E** and **7E** vs. **6E**). Steric effects of similar magnitude were observed in corresponding reactions of the radical cations of benzyltrialkylsilanes (7). Interestingly, a comparison of the *tert*-butyl esters and the corresponding carboxylate salts shows that the carboxylates react with water more *slowly* by a factor of ca. 3 (Fig. 7 and Table 1, see **4S** vs. **4E** and **6S** vs. **6E**). A definitive explanation of this effect cannot be given, but it may be attributed to hydration of the carboxylate group, which will decrease the nucleophilicity of the water in the microenvironment of the C—Si bond (11).

The literature experiment that most closely relates to the present work is the water-assisted radical cation fragmenta-

tion reaction shown in eq. [8], studied by Mariano and co-workers (6c). As mentioned above, a nonlinear dependence on water concentration was also observed in this previous work, and a rate constant was estimated at low water concentrations to be 1.3×10^6.

[8]

This value is somewhat higher than the $(K_{eq}k_{Nu})$ for either of the p-H-substituted trimethylsilyl-radical cations included in the present study (Table 1). The reasons for this small effect is not exactly clear. It may further illustrate the subtle effects that substituents on nitrogen can have on the micropolarity and, thus, the nucleophilicity of the water. Alternatively, it may reflect the somewhat different methods of kinetic analysis used in the two studies.

The nature of the decay process of the radical cation in the absence of added water, k_0, has not been established. These values are either measured directly in the absence of water or are obtained as part of the fitting procedure described below. Pseudo-first-order rate constants less than ca. 10^6 s^{-1} are often difficult to measure accurately in experiments such as these because of competing second-order recombination reactions. They are also the least accurately determined parameters obtained from the fitting procedure. Nevertheless, it is clear that the decay constants of the unsubstituted, aminosilane radical cations 4E and 5E, in the absence of water, are in the range of $\sim 5 \times 10^4$ s^{-1}, whereas those of the 4-formyl analogues 6E and 7E are nearly an order of magnitude larger, ~ 4–5×10^5 s^{-1}. The higher reactivity of the 4-formyl derivatives, relative to the unsubstituted analogues, is understandable based on the thermodynamic arguments given above. It is not possible to confirm fragmentation by the observation of two-electron reduction under these conditions, because the k_{fr} would be too small. It is possible that the decays under these conditions may be due to deprotonation (6) or perhaps to reaction with impurities.

Conclusions

The properties of a series of aminosilanes have been investigated as potential two-electron donors for silver halide photography. Solution-phase studies have been performed that confirm the radical cations of the donors fragment to give appropriately reducing radicals in the presence of an appropriate nucleophile. By varying the steric bulk of the substituents on the silicon, the rate of fragmentation of the radical cations can be varied substantially with minimal changes in the oxidation potential of the donor. Pseudo-first-order rate constants for fragmentation varying over ca. 2 orders of magnitude have been measured by varying the silane oxidation potential, the size of the substituents at silicon, and the concentration of water as an external nucleophile.

Experimental

The solvents were spectrograde and used as received. 9,10-Dicyanoanthracene and biphenyl were available from previous studies (3). The laser flash photolysis experiments

Fig. 7. Observed rate constants for pseudo-first-order decay of the radical cations 6E$^{•+}$ and 6S$^{•+}$ as a function of water concentration, in acetonitrile at room temperature, illustrating the effect of a proximal carboxylate group. The curves are calculated as described in the text, with values for effective bimolecular rate constants, $K_{eq}k_{Nu}$, of 3.6×10^6 M^{-1} s^{-1} for 6E$^{•+}$ and 1.4×10^6 M^{-1} s^{-1} for 6S$^{•+}$.

were performed using a nanosecond pulsed excimer (Questek model 2620, 308 nm, ca. 20 ns, ca. 100 mJ) pumped dye laser (Lambda Physik model FL 3002). The laser dye was DPS in dioxane (410 nm, ca. 20 ns, ca. 10 mJ). The analyzing light source was a pulsed 150W xenon arc lamp (Osram XBO 150/W). The arc lamp power supply was a PRA model 302, and the pulser was a PRA model M-306. The pulser increased the light output by ca. 100-fold for a time period of ca. 2–3 ms. The analyzing light was focused through a small aperture (ca. 1.5 mm) in a cell holder designed to hold 1 cm^2 cuvettes. The laser and analyzing beams irradiated the cell from opposite directions and crossed at a narrow angle (ca. 15°). After leaving the cell, the analyzing light was collimated and focused onto the slit (1 mm, 4 nm bandpass) of an ISA H-20 monochromator. The light was detected using a Hamamatsu model R446 photomultiplier. The output of the photomultiplier tube was terminated into 50 ohm and captured using a Tektronix DSA-602 digital oscilloscope. The experiments were performed in 1 cm^2 cuvettes, equipped with arms for degassing. The DCA and biphenyl concentrations in all of the time-resolved experiments were ca. 10^{-4} and ca. 0.1 M, respectively. The concentrations of the aminosilanes was typically ca. 2–4×10^{-3} M.

NMR spectra were run on a Varian 300 MHz spectrometer, generally at a concentration of ca. 100 mg mL^{-1}. For selected examples, additional NMR data obtained from measurements at concentrations of 10–20 mg mL^{-1}, including coupling constants, are given in Table 2. Preparation of the materials was performed as follows:

tert-Butyl 3-(*N*-phenylamino)propionate

Aniline (126.7 g, 1.36 mol), *tert*-butyl acrylate (174.5 g, 1.36 mol), and methanesulfonic acid catalyst (4 mL) were combined and stirred at gentle reflux (135°C) for 4 h. The mixture was cooled and petroleum ether (1 L) was added. The resulting precipitated salt was removed by filtration and discarded. The filtrate was concentrated in vacuo at 90°C to an oil (232 g). The desired pure ester was obtained by vacuum distillation (138 g, 46%, 115–125°C at 0.3–0.5 mmHg (1 mmHg = 133.322 Pa)).

^{1}H NMR (300 MHz, $CDCl_3$) δ: 1.45 (s, 9H, -C(CH_3)_3), 2.50 (t, 2H, -CH_2C*H*_2CO-), 3.40 (t, 2H, -NHC*H*_2CH_2CO-), 4.20 (s, 1H, -NH-), 6.60 (d, 2H, *o*-H), 6.70 (t, 1H, *p*-H), 7.30 (t, 2H, *m*-H).

^{13}C NMR (75 MHz, $CDCl_3$) δ: 8.11 (-CH_3), 35.16 (-CH_2CH_2CO-), 39.69 (-NHCH_2CH_2-), 80.82 (-O-C(CH_3)_3), 113.06 (2,6-aromatic C), 117.60 (4-aromatic C), 129.25 (3,5-aromatic C), 147.80 (1-aromatic C), 171.69 (-COO-).

1-Trimethylsilylethyl trifluoromethanesulfonate

Pyridine (6.7 g, 84.6 mmol) and dichloromethane (200 mL) were cooled to –25°C. Trifluoromethanesulfonic anhydride (23.9 g, 84.6 mmol) was added over 2 min. A thick slurry resulted. 1-Trimethylsilylethanol (10.0 g, 84.6 mmol) was added and the mixture stirred for 1 h while the temperature was allowed to rise to 25°C. The resulting pyridine trifluoromethanesulfonate was removed by filtration. The filtrate was concentrated in vacuo at 25°C to give 18.2 g (86 %) of the sulfonate.

^{1}H NMR (300 MHz, $CDCl_3$) δ: 0.12 (s, 9H, -Si(CH_3)_3), 1.55 (d, 3H, C*H*_3CH-), 4.92 (q, 1H, -SiC*H*OTfCH_3).

^{13}C NMR (75 MHz, $CDCl_3$) δ: –4.47 (-Si(CH_3)_3), 17.38 (*C*H_3CH-), 85.36 (CH_3*C*H-), 118.0 (q, -SO_2CF_3).

1-Triethylsilylethanol

Borane–tetrahydrofuran complex (1.0 M solution in tetrahydrofuran, 290 mL, 0.29 mol) was cooled to 0°C. Triethylvinylsilane (41.2 g, 0.29 mol) was added over 10 min, keeping the reaction temperature between 0 and 10°C. The mixture was stirred for 1 h, and the temperature was allowed to rise to 25°C. Water (10 mL) was cautiously added dropwise, followed by 3 M aqueous sodium hydroxide (97 mL, 0.29 mol) over 10 min. Hydrogen peroxide (30%, 99 mL, 0.96 mol) was added over 10 min, keeping the reac-

tion temperature at ca. 30°C. The mixture was refluxed for 1 h. Cooling to 25°C gave three liquid phases. The addition of anhydrous potassium carbonate (150 g, 1.09 mol) produced two clear liquid phases. The top organic phase was dried over magnesium sulfate and concentrated in vacuo at 25°C to give a ca. 1:1 mixture (53.6 g) of the desired 1-triethylsilylethanol and the unwanted isomer 2-triethylsilylethanol. The crude mixture was distilled, and the fraction boiling at 90–100°C, 12 mmHg, was collected (26.8 g). This material was distilled again, and the fraction boiling at 87–90°C, 12 mmHg, was the desired pure isomer (10.0 g, 22%).

^{1}H (300 MHz, CDCl$_3$) δ: 0.60 (q, 6H, -Si(CH_2CH$_3$)$_3$), 0.90 (t, 9H, -Si(CH$_2$CH_3)$_3$), 1.25 (s, 1H, -OH), 1.30 (d, 3H, CH_3CH-), 3.62 (q, 1H, CH$_3$CH-).

^{13}C (75 MHz, CDCl$_3$) δ: 1.46 (-Si(CH_2CH$_3$)$_3$), 7.42 (-Si(CH$_2$CH_3)$_3$), 20.21 (-CHCH_3), 60.07 (-CHCH$_3$).

1-Triethylsilylethyl trifluoromethanesulfonate

A mixture of pyridine (4.9 g, 62 mmol) and dichloromethane (150 mL) was cooled to –25°C. Trifluoromethanesulfonic acid anhydride (17.5 g, 62 mmol) in dichloromethane (25 mL) was added, resulting in a thick slurry. A solution of 1-triethylsilylethanol (9.96 g, 62 mmol) and dichloromethane (25 mL) was added and the reaction mixture stirred for 1 h while the temperature was allowed to rise to 25°C. Most of the solid had dissolved. Additional pyridine (ca. 1.5 mL) was added to raise the pH of the reaction mixture from ca. 3 to 5, resulting again in a thick slurry. The salt (14.7 g) was removed by filtration and the filtrate concentrated in vacuo at 25°C to a semi-solid (20 g). Petroleum ether (200 mL) was added, and more resulting salt was removed by filtration. The filtrate was treated with decolorizing carbon and concentrated in vacuo at 25°C to an oil (13.12 g). The oil was determined by ^{1}H NMR to be a 70:30 mixture of the desired triflate – starting 1-triethylsilylethanol and was used without further purification.

^{1}H NMR (300 MHz, CDCl$_3$) δ: 0.50–0.72 (m, -Si(CH_2CH$_3$)$_3$), 0.90–1.05 (m, -Si(CH$_2$CH_3)$_3$), 1.30 (d, -CH(OH)CH_3), 1.60 (d, -CH(OTf)CH_3), 3.65 (q, -CH(OH)CH$_3$), 5.08 (q, -CH(OTf)CH$_3$).

^{13}C NMR (75 MHz, CDCl$_3$) δ: 1.17 (-CHOTfSi(CH_2CH$_3$)$_3$), 1.47 (-CHOHSi(CH_2CH$_3$)$_3$), 6.92 (-CHOTfSi(CH$_2$CH_3)$_3$), 7.42 (-CHOHSi(CH$_2$CH_3)$_3$), 17.96 (-CHOTfCH_3), 20.17 (-CHOHCH_3), 60.07 (-CHOHCH$_3$), 83.97 (-CHOTfCH$_3$), 118.0 (q, -SO$_2$CF$_3$).

Compound 4E

A mixture of 1-trimethysilylethyl trifluoromethanesulfonate (6.38 g, 25.5 mmol), *tert*-butyl 3-anilinopropionate (5.64 g, 25.5 mmol), potassium carbonate (3.52 g, 25.5 mmol), and butyronitrile (25 mL) was stirred at reflux for 16 h. The mixture was filtered to remove salt, and the filtrate was concentrated in vacuo at 50°C to give 6.9 g of a yellow oil. The desired product was the first eluting material (3.7 g, 45%) obtained via flash chromatography (silica gel, 9 parts petroleum ether : 1 part ethyl acetate).

^{1}H NMR (300 MHz, CDCl$_3$) δ: 0.12 (s, 9H, -Si(CH$_3$)$_3$), 1.25 (d, 3H, CH_3CH-), 1.48 (s, 9H, -C(CH$_3$)$_3$), 2.40–2.65 (m, 2H, -CH$_2$CH_2CO-), 3.35 (q, 1H, CH$_3$CH-), 3.45–3.7 (m, 2H, -NCH_2CH$_2$-), 6.65 (t, 1H, *p*-CH), 6.75 (d, 2H, *o*-CH), 7.20 (m, 2H, *m*-CH).

^{13}C NMR (75 MHz, CDCl$_3$) δ: –1.89 (-Si(CH$_3$)$_3$), 13.61 (CH_3CH-), 28.13 (-C(CH$_3$), 34.87 (-CH$_2$$CH_2$CO-), 44.47 (-N$CH_2CH_2$-), 47.05 (CH$_3$$C$H-), 80.50 (-$C$(CH$_3$)$_3$), 112.89 (*o*-CH), 115.98 (*p*-CH), 129.12 (*m*-CH), 148.63 (aromatic C-N), 171.47 (-CO-).

Compound 4S

The *tert*-butyl ester **4E** (3.70 g, 11.5 mmol) and trifluoroacetic acid (10 mL, ca. 130 mmol) were stirred at 25°C for 16 h. The reaction mixture was concentrated in vacuo at 25°C. The oil was dissolved in ethyl ether (100 mL) and washed with water (2 × 25 mL). The ether layer was washed with aqueous sodium bicarbonate (3.5 g, 42 mmol, 25 mL water). The bottom aqueous layer (pH ca. 7) was discarded and the top ether layer treated with anhydrous sodium bicarbonate – magnesium sulfate. The dried organic extract was concentrated in vacuo at 25°C to give the free acid as a golden oil (2.7 g, 88%). The acid (2.50 g, 9.4 mmol) was stirred with a mixture of diethyl ether (50 mL), water (50 mL), and sodium hydroxide (0.37 g, 9.3 mmol). The top ether layer was discarded. The bottom aqueous layer (pH 10) was washed with fresh ether and the ether layer again discarded. The bottom aqueous layer was treated with decolorizing carbon and silica gel, resulting in a pH ca. 9. A few drops of acetic acid were added to bring the pH to ca. 7–8. The solution was concentrated in vacuo at 25°C to give a brown oil (2 g, 74%). The oil was dissolved in acetonitrile and treated with anhydrous sodium sulfate and decolorizing carbon. The solvent was removed at 25°C to give **4S** as a hygroscopic gum.

^{1}H NMR (300 MHz, D$_2$O) δ: 0.00 (s, 9H, -Si(CH$_3$)$_3$), 1.23 (bs, 3H, CH_3CH-), 2.20–2.60 (bm, 2H, -NCH$_2$CH_2CO-), 3.30 (m, 1H, CH$_3$CH-), 3.40–3.80 (bd, 2H, -NCH_2CH$_2$-), 4.80 (s, HOD), 6.65 (bm, 1H, *p*-CH), 6.77 (bs, 2H, *o*-CH), 7.07 (bm, 2H, *m*-CH). See also Table 2.

^{13}C NMR (75 MHz, D$_2$O) δ: 0.00 (-Si(CH$_3$)$_3$), 15.12 (CH_3CH-), 36.84 (-CH$_2$$CH_2$CO-), 50.23 (-N$CH_2CH_2$-), 52.11 (CH$_3$$C$H-), 118.69 (*o*-CH), 122.55 (*p*-CH), 132.40 (*m*-CH), 148.80 (aromatic C-N), 182.38 (-COO-).

Compound 5E

tert-Butyl 3-(*N*-phenylamino)propionate (9.96 g, 45 mmol), diisopropylethylamine (5.80 g, 45 mmol), and acetonitrile (25 mL) were combined. 1-Triethylsilylethyl triflate (13.12 g, 45 mmol, ca. 70% pure, the remainder being the parent alcohol) was added, followed by additional acetonitrile (25 mL). The mixture was stirred for 2 h at 25°C, then at reflux for 3 h. The mixture was concentrated in vacuo at 40°C to give an oil. Petroleum ether (100 mL) was added and the resulting salt filtered and discarded. The filtrate was concentrated in vacuo at 40°C to give an oil (13.5 g). Flash chromatography (silica gel, 9 parts petroleum ether : 1 part ethyl acetate) gave the crude product, **5E** (4.6 g) with trace silyl impurities. A second flash chromatographic operation gave the pure desired product (3.0 g, 18%).

^{1}H NMR (300 MHz, CDCl$_3$) δ: 0.65 (q, 6H, -Si(CH_2CH$_3$)$_3$), 1.00 (t, 9H, -Si(CH$_2$CH_3)$_3$), 1.28 (d, 3H, -CHCH_3), 1.50 (s, 9H, -C(CH$_3$)$_3$), 2.40–2.50 and 2.55–2.70 (m, m, 1H, 1H,

-CH$_2$CH_2CO-), 3.45–3.70 (m, 3H, -NCH_2CH$_2$- and -NCHCH_3), 6.65 (t, 1H, p-H), 6.75 (d, 2H, o-H), 7.20 (m, 2H, m-H). See also Table 2.

^{13}C NMR (75 MHz, CDCl$_3$) δ: 3.75 (-Si(CH_2CH$_3$)$_3$), 7.62 (-Si(CH$_2$$CH_3$)$_3$), 12.79 (-CH$CH_3$), 28.13 (-C($CH_3$)$_3$), 34.86 (-$CH_2CH_2$CO-), 44.85 (-N$CH_2CH_2$-), 45.47 (-$CHCH_3$), 80.49 (-O-$C$(CH$_3$)$_3$), 113.63 ($o$-CH), 115.98 ($p$-CH), 129.15 ($m$-CH), 148.42 (aromatic C-N), 171.52 (-CO-).

Compound 6E

Dimethylformamide (DMF, 50 mL) was chilled to –10°C. Phosphorous oxychloride (3.20 g, 21 mmol) was added. A solution of $tert$-butyl 3-(N-phenylamino)propionate (3.36 g, 10.4 mmol) and DMF (15 mL) was added and the mixture stirred at 25°C for 16 h. The reaction mixture was added to a solution of sodium acetate (17.22 g, 220 mmol) and water (230 mL) and allowed to stir for 2 h. The product was extracted with petroleum ether (3 × 50 mL). The petroleum ether extracts were dried over magnesium sulfate and treated with carbon. The treated extracts were concentrated in vacuo at 25°C to give 3.4 g of oil. The pure 6E, 3.04 g (84%), was obtained via flash chromatography (silica gel, 9 parts petroleum ether : 1 part ethyl acetate).

^{1}H NMR (300 MHz, CDCl$_3$) δ: 0.10 (s, 9H, -Si(CH$_3$)$_3$), 1.32 (d, 3H, CH_3CH), 1.45 (s, 9H, -C(CH$_3$)$_3$), 2.40–2.70 (m, 2H, -NCH$_2$CH_2CO-), 3.50 (q, 1H, CH$_3$CH-), 3.55–3.80 (m, 2H, -NCH_2CH$_2$-), 6.70 (d, 2H, o-CH), 7.70 (d, 2H, m-CH), 9.70 (s, 1H, -CHO). See also Table 2.

^{13}C NMR (75 MHz, CDCl$_3$) δ: –2.03 (-Si(CH$_3$)$_3$), 14.12 (CH_3CH-), 28.03 (-C(CH_3)$_3$), 34.40 (-CH_2CH$_2$CO-), 44.68 (-NCH_2CH$_2$-), 47.10 (CH$_3$$CH$-), 81.04 (-$C$(CH$_3$)$_3$), 111.61 ($o$-CH), 125.01 ($p$-$C$-CHO), 132.01 ($m$-CH), 152.84 (aromatic C-N), 170.63 (-COO-), 189.69 (-CHO).

Compound 6S

The 4-formyl $tert$-butyl ester 6E (3.04 g, 8.7 mmol) was cooled to –25°C, trifluoroacetic acid (10 mL, ca. 130 mmol) was added, and the solution was stirred at 25°C for 16 h. The reaction mixture was concentrated in vacuo at 25°C to a dark oil (9.23 g). The oil was partitioned between ethyl ether (100 mL) and aqueous sodium bicarbonate (4.92 g, 58.6 mmol, 100 mL water). The bottom aqueous layer had a pH ca. 7–8. The top organic layer was treated with magnesium sulfate and decolorizing carbon and concentrated in vacuo at 25°C to an oil (1.9 g). Pure free carboxylic acid (1.46 g, 57%) was obtained via flash chromatography (silica gel: 9 parts dichloromethane : 1 part methanol). The free acid (1.46 g, ca. 5 mmol) was combined with methanolic sodium methoxide (0.5 M, 9.5 mL, 4.75 mmol) to give a pH of ca. 8. Acetic acid was added to lower the pH to ca. 7. The solution was concentrated in vacuo at 25°C to give an oil (1.96 g). The oil was triturated with acetonitrile (3 × 5 mL) and the solvent again removed in vacuo at 25°C to give 6S as a hygroscopic gum (0.83 g).

^{1}H NMR (300 MHz, D$_2$O) δ: 0.12 (bs, 9H, -Si(CH$_3$)$_3$), 1.38 (bd, 3H, CH_3CH-), 2.0 (bs, acetonitrile), 2.15 (bs, acetic acid), 2.40–2.70 (bm, 2H, -CH$_2$CH_2CO-), 3.55–3.85 (bq and bm, 3H, CH$_3$CH-, NCH_2CH$_2$-), 6.90 (bd, 2H, o-CH), 7.75 (bd, 2H, m-CH), 9.45 (bs, 1H, -CHO). See also Table 2.

^{13}C NMR (75 MHz, D$_2$O) δ: 0.02 (-Si(CH$_3$)$_3$), 16.48 (CH_3CH-), 39.02 (-CH_2CH$_2$CO-), 48.62 (-NCH_2CH$_2$-), 49.76 (CH$_3$$CH$-), 114.59 ($o$-CH), 125.37 ($p$-$C$-CHO), 135.93 ($m$-CH), 157.02 (aromatic C-N), 183.03 (-COO-), 195.47 (-CHO).

Compound 7E

DMF (40 mL) was cooled to –10°C. Phosphorous oxychloride (2.11 g, 13.7 mmol) was added, followed by the $tert$-butyl ester 5E. The mixture was allowed to warm to 25°C and stirred for 16 h. The yellow solution was added to a solution of sodium acetate (11.2 g, 137 mmol) and water (150 mL) and the resulting mixture stirred for 1 h. The product was extracted with petroleum ether (3 × 50 mL), the extracts treated with magnesium sulfate and decolorizing carbon and concentrated in vacuo at 35°C to an oil (2.9 g). Flash chromatography (silica gel: 9 parts petroleum ether : 1 part ethyl acetate) gave the purified 4-formyl $tert$-butyl ester, 7E (2.3 g, 85%).

^{1}H NMR (300 MHz, CDCl$_3$) δ: 0.65 (q, 6H, -Si(CH_2CH$_3$)$_3$), 0.90 (t, 9H, -Si(CH$_2$CH_3)$_3$), 1.30 (d, 3H, -CHCH_3), 1.45 (s, 9H, -C(CH$_3$)$_3$), 2.35–2.50 and 2.60–2.75 (m, m, 1H, 1H, -CH$_2$CH_2CO-), 3.45–3.60, 3.65, and 3.70–3.80 (m, q, m, 1H, 1H, 1H, -NCH_2CH$_2$-, -CHCH$_3$), 6.73 (d, 2H, o-H), 6.80 (d, 2H, m-H), 9.70 (s, 1H, -CHO).

^{13}C NMR (75 MHz, CDCl$_3$) δ: 3.25 (-Si(CH_2CH$_3$)$_3$), 7.47 (-Si(CH$_2$$CH_3$)$_3$), 15.12 (-CH$CH_3$), 28.06 (-C($CH_3$)$_3$), 34.45 (-$CH_2CH_2$CO-), 45.13 (DEPT confirmed, -NCH_2CH$_2$- and -NCHCH$_3$), 81.07 (-O-C(CH$_3$)$_3$), 111.61 (o-CH), 125.06 (p-C-CHO), 131.80 (m-CH), 152.64 (aromatic C-N), 170.68 (-COO-), 189.72 (-CHO).

Photochemistry of rhodamine dye salts involving intra-ion-pair electron transfer

Guilford Jones II, Xiaochun Wang, and Jingqiu Hu

Abstract: The electron-transfer photochemistry of rhodamine 6G thiocyanate ion pairs has been investigated. For dye in a low polarity solvent, such as ethyl acetate, the emission of rhodamine 6G is significantly quenched by thiocyanate counterions. Laser photolysis of rhodamine 6G and thiocyanate in ethyl acetate was studied in detail with the identification of the reduced rhodamine 6G radical species (λ_{max} = 410 nm). The growth and decay of the R6G radical could be accounted for in part by a mechanism involving initial formation of dye triplet followed by electron transfer which provides a triplet radical-pair state on a µs timescale.

Key words: electron transfer, ion pair, rhodamine 6G, triplet state.

Résumé : On a étudié la photochimie par transfert d'électron de la paire d'ions rhodamine 6G/thiocyanate. Pour les colorants dans des solvants de faible polarité, comme l'acétate d'éthyle, l'émission de rhodamine 6G est désactivée de façon significative par le contre-ion thiocyanate. On a étudié soigneusement la photolyse au laser de la rhodamine 6G et du thiocyanate dans l'acétate d'éthyle en identifiant l'espèce radicalaire rhodamine 6G réduite (λ_{max} = 410 nm). On peut, en partie, attribuer la croissance et la décroissance du radical de R6G à un mécanisme impliquant la formation initiale d'un triplet colorant suivie d'un transfert d'électron qui conduit à l'état triplet de la paire de radicaux dans une échelle de temps de l'ordre de la µs.

Mots clés : transfert d'électron, paire d'ions, rhodamine 6G, état triplet.

[Traduit par la Rédaction]

Introduction

A large variety of organic dyes that are used in dye lasers, printing, and photography are ionic, including members of the rhodamine, triarylmethane, and cyanine families. The likelihood that dyes of this type will be paired or complexed with cationic or anionic partners has often been neglected in the examination of dye properties. The phenomenon of ion pairing is well-established as a mechanistic feature for numerous organic systems that incorporate species of opposite charge in media of moderate polarity (1). Although incompletely understood, there are a number of potential effects on the photochemical and photophysical properties of dyes that are ion paired, which will depend on the nature of the counterions that accompany dye salts and other medium conditions. For media less polar than water, including solid hosts such as organic polymers, it is indeed probable that electrostatic complexes will be important, if not dominant. Under these circumstances, dye species are more properly understood to exist as "tight" or "contact" ion pairs (1–3).

Several recent reports, including the work of Schuster and co-workers (4), Armitage and O'Brien (5), and Neckers and co-workers (6), have documented the spectroscopic or photochemical effects of ion pairing on cyanine and other chromophores and borate anions in organic solvents and other media such as aqueous liposomes. The photochemistry that results from visible photolysis, which appears to have practical utility in photoinduced radical polymerization (4, 6), involves a general mechanism of intra-ion-pair electron transfer, followed by the fragmentation of initial radical pair species to give free radical intermediates.

Ion-pairing or charge-type effects have been observed in photochemical studies of dyes that are commonly used in dye lasers. For example, charge and counterion effects on the laser output and other parameters for pyridiniumoxazoles have been reported (7). The quenching of emission of rhodamine-6G (R6G) (Scheme 1) by ferrocyanide has been investigated through phototransient studies that revealed interactions involving both ion diffusion and ion pairing (8). Other recent reports document the roles of counterions and ion pairing in the alteration of spectra, photobleaching, and the distribution of geometric isomers for cyanine and triarylmethane dyes (9).

We became interested in the effects of ion pairing on the photochemistry of cationic dyes on the basis that electrostatic attraction and tight ion pairing by counterions would introduce a special type of medium effect (10) based on electrostatic charge for laser dyes. Depending on the nature

Scheme 1. Structure of the R6G$^+$ cation.

of the counterion, it seemed likely that most photophysical properties such as fluorescence yield and lifetime, as well as dye photostability, could be altered to some degree in comparison with the behavior of "free" dye in fluid medium, where the principal interaction with solvent overshadows the interaction with a neighboring charged species. Also of interest was the previous observation (11) that the triarylmethane dye, crystal violet (CV$^+$), on UV or visible photolysis with excess polyacrylate as counterion in water led to efficient dye photobleaching. The photobleaching of dye for CV$^+$X$^-$ salts in a solvent of moderate polarity (e.g., 2-propanol) is also counterion dependent with the observed trend in rate of bleaching (Cl$^-$ > Br$^-$ > I$^-$) (12).

The most widely studied rhodamine dye, rhodamine-6G (R6G$^+$ cation, Scheme 1) features outstanding photophysical and photochemical properties for use in dye lasers (10). Its fluorescence yield is high for many solvents suitable for lasing applications (e.g., $\phi_f = 0.88$, methanol solvent) (13). The general insensitivity of the emission yield to excitation wavelength and medium makes it a popular fluorescence yield standard. The dominance of radiative decay is also reflected in the low value that has been obtained for the quantum yield of intersystem crossing for R6GCl; for ethanol solutions $\phi_T = 0.0021$ and a triplet decay time ($\tau_T = 3.5\ \mu s$) have been recorded (14). Accounts have been published previously of the investigation of rhodamine and other dyes under conditions in which they form electrostatic complexes with anionic polyelectrolytes in water (11, 15, 16).

In the present study, we have focused on ion-pair effects on the photochemistry of rhodamine-6G under circumstances in which salts of the cationic dye are dissolved in organic solvents of low to intermediate polarity. The role of ion pairing with several different counterions for R6G$^+$ could be confirmed through observation of alteration in dye spectra and dye fluorescence quenching. Ion pairing with the thiocyanate anion (SCN$^-$) was particularly effective. Along with the finding of significant emission quenching, laser flash photolysis experiments showed that free radicals are generated on ion pair photolysis. From the phototransient data, it was possible to determine radical yields and the relative rate constants associated with the competition between return electron transfer and cage escape. A mechanism in which electron transfer proceeds via the formation of dye triplets (i.e., an alternate mechanism of intersystem crossing for a rhodamine) was established. From the results, some insight is provided regarding the participation and consequences of intra-ion-pair electron transfer for dyes that have affinity for oppositely charged sites in self-assembled systems.

Experimental methods

Materials

Rhodamine 6G chloride (Aldrich) was recrystallized from ethanol three times. Its purity was confirmed by NMR and by TLC (alumina, ethanol solvent). Tetrabutylammonium thiocyanate (TBASCN), tetrabutylammonium acetate (TBAOAc), and tetrabutylammonium iodide (TBAI) (Aldrich) were recrystallized from ethyl acetate before use. All solvents used for spectroscopic measurements were either spectrograde or HPLC quality and used as received.

Instrumentation

Absorption measurements were conducted using a Beckman model DU-7 spectrophotometer with wavelength resolution of 0.5 nm. For some measurements which accompanied spontaneous dye photodegradation (mostly with I$^-$ in nonpolar solvents), spectra were measured immediately after the solution was prepared (within 5 s, and the measurement completed within about 20 s). Emission measurements were conducted using an SLM 48000 fluorimeter.

Absolute fluorescence quantum yields ($\phi_{f(s)}$) were measured by comparing the spectrally corrected emission intensity (F) of the sample to that of a fluorescence standard using the following equation.

$$[1] \qquad \phi_{f(s)} = \phi_{f(r)} \left(\frac{\int F_s(\lambda)\,d\lambda}{\int F_r(\lambda)\,d\lambda} \right) \left(\frac{A_r}{A_s} \right) \left(\frac{n_s^2}{n_r^2} \right)$$

where $\int F_s(\lambda)d(\lambda)$ and $\int F_r(\lambda)d(\lambda)$ are the integrated emission intensities for the sample (s) and the reference (r), A_r/A_s is the ratio of light intensities absorbed by the two solutions at the excitation wavelength, and n is the refractive index of the solvents. The fluorescence standard chosen for this study (10-methylacridinium hexafluorophosphate) has a known fluorescence quantum yield of 1.0 in water. The excitation wavelength was selected toward the blue side of the $S_o \rightarrow S_1$ absorption of rhodamine dye (500 nm); absorbance at the excitation wavelength was less than 0.2.

Laser flash photolysis measurements were conducted using a nanosecond laser flash photolysis system (16) that is based on a Quantel YG-581 Nd:YAG laser, whose second (532 nm) or third (355 nm) harmonic were used as excitation sources. The system included a Lecroy TR8818 transient recorder, a Kinetic Systems CAMAC dataway, and a 150 W Xe lamp. The Xe lamp was synchronously fired with the laser and used as a monitoring light for the transient signals. A monochromator and PMT were used to obtain transient spectra with a spectral resolution of 1 nm. Solution samples were prepared in either 1 × 2 cm and 1 × 1 cm pyrex cells (0.1–10 μM in dye) and were purged 20 min with argon gas prior to the initiation of experiments. Rate constants were calculated based on the rise and decay profiles.

Quantum yields of phototransient formation were measured by monitoring the signal associated with the R6G· transient at 410 nm and using the triplet absorption at 520 nm ($\varepsilon = 6500$ M^{-1} cm^{-1}) (17) of benzophenone (0.5 mM in acetonitrile) as a standard. The ratio of the time-zero transient ODs was multiplied by the inverse ratio of both absorbances at the excitation wavelength (355 and 532 nm)

Table 1. Photophysical properties of R6GCl with and without added salts in three solvents.

Solvents	Ethanol (ε 24.6)	THF (ε 7.58)	Ethyl acetate (ε 6.02)

and the extinction coefficients of R6GX and the standard. The following equation was utilized:

$$[2] \qquad \phi_{R6G\bullet} = \phi_{3BP} \left(\frac{P_{355}}{P_{532}} \right) \left(\frac{\varepsilon_{3BP}^{520}}{\varepsilon_{R6G\bullet}^{410}} \right) \left(\frac{A_{BP}^{355}}{A_{R6G}^{532}} \right) \left(\frac{OD_{R6G\bullet}^{410}}{OD_{3BP}^{520}} \right)$$

where P_{532} and P_{355} are the respective photon fluxes for the laser pulses for the YAG second and third harmonic wavelengths. The latter were obtained by measurement of pulse energies for 532 and 355 nm beams with a calorimeter (e.g., 70 and 28 mJ/pulse, respectively). Thus, a photon flux ratio could be calculated (e.g., 70/28 × 532/355 = 3.75). The ratio of R6G ground state absorbances at 532 and 355 nm was 9.5. Also used in the application of eq. [2] are the values $\varepsilon_{R6G\bullet}^{410} = 43\,000$ M^{-1} cm^{-1} and $\varepsilon_{3BP}^{520} = 6500$ M^{-1} cm^{-1} (17) for the radical and benzophenone triplet transients, respectively.

Cyclic voltammetry was carried out using an EG&G PAR 273 potentiostat/galvanostat controlled by the EG&G M270A (version 4.0) software package (scan rates: 1 mV/s – 5 V/s), or an EG&G PARC model 175 Universal Programmer function generator equipped with a Tektronix TD 320 two-channel oscilloscope (scan rate: 1 mV/s – 10 000 V/s) and using Tektronix Docuwave software. The three-electrode system consisted of a glass carbon (GC) working electrode, an aqueous Ag/AgCl, KCl (satd.) reference electrode (E° vs. NHE = E° vs. Ag/AgCl + 0.197), and a Pt counter-electrode. The reference electrode potential was checked against the ferrocene–ferrocenium couple and the electrochemical cell was thermostated at 20°C. Experiments were performed on argon-purged methylene chloride solutions containing 5 mM R6GCl and 0.1 M tetrabutylammonium hexafluorophosphate (TBAPF$_6$, Aldrich) at scan rates ranging from 50 to 1000 mV/s.

Results and discussion

Photophysical properties of R6G in the presence of excess salts in different solvents

Ethanol ($\varepsilon = 24.6$) has served as a solvent of choice for rhodamine dyes in dye lasers and other spectroscopic applications (10). In the present study, ethanol served as a reference solvent in the sense that its polarity is sufficiently high that the formation of ion pairs was expected to be suppressed for moderate concentrations of rhodamine dye and added salts. Ethyl acetate ($\varepsilon = 6.02$) was selected for investigation to represent a typical nonpolar solvent which is capable of dissolving the salts of relatively hydrophobic dye cations. Additional data were obtained for THF ($\varepsilon = 7.58$), a complementary solvent of intermediate polarity. Three anions, thiocyanate (SCN$^-$), iodide (I$^-$), and acetate (OAc$^-$), as their tetrabutylammonium (TBA) salts were used as additives to R6GCl solutions for inspection of ion-pairing effects in the aforementioned solvents. A low dye concentration of 10 µM was employed to minimize complicating features associated with dye aggregation (18) (but note discussion below).

The data regarding absorption and emission properties for R6G$^+$ with chloride as counterion (10 µM) and for the dye with excess SCN$^-$ or with hexafluorophosphate (PF$_6^-$) in three solvents are shown in Table 1. For the more polar solvent, ethanol, absorption and emission maxima and spectral shapes were perturbed only slightly on addition of excess salts (Fig. 1). Absorption was characterized for all media by the familiar (10) low energy visible band (S$_o$ → S$_1$, 528–530 nm) or the weaker transition in the UV (S$_o$ → S$_2$, 347 nm), up to the concentration limit for added salt (~0.3 M). Fluorescence spectra were also almost identical in shape and λ_{max} for ethanol solutions with the various addi-

tives. For the less polar media (THF and ethyl acetate) alterations in spectra were more pronounced. The noticeable trends included a shift to the red (5–12 nm) of the λ_{max} for visible absorption bands as well as emission bands. This effect was observed for solutions in which the counterion was simply chloride or for added excess SCN⁻, but not for the case of PF₆⁻. Extinction coefficients were also moderately perturbed (generally, a 10–20% reduction, Table 1) for salts in the less polar THF and ethyl acetate. Modest perturbations associated with the alteration of transition moments and oscillator strengths on binding of polarizable counterions (e.g., for SCN⁻ or Cl⁻ but not PF₆⁻) have been reported (18).

Aggregation effects are common for organic dyes in a variety of media (11, 15, 16, 18, 20– 22), and several subtle spectral clues suggest that dye–dye interaction may play a role for the rhodamine salts. For R6GCl in ethyl acetate (Fig. 2a), a noticeable shoulder appears with λ_{max} ~ 500 nm, a feature that is diminished on addition of excess SCN⁻. The broad spectral features that appear as blue shifts of the prin-

cipal absorption bands, consistent with the formation of dye dimers, are also observed on addition of other excess salts. Addition of both acetate and iodide results in strong perturbation of the visible band. A new band of this type assigned to the dye aggregate (λ_{max} ~ 500 nm) has been identified for R6G⁺ (e.g., for more concentrated dye–alcohol solutions) (13, 18). As reference points, the equilibrium constants for dimerization of R6GCl in ethanol and water are K_D = 0.27 M⁻¹ (22) and 6.2 × 10³ M⁻¹ (18), respectively. For a 10 µM solution of R6GCl in ethanol, the ratio of dimer to monomer at equilibrium is computed from the K_D value to be 2.7 × 10⁻⁶.

The "deaggregation" of R6GCl by SCN⁻ in ethyl acetate displayed novel behavior. As shown in Fig. 2a, the maximum in the visible is shifted slightly to the blue and then back to the red on progressive addition of TBASCN. This subtle effect could be associated with an alteration in the stoichiometry of ion pairing as shown with the following equilibria.

[3] $R6G^+ + SCN^- \leftrightarrows (R6G^+, SCN^-)$

$(R6G^+, SCN^-) + SCN^- \leftrightarrows (R6G^+, 2SCN^-)$

$2(R6G^+, SCN^-) \leftrightarrows (R6G^+, SCN^-)_2$

$2(R6G^+, SCN^-) + 2SCN^- \leftrightarrows 2(R6G^+, 2SCN^-)$

In this model the dimer aggregate that is formed in a modest amount on dissolution of salt in ethyl acetate is shifted via the second equilibrium to a complex of 2:1 stoichiometry which favors the counterion and relieves dye–dye interaction on addition of excess X^-. This model is reminiscent of that proposed by Armitage and O'Brien (5) which dealt with the 2:1 stoichiometry of complexation of two positively charged dyes and a bulky counterion triphenylbenzyl borate $(R6G^+:Ph_3BnB^- = 2:1)$. For the present case of R6GSCN, the 1:2 cluster might adopt a sandwich structure in which two SCN^- ions lie on opposite sides of the xanthene ring. Another case of deaggregation has been reported (15) in which $R6G^+$ at moderate concentration in water $(>1 \times 10^{-5}$ M) is relieved of dye–dye interaction on addition of the domain-forming polyelectrolyte, poly (methacrylic acid). Depending on the pH of solutions, dye is either bound to spaced charges on the polyelectrolyte chain or sequestered as individual dye cations in folded polymer interior (hydrophobic) spaces (15).

The most pronounced influence of non-polar solvents on the photophysics of rhodamine salts is observed in the quenching of fluorescence (Fig. 2*b*). As shown in Fig. 3, the quantum yield of emission that peaks at about 565 nm is diminished substantially with added TBASCN for ethyl acetate solvent. An important part of the trend is that the chloride counterion results in about a twofold quenching, whereas the effect is nearly an order of magnitude larger for the SCN^- counterion (ethyl acetate vs. ethanol). The series of Stern–Volmer plots (Fig. 4) shows different profiles of emission quenching, depending on the selected excess salt. For the more polar solvent (ethanol) the amount of excess counterion required for complete or nearly complete fluorescence quenching was much higher (e.g., 0.29 M TBASCN), whereas lower concentrations of added salts resulted in substantial quenching for ethyl acetate solutions (<5 mM). Notably, the addition of acetate was markedly less effective than addition of SCN^- or I^-.

The fluorescence quenching mechanism — ion pairing

The results of the fluorescence measurements in which various salts were employed as quenchers (counterions, acetate vs. iodide vs. thiocyanate) for $R6G^+$ in ethanol are shown in Fig. 4. Notably, all of the Stern–Volmer plots showed downward curvature. Furthermore, if the approximately linear portions of the plots are used to obtain nominal slopes, with values 25 M^{-1} and 1.7×10^4 M^{-1} for quenching by SCN^- in ethanol and ethyl acetate, respectively, quenching constants are obtained $(k_q = 5.9 \times 10^9$ and 6.1×10^{12} M^{-1} $s^{-1})$ that are quite different. The latter value (ethyl acetate samples) is much larger than that allowed by a diffusion-limited mechanism (23), whereas, for ethanol solutions, the quenching constant observed is quite close to that predicted for bimolecular diffusion $(k_{diff} = 6.1 \times 10^9$ M^{-1} s^{-1} at 25°C) (24). For this analysis, fluorescence lifetimes for dye solutions with no added salt $(\tau_f = 4.2$ and 2.8 ns) for

Fig. 4. Stern–Volmer plot of fluorescence quenching data for 10 μM R6GCl with added TBASCN, TBAI, and TBAOAc in aerated ethanol $(\lambda_{ex} = 500$ nm).

10 μM R6GCl in ethanol and ethyl acetate, respectively, were obtained by phase-shift fluorimetry.

The conclusion from the fluorescence quenching measurements is that, for the ethyl acetate medium, quenching takes place by a static mechanism involving complexation of dye and counterion. For ethanol solutions a dynamic quenching mechanism is most likely, or a small contribution by ion pairing may be important (vide infra). The quenching results thus provided, for the less polar medium, an opportunity to examine dye–counterion complexation in terms of an ion pair equilibrium:

[4] $D^+ + X^- \xrightleftharpoons{K_{IP}} (D^+, X^-)$

If a 1:1 ion-pairing stoichiometry is assumed, and the unquenched emission yield is taken as that value obtained for R6GCl fluorescence (ϕ_o), the relationship eq. [5] can be

Scheme 2. State energy diagram for the photochemistry of the R6G$^+$SCN$^-$ ion pair.

used to obtain an ion pairing constant (K_{IP}). The Benesi–Hildebrand procedure (25) and eq. [5] utilize values recorded for ϕ, the total emission yield for complexed and uncomplexed species and Δ, the difference between yields of complexed and uncomplexed species, as a function of quencher concentration (D_o).

$$[5] \qquad \frac{1}{\phi_o - \phi} = \frac{1}{\Delta} + \frac{1}{K_{IP} \, \Delta D_o}$$
Linear plots were obtained from the fluorescence quenching data for the R6G$^+$–SCN$^-$ system for the three solvents ethyl acetate (Fig. 3, insert plot), THF, and (for completeness) ethanol. These plots were used to calculate K_{IP} values (K_{IP} = 71, 9.3 × 10^3, and 3.1 × 10^4 M^{-1} for dye complexation in ethanol, THF, and ethyl acetate, respectively). Not unexpectedly, as solvent polarity decreases, K_{IP} increases; i.e., a lower polarity medium facilitates ion pairing, consistent with numerous studies of the ion-pairing phenomenon (1–3). Also, for the completely complexed dye cations, quenching by thiocyanate reduces the yield of emission to <10% of its value for uncomplexed R6G$^+$ (Fig. 3).

Electrochemistry of R6G$^+$ and the driving force for ion pair electron transfer

Redox potentials were required to evaluate the energetics of a hypothetical electron transfer that could occur for dye ion pairs. Reversible waves associated with R6G$^+$ reduction were obtained with an assembly that employed an Ag working electrode and with scan rates of 200 mV/s for dye in methylene chloride (ε = 8.90) with supporting electrolyte. From these data the half-wave potential ($E_{1/2}$ (R6G$^+$/R6G·) = –0.92 V vs. SCE in CH$_2$Cl$_2$) was obtained. Using this value and a reported value ($E_{1/2}$(SCN$^-$/SCN·) = +0.77 V vs. SCE) (26) for (reversible) thiocyanate oxidation in water, the radical pair energy (relative to the ground state for R6GSCN) was obtained: $\Delta G_o = E°$ (SCN/SCN$^-$) – $E°$ (R6G$^+$/R6G·) = 1.69 eV. This estimated value for the radical pair energy is well below that for the dye singlet state (ca. 0.5 eV) and

close to but below the energy of the dye triplet. The relationships among the energies of the various states are depicted in Scheme 2.

Flash photolysis of rhodamine ion pairs: free radical transients and photokinetics

Since R6G$^+$ has a dominant fluorescence that occurs in the ns regime (τ_f = 3 to 4 ns, Table 1), and since non-radiative decay is inefficient, the dye fails to generate appreciable phototransients in the 100 ns to 1 ms time domain in laser pump–probe experiments (e.g., the triplet yield = 0.0021 for R6G$^+$ in ethanol) (14). However, our preliminary results showed that ion pairing of the dye with the counterion SCN$^-$ (also I$^-$) led to a significant yield of phototransients on laser photolysis. Investigation of R6G$^+$ with other anions in non-polar solvents was included for comparison.

On pulsed photolysis of an ethyl acetate solution of 10 mM R6GCl with a Nd/YAG laser (532 nm, 60 mJ/pulse), the transient spectrum that was observed consisted of weak bands broadly absorbing at ca. 400 and 600 nm, along with a dominant dye bleach centered at 540 nm. The assignments are consistent with the appearance of the rhodamine triplet state (^{3}R6G^{+*} with λ_{max} = 620 nm and ε = 16 000 M^{-1} cm^{-1}) (27) and the semireduced dye species, the R6G· radical (λ_{max} = 410 nm) (28). These transients were also recorded for solutions that contained TBASCN with levels of salt concentration that corresponded to 75–97% ion pairing (0.1–1.0 mM), >99% ion pairing (3.0 mM, Fig. 5), and a level at which clustering of ions (vide supra) is important (20 mM, and up to the saturation limit of 30 mM). The transient bleach is associated with ground state depletion for which ε^{540} = 67 000 M^{-1} cm^{-1}.

On addition of excess SCN$^-$ the radical signal at 410 nm increased in intensity, with a fast onset (<30 ns) and a slower rise that could be followed accurately (~1 μs) (Fig. 6). The fraction of the fast process increased until [SCN$^-$] reached 1.0 mM (where ion pairing is complete). The slow rise appeared with [SCN$^-$] = 1.0 mM and became increasingly important (up to 20 mM TBASCN). Notably, the fast rise

Fig. 5. Transient spectra of 10 μM R6GCl with 3.0 mM TBASCN in Ar-purged ethyl acetate (λ_{ex} = 532 nm).
Fig. 6. Growth and decay profiles for the radical transient (λ_{max} = 410 nm) for 10 μM R6GCl as a function of added TBASCN in Ar-purged ethyl acetate (λ_{ex} = 532 nm).
time recorded at 410 nm was constant for this range of [SCN$^-$]. The decay of the R6G· radical occurred on the 100 ms timescale by a process that could be evaluated as second order or the sum of two exponentials; for example, a half-life of the dye-derived radical of 150 μs was recorded for a solution having 10 μM R6G$^+$ and 3.0 mM SCN$^-$ (Fig. 5).

The signal associated with the dye triplet species (^{3}R6G^{+*}) at 620 nm grew in intensity on addition of thiocyanate up to about 1.0 mM [SCN$^-$]. Notably also, its decay accelerated with added excess salt, reaching a rate corresponding to a decay time of ~1 μs (Fig. 7). Transient depletion of the absorption because of the R6G$^+$ ground state at 540 nm and its recovery were observed in all samples. For R6GCl without added salt, the recovery was comprised of two components, a dominant fast process (<50 ns),

Fig. 7. Decay profiles for the triplet transient (620 nm) for 10 μM R6GCl with TBASCN in Ar-purged ethyl acetate (λ_{ex} = 532 nm).
accompanied by a small contribution from a slow recovery (~200 μs). With the addition of excess SCN$^-$, the proportion due to the slow recovery was greatly enhanced and an intermediate recovery time developed (~1 μs).

Another finding in parallel with the evidence involving excess SCN$^-$ came on flash photolysis of 10 mM R6G$^+$ with 1.0 mM I$^-$, excited at 532 nm in ethyl acetate. These results were also consistent with a mechanism in which the decay of the observed R6G radical and the recovery of ground state dye are coupled, for long time regimes (>10 μs). This recovery mechanism is most readily related to a return electron transfer that occurs involving R6G radical and oxidized species through bimolecular encounter (vide infra).

Rise time for the R6G radical transient: mechanisms of intra-ion-pair electron transfer

The profile of growth and decay for the 410 nm signal vs. [SCN$^-$] is shown in Fig. 8. The findings include observation of a fast rise that occurs essentially with the laser pulse, followed by a slower process of transient formation in about 1 μs. The evolution of species is recorded in Fig. 9 for samples (3.0 mM in TBASCN) in terms of the growth of R6G radicals (410 nm), the decay of triplets (620 nm), and the recovery of dye bleaching (540 nm). The first-order rise and (or) decay times obtained from these plots are 1.4, 1.7, and 1.9 μs, respectively.

Proceeding on the assumption that dye photoreduction occurred via ion-pair electron transfer, we sought to establish further the respective roles of dye singlet and triplet states. Most noticeable was the finding that about 1 μs was required in order for the 410 nm transient to reach its maximum absorbance; in other words, there is a slow rise on the μs timescale that follows a more prompt mechanism for radical formation. This feature requires either (*i*) that a slower process of radical formation involving a diffusive encounter of the dye excited singlet state is important, or (*ii*) that another intermediate precedes the semireduced dye transient. Since, under the optimum conditions for radical formation (3.0 mM SCN$^-$, corresponding to virtually complete association of

Fig. 8. Growth and decay profiles for the radical transient (R6G·, 410 nm) for 10 μM R6GCl with 3.0 mM TBASCN in Ar-purged ethyl acetate (λ_{ex} = 532 nm), shown with regard to three timescales (10, 50, and 500 μs full scale).

Fig. 9. Growth and decay profiles for the radical (410 nm) and triplet (620 nm) transients and ground state bleach (540 nm) observed on laser photolysis of 10 μM R6GCl with 3.0 mM TBASCN in Ar-purged ethyl acetate (λ_{ex} = 532 nm).
R6G$^+$ and SCN$^-$ and quenching of rhodamine fluorescence (Fig. 3)), the probability of a diffusional step that would compete with dye singlet decay is eliminated. More telling is the observation that the decay of the 620 nm dye triplet transient matches substantially the growth of the 410 nm species (Fig. 9). Although the data are limited to inspection of only about two 1/e times, estimates can be made from these curves for radical growth and triplet decay (k_r = 7 × 10^5 s^{-1} and k_d = 6 × 10^5 s^{-1}, respectively) based on reasonable fits of the data to a first-order rate law.

A compelling feature of the phototransient data had to do with the relative yields of triplet and radical intermediates, as a function of the concentration of excess SCN$^-$. As noted in Fig. 7, the yield of the triplet (600 nm transient) is not enhanced for [SCN$^-$] > 1.0 mM (i.e., after ion pairing is substantially complete). In contrast, on further addition of excess salt, the proportion of the signal at 410 nm grows (in the interval of 1.0 to 20.0 mM SCN$^-$). Thus, an increase in yield of radical is not the result of a further increase in triplet yield, but has to do with a more competitive rate or yield for the electron transfer that occurs via the dye triplet ion pair. The key may lie in the 1:2 clustering of rhodamine with excess SCN$^-$ which could be responsible for a reduced rate of the back electron transfer that competes with the release of caged radicals (see below for the potential involvement of the oxidized species ((SCN)$_2^{·-}$)).

A mechanism that includes two possible pathways for formation of radical transients for R6GSCN can be understood in terms of the energy diagram of Scheme 2. Intra-ion-pair electron transfer may originate from singlet states on a relatively fast timescale and correspond to the appearance of the radical transient within the time of the laser pulse in ns measurements. A slower process follows intersystem crossing of ion-paired rhodamine dye and intra-pair electron transfer of dye triplet species. The latter sequence, which is apparently slowed in comparison to the singlet mechanism by two orders of magnitude (1 × 10^6 vs. 1 × 10^8 s^{-1}), proceeds with a
driving force that is diminished by 0.39 eV (the difference in S$_1$ and T$_1$ excitation energies (Scheme 2)).

An effort was made to characterize the formation of a thiocyanate-derived radical species. The product of one-electron oxidation of thiocyanate that is well-characterized is the pseudodimeric species ((SCN)$_2^{·-}$) a radical that could result in the present case from diffusion of radicals SCN· into bulk solution and trapping by SCN$^-$ (or by in-cage capture in the case of a 2:1 ion-pair stoichiometry). Although its visible absorption is weak, the (SCN)$_2^{·-}$ radical has been observed on flash photolysis or pulse radiolysis in a variety of settings (for water solutions λ_{max} = 480 nm, ε^{480} = 7800 M^{-1}) (26). Unfortunately, this spectral region is congested by strong local dye absorption (ε^{540} = 67 000 M^{-1} cm^{-1} and for the shoulder ε^{472} = 12 200 M^{-1} cm^{-1}).

Further comparison can be made with spectra obtained on flash photolysis of ethyl acetate solutions having excess iodide. What appears in the case of iodide is a feature also associated with a trapped (secondary) radical product, a contribution at 380 nm which is convoluted with the R6G transient absorption at 405 nm. The iodide derived radical (I$_2^{·-}$) is also a well-established intermediate (ε^{380} = 15 600 M^{-1} cm^{-1}) (29) whose observation provides further confirmation of an overall electron transfer mechanism.

Estimate of dye triplet and R6G free radical yields

Based on the calculated ε^{410} for the R6G radical (43 000 M^{-1} cm^{-1}, vide supra) and the absence of any excitation wavelength dependence on the photochemistry, an estimate of R6G radical yield on pulsed photolysis for several conditions of ion pairing was made (Table 2). The method required the recording of transient ODs that were extrapolated to zero time from decay data recorded on the 0–1 μs timescale. Samples of rhodamine dye with added salts were

Table 2. Radical and triplet quantum yield[a] for R6GSCN in ethyl acetate on laser flash photolysis (λ_{ex} = 532 nm).

$\Phi_{R6G\cdot}$	0.001	0.005	0.011	0.014	0.024	0.022
Φ_T	0.003	0.008	0.016	0.016	0.016	0.016

[a]Quantum yields of transient formation (R6G· (410 nm) and R6G$^+$ triplet state (620 nm)) based on benzophenone triplet (520 nm, Φ = 1.0).

photolyzed at 532 nm, whereas the actinometric standard based on the observation of the triplet state transient for benzophenone (λ_{max} = 520 nm, ε = 6500 M^{-1} cm^{-1}) (17) required use of the 355 nm laser wavelength with correction factors applied as described in the *Experimental* section. Estimation of the yield of long-lived rhodamine triplets for the ion pairs was more difficult, since decay times are relatively short for this weaker transient and the data comparatively noisy at early times following the laser pulse.

What is confirmed again is that SCN$^-$ ion pairing for R6G$^+$ results in an elevated transient yield, well above the reported triplet yield for dye in ethanol (0.002) (14). There are at least two scenarios involving ion-pair effects that could account for enhanced triplet formation and therefore allow an appreciable yield of electron transfer product via dye triplets. The counterion itself could play a special role as part of the dye "medium", namely, introducing spin orbit interactions not present for the free dye (including a heavy atom effect involving the S center). Not to be ruled out also is the possibility that dye aggregates are important (even for SCN$^-$ complexes which show little spectral perturbation); dye dimers and higher order species are known to give higher yields of triplets (28). Some insight regarding these possibilities is provided in the finding that the quenching of R6G$^+$ in the presence of I$^-$ in ethyl acetate results in a significantly lower residual fluorescence for the complexed ion pair. Increased yields of triplets on iodide complexation have been rationalized previously in terms of the halide counterion providing enhanced spin orbit coupling (30).

Conclusions

The addition of excess salts that include the counterions SCN$^-$, OAc$^-$, and I$^-$ result in moderate alteration of the absorption spectra for the rhodamine dye R6G$^+$. The counterions SCN$^-$ and I$^-$ are especially effective in that they lead to significant quenching of rhodamine dye fluorescence. The iodide and thiocyanate counterions are distinguished particularly in having relatively low ionization energies as reflected in their potentials for oxidation in solution. The data are consistent with the formation of ion-pair complexes of cationic dyes and counterions, with the photochemical outcome dictated by the counterion oxidation potential. The quenching of rhodamine dye fluorescence on addition of thiocyanate was used to determine equilibrium constants for ion pairing; complexation with counterions is much suppressed for R6G$^+$ in ethanol.

A mechanism for excited-state quenching was established using laser flash photolysis methods. Phototransients associated with intra-ion-pair electron transfer were identified (for the rhodamine radical transient λ_{max} = 410 nm). The growth and decay of the R6G radical could be accounted for in part

by a mechanism involving initial formation of a dye triplet followed by electron transfer which provides a triplet radical pair on a μs timescale. The enhancement of the yield of triplets observed for rhodamine ion pairs in ethyl acetate solvent may be due to enhanced spin orbit coupling involving counterion orbitals or the subtle alteration of the triplet radical pair energy gaps brought about by ion pairing. In summary, the data provide some insight to the competition kinetics that dictate the yield of long-lived free radical phototransients for an important class of cationic (rhodamine) dyes that are capable of ion pair formation in lower polarity media.

Generation and reactivity of the radical cations of coniferyl alcohol and isoeugenol in solution

N.P. Schepp and Y. Rodríguez-Evora

Abstract: Nanosecond laser flash photolysis of coniferyl alcohol and isoeugenol in acetonitrile leads to the formation of transient species that are identified as the corresponding radical cations. These radical cations decay with rate constants of ca. 1×10^6 s^{-1} in dry acetonitrile. Both radical cations react rapidly with hydroxylic solvents like water and alcohols to give 4-vinylphenoxyl radicals, indicating that these reagents behave as bases rather than nucleophiles. In addition, anionic reagents (acetate, cyanide, and chloride) react rapidly with the radical cations with second-order rate constants that are close to diffusion controlled. The main products generated in the presence of the anionic reagents are again the 4-vinylphenoxyl radicals, suggesting that these reagents also behave as bases. The lifetime of the radical cations in acidic acetonitrile was found to increase dramatically due to a shift in the radical cation – vinyl phenoxyl radical acid–base equilibrium to the side of the radical cation. An estimate of the pK_a of the radical cation in acetonitrile of 4.0 was obtained from the data.

Key words: radical cations, laser flash photolysis, lignan, vinylphenols.

Résumé : La photolyse éclair au laser, avec des impulsions de l'ordre de la nanoseconde, de l'alcool du coniféryle et de l'isoeugénol dans l'acétonitrile conduit à la formation d'espèces intermédiaires qui sont en fait les cations radicalaires correspondants. Ces cations radicalaires se désintègrent avec une constante de vitesse de l'ordre de 1×10^6 s^{-1} dans l'acétonitrile. Les deux cations radicalaires réagissent rapidement avec les solvants hydroxylés tels que l'eau et les alcools pour donner des radicaux 4-vinylphénoxyles, indiquant ainsi que ces réactifs se comportent plutôt comme des bases que comme des nucléophiles. De plus, les réactifs anioniques (acétate, cyanure et chlorure) réagissent rapidement avec les cations radicalaires avec des constantes de vitesse d'ordre deux qui sont très proches de celles d'une diffusion contrôlée. Les produits majoritaires générés en présence des réactifs anioniques sont encore des radicaux 4-vinylphénoxyles, ces résultats suggèrent que ces réactifs se comportent également comme des bases. On a trouvé que le temps vie de ces cations radicalaires, dans l'acétonitrile en milieu acide, augmente dramatiquement à cause d'un déplacement de l'équilibre acide–base, cation radicalaire – radical vinylphénoxyle, du côté du cation radicalaire. A partir des données on a pu évaluer à 4,0 le pK_a du cation radicalaire dans l'acétonitrile.

Mots clés : cations radicalaires, photolyse éclair au laser, lignan, vinylphénols.

[Traduit par la Rédaction]

Introduction

Naturally occurring compounds (including 4-hydroxy-cinnamates like syrginic acid and 1-(4-hydroxyphenyl)-propen-3-ols like coniferyl alcohol) that contain a 4-vinylphenol moiety are important materials in a number of biological systems. In particular, these kinds of organic molecules are building blocks for the biosynthesis of natural products such as plant lignans (1), which often have important medicinal properties, and lignin, a major constituent of wood. While specific details concerning the biosynthesis of these compounds are not well understood, it is generally accepted that initial oxidation induced by an oxidizing enzyme such as a peroxidase or a laccase to give a resonance-stabilized 4-vinylphenoxyl radical is a key step. Enzyme-mediated dimerization of these 4-vinylphenoxyl radicals then leads to production of the lignan-type materials (2, 3).

One pathway for the formation of the 4-vinylphenoxyl radicals involves enzyme-induced, one-electron oxidation of the 4-vinylphenol substrate to its corresponding radical cation which then undergoes rapid deprotonation, Scheme 1.

While the chemistry of 4-vinylphenoxyl radicals has been studied using several methods, including direct detection methods such as flash photolysis and ESR spectroscopy (4–6), the radical cations of the 4-vinylphenol substrates have not yet been investigated. In the present work, we focus on the chemistry of two 4-vinylphenol radical cations, namely the coniferyl alcohol and isoeugenol radical cations, Scheme 2.

Our principle goals were to obtain rate constants for the reactions of these radical cations, both with solvent and with

added bases and nucleophiles, and to examine the effect of acidity on their reactivity. We were also interested in determining if these radicals cations are sufficiently long-lived to participate in bimolecular reactions. If so, it may be possible that such species play a more significant role in the biosynthesis of lignans by participating directly in the dimerization process.

Experimental

Materials

Coniferyl alcohol and isoeugenol were purchased (Aldrich) and used as received. Acetonitrile was spectroscopic grade (Omnisolve, BDH). All other materials were the best available commercial grades and used without further purification.

Laser flash photolysis

The nanosecond laser flash photolysis system at Dalhousie University has been described previously (7). A Lambda Physiks excimer laser (308 nm, XeCl, 10 ns/pulse, <100 mJ/pulse) was used as the excitation source for most experiments. In experiments using chloranil or di-*tert*-butylperoxide, a Continuum Nd:YAG NY-61 laser (355 nm; 8 ns/pulse; <35 mJ/pulse) was used as the excitation source.

Solutions for kinetics experiments were prepared by addition of small aliquots (ca. 10 µL) of stock solutions of coniferyl alcohol or isoeugenol to 2.0 or 3.0 mL of acetonitrile in 7 × 7 mm^2 laser cells made out of Suprasil quartz tubing. The absorption of the 4-vinylphenols in the laser cells was approximately 0.4 at 308 nm, corresponding to concentrations of ca. 0.1 mM. Most laser experiments were carried out using aerated samples. When oxygen-free solutions were required, the samples were bubbled with a slow stream of dry nitrogen 20 min prior to laser irradiation. Measurements of quenching rate constants were made by adding small amounts (1–20 µL) of a stock solution with a known concentration of the quencher (*n*-Bu$_4$NCl, *n*-Bu$_4$NCN, or *n*-Bu$_4$NO$_2$CCH$_3$) dissolved in acetonitrile. Solutions for the experiments carried out under acidic conditions were prepared by making a 0.010 M HClO$_4$ stock solution in acetonitrile and then making appropriate dilutions of this solution using acetonitrile. To minimize the possibility of acid-catalyzed decomposition of coniferyl alcohol or isoeugenol, these materials were added to the acidic sample solutions just prior to performing the laser experiments. All kinetics experiments were carried out at room temperature (22 ± 1°C). For measurement of absorption spectra, a flow cell system was used to ensure that only fresh solution was subjected to each laser pulse.

Results and discussion

Laser irradiation in acetonitrile

Laser irradiation of coniferyl alcohol in dry acetonitrile leads to the formation of distinct absorption bands at 380 and 580 nm, Fig. 1. These two bands are formed promptly within the laser pulse, and both decay in a first-order manner with identical rate constants of 8 × 10^5 s^{-1} (Fig. 1, inset). The similar kinetic behaviour of these two bands indicates that both bands belong to a single transient species.

The absorption spectrum is very similar to the known spectra of substituted styrene radical cations that have two strong bands near 360 and 580 nm (8). In addition, the decay of the transient is insensitive to oxygen, but is greatly accelerated in the presence of hydroxylic solvents like water and methanol and in the presence of anionic reagents like bromide and chloride. These observations provide strong evidence for the identification of the transient species as the radical cation of coniferyl alcohol produced by laser-induced photoionization of coniferyl alcohol, eq. [1].

[1]
Evidence to support this assignment comes from results obtained under photoinduced electron-transfer conditions. Selective laser irradiation (355 nm) of chloranil in the presence of 1.0 mM coniferyl alcohol in acetonitrile leads initially to the formation of the triplet of chloranil with an absorption maximum at 500 nm (9). This band decays rapidly in the presence of coniferyl alcohol, Fig. 2 (inset), and leads to the formation of absorption bands at 380 and 580 nm, Fig. 2, that are closely similar to those produced upon direct laser irradiation of coniferyl alcohol. Absorption due to the presence of the chloranil radical anion at 450 nm (9) is also observed, with the rate constant for the growth of this band being identical to that for the decay of the triplet and for the growth of the bands at 380 and 580 nm. These results are consistent with initial formation of the chloranil triplet with absorption at 500 nm, which then undergoes an electron-transfer reaction with coniferyl alcohol to produce

Fig. 1. Transient absorption spectra generated (○) 200 ns, (●) 920 ns, (□) 3.2 μs, and (■) 6.4 μs after 308 nm laser irradiation of coniferyl alcohol in air-saturated acetonitrile. the 4-vinylphenol radical cation and the radical anion of chloranil, eq. [2].

[2]
As shown in Fig. 1, a strong absorption band centered at 340 nm is observed upon 308 nm irradiation of coniferyl alcohol in addition to the radical cation absorption at 380 and 580 nm. However, unlike the radical cation absorption, which appears promptly after the laser pulse, the 340 nm band grows in as a function of time. The observed rate constant of 8×10^5 s^{-1} for the formation of this band is identical to that for the decay of the 380 and 580 nm bands, Fig. 1 (inset), indicating the transient responsible for the absorption at 340 nm is a product of the reaction of the radical cation. The decay of the 340 nm transient is not affected by the

presence or absence of oxygen, nor is its decay influenced by the addition of protic reagents like water or methanol or anionic reagents like chloride or cyanide.

As observed for methoxy-substituted phenol radical cations, which rapidly deprotonate to give simple phenoxyl radicals (10), the main reaction of the 4-vinylphenol radical cation is likely to be deprotonation to give in this case a 4-vinylphenoxyl radical, eq. [3].

[3]
It is therefore reasonable to suggest that the 340 nm absorption band generated upon decay of the coniferyl alcohol radical cation is the 2-methoxy-4-(3-hydroxy-1-propenyl) phenoxyl radical. Evidence supporting this suggestion was obtained upon 355 nm laser irradiation of a solution of di-*tert*-butylperoxide in the presence of small amounts of coniferyl alcohol. This is expected to lead to the formation of the phenoxyl radical by initial photochemical formation of the *tert*-butoxy radical, followed by rapid hydrogen abstraction from the phenol hydroxy group of the coniferyl alcohol. As shown in Fig. 3, a transient with an absorption maximum at 340 nm identical to that produced upon reaction of the coniferyl alcohol radical cation is observed. These results therefore provide good evidence that the main reaction of the radical cation is indeed deprotonation to the 4-vinylphenoxyl radical, eq. [3].

A long-lived species with an absorption maximum at 350 nm has been observed previously upon irradiation of coniferyl alcohol in aqueous or alcoholic solvents (6, 11, 12). This transient has been assigned as the quinone methide generated by a mechanism that is thought to involve

Fig. 3. Transient absorption spectra generated (●) 480 ns, (○) 1.9 μs, and (■) 13 μs after 355 nm laser irradiation of di-*tert*-butylperoxide in air-saturated acetonitrile with 0.001 M coniferyl alcohol. Inset shows time-resolved changes in optical density at 340 nm.

Fig. 4. Transient absorption spectra generated (●) 400 ns, (□) 1.8 μs, and (■) 3.0 μs after 308 nm laser irradiation of isoeugenol in air-saturated acetonitrile. Inset shows time-resolved changes in optical density at 380, 580, and 340 nm observed upon 308 nm irradiation of isoeugenol in air-saturated acetonitrile.
photoinduced protonation of the β-OH group, followed by elimination of water and deprotonation (6) (12), eq. [4].

[4]
However, the absorption band at 340 nm generated in our experiments decays completely within 1 ms after the laser pulse, which is consistent with the reactivity of other phenoxyl radicals (13). This reactivity is considerably different from that observed for the quinone methide in aqueous solution at room temperature, where its lifetime is several minutes (12). Furthermore, our results clearly show that the 340 nm transient is a product of the reaction of the radical cation; it is difficult to assign a reasonable mechanism for the conversion of the radical cation to the quinone methide, while conversion to the phenoxyl radical by deprotonation is a sensible reaction pathway.

Similar results to those described above were observed upon direct 308 nm irradiation of isoeugenol in acetonitrile, Fig. 4, and upon 355 nm irradiation of chloranil in the presence of isoeugenol. In both cases, the isoeugenol radical cation was observed with absorption bands at 380 and 580 nm. The radical cation decayed in a first-order manner in dry acetonitrile with a rate constant of 9×10^5 s^{-1}. As the radical cation decayed, a new absorption band at 340 nm was observed. This new absorption band is assigned to the corresponding 4-vinylphenoxyl radical on the basis of its similarity to the absorption band observed upon 355 nm irradiation of di-*tert*-butylperoxide in the presence of isoeugenol.
Effect of water and alcohols on decay of coniferyl alcohol radical cation in acetonitrile

Throughout the course of our experiments into the reactivity of the coniferyl alcohol and isoeugenol radical cations in neat acetonitrile, rate constants measured for the decay of the radical cations varied somewhat between 7×10^5 and 1×10^6 s^{-1}. This variability depended mainly on the quality of the acetonitrile used: in acetonitrile from a freshly opened bottle, the radical cation was longer-lived, while the radical cation in acetonitrile that had previously been exposed to air was somewhat shorter-lived. The most likely source of this variability was the presence or absence of water in the acetonitrile, with acetonitrile from a freshly opened bottle having a lower water content compared with that from an already opened bottle. The rate constants of 7×10^5 and 9×10^5 s^{-1} were the slowest rate constants measured for the coniferyl alcohol and the isoeugenol radical cations, respectively, in acetonitrile dried with activated molecular sieves.

To quantitatively determine the influence of water content, the decay of the radical cation was measured as a function of water concentration in acetonitrile. As shown in Fig. 5 (inset), even small quantities of water greatly accelerate the rate constant for the decay, such that in the presence of 0.034 M water, the rate constant more than triples from 0.8×10^6 to 3.0×10^6 s^{-1}. The relationship between the observed rate constants[2] for the decay of the coniferyl alcohol radical cation and water concentration is linear. Least-squares analysis leads to the second-order rate constant for the reaction with water of 6.5×10^7 M^{-1} s^{-1}.

The decay of the coniferyl alcohol radical cation also increased rapidly with increasing concentrations of methanol, ethanol, 2-propanol, and *tert*-butyl alcohol. In each case, a linear relationship was obtained between the observed rate constants and alcohol concentration. Least-squares analysis

---

[2] Tables of rate data (Tables S1–S10) have been deposited and may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0S2, Canada (http://www.nrc.ca/cisti/irm/unpub_e.shtml for information on ordering electronically).

Fig. 5. Transient absorption spectra generated (○) 90 ns, (●) 460 ns, (□) 1.8 μs, and (■) 3.2 μs after 308 nm laser irradiation of isoeugenol in air-saturated acetonitrile with 0.03 M water. Inset shows the relationship between the observed rate constants for the decay of the coniferyl alcohol radical and the concentration of added water in acetonitrile.

Table 1. Second-order rate constants for the reaction of the coniferyl alcohol radical cation with water and alcohols in acetonitrile ($22 \pm 1°C$).

Water or alcohol	Coniferyl alcohol k_{Nuc} (M^{-1} s^{-1})
H_2O	$(6.5 \pm 0.5) \times 10^7$
CH_3OH	$(3.1 \pm 0.1) \times 10^7$
CH_3CH_2OH	$(2.0 \pm 0.1) \times 10^7$
$(CH_3)_2CHOH$	$(4.7 \pm 0.2) \times 10^7$
$(CH_3)_3COH$	$(4.9 \pm 0.2) \times 10^7$
gave second-order rate constants that were similar for each alcohol, ranging from 2×10^7 to 4×10^7 M^{-1} s^{-1}. These rate constants are summarized in Table 1.

In the presence of added water or alcohols, the accelerated decay of the radical cation continued to lead to the formation of the 340 nm band assigned to the substituted 4-vinylphenoxyl radical, Fig. 5, and the rate constants for the growth of the radical continued to match the rate constants for the radical cation decay. No evidence was found for the presence of an oxygen-sensitive phenethyl radical that would have been formed upon nucleophilic addition of water or alcohol to the radical. Thus, water and the alcohols appear to act as bases rather than nucleophiles in their reaction with the radical cation, eq. [5].

[5]
In addition, little variation is observed in the second-order rate constants for the reaction of the radical cation with the four alcohols, Table 1. Such a lack of sensitivity to the steric bulk of the alcohols is expected for a situation in which the alcohols, which have similar basicities but different nucleophilicities, act as bases rather than nucleophiles. Furthermore, the rate constants given in Table 1 are considerably larger than the rate constant of 3×10^4 M^{-1} s^{-1} for the reaction of methanol with the 1-(4-methoxyphenyl)propene radical cation (8). This radical cation is analogous to the 4-

vinylphenol radical cations, with the hydroxy group on the aromatic ring being replaced by a methoxy group. The 1-(4-methoxyphenyl)propene radical cation thus has no strongly acidic proton, and the low value for the rate constant for its reaction with water and alcohols indicates a relatively slow nucleophilic addition reaction. Rate constants for nucleophilic addition to the coniferyl alcohol radical cation should be similar; the fact that the measured rate constants are greater is consistent with the availability of a more rapid deprotonation reaction.

The rate constants for deprotonation from the coniferyl alcohol radical cation are of the same order of magnitude for the deprotonation from methoxy-substituted phenols in acetonitrile. For example, deprotonation of 3,5-dimethoxyphenol radical cation by water and methanol in acetonitrile takes place with rate constants of 2.5×10^8 and 8.2×10^7 M^{-1} s^{-1} (10), respectively, which are about three-fold greater than the rate constants for the deprotonation of coniferyl alcohol.

Effect of anions on decay of coniferyl alcohol and isoeugenol radical cations in acetonitrile

In acetonitrile, styrene radical cations react with anionic reagents like halide, cyanide, and acetate ions at diffusion-controlled rate constants of approximately 10^{10} M^{-1} s^{-1}, with the primary reaction being nucleophilic addition to generate substituted phenethyl radicals (8). In the present work, the reactivity of the coniferyl alcohol and isoeugenol radical cations in the presence of these anions in acetonitrile was also measured. In each case, the decay of the radical cations did increase rapidly as a function of increasing concentration of the anions. The relationships between the observed rate constant for the decay of the radical cations and the concentrations of the anions were all linear. Least-squares analysis gave second-order rate constants in the $1–2 \times 10^{10}$ M^{-1} s^{-1} range for reaction of acetate and cyanide ions, Table 2, indicating that these two anions react with the radical cations at the diffusion-controlled limit. The second-order rate constant for the reaction of the chloride ion with the two radical cations was similar at about 2×10^{10} M^{-1} s^{-1}.

Figure 6 shows the absorption spectrum generated upon quenching of the coniferyl alcohol radical cation in the presence of 0.1 mM chloride. At this concentration of chloride, the bands at 380 and 580 nm associated with the radical cation are almost completely quenched, and in their place is an absorption band with a maximum at 340 nm. This absorption band, which is also formed upon reaction of the radical cation with acetate and cyanide ions, is identical to that of the 4-vinylphenoxyl radical produced by deprotonation of

Fig. 6. Absorption spectra generated (●) 900 ns, (□) 3.6 μs, and (■) 6.4 μs after 308 nm irradiation of coniferyl alcohol in acetonitrile with 0.10 mM *n*-Bu₄NCl.
Table 2. Second-order rate constants for the reaction of the coniferyl alcohol and isoeugenol radical cations with anionic reagents (22 ± 1°C).

Anion	Coniferyl alcohol$^{+\bullet}$ k_{Nuc} (M^{-1} s^{-1})	Isoeugenol$^{+\bullet}$ k_{Nuc} (M^{-1} s^{-1})
CH₃CO₂⁻	$(1.9 \pm 0.2) \times 10^{10}$	$(1.0 \pm 0.1) \times 10^{10}$
CN⁻	$(2.0 \pm 0.2) \times 10^{10}$	$(1.4 \pm 0.2) \times 10^{10}$
Cl⁻	$(2.5 \pm 0.4) \times 10^{10}$	$(1.9 \pm 0.3) \times 10^{10}$

the coniferyl alcohol radical cation in neat acetonitrile or in acetonitrile containing water. The 340 nm band is also unaffected by the presence of oxygen.

These observations indicate that the 4-vinylphenoxyl radical observed in neat acetonitrile and in acetonitrile containing hydroxylic additives is still generated upon reaction of the radical cations with anionic nucleophiles. Thus, despite the demonstrated ability of acetate, cyanide, and chloride to react rapidly with styrene radical cations by nucleophilic addition, deprotonation continues to be an important reaction pathway in the case of the coniferyl radical cation, due to the presence of its acidic proton.

We considered the possibility that the vinylphenoxyl radicals are generated as secondary products, with the nucleophile adding to the radical cation to generate a substituted phenethyl radical that then undergoes a hydrogen atom abstraction reaction with the pool of unreacted coniferyl alcohol. However, bimolecular rate constants for hydrogen atom transfer from phenols to alkyl radicals are typically slow (14), and such a reaction at the low concentration of coniferyl alcohol (ca. 0.15 mM) used in the present study is unlikely. Thus, the most likely explanation for the observation that reaction of the radical cation with anionic nucleophiles leads to 4-vinylphenoxyl formation is that the anionic reagents like chloride and cyanide are acting as bases rather than nucleophiles.

Acidity of isoeugenol radical cation in acetonitrile

Figure 7 shows the transient absorption spectra generated upon 308 nm irradiation of isoeugenol in acetonitrile con-

Fig. 7. Transient absorption spectra generated (●) 480 ns, (○) 3 μs, and (■) 6 μs after 308 nm laser irradiation of isoeugenol in air-saturated acetonitrile with 0.7 mM HClO₄. Inset shows time-resolved changes in absorption at 580 nm because of the decay of the isoeugenol radical cation in acetonitrile at different concentrations of HClO₄.
taining 0.7 mM HClO₄. Clearly, the radical cation is still generated under these conditions in the same manner as observed for experiments in acetonitrile without added acid. However, unlike the situation in neat acetonitrile where the radical cation decayed rapidly, absorption due to the presence of the radical cation remains essentially unchanged over the 10 μs time range of the experiment. Thus, the lifetime of the radical cation is dramatically increased in the presence of low concentrations of the strong acid.

This situation is more clearly illustrated in Fig. 7 (inset), which shows the effect of perchloric acid concentration on the lifetime of the radical cation in acetonitrile. In very dilute acidic acetonitrile, [HClO₄] = 0.01 mM, absorption due to the radical cation at 580 nm decays in a first-order manner to almost zero absorbance with a rate constant of approximately 10⁶ s⁻¹. In the presence of 0.1 mM perchloric acid, the radical cation no longer decays via simple first-order kinetics. Instead, the radical cation now decays via two sequential first-order processes. The fast process occurs with a rate constant of ca. 10⁶ s⁻¹, while the second component is considerably slower, taking place with a rate constant of approximately 2×10^4 s⁻¹. As the acid content increases, the significance of the faster component continues to decrease, while the second component becomes more dominant. By the time the acid concentration reaches 0.7 mM perchloric acid, the fast component is no longer visible, and the radical cation now decays with a single slow component having a rate constant of ca. 2×10^4 s⁻¹.

These results indicate that, at increasing acid concentrations, the radical cation is no longer completely converted to its conjugate base, the 4-vinylphenoxyl radical. Instead, the radical cation decays until an equilibrium state consisting of significant amounts of both the radical and the radical cation is reached. The equilibrium state then decays more slowly either by reaction of the 4-vinylphenoxyl radical or by nucleophilic addition of solvent or residual water to the radical cation.

By measuring the fraction of radical cation present after the equilibrium state is reached as a function of acid concentration, an estimate of the pK_a of the radical cation in acetonitrile can be determined. According to eq. [6], the ratio of the absorption of the radical cation at 580 nm after the equilibrium state is reached, Abs_{eq}^{580nm}, to the initial absorption of the radical cation at 580 nm immediately after the laser pulse, $Abs_{initial}^{580nm}$, will change as a function of acid concentration.

$$[6] \quad \frac{Abs_{eq}^{580nm}}{Abs_{initial}^{580nm}} = \frac{[H^+]}{[H^+] + K_a}$$

The ratio is plotted as a function of H^+ concentration in Fig. 8. As can be seen, the ratio is small at low acid concentrations because of the 4-vinylphenoxyl radical being the dominant species. As the concentration of acid increases, the ratio increases as the equilibrium is shifted to the side of the radical cation. At acid concentrations greater than 0.5 mM, the ratio reaches a maximum value near one, and no further increase is observed. Fitting of these data to eq. [6] then leads to a value for $K_a = 1.1 \times 10^{-4}$ M, indicating that the radical cation has a $pK_a \approx 4$ in acetonitrile. Since cationic acids are typically 7 to 8 orders of magnitude less acidic in acetonitrile than in water (15), we can estimate a $pK_a \approx -3$ to -4 for the acidity of the isoeugenol radical cation in aqueous solution. This value is consistent with pK_a values near -5 estimated for other methoxy-substituted phenol radical cations in aqueous solution (16).

Conclusions

The results presented here demonstrate that the radical cations of 4-vinylphenols in a dry polar solvent are short-lived species, with deprotonation to the corresponding 4-vinylphenoxyl radical being the major reaction pathway. However, in an acidic environment, the lifetimes of the radical cations are dramatically enhanced. Under these conditions, the radical cations should be sufficiently long-lived to participate in an addition reaction with their neutral counterpart to give lignan-like dimers in a manner similar to that previously demonstrated for 4-methoxystyrene radical cations (8, 17–19). The enhanced lifetime also raises the possibility that the biosynthesis of lignans could, at least in principle, proceed via a radical-cation-mediated dimerization process instead of via vinylphenoxyl radical coupling, especially if the enzyme active site provides a dry, acidic environment.

It is worth noting that no quenching of the coniferyl alcohol or isoeugenol radical cations by their neutral precursor was observed in our experiments even under acidic conditions where the radical cations are long-lived. However, this inability to detect coupling by time-resolved techniques does not necessarily indicate that radical-cation-mediated dimerization cannot take place. For example, the decay of 4-methoxystyrene derivatives such as the 1-(4-methoxyphenyl)-propene radical cation with a methyl group attached to the β-position of the carbon–carbon double bond shows no dependence on precursor concentration in time-resolved experiments (20), while product studies clearly demonstrate radical-cation-mediated dimerization does indeed occur (21). Further experiments using potentially more reactive species

Fig. 8. Fraction long-lived isoeugenol radical cation measured from the absorption at 580 nm after equilibration (Abs_{eq}) and immediately after the laser pulse ($Abs_{initial}$) as a function of acid content in acetonitrile. The data point (■), corresponding to $-\log[HClO_4] = 7$, is for the ratio measured in neat acetonitrile and was not included in determining the line-of-best-fit.
such as the 2-methoxy-4-vinylphenol radical cation are currently under way to determine if 4-vinylphenol radical cations lacking a β-alkyl group are capable of undergoing coupling reactions in competition with deprotonation.

Photolabile calixarene-based rosette

Zaiguo Li, Huy Chiu, and Andrei G. Kutateladze

Abstract: A model calix[4]arene-based rosette carrying two alternating photocleavable dithianyl-hydroxy-methyl moieties and two benzophenonecarboxylates was synthesized and shown to be capable of photoinduced fragmentation, with efficiency comparable to that of the externally sensitized parent dithiane–benzaldehyde adducts.

Key words: photoinduced electron transfer, photofragmentation, calixarene, dithiane–carbonyl adducts.

Résumé : On a effectué la synthèse d'une rosette modèle à base de calix[4]arène portant deux portions alternées de dithianyl-hydroxy-méthyle photoclivables et de deux benzophénonecarboxylates; on a démontré qu'il est possible d'en provoquer une fragmentation photoinduite avec une efficacité comparable à celle des adduits parents dithiane–benzaldéhyde sensibilités d'une façon externe.

Mots clés : transfert d'électron photoinduit, photofragmentation, calixarène, adduits dithiane–carbonyle.

[Traduit par la Rédaction]

Introduction

Calixarenes modified at their upper or lower rim are often used as scaffolds for modular assembly of complex macromolecules. The relative rigidity of the calixarenic macrocycle makes it a spacer of choice for positioning various substituents and (or) molecular blocks in a daisy-wheel-like fashion. Specific examples range from ion-selective chelators and ionophores (1) to tethered polypeptides capable of protein surface recognition (2) to recognition-based sensing of other peptides (3), etc. We suggest that an attractive functional feature for such modular designs would be to assemble them by interconnecting the core scaffold and the auxiliary peripheral modules via photolabile tethers. This in essence is the approach that we have been developing based on the recently discovered photofragmentation reaction of α-hydroxyalkyl dithianes and related compounds in the presence of an electron transfer sensitizer, such as benzophenone (4). These compounds are readily available through nearly quantitative lithiodithiane additions to carbonyl compounds — a reaction that was developed three decades ago by Corey and Seebach (5), and that over the years has been implemented in numerous successful synthetic procedures.
The photofragmentation is initiated by photoinduced electron transfer from the dithiane moiety to the excited triplet benzophenone, followed by mesolytic cleavage in the generated cation–radical (4).
Mechanistic aspects of similar fragmentations in cation–radicals containing other heteroatoms were studied by Arnold, Whitten, Maslak, and co-workers (6).

We use such dithiane–carbonyl adducts as photolabile "latches" that can hold together various molecular blocks, and are capable of releasing them upon photoirradiation (7).

Photolabile latch
In this communication, we report the synthesis of a model calixarene-based photocleavable rosette outfitted with an internal sensitizer, and its photoinduced fragmentation. Unsubstituted dithiane is used as a simple "model" of a macromolecular block that potentially can be attached to the calixarenic scaffold via dithianes substituted at position 5, for example 5-carboxy- or 5-hydroxymethyldithiane.

R=CH$_2$CH$_2$OCH$_2$CH$_3$
The overall synthetic scheme is presented below (Scheme 1). Commercially available calix[4]arene was tetraalkylated with 2-ethoxyethylbromide to give **1** and then bis-formylated according to the procedure by Arduini et al. (8) yielding **2**. The dialdehyde **2** was reduced with sodium borohydride and the formylation was repeated. The C_2-symmetric dialdehyde–diol **4** was reacted with excess lithiated dithiane to furnish bis-adduct **5** (42%).

Addition of dithianyl anion to dialdehyde **4** was expected to produce a pair of diastereomers. Given the large spatial separation of the chiral centers, we did not expect any diastereoselectivity and the NMR spectrum of bis-adduct **5** seems to corroborate this conclusion. As is shown in Fig. 1, the proton signal for the primary benzylic alcohols, which is a singlet in **4**, is represented by two separate peaks in **5** (4.17 and 4.15 ppm). Also, the calixarenic methylenes, Ar-CH$_2$-Ar (both sets of four "in" and four "out"), which are doublets in

1–**4**, are represented by two sets of doublets each in the compound **5** (and **7**).[2]

An alternative rationale for the observed doubling of the benzylic peaks is that **5** is a single diastereomer, but the crowded steric environment in it prevents free rotation of the dithianyl groups and they are caught in an unsymmetrical conformation, resulting in magnetically nonequivalent protons. Formation of only one diastereomer is, however, unlikely. We heated the sample of **5** in deuterated chloroform to 55°C and did not observe any coalescence of the benzylic signals in NMR. We, therefore, interpret the observed NMR spectrum as a 1:1 mixture of diastereomers. Both diastereomers are suitable for the assembly of the target photolabile rosettes. In this study we employed benzophenone-4-carboxylic acid as a tethered internal sensitizer. It was first converted into *p*-benzoylbenzoyl chloride via reaction with oxalyl chloride in dichloromethane and then cou-

Fig. 1. Comparison of ^{1}H NMR spectra (CDCl$_3$) for **2**, **4**, and **5**; signals of the protons belonging to ethoxyethoxy tails (CH$_3$CH$_2$OCH$_2$CH$_2$O -) are marked by asterisks.

Fig. 2. Irradiation of **7** in CD$_3$CN.
pled with alcohol **5** in the presence of triethylamine. We expected that the difference in reactivity between the primary benzylic and the more hindered secondary benzylic alcohols will ensure chemoselectivity. It appeared, however, that the difference in reactivities was not sufficient to completely shut off acylation of the latter. Judging by ^{1}H NMR, benzoylation produced several products. We speculate that acylation of the secondary alcohol groups may have triggered dehydrative ring expansion producing seven-membered dithiepines (**9**) and lowering the yield of the target rosette **7**.
Direct dicyclohexylcarbodiimide-mediated coupling of **5** with benzoylbenzoic acid did not improve the yield of the bis-adduct **7**. The presence of the carbonyl group in the sensitizer moiety precluded an alternative route to **7** via benzoylation of the diol **4** with the subsequent addition of dithianyl anion. Our attempt to implement this route produced a mixture of dithiane addition products to both formyl groups and also to benzophenone carbonyls. Successful synthesis of **7** was achieved via the acylation of **5** with *p*-benzoylbenzoyl chloride under partial (45%) conversion conditions. HPLC separation of the reaction mixture on a C-18 reversed phase column (MeCN–H$_2$O, 1:1) produced diester **7** (18% based on reacted **5**) and monobenzoylated adduct **6** (25%).

Having isolated the diastereomers **7**, we then proceeded with photochemical studies. Irradiation of **7** in acetonitrile

with a medium pressure mercury lamp and Pyrex filter (300 nm cutoff) was monitored by ^{1}H NMR by following the disappearance of the benzylic dithianyl-C*H*-OH doublet. As shown in Fig. 2, the relative intensity of the doublet decreases with irradiation. In our previous work, we also followed the photofragmentation by NMR monitoring of the release of aromatic aldehydes (4). In the present study, while we see formyl singlets appearing in the NMR spectrum of the irradiated **7**, the aldehydes do not accumulate significantly upon extended photolysis. Our rationale is that the photoexcited benzophenone, being tethered in close proximity, oxidizes the liberated aldehyde. The overall efficiency of the self-sensitized photofragmentation of rosette **7** is comparable to that of a simple parent adduct of benzaldehyde and dithiane (quantum yield of about 0.12).

To rule out the involvement of calixarenic framework in sensitization of the dithiane–carbonyl fragmentation, we carried out a control experiment by irradiating tetra-alcohol **5**, which lacks the benzophenone-based sensitizing units. Irradiation of **5** under similar conditions (medium pressure mercury lamp, Pyrex filter) for 1 h produced no changes in the ^{1}H NMR spectrum of **5**, ruling out self-sensitization by the calixarene itself.

In summary, we have synthesized a model calixarene-based photolabile rosette capable of self-sensitized photofragmentation. Work is in progress in our laboratory to assemble functional rosettes with 5-substituted dithianes carrying macromolecular modules, for example, modules equipped with hydrogen bond-based elements of molecular recognition.[3]

Professor Donald R. Arnold

TRIBUTE / HOMMAGE

Professor Donald R. Arnold

Professor Arnold was born and raised in Buffalo, New York, and graduated from Amherst High School in 1953. His undergraduate years were spent at Bethany College in Bethany, West Virginia, from which he graduated in 1957 with a B.S. degree in mathematics and chemistry. While at Bethany, Don married Janet Price whom he had met in high school. He graduated with a Ph.D. from the University of Rochester, New York, in 1961. His thesis *Part I: Attempted Synthesis of Some Nonbenzenoid Aromatic Compounds; Part II: Cleavage of* vic-*Primary Amines* was directed by Professor Marshall Gates, a distinguished natural products chemist and long-time editor of the J*ournal of the American Chemical Society*. Professor Gates instilled in his students a regimen of careful experimental work, attention to detail, and precise writing, qualities that Don has encouraged his own students to acquire throughout his professional career.

In 1960, Don accepted a position at the Union Carbide Research Institute in White Plains, New York, where he pioneered applied research in organic photochemistry. After a decade at Union Carbide, Don was lured into an academic career by the late Professor Paul de Mayo who persuaded him to join the Photochemistry Unit at the University of Western Ontario in London, Ontario. This unit was one of a number of specialized research centres set up with funding from the National Research Council of Canada to foster collaborative research on specific themes. Led by Paul de Mayo, the unit at its peak boasted seven internationally recognized faculty members, all of whom were also members of the Department of Chemistry at UWO.

In 1979, Don was attracted to move to Nova Scotia by Dalhousie University's offer of an Izaak Walton Killam Research Professorship. He proceeded to build an impressive research group, while also serving as the nucleus of an active cadre of physical organic chemists at Dalhousie, raising the levels of research and teaching in the department. For these contributions he was named to the Alexander McLeod Chair of Chemistry in 1991. In the process, he determined that the first incumbent of the Chair was appointed in 1884 and he encouraged historian Michael Haines to document the history behind the endowing of the Chair. This documentation was included in Don's inaugural lecture on October 16, 1992.

Don is an internationally recognized leader in the field of organic photochemistry. His astute use of a broad range of techniques to study organic photochemical problems has enabled him to bridge organic and physical photochemistry, thus, contributing to the virtual disappearance of this division. These techniques include electrochemistry, electron spin resonance spectroscopy, flash photolysis, single-photon counting fluorescence lifetime measurements, chemically induced dynamic nuclear polarization, quantum yields, pK_a measurements, and mass spectrometry as well as molecular orbital and molecular mechanics calculations.

While Don's fundamental studies as one of the pioneers of modern organic photochemistry are well-known, his research in free radical chemistry is equally distinguished. Among other seminal contributions, he developed a comprehensive scale of substitutent constants for benzylic free radicals based on the α-hyper fine coupling constants of ring-

Professeur Donald R. Arnold

Le professeur Arnold naît et grandit à Buffalo (New York) et il termine ses études secondaires à l'école Amherst en 1953. Il suit des études de premier cycle au Collège Bethany, à Bethany (Virginie-Occidentale), d'où il décroche un baccalauréat en mathématiques et en chimie en 1957. Pendant ses études, Don épouse Janet Price, une amie qu'il avait connue à l'école secondaire. En 1961, il obtient un doctorat de l'Université de Rochester (New York). Sa thèse, qui est divisée en deux parties : *(I) Attempted Synthesis of Some Nonbenzenoid Aromatic Compounds; (II) Cleavage of* vic-*Primary Amines*, est menée sous la direction du professeur Marshall Gates, éminent chimiste spécialiste des produits naturels et rédacteur de longue date du *Journal of the American Chemical Society*. Le professeur Gates a su inculquer à ses étudiants le souci du détail et le goût du travail expérimental minutieux et de la rédaction précise, qualités que Don a incité ses propres étudiants à acquérir pendant sa carrière professionnelle.

En 1960, Don accepte un poste à l'Institut de recherches d'Union Carbide, à White Plains (New York) où il amorce des recherches appliquées en photochimie organique. Après dix ans chez Union Carbide, Don est attiré dans une carrière universitaire par le défunt professeur Paul de Mayo, qui le persuade de se joindre à l'unité de photochimie de l'Université Western Ontario, à London (Ontario). Cette unité était l'un des nombreux centres de recherches spécialisés subventionnés par le Conseil national de recherches du Canada afin de favoriser la recherche concertée sur des thèmes particuliers. Sous la direction de Paul de Mayo, l'unité de recherche, à ses plus belles heures, a mis en valeur sept professeurs de réputation internationale qui étaient aussi tous membres du Département de chimie de l'UWO.

En 1979, Don est attiré par un professorat de recherche Izaak Walton Killam que lui offre l'Université Dalhousie de Nouvelle-Écosse. Il constitue alors un impressionnant groupe de chercheurs qui deviennent aussi le noyau d'un cadre actif de chimistes en physique organique à Dalhousie, qui permet d'élever les niveaux de la recherche et de l'enseignement au département. Pour souligner ses contributions, on le nomme à la chaire de chimie Alexander McLeod en 1991. Il détermine alors que le premier titulaire de la chaire a été nommé en 1884 et il incite l'historien Michael Haines à documenter l'historique de cette chaire. Cette documentation fait partie de la première conférence de Don livrée le 16 octobre 1992.

Don est un chef de file de réputation internationale dans le domaine de la photochimie organique. Son utilisation avisée d'une vaste gamme de techniques d'étude des problèmes en photochimie organique lui permet de faire le pont entre la photochimie organique et physique et ainsi d'éliminer presque complètement la division entre les deux branches. Les techniques qu'il utilise comprennent l'électrochimie, la spectroscopie par résonance paramagnétique électronique, la photolyse éclair, des mesures de la durée de vie de la fluorescence par comptage de photons uniques, la polarisation nucléaire dynamique par voie chimique, les rendements quantiques, les mesures pK_a, la spectrométrie de masse

substituted benzyl radicals. This scale provides an accurate measure of substituent effects on the thermodynamic stabilities of benzylic free radicals. He showed remarkable foresight when he initiated his research on photo-induced electron-transfer reactions. He has written several classic papers to a field on which the majority of the published literature in photochemistry is now based. Part I of this series is summarized in this issue of the Journal. Although he is not considered to be a synthetic organic chemist, the quest for new, synthetically useful reactions has been the common thread of his distinguished research career which has resulted in more than 120 publications.

He has received numerous awards and honours including an Alfred P. Sloan Research Fellowship (1971–73), a John Simon Guggenheim Memorial Fellowship (1980–81), and the Alfred Bader Award in Organic Chemistry (1995). In April of 2001 he was honoured by his alma mater, Bethany College, with an "Alumni Distinction Award". He has served on the editorial boards of several journals and on a number of NSERC committees, including the Chemistry Grant Selection Committee (1978–81) and Grant and Scholarship Committee (1983–86). He has held important positions in many organizations, including President of the Inter-American Photochemical Society and Director of Organic Chemistry of the Canadian Society for Chemistry. In addition, his participation in conferences, whether as an organizer, an invited lecturer, a contributor of a talk or poster, or as one taking part in the questions, answers, and comments following a talk, he always raised the scientific level for all who attended.

Dalhousie University requires that all its staff retire in the year after their 65th birthday. Don was again honoured, this time with the title of Professor Emeritus and he continues to be an active presence in the life of the Department. He does, however, have more time to indulge in his long-held interests of enjoying and preserving the outdoors, in reading, especially Arthur Conan Doyle, and in taking pride in his children and grandchildren. He is delighted that one of his children, Bradley (Department of Chemistry and Biochemistry, University of Maryland, Baltimore County) has followed his footsteps in an academic career including research in physical organic photochemistry.

This issue of the Canadian Journal of Chemistry honours Don's contribution to chemistry. This dedication is especially appropriate in view of Don's unflagging support over the years as a member of the Editorial Advisory Board and especially for choosing to publish his work almost exclusively in this journal.

James A. Pincock

ainsi que les calculs des orbites moléculaires et de la mécanique moléculaire.

Même ses études fondamentales font partie des grandes innovations dans le domaine de la photochimie organique moderne, ses recherches dans la chimie des radicaux libres sont également dignes de mention. Parmi ses autres contributions de taille, il a mis au point une échelle globale des constantes substituantes pour les radicaux libres benzyliques reposant sur les constantes de couplage α-hyperfin des radicaux benzyliques de substitution. Cette échelle permet de mesurer avec précision les effets des substituants sur la stabilité thermodynamique des radicaux libres benzyliques. Il a fait preuve d'une remarquable perspicacité dans ses recherches sur les réactions de transfert d'électron photo-induit. Il a rédigé dans ce domaine plusieurs communications classiques sur lesquelles repose dorénavant la plus grande partie des documents publiés en photochimie. Le présent numéro de cette Revue résume la partie I de cette série. Même s'il n'est pas considéré comme un chimiste spécialiste de la chimie organique synthétique, la recherche de nouvelles réactions synthétiquement utiles est le fil conducteur de sa brillante carrière de chercheur qui débouche sur plus de 120 publications.

Il a reçu un grand nombre de distinctions et de prix, notamment une bourse de recherche Alfred P. Sloan (1971–1973), une bourse John Simon Guggenheim Memorial (1980–1981) et le prix Alfred Bader en chimie organique (1995). En avril 2001, son alma mater, le Collège Bethany, lui rend hommage en lui décernant un « Prix de distinction de classe ». Il a siégé au comité de rédaction de plusieurs journaux ainsi qu'à de nombreux comités du CRSNG, notamment le comité de sélection des subventions en chimie (1978–1981) et le comité des subventions et des bourses (1983–1986). Il a occupé des postes importants dans de nombreux organismes, notamment celui de président de l'Inter-American Photochemical Society et de directeur de la chimie organique de la Société canadienne de chimie. De plus, sa participation à des conférences, que ce soit à titre d'organisateur, de conférencier invité, de collaborateur à un exposé ou à une affiche ou encore de participant pendant les périodes de questions, réponses et commentaires à la suite d'un exposé, a toujours élevé le niveau scientifique de tous les autres participants.

L'Université Dalhousie exige que tous les membres de son personnel se retirent de la vie active dans l'année qui suit leur 65e anniversaire. Don a reçu un autre hommage, soit le titre de professeur émérite, et il continue de jouer un rôle actif dans la vie du département. Il a cependant plus de temps à consacrer à ses activités de longue date, par exemple, profiter du grand air et préserver la nature, lire, surtout les romans d'Arthur Conan Doyle, et s'enorgueillir de ses enfants et petits-enfants. Il est ravi que l'un de ses enfants, Bradley (Département de chimie et de biochimie, Université du Maryland, comté de Baltimore), chercheur en photochimie organique et physique, ait suivi ses traces dans une carrière universitaire.

Le présent numéro de la *Revue canadienne de chimie* souligne la contribution de Don à la chimie. Cet hommage est tout particulièrement approprié compte tenu du soutien indéfectible dont Don a fait preuve au fil des ans à titre de membre du comité consultatif de rédaction et surtout du fait qu'il ait choisi de publier le fruit de ses recherches presque exclusivement dans cette Revue.

James A. Pincock

Synthetic studies related to CP-225,917[1]

Derrick L.J. Clive, Paulo W.M. Sgarbi, Xiao He, Shaoyi Sun, Junhu Zhang, and Ligong Ou

Abstract: Synthetic studies related to CP-225,917 are described, including the preparation of the fully oxygenated tetracyclic central core **3**.

Key words: CP-225,917, siloxy-Cope rearrangement, Cope rearrangement, strain-assisted rearrangement, furan, ruthenium dioxide, bridgehead olefin.

Résumé : On décrit des études synthétiques reliées au CP-225,917 comprenant la préparation du noyau central tétracyclique complètement oxygéné **3**.

Mots clés : CP-225,917, réarrangement siloxy-Cope, réarrangement de Cope, réarrangement assisté par la tension, furane, dioxyde de ruthénium, oléfine pontée.

[Traduit par la Rédaction]

Introduction

I am going to describe synthetic work related to the natural product CP-225,917 (**1**) (1, 2).[3] The compound is an inhibitor of *ras* farnesyl transferase, and this fact means that it might serve as a lead structure for the design of anticancer drugs (1). It also has another significant biological property — it inhibits squalene synthase (1) — but the real attraction to an organic chemist is the structural complexity of the molecule, and a great deal of synthetic work has now been published in this area.[4] The unnatural enantiomer of CP-225,917 has been made by the Nicolaou group (3) and racemic material by the Danishefsky group (4). Two syntheses of the related compound CP-263,114 (**2**) have also been reported (5). This compound can be generated from **1** by treatment with methane sulfonic acid (1), and the reverse transformation — conversion of **2** into **1** — has been achieved under controlled basic conditions (3).

My own research has led to the synthesis of the fully oxygenated core structure **3**, which is a crystalline substance whose dimensions were obtained by single crystal X-ray analysis (Scheme 1).

CP-225,917 is an unusual molecule in which the bridgehead double bond is embedded within a framework that can fairly easily accommodate such a bond without violating Bredt's rule. This accommodation is possible mainly because the double bond is in a nine-membered ring.

When we began work in this area no synthesis had yet been published, but there was some background information available in the literature. CP-225,917 is really a hemiacetal of the structural type **4**, and the two related substances **6** and **7** had been prepared many years ago (6) as a mixture, but the method used to make them — acid catalyzed dehydration of alcohols **5** — did not seem to be well-suited to the task of synthesizing the natural product, mainly because there was little control over the final position of the double bond. In fact, the bridgehead olefin **7** was the minor product (Scheme 2).

There are a good many ways in which the synthesis of ketones of type **4** might be attempted, and after some exploratory experiments, we decided to look at the possibility of using an oxy-Cope rearrangement (7).

We had noticed a potential relationship between the CP-225,917 bridgehead olefinic core and the [2.2.1] bicyclic structure **8** (Scheme 3).

If **8** is subjected to conditions for an anionic oxy-Cope rearrangement, then enolate **9** would be formed, and we hoped it could be trapped by a suitable electrophile, such as Mander's reagent, so as to generate a keto ester (**9** →**10**). When the keto ester is redrawn as **11**, its resemblance to the

core of CP-225,917 is obvious. Structures **8–11** include several generic groups, R^1–R^5, in order to show that this approach should accommodate the early introduction of some of the substituents that are present in the natural product.

To test our plan, we carried out a model study in which most of these generic substituents were absent.

The short sequence shown in Scheme 4, which is reported in the literature (8), was repeated: a Diels–Alder reaction between tetrachlorocyclopentadienone dimethyl acetal (**12**) and vinyl acetate, followed by acetate hydrolysis (**13** →**14**), and dechlorination (**14** → **15**) gave us the basic [2.2.1] bicyclic skeleton. The yields are good, but the starting material **12** is expensive.

The double bond in **15** was then hydrogenated, and the hydroxyl was protected as its benzoyl ester (Scheme 5). We later found that this hydrogenation is unnecessary because, if

Scheme 6.
Scheme 7.

Scheme 8.

Scheme 9.
an excess of sodium is used in the dechlorination step, as well as a longer reaction time (1 h instead of 5 min), then the double bond is also reduced and in better overall yield. Finally, acid hydrolysis of the acetal released the parent ketone (16 → 17). When we tried to hydrolyze the acetal without protecting the hydroxyl, extensive decomposition occurred, presumably, by a retroaldol process.

Ketone 17 reacted with vinylmagnesium bromide to give mainly alcohol 18. We did not separate the C(2) isomer at this stage, but the yield of isomer 18 is at least 53%.

The facial selectivity is presumably because of the fact that, of the two single bonds "a" and "b" (see 18), the former is more electron-rich and interacts preferentially with the developing sigma star orbital at C(2) (9) if the organometallic attacks from the right.

The mixture of hydroxy vinyl benzoates resulting from the Grignard addition was then hydrolyzed (Scheme 6). Initially, the hydrolysis was done with lithium hydroxide, but later, the process of removing the benzoyl group was improved by using LiAlH$_4$. The diol 19 was easy to purify, and at this point the C(2) epimers were separated.

The secondary hydroxyl of 19 was now oxidized with the Dess–Martin reagent, and then the tertiary hydroxyl was protected by silylation. This was done in order to hinder the
possibility of fragmentation by a retroaldol mechanism. We tried to make the *tert*-butyldimethylsilyl ether or a *p*-methoxybenzyl ether, but those experiments were not successful.

At this point, to set the stage for an anionic oxy-Cope rearrangement, we had to introduce an exocyclic double bond at the CH$_2$ group adjacent to the carbonyl. Formation of the double bond was accomplished by a short sequence (Scheme 7) starting with an aldol condensation with acetaldehyde (21 → 22).

The aldol mixture was treated with mesyl chloride and then with DBU. Those operations gave ketone 24a in reasonable yield, plus a small amount of the Z isomer (24b). The compounds are easy to separate, and we continued our experiments using only the major isomer — the E olefin.

Sodium borohydride reduction in the presence of cerium chloride gave a 1:1 mixture of *exo* and *endo* alcohols (Scheme 8, 25-*exo*, 25-*endo*). Each of these was separately benzylated under standard conditions and then desilylated (25 → 26 → 27), and we were then ready to test the anionic oxy-Cope rearrangement.

When the alcohols 27-*endo* and 27-*exo* were individually heated in toluene in the presence of potassium hexamethyldisilazide, they were slowly converted into the desired enolates, and workup gave ketones 28 and 29, respectively, in good yield (Scheme 9). When we tried the reaction in

Scheme 10. (*a*) LDA, THF, –78°C, then excess BnOCH₂CHO, –78°C; (*b*) MsCl, Et₃N; DBU; (*c*) BnOCH₂SnBu₃, BuLi, *i*-PrMgCl, CuBr·SMe₂, BF₃·Et₂O, –78°C; (*d*) BF₃·OEt₂, –45°C; PhSeCl, HMPA, –45 to 0°C; 66% for *E*, 65% for *Z*-isomer; (*e*) H₂O₂, pyridine, CH₂Cl₂, 30–35°C; 84%; (*f*) LiBH₄, CeCl₃·7H₂O, MeOH, 0°C; (*g*) BnBr, NaH, THF, reflux.

Scheme 11.
refluxing THF the process was slower, and addition of 18-crown-6 did not accelerate the reaction. Although these anionic oxy-Cope rearrangements are slow, the experiments served the purpose of showing that bridgehead olefins structurally related to CP-225,917 could be generated from [2.2.1] bicyclic systems.

What we had to do next was to repeat the sequence with an additional carbon at C(5) in place of the hydrogen (see structures **27**), so that the required C(5) quaternary center would be generated in the rearrangement.

To that end, ketone **21** was condensed with benzyloxyacetaldehyde (Scheme 10), and the hydroxyl in the products was eliminated by mesylation and base treatment to afford enones **31**. These underwent conjugate addition with [(benzyloxy)methyl]cuprate in the presence of boron trifluoride and isopropylmagnesium chloride. The latter scavenges traces of copper(II) that would otherwise cause dimerization of the cuprate reagent. The purpose of the borontrifluoride is simply to activate the enone to conjugate addition. The resulting enolate reacted with benzeneselenenyl chloride. We found that if the enolate from the conjugate addition is quenched to afford the ketone, then we could not introduce the selenium by deprotonation with LDA and reaction with benzeneselenenyl chloride. Evidently, the selenation is dependent on the precise nature of the enolate; we also found
that the presence of HMPA is essential. Finally, selenoxide elimination (**32** → **33**) proceeded without incident, bringing us to ketone **33**. Reduction with lithium borohydride in the presence of ceric chloride gave the corresponding alcohol as a separable mixture of *endo* and *exo* isomers.

The hydroxyl was protected by benzylation (**34** → **35**), and we then removed the silyl group by treatment with tetrabutylammonium fluoride in the usual way (Scheme 11).

With **36** (and the corresponding *exo*-isomer) in hand, we were ready to test the oxy-Cope rearrangement. Surprisingly, this reaction did not work. We tried a variety of conditions and, besides an anionic process, we also examined purely thermal reactions, as well as potential catalysis by palladium or mercuric ion. Scheme 11 shows our observations with an *endo O*-benzyl group (see **36**), but the *exo* isomer behaved in the same way. We also heated the silyl ether **35**-*endo* neat at 230°C. Again no rearrangement occurred.

The fact that our first model, in which the exocyclic double bond is only trisubstituted (see Scheme 9), did rearrange prompted us to make compounds **38** (Scheme 11) in the hope that the trisubstituted nature of the double bond would permit oxy-Cope rearrangement. However, even these compounds did not rearrange under anionic conditions or in the presence of a palladium catalyst.

49

50, 20 h, 50%
It was clear that the number as well as the length of the substituents on the exocyclic double bond are critical factors that determine the ease of rearrangement, and so we studied the two truncated models **39** and **40**. Again we tried a number of conditions: anionic for alcohol **39** and catalyzed and purely thermal for the silyl ether **40**. However, only simple heating of the silyl ether as a neat oil gave the desired product **41**, although the yield was poor (23%).

In the compounds we had examined so far the C(2) vinyl group was free to adopt a conformation in which it points away from the exocyclic double bond, and so we decided to try to bias the conformational preference by placing a bulky substituent on the vinyl group. To this end we prepared compounds **42**, but even they did not rearrange when heated to 300°C.

The modest conversion of **40** into **41** caused us to examine thermal processes more closely, and we soon found that

Scheme 13.

51 → **52**
1-methyl-2-pyrrolidinone (NMP) is an excellent solvent that facilitates the desired rearrangement (Scheme 12).

Heating compound **35**-*endo* for a very long time gave ketone **37** in high yield, if correction is made for recovered starting material. The initial product is, of course, a silyl enol ether, but the silyl group is probably transferred to the solvent, so that on workup we get the corresponding ketone.

We have carried out a number of related reactions in which we vary the substitution pattern on the exocyclic double bond, the orientation (*exo* or *endo*) of the oxygen function on the [2.2.1] bicycle, as well as the nature of the protecting groups. In all cases, we observe rearrangement (see Scheme 12, compounds **41**, **43–48**, and **50**). Sometimes, as in the formation of **45** and **46**, which both arise from the same starting material, some of the silyl enol ether is actually isolated. The same is true in the case of **47** and **48**.

When the phenylthio substrate **49** was heated it gave **50**, as expected. The reaction is faster than the other cases, although the yield is not very good.

1-Methyl-2-pyrrolidinone has been reported before (10, 11) as a solvent for oxy-Cope rearrangement, but only for alcohols, where it can become involved in hydrogen bonding; its use for silyl ethers has not been recognized. All of our rearrangements are very clean if degassed 1-methyl-2-pyrrolidinone is used, and so we now had a method for making the simplified bridgehead olefin substructure of CP-225,917.

While these studies were going on, another member of my group examined an alternative way of speeding up the siloxy-Cope rearrangement.

We had noticed from inspection of models that incorporation of the exocyclic double bond into a lactone ring, as in structure **51** (Scheme 13), generates some strain in the [2.2.1] bicyclic system; this should provide a driving force for rearrangement, and in the event, that is exactly what was observed. Lactone **51** was prepared as shown in Schemes 14 and 15.

Aldol condensation of ketone **21** with (*p*-methoxybenzyloxy)acetaldehyde (**53**) worked very well, and the aldols were mesylated and treated with DBU. Those experiments allowed us to isolate the desired *Z* olefin **55** in just under 60% yield. The *p*-methoxybenzyl group was removed by the action of DDQ, and with this reagent an aldehyde (**56**) was obtained directly. Oxidation in the standard manner gave the corresponding acid, and that was trapped as its methyl ester (**56** → **57** → **58**).

Reduction of **58** with sodium borohydride in the presence of ceric chloride gave largely the desired *exo* alcohol **59** (Scheme 15). The *endo* isomer was isolated in a little under 20% yield, but we did not try to recycle the material by oxidation and reduction.

Ester hydrolysis now gave the hydroxy acid **60**, and the material was cyclized to lactone **51** using *N*-methyl-2-

Scheme 14.

Pmb = CH$_2$C$_6$H$_4$OMe-p

Scheme 15.

Scheme 16.
chloropyridinium iodide. When the lactone was heated in o-dichlorobenzene it rearranged smoothly in the required manner, and we could isolate the product in almost 80% yield. We later found that these conditions are harsher than they need to be, but it was clear that the additional strain associated with the lactone unit does indeed facilitate the oxy-Cope process. It is also very fortunate that the additional strain is not so large as to hinder formation of the lactone or to make it very sensitive to hydrolysis. The use of a strained lactone has also been investigated independently by Bio and Leighton, who have priority of publication (2b, 12).

At this point in our research we had two methods for converting [2.2.1] bicyclic systems into bridgehead olefins that resemble CP-225,917, but we decided to use only the strained lactone approach for further work, and we dealt first of all with the problem of generating the quaternary center.

Ketone **21** was hydroxylated under standard conditions (Scheme 16), and then oxidation by the Dess–Martin procedure afforded the corresponding α-diketone **62**. This was condensed with the dianion derived from methyl 3-hydroxy-propanoate (**63**). That experiment afforded a mixture of two isomers, which were easily separated, but the stereochemistry was not determined. The primary hydroxyl of the major isomer was silylated (t-BuPh$_2$SiCl), and dehydration with thionyl chloride and pyridine served to generate the Z enone **66**. The yields in this sequence are good, but there is no stereocontrol in the aldol condensation; that is a factor that still has to be dealt with.

Reduction of ketone **66** with the sodium borohydride – ceric chloride combination gave mainly the *exo* alcohol **67** (Scheme 17), and again we did not try to recycle the *endo* isomer. Demethylation of the ester was accomplished this time with the lithium salt of propanethiol, and then cyclization, as before, generated the strained lactone **68**. When this was heated in o-dichlorobenzene for 10 min it seemed to
have rearranged completely, and after a further 10 min we could isolate the siloxy-Cope rearrangement product **69** in quantitative yield.

That experiment showed that we now had a procedure for dealing with the C(5) quaternary center, and the next thing to do was to find out how to construct the anhydride and how to make the exocyclic double bond of **66** in a stereocontrolled manner. We dealt first of all with the stereochemical problem.

In our earlier work we had used the dianion derived from hydroxy ester **63**; we now (Scheme 18) used an ester with a protected hydroxyl (**70**), and we found that the isomer ratio

was improved from 4:3 for **64a:64b** to 10:1 for **71a:71b**. It is not clear why this happens, but it was certainly a very welcome fact.

When the major isomer (**71a**) was dehydrated with thionyl chloride and pyridine (Scheme 19), we were very pleased to obtain the desired *Z* olefin **72** (Scheme 19). Reduction of the ketone carbonyl with sodium borohydride showed only a 3:1 selectivity in favor of the required *exo* alcohol, but the *endo* isomer was easily reconverted into the starting ketone (**73-endo → 72**). Once again, the ester was demethylated with the lithium salt of propanethiol, and the resulting hydroxy acid was cyclized to the lactone (**73-exo → 74**). Finally, thermal rearrangement gave us a product (**75**) with the quaternary center and the correct chain length at C(5).

At this point we needed to develop a method for making the anhydride unit that is characteristic of CP-225,917.

Our initial experiments (Scheme 20) were done with **45** and some related compounds, which were all obtained by the method using thermolysis in 1-methyl-2-pyrrolidinone. We discovered that these compounds have a tendency to enolize towards the bridgehead, and so, in order to introduce C(15) (which is needed for the eventual anhydride), we had to block the bridgehead position. That can be done, as shown in Scheme 20, but such a route is cumbersome, and so we modified our approach in such a way that C(15) is introduced at a very early stage — in fact, before oxy-Cope rearrangement.

Our route (Scheme 21) follows along the lines of our previous experiments, except that we treat ketone **17** with isopropenylmagnesium bromide instead of vinylmagnesium bromide. Alcohol **78** is formed in acceptable yield, and we then oxidized what I call C(15), using *tert*-butylhydroperoxide in the presence of a catalytic amount of selenium dioxide. This allylic oxidation is quite slow — it takes 3 days at room temperature. The desired alcohol **79** can be isolated in 60% yield, but almost 30% of the corresponding aldehyde **80** is also formed. Fortunately, the two compounds are easy to separate, and the aldehyde can be reduced efficiently to the alcohol, so that the overall transformation to **79** is quite efficient (81%).
Next, the primary hydroxyl at C(15) was protected as its *p*-anisyloxymethyl (AOM) ether, under phase-transfer conditions (**79 → 81**, 69%). The selectivity is not as high as I would have wished, and 16% of the doubly etherified material is also formed, but that product can be hydrolyzed in over 80% yield back to the starting diol **79**, and so, after one recycling, the mono-protected compound **81** can be obtained in 82% yield.

The remaining tertiary hydroxyl (at C(2)) was then silylated (Scheme 22, **81 → 82**); the benzoate group was removed by treatment with lithium aluminum hydride, and the

Scheme 20.
Scheme 21.

Scheme 22.

Scheme 23.
alcohol released in that experiment was oxidized with the Dess–Martin reagent ($82 \rightarrow 83 \rightarrow 84$). The resulting ketone was subjected to α-hydroxylation and then to oxidation, again with the Dess–Martin reagent, so as to generate diketone **85**. All these experiments are very simple, and the yields are good. We condensed the diketone with our silylated ester (**70**) and obtained the condensation product **86** as a single isomer in nearly 80% yield. We did not look for other isomers in the reaction mixture. Dehydration with thionyl chloride generated the required Z double bond in high yield ($86 \rightarrow 87$), and once again we were at a stage where we needed to form a strained lactone and then carry out the thermal rearrangement.

All those transformations were achieved by the methods that had served us well in the simpler models, although we did make some improvements.

The reduction of ketone **87** was done with a very hindered hydride (Scheme 23). The reaction was quite slow — it took
6 h at room temperature — but the stereoselectivity was good. The ester was demethylated in the usual way, and lactonization was again achieved in high yield with the pyridinium reagent ($87 \rightarrow 88 \rightarrow 89$). When we did the siloxy-Cope rearrangement ($89 \rightarrow 90$), we used chlorobenzene instead of o-dichlorobenzene. Its boiling point is 55°C lower, and so the reaction takes longer, but the yield is al-

most the same, and we felt it was advisable to practice with milder conditions, with a view to eventually using more delicate substrates.

In order to construct the anhydride unit, we need to add one carbon at C(2) (see **90**, Scheme 24), and so we had to first liberate the potential carbonyl at C(2) and protect the lactone carbonyl.

The lactone ring was opened by reduction with lithium borohydride (**90** → **91**), and then the silyl enol ether was hydrolyzed (**91** → **92**) to set the stage for introduction of C(14) of the anhydride unit.

The primary hydroxyl of **92** was selectively protected as its *tert*-butyldiphenylsilyl ether, after which the secondary hydroxyl was silylated with *tert*-butyldimethylsilyl triflate. Both protection steps go in good yield, and the next task was to introduce a carbon at C(2).

In some earlier studies we had found that ketones of similar structure to **93** did not behave properly with Wittig or Peterson reagents, but that they did react with the Tebbe reagent, and in the present case (Scheme 25), treatment of

93 with 2 equiv of the Tebbe reagent gave the desired olefin **94** in acceptable yield (77%).

Removal of the AOM group (**94** → **95**) was carried out with bromocatechol borane. With a number of related substrates we had found that ceric ammonium nitrate, magnesium bromide, bromodimethylborane, or *N*-bromosuccinimide did not work, but bromocatecholborane was satisfactory.

The homoallylic alcohol **95** was amenable to epoxidation, which brought the sequence to compound **96**, from which point we could finish construction of the anhydride, as shown in Scheme 26.

The free hydroxyl group of **96** was oxidized to the corresponding aldehyde with the Dess–Martin reagent. In this case, the Swern procedure gave a complex mixture. Treatment of the epoxy aldehyde first with DBU to open the epoxide by deprotonation α to the aldehyde group, followed by brief treatment with acid to effect dehydration, gave the

Scheme 28.

Scheme 29.
expected furan **98**. This was then converted by photo-oxygenation to a mixture of hydroxybutenolides **99** (and the regioisomers with the OH and C=O interchanged), which were oxidized with TPAP. Those experiments all work in good yield, and they afforded anhydride **100**.

Having reached a model with the quaternary center and the anhydride, the next step was to generate the lactone unit that spans C(10) and C(11).

Our attempts to do that, starting from **100** or its furan precursor **98**, were not at all promising, and so we returned to the product of the siloxy-Cope rearrangement (**90**) and elaborated it in a different way.

Previously, we had reduced the lactone **90** down to the diol stage (see Scheme 24); this time we took the lactone only to the lactol oxidation level (Scheme 27, **90** → **101**). The lactols were then treated with acid in order to hydrolyze the silyl enol ether. That experiment gave a single lactol (**102**) whose stereochemistry was not established. Another isomer was isolated in 7% yield. The major product (**102**) was converted into lactol methyl ether **103**, which has the stereochemistry shown.

The next task was to introduce a carbon at C(2) (see **103**). Use of the Tebbe reagent gave a very low yield, but we eventually found that a modified Peterson reaction (13) worked very well.

The lithium salt **104** was added to ceric chloride to generate a reagent that gave alcohol **105** very efficiently (Scheme 28).

The alcohol is crystalline, and its structure was assigned by X-ray analysis. Deprotonation of the alcohol with potassium hexamethyldisilazide gave the desired olefin **106**. When we then tried to remove the AOM group, we found the reaction very troublesome. In fact, treatment with ceric ammonium nitrate under standard conditions simply did not work — the AOM group is inert, to our surprise. We tried a variety of methods and almost abandoned this protecting group, but, fortunately, we recognized something about the deprotection that proved to be very helpful.

We realized that the mechanism for deprotection should be similar to that for converting *p*-dimethoxybenzene (**107**) into *p*-benzoquinone (**109**) (Scheme 29), and so we examined the literature for that transformation and found that the pyridinedicarboxylic acid *N*-oxide **108** facilitates reaction
when ceric ammonium nitrate is used as the oxidant (14). Scheme 29 shows compound **106** drawn in such a way as to emphasize the structural similarity between an AOM group and *p*-dimethoxybenzene. We found that, although ceric ammonium nitrate itself causes no reaction with **106**, in the presence of the pyridine oxide diacid we can get almost 80% yield of the parent alcohol **110**. The beneficial effect of the catalyst appears to be a general one for removal of AOM groups.

Epoxidation under standard conditions (Scheme 30) took us to **111**, and the corresponding aldehyde was made by Dess–Martin oxidation. Treatment with base served to open the epoxide, and then brief treatment with hydrochloric acid completed assembly of the furan (**111** → **112**). Once again, photo-oxygenation and TPAP oxidation converted the furan into the anhydride (**112** → **113**).

At this point the remaining transformations were oxidation of the side chain on the quaternary center and introduction of oxygen at C(10).

We decided to approach these tasks by regenerating the lactone unit that spans C(5) and C(10). We would then open the lactone by basic hydrolysis so as to expose the C(10) oxygen as an alcohol, which we would oxidize in the basic medium to the corresponding ketone. The ketone, in turn, should spontaneously form the desired hemiacetal on acidification.

Scheme 30.
Scheme 31.

Scheme 32.

To regenerate the lactone, we needed to replace the methoxy group of the lactol ether **113** by an OH group. Acid hydrolysis and trimethylsilyl iodide were unsuitable, but boron trichloride – dimethyl sulfide complex performed well (Scheme 31) and gave the desired lactols **114** as a mixture of two isomers, together with some of the corresponding chloride. Treatment with aqueous silver nitrate converted the chlorine byproduct into the lactols, so that the overall yield is high. Finally, Dess–Martin oxidation regenerated the lactone subunit (**114 → 115**). Most of our Dess–Martin oxidations are done at room temperature; this one required rather more vigorous conditions but was still efficient. Lactone **115** is crystalline, and X-ray analysis confirmed the structure.

With the lactone in place, we now had to oxidize the side chain, and to prepare for that the silicon group was removed by prolonged exposure — some 50 h — to aqueous trifluoroacetic acid.

The resulting primary alcohol (**116**) was oxidized first to the aldehyde and then to the carboxylic acid (Scheme 32), so as to obtain compound **117**. This substance does not have very convenient chromatographic behavior and was, therefore, used crude.

The material was stored for 12 h in 1 M aqueous sodium hydroxide with the intention of opening both the lactone and the anhydride. The resulting salt was oxidized by addition of ruthenium dioxide (15) to the basic solution, which was kept at 70–80°C for 12 h. After acidification, we were able to isolate the complete tetracyclic core of CP-225,917 (**3**) in 40% yield from alcohol **116**.

The core is crystalline, and X-ray analysis gave us the dimensions of the molecule. A noticeable feature of the structure is the shape of the bridgehead double bond. The four atoms C(8), C(7), C(6), and C(10) are in a plane — the deviation is less than 1° — but C(5) is 19° out of that plane. The other dimensions of the molecule are not unusual, although the lactone carbonyl angle is on the small side — 110°.

During this work we had encountered a large number of unexpected difficulties, and so we took the precaution of devising an alternative route to the core. This route, which
turned out to be shorter, involves a strain-assisted Cope rearrangement as opposed to oxy-Cope or siloxy-Cope rearrangement, and we also used a different method for making the anhydride.

The starting point is norbornene (**120**), which was converted in four simple steps into ester acetal **123** (Scheme 33). These steps are all reported in the literature (16). A Prins reaction converts norbornene into the bisformate **121**; Jones oxidation gives the corresponding keto acid **122**, and methylation with diazomethane, followed by ketalization, provides **123**. Although the yield in the oxidation step is low, the experiments are simple, and the ketal ester is easily made on a 20-g scale.

Scheme 33.

Scheme 34.

Scheme 35.
Deprotonation with LDA and condensation with paraformaldehyde affords a mixture of alcohols, and the major isomer (**124**) can be isolated in 43% yield. The carbon of the hydroxymethyl group was destined to become one of the carbonyl carbons of the anhydride, and it has been introduced very early, thereby bypassing some of the difficulties we had experienced in the first route.

After protection of the hydroxyl, the ester was treated with methyllithium. That experiment gave ketone **126**.

The next task was to introduce the second carbonyl carbon of the anhydride. To that end, our ketone was first converted into an enol phosphate.

That was accomplished (Scheme 34) in the usual way, by deprotonation and treatment with diethyl chlorophosphate (**126** → **127**). The product was treated with methylmagnesium bromide in the presence of nickel acetylacetonate (17) in warm dibutyl ether, and the result was introduction of a methyl group that was destined to become one of the carbonyl carbons of the anhydride.

Next the ketal was hydrolyzed, and the resulting ketone (**129**) was reduced with DIBAL and acetylated to give a mixture of epimeric acetates (**130**).

To place an oxygen at C(15), the acetates were treated with a catalytic amount of selenium dioxide in the presence of *tert*-butyl hydroperoxide (Scheme 35). The reaction was very slow and there was some overoxidation to the aldehyde, but treatment with sodium borohydride in the presence of ceric chloride served to make the necessary adjustment, and desilylation in the usual way gave diols **131** in a little under 70% from ketone **129**.

The free hydroxyls were protected as MOM ethers (**131** → **132**), and we removed the acetyl group with DIBAL. Finally, Dess–Martin oxidation gave the expected ketone **133** — as a single compound, of course. During the last
seven steps we had been working with mixtures of epimeric acetates, and that is why the Schemes do not indicate individual yields. The overall transformation can be done in 45% yield from ketone **129**, representing an average of 89% per step.

With ketone **133** in hand we were now in familiar territory. Both carbons for the anhydride carbonyls were in place, and we now had to build up the strained lactone system.

We used almost the same reactions that had served us well in the previous experiments. Ketone **133** was hydroxylated (Scheme 36) by treating the derived enolate with MoOPH (oxodiperoxymolybdenum(pyridine)(hexamethylphosphoric-triamide)), and then oxidation gave the symmetrical diketone

134. That was condensed with the enolate derived from the
protected ester **70**, and the resulting alcohols were dehy-
drated with the thionyl chloride – pyridine combination.
Finally, reduction with sodium borohydride afforded alcohol
135 (**134** → **135**). In retrospect, we should have tried a very
hindered reducing agent because it ought to have given
better stereoselectivity, but nonetheless, the overall yield for
the three steps used to convert **134** into **135** was acceptable.

Demethylation of the ester with lithium propanethiolate
and lactonization brought us to the intended substrate for the
Cope rearrangement (**135** → **136**). That process does not
benefit from the factors that make the oxy-Cope rearrange-
ment especially favorable, and so we wondered if the strain
in the lactone would be sufficient to allow reaction under
reasonably mild conditions.

We heated the lactone in *o*-dichlorobenzene and were very
pleased to find that rearrangement does indeed occur
(Scheme 37, **136** → **137**) and in good yield, although the
rate is lower than for the corresponding siloxy process.

Global deprotection with hydrochloric acid gave triol **138**,
and that was subjected to Dess–Martin oxidation to afford
furan aldehyde **139**. There are several reactions involved
here, of course. We assume that each of the hydroxyls at
C(14) and C(15) is independently converted into an alde-
hyde, and the remaining hydroxyl — either C(15) or C(14) —
forms a lactol, which, in turn, is dehydrated.

Next, we oxidized the aldehyde function to the corre-
sponding acid, using standard conditions (Scheme 38), and
we were very pleased to find that at the same time the furan
was converted into the isomeric hydroxybutenolides **140** and
141, each of which is equally suitable for the next step. That
involves oxidation to the anhydride. The conversion of a
β,β′-disubstituted furan into an hydroxybutenolide under
these conditions seems to be general. Finally, we dissolve
anhydride **142** in aqueous sodium hydroxide, as before. The
base opens up the lactone function to expose an hydroxyl
group at C(10). That hydroxyl was converted into a ketone,
and, after acidic workup, we were able to isolate once more
the complete core of CP-225,917.

Conclusion

In summary, we have developed two routes to the fully
oxygenated core of CP-225,917. One route is based on a
siloxy-Cope rearrangement and the other on a Cope rear-
rangement. Both processes are driven by release of strain in
the [2.2.1] bicyclic starting materials. The core of CP-
225,917 is crystalline, and X-ray analysis has provided

structural details of this unusual system. Further work is being directed to the task of repeating one or both of our approaches with suitable substituents that can be elaborated into the C_8 side chains of the natural product.

Synthesis and characterization of a linked, π-π stacked organotin compound of 2-mercapto-6-nitrobenzothiazolyl diphenyltin chloride with 2-ethoxyl-6-nitrobenzothiazole

Chunlin Ma, Qin Jiang, and Rufen Zhang

Abstract: The new organotin compound, $Ph_2Sn(Cl)[S(C_7H_3N_2O_2S)]\cdot[(C_7H_3N_2O_2S)OEt]$, assembled by an intermolecular aromatic benzothiazole–benzothiazole π-π stacking interaction, has been synthesized by the reaction of diphenyltin dichloride with 2-mercapto-6-nitrobenzothiazole. The title compound was characterized by elemental, IR, ^{1}H NMR, and X-ray crystallography analyses. Single-crystal X-ray diffraction data reveals that the title compound has two different molecular components. The component $Ph_2Sn(Cl)[S(C_7H_3N_2O_2S)]$ has a pentacoordinate tin, which further forms an infinite one-dimensional chain by intermolecular non-bonded Cl···S interactions, resulting in an intercalation lattice that holds $(C_7H_3N_2O_2S)OEt$ molecules. The formation of the molecule $(C_7H_3N_2O_2S)OEt$ as well as its intercalated mechanism has also been discussed.

Key words: organotin, assemble, π-π stacking interaction, 2-mercapto-6-nitrobenzothiazole, non-bonded interaction, crystal structure.

Résumé : Le nouveau composé organostannique $Ph_2Sn(Cl)[S(C_7H_3N_2O_2S)]\cdot[(C_7H_3N_2O_2S)OEt]$, assemblé par interaction aromatique intermoléculaire d'empilement π-π benzothiazole–benzothiazole, a été synthétise par la réaction du dichlorure de diphénylétain avec le 2-mercapto-6-nitrobenzothiazole. Le composé mentionné dans le titre a été caractérisé par des analyses élémentaires, IR, de RMN ^{1}H et par diffraction des rayons X sur un cristal unique qui révèle qu'il est formé de deux composantes moléculaires différentes. Le composant $Ph_2Sn(Cl)[S(C_7H_3N_2O_2S)]$ comporte un atome d'étain pentacoordonné qui forme une chaîne infinie monodimensionnelle par le biais d'interactions intermoléculaires non liées Cl···S qui sert de réseau d'intercalation pour retenir des molécules de $(C_7H_3N_2O_2S)OEt$. On discute aussi de la formation de la molécule de $(C_7H_3N_2O_2S)OEt$ ainsi que du mécanisme d'intercalation.

Mots clés : organostannique, assemblage, interaction d'empilement π-π, 2-mercapto-6-nitrobenzothiazole, interaction non liée, structure cristalline.

[Traduit par la Rédaction]

Introduction

The coordination chemistry of tin is extensive with various geometries and coordination numbers known for both inorganic and organometallic complexes (1). Higher coordination numbers can be generated either by inter- and (or) intramolecular interaction, especially in complexes where tin bonds to electronegative atoms, such as oxygen, nitrogen, and sulfur. Studies of adducts of organotin halides continue to provide fundamental information about both the Lewis acid–base model and the reactivity of organotin species (2).

While tin is generally classified as a hard acid, many organotin—sulfur bonded complexes are known. To date only a few papers have been published on the X-ray structures of organotin(IV) complexes formed with thiol S and heterocyclic N (3). To investigate these kinds of complex structures, we used the reaction of diphenyltin dichloride with 2-mercapto-6-nitrobenzothiazole, and we wished to gain a one- or two-dimensional complex by the coordination of sulfur and nitrogen atoms with tin. To our surprise, we obtained an infinite one-dimensional linked compound assembled by aromatic benzothiazole–benzothiazole π-π stacking interactions. π-π stacking interaction has been extensively studied in recent years (4–6), including that of phenyl–phenyl (7), imidazole–imidazole (8), and so on. It has been proved that this strong attractive interaction can stabilize the packing of aromatic molecules in crystals (9) and play an important part in the field of host–guest chemistry (10). Through in-depth investigation into the intermolecular interactions, new light may be thrown on supramolecular architecture of organotin complexes possessing a particular structure and property. In this paper, we characterized the

Scheme 1.
title compound by elemental, IR, ^{1}H NMR, and X-ray diffraction analyses and give a discussion on its reactive mechanism and structure. The procedure is described in Scheme 1.

Experimental

Materials and measurements

Diphenyltin dichloride and 2-mercapto-6-nitrobenzothiazole were commercially available, and they were used without further purification. The melting points were obtained with Kofler micro melting point apparatus and are uncorrected. Infrared spectra were recorded on a Nicolet-460 spectrophotometer using KBr discs and sodium chloride optics. ^{1}H NMR spectra were obtained on a JEOL-FX-90Q NMR spectrometer; chemical shifts were given in ppm relative to Me$_4$Si in CDCl$_3$ solvent. Elemental analyses were performed with a PE-2400II apparatus.

Synthesis

The reaction was carried out under nitrogen atmosphere. The 2-mercapto-6-nitrobenzothiazole (0.212 g, 1.0 mmol) and sodium ethoxide (0.102 g, 1.5 mmol) were added to a solution of benzene (20 mL) in a Schlenk flask and stirred for 0.5 h. After the diphenyltin dichloride (0.343 g, 1.0 mmol) was added to the reactor, the reaction mixture was stirred for 12 h at 40°C and then filtrated. The filtrate was gradually removed by vaporization under vacuum until solid product was obtained. The solid was then recrystallized from ether–dichloromethane. There were two colored crystal compounds formed. One is yellow while the other is orange. Total yield: 0.462 g.

The compound **3** (orange crystal): mp 88–90°C. IR (KBr)(cm^{-1}): υ_{as}(Sn-C), 275; υ_s(Sn-C), 229; υ(Sn-Cl), 260; υ(Sn-S), 290; υ(Sn-N), 453; υ(C-S), 746; υ(C=N), 1637, 1598; υ_s(C-O) 1065. ^{1}H NMR (CDCl$_3$, ppm): 6.81–7.86 (m, 16H), 2.50–2.62 (q, 2h), 0.90–1.10 (t, 3H). Anal. calcd. for C$_{28}$H$_{21}$ClN$_4$O$_5$S$_3$Sn: C 45.20, H 2.85, N 7.53, S 12.91; found: C 45.51, H 2.93, N 7.44, S 12.87.

The complex **1** (yellow crystal): mp 149–151°C. IR (KBr): υ_s(Sn-C), 278; υ_s(Sn-C), 232; υ(Sn-Cl), 266; υ(Sn-S), 290; υ(Sn-N), 448; υ(C-S), 748; υ(C=N), 1599. ^{1}H NMR (CDCl$_3$, ppm): 7.46–7.79 (m, 13H). Anal. calcd. for C$_{19}$H$_{13}$ClN$_2$O$_2$S$_2$Sn: C 43.91, H 2.52, N 5.39, S 12.32; found: C 43.86, H 2.52, N 5.29, S 12.31.

X-ray structure determination

All X-ray crystallographic studies were done using a Bruker Smart 1000 diffractometer fitted with graphite-monochromated Mo Kα radiation (λ = 0.71073 Å). The ω/2θ scan technique was employed. Corrections were applied for Lorentz and polarization effects but not for absorption, satisfying $I \geq 2\sigma(I)$. Criterion of observability was used for the solution and refinement. The structure was solved using direct methods and refined by a full-matrix least squares procedure based on F^2, using the SHELXL-97 program system. All non-H atoms were included in the model at their calculated positions. All data were collected at a temperature of 298(2) K. For complex **1** and compound **3**, the crystal structures and unit cells are shown in Figs. 1–4, respectively. Selected bond distances and angles are listed in Table 1.

Crystal data for compound **3**: formula C$_{28}$H$_{21}$ClN$_4$O$_5$S$_3$Sn, M = 743.81, monoclinic, space group $P2_1/c$, a = 15.041(6), b = 16.647(6), c = 12.742(5), β = 109.973(6)°, V = 2999(2) Å^3, Z = 4, D_{calcd} = 1.648 g cm^{-3}, μ = 1.195 mm^{-1}, $F(000)$ = 1488, GoF = 0.886, 16 278 reflections collected (θ = 1.44° to 26.47°), 5821 of which were used in the refinement to give the final R_1 = 0.0658 and wR_2 = 0.1238. Residual electron density: 0.567 and –0.883 e Å^{-3}.

Crystal data for complex **1**: formula C$_{19}$H$_{13}$ClN$_2$O$_2$S$_2$Sn, M = 519.57, triclinic, space group $P\bar{1}$, a = 12.961(6), b = 13.835(7), c = 16.412(8) Å, α = 69.184(8)°, β = 89.862(9)°, γ = 62.579(8)°, V = 2395(2) Å^3, Z = 4, D_{calcd} = 1.441 g cm^{-3}, μ = 1.367 mm^{-1}, $F(000)$ = 1024. GoF = 0.748, 13 476 reflections collected (θ = 1.80° to 26.63°), 9316 of which were used in the refinement to give the final R_1 = 0.0591 and wR_2 = 0.0828. Residual electron density: 0.605 and –0.642 e Å^{-3}.

Results and discussion

Syntheses aspects

It was surprising that we obtained an infinite one-dimensional linked compound **3** assembled by aromatic benzothiazole–benzothiazole π-π stacking interactions. To investigate the synthetical mechanism of the reaction, we carried out a series of further experiments (with the same approach as that for compound **3**), as shown in Table 2.

According to experiments (*a*), (*b*), and (*c*), we can conclude that the possible synthetical mechanism of **3** is a three-step process, as follows: First, the 2-mercapto-6-nitrobenzo-

Fig. 4. Unit cell of the complex **1**.
thiazole (**B**) reacts with sodium ethoxide (**C**) to form its sodium salt, which then reacts with the diphenyltin dichloride to form **1**. Second, **1** continues to react with excess **C** to form **2**. Finally, through the benzothiazole–

benzothiazole π-π stacking interaction, **1** and **2** constitute the linked compound **3**.

The formation of substitutional product **2** is owed to the existence of **1** and excess **C**. Because of the interaction of

the S-Sn, the sulfur—carbon (Sn-S-C) bond strength in **1** becomes weaker and the carbon atom [C=N(S)(S)] becomes more electropositive than those of **B**, respectively, which makes the carbon—sulfur bond much easier to cleave. So, the group EtO- can substitute for the -S-SnPh$_2$(Cl) group and form **2**. Here, Ph$_2$SnCl$_2$ functions as a Lewis-acid catalyst in the replacement reaction. This point of view is well support by the results of experiments (*a*), (*b*), and (*c*). There were several mechanisms of carbon—sulfur bond cleavage put forward before (11), but the conditions of all those reactions were rigid, catalysts were needed, and the reaction was often accompanied with oxidation. Our results may provide a new way to these kinds of reactions.

It is worthy to note that despite using a 1:2:2 molar ratio of **A**:**B**:**C**, we didn't obtain the product with two chlorides replaced in Ph$_2$SnCl$_2$; see experiment (*d*). The result suggested that the spatial resistance from two phenyl groups is strong enough to prevent another ligand chelating to the central tin atom. The conclusion coincides well with the case of Ph$_2$SnCl(MBT) reported in the literature (12).

IR data

The explicit feature in the infrared spectra of the title compound is the absence of the band in the region 2600–2550 cm^{-1}, which appears in the free ligand as the υ(S-H) vibration, thus indicating metal—ligand bond formation through this site. In the far-infrared spectra, strong absorption at 290 cm^{-1} (for both compound **3** and complex **1**), which is absent in the spectrum of the ligand, is assigned to the Sn-S stretching mode of vibration, and all the values are consistent with that detected for a number of organotin(IV)–sulfur derivatives (3). Medium-intensity bands at 275 and 229 cm^{-1} for compound **3** and 278 and 232 cm^{-1} for complex **1** can be assigned to υ_{as}(Sn-C) and υ_s(Sn-C). The υ(C=N) band, occurring at 1599 cm^{-1} for **1**, is shifted considerably towards a lower frequency with respect to that of the free ligand, confirming the coordination of the heterocyclic N to the tin. The stretching frequency is lowered due to the displacement of electron density from the N to the Sn atom, thus resulting in the weakening of the C=N bond, as reported in the literature (13). Therefore, the weak- or medium-intensity band at 448 cm^{-1} (for complex **1**) can be assigned to Sn-N stretching vibrations, while in the title compound **3**, there occur two bands that can be attributed to the υ(C=N). The band at 1598 cm^{-1} is similar to the υ(C=N) band of complex **1**, and the band at about 1637 cm^{-1} is near to the υ(C=N) value of the free ligand. Together with the band at 1065 cm^{-1}, recognized as υ_s(C-O), these messages provide evidence for the existence of the molecule (C$_7$H$_3$N$_2$O$_2$S)OEt.

^{1}H NMR data

^{1}H NMR data showed that the signal of the -SH proton, present in the spectrum of the ligand, is absent in the title compound **3** and the complex **1**, indicating the removal of the SH proton and the formation of Sn—S bonds. The information accords well with what the IR data revealed. As anticipated, the spectrum consists of the phenyl hydrogen resonance at 7.32–7.86 ppm for complex **1** and the phenyl hydrogen resonance at 6.81–7.86 ppm for the mixture of **1** and **2** in compound **3**. In addition, there is a resonance due to the ethoxyl hydrogen in compound **3** at 2.50–2.62 ppm (q, 2h) and 0.90–1.10 ppm (t, 3H), which also proves the presence of the molecule (C$_7$H$_3$N$_2$O$_2$S)OEt **2**.

Molecular structures

For compound **3**, single crystal X-ray diffraction data reveal that it has two different molecular components. The component Ph$_2$Sn(Cl)[S(C$_7$H$_3$N$_2$O$_2$S)] has a pentacoordinated tin. The four primary bonds to the centered tin atom are two to the phenyl groups and one each to sulfur and chloride atoms. In addition, there exists interaction between tin and nitrogen atoms. The Sn(1)—N(1) bond length (2.582(7) Å) coincides with those of the type "SnCl$_2$N$_2$C$_2$" recorded in the Cambridge Crystallographic Database (14), ranging from

Table 2. A series of further experiments.

	A (mmol)	**B** (mmol)	**C** (mmol)	Solution	Temperature (°C)	Products
a	1.0	1.0	1.5	Benzene (20 ml)	40	Complex **1** and compound **3**
b	1.0	1.0	1.0	Benzene (20 ml)	40	Complex **1**
c	0.0	1.0	1.0	Benzene (20 ml)	40	Complex **2**
d	1.0	2.0	2.0	Benzene (20 ml)	40	Complex **1**

2.27 to 2.58 Å; equal to that of $[2\text{-}(Me_2NCH_2)C_6H_4]SnPh_2Cl$ (2.52 Å) (15); and longer than that of $Ph_2SnCl(MBT)$ (2.41 Å) (12), but much shorter than the sum of the van der Waals radii of Sn and N, 3.74 Å (16), thus providing a 4-membered chelate ring with a bite angle, N(1)-Sn(1)-S(2), of 63.02(17)°. If the tin–nitrogen interaction is included, the geometry at Sn then becomes a distorted *cis*-trigonal bipyramidal with Cl(1) and N(1) in axial sites (Cl(1)-Sn(1)-N(1) = 153.97(18)°) and C(8), C(14), and S(2) occupying the equatorial plane (C(14)-Sn(1)-C(8) = 124.6(4)°). The sum of the angles subtended at the tin atom in the trigonal plane is 358.3°, so the tin atom shows no significant deviation from the equatorial plane. The Sn(1)—Cl(1) bond length (2.384(3) Å) lies in the range of the covalent radii (2.37–2.60 Å) (15). The Sn(1)—S(2) bond length (2.448(3) Å) is well within the range — from 2.41 to 2.48 Å — that is reported for triphenyltin heteroarenethiolates (3), slightly shorter than that of $Ph_2SnCl(MBT)$ (2.49 Å) (12), and almost equal to that of $Ar_3Sn[S(C_5H_4N)]$ (17). Finally, the Sn—C bond lengths are approximately equal (Sn(1)—C(8) = 2.110(11) and Sn(1)—C(14) = 2.103(13) Å) and are similar to the average value, 2.13 Å (14).

Besides, in the represented crystalline structure, a relatively close contact between the Cl atom of $Ph_2Sn(Cl)$-$[S(C_7H_3N_2O_2S)]$ and the two S atoms of its adjacent molecule (Cl(2)···S(1), 3.45 Å and Cl(2)···S(2), 3.45 Å) was recognized, which coincided well with that reported in $(PhCH_2)_2SnClS_2CNC_4H_8O$ (3.49 Å) (18) but was much shorter than the sum of the van der Waals radii (3.97 Å) for these atoms (19). And it is the intermolecular, non-bonded Cl···S interaction that favored the regular self-assembly of $Ph_2Sn(Cl)[S(C_7H_3N_2O_2S)]$ and further made it an infinite 1D chain. Intermolecular, non-bonded S···X (X = O, S, N, etc.) interactions have been investigated for characterization of the molecular structures of a large number of organosulfur compounds (20). But we have seen few discussions about the Cl···S interaction up to now. So, we can regard it as another new type of close contact.

Quite unexpectedly, the two different molecular components $Ph_2Sn(Cl)[S(C_7H_3N_2O_2S)]$ and $(C_7H_3N_2O_2S)OEt$ are accommodated in parallel layers. The layers of $Ph_2Sn(Cl)$-$[S(C_7H_3N_2O_2S)]$ result in an intercalation lattice that holds $(C_7H_3N_2O_2S)OEt$ molecules. All those atoms on the benzothiazole ring in $Ph_2Sn(Cl)[S(C_7H_3N_2O_2S)]$ are in the same plane, with only a negligible tilt (dihedral angle between the phenyl ring (C(2)–C(7)) and the heterocyclic ring (C(1)–C(3),N(1),S(1)), 0.6°), while two benzothiazole–benzothiazole ring planes, C(1)–C(7) in $Ph_2Sn(Cl)[S(C_7H_3N_2O_2S)]$ and C(20)–C(26) in $(C_7H_3N_2O_2S)OEt$, are almost parallel to each other, and the dihedral angle is 4.1°. The shortest distance of C(25) to C(1)–C(7) is 3.30 Å and the average distance is 3.42 Å, which is terribly consistent with that of a benzene polymer in theoretical studies (3.4 Å) (21) and ap-

proaches that of imidazole–imidazole (3.29 Å) (6). It implies that there exists a strong face-to-face π-π stacking interaction between the two benzothiazole–benzothiazole ring planes. In virtue of the significant interlayer interaction, the gaps between netlike layers of $Ph_2Sn(Cl)[S(C_7H_3N_2O_2S)]$ are filled by the molecule $[C_7H_3N_2O_2S]OEt$. The molar ratio of $(C_7H_3N_2O_2S)OEt:Ph_2Sn(Cl)[S(C_7H_3N_2O_2S)]$ is 1:1, so that the molecular formula can be written in brief as $Ph_2Sn(Cl)\text{-}[S(C_7H_3N_2O_2S)]\cdot[(C_7H_3N_2O_2S)OEt]$.

For the complex **1**, as far as bond lengths, bond angles, and intermolecular Cl···S non-bonded interactions are concerned, its structure is very similar to that of the title compound **3**, and it is a one-dimensional chain, too. However, there exits no molecule in its crystal grids and no intermolecular π-π stacking interaction. The Cl···S distance ranges from 3.42 Å to 3.57 Å. For detailed data see Table 1.

Dediazoniation of *p*-hydroxy and *p*-nitrobenzenediazonium ions in an aqueous medium: Interference by the chelating agent diethylenetriaminepentaacetic acid

B. Quintero, M.C. Cabeza, M.I. Martínez, P. Gutiérrez, and P.J. Martínez

Abstract: We have made a comparative study of the dediazoniation of *p*-hydroxy and *p*-nitrobenzenediazonium ions. The electron-withdrawing and donating properties of the -NO$_2$ and -OH groups strongly determine the reactivity of both compounds, thus exerting different influences upon the dediazoniation reaction. We describe here how the decomposition of *p*-hydroxy and *p*-nitrobenzenediazonium ions in a neutral aqueous medium follows a different pattern in the presence of the metal-chelator diethylenetriaminepentaacetic acid (DTPA). The decomposition rate of *p*-hydroxybenzenediazonium decreases whilst the decomposition of the *p*-nitrobenzenediazonium ion is enhanced. The experimental data are discussed with reference to a common scheme of interference for both benzenediazonium ions in the light of the radical-scavenging capacity of DTPA.

Key words: *p*-hydroxybenzenediazonium ion, *p*-nitrobenzenediazonium ion, di-ethylenetriaminepentaacetic acid, dediazoniation, radical scavenging, artifacts.

Résumé : On a réalisé une étude comparative des réactions de dédiazotation des ions *p*-hydroxy et *p*-nitrobenzènediazonium. Les propriétés électroaffinitaires et électrorépulsives des groupes -NO$_2$ et -OH influencent fortement la réactivité de ces deux composés et exercent donc des influences différentes sur leur réaction de dédiazotation. La décomposition des ions *p*-hydroxy- et *p*-nitrobenzènediazonium dans un milieu aqueux neutre, en présence de l'acide diéthylènetriaminepentaacétique (DPTA) qui agit comme chélatant de métaux se produit selon des voies différentes. La vitesse de décomposition de l'ion *p*-nitrobenzènediazonium diminue alors que celle de l'ion *p*-hydroxynitrobenzènediazonium augmente. On discute des données expérimentales en fonction d'un schéma commun d'interférence pour les deux ions benzènediazonium et en tenant compte de la capacité du DTPA à piéger les radicaux.

Mots clés : ion *p*-hydroxybenzènediazonium, ion *p*-nitrobenzènediazonium, acide diéthylènetriaminepentaacétique, dédiazotation, piège de radicaux, artefacts.

Introduction

Arenediazonium ions are widely used in chemical synthesis. Apart from diazo-coupling reactions (1–3), these ions can undergo either thermal or photochemical heterolytic dediazoniation, yielding the aryl cation (1, 4, 5). Arenediazonium ions can also be dediazoniated in a homolytic process via one-electron reduction, thus generating aryl radicals. Arenediazonium ions and their precursors, arylhydrazides and arylhydrazines, are believed to be genotoxic (6, 7). Although most arenediazonium ions are recognised as being oxidants, such structural characteristics as the electron-donating and withdrawing properties of the substituents in the aromatic ring, together with interference from solvent

interactions, other reducing and (or) oxidizing compounds, light, or the conditions of the reaction medium may substantially modify their reactivity, giving rise to different patterns of decomposition and resulting in different biological effects. In this context heterolytic dediazoniation has been reported to occur with methylbenzenediazonium and *p*-nitrobenzenediazonium (pNO) ions in an aqueous medium (8, 9), whilst other authors have interpreted their results as showing evidence of heterolytic and homolytic processes during the thermal and photochemical dediazoniation of several arenediazonium ions in trifluoroethanol and ethanol (10, 11). Furthermore, in certain cases the reducing capacity of water has been sufficient to reduce arenediazonium to the aryl radical (12). It is obvious therefore that reaction conditions need to be chosen carefully when trying to establish the mechanisms involved in the decomposition of such versatile compounds as arenediazonium ions. We have studied the dediazoniation of the *p*-hydroxybenzenediazonium ion (PDQ) in a neutral aqueous medium (13) and have observed that in the presence of DTPA the rate of dediazoniation decreases together with the intensity of the signal produced by the aryl radical adduct as measured in EPR, using the spin

trap DMPO (5,5-dimethyl-1-pyrroline-N-oxide). The use of DTPA as metal chelator has been recommended in the literature to avoid interference from the redox activity of any contaminating metal ions present in solution (14–17). We report here on a comparative study carried out with pNO and PDQ, the dediazoniation rates of which are influenced differently by the chelating agent DTPA.

Experimental

Chemicals of the highest available purity (Merck and Aldrich) were used. Chelex 100 resin (50–100 dry mesh, sodium form), nitrobenzene, p-nitrophenol, and pNO tetrafluoroborate were bought from Sigma and used as received. PDQ tetrafluoroborate was synthesized following the procedure described by Danêk et al. (18) with slight modifications. Sodium tetrafluoroborate (2.24 g) in distilled water (6 mL) was treated with perchloric acid (70%, 1.7 mL) and used to dissolve p-aminophenol (1.09 g) (Solution 1). Another solution was made by dissolving sodium nitrite (0.71 g) in distilled water (2.5 mL) (Solution 2). Solution 2 was added gradually to Solution 1, while stirring continuously and keeping the reaction in darkness within a temperature range of 0–5°C. The resulting mixture was kept at –10°C for 24 h. A solid was separated by filtration and washed first with cold ethanol and then with diethyl ether. Crystallization was made by precipitation from the solution obtained, dissolving the solid in ethanol at 70°C. A second crystallization was carried out by adding diethyl ether to an acetone solution of the solid. Re-crystallized PDQ tetrafluoroborate is a yellowish crystalline solid that melts between 135 and 140°C accompanied by a noticeable change in colour and the production of a gas. Elemental analysis revealed C 42.8%, H 2.76%, and N 17.05%, which agrees very well with the formation of the tetrafluoroborate of the PDQ dimer. IR: 2189 cm^{-1} (N≡N stretching) and 1591 cm^{-1} (aromatic group). Both benzenediazonium salts were stored below –18°C in darkness.

A Hucoa Erlöss Cintra 10 spectrophotometer was used for spectrophotometric analysis. HPLC was done with a Merck L-6220 biocompatible pump and a Merck L-4500 diode array detector (Merck-Hitachi). Aqueous media were filtered through Millipore HA filters with a pore size of about 0.45 μm. The column was a Spherisorb ODS-2 (4.6 mm × 200 mm) with a particle size of 5 μm. Mobile phase acetonitrile–methanol–acetic acid (1%) (30:30:40) with a flow of 0.7 mL·min^{-1} was routinely used. Samples were dissolved in phosphate buffer (0.1 M, pH 7.2) previously treated with Chelex 100 resin by the column method. A Radiometer pH M64 potentiometer with a GK2401C mixed electrode was used whenever called for. The calibrations were carried out with Crison buffer references (pH 4 and pH 7). pH values were checked throughout the kinetic measurements, and no significant changes were observed. An oxygraph equipped with a Clark-type electrode was used to measure oxygen consumption. Twice-distilled water was obtained by the Milli Q system and used in all experiments. Oxygen for deaerated samples was purged by bubbling with argon for at least 10 min.

We checked for any effects on PDQ and pNO decomposition that might be caused by either environmental laboratory light or apparatus light sources. The results were taken into account when designing the methods for spectrophotometric measurement. In the case of PDQ, measurements were routinely made with aliquots taken from a stock solution kept in darkness. Neither environmental nor instrumental light interference was observed in the case of pNO.

Kinetic analyses were made by incubating 0.4 mM PDQ solutions kept in darkness at 37°C either in the presence or absence of DTPA. Aliquots were taken from these solutions to make PDQ 0.01 mM solutions, which were then used for spectrophotometric measurements. Kinetic measurements were made with pNO in the presence or absence of DTPA either by incubating 1.33 mM pNO solutions and then taking aliquots to make 3.26×10^{-5} M pNO solutions or by placing the sample (0.11 mM) directly into the spectrophotometric cell.

Results and discussion

Dediazoniation of PDQ and pNO in the absence of DTPA

The absorption spectrum of PDQ in a phosphate-buffered aqueous medium (pH 7.2) presented a band with its maximum at 350 nm (ε : 41 990 L·mol^{-1}·cm^{-1}) and a less intense band at 250 nm (ε : 3010 L·mol^{-1}·cm^{-1}), whereas the absorption spectrum of pNO obtained in an identical medium showed a band with its maximum at 259 nm (ε : 15 590 L·mol^{-1}·cm^{-1}) and a minor absorption at 314 nm (ε : 2234 L·mol^{1}·cm^{-1}).

We have reported previously (13) that, under experimental conditions controlled to prevent photochemical and (or) heterolytic side reactions, the dediazoniation of PDQ in a neutral aqueous medium (37°C in phosphate buffer, pH 7.2) occurs via three pathways (Scheme 1): Pathway **1** represents dediazoniation induced by a hydroxyl ion, a slow process at neutral pH and even slower with deaerated samples. In pathway **2** the formation of a semiquinone radical via the reaction of an aryl radical with oxygen is considered to justify the increase in the dediazoniation rate in the presence of oxygen. Finally, in pathway **3**, hydroquinone, produced by semiquinone dismutation, may act as an additional reducing agent. PDQ dediazoniation was characterized by a gradual decrease in absorbance at 350 nm. pNO dediazoniation, on the other hand, using a sample concentration of 1.33 mM, led to a decrease at 259 nm followed by the simultaneous appearance of an absorption band at 350 nm, which increased with time. No band was recorded beyond 370 nm (Fig. 1). As the concentration of pNO fell (0.11 mM), the picture changed, with a new band appearing at about 390 nm, as well as the absorption at 350 nm (Fig. 2). A chromatographic analysis of these samples containing a low concentration of pNO was made using acetonitrile–methanol–acetic acid 0.2 M (30:30:40) as the mobile phase. The chromatograms showed three main peaks with retention times of 3.05, 4.01, and 7.26 min, respectively, and a minor peak at 10.41 min, which, by comparing the associated UV spectra with those of the authentic products, were assigned to pNO, PDQ, p-nitrophenol (pNP), and nitrobenzene (NB), respectively. The unexpected presence of NB led us to repeat the HPLC analysis using fresh samples of pNO in 1×10^{-4} M HCl at 25°C, which should be very stable according to the

Scheme 1.
Fig. 1. Absorption spectra measured at different times (total time: 2 h) with 3.26×10^{-5} M aliquots taken from 1.36 mM pNO buffered solutions (phosphate buffer, pH 7.2, 0.1 M, treated with Chelex 100) kept in darkness at 37°C.
data published in the literature (9–11), and once again we found an NB peak. Since no hydrogen-atom donor could be present under our experimental conditions we are currently investigating the possible interference of an instrumental artifact.

The lack of reactivity of pNO to thermal solvolytic decomposition and the subsequent formation of the aryl ion has been reported elsewhere (11), where it has been put down to the propensity of the nitro substituent to destabilize the aryl cation more than it does the arenediazonium ion (11, 19). In addition to this we checked the photochemical stability of pNO during our experiments by comparing the spectrum of a sample irradiated in a quartz UV spectrophotometer cuvette under the experimental conditions routinely used throughout the spectrophotometric analysis with that of an aliquot kept in darkness at the same temperature. These data

Fig. 2. Absorption spectra measured at different times (total time: 4 h 40 min) with a 0.11 mM pNO buffered solution (phosphate buffer, pH 7.2, 0.1 M, treated with Chelex 100) kept at 37°C.

$$[2] \qquad \frac{-d[\text{pNO}]}{dt} = kK_aK_b\frac{[\text{OH}^-]}{[\text{H}^+]}[\text{pNO}]^2 = k_g[\text{pNO}]^2$$

in which the rate of PDQ formation is equal to the pNO decomposition rate (eq. [1]), in accordance with the spectroscopic results shown in Fig. 1, where it is apparent that very little interference from pNP should be expected. We tested the final equation (eq. [2]) with the absorbance values measured at 350 nm and thus obtained a plot with a value of 88.9 $M^{-1}\cdot min^{-1}$ for the global constant k_g (Fig. 3). This value, which is significantly lower than that obtained for the reduction of pNO with hydroquinone (22), suggests the absence of any reductant capable of directly reducing pNO by a "non-bonded" outer-sphere mechanism. Besides this, the kinetic results support a bimolecular reaction, involving diazotate anion as a nucleophile, since no better fitting of the experimental data was obtained by considering a first-order reaction, which might be expected as a result of a nucleophilic substitution by OH^-.

The other product (RArOH) formed from the dediazoniation of PDQ and pNO might be the result of a reaction between the diazotate anion and the diazonium ion to give diazoanhydride, which then breaks down homolytically to produce the diazenyl radical, from whence is formed the aryl radical, and a further reaction with molecular oxygen leads to a substituted phenol, as indicated for PDQ in Scheme 1. Nevertheless, such a mechanism is not supported by the concentration dependence observed in the proportion of the major products (PDQ and pNP) derived from the decomposition of pNO. If pNP and PDQ were the products that occurred as a result of a parallel reaction during pNO decomposition, an increase in the concentration of pNO would not justify an increase in PDQ concomitant with a decrease in pNP, as can be observed by comparing Figs. 1 and 2. Furthermore, the formation of hydroquinone from PDQ occurs as a result of a homolytic pathway that involves molecular oxygen (Scheme 1), whereas pNP appears when either aerated or deaerated samples of pNO are incubated. An alternative pathway for pNP formation can be formulated on the basis of the homolytic breakdown of diazohydroxide, which leads to the appearance of the aryl and hydroxyl radicals. In fact it has been pointed out (16) that pNO is particularly reactive in neutral buffers, giving EPR signals corresponding to adducts of •OH and aryl radicals even without any added electron donors. A few years ago some discussion arose as to whether a hydroxyl radical might not be involved in the dediazoniation of benzenediazonium ions. Thus •OH adducts detected by EPR have been considered to be artifacts resulting from the fragmentation of a transient hydroxylamine (16). On the other hand, the results obtained by Lawson, Gannett, and co-workers (23, 24) under conditions where no reducing agent was present appear to be consistent with the homolytic fragmentation of a diazohydroxide intermediate. In the light of this latter experimental evidence, therefore, we believe that the recombination of aryl and hydroxyl radicals would provide a simple explanation for the appearance of pNP.

Thus, on the basis of the experimental results obtained, a tentative general mechanism can be proposed, as described in Scheme 3.

led us to conclude that the formation of an aryl cation from the thermal and (or) photochemical heterolytic decomposition of pNO should not be expected. Therefore, we have initially considered that the decomposition of both benzenediazonium ions can be described according to Scheme 2.

In this scheme it is accepted, according to the well known Gomberg–Bachman reaction and the mechanism described by Rüchardt and Merz (20), that in the absence of any other reductant the dediazoniation process for both benzenediazonium ions has a common starting point, the attack of the hydroxide anion (reaction **a**) to form a covalently bound intermediate, diazohydroxide, in equilibrium with its dissociated form, diazotate (reaction **b**).

In principle, two parallel pathways (Scheme 2), both mediated by the diazotate anion, would explain the products derived from the dediazoniation of PDQ and pNO. Thus, -OArN$_2^+$ might be formed via aromatic nucleophilic displacement. Clearly, this process would only be detectable with pNO since with PDQ the reactant (RArN$_2^+$, where R = $^-$O at the pH of the medium) and reaction product (-OArN$_2^+$) are identical. Whilst a hydroxide ion may act as the nucleophile to displace the nitrite ion from the initial arenediazonium ion, Kuplet-skaya and Kazitsyna (21) have also described such a substitution involving the diazotate ion as the nucleophile. Here an attack by O$_2$NArN = N-O$^-$ on pNO followed by the displacement of NO$_2^-$ would give a diazotate ether, O$_2$NArN = N-O-ArN$_2^+$; heterolytic dissociation of this ether regenerates pNO and gives the $^-$OArN$_2^+$ product. Thus we checked whether a kinetic analysis could confirm this bimolecular process. The nucleophilic attack by the diazotate anion can be expressed by the following set of equations:

$$[1] \qquad \frac{-d[\text{pNO}]}{dt} = \frac{d[\text{PDQ}]}{dt} = k[\text{diazotate}][\text{pNO}]$$

$$K_b = \frac{[\text{diazotate}][\text{H}^+]}{[\text{diazohydroxide}]} \quad K_a = \frac{[\text{diazohydroxide}]}{[\text{pNO}][\text{OH}^-]}$$

Scheme 2.

Fig. 3. Kinetic analyses of the data obtained from the absorbance measured at 350 nm in the spectra shown in Fig. 1.

It is clear that under our experimental conditions PDQ dediazoniation occurs mainly via the reaction sequence (**a**) → (**b**) → (**f**) → (**h**) → (**i**), wherein reaction **i** encompasses the processes detailed in Scheme 1, producing hydroquinone–quinone as stable products of the reaction and secondary reductant (hydroquinone), whereas pNO decomposition might occur either via (**a**) → (**b**) → (**e**) → (**g**), which generates PDQ, or the homolytic path (**a**) → (**c**) → (**d**), which produces pNP.

The differences observed in the dediazoniation mechanisms for PDQ and pNO might be put down to the different chemical natures of the aromatic substituents in the compounds analysed. The electron-withdrawing and donating properties of the -NO$_2$ and -OH groups strongly determine the reactivity of either compound and consequently exert different influences upon the dediazoniation reaction, as observed experimentally.

DTPA interference into PDQ and pNO dediazoniation

PDQ dediazoniation in a neutral aqueous medium was clearly affected by the presence of DTPA either using a phosphate buffer treated with Chelex resin or an untreated phosphate buffer. No change in the spectrum shape was no-

ticeable following the addition of DTPA, suggesting that any interaction between DTPA and PDQ to block the reduction of this latter compound might be ruled out. Apart from this, the introduction of DTPA led to a period of about 2 h during which the reaction seemed to cease. After this period decomposition continued at a rate very close to that observed for the reaction in the absence of DTPA (Fig. 4). Moreover, the presence of DTPA appears to be associated with a decrease in oxygen consumption, as shown in Fig. 5.

On the other hand, the dediazoniation of pNO behaved differently in the presence of DTPA, its dediazoniation rate increasing (Table 1). Likewise, DTPA brought about an increase in the proportion of pNP in relation to PDQ (cf. Table 1 and Fig. 6). Furthermore, pNO underwent complete and immediate decomposition when the initial DTPA:pNO ratio was 5 or higher. In this case only two absorption bands were recorded, with maxima at 270 nm and 369–370 nm. Similar results (Fig. 7) were obtained by adding ethanol (4%) to the buffered solutions of pNO (maxima at 268 and 388–390 nm).

If we exclude any association between the arenediazonium ions and DTPA or chelating effects upon any residual metal ions present in the buffer, an additional pathway must be considered to justify the observed increase in the decomposition rate, wherein DTPA would promote the homolysis of pNO. As a matter of fact, on using a higher concentration of DTPA (6.6 mM) this additional pathway plays a more important part, as indicated by the appearance of an absorption band with a maximum at about 270 nm. This band also appears when pNO decomposes in the presence of ethanol (4%), which may scavenge aryl radicals by donating a hydrogen atom (11). These spectrophotometric results are consistent with HPLC analyses, which showed, together with the peaks corresponding to PDQ and pNP, the competitive formation of an appreciable quantity of NB, resulting in the almost complete conversion of pNO into NB when the ethanol concentration was increased to 50%.

Bearing in mind the fast rate of dediazoniation in the presence of a relatively high concentration of DTPA and also the appearance of NB under such conditions, it is reasonable to suppose that DTPA triggers the homolytic decomposition of pNO. Some experimental evidence is reported in the literature concerning the scavenging capacity of DTPA to react with •OH and CO$_3$•$^-$ when used in relatively high concentrations (>100 µM) (25). The data obtained during pNO dediazoniation suggest the possible formation of a DTPA

Scheme 3.
Fig. 4. Plot of the absorbance measured at 348 nm vs. time obtained with 1:40 diluted aliquots taken from 0.4 mM PDQ buffered solutions (phosphate buffer pH 7.2; 0.1 M) kept in darkness at 37°C. Influence of the DTPA concentration: (*a*) without DTPA; (*b*) in the presence of 1 mM DTPA; and (*c*) in the presence of 1.5 mM DTPA.
Fig 5. Plot of oxygen consumption vs. time for samples containing distilled water (♦), 10 mM PDQ in the presence of 0.5 mM DTPA in phosphate buffer pH 7 (□), and 10 mM PDQ solution in phosphate buffer pH 7 (●). $T = 37$°C.
radical that interacts with pNO, thus increasing the decomposition rate according to the following general scheme:

[3] $pNO \rightarrow O_2NArN_2\bullet$

[4] $O_2NArN_2\bullet \rightarrow O_2NAr\bullet + N_2$

[5] $O_2NAr\bullet + DTPA \rightarrow NB + [DTPA]\bullet$

[6] $pNO + [DTPA]\bullet \rightarrow O_2NArN_2\bullet + DTPA(H+)$
wherein reaction [3] summarizes pathways (**a**) → (**b**) → (**f**) → (**h**) whilst reactions [3] and [4] are equivalent to the pathway

(**a**) → (**c**). In any case the occurrence of the aryl radical $O_2NAr\bullet$, derived from pNO (11), allows the interfering DTPA scavenging aryl radical to produce NB (reaction [5]) and also leads to the subsequent attack on pNO (reaction [6]), which could go on to give pNP via pathway (**i**).

It is apparent that these reactions do not work in the case of PDQ because an increase in the concentration of DTPA is not followed by a concomitant increase in the decomposition of PDQ, as observed for pNO. Nevertheless, a similar reac-

Table 1. Influence of DTPA upon pNO (0.11 mM) decomposition rate at 37°C in phospate buffer (pH = 7.2).[a]

[DTPA] (mol·L^{-1})	Total time (min)	[PDQ] (mol·L^{-1} (%))	[pNP]$_T$[b] (mol·L^{-1} (%))	[pNO][c] (mol·L^{-1} (%))

[a]Analyses carried out by monitoring absorbance at 259, 350, and 400 nm and using the following ε (L·mol^{-1}·cm^{-1}) values: 2500 (dissociated pNP, 259 nm); 1320 (undissociated pNP, 259 nm); 5230 (dissociated pNP, 350 nm); 3950 (undissociated pNP, 350 nm); 15 480 (dissociated pNP, 400 nm); 70 (undissociated pNP, 400 nm); 3050 (PDQ, 259 nm); 41 990 (PDQ, 350 nm); 15 590 (pNO, 259 nm); 325 (pNO, 350 nm). pK_a = 7.15 for pNP at 25°C was taken from ref. 26.

[b][pNP]$_T$ = total concentration of p-nitrophenol.

[c]pNP and PDQ are taken to be the main products derived from the decomposition of pNO.

Fig. 6. Absorption spectra measured at different times (total time: 1 h 39 min) with a 0.11 mM pNO buffered solution (phosphate buffer, pH 7.2, 0.1 M, treated with Chelex 100) kept at 37°C in the presence of 0.1 mM DTPA.
Fig. 7. Absorption spectra measured at 5 min with 1:10 diluted aliquots taken from 1.33 mM pNO buffered solutions (phosphate buffer, pH 7.2, 0.1 M, treated with Chelex 100) kept at 37°C in the presence of (a) 6.65 mM DTPA; (b) ethanol 4% (v/v).

Fig. 8. Absorption spectra measured at different times with 0.44 mM hydroquinone (H2Q) buffered solutions (phosphate buffer pH 7) both in the presence and absence of DTPA (2.8 mM). T = 37°C. See legends in the inset to identify the spectra.
tion pattern might occur with PDQ in the presence of DTPA, although not affecting PDQ directly. In fact we have observed that the absorption spectrum of a 0.44 mM hydroquinone (H2Q) solution in phosphate buffer at pH 7 changes 24 h after the solution is prepared. The band located at 288 nm decreases (approx. 11%), and a new band appears centred at 245 nm. In the presence of DTPA (2.8 mM) the band at 288 nm remains practically constant, and the band at 245 nm is significantly less intense (Fig. 8). These results indicate that a relatively high concentration of DTPA can lead to an interference that affects the intermediate semiquinone radical in hydroquinone auto-oxidation. Bearing this in mind, the decrease observed in the PDQ decomposition rate would be justified since PDQ reduction by the semiquinone scavenger radical would be partially interrupted, thus giving rise to a concomitant decrease in oxygen consumption.

Conclusion

In summary, we have found that the chelating agent DTPA interferes with the dediazoniation of p-hydroxybenzene-diazonium and p-nitrobenzenediazonium ions. Although the different pattern of decomposition observed for both ions,

either in the absence or presence of DTPA, suggests the existence of different mechanisms for each, most of our observations strongly support the idea that this interference may be because of a common mechanism based on the scavenging activity of DTPA. Therefore any possible interference by DTPA should be thoroughly investigated when it is used as a chelator in biochemical and biological systems in which radical reactions occur.

Pressure and temperature dependence of the excess thermodynamic properties of binary dimethyl carbonate + *n*-octane mixtures

Luis Lugo, María J.P. Comuñas, Enriqueta R. López, Josefa García, and Josefa Fernández

Abstract: In this work we report several excess thermodynamic properties for the dimethyl carbonate + *n*-octane system in an effort to better understand their behavior over wide temperature and pressure ranges. From previous experimental *pVTx* data for this system, the changes in the excess molar Gibbs energies, in the excess molar entropies, and in the excess molar enthalpies due to pressure have been determined over a wide temperature range and for pressures up to 25 MPa. A correlation of the excess volume as a function of pressure was used for each composition and temperature, together with a new, recently proposed equation for the excess molar volume as a function of temperature, pressure, and composition. Excess molar enthalpies and excess molar Gibbs energies at 298.15 K and for pressures up to 25 MPa were calculated using literature data at atmospheric pressure. Furthermore, the excess isothermal compressibility, the excess isobaric expansivity, and the excess internal pressure were calculated. The expression for the internal pressure of an ideal mixture suggested recently by Marczak has been used.

Key words: excess thermodynamic properties, dimethyl carbonate, *n*-octane, high pressure.

Résumé : Dans ce travail nous donnons les valeurs de plusieurs propriétés thermodynamiques d'excès pour le système binaire carbonate de diméthyle + *n*-octane avec l'objectif de comprendre le comportement de ces grandeurs d'excès dans un large domaine de températures et de pressions. Nous avons déterminé à partir des valeurs *pVTx* de ce système, l'évolution avec la pression des énergies de Gibbs d'excès, des entropies molaire d'excès et des enthalpies molaires d'excès dans un large domaine de températures et jusqu'à 25 MPa. Une corrélation du volume d'excès fonction de la pression, à chaque térature et composition a été utilisée, et aussi une nouvelle expression proposée dans un article précédent, pour faire le lissage du volume d'excès en fonction du triplet, température, pression et composition. La compressibilité isotherme d'excès, l'expansivité isobare d'excès et la pression interne d'excès, on été aussi déterminées. L'expression pour la pression interne d'un mélange idéal proposée par Marczak a été utilisée.

Mots clés : propriétés thermodynamiques d'excès, carbonate de diméthyle, *n*-octane, haute pression.

Introduction

In recent years, the number of patents and papers on dimethyl carbonate (DMC) has increased because DMC is environmentally benign, biodegradable, made by a clean chemical process, and is a prototype of a green reagent because it is nontoxic (1). DMC has been proposed as a gasoline additive and as a paint solvent (2). Furthermore, several lubricants containing dimethyl carbonate and other organic carbonates have been patented or proposed (3, 4) and are used in automobile air-conditioning apparatus. Concerning the thermophysical properties of dimethyl carbonate and diethyl carbonate, Comuñas et al. (5) recently published the densities, isothermal compressibilities, and internal pressures from 283.15 to 353.15 K and for pressures up to 60 MPa, to-

gether with the viscosities, and both temperature and pressure viscosity coefficients up to 100 MPa.

The physical properties of DMC + octane mixtures are important in establishing DMC as a potential fuel additive. Also, to develop models that are able to predict properties of pure and mixed lubricants of the carbonate type, experimental properties of carbonate + alkane systems are needed.

For systems containing alkyl carbonate (6–10), a substantial body of thermodynamic data exists, mainly at atmospheric pressure. The work reported here is a study of DMC + *n*-octane mixtures. García et al. (11) and Cocero et al. (12) have measured, respectively, the excess enthalpies and the VLE of this mixture at 298.15 K and atmospheric pressure. The excess volumes at the same temperature and pressure are also available (13). Recently, we measured densities of

liquid DMC + n-octane mixtures (14) at temperatures from 278.15 to 353.15 K and for pressures up to 25 MPa or up to the appearance of liquid–liquid equilibrium (LLE). From these data, excess volumes were determined and correlated with a new $V_m^E(T,p,x)$ function (15).

In the present work we report several excess thermodynamic properties at high pressures calculated from these experimental $pVTx$ data. For this purpose the Maxwell relations are very useful (16) in order to relate different thermodynamic properties. Particularly, the change of the excess molar Gibbs energy, $\Delta G_m^E(T,p,x)$, of the excess molar entropy, $\Delta S_m^E(T,p,x)$, and of the excess molar enthalpy, $\Delta H_m^E(T,p,x)$ due to pressure were determined over wide ranges of pressure and temperature. Taking into account the excess Gibbs energies reported by Cocero et al. (12) and the excess enthalpies reported by García et al. (11) at 298.15 K and atmospheric pressure, the excess molar Gibbs energy, $G_m^E(298.15\ \text{K},p,x)$, and the excess molar enthalpy, $H_m^E(298.15\ \text{K},p,x)$, were determined up to 25 MPa. Moreover, we have evaluated the excess isothermal compressibilities, κ_T^E, the excess isobaric expansivities, α_p^E, and the excess internal pressures, π^E. The aim of this work is to analyze how the pressure and the temperature affect these thermodynamic properties, thereby providing information on the intermolecular interactions and on packing and ordering effects for this type of mixture.

Derived properties

The database for the DMC + n-octane system used in this work consists of 717 experimental density values at nine pressures (from 0.1 to 25 MPa) and nine temperatures (from 278.15 to 353.15 K) and nine mole fractions of DMC between 0.10449 and 0.90164. We have also utilized 162 experimental density values for pure octane and pure DMC in the same pressure and temperature ranges. These experimental density values have been published in a previous paper (14). Using this database we have determined the excess molar volumes, V_m^E, of the DMC + n-octane system over the complete composition range (15). To obtain the derived thermodynamic properties, we have correlated the V_m^E data in two ways: as a rational polynomial function of pressure, $V_m^E(p) = 1/(a + bp)$, for each composition and each temperature and as a function of temperature, pressure, and DMC mole fraction, $V_m^E(T,p,x)$, using the new correlation

$$[1] \qquad V_m^E(T, p, x) = (1/(a + bp))x(1 - x)$$
$$\times \sum_{i=1}^{3} \sum_{j=1}^{3} B_{ij} (2x - 1)^{i-1} (T - T_0)^{j-1}$$

proposed previously (15). The reference temperature was $T_0 = 273.15$ K. This last equation involves 11 parameters and correlates the 717 V_m^E experimental data points for the DMC + n-octane system with a standard deviation of 0.02 cm^3·mol^{-1}, which is only marginally higher than the experimental accuracy. These results and the parameter values were reported in a previous work (15).

Excess molar Gibbs energy, G_m^E

The effect of pressure on the excess molar Gibbs energy can be calculated using the relation

$$[2] \qquad \Delta G_m^E(T, p, x) = G_m^E(T, p, x) - G_m^E(T, p_0, x)$$
$$= \int_{p_0}^{p} V_m^E(T, p, x)\,\mathrm{d}p$$

where p_0 is the reference pressure. In this work we use $p_0 = 0.1$ MPa.

The two-parameter rational polynomial function, $V_m^E(p) = 1/(a + bp)$, has been fitted to the values of the excess molar volumes at fixed T and x. This function has been used to evaluate the integral in eq. [2], thereby obtaining values of ΔG_m^E for each temperature–composition pair at different pressures. This method has been used before by several authors for different mixtures (17–20). Taking into account the uncertainties in the temperature (± 0.01 K), pressure (± 0.001 MPa), mole fraction ($\pm 5 \times 10^{-5}$), and excess molar volumes ($\pm 5 \times 10^{-3}$ cm^3·mol^{-1}), this procedure provides values for ΔG_m^E with an estimated error of ± 1 J·mol^{-1}. The results for ΔG_m^E are reported in Table 1. We have also determined ΔG_m^E using eqs. [1] and [2]. The absolute average deviation (AAD) between both sets of ΔG_m^E values is 2%.

In Fig. 1a, ΔG_m^E at 323.15 K is plotted against the mole fraction of DMC, whereas in Fig. 1b the variation of ΔG_m^E with the temperature for $x = 0.50160$ is presented. At a given temperature and composition, ΔG_m^E becomes more positive as the pressure increases. When ΔG_m^E increases it is possible to reach the conditions in which $G^M(x)$ becomes convex for a composition range, i.e., immiscibility occurs. In fact, we have detected this immiscibility through the large fluctuations in the oscillation period of the densimeter for the highest pressures and the lowest temperature for the following DMC mole fractions: $x = 0.50160$, $x = 0.60227$, and $x = 0.69048$. Consequently, we do not report thermodynamic property values for these Tpx conditions. We must point out that González et al. (21) have determined LLE experimental data at atmospheric pressure for DMC + (n-decane, n-dodecane, n-tetradecane, or n-hexadecane). From these values we estimate that the upper critical solution temperature (UCST) for the DMC + octane system is about 273 K at atmospheric pressure.

Taking into account the Redlich-Kister correlation made by Cocero et al. (12) for the excess molar Gibbs energy of DMC + n-octane at 298.15 K and 0.1 MPa, we have calculated the values of G_m^E at 298.15 K and at different pressures up to 25 MPa using the equation

$$[3] \qquad G_m^E(298.15\ \text{K}, p, x) = G_m^E(298.15\ \text{K}, 0.1\ \text{MPa}, x)$$
$$+ \int_{0.1}^{p} V_m^E(298.15\ \text{K}, 0.1\ \text{MPa}, x)\,\mathrm{d}p$$

At each isobar and each mole fraction, a polynomial temperature function has been fitted to the V_m^E values to determine the integral of eq. [3]. The values of the excess molar Gibbs energy obtained in this manner are reported in Table 2 at 298.15 K for several pressures. We have also determined

[a]Cocero et al. (12).

Fig. 2. Excess molar Gibbs energy for x DMC + $(1 - x)$ n-octane at T = 298.15 K against the mole fraction. ○ 0.1 MPa [12]; ◇ 25 MPa.
fraction, and at 298.15 K. $\Delta G_m^E / G_m^E(T, 0.1 \text{ MPa}, x)$ rises linearly with pressure for all mole fractions, ranging from 0.1% at 1 MPa to 2.5% at 25 MPa. In Fig. 2 we show the mole fraction dependence of the excess Gibbs energy for the DMC + n-octane system. This figure shows that there are no changes in the symmetry of the $G_m^E(x)$ curve with pressure.

Change in the excess molar entropy, ΔS_m^E

The change in the excess molar entropy, ΔS_m^E, due to pressure can be calculated from the following thermodynamic relations

[4] $\Delta S_m^E(T, p, x) = S_m^E(T, p, x) - S_m^E(T, 0.1 \text{ MPa}, x)$

$$= -\left(\frac{\partial \Delta G_m^E}{\partial T} \right)_{p, x}$$

$(\partial \Delta G_m^E / \partial T)_{p,x}$ has been evaluated for each pressure, p, and for each mole fraction, x, using a quadratic temperature fit of ΔG_m^E. In Table 3 the values of the entropic contribution, $T\Delta S_m^E$, obtained from the Gibbs energy, are reported, with an estimated error close to 3%. We have also determined $T\Delta S_m^E$ by using the overall correlation, $V_m^E(T, p, x)$, given by eq. [1],

and by using eqs. [2] and [4], but in this case no additional correlations are needed. The absolute average deviation between both sets of values is 5%. As can be seen in Table 3, the values of $T\Delta S_m^E$ are negative over the entire temperature and pressure ranges, and they become more negative when the pressure and the temperature increase. This is because of the fact that when the mixture is compressed, the molecules become more ordered. From the Maxwell relation for the Gibbs function, it is easy to show that if the excess volume increases with the temperature (as occurs in the DMC + n-octane system), then the excess entropy must decrease with the pressure.

Excess molar enthalpy, H_m^E

The excess molar enthalpy due to changes in pressure can be obtained from the following expression

[5] $\Delta H_m^E(T, p, x) = H_m^E(T, p, x) - H_m^E(T, 0.1 \text{ MPa}, x)$

$$= \int_{p_0}^{p} \left[V_m^E(T, p, x) - T \left(\frac{\partial V_m^E}{\partial T} \right)_{p, x} \right] dp$$

Moreover, since we have obtained the values of ΔG_m^E and ΔS_m^E, we can also get the values of ΔH_m^E from the thermodynamic relation

[6] $\Delta H_m^E(T, p, x) = \Delta G_m^E(T, p, x) + T\Delta S_m^E(T, p, x)$

We have calculated ΔH_m^E by using both procedures, and the two sets of values are in agreement within 4%. The observed discrepancy includes errors introduced by the approximate numerical procedures (integration and differentiation). Nevertheless, by using eq. [6], additional errors in the calculation of the derivative $(\partial V_m^E / \partial T)_{p,x}$ are avoided. The values of ΔH_m^E at x = 0.50160 and at different temperatures are plotted against the pressure in Fig. 3a. ΔH_m^E becomes more negative when the pressure and the temperature increase. In Fig. 3b it can be seen that the $\Delta H_m^E(x)$ curve is symmetric over the entire pressure interval.

For the DMC + n-octane system, both the excess molar Gibbs energy and the excess molar enthalpy at 298.15 K and atmospheric pressure are available in the literature (11), so we can calculate H_m^E for this system over the entire pressure range at this temperature using the following:

Table 3. Change in excess molar entropy, $T\Delta S_m^{\mathrm{E}}$ (J·mol^{-1}), for xDMC + $(1-x)$ n-octane mixtures.

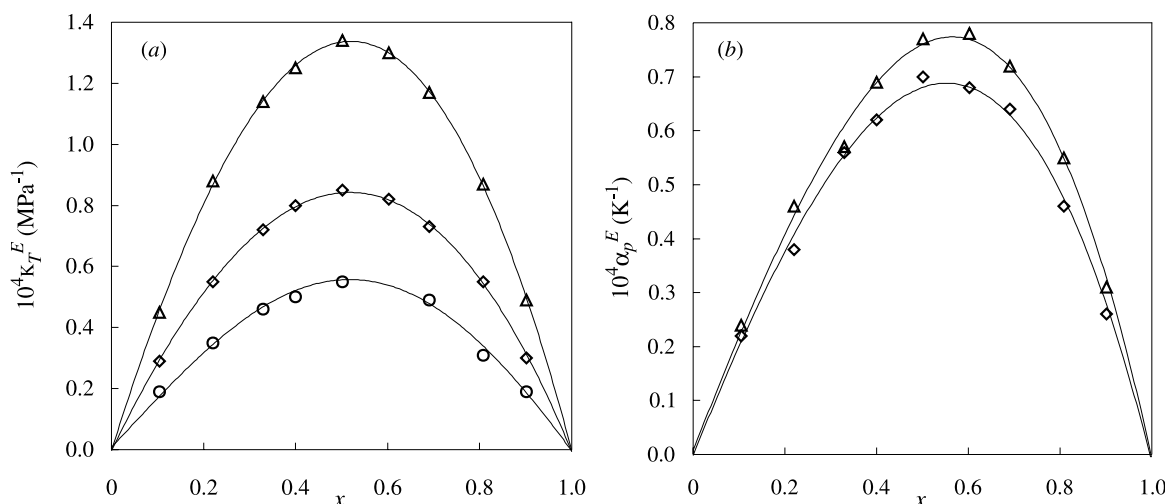
H_m^E(298.15 K,0.1 MPa,x) published by García et al. (11) with a standard deviation of 10 J·mol^{-1}. The values of $\Delta G_m^E(p,x)$ at T_0 = 298.15 K have been obtained from the data in Table 2 and ΔS_m^E(298.15 K,0.1 MPa,x) from eq. [4].

The values of $H_m^E(p,x)$ obtained using eq. [7] over the pressure range 0.1–25 MPa at 298.15 K are presented in Table 4. We have also calculated H_m^E(298.15 K,p,x) using eqs. [1] and [7]; an absolute average deviation of 0.04% and a bias of –0.002% between both sets of data were found. The pressure dependence of the excess molar enthalpy for all the analyzed mole fractions is shown in Fig 4*a*. It can be observed in this Figure that H_m^E is positive in all the cases (diminishing slightly throughout isopleths for a given temperature), ranging from 0.5% for x = 0.10449 to 2% at the equimolecular composition. The curves for H_m^E(298.15 K,p,x) along two isobars (0.1 MPa (11) and 25 MPa) are plotted in Fig 4*b*, which shows that both curves have approximately the same symmetry. For DMC + n-octane mixtures, the excess volumes are positive and increase as the temperature increases, so there is a compensation between the two terms in eq. [5]. For this reason the pressure dependence of the enthalpy is very weak. For this system, the absolute values of $T(\partial V_m^E/\partial T)_{p,x}$ are greater than

the V_m^E values over the entire temperature and pressure range. Concerning the temperature dependence of excess enthalpy for this type of system, it is interesting to point out that Lohmann et al. (22) have recently published experimental excess enthalpies for DMC + n-heptane mixtures. These authors find that H_m^E increases very slightly as the temperature increases.

We have shown above that the excess enthalpies are positive at 298.15 K up to 25 MPa. Taking into account our V_m^E(298.15 K,p,x) data, it can be concluded that the excess internal energy is also positive over the pressure range. This means that during the mixing process the overall molecular interaction energy diminishes in absolute terms. Furthermore, from the H_m^E(298.15 K,p,x) and G_m^E(298.15 K,p,x) values, it can be concluded that the excess molar entropy at 298.15 K is positive, which means that dimethyl carbonate + n-octane mixtures are less ordered than the ideal mixture. This is because of the destruction of both the dipolar order of the carbonate and the orientational order of the alkane during the mixing process.

Analyzing the energetic and entropic terms involved in the excess Gibbs energy using eq. [6], it turns out that both ΔH_m^E and $T\Delta S_m^E$ are negative, whereas ΔG_m^E is positive for the

Fig. 5. (*a*) Excess isothermal compressibilities, κ_T^E, and (*b*) excess isobaric expansivities, α_p^E, for x DMC + $(1 - x)$ n-octane vs. the composition at p = 5 MPa for several temperatures: $\bigcirc$ 283.15 K; $\diamondsuit$ 313.15 K; $\triangle$ 343.15 K.


DMC + n-octane system. This means that when the pressure changes, the entropic contribution to the Gibbs energy dominates, being about twice as large as the enthalpic contribution.

Several authors (17, 20) have found similar variations in ΔG_m^E, ΔH_m^E, and ΔS_m^E with pressure and temperature for binary systems containing a polar compound and an alkane (2-butanone + 2,2,4-trimethylpentane and 1,2-dichloroethane + 2,2,4-trimethylpentane).

Excess quantities for the derived properties α_P and κ_T

The excess isobaric expansivity and the excess isothermal compressibility, denoted by α_p^E and κ_T^E, were calculated using the following expressions

$$[8] \qquad \alpha_p^E = \alpha_{pm} - \alpha_p^{id} = \alpha_{pm} - \sum_{i=1}^{2} \phi_i \alpha_{pi}^*$$

$$[9] \qquad \kappa_T^E = \kappa_{Tm} - \kappa_T^{id} = \kappa_{Tm} - \sum_{i=1}^{2} \phi_i \kappa_{Ti}^*$$

where the superscript * denotes the properties for pure liquids, which have been reported in a previous paper (14), and ϕ_i is the volume fraction calculated by

$$[10] \qquad \phi_i = \frac{x_i V_{m,i}^*}{\sum_{i=1}^{2} x_i V_{m,i}^*}$$

Taking into account the temperature, pressure, and mole fraction uncertainties and the accuracy of the derived properties and the molar volumes of pure compounds, the estimated uncertainties for α_p^E and κ_T^E are $\pm 1.4 \times 10^{-5}$ K^{-1} and $\pm 3.9 \times 10^{-6}$ MPa^{-1}, respectively. As shown in Fig. 5a, the excess isothermal compressibilities are positive over the entire temperature and pressure ranges and are symmetric around the equimolar composition, increasing with temperature and decreasing with pressure along isopleths. The positive values of κ_T^E and V_m^E indicate that the mixture is more compressible and less compact than the pure components.

In Fig. 5b we present the excess isobaric expansivities, which are positive and slightly asymmetric with respect to the equimolar composition, with a maximum in the DMC-rich region. As in the case of κ_T^E, the excess isobaric expansivities increase with temperature and decrease with pressure at constant composition. Pardo and co-workers (7, 23, 24) have also found that α_p^E and κ_T^E are positive at atmospheric pressure for other dialkyl carbonate + alkane systems. The positive values of α_p^E indicate that the mixture is more expansible than the pure compounds and that its structure is less rigid. These properties are in agreement with the sign of V_m^E, κ_T^E, and H_m^E.

The DMC + n-octane system shows positive values of V_m^E, H_m^E, G_m^E, α_p^E, and κ_T^E. The analysis of these properties for dialkyl carbonate + alkane systems in terms of interaction energies, packing effects, and order creation was carried out previously by García and co-workers (11, 13, 25) and by Pardo and co-workers (7, 23, 24). In the mixture process, the rupture of strong dipole–dipole interactions between the DMC molecules is predominant; this causes expansion and endothermicity. This interpretation agrees with the result reported in a previous paper (8) in which we had determined, in the framework of the Nitta–Chao model, the diminution of the number of contacts between the carbonate groups during the mixing process.

Furthermore, the DMC + n-octane system gives a W-shape for the excess molar isobaric capacities (26) from 288.15 to 308.15 K. The interpretation of the properties of systems containing a polar component and an alkane has been subject of controversy. First, Grolier et al. (27) and Wilhelm (28) explained the excess properties for this class of systems in terms of the conformational and molecular orientation changes in the mixing process. Later, Saint-Victor and Patterson (29) proposed a semi-quantitative model that involves two contributions, one random and the other non-random. Their model can explain the appearance of the W-shape in the $C_{p,m}^E$ curves in the region close to the upper critical solution temperature (UCST).

Excess internal pressure, π^E

In recent years several studies concerning the expressions for the properties of ideal mixtures (30–33), such as isentropic expansivity, speed of sound, or internal pressure, have been published. Marczak (32) has suggested that the correct expression for the internal pressure of a thermodynamically ideal mixture is given by

$$[11] \quad \pi^{id} = \sum_i \psi_i \pi_i(T, p)$$

where $\pi_i(T,p)$ is the internal pressure of the component i in the mixture and ψ_i is the compression fraction given by

$$[12] \quad \psi_i = \frac{x_i V_{mi} \kappa_{Ti}}{\sum_j x_j V_{mj} \kappa_{Tj}}$$

This suggests that the excess internal pressure should be calculated using the following expression

$$[13] \quad \pi^E(T,p,x) = \pi^M(T,p,x) - \psi_1 \pi_1(T,p) - \psi_2 \pi_2(T,p)$$

where $\pi^M(T,p,x)$ is the internal pressure of the mixture. The same equation can be obtained using the ideal mixing law proposed by Douheret and Viallard (33) for the isochoric

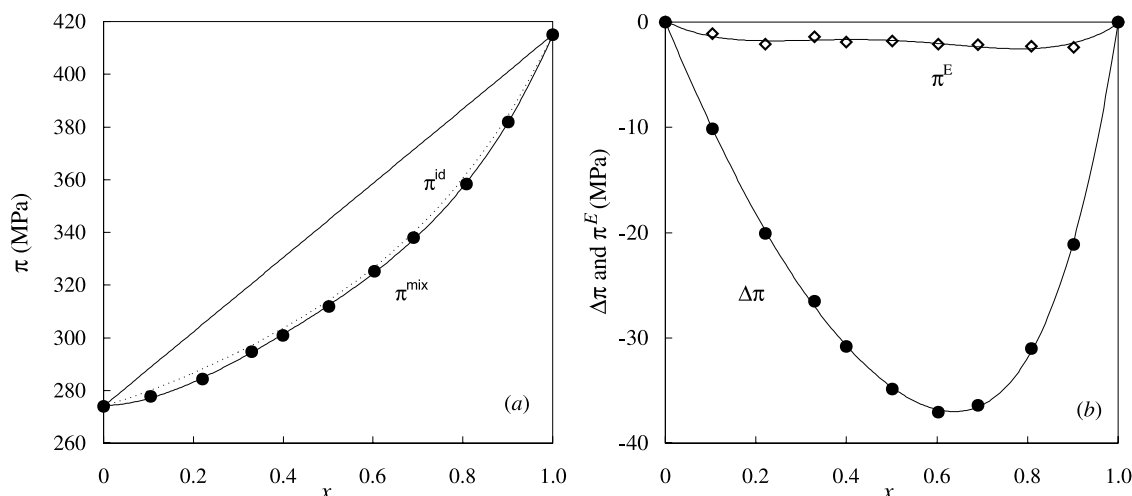
pressure coefficient, $\gamma_V = (\partial p/\partial T)_V$, using the relation $\pi = T(\partial p/\partial T)_V - p$. The estimated uncertainty of π^E is ± 1.4 MPa.

The internal pressure of an ideal mixture is usually considered to be the mole-fraction-weighted average of the internal pressure of the pure compounds. Several authors (34–37) have erroneously used this definition to determine the excess internal pressure. We will define the deviation of internal pressure, following Aminabhavi et al. (38), using the following expression

$$[14] \quad \Delta\pi(T,p,x) = \pi^M (T,p,x) - x_1\pi_1 (T,p) - x_2\pi_2 (T,p)$$

We have evaluated both $\Delta\pi$ and π^E using the internal pressures of the mixtures reported in Table 5. Figure 6a illustrates the dependence on composition of the internal pressure of the mixture π^M and of the ideal mixture π^{id}. For the DMC + n-octane mixtures at the indicated p and T conditions, π^M and π^{id} are very similar in magnitude. This means that the variation of the internal energy during expansion for this system is almost identical to that of an ideal mixture.

Figure 6b illustrates the significant differences between the excess internal pressure π^E and the deviation of the internal pressure $\Delta\pi$. Examining all the pressure and temperature intervals, we have found that π^E ranges from –10 to 6 MPa,

Fig. 6. (*a*) Internal pressure for x DMC + $(1 - x)$ n-octane mixture at 303.15 K and at 20 MPa: —, $x_1\pi_1(T,p) + x_2\pi_2(T,p)$; - - -, correct ideal internal pressure, eq. [11] and (●) internal pressure of the mixture; (*b*) Excess internal pressure for xDMC + $(1 - x)$ n-octane mixture at 1 MPa: (◇) calculated with eq. [13] and (●) deviation in the internal pressure taking into account eq. [14].


whereas $\Delta\pi$ is always negative, reaching a minimum value of –40 MPa. The large differences between π^E and $\Delta\pi$ are owing to the fact that the compressibilities and the molar volumes are much higher for pure n-octane than for pure dimethyl carbonate. Marczak (32) has calculated both $\Delta\pi$ and π^E for methanol + 1-propanol mixtures, obtaining a sigmoidal shape for the $\Delta\pi(x)$ curve with a maximum value around 0.3 MPa and a minimum value near –0.2 MPa, whereas the $\pi^E(x)$ curve is parabolic with a minimum near –1.1 MPa.

In a previous paper (14) we used $pVTx$ data to determine the values of the attractive and repulsive contributions to the internal pressure for DMC + n-octane mixtures using Mie's potential and the Tait equation. Applying eq. [13] to these previous values, it is easy to obtain the attractive and repulsive contributions to the excess internal pressures. We have shown that the first contribution of π^E is negative and decreases when the temperature and the pressure increase reaches a minimum value of –15 MPa, whereas the second contribution is positive and increases when the pressure rises and when the temperature decreases. Over the entire pressure and temperature range the more important contribution to the total excess internal pressure comes from the attractive excess internal pressure.

Conclusions

pVT data have been used to calculate the changes with pressure of several thermodynamic excess properties — ΔG_m^E, ΔS_m^E, ΔH_m^E, π^E, α_p^E, and κ_T^E — for DMC + n-octane mixtures over wide temperature and pressure ranges. The results obtained using two different correlations of V_m^E (as a function of p at fixed temperature and mole fraction and as function of temperature, pressure, and mole fraction) were very similar, though the first equation involves two parameters for each mole fraction and each temperature, and only 11 parameters are needed for the second correlation. The changes with pressure in the excess Gibbs energy are positive, whereas the enthalpic, ΔH_m^E, and entropic, $T\Delta S_m^E$, terms are negative. The absolute values of G_m^E and H_m^E at 298.15 K

and at several pressures up to 25 MPa have also been obtained and show that G_m^E increases whereas H_m^E decreases with pressure.

This system shows very large positive H_m^E values, positive V_m^E, U_m^E, and S_m^E values, and the W-shaped $C_{p,m}^E$ curve is a typical example of the so-called non-randomness proposed by Saint-Victor and Patterson (29). According to the positive values of V_m^E, κ_T^E, and α_p^E, DMC + n-octane mixtures are less compact, more compressible, and less expansible than the pure compounds.

List of symbols

a	coefficient in eq. [1]
AAD	absolute average deviation
b	coefficient in eq. [1]
bias	average deviation
B_{ij}	coefficient in eq. [1]
C_p	isobaric capacity
G_m^{E}	excess molar Gibbs energy
H_m^{E}	excess molar enthalpy
p	pressure
p_0	reference pressure
S_m^{E}	excess molar entropy
T	temperature
T_0	reference temperature
U	internal energy
U_m^{E}	excess molar internal energy
V	volume
V_m	molar volume
V_m^{E}	excess molar volume
x	mole fraction of DMC

Greek symbols

α_p	isobaric thermal expansivity
α_p^{E}	excess isobaric thermal expansivity
ΔG_m^{E}	change in the excess molar Gibbs energy
ΔH_m^{E}	change in the excess molar enthalpy
ΔS_m^{E}	change in the excess molar entropy
ϕ	volume fraction of DMC
κ_T	isothermal compressibility
κ_T^{E}	excess isothermal compressibility
π_i	internal pressure of component i
π^{id}	internal pressure of an ideal mixture
π^{M}	internal pressure of the mixture
π^{E}	excess internal pressure
ρ	density
ψ	compression fraction

The dissolution of organic solvents from Amerlock 400 epoxy paint

J.M. Ball, J.C. Wren, and J.R. Mitchell

Abstract: The dissolution of organic solvents from containment coatings into the sump water is expected to be a key rate-controlling process, influencing the pH, the steady-state water radiolysis product concentration, and the formation of organic iodides in containment following a postulated reactor accident. The dissolution process is therefore an important component in modelling iodine behaviour in post-accident containment. The rate of release of ethyl benzene and *m*- and *o*-xylene from Amerlock 400 epoxy paint in contact with water has been measured. The release rate was found to be comparable to the release rate of methyl isobutyl ketone from various polyurethane, vinyl, and epoxy paints. The pseudo-first-order rate constant for dissolution of the solvents from these containment coatings is dependent only upon paint thickness and temperature, whereas the total amount of solvent released depends upon paint thickness. The solvent-release process is governed by the rate of uptake of water by the coupons, a Fickian diffusion-controlled process.

Key words: dissolution, kinetics, organic solvents, paint.

Résumé : On s'attend à ce que la dissolution des solvants organiques, provenant des couches protectrices, dans les puisards soit l'étape déterminante des processus qui influencent le pH, la concentration des produits de radiolyse de l'eau à l'état stationnaire, et la formation d'iodures organiques dans la couche protectrice à la suite accident impliquant un réacteur. Le processus de dissolution est alors une composante importante dans la modélisation du comportement de l'iode à la suite d'un accident dans la couche protectrice. On a mesuré la vitesse de dégagement de l'éthyl benzène, du *m*-xylène et du *o*-xylène à partir de la peinture époxy Amerlock-400 au contact de l'eau. On a trouvé que la vitesse de dégagement est comparable à celle de la méthyl isobutyl cétone produite par divers polyuréthanes et par des peintures à base de vinyle et à base d'époxy. Le pseudo ordre 1 de la constante de vitesse de dissolution des solvants provenant de ces couches protectrices dépend uniquement de la consistance de la peinture et de la température, tandis que la quantité totale de solvant dégagée dépend de la consistance de la peinture. Le processus de dégagement du solvant est régi par la vitesse d'absorption d'eau par les échantillons, un processus de diffusion contrôlée de Fickian.

Mots clés : dissolution, cinétique, solvants organiques, peinture.

Introduction

The behaviour of iodine under postulated nuclear reactor accident conditions has been the subject of extensive studies by the nuclear industry for many years. Iodine species are important in the assessment of the radiological consequences of a nuclear reactor accident because the radiologically toxic ^{131}I is one of the most abundant fission products that would be released from fuel. Iodine has the potential to form numerous volatile species, which, once airborne in nuclear reactor containments, could be released to the atmosphere through containment leakage or during controlled venting.

It has been established that the pH and the steady-state concentration of water radiolysis[2] products in the containment sump water will determine the overall rate of production of volatile iodine species in containment (1, 2). These factors control the rate of interconversion between the non-volatile I$^-$ initially dissolved in the sump water and volatile I$_2$ (1, 2).[3] Organic impurities in the sump water would have a profound influence on both factors. Furthermore, organic

[2]4.1 H$_2$O = 2.6 e$^-_{aq}$ + 0.6 •H + 2.7 •OH + 0.7 H$_2$O$_2$ + 2.6 H$^+$ + 0.45 H$_2$. Coefficients in this equation are the G-values for γ-radiolysis products of water (units of molecules produced per 100 eV absorbed dose).

[3]In the presence of a radiation field, I$_2$ is formed from aqueous solutions containing I$^-$ by reaction with •OH, a water radiolysis product:

I$^-$ + •OH → I• + OH$^-$

I• + I•   → I$_2$(aq)
and reduced to I$^-$ by reaction with water, O$_2^-$, and H$_2$O$_2$. The reduction reactions are strongly dependent upon aqueous pH.

Table 1. Constituents of Amerlock 400 epoxy paint.

Component	Organic compound	% by weight
Part A (Amerlock 400 White Resin)	Aromatic hydrocarbons	5–10
	Epoxy resin	30–60
	Fatty amine carboxylate	1–5
	Furfuryl alcohol	1–5
	Methanol	1–5
Part B (Amerlock 400FD Cure)	Nonyl phenol	10–30
	Polyamide resin	5–10
	Polyoxyalkyleneamine	1–5
	Tri(dimethylaminomethyl) phenol	1–5
	Xylene	10–30
Amercoat 65 Thinner	Ethylbenzene	10–30
	Xylenes	60–100

Note: As reported in Material Safety Data Sheets provided by manufacturer. Only hazardous materials are listed in the table.

impurities in sump water would lead to the formation of organic iodides, some of which are volatile, and could contribute directly to the gaseous iodine fraction.

The dissolution of organic solvents from containment coatings into the sump water is expected to be a key rate-controlling process influencing the pH, the steady-state water radiolysis product concentration, and the formation of organic iodides in containment following an accident (1, 2). The dissolution process is therefore an important component in modelling iodine behaviour in post-accident containment.

Previous studies, on coupons coated with prototypical epoxy, polyurethane, and vinyl containment paints, established that these paints released organic solvents when immersed in water. The rate constant for release of organic solvents from these surfaces was observed to be dependent on temperature but relatively independent of paint or solvent type (3). Dissolution rate constants were also found to be unaffected by radiation. The total amount of organic solvent released was found to be a function of paint ageing, indicating that evaporative losses of solvents from paints did occur over time.

The present study was undertaken to examine the effect of coating thickness, wetted surface area : volume ratio, and absorption of water on the dissolution kinetics of solvents from painted surfaces. The paint used in the studies was Amerlock 400, an epoxy resin based paint. Limited measurements were also performed with Ripolin epoxy paint.

Experimental

Painted coupons were made from cylindrical slabs of carbon steel with a surface area of approximately 5.7 cm^2. Each coupon was sandblasted and then within 2 h was painted with Amerlock 400 paint. Subsequently, additional layers of coating were applied, each after the underlying layer had been dried for the recommended curing time. Amerlock 400 epoxy paint consists of two separate components, a resin and a curing agent. A thinner was used to reduce the viscosity of the paint for application to the coupons. The main constituents for each of the Amerlock 400 epoxy paint components are listed in Table 1. Amerlock painted coupons were stored for a period of 4–7 months in a ventilated area at room temperature (i.e., under conditions that did not inhibit solvent release by evaporation).

Ripolin painted coupons were prepared in a similar manner, with four coats of paint applied to give an approximate coating thickness of 0.03 cm. Ripolin paint uses only water as a thinner; however, the epoxy polyamide resin contains an unspecified quantity of ketones and xylenes. Ripolin painted coupons were stored for 6 years prior to being used.

The average thickness of successive layers of Amerlock 400 coating was determined by performing 30 paint-thickness measurements on 6 coupons. Each coupon was measured prior to painting and then measured after the application of 5 successive coatings of paint. The measurements, average thickness, and standard deviations are given in Table 2.

Glass vessels with total volumes ranging from 385 to 455 cm^3 were used for the experiments. Prior to each test the vessels were baked at 500°C to remove any trace organic compounds. One or two painted coupons were placed inside a glass vessel, a known amount of distilled and deionized water was added, and then the vessel was sealed and kept at a constant temperature for a set period of time. The pH was not controlled and did not change appreciably throughout the experiment. The amount of water used in each vessel was varied to maintain a gas–liquid volume ratio of approximately 6:1.

Dissolution studies were done at 25, 40, and 90°C. The temperature was controlled by the use of a circulating water bath for the 25 and 40°C tests. For the 90°C tests it was controlled by the use of a heating tape, a variac power regulator, and an insulated aluminum cylinder block. Each vessel was fitted with an internal thermo-well that allowed temperature monitoring of the liquid phase by thermocouples.

During the experiments, samples were taken at regular intervals and analyzed using a Hewlett-Packard model 5890 gas chromatograph fitted with an O/I Analytical photoionization detector. The gas chromatography instrument was regularly calibrated using gas mixtures of known composition.

Vessels were sealed with a screw-on cap using a Teflon seal and a Mininert push button valve with a replaceable septum. The valve system allowed each vessel to remain sealed while taking a gas sample. All gas samples were taken using a Hamilton gas-tight syringe. At the conclusion of some of the dissolution experiments at 90°C, coupons with 1 and 2 coats of paint had formed blisters on the bot-

Table 2. Measured coating thickness (in cm).

tom surface of the coupon (the portion of the surface in contact with the glass vessel). In dissolution experiments performed on coupons containing only 1 coat of paint at 90°C, the coupons had rust spots showing through the painted surface. It was also noticed that there was sometimes a decrease in the concentration of organic solvents measured in the gas phase during the latter stages of some of the 90°C experiments. The concentration decrease suggests that there were small leaks in the system. These leaks would be expected to have a larger impact on the gas phase concentrations measured at higher temperatures, because a larger portion of the inventory of the organic compound is in the gas phase at higher temperatures.

Water absorption measurements were performed at various temperatures between 25 and 60°C by placing a known quantity of distilled, deionized water into a glass vessel along with one Amerlock 400 epoxy painted coupon. Limited measurements were also performed on coupons painted with Ripolin epoxy paint. The glass vessel with water and coupon was sealed and heated to the desired test temperature. At specified time intervals, the glass vessel was opened and the coupon was removed, surface dried, and weighed. Following the weighing, the coupon was placed back into the glass vessel with fresh distilled, deionized water, sealed, and heated. The duration of each test varied depending upon the test temperature and number of coats of the Amerlock 400 epoxy paint on each coupon. Tests were performed on coupons containing paint of varying thickness. Attempts were made to measure water absorption at 90°C, but at this temperature the paint became detached from the underlying coupon structure. At this temperature the coupons underwent an initial weight loss (greater than that expected, owing to release of solvents) and became bubbled and cracked. The overall weight change as a result of water absorption was also lower for the coupons at 90°C than those at 25 and 60°C.

Measurements of the amount of organic solvent released from the immersed coupons were performed by monitoring gas-phase concentrations; therefore, partitioning of the solvents between the gas and aqueous phase had to be accounted for. The solvent-release kinetics were obtained by assuming instantaneous equilibrium partitioning of the organic compounds between the gas and aqueous phase. Previous experimental studies have established that partitioning is fast with respect to the dissolution process (3). Partition coefficients of 3.67, 3.91, and 6.11 (4) were assumed for ethyl benzene, m-xylene, and o-xylene, respectively, at room tem-

perature. The partition coefficients at 40 and 90°C were calculated from the reported values of $\Delta H/R$ (4) according to

$$[1] \qquad k_{HT} = k_{H298} \exp\left[\frac{\Delta H}{R}\left(\frac{1}{T} - \frac{1}{298K} \right) \right]$$

where k_{HT} and k_{H298} are the dimensionless Henry's law constants (dimensionless ratio between the aqueous phase concentration and the gas phase concentration) at temperatures T and 298 K, respectively; R is the gas constant (J·K^{-1}·mole^{-1}); and ΔH is the enthalpy of solution.

Results and discussion

Water uptake

Measurements were performed to determine the rate of the uptake of water by painted coupons at several temperatures, to compare the rate of absorption of water into the polymer with the rate of dissolution of solvents out of the polymer. The fractional uptake of water at various temperatures is shown in Fig. 1. Water absorption by both Amerlock and Ripolin painted coupons displays classical Fickian diffusion behaviour (5). When the concentration of a sorbent at the surface is kept constant, absorption into a membrane containing an initial uniform concentration of the sorbent can be represented by (5)

$$[2] \qquad k_{HT} = k_{H298} \exp\left[\frac{\Delta H}{R}\left(\frac{1}{T} - \frac{1}{298K} \right) \right]$$

where M_t is the mass of sorbent in the film at time t, M_∞ is the equilibrium mass, D is the diffusion coefficient, t is the time, and ℓ is the film or paint thickness.

The solution can be approximated by

$$[3] \qquad \frac{M_t}{M_\infty} =$$

$$2(Dt/\ell^2\pi)^{1/2} \text{ at small values of } t \left(\text{i.e., } \frac{M_t}{M_\infty} \le 0.5\right)$$

$$[4] \qquad \frac{M_t}{M_\infty} =$$

$$1 - \frac{8}{\pi^2} e^{-\pi^2 Dt/4\ell^2} \text{ at large values of } t \left(\text{i.e., } \frac{M_t}{M_\infty} \ge 0.5\right)$$

Fig. 1. Fractional uptake of water by Amerlock 400 (epoxy) coupons (coating thickness 0.033 cm) at 25, 40, and 60°C.
From eq. [3], it can be seen that the slope of a plot of M_t/M_∞ vs. $2t^{1/2}/\pi^{1/2}\ell$ for values of M_t/M_∞ up to 0.5 can be used to estimate the diffusion coefficient D. Plots of the fractional uptake of water (M_t/M_∞) as a function of $2t^{1/2}/\pi^{1/2}\ell$ at various temperatures and paint thickness are shown in Fig. 2, and the estimates for the diffusion coefficients obtained from taking an average of several measurements at each temperature are listed in Table 3. Note that at a given temperature, the curves for coatings of different thickness are, within experimental error, superimposable on one another.

An Arrhenius plot of the temperature dependence of the diffusion coefficient is shown in Fig. 3. An activation energy of 51 ± 7 kJ·mol^{-1} was estimated from the plot. Note that an additional uncertainty in the value for D exists, owing to the uncertainty in the coating thickness ℓ, which varies by about 30% from coupon to coupon (see Table 2).

Solvent release

Previous solvent-release experiments performed on painted coupons established that solvent evaporation from paints was very slow under dry conditions and that significant quantities of solvents (millimolar, based on paint volume) were retained in painted coupons aged for several years (2, 3). In the presence of water, however, it was observed that solvent was released relatively rapidly, indicating that diffusion of the solvent out of the paint matrix was en-

hanced in the presence of water (2, 3). The dissolution of methyl isobutyl ketone (MIBK) and other solvents from polyurethane, vinyl, and epoxy paints was found to obey simple first-order kinetics, with the total amount of solvent released into the aqueous phase as a function of time expressed as[4]

[5] $[ORG(aq)_t] = [ORG(aq)_\infty]\cdot(1 - \exp(-kt))$

where $[ORG(aq)_t]$ is the amount of solvent in the water at time t; $[ORG(aq)_\infty]$ is the amount of solvent released in total at the end of the test (i.e., after dissolution is complete) and is related to the amount of solvent initially in the paint;[5] and k is the pseudo-first-order rate constant for solvent release.

The current study has found that the dissolution of ethyl benzene, m-xylene, and o-xylene from Amerlock 400 paint immersed in water also obeys the same first-order kinetic behaviour. Table 3 summarizes the rate constants k obtained from non-linear regression analysis of experimental data using eq. [5]. It also shows the total amount of solvent $ORG(p)_\infty$ calculated[6] to have been released at test end. Figure 4 shows typical fits to the data using eq. [5] and the values of $[ORG(aq)_\infty]$ presented in Table 3. For a given set of conditions, values determined for the rate constants (k) for release of ethyl benzene, m-xylene, and o-xylene were statistically indistinguishable. Consequently, an average value of

---

[4] Note that the release kinetics can also be expressed in terms of the amount of solvent in the gas phase.

[5] The sum of the amounts of organic compound in the gas ($ORG(g)_\infty$) and aqueous ($ORG(aq)_\infty$) phases at test end will be equal to the amount in the paint ($ORG(p)_0$) at the start of the test ($ORG(aq)_\infty + ORG(g)_\infty = ORG(p)_0$). The amount in each phase can be calculated from the concentrations by multiplying the concentration by the volume (e.g., $ORG(g)_\infty = [ORG(g)_\infty] \times V_g$ where V_g is the volume of the gas phase). Using $[ORG(g)_\infty] = [ORG(aq)_\infty]/H$, where H is the partition coefficient, and solving the mass balance equation, one obtains

$$[ORG(aq)_\infty] = \frac{[ORG(p)_0]\cdot V_p}{V_g/H + V_{aq}}$$

[6] $ORG(p)$ is the total amount of solvent released. This was obtained by summing the total amount in the gas and aqueous phase at test end. The amount in the gas phase at test end was calculated using non-linear least squares regression analysis of the data. The amount of solvent in the aqueous phase was calculated from the final gas phase concentration by using the partition coefficient at the appropriate temperature.

[a]e-benz = ethyl benzene, o-xyl = o-xylene, m-xyl = m-xylene.

[b]k is an average value for ethyl benzene, o-xylene, and m-xylene.

[c]o-xyl(p)$_\infty$ is the total amount of o-xylene released. This was obtained by summing the total amount in the gaseous and aqueous phases at test end. The amount in the gas phase at test end was calculated using non-linear least squares regression analysis of the data. The amount of solvent in the aqueous phase was calculated from the final gas phase concentration by using the partition coefficient at the appropriate temperature.

[d]Estimated from Arrhenius plots of diffusion coefficients obtained from 20 to 65°C.

k is listed in Table 3 and was used to generate the data fits shown in Fig. 4.

From Table 3, it is apparent that the rate constant, k, does not depend upon surface area; i.e., within the error limits of the coating thickness, the rate constant for solvent release from one coupon with two coats of paint was the same as from two coupons with two coats of paint. Intuitively, the value of ORG(p)$_\infty$ should increase with increasing paint thickness, since one would expect that a larger volume of paint would lead to a greater amount of solvent being released. This general trend was observed in some instances, with coupons containing four coats of paint releasing more solvent than those containing only one coat of paint. However, in two cases, the amount of solvent released from coupons containing only 1 coat of paint was similar or higher than the amount released from coupons painted with 2 coats of paint. Likewise, for a given paint thickness, the value of ORG(p)$_\infty$ (total amount of solvent released at test end) should increase with increasing surface area; therefore, the *overall* amount of solvent released from two coupons with one coat of paint each should be higher than from one coupon with one coat of paint. This is not borne out by the data,

Fig. 3. Arrhenius plot for the diffusion coefficient of water in Amerlock 400 painted coupons.
Fig. 4. Gas-phase concentrations of ethyl-benzene, *m*-xylene, and *o*-xylene from an Amerlock 400 painted coupon (coating thickness 0.022 cm) immersed in water at 25°C. The lines drawn through the data are those calculated using eq. [5].
however. In previous studies it was observed that there was a wide variation in the amount of solvent released from coupons covered with nominally uniform thickness of polyurethane, epoxy, and vinyl paints (3). This was attributed to differences in the ageing of individual coupons, and the same phenomena could be responsible for the fact that in these studies, an increased immersed paint volume does not necessarily lead to more solvent being released from the paint.

The pseudo-first-order rate constant *k*, used to obtain a fit of the data to eq. [5], was found to be inversely dependent upon the coating thickness, with *k* increasing as coating thickness decreased (Table 3). An inverse relationship between coating thickness and rate of uptake or evaporation from the coating is indicative of a diffusion-controlled process (5). Note that the magnitude of the values for the first-order rate constant *k* measured in these experiments was similar to those measured for MIBK release from coupons coated with various paints but with similar paint thickness (Table 4).

The effect of temperature on the pseudo-first-order rate constant *k* for release of *m*-xylene from coupons having three different coating thickness is shown in the Arrhenius plot in Fig. 5. The average of the slopes of the three plots,

Table 4. Comparison of rate constants for solvent release from various painted surfaces of similar thickness.[a,b]

[a]Coupon thickness 0.022 ± 0.002 cm. k is the first-order rate constant used to obtain best fit (eq. [5]) to the data for release of ethylbenzene, *m*-, and *o*-xylene.
[b]Coupon thickness ≈ 0.03 cm. k is the first-order rate constant used to obtain best fit (eq. [5]) to the data for release of methyl isobutyl ketone. The first-order rate constant k for release of other organic compounds was similar.

Fig. 5. Arrhenius plot of the dissolution rate constants observed for the release of *o*-xylene from Amerlock 400 painted coupons.
ln k vs. $(1/T)$, provides an activation energy, E_a, of 50 ± 4 kJ·mol^{-1} for the dissolution process. This value is slightly smaller than the average value of 65 ± 4 kJ·mol^{-1} reported for *m*-xylene release from polyurethane, epoxy, and vinyl painted surfaces (3). It was previously reported that, for a given ageing time, the temperature-dependent dissolution rate constant is nearly independent of the type of organic solvent and the type of paint. The smaller activation energy obtained from these experiments in comparison to previous experiments would suggest otherwise; however they are based on a considerably smaller sample size, and there were some experimental difficulties associated with obtaining measurements at 90°C. It is worth noting that the activation energy estimated only from data at 25 and 40°C is 57 ± 5 kJ·mol^{-1}. The small differences observed in the slopes of the plots for coupons containing different numbers of coats are not significant in view of the uncertainty in the width of each coating layer (see Table 2).

A comparison of the rate of water uptake and solvent release is shown in Fig. 6. For a given thickness of paint, solvent release is slower than water absorption. There is also a delay between the onset of water absorption and solvent release, indicating that solvent diffusion out of the paint polymer occurs only after water is adsorbed. These findings, coupled with previous observations that significant quantities of solvent are retained for several years in painted cou-

pons not exposed to water (3), suggest that solvent release is dependent upon the presence of water in the paint matrix.

Diffusion of water through various paints is expected to have an activation energy ranging between 50 and 100 kJ·mol^{-1} (6) whereas the activation energy for diffusion of organic compounds in water is lower (10–20 kJ·mol^{-1} (7)). The activation energy of 50 kJ·mole^{-1} for solvent release measured in these studies suggests that the rate-determining step for the process is transport of water by diffusion into the paint matrix and not transport of the solvents through a diffusional boundary layer in the water outside of the paint. Similar observations have been made for the release of ethyno-diol from silicone polymers in the presence of polyethylene glycol (8) and for the release of various pharmaceuticals from cross-linked polymer systems immersed in water (9). It should also be noted that the average activation energy of 50 kJ·mol^{-1} estimated for solvent release from these experiments is, within experimental error, very close in value to the estimated activation energy (51 kJ·mol^{-1}) for diffusion of water through the paint.

The kinetics for solvent release shown in Fig. 4 can be rationalized by viewing the process as being analogous to solvent evaporation from a membrane (5) in which the driving force for transport of the solvent from inside the membrane to the gas phase is the difference between the solvent concentration inside the membrane and the concentration on the

Fig. 6. Fractional uptake of water and release of *m*-xylene from Amerlock 400 painted (0.013 cm thick) coupons. The lines drawn through the data are those calculated using eqs. [2] and [5].
membrane exterior. In the case of immersed paint, the medium is water rather than air, and the dissolution is dependent upon the rate of diffusion of the water–solvent mixture through the polymer. The driving force for water adsorption is the water concentration differential between the interior and exterior of the membrane. For solvent evaporation, the diffusion equations for the rate of loss from the surface of a membrane can be represented by

$$[6] \quad -D\frac{\partial C}{\partial x} = \alpha(C_{eq} - C_s)$$

$$[7] \quad \frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x}$$

where C_s is the solvent concentration inside the membrane; C_{eq} is the solvent concentration required to maintain equilibrium with the surrounding medium; and α is a constant of proportionality[7] (5).

Solving for the concentration of solvent at the water–paint interface ($x = 0$) as a function of time leads to an expression for the total amount of solvent leaving the interface as a fraction of the corresponding quantity after infinite time

$$[8] \quad \frac{M_t}{M_\infty} = 1 - \sum_{n=1}^{\infty} \frac{2L^2 \exp(-\beta_n^2 Dt/\ell^2)}{\beta_n^2(\beta_n^2 + L^2 + L)}$$

where the β_ns are the positive roots of $\beta\tan(\beta) = L$; $L = \ell\alpha/D$; M_t is the mass (or concentration) of a species in solution at time t; M_∞ is the final mass (or concentration) of the species in solution; D is the diffusion coefficient of water inside the polymer; t is the time; n is a positive integer; and ℓ is the film or paint thickness. That is, M_t is equivalent to

$$-\int_0^x C_s dx$$

where x is changing with time, owing to water diffusion into the paint.

The solvent-release kinetics observed in Fig. 4 can be modeled very accurately, using eq. [8] and assuming that the diffusion coefficient for the solvent through the water polymer mixture is the same as the diffusion coefficient obtained from measurements of the uptake of water at the appropriate temperature. Figure 7 shows a typical example of solvent-release data and a comparison of the fit obtained using eq. [8] to that obtained using the simple exponential fit in eq. [5]. The models predict very similar time-release behaviour, and the subtle differences are well within the error in the experimental measurements.

The exponential form of eq. [8] explains the observation that solvent release from all of the paints we have studied follows simple first-order kinetics. In fact, for the conditions in our experiments, eq. [8] is approximately

$$[9] \quad \frac{M_t}{M_\infty} = 1 = \exp(-\beta^2 Dt/\ell^2)$$

Equation [9] is identical to eq. [5], with k replaced by $\beta^2 D/\ell^2$.

The relationship between the value k, the diffusion coefficient D, and the coupon thickness is not immediately obvious from eqs. [5] and [8]. However, within the error limits of the data, an empirical relationship between the values for k and D can be derived from the expression[8]

$$[10] \quad k = 25 \text{ cm}^{-1} D/\ell$$

---

[7] The proportionality constant α can be viewed as being a mass transfer coefficient $D/\delta x$ where δx is a diffusional boundary layer. α has the units length × time^{-1}.

[8] Using $k = \beta^2 D/\ell$ and the approximation $\beta^2 = L$, which holds for values of L up to 1, the relationship $k = LD/\ell$ or $k = \alpha/\ell$ can be derived. The relationship in eq. [10] is therefore equivalent to stating that $\alpha = (25 \text{ cm}^{-1}) D$.

Fig. 7. Fractional release of solvents from an immersed coupon painted with two layers of Amerlock 400 paint at 25°C. Lines show the fit of the data using eqs. [5] and [8].
Table 5. Comparison of values for first-order rate constant k.

Sample No.	Paint type	Thickness (µm)	T (°C)	D (10^{-6}cm^{2}h^{-1})	k_{calcd}[a] (h^{-1})	k_{fit}[b] (h^{-1})

9, 11	Amerlock	68	90	9	0.33	0.22, 0.35[c]
10, 12	Amerlock	120	90	9	0.19	0.20
13	Amerlock	220	90	9	0.1	0.10
14	Ripolin	33	40	6	0.045	0.040

[a]Calculated from eq. [10] and the measured diffusion coefficient of water in the polymer.

[b]k used in eq. [5] to fit the solvent-release data (methyl isobutyl ketone in the case of Ripolin paint; m-, o-xylene, and ethylbenzene in the case of Amerlock 400 paint) from immersed surfaces.

[c]Two samples gave slightly different values.

Values calculated for k, as compared with those obtained from a best fit to the data, are listed in Table 5. The values are in very good agreement for every experiment. The applicability of eq. [10] to deriving the first-order rate constants for solvent release from other paints, or paint aged for different time periods, has not been established. However, for measurements performed on the uptake of water by and release of methyl isobutyl ketone from Ripolin (epoxy) paint, the relationship appears to hold (see Table 5). The correlation between the value for k and the diffusion coefficient for water uptake also supports the argument that solvent release is dependent upon the rate of water uptake.

The observed difference between the rates of water uptake and solvent release (Fig. 6) can be explained by the difference in the concentrations of the species at the interface between the paint and the water. For water absorption, the concentration of the sorbent (i.e., water) at the paint–solution interfacial boundary is constant. The water concentration within the diffusional boundary layer (i.e., inside the paint) is also constant, although the length of the boundary layer changes with time. The net driving force for water diffusion is therefore always large; water is always diffusing from an area of constant concentration into an area of zero concentration. In the case of solvent release, the concentra-

Fig. 8. Normalized release rate of *m*-xylene, MIBK, and toluene from vinyl painted zinc-primed coupons immersed in water at 25°C and at pH 10. The lines drawn through the data are those calculated using eq. [5].
tion gradient of the solvent decreases as time proceeds, because the solvent concentration in solution (and therefore at the water paint interface) continually increases. This decrease in the concentration gradient reduces the driving force for the net diffusion of the solvent out of the paint. As a result, diffusion of solvent out of the paint matrix is always slower than diffusion of water into the matrix.

A number of mechanisms have been proposed for solvent release from, or solute uptake into, immersed surfaces. Pseudo-first-order kinetic behaviour has been observed for the release or uptake of dyes into natural and synthetic polymers (9) and the release of drugs from various gels (8). Models for the kinetic behaviour vary, however. Some models incorporate moving boundary layer analysis, in which a diffusional boundary layer exists between a water front advancing into a membrane and the edge of the membrane (8). Other analyses incorporate an assumption that there is a thick skin on the membrane that inhibits diffusion (9), and still others assume that there is a diffusional boundary layer on the outside of the membrane (9). What the models all have in common is that release or uptake of a water-soluble substrate by a given material is primarily dependent upon the rate of diffusion of the solvent–water mix in the material. The dependence on the rate of diffusion of water is believed to arise because the movement of materials through the polymer requires that the polymer segments are mobile. Absorption of water is believed to significantly enhance polymer segment mobility and, therefore, transport of materials through the polymer by relaxing and swelling the paint matrix (7–9).

In transport of dyes or drugs through polymers, the uptake or release of a substrate dissolved in solvent has been observed to be somewhat dependent also upon other factors besides the rate of diffusion of water in the polymer (7–9). These factors are: (*a*) the diffusion coefficient of the sub-

strate in water; (*b*) the size of the substrate; and (*c*) the size exclusion characteristics of the polymer.

None of these factors have been examined in detail in the present study. However, the solvent-release rate constants for ethyl benzene and *o*- and *m*-xylene from Amerlock 400 were very similar, and previous studies (3) on polyurethane, epoxy, and vinyl containment paints established that solvent-release rate constants for a very wide range of solvent types (e.g., chlorinated hydrocarbons, aldehydes, ketones, and aromatic hydrocarbons) were relatively independent of the nature of the solvent (see Figs. 8 and 9). The independence of the solvent-release rate constant on the nature of the solvents from all of these experiments is not surprising given that the diffusion coefficients of small organic molecules in water span a very narrow range (10).

In all of the studies performed to date on the release of solvents from containment paints, the rate constant (k) appears to be relatively independent of paint type. If, as the current studies indicate, the rate constant is dependent upon the diffusion coefficient of water in the polymers, the independence of the rate constant on paint type implies that the diffusion coefficient of water in all of the paints is similar. The independence of solvent release on paint type also implies that, under the conditions of our experiments (and those expected in containment), the solvent-release rate is independent of the size exclusion characteristics of the polymer.

Conclusions

The release of solvents from Amerlock 400 painted coupons exhibits the same pseudo-first-order behaviour as the rate of release of other solvents from polyurethane, vinyl, and epoxy paints. The release rate is dependent upon the rate of water uptake by the coupons and can be modelled by as-

Fig. 9. Normalized release rate of methyl isobutyl ketone (MIBK), heptanone, and *m*-xylene from epoxy painted zinc-primed coupons immersed in water at 40°C and at pH 5. The lines drawn through the data are those calculated using eq. [5].
suming Fickian diffusion kinetics (5). The pseudo-first-order rate constant (k) was found to be inversely proportional to the coating thickness. A value for k for the coupons used in this study can be estimated from the relationship $k = (25 \text{ cm}^{-1}) D/\ell$, where D is the diffusion coefficient of water in the paint and ℓ is the paint thickness. The activation energy for solvent release does not appear to depend upon the coating thickness (Fig. 5).

Values of k for solvent release from immersed Amerlock 400 paint are similar to those determined for release of methyl isobutyl ketone from polyurethane, vinyl, and epoxy containment paints, implying that the diffusion coefficient for water in these paints is very similar to that in Amerlock 400. The insensitivity of the solvent-release kinetics to solvent type or paint type suggests that it might be possible to construct a model for dissolution of solvents from containment paints that will be applicable to all containment paints. This study, in agreement with previous studies, indicates that the rate for solvent release can be described by eq. [5] and

$$[11] \quad D_T = D_{298} \exp\left[\frac{-\Delta E}{T}\left(\frac{1}{T} - \frac{1}{298\,\text{K}}\right)\right]$$

where D_T and D_{298} are the diffusion coefficients of water in the paint at temperatures T and 298 K, respectively.

A comprehensive study on the activation energy (ΔE) for water absorption by paint and the amount of solvent initially in the paint, as a function of paint ageing, is currently being performed.

2-Thiophen-2-ylbenzothiazole, -benzoxazole, and -benzimidazole platinum complexes

Xiao-Feng He, Christopher M. Vogels, Andreas Decken, and Stephen A. Westcott

Abstract: Oxidative cyclization of 2-aminothiophenol, 2-aminophenol, and 1,2-phenylenediamine with 2-thiophenecarboxaldehyde affords the corresponding 2-thiophen-2-ylbenzothiazole, -benzoxazole, and -benzimidazole compounds. Addition of these ligands (L) to [PtCl$_2$(coe)]$_2$ (coe = *cis*-cyclooctene) gives complexes of the type *trans*-PtCl$_2$L(coe) in moderate yields. Crystals of the benzothiazole derivative (**1**) were monoclinic, space group *P*2(1)/*c*, *a* = 11.561(4) Å, *b* = 15.335(15) Å, *c* = 11.769(4) Å, β = 105.182(5)°, *Z* = 4.

Key words: platinum, imine, benzothiazole, benzoxazole, benzimidazole.

Résumé : La cyclisation oxydante du 2-aminothiophénol, du 2-aminophénol et de la 1,2-phénylènediamine avec le 2-thiophènecarboxaldéhyde fournit les composés correspondants : le 2-thiophène-2-ylbenzothiazole, le benzoxazole et le benzimidazole. L'addition de ces ligands (L) sur le [PtCl$_2$(coe)]$_2$ (coe = cyclooctène *cis*) donne des complexes du type PtCl$_2$L(coe) *trans* avec des rendements modérés. Les cristaux du dérivé du benzothiazole (**1**) sont monocliniques et appartiennent au groupe d'espace *P*2(1)/*c*, avec *a* = 11,561(4) Å, *b* = 15,335(15) Å, *c* = 11,769(4) Å, β = 105,182(5)°, *Z* = 4.

Mots clés : platine, imine, benzothiazole, benzoxazole, benzimidazole.

[Traduit par la Rédaction]

Introduction

Since the discovery that cisplatin (*cis*-[PtCl$_2$(NH$_3$)$_2$]) can be used as an effective treatment against testicular, ovarian, and head and neck carcinomas, considerable research has focussed on designing new platinum-based drugs with improved therapeutic regimes (1–10). The generation of most platinum complexes for this application was based on an early structure–activity relationship which stated that potentially active complexes should be neutral and contain two inert amine ligands (with at least one N—H bond) in the *cis* orientation and two semilabile leaving groups (11). More recent work, however, has shown that derivatives of transplatin (*trans*-[PtCl$_2$(NH$_3$)$_2$]) also show significant cytotoxicities, paving the way for future studies on *trans*-Pt complexes (12–17). Our interest in making platinum complexes containing biologically active ligands (18), along with the discovery that [PtCl$_2$(coe)]$_2$ (coe = *cis*-cyclooctene) can be used as an organic soluble starting material to generate both *cis*-bidentate and *trans*-monodentate amine dichloroplatinum complexes, prompted us to investigate its reactivity with 2-thiophen-2-ylbenzothiazole, -benzoxazole, and -benzimidazoles. The results of which are presented within.

Experimental

Reagents and solvents used were obtained from Aldrich Chemicals. Platinum salts were obtained from Precious Metals Online Ltd. [PtCl$_2$(coe)]$_2$ was prepared by established procedures (19). NMR spectra were recorded on a JEOL JNM-GSX270 FT NMR spectrometer. ^{1}H NMR chemical shifts are reported in ppm and referenced to residual protons in deuterated solvent at 270 MHz. ^{13}C NMR chemical shifts are referenced to solvent carbon resonances as internal standards at 68 MHz. Multiplicities are reported as singlet (s), doublet (d), triplet (t), quartet (q), multiplet (m), broad (br), and overlapping (ov). Infrared spectra were obtained using a Mattson Genesis II FT IR spectrometer and reported in cm^{-1}. Melting points were measured uncorrected with a Mel-Temp apparatus. Microanalyses for C, H, and N were carried out at Chemisar Laboratories Inc. (Guelph, Ontario). All reactions were carried out in the air and products are stable indefinitely under such conditions.

General procedure for the preparation of complexes 1–3

The starting benzothiazole (20), benzoxazole (20), and the benzimidazole (21) compounds were prepared by established procedures.

Complex 1

2-Thiophen-2-ylbenzothiazole (62 mg, 0.29 mmol) in 10 mL of CH$_2$Cl$_2$ was added dropwise to a stirred solution of [PtCl$_2$(coe)]$_2$ (100 mg, 0.13 mmol) in 10 mL of CH$_2$Cl$_2$.

Complex 2

2-Thiophen-2-ylbenzoxazole (30 mg, 0.15 mmol) in 10 mL of CH$_2$Cl$_2$ was added dropwise to a stirred solution of [PtCl$_2$(coe)]$_2$ (59 mg, 0.08 mmol) in 10 mL of CH$_2$Cl$_2$. The reaction mixture was heated at reflux for 7 h, at which point the solvent was removed under vacuum to afford a red solid. Ethanol (2×3 mL) was used to wash the solid. Yield: 38 mg (42%); mp 170°C (decomposition). IR (Nujol): 3064 (w), 2947 (s), 2906 (s), 2868 (s), 1605 (m), 1574 (s), 1468 (s), 1454 (s), 1416 (m), 1379 (m), 1356 (m), 1298 (w), 1254 (m), 1232 (m), 1171 (m), 1078 (m), 1041 (m), 997 (w), 955 (w), 924 (w), 852 (m), 796 (m), 764 (s), 658 (w), 604 (w), 567 (w), 528 (m). ^{1}H NMR (CDCl$_3$) δ: 8.51 (d, J = 4 Hz, 1H), 8.29 (d, J = 8 Hz, 1H), 7.87 (d, J = 4 Hz, 1H), 7.63–7.49 (ov m, 3H), 7.30 (d, J = 4 Hz, 1H), 5.80 (m, J_{H-Pt} = 64 Hz, 2H, -CH=CH-), 2.73 (br m, 2H), 2.56 (br m, 2H), 1.92 (br m, 2H), 1.53 (br m, 6H). ^{13}C NMR δ: 159.1, 149.0, 137.9, 134.9, 134.6, 128.4, 127.2, 126.3, 125.4, 119.6, 111.2, 96.0 (-CH=CH-), 29.3, 28.3, 26.3. Anal. calcd. for PtCl$_2$C$_{19}$H$_{21}$NSO: C 39.52, H 3.67, N 2.43; found: C 39.60, H 3.74, N 2.45.

Complex 3

2-Thiophen-2-ylbenzimidazole (27 mg, 0.13 mmol) in 10 mL of CH$_2$Cl$_2$ was added dropwise to a stirred solution of [PtCl$_2$(coe)]$_2$ (50 mg, 0.07 mmol) in 10 mL of CH$_2$Cl$_2$. The reaction mixture was heated at reflux for 7 h, at which point the solvent was removed under vacuum to afford a yellow solid. Ethanol (2×3 mL) was used to wash the solid. Yield: 32 mg (40%); mp 210°C (decomposition). IR (Nujol): 3199 (m), 3180 (m), 2920 (s), 2860 (s), 1566 (m), 1498 (w), 1458 (s), 1377 (s), 1319 (m), 1286 (m), 1234 (m), 1173 (w), 1151 (w), 1117 (w), 1005 (w), 958 (w), 926 (w), 843 (m), 820 (w), 798 (w), 756 (s), 739 (s), 700 (s), 669 (w), 636 (w), 609 (w), 569 (w), 528 (w). ^{1}H NMR (CDCl$_3$) δ: 10.51 (s, 1H), 8.22 (d, J = 8 Hz, 1H), 7.43–7.39 (ov m, 2H), 7.22 (t, J = 8 Hz, 1H), 6.98–6.87 (ov m, 2H), 6.68 (t, J = 8 Hz, 1H), 5.75 (m, J_{H-Pt} = 62 Hz, 2H, -CH=CH-), 2.68 (br m, 2H), 2.60 (br m, 2H), 1.92 (br m, 2H), 1.54 (br m, 6H). ^{13}C NMR (CDCl$_3$) δ: 145.6, 139.4, 131.8, 130.6, 130.4, 127.8, 127.6, 125.2, 123.9, 118.0, 111.5, 95.7 (-CH=CH-), 29.4, 28.2, 26.4. Anal. calcd. for PtCl$_2$C$_{19}$H$_{22}$N$_2$S: C 39.56, H 3.85, N 4.86; found: C 39.70, H 3.88, N 4.78.

Scheme 1. Synthesis of organometallic platinum 2-thiophen-2-yl-benzothiazole derivatives **1–3**.
X-ray crystallography

Crystals of **1** were grown from a saturated acetone solution at 5°C. Single crystals were coated with Paratone-N oil, mounted using a glass fibre, and frozen in the cold stream of the goniometer. A hemisphere of data were collected on a Bruker AXS P4/SMART 1000 diffractometer using ω and θ scans with a scan width of 0.3° and 10 s exposure times. The detector distance was 5 cm. The data were reduced (22) and corrected for absorption (23). The structure was solved by direct methods and refined by full-matrix least-squares on F^2 (24). All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were located in Fourier difference maps and refined isotropically.

Results and discussion

2-Arylbenzothiazole derivatives are an important class of biologically active compounds (25–30). For instance, the unusual antitumor activity associated with 2-(4-amino-phenyl)benzothiazole was originally discovered in a program designed for screening tyrosine kinase inhibitors (31). Analogues possessing superior growth inhibitory properties have since been synthesized and their biological profiles are unlike that of any known anticancer agent (32). Analysis of the structure–activity relationship identified the benzothiazole unit as being essential for potent activity.

Our interest in generating platinum compounds with biologically active carrier ligands prompted us to make complexes containing arylbenzothiazole, and related benzoxazole and benzimidazole groups. Our initial efforts in this area focussed on thiophene derivatives **a–c** as compounds containing a thiophene group have also shown remarkable biological activities (33, 34) and can act as ligands by binding through the sulfur atom (35). Compounds **a–c** were prepared by the oxidative cyclization of the appropriate Schiff bases (20, 21).

Addition of benzothiazole **a** to a solution of [PtCl$_2$(coe)]$_2$ in CH$_2$Cl$_2$ gave the novel organometallic complex *trans*-PtCl$_2$(coe)(**a**) (**1**) in moderate yields (63%, Scheme 1). NMR spectroscopic data confirmed the presence of a bound coe group. For instance, ^{1}H NMR data showed a broad peak at δ 5.74 ppm attributed to the olefinic C—H bonds and platinum coupling (J_{H-Pt} = 62 Hz) suggests that the cyclooctene unit is still coordinated to the metal centre. Similarly, the coordinated alkene shows up at δ 95.4 ppm in the ^{13}C NMR spectra.

Although NMR data can be used to confirm the coordination of the cyclooctene group, it cannot unambiguously show how the thiophene benzothiazole unit is bound to the metal

and selected bond distances and angles shown in Table 2. The benzothiazole ligand is bound to the metal through the imine nitrogen with a nitrogen–platinum bond distance of 2.064(7) Å, similar to those reported in other platinum–imine complexes (14, 36, 37). Slightly longer Pt—N bond distances have been observed in related five-coordinate [PtMe(cod)(N-N)]BF$_4$ (cod = 1,5-cyclooctadiene, N-N = diimine) complexes (38). The structure confirms the pres-

ence of the *trans* cyclooctene group, showing a typical Pt—C bond distance of 2.169(8) Å (19). The carbon–carbon bond distance of 1.367(11) Å shows a slight weakening because of π-backbonding from the metal to the empty π^* orbital of the alkene (39). A Pt-S(9) distance of 3.110(3) Å precludes any significant interaction of the metal with the thiophene group.

Complex **1** was heated at reflux in toluene in the presence of excess ligand for prolonged periods of time in an effort to remove the bound cyclooctene group and generate *cis*-PtCl$_2$(2-thiophen-2-ylbenzothiazole). No changes were observed by ^{1}H NMR spectroscopy, however, and attempts to generate this latter complex by addition of 2-thiophen-2yl-benzothiazole to aqueous solutions of K$_2$PtCl$_4$ also proved unsuccessful and resulted in the generation of several new products. Similar decomposition products arising from a ring opening of the benzothiazole have been reported previously (40, 41).

Platinum complexes **2** and **3** were prepared as described for **1**, and displayed similar spectroscopic characteristics. For instance, a significant chemical shift is observed for the alkene peaks in the ^{1}H NMR when the imine is *trans* to the cyclooctene group (5.80 ppm for **2** and 5.75 ppm for **3**; cf. 5.62 ppm for free coe). The olefinic carbons are observed at 96.0 ppm (**2**) and 95.7 ppm (**3**) in the ^{13}C NMR spectra, compared to 130 ppm for free coe.

Interestingly, recent studies have shown that certain *trans* imine complexes display cytotoxicities against both cisplatin-sensitive and cisplatin-resistant cell lines (42–44). With this in mind, we will examine complexes **1–3** for their potential anticancer activities, the results of which will be published in due course.

Determination of potential energy functions of argon, krypton, and xenon via the inversion of reduced-viscosity collision integrals at zero pressure[1]

Elaheh K. Goharshadi, Mina JamiAlahmadi, and Bijan Najafi

Abstract: The pair potential energy functions of argon, krypton, and xenon have been determined via the inversion of reduced-viscosity collision integrals at zero pressure. A comparison of the potentials with the previously determined potentials are included. The viscosity and thermal conductivity of argon, krypton, and xenon at different temperatures and pressures have been calculated and compared with experimental values. The present potentials for argon, krypton, and xenon provide a good overall account of the experimental properties of these compounds, considering the stated uncertainty in the measurements.

Key words: potential energy function, collision integral, viscosity, thermal conductivity.

Résumé : On a déterminé la paire de fonctions d'énergie potentielle de l'argon, du krypton et du xénon en utilisant l'inversion des intégrales de collision à viscosité réduite et à pression nulle. On inclut une comparaison des potentiels avec ceux déterminés antérieurement. On a calculé la viscosité et la conductivité thermique de l'argon, du krypton et du xénon à différentes températures et à différentes pressions et on les a comparées aux valeurs expérimentales. Les potentiels actuels de l'argon, du krypton et du xénon fournissent une bonne analyse des propriétés expérimentales de ces composés en tenant compte de l'incertitude reconnue de ces mesures.

Mots clés : fonction d'énergie potentielle, intégrale de collision, viscosité, conductivité thermique.

[Traduit par la Rédaction]

Introduction

Molecular interactions are the key to understanding the structure and properties of liquids and solids and the properties of gases.

There are two fundamental methods for obtaining the potential energy functions, theoretical calculations and experimental measurements of macroscopic and microscopic properties of matter such as gas imperfection, spectroscopic methods, molecular beam scattering measurements, and transport properties.

There exists two ways for extracting the potential energy function from experimental data. One is a fitting procedure and the other is an inversion method. A potential model with a few adjustable parameters is assumed in fitting procedures. The parameters of the potential model are varied so as to obtain the optimum agreement between experiment and theory. The potentials from this method do not appear to be unique. Specific information about a potential energy function can be extracted by the inversion of experimental data. In particular, direct inversion techniques for the determination of po-

tential from data on molecular transport properties and second virial coefficients that do not require any explicit assumption to be made about the functional form of the potential have been developed (1–4).

Knowledge of pair potentials in addition to three-body interactions is sufficient to reproduce the thermodynamic properties of argon, krypton, and xenon through a wide range of temperatures and pressures (5–7). For example, Anta et al. (5) have showed that the combination of an accurate pair potential plus three-body interactions reproduces the gas–liquid coexistence curve of argon. These authors also indicated that, when an inaccurate pair potential such as Lennard-Jones is combined with the three-body interactions, the calculated curve deviates appreciably from the experimental data.

The main purpose of the present paper is to determine accurate pair potential energy functions of argon, krypton, and xenon by inversion of the reduced-viscosity collision integrals at zero pressure.

The second objective of the work is to present the tables of collision integrals at zero pressure that are needed in eval-

uating the transport coefficients of argon, krypton, and xenon at any pressure.

Finally, we have calculated the viscosity and thermal conductivity for argon, krypton, and xenon at different temperatures and pressures.

Theory

Inversion procedure from viscosity data

The macroscopic properties of gases can be explained in terms of the motion and interaction of molecules. Enskog and Chapman developed this theory for transport properties of monatomic dilute gases (8, 9). The most significant feature of their theory is that each transport coefficient of the gas or gas mixture can be expressed in terms of a series of collision integrals, namely $\Omega^{(l,s)}(T)$ (characterized by the values of l and s), over the intermolecular potential for each of the possible binary encounters in the system. For example, viscosity of a pure monatomic gas is related to $\Omega^{(2,2)}$, and the binary diffusion depends on $\Omega^{(1,1)}$. The collision integrals are determined by the dynamics of binary collisions between molecules and hence depend upon the intermolecular potential itself. All of the information about the intermolecular potential from transport coefficients is therefore contained in the collision integrals. Of the transport coefficients, the viscosity has proved the easiest to measure accurately.

The kinetic theory expression for the coefficient of viscosity of a pure dilute monatomic gas of molecular mass m at a temperature T is

$$[1] \qquad \eta = \frac{5}{16} \frac{\sqrt{m\pi kT}}{\Omega^{(2,2)}(T)} f_\eta$$

where k is the Boltzmann constant and f_η represents the higher-order correction to the first order kinetic theory approximation (8).

The temperature-dependent collision integral $\Omega^{(2,2)}$ for monatomic gases is explicitly related to $V(r)$ through the following classical mechanical expressions (9):

$$[2] \qquad \Omega^{(2,2)}(T) = \frac{1}{6(kT)^4} \int_0^\infty Q^{(2)}(E) e^{-E/kT} E^3 dE$$

$$[3] \qquad Q^{(2)}(E) = 3\pi \int_0^\infty b(1 - \cos^2 \chi) db$$

and

$$[4] \qquad \chi(b,E) = \pi - 2b \int_{r_o}^\infty \left(1 - \frac{b^2}{r^2} - \frac{V(r)}{E}\right)^{-1/2} \frac{dr}{r^2}$$

where E is the relative kinetic energy of a pair of colliding molecules, $Q^{(2)}(E)$ is a transport cross section, b is the impact parameter, χ is the scattering angle, and r_o is the classical distance of closest approach in a collision.

It is convenient to define reduced collision integrals $\Omega^{(2,2)*}(T^*)$ by

$$[5] \qquad \Omega^{(2,2)*}(T^*) = \Omega^{(2,2)}(T) / \Omega_{rs}^{(2,2)}(T)$$

where $\Omega_{rs}^{(2,2)}(T)$ is the collision integral for rigid spheres of diameter σ,

$$[6] \qquad \Omega_{rs}^{(2,2)}(T) = \pi\sigma^2$$

and the reduced temperature, T^*, is defined by $T^* = kT/\varepsilon$, where ε is the potential well depth.

The direct inversion procedure for the viscosity is based on the idea that at a given temperature the values of $\Omega^{(2,2)*}$ are determined by the potential over only a small range of separation distance around a value r_o (1, 2). For a given potential it is always possible to make this idea exact by defining a function G_η such that

$$[7] \qquad \Omega^{(2,2)*} = \pi r_o^2$$

and

$$[8] \qquad V(r_o) = G_\eta T^*$$

The parameter G_η depends almost entirely on the single variable T^* and is only weakly dependent on other features of the potential (1). Finding $V(r)$ from $\Omega^{(2,2)*}$ is straightforward when ε is unity. A reasonable potential model is chosen to start the iteration, from which trail values of $V(r_o)$ are calculated, and so on until convergence is obtained and the $\Omega^{(2,2)*}$ calculated from the potential agrees with the correlated values within some predicted limit over the available temperature range. An initial estimate of G_η is calculated from Table 1 of ref. 10. Convergence is usually obtained after only two iterations.

The inversion method based on viscosity collision integrals usually utilizes the principle of corresponding states (11, 12) for obtaining the interaction potential. It has been proved that these principles are capable of correlating the equilibrium and transport properties of noble gases, some polyatomic gases, and multi-component mixtures over a very wide temperature range with an accuracy comparable to the best measurements (11, 12).

The initial density dependence of transport properties

The physical properties of moderately dense gases may be expanded in powers of the density ρ by expressions of the form:

$$[9] \qquad X(P,T) = X_o(T) [1 + B_X(T)\rho + \ldots]$$

where $X_o(T)$ is the zero-density physical property.

For example, the pressure P and the viscosity η are expanded as

$$[10] \qquad P = \rho kT (1 + B\rho + \ldots)$$

$$[11] \qquad \eta = \eta_o (1 + B_\eta \rho + \ldots)$$

where B is the second pressure virial coefficient. η_o represents the zero-density viscosity coefficient. B_η is the second viscosity virial coefficient.

According to the theory of Rainwater and Friend (13, 14), the second transport virial coefficient, B_x (x can be viscosity (η), thermal conductivity (λ), etc.), consists of three contributions:

$$[12] \qquad B_x = B_x^{(2)} + B_x^{(3)} + B_x^{(M-D)}$$

where $B_x^{(2)}$ is the contribution of two free monomers, $B_x^{(3)}$ represents the effect of three monomers contribution, and $B_x^{(M-D)}$ is the contribution from monomer–dimer collisions.

Najafi and his colleagues (15) have calculated the second viscosity virial coefficient of the noble gases based on the Rainwater–Friend theory. Their results implied that there may be a universal function for the calculation of B_η for all noble gases at moderate densities over a wide temperature range. According to this correlation, the reduced second viscosity virial coefficient, B_η^* ($B_\eta^* \equiv B_\eta/\sigma^3$), is the universal function of $(T^*)^{-i}$ in the form of a sixth order polynomial:

[13] $B_\eta^* = \sum_{i=1}^{6} b_i(T^*)^{-i}$

where b_i is the coefficient of the universal correlation function. The values of b_i for the noble gases were given in ref. 15. The viscosity of moderately dense gases at a specified temperature and density can be calculated via the equation:

[14] $\eta = \eta_o \, (1+ N_A\sigma^3 B_\eta^* \rho)$

where N_A is Avogadro's number, σ is the collision diameter, and ρ is the density.

Najafi et al. (16) have extended eq. [17] to a very high density range (up to 40 mol dm^{-3} and 900 MPa) by the following equation:

[15] $\eta = \eta_o(1 + N_A\sigma^3 B_\eta^* \rho) + (1 + aT)^2\left(\dfrac{b_1\rho + b_2\rho^2}{1 + c_1\rho + c_2\rho^2}\right)$

where the values of parameters a, b_1, b_2, c_1, and c_2 have been given in ref. 15.

The thermal conductivity of moderately dense gases (up to 2 mol dm^{-3}) at a specified temperature and density can be calculated via the following equation (17):

[16] $\lambda = \lambda_o \, (1+ N_A\sigma^3 B_\lambda^* \rho)$

where B_λ^* is the reduced second thermal conductivity virial coefficient. Najafi et al. (17) have shown that there exists a corresponding states behavior for B_λ^* for all noble gases:

[17] $B_\lambda^* = a_o + a_1/T^*$

The values of parameters a_o and a_1 have been given in ref. 17.

The thermal conductivity of gases at high density, up to 40 mol dm^{-3}, at a specified temperature and pressure can be calculated via the following equation (17):

[18] $\lambda = \lambda_o \, (1+ N_A\sigma^3 B_\lambda^* \rho) + D_\lambda$

where D_λ is a function of the fluid density (17) and is represented by

[19] $\dfrac{D_\lambda}{\lambda^*} = \sum_{j=2,4,5,8} \mathrm{d}_j(\rho/\rho^*)^j$

where the expansion coefficients, d_j, and the coefficients λ^* and ρ^* have been given in ref. 17.

Determination of interatomic potentials via the inversion of reduced-viscosity collision integrals at zero pressure

In the previous inversion algorithms for direct determination of interaction potentials from the extended principle of corresponding states, it has been assumed that the influence

Fig. 1. Reduced potential energy function of argon by inversion of corresponding states reduced-viscosity collision integrals (▲) (21) and by inversion of reduced-viscosity collision integrals at zero pressure (□). The solid curve is the Aziz and Slaman potential (19).
of the initial density dependence of transport properties is small and negligible in comparison with the uncertainties associated with the experimental methods (1–4, 18). In other words, the framework of the law of corresponding states (11, 12) is based on experimental values at relatively low densities, since values at zero density are not accessible to direct measurements. In principle, such an assumption cannot be accepted because the difference between the zero density and the atmospheric viscosity data is not always negligible, especially at low temperatures.

The reduced-viscosity collision integral at zero pressure, $\Omega_o^{(2,2)*}$, can be obtained by inserting eq. [1] into eq. [14]:

[20] $\dfrac{1}{\sigma_{cs}^2 \Omega_{cs}^{(2,2)*}} = \dfrac{[1 + N_A\sigma^3 B_\eta^* \rho]}{\sigma_o^2 \Omega_o^{(2,2)*}}$

where σ_{cs} and $\Omega_{cs}^{(2,2)*}$ have their usual meanings and are taken from a corresponding states correlation (11). σ_o is the corresponding value of an accurate potential (19, 20).

The $\Omega_o^{(2,2)*}$ can be used to determine the interaction potential by an inversion procedure as described above. One of the peculiar feature of the inversion procedure is that it identifies a point on the experimental $\Omega^{(2,2)}$ vs. T curve with a single point on the $V(r)$ vs. r curve. The inversion method based on viscosity collision integrals usually utilizes the principle of corresponding states for obtaining the interaction potential. In this work, we have used the extended principle of corresponding states (12) to obtain the viscosity collision integrals, $\Omega_{cs}^{(2,2)*}$, and then using eq. [20] the collision integrals at zero pressure, $\Omega_o^{(2,2)*}$, can be obtained.

Results

The potential energy functions of argon, krypton, and xenon have been obtained using the inversion of the reduced-viscosity collision integrals at zero pressure. A comparison of these potentials with the previously determined potentials (19–23) are included (Figs. 1–3). These accurate potentials can be used to obtain the kinetic-theory collision integrals needed to calculate transport properties other than viscosity. The most commonly needed collision integrals and their ratios for argon, krypton, and xenon at zero pressure are given in Tables 1–3.

The accurate tables of the viscosity and thermal conductivity for argon, krypton, and xenon have been generated in the temperature range from the normal boiling point of the relevant gas up to 5000 K for zero density and for different pressures. The results are summarized in Tables 4 and 5, including the pressure range, P_{min}–P_{max}, and the temperature range, T_{min}–T_{max}, along with the minimum and maximum percent deviation of the calculated values from their corresponding literature values.

Concluding remarks

As Figs. 1 to 3 show, there exists a good agreement between the potentials calculated by the inversion of corre-

dominate, since the density dependence of viscosity is very significant at low temperatures. Therefore, the potentials obtained in this work are superior representations to those provided by the inversion of the corresponding states reduced-viscosity collision integrals (21–23).

The results show that the density dependence of the viscosity is much weaker at higher temperature. This is due to the diminishing of the monomer–dimer contribution and the near cancellation of the two-monomer and three-monomer contributions at high temperatures (15).

From the present results, we can draw some important conclusions:

1. The remarkable feature of the inversion method employed in this work is that the specific information about potential energy function is obtained using experimental data directly without assuming a functional form for the potential.

The present potentials for argon, krypton, and xenon provide a good overall account of the experimental properties of these compounds, considering the stated uncertainty in their measurements.

2. The present paper provides the collision integrals and their ratios for argon, krypton, and xenon at zero density, for which one would need to calculate the transport coefficients of these compounds in the moderate and high densities ranges, at any temperature, in a predictive mode, within experimental errors.

4. This work results in much greater confidence in the precision and (or) accuracy of transport coefficients in the moderately and highly dense regions of argon, krypton, and xenon than those found in previous, similar works (21–23).

Synthesis, characterization, and molecular structures of nitrosyl nitrito complexes of osmium porphyrins: Disproportionation of nitric oxide in its reaction with Os(P)(CO) (P = porphyrinato dianion)

Felipe A. Leal, Ivan M. Lorkovic, Peter C. Ford, Jonghyuk Lee, Li Chen, Lindsey Torres, Masood A. Khan, and George B. Richter-Addo

Abstract: The Os(P)(NO)(ONO) compounds (P = TTP, TMP, OEP, TmTP; TTP = 5,10,15,20-tetra-*p*-tolylporphyrinato dianion, TMP = 5,10,15,20-tetramesitylporphyrinato dianion, OEP = octaethylporphyrinato dianion, TmTP = tetra(*m*-tolyl)porphyrinato dianion) have been prepared from the reaction of the precursor carbonyl complexes Os(P)(CO) with excess nitric oxide. Nitrous oxide was detected as a by-product of the reaction. The IR spectra of the Os(P)(NO)(ONO) compounds (as KBr pellets) reveal bands in the 1790–1804 cm^{-1} range that are assigned to υ_{NO}. The IR spectra also reveal two new bands for each complex in the 1495–1531 and 913–962 cm^{-1} ranges indicative of O-bound nitrito ligands. The linearity of the bound NO groups and the O-binding of the *trans* nitrito ligands in the Os(P)(NO)(ONO) complexes are evident in the single-crystal X-ray crystal structures of the TTP and TMP derivatives. The kinetics of the reaction were studied by stopped-flow mixing techniques. Spectroscopic analysis of rapidly mixed solutions of Os(P)CO and NO in toluene showed a biphasic approach to the Os(P)(NO)(ONO) and N$_2$O products, owing to the starting material Os(P)CO scavenging CO formed during the reaction to give Os(P)(CO)$_2$ ($K_{CO} = 10^6$ M^{-1}). The dicarbonyl was the only transient species observed. It is proposed that the rate-determining step of the reaction leading to Os(P)(NO)(ONO) is NO displacement of CO from Os(P)(CO) via initial formation of an unstable 19 electron Os(P)(NO)(CO) intermediate.

Key words: osmium, nitric oxide, X-ray, nitrosyl, porphyrin, kinetics.

Résumé : Les composés du type Os(P)(NO)(ONO), où P = TTP, TMP, OEP, TmTP; TTP= le dianion 5,10,15,20-tétra-*p*-tolylporphyrinato, TMP = le dianion 5,10,15,20-tétramésitylporphyrinato, OEP = le dianion octaéthylporphyrinato, TmTP = le dianion tétra(*m*-tolyl)porphyrinato, ont été préparés à partir de la réaction des complexes carbonylés précurseurs OS(P)(CO) en présence d'un excès d'oxyde nitrique. On a détecté l'oxyde nitreux comme produit secondaire de la réaction. Les spectres IR des composés Os(P)(NO)(ONO) (sous forme de pastilles de KBr) révèlent des bandes dans la région de 1790–1804 cm^{-1} que l'on attribue à la vibration υ_{NO}. Les spectres IR révèlent également, pour chaque complexe, deux nouvelles bandes dans les régions : 1495–1531 et 913–962 cm^{-1} caractéristiques des ligands nitrito liés par l'oxygène. La linéarité des liens des groupes NO et le lien impliquant l'oxygène des ligands nitrito *trans* dans les complexes Os(P)(NO)(ONO) apparaissent clairement dans les structures des dérivés TTP et TMP déterminées par cristallographie de rayons X sur un monocristal. On a étudié la cinétique de la réaction par les techniques de mélange à flux stoppé. L'analyse spectroscopique des solutions OS(P)CO et de NO rapidement mélangées dans le toluène montrent une approche biphasique aux produits Os(P)(NO)(ONO) et N$_2$O à cause du produit de départ OS(P)CO qui piège le CO formé au cours de la réaction pour donner le OS(P)(CO)$_2$ ($K_{CO} = 10^6$ M^{-1}). Le composé dicarbonylé est la seule espèce transitoire observée. On suggère que l'étape déterminante de la réaction conduisant au Os(P)(NO)(ONO) est le déplacement du CO par NO à partir du OS(P)(CO) via la formation initiale d'un intermédiaire instable Os(P)(NO)(CO) à 19 électrons.

Mots clés : osmium, oxyde nitrique, rayons X, nitrosyle, porphyrine, cinétique.

Introduction

Metalloporphyrin-induced NO→N$_2$O conversions are very important biologically in the global nitrogen cycle (1). For example, nitric oxide reductase cytochrome P450nor from the fungus *Fusarium oxysporum* reduces NO to N$_2$O, and the enzyme contains heme at the active site (2, 3). The bacterial nitric oxide reductase from *Paracoccus denitrificans* also contains heme at the dinuclear active site and catalyzes the reduction of NO to N$_2$O (4, 5). The subject of biological NO reduction has been recently reviewed (1).

Heme-dependent NO oxidations are gaining widespread recognition in the chemistry of NO. For example, some flavohemoglobins have recently been described as NO dioxygenases (6, 7). Metal-assisted NO→NO$_2$ conversions are also important in the biological and urban environment. In particular, knowledge of the efficiency of metal-assisted conversions of NO → N$_x$O$_y$ is an essential component in the design of catalytic converters for automobile engines (8). While the mechanisms of such conversions are not known with certainty, synthetic metal complexes that catalyze the formation of NO$_2$ (bound or free) from NO and vice versa, as well as the structures of metal–NO$_2$ coordination complexes, are of interest in this regard. In some instances, the addition of oxygen (or air) to the metal–NO precursor is necessary for the production of the metal–NO$_2$ complex. We recently demonstrated such a metal–NO to metal–NO$_2$ conversion using an iron nitrosyl porphyrin (9). Other metalloporphyrin–NO complexes of Co and Rh have been shown to behave similarly (10, 11).

There are many examples of non-heme transition metal complexes that promote NO disproportionation to give metal nitrite derivatives and N$_2$O (12). However, we have found that ferrous porphyrins do *not* promote NO disproportionation in the absence of oxygen; they react with NO to produce only mononitrosyl or weakly bound dinitrosyl complexes (13). The apparently contradictory results concerning the ability of iron porphyrins to promote the disproportionation of NO (in the presence or absence of trace air) are discussed in ref. 14. Iron porphyrin nitrite complexes containing the N-bound nitrite ligand are known, and their solid-state structures have been reviewed (15). We reported that ruthenium porphyrins react with NO *in the absence of oxygen* to produce the nitrosyl nitrito complexes Ru(P)(NO)(ONO) and N$_2$O (16–18), and we spectroscopically characterized a *trans*-dinitrosyl intermediate Ru(P)(NO)$_2$ during this NO disproportionation reaction (19, 20). The occurrence of NO disproportionation with ruthenium, but not with iron, led us to extend these studies to the osmium porphyrin congeners.

In this paper, we show that osmium porphyrins react with NO to give nitrosyl nitrito products with the release of N$_2$O. Solid-state molecular structures for two of these nitrosyl nitrito products have been obtained and, to the best of our knowledge, represent the first published osmium nitrito X-ray crystal structures to be reported. While the products are analogous to those found for the reaction of NO with similar ruthenium porphyrins Ru(P)(CO) (19, 20), unlike the ruthenium analogues, reactions of NO with Os(P)(CO) proceed without the generation of observable nitrosyl-containing intermediates. Instead, the CO released from reaction of NO with Os(P)(CO) is scavenged by the remaining Os(P)(CO) to give the dicarbonyl complex Os(P)(CO)$_2$ in a "dead-end" equilibrium. The latter eventually is also converted to Os(P)(NO)(ONO).

Experimental section

All reactions were performed under an atmosphere of prepurified nitrogen using standard Schlenk glassware and (or) in an Innovative Technology Labmaster 100 Dry Box. Solutions for spectral studies were also prepared under a nitrogen atmosphere. Solvents were distilled from appropriate drying agents under nitrogen just prior to use: benzene (Na), toluene (Na or CaH$_2$), hexane, chloroform, and cyclohexane (CaH$_2$).

Chemicals

The Os(P)(CO) compounds were prepared by literature methods (P = TTP, TMP, OEP, TmTP; TTP = 5,10,15,20-tetra-*p*-tolylporphyrinato dianion, TMP = 5,10,15,20-tetramesitylporphyrinato dianion, OEP = octaethylporphyrinato dianion, TmTP = tetra(*m*-tolyl)porphyrinato dianion) (21). Os(OEP)(CO) was also purchased from Midcentury Chemicals. Chloroform-*d* (99.8%) was obtained from Cambridge Isotope Laboratories. Nitric oxide (98%, Matheson Gas) for the synthesis work was passed through KOH pellets and two cold traps (dry ice–acetone, –78°C) to remove higher nitrogen oxides. For experiments involving detection of evolved N$_2$O, NO was purified as described elsewhere (14).

Instrumentation

Infrared spectra were recorded on a Bio-Rad FT-155 FT-IR spectrometer. ^{1}H NMR spectra were obtained on Varian 300 MHz or 400 MHz spectrometers and the signals referenced to the residual signal of the solvent employed. All coupling constants are in Hz. FAB mass spectra were obtained on a VG-ZAB-E mass spectrometer.

Preparation of Os(TTP)(NO)(ONO)

A Schlenk flask was charged with Os(TTP)(CO) (0.055 g, 0.062 mmol) and benzene (30 mL). The mixture was stirred to generate an orange-red solution, and NO gas was then bubbled through the solution for ~15 min. The solvent was removed in vacuo, and the residue was redissolved in benzene (10 mL) and filtered through a neutral alumina column (1.5 × 15 cm). The red band was collected and dried in vacuo. The product was further purified by crystallization from a toluene–hexane mixture at –20°C to give Os(TTP)(NO)(ONO) (0.025 g, 0.027 mmol, 43% isolated yield). IR (KBr) (cm^{-1}): υ_{NO} = 1804 (s), υ_{ONO} = 1528 (m), 921 (m). ^{1}H NMR (CDCl$_3$) δ: 9.00 (s, 8H, *pyrrole*-H of TTP), 8.15 (d, *J* = 8 Hz, 4H, *o*-H of TTP), 8.05 (d, *J* = 8 Hz, 4H, *o'*-H of TTP), 7.56 (app t (overlapping d's), 8H, *m/m'*-H of TTP), 2.70 (s, 12H, C*H*$_3$ of TTP). Low-resolution FAB-MS *m/z* (%): 906 ([Os(TTP)(ONO)]$^+$, 15%), 890 ([Os(TTP)(NO)]$^+$, 100%), 860 ([Os(TTP)]$^+$, 18%). This compound was prepared previously in low yield from the reaction of Os(TTP)(NO)(S-*i*-C$_5$H$_{11}$) with excess NO (22).

Preparation of Os(TMP)(NO)(ONO)

A Schlenk flask was charged with Os(TMP)(CO) (0.082 g, 0.082 mmol) and benzene (30 mL). The mixture was stirred to generate a dark orange-red solution, and NO gas was then bubbled through the solution for 30 min. During this time, the color of the reaction mixture turned bright red. The solvent was removed in vacuo, and the residue was redissolved in benzene (15 mL) and filtered through a neutral alumina column (2×20 cm). The red band was collected, and the filtrate was dried in vacuo to give Os(TMP)(NO)(ONO) (0.077 g, 0.073 mmol, 90% isolated yield). IR (KBr) (cm^{-1}): ν_{NO} = 1799 (s), ν_{ONO} = 1531 (m), 919 (m). ^{1}H NMR (CDCl$_3$) δ: 8.77 (s, 8H, *pyrrole*-H of TMP), 7.29 (s, 4H, *m*-H of TMP), 7.26 (s, 4H, *m'*-H of TMP), 2.62 (s, 12H, *p*-C*H*$_3$ of TMP), 1.95 (s, 12H, *o*-C*H*$_3$ of TMP), 1.69 (s, 12H, *o'*-C*H*$_3$ of TMP). Low-resolution FAB-MS *m/z* (%): 1048 ([Os(TMP)(NO)(ONO)]$^+$, 6%), 1019 ([Os(TMP)(ONO) + H]$^+$, 43%), 1002 ([Os(TMP)(NO)]$^+$, 100%), 972 ([Os(TMP)]$^+$, 13%).

The following two compounds were also prepared similarly.

Os(OEP)(NO)(ONO)

43% isolated yield. IR (KBr) (cm^{-1}): ν_{NO} = 1790 (s), ν_{ONO} = 1495 (m), 962 (s br (overlap with porphyrin band)). ^{1}H NMR (CDCl$_3$) δ: 10.41 (s, 4H, *meso*-H of OEP), 4.16 (q, *J* = 8 Hz, 16H, C*H*$_2$CH$_3$ of OEP), 2.00 (t, *J* = 8 Hz, 24H, CH$_2$C*H*$_3$ of OEP). This compound has similar spectral properties to a compound formulated as Os(OEP)(NO)$_2$ (23).

Os(TmTP)(NO)(ONO)

This compound was obtained in 95% yield (by ^{1}H NMR spectroscopy) when the reaction was performed in dry toluene or methylcyclohexane and in 25% yield (by ^{1}H NMR spectroscopy) when performed in CH$_2$Cl$_2$. The compound was further purified by chromatography over silica gel using a pentane–CH$_2$Cl$_2$ (2:1) solvent mixture. IR (KBr) (cm^{-1}): ν_{NO} = 1803 (s), ν_{ONO} = 1528 (m), 913 (m). IR (cyclohexane) (cm^{-1}): ν_{NO} = 1805 (s), ν_{ONO} = 1540 (m). ^{1}H NMR (CDCl$_3$) δ: 9.02 (s, 8H, *pyrrole*-H of TmTP), 8.10 (m, 4H, *o*-H of TmTP), 7.99 (m, 4H, *o'*-H of TmTP), 7.50–7.60 (m, 8H, *m/p*-H of TmTP), 2.66 (s, 6H, C*H*$_3$ of TmTP), 2.62 (s, 6H, C*H*$_3$ of TmTP).

Kinetics experiments

NO was plumbed via stainless steel lines through a stainless steel column of Ascarite (Thomas Scientific) to scrub out NO$_2$ and (or) N$_2$O$_3$. When desired, the N$_2$O impurity was removed by passage of NO through a cold (–78°C) activated silica column (6' $\times$ 1/4" i.d. stainless steel, Alltech). NO was quantified manometrically using known solubilities in toluene and cyclohexane (24) and transferred cryogenically to desired reaction flasks of known total volume and solution volume fitted with Teflon high vacuum stopcocks. Infrared solution spectra were recorded in amalgam-sealed cells with CaF$_2$ windows (ICL) on a Bio-Rad FTS-60 FT-IR

instrument. Stopped-flow mixing experiments were performed on an Applied Photophysics SX17-MV instrument with custom made tonometers (20) for NO solution preparation and transfer to drive syringes. Flow IR experiments were performed with a home-built, manually actuated stopped-flow mixing apparatus utilizing gas tight syringes (Hamilton 5 mL) and PEEK tubing, valves, and fittings (Upchurch), connected after mixing to a standard amalgam-sealed CaF$_2$ cell inserted into the FT-IR instrument. To avoid back-pressure-induced IR cell rupture, the stop syringe was disconnected and the output directed to a waste container. FT-IR spectra showing intermediate species in the reaction of Os(P)(CO) with NO were obtained by a single interferometric scan during constant flow of freshly mixed (aging time ~0.2 s) solutions through the cell.

CO binding equilibrium constant measurements

Carbon monoxide (Praxair, 99.5%) was added by gas-tight syringe to toluene solutions (~5 mL) of Os(OEP)(CO) and Os(TmTP)(CO) (~8 μM) under Ar (P_T = 760 torr (1 torr = 133.322 Pa)) within special cuvette cells (~70 mL total volume) at 21 ± 1°C. [CO] was calculated from the known solubility of CO in toluene (25) and the known volume of solution and headspace. Under these conditions the [CO] may be less than [Os] within the solution, but the total amount of CO within the closed system of the cell is always at least ten times greater than the amount of Os in the solution, and therefore [CO] may be considered to be constant, independent of the extent of reaction.

Structural determinations by X-ray crystallography

Crystal data were collected on a Siemens (Bruker) P4 diffractometer using monochromated Mo Kα radiation (λ = 0.71073 Å).[3] The data were corrected for Lorentz and polarization effects, and empirical absorption corrections based on ψ-scans were applied (26). The structures were solved by the heavy atom method using the SHELXTL 5.03 (Bruker) system and refined by full-matrix least squares on F^2 using all reflections (SHELXL-93). The thermal ellipsoids in Figs. 1 and 2 are drawn at the 35% probability level. Details of the crystal data and refinement are given in Table 1.

Os(TTP)(NO)(ONO)·toluene

A suitable crystal for structure determination was grown by recrystallization of the compound from toluene–hexane at –20°C. All the non-hydrogen atoms were refined anisotropically except the atoms (C25–C33) belonging to the disordered toluene molecules, which were refined isotropically. Hydrogen atoms were included in the refinement with idealized parameters; the hydrogen atoms for the disordered solvent molecules were not included.

Considerable difficulty was encountered during the refinement because of the disorder of the Os atom and the atoms belonging to the axial groups and the solvent molecules. The structure was solved initially in the non-centric space group *Cc* and gave very poor refinement with unreasonable N—O

Fig. 1. (*a*) Molecular structure of Os(TTP)(NO)(ONO). Hydrogen atoms have been omitted for clarity. Only one of the two disordered positions of the Os atom and the NO and ONO groups is shown; (*b*) View of the orientation of the nitrito ligand relative to the porphyrin skeleton. The porphyrin tolyl substituents and the *trans* NO ligand have been omitted for clarity.

(*a*)

(*b*)
and O—N—O bond lengths and several non-positive definite temperature factors. The structure was then solved and refined in the centric space group *C*2/*c*, where the molecule lies on the inversion center and only half of the molecule is unique. Thus, the axial NO and ONO groups are disordered over both sides of the porphyrin plane. The initial refinement used a model in which the Os atom was placed on a special position at the inversion center. This model gave elongated thermal ellipsoids for the Os atom, and the Os—N3 and Os—O2 distances were unreasonable. Finally, the Os atom was allowed to refine out of the porphyrin plane towards the NO ligand (0.241(3) Å out of the 24-atom mean porphyrin plane). In the final model, the Os atom and the NO and ONO groups are completely disordered over two sites. In addition to the disorder of the molecule, the crystal lattice contains two sites with partially disordered toluene solvent molecules. One of these toluene solvent sites is 50% populated, and the other site is also 50% populated; disorder at these sites results in the two sites having only 25% occupancy. The toluene solvent molecules were refined isotropically because of this disorder, and hydrogen atoms for these molecules were not included in the refinement. SHELXTL restraints (ISOR, DELU, SIMU, and DFIX) were needed to stabilize the refinement. The final values of $R_1 =$
0.0583 for 3651 "observed reflections" [$I > 2\sigma(I)$] and $wR_2 = 0.1665$ for all reflections (4421 unique data) were obtained.

Os(TMP)(NO)(ONO)·3(benzene)

Suitable crystals for X-ray crystallography were grown by slow evaporation of a benzene solution of the compound at room temperature under inert atmosphere. All the non-hydrogen atoms were refined anisotropically, and the hydrogen atoms were included in the refinement with idealized parameters. The asymmetric unit contains one molecule of Os(TMP)(NO)(ONO) and three molecules of benzene. The Os atom and the NO and ONO groups are disordered over two sites along the axial direction. In addition, one of the benzene solvent molecules is disordered over two sites. Attempts to refine the two fragments did not yield a stable refinement. Thus, the geometry of the two fragments was idealized in the final cycles of refinement, and the thermal parameters were fixed at the values obtained from the earlier refinement cycles. The final values of $R_1 = 0.0374$ for 8660 "observed reflections" [$I > 2\sigma(I)$] and $wR_2 = 0.1036$ for all reflections (10 961 unique data) were obtained.

Os(OEP)(NO)(ONO)

Both laboratories have independently crystallized this compound. Although we have not been able to grow high-

quality, good-sized crystals, the results of separate preliminary X-ray crystallographic analyses (by both laboratories) on the crystals obtained to date unambiguously confirm the nitrosyl nitrito Os(OEP)(NO)(ONO) formulation.

Results and discussion

We reported that the Ru(P)(CO) compounds (P = OEP, TPP, TmTP) react with NO in solution to give the nitrosyl nitrito complexes Ru(P)(NO)(ONO) and N_2O as the final products (16, 17, 19, 20). Using similar methodologies, we have prepared the nitrosyl nitrito complexes of osmium porphyrins. Thus, the reaction of Os(TTP)(CO) with NO in benzene at ambient temperature for ~15 min gives, after workup, the nitrosyl nitrito product Os(TTP)(NO)(ONO) in 43% isolated yield. The product is soluble in dichloromethane, benzene, and toluene, but is insoluble in hexane. The IR spectrum of Os(TTP)(NO)(ONO) (as a KBr pellet) reveals a band at 1804 cm^{-1} assigned to υ_{NO}. This υ_{NO} band is of higher frequency than the corresponding bands for the alkoxide complex Os(TTP)(NO)(O-i-C_5H_{11}) (1770 cm^{-1}) (22), the thiolate derivative Os(TTP)(NO)(S-i-C_5H_{11}) (1760 cm^{-1}) (22), and the organometallic compound Os(TTP)(NO)Me (1732 cm^{-1}) (27). In addition, the IR spectrum indicates new bands at 1528 and 921 cm^{-1} due to the O-bound nitrito ligand (28).

The ^{1}H NMR spectrum of Os(TTP)(NO)(ONO) (in CDCl$_3$) reveals peaks due to the pyrrole protons of the porphyrin macrocycle (at δ 9.00) and the tolyl substituents. The inequivalence of the *ortho* protons of the tolyl substituents suggests restricted rotation of the tolyl groups in this unsymmetrical Os(P)(NO)X compound; such a feature of restricted rotation is not uncommon for *p*-substituted tetraphenyl-

porphyrin complexes of the form M(P)(X)(Y) (29, 30). The FAB mass spectrum of Os(TTP)(NO)(ONO) reveals peaks due to loss of the NO and (or) ONO ligands.

We were also able to prepare other nitrosyl nitrito complexes of the type Os(P)(NO)(ONO), where P = TMP, OEP, and TmTP. The IR spectra of the complexes (as KBr pellets) reveal their nitrosyl υ_{NO} bands at 1803 cm^{-1} (TmTP), 1799 cm^{-1} (TMP), and 1790 cm^{-1} (OEP), reflecting the increasing electron donor properties of the porphyrin macrocycles along the series TTP $\cong$ TmTP < TMP < OEP, as expected. The TMP, OEP, and TmTP derivatives also show medium intensity bands assignable to nitrito υ_{N-O}. The N_2O gaseous by-product formed during the reaction was identified by IR spectroscopy as described previously (19).

Solid-state molecular structures

As mentioned in the Introduction, no X-ray crystal structures of osmium nitrito complexes had been reported prior to our study. Interestingly, there is only a single report of an osmium nitro (i.e., η^1-N bound) structure in the literature, namely that for Os(H_2L)(PPh$_3$)$_2$(CO)(η^1-NO$_2$)·H_2O (L = 3-ethyliminio-5-methyl-2-oxidophenyl-C^1,O) (31), although some bridging nitro moieties [Os-N(O)O-Os] have been characterized by crystallography (32–34).

We were successful in obtaining suitable crystals of two of the Os(P)(NO)(ONO) compounds for single-crystal X-ray diffraction studies. The solid-state molecular structure of Os(TTP)(NO)(ONO) is shown in Fig. 1*a*, and the axial nitrito ligand conformation is shown in Fig. 1*b*. As is evident in Fig. 1, the ONO group is bound to the Os center through an O-atom, and the ONO group essentially bisects adjacent porphyrin nitrogen atoms, with an N2-Os-O2-N4 torsion angle of 33° (Fig. 1*b*). The molecular structure of the related

Fig. 3. Structural data for Os(TTP)(NO)(ONO) and Os(TMP)(NO)(ONO). Selected bond lengths and angles are shown in the top sketches. Perpendicular atom displacements from the 24-atom porphyrin planes (in 0.01 Å units) are shown in the bottom sketches.

(*a*) Os(TTP)(NO)(ONO)
(*b*) Os(TMP)(NO)(ONO)
1st disordered component
(*c*) Os(TMP)(NO)(ONO)
2nd disordered component

axial N-Os-O = 175.0(3)°
axial N-Os-O = 178.5(2)°

axial N-Os-O = 178.7(2)°

Os(TMP)(NO)(ONO) is shown in Fig. 2. In this compound, the nitrito ligand is also bound to osmium through an O-atom, and the ONO ligand essentially bisects adjacent porphyrin nitrogens, with an N1-Os-O1-N6 torsion angle of 46°. Selected bond lengths and angles for both compounds and atom displacements from the 24-atom mean porphyrin planes are displayed in Fig. 3.

There are several features to note from these solid-state structures. First, the nitrosyl Os-NO groups are essentially linear. Second, the Os atoms are displaced from the 24-atom mean porphyrin plane *towards* the axial NO ligand; 0.24 Å for the TTP compound and 0.22 Å (or 0.15 Å for the second disordered component) for the TMP compound. Third, the bond lengths within the nitrito ligand are consistent with the Os-O-N=O formulation; thus, the O—N bond lengths are longer than the nitrito N=O bond lengths. Surprisingly, this is not always the case for metal nitrito crystallographic data. Selected structural data for M(NO)(ONO)-containing complexes reported to date are collected in Table 2. However, there is little consistency in the reported bond lengths involving the ONO ligand, and this may be partly because of the fact that many of these structures suffer from ligand disorder problems.

Proposed reaction pathway for the formation of nitrosyl nitrito species

UV–vis spectroscopic monitoring of the reaction of a dilute solution of Os(OEP)(CO) in toluene with NO (Fig. 4, top) reveals an apparent clean conversion of Os(OEP)(CO) to Os(OEP)(NO)(ONO). Stopped-flow experiments monitored at several single-wavelengths suggest that the reaction is biphasic, involving the formation of a transient species with spectral features similar but not identical to that of Os(OEP)(CO) (Fig. 4, bottom and inset). Within a few seconds, this intermediate spectrum gives way to that of the final Os(OEP)(NO)(ONO) product. Isosbestic points for the slower and faster processes are observed at 536 and 553 nm and therefore the faster and slower processes may be individually followed at these monitoring wavelengths. Under these conditions, the reactions appeared to be first order with the respective rate constants $k_{obs}(536) = 7 \pm 1$ s^{-1} (fast) and $k_{obs}(553) = 0.7 \pm 0.1$ s^{-1} (slow). Analogous UV–vis spectral features are observed for the TmTP derivative as well.

To gain further insight into these processes, stopped-flow mixing experiments coupled with FT-IR spectroscopic detection were performed on the more soluble TmTP and OEP derivatives. The FT-IR difference spectrum of the solution

obtained from the reaction of Os(TmTP)(CO) in cyclohexane with NO (Fig. 5, top) revealed, in addition to Os(TmTP)(CO) (υ_{CO} 1924 cm^{-1}) and the final product Os(TmTP)(NO)(ONO) (υ_{NO} 1805 cm^{-1}; υ_{ONO} 1540 cm^{-1}), a new species displaying a strong band at 1974 cm^{-1}.

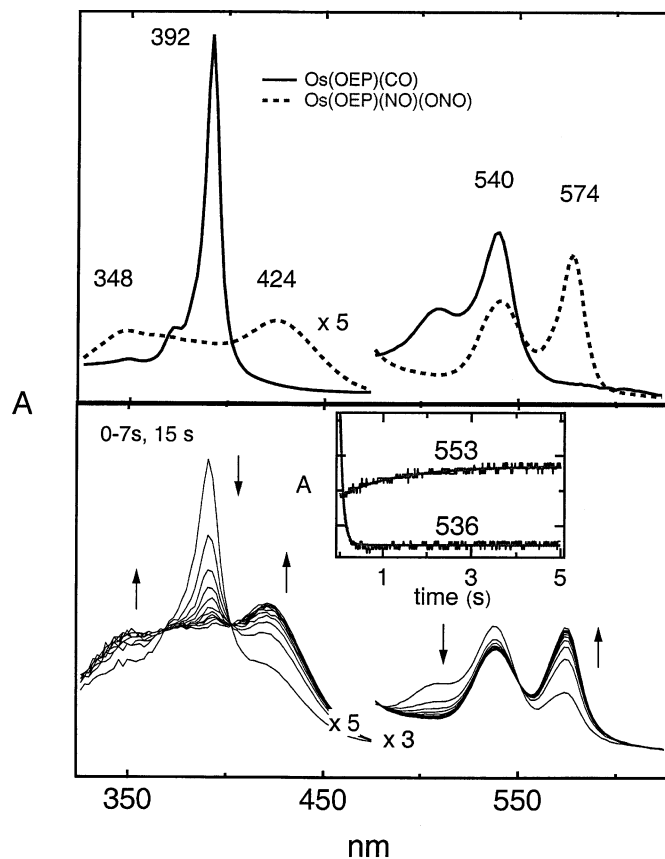
Since the independent reaction of Os(TmTP)(CO) with added CO gave a new species displaying a υ_{CO} band at 1974 cm^{-1} twice as intense as that of Os(TmTP)(CO) (Fig. 5, bottom), we assign this band to the *trans* dicarbonyl complex Os(TmTP)(CO)$_2$. Therefore, its appearance as a transient in the reaction of NO with Os(TmTP)(CO) can be attributed to the Os(TmTP)(CO) scavenging the CO released during the reaction.

Formation of the dicarbonyl complexes Os(P)(CO)$_2$ (eq. [1]) was studied independently in toluene by probing optical spectrum changes upon addition of CO to toluene solutions of Os(P)(CO) (e.g., Fig. 6). In this manner the equilibrium constants $K_2 = 0.9 \pm 0.2 \times 10^6$ and $1.0 \pm 0.2 \times 10^6$ M^{-1} were determined for P = TmTP and OEP, respectively. The latter value is ~10^2 larger than that observed for the corresponding Ru(OEP)(CO) complex (1.1×10^4 M^{-1}) (20).

[1]   Os(P)(CO) + CO ↔ Os(P)(CO)$_2$

The high affinity of Os(P)(CO) for CO explains the detection of Os(P)(CO)$_2$ as a transient in the stopped-flow experiment described above. No other species with distinctive IR spectral signatures, such as expected for Os–nitrosyl intermediates, were detected during the stopped-flow study of the reaction of Os(P)(CO) with NO. This is in sharp contrast to the analogous reaction of Ru(P)(CO) with NO where the dinitrosyl complex Ru(P)(NO)$_2$ was a spectroscopically observable intermediate (20). Given that under the reaction conditions [NO] is always much greater than [CO], detecting Os(P)(CO)$_2$ as the only transient suggests that K_2 for CO binding to Os(P)(CO) is at least four orders of magnitude larger than the equilibrium constant for analogous binding of NO.

Scheme 1 is a proposed explanation for these kinetics and spectral observations during the formation of Os(P)(NO)(ONO) from Os(P)(CO) and NO. This is based largely on the behavior of the ruthenium analogues for which the dinitrosyl intermediate Ru(P)(NO)$_2$ was observed (19, 20). The initial step is very likely the reversible and endergonic formation of the 19-electron complex Os(P)(CO)(NO). Upon rate-limiting CO dissociation from Os(P)(CO)(NO), a rapid sequence of steps would lead to the disproportionation products. However, CO is also a product, and it will be rapidly scavenged by Os(P)(CO) to give the much less reactive Os(P)(CO)$_2$ in a dead-end equilibrium. Thus, the reaction slows, owing to the lower effective concentration of Os(P)(CO). Since no other transient species

Fig. 4. *Top*: UV–vis spectra of the reactant Os(OEP)(CO) in toluene and the product of its reaction with nitric oxide, Os(OEP)(NO)(ONO). *Bottom*: Spectral changes upon stopped-flow mixing of a solution of Os(OEP)(CO) (10 μM after mix) with nitric oxide (5 mM after mix). The stacked plot shows no obvious intermediate, but single wavelength observation shows evidence for a fast (7 s^{-1}) and a slow (0.7 s^{-1}) process in this reaction. However, the two stages in the kinetics suggest the formation of an intermediate in solution whose spectrum is very similar to that of the starting solution.


Scheme 1.
Fig. 5. *Top*: Difference FT-IR spectrum of the solution obtained by mixing solutions of Os(TmTP)(CO) (~100 μM in cyclohexane after mix) with NO (~4 mM in cyclohexane after mix). The difference spectra shown are the result of subtracting the spectrum of the final product solution. Therefore, the υ_{NO} at 1805 cm^{-1} and υ_{ONO} at 1540 cm^{-1} for the product Os(TmTP)(NO)(ONO) are seen as negative peaks. The only observable new species in this reaction is the dicarbonyl Os(TmTP)(CO)$_2$ identified by its peak at 1974 cm^{-1} (see below). The peak marked with an asterisk is a cyclohexane subtraction artifact and that marked "x" is suspended insoluble Os(TmPP)(CO). *Bottom*: Difference infrared spectrum of Os(TmTP)(CO)$_2$ in cyclohexane after CO addition to a solution of Os(TmTP)(CO), minus the spectrum observed prior to CO addition. The new species shows a single carbonyl band at 1974 cm^{-1} that is twice as intense as that for the monocarbonyl (at 1924 cm^{-1}), consistent with a *trans*-dicarbonyl structure.
were observed in the stopped-flow IR experiments, we conclude that likely intermediates along the productive pathway — for example, the dinitrosyl Os(P)(NO)$_2$ — are too reactive to build to detectable steady-state concentrations.

This scheme would explain the observation of the two-stage kinetics observed under a large excess of NO. Initially all the osmium carbonyl is in the monocarbonyl form, and the reaction proceeds rapidly. Since the fast reaction was monitored near the Os(P)(CO)–Os(P)(CO)$_2$ isosbestic point (Fig. 6), this will show (pseudo) first order kinetics for the

Fig. 6. Measurement of the equilibrium constant for the reaction of CO with Os(OEP)(CO) in toluene. The inset shows a Lineweaver–Burke fit for the spectral change induced by addition of CO aliquots to a dry toluene solution of Os(OEP)(CO) (~10 µM). The total amount of CO (most of which is contained in the headspace but in equilibrium with that in solution) available for the equilibrium reaction is much greater than the total amount of Os in the solution. Thus, [CO] in solution can be approximated as being constant, although it is much lower than [Os]. The measured equilibrium constant is $1.0 \pm 0.2 \times 10^6$ M^{-1}.
absorbance changes due to reaction along the productive pathway to give Os(P)(NO)(ONO) (reaction of Os(P)(CO) with the released CO is not observed owing to the isosbestic behavior at that wavelength). Once most of the remaining osmium carbonyl is sequestered as the dicarbonyl, further reaction will be slower, owing to the low steady-state concentration of the monocarbonyl. Consistent with this interpretation is the qualitative observation that the overall reaction is dramatically slowed in the presence of excess added CO. The slow second stage observed in the absence of added CO also appeared to follow first order kinetics; however, this may result from a fortuitous combination of conditions, since the continued production of CO should make the reaction auto-inhibitory.

Conclusion

We have successfully prepared several nitrosyl nitrito complexes of the form Os(P)(NO)(ONO) from the reaction of the precursor carbonyl complexes Os(P)(CO) with nitric oxide. Single-crystal X-ray crystallographic studies of two of these compounds confirm the O-binding modes of the nitrito ligands. To the best of our knowledge, these are the first X-ray crystal structures of osmium nitrito moieties to be reported.

Results from stopped-flow kinetics studies of the reactions suggest a mechanism in which initial adduct formation between Os(P)(CO) and NO is followed by a rate-determining replacement of CO by a second NO molecule. Subsequent reaction with more NO leads to an effective NO disproportionation to give the final nitrosyl nitrito product Os(P)(NO)(ONO) and nitrous oxide. The behavior of the osmium complexes is in marked contrast to the failure of

Fe(P)(NO) analogs to promote such disproportionation in rigorously dried and deaerated solvents (14). A greater parallel can be drawn to the Ru(P)(CO) analogues (20); however, the likely osmium nitrosyl intermediates suggested by this analogy are apparently too reactive to build to detectable concentrations.

A new class of bolaforms bearing sulfobetaine and cationic heads: Synthesis and aggregation properties

Souad Souirti and Michel Baboulene

Abstract: We describe here a convenient route to a new family of bolaforms bearing sulfobetaine and cationic heads, which could be scaled up for industrial applications. Their aggregation modes were studied by measurement of surface tension and by dynamic light scattering and transmission electronic microscopy methods. Grafting a hydrophobic chain onto the cationic head modifies both the surface properties and aggregation. Compared to conventional bolaforms, the relationship between the length of the spacer and the side-chain and the resultant hydrophobic interactions are at the origin of these novel properties. Various models of these molecular associations were proposed.

Key words: dissymmetric bolaform, sulfobetaine, cationic amphiphile, aggregation.

Résumé : Nous décrivons une nouvelle famille de bolaformes comportant une tête sulfobétaine et une tête cationique. Les synthèses proposées sont aisément transposables à l'échelle industrielle. Le mode d'agrégation de ces bolaformes a été étudié par diverses techniques: tensiométrie, diffusion de la lumière et miscroscopie électronique à transmission. Il en résulte que le greffage d'une chaine hydrophobe sur la tête cationique modifie les propriétés de surface et d'agrégation comparativement aux conventionnels bolaformes. Une relation entre la longueur de l'espaceur et celle de la chaîne carbonée additive est mise en évidence en fonction des intéractions hydrophobes propres à la structure chimique de ces nouveaux bolaformes. Différents modèles d'association moléculaire sont dés lors proposés.

Mots clés : bolaforme dissymétrique, sulfobétaine, amphiphile cationique, agrégation.

Introduction

There is growing interest in the properties of difunctional surfactants such as bolaforms. Surfactants of this category, characterized by two hydrophilic heads linked by a hydrophobic chain, are attractive models for biological membranes (1–3) and can display various properties (4, 5). The potential applications suggested by these properties have led to a renewed interest in bolaforms by the industrial community (6, 7). However, from an academic standpoint, the molecular self-association of these molecules still leaves various questions unanswered. To further our understanding of these systems, it therefore appears necessary to make available a large range of these compounds with varied chemical structures. But the synthesis of bolaforms with non-identical head-groups presents certain technical difficulties, which explains the rather limited number of studies reported to date. Recently, we proposed a simple, efficient, and industrially realistic route to obtain bolaforms either with two betaine heads (carboxybetaine and (or) sulfobetaine) (8) or with at least one sulfobetaine head (9) (Fig. 1). These molecules have also shown interesting surfactant properties that depend on the structure of the polar head as well as on the length of the spacer that links them (10).

Pursuing this line of research, the reaction scheme we developed was used to graft a second long hydrophobic chain onto one of the nitrogen atoms. This generated original compounds **1** with a structure intermediate between that of conventional bolaforms and of gemini surfactants (Fig. 2). Longer than the rather rigid C6 spacer but shorter than the very flexible C16 spacer, the dodecyl spacer appeared to be the most suitable for our research aims. Owing to the molecular organisation properties of these novel compounds, we were able to study the influence of chain–chain interactions in relation with the different structures of the polar heads. It is in this perspective that we report a new extended range of hybrid molecules **1** and the study of their aggregation properties.

Results and discussion

Synthesis

The synthetic approach used is based on previous studies (9) into the preparation of sulfobetaine bolaforms. From the monosulfobetaine intermediate **3**, formation of a quaternary nitrogen by reaction with dodecyl bromide led quantitatively to the required bolaforms **1** (Scheme 1). Table 1 reports the various bolaforms **1** synthesized.

conventional bolaforms　　**hybrid bolaforms**　　**gemini surfactants**
Surface properties

The surfactant properties of these hybrid bolaforms **1** were studied by measuring interfacial tension in water and calculating the surface property parameters using the Gibbs' equation (11). The data are illustrated in Fig. 3 and listed in Table 2.

All compounds tested led to a marked reduction in interfacial tension at the air–water interface (29–36 mN·m^{-1}). In the interfacial tension vs. concentration plots, we noted that the values of the critical micellar concentration (cmc) (2.4–8.2 mmol^{-1}) were strongly decreased in comparison with those of conventional bolaforms, which is promising for industrial applications. This was attributed to increased hydrophobicity on addition of the second alkyl chain (comparison between **1a**, **1c**, **1e**, and **1f**) and is in agreement with the values reported in the literature. However, an "anomaly" was observed with compound **1e** ($n = 16$), as shown in the curve of Fig. 3 where the linear decrease in the value of the cmc vs. increasing spacer length shows that the cmc of **1e** ($n = 16$; cmc = 3.1 mmol^{-1}) is greater than that of **1d** ($n = 12$; cmc = 2.4 mmol^{-1}).

This result is difficult to explain, but it can be proposed that differences in chain–chain interactions are responsible. This hypothesis is supported by the analysis of the curve in Fig. 4, which reveals differences in the conformations of the various bolaforms at the air–water interface. Compounds **1a**, **1b**, and **1c** present total areas for the polar heads of 280, 275, and 284 Å^2, respectively, which is much greater than the sum of the head areas taken individually (135 Å^2). This suggests that a "straight" conformation is taken up by the bolaforms, leaving the hydrophobic side chain as far from the interface as possible (Fig. 5a). This arrangement could

be favoured because the chain (C12) is longer than the spacer (C6–C10). This hypothesis is supported by data from the literature, which attribute strong rigidity to bolaforms with a spacer of 10 carbon atoms or fewer (12, 13). A spacer with 12 carbons is known to make the molecule take up a looped ("wicket-like") conformation, bringing about a total polar surface area equivalent to the sum of the areas of the two polar heads. This is what was observed for compound **1d** ($n = 12$, total area 188 Å^2 (Fig. 4)), as illustrated by Fig. 5b. Moreover, it should be noted that this value is close to the total polar head area (167 Å^2) found for a similar compound **1f** ($n = 12$) in which the side-chain only has two carbon atoms (R = C$_2$H$_5$).

Taking into account the margins of error inherent in the measurements, it could also be proposed that the slightly higher value for the total area of bolaform **1d** with respect to **1f** indicates the beginnings of chain–chain interactions, impeding the flexibility of the spacer and not allowing complete folding (Fig. 5b). But there is once more a spread-out conformation for bolaform **1e** ($n = 16$, total area 254 Å^2), as illustrated in Fig. 5c. However, the chain–chain interactions (side-chain shorter than the spacer) reduce the flexibility of the spacer, making these structures act similarly to bicatenar bolaforms. Overall, from these results, it appears that the term of critical aggregation concentration (cac) would be more appropriate for this type of compound.

Dynamic light scattering

With the exception of compound **1e** ($n = 16$), none of the bolaforms synthesized here underwent spontaneous molecular aggregation without sonication. After 15 min sonication all the bolaforms generated various objects. Typical results,

from an average of 10–15 trials for each determination of the diameter, are reported in Table 2. In general, for 10 carbons or more, the distribution of the objects was found to follow a dispersion with a fairly low percentage. The diameter of the objects, which was closely linked to the spacer length, decreased as the number of carbon atoms increased. However, for 8 carbons, polydispersion occurred, but the size of the main objects remained close to that obtained for molecules with spacers 10 or more carbons long.

Transmission electronic microscopy (TEM)

The sonicated aqueous solutions prepared for TEM observation remained optically translucent for several weeks. As mentioned, without sonication only compound **1e** spontaneously formed aggregates. This self-organisation was not modified by sonication. This result illustrates the influence of spacer length (only parameter modified) and thus the role played by variations in the hydrophobic interactions allowed by the structure of the hybrid molecules studied here. The analogy with 2-chain bolaforms is again possible in that the latter are known to spontaneously form vesicles when the spacer is over 8 carbons long (14). It should however be noted that whereas sonication gave rise to vesicles for compounds with from C10 to C16 spacers (examples **1d** and **1e** given in Fig. 6), no aggregates were found for compound **1a** ($n = 6$). These results call for comments.

Based on previous results and on the "straight" molecular organisation that bicatenar bolaforms tend to adopt (15), we propose that compound **1e** ($n = 16$) is organised in a monolayer. However, the possibility for the spacer in compound **1d** ($n = 12$) to fold suggests bilayer aggregation similar to that proposed for cationic (16) and gemini (17, 18) bolaforms. These types of molecular association present an interesting advantage, owing to the difficulties of the synthesis of the bicatenar and gemini bolaforms with two different heads.

Conclusion

During this study, we have shown that the synthesis route we recently proposed for bolaforms with sulphobetain heads can be easily generalized to obtain high yields of cationic sulphobetain hybrid bolaforms. Grafting a hydrophobic

hybrid bolaform **1d** (*n*=12)   hybrid bolaform **1e** (*n*=16)
chain onto the cationic head modifies both the surface properties and aggregation in aqueous medium. Compared to conventional bolaforms, the relationship between the length of the spacer and of the side-chain and the resulting hydrophobic interactions are at the origin of these novel properties. Favouring a given molecular association can therefore be envisaged by modulating these interactions by adjusting the chemical structure of the two chains. Access to new molecules should be possible using the reaction scheme proposed here. Work along these lines is in progress.

Experimental

General

Reagents were of commercial quality and were used without purification. Anhydrous acetone and methanol were of extra dry quality (Acros Organics France). IR spectra (ν, cm^{-1}) were recorded on a PerkinElmer 683 spectrophotometer. ^{1}H and ^{13}C NMR spectra (δ, ppm; J, hertz) were obtained on Bruker AC 80 or Bruker AC 200 instruments.

Aggregation mode

Parameters of the surface-active properties were calculated using Gibbs' equation (11) with the data obtained from measurements carried out on a Prolabo n°3 tensima using the stirrup detachment method. The size of aggregates was determined by light scattering using a Malvern Zetasizer 3000 instrument. An EM-301 Philips transmission electron microscope was used for TEM studies. Vesicles were prepared by sonication (Sonics instrument: 600 W) at 110 W for 15–20 min. Dust was removed by centrifugation (3000 rpm for 10 min) and filtration through a millipore 0.45 μ filter. One drop of the above dispersion was placed onto a carbon-coated grid (400 mesh). Filter paper was employed to wick away the excess water. One drop of 2% uranyl acetate solution was added.

It was then kept under mechanical vacuum for approximately 1 h. Micrographs were then recorded.

Typical procedure for the synthesis of compounds 2

A solution of dimethylamine (33% of ethanol) (3 × 10^{-2} mol) and dibromoalkane (10^{-2} mol) were added with sodium carbonate (2 × 10^{-2} mol) into 60 mL of ethanol and 15 mL of water. The reaction mixture was refluxed and stirred for 24 h. Then the resulting compound was isolated by evaporation of the solvent under reduced pressure. The crude product, washed with 10 mL of water, was extracted with EtO$_2$. The organic phase was dried on anhydrous Na$_2$SO$_4$ and evaporated in vacuo. The crude oil was purified by distillation.

1,6 Bis (N,N-dimethylamino)hexane, 2a

Yield: 98%. Colourless oil, bp = 68°C at 1 mmHg (1 mmHg = 133.322 Pa). ^{1}H NMR (200 MHz, CDCl$_3$) δ: 1.10 (m, 8H, (CH_2)$_4$), 1.92 (s, 12H, 2 × N(CH_3)$_2$), 2.31 (t, J = 6.4, 4H, 2 × NCH_2). ^{13}C NMR (200 MHz, CDCl$_3$) δ: 27.23–28.30 ((CH$_2$)$_4$), 45.20 (NCH$_3$), 59.66 (NCH$_2$). Anal calcd. (%) for C$_{10}$H$_{24}$N$_2$ (172.30): C 69.70, H 14.04, N 16.25; found: C 69.82, H 14.24, N 16.02.

1,8 Bis (N,N-dimethylamino)octane, 2b

Yield: 98%. Colourless oil, bp = 60°C at 0.06 mmHg. ^{1}H NMR (200 MHz, CDCl$_3$) δ: 1.12 (m, 12H, (CH_2)$_6$), 1.92 (s, 12H, 2 × N(CH_3)$_2$); 2.31 (t, J = 6.5, 4H, 2 × NCH_2). ^{13}C NMR (200 MHz, CDCl$_3$) δ: 27.23–28.30 ((CH$_2$)$_6$), 45.20 (NCH$_3$), 59.66 (NCH$_2$). Anal calcd. (%) for C$_{12}$H$_{28}$N$_2$ (200.37): C 71.86, H 13.97, N 13.97; found: C 71.66, H 14.15, N 14.13.

1,10 Bis (N,N-dimethylamino)decane, 2c

Yield: 92%. Colourless oil, bp = 62°C at 0.05 mmHg. ^{1}H NMR (200 MHz, CDCl$_3$) δ: 1.09 (m, 12H, (CH_2)$_6$), 1.24 (m, 4H, 2 × CH_2-C-N), 1.92 (s, 12H, 2 × N(CH_3)$_2$), 2.03 (t, J =

6.3, 4H, 2 × CH_2N). ^{13}C NMR (200 MHz, CDCl$_3$) δ: 27.4–28.51 ((CH$_2$)$_8$), 45.42 (NCH$_3$), 59.87 (NCH$_2$). Anal calcd. (%) for C$_{14}$H$_{32}$N$_2$ (228.40): C 73.61, H 14.12, N 12.26; found: C 74.08, H 13.96, N 12.62.

1,12 Bis (N,N-dimethylamino)dodecane, 2d

Yield: 98%. Colourless oil, bp = 80–82°C at 0.05 mmHg. ^{1}H NMR (200 MHz, CDCl$_3$) δ: 1.12 (m, 20H, (CH_2)$_{10}$), 1.91 (s, 12H, 2 × N(CH_3)$_2$), 2.12 (t, J = 6.3, 4H, 2 × NCH_2). ^{13}C NMR (200 MHz, CDCl$_3$) δ: 27.43–28.53 ((CH$_2$)$_{10}$), 45.42 (NCH$_3$), 59.87 (NCH$_2$). Anal calcd. (%) for C$_{16}$H$_{36}$N$_2$ (256.47): C 74.86, H 14.03, N 10.92; found: C 74.73, H 13.90, N 11.62.

1,16 Bis (N,N-dimethylamino)hexadecane, 2e

Yield: 75%. Colourless oil, decomposition during the distillation. ^{1}H NMR (200 MHz, CDCl$_3$) δ: 1.19 (m, 24H, (CH_2)$_{12}$), 1.23 (m, 4H, 2 × CH_2CN), 2.16 (s, 12H, 2 × N(CH_3)$_2$), 2.25 (t, J = 6.4, 4H, 2 × NCH_2). ^{13}C NMR (200 MHz, CDCl$_3$) δ: 27.43–28.53 ((CH$_2$)$_{14}$), 45.42 (NCH$_3$), 59.87 (NCH$_2$). Anal calcd. (%) for C$_{20}$H$_{44}$N$_2$ (312.56): C 76.85, H 14.19, N 8.96; found: C 76.73, H 13.92, N 8.62.

Typical procedure for the synthesis of compounds 3

Sulfobetaine **3** was prepared by the addition of α,ω-bis(N,N-dimethylamino) alkane **2** (10^{-2} mol) to a stirred solution of 1,3-propane sultone (7 × 10^{-3} mol) in 50 mL of anhydrous acetone. The reaction mixture was stirred at room temperature for 3 h, cooled, and filtered. The amphiphilic product was purified by recrystallization from methanol–ether (1:9) and dried in vacuo over phosphorus pentoxide.

1-(N,N-Dimethylammonio,N-propyl-1-sulfonate)-8-(N′,N′-dimethylamino) octane, 3b

Yield: 96%. White powder, mp = 198–200°C. IR (KBr) ν: 1480 (C-N$^+$), 1040 (S = 0). ^{1}H NMR (80 MHz, D$_2$O) δ: 1.25 (m, 12H, (CH_2)$_6$), 1.99–2.18 (m, 10H, NCH_2, N(CH_3)$_2$, CH_2-C-SO$_3$), 2.72–3.21 (m, 12H, N$^+$(CH_3)$_2$, N$^+$CH_2, CH_2SO$_3^-$). ^{13}C NMR (200 MHz, D$_2$O) δ: 20.73–31.66 ((CH$_2$)$_6$), 46.52 (NCH$_3$), 49.81 (CH$_2$-C-SO$_3$), 53.16 (N$^+$CH$_3$), 61.43 (NCH$_2$), 64.54 (N$^+$CH$_2$), 66.71 (CH$_2$SO$_3^-$). Anal. calcd. (%) for C$_{15}$H$_{34}$N$_2$SO$_3$ (322.5): C 55.86, H 10.63, N 8.69, S 9.94; found: C 55.50, H 10.46, N 8.46, S 9.62.

1-(N,N-Dimethylammonio,N-propyl-1-sulfonate)-10-(N′,N′-dimethylamino) decane, 3c

Yield: 97%. White powder, mp = 218°C. IR (KBr) ν: 1480 (C-N$^+$), 1040 (S = 0). ^{1}H NMR (80 MHz, D$_2$O) δ: 1.27 (m, 16H, (CH_2)$_8$), 1.82–2.16 (m, 8H, NCCH_2, N(CH_3)$_2$), 2.33 (t, J = 6.6, 2H, NCH_2), 2.65 (t, J = 8.1, 2H, CH_2SO$_3^-$), 3 (s, 6H, N(CH_3)$_2$). ^{13}C NMR (200 MHz, D$_2$O) δ: 20.72–31.65 ((CH$_2$)$_{10}$), 46.52 (NCH$_3$), 49.84 (CH$_2$-C-SO$_3$), 53.16 (N$^+$CH$_3$), 61.44 (NCH$_2$), 64.52 (N$^+$CH$_2$), 66.71 (CH$_2$SO$_3^-$). Anal. calcd. (%) for C$_{17}$H$_{38}$N$_2$SO$_3$ (350): C 58.09, H 10.52, N 4.7, S 5.34; found: C 57.80, H 10.57, N 4.3, S 5.27.

1-(N,N-Dimethylammonio,N-propyl-1-sulfonate)-12-(N′,N′-dimethylamino) dodecane, 3d

Yield: 95%. White powder, mp = 230°C. IR (KBr) ν: 1480 (C-N$^+$), 1040 (S = 0). ^{1}H NMR (80 MHz, D$_2$O) δ: 1.22 (m, 20H, (CH_2)$_{10}$), 1.91–2.15 (m, 10H, NCH_2, N(CH_3)$_2$,

CH_2-C-SO$_3^-$)), 2.91–3.25 (m, 12H, N$^+$(CH$_3$)$_2$, N$^+$CH_2, CH$_2$-CH_2SO$_3^-$). ^{13}C NMR (200 MHz, D$_2$O) δ: 20.75–31.65 ((CH$_2$)$_{10}$), 46.52 (NCH$_3$), 49.84 (CH$_2$-C-SO$_3$), 53.16 (N$^+$CH$_3$), 61.4 4 (NCH$_2$), 64.52 (N$^+$CH$_2$), 66.72 (CH$_2$SO$_3^-$). Anal. calcd. (%) for C$_{19}$H$_{42}$N$_2$SO$_3$ (378.6): C 60.27, H 11.18, N 7.40, S 8.47; found: C 59.93, H 11.02, N 7.07, S 8.54.

1-(N,N-Dimethylammonio,N-propyl-1-sulfonate)-12-(N′,N′-dimethylamino) hexadecane, 3e

Yield: 75%. White powder, mp = 238°C. IR (KBr) ν: 1480 (C-N$^+$), 1040 (S = 0). ^{1}H NMR (80 MHz, D$_2$O) δ: 1.22 (m, 28H, (CH$_2$)$_{14}$), 1.72 (m, 2H, NCCH$_2$), 2.13–2.55 (m, 8H, N(CH$_3$)$_2$, NCH$_2$), 2.84 (m, 2H, CH$_2$-CSO$_3^-$), 3.18 (m, 8H, N$^+$(CH$_3$)$_2$, N$^+$CH$_2$), 3.45 (t, J = 7.9, 2H, SO$_3$CH$_2$). ^{13}C NMR (200 MHz, D$_2$O) δ: 19.51–29.6 ((CH$_2$)$_{14}$), 45.54 (NCH$_3$), 47.6 3 (CH$_2$-C-SO$_3$), 50.61 (N$^+$CH$_3$), 60.40 (N$^+$CH$_2$), 63.52 (N$^+$CH$_2$), 63.4 2 (N$^+$CH$_2$), 64.54 (CH$_2$SO$_3$). Anal. calcd. (%) for C$_{23}$H$_{50}$N$_2$SO$_3$ (434.4): C 63.59, H 11.52, N 6.44, S 7.37; found: C 62.93, H 11.22, N 7.01, S 7.54.

Typical procedure for the synthesis of compounds 1

A mixture of sulfobetaine **3** (10^{-2} mol) and of haloalkane (1.2 × 10^{-2} mol) in 50 mL of absolute MeOH was heated at reflux for 4 h. After removing the solvent in vacuo, the residual oil was precipitated by trituration with anhydrous ether. After filtration, the solid was washed by 3 × 20 mL of anhydrous ether and dried in vacuo over phophorus pentoxide.

1-(N,N-Dimethylammonio,N-propyl-1-sulfonate)-8-(N′,N′-dimethyl,N′-dodecylammonium bromide) octane, 1b

Yield: 87%. White powder, mp = 120°C. IR (KBr) ν: 1480 (C-N$^+$), 1040 (S = 0). ^{1}H NMR (80 MHz, D$_2$O) δ: 0.85 (t, J = 7.3, 3H, CH$_3$-C$_{11}$), 1.26 (m, 32H, (CH$_2$)$_{10}$, (CH$_2$)$_6$), 2.09 (m, 2H, CH$_2$-C-SO$_3^-$)), 2.64–3.33 (m, 22H, 2 × N(CH$_3$)$_2$, 4 × NCH$_2$, CH$_2$SO$_3^-$). ^{13}C NMR (200 MHz, D$_2$O) δ: 16.61 (C-CH$_3$), 20.75–34.61 ((CH$_2$)$_6$, (CH$_2$)$_{10}$), 49.90 (CH$_2$-C-SO$_3$), 53.51 and 54.45 (NCH$_3$), 64.46 and 66.32 (NCH$_2$), 66.69 (CH$_2$SO$_3^-$), 69.35 (N$^+$CH$_2$). Anal. calcd. (%) for C$_{27}$H$_{59}$N$_2$SO$_3$Br (574.77): C 56.61, H 10.38, N 4.89, S 5.59; found: C 56.95, H 10.95, N 4.80, S 6.00.

1-(N,N-Dimethylammonio,N-propyl-1-sulfonate)-10-(N′,N′-dimethyl,N′-dodecylammonium bromide) decane, 1c

Yield: 92%. White powder, mp = 115°C. IR (KBr) ν: 1480 (C-N$^+$), 1040 (S = 0). ^{1}H NMR (80 MHz, D$_2$O) δ: 0.85 (t, J = 7.1, 3H, CH$_3$-C), 1.23 (m, 36H, (CH$_2$)$_{10}$, (CH$_2$)$_8$), 1.72–2.15 (m, 10H, CH$_2$CN, CH$_2$-C-SO$_3^-$), 2.84–3.05 (m, 12H, 2 × N(CH$_3$)$_2$), 3.35 (m, 2H, CH$_2$SO$_3$). ^{13}C NMR (200 MHz, D$_2$O) δ: 16.63 (C-CH$_3$), 20.75–34.59 (CH$_2$)$_8$, (CH$_2$)$_{10}$), 49.96 (CH$_2$-C-SO$_3$), 53.25 and 53.63 (NCH$_3$), 64.33 and 66.96 (NCH$_2$), 66.48 (CH$_2$SO$_3^-$), 69.76 (N$^+$CH$_2$). Voltammetric studies and assay of the anti-inflammatory drug ketoprofen in pharmaceutical formulation and human plasma at a mercury electrode

M.M. Ghoneim and A. Tawfik

Abstract: The electrochemical reduction of the anti-inflammatory drug ketoprofen was studied in a Britton-Robinson (B-R.) buffer series of pH 2–11 using dc-polarography, cyclic voltammetry, and coulometry techniques. The electrode reaction pathway of the drug at the dropping mercury electrode was proposed and discussed. A new adsorptive cathodic stripping square-wave voltammetric procedure was optimized for the assay of bulk drug in a B-R. buffer of pH 2.0. The peak current was linear with the drug concentration over the ranges 2×10^{-9} to 2×10^{-7} M of the bulk drug, using a 60 s accumulation time period at -0.6 V (vs. $Ag/AgCl/KCl_s$). The percentage recovery of the bulk drug was 99.57 ± 0.54 and a detection limit of 0.10 ng mL^{-1} was achieved. The proposed procedure was successfully applied for the assay of ketoprofen in pharmaceutical formulation (Ketofan®) and human plasma. The percentage recoveries were 99.66 ± 0.47 and 101.76 ± 0.64 in pharmaceutical formulation and human plasma, respectively. A detection limit of 0.14 ng mL^{-1} plasma was achieved which was below that reported in literature using the different analytical techniques.

Key words: ketoprofen (Ketofan®) determination, polarography, cyclic voltammetry, adsorptive cathodic stripping square-wave voltammetry, human plasma.

Résumé : On a étudié la réduction électrochimique de la drogue anti-inflammatoire le cétopropfène, dans une série de tampons de Britton-Robinson (B-R.) dont les pH varient de 2 à 11, en faisant appel à des techniques de polarographie dc, de voltamétrie cyclique et de coulométrie. On propose en détail un schéma réactionnel pour la réaction à l'électrode de la drogue au niveau de l'électrode à goutte de mercure. On a optimisé un nouveau procédé de voltamétrie à impulsion carrée avec accumulation à la surface de la cathode, pour un essai avec la drogue encombrée dans le B-R. à un pH de 2,0. L'intensité des courants de pic est proportionnelle la concentration de la drogue encombrée pour des concentrations supérieures à l'intervalle de 2×10^{-9} à 2×10^{-7} en utilisant des période de temps d'accumulation de 60 s à 0,6 V (vs. $Ag/AgCl/KCl_s$). Le pourcentage de récupération de la drogue encombrée est de $99,57 \pm 0,54$ avec une limite de détection de 0,10 ng mL^{-1}. On a utilisé avec succès la méthode proposée lors d'un essai du cétoprofène en formule pharmaceutique (Ketofan®) et dans le plasma humain. Les pourcentages de récupération sont de $99,66 \pm 0,47$ et de $101,76 \pm 0,64$ respectivement. On a atteint une limite de détection de 0,14 ng mL^{-1} de plasma, cette limite est inférieure à celles reportées dans la littérature pour des techniques analytiques différentes.

Mots clés : cétoprofène (Ketofan®) détermination, polarographie, voltamétrie cyclique voltamétrie à impulsion carrée avec accumulation à la surface de la cathode, plasma humain.

Introduction

Ketoprofen (**I**): a-(3-benzoylphenyl) propionic acid, is a nonsteroidal anti-inflammatory agent with pronounced analgesic properties (1). Ketoprofen is used for anti-inflammatory and analgesic effects in the symptomatic treatment of acute and chronic rheumatoid arthritis and osteoarthritis. Ketoprofen is also used to relieve mild to moderate pain and for the management of primary dysmenorrhea (2). It is formulated as a 50 mg capsule or a 100 mg suppository.
(I)

Ketoprofen is absorbed rapidly regardless of the route of administration. It reaches a peak maximum in the first hour of administration if taken by the oral and 6 h if taken by the subcutaneous route (3).

M.M. Ghoneim[1] and A. Tawfik. Chemistry Department, Faculty of Science, Tanta University, 31527 Tanta, Egypt.

[1]Corresponding author (e-mail: mmghoneim@hotmail.com).

The metabolism of ketoprofen undergoes through two major processes a hydroxylation process and glucuronide conjugation. The glucuronide conjugation pathway is predominant in the rabbit and in man but in man the hydroxylation is not totally absent (4, 5).

It is generally assumed that the nonsteroidal anti-inflammatory drugs diffuse back to plasma and that the metabolism of the drug within the joint does not occur (4). Ketoprofen and *p*-hydroxy ketoprofen are the major drug-related components in human plasma and the concentration of the metabolite (*p*-hydroxy ketoprofen) is very low (5, 6).

Various methods of determination of ketoprofen in pharmaceutical formulations and biological fluids have been reported. These mainly include: NMR spectroscopy (7), UV spectrophotometry (8–10), Fourier transform IR spectrometry (11, 12), capillary electrophoresis (13, 14), chromatography (15, 16), HPLC (17–42), GC–MS (43–47), and electrochemistry (9, 48). The electrochemical reduction of ketoprofen and its assay in pharmaceutical formulations were studied by differential-pulse polarography in a buffer of pH 6 (48), in which a single peak was observed at $E_p = -1.15$ V vs. SCE. The peak current varied linearly with the concentration of the drug over the range 1×10^{-5} to 5×10^{-4} M. This procedure was sensitive to about 2.5 µg mL^{-1}. Also, the assay of ketoprofen in capsules was studied in 0.1 M perchlorate (pH 3.8) using direct current stripping voltammetry (9). The peak current varied linearly with the drug concentration over the range 1×10^{-8} to 1×10^{-6} M with a detection limit of 0.50 ng mL^{-1}. In general, the detection limit of the reported procedures varied from 10 µg mL^{-1} to 0.5 ng mL^{-1} depending on the applied analytical technique (7–48).

The aim of the present work was to clarify the polarographic behavior of ketoprofen in a Britton-Robinson (B-R.) buffer series (pH 2–11) and to shed light on its electrode reaction pathway at the dropping mercury electrode. Also, an adsorptive stripping square-wave voltammetry procedure was optimized for determination of the drug in bulk, pharmaceutical formulation, and human plasma with detection limits lower than those reported in literature (7–48).

Experimental

Materials

Bulk ketoprofen was kindly supplied by Squibb Company Cairo, Egypt and Ketofan® capsules (Amriya Pharm. Ind., Egypt) were purchased from the Egyptian local market. Human plasma samples were kindly supplied by the Tanta City Blood Bank.

Reagents and solutions

A standard stock solution of 1×10^{-3} M bulk ketoprofen was prepared in ethanol (Merck) and stored in the dark at 4°C. More dilute solutions (1×10^{-6} to 1×10^{-4} M) were prepared daily by accurate dilution with ethanol just before use. The ketoprofen solutions were stable and their concentrations did not change with time. A series of B-R. buffers of pH 2–11 was prepared (49).

Human plasma spiked with ketoprofen and a solution of ketoprofen extracted from Ketofan® capsules were prepared according to the procedure described previously (50).

A Mettler balance (Toledo AB104) was used for weighing the solid materials. Deionized water was obtained from an AquaMatic bi-distillation water system connected to a Purite Still Plus HP deionizer.

Instrumentation

A Polarograph model 4001 (Sargent-Welch) was used for study of the polarographic behaviour of ketoprofen. A polarographic cell, with a dropping mercury electrode (DME) as a working electrode (mass of mercury flowing from the capillary per second m = 1.03 mg s^{-1}, t = 3.3 s at mercury height = 60 cm) and a saturated calomel electrode (SCE) as a reference electrode, was used.

The Potentiostat/Galvanostat model 173 supplied with a digital Coulometer model 179 (PAR) was used for the controlled-potential coulometry measurements. A coulometric microcell, incorporated with a platinum wire sealed through the cell bottom for contact with a mercury pool as a working electrode, a SCE as a reference electrode, and a platinum gauze immersed in a bridge tube as a counter electrode, was used.

The cyclic and square-wave voltammograms were recorded using a Potentiostat/Galvanostat model 273A-PAR interfaced with a PC loaded with the software package 270/250 (PAR). The electrode assembly 303A (PAR), with a dark microelectrolysis cell incorporated with a hanging mercury drop electrode (HMDE) as a working electrode, Ag/AgCl/ KCl$_s$ as a reference electrode, and a platinum wire as a counter electrode, was used.

Analysis procedure

A known volume of ketoprofen solution was pipetted into a 10 mL-calibrated flask and made up to the mark with a B-R. buffer of pH 2.0. The solution was then transferred into the electrolysis cell and deoxygeneted with pure nitrogen for 15 min. The accumulation potential ($E_{acc} = -0.6$ V vs. Ag/AgCl/KCl$_s$) was applied to the working electrode for a selected accumulation time period ($t_{acc} = 60$ s) while the solution was stirred. At the end of the accumulation period, the stirrer was stopped and 10 s were allowed for the solution to become quiescent. Stripping voltammograms were then recorded by scanning the potential towards the negative direction using the square-wave waveform. A calibration graph was constructed under the optimized conditions of the assay.

Results and discussion

dc-Polarography

The dc-polarograms for the 2.6×10^{-4} M bulk ketoprofen drug in the B-R. buffers of pH values ≤3.0 showed two one-electron irreversible waves of equal heights, both intermingled into a single two-electron irreversible wave in solutions of 4 < pH < 6. On the increase of pH of the medium, the single wave started to split again into two waves, the height of the second wave increased at the expense of the first one until the latter disappeared completely in solutions of pH > 9 (Fig. 1a). In solutions of pH > 9, a single two-electron wave was observed at more negative potentials. The total limiting current (i_l) was pH independent throughout the entire pH range of 2–11 (Fig. 2a). The i_l–pH curves for the first wave (pH < 9) and the second wave or the single wave (pH > 6)

Fig. 1. dc-Polarograms for 2.6×10^{-4} M ketoprofen in: (*a*) B-R. buffers of different pH values (1) pH 2.0, (2) pH 3.0, (3) pH 4.0, (4) pH 5.0, (5) pH 6.0, (6) pH 7.0, (7) pH 7.8, (8) pH 8.2, (9) pH 9.1, (10) pH 9.9, (11) pH 11.0; and (*b*) 0.1 M HCl.

recalled dissociation and association curves, respectively (Fig. 2*b*, 2*c*) which may be attributed to the presence of the ketoprofen molecules in an acid–base equilibrium (51).

Controlled-potential coulometry studies revealed that the number of electrons involved in the reduction process of ketoprofen was two electrons/reactant molecule over the entire pH range of 2–11, which corresponded to the reduction of the carbonyl group site of the ketoprofen molecule.

The half-wave potentials ($E_{1/2}$) of the ketoprofen reduction waves recorded in solutions of pH < 6.0, and that of the first wave recorded in solutions of pH values 6–9 shifted toward more negative values with the increase of pH of the

medium. This behaviour indicated the involvement of protons in the rate-determining step and that the proton transfer precedes the electron transfer reaction (51). On the other hand, the $E_{1/2}$ of both the second wave (pH 6–9) and the single wave (pH > 9) were practically pH independent.

The $E_{1/2}$–pH plot for the single wave (pH < 6) was a straight line (Fig. 3*a*) with a slope value ($\delta E_{1/2}/\delta pH = S_1$) reported in Table 1 ($S_1 = [0.0591/\alpha n_a] \cdot Z_H^+$, where Z_H^+ and n_a are the number of hydrogen ions and number of electrons, respectively, participating in the rate-determining step and α is the transfer coefficient). Also the $E_{1/2}$–pH plots for the first wave (Fig. 3*b*) and for the second wave (pH 6–9) or the single wave (pH > 9) (Fig. 3*c*) were straight lines. These plots indicated that the $E_{1/2}$ of the first wave (pH 6–9) was pH dependent while those of the second wave (pH 6–9) and the single wave (pH > 9) were practically pH independent. The pH value at the point of intersection of curves a and c (Fig. 3) was approximately equal to the pK_a' value of ketoprofen (pH = $pK_a' \approx 7.5$) (52).

The ketoprofen reduction waves at the DME were analysed using the fundamental equation for the irreversible polarographic waves (53):

$$E_{d.e.} = E_{1/2} - (0.0591/\alpha n_a) \log (i/i_d - i)$$

The plots of the potential of the dropping mercury electrode ($E_{d.e.}$) against $\log (i/i_d - i)$ at different pH values were straight lines with the slope values S_2 reported in Table 1 ($S_2 = 0.0591/\alpha n_a$).

The number of hydrogen ions (Z_H^+) participating in the rate-determining step (pH < 6) were determined by applying the relationship (53, 54):

$$\delta E_{1/2}/\delta pH = (0.0591/\alpha n_a) \cdot Z_H^+$$

$$(i.e., \ Z_H^+ = (\delta E_{1/2}/\delta pH)/(0.0591/\alpha n_a) = S_1/S_2)$$

The data reported in Table 1 indicated that, in acidic media (pH < 6), the rate-determining step involved the consumption of one proton ($Z_H^+ = 1$) and one electron ($n_a = 1$), while in solutions of pH > 9, $n_a = 2$. Accordingly, the reduc-

*$E_{1/2}$ was practically pH independent in solutions of pH > 9.

Fig. 3. $E_{1/2}$–pH plots for 2.6×10^{-4} M ketoprofen in B-R. buffers: (*a*) single wave (pH < 6); (*b*) first wave (pH 6–9); and (*c*) second wave (pH 6–9) and single wave (pH > 9).
tion reaction pathway of the carbonyl group of the ketoprofen molecule at the DME surface can be expressed as follows:

(*i*) In acidic solutions (pH < 6.0): the sequence of the electrode reaction was proton, electron, electron, proton (H$^+$, e, e, H$_f{}^+$) (51).

[1]
$$-\overset{\displaystyle O}{\underset{\displaystyle \|}{C}}- \;+\; H^+ + e \xrightarrow{\;E_1\;} -\overset{\displaystyle OH}{\underset{\displaystyle |}{\overset{\bullet}{C}}}-$$

[2]
$$-\overset{\displaystyle OH}{\underset{\displaystyle |}{\overset{\bullet}{C}}}- \;+\; e \;+\; H^+ \;(\text{fast}) \xrightarrow{\;E_2\;} -\overset{\displaystyle OH}{\underset{\displaystyle |}{CH}}-$$
In solutions of pH < 4, $E_1 \neq E_2$, thus, the reduction of the carbonyl group took place via two one-electron irreversible waves of equal heights (rxns. [1] and [2] represent the first and second waves, respectively). In 0.1 M HCl (pH 1), two one-electron irreversible waves of equal heights were also

observed (Fig. 1*b*). At higher pH values (4 < pH < 6), $E_1 = E_2 = E_{1/2}$, thus, a single two-electron irreversible wave was recorded (sum of rxns. [1] + [2]), while the total limiting current (i_l) was still practically pH independent over the entire pH range.

(*ii*) In alkaline solutions (pH > 9): the sequence of the electrode reaction was electron, electron, proton, proton (e, e, H$^+{}_f$, H$^+{}_f$) (51). The protons required were supplied from the water molecules.

[3]
$$-\overset{\displaystyle O}{\underset{\displaystyle \|}{C}}- \;+\; 2e + 2H \cdot OH \xrightarrow{\;E_3\;} -\overset{\displaystyle OH}{\underset{\displaystyle |}{CH}}-$$
Over this pH range, the reduction of the carbonyl group took place at more negative potentials ($E_3 > E_1$ and E_2) via a single two-electron irreversible wave (rxn.[3]).

(*iii*) In solutions of intermediate pH values 6–9: over this pH range, the ketoprofen molecule was expected to be present in an acid–base equilibrium (p$K_a \approx 7.5$) (52), both the acidic (AH) and basic (A$^-$) forms were electroactive.

$$AH \;\underset{k_r}{\overset{k_d}{\rightleftharpoons}}\; A^- + H^+ \qquad (K = k_d/k_r)$$
Thus, the reduction of the drug within the pH range 6–9 took place via two steps, and the height of the second step (because of the reduction of the basic form) increased at the expense of the first one (due to the reduction of the acidic form) on the increase of pH of the medium until the latter one disappeared completely at pH values >9 (Figs. 1 and 2). Thus, the electrode reaction of ketoprofen over the pH range (6–9) was considered to consist of mixed processes (rxns. [1], [2], and [3]). As the pH of the medium was increased, rxn. [3] became the dominant one.

According to Zuman (51), the existence of an electroactive compound in an acid–base equilibrium leads to the variation of the reduction current with the change of hydrogen ion concentration [H$^+$] as governed by the equation (55):

$$\frac{i_{AH}}{i_l} = \frac{0.886\left\{\left(\dfrac{k_r t_1}{K}\right)[H^+]\right\}^{1/2}}{1 + 0.886\left\{\left(\dfrac{k_r t_1}{K}\right)[H^+]\right\}^{1/2}}$$

which was modified to the following forms (51, 56):

$$pH = \log 0.886 \left(\frac{k_r t_1}{K} \right)^{1/2} + \log \left(\frac{i_1 - i_{AH}}{i_{AH}} \right)$$

$$pH = \log 0.886 \left(\frac{k_r t_1}{K} \right)^{1/2} + \log \left(\frac{i_1 - i_A}{i_{A^-}} \right)$$

(i_{AH} and i_{A^-} are the reduction currents of acidic and basic forms, respectively).

The plots of $[\log (i_1 - i_{AH})/i_{AH}]$ or $[\log (i_1 - i_{A^-})/i_{A^-}]$ vs. the pH values 6–9, respectively, for the first and second waves, yielded straight lines (Fig. 4) which indicated the validity of the previous equations and consequently confirmed the presence of ketoprofen molecules in an acid–base equilibrium within the pH range 6–9. The pH value corresponded to the intersection point of the two curves (Fig. 4a, 4b) equaled to the pK_a' value of ketoprofen (pH = $pK_a' \approx 7.5$) (52).

Cyclic voltammetry

The cyclic voltammograms of ketoprofen in B-R. buffers of pH < 6 and pH > 9 showed a single cathodic peak, while two cathodic peaks were observed in solutions of pH 6–9. No anodic peaks were observed in the reverse scan, which confirmed the irreversible nature of the ketoprofen electrode reaction. These results agree well with that of the polarographic studies of the drug over the pH range 2–11. The irreversible nature of the reduction process was also confirmed by the shift of the peak potential (E_p) to more negative values with the increase of the scan rate ν from 20 to 500 mV s^{-1} (57). On plotting log i_p vs. log ν, a linear correlation was obtained with a slope value close to the theoretical expected value of 1.0 for an ideal reaction of surface species (58). So in this case the process appears to have an important adsorptive component. The electrode surface coverage can be calculated from the amount of charge consumed by the surface process as calculated by the integration of the area under the peak of the cyclic voltammogram corrected to residual current (59). According to the equation: $\Gamma = Q/nFA$, the surface coverage Γ (mol cm^{-2}) was calculated, where n is the overall number of electrons consumed in the reduction process ($n = 2$), F is Faraday's constant (96 487 C) and A is the electrode surface area (0.026 cm^2). On dividing the number of coulombs transferred (1.267 μC) by the conversion factor (nFA), a monolayer surface coverage of 2.525×10^{-10} mol cm^{-2} was obtained. Each adsorbed ketoprofen molecule therefore occupies an area of 6.5748 nm^2.

Adsorptive stripping square-wave voltammetry

The adsorptive preconcentration of ketoprofen at the HMDE surface and the application of a subsequent scan in the negative direction using the square-wave waveform gave rise to a single reduction peak in B-R. buffers of different pH values. A well-developed and sharper peak was observed in a B-R. buffer of pH 2.0. Figure 5 shows a large response for 2×10^{-7} M ketoprofen after preconcentration for 60 s. On the contrary, the direct response ($t_{acc} = 0$) showed a smaller reduction peak current. This indicates that ketopro-

Fig. 4. Plots of log $[(i_1 - i_{HA})/i_{HA}]$ and log $[(i_1 - i_A^-)/i_A^-]$ vs. pH for 2.6×10^{-4} M ketoprofen in B-R. buffers of different pH values. (a) First wave; (b) second wave recorded in solutions of pH 6–9.
Fig. 5. Square-wave voltammograms for 2×10^{-7} M ketoprofen in a B-R. buffer of pH 2: (a) background; (b) without preconcentration ($t_{acc.} = 0$); and (c) after preconcentration for 60 s. $E_{acc.} = -0.6$ V, frequency = 120 Hz, scan increment = 8 mV, pulse amplitude = 25 mV, and rest period = 10 s.
fen can be preconcentrated at the HMDE surface by adsorption.

Considering the large response obtained by adsorptive stripping square-wave (AdSSW) voltammetry compared to that of direct square-wave stripping (SWS) voltammetry, it was possible to determine trace levels of ketoprofen using AdSSW voltammetry. Experiments were made to optimize the conditions for the adsorption of the drug onto the HMDE surface. Several stripping voltammograms were recorded at

Fig. 6. Influence of the accumulation time on the peak current of AdSSW voltammograms for: (*a*) 2×10^{-8} M ketoprofen; and (*b*) 2×10^{-7} M ketoprofen. Other conditions as illustrated in Fig. 5.

Fig. 7. AdSSW voltammograms for different concentrations of ketoprofen spiked to human plasma: (*a*) background; (*b*) 2×10^{-9} M ketoprofen; (*c*) 6×10^{-9} M ketoprofen; (*d*) 1×10^{-8} M ketoprofen; (*e*) 1.4×10^{-8} M ketoprofen; and (*f*) 1.8×10^{-8} M ketoprofen ($t_{\mathrm{acc}} = 60$ s, other conditions as illustrated in Fig. 5).
different accumulation potentials, E_{acc}, (0 to -1.0 V), pulse amplitudes (10–70 mV), scan increments (2–10 mV), and frequencies (20–120 Hz). Finally, the effect of the accumulation time (t_{acc}) was studied for two concentrations (2×10^{-8}M and 2×10^{-7}M) of ketoprofen under the optimized conditions: $E_{\mathrm{acc}} = -0.6$ V, pulse amplitude = 25 mV, scan increment = 8 mV, frequency = 120 Hz, rest period = 10 s, and drop size = 0.026 cm^2. The resultant peak current showed a linear relationship with the accumulation time up to 60 s for both concentrations studied (Fig. 6).

The applicability of the AdSSW voltammetry technique as an analytical method for the determination of bulk ketoprofen was tested as a function of its concentration (Fig. 7). Linear response was obtained over the concentration ranges 2×10^{-9} to 2×10^{-7} M ($t_{\mathrm{acc}} = 60$ s) or 1×10^{-8} to 3×10^{-7} M of ketoprofen ($t_{\mathrm{acc}} = 30$ s). The variations of peak current (i_{p}) with ketoprofen concentration (C) after preconcentration for 60 s and 30 s were represented by the following straight line equations:

$$i_{\mathrm{p}}(nA) = 10.4024C(nM) + 42.75,$$

$$\text{correlation coefficient } r = 0.998 \ (n = 14),$$

$$t_{\mathrm{acc}} = 60 \text{ s and,}$$

$$i_{\mathrm{p}}(nA) = 7.2896C(nM) + 18.22,$$

$$r = 0.995 \ (n = 14), \ t_{\mathrm{acc}} = 30 \text{ s}$$

The percentage recovery of the drug was 99.57 ± 0.54. The drug detection limit was calculated using the equation $dl = 3sd/a$ (60) where sd is the standard deviation of the blank and a is the slope of the calibration curve. A detection limit of 0.10 ng mL^{-1} of the bulk drug was achieved.

Interference studies

Selectivity of the optimized procedure for the assay of 3×10^{-8} M ketoprofen was examined in the presence of some common excipients in the same ratios usually used in pharmaceutical preparations (e.g., starch, gelatin, lactose, talc, and magnesium stearate). The mean percentage recovery of 98.56 ± 0.61 showed no significant interference from excipients, thus, the procedure was able to assay ketoprofen in the presence of excipients and hence, it can be considered selective.

Applications

Analysis of Ketofan® capsules

The proposed procedure was successfully applied for the assay of ketoprofen in pharmaceutical formulation (Ketofan® capsules). The percentage recovery of ketoprofen based on the average of four replicate experiments was found to equal 99.66 ± 0.47. The results were favorably compared with those obtained by assay of the same capsules using a reported HPLC method (20).

Analysis of spiked human plasma

The present optimized AdSSW voltammetry procedure was also successfully applied for the determination of ketoprofen in protein-free spiked human plasma (Fig. 7). The variation of peak current (i_{p}) vs. ketoprofen concentration (C) was represented by a straight-line equation: $i_{\mathrm{p}}(nA) = 9.28151C(nM) + 45.3146$, $r = 0.997$ ($n = 14$). The linear concentration range was 5×10^{-9} to 2×10^{-7} M ketoprofen. The percentage recovery of ketoprofen based on the average of four replicate experiments was found to equal $101.76 \pm$

0.64, which compared well with that obtained by a reported HPLC method (20). A drug detection limit of 0.14 ng mL^{-1} plasma was achieved.

Conclusions

In this work, the reduction reaction pathway of ketoprofen at the mercury electrode surface in B-R. buffers of pH 2–11 was clearly elucidated and discussed. Also, a simple, fast, accurate, highly sensitive and a less cost adsorptive cathodic stripping square-wave voltammetric procedure was optimized and successfully applied for the determination of ketoprofen in bulk, pharmaceutical formulation, and human plasma. The reached detection limits of the drug were below those reported in the literature when applying the different analytical techniques (7–48). The optimized procedure did not require sample pretreatment or any time-consuming extraction steps other than centrifugal separation of the precipitated proteins from plasma samples prior to the drug assay. The proposed procedure could possibly be adopted for the pharmacokinetic as well as quality control laboratories.

Phase behaviour and structure of amphiphilic poly(ethylene oxide)–poly(propylene oxide) triblock copolymers ((EO)$_4$(PO)$_{59}$(EO)$_4$ and (EO)$_{17}$(PO)$_{59}$(EO)$_{17}$) in ternary mixtures with water and xylene

Pius Kipkemboi, Ali Khan, Björn Lindman, and Viveka Alfredsson

Abstract: The isothermal ternary phase behaviour and structure of amphiphilic copolymer–water–xylene systems was investigated for two poly(ethylene oxide)–poly(propylene oxide) (PEO–PPO) triblock copolymers, (EO)$_4$(PO)$_{59}$(EO)$_4$ and (EO)$_{17}$(PO)$_{59}$(EO)$_{17}$, at 25°C. The phase boundaries were identified using ^{2}H NMR and inspection under polarized light. The microstructure and structural length scales in the lyotropic liquid crystalline phases were determined and characterized by small-angle X-ray scattering. The amounts and relative proportions of the selective solvents can modulate the resulting microstructures, although the phase sequence observed depends on the relative PEO–PPO block ratio. A variety of lyotropic liquid crystalline (LLC) phases are thermodynamically stable in the system with copolymer (EO)$_{17}$(PO)$_{59}$(EO)$_{17}$, both of the normal ("oil-in-water") and of the reverse ("water-in-oil") morphology. The high hydrophobic content of copolymer (EO)$_4$(PO)$_{59}$(EO)$_4$, however, favours reverse LLC structures with low interfacial curvature. No normal LLC phases are formed by this system.

Key words: amphiphilic, triblock copolymers, poly(ethylene oxide), poly(propylene oxide), ternary mixtures, phase behaviour, lyotropic liquid crystals, SAXS, ^{2}H NMR.

Résumé : Opérant à 25 °C, on a étudié le comportement de la phase ternaire isotherme et de la structure des systèmes copolymère–eau–xylène amphiphiles de deux copolymères à trois blocs de poly(oxyde d'éthylène)–poly(oxyde de propylène) (PEO–PPO), (EO)$_4$(PO)$_{59}$(EO)$_4$ et (EO)$_{17}$(PO)$_{59}$(EO)$_{17}$. On a identifié les barrières des phases par RMN du ^{2}H et par inspection sous de la lumière polarisée. On a déterminé la microstructure et les échelles de longueur dans des phases de cristaux liquides lyotropes et on les a caractérisées par diffraction des rayons X à angle faible. Les quantités et les proportions relatives de solvants choisis peuvent moduler les microstructures qui en résultent, même si la séquence de phase qui est observée dépend du rapport relatif des blocs PEO–PPO. Une variété de phases de cristaux liquides lyotropes (LLC) sont thermodynamiquement stables dans le système ave le copolymère (EO)$_{17}$(PO)$_{59}$(EO)$_{17}$ de morphologie tant normale (huile dans l'eau) qu'inversée (eau dans l'huile). Toutefois, le contenu hydrophobe élevé du copolymère (EO)$_4$(PO)$_{59}$(EO)$_4$ favorise les structures LLC inversées avec de faibles courbures interfaciales. Il n'y a pas de phases LLC normales qui se forment dans ce système.

Mots clés : amphiphile, copolymères à trois blocs, poly(oxyde de propylène), poly(oxyde de propylène), comportement de phase, cristaux liquides lyotropes, SAXS, RMN du ^{2}H.

[Traduit par la Rédaction]

Introduction

Amphiphilic molecules can self-assemble in solution, forming thermodynamically stable aggregates. The amphiphilic molecules can be low molecular weight synthetic surfactants, natural lipids, or large molecules such as block copolymers. Block copolymers are an interesting class of amphiphiles. Amphiphilic triblock copolymers consisting of

a relatively hydrophobic poly(propylene oxide) (PPO) middle block and two hydrophilic poly(ethylene oxide) (PEO) end blocks are commercially available as Poloxamers or Pluronics in a large variety of molecular weights and PEO–PPO ratios (1, 2). The interest in the self-assembly of poly(ethylene oxide)–poly(propylene oxide)–poly(ethylene oxide) (PEO–PPO–PEO) block copolymers has grown considerably over the past decade (1–4). Self-assembly of these polymers is facilitated, as in the case of common low-molecular-weight surfactants, by the presence of the two different but covalently bonded parts. In the presence of a solvent selective for the hydrophilic PEO blocks such as water and a solvent selective for the hydrophobic PPO block such as xylene ("oil"), PEO–PPO–PEO block copolymers self-organize into a whole spectrum of self-assembled structures, from micellar solutions to lyotropic liquid crystalline phases with lamellar, hexagonal, and micellar or bi-

continuous cubic microstructures (3). The micellar solutions possess only short-range order (at the micelle level). The lyotropic liquid crystals exhibit long-range order beyond the level of the structural element (i.e., spherical, cylindrical, or planar block copolymer micelles). Both normal (oil-in-water) and reverse (water-in-oil) morphologies can be formed at constant temperature, depending on the ternary composition (4, 5). A notable feature that distinguishes the self-assembling behaviour of the PEO–PPO–PEO block copolymers from that of the low-molecular-weight surfactants (6) is the ability of the block copolymer to exhibit much richer structural polymorphism and to form a great variety of both normal and reverse liquid crystalline microstructures, as demonstrated in recent reports (3, 5, 7–10). Such an ability to form many normal and reverse structures at the same temperature has never before been observed in ternary systems of common surfactants with water and oil. The presence of oil enables the formation of reverse phases, where the oil is the continuous phase, in addition to the normal ones, where water is the continuous one. The concentration range over which the different phases form depend on the block copolymer molecular weight, the block PEO–PPO ratio, and the solvent quantity and quality. PEO–PPO–PEO block copolymers thus allow for great flexibility in attaining the desired structure under different conditions and can be viewed as model self-assembled systems (5).

For a PEO–PPO block copolymer of a given composition and molecular weight, the type of structures obtained in the presence of selective solvents appears to be a function of the volume fraction of the polar (water-like) – apolar (oil-like) components; this is attributed to the ability of the macromolecular blocks to swell to a different extent (based on the amount of solvent available) with the respective solvents and to thus modulate the interfacial "curvature" and resulting structure (11). The initial interfacial curvature can be readily modified by the ability of the copolymer blocks to swell to different extents with selective solvents. Thus the proper solvent selection allows for a large diversity in the microstructure of the final product and its corresponding properties. The quality of the solvent and its ability to swell the different blocks will of course affect the phase behaviour and structure, as a recent study suggests (8). Owing to the great potential for modification of their phase behaviour and to the variety of their physico-chemical properties, numerous industrial applications are found for Polaxamers (12). This class of materials is a rather new field of research, and ternary phase diagrams of many different systems have been reported recently (3, 5, 8–11, 13–22).

The phase behaviour and microstructure in ternary systems composed of amphiphilic copolymers, an aqueous solvent ("water"), and an organic solvent ("oil") are the subjects of an ongoing investigation by our research group (3, 5, 7–11, 16–18, 20–22). The work described here focuses on the isothermal phase behaviour and microstructure of ternary systems based on $(EO)_4(PO)_{59}(EO)_4$ and $(EO)_{17}(PO)_{59}(EO)_{17}$, triblock copolymers containing water and p-xylene as selective solvents for PEO and PPO, respectively. The two triblock copolymers studied have the same hydrophobic PPO block length, but the size of the PEO blocks differ and allow us to examine the effects of hydrophilic block size on the phase behaviour. Visual observation under polarized light

and ^{2}H NMR quadrupolar splittings have been used to delineate the phase boundaries, and small-angle X-ray scattering (SAXS) was used to characterize the structures.

Experimental section

Materials and sample preparation

The poly(ethylene oxide)–poly(propylene oxide)–poly-(ethylene oxide) copolymers with the trade names Pluronic L101 and P103 were obtained as a gift from BASF Corp., New Jersey, U.S.A. and were used as received. The polymers have nominal molecular weights of 3800 (10% PEO content) and 4950 (30% PEO content) g mol^{-1}, respectively. The resulting compositions are as follows: L101 — $(EO)_4$-$(PO)_{59}(EO)_4$ and P103 — $(EO)_{17}(PO)_{59}(EO)_{17}$. Deuterated water (99.80 atom % ^{2}H) was purchased from Dr. Glaser AG, Basel, Switzerland. p-Xylene (1,4-dimethylbenzene) of purity >99.0% was obtained from Aldrich. The bulk density of the two copolymers is approximately 1.03 and 1.05 g mL^{-1}, respectively. The bulk densities of p-xylene and deuterated water at 25°C are 0.861 and 1.105 g mL^{-1}, respectively. The above stated densities were used in calculating volume fractions from weight fractions. The samples were prepared individually by weighing appropriate amounts in 8 mm (i.d.) glass tubes, which were flame-sealed immediately. The samples were centrifuged repeatedly in alternating directions at regular intervals over a few days to facilitate proper mixing. After this treatment the samples were left to stand in a 25°C temperature-controlled room for at least one month for homogenization and to reach equilibration.

Delineation of phase boundaries

The equilibrated samples were examined by visual inspection in normal light and between crossed polarizers to check for phase separation, homogeneity, and birefringency. One-phase samples are clear and macroscopically homogeneous. Anisotropic phases can be recognized from their optical birefringence. Micellar solutions and cubic liquid crystals are optically isotropic and nonbirefringent. Whether a certain sample consisted of a single homogeneous phase or of two or three phases was also established from ^{2}H NMR measurements (carried out at a resonance frequency of 15.37 MHz on a Bruker MSL 100 superconducting spectrometer working in the Fourier transform mode). The sample temperature was controlled by passing air of 25 ± 0.5°C through the sample holder. The method uses the fact that the spectrum of an isotropic phase consists of a sharp singlet whereas anisotropic phases (hexagonal and lamellar) give rise to a doublet of broad peaks (a so-called quadrupolar splitting), and significant differences in magnitude are often observed (7). Mixtures of phases then display superposition of the known spectra of the individual phases, whereby the phase equilibrium can be determined.

Structural characterization using small-angle X-ray scattering (SAXS)

SAXS measurements were performed on a kratky compact small-angle system equipped with a position-sensitive detector (OED 50M from MBraun, Austria), containing 1024 channels of width 53.6 μm. Cu Kα radiation of wavelength 1.542 Å was provided by a Seifert ID-300 X-ray gen-

erator, operating at 50 kV and 40 mA. The obtained Bragg peaks were relatively sharp, in which case the peak positions were evaluated from the slit-smeared SAXS data (3, 7). The sample-to-detector distance was 277 mm. The volume between the sample and the detector was kept under vacuum during the measurements to minimize scattering from the air. The samples were filled into a 0.5-mm quartz capillary using a syringe; samples whose consistencies were very stiff were filled into a paste sample holder with thin mica windows. The temperature was controlled by a Peltier element with an accuracy of ±0.1°C. All SAXS measurements were performed at 25°C.

The structure of the lyotropic liquid crystalline phases was determined from the relative positions of the SAXS diffraction peaks. For the lamellar (smectic) and hexagonal (cylindrical assemblies crystallized in a two-dimensional hexagonal lattice) structures, the scattering pattern consists of a γ-function at each reciprocal-lattice vector, i.e., Bragg peaks whose positions are in the ratio 1:2:3:4… and 1:$\sqrt{3}$:2:$\sqrt{7}$:3…, respectively. The lattice parameters d (lamellar periodicity) and α (distance between the centers of adjacent cylinders) of the lamellar and hexagonal structures, respectively, were obtained from the position (q^*) of the first and most intense diffraction peak according to

[1]   lamellar: $q^* = \dfrac{2\pi}{d}$,   hexagonal: $q^* = \dfrac{4\pi}{\alpha\sqrt{3}}$

For the calculations involved in the SAXS analysis of the liquid–crystalline phases identified in the ternary system, the system is assumed to contain only two types of components, apolar and polar, separated by a sharp interface. The assumption made above concerning the components that constitute the polar and apolar domains is equivalent to strong segregation. The apolar component is the PPO part of the copolymer and the p-xylene, and the polar component is the PEO of the copolymer and the water. The volume fraction of the apolar domain, f, is defined as (3):

[2] $f = x\Phi_p + \Phi_{oil}$

where x is the volume fraction of PPO in the copolymer and Φ_p is the total volume fraction of the copolymer. The thickness of the apolar domains, δ, in the lamellar structure and the radius of the apolar domains, R, in the normal hexagonal structure were calculated from the lattice parameters and the volume fraction, f, of the apolar components for a ternary system (3, 7):

[3]   lamellar: $\delta = df$ hexagonal: $R = \alpha\sqrt{\left(\dfrac{\sqrt{3}}{2\pi}f\right)}$

The interfacial area per PEO block, a_p, or the area that a PEO block of the PEO–PPO–PEO block copolymer occupies at the interface between polar and apolar domains is another characteristic parameter of the microstructure, providing valuable information on the packing of the macromolecules. In the lamellar structure, the effective area per PEO block at the interface between polar and apolar domains can be determined from the lattice parameters without any assumptions concerning the degree of segregation or the local structure of the copolymer film (3, 7). The calculation

of a_p in the normal hexagonal structure also involved the copolymer and apolar volume fractions. The interfacial area can be calculated from

[4]   lamellar: $a_p = \dfrac{\upsilon_p}{d\Phi_p}$

hexagonal: $a_p = \dfrac{\upsilon_p}{\alpha\Phi_p}\sqrt{\left(\dfrac{2\pi}{\sqrt{3}}f\right)}$

where υ_p is the volume of one block-copolymer molecule (~6126 Å^3 for EO$_4$PO$_{59}$EO$_4$ and ~7828 Å^3 for EO$_{17}$PO$_{59}$EO$_{17}$, calculated from their bulk densities).

Results

Overview of the ternary phase behavior and structure of the (EO)$_{17}$(PO)$_{59}$(EO)$_{17}$–D$_2$O–p-xylene system

The isothermal phase diagram of the (EO)$_{17}$(PO)$_{59}$(EO)$_{17}$–D$_2$O–p-xylene ternary system at 25°C is presented in Fig. 1. Solid lines indicate the boundaries of the one-phase regions. The samples whose compositions fall outside the one-phase regions are dispersions of two or three (depending on the location in the phase diagram (3, 5, 7)). This system is remarkable in that six different lyotropic liquid crystalline phases have been identified: a lamellar (L$_\alpha$), normal (H$_1$) and reverse hexagonal (H$_2$) phases; a reverse bicontinuous cubic (V$_2$) phase; normal (I$_1$) and reverse micellar cubic (I$_2$) phases; as well as two isotropic solution phases, one (normal micellar) rich in water (L$_1$) and one with a high xylene-to-water ratio (L$_2$). The relative location of the various phases in the block copolymer – water – oil phase diagram follows the sequence L$_1$ → I$_1$ → H$_1$ → L$_\alpha$→ V$_2$ → H$_2$ → I$_2$ → L$_2$ (clockwise, starting from the water-rich corner of the ternary phase diagram Fig.1). This structural phase sequence is consistent with a decreasing interfacial mean curvature (H) from left ($H > 0$) to the right ($H < 0$), with $H = 0$ in the lamellar phase (23). This modulation of the interfacial curvature (and the resulting structure) has been attributed to the ability of the macromolecular blocks to swell with solvent to a varying extent depending on the amounts of solvent available. The interfacial curvature decreases because of a decreased swelling (solvation) of the PEO blocks with increasing solvent content. For the liquid crystalline phases the structures were ascertained based on the characteristic X-ray scattering patterns. The L$_\alpha$, H$_2$, I$_2$, and L$_2$ phases dominate the triangular diagram, whereas the L$_1$, I$_1$, H$_1$, and V$_2$ phases have more limited stability ranges. The L$_1$, I$_1$, H$_1$, and L$_\alpha$ structures are all formed along the copolymer–water axis and can swell to a varying extent with the oil. The ordered lyotropic liquid crystalline phases accommodate xylene to different degrees. The amount of xylene it is possible to accommodate increases from the I$_1$ phase to the I$_2$ phase. A presentation of the different phases and their structures follows.

Normal and reverse hexagonal phases, H$_1$ and H$_2$

The samples in the hexagonal regions are relatively stiff, transparent, and optically birefringent (anisotropic) and exhibit a splitting in the ^{2}H NMR spectrum. The structure in hexagonal phases consists of long parallel cylindrical aggregates arranged on a two-dimensional hexagonal lattice in the

$^a f$ is the apolar volume fraction.

$^b d$ and α are the lattice parameters.

$^c R$ is the hexagonal cylinder radius and δ is the lamellar thickness.

$^d a_p$ is the interfacial area per PEO block.

plane perpendicular to the cylinder axis. In the H_1 phase the cylinders have an apolar interior (oil and PPO) while in the H_2 phase the interior is polar (water and PEO). The H_1 region is stable in the 25–55 wt % copolymer range along the binary water–$(EO)_{17}(PO)_{59}(EO)_{17}$ axis and swells with up to 6 wt % xylene. Typical scattering diffraction patterns of samples belonging to the H_1 domains are reported in Fig. 2a. The relative positions of the Bragg reflections, $1:\sqrt{3}:\sqrt{4}:\sqrt{7}$, are consistent with the two-dimensional hexagonal order. Characteristic structural parameters for samples in the H_1 region are given in Table 1. The nearest neighbour (cylinder) distance decreased with increasing $(EO)_{17}(PO)_{59}(EO)_{17}$ copolymer content from 194 to 127 Å, consistent with a denser packing of the cylinders as their number increased. The interfacial area per PEO block was found to be in the range 133–147 Å^2.

The reverse H_2 phase in the $(EO)_{17}(PO)_{59}(EO)_{17}$–$D_2O$–$p$-xylene system appears between about 40 and 81 wt % of copolymer with a maximum water content of about 25 wt %. SAXS diffraction pattern from an H_2 sample ternary system of $(EO)_{17}(PO)_{59}(EO)_{17}$–$D_2O$–xylene is presented in Fig. 2b; the $1:\sqrt{3}:2:\sqrt{7}$ relative position of the four Bragg peaks observed confirmed the two-dimensional hexagonal structure. The reverse (water-in-oil) morphology was ascertained from the location of the H_2 region in the ternary phase diagram between the L_α and I_2 phases. Characteristic structural parameters for samples spanning the reverse hexagonal region are summarized in Table 1. The distance between the centers of two adjacent cylinders decreased (from 153 to 112 Å) with increasing copolymer concentration; the polar (PEO + water) cylinder radius, R, also decreased (from 45 to 33 Å). The interfacial area per PEO block decreased in the range 127–103 Å^2 with increasing copolymer concentration.

The lamellar phase (L_α)

The samples in the L_α regions have the simplest, one-dimensional microstructure, consisting of lamellae (planar

micelles). Macroscopically the samples in the L_α regions are transparent, optically birefringent and less stiff compared with the samples in the H_1 and H_2 phases. They exhibit a splitting in the ^2H NMR spectrum with a higher value than the splitting in the H_1 and H_2 phases. The L_α phase is formed on the binary water–$(EO)_{17}(PO)_{59}(EO)_{17}$ axis at copolymer concentrations greater than 38 wt % and continues up to about 81% copolymer (Fig. 1). L_α is the most extensive of the one-phase regions; it can accommodate up to 21 wt % xylene and allows a high degree of swelling with oil.

The one-dimensional structure of the samples in the L_α region was established by SAXS measurements that gave diffraction patterns with second- and even third-order Bragg peaks. The relative positions of the peaks follow the expected sequence for a lamellar structure: $1:2:3: \ldots$ (see Fig. 3a). Values for the lamellar lattice periodicity (spacing), d, the apolar (PPO + xylene) thickness, δ, and the interfacial area per block, a_p, determined in the L_α regions of the $(EO)_{17}(PO)_{59}(EO)_{17}$–$D_2O$–xylene system are given in Table 1. The lamellae domain lengths vary according to varia-

tions in volume fractions, i.e., increased copolymer concentration leads to decreased *d* values at constant oil concentration. The interfacial area per PEO block is found to be in the range 95–122 $Å^2$. The δ values are in the range 46–73 Å.

Reverse bicontinuous cubic liquid crystalline phase (V_2)

The V_2 region is observed in the $(EO)_{17}(PO)_{59}(EO)_{17}$–water–xylene system as a small region at high (75–82 wt %) copolymer concentration. The relative position of this cubic phase in the phase diagram (between the L_α and H_2 phases) indicates that its structure is bicontinuous with the curvature of the polar–apolar interface toward water (23). The corresponding V_1 phase was not observed. The homogeneous samples in this region are clear, optically isotropic, and very stiff and exhibit a sharp singlet in the ^2H NMR spectrum,

features characteristic of a cubic structure. A typical SAXS diffraction pattern is shown in Fig. 3*b*. Scattering data from lyotropic cubic liquid crystalline phases generally contain only a small number of reflections, which makes a proper indexation and space group determination essentially difficult. As seen in Fig. 3*b*, the present system is no exception in this respect. The scattering function is dominated by a strong correlation peak at $q = 0.035$, while another reflection is observed at $q = 0.057$ $Å^{-1}$. The most commonly observed crystallographic space group for the bicontinuous cubic phases of surfactants and lipids (23, 24), as well as in amphiphilic block copolymer systems (3, 5, 9, 11, 16), is $Ia3d$ (Q^{230}). This space group allows the Bragg reflections $hkl = 211, 220, 321, 400, ...,$ which give peaks in the relative (scattering vector) positions $\sqrt{6}, \sqrt{8}, \sqrt{14}, \sqrt{16}, ...$ Recent structure factor calculations (25) have shown the first reflec-

Fig. 4. SAXS diffraction patterns from representative samples in the (*a*) normal micellar cubic phase, I_1, and (*b*) reverse micellar cubic phase, I_2, of the $(EO)_{17}(PO)_{59}(EO)_{17}$–$D_2O$–*p*-xylene system at 25°C. The sample compositions are 30.2:69.8:0 and 34.6:10.1:55.4 wt % copolymer:water:oil, respectively. The scattering positions are marked with arrows and the Miller indices.
tion, corresponding to *hkl* = 211, to be the most intense. The two reflections in the present cubic phase are $\sqrt{6}$ and $\sqrt{8}$, which are consistent with the first two reflections of the *Ia*3*d* space group. The first two Bragg peaks in the diffraction pattern shown in Fig. 3*b* are indexed as 211 and 220. Therefore, although the reflections are very few, the two peaks of the cubic lattice matches only, and is assigned to, the *Ia*3*d* crystallographic space group. The cubic lattice of the *Ia*3*d* space group is consistent with that afforded by the Gyroid minimal surface (23, 26).

Micellar cubic structures (normal, I_1, and reverse, I_2)

Macroscopically the samples in the homogeneously one-phase I_1 and I_2 regions are very stiff with a clear glassy appearance, and they are optically isotropic (nonbirefringent) gels. They exhibit a sharp singlet in the H^2 NMR spectrum, characteristic of an isotropic structure. The L_1–I_1 and L_2–I_2 phase transitions are easy to detect with the eye, since the cubic phases are significantly more viscous. The micellar cubic lyotropic liquid crystalline structural elements (micelles) can be arranged in a large number of cubic lattices belonging to different crystallographic space groups (23, 26). The positions of the Bragg diffraction peaks obey different relationships for the different space groups. However, all space groups can be classified in three main families of cubic lattices (26): primitive (P), body-centered (I), and face-centered (F). A small homogenous one-phase I_1 region is found in the $(EO)_{17}(PO)_{59}(EO)_{17}$–$D_2O$–xylene system along the copolymer–water binary axis between the isotropic micellar solution L_1 and the hexagonal H_1 phase. The cubic structure forms over a more limited copolymer concentration range (25–35 wt %) at 25°C. The location of this cubic phase in the ternary phase diagram suggests (23) that it is composed of normal micelles that have crystallized into a cubic lattice. A SAXS diffraction pattern, typical of samples in the I_1 region for the $(EO)_{17}(PO)_{59}(EO)_{17}$–$D_2O$–xylene system, is presented in Fig. 4*a*. A total of four Bragg peaks are identified, which can be indexed as the *hkl* = 111, 220, 311, and 422 reflections of a face-centered space group,

*Fd*3*m* (Q^{227}), characterized by Bragg reflections whose reciprocal *d* spacings follow the relationship $\sqrt{3}, \sqrt{8}, \sqrt{11}, \sqrt{24}$. The four reflections in the present cubic phase are hence consistent with the first, second, third, and sixth reflections in the *Fd*3*m* space group. The *Fd*3*m* face-centered micellar cubic structure has also been found in other similar copolymer–water–oil systems (5, 11). A proposed structural model for the *Fd*3*m* cubic phases involves a total of 24 spherical micelles per unit cell, with a bimodal size distribution composed of 8 larger and 16 smaller micelles (27).

A large isotropic liquid crystalline I_2 region is observed between the isotropic reverse micellar solution L_2 and the reverse hexagonal H_2 phase. The cubic I_2 structure is stable over a wide copolymer concentration range of about 20–60 wt % at 25°C. The location of this cubic phase in the ternary phase diagram suggests (11, 23) that its microstructure consists of reverse micelles that have crystallized into a cubic lattice. A SAXS diffraction pattern obtained from an I_2 sample is presented in Fig. 4*b*. Only three Bragg peaks can be identified in the diffraction pattern as the higher order peaks have very low intensities. The relative intensity of the observed peaks and the inability to discern higher-order reflections follow the trend expected from structures of cubic aspect 8 and, more specifically, from the centrosymmetric *Im*3*m* (Q^{229}) space group (26). The first strong correlation peak and other weaker reflections have been indexed according to a body-centered structure (bcc, space group *Im*3*m*) that allows the Bragg reflections *hkl* = 110, 200, 211, 220, 310, 222, 321, 400, 441, and so forth, which give peaks in the relative (scattering vector *q*) positions $\sqrt{2}, \sqrt{4}, \sqrt{6}, \sqrt{8}, \sqrt{10}, \sqrt{12}, \sqrt{14}, \sqrt{16}$, and so forth. The three reflections in the present cubic phase are hence consistent with the first, fourth, and sixth reflections in the *Im*3*m* space group.

Water-rich and water-lean solution (normal micellar, L_1, and reverse micellar, L_2)

In addition to the phases of liquid crystalline microstructure that occupy the major part of the $(EO)_{17}(PO)_{59}(EO)_{17}$–$D_2O$–*p*-xylene phase diagram (above 25 wt %

copolymer), two isotropic solution regions, L_1 and L_2, are present in the water-rich corner and the water-lean side, respectively, of the phase diagram. In the L_1 phase, micelles can form without the presence of oil, while in the L_2 phase, micelle formation appears to require a small amount of water (28–31). In this respect the polyoxyalkylene block copolymers are similar to nonionic surfactants of the alkyl-oligoethylene oxide type (32). An isotropic (as judged from optical inspection as well as the single sharp peak in the deuterium NMR spectra) water-rich solution region (L_1) is found along the copolymer–water axis, up to 25 wt % $(EO)_{17}$-$(PO)_{59}(EO)_{17}$ copolymer, and can solubilize no more than 2 wt % xylene. The L_2 phase in the $(EO)_{17}(PO)_{59}(EO)_{17}$–$D_2O$–$p$-xylene ternary system is more extensive, extending up to about 80 wt % copolymer. The reverse micelles can solubilize a maximum of 7 wt % water before phase separation occurs. The L_1 and L_2 micellar solution phases are isotropic, optically transparent, and fluid, but they progressively become more viscous as the copolymer increases.

Overview of the ternary phase behavior and structure of the $(EO)_4(PO)_{59}(EO)_4$–D_2O–p-xylene system

The $(EO)_4(PO)_{59}(EO)_4$ triblock copolymer is a cloudy liquid at 25°C. The copolymer is very hydrophobic and asymmetric in PEO–PPO composition (contains 10 wt % PEO and 90 wt % PPO). Owing to the low PEO block molecular weight, the PEO does not crystallize at low temperatures. Hence, the copolymer is disordered in the dry state at ambient temperatures. The isothermal phase diagram of the $(EO)_4(PO)_{59}(EO)_4$–D_2O–p-xylene ternary system at 25°C is presented in Fig. 5. The phase boundaries of the one-phase regions are shown by solid lines. The homogeneous one-phase regions observed, when starting on the water axis and progressing clockwise over to the oil corner, are the following: lamellar L_α phase, reverse hexagonal H_2 phase, reverse micellar cubic phase I_2, reverse micellar L_2 phase. The L_2 phase dominates the triangular diagram, whereas L_α, H_2, and I_2 phases have more limited stability ranges. The high PPO (hydrophobic) content of $(EO)_4(PO)_{59}(EO)_4$ favors reverse (water-in-oil) phases with low interfacial curvature. No phase of normal (oil-in-water) morphology has been found for any composition at 25°C in this system. The copolymer is completely miscible with p-xylene. An abrupt increase in water solubilization is observed in the L_2 phase at copolymer concentrations above 40 wt %. This is characteristic for micelle formation (33). Increased water content at high copolymer concentrations increases interactions between the micelles and a reverse micellar cubic phase is formed (34). The samples in the I_2 phase are stiff and isotropic. Upon even higher water concentrations, the curvature of the formed aggregates changes and an anisotropic liquid crystalline hexagonal H_2 phase is formed. A narrow anisotropic lamellar liquid crystalline L_α phase with zero interfacial curvature is found on the binary copolymer–water axis. A presentation of the different phases and their structures follows.

The lamellar phases (L_α)

The samples in the L_α regions have the simplest, one-dimensional microstructure consisting of lamellae (planar micelles). The samples in the L_α regions are soft, optically birefringent with a cloudy appearance and exhibit splittings

Fig. 5. Phase diagram of the $(EO)_4(PO)_{59}(EO)_4$–p-xylene system at 25°C.
in the ^2H NMR spectrum with a higher value than the splittings in the H_2 phases. The L_α region is stable in the 40–65 wt % copolymer range along the binary water–$(EO)_4$-$(PO)_{59}(EO)_4$ axis and swells with up to 5 wt % xylene (Fig. 5). The L_α phase contains quite a lot of water.

The one-dimensional lamellar structure was established by SAXS measurements. The scattering profiles of the samples proved the lamellar structure by showing diffraction peaks in the relative position 1:2:3 (see Fig. 6a). In each sample, two to three peaks following this sequence are usually registered, confirming the lamellar microstructure. The lattice parameter, d, was obtained directly from the position of the first peak of the SAXS spectra using eq. [1]. The results for the lattice parameter, including the apolar thickness, δ, and the interfacial area per PEO block, are summarized in Table 2. The d values decreased from 145 to 85 Å with increasing copolymer volume fraction from 0.4 to 0.6. The apolar thickness indeed remained almost constant (at 51–58 Å²) throughout the wide composition range examined, whereas the interfacial area increased to a limited extent with increasing copolymer concentration.

Reverse hexagonal lyotropic liquid crystalline phases (H_2)

In the reverse hexagonal phase water is inside and the oil is outside the cylinders. The samples in the H_2 region are clear, relatively stiff, and optically anisotropic and exhibit a splitting in the ^2H NMR spectrum. The two-dimensional hexagonal structure (hexagonally packed array of cylindrical micelles) was established by SAXS experiments, while the reversed morphology was ascertained from the location of the hexagonal region, H_2, in the ternary phase diagram.

The reverse hexagonal phase, H_2, is formed between the L_α and I_2 phases. The H_2 region extends in the 60–75 wt % copolymer range. The polar domain of the H_2 phase can swell with a large amount of water, up to a maximum content of about 34 wt %. A SAXS diffraction pattern, typical of samples in the H_2 region, is presented in Fig. 6b. The 1:

Fig. 6. SAXS diffraction patterns from representative samples in the (*a*) lamellar phase, L_α; (*b*) reverse hexagonal phase, H_2; and (*c*) reverse micellar cubic phase, I_2, of the $(EO)_4(PO)_{59}(EO)_4$–D_2O–*p*-xylene system at 25°C. The sample compositions are 49.7:50.3:0, 69.6:25.2:5.2, and 79.4:15.2:5.4 wt % copolymer:water:oil, respectively. The Bragg peaks are marked with arrows and the Miller indices.

Table 2. Characteristic parameters in the H_2 and L_α phases of the $(EO)_4(PO)_{59}(EO)_4$–D_2O–*p*-xylene system.

| Phase | Volume fractions | | | f^a | d, α^b (Å) | R, δ^c (Å) | $a_p{}^d$ (Å^2) |
	Φ_P	Φ_{D_2O}	Φ_{oil}				
H_2	0.69	0.31	0	0.64	127	40	80
H_2	0.7	0.3	0	0.65	145	45	67
H_2	0.75	0.25	0	0.7	126	36	67
H_2	0.66	0.28	0.06	0.61	166	54	66
H_2	0.7	0.24	0.06	0.71	152	43	58
H_2	0.71	0.26	0.03	0.69	150	44	61
H_2	0.8	0.17	0.03	0.78	122	30	49
L_α	0.41	0.59	0	0.38	145	52	104
L_α	0.45	0.55	0	0.41	123	51	111
L_α	0.51	0.49	0	0.48	122	58	98
L_α	0.6	0.4	0	0.56	101	56	101
L_α	0.61	0.36	0.03	0.6	85	51	117

$^a f$ is the apolar volume fraction.
$^b d$ and α are the lattice parameters.
$^c R$ is the hexagonal cylinder radius and δ is the lamellar thickness.
$^d a_p$ is the interfacial area per PEO block.

$\sqrt{3}:2:\sqrt{7}$ relative position of the Bragg peaks (with respect to that of the first and most intense peak) confirms the two-dimensional hexagonal structure. Characteristic structural parameters for some representative samples in the H_2 region are given in Table 2. The distance between the centers of two adjacent cylinders decreased (from 166 to 122 Å) with increasing copolymer volume fraction (from 0.66 to 0.80). The polar (PEO + D_2O) cylinder radius, R, is found in the range 30–54 Å, while the interfacial area per PEO copolymer block decreased to a limited extent with increasing copolymer concentration.

Reverse micellar cubic lyotropic liquid crystalline phase (I_2)

The homogeneous reverse I_2 phase is found in a rather narrow and restricted region but stretching inside the ternary phase diagram between the H_2 and L_2 phases at fairly higher copolymer concentration. The one-phase I_2 region exists only when xylene is present in the system. The samples in the I_2 region are very stiff, clear, optically isotropic (nonbirefringent), and exhibit a sharp singlet in their ^2H NMR spectra, all characteristic of the cubic structure. The cubic structure forms over a more limited copolymer concentration range (25–35 wt %) at 25°C. The location of this cubic phase in the ternary phase diagram suggests (23) that it is composed of reverse micelles that have crystallized into a cubic lattice. A SAXS diffraction pattern, typical of sam-

ples in the I_2 region for the $(EO)_4(PO)_{59}(EO)_4$–water–xylene system, is presented in Fig. 6c. Samples in the I_2 region display two fairly strong Bragg peaks at low q for all compositions, indicating long-range order of micelles with a
relatively large unit cell characteristic of an ordered structure, but the scattering peaks at higher q are badly resolved. As the reflections are too few, indexation to a cubic space group is very uncertain.

Reverse (oil-rich) micellar solution phase, L_2

The L_2 phase occupies a large area in the diagram of Fig. 5. $(EO)_4(PO)_{59}(EO)_4$ is miscible with p-xylene in all proportions, and the L_2 phase extends along the whole water-lean side of the phase diagram. Water can be solubilized in the p-xylene–$(EO)_4(PO)_{59}(EO)_4$ solution; the amount of solubilized water increases with increasing copolymer concentration (see Fig. 5). These binary solutions can dissolve up to a maximum of about 13 wt %, producing an isotropic L_2 phase.

Deuterium NMR in liquid crystalline phases for both systems

The NMR spectrum from the deuterated water is dominated by the interaction of the deuteron-quodrupole moment with the electric-field gradients in the nucleus. In anisotropic lyotropic liquid–crystalline (LLC) samples the quadrupole interaction generates an NMR spectrum with two peaks of equal intensity, while for an isotropic LLC or solution a single sharp peak will be the result because of the rapid and isotropic molecular motion, which averages the interaction to zero (35, 36). The magnitude of the deuterium-quadrupole splitting also contains information on the hydration of the amphiphilic copolymers and additional evidence of the structural identification can be obtained from ^2H NMR experiments. The observed quadrupole splittings in LLC phases can be further analyzed by the conventional two-site model (35), which assumes that water is either "free" or "bound", with a fast exchange between the free and bound water within the NMR time scale and the ordering of free water molecules being negligible:

$$[5] \qquad \Delta(^2H) = n\upsilon_Q S(X_P/X_W)$$

where υ_Q is the quadrupole splitting constant, S the order parameter of bound water molecules, n is the hydration number, and (X_P/X_W) is the molar ratio between polymer and water.

Representative ^2H NMR spectra are presented in Fig. 7. The presence of an isotropic phase is directly noted from the presence of a sharp singlet (Fig. 7a) and that of an anisotropic phase from a doublet of peaks. The hexagonal phase is characterized by a pair of sharp peaks (Fig. 7b). The lamellar phase exhibits a broader doublet with a larger quadrupole splitting than for the hexagonal phase (Fig. 7c). Deuterium quadrupole splitting values (Δ^2H) for some typical samples in the liquid crystalline phases of the $(EO)_{17}$-$(PO)_{59}(EO)_{17}$–D_2O–p-xylene and $(EO)_4(PO)_{59}(EO)_4$–D_2O–xylene systems at 25°C are shown in Tables 3 and 4, respectively. Δ^2H values observed in the lamellar phase region are much larger than those in the hexagonal phase region for both systems. The magnitude of the Δ^2H values is found to depend not only on copolymer-to-water molar ratio but also on the xylene content. Samples with high water content give rather small Δ^2H values, while those with low water contents give rise to Δ^2H values of larger magnitude. However, Δ^2H

values recorded for the $(EO)_{17}(PO)_{59}(EO)_{17}$– D_2O–p-xylene system are larger than those measured for $(EO)_4$-$(PO)_{59}(EO)_4$–D_2O–xylene system in both hexagonal and lamellar phase regions. Tables 3 and 4 show that, for samples with fairly constant xylene content, the values of Δ^2H increase with increasing copolymer–water molar ratio for both liquid crystalline phases. Further analysis of the Δ^2H values shows no linear increase with increasing molar ratio of copolymer–water. Deviations from the two-site model with constant hydration number and order parameter as expected from eq. [5] may be due to the non-ideal swelling of liquid crystals (35).

Discussion

The isothermal phase diagrams of the $(EO)_{17}(PO)_{59}(EO)_{17}$–$D_2O$–$p$-xylene and the $(EO)_4(PO)_{59}(EO)_4$–D_2O– p-xylene ternary systems at 25°C are presented in Figs. 1 and 5, respectively. The difference in the phase behavior in water–xylene of the two copolymers $(EO)_{17}(PO)_{59}(EO)_{17}$ and $(EO)_4(PO)_{59}(EO)_4$ with similar hydrophobic middle block is striking. The $(EO)_{17}(PO)_{59}(EO)_{17}$–$D_2O$–$p$-xylene system exhibited a nearly identical phase diagram to the $(EO)_{27}(PO)_{61}(EO)_{27}$–$D_2O$–$p$-xylene system (9), whereas the $(EO)_4(PO)_{59}(EO)_4$–D_2O–p-xylene system displayed a phase diagram similar to that of the $(EO)_5(PO)_{68}(EO)_5$– D_2O–p-xylene system (22). As is seen in Figs. 1 and 5, the two phase diagrams are quite different. The major difference between the two systems concerns the observed phase sequence. The fairly symmetric copolymer $(EO)_{17}(PO)_{59}(EO)_{17}$ exhibits a ternary phase behaviour, which is almost symmetric with respect to the interchange of water and oil volume fractions. $(EO)_{17}(PO)_{59}(EO)_{17}$ allows a greater variation in the phase behavior both along the copolymer–water axis and when "oil" is present. A full phase sequence from L_1 to L_2 is observed, i.e., $L_1 \rightarrow I_1 \rightarrow H_1 \rightarrow L_\alpha \rightarrow V_2 \rightarrow H_2 \rightarrow I_2 \rightarrow L_2$. Thus the ternary-phase diagram of $(EO)_{17}(PO)_{59}(EO)_{17}$–$D_2O$–$p$-xylene, as presented here, is very rich with a record number of eight different phases. The sequence of microstructures formed by $(EO)_{17}(PO)_{59}(EO)_{17}$ in water–oil mixtures is similar to that encountered in solvent-free block copolymers at temperatures below the order–disorder transition (ODT) (37, 38). However, copolymers of different relative block composition are needed to attain the different structures in the solvent-free case (38). On the other hand, with the highly hydrophobic and asymmetric copolymer $(EO)_4(PO)_{59}(EO)_4$, the sequence is "truncated" and gives preferably reverse structures. It is worth noting here that a truncated phase sequence is normally observed in ternary surfactant–water–oil systems (39). The phase of surfactants is influence-limited by a "preferred" interfacial curvature (originating from the surfactant geometry) so that a ternary isothermal surfactant–water–oil phase diagram exhibits either normal (oil-in-water) or reverse (water-in-oil) phases, but usually not both (6, 22, 40). The high hydrophobic PPO content of $(EO)_4(PO)_{59}(EO)_4$ results in an interfacial curvature that is biased towards water-in-oil structures. Thus the similarity of the $(EO)_4(PO)_{59}(EO)_4$ and surfactant phase diagrams is striking. Similar observations have been obtained for the $(EO)_5(PO)_{68}(EO)_5$–D_2O–p-xylene system (22).

Fig. 7. Typical ^{2}H NMR spectra for various samples of the $(EO)_{17}(PO)_{59}(EO)_{17}$–$D_2O$–$p$-xylene system at 25°C: (*a*) sharp singlet indicative of an isotropic phase (line width at half-maximum height $\approx$13 Hz); (*b*) one splitting from a hexagonal phase ($\Delta^2H = 88$ Hz); (*c*) one splitting from a lamellar phase ($\Delta^2H = 234$ Hz); (*d*) a two-phase region consisting of isotropic and anisotropic mixtures; (*e*) a two-phase region containing a mixture of hexagonal and lamellar phases. The sample compositions are 38.6:15.6:45.8, 30.0:65.1:4.9, 64.7:24.7:10.6, 81.2:17.1:1.7, and 42.3:34.8:22.9 wt % copolymer:water:oil, respectively.

In the ternary block copolymer systems, the structural sequence is driven as a function of the related composition parameter (11), which has been defined as f (see eq. [4]). The phase sequence for the $(EO)_{17}(PO)_{59}(EO)_{17}$ copolymer is symmetric around $f = 0.5$ with lamellar stability in the range $0.4 < f < 0.7$, and the normal and reverse hexagonal phases in the range $0.3 < f < 0.4$ and $0.6 < f < 0.7$, respectively. For the system with short PEO blocks ($(EO)_4(PO)_{59}(EO)_4$–D_2O–p-xylene system), the lamellar phase is shifted towards higher f. Thus the PEO–PPO block ratio determines the stability range of the various phases in any copolymer– water– oil system. The results of the present study corroborate the observations and findings reported by Svensson et al. (22),

as could be expected, since phase behaviour depends more on the PEO–PPO ratio than on molecular weight, which was fixed for their copolymers. Reference is therefore made to their work (see ref. 22) for further discussion concerning our present study.

Conclusion

The complete ternary phase diagrams for the two systems $(EO)_{17}(PO)_{59}(EO)_{17}$–$D_2O$–$p$-xylene and $(EO)_4(PO)_{59}(EO)_4$–D_2O–p-xylene have been determined at 25°C. The two copolymers have the same size middle-block (PPO) but different size end-blocks (PEO) and asymmetry. The $(EO)_{17}$-$(PO)_{59}(EO)_{17}$–D_2O–p-xylene system exhibits a record eight different phases, all thermodynamically stable at the same temperature: normal micellar cubic (I_1), normal hexagonal (H_1), lamellar (L_α), reverse bicontinuous cubic (V_2), reverse hexagonal (H_2), and reverse micellar cubic (I_2) lyotropic liquid crystalline phases, as well as water-rich (L_1) and water-lean micellar (L_2) solutions. In the $(EO)_4(PO)_{59}(EO)_4$–D_2O–p-xylene system the L_1, I_1, H_1, and V_2 structures are absent. An extensive L_2 region is observed. The highly asymmetric and hydrophobic $(EO)_4(PO)_{59}(EO)_4$ copolymer shows a truncated phase sequence, which is a consequence of early solvent water saturation of the short PEO blocks (22). The self-assembly mode of the $(EO)_4(PO)_{59}(EO)_4$ copolymer in water + oil is strikingly similar to the self-assembly of $(EO)_5(PO)_{68}(EO)_5$ as well as surfactants in solutions (22). Normally, the surfactant phase diagrams are less rich than the ones observed with most polyoxyalkene block copolymers. The surfactants, and in particular the nonionic surfactants, can often be described as having a preferred or spontaneous mean curvature of the polar–apolar interface, which limits the range of stable structures and reduces the richness of the phase diagram (22, 40). The high hydrophobic (PPO) content of the $(EO)_4(PO)_{59}(EO)_4$ copolymer results in an interfacial curvature that is biased towards water-in-oil structures. No normal (oil-in-water) phases were observed in $(EO)_4(PO)_{59}(EO)_4$–D_2O–p-xylene system at 25°C.

The activity of 3- and 7-hydroxyflavones as scavengers of superoxide radical anion generated from photo-excited riboflavin

Paulina Montaña, Nora Pappano, Nora Debattista, Vicente Ávila, Ariana Posadaz, Sonia G. Bertolotti, and Norman A. García

Abstract: The visible-light irradiation of the system Rivoflavin plus 3-hydroxyflavone or plus 7-hydroxyflavone, under aerobic conditions, produces a series of competitive processes that depend on the relative concentrations of the pigment and the flavones. The picture comprises photochemical mechanisms that potentially operate in nature. They mainly include the quenching of Rf singlet ($^1Rf^*$) and triplet ($^3Rf^*$) excited states (with bimolecular rate constants in the order of 10^9 M^{-1} s^{-1}) and superoxide radical anion-mediated reactions. The participation of the oxidative species singlet molecular oxygen was not detected. The overall result shows chemical transformations in both Rf and 3-hydroxyflavone. No experimental evidence was found indicating any chemical reaction involving 7-hydroxyflavone. The fate of the pigment also depends on the amount of the dissolved flavonoid. At 50 mM concentrations of these compounds or higher, practically no photochemistry occurs, owing to the extensive quenching of $^1Rf^*$. When the concentration of the flavones is in the mM range or lower, $^3Rf^*$ is photogenerated. Then, the excited triplet species can be quenched mainly by the flavones through an electron-transfer process, yielding the semireduced pigment. The latter interacts with dissolved oxygen producing $O_2^{\bullet-}$, which reacts with both the pigment and 3-hydroxyflavone. In summary, 3-hydroxyflavone and 7-hydroxyflavone participate in the generation of superoxide ion in an Rf-sensitized process, and simultaneously 3-hydroxyflavone constitutes a degradable quencher of the oxidative species.

Key words: flavones, riboflavin, sensitization, singlet molecular oxygen, superoxide radical anion.

Résumé : L'irradiation en lumière visible du système Riboflavine plus 3-hydroxyflavone ou plus 7-hydroxyflavone, dans des conditions aérobiques, produit une série de processus compétitifs qui dépendent des concentrations relatives du pigment et des flavones. L'étude englobe les mécanismes photochimiques qui potentiellement se produisent dans la nature. Ils comprennent principalement la désactivation des états excités singulet Rf ($^1Rf^*$) et triplet ($^3Rf^*$) (avec des constantes de vitesse bimoléculaire de l'ordre de 10^9 M^{-1} s^{-1}) et des réactions du radical superoxyde induites par un anion. On n'a pas mis en évidence la participation de l'espèce oxydante : l'oxygène moléculaire singulet. Le résultat global montre les transformations chimiques à la fois dans les états excités Rf et dans la 3-hydroxyflavone. On n'a pas trouvé de preuves expérimentales d'une réaction chimique impliquant la 7-hydroxyflavone. Le sort du pigment dépend également de la quantité de flavonoïde dissoute. A des concentrations en flavonoïdes de l'ordre de 50 mM ou plus, il ne se produit pratiquement pas de photochimie à cause de la désactivation importante de l'état singulet excité $^1Rf^*$. Quand la concentration en flavones est de l'ordre du mM ou moins, l'état triplet $^3Rf^*$ est photorégénéré. Dans ces conditions l'espèce à l'état triplet peut-être désactivée principalement par les flavones, via un processus impliquant un transfert d'électrons, conduisant alors au pigment semi réduit. Ce dernier interagit avec l'oxygène dissous produisant $O_2^{\bullet-}$, qui réagit à la fois avec le pigment et avec la 3-hydroxyflavone. En résumé, la 3-hydroxyflavone et la 7-hydroxyflavone participent à la génération de l'ion superoxyde dans un processus sensibilisé par l'état excité Rf, et simultanément la 3-hydroxyflavone constitue un désactiveur dégradable des espèces oxydantes.

Mots clés : flavones, riboflavine, sensibilisation, oxygène moléculaire singulet, anion radicalaire superoxyde.

Introduction

A considerable number of articles have been published, specially in the last decade, on the isolation (1), synthesis (2), and properties (3–5) of natural and artificial flavonoids. The interest is mainly because of the antioxidative properties (6–8) of this family of compounds, widely distributed in nature, whose applications, among others, include the signifi-

cant protective effect against fat deterioration (9–11), antibacterial activities (1), and potential inhibitory action against cancer initiation (2, 5). These processes take place by different mechanisms, including the scavenging or trapping of activated electrophilic forms of carcinogenics: oxygen radicals such as peroxy radicals, singlet molecular oxygen [$O_2(^1\Delta_g)$], superoxide anion ($O_2^{\bullet-}$), or hydroxyl radicals. Nevertheless, the antioxidant properties of certain flavonoids have been the subject of contradictory interpretations, and even promotion of oxidizing activity has been suggested (12–14).

In recent years we have studied the ability of different flavonoids to act as quenchers of $O_2(^1\Delta_g)$ photochemically generated from Rose Bengal (RB), the synthetic xanthene dye most frequently used as an $O_2(^1\Delta_g)$ sensitizer (15). The whole process is depicted by steps [11], [12], and [13], as shown in Scheme 1 (see Results section). In the scheme, S is a dye sensitizer responsible for the visible light absorption (RB), whereas $^1S^*$ and $^3S^*$ are the respective singlet and triplet-excited states of S and $O_2(^3\Sigma_g^-)$ is the ground state molecular oxygen. $O_2(^1\Delta_g)$ is the singlet molecular oxygen generated by energy transfer from $^3S^*$ to $O_2(^3\Sigma_g^-)$. $O_2(^1\Delta_g)$ can be physically deactivated by collision with solvent molecules (process [13]) or with the flavonoid and (or) the sensitizer (process [11]), or it can react with the latter compounds, giving rise to oxidation products (step [12]). Results from other authors (14) and from ourselves (9–11) indicate that the effectiveness of flavones as $O_2(^1\Delta_g)$ quenchers mainly depends on structural effects and particularly on the number and position of the OH groups in the flavonoid skeleton.

Regarding the involvement of flavonoids in the generation and quenching of oxidative species, a satisfactory approach to the actual situation in living environments can be the study of photoprocesses occurring in the presence of natural dye-sensitizers. A pigment of particular interest is vitamin B2 or Riboflavin (Rf) (Fig. 1), which has been postulated as a possible sensitizer for the photooxidative degradation of a number of relevant natural substrates present in different classes of foods and living organisms (16). Nevertheless, the potential properties of Rf as a redox intermediary of the visible-light-transparent flavones in its presence (as a visible-light sensitizer) has not been investigated, according to our knowledge. This is the aim of the present kinetic and mechanistic study, employing 3-hydroxyflavone (3-OHF) and 7-hydroxyflavone (7-OHF) (Fig. 1). Since both Rf and the hydroxyflavones (OHF) can occupy common locations in diverse biological assemblies, all information about the behaviour of the visible-light-promoted interactions between the flavones and the relevant pigment Rf will help increase the knowledge of the behaviour of activated oxidative species in nature.

Experimental

Materials

3-Hydroxyflavone, 7-hydroxyflavone, Riboflavin (all from Sigma), and sodium azide (NaN_3) (Aldrich) were employed as received. The solvent was MeOH, HPLC grade from Sintorgan (Argentina).

Scheme 1. Possible photoprocesses upon visible light irradiation of the system Rf–OHF in MeOH; S = Riboflavin and OHF = 3- or 7-hydroxyflavone.
Methods

Aerobic photolysis of methanolic solutions containing OHF (0.4–0.5 mM for the observation of changes in the UV spectra) and Rf (ca. 0.02 mM) were carried out in a PTI unit provided with a high-pass monochromator and 150 W Xe lamp, irradiating the Rf solutions with 440 ± 10 nm and ensuring that the light was only absorbed by the sensitizer. The rates of Rf photodecomposition in nitrogen-saturated solutions, either in the presence or in the absence of the OHF, were evaluated by monitoring the absorbance decrease at 445 nm as a function of irradiation time.

The Rf-sensitized photooxygenation rates of the flavones were determined from the initial slopes of oxygen consumption vs. irradiation time, employing a specific oxygen electrode (Orion 97–08).

The steady-state quenching of the Rf fluorescence (absorbance at 445 nm ≅ 0.1) was studied with an RF 5301-PC Shimadzu spectrofluorimeter at 25 ± 1°C in air-equilibrated solutions. Fluorescence lifetimes were measured by the time-correlated single photon counting technique on an Edinburgh FL-9000CD instrument. In both cases excitation and emission wavelengths were 445 and 515 nm, respectively. Ground-state absorption spectra were registered in a Hewlett-Packard 8452A diode array spectrophotometer.

N_2-saturated aqueous solutions of Rf (0.01 mM) were photolysed using a flash photolysis apparatus. A nanosecond Nd:YAG laser system (Spectron) at 355 nm was the excitation source, employing a 150 W xenon lamp as the analysing light. The detection system comprised a PTI monochromator and a red-extended photomultiplier (Hamamatsu R666). The signal, acquired and averaged by a digital oscilloscope (Hewlett-Packard 54504A), was transferred to a PC via an HPIB parallel interface, where it was analysed and stored.

Results

It is known that many aromatic compounds form relatively stable ground-state complexes with Rf (17–19). Nevertheless, no ground state interactions could be detected by

Fig. 1. Chemical structures of Riboflavin and the flavonoids, 3-hydroxyflavone and 7-hydroxyflavone.

3-hydroxyflavone

7-hydroxyflavone

Riboflavin
absorption spectroscopy in the cases of the systems 3-OHF – Rf and 7-OHF – Rf.

The Rf-sensitized photoirradiation of air-equilibrated methanolic solutions of 3-OHF (ca. 0.5 mM) produces different changes in the whole absorption spectrum of the mixture, which reflect the addition of chemical changes in both the OHF and the Rf itself (Fig. 2). No spectral changes in the absorption of the flavonoid moiety were observed when 7-OHP was irradiated under identical experimental conditions, even when employing irradiation times ca. 10-fold higher. The spectral changes in the 3-OHF – Rf system were qualitatively similar, although slightly reduced in magnitude when similar irradiation doses were delivered to the described solutions in the presence of NaN_3 (20 mM). The salt is a known physical quencher of $O_2(^1\Delta_g)$ with a rate constant (20) in MeOH of 2.3×10^8 M^{-1} s^{-1} for process [11]. Under these experimental conditions the lifetime of $O_2(^1\Delta_g)$ in MeOH (20) is reduced from 10 μs to approximately 0.2 μs, owing to the presence of NaN_3, making negligible, in practice, any $O_2(^1\Delta_g)$-mediated reaction.

Photoirradiation of diluted individual methanolic solutions of Rf (0.02 mM) + 3-OHF (0.5 mM) gave rise to measurable oxygen consumption (approximately 0.1 ppm O_2 min^{-1}). No oxygen consumption was detected when 3-OHF was replaced by 7-OHF.

It is known that anaerobic photodegradation of Rf under visible light irradiation predominantly proceeds through the triplet state (21), and the rate of the process can be estimated by absorption spectroscopy. Comparative irradiations of N_2-saturated methanolic solutions of Rf in the absence and in the presence of ca. 0.05 mM 3-OHF and 7-OHF showed that this rate is decreased in the presence of the flavones (Fig. 2,

Fig. 2. Spectral evolution of the mixture Rf (ca. 0.015 mM) plus 3-hydroxyflavone (0.5 mM) in MeOH vs. MeOH. Numbers on the spectra represent irradiation time in seconds. Left inset: time evolution of the difference spectra Rf (ca. 0.015 mM) plus 3-hydroxyflavone (0.5 mM) vs. Rf (ca. 0.015 mM). Numbers on the spectra represent irradiation time in seconds. Right inset: decrease in the 445 nm absorption band of Rf (ca. 0.015 mM) upon irradiation in argon-saturated solutions: (*a*) without irradiation; (*b*) irradiated 2 min in the presence of 7-OHF (0.2 mM); (*c*) irradiated 2 min. In all cases, irradiation at 450 ± 10 nm at room temperature (RT).
right inset), suggesting a quenching process of electronic excited states of Rf.

Most of the above-mentioned experimental evidence strongly indicates the occurrence of specific interactions of

the OHF with the singlet- and triplet-excited states of the pigment under aerobic and anaerobic conditions. To elucidate the reaction mechanism, the following kinetic scheme was employed in the interpretation and discussion of the experimental results (Scheme 1).

Rf represents the sensitizer S, i.e., a species that absorbs radiation in a wavelength range, typically that of visible light where the OHF are transparent. The absorption of incident light promotes Rf to the electronically excited singlet (reaction [1]) and triplet (reaction [4]) states. Both states can be quenched, through reactions [3], and [6] and [8], respectively. The excited triplet state can react (process [8]) with ground-state-triplet molecular oxygen $O_2(^3\Sigma^-_g)$ dissolved in the medium, generating $O_2(^1\Delta_g)$ [9] and (or) $O_2^{\bullet-}$ [10]. By means of the electron-transfer reaction [6], the respective semireduced and semioxidized Rf and OHF forms can be produced. The first one, by means of reaction [7], generates $O_2^{\bullet-}$, which can react with OHF and (or) with the pigment (reactions [14] and [15], respectively).

Quenching of the excited singlet state of Rf by OHF

The emissive properties of Rf are well known. The pigment has an intense fluorescence emission band, centred at 515 nm, with a reported quantum yield of 0.25 (16). The steady-state fluorescence, the intensity, and the excited singlet lifetime were decreased in the presence of OHF > 1 mM. Through the classical Stern–Volmer treatment ($1/^1\tau = (1/^1\tau_o) + k_3$ [OHF]), the rate constant values, k_3 (process [3]), were graphically determined for 3-OHF and 7-OHF, respectively (Table 1, Fig. 3). The intercept gave a value of the fluorescence lifetime for Rf ($^1\tau_o$) of 5.75 ns, in excellent agreement with previous published data (22).

Quenching of the excited triplet state of Rf by OHF

The disappearance of the Rf triplet state (^{3}Rf*) in MeOH, generated by a 355 nm laser pulse, was monitored from the first-order decay of the absorbance at 670 nm, a region where the interference from other possible species is negligible. The triplet decay was measured at low Rf concentration (typically 0.02 mM) and at low enough laser energy to avoid undesired effects such as self quenching and triplet–triplet annihilation, respectively. In this way, it was observed that the lifetime of ^{3}Rf* decreases appreciably in the presence of OHF in the mM concentration range. Analysis of the triplet quenching (Fig. 4), using the expression $1/^3\tau = (1/^3\tau_o) + k_6$ [OHF] (where $^3\tau_o$ and $^3\tau$ are the experimentally determined triplet lifetimes of Rf in the absence and in the presence of OHF, respectively), yielded the bimolecular rate constant value for the quenching of ^{3}Rf by OHF shown in Table 1.

In Fig. 5, the transient absorption spectrum of Rf immediately after the laser pulse is shown. This spectrum is similar to the one reported for the Rf neutral triplet state in MeOH (23). The lower trace in Fig. 5, recorded at 20 μs after the laser pulse under identical experimental conditions as described above but in the presence of 0.5 mM OHF (either 3-OHF or 7-OHF), possesses a similar shape to those that have been assigned to the presence of the well known Rf radical anion (24, 25) This experimental evidence could indicate that the triplet quenching by OHF is due to an electron-transfer process from OHF to the pigment, with the concomitant production of the semireduced pigment (Rf$^{\bullet-}$, reaction

Table 1. Rate constants for the quenching of singlet-excited (^{1}Rf*) and triplet-excited (^{3}Rf*) riboflavin, k_3 and k_6, respectively, by 3-hydroxyflavone (3-OHF) and 7-hydroxyflavone (7-OHF) in MeOH at room temperature.

Compound	k_3 (10^{-9} M^{-1} s^{-1})	k_6 (10^{-9} M^{-1} s^{-1})

[6] from Scheme 1). This reaction has already been described for other hydroxyaromatic derivatives, including chlorophenols (26), hydroxypyridines (27), and indoles (17).

Discussion

Reactions [5], [6], and [8], in Scheme 1, are competitive. The predominance of a given process will depend on the competition between O_2 and OHF for the quenching of ^{3}Rf*. It is known (28) that the quenching of ^{3}Rf* by O_2 occurs with a rate constant, k_8, in water of 9×10^8 M^{-1} s^{-1}. Nevertheless, in kinetic terms, and taking into account that the reported quantum yield value for the generation of $O_2(^1\Delta_g)$

Fig. 5. Transient absorption spectra of Rf (0.02 mM) in argon-saturated methanolic solution (■) 2 μs after the laser pulse and in the presence (○) of 3-OHF (0.5 mM) at 20 μs after the laser pulse.
(process [9], with S = Rf) and of $O_2^{\bullet-}$ (process [10]) from ^{3}Rf* are 0.5 and 0.009, respectively (29), the direct generation of $O_2^{\bullet-}$ by electron transfer from ^{3}Rf* to O_2 can be considered insignificant.

In a previous paper (10), we studied the interaction of 3-OHF and 7-OHF with $O_2(^1\Delta_g)$ in MeOH–CHCl$_3$ 3:1 (v/v), employing Rose Bengal as a dye-sensitizer. The 7-OH derivative was a mere physical quencher of $O_2(^1\Delta_g)$ with a rate constant, k_{11}, of 2.3×10^8 M^{-1} s^{-1}, whereas 3-OHF reacted chemically with the oxidative species with a rate constant, k_{12}, of 1.7×10^6 M^{-1} s^{-1}. Nevertheless our present results show an aerobic phototransformation of 3-OHF even in the presence of NaN$_3$ (20 mM), with a slightly diminished rate as compared with that in the absence of the salt. This observation indicates that there is no significant contribution of an $O_2(^1\Delta_g)$-mediated degradation of 3-OHF. The small inhibitory effect in the rate of 3-OHF decomposition observed in the irradiation of the 3-OHF – Rf – O$_2$(air) – NaN$_3$ system possibly conforms to the known quenching of ^{3}Rf* by the azide anion, for which a rate constant, k_6, of 6×10^7 M^{-1} s^{-1} has been reported (20) (process [6] with OHF being replaced by NaN$_3$ in Scheme 1). According to the rate constants reported in Table 1, the excited singlet state of Rf is effectively unquenched by the OHF at concentrations in the range 0.1–0.5 mM, concentrations similar to those employed in the experiments shown in the spectra (Fig. 2). The data in Table 1 also indicates that the triplet-excited Rf can be effectively quenched by both 3-OHF and 7-OHF in the range of concentrations used, with the subsequent production of the semireduced form of Rf (step [6]). According to flash photolysis results, process [6] with [OHF] = 5–10 mM could compete with the generation of $O_2(^1\Delta_g)$ (process [9]). Consequently, under air-saturated conditions, i.e., with a concentration of dissolved oxygen approximately equals to 2.1 mM (30), the species Rf$^{\bullet-}$ could be formed by electron transfer from OHF (process [6]). In the presence of dissolved oxygen, superoxide ion can be generated through an electron-transfer process (step [7]). A rate constant value of 1.4×10^8 M^{-1} s^{-1} has been recently reported (29) for this process, a reaction that at the same time regenerates ground state Rf.

The Rf-sensitized photooxidation, mediated by superoxide ion, has been postulated to account for a series of hydroxy-aromatic compounds belonging to biologically relevant families (11, 17). El-Sukkary and Speier (31) reported, in 1981, the oxidation of 3-hydroxyflavone in tetrahydrofuran by thermally generated $O_2^{\bullet-}$. According to our experimental evidence (spectral changes and oxygen uptake measurements), in the present case superoxide ion effectively reacts with 3-OHF and Rf (steps [14] and [15], respectively).

As already reported by Tournaire et al. for polyhydroxy-flavonoids (14) and later confirmed by ourselves for mono-hydroxyflavones (9, 10), the activation of the double bond on ring C by the presence of the hydroxyl group (the case of 3-OHF, see Fig. 1) is the main factor that determines the reactivity towards the oxidative species. It should also be considered that 3-OHF might be more reactive than 7-OHF because of the intramolecular H-bonding in the 3-hydroxy compound, which results in a conjugated enolate system. This case could be similar to that reported for the peri-naphthenone-sensitized photooxidation of methyl salicylate, methyl-3-hydroxy benzoate, and methyl-4-hydroxy benzoate, in which the higher photooxidation efficiency was reached by the H-bonded compound methyl salicylate (32).

In summary, we conclude that the kinetic results indicate the participation of ground state 3-OHF and 7-OHF in the visible-light-mediated photogeneration of superoxide ion in MeOH, sensitized by Rf. The process involves triplet-excited Rf and also dissolved atmospheric oxygen. At concentrations of the flavones in the order of mM or lower, only the excited triplet state of Rf is quenched by these compounds. Electron-transfer processes produce the superoxide ion and the subsequent photodecomposition of the pigment and 3-OHF. Nevertheless this flavonoid simultaneously acts as a sacrificial scavenger of superoxide ion, provided that it is consumed in the quenching process. There is no evidence for the reactive quenching of the superoxide ion by 7-OHF. By successive increases of the OHF concentration, starting from the mM range, the partial, and subsequently the substantial, quenching of singlet-excited Rf is achieved. As a result, superoxide ion is not generated and the photodecomposition of both 3-OHF and the pigment is prevented.

5-Hydroxy[1,2]oxazinan-3-ones as potential carbapenem and D-ala-D-ala surrogates

Saul Wolfe, Christiana Akuche, Stephen Ro, Marie-Claire Wilson, Chan-Kyung Kim, and Zheng Shi

Abstract: The title compounds are amino acids whose nitrogen atom is enclosed in a six-membered cyclic hydroxamate bearing a C5-hydroxyl group. They belong to a proposed new family of antibacterial agents targeted to the penicillin receptor. The glycine and alanine members of the family have been synthesized, as racemates, in seven steps from the four-carbon synthon diketene and the *tert*-butyl esters of *N*-hydroxyglycine and *N*-hydroxyalanine. Numerous alternatives to diketene have also been examined, but these lead mainly to five-membered cyclic hydroxamates. The theoretical considerations that have led to this synthetic programme are discussed in some detail. They include analysis of the structures of natural and unnatural penicillin surrogates, analysis of the penicillin pharmacophore, and a treatment of the chemical reaction with which penicillin blocks bacterial cell wall synthesis. The glycine derivative exhibits marginal but real activity vs. *Micrococcus luteus*. The alanine derivative, which more closely resembles D-ala-D-ala, is fifty times more active. Two five-membered structural isomers of the glycine derivative are inactive.

Key words: cyclocanaline, cycloserine, lactivicin, oxamazins, peptidoglycan, penicillin-binding proteins.

Résumé : Les composés mentionnés dans le titre sont des acides aminés dont l'atome d'azote est compris dans un hydroxamate cyclique à six chaînons portant un groupe hydroxyle en position 5. Ils font partie de ce qui est proposé comme une nouvelle famille d'agents antibactériens orientés vers les récepteurs de la pénicilline. On a synthétise les membres glycine et alanine de la famille, sous la forme de racémiques, en sept étapes à partir du dicétène, un synthon à quatre atomes de carbone, et des esters *t*-butyliques de la *N*-hydroxyglycine et de la *N*-hydroxyalanine. On a examiné la possibilité d'utiliser plusieurs autres composés à la place du dicétène, mais dans chacun des cas ces dérivés de remplacement ont conduit principalement à la formation d'hydroxamates cycliques à cinq chaînons. On discute en détail des considérations théoriques qui ont conduit à ce programme de synthèse. Elles comprennent l'analyse des structures de substituts naturels et non naturels à la pénicilline, l'analyse du pharmacophore de la pénicilline et à un traitement de la réaction chimique par laquelle la pénicilline bloque la synthèse de la membrane de la cellule des bactéries. Le dérivé de la glycine présente une activité faible, mais réelle vis-à-vis du *Micrococcus luteus*. Le dérivé de l'alanine, qui ressemble plus au D-ala-D-ala, est cinquante fois plus actif. Deux isomères de structure à cinq chaînons du dérivé de la glycine sont inactifs.

Mots clés : cyclocanaline, cyclosérine, lactivicine, oxamazines, peptidoglycane, protéines se liant à la pénicilline.

Introduction

Cycloserine (Oxamycin, Seromycin, **1**), produced by *Streptomyces orchidaceus* (1), and lactivicin (**2**), isolated from culture filtrates of *Empedobacter lactagenus* YK-258 and *Lysobacter albus* YK-422 (2), are antibiotics whose action is directed against the biosynthesis of the bacterial cell wall peptidoglycan. Although both antibiotics contain an isoxazolidinone ring (a cyclic hydroxamate), they have different configurations at C4 and they operate at different stages of cell wall synthesis. D-Cycloserine, a cyclic analog of D-alanine (**3**), is a competitive inhibitor of both alanine racemase (3) and D-alanyl-D-alanine synthetase (4). Lactivicin has the L-configuration at C4 and a 2-oxoglutarate appendage attached to the ring nitrogen. Because it exhibits affinity to penicillin-binding proteins and susceptibility to β-

lactamases (2, 5), lactivicin can be regarded as a structural analog of penicillin (**4**), which is, in turn, a structural analog of the *N*-acyl-D-ala-D-ala terminus (**5**) of the growing peptidoglycan (6). The isoxazolidin-3-one ring of lactivicin thus appears to function as a β-lactam surrogate, and the 5-oxo-tetrahydrofuran-2-carboxylic acid substituent appears to function as a D-alanine surrogate.

droxylamine (17) on appropriately protected and activated homoserine synthons.

Khomutov and co-workers have reported that DL-

The 6-membered homolog of cycloserine is cyclocanaline (**6**), the cyclodehydration product of canaline (**7**). L-Canaline, the 5-oxa isostere of ornithine, is the only naturally occurring amino acid that possesses an aminooxy moiety. The compound is found in leguminous plants and is derived from L-canavanine (**8**), the 5-oxa isostere of L-arginine, by arginase-mediated hydrolysis (7). Canavanine is an important metabolite of higher plants, as it has a dual function in chemical defense against herbivores and in nitrogen storage, where it can account for 90% or more of the seed nitrogen allocated to free amino acids (8). The free aminooxy group of L-canaline forms Schiff base adducts with α-keto acids (9) and with the pyridoxal phosphate (B$_6$) cofactor of many B$_6$-dependent enzymes (10). These properties endow canaline with antimetabolite (11), anticancer (11), and antimalarial activities (12).

The first syntheses of [1,2]oxazinan-3-one (**9**) and cyclocanaline were accomplished by cyclization of 4-aminooxy-butyric esters under forcing basic or acidic conditions, i.e., N2—C3 bond formation (13).

Attempts to secure these compounds by O1–C6 cyclization of halohydroxamic acids (**10**→**11**) were frustrated by competing N2—C6 bond formation (**10**→**12**) (14). The introduction of the aminooxy substituent into canaline has been achieved using ethyl *N*-hydroxyacetimidate (15), acetone oxime (13*a*), hydroxyurethane (16), or *N*-benzoylhy-

cyclocanaline has activity against *Mycobacterium tuberculosis* (18, 19).

The parent 5-membered and 6-membered cyclic hydroxamates are structural isomers of the *N*-hydroxylactams **13** and **14**, and rearrangement of an *N*-hydroxy-2-azetidinone into a 5-membered cyclic hydroxamate has been observed by Hirose et al. (20*a*) and by Miller and co-workers (20*b*), who have published extensively on oxamazins (**15**), heteroatom-activated β-lactams (21). Monocyclic oxamazins exhibit significant antibacterial activity vs. Gram negative bacteria. Their mechanism of action has not been established with certainty,[2] but it is noteworthy that the carboxyl group of **15** is one carbon further removed from the β-lactam nitrogen than in β-lactam antibiotics. In the case of the bicyclic [4.2.0] oxamazins **16**, both diastereomers at the point of attachment of the carboxyl group are claimed to have good antibacterial activity (22). In contrast, thiamazins (**17**) are inactive (23).

Boyd, Miller, and co-workers (24) have discussed the difference in the activities of oxamazins and thiamazins in terms of their putative three-dimensional relationship to the penicillin nucleus, i.e., their ability to "fit" into the active sites of the serine peptidase receptors of β-lactam antibiotics. The chemical reaction that follows — namely, acylation of the serine hydroxyl group by the β-lactam ring — has been

Table 1. Calculated "barriers"[a] and nitrogen pyramidality[b] in various azetidinones.

Azetidinone	"Barrier" (kcal/mol)[a]	Pyramidality[b]
Penam	29.4	336.1
Penem	28.0	333.9
N-methylazetidinone	30.7	360.0
N-methoxyazetidinone	29.6	337.5
N-methylthioazetidinone	34.2	357.0
Bicyclic oxamazin	32.5	348.6
Bicyclic thiamazin	34.2	352.4

[a]See text for definition of "barrier".
[b]Sum of the angles at nitrogen (3–21G or 3–21G* calculations; the 3–21G* basis set is used with sulfur-containing compounds).

It can be seen that *N*-methoxyazetidinone is comparable in "reactivity" to the bicyclic penam and is substantially more "reactive" than *N*-methylthioazetidinone. In addition, unlike compounds in which carbon or sulfur is attached to the β-lactam nitrogen, the monocyclic *N*-methoxyazetidinone is substantially more "reactive" than the bicyclic structure.

These trends can be understood by consideration of the pyramidality of the β-lactam nitrogen, as given by the sum of the angles at this center. This sum is included in Table 1. The geometry at nitrogen has received continuous attention (30) since Woodward first proposed (31) that the O=C-N↔(–)O-C=N(+) amide resonance, which contributes to the stability and planarity of an amide linkage, is suppressed in a four-membered ring and cannot be achieved within the bicyclic penam structure. An equivalent, molecular orbital interpretation (32) is that $n_p-\pi^*_{CO}$ charge transfer in an amide is most effective when the nitrogen *p*-orbital can conjugate with the π-system, i.e., when the nitrogen is planar. This is not possible when the β-lactam nitrogen is at a bridgehead position. In *N*-methoxy- and *N*-methylthioazetidinone, minimization of lone-pair – lone-pair repulsion between the *p*-orbital on nitrogen and the *p*-orbital on oxygen or sulfur (33) causes the methyl group to be perpendicular to the ring, so that the nitrogen *p*-orbital and the X—C bond are eclipsed. If the resulting $n_p-\sigma^*_{XC}$ interaction competes with the $n_p-\pi^*_{CO}$ interaction, the combined effects will produce nonplanarity at nitrogen, as is seen in *N*-methoxyazetidinone.

the subject of extensive theoretical research (25). In our laboratory (26) the relative "reactivities" of different substrates are calculated, as shown in Fig. 1, for penam, the penicillin nucleus. The reaction is modeled theoretically as a one-step, cooperative process (27), in which O=C⋯O bond formation by methanol and N⋯H bond formation by a catalytic water molecule are concerted with the cleavage of the β-lactam bond. The structure on the left of Fig. 1 is the reactant complex, optimized at the 3–21G* level (28); the optimized transition structure is shown on the right. The barrier, based on single-point MP2/6–31G* calculations, is 29.36 kcal/mol. This number is shown in Table 1, together with the barriers calculated similarly for the water-assisted methanolyses of penem, *N*-methylazetidinone, and mono- and bicyclic oxamazins and thiamazins. In the latter two systems, there is more than one conformation of the 6-membered ring; based on a recent quantitative treatment of the Curtin–Hammett principle (29), the number shown in the table refers to the energy difference between the most stable reactant complex and the most stable transition structure.

Fig. 2. A plot of the MP2/6–31G*//3–21G(G*) "barriers" vs. the sum of the angles at nitrogen of some β-lactam compounds (from Table 1).
The magnitude of the n_p–σ^*_{XC} interaction depends inversely upon the energy difference between n_p and σ^*_{XC} and also upon the square of the overlap between the interacting orbitals (34). Although the sulfur σ^* acceptor orbital is lower-lying than the oxygen σ^* acceptor orbital, the n_p–σ^*_{SC} interaction is not effective because of the longer nitrogen—sulfur bond (33). Consequently, the monocyclic and bicyclic thiamazins exhibit similar "barriers" and near planarity at nitrogen. In the case of the oxamazins, closing the second ring increases the dihedral angle between n_p and σ^*_{OC} and decreases the contribution of the n_p–σ^*_{OC} interaction, resulting in increased planarity at nitrogen and an increased "barrier".

As seen in Fig. 2, there is a rough linear relationship ($R^2 = 0.81$) between the calculated sum of the angles at nitrogen and the calculated "barriers".

Cyclic hydroxamates as β-lactam surrogates

The foregoing considerations suggested that the cyclic hydroxamate 2-methyl-isoxazolidin-3-one (**18**), identified earlier as a β-lactam surrogate from its presence in lactivicin, would exhibit somewhat greater planarity at nitrogen and a somewhat higher "barrier" than its isomer *N*-methoxyazetidinone. The calculations on **18** and its homolog 2-methyl-[1,2]-oxazinan-3-one (**19**), which are summarized in Fig. 3, are consistent with this prediction. Nonetheless, both **18** and **19** are found to have significant "reactivity", intermediate between penam and *N*-methylazetidinone, so that 2-substituted 4-acylaminocycloserines and cyclocanalines such as

20–**22** might be expected to behave as penicillin–lactivicin–*N*-acyl-D-ala-D-ala analogs and exhibit antibacterial activity.

This proposal is not new. Phenylacetylation of L- and D-cycloserine, followed by coupling to *tert*-butyl (DL)-2-bromopropionate, separation of isomers, and deprotection,
Fig. 3. Left: 3–21G optimized structures and the sum of the angles at nitrogen in **18** and **19**. Centre: 3–21G reactant complexes for the methanolyses of **18** and **19**, with catalysis by one water molecule. Right: 3–21G transition structures. The "barriers" are based on single point MP2/6–31G* calculations.
afforded all four stereoisomers of **20** (R = phenylacetyl, R′ = Me) (35). However, none of these compounds exhibited activity vs. *Staphylococcus aureus* or *Escherichia coli*. Likewise, phenoxyacetylation of L-cycloserine, followed by coupling to allyl 2-chloro-2-ethoxyacetate, deprotection, and separation of isomers yielded **20** (R = phenoxyacetyl, R′ = OEt) (36), which were inactive against *S. aureus* and *E. coli* at concentrations up to 1000 µg/mL. Although **21** has been claimed to have antibacterial activity (37), this claim cannot be confirmed (38); **22** is also inactive (38).
